▶ Remark 7. Later calls to the DRPO oracle during the run of Algorithm 1 may be cheaper since there will be a significant amount of dual regularization at that point (namely, $\Lambda_k = \sum_{j=0}^{k-1} \lambda_j$ is large). One can sometimes take advantage of this (in particular, if the cost of a DRPO oracle call scales inverse polynomially with the regularization) to design schedules that avoid even the typically additional multiplicative logarithmic cost of Corollary 4 over the cost of a single DRPO oracle call. In such cases, a choice of schedules similar to those of Corollary 6 is often appropriate. With this choice of schedules, later rounds require very high accuracy. However, if one can argue that the increasing dual regularization Λ_k makes the DRPO oracle call cheaper at a faster rate than the decreasing error ϵ_k makes it more expensive (as we do in Section 5), the total cost of applying the framework may collapse geometrically to the cost of a single DRPO oracle call made with target error approximately ϵ.

We purposely state Corollary 6 without the assumption that ϕ is Lipschitz because that is the form we will use in Section 5. However, it is straightforward to reformulate a version of Corollary 6 with the Lipschitz assumption. Here the focus was to illustrate different possible choices of schedules.

1.3 Related work

Black-box reductions

Our main contribution can be viewed as a black-box reduction from (regularized) primal optimization to dual optimization. Similar black-box reductions exist in the optimization literature. For example, [3] develops reductions between various fundamental classes of optimization problems, e.g., strongly convex optimization and smooth optimization. In a similar vein, the line of work [30, 18, 7] reduces convex optimization to approximate proximal point computation (i.e., regularized minimization).

Bilinear matrix games

Consider the bilinear objective $\psi(x, y) = x^\top A y$ where $\mathcal{X}$ and $\mathcal{Y}$ are either the simplex, $\Delta^k := \{x \in \mathbb{R}^k_{\geq 0} : \|x\|_1 = 1\}$, or the Euclidean ball, $B^k := \{x \in \mathbb{R}^k : \|x\|_2 \leq 1\}$. State-of-the-art methods in regard to runtime for obtaining an approximately optimal primal and/or dual solution can be divided into second-order interior point methods [11, 42] and stochastic first-order methods [22, 10, 9, 8]; see Table 2 in [8] for a summary of the best known runtimes as well as other references. Of importance to this paper, all state-of-the-art algorithms other than that of [8] are either (i) primal-dual algorithms which return both an ϵ-optimal primal and dual solution simultaneously, and/or (ii) achieve runtimes which are symmetric in the primal dimension d and dual dimension n, meaning the cost of obtaining an ϵ-optimal dual solution is the same as that of obtaining an ϵ-optimal primal solution. The algorithm of [8], on the other hand, only returns an ϵ-optimal primal point and further has a runtime which is not symmetric in n and d (see the footnote on the first page of that paper). As a result, solving the dual by simply swapping the roles of the primal and dual variables may be more expensive than solving the primal. (In fact, swapping the variables in this way may not even always be possible without further modifications due to restrictions on the constraint sets.)

CVaR at level α distributionally robust optimization (DRO)

The DRO objectives we study are of the form $\psi(x, y) = \sum_{i=1}^n y_i f_i(x)$, where the functions $f_i : \mathbb{R}^d \to \mathbb{R}$ are convex, bounded, and Lipschitz, and $\mathcal{Y}$, known as the uncertainty set, is a subset of the simplex. This objective corresponds to a robust version of the empirical risk

minimization (ERM) objective where instead of taking an average over the losses (namely, y_i is fixed at $1/n$), larger losses may be given more weight. In particular, in this paper we focus on a canonical DRO setting, *CVaR at level α,* where the uncertainty set is given by $\mathcal{Y} \coloneqq \left\{y \in \Delta^n : \|y\|_\infty \leq \frac{1}{\alpha n}\right\}$ for a choice of $\alpha \in [1/n, 1]$. CVaR DRO, along with its generalization f-divergence DRO, has been of significant interest over the past decade; see [29, 5, 13, 32, 16] and the references therein. [29] is the most relevant to this paper – omitting parameters other than α, the number of losses n, and the target accuracy $\epsilon > 0$, they give a matching upper and lower bound (up to logarithmic factors) of $\widetilde{O}(\alpha^{-1}\epsilon^{-2})$ first-order queries of the form $(\nabla f_i(x), f_i(x))$ to obtain an expected ϵ-optimal point of the primal objective. Their upper bound is achieved by a stochastic gradient method where the gradient estimator is based on a multilevel Monte Carlo (MLMC) scheme [19, 20]. However, the best known complexity for obtaining an expected ϵ-optimal point of the dual of CVaR at level α is $O(n\epsilon^{-2})$ via a primal-dual method based on [33]; see also [13, 32] as well as [5, Appendix A.1], the last of which obtains complexity $\widetilde{O}(n\epsilon^{-2})$ in the more general setting of the uncertainty set being an f-divergence ball.

Stationary point computation

For $\gamma > 0$, convex and β-smooth $h : \mathbb{R}^n \to \mathbb{R}$ with global minimum $z^\star$, and initialization point z_0, consider the problem of computing a point z such that $\|\nabla h(z)\|_2 \leq \gamma$. Two worst-case optimal gradient query complexities for this problem exist in the literature: $O\left(\sqrt{\beta(h(z_0) - h(z^\star))}/\gamma\right)$ and $O\left(\sqrt{\beta\|z_0 - z^\star\|_2}/\gamma\right)$. An algorithm (the OGM-G method) which achieves the former complexity was given in [24], and [37] pointed out that any algorithm which achieves the former complexity can achieve the latter complexity. This is obtainable by running N iterations of any optimal gradient method for reducing the function value, followed by N iterations of a method which achieves the former complexity for reducing the gradient magnitude. In what may be of independent interest, we observe in Section 5.1 that a reduction in the opposite direction is also possible. More broadly, algorithms and frameworks for reducing the gradient magnitude of convex functions have been of much recent interest, and further algorithms and related work for this problem include [25, 27, 26, 28, 15, 37, 21], with lower bounds given in [34, 35].

1.4 Paper organization

In Section 2, we go over notation and conventions for the rest of the paper. We give our general dual-extraction framework and its guarantees in Section 3. In Section 4, we apply our framework to bilinear matrix games and the CVaR at level α DRO problem. Finally, in Section 5 we give an optimal algorithm (in terms of query complexity) for computing an approximate stationary point of a convex and β-smooth function.

2 Notation and conventions

We defer standard notation and conventions to the full version, and only include paper-specific notation here.

For $\psi : \mathbb{R}^d \times \mathbb{R}^n \to \mathbb{R}$, we use the notation $\psi(\cdot, y) : \mathbb{R}^d \to \mathbb{R}$ for a fixed $y \in \mathbb{R}^n$ to denote the map $x \mapsto \psi(x, y)$ (and define $\psi(x, \cdot)$ analogously). When we say $\psi(\cdot, y)$ satisfies a property, we mean it satisfies that property for any fixed $y \in \mathbb{R}^n$ (and analogously for $\psi(x, \cdot)$). We let $[K] \coloneqq \{1, 2, \ldots, K\}$, $\Delta^n \coloneqq \left\{x \in \mathbb{R}^n_{\geq 0} : \|x\|_1 = 1\right\}$, and $B^n_r(x) \coloneqq \{x \in \mathbb{R}^n : \|x\|_2 \leq r\}$. In the latter two definitions, we may drop the superscript n if it is clear from context, the

argument x if it is 0, and the subscript r if it is 1. For $y \in \mathbb{R}^n$, we may use either the notation y_i or $[y]_i$ to denote its i-th entry. $\mathbf{1}$ denotes the all-ones vector. For a function f which depends on some inputs $x_1, \ldots, x_k \in \mathbb{R}$, we write $f \leq \mathrm{poly}(x_1, \ldots, x_k)$ to denote the fact that f is uniformly bounded above by a polynomial in $x_1, \ldots, x_k$ as $x_1, \ldots, x_k$ vary. We use the notation f^* for the convex or Fenchel conjugate of f. For $S \subseteq \mathbb{R}^n$, we let $\mathbb{I}_S$ denote the infinite indicator of S, namely $\mathbb{I}_S(x) = 0$ if $x \in S$ and $\mathbb{I}_S(x) = \infty$ if $x \notin S$. For a function $f : S \to [-\infty, \infty]$ initially defined on a strict subset $S \subset \mathbb{R}^n$, we may implicitly extend the domain of f to all of $\mathbb{R}^n$ via its indicator as $f + \mathbb{I}_S$ without additional comment. For a function $f : U \to [-\infty, \infty]$ with $S \subseteq U \subseteq \mathbb{R}^n$, we let $f_S \coloneqq f + \mathbb{I}_S$ denote the restriction of f to S. We note that f_S^* denotes the convex conjugate of f_S (and not f^* restricted to S).

Following [38, Sec. 6.4], we encapsulate the setup for a dgf as follows. See the full version for additional discussion of this definition.

▶ **Definition 8** (dgf setup). *We say $(\mathcal{U}, \mathcal{P}, \|\cdot\|, r)$ is a* dgf setup *over $\mathbb{R}^n$ for closed and convex sets $\mathcal{U} \subseteq \mathcal{P} \subseteq \mathbb{R}^n$ with $\mathcal{U} \cap \operatorname{int} \mathcal{P} \neq \emptyset$ if: (i) the distance-generating function (dgf) $r : \mathcal{P} \to \mathbb{R}$ is convex and continuous over $\mathcal{P}$, differentiable on $\operatorname{int} \mathcal{P}$, and μ_r-strongly convex with respect to the chosen norm $\|\cdot\|$ on $\mathcal{U} \cap \operatorname{int} \mathcal{P}$ for some $\mu_r > 0$; and (ii) either $\lim_{u \to \operatorname{bd} \mathcal{P}} \|\nabla r(u)\|_2 = \infty$ or $\mathcal{U} \subseteq \operatorname{int} \mathcal{P}$.*

For a given dgf setup, we define its induced Bregman divergence $V_u^r(v) \coloneqq r(v) - r(u) - \langle \nabla r(u), v - u \rangle$ for $u \in \operatorname{int} \mathcal{P}, v \in \mathcal{P}$, and drop the superscript r when it is clear from context.

3 Dual-extraction framework

In this section, we provide our general dual-extraction framework and its guarantees. In Section 3.1, we give the general setup, oracle definitions, and assumptions with which we apply and analyze the framework. Section 3.2 contains the statement and guarantees of the framework and Section 3.3 in the full version contains the associated proofs.

3.1 Preliminaries

We bundle all of the inputs to our framework into what we call a *dual-extraction setup*, defined below. Recall that when we say $\psi(x, \cdot)$ satisfies a property, we mean it satisfies that property for any fixed $x \in \mathbb{R}^d$ (and analogously for $\psi(\cdot, y)$).

▶ **Definition 9** (Dual-extraction setup). *A* dual-extraction setup *is a tuple $(\psi, \mathcal{X}, \mathcal{Y}, \mathcal{U}, \mathcal{P}, \|\cdot\|, r)$ where:*

1. *$\psi(x, \cdot)$ is differentiable;*
2. *$\psi(\cdot, y)$ and $\psi(x, \cdot)$ are convex and concave respectively;*
3. *$(\mathcal{U}, \mathcal{P}, \|\cdot\|, r)$ is a dgf setup over $\mathbb{R}^n$ per Definition 8;*
4. *the constraint sets $\mathcal{X} \subseteq \mathbb{R}^d$ and $\mathcal{Y} \subseteq \mathbb{R}^n$ are nonempty, closed, and convex with $\mathcal{Y} \subseteq \mathcal{U}$ and $\mathcal{Y} \cap \operatorname{int} \mathcal{P} \neq \emptyset$;*
5. *$\mathcal{X}$ is bounded or $\psi(\cdot, y)$ is strongly convex;*
6. *$\mathcal{Y}$ is bounded or $\psi(x, \cdot)$ is strongly concave;*
7. *over all $p \in \mathcal{U} \cap \operatorname{int} \mathcal{P}$ and $w \in \partial \mathbb{I}_{\mathcal{U}}(p)$, the map $y \mapsto \langle w, y \rangle$ is constant over $\mathcal{Y}$.*[3]

[3] In all of our applications, this map will in fact be constant over $\mathcal{U}$.

Assumption 1 is only used in the proofs of Lemma 3 in the full version (the general version of Lemma 1 from Section 1.2) and Corollary 13 in the full version (used to show the framework is well-defined when $\operatorname{dom} r \neq \mathbb{R}^n$). Assumptions 2, 5, and 6 ensure that the minimax optimization problem with objective ψ and constraint sets $\mathcal{X}$ and $\mathcal{Y}$ satisfies the *minimax principle*; see below. Regarding Assumptions 3, 4, and 7, the fact that $\mathcal{Y}$ is potentially a strict subset of $\mathcal{U}$ as well as the necessity of the technical assumption 7 is discussed in Remark 4 in the full version. In particular, Assumption 7 is only used to derive an equivalent formulation of the framework to Algorithm 1 which often allows for easier instantiations in applications, but is not strictly necessary to obtain our guarantees.

While our main results are stated in the full generality of Definition 9, in our applications we only particularize to Definition 10 and Definition 11 introduced below.

▶ **Definition 10** (Unbounded setup). *A $(\psi, \mathcal{X}, \mathcal{Y}, r)$-unbounded setup is a $(\psi, \mathcal{X}, \mathcal{Y}, \mathbb{R}^n, \mathbb{R}^n, \|\cdot\|_2, r)$-dual-extraction setup.*

In other words, in an unbounded setup we choose $\mathcal{U} = \mathcal{P} = \mathbb{R}^n$ and the Euclidean norm, in which case the dgf r can be any differentiable and strongly convex function with respect to $\|\cdot\|_2$. Note that Assumption 7 is trivial as $\partial \mathbb{I}_{\mathcal{U}}(p) = \{0\}$ for all $p \in \mathbb{R}^n$.

▶ **Definition 11** (Simplex setup). *A $(\psi, \mathcal{X}, \mathcal{Y})$-simplex setup is a $(\psi, \mathcal{X}, \mathcal{Y}, \Delta^n, \mathbb{R}^n_{\geq 0}, \|\cdot\|_1, r)$-dual-extraction setup where $r(u) \coloneqq \sum_{i=1}^n u_i \ln u_i$ (with $0 \ln 0 \coloneqq 0$).*

In other words, in a simplex setup we choose $\mathcal{U} = \Delta^n$, $\mathcal{P} = \mathbb{R}^n_{\geq 0}$, we are using the ℓ_1-norm, and the dgf is negative entropy when restricted to the simplex. It is a standard result known as Pinsker's inequality that r is 1-strongly convex over $\Delta^n_{>0}$ with respect to $\|\cdot\|_1$, and the associated Bregman divergence is given by the Kullback-Leibler (KL) divergence $V_u(w) = \sum_{i=1}^n w_i \ln \frac{w_i}{u_i}$ for $u \in \Delta^n_{>0}$ and $w \in \Delta^n$. We verify that Assumption 7 holds in Appendix A.1 in the full version.

Notation associated with a setup

Whenever we instantiate a dual-extraction setup (Definition 9), we use the following notation and oracles associated with that setup without additional comment. We define the associated primal $f : \mathcal{X} \to \mathbb{R}$ and dual $\phi : \mathcal{Y} \to \mathbb{R}$ functions, along with their corresponding primal and dual optimization problems, as they were introduced above in (P) and (D). We let $x^\star \in \operatorname{argmin}_{x \in \mathcal{X}} f(x)$ and $y^\star \in \operatorname{argmax}_{y \in \mathcal{Y}} \phi(y)$ denote arbitrary primal and dual optima. To facilitate the discussion of dual-regularized problems, we define $f_{\lambda,q}(x) : \mathcal{X} \to \mathbb{R}$ as follows

$$f_{\lambda,q}(x) \coloneqq \max_{y \in \mathcal{Y}} \{\psi(x, y) - \lambda V_q(y)\} \text{ for } \lambda > 0 \text{ and } q \in \mathcal{U} \cap \operatorname{int} \mathcal{P}\,.$$

The minimax principle

Assumptions 2, 5, and 6 in Definition 9 guarantee $f(x^\star) = \psi(x^\star, y^\star) = \phi(y^\star)$, which we refer to as the *minimax principle*. See, e.g., [39, 41] as well as Propositions 1.2 and 2.4 in [17, Ch. VI].

Oracle definitions

Our framework assumes black-box access to ψ, $\mathcal{X}$, and $\mathcal{Y}$ via a dual-regularized primal optimization (DRPO) oracle and a dual-regularized dual best response (DRBR) oracle defined below. Note that we generalize the setting of Section 1.2 by allowing the DRPO oracle to return an expected ϵ-optimal point; this is used in our applications in Section 4.

▶ **Definition 12** (DRPO oracle). *A* $(q \in \mathcal{U} \cap \operatorname{int} \mathcal{P}, \lambda > 0, \epsilon_{\mathrm{p}} > 0)$*-dual-regularized primal optimization oracle,* $DRPO(q, \lambda, \epsilon_{\mathrm{p}})$*, returns an expected* ϵ_{p}*-minimizer of* $f_{\lambda,q}$*, i.e., a point* $x \in \mathcal{X}$ *such that* $\mathbb{E} f_{\lambda,q}(x) \le \inf_{x' \in \mathcal{X}} f_{\lambda,q}(x') + \epsilon_{\mathrm{p}}$*, where the expectation is over the internal randomness of the oracle.*

▶ **Definition 13** (DRBR oracle). *A* $(q \in \mathcal{U} \cap \operatorname{int} \mathcal{P}, \lambda > 0, x \in \mathcal{X})$*-dual-regularized best response oracle,* $DRBR(q, \lambda, x)$*, returns* $\operatorname{argmax}_{y \in \mathcal{Y}} \left\{ \psi(x, y) - \lambda V_q(y) \right\}$.

We also define a version of the DRPO oracle, called the DRPOSP oracle, which allows for a failure probability. We include this definition here due to its generality and broad applicability, but it is only used in Section 4.1 since the external result we cite to obtain an expected ϵ_{p}-minimizer of $f_{\lambda,q}$ in that application has a failure probability. We also show in Appendix A.4 in the full version how to boost the success probability of a DRPOSP oracle.

▶ **Definition 14** (DRPOSP oracle). *A* $(q \in \mathcal{U} \cap \operatorname{int} \mathcal{P}, \lambda > 0, \epsilon_{\mathrm{p}} > 0, \delta \in [0, 1))$*-dual-regularized primal optimization oracle with success probability,* $DRPOSP(q, \lambda, \epsilon_{\mathrm{p}}, \delta)$*, returns an expected* ϵ_{p}*-minimizer of* $f_{\lambda,q}$ *with success probability at least* $1 - \delta$*, where the expectation and success probability are over the internal randomness of the oracle.*

3.2 The framework and its guarantees

Algorithm 2 Dual-extraction framework.

Input: $(\psi, \mathcal{X}, \mathcal{Y}, \mathcal{U}, \mathcal{P}, \|\cdot\|, r)$-dual extraction setup (Definition 9), initial dual-regularization center $y_0 \in \mathcal{Y} \cap \operatorname{int} \mathcal{P}$, iteration count $K \in \mathbb{N}$, dual-regularization schedule $(\lambda_k \in \mathbb{R}_{>0})_{k=0}^{K-1}$, primal-accuracy schedule $(\epsilon_k \in \mathbb{R}_{>0})_{k=1}^{K}$, DRPO and DRBR oracles (Definitions 12 and 13)

1 **for** $k = 1, 2, \ldots, K$ **do**
2 $\quad \Lambda_k = \sum_{j=0}^{k-1} \lambda_j$
3 $\quad q_k = \operatorname{argmin}_{q \in \mathcal{U}} \frac{1}{\Lambda_k} \sum_{j=0}^{k-1} \lambda_j V_{y_j}(q)$ // Or, $q_k = \nabla r^*_{\mathcal{U}} \left(\frac{1}{\Lambda_k} \sum_{j=0}^{k-1} \lambda_j \nabla r(y_j) \right)$; see Appendix A.2 in the full version
4 $\quad x_k = \mathrm{DRPO}(q_k, \Lambda_k, \epsilon_k)$ // $\mathbb{E}[f_{\Lambda_k, q_k}(x_k) \mid x_{k-1}] \le \inf_{x \in \mathcal{X}} f_{\Lambda_k, q_k}(x) + \epsilon_k$
5 $\quad y_k = \mathrm{DRBR}(q_k, \Lambda_k, x_k)$ // $y_k = \operatorname*{argmax}_{y \in \mathcal{Y}} \left\{ \psi(x_k, y) - \Lambda_k V_{q_k}(y) \right\}$
6 **return** y_K

We now state the general dual-extraction framework, Algorithm 2, and its guarantees, with proofs in the next section. As mentioned in Section 1.2, Algorithm 2 generalizes Algorithm 1 in three major ways: (i) we allow for stochasticity in the DRPO oracle; (ii) we allow for distance-generating functions r where $\operatorname{dom} r \neq \mathbb{R}^n$; and (iii) we give different but equivalent characterizations of x_k and y_k which often allow for easier instantiations of the framework.

Regarding (iii), consider the case where the DRPO oracle is deterministic and $\operatorname{dom} r = \mathbb{R}^n$ for the sake of discussion. Note that in this case, the definitions of x_k and y_k in Lines 4 and 5 of Algorithm 2 may seem different than those in Lines 4 and 5 of Algorithm 1 at first glance. In particular, x_k in Line 4 of Algorithm 2 is an ϵ_k-minimizer of $x \mapsto \max_{y \in \mathcal{Y}} \{\psi(x, y) - \Lambda_k V_{q_k}(y)\}$ over $\mathcal{X}$, whereas x_k in Line 4 of Algorithm 1 is an ϵ_k-minimizer of $x \mapsto \max_{y \in \mathcal{Y}} \{\psi(x, y) - \sum_{j=0}^{k-1} \lambda_j V_{y_j}(y)\}$ over $\mathcal{X}$. Similarly, $y_k = \operatorname{argmax}_{y \in \mathcal{Y}} \{\psi(x_k, y) - \Lambda_k V_{q_k}(y)\}$ in Line 5 of Algorithm 2, whereas $y_k = \operatorname{argmax}_{y \in \mathcal{Y}} \{\psi(x, y) - \sum_{j=0}^{k-1} \lambda_j V_{y_j}(y)\}$ in Line 5 of Algorithm 1.

In fact, we show in Section 3.3 in the full version that these are equivalent; see Lemma 2 and Remark 4 in the full version. The potential advantage of the expressions in Algorithm 2 compared to those in Algorithm 1 is that they involve only a single regularization term.

Note also that Line 3 of Algorithm 2 gives two equivalent expressions for the iterate q_k; their equivalence is proven in Appendix A.2 in the full version. Also, note that Line 4 is the only potential source of randomness in Algorithm 2; in particular, y_k and q_{k+1} are deterministic upon conditioning on x_k. Finally, we show that Algorithm 2 is well-defined in Appendix A.3 in the full version; in particular, whenever a Bregman divergence $V_u(w)$ is written in Algorithm 2, it is the case that $u \in \mathcal{U} \cap \operatorname{int} \mathcal{P}$. For example, in the context of a simplex setup per Definition 11, this corresponds to $u \in \Delta^n_{>0}$.

We now give the main guarantee for Algorithm 2. See Remark 3 for additional explanation.

▶ **Theorem 15** (Algorithm 2 guarantee)**.** *With K calls to a DRPO oracle and K calls to a DRBR oracle, Algorithm 2 returns y_K satisfying*

$$\mathbb{E}V_{y_K}(u) \le \frac{\epsilon_K}{\Lambda_K},$$

where $u \in \mathcal{Y}$ is a point with expected suboptimality bounded as

$$\phi(y^\star) - \mathbb{E}\phi(u) \le \lambda_0 V_{y_0}(y^\star) + \sum_{k=1}^{K-1} \frac{\lambda_k}{\Lambda_k}\epsilon_k.$$

If we additionally assume that ϕ is L-Lipschitz with respect to $\|\cdot\|$, the expected suboptimality of y_K can be directly bounded as

$$\phi(y^\star) - \mathbb{E}\phi(y_K) \le \lambda_0 V_{y_0}(y^\star) + \sum_{k=1}^{K-1} \frac{\lambda_k}{\Lambda_k}\epsilon_k + L\sqrt{\frac{2}{\mu_r}\frac{\epsilon_K}{\Lambda_K}}. \tag{9}$$

We now particularize Theorem 15 using two exemplary choices of the dual-regularization and primal-accuracy schedules. See Remarks 5 and 7 for additional comments.

▶ **Corollary 16.** *Suppose ϕ is L-Lipschitz with respect to $\|\cdot\|$, and let $B > 0$ be such that $V_{y_0}(y^\star) \le B$. Then for any $\epsilon > 0$, and $K \ge \max\left\{\log_2 \frac{L^2 B}{\mu_r \epsilon^2}, 1\right\} + 10$, the output of Algorithm 2 with dual-regularization and primal-accuracy schedules given by*

$$\lambda_k = 2^k \frac{\epsilon}{4B} \text{ for } k \in \{0\} \cup [K-1] \text{ and } \epsilon_k = \frac{\epsilon}{4K} \text{ for } k \in [K]$$

satisfies $\phi(y^\star) - \mathbb{E}\phi(y_K) \le \epsilon$.

▶ **Corollary 17.** *Let $B > 0$ be such that $V_{y_0}(y^\star) \le B$. Then for any $\epsilon > 0$ and $K \in \mathbb{N}$, the output of Algorithm 2 with dual-regularization and primal-accuracy schedules given by*

$$\lambda_k = 2^k \frac{\epsilon}{4B} \text{ for } k \in \{0\} \cup [K-1] \text{ and } \epsilon_k = \frac{\epsilon}{8 \cdot 1.5^k} \text{ for } k \in [K] \tag{10}$$

satisfies

$$\mathbb{E}\|y_K - u\| \le \frac{1}{1.5^K}\sqrt{\frac{2B}{\mu_r}},$$

where $u \in \mathcal{Y}$ is a point whose expected suboptimality is at most ϵ, i.e., $\phi(y^\star) - \mathbb{E}\phi(u) \le \epsilon$.

4 Efficient maximin algorithms

In this section, we obtain new state-of-the-art runtimes for solving bilinear matrix games in certain parameter regimes (Section 4.1), as well as an improved query complexity for solving the dual of the CVaR at level α distributionally robust optimization (DRO) problem (Section 4.2). In each application, we apply Corollary 16 to compute an ϵ-optimal point for the dual problem at approximately the same cost as computing an ϵ-optimal point for the primal problem (up to logarithmic factors and the cost of representing a dual vector when it comes to CVaR at level α).

4.1 Bilinear matrix games

In this section, we instantiate $\psi(x, y) \coloneqq x^\top A y$ for a matrix $A \in \mathbb{R}^{d\times n}$. Given $p, q \geq 1$, we write $\|A\|_{p\to q} \coloneqq \max_{v\in\mathbb{R}^d, v\neq 0} \frac{\|Av\|_q}{\|v\|_p}$, and use the notation A_{ij}, $A_{i:}$, and $A_{:j}$ for the (i, j) entry, i-th row as a row vector, and j-th column as a column vector. We consider two setups:

▶ **Definition 18** (Matrix games ball setup)**.** *In the* matrix games ball setup, *we set* $\mathcal{X} \coloneqq B^d$ *(the unit Euclidean ball in* $\mathbb{R}^d$*),* $\mathcal{Y} \coloneqq \Delta^n$*, and fix a* $(\psi, \mathcal{X}, \mathcal{Y})$*-simplex setup (Definition 11). We assume* $\|A^\top\|_{2\to\infty} = \max_{i\in[n]} \|A_{:i}\|_2 \leq 1$.

▶ **Definition 19** (Matrix games simplex setup)**.** *In the* matrix games simplex setup, *we set* $\mathcal{X} \coloneqq \Delta^d$, $\mathcal{Y} \coloneqq \Delta^n$, *and fix a* $(\psi, \mathcal{X}, \mathcal{Y})$*-simplex setup (Definition 11). We assume* $\|A^\top\|_{1\to\infty} = \max_{i,j} |A_{ij}| \leq 1$.

Throughout Section 4.1, any theorem, statement, or equation which does not make reference to a specific choice of Definition 18 or 19 applies to both setups. Specializing the primal (P) and dual (D) to this application gives

$$\underset{x\in\mathcal{X}}{\text{minimize}}\, f(x) \text{ for } f(x) \coloneqq \max_{y\in\Delta^n} x^\top A y, \text{ and} \tag{P-MG}$$

$$\underset{y\in\Delta^n}{\text{maximize}}\, \phi(y) \text{ for } \phi(y) \coloneqq \min_{x\in\mathcal{X}} x^\top A y. \tag{D-MG}$$

Regarding the assumptions on the norm of the matrix A in Definitions 18 and 19, note that we can equivalently write $f(x) = \max_{y\in\Delta^n} \sum_{i=1}^n y_i f_i(x)$ with $f_i(x) \coloneqq [A^\top x]_i$. Then the assumptions on the norm of A correspond to ensuring f_i is 1-Lipschitz with respect to the ℓ_2-norm in Definition 18 and ℓ_1-norm in Definition 19 (which in turn implies f is 1-Lipschitz in the respective norms). This normalization is performed to simplify expressions as in [8]. (In particular, [8] also considers the more general problem where each f_i can be any smooth, Lipschitz, convex function.)

Recently, [8, Cor. 8.2] achieved a state-of-the-art runtime in certain parameter regimes of $\widetilde{O}(nd + n(d/\epsilon)^{2/3} + d\epsilon^{-2})$ for obtaining an ϵ-optimal point for (P-MG). However, unlike previous algorithms for (P-MG) (see Section 1.3 for an extended discussion), their algorithm does not yield an ϵ-optimal point for (D-MG) with the same runtime.

Our instantiation of the dual-extraction framework in Algorithm 3 and the accompanying guarantee Theorem 21 resolves this asymmetry between the complexity of obtaining a primal versus dual ϵ-optimal point by obtaining an ϵ-optimal point of (D-MG) with the same runtime of $\widetilde{O}(nd + n(d/\epsilon)^{2/3} + d\epsilon^{-2})$. At the end of Section 4.1, we observe that Theorem 21 also yields a new state-of-the-art runtime for the primal (P-MG) in the setting of Definition 19 due to the symmetry of the constraint sets and ψ.

Algorithm 3 Dual extraction for matrix games.

Input: $(\psi, \mathcal{X}, \Delta^n)$-simplex setup (Definition 11), iteration count $K \in \mathbb{N}$, dual-regularization schedule $(\lambda_k \in \mathbb{R}_{>0})_{k=0}^{K-1}$, primal-accuracy schedule $(\epsilon_k \in \mathbb{R}_{>0})_{k=1}^{K}$, DRPOSP oracle (Definition 14)

$y_0 \coloneqq \frac{1}{n}\mathbf{1}$

for $k = 1, 2, \ldots, K$ **do**

  $\Lambda_k = \sum_{j=0}^{k-1} \lambda_j$

  $[q_k]_i \propto \prod_{j=0}^{k-1} [y_j]_i^{\lambda_j/\Lambda_k},\ \forall i \in [n]$ // Note: $q_k \in \Delta^n$

  $x_k = \mathrm{DRPOSP}(q_k, \Lambda_k, \epsilon_k, \frac{1}{10K})$

  $[y_k]_i \propto [q_k]_i \cdot \exp(\Lambda_k^{-1} \cdot [A^\top x_k]_i),\ \forall i \in [n]$ // $y_k = \operatorname{argmax}_{y \in \Delta^n} \left\{ x_k^\top A y - \Lambda_k V_{q_k}(y) \right\}$

return y_K

Before giving the guarantee Theorem 21 for Algorithm 3, the following lemma provides a runtime bound for the DRPOSP oracle when the success probability is 9/10 (see Appendix B.1 in the full version for the proof). In particular, Lemma 20 shows that adding dual regularization to (P-MG) does not increase the complexity of obtaining an ϵ-optimal point over the guarantee of [8, Cor. 8.2] discussed above.

▶ **Lemma 20** (DRPOSP oracle for matrix games). *In the settings of Definitions 18 and 19, for any $q \in \Delta^n_{>0}$, $\epsilon_{\mathrm{p}} > 0$, and $\lambda > 0$, with success probability at least 9/10, there exists an algorithm which returns an expected ϵ_{p}-optimal point of $f_{\lambda,q}$ with runtime $\widetilde{O}(nd + n(d/\epsilon_{\mathrm{p}})^{2/3} + d\epsilon_{\mathrm{p}}^{-2})$. (Equivalently, per Definition 14, we have that DRPOSP$(q, \lambda, \epsilon_{\mathrm{p}}, 1/10)$ can be implemented with this runtime.)*

Now for the main guarantee (we defer the proof to the full version):

▶ **Theorem 21** (Guarantee for Algorithm 3). *In the settings of Definitions 18 and 19, given target error $\epsilon > 0$ and with success probability at least 9/10, Algorithm 3 with dual-regularization and primal-accuracy schedules given by*

$$\lambda_k = 2^k \frac{\epsilon}{4 \ln n} \text{ for } k \in \{0\} \cup [K-1] \text{ and } \epsilon_k = \frac{\epsilon}{4K} \text{ for } k \in [K]$$

for $K = \left\lceil \max\left\{ \log_2 \frac{\ln n}{\epsilon^2}, 1 \right\} \right\rceil + 10$ returns an expected ϵ-optimal point for (D-MG)*, and can be implemented with runtime $\widetilde{O}(nd + n(d/\epsilon)^{2/3} + d\epsilon^{-2})$.*

The primal perspective

As alluded to above, the guarantee of Theorem 21 also implies a new state-of-the-art runtime for the primal (P-MG) in the setting of Definition 19. This follows because in the matrix games simplex setup, (P-MG) and (D-MG) are symmetric in terms of their constraint sets, so we can obtain an expected ϵ-optimal point for (P-MG) via Theorem 21 by negating and treating (P-MG) as if it were the dual problem. Formally (we defer the proof to the full version):

▶ **Corollary 22** (Guarantee for (P-MG) in the matrix games simplex setup). *In the setting of Definition 19, there exists an algorithm which, given target error $\epsilon > 0$ and with success probability at least 9/10, returns an expected ϵ-optimal point for* (P-MG) *with runtime $\widetilde{O}(nd + d(n/\epsilon)^{2/3} + n\epsilon^{-2})$.*

See the full version for a discussion of how this runtime compares to the prior art.

4.2 CVaR at level α DRO

In this section, we instantiate $\psi(x, y) \coloneqq \sum_{i=1}^n y_i f_i(x)$ for convex, bounded, and G-Lipschitz (with respect to the Euclidean norm) functions $f_i : \mathbb{R}^d \to \mathbb{R}$.[4] Given a compact, convex set $\mathcal{X}$ and $\alpha \in [1/n, 1]$, the primal and dual problem for CVaR at level α are as follows (we explain the reason for the notation $\bar{f}$ as opposed to f in the full version; in short, we apply the framework to a proxy objective):

$$\underset{x\in\mathcal{X}}{\text{minimize}}\ \bar{f}(x) \qquad \text{for } \bar{f}(x) \coloneqq \max_{y\in\Delta^n, \|y\|_\infty \le \frac{1}{\alpha n}} \sum_{i=1}^n y_i f_i(x), \text{ and} \tag{P-CVaR}$$

$$\underset{y\in\Delta^n, \|y\|_\infty \le \frac{1}{\alpha n}}{\text{maximize}}\ \phi(y) \text{ for } \phi(y) \coloneqq \min_{x\in\mathcal{X}} \sum_{i=1}^n y_i f_i(x). \tag{D-CVaR}$$

Our complexity model in this section is the number of computations of the form $(f_i(x), \nabla f_i(x))$ for $x \in \mathcal{X}$ and $i \in [n]$. We refer to the evaluation of $(f_i(x), \nabla f_i(x))$ for a given $x \in \mathcal{X}$ and $i \in [n]$ as a single *first-order query*. Omitting the Lipschitz constant G and bounds on the range of the f_i's and size of $\mathcal{X}$ for clarity, [29, Sec. 4] gave an algorithm which returns an expected[5] ϵ-optimal point of (P-CVaR) with $\widetilde{O}(\alpha^{-1}\epsilon^{-2})$ first-order queries, and also proved a matching lower bound up to logarithmic factors when n is sufficiently large. However, to the best of our knowledge, the best known complexity for obtaining an expected ϵ-optimal point of (D-CVaR) is $\widetilde{O}(n\epsilon^{-2})$ via a primal-dual method based on [33]; see also [13, 32, 5]. In our main guarantee for this section, Theorem 24, we apply Algorithm 2 to obtain an expected ϵ-optimal point of (D-CVaR) with complexity $\widetilde{O}(\alpha^{-1}\epsilon^{-2} + n)$, which always improves upon or matches $\widetilde{O}(n\epsilon^{-2})$ since $\alpha \in [1/n, 1]$.

Toward stating our main guarantee, we encapsulate the formal assumptions of [29, Sec. 2] in the following definition:

▶ **Definition 23** (CVaR at level α setup)**.** *We assume $\mathcal{X}$ is nonempty, closed, convex, and satisfies $\|x - y\|_2 \le R$ for all $x, y \in \mathcal{X}$. We also assume, for all $i \in [n]$, that f_i is convex, G-Lipschitz with respect to $\|\cdot\|_2$, and satisfies $f_i(x) \in [0, M]$ for all $x \in \mathcal{X}$.*

We ultimately obtain the following guarantee via Algorithm 2. Note that the upper bound on ϵ in Theorem 24 is without loss of generality since if $\epsilon \ge M$, any feasible point is ϵ-optimal. We defer the proof to the full version.

▶ **Theorem 24** (Guarantee for (D-CVaR))**.** *In the setting of Definition 23 with target error $\epsilon \in (0, 4M)$ and $\alpha \in [1/n, 1]$, there exists an algorithm which computes an expected ϵ-optimal point of* (D-CVaR) *with complexity $\widetilde{O}(n + G^2R^2\alpha^{-1}\epsilon^{-2})$.*

5 Obtaining critical points of convex functions

In this section, our goal is to obtain an approximate critical point of a convex, β-smooth function $h : \mathbb{R}^n \to \mathbb{R}$, given access to a gradient oracle for h. We show that our general framework yields an algorithm with the optimal query complexity for this problem. In

[4] Note that we do not require the functions f_i to be differentiable. Here, it is important that Definition 9 only requires $\psi(x, \cdot)$ to be differentiable.

[5] To be precise, [29] gives a $\widetilde{O}(\alpha^{-1}\epsilon^{-2})$-complexity high probability bound in Theorem 2. They do not state a $\widetilde{O}(\alpha^{-1}\epsilon^{-2})$-complexity expected suboptimality bound explicitly in a theorem, but they note in the text above Theorem 2 that such a bound follows immediately from Propositions 3 and 4 in their paper.

Section 5.1, we give the formal problem definition and some important preliminaries. In Section 5.2, we give the setup for applying our main framework Algorithm 2 to this problem and a sketch of why the resulting algorithm works. In Section 5.3, we formally state the resulting algorithm for obtaining an approximate critical point of h and prove that it achieves the optimal rate using the guarantees associated with Algorithm 2.

5.1 Preliminaries for Section 5

Throughout Section 5, we fix $\|\cdot\|$ to be the standard Euclidean norm over $\mathbb{R}^n$. We assume $h : \mathbb{R}^n \to \mathbb{R}$ is convex, β-smooth with respect to $\|\cdot\|$, and $\Delta \coloneqq h(x_0) - \inf_{x\in\mathbb{R}^n} h(x) < \infty$ for an arbitrary initialization point $x_0 \in \mathbb{R}^n$. We access h through a gradient oracle. For $\gamma > 0$, our goal will be to obtain a γ-critical point of h, i.e., a point $x \in \mathbb{R}^n$ such that $\|\nabla h(x)\| \le \gamma$. Instead of operating on h itself, our algorithm will operate on a regularized version of h:

$$f(x) \coloneqq h(x) + \frac{\gamma^2}{16\Delta}\|x - x_0\|^2. \tag{11}$$

This notation was chosen to mirror the notation of Section 3.1; f will be the primal function when we apply the framework. Let $x_f^\star$ denote the unique global minimum of f. The following corollary of Lemma 13 in Appendix C in the full version summarizes the key properties of f:

▶ **Corollary 25** (Properties of the regularized function f)**.** *We have*
1. $\|x_f^\star - x_0\| \le 4\Delta/\gamma$.
2. *If* $u \in \mathbb{R}^n$ *is such that* $\|\nabla f(u)\| \le \gamma/4$*, then* $\|\nabla h(u)\| \le \gamma$.

Proof. This follows immediately from Lemma 13 in the full version with $\alpha \leftarrow \frac{\gamma^2}{8\Delta}$ and $\nu \leftarrow \gamma/4$. ◀

The second part of Corollary 25 says that to find a γ-critical point of h, it suffices to find a $(\gamma/4)$-critical point of f. Furthermore, clearly a single query to ∇h suffices to obtain ∇f at a point. As a result, we will focus on finding a $(\gamma/4)$-critical point of f. Furthermore, Corollary 25 may be of independent interest since it trivially allows one to achieve a gradient query complexity of $O\left(\sqrt{\beta\Delta}/\gamma\right)$ via a method which achieves query complexity $O\left(\sqrt{\beta\|x_0 - x_h^\star\|/\gamma}\right)$ (for $x_h^\star$ defined as some minimizer of h over $\mathbb{R}^n$, assuming one exists); see Section 1.3.

The reason we perform this regularization before applying our framework is it enables us to obtain a sufficiently tight bound on $V_{y_0}(y^\star)$ (equivalently, a small enough value of B when we ultimately apply Corollary 17). It is possible to apply the framework more directly to h, but it is not clear how to do so in a way that achieves an optimal complexity.

Finally, we provide a notation guide for Section 5 in Table 1, which may be useful to reference as additional notation is introduced in Sections 5.2 and 5.3.

5.2 Instantiating the framework

For this application, we instantiate

$$\psi(x, y) \coloneqq \langle x, y\rangle - f^*(y).$$

Recall that ψ is the *Fenchel game* [1, 43, 12, 23]; see Section 1.1 for a discussion of why it is a natural choice in this setting. For the rest of Section 5, we fix a $(\psi, \mathcal{X} \coloneqq B_R^n(x_0), \mathcal{Y} \coloneqq \mathbb{R}^n, f^*)$-unbounded setup (Definition 10) with $R \coloneqq 5\Delta/\gamma$. f^* is a valid choice for the dgf because

Table 1 Notation guide for Section 5.

Notation	Description	Section
$\|\cdot\|$	Euclidean norm	5.1
h	Convex, β-smooth function	
γ	Target critical point error for h	
x_0	Arbitrary initialization point	
Δ	$h(x_0) - \inf_{x\in\mathbb{R}^n} h(x) < \infty$	
$f(x)$	$h(x) + \frac{\gamma^2}{16\Delta}\|x - x_0\|^2$	
$x_f^\star$	The global minimizer of f	
$\psi(x, y)$	$\langle x, y\rangle - f^*(y)$	5.2
R	$5\Delta/\gamma$	
$\mathcal{X}$	$B_R^n(x_0)$	
$\mathcal{Y}$	$\mathbb{R}^n$	
dgf r	f^*	
$\phi(y)$	$\langle x_0, y\rangle - R\|y\| - f^*(y)$	
λ_k	$2^k/32$	5.3
ϵ_k	$\Delta/(64 \cdot 1.5^k)$	
CGM	Fast composite gradient method oracle	

f^* is differentiable and $\left(\beta + \frac{\gamma^2}{8\Delta}\right)^{-1}$-strongly convex [38, Thm. 6.11]. The strong convexity of f^* also implies that Assumption 6 holds. Note that the associated primal function $x \mapsto \max_{y\in\mathbb{R}^n} \psi(x, y)$ is precisely $f^{**} = f$ (hence the choice of notation in (11)), and the dual function is given by

$$\phi(y) = \min_{x\in B_R^n(x_0)} \{\langle x, y\rangle - f^*(y)\} = \left\langle x_0 - R\frac{y}{\|y\|}, y\right\rangle - f^*(y) = \langle x_0, y\rangle - R\|y\| - f^*(y).$$

Next, the following lemma fulfills part of the outline given in Section 1.1 by showing that approximately optimal points for the dual objective (D) must have small norm. We defer the proof to the full version.

▶ **Lemma 26** (Bounding the norm by dual suboptimality). *If $y \in \mathbb{R}^n$ is ϵ-optimal for* (D) *for some $\epsilon > 0$, then $\|y\| \le \epsilon\gamma/\Delta$.*

We now derive the oracles of Definitions 12 and 13. Regarding Definition 12, for the rest of Section 5 we restrict DRPO$(\cdot)$ to denote a deterministic implementation of the DRPO oracle, since we can always obtain a deterministic implementation in this application. Then the following corollary is an immediate consequence of a more general lemma given in Appendix C in the full version which characterizes the properties of the Fenchel game with added dual regularization; see also Section 1.1.

▶ **Corollary 27.** *The set of valid output points of $DRPO(q \in \mathbb{R}^n, \lambda > 0, \epsilon_{\mathrm{p}} > 0)$ is precisely*

$$\operatorname*{argmin}^{\epsilon_{\mathrm{p}}}_{x\in B_R^n(x_0)} (1+\lambda)\cdot f\left(\frac{x + \lambda\nabla f^*(q)}{1+\lambda}\right), \text{ and}$$

$$DRBR(q \in \mathbb{R}^n, \lambda > 0, x \in B_R^n(x_0)) = \nabla f\left(\frac{x + \lambda\nabla f^*(q)}{1+\lambda}\right).$$

Proof. Apply Lemma 14 in the full version with $g \leftarrow f$. ◀

Taken together, Lemma 26 and Corollary 27 nearly immediately imply that Algorithm 2 can be applied to the above setup to obtain a $(\gamma/4)$-critical point of f (and therefore a γ-critical point of h). In particular, we will apply the schedules of Corollary 17 to certify that the output y_K of Algorithm 2 is close in distance to an ϵ-optimal point for (D) for an appropriate choice of $\epsilon > 0$. Then Lemma 26 and a triangle inequality yield a bound on $\|y_K\|$. Finally, since

$$y_K \coloneqq \mathrm{DRBR}(q_K, \Lambda_K, x_K) = \nabla f\left(\frac{x_K + \Lambda_K \nabla f^*(q_K)}{1 + \Lambda_K}\right)$$

by Corollary 27, we have that $\frac{x_K+\Lambda_K\nabla f^*(q_K)}{1+\Lambda_K}$ is an approximate critical point of f (and therefore h). One may worry about the presence of $\nabla f^*(q_K)$ here and, more generally, the presence of $\nabla f^*(q)$ in the expressions for the oracles in Corollary 27. However, $\nabla f^*(\cdot)$ never needs to be evaluated explicitly since per the alternate expression for q_k given in Line 3 of Algorithm 2, note that q_k was itself computed as the gradient of f at a point (recall the dgf is f^* and $f = f^{**}$), in which case ∇f^* simply undoes this operation by Lemma 16 in the full version.

We formalize this sketch and provide a complexity guarantee in the next section. We also reframe this sketch and treat the sequence of $\frac{x_k+\Lambda_k\nabla f^*(q_k)}{1+\Lambda_k}$ terms as our iterates (as opposed to the sequence of x_k's), as this leads to a simpler statement and interpretation of the resulting algorithm.

5.3 The resulting algorithm and guarantee

We now formalize the sketch given at the end of the previous section, state the resulting algorithm, and provide a complexity guarantee. But first, we define a subroutine which will be used by the algorithm to implement the DRPO oracle:

▶ **Definition 28** (CGM oracle [40, 36]). *A $(\zeta > 0, w \in \mathbb{R}^n, \epsilon > 0)$-fast composite gradient method oracle, $CGM(\zeta, w, \epsilon)$, returns an ϵ-minimizer of f over $x \in B_\zeta^n(w)$, i.e., an element of $\operatorname{argmax}^{\epsilon}_{x \in B_\zeta^n(w)} f(x)$, using at most $O\left(1 + \sqrt{\frac{\beta\zeta^2}{\epsilon}}\right)$ queries to ∇f.*

For example, implementations with a small constant can be found in [40] or [36, Sec. 6.1.3]. The implementation of the CGM oracle falls under fast gradient methods for composite minimization, where letting g denote a convex, β-smooth function and Ψ a "simple regularizer" (a quadratic in our case), the goal is to minimize $\tilde{g}(x) \coloneqq g(x) + \Psi(x)$ with the same complexity as it takes to minimize g. The domain constraint can also be baked into the regularizer Ψ by adding an indicator.

Our method for computing a γ-critical point of h is given in Algorithm 4, with the associated guarantee in Theorem 30. We note that the decision to introduce the equivalent notation z_0 for x_0 in Line 1 is aesthetic (to make Line 5 simpler to state and interpret). Furthermore, we state Algorithm 4 for general schedules $(\lambda_k)_{k=0}^{K-1}$ and $(\epsilon_k)_{k=1}^{K}$ for clarity, but ultimately we will choose the schedules given in Theorem 30, which correspond to particularizing the schedules of Corollary 17 to this setting. With this choice of schedules, $\Lambda_k \approx 2^k$ and $\epsilon_k \approx \Delta/1.5^k$ so that $\frac{\epsilon_k}{1+\Lambda_k} \approx \Delta/3^k$. As a result, Algorithm 4 can be interpreted as optimizing f in a sequence of balls where the radius and target error are both decreasing geometrically, and the center is a convex combination of the past iterates. While we choose the iteration count K to be logarithmic in the problem parameters, we avoid multiplicative

logarithmic factors in the total complexity because the ratio ζ^2/ϵ in the complexity of the CGM oracle call (to borrow the notation of Definition 28) in Line 5 of Algorithm 4 is $\approx \frac{R^2}{4^k} \cdot \frac{3^k}{\Delta}$ at the k-th iteration, meaning it is collapsing geometrically.

Algorithm 4 Algorithm for obtaining a γ-critical point of h.

Input: Sequences $(\lambda_k)_{k=0}^{K-1}$ and $(\epsilon_k)_{k=1}^{K}$ specified in Theorem 30, iteration count $K \in \mathbb{N}$, CGM oracle (Definition 28)

1 $z_0 := x_0$
2 **for** $k = 1, 2, \ldots, K$ **do**
3 $\quad \Lambda_k = \sum_{j=0}^{k-1} \lambda_j$
4 $\quad w_k = \frac{z_0 + \sum_{j=0}^{k-1} \lambda_j z_j}{1+\Lambda_k}$
5 $\quad z_k = \mathrm{CGM}\left(\frac{R}{1+\Lambda_k}, w_k, \frac{\epsilon_k}{1+\Lambda_k}\right)$ // $z_k \in \operatorname{argmin}^{\epsilon_k/(1+\Lambda_k)}_{z \in B^n_{R/(1+\Lambda_k)}(w_k)} f(z)$
6 **return** z_K

Toward analyzing Algorithm 4, we first connect the sequence of iterates z_k produced by Algorithm 4 to the sequence of iterates x_k, y_k, q_k produced by Algorithm 2 with the same input parameters. Namely, we are formalizing the comment made at the end of Section 5.2 about reframing the sequence of iterates to achieve a more interpretable algorithm. We defer the proof to the full version.

▶ **Lemma 29** (Connecting Algorithm 4 to Algorithm 2). *Consider Algorithm 2 with input given by a $(\psi, B_R^n(x_0), \mathbb{R}^n, f^*)$-unbounded setup (Definition 10); $y_0 := \nabla f(x_0)$; and K, $(\epsilon_k)_{k=1}^K$, and $(\lambda_k)_{k=0}^{K-1}$ as in Algorithm 4. Then letting $(z_k)_{k=0}^K$ denote the sequence of iterates generated by Algorithm 4, the following are valid sequences of iterates for Algorithm 2:*

$$q_k = \nabla f\left(\frac{1}{\Lambda_k}\sum_{j=0}^{k-1} \lambda_j z_j\right) \quad \text{for } k \in [K], \tag{12}$$

$$x_k = (1+\Lambda_k) z_k - \sum_{j=0}^{k-1} \lambda_j z_j \quad \text{for } k \in [K], \text{ and} \tag{13}$$

$$y_k = \nabla f(z_k) \quad \text{for } k \in \{0\} \cup [K]. \tag{14}$$

Having connected Algorithm 4 to Algorithm 2, we can apply the schedules given in Corollary 17 to show that Algorithm 4 returns a γ-critical point of h with an optimal complexity. We defer the proof to the full version.

▶ **Theorem 30** (Guarantee for Algorithm 4). *For any[6] $\gamma \in (0, \sqrt{2\beta\Delta})$ and with $K = O(\log(\beta\Delta/\gamma))$, the output of Algorithm 4 with schedules given by*

$$\lambda_k = \frac{2^k}{32} \text{ for } k \in \{0\} \cup [K-1] \text{ and } \epsilon_k = \frac{\Delta}{64 \cdot 1.5^k} \text{ for } k \in [K] \tag{15}$$

satisfies $\|\nabla h(z_K)\| \le \gamma$, and the algorithm makes at most $O\left(\frac{\sqrt{\beta\Delta}}{\gamma}\right)$ gradient queries to h.

[6] The restriction on γ is without loss of generality since $\|\nabla h(x_0)\| \le \sqrt{2\beta\Delta}$ by smoothness. We add it because it simplifies the analysis.

Abstract

The *Circuit Size Hierarchy* (CSH^a_b) states that if $a > b \geq 1$ then the set of functions on n variables computed by Boolean circuits of size n^a is strictly larger than the set of functions computed by circuits of size n^b. This result, which is a cornerstone of circuit complexity theory, follows from the *non-constructive* proof of the existence of functions of large circuit complexity obtained by Shannon in 1949.

Are there more "constructive" proofs of the Circuit Size Hierarchy? Can we quantify this? Motivated by these questions, we investigate the provability of CSH^a_b in theories of bounded arithmetic. Among other contributions, we establish the following results:

- **(i)** Given any $a > b > 1$, CSH^a_b is provable in Buss's theory T^2_2.
- **(ii)** In contrast, if there are constants $a > b > 1$ such that CSH^a_b is provable in the theory T^1_2, then there is a constant $\varepsilon > 0$ such that P^{NP} requires non-uniform circuits of size at least $n^{1+\varepsilon}$.

In other words, an improved *upper bound* on the proof complexity of CSH^a_b would lead to new *lower bounds* in complexity theory.

We complement these results with a proof of the *Formula Size Hierarchy* (FSH^a_b) in PV_1 with parameters $a > 2$ and $b = 3/2$. This is in contrast with typical formalizations of complexity lower bounds in bounded arithmetic, which require APC_1 or stronger theories and are not known to hold even in T^1_2.

1 Introduction

1.1 Context and Motivation

The existence of Boolean functions requiring large circuits can be shown by a non-constructive counting argument, as established by Shannon in 1949 [24]. It follows from Shannon's seminal result and a simple padding argument that if $a > b \geq 1$ there are functions computable by circuits of size n^a that cannot be computed by circuits of size n^b. In other words, the classification of Boolean functions by their minimum circuit size forms a strict *hierarchy*.

Obtaining a "constructive" form of these results has been a holy grail in computational complexity theory for several decades due to its connections to derandomization and as an approach to separating P and NP. For instance, if there is a polynomial-time algorithm that given 1^n outputs the truth-table of a function $f\colon \{0,1\}^{\log n} \to \{0,1\}$ that requires circuits of size $n^{\Omega(1)}$, then $\mathsf{P} = \mathsf{BPP}$ [9]. In results of this form, a constructive form of the (non-constructive) proof of the existence of hard functions is interpreted *computationally* as the existence of an algorithm of bounded complexity that computes a hard function.

In this paper, rather than focusing on the existence of algorithms to capture the constructiveness of a statement, we explore this notion from the perspective of mathematical logic, specifically concerning its *provability* in certain mathematical theories. We are interested in identifying the weakest theory capable of establishing the aforementioned circuit size hierarchy for Boolean circuits and related results.

As one of our contributions, we present a tight connection between the computational and proof-theoretic perspectives. We demonstrate that proving the non-uniform circuit size hierarchy in a theory known as T^1_2 implies the existence of a function in P^{NP} that requires Boolean circuits of size at least $n^{1+\varepsilon}$. The latter is a frontier question in complexity theory (see, e.g., [5]). Thus, in a precise sense, developing more constructive proofs of the circuit size hierarchy would lead to significant progress on explicit circuit lower bounds.

We now proceed to describe this result and other contributions of this work in detail.

1.2 Results

We will be concerned with standard theories of bounded arithmetic. These theories are designed to capture proofs that manipulate and reason with concepts from a specified complexity class. Notable examples include Cook's theory PV_1 [7], which formalizes polynomial-time reasoning; Jeřábek's theory APC_1 [10, 11, 13], which extends PV_1 by incorporating the dual weak pigeonhole principle for polynomial-time functions and formalizes probabilistic polynomial-time reasoning; and Buss's theories T^i_2 [2], which incorporate induction principles corresponding to various levels of the polynomial-time hierarchy.

For an introduction to bounded arithmetic, we refer to [3]. For its connections to computational complexity and a discussion on the formalization of complexity theory, we refer to [23].[1] Here we only recall that theory PV_1 corresponds essentially to T^0_2 [12], and that $\mathsf{T}^0_2 \subseteq \mathsf{T}^1_2 \subseteq \mathsf{T}^2_2$ correspond to the first levels of Buss's hierarchy. A brief overview of the theories is provided in Section 2.

For a given $n \in \mathbb{N}$, we use $\mathsf{CIRCUIT}[s(n)]$ to denote the set of Boolean functions $f\colon \{0,1\}^n \to \{0,1\}$ computed by circuits of size at most $s(n)$. Similarly, when referring to formula size, we write $\mathsf{FORMULA}[s(n)]$. We use $\mathsf{SIZE}[s(n)]$ to denote the set of languages $L \subseteq \{0,1\}^*$ that admit a sequence of circuits of size at most $s(n)$.

[1] In particular, the reference [23] contains a detailed discussion of some aspects of the formalization of the statements appearing below.

Circuit Size Hierarchy

For rationals $a > b \geq 1$ and n_0, we consider the following sentence:[2]

$$\mathsf{CSH}[a,b,n_0] \equiv \forall n \geq n_0 \in \mathsf{Log},\ \exists \text{ circuit } D\colon \{0,1\}^n \to \{0,1\} \text{ of size} \leq n^a,$$
$$\forall \text{ circuit } C\colon \{0,1\}^n \to \{0,1\} \text{ of size} \leq n^b,\ \exists x \in \{0,1\}^n \text{ such that } D(x) \neq C(x).$$

In other words, $\mathsf{CSH}[a,b,n_0]$ states that $\mathsf{CIRCUIT}[n^a] \not\subseteq \mathsf{CIRCUIT}[n^b]$ whenever $n \geq n_0$.

Next, we state our first result.

▶ **Theorem 1.** *The following results hold:*

(i) *For every choice of rationals a and b with $a > b > 1$, and for every large enough $n_0 \in \mathbb{N}$,*

$$\mathsf{T}^2_2 \vdash \mathsf{CSH}[a,b,n_0]\,.$$

(ii) *If there are rationals $a > b > 1$ and a constant $n_0 \in \mathbb{N}$ such that*

$$\mathsf{T}^1_2 \vdash \mathsf{CSH}[a,b,n_0]\,,$$

then there is a constant $\varepsilon > 0$ and a language $L \in \mathsf{P}^{\mathsf{NP}}$ such that $L \notin \mathsf{SIZE}[n^{1+\varepsilon}]$.

(iii) *Similarly to the previous item, if $\mathsf{PV}_1 \vdash \mathsf{CSH}[a,b,n_0]$, there is $L \in \mathsf{P}$ such that $L \notin \mathsf{SIZE}[n^{1+\varepsilon}]$.*

To put it another way, we can establish a circuit size hierarchy within the theory T^2_2. If this result could also be proven in the theory T^1_2, it would lead to a significant breakthrough in circuit lower bounds. Thus, by enhancing the proof complexity upper bound for the provability of the circuit size hierarchy, we can achieve new circuit lower bounds.

The proof technique of Item (ii) also applies to the theory T^2_2, which combined with Item (i) gives us a superlinear lower bound for a language in $\mathsf{P}^{\Sigma^p_2}$, but this is already known by Kannan's theorem [15].

Note that in Theorem 1 Items (ii) and (iii) we obtain a lower bound against circuits of size $n^{1+\varepsilon}$, where the constant $\varepsilon > 0$ depends on the proof of $\mathsf{CSH}[a,b,n_0]$ in the corresponding theory. In other words, while the sentence claims the existence of hardness against circuits of size n^b, we are only able to extract a weaker lower bound for an explicit problem.

In our next result, we describe a setting where we can extract all the hardness from a proof of the corresponding sentence.

Succinct Circuit Size Hierarchy

We define what we call the succinct version of the circuit size hierarchy, where we substitute the upper bound circuit with a collection of labelled examples for the function, which can always represent a circuit. For rationals $a > b \geq 1$ and n_0, we consider the following sentence:

$$\begin{aligned}\mathsf{SCSH}[a,b,n_0] \equiv\ & \forall n \geq n_0 \in \mathsf{Log},\ \exists \text{ collection } \{(x^1,b^1),\ldots,(x^\ell,b^\ell)\} \text{ of size } \ell \leq n^a \text{ with}\\ & |x^i| = n \wedge |b^i| = 1 \text{ for each } i \in [\ell] \text{ and } x^i \neq x^j \text{ for distinct } i,j \in [\ell]\,,\\ & \forall \text{ circuit } C\colon \{0,1\}^n \to \{0,1\} \text{ of size} \leq n^b,\ \exists i \in [\ell] \text{ s.t. } C(x^i) \neq b^i.\end{aligned}$$

In other words, $\mathsf{SCSH}[a,b,n_0]$ states that for every $n \geq n_0$ there is a collection of $\ell \leq n^a$ labelled examples such that every circuit of size at most n^b disagrees with at least one of its labels. The truth of this statement can be validated by a counting argument, similarly with the circuit size hierarchy proof.

[2] The abbreviation $n \in \mathsf{Log}$ denotes that n is the length of a variable N (see, e.g., [23] for more details).

We obtain the following results on the proof complexity of the succinct circuit size hierarchy.

▶ **Theorem 2.** *The following results hold:*

(i) *For every choice of rationals $a > b > 1$ and for every large enough $n_0 \in \mathbb{N}$,*

$$\mathsf{T}^2_2 \vdash \mathsf{SCSH}[a, b, n_0]\,.$$

(ii) *If there are rationals $a > b > 1$ and a constant $n_0 \in \mathbb{N}$ such that*

$$\mathsf{T}^1_2 \vdash \mathsf{SCSH}[a, b, n_0]\,,$$

then there is a language $L \in \mathsf{P}^{\mathsf{NP}}$ such that $L \notin \mathsf{SIZE}[n^b]$.

In our final result, we investigate the provability of size hierarchies for more restricted computational models in T^1_2 and weaker theories.

Formula Size Hierarchy

For rationals $a > b \geq 1$ and n_0, we consider the following sentence:

$$\mathsf{FSH}[a, b, n_0] \equiv \forall n \geq n_0 \in \mathsf{Log},\ \exists \text{ formula } F\colon \{0,1\}^n \to \{0,1\} \text{ of size} \leq n^a,$$
$$\forall \text{ formula } G\colon \{0,1\}^n \to \{0,1\} \text{ of size} \leq n^b,\ \exists x \in \{0,1\}^n \text{ such that } F(x) \neq G(x).$$

In other words, $\mathsf{FSH}(a, b, n_0)$ states that $\mathsf{FORMULA}[n^a] \not\subseteq \mathsf{FORMULA}[n^b]$ whenever $n \geq n_0$.

We establish that for some parameters a formula size hierarchy is provable already in PV_1.

▶ **Theorem 3.** *Consider rationals $a > 2$ and $b = 3/2$, and let n_0 be a large enough positive integer. Then*

$$\mathsf{PV}_1 \vdash \mathsf{FSH}[a, b, n_0]\,.$$

While many lower bounds can be proven in APC_1 and stronger theories (see [22, 23, 4] and references therein), Theorem 3 provides an example of a non-trivial lower bound (under a "Log" formalization; see [23, Section 4.1]) that can be established in PV_1, which might be of independent interest.

1.3 Techniques

The proofs of Items (ii) and (iii) in Theorem 1 are inspired by arguments from [18, 17] that rely on a combination of a witnessing theorem with a term elimination strategy. Recall that the witnessing theorem allows us to extract computational information from a proof of the sentence in the theory. Roughly speaking, in our context this implies that the first existential quantifier in the sentence $\mathsf{CSH}[a, b, n_0]$, which corresponds to a circuit computing a hard function, can be witnessed by a finite number of terms $t_1, \ldots, t_k$ of the corresponding theory. In PV_1, a term yields a polynomial-time function, while in T^1_2 a term yields a polynomial-time function with access to an NP oracle. The main difficulty is that (1) for a given input length n it is not clear which term among $t_1, \ldots, t_k$ succeeds in constructing a hard function, and (2) for a term to succeed we must provide counter-examples to the candidate witnesses provided by previous terms.

As in previous papers, we assume that the conclusion of the theorem does not hold, and use this assumption to rule out the correctness of each term. This leads to a contradiction, meaning that the original sentence is not provable in the corresponding theory. Implementing

this plan requires a careful argument, and we are currently only able to carry it out under a complexity inclusion in $\mathsf{SIZE}[n^{1+\varepsilon}]$ as opposed to $\mathsf{SIZE}[n^b]$. The proof of the result is given in Section 3.1.

On the other hand, in the case of the succinct circuit size hierarchy, the argument for Item (ii) of Theorem 2 is simpler and allows us to start with the weaker assumption that $\mathsf{P}^{\mathsf{NP}} \subseteq \mathsf{SIZE}[n^b]$. Without getting into the technical details, the main reason for not losing hardness in this result is that given a labelled list of examples and access to an NP oracle, we can efficiently compute a minimum size circuit that agrees with this list of inputs. Consequently, we can check if a candidate labelled list provided by a term is indeed hard, or produce a counter-example when this is not the case. The same computation is not available in the case of Theorem 1, since it is not clear how to efficiently compute with access to an NP oracle if a given circuit admits a smaller equivalent circuit. The proof of Item (ii) of Theorem 2 appears in Section 3.2.

The proofs of Theorem 1 Item (i) and Theorem 2 Item (i) are given in Section 3.3. The formalization of these hierarchies in T^2_2 is easily done with access to the dual Weak Pigeonhole Principle for polynomial-time functions, a principle which is known to be available in T^2_2. In more detail, CSH follows from SCSH in PV_1, while SCSH can be established in theory APC_1, which is contained in T^2_2.

Finally, in the proof of Theorem 3 we formalize in PV_1 that the parity function on n bits can be computed by formulas of size $O(n^2)$ and require formulas of size $\Omega(n^{3/2})$. This yields in PV_1 a proof of $\mathsf{FSH}[a, b, n_0]$ for any choice of parameters $a > 2$, large enough n_0, and $b = 3/2$. The upper bound on the complexity of parity follows from a straightforward formalization of the correctness of the formula obtained via a divide-and-conquer procedure. On the other hand, in order to show the formula lower bound we formalize Subbotovskaya's argument [25] based on the method of restrictions. To implement the proof in PV_1, we directly define an efficient refuter that given a small formula outputs an input string where it fails to compute the parity function. The correctness of the refuter is established by induction using an induction principle available in the theory S^1_2. We then rely on a conservation result showing that the proof can also be done in PV_1. A detailed exposition of the argument appears in Section 4.

2 Preliminaries

2.1 Complexity Theory

We employ standard definitions from complexity theory, such as basic complexity classes, Boolean circuits, and Boolean formulas (see, e.g., [1]).

Let $\mathbb{N}$ represent the set of non-negative integers. For any $a \in \mathbb{N}$, let $|a|$ denote the length of its binary representation, defined as $|a| \triangleq \lceil \log_2(a+1) \rceil$. For a constant $k \geq 1$, a function $f\colon \mathbb{N}^k \to \mathbb{N}$ is said to be computable in polynomial time if $f(x_1, \ldots, x_k)$ can be computed in time polynomial in $|x_1|, \ldots, |x_k|$. For convenience, we might write $|\vec{x}| \triangleq |x_1|, \ldots, |x_k|$. The class FP denotes the set of polynomial-time computable functions. Although the definition of polynomial time typically refers to a machine model, FP can also be defined in a machine-independent manner as the closure of a set of base functions $\mathcal{F}$ (not described here) under *composition* and *limited recursion on notation*. A function $f(\vec{x}, y)$ is defined from functions $g(\vec{x})$, $h(\vec{x}, y, z)$, and $k(\vec{x}, y)$ by *limited recursion on notation* if

$$f(\vec{x}, 0) = g(\vec{x})$$
$$f(\vec{x}, y) = h(\vec{x}, y, f(\vec{x}, \lfloor y/2 \rfloor))$$
$$f(\vec{x}, y) \leq k(\vec{x}, y)$$

for every sequence $(\vec{x}, y)$ of natural numbers. Cobham [6] established that FP is the smallest class of functions that contains the base functions $\mathcal{F}$ and is closed under composition and limited recursion on notation.

2.2 Bounded Arithmetic

2.2.1 Logical Theories

We recall the definitions of some standard theories of bounded arithmetic. For more details, the reader can consult [16, 8, 20].

2.2.1.1 Cook's Theory PV [7]

The theory PV_1 is designed to model the set $\mathbb{N}$ of natural numbers with the standard interpretations for constants and function symbols like $0, +, \times$, etc. The vocabulary (language) of PV, denoted $\mathcal{L}_{\mathsf{PV}}$, includes a function symbol for each polynomial-time algorithm $f\colon \mathbb{N}^k \to \mathbb{N}$, where k is any constant. These function symbols and their defining axioms are derived using Cobham's characterization of polynomial-time functions discussed above. While Cook's PV was an equational theory, it was later extended in [19] to a first-order theory PV_1, which includes an induction axiom scheme that simulates binary search. It can be shown that PV_1 allows induction over quantifier-free formulas (i.e., polynomial-time predicates).

PV_1 can be formulated with all axioms as universal formulas (i.e., $\forall \vec{x}\, \phi(\vec{x})$, where ϕ is free of quantifiers). Thus, PV_1 is a *universal theory*. Although the definition of PV_1 is quite technical, the theory is fairly robust and the details of its definition are often unnecessary for practical purposes. In particular, PV_1 has an equivalent formalizations that does not rely on Cobham's result, e.g. [12].

2.2.1.2 Jeřábek's Theory APC_1 [10, 11, 13]

APC_1 extends PV_1 with the *dual Weak Pigeonhole Principle* (dWPHP) for PV_1 functions:

$$\mathsf{APC}_1 \triangleq \mathsf{PV} \cup \{\mathsf{dWPHP}(f) \mid f \in \mathcal{L}_{\mathsf{PV}}\}.$$

Each sentence $\mathsf{dWPHP}(f)$ postulates that, for every length $n = |N|$ and for every choice of $\vec{z}$, there is $y < (1 + 1/n) \cdot 2^n$ such that $f(\vec{z}, x) \neq y$ for every $x < 2^n$. It is known that APC_1 is contained in T^2_2 [21].

2.2.1.3 Buss's Theories S^i_2 and T^i_2 [2]

The language $\mathcal{L}_B$ for these theories includes predicate symbols $=$ and $\leq$, constant symbols 0 and 1, and function symbols S (successor), $+$, $\cdot$, $\lfloor x/2 \rfloor$, $|x|$ (interpreted as the length of x), and $\#$ (interpreted as $x\#y = 2^{|x|\cdot|y|}$, known as "smash").

Recall that a *bounded quantifier* is a quantifier of the form $Qy \leq t$, where $Q \in \{\exists, \forall\}$ and t is a term not involving y. Similarly, a *sharply bounded quantifier* is one of the form $Qy \leq |t|$. A formula where each quantifier appears bounded (or sharply bounded) is called a bounded (or sharply bounded) formula.

We can create a hierarchy of formulas by counting alternations of bounded quantifiers. The class $\Pi^b_0 = \Sigma^b_0$ contains the sharply bounded formulas. Recursively, for each $i \geq 0$, the classes Σ^b_i and Π^b_i are defined by the quantifier structure of the sentence, ignoring sharply bounded quantifiers. For instance, if $\varphi \in \Sigma^b_0$ and $\psi \triangleq \exists y \leq t(\vec{x})\ \varphi(y, \vec{x})$, then $\psi \in \Sigma^b_1$. For

the general case of the definition, see [16]. It is known that for each $i \geq 1$, a predicate $P(\vec{x})$ is in Σ_i^p (the i-th level of the polynomial hierarchy) if and only if there is a Σ_i^b-formula that agrees with it over $\mathbb{N}$.

These theories share a common set of finitely many axioms, BASIC, which postulate the expected arithmetic behavior of the constants, predicates, and function symbols. The only difference among the theories is the type of induction axiom scheme each one postulates.

T_2^i is a theory in the language $\mathcal{L}_B$ that extends BASIC by including the induction axiom IND:

$$\varphi(0) \wedge \forall x\,(\varphi(x) \to \varphi(x+1)) \to\ \forall x\,\varphi(x)$$

for all Σ_i^b-formulas $\varphi(a)$. The formula $\varphi(a)$ may contain other free variables in addition to a.

S_2^i is a theory in the language $\mathcal{L}_B$ that extends BASIC by including the polynomial induction axiom PIND:

$$\varphi(0) \wedge \forall x\,(\varphi(\lfloor x/2 \rfloor) \to \varphi(x)) \to\ \forall x\,\varphi(x)$$

for all Σ_i^b-formulas $\varphi(a)$. The formula $\varphi(a)$ may contain other free variables in addition to a.

2.2.1.4 Theory $\mathsf{S}_2^1(\mathsf{PV})$

When proving some results in S_2^1, it is often convenient to use a more expressive vocabulary that easily describes any polynomial-time function. This can be done in a *conservative* manner, meaning the power of the theory is not increased. Specifically, let Γ be a set of $\mathcal{L}_B$-formulas. We say that a polynomial-time function $f\colon \mathbb{N}^k \to \mathbb{N}$ is Γ-*definable* in S_2^1 if there exists a formula $\psi(\vec{x}, y) \in \Gamma$ such that the following conditions are met:

(i) For every $\vec{a} \in \mathbb{N}^k$, $f(\vec{a}) = b$ if and only if $\mathbb{N} \models \varphi(\vec{a}, b)$.

(ii) $\mathsf{S}_2^1 \vdash \forall \vec{x}\,(\exists y\,(\varphi(\vec{x}, y) \wedge \forall z\,(\varphi(\vec{x}, z) \to y = z)))$.

Every function $f \in \mathsf{FP}$ is Σ_1^b-definable in S_2^1. By incorporating all functions in FP into the vocabulary of S_2^1 and extending the axioms of S_2^1 with their defining equations, we obtain a theory $\mathsf{S}_2^1(\mathsf{PV})$. This theory allows polynomial-time predicates to be referred to using quantifier-free formulas. $\mathsf{S}_2^1(\mathsf{PV})$ remains conservative over S_2^1, meaning any $\mathcal{L}_B$-sentence provable in $\mathsf{S}_2^1(\mathsf{PV})$ is also provable in S_2^1. Finally, it is known that $\mathsf{S}_2^1(\mathsf{PV})$ proves the polynomial induction scheme for both Σ_1^b-formulas and Π_1^b-formulas within the extended vocabulary.

2.2.2 The KPT Witnessing Theorem

The following witnessing theorem (a variant of Herbrand's theorem) is proved in [19] (cf. also [16, Theorem 7.4.1]) for universal theories (like the theory PV_1).

▶ **Theorem 4** (KPT Theorem for $\forall\exists\forall\exists$ sentences)**.** *Let* T *be a universal theory with vocabulary* $\mathcal{L}$*. Let* φ *be an open* $\mathcal{L}$*-formula, and suppose that*

$$\mathsf{T} \vdash\ \forall x\,\exists y\,\forall z\,\exists w\ \varphi(x, y, z, w).$$

Then there is a finite sequence $s_1, \ldots, s_k$ *of* $\mathcal{L}$*-terms such that*

$$\mathsf{T} \vdash\ \forall x, z_1, \ldots, z_k\ \big(\psi(x, s_1(x), z_1) \vee \psi(x, s_2(x, z_1), z_2) \vee \cdots \vee \psi(x, s_k(x, z_1, \ldots, z_{k-1}), z_k)\big),$$

where

$$\psi(x, y, z) \triangleq \exists w\ \varphi(x, y, z, w).$$

We can also apply the KPT Theorem to each theory T^i_2 (for $i \geq 1$) using a conservative extension of the theory that admits a universal axiomatization. The corresponding theory is called PV_{i+1} [19]. In PV_{i+1}, each term is equivalent to an $\mathsf{FP}^{\Sigma^p_i}$ function over the standard model. This leads to the following result.

▶ **Theorem 5** (Consequence of the KPT Theorem for Theory T^i_2)**.** *Let $i \geq 1$, $\varphi(x, y, w, z)$ be a Π^b_i-formula, and suppose that*

$$\mathsf{T}^i_2 \vdash \forall x\, \exists y \forall z\, \exists w\, \varphi(x, y, w, z).$$

Then there is a finite sequence $f_1, \ldots, f_k$ of function symbols, each corresponding to an $\mathsf{FP}^{\Sigma^p_i}$ function, such that

$$\mathbb{N} \models \forall x, z_1, \ldots, z_k \left(\psi(x, f_1(x), z_1) \vee \psi(x, f_2(x, z_1), z_2) \vee \cdots \vee \psi(x, f_k(x, z_1, \ldots, z_{k-1}), z_k)\right),$$

where

$$\psi(x, y, z) \triangleq \exists w\, \varphi(x, y, z, w).$$

3 Circuit Size Hierarchies in Bounded Arithmetic

3.1 Explicit Circuit Lower Bounds from Provability in PV_1 and T^1_2

In this section, we prove Theorem 1 Items (ii) and Items (iii).

▶ **Theorem 6** (Theorem 1 Item (iii))**.** *If there are rationals $a > b > 1$ and $n_0 \in \mathbb{N}$ such that*

$$\mathsf{PV}_1 \vdash \mathsf{CSH}[a, b, n_0]\,,$$

then there is a constant $\varepsilon > 0$ and a language $L \in \mathsf{P}$ such that $L \notin \mathsf{SIZE}[n^{1+\varepsilon}]$.

Proof. Towards a contradiction, suppose that $\mathsf{PV}_1 \vdash \mathsf{CSH}[a, b, n_0]$ for rationals $a > b > 1$ and some constant n_0 and that $P \subseteq \bigcap_{\varepsilon>0} \mathsf{SIZE}[n^{1+\varepsilon}]$. The sentence $\mathsf{CSH}[a, b, n_0]$ has the form $\forall\exists\forall\exists$:

$$\mathsf{CSH}[a, b, n_0] \triangleq \forall n \geq n_0 \in \mathsf{Log},\ \exists \text{ circuit } D\ \forall \text{ circuit } C\ \ \psi_{a,b}(n, D, C)\,,$$

where $\psi_{a,b}(n, D, C)$ is the existential formula:

$$\psi_{a,b}(n, D, C) \triangleq \exists x\ |x| \leq n \wedge \mathsf{SIZE}(D) \leq n^a \wedge (\mathsf{SIZE}(C) \leq n^b \rightarrow\ D(x) \neq C(x)).$$

Therefore, we can apply the KPT Theorem (Theorem 4), which provides PV_1-terms, equivalently FP functions, $s_1, \ldots, s_k$, where k is a constant, such that

$$\mathbb{N} \models \psi_{a,b}(n, s_1(1^{(n)}), C_1) \vee \psi_{a,b}(n, s_2(1^{(n)}, C_1), C_2) \vee \cdots \vee \psi_{a,b}(n, s_k(1^{(n)}, C_1, \ldots, C_{k-1}), C_k). \tag{1}$$

In the formula above the circuits $C_1, \ldots, C_k$ are universally quantified.

Next, we use $P \subseteq \bigcap_{\varepsilon>0} \mathsf{SIZE}[n^{1+\varepsilon}]$ to refute each of these disjuncts. We start by considering the following language, D-Eval:

D-Eval is in P due to the fact that $s_1, \ldots, s_k \in \mathsf{FP}$ and circuit evaluation is in FP. By our assumption on the circuit complexity of the complexity class P, for every input length m and every $\varepsilon > 0$, D-Eval $\in \mathsf{SIZE}[m^{1+\varepsilon}]$, so we can choose

$$\varepsilon_0 \triangleq b^{1/(2k)} - 1 > 0$$

Algorithm 1 The pseudocode of an algorithm that decides the language D-Eval.

Input : A string x and a sequence $\langle C_1, C_2, \ldots, C_r \rangle$ of $r \leq k-1$ circuits
Define $n \triangleq |x|$;
Simulate $s_{r+1}(1^{(n)}, C_1, \ldots, C_r)$ and interpret the output as a Boolean circuit $D\colon \{0,1\}^n \to \{0,1\}$;
// We assume w.l.o.g. that D is a valid n-bit circuit of size $\leq n^a$, since otherwise the disjunct is trivially false.
Evaluate D on input x and output the result.

and have D-Eval $\in \mathsf{SIZE}[m^{b^{1/(2k)}}]$. We also define the constants

$$\epsilon_i \triangleq b^{i/k} \quad \text{and} \quad \delta_i \triangleq b^{(2i-1)/(2k)}$$

for $i = 1, \ldots, k$. Note that $\epsilon_i = (1+\varepsilon_0)\delta_i$ and $\delta_{i+1} > \epsilon_i$.

We start by refuting $\psi_{a,b}(n, s_1(1^{(n)}), C_1)$. We consider inputs of the form x, λ to D-Eval, where λ is the empty sequence. Then the input has length $n + c$, where $c = O(\log n)$ accounts for the overhead in the encoding of the input. We consider the circuit $C_1^* \in \mathsf{CIRCUIT}[(n+c)^{1+\varepsilon_0}]$, which evaluates as D-Eval on inputs of length $n+c$, and we fix the input variables not related to x to represent the empty sequence. The resulting circuit has as input an n-bit string x and computes according to $s_1(1^{(n)})$ by definition of the D-Eval algorithm. For sufficiently large n, we have that $n + c \leq n^{\delta_1} \Rightarrow (n+c)^{1+\varepsilon_0} \leq n^{(1+\varepsilon_0)\delta_1} = n^{\epsilon_1}$, therefore we have the circuit $C_1^* \in \mathsf{CIRCUIT}[n^{\epsilon_1}]$ which agrees with the circuit $s_1(1^{(n)})$ on all n-bit inputs. Since $\epsilon_1 \leq b$, we have that $\mathbb{N} \not\models \psi_{a,b}(n, s_1(1^{(n)}), C_1^*)$.

We can apply a similar argument to the next disjunct using the aforementioned circuit C_1^*. In more detail, we consider the input $(x, \langle C_1^* \rangle)$ on D-Eval, which has length $m = n + 9n^{\epsilon_1}\log(n^{\epsilon_1}) + c \leq n^{\delta_2}$ for sufficiently large n due to $\delta_2 > \epsilon_1$, and a corresponding circuit $C_2^* \in \mathsf{CIRCUIT}[m^{1+\varepsilon_0}]$ provided by the circuit upper bound hypothesis. Similarly, we can fix the $9n^{\epsilon_1}\log(n^{\epsilon_1}) + c$ variables not related to the input string x. This provides an n-bit circuit $C_2^* \in \mathsf{CIRCUIT}[n^{\epsilon_2}]$ that computes according to the circuit $s_2(1^{(n)}, C_1^*)$, due to the definition of the D-Eval algorithm. Since $\epsilon_2 < b$, we have that $\mathbb{N} \not\models \psi_{a,b}(n, s_2(1^{(n)}, C_1^*), C_2^*)$.

Inductively, if we have circuits $C_1^*, C_2^*, \ldots, C_i^*$ for some $i \leq k-1$ of sizes at most $n^{\epsilon_1}, n^{\epsilon_2}, \ldots, n^{\epsilon_i}$, respectively, we consider the input $(x, \langle C_1^*, \ldots, C_i^* \rangle)$ to D-Eval, which has length $m = n + 9n^{\epsilon_1}\log(n^{\epsilon_1}) + \cdots + 9n^{\epsilon_i}\log(n^{\epsilon_i}) + c \leq n^{\delta_{i+1}}$ for sufficiently large n. Therefore, by taking a corresponding $m^{1+\varepsilon_0}$-size circuit for D-Eval and fixing all the inputs except for x, we get the circuit $C_{i+1}^* \in \mathsf{CIRCUIT}[n^{\epsilon_{i+1}}] \subseteq \mathsf{CIRCUIT}[n^b]$ which agrees with the circuit $s_{i+1}(1^{(n)}, C_1^*, \ldots, C_i^*)$ on all n-bit inputs. Consequently, $\mathbb{N} \not\models \psi_{a,b}(n, s_{i+1}(1^{(n)}, C_1^*, \ldots, C_i^*), C_{i+1}^*)$.

Overall, we can refute all disjuncts in Equation (1), which gives us a contradiction. This completes the proof. ◀

▶ **Theorem 7** (Theorem 1 Item (ii)). *If there are rationals $a > b > 1$ and $n_0 \in \mathbb{N}$ such that*

$$\mathsf{T}_2^1 \vdash \mathsf{CSH}[a, b, n_0]\,,$$

then there is a constant $\varepsilon > 0$ and a language $L \in \mathsf{P}^{\mathsf{NP}}$ such that $L \notin \mathsf{SIZE}[n^{1+\varepsilon}]$.

Proof. In this case, provability in T_2^1 provides by the KPT Theorem (Theorem 5) functions $s_1, \ldots, s_k$ which are in $\mathsf{FP}^{\mathsf{NP}}$ instead of FP as in the previous proof. Therefore, the algorithm D-Eval is in P^{NP} and we use the upper bound $\mathsf{P}^{\mathsf{NP}} \subseteq \bigcap_{\varepsilon>0} \mathsf{SIZE}[n^{1+\varepsilon}]$ to get a contradiction in the same way as above. ◀

Note that in the arguments above we have no control over the constant $\varepsilon > 0$. It depends on the number of disjuncts obtained from the KPT Theorem, which depends on the supposed proof of the hierarchy sentence.

3.2 Extracting All the Hardness from Proofs of a Succinct Hierarchy Theorem

In this section, we prove Theorem 2 Item (ii).

▶ **Theorem 8** (Theorem 2 Item (ii)). *If there are rationals $a > b > 1$ and a constant $n_0 \in \mathbb{N}$ such that*

$$\mathsf{T}^1_2 \vdash \mathsf{SCSH}[a, b, n_0]\,,$$

then there is a language $L \in \mathsf{P}^{\mathsf{NP}}$ such that $L \notin \mathsf{SIZE}[n^b]$.

Proof. The main idea here is to use the proof of SCSH in order to define a Turing machine M which runs in polynomial time using an NP oracle and its language is hard against n^b-size circuits.

Starting from $\mathsf{T}^1_2 \vdash \mathsf{SCSH}[a, b, n_0]$, we see that the structure of the sentence is $\forall\exists\forall\exists$:

$$\mathsf{SCSH}[a, b, n_0] \triangleq \forall n \geq n_0 \in \mathsf{Log},\ \exists \text{ collection } \mathcal{F},\ \forall \text{ circuit } C\ \ \phi_{a,b}(n, \mathcal{F}, C),$$

where $\phi_{a,b}(n, \mathcal{F}, C)$ is the formula that states that $\mathcal{F}$ is a collection $\{(x^1, b^1), \ldots, (x^\ell, b^\ell)\}$ with $\ell \leq n^a$, where $|x^i| = n$ and $|b^i| = 1$, and that if C is a circuit on n variables and of size $\leq n^b$, then there is some $i \in [\ell]$ such that $C(x^i) \neq b^i$ (we can move the existential quantifier at the front of the formula).

Thus, by the KPT Theorem (Theorem 5), there are $\mathsf{FP}^{\mathsf{NP}}$ functions $f_1, \ldots, f_k$, where k is a fixed constant, such that

$$\mathbb{N} \models \phi_{a,b}(n, f_1(1^{(n)}), C_1) \vee \phi_{a,b}(n, f_2(1^{(n)}, C_1), C_2) \vee \cdots \vee \phi_{a,b}(n, f_k(1^{(n)}, C_1, \ldots, C_{k-1}), C_k). \tag{2}$$

From the relation above, we can see that one of the functions $f_1, \ldots, f_k$ will output a collection that refutes every circuit of size $\leq n^b$. If it is not f_1, then there is a counterexample circuit C_1, which is used as extra input in f_2 and so on. Since $f_1, \ldots, f_k$ are in $\mathsf{FP}^{\mathsf{NP}}$, we can simulate this procedure in a P^{NP} Turing machine $M_{a,b}$, described below.

▶ Remark. In contrast with Algorithm 1, the algorithm of the Turing machine $M_{a,b}$ does not need to have the counterexample circuits as input, since it can guess and check them during its process, using the NP oracle. This difference in the input size is what gives us the n^b lower bound instead of $n^{1+\epsilon}$.

It is easy to see that the language $L(M_{a,b})$ recognised by the Turing machine $M_{a,b}$, is in P^{NP}. It suffices to show that $L(M_{a,b}) \notin \mathsf{SIZE}[n^b]$.

Consider a circuit $C \in \mathsf{CIRCUIT}[n^b]$. We will show that it fails to recognise $L(M_{a,b})$. Assume that the for-loop in Algorithm 2 ends in the r-th iteration with $r \leq k$. We fix the circuits $C_1, C_2, \ldots, C_{r-1}$ found by the algorithm. Then the formula $\phi_{a,b}(n, f_r(1^{(n)}, C_1, \ldots, C_{r-1}), C)$ always holds. If $r < k$ and C did not satisfy it, then the NP oracle would find C as a counterexample and it would continue to the $(r+1)$-th iteration. If $r = k$, then by the construction of $C_1, C_2, \ldots, C_{k-1}$, the formulas $\phi_{a,b}(n, f_i(1^{(n)}, C_1, \ldots, C_{i-1}), C_i)$ for $i < k$ do not hold, which means by Equation (2) that $\phi_{a,b}(n, f_k(1^{(n)}, C_1, \ldots, C_{k-1}), C)$ is true.

Algorithm 2 The Turing machine $M_{a,b}$, whose language is hard for n^b-size circuits.

Input : A bit-string x
Define $n \triangleq |x|$;
for $i = 1, \ldots, k$ **do**
  Simulate f_i with input $1^{(n)}$ and, if $i > 1$, $C_1, \ldots, C_{i-1}$. Interpret the output as a collection $\mathcal{F} = \{(x^1, b^1), \ldots, (x^\ell, b^\ell)\}$ with $\ell = n^a$;
  Check with an NP oracle whether there exists a circuit C of size $\leq n^b$, such that $C(x^i) = b^i$ for all $i \in [\ell]$;
  If not or if $i = k$, exit the for-loop with the current $\mathcal{F}$;
  If there is such a circuit, then use the NP oracle to find it and name it C_i.
end
If the pair $(x, 1)$ is in the collection $\mathcal{F}$, then **accept**. Else **reject**.

Since $\mathcal{F} \equiv f_r(1^{(n)}, C_1, \ldots, C_{r-1})$, from $\phi_{a,b}(n, \mathcal{F}, C)$ we get that there is some $i \in [\ell]$, such that $C(x^i) \neq b^i$. However, if $b^i = 1$, then $x^i \in L(M_{a,b})$, and if $b^i = 0$, then $x^i \notin L(M_{a,b})$. In both cases, the circuit C fails to recognise the language $L(M_{a,b})$, and the proof is complete. ◀

3.3 Formalization in T^2_2

In this section, we prove Theorem 1 Item (i) and Theorem 2 Item (i). To achieve this, we show that the succinct circuit size hierarchy is provable in APC_1, which is contained in T^2_2. We then observe that the circuit size hierarchy is easily provable from the succinct circuit size hierarchy.

▶ **Theorem 9.** *For every choice of rationals $a > b > 1$ and for every large enough $n_0 \in \mathbb{N}$,*

$$\mathsf{APC}_1 \vdash \mathsf{SCSH}[a, b, n_0]\,.$$

In particular, $\mathsf{SCSH}[a, b, n_0]$ *is provable in* T^2_2.

Proof. We define the polynomial-time function, f, which takes as input the description of a circuit, C, of size n^b, which means that the length of the description of C is $9n^b \log n^b$, and outputs a bit string y of length n^a with the property that for all $i = 0, 1, \ldots, n^a - 1$, $y_i = C(i)$.

The correctness of the polynomial-time algorithm f is provable in PV_1. In other words,

$$\mathsf{PV}_1 \vdash \forall n \in \mathsf{Log}\,(\,|x| \leq 9n^b \log n^b \,\wedge\, |y| \leq n^a\,) \rightarrow (\,|f(x)| \leq n^a \,\wedge\, (f(x) = y \leftrightarrow \forall i < n^a\; y_i = \mathsf{Eval}(x, i))). \tag{3}$$

The quantifier $\forall i \leq n^a$ is sharply bounded, so this formula is provable in PV_1.

The theory APC_1 includes the dWPHP axiom for all PV functions with input length n and output length $n + 1$, or equivalently input length n and output length m with $n < m$. From the first part of Equation (3), the input length of f is $9n^b \log n^b$, while the output length is n^a. Furthermore, it is provable in PV_1 that there is some constant n_0, such that $\forall n \geq n_0\; n^a > 9n^b \log n^b$. Therefore, we can use the axiom:

$$\mathsf{dWPHP}(f) \triangleq \forall n \geq n_0\; \exists y\; (|y| = n^a)\; \forall x\; (|x| = 9n^b \log n^b)\; f(x) \neq y \tag{4}$$

Every circuit of size n^b can be described by a string of size $9n^b \log n^b$, which means that

$$\forall C \in \mathsf{CIRCUIT}[n^b]\; |C| \leq 9n^b \log n^b.$$

Also, from the second part of Equation (3), using the notation for the circuit C, we get that

$$f(C) \neq y \leftrightarrow \exists i < n^a \; C(i) \neq y_i.$$

Substituting the last two relations to Equation (4), we get that

$$\mathsf{APC}_1 \vdash \forall n \geq n_0 \in \mathsf{Log} \; \exists y \; (|y| = n^a) \; \forall C \in \mathsf{CIRCUIT}[n^b] \; \exists i < n^a \; C(i) \neq y_i,$$

which is equivalent with $\mathsf{SCSH}[a, b, n_0]$, if we interpret y as the collection

$$\mathcal{F}_y \triangleq \{(0, y_0), (1, y_1), \ldots\}. \qquad \blacktriangleleft$$

▶ **Corollary 10.** *For every choice of rationals $a > b > 1$ and for every large enough $n_0 \in \mathbb{N}$,*

$$\mathsf{T}^2_2 \vdash \mathsf{CSH}[a, b, n_0]\,.$$

Proof. Since $a > b$, there is some rational $\epsilon > 0$, such that $a - \epsilon > b$. From Theorem 9, we have got a collection $\mathcal{F} = \{(x^1, b^1), \ldots, (x^\ell, b^\ell)\}$ of size $\ell \leq n^{a-\epsilon}$, such that for all circuits C of size less than n^b, there exists $i \in [\ell]$ such that $C(x^i) \neq b^i$. So, we only need to prove that

$$\mathsf{PV}_1 \vdash \exists \text{ circuit } D\colon \{0,1\}^n \to \{0,1\} \text{ of size} \leq n^a, \; \forall i \in [\ell] \; D(x^i) = b^i,$$

and then we can easily deduce that $\mathsf{APC}_1 \vdash \mathsf{CSH}[a, b, n_0]$. The same holds also for T^2_2.

It is sufficient to argue in PV_1 that there is a polynomial-time function $\mathsf{Circuit}(\mathcal{F})$ such that given the collection $\mathcal{F}$ from Theorem 9 outputs a circuit $D\colon \{0,1\}^n \to \{0,1\}$ of the required size such that $\forall i \in [\ell] \; D(x^i) = b^i$. In order to optimize the circuit size, we use that the obtained collection has a specific structure. More precisely, we have that for any $i \in [\ell]$, the strings x^i is the n-bit binary representation of the integer $i - 1$. Therefore, we can construct the circuit D in the following way: For every n-bit string x^i such that $(x^i, 1) \in \mathcal{F}$, we construct the term T^i, which is the conjunction of the first $|\ell|$ least significant bits of x^i (we put the literal z_j if the j-th bit of x^i is 1 and $\neg z_j$ if the j-th bit of x^i is 0, where $j \leq |\ell|$). Then we make the DNF

$$D \triangleq \bigvee_{(x^i,1)\in\mathcal{F}} T^i.$$

It is easy to see that D agrees with all the pairs of the collection $\mathcal{F}$. For an arbitrary pair (x^i, b^i), if $b^i = 1$, then the bits of x^i satisfy the term T^i, hence $D(x^i) = 1$. Otherwise, if $b^i = 0$, we know that the first $|\ell|$ least significant bits of x^i do not satisfy any term of the disjunction (since for all i, $x^i \leq \ell$), thus we get that $D(x^i) = 0$.

The DNF D can be viewed as a circuit and its correctness is easily provable in PV_1. This circuit has size at most $n^{a-\epsilon}|\ell|$ (derived by $|\ell| - 1$ $\wedge$-gates for each one of the at most $n^{a-\epsilon}$ terms and at most $n^{a-\epsilon}$ $\vee$-gates for the final disjunction), which is at most $n^{a-\epsilon}(\log n^{a-\epsilon} + 1)$. For large enough n_0, we can prove that $\forall n \geq n_0, \; n^{a-\epsilon}(\log n^{a-\epsilon} + 1) \leq n^a$, hence we have the desired result. $\blacktriangleleft$

4 Provability of Formula Size Bounds in PV_1

In this section, we prove Theorem 3. To achieve this, we establish that:

1. The parity function on n bits requires formulas of size $\geq n^{3/2}$ (Section 4.1).
2. The parity function on n bits can be computed by formulas of size $O(n^2) \leq n^a$ for any fixed rational $a > 2$ and large enough n (Section 4.2).
3. Consequently, the formula size hierarchy holds with parameters $a > 2$ and $b = 3/2$, provided that n_0 is large enough (Section 4.3).

4.1 Subbotovskaya's Lower Bound

4.1.1 High-Level Details of the Formalization

In this section, we sketch a formalization in PV_1 of the proof that the parity function on n bits requires Boolean formulas of size $\geq n^{3/2}$ [25].[3] We adapt the argument presented in [14, Section 6.3], which proceeds as follows:

1. [14, Lemma 6.8]: Given a Boolean formula F on n-bit inputs, it is possible to fix one of its variables so that the resulting formula F_1 satisfies

   $$\mathsf{Size}(F_1) \leq (1 - 1/n)^{3/2} \cdot \mathsf{Size}(F).$$

   In order to pick the variable to be restricted and its value, one first "normalizes" the formula F, as implicitly described in [14, Claim 6.9] (see more details below).
2. [14, Theorem 6.10]: By applying this result $\ell \triangleq n - k$ times, it is possible to obtain a formula F_ℓ on k-bit inputs such that

   $$\mathsf{Size}(F_\ell) \leq \mathsf{Size}(F) \cdot (1-1/n)^{3/2} \cdot (1-1/(n-1))^{3/2} \dots (1-1/(k+1))^{3/2} = \mathsf{Size}(F) \cdot (k/n)^{3/2}.$$

3. [14, Example 6.11]: If the initial formula F computes the parity function, by setting $\ell = n - 1$ we obtain

   $$1 \leq \mathsf{Size}(F_\ell) \leq (1/n)^{3/2} \cdot \mathsf{Size}(F),$$

   and consequently $\mathsf{Size}(F) \geq n^{3/2}$.

We recommend reading this section with [14, Section 6.3] at hand. We will slightly modify the argument when formalizing the lower bound in PV_1. In more detail, given a small formula F, we recursively construct (and establish correctness by induction) an n-bit input y witnessing that F does not compute the parity function. (Actually, for technical reasons related to the induction step, we will simultaneously construct an n-bit input y_n^0 witnessing that F does not compute the parity function and an n-bit input y_n^1 witnessing that F does not compute the negation of the parity function.)

Let $s(n)$ be a size bound and $\oplus(x)$ be a PV function that computes the parity of the binary string described by x, i.e., $\oplus(x) \triangleq x_1 \oplus x_2 \oplus \ldots \oplus x_n$, where x_i denotes the i-th bit of x. To simplify notation, we tacitly view x as a binary string. We assume that the formalization employs a well-behaved function symbol $\oplus$ such that PV_1 proves the basic properties of the parity function, e.g., $\mathsf{PV}_1 \vdash \oplus(x1) = 1 - \oplus(x)$ and $\mathsf{PV}_1 \vdash \oplus(x0) = \oplus(x)$.

We consider the following $\mathcal{L}_{\mathsf{PV}}$-sentence stating that the parity function requires formulas of size at least $s(n)$ for every input length $n \geq 1$:

$$\mathsf{FLB}_s \triangleq \forall N\, \forall n\, \forall F\, (n = |N| \geq 1 \wedge \mathsf{Size}(F) < s(n) \rightarrow \exists x\, (|x|_\ell = n \wedge \mathsf{Eval}(F, x) \neq \oplus(x)),$$ [4]

where for convenience of notation we use the function symbol $|w|_\ell$ to compute the bit-length of the string represented by w (under some reasonable encoding).

▶ **Theorem 11.** *Let* $s(n) \triangleq n^{3/2}$. *Then* $\mathsf{PV}_1 \vdash \mathsf{FLB}_s$.

[3] For concreteness, we let the size of a Boolean formula F be the number of leaves of F labeled by an input literal. We allow leaves that are labeled by constants, but we do not charge for them. Consequently, a constant function has formula complexity 0, while a non-constant function has formula complexity at least 1.

Proof. Given $b \in \{0,1\}$, we introduce the function $\oplus^b(x) \triangleq \oplus(x) + b \pmod 2$. In order to prove FLB_s in PV_1, we explicitly consider a polynomial-time function $R(1^{(n)}, F, b)$ with the following properties:[5]

1. Let $b \in \{0,1\}$.
2. If $\mathsf{Size}(F) < s(n)$ then $R(1^{(n)}, F, b)$ outputs an n-bit string y_n^b such that $\mathsf{Eval}(F, y_n^b) \neq \oplus^b(y_n^b)$.

In other words, $R(1^{(n)}, F, b)$ witnesses that the formula F does not compute the function $\oplus^b$ over n-bit strings. Note that the correctness of R is captured by the bounded universal sentence:

$$\mathsf{Ref}_{R,s} \triangleq \forall 1^{(n)}\, \forall F\, (\mathsf{Size}(F) < s(n) \to |y_n^0|_\ell = |y_n^1|_\ell = n \wedge F(y_n^0) \neq \oplus^0(y_n^0) \wedge F(y_n^1) \neq \oplus^1(y_n^1))\,,$$

where we employed the abbreviations $y_n^0 \triangleq R(1^{(n)}, F, 0)$ and $y_n^1 \triangleq R(1^{(n)}, F, 1)$. Our plan is to define R and show that $\mathsf{PV}_1 \vdash \mathsf{Ref}_{R,s}$. Note that this implies FLB_s in PV_1. Jumping ahead, the correctness of $R(1^{(n)}, F, b)$ will be established by polynomial induction on N (equivalently, induction on $n = |N|$). Since $\mathsf{Ref}_{R,s}$ is a universal sentence and S_2^1 is $\forall\Sigma_1^b$-conservative over PV_1, polynomial induction for NP and coNP predicates (admissible in S_2^1; see, e.g., [16, Section 5.2]) is available during the formalization. More details follow.

The procedure $R(1^{(n)}, F, b)$ makes use of a few polynomial-time sub-routines (discussed below) and is defined in the following way:

Algorithm 3 Refuter Algorithm $R(1^{(n)}, F, b)$.

Input : $1^{(n)}$ for some $n \geq 1$, formula F over n-bit inputs, $b \in \{0,1\}$.

1 Let $s(n) \triangleq n^{3/2}$. If $\mathsf{Size}(F) \geq s(n)$ **return** *"error"*;

2 If $\mathsf{Size}(F) = 0$, F computes a constant function $b_F \in \{0,1\}$. In this case, **return** *the n-bit string $y_n^b \triangleq y_1^b 0^{n-1}$ such that $\oplus^b(y_1^b 0^{n-1}) \neq b_F$*;

3 Let $\widetilde{F} \triangleq \mathsf{Normalize}(1^{(n)}, F)$;

// $\widetilde{F}$ satisfies [14, Claim 6.9], $\mathsf{Size}(\widetilde{F}) \leq \mathsf{Size}(F)$, $\forall x \in \{0,1\}^n\ F(x) = \widetilde{F}(x)$.

4 Let $\rho \triangleq \mathsf{Find\text{-}Restriction}(1^{(n)}, \widetilde{F})$, where $\rho\colon [n] \to \{0,1,\star\}$ and $|\rho^{-1}(\star)| = n - 1$;

// ρ restricts a suitable variable x_i to a bit c_i, as in [14, Lemma 6.8].

5 Let $F' \triangleq \mathsf{Apply\text{-}Restriction}(1^{(n)}, \widetilde{F}, \rho)$. Moreover, let $b' \triangleq b \oplus c_i$ and $n' \triangleq n - 1$;

// F' is an n'-bit formula; $\forall z \in \{0,1\}^{\rho^{-1}(\star)}\ F'(z) = \widetilde{F}(z \cup x_i \mapsto c_i)$.

6 Let $y_{n'}^{b'} \triangleq R(1^{n'}, F', b')$ and **return** *the n-bit string $y_n^b \triangleq y_{n'}^{b'} \cup y_i \mapsto c_i$*;

4.1.1.1 Normalize$(1^{(n)}, F)$ and its properties (in S_2^1)

We say that a subformula G of F is a *neighbor* of a leaf z if either $z \wedge G$ or $z \vee G$ is a subformula of F. We say that a formula F over variables $\{x_1, \ldots, x_n\}$ is in *normal form* if for every $i \in [n]$ and every literal $z \in \{x_i, \overline{x_i}\}$, if z is a leaf of F and G is a neighbor of z in F, then G does not contain the variable x_i.

[5] For convenience, we often write $1^{(n)}$ instead of explicitly considering parameters N and $n = |N|$. We might also write just $F(x)$ instead of $\mathsf{Eval}(F, x)$.

▶ **Lemma 12.** *There is a polynomial-time function* $\mathsf{Normalize}(1^{(n)}, F)$ *that given a Boolean formula* F *over* n *input variables, outputs a formula* $\widetilde{F}$ *over* n *input variables such that the following holds:*

(i) $\mathsf{Size}(\widetilde{F}) \leq \mathsf{Size}(F)$.
(ii) *For every input* $x \in \{0,1\}^n$, $\widetilde{F}(x) = F(x)$.
(iii) $\widetilde{F}$ *is in normal form.*
(iv) $\widetilde{F}$ *is either a constant* 0 *or* 1*, or* $\widetilde{F}$ *contains no leaves labeled by constants* 0 *and* 1.

Moreover, the correctness of $\mathsf{Normalize}(1^{(n)}, F)$ *is provable in* S^1_2.

Proof Sketch. It is enough to verify that the proof of [14, Claim 6.9] provides such a polynomial-time function and that its correctness can be established in S^1_2. In more detail, if F is not in normal form, we can efficiently compute a literal $z \in \{x_i, \overline{x_i}\}$ and a neighbor G of z that violates the corresponding property. As shown in [14, Claim 6.9], we can fix any leaf $z' \in \{x_i, \overline{x_i}\}$ in G by an appropriate constant c so that the resulting formula F_1 satisfies conditions (i) and (ii) of Lemma 12. After at most $\ell \triangleq \mathsf{Size}(F)$ iterations, we obtain a sequence $F_1, \ldots, F_\ell$ of formulas such that $\widetilde{F} \triangleq F_\ell$ satisfies conditions (i), (ii), and (iii) of the lemma. Moreover, condition (iv) can always be guaranteed by simplifying the final formula, i.e., by replacing subformulas $0 \vee G$ by G, $1 \vee G$ by 1, $0 \wedge G$ by 0, and $1 \wedge G$ by G. The correctness of $\widetilde{F} \triangleq \mathsf{Normalize}(1^{(n)}, F)$ can be established by polynomial induction for coNP predicates (i.e., Π^b_1 formulas), which is available in S^1_2. ◀

4.1.1.2 Find-Restriction$(1^{(n)}, \widetilde{F})$ and its properties (in S^1_2)

We argue in S^1_2 and follow the argument from the proof of [14, Lemma 6.8]. Let $\widetilde{F}$ be a formula over n input variables in normal form. We focus on the non-trivial case, and assume that $n \geq 2$, $\mathsf{Size}(\widetilde{F}) \geq 2$, and that $\widetilde{F}$ contains no leaves labeled by constants. Let $\mathsf{Count}(1^{(n)}, F, i)$ be a polynomial-time algorithm that outputs the number of leaves of F that contain the variable x_i (including its appearances as $\overline{x_i}$). Let $w = (w_1, \ldots, w_n)$ be the corresponding sequence of multiplicities, i.e., $w_i \triangleq \mathsf{Count}(1^{(n)}, F, i)$. Note that $\sum_i w_i = \widetilde{s}$, where $\widetilde{s} \triangleq \mathsf{Size}(\widetilde{F})$.

We claim that S^1_2 proves the existence of an index $i \in [n]$ such that $w_i \geq \widetilde{s}/n$. First, for each $j \in [n]$, we define the cumulative sum $v_j \triangleq \sum_{i \leq j} w_j$. Let $v \triangleq (v_0, v_1, \ldots, v_n)$ be the corresponding sequence, where we set $v_0 \triangleq 0$. Notice that $v_n = \widetilde{s}$. Since v contains $n+1$ elements, it can be efficiently computable from w. We now argue by induction on n that for some index $j \in [n]$ we have $v_j - v_{j-1} \geq v_n/n$. This implies that $w_j = v_j - v_{j-1} \geq v_n/n = \widetilde{s}/n$, as desired.

If $n = 1$, then $v_1 - v_0 = v_1 = v_1/1$ and the result holds for $j = 1$. Assume the result holds for $n-1$, and consider v_n. If $v_n - v_{n-1} \geq v_n/n$, we can pick $j = n$ and we are done. Otherwise, $v_{n-1} \geq v_n - v_n/n = v_n(n-1)/n$. By the induction hypothesis, there is an index $j \in [n-1]$ such that $v_j - v_{j-1} \geq v_{n-1}/(n-1)$. Using the lower bound on v_{n-1}, we get that $v_j - v_{j-1} \geq v_n/n$, which concludes the proof.

Consequently, S^1_2 proves the existence of a variable x_i which appears $t \geq \widetilde{s}/n$ times as a leaf of $\widetilde{F}$. Let $z_1, \ldots, z_t$ be the leaves of $\widetilde{F}$ labeled by either x_i or $\overline{x_i}$. Recall that we assume that $n \geq 2$, $\mathsf{Size}(\widetilde{F}) \geq 2$, and that $\widetilde{F}$ satisfies conditions (iii) and (iv) of Lemma 12. Therefore, each leaf z_j has a neighbor subformula G_j in $\widetilde{F}$ that contains some leaf labeled by a literal not in $\{x_i, \overline{x_i}\}$. For this reason, if we set x_i to an appropriate constant c_j, G_j will disappear from F, thereby erasing at least another leaf not among $z_1, \ldots, z_t$. As in the proof of [14, Lemma 6.8], if we let $c \in \{0,1\}$ be the constant that appears more often among

$c_1, \ldots, c_t$ and set $x_i \mapsto c$ in the restriction ρ, all the leaves $z_1, \ldots, z_t$ will be eliminated from $\widetilde{F}$ together with at least $t/2$ additional leaves.[6] Thus the total number of eliminated leaves, which we specify using a polynomial-time function $\mathsf{NumRemoved}(1^{(n)}, \widetilde{F}, \rho)$, satisfies

$$\mathsf{NumRemoved}(1^{(n)}, \widetilde{F}, \rho) \geq t + \frac{t}{2} \geq \frac{3\widetilde{s}}{2n}.$$

Overall, it follows that

$$\mathsf{S}^1_2 \vdash \widetilde{F} = \mathsf{Normalize}(1^{(n)}, F) \wedge \rho = \mathsf{Find\text{-}Restriction}(1^{(n)}, \widetilde{F}) \rightarrow \mathsf{NumRemoved}(1^{(n)}, \widetilde{F}, \rho) \geq \frac{3}{2n} \cdot \mathsf{Size}(\widetilde{F})\,.$$

4.1.1.3 Apply-Restriction$(1^{(n)}, \widetilde{F}, \rho)$ and its properties (in S^1_2)

We only sketch the details. This is simply a polynomial-time algorithm that, given a formula $\widetilde{F}$ on n input variables and a restriction $\rho\colon [n] \to \{0, 1, *\}$ with $|\rho^{-1}(\star)| = n - 1$ (i.e., ρ restricts a single variable x_i to a constant $c_i \in \{0, 1\}$), outputs a formula F' over $n-1$ input variables that sets every literal $z \in \{x_i, \overline{x_i}\}$ to the corresponding constant and simplifies the resulting formula, e.g., replaces subformulas $0 \vee G$ by G, $1 \vee G$ by 1, $0 \wedge G$ by 0, and $1 \wedge G$ by G. Additionally, for $F' = \mathsf{Apply\text{-}Restriction}(1^{(n)}, \widetilde{F}, \rho)$, we have

$$\mathsf{S}^1_2 \vdash \mathsf{Size}(F') \leq \mathsf{Size}(\widetilde{F}) - \mathsf{NumRemoved}(1^{(n)}, \widetilde{F}, \rho) \wedge \forall z \in \{0,1\}^{\rho^{-1}(\star)}\ F'(z) = \widetilde{F}(z \cup x_i \mapsto c_i)\,. \tag{5}$$

Using the computed bound on $\mathsf{NumRemoved}(1^{(n)}, \widetilde{F}, \rho)$ for $\rho = \mathsf{Find\text{-}Restriction}(1^{(n)}, \widetilde{F})$, we obtain that for $\widetilde{F}$ and F' defined as above (with $s' \triangleq \mathsf{Size}(F')$ and $\widetilde{s} \triangleq \mathsf{Size}(\widetilde{F})$), and assuming that $n \geq 2$,

$$\mathsf{S}^1_2 \vdash s' \leq \widetilde{s} - \frac{3}{2n} \cdot \widetilde{s} = \widetilde{s} \cdot \left(1 - \frac{3}{2n}\right) \leq \widetilde{s} \cdot \left(1 - \frac{1}{n}\right)^{3/2}. \tag{6}$$

The last inequality uses that $\mathsf{S}^1_2 \vdash \forall a,\ a \geq 2 \rightarrow (1 - 3/(2a))^2 \leq (1 - 1/a)^3$, which one can easily verify.

Note that $R(1^{(n)}, F, b)$ runs in time polynomial in $n + |F| + |b|$ and that it is definable in S^1_2. Next, we establish the correctness of $R(1^{(n)}, F, b)$ in S^1_2 .

▶ **Lemma 13.** *Let $s(n) \triangleq n^{3/2}$. Then $\mathsf{S}^1_2 \vdash \mathsf{Ref}_{R,s}$.*

Proof. We consider the formula $\varphi(N)$ defined as

$$\forall F\, \forall n = |N| \geq 1 (\mathsf{Size}(F) < s(n)) \rightarrow (|y^0_n|_\ell = |y^1_n|_\ell = n \wedge F(y^0_n) \neq \oplus^0(y^0_n) \wedge F(y^1_n) \neq \oplus^1(y^1_n))\,,$$

where as before we use $y^0_n \triangleq R(1^{(n)}, F, 0)$ and $y^1_n \triangleq R(1^{(n)}, F, 1)$. Note that $\varphi(N)$ is a Π^b_1 formula. Below, we argue that

$$\mathsf{S}^1_2 \vdash \varphi(1) \quad \text{and} \quad \mathsf{S}^1_2 \vdash \forall N\, \varphi(\lfloor N/2 \rfloor) \rightarrow \varphi(N)\,.$$

Then, by polynomial induction for Π^b_1 formulas (available in S^1_2) and using that $\varphi(0)$ trivially holds, it follows that $\mathsf{S}^1_2 \vdash \forall N\, \varphi(N)$. In turn, this yields $\mathsf{S}^1_2 \vdash \mathsf{Ref}_{R,s}$.

[6] The existence of such a constant c can be proved in S^1_2 in a way that is similar to the proof that some variable x_i appears in at least $\widetilde{s}/n$ leaves.

Base Case: $\mathsf{S}^1_2 \vdash \varphi(1)$. In this case, for a given formula F and length n, the hypothesis of $\varphi(1)$ is satisfied only if $n = 1$ and $\mathsf{Size}(F) = 0$. Let $y^0_1 \triangleq R(1, F, 0)$ and $y^1_1 \triangleq R(1, F, 1)$. We need to prove that

$$|y^0_1|_\ell = |y^1_1|_\ell = 1 \wedge F(y^0_1) \neq \oplus^0(y^0_1) \wedge F(y^1_1) \neq \oplus^1(y^1_1)\,.$$

Since $n = 1$ and $\mathsf{Size}(F) = 0$, F evaluates to a constant b_F on every input bit. The statement above is implied by Line 2 in the definition of $R(n, F, b)$.

(Polynomial) Induction Step: $\mathsf{S}^1_2 \vdash \forall N\, \varphi(\lfloor N/2 \rfloor) \to \varphi(N)$. Fix an arbitrary N, let $n \triangleq |N|$, and assume that $\varphi(\lfloor N/2 \rfloor)$ holds. By the induction hypothesis, for every formula F' with $\mathsf{Size}(F') < n'^{3/2}$, where $n' \triangleq n - 1$, we have

$$|y^0_{n'}|_\ell = |y^1_{n'}|_\ell = n' \;\wedge\; F'(y^0_{n'}) \neq \oplus^0(y^0_{n'}) \;\wedge\; F'(y^1_{n'}) \neq \oplus^1(y^1_{n'})\,, \tag{7}$$

where $y^0_{n'} \triangleq R(1^{n'}, F', 0)$ and $y^1_{n'} \triangleq R(1^{n'}, F', 1)$.

Now let $n \geq 2$, and let F be a formula over n-bit inputs of size $< n^{3/2}$. By the size bound on F, $R(1^{(n)}, F, b)$ ignores Line 1. If $\mathsf{Size}(F) = 0$, then similarly to the base case it is trivial to check that the conclusion of $\varphi(N)$ holds. Therefore, we assume that $\mathsf{Size}(F) \geq 1$ and $R(1^{(n)}, F, b)$ does not stop at Line 2. Let $\widetilde{F} \triangleq \mathsf{Normalize}(1^{(n)}, F)$ (Line 3), $\rho \triangleq \mathsf{Find\text{-}Restriction}(1^{(n)}, \widetilde{F})$ (Line 4), $F' \triangleq \mathsf{Apply\text{-}Restriction}(1^{(n)}, \widetilde{F}, \rho)$ (Line 5), $n' \triangleq n - 1$ (Line 5), and $b' \triangleq b \oplus c_i$ (Line 5), where ρ restricts the variable x_i to the bit c_i. Moreover, for convenience, let $s \triangleq \mathsf{Size}(F)$, $\widetilde{s} \triangleq \mathsf{Size}(\widetilde{F})$, and $s' \triangleq \mathsf{Size}(F')$. By Lemma 12 Item (i), Equation (6), and the bound $s < n^{3/2}$,

$$\mathsf{S}^1_2 \vdash s' \leq \widetilde{s} \cdot (1 - 1/n)^{3/2} \leq s \cdot (1 - 1/n)^{3/2} < n^{3/2} \cdot (1 - 1/n)^{3/2} = (n - 1)^{3/2}\,.$$

Thus F' is a formula on n'-bit inputs of size $< n'^{3/2}$. Recall that for a given $b \in \{0, 1\}$ we have $b' = b \oplus c_i$. Let $y^{b'}_{n'} \triangleq R(1^{n'}, F', b')$ (Line 6). By the first condition in the induction hypothesis (Equation (7)) and the definition of each $y^b_n \triangleq y^{b'}_{n'} \cup y_i \mapsto c_i$, we have $|y^0_n|_\ell = |y^1_n|_\ell = n$. Below, we also rely on the last two conditions in the induction hypothesis (Equation (7)), Lemma 12 Item (ii), and the last condition in Equation (5). We derive the following statements, where $b \in \{0, 1\}$:

$$\begin{aligned} F'(y^{b'}_{n'}) &\neq \oplus^{b'}(y^{b'}_{n'})\,,\\ F(y^b_n) &= F'(y^{b'}_{n'})\,,\\ F(y^b_n) &\neq \oplus^{b'}(y^{b'}_{n'})\,. \end{aligned}$$

Notice that

$$\oplus^{b'}(y^{b'}_{n'}) = \oplus^{b \oplus c_i}(y^{b'}_{n'}) = c_i \oplus (\oplus^b(y^{b'}_{n'})) = c_i \oplus (\oplus^b(y^b_n) \oplus c_i) = \oplus^b(y^b_n)\,.$$

These statements imply that, for each $b \in \{0, 1\}$, $F(y^b_n) \neq \oplus^b(y^b_n)$. In other words, the conclusion of $\varphi(N)$ holds. This completes the proof of the induction step. ◀

As explained above, the provability of $\mathsf{Ref}_{R,s}$ in S^1_2 implies its provability in PV_1. Since $\mathsf{PV}_1 \vdash \mathsf{Ref}_{R,s} \to \mathsf{FLB}_s$, this completes the proof of Theorem 11. ◀

4.1.2 On the Low-Level Details of the Formalization

In order to make our presentation accessible to a broader audience, in this section we provide more details about the formalization of algorithms and about the proofs of their basic properties. However, due to space restriction, the section is included only in the full version.

4.2 Upper Bound

In this section, we show that the parity function on n bits can be computed by formulas of size $O(n^2)$, provably in PV_1. We can formalize this upper bound in the language of PV, defining an $\mathcal{L}_{\mathsf{PV}}$-sentence stating that the parity function can be computed by a formula of size $s(n)$ for every input length $n \geq 1$:

$$\mathsf{FUB}_s \triangleq \forall N\, \forall n\, \exists F\, (n = |N| \geq 1 \wedge \mathsf{Size}(F) < s(n) \wedge \forall x\, (|x| \leq n \to \mathsf{Eval}(F, x) = \oplus_n^0(x))\,.$$

▶ **Theorem 14.** *Let $s(n) \triangleq 4n^2$. Then $\mathsf{PV}_1 \vdash \mathsf{FUB}_s$.*

Proof. FUB_s is a $\forall\Sigma_2^b$ sentence and our intended theory is PV_1. In order to implement some inductive proofs, it will be helpful to reduce the complexity of the formula. For this, we introduce a new polynomial-time function, $\mathsf{ParForm}(1^{(n)})$, which generates the desired formula that computes the parity function on n bits. Since it is a polynomial-time function, there is a symbol for it in PV and we can use it in the new formalization:

$$\begin{aligned}\mathsf{FUB}'_s \triangleq &\forall N\, \forall n\, (n = |N| \geq 1 \wedge \mathsf{Size}(\mathsf{ParForm}(1^{(n)})) < s(n) \wedge \\ &\forall x\, (|x| \leq n \to \mathsf{Eval}(\mathsf{ParForm}(1^{(n)}), x) = \oplus_n^0(x))\,.\end{aligned}$$

It is immediate that $\mathsf{FUB}'_s \Rightarrow \mathsf{FUB}_s$, thus we focus on proving FUB'_s. We continue with the following steps:

1. We prove an upper bound of n^2 for the formulas calculating the parity function and its negation, when n is a power of 2.
2. We use this construction to derive the $4n^2$ upper bound for any n.

Next, we define a polynomial-time algorithm $\mathsf{Par}(1^{(n)})$ which computes a formula that calculates the parity function on n bits and a formula that calculates the negation of the parity function on n bits, if n is a power of 2.

Algorithm 4 $\mathsf{Par}(1^{(n)})$ outputs Boolean formulas for $\oplus_n^0$ and $\oplus_n^1$ when n is a power of 2.

Input : $1^{(n)}$ for some $n \geq 1$.
Let $k \triangleq |n-1|$. If $n \neq 2^k$ (n is not a power of 2), then **return** *"error"*;
`// F will compute the parity function, while` $\overline{F}$ `will compute its negation`
if $k = 0$ **then**
  Define F to be the formula with one leaf x_1 and $\overline{F}$ to be the formula with one leaf $\neg x_1$.
else if $k \geq 1$ **then**
  `// Construct a pair` $(F, \overline{F})$ `of formulas on input bits` $x_1, \ldots, x_{2^k}$ `as follows:`
  Let $(F_1, \overline{F_1}) \triangleq \mathsf{Par}(1^{n/2})$, and define a corresponding pair $(F_2, \overline{F_2})$:
  In F_2 and $\overline{F}_2$, relabel the leaves by putting $x_{2^{k-1}+i}$ instead of x_i for every $i = 1, \ldots, 2^{k-1}$;
  Now let $F \triangleq (F_1 \vee F_2) \wedge (\overline{F}_1 \vee \overline{F}_2)$ and $\overline{F} \triangleq (F_1 \wedge F_2) \vee (\overline{F}_1 \wedge \overline{F}_2)$.
end
return $(F, \overline{F})$.

▶ **Lemma 15.** *If n is a power of 2, the algorithm $\mathsf{Par}(1^{(n)})$ correctly outputs two formulas $(F, \overline{F})$ of size n^2 which calculate the parity function and its negation, provably in $\mathsf{S}_2^1(\mathsf{PV})$.*

Proof. We split the proof of the correctness for the algorithm $\mathsf{Par}(1^{(n)})$ into 3 properties:

1. $\phi_1(n) \triangleq F, \overline{F} \in \mathsf{VALIDFORM}(n)$, where $\mathsf{VALIDFORM}(n)$ is the set of formulas on n variables;
2. $\phi_2(n) \triangleq \mathsf{Size}(F) = \mathsf{Size}(\overline{F}) = n^2$;
3. $\phi_3(n) \triangleq \forall x\ |x| \leq n \to \mathsf{Eval}(F, x) = \oplus_n^0(x) \wedge \mathsf{Eval}(\overline{F}, x) = \oplus_n^1(x)$.

For now we only care about the case that n is a power of 2, so we prove these properties conditionally (equivalently we prove $(n = (n-1)\#1) \to \phi(n)$).[7] That is why it suffices to use polynomial induction on n, which is available in S_2^1, since our formulas are at most Π_1^b.

We skip the proof of ϕ_1, which is proven by simple induction as below, using the fact that if F_1, F_2 are formulas then $F_1 \wedge F_2$ and $F_1 \vee F_2$ are also formulas.

Property 2: $\mathsf{S}_2^1 \vdash \phi_2(n)$. For the base case, $\phi_2(1)$, we have $k = 0$, which means that the output $(F, \overline{F}) \triangleq \mathsf{Par}(1^1)$ will be two formulas with one leaf each, hence

$$\mathsf{Size}(F) = \mathsf{Size}(\overline{F}) = 1.$$

For the induction step, we need $\mathsf{S}_2^1 \vdash \forall n\, \phi_2(\lfloor n/2 \rfloor) \to \phi_2(n)$. If n is not a power of 2, then the statement is true by default. In the case of n being a power of 2, we fix $k = |n-1|$ and we want to prove equivalently:

$$\mathsf{S}_2^1 \vdash \phi_2(2^{k-1}) \to \phi_2(2^k).$$

Assume that $\phi_2(2^{k-1}) \equiv \phi_2(n/2)$ holds. From Line 8 we have that

$$F = (F_1 \vee F_2) \wedge (\overline{F}_1 \vee \overline{F}_2) \text{ and } \overline{F} = (F_1 \wedge F_2) \vee (\overline{F}_1 \wedge \overline{F}_2), \tag{8}$$

where $(F_1, \overline{F_1})$ and $(F_2, \overline{F_2})$ are copies of $\mathsf{Par}(1^{n/2})$. From the induction hypothesis, this means that $\mathsf{Size}(F_1) = \mathsf{Size}(\overline{F_1}) = \mathsf{Size}(F_2) = \mathsf{Size}(\overline{F_2}) = (n/2)^2 = 2^{2(k-1)}$. Therefore, from (Equation (8)) and the properties of the function Size, we get

$$\mathsf{Size}(F) = \mathsf{Size}(F_1) + \mathsf{Size}(\overline{F_1}) + \mathsf{Size}(F_2) + \mathsf{Size}(\overline{F_2}) = 4 \cdot 2^{2(k-1)} = 2^{2k} = n^2.$$

Similarly for $\overline{F}$, which means that $\phi_2(2^k) \equiv \phi_2(n)$ holds. This completes the proof of the induction for ϕ_2.

Property 3: $\mathsf{S}_2^1 \vdash \phi_3(n)$. Here the base case is trivial: for $F \triangleq x_1$ and $x \in \{0, 1\}$, then $\mathsf{Eval}(F, x) = x = \oplus_1^0(x)$. Similarly for $\overline{F}$.

For the induction step, we assume as above that $n = 2^k$ and we want to prove:

$$\mathsf{S}_2^1 \vdash \phi_3(2^{k-1}) \to \phi_3(2^k).$$

We assume that $\phi_2(2^{k-1}) \equiv \phi_2(n/2)$ holds and we write F in the form

$$F = (F_1 \vee F_2) \wedge (\overline{F}_1 \vee \overline{F}_2) \text{ and } \overline{F} = (F_1 \wedge F_2) \vee (\overline{F}_1 \wedge \overline{F}_2),$$

where $(F_1, \overline{F_1})$ and $(F_2, \overline{F_2})$ are copies of $\mathsf{Par}(1^{n/2})$. Therefore, instead of $\mathsf{Eval}(F, x)$, we can calculate

$$\mathsf{Eval}((F_1 \vee F_2) \wedge (\overline{F}_1 \vee \overline{F}_2), x).$$

[7] It is easy to check that this is true if and only if n is a power of 2.

We need to prove that $\mathsf{Eval}(F, x) = \oplus^0_n(x)$ for all x with $|x| \leq n$. So, taking one such x we can split its binary representation into two parts x_1, x_2 with lengths $|x_1|, |x_2| \leq n/2$, such that $x = (x_2 x_1)_b = x_1 + 2^{n/2} x_2$.

The input to subformulas $F_2, \overline{F_2}$ from the definition are the bits x_{2^k-1+i} for $i = 1, \ldots, 2^{k-1}$, which means that their input is x_2. Similarly, the input to subformulas $F_1, \overline{F_1}$ is x_1. Hence, we can define

$$b_1 \triangleq \mathsf{Eval}(F_1, x_1) b_3 \triangleq \mathsf{Eval}(\overline{F_1}, x_1)$$
$$b_2 \triangleq \mathsf{Eval}(F_2, x_2) b_4 \triangleq \mathsf{Eval}(\overline{F_2}, x_2)$$

From the properties of the evaluation function and the form of F, we can prove in S^1_2 that $\mathsf{Eval}(F, x) = (b_1 \vee b_2) \wedge (b_3 \vee b_4)$, where the symbols $\vee, \wedge$ are used as Boolean symbols here.

However, since $|x_1|, |x_2| \leq n/2$ and $(F_1, \overline{F_1}) = (F_2, \overline{F_2}) = \mathsf{Par}(1^{n/2})$, from the induction hypothesis we get that

$$b_1 = \oplus^0(x_1) b_3 = \oplus^1(x_1) = 1 - b_1$$
$$b_2 = \oplus^0(x_2) b_4 = \oplus^1(x_2) = 1 - b_2$$

Next, it is easy to prove by checking all the 4 cases that

$$\forall b_1, b_2 \in \{0, 1\}\ (b_1 \vee b_2) \wedge ((1 - b_1) \vee (1 - b_2)) = b_1 \oplus b_2,$$

and as a result, we get

$$\mathsf{Eval}(F, x) = (\oplus^0(x_1)) \oplus (\oplus^0(x_2)) = \oplus^0(x_2 x_1) = \oplus^0(x)$$

by the properties of the parity function. Similarly, we can prove that $\mathsf{Eval}(\overline{F}, x) = \oplus^1_n(x)$, which concludes the induction. ◀

For the general case, we use a simple padding argument. For a number n, we can define the number

$$\tilde{n} \triangleq (n - 1)\#1.$$

This number is the least power of 2 that is greater or equal to n. It is easy to see that

$$\mathsf{PV}_1 \vdash n \leq \tilde{n} < 2n.$$

If we replace $\mathsf{ParForm}(1^{(n)})$ by $\mathsf{Par}_1(1^{\tilde{n}})$ (the first coordinate of $\mathsf{Par}(1^{\tilde{n}})$), we have by the above lemma that

1. $\mathsf{Size}(\mathsf{ParForm}(1^{(n)})) = \mathsf{Size}(\mathsf{Par}_1(1^{\tilde{n}})) = \tilde{n}^2 < (2n)^2 = s(n)$.
2. For all x with $|x| \leq n$, we have $|x| \leq \tilde{n}$, which by the lemma gives us

   $$\mathsf{Eval}(\mathsf{ParForm}(1^n), x) = \mathsf{Eval}(\mathsf{Par}_1(1^{\tilde{n}}), x) = \oplus^0_{\tilde{n}}(x).$$

   Since $|x| \leq n$, we also have $\oplus^0_{\tilde{n}}(x) = \oplus^0_n(x)$. Consequently, we have $\mathsf{Eval}(\mathsf{ParForm}(1^n), x) = \oplus^0_n(x)$.

These two together show that $\mathsf{PV}_1 \vdash \mathsf{FUB}'_s$ and the proof is complete. ◀

4.3 Formula Size Hierarchy

In this section, we provide the proof of Theorem 3.

▶ **Theorem 16** (Theorem 3). *Consider rationals $a > 2$ and $b = 3/2$, and let n_0 be a large enough positive integer. Then*

$$\mathsf{PV}_1 \vdash \mathsf{FSH}[a, b, n_0]\,.$$

Proof. We combine the results of Section 4.1 and Section 4.2. We argue in PV_1. From Theorem 11, we get that

$$\forall n \in \mathsf{Log}\ \forall F \in \mathsf{FORMULA}[n^{3/2}]\ \exists x\ (|x| \leq n \wedge F(x) \neq \oplus_n(x)), \tag{9}$$

and from Theorem 14, we have that

$$\forall n \in \mathsf{Log}\ \exists G \in \mathsf{FORMULA}[4n^2]\ \forall x\ (|x| \leq n \to G(x) = \oplus_n(x)).$$

We can eliminate the constant 4 from the latter using that $a > 2$ and choosing a large enough n_0, such that for every $n \geq n_0$, $n^a \geq 4n^2$ (provably in PV_1). Consequently,

$$\forall n \geq n_0 \in \mathsf{Log}\ \exists G \in \mathsf{FORMULA}[n^a]\ \forall x\ (|x| \leq n \to G(x) = \oplus_n(x)). \tag{10}$$

Finally, combining Equation (9) and Equation (10), we get that

$$\forall n \geq n_0 \in \mathsf{Log}\ \exists G \in \mathsf{FORMULA}[n^a]\ \forall F \in \mathsf{FORMULA}[n^{3/2}]\ \exists x\ (|x| \leq n\ \wedge\ F(x) \neq G(x)),$$

which is exactly the formula size hierarchy, $\mathsf{FSH}[a, b, n_0]$, for our choice of parameters $a > 2$ and $b = 3/2$. ◀

Abstract

It is well known that quantum, randomized and deterministic (sequential) query complexities are polynomially related for total boolean functions. We find that significantly larger separations between the parallel generalizations of these measures are possible. In particular,

1. We employ the cheatsheet framework to obtain an unbounded parallel quantum query advantage over its randomized analogue for a total function, falsifying a conjecture of [Jeffery et al. 2017].
2. We strengthen 1 by constructing a total function which exhibits an unbounded parallel quantum query advantage despite having no sequential advantage, suggesting that genuine quantum advantage could occur entirely due to parallelism.
3. We construct a total function that exhibits a polynomial separation between 2-round quantum and randomized query complexities, contrasting a result of [Montanaro. 2010] that there is at most a constant separation for 1-round (nonadaptive) algorithms.
4. We develop a new technique for deriving parallel quantum lower bounds from sequential upper bounds. We employ this technique to give lower bounds for Boolean symmetric functions and read-once formulas, ruling out large parallel query advantages for them.

We also provide separations between randomized and deterministic parallel query complexities analogous to items 1-3.

1 Introduction

Quantum query complexity is a widely studied model for understanding the capabilities and limitations of quantum computers. Many of the important quantum algorithms and quantum-classical separation results are expressed in this model. For instance, the quantum period finding algorithm, a major ingredient in Shor's factoring algorithm [32], was first developed in the query model. There are many other examples of query problems for which quantum algorithms provably achieve exponential query advantage over their classical counterparts [33, 18].

However, these problems have partial domains, meaning they are not defined on most inputs. For functions whose domain includes all inputs (total functions), it is known that the quantum, randomized and deterministic query complexities are all polynomially related [10, 4]. Grover's seminal algorithm [24] for unstructured search achieves a quadratic speed-up over classical algorithms, and Ambainis et al. [6] and Aaronson et al. [3] construct functions that separate quantum and deterministic query complexities by a 4th power, and quantum and randomized query complexities by a 3rd power respectively.[1] These separations cannot be significantly improved in the sequential query model [10, 4].

A natural question is whether these algorithmic limitations are robust against generalizations of sequential query complexity. In this work, we consider a parallel model where an algorithm is allowed to make many queries at each step, as introduced in [27]. In particular, the p-parallel quantum query complexity, denoted by $\mathsf{Q}^{p\|}$, of a function is the minimum number of steps needed to compute it with bounded error, if at each step the algorithm is allowed to make p non-adaptive quantum queries.[2] We will also refer to this quantity by *p-query depth*, *p-query rounds* and *p-query layers* interchangeably. Notice that, for any function f and any parallelism p, $\mathsf{Q}(f)/p \leq \mathsf{Q}^{p\|}(f) \leq \mathsf{Q}(f)$ since any q-round p-parallel algorithm can be simulated by a pq-query sequential algorithm, and any q-query sequential algorithm can be simulated by a q-round p-parallel algorithm.[3]

This model is motivated by the fact that fault tolerant quantum computers must be inherently parallel: a large scale quantum computer which cannot do many gates at once cannot correct local errors faster than they occur. Therefore, quantum computers will necessarily be able to perform operations in parallel, meaning one should design algorithms to take maximum advantage of this capability. Further, near term quantum computations are limited to low depth due to short decoherence times. These factors make the parallel query model a more natural abstraction of real devices than a purely sequential model.

Prior work addressing parallel query complexity has indicated that quantum advantage tends to disappear as parallelism increases. Zalka [37] showed the parallel complexity for searching an unstructured list of size N is $\Theta\left(\sqrt{N/p}\right)$. This was generalized by Grover and Radhakrishnan [25], who proved that $\tilde{\Theta}\left(\sqrt{Nt/(p\cdot\min\{t,p\})}\right)$ p-parallel queries are necessary and sufficient to find t marked elements in a list of size N. Along with providing a systematic study of parallel quantum query complexity, Jeffery, Magniez and de Wolf [27] showed that the p-parallel quantum query complexity of k-SUM is $\tilde{\Theta}\left((N/p)^{k/k+1}\right)$.

---

[1] [3] originally showed a 2.5th power separation, which was boosted to a 3rd power via tight lower bounds on k-fold Forrelation shown in [8, 31].

[2] We define the deterministic parallel query complexity $\mathsf{D}^{p\|}$ and randomized bounded error parallel query complexity $\mathsf{R}^{p\|}$ similarly.

[3] Similar bounds hold for $\mathsf{R}^{p\|}$ and $\mathsf{D}^{p\|}$.

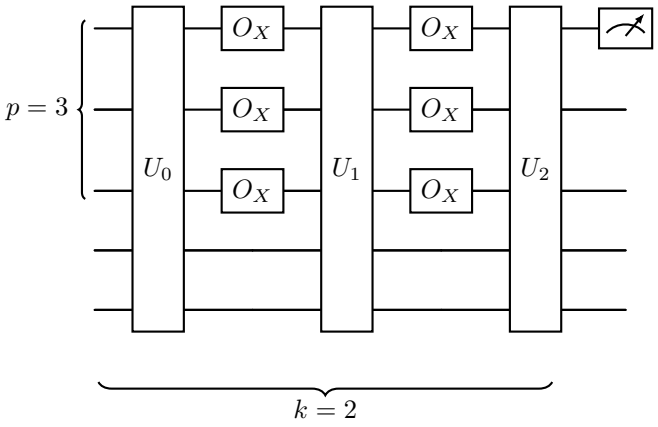

Figure 1 A parallel quantum algorithm with $k = 2$ adaptive steps and $p = 3$ queries per step; the last two wires are for workspace. In general, p denotes the number of non-adaptive queries per step, and k denotes the number of steps. The measure $Q^{p\|}$ denotes the minimal k needed to compute a function for a fixed p, while the measure $Q^{k\perp}$ denotes the minimal p needed to compute a function for a fixed k.

Furthermore, [27] introduce the following conjecture:

▶ **Conjecture 1** ([27]). *For any total function $f : \{0,1\}^N \to \{0,1\}$ and any p, there is at most a polynomial quantum advantage for p-parallel query algorithms. That is,*

$$\mathsf{D}^{p\|}(f) = \mathit{poly}(\mathsf{Q}^{p\|}(f)).$$

In fact, [27] proved this conjecture for all p polynomially smaller than the block sensitivity (bs), generalizing a result of Beals et al. [10].

The notion of p-parallel query complexity captures the minimum "depth" needed to compute some function for a given "width" (see Figure 1). An alternative complexity measure relevant to parallelism is the minimum "width" needed to compute some function for a fixed "depth", which we call the k-adaptive query complexity, and denote by $\mathsf{Q}^{k\perp}(f)$ (respectively $\mathsf{R}^{k\perp}(f)$, $\mathsf{D}^{k\perp}(f)$). Precisely, we define k-adaptive query complexity as the minimum p such that there is a p-parallel quantum (respectively randomized, deterministic) algorithm which makes k many p-parallel queries and computes f. This complexity measure is not widely studied for total functions. However, a result of Montanaro [28] fully characterizes the relevant 1-adaptive (or non-adaptive) query complexities, up to a factor of 2: for any total $f : \{0,1\}^N \to \{0,1\}$, $\mathsf{Q}^{1\perp}(f) \geq \mathsf{D}^{1\perp}(f))/2$. In the context of partial functions, a result by Girish et al. [22] characterized the maximal separation between $\mathsf{Q}^{k\perp}$ and $\mathsf{Q}^{k+1\perp}$.

In this paper, we present the high level overview of our work. See the full version on arxiv [14].

1.1 Main results

1.1.1 Unbounded parallel separations for total functions

Our first result involves adapting the cheatsheet framework of Aaronson et al. [3] to the parallel query setting, and using it to exhibit total function separations between parallel query complexity measures. In particular, we show that the canonical cheatsheet function of [3] exhibits unbounded separation between quantum and randomized parallel query complexities,

falsifying Conjecture 1. Further, we observe that this function demonstrates that 3-adaptive quantum algorithms can be more efficient in terms of total queries than even fully sequential randomized algorithms. More formally, we prove the following theorem.

▶ **Theorem 2.** *There exists a (total) Boolean function $h : \{0,1\}^N \to \{0,1\}$ such that for some $p = \tilde{O}(\mathsf{bs}(h))$ and some constants $\epsilon, \delta > 0$, we have*

(i) $\mathsf{R}^{p\|}(h) = \tilde{\Omega}(N^{\epsilon})$, **(ii)** $\mathsf{Q}^{p\|}(h) \leq 3$, **(iii)** $\mathsf{Q}^{3\perp}(h) = \tilde{O}\left(\mathsf{R}(h)^{1-\delta}\right)$.

It is worth noting that the large separation in parallel query complexity occurs when the parallelism almost exactly equals the block sensitivity $\mathsf{bs}(f)$, contrasting a result of Jeffery et al ([27], Theorem 12) which eliminates this possibility for $p = O(\mathsf{bs}(f)^{1-\epsilon})$ for any constant $\epsilon > 0$. Furthermore, the separation between $\mathsf{Q}^{3\perp}(f)$ and $\mathsf{R}(f)$ contrasts Montanaro's result ([28], Theorem 1) that for total functions, 1-adaptive quantum algorithms cannot be more than twice as efficient as the trivial 1-adaptive deterministic algorithm.

We also show a total function that achieves a similar separation between randomized and deterministic parallel query complexities. We do this by modifying the canonical cheatsheet function to instead embed a partial function with a large randomized-deterministic separation.

It is worth noting that this result is also sufficient to falsify Conjecture 1.

These results provide a recipe for achieving exponential parallel query advantages (from quantumness or randomness) for total functions by amplifying a polynomial sequential advantage for such functions. However, it is unclear whether an advantage can originate entirely from a quantum or randomized algorithm's ability to utilize parallelism more effectively than a randomized or deterministic algorithms. In other words, is there a function which has no sequential quantum query advantage, yet a large parallel quantum query advantage? We answer this question in the affirmative, even for total functions.

1.1.2 Unbounded genuine parallel separations

Our starting point is a partial function with the desired property. That is, we construct a partial function with (almost) equal randomized and quantum sequential query complexities, that does not admit any parallel advantage for randomized algorithms, yet admits near-maximal parallel advantage for quantum algorithms. In particular, we show the following theorem.

▶ **Theorem 3.** *There exists a (partial) Boolean function $f : \mathcal{D} \to \{0,1\}$ with $\mathcal{D} \subset \{0,1\}^N$ such that for some $p = O(\mathsf{Q}(f))$ and some constant $\epsilon > 0$, we have*

(i) $\mathsf{R}(f) = \tilde{\Theta}(N^{\epsilon})$, **(ii)** $\mathsf{Q}(f) = \tilde{\Omega}(\mathsf{R}(f))$, **(iii)** $\mathsf{R}^{p\|}(f) = \tilde{\Omega}(\mathsf{R}(f))$, **(iv)** $\mathsf{Q}^{p\|}(f) = 1$.

Note that the function f in the above theorem perfectly parallelizes quantumly but does not parallelize at all classically. We discuss the construction of f in more detail in the technical overview. We totalize f using the cheatsheet framework to give a total function with no sequential quantum advantage but unbounded parallel quantum advantage, giving rise to the following theorem.

▶ **Theorem 4.** *There exists a (total) Boolean function $h : \{0,1\}^N \to \{0,1\}$ such that for some p and some constants $\epsilon, \delta > 0$ (with $\delta < \epsilon$), we have*

(i) $\mathsf{R}(h) = \tilde{\Theta}(N^{\epsilon})$, **(ii)** $\mathsf{Q}(h) = \tilde{\Omega}(\mathsf{R}(h))$, **(iii)** $\mathsf{R}^{p\|}(h) = \tilde{\Omega}(N^{\delta})$, **(iv)** $\mathsf{Q}^{p\|}(h) \leq 3$.

We also obtain analogous separations between the randomized and deterministic query complexities using the same techniques.

1.1.3 Separations with two layers of adaptivity

We earlier noted (in Theorem 2) that for some total function h, $\mathsf{Q}^{3\perp}(h)$ can be polynomially smaller than $\mathsf{R}^{3\perp}(h)$ (and even $\mathsf{R}(h)$), however $\mathsf{Q}^{1\perp}(h) = \Theta(\mathsf{D}^{1\perp}(h))$ for all total functions h. A natural question to ask is whether it is possible for $\mathsf{Q}^{2\perp}(h)$ to be much smaller than $\mathsf{R}^{2\perp}(h)$ for some total h? We answer this question in the affirmative by presenting a general framework that transforms an (at least) polynomial separation between $\mathsf{Q}^{1\perp}(f)$ and $\mathsf{R}^{1\perp}(f)$ for some partial f to a polynomial separation between $\mathsf{Q}^{2\perp}(h)$ and $\mathsf{R}^{2\perp}(h)$ for some total h constructed from f. Since there exists a partial function f (such as Forrelation in [2]) with $\mathsf{Q}(f) = 1$ (so $\mathsf{Q}^{1\perp}(f) = 1$) and $\mathsf{R}(f) = \Omega(N^\epsilon)$ (so $\mathsf{R}^{1\perp}(f) = \Omega(N^\epsilon)$) for some $\epsilon > 0$, we get a total function h exhibiting a polynomial separation between $\mathsf{Q}^{2\perp}(h)$ and $\mathsf{R}^{2\perp}(h)$. Precisely, we show the following theorem:

▶ **Theorem 5.** *Let $f : \mathcal{D} \to \{0,1\}$ with $\mathcal{D} \subseteq \{0,1\}^N$ be a (partial) function that satisfies $\mathsf{Q}^{1\perp}(f) = \tilde{O}(N^\epsilon)$ and $\mathsf{R}^{1\perp}(f) = \tilde{\Omega}(N^\delta)$ for some constants $\epsilon < \delta$. Then there exists a total $h : \{0,1\}^M \to \{0,1\}$ (with $M = \Theta(N^3)$) and constants $\epsilon' < \delta'$ such that $\mathsf{Q}^{2\perp}(h) = \tilde{O}(M^{\epsilon'})$ and $\mathsf{R}^{2\perp}(h) = \tilde{\Omega}(M^{\delta'})$.*

We also obtain a similar separation between $\mathsf{R}^{2\perp}$ and $\mathsf{D}^{2\perp}$.

1.1.4 Quantum parallel lower bound framework and applications

Finally, we develop a new method for deriving parallel quantum query lower bounds from sequential quantum query upper bounds. It is simpler to reason about sequential algorithms than parallel algorithms, and upper bounds are often easier to give than lower bounds. Thus, our result allows reducing the hard problem of lower bounding parallel quantum query complexity to the potentially easier problem of upper bounding its sequential analogue. Our technique is based on the parallel spectral adversary method [27], and is especially well suited to problems with optimal adversary matrices that only distinguish input pairs that differ at a single index. We also show that, for any total function f, the combinatorial parallel adversary method [25, 13] fails to show a lower bound better than $\Omega\left(\sqrt{\left\lceil \frac{\mathsf{C}_0(f)}{p} \right\rceil \left\lceil \frac{\mathsf{C}_1(f)}{p} \right\rceil}\right)$ where C_b denotes the bth certificate complexity of f. Moreover, we show that our method surpasses this barrier and provides a better lower bound, for instance, to the And $\circ$ Or problem.

We let $\lambda(f)$ denote the spectral sensitivity of f, as defined in [4]. Let $\mathcal{F}^{(f)}_{p-\text{res}}$ denote the set of all functions obtained from restricting f to p input bits, and fixing the rest. We call this a $p-$restriction of f.

▶ **Theorem 6.** *For any total Boolean function $f : \{0,1\}^N \to \{0,1\}$, we have*

$$\mathsf{Q}^{p\|}(f) = \Omega\left(\lambda(f) \cdot \frac{1}{\max_{g \in \mathcal{F}^{(f)}_{p-res}} \lambda(g)}\right)$$

Recalling that $\lambda(f) = O(\mathsf{Q}(f))$, as shown by Aaronson et al. [4], we can write this as $\mathsf{Q}^{p\|}(f) = \Omega\left(\lambda(f) \cdot (\max_{g \in \mathcal{F}^{(f)}_{p-\text{res}}} \mathsf{Q}(g))^{-1}\right)$, where we note that the second term can be lower bounded by giving a (sequential) quantum algorithm for any $p-$restriction of f. We apply Theorem 6 to the following classes of well-studied functions.

1. *Read-once formulas*: While the combinatorial adversary method [5] is sufficient to lower bound the sequential quantum query complexity of the two-layer AND ∘ OR tree by $\Omega(\sqrt{N})$ [9], the best lower bound the parallel combinatorial adversary method can give for the Read-once formula problem $\mathsf{And}_{\sqrt{N}} \circ \mathsf{Or}_{\sqrt{N}}$ is $\Omega(\sqrt{N}/p)$. Using Theorem 6, we show a $\Omega\left(\sqrt{N/p}\right)$ lower bound for any read-once formula.
2. *Symmetric functions*: From Theorem 6, we get the tight lower bound of $\Omega\left(\sqrt{Nt/p \cdot \min\{t,p\}}\right)$ where t is the largest hamming weight less than $N/2$ such that the function value either differs on inputs of hamming weight t and $t+1$ or differs on inputs of hamming weight $N-t$ and $N-t-1$. This result recovers the combinatorial adversary lower bound implicit in [25] using an arguably simpler proof.

1.2 Related work

Prior work on parallel quantum algorithms in the query model has primarily demonstrated the need for quantum depth in solving certain problems.

Cryptography

There has been a recent line of work studying problems which can only be efficiently solved by quantum algorithms with high depth [15, 7, 16, 17, 21], constructing cryptographic proofs of quantum depth. In this vein, Chung et al [19] and Blocki et al [11] show parallel quantum lower bounds against producing the output of an iterated hash function to give a cryptographic proof of sequential work that is secure against quantum computers.

Partial functions

Burchard [13] gives a characterization of parallel quantum approximate counting, showing that, approximating to multiplicative error ϵ, the number K of marked elements in a list of size N requires $\Omega\left(\frac{\sqrt{N}}{\epsilon\sqrt{pK}}\right)$ p-parallel quantum queries. Girish et al [22] constructs a partial function which exhibits a large total query separation between r-adaptive and $r-1$-adaptive quantum algorithms for any constant r.

Circuit complexity

Another setting one could study the intersection of quantum and parallelism is in the circuit model. For instance, Cleve and Watrous [20] show how to implement the quantum fourier transform on n qubits in $O(\log n)$ depth, allowing for a highly parallel implementation of Shor's factoring algorithm. There are known examples of relational problems which can be computed in constant quantum depth, yet require at least logarithmic depth for classical circuits [12, 35, 36]. More generally, quantum circuit classes such as QAC_n and QNC_n have been extensively studied [23, 26, 34].

2 Technical overview

In this section, we outline the techniques used in showing our main results. For our results involving separations between query complexity measures, we will primarily describe the techniques involved in separating quantum from randomized query complexity measures unless the techniques for separating randomized and deterministic query complexity measures are significantly different.

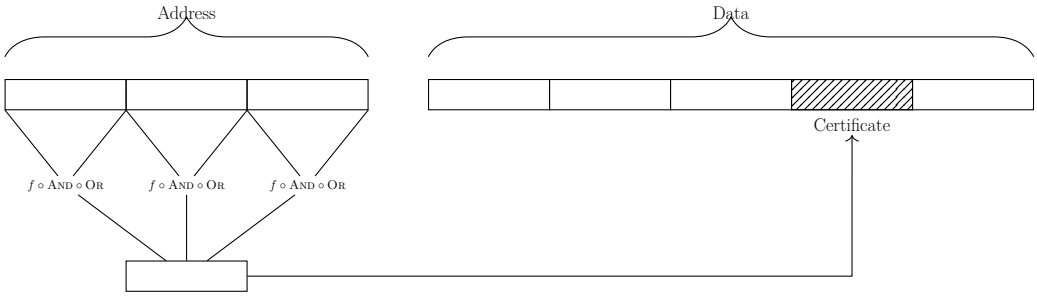

Figure 2 The canonical cheat sheet function f_{ccs} which lifts a partial function f to a total function, while retaining some of the speedup of f.

2.1 Unbounded parallel separations for total functions

The cheatsheet framework [3] lifts a partial function f, potentially with an exponential quantum query advantage to a total function that retains some of the advantage (although now polynomial). The natural way to do this is to define a total function such that when the input is in the domain of f, answer as f does, and when it is not answer 0. The cheat sheet framework does this "domain check" in a clever way so that the quantum advantage is not lost in the process. As shown in Figure 2, the input for the total function f_{ccs} is divided into two components, the Address section and the Data section. The partial function f is composed with a total function that has low certificate complexity, which in this case is $\textsc{And} \circ \textsc{Or}$. This composition $f \circ \textsc{And} \circ \textsc{Or}$ produces a single bit. This is repeated such that enough bits to address a block in the data component are obtained. If this block contains the certificate (or "cheatsheet") for the $\textsc{And} \circ \textsc{Or}$'s, and these certify that the input of f is in its domain, then the output of f_{ccs} is 1, else, the output is 0. As the data component is large, an algorithm is forced to solve the partial function f to obtain the address of the block, and can use the certificate present there to check whether the input of f is in the domain (and thus does not need to read the full Address to perform the domain check).

Thus, computing a cheatsheet function involves

1. Solving $f \circ \textsc{And} \circ \textsc{Or}$ to get the certificate location,
2. Reading out the certificate,
3. Checking the validity of the input of f.

For concreteness, consider the canonical cheatsheet function defined by Aaronson et al [3] composing $f = \textsc{Forrelation}$ [1, 2] on N bits with $\textsc{And} \circ \textsc{Or}$ on N^2 bits. This function was originally constructed to exhibit a superquadratic separation between sequential quantum and randomized query complexities. Observe that with $p = N^2$ parallelism, solving any given instance of the internal $\textsc{And} \circ \textsc{Or}$ can be done in a single p-parallel query by reading out all the inputs. A quantum algorithm can utilize this to quickly solve the whole composition, as Forrelation is quantumly easy. However, any classical algorithm would seem to need $\mathsf{R}(\textsc{Forrelation})$ p-parallel queries to solve this composition since it requires at least $p \cdot \mathsf{R}(\textsc{Forrelation})$ sequential queries. Thus, with p parallelism, step (1) is quantum efficient but not classically efficient. We show that for the canonical choice of parameters, steps (2) and (3) are also possible with few p-parallel queries, resulting in the desired separation.

The same technique can be used to give an exponential total function separation between randomized and deterministic parallel query complexity.

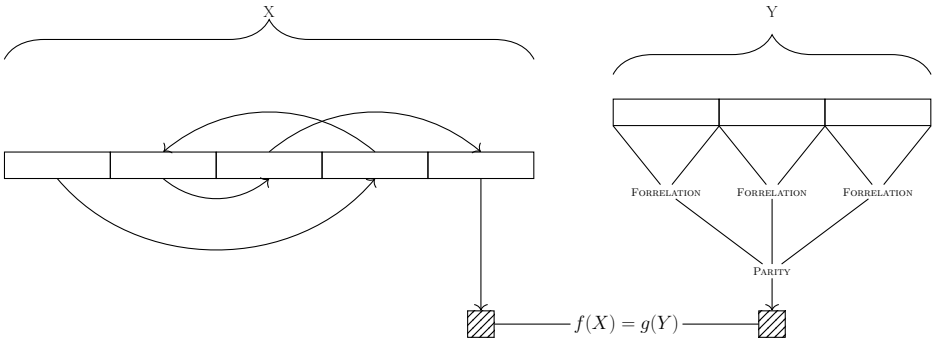

Figure 3 Partial function that admits unbounded genuine parallel separation.

Our result, combined with an aforementioned result of [27], which states that $\mathsf{D}^{p\|}(h) = \mathsf{poly}(\mathsf{Q}^{p\|}(h))$ for all total h and $p = O(\mathsf{bs}(h)^{1-\epsilon})$ with $\epsilon > 0$, provides a new way of upper bounding the block sensitivity of total Boolean functions. In particular, using our separation and a lower bound argument for the canonical cheatsheet function, we characterize its block sensitivity.

2.2 Unbounded genuine parallel separations

Is some polynomial sequential separation necessary for unbounded parallel quantum speedup, or can the advantage emerge purely from a quantum algorithm's ability to utilize parallelism (which we call a genuine parallel advantage)? We argue that the latter can indeed be the case, by first describing our construction for the partial function h that allows proving Theorem 3. As shown in Figure 3, the input to h here involves two components X and Y. The function f requires a sequence of adaptive queries to solve (in either model) whereas the function g achieves quantum-randomized separation and can be fully parallelized. We are promised that the output of both will be the same, so any algorithm can choose to solve either. We then argue that any algorithm will require solving at least one of f and g.

For concreteness, let $\epsilon > 0$ and suppose that $\mathsf{Q}(f) = \Theta(\mathsf{R}(f)) = \Theta(N^{\epsilon})$ and $\mathsf{R}^{p\|}(f) = \Omega(N^{\epsilon})$, and $\mathsf{Q}^{p\|}(g) = \Theta(N^{\epsilon})/p$ and $\mathsf{R}^{p\|}(g) = \Theta(N^{2\epsilon})/p$ for small enough p.[4] Then, a randomized sequential algorithm can choose to solve f, while a quantum sequential algorithm will not benefit from choosing to solve either f or g. Thus, $\mathsf{R}(h) = O(N^{\epsilon})$ and we would have $\mathsf{Q}(h) = \Omega(N^{\epsilon})$. Similarly, for $p = \mathsf{Q}(g)$, a p-parallel quantum algorithm can choose to solve g, while a p-parallel randomized algorithm will not benefit from choosing to solve either f or g. Therefore, $\mathsf{Q}^{p\|}(h) = 1$ and we would have $\mathsf{R}^{p\|} = \Omega(N^{\epsilon})$.

To show our desired randomized parallel and quantum lower bounds, we consider the general problem, which we call COR, where we are given inputs X and Y to arbitrary functions f and g respectively along with the promise that $f(X) = g(Y)$, our goal is to output $f(X) = g(Y)$. We use the hybrid argument to establish that any randomized parallel algorithm that solves $\textsc{cor}(f, g)$ will be able to either distinguish an input sampled from a hard 0-distribution for f from an input sampled from a hard 1-distribution for f, or will succeed at a similar distinguishing task for g. Therefore, we must have $\mathsf{R}^{p\|}(\textsc{cor}(f, g)) = \Omega(\min(\mathsf{R}^{p\|}(f), \mathsf{R}^{p\|}(g)))$. For the quantum lower bound, we show that that for any adversary

[4] For more concreteness, one may think of f as the pointer chasing function with chain length N^{ϵ} and g as the composition of parity on N^{ϵ} bits composed with FORRELATION on $N^{2\epsilon}$ bits as shown in Figure 3.

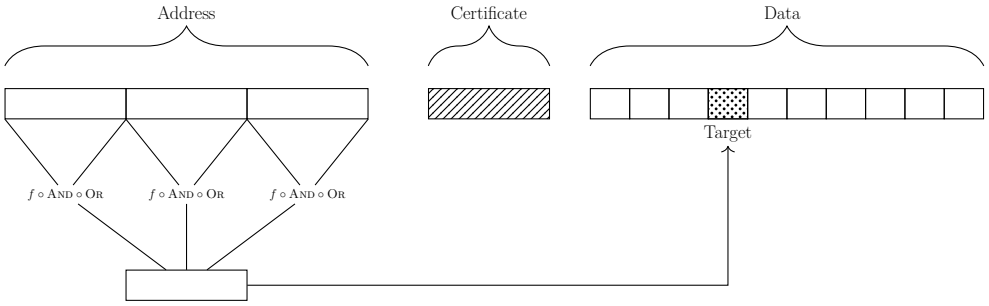

Figure 4 A framework that converts a partial function separation with one layer of adaptivity to a total function with two layers of adaptivity.

matrices $\Gamma^{(f)}$ and $\Gamma^{(g)}$ for f and g respectively, the matrix $\Gamma = \Gamma^{(f)} \otimes \Gamma^{(g)}$ is an adversary matrix for $\textsc{cor}(f,g)$ and $\max_i \|\Gamma_i\| = \max\left(\max_i \left\|\Gamma_i^{(f)}\right\|, \max_i \left\|\Gamma_i^{(g)}\right\|\right)$[5] It follows that $\mathsf{Adv}\left(\textsc{cor}(f,g)\right) = \Omega(\min(\mathsf{Adv}(f), \mathsf{Adv}(g)))$, which implies the desired lower bound.

Next, we describe a way to totalize the partial function h that we constructed in the previous section while maintaining some of its properties. We will use the cheatsheet framework. However, we will need a function with relatively small certificate complexity that does not admit any significant quantum speed-up so $\textsc{And} \circ \textsc{Or}$ will not work. Fortunately, [3] found a function, which they called Bkk, that satisfies $\mathsf{Q}(\textsc{Bkk}_N) = \tilde{\Theta}(\textsc{Bkk}_N) = \tilde{\Theta}(N)$ and $\mathsf{C}(\textsc{Bkk}_N) = \tilde{O}(\sqrt{N})$. We compose h on N bits with Bkk on N^2 bits, and then plug it into the cheatsheet framework. The desired upper bounds for $\mathsf{Q}^{p\|}$ and R in Theorem 4 are relatively straightforward and follows from the discussion in the previous sections. The quantum lower bound follows from quantum query complexity composition theorem and results in [3]. For the randomized parallel lower bound, we show a composition theorem where the inner function is Bkk.

The same lower bound techniques do not follow for the analogous separation between the randomized and deterministic query complexity measures. In particular, there is no general randomized composition theorem. Fortunately, for our constructions, the known randomized composition theorems suffice. For the deterministic parallel lower bound, we show a general composition theorem when the degree of the inner function is almost full, which might be of independent interest.

2.3 Separations with two layers of adaptivity

As we noted earlier (see Theorem 2), the cheat sheet framework can be employed to show a polynomial separation between $\mathsf{Q}^{3\perp}$ and $\mathsf{R}^{3\perp}$. We modify this framework to show a polynomial separation between $\mathsf{Q}^{2\perp}$ and $\mathsf{R}^{2\perp}$. As shown in Figure 4, our strategy is essentially to separate the cheatsheet into two parts: the first part contains the certificate, and the second just contains a long data string with one relevant index. Let f be a partial function with a polynomial separation between $\mathsf{Q}^{1\perp}(f)$ and $\mathsf{R}^{1\perp}(f)$. Informally, embedding f in our framework results in a function that requires (1) verifying the input to the f is in the domain (using the certificate) and if so, (2) outputting the bit of the data string present at the address obtained by solving the f.

[5] All the max are over relevant indices.

The quantum algorithm easily succeeds as follows. In the first round, it can read the certificate as well as solve f to obtain the address. In the second round, it verifies the certificate and queries the bit at the right address in the data string, hence is able to output the result. The randomized algorithm is unable to succeed in the same amount of parallelism because after the first round, it cannot compute f, so it would not find the right address by the first round, and can only make a query to the right address by the second round if it guesses the location correctly, which happens with very low probability. We also note that there is a caveat: the structure of a zero-certificate might be easy to distinguish from the structure of a one-certificate, allowing the algorithm to infer the inputs to the partial function from just the structure of the certificates. In that case, the randomized algorithm can use this to compute the partial function in the first round itself. To prevent this from happening, we use "bi-certificates" instead of certificates, where a "bi-certificate" corresponds to a set of indices that could certify both a zero and a one instance. This prevents the randomized algorithm from learning any information just by knowing the certificate.

Therefore, we present a framework to lift a partial function $\mathsf{Q}^{1\perp}$ vs $\mathsf{R}^{1\perp}$ separation to a total function $\mathsf{Q}^{2\perp}$ vs $\mathsf{R}^{2\perp}$ separation. The analogous result holds for randomized vs deterministic algorithms.

2.4 Quantum parallel lower bound framework and applications

There are few known techniques for lower bounding parallel quantum query complexity. Consider for instance lower bounding the quantum parallel query complexity for the balanced $\textsc{And} \circ \textsc{Or}$ function,

which is an example of a read-once formula. It is well known that this function has sequential quantum query complexity $\Theta(\sqrt{N})$ [9, 29]. Since both $\mathsf{Q}^{p\|}(\textsc{And})$ and $\mathsf{Q}^{p\|}(\textsc{Or})$ are $\Omega\left(\sqrt{N/p}\right)$, a natural guess for $\mathsf{Q}^{p\|}(\textsc{And} \circ \textsc{Or})$ is $\Omega\left(\sqrt{N/p}\right)$.

The bound $\mathsf{Q}(\textsc{And} \circ \textsc{Or}) = \Omega(\sqrt{N})$ was shown using the (sequential) combinatorial adversary method. However, as mentioned in Section 1.1.4, the corresponding parallel version fails to show a lower bound better than $\Omega\left(\sqrt{\left\lceil \frac{\mathsf{C}_0(f)}{p} \right\rceil \left\lceil \frac{\mathsf{C}_1(f)}{p} \right\rceil}\right)$ for any function f. This means that the best lower bound this method could help prove for $\textsc{And} \circ \textsc{Or}$ is $\Omega(\sqrt{N}/p)$, since $\mathsf{C}_0(\textsc{And} \circ \textsc{Or}) = \mathsf{C}_1(\textsc{And} \circ \textsc{Or}) = \sqrt{N}$.

We use the parallel spectral adversary method of [27], which is known to be optimal, to derive a method that is easier to apply and is sometimes stronger than the combinatorial adversary method (see Theorem 6). For the case of read-once formulas, we use the adversary sets of [9] to construct an adversary matrix Γ. It is easy to lower bound $\|\Gamma\|$ by a simple counting argument, but upper bounding $\|\Gamma_S\|$ for all $S \subseteq [N]$ with $|S| = p$ can be challenging. We show that if Γ satisfies the property that $\Gamma[x, y] = 0$ for all x, y that differs in more than 1 bit, then all the induced Γ_S can be rearranged to form block-diagonal matrices with blocks of size $2^p \times 2^p$. Moreover, each of these blocks are adversary matrices for some restricted function $g \in \mathcal{F}^{(f)}_{p-\text{res}}$ (Figure 5), where a restricted version of f is one where all but p input bits are fixed and known by the algorithm. Thus, we know that the spectral norm of these blocks is upper bounded by $\mathsf{Q}(g)$ (up to the normalizing factor of $\max_{i\in[2^p]} \|\Gamma_i\|$, and with a max taken over all $g \in \mathcal{F}^{(f)}_{p-\text{res}}$), which we can use to upper bound the spectral norm of any Γ_S. In our case, noting that g is a read-once formula of size p, we have $Q(g) = O(\sqrt{p})$ and we obtain the desired lower bound of $\Omega\left(\sqrt{N/p}\right)$. Hence, we are able to reduce the task of finding parallel lower bounds to the potentially easier task of finding sequential upper bounds.

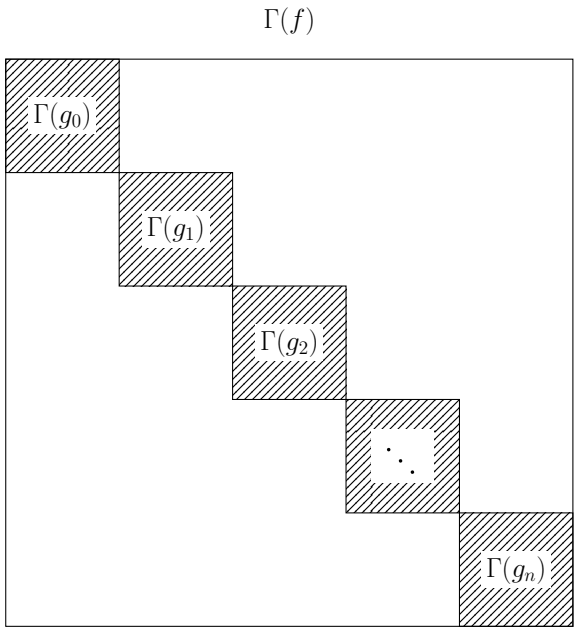

Figure 5 Nearest neighbor adversaries can be block-diagonalized, where the blocks are adversary matrices for restricted versions of the function f.

3 Conclusion

In this work, we have presented a few results on parallel quantum query complexity (See [14] for the full version). *A priori*, it seems unintuitive that an exponential advantage in number of rounds is possible for total functions, and also seems like lower bounding a simple function like AND ∘ OR in the parallel setting should be possible by standard techniques. Our results in Section 1.1.1 and Section 1.1.4 show that former is indeed true, and the latter is not the case and in fact requires "parallel-specific" thinking. Thus, one of our contributions is highlighting that there are still several fundamental query complexity questions unanswered in the parallel setting. We conclude by discussing a couple of these.

Limitations of parallel speedup

Can classical (randomized or deterministic) query algorithms simulate quantum query algorithms when allowed *both* a polynomial overhead in parallelism as well as number of rounds (as opposed to just a polynomial overhead in number of rounds as in Conjecture 1)? We conjecture that this is true:

▶ **Conjecture 7.** *For all total functions $f : \{0,1\}^M \to \{0,1\}$ and parallelism p, we have* $\mathsf{D}^{poly(p)\|}(f) = poly(\mathsf{Q}^{p\|}(f))$.

- When $p < \mathsf{bs}(f)^{1-\epsilon}$ for any $\epsilon > 0$, [27] prove that this is true.
- When $p \geq \mathsf{bs}(f) = \Omega(M^{\epsilon})$ for any $\epsilon > 0$, clearly this is true. This is the case in our result as well, where the canonical cheat sheet function was used to show Theorem 2 has $\mathsf{bs}(f) = \tilde{\Omega}(M^{1/6})$ and $\mathsf{D}^{p^{3/2}\|} = O(\mathsf{Q}^{p\|}(f)^3)$ for any p.
- Thus, the conjecture must be proven/falsified in the regime where bs and p are subpolynomial but superconstant. Moreover, what is the smallest power of p required to show this for all total f? Analogous questions remain open for $\mathsf{D}^{p\|}$ vs $\mathsf{R}^{p\|}$ as well.

Parallel composition theorem

It is known that $\mathsf{Q}(f \circ g) = \Theta(\mathsf{Q}(f) \cdot \mathsf{Q}(g))$ for boolean decision functions, a widely applicable and powerful result [30]. Is there an analogous theorem for p-parallel query complexity? In particular, do we have

$$\mathsf{Q}^{p\|}(f \circ g) = \Theta\left(\min_{q \in [p]} \mathsf{Q}^{q\|}(f) \cdot \mathsf{Q}^{\lceil p/q \rceil \|}(g)\right)$$

for boolean f, g? Such a result would suffice to reproduce our lower bound for $\textsc{And} \circ \textsc{Or}$, and likely be widely applicable for understanding parallel quantum query complexity. A straightforward attempt to show composition of the p-parallel adversary quantity using the reduction in [25] fails. This is because the partial function f' whose sequential query complexity characterizes the p-parallel complexity of f is no longer boolean.

Natural functions giving unbounded separation in rounds

Our results in Section 1.1.1 and Section 1.1.2 answer affirmatively whether it is possible for total functions to have unbounded separations in rounds, and whether this is still possible when no sequential separation exists. However, finding more natural functions to answer both these questions remains open and could help in understanding the interplay between quantum algorithms and parallel queries better.

Abstract

Simulating fermionic systems on a quantum computer requires representing fermionic states using qubits. The complexity of many simulation algorithms depends on the complexity of implementing rotations generated by fermionic creation-annihilation operators, and the space depends on the number of qubits used. While standard fermion encodings like Jordan-Wigner are space optimal for arbitrary fermionic systems, physical symmetries like particle conservation can reduce the number of physical configurations, allowing improved space complexity. Such space saving is only feasible if the gate overhead is small, suggesting a (quantum) data structures problem, wherein one would like to minimize space used to represent a fermionic state, while still enabling efficient rotations.

We define a structure which naturally captures mappings from fermions to systems of qubits. We then instantiate it in two ways, giving rise to two new second-quantized fermion encodings of F fermions in M modes. An information theoretic minimum of $\mathcal{I} := \lceil \log_2 \binom{M}{F} \rceil$ qubits is required for such systems, a bound we nearly match over the entire parameter regime.

1. Our first construction uses $\mathcal{I} + o(\mathcal{I})$ qubits when $F = o(M)$, and allows rotations generated by creation-annihilation operators in $O(\mathcal{I})$ gates and $O(\log M \log\log M)$ depth.
2. Our second construction uses $\mathcal{I} + O(1)$ qubits when $F = \Theta(M)$, and allows rotations generated by creation-annihilation operators in $O(\mathcal{I}^3)$ gates.

In relation to comparable prior work, the first represents a polynomial improvement in both space and gate complexity (against Kirby et al. 2022), and the second represents an exponential improvement in gate complexity at the cost of only a constant number of additional qubits (against Harrison et al. or Shee et al. 2022), in the described parameter regimes.

1 Introduction

The simulation of many interacting fermions is a promising application of quantum computers. Such systems quickly become difficult to simulate classically, with accurate simulation being computationally intractable for complex systems [28]. A quantum computer can perform highly accurate simulations with only polynomial resources for local systems, a wide and powerful class beyond what can be simulated classically.

Many quantum algorithms for fermionic simulation require a mapping from fermionic Fock states and creation/annihilation operators to qubit states and operators. Two of the most well known such mappings are the ones due to Jordan-Wigner [17] and Bravyi-Kitaev [7].

Theorem 2	$\mathcal{I} + O(\log(M/F))$	$O(MF\mathcal{I})$

These require M qubits to represent a fermion system with M modes, which is prohibitive in some cases. In particular, for particle preserving systems where the number of fermions F is much smaller than M, these encodings have a large amount of redundancy. In this case, the information theoretic lower bound of

$$\mathcal{I} := \left\lceil \log \binom{M}{F} \right\rceil \tag{1}$$

qubits is potentially much smaller than M.

Encodings which take advantage of this fact are relevant whenever the number of fermions is small compared to the number of modes, for instance in quantum chemistry simulations where the number of electrons (F) is fixed by a physical system yet the orbital basis size (M) should be as large as possible to correctly resolve the continuum behaviour. The discretization error in such systems scales like $1/M$ for reasonable bases [26], so large M is required for high accuracy – this is especially important when using basis sets that have not been classically optimized, such as the plane wave basis. This motivates developing simulation algorithms with as mild a dependence on M as possible in both space and gate usage, and a key component of many simulation algorithms is the qubit-to-fermion mapping used. Utilizing as few qubits as possible is important both for near term and fault tolerant devices, due to their limited size and the expense of qubits. However, space savings that incur an exponential gate overhead are not scalable. We therefore seek to minimize space complexity while still allowing relevant operations to be performed efficiently.

1.1 Prior work

There has been a line of work on second-quantized fermion encodings for saving space when the number of fermions is fixed. Bravyi et al. give a scheme for utilizing symmetries in particle preserving Hamiltonians to remove degrees of freedom, using parity symmetries to achieve $M - O(1)$ qubits generically and LDPC codes for few fermion systems to achieve $M - O(M/F)$ qubits [6], but with gate overhead $O(M^3)$ in the worst case[1]. Steudtner and Wehner give a

[1] Gate complexity here refers to the complexity of performing a single $\exp(-i\theta K)$, for some angle θ and number-preserving product of $O(1)$ many creation/annihilation operators K. For our discussions, we will not consider geometric locality.

scheme based on segmenting the space of fermions which again achieves $M - O(M/F)$ qubits, though allows more efficient $O(F^2)$ gate overhead [25, 24]. The same work also proposed a binary addressing code which shares some similarities with the encodings described here, but did not provide circuits for fermion operations nor bound the resource costs in the general case. The work of Babbush et al. [2] describes a way to store and manipulate few fermion systems using a sparse oracle, but do not provide explicit circuits for particle preserving rotations generated by creation-annihilation operators.

The work of Kirby et al. [19] describes a second quantized fermion encoding achieving $O(F^2 \log^4 M)$ space complexity and $O(F^2 \log^5 M)$ gate complexity, subject to a certain conjecture about Hermite interpolation. Additionally, the work of Harrison et al. [14] and Shee et al. [23] give methods for achieving exactly $\mathcal{I}$ qubit usage in second quantization, but at the cost of an exponential $M^{O(F)}$ gate complexity.

There are also first-quantized representations of fermion systems [26, 18, 1], where a list of occupied fermion modes is anti-symmetrized. This can save significant space when F is much smaller than M. However, such encodings allow for a different class of operations[2] to be performed efficiently as compared to second quantized encodings, making circuit complexity results within these two paradigms not directly comparable. Other works consider utilizing more than M qubits and restricting to an entangled subspace, allowing certain sets of k-local fermion operations to be extremely efficient (see e.g. [29, 30, 11, 7]). These encodings are most relevant for geometrically local systems, and in fact increase space beyond the standard Jordan-Wigner encoding – we therefore omit them from comparisons.

1.2 Contributions

We describe a quantum data structure which naturally captures the problem of encoding (second quantized) fermion systems in qubits. This structure represents bitstrings of length M and Hamming weight F, which naturally correspond to fermionic Fock states. We consider the (quantum circuit) gate/depth complexity of a sgn-rank ("sign rank") operator, which applies a phase conditioned on how many ones exist in some prefix of the bitstring, as well as a bit-flip operator which flips one of the bits. These operators allow us to straightforwardly express the fermionic operations which are relevant to quantum simulation, as we show in Section 3.

Within this framework, the Jordan-Wigner encoding can be seen as a data structure which encodes bitstring $b \in \{0,1\}^M$ by the quantum state $|b\rangle$, e.g. the trivial encoding. The sign rank operation is then simply a contiguous string of Z operators on some prefix, and the bit flip operator is a single X operator. Our encodings employ a different representation of bitstrings which is more efficient when F is small, requiring different quantum circuits.

1.2.1 Succinct structure

We first give a second quantized encoding for number preserving fermion systems which is nearly optimal in space usage, yet allows fermionic rotations with linear complexity and low depth. Our encoding uses sublinear redundancy, i.e. it is within a factor $1 + o(1)$ of optimal space usage (this is the meaning of "succinct" in the context of data structures) whenever $F = o(M)$. In particular, we prove the following theorem.

[2] In particular, first-quantized operations. See [26] for examples of usage of these encodings in quantum simulation.

▶ **Theorem 1** (Informal). *A system of F fermions in M modes can be represented by $\mathcal{I}+O(F)$ qubits such that particle preserving fermionic rotations*[3] *have circuits of complexity $O(\mathcal{I})$ and depth $O(\log M \log\log M)$.*

A summary of comparable prior work is shown in Table 1; notably, all previous second-quantized encodings either incur a polynomial overhead in space complexity[4], or the gate complexity of fermionic rotations is exponential in the number of qubits. We build up to this main result by presenting intermediary encodings achieving some, but not all of the aforementioned scalings. These encodings may be of independent interest due to their simplicity.

1.2.2 Implicit structure

We also give a construction which uses essentially the exact information-theoretic space minimum, except for an $O(1)$ number of ancilla (at constant filling). This construction achieves $\mathsf{poly}(M)$ gate complexity. The relevant regime for this encoding is constant filling, e.g. $F = M/3$ or more generally $F = \Theta(M)$. In this regime, the prior space complexity of $\mathcal{I} + O(F)$ may be a significant overhead, whereas when $F = o(M)$ the additive $O(F)$ term is asymptotically negligible. The information theoretic limit in the $F = \Theta(M)$ regime goes like $\mathcal{I} = \Theta(F)$, meaning there can be significant space to save if F is any constant fraction below $M/2$.

▶ **Theorem 2** (Informal). *A system of F fermions in M modes can be represented by $\mathcal{I} + O(\log(M/F))$ qubits such that particle preserving fermionic rotations have circuits of complexity $O(MF\mathcal{I})$.*

The most comparable prior work is that of Harrison et al. [14] and Shee et al. [23], which both achieve exactly $\mathcal{I}$ qubit complexity. However, these require an $\Omega\left(\binom{M}{F}\mathsf{poly}(M)\right)$ (e.g. exponential in M at constant filling) circuit complexity overhead for performing rotations generated by creation-annihilation operators, in the worst case. Our encoding improves exponentially on this gate complexity, achieving $\mathsf{poly}(M)$ in this regime. We do this at the cost of $O(1)$ ancilla qubits.

1.3 Technical overview

We begin in Section 3 by developing a data structure which naturally captures fermion to qubit mappings of number preserving systems. This definition is not fully general, but provides a framework for thinking about such mappings. We then instantiate this data structure in two ways.

1.3.1 First result: a succinct structure

To build up to the first main result, we begin by developing a fermion data structure in Section 4 based on a straightforward idea. Instead of storing the explicit string of ones and zeros, store a sorted list of pointers to the $\leq F$ positions containing a one. This approach builds

[3] By fermionic rotation, we mean the unitary $\exp(-i\theta K)$ for angle θ, where K is a number-preserving product of creation/annihilation operators, e.g. $K = a_j^\dagger a_k$ for some $j, k \in [M]$. We require that K is $O(1)$ local in the sense that it is the product of $O(1)$ creation/annihilation operators (but not geometrically local).

[4] i.e. have asymptotic space usage $\Omega(\mathcal{I}^c)$ for some $c > 1$ when $F \ll M$.

off ideas presented in prior fermion encodings [2, 25] as well as work compressing quantum states [8, 13], though we present these ideas in a way which will facilitate understanding our full encoding. Observe that, in contrast to first quantized representations [26] (which also store a list of pointers to occupied positions), we will not antisymmetrize the state. This enables us to efficiently implement sgn-rank and bit-flip queries (analogous to second-quantized rather than first-quantized operations), which we provide in Section 4.2. In Section 4.3 we describe a procedure using buffer registers that reduces the depth in this construction to logarithmic.

From this simple starting point, our next fermion data structure in Section 5 reduces the space requirements using combinatorial ideas, without affecting gate complexity. We accomplish this by splitting the most and least significant bits of each register, and using different representations for each. The most significant bits have a large amount of redundancy from being non-increasing, which we avoid by storing them using the stars and bars method. We give circuits for combining information between these two representations to efficiently implement the required operations.

We combine the two previous ideas with a succinct data structure that enables low-depth access to the most significant bits to show Theorem 1, with details given in the full version.

The key technical idea in this construction is a tree data structure used to store prefix sums related to the most significant bits. This prefix sum tree allows retrieving information about any specific entry in low depth, but requires less total space than a sorted list of numbers. This data structure therefore allows log depth fermionic rotations while being near-optimal in space usage, our first main result.

1.3.2 Second result: an implicit structure

Using a different approach, detailed in the full version, our second data structure achieves $\mathcal{I} + O(1)$ qubits and $\mathsf{poly}(M)$ gate complexity when $F = \Theta(M)$. We represent a bit string b (which itself represents a Fock state) by storing b's rank among feasible strings, where we determine rank by the number of bit-strings which are lexicographically before b or have a smaller Hamming weight than b. This encoding uses $\mathcal{I} + O(1)$ many qubits, but it is unclear how to interpret the encoded string to perform efficient operations. This obscurity is, essentially, the reason for the exponential gate overhead in prior works achieving this level of space efficiency.

We show how to perform both bit-flip and sign-rank efficiently on the first (unencoded) position, intuitively because the first and most-significant bit determines whether a given string has rank at most $\binom{M-1}{F-1}$ (first bit a 0) or rank above $\binom{M-1}{F-1}$ (first bit a 1) among strings of a given Hamming weight. This means that we can extract the first bit by comparing the encoded label against a fixed value, which can be done efficiently and with a small number of ancilla.

We then transform the ordering to one in which bit-flip and sign-rank can be performed efficiently on the second bit, and so on for each position. This is based on a construction of a certain set of orderings, which we denote $<_j$ for $j \in [0, ..., M]$, of the labels. These orderings have the property that, given just the rank of a configuration over order $<_j$, operations on the j-th encoded bit can be performed efficiently ($O(F\mathcal{I})$ gates) and with few ($O(1)$) ancillas on the label string. Further, we show how to transform a label under the order $<_j$ to a label under either $<_{j+1}$ or $<_{j-1}$ in the same complexity. By cycling over the M possible orderings, we can perform relevant operations with $O(MF\mathcal{I})$ gates and $O(1)$ ancillas.

2 Preliminaries

2.1 Fermions

A system of fermions with M modes can be defined by the algebra of creation ($a_i^\dagger$ for $i \in [M]$) and annihilation (a_i for $i \in [M]$) operators – this formalism is referred to as second quantization. These operators are determined by the anti-commutation relations

$$\{a_i^\dagger, a_j\} = \delta_{ij}, \qquad \{a_i^\dagger, a_j^\dagger\} = 0, \qquad \{a_i, a_j\} = 0. \tag{2}$$

Let $|00...0\rangle_f$ denote the vacuum state, the unique state which is not annihilated by any of the $a_i^\dagger$. We will primarily work with the Fock states, which are of the form

$$\begin{aligned} |\psi^{\mathbf{b}}\rangle_f :=& (a_1^\dagger)^{b_1}(a_2^\dagger)^{b_2}...(a_M^\dagger)^{b_M}\,|00...0\rangle_f \qquad \text{(for all } \mathbf{b} \in \{0,1\}^M\text{)} \\ =& |b_1, b_2, ..., b_M\rangle_f\,. \end{aligned} \tag{3}$$

We denote the span of these states $\mathcal{H}^{(fock)}$. Note that the M-mode Fock states are in natural correspondence with M-bit strings – this observation underlies the famous Jordan Wigner encoding [17], and will similarly underlie our data structures. It will be convenient for us to work in the Majorana basis determined by γ_j for $j \in [2m]$. These operators are defined as follows:

$$\gamma_{2j-1} = \frac{a_j^\dagger + a_j}{2}, \qquad \gamma_{2j} = \frac{i(a_j^\dagger - a_j)}{2}, \qquad \text{such that: } \{\gamma_j, \gamma_k\} = \delta_{jk}. \tag{4}$$

The action of Majorana operators on the Fock states can now be written as follows, where $\neg b$ is the negation of bit b,

$$\begin{aligned} \gamma_{2j-1}\,|b_1...b_j...b_M\rangle_f &= \left(\prod_{n=0}^{j-1}(-1)^{b_n}\right)|b_1...(\neg b_j)...b_M\rangle_f\,, \\ \gamma_{2j}\,|b_1...b_j...b_M\rangle_f &= i\cdot\left(\prod_{n=0}^{j}(-1)^{b_n}\right)|b_1...(\neg b_j)...b_M\rangle_f\,. \end{aligned} \tag{5}$$

In particular, these operators flip the occupation of a certain mode and apply a phase depending on the occupation of all preceding modes.

2.2 Fermion to Qubit Mappings

A fermion to qubit mapping can be defined by a linear mapping $\mathcal{E}_s$ from Fock states to qubit states, as well as a mapping $\mathcal{E}_o$ from Majorana operators to qubit operators. The qubit states/operators should be isomorphic to Fock states and Majorana operators, i.e. satisfy Equations 4, 5. Though some encodings do not fit into this paradigm (discussed in Section 1.1), this definition suffices for the encodings relevant to this paper. In particular, to define a mapping of an M mode system it suffices to construct $2M$ mutually anti-commuting qubit operators which each square to the identity.

We note that it is not always necessary to encode every possible Fock state, e.g. when simulating a system that does not explore every state. Particularly relevant for us will be particle preserving systems, which live in the subspace of Fock states with exactly F many fermions.

A well known example of a fermion-to-qubit mapping is the Jordan-Wigner encoding [17], which defines M-qubit operators as follows (where P_i denotes a Pauli P on the i-th qubit, acting trivially on the rest)

$$\mathcal{E}_{JW}(\gamma_{2i-1}) = \left(\prod_{j=1}^{i-1} Z_j\right) \otimes X_i, \qquad \mathcal{E}_{JW}(\gamma_{2i}) = \left(\prod_{j=1}^{i-1} Z_j\right) \otimes Y_i. \tag{6}$$

The mapped qubit operators in this encoding act on M qubits, which means M qubits are used to store fermionic states. Additionally, the circuit complexity of the mapped operators is $\Omega(M)$, as some mapped operators act non-trivially on all qubits.

2.3 Simulating Fermions

The main use case for fermion to qubit mappings is in the simulation of interacting fermions. In many such applications the dynamics are governed by a Hamiltonian H which is both k-local and term-wise number preserving (i.e. each term commutes with $\sum_i a_i^\dagger a_i$). If we wish to simulate such a system with M modes, the most general Hamiltonian is

$$H = \sum_{l\leq k; l \text{ even}; i_1 i_2 \ldots i_l \in [M]} h_{i_1 i_2 \ldots i_l} a_{i_1}^\dagger a_{i_2} \ldots a_{i_{l-1}}^\dagger a_{i_l} + h.c. \tag{7}$$

where the indices run over the M modes and $h.c.$ denotes the hermitian conjugate of the preceding term. This type of system is ubiquitous in quantum chemistry and physics. To simulate a fermionic system, one requires a mapping from fermion states/operators to qubit states/operators, as discussed in Section 2.2. Almost all second quantized algorithms for approximating evolution $\exp(-iHt)$ involve performing rotations generated by terms in H [9, 10, 4, 3, 20, 5, 21], so it is better for these rotations to require few gates and act on few qubits. Let V be a product of k Majorana operators, where k is even. Our encodings give efficient circuits for rotations of the form $\exp(-i\theta V)$ (k a multiple of 4) or $\exp(-\theta V)$ (k not a multiple of 4)[5]. This is sufficient to implement any rotation generated by the product of $O(1)$ creation/annihilation operators and its hermitian conjugate. For an illustrative example, consider a hopping term $a_j^\dagger a_k + h.c.$ for $j \neq k$,

$$\begin{aligned}\exp\Big(-i\theta(a_j^\dagger a_k + a_k^\dagger a_j)\Big) &= \exp(2\theta(\gamma_{2j-1}\gamma_{2k} - \gamma_{2j}\gamma_{2k-1})) \\ &= \exp(2\theta\gamma_{2j-1}\gamma_{2k}) \exp(-2\theta\gamma_{2j}\gamma_{2k-1}),\end{aligned}$$

from which it is clear that it suffices to implement two Majorana rotations. Note that although each Majorana operator itself need not preserve particle number, it changes the occupation number by at most k (in this case at most two). Further, the whole operator does preserve particle number. Therefore, so long as our encoding has enough "space" to fit the intermediate states, we will remain in the proper subspace after implementing the full operator $\exp\Big(-i\theta(a_j^\dagger a_k + a_k^\dagger a_j)\Big)$. We refer the reader to the full version for a more general discussion of this procedure.

[5] Actually, in most places we give circuits for the operator V up to a global phase. In the full version, we discuss how to generically implement the aforementioned rotations in the same complexity. Further, whether k is a multiple of 4 dictates whether $\exp(-i\theta V)$ or $\exp(-\theta V)$ is unitary; we implement the unitary one.

3 Fermion Data Structures

In this section we introduce an alternative perspective of fermion encodings, in a way which makes the connection to data structures explicit. This perspective will facilitate the development of efficient fermion-to-qubit mappings later on.

3.1 Definitions

We first define two useful combinatorial operations, sgn-rank and bit-flip. These are analogous to rank and bit flip queries respectively, which are well-studied in succinct classical data structures for bit-vectors [15, 22][6]. These operators act on a bit string $\mathbf{b} = (b_1, ..., b_M) \in \{0,1\}^M$ and depend on an index $j \in [M]$, and are combinatorial operations with no direct relation to fermions. However, they both show up naturally when writing down the action of fermionic creation-annihilation operators on Fock states: one can notice the similarities between Definitions 3, 4 and the action of Majorana operators in Equation 5.

▶ **Definition 3.** *The operator* sgn-rank *("sign rank") of an index $j \in [M]$ and bit string $\mathbf{b} \in \{0,1\}^M$ is the operator which returns the parity of the first j bits of $\mathbf{b}$ (represented as $+1$ for even, -1 for odd). In particular,*

$$\mathsf{sgn\text{-}rank}(j, \mathbf{b}) := \prod_{n=0}^{j} (-1)^{b_n}.$$

▶ **Definition 4.** *The* bit-flip *operator of an index $j \in [M]$ and bit string $\mathbf{b} \in \{0,1\}^M$ flips the j-th bit of $\mathbf{b}$. In particular, we have the following, where $\neg$ is logical negation,*

$$\mathsf{bit\text{-}flip}(j, \mathbf{b}) := (b_1, ..., (\neg b_j), ..., b_M).$$

With these two operations in hand, we can now describe the relevant type of (quantum) data structure for encoding fermionic states. Intuitively, we would like to represent a bit string $\mathbf{b} \in \{0,1\}^M$ in such a way that both sgn-rank and bit-flip queries can be implemented efficiently. Furthermore, in the settings we will care about we will be promised that the Hamming weight of $\mathbf{b}$ (the number of 1's) will never exceed $F + k$ or subceed $F - k$, for some $F < M$ and constant $k = O(1)$ (see the full version for more discussion). We use the notation $\mathcal{H}^{(fock)}_{M,F,k}$ to denote the Fock space of an M-mode system of fermions, restricted to states with occupation between $F - k$ and $F + k$: we call this range the capacity. We use the notation $\mathcal{H}^{(qubit)}_n$ to denote the Hilbert space of n qubits.

▶ **Definition 5.** *A* fermion data structure *of size M and capacity F, k is a qubit representation of Fock states with M modes and occupation at most $F + k$ and at least $F - k$, i.e. a linear and invertible mapping $\mathcal{E}_s : \mathcal{H}^{(fock)}_{M,F,k} \to \mathcal{H}^{(qubit)}_n$ that maps Fock states to computational basis states. We denote $\mathcal{E}_s(|\mathbf{b}\rangle_f)$ as $|\mathbf{b}\rangle$. We further require two n-qubit quantum circuit families F_j and R_j, answering* bit-flip *and* sgn-rank *queries respectively. Formally, we require*

$$F_j |\mathbf{b}\rangle := |\mathsf{bit\text{-}flip}(j, \mathbf{b})\rangle \qquad (\textit{if } \mathsf{bit\text{-}flip}(j, \mathbf{b}) \textit{ has } F - k \leq \mathsf{HW} \leq F + k), \tag{8}$$

$$R_j |\mathbf{b}\rangle := \mathsf{sgn\text{-}rank}(j, \mathbf{b}) |\mathbf{b}\rangle . \tag{9}$$

[6] Note that the differing models of complexity (RAM programs/cell probe versus quantum circuits) prevent most of these classical results from being directly applicable to our problems.

The gate/depth complexity of the above structure is the max gate count/depth, respectively, of the F_j, R_j over all $j \in [M]$. The space complexity is n – note that ancillas used in F_j, R_j are counted in this complexity, as they are circuits acting on exactly n qubits.

We remark that we consider quantum circuit complexity as the relevant cost measure, which prevents us from using many standard data structures results. Classical results often use the cell probe model [12], which is based on a RAM machine that allows random access to data. This model may not capture complexity in a real world quantum computer [16]. This necessitates new data structures and new ideas, which will be the focus of this paper.

3.2 Properties of fermion data structures

We first observe a subtlety in Definition 5: the operation of bit-flip is only required to be "correct" so long as the capacity is not exceeded. When one is interested in simulating a k-local Hamiltonian on a system with exactly F Fermions, then it often suffices to instantiate a Fermion data structure with capacity F, k[7]. In particular, it is straightforward to show that such a data structure can be used to instantiate a Trotterization scheme, or any simulation algorithm which relies on applying k-local particle-preserving rotations generated by products of k creation/annihilation operators. Intuitively, so long as we can "fit" the intermediate states necessary while performing these rotations, we will be able to perform any arbitrary sequence of rotations.

▶ **Proposition 6.** *Let $|\psi\rangle_f$ be a fermionic Fock state of F fermions in M modes, and C_f be a sequence of k-local fermionic rotations which preserve particle number, followed by a measurement in the Fock basis. If there is a fermion data structure of size M and capacity $F-k, ..., F+k$, using space n and gate complexity m, then there is a qubit state $|\psi\rangle$ on n qubits and a quantum circuit C of size $O(|C_f| \cdot m)$ such that measuring $C|\psi\rangle$ in the computational basis samples from the same distribution as $C_f|\psi\rangle_f$ (up to permuting bit-string labels).*

Proof. The initial state $|\psi\rangle$ is simply the encoding $\mathcal{E}_s(|\psi\rangle_f)$. To construct the circuit C, we will replace every gate of C_f (which are of the form $g_f = \exp(i\theta V)$ for k-local, particle preserving V) with the corresponding encoded circuit for performing the rotation, as detailed in Section 2.3. Let us call this encoded circuit g. Letting $|\phi\rangle$ be some superposition of Fock states with F fermions, then with a data structure $\mathcal{E}_s$ of capacity $F-k, ..., F+k$ we have the guarantee that

$$g\mathcal{E}_s(|\phi\rangle) = \mathcal{E}_s(g_f|\phi\rangle),$$

as g_f corresponds to a sequence of sgn-rank and bit-flip operations satisfying the necessary promises. Noting that $g_f|\phi\rangle$ will also have F fermions by the hypothesis that g_f preserves particle number, we can similarly perform this transformation for every following gate. Finally, by the invertibility of $\mathcal{E}_s$ we will obtain the same final output distribution by measuring in the computational basis, up to decoding the bit-strings (i.e. some permutation on the labels). ◀

Given the above discussion, the curious reader may note that our definition of fermionic data structures encodes all states of Hamming weight between $F-k$ and$F+k$ for some constant k. This is redundant in that $F+k > F$, and also that there are more states having Hamming weight between $F-k$ and $F+k$ than there are of Hamming weight exactly equal

[7] Note that this does incur some space overhead, but it is only an additive $O(1)$ (if $F = \Theta(M)$) or $O(\log M)$ (if $F = O(M/\log M)$)

to $F + k$. However, both of these redundancies result in negligible additive space overheads (either $O(1)$ or $O(\log M)$ depending on the regime). The conclusions we draw about space efficiency includes these overheads.

We remark that our encoding can also apply to some post-Trotter methods, e.g. certain linear combination of unitaries algorithms. We also remark for clarity that the encodings leading up to Theorem 1 will allow encoding every Fock state of occupation at most $F + k$ (though those leading up to Theorem 2 will only encode occupations $F - k$ through $F + k$).

4 Sorted List Fermion Data Structure

In this section, we describe a fermion data structure (Definition 5) based on storing a sorted list of pointers, rather than a full sparse string. While this encoding has some similarities to first-quantized encodings [26] and sparse oracle encodings [2], we emphasize that we present a generic second-quantized encoding capable of performing any $O(1)$-local particle preserving rotation generated by creation/annihilation operators in the described complexity. Furthermore, this encoding will lay the groundwork for our later, more efficient encodings.

▶ **Theorem 7.** *There is a fermion data structure for strings of M qubits having Hamming weight at most F that uses $O(F \log M)$ qubits, with gate complexity $O(F \log M)$.*

We will constructively establish this theorem throughout Section 4.1 and 4.2 – in particular Lemma 9 and Lemma 10 demonstrate the requisite circuit complexities. An immediate corollary is that a similar statement holds for fermion encodings.

▶ **Corollary 8.** *There exists a fermion encoding of an M mode system having at most F fermions which uses $O(F \log M)$ qubits such that any k-local, particle preserving rotation can be implemented with $O(F \log M)$ gates.*

4.1 Algebraic Definition

We formally define the state encoding function $\mathcal{E}_s^{(1)}$ and give the algebraic properties it satisfies. Let $e_i \in \{0,1\}^M$ be a binary string that is all 0's, except for a single 1 at position i (using 1-based indexing). Consider strings of the form

$$x = e_{i_1} \oplus e_{i_2} \oplus ... \oplus e_{i_f}$$
$$i_1 < i_2 < ... < i_f$$

with $f \leq F$. Define $\mathcal{E}^{(1)} : \mathcal{D} \to \{0,1\}^{F\lceil \log(M+1) \rceil}$, where $\mathcal{D} \subset \{0,1\}^M$ is the set of strings of Hamming weight at most F, as

$$\mathcal{E}^{(1)}(x) = |i_1\rangle |i_2\rangle \cdots |i_f\rangle |\infty\rangle \cdots |\infty\rangle \tag{10}$$

where ∞ is a placeholder for "no fermion", and is the larger of any comparison with a non-∞. Concretely, we adopt the convention that ∞ is represented by a register of all 1's. We can interpret the output as a sorted array of f elements, each element (also referred to as register) of size $\lceil \log(M+1) \rceil$, and padded out to F entries by ∞'s. We will now describe the action of sign-rank and bit-flip queries on this list.

1. A $\mathsf{sgn\text{-}rank}(j, \mathbf{b})$ query should apply a -1 phase if there are an odd number of registers having values less than or equal to j. Otherwise, it should act like the identity.
2. A $\mathsf{bit\text{-}flip}(j, \mathbf{b})$ should insert a register $|j\rangle$ into the list if it is not present, and otherwise delete $|j\rangle$. This operation should maintain sorted order, and act as described so long as both input and output states have Hamming weight less or equal to F.

Observe that both of the aforementioned operations are reversible. This suffices to define a fermion data structure.

4.2 Efficient Circuits

We will utilize comparison circuits between unsigned integers as a black box. As described in Section 4.1, we will assume an upper limit F on the number of pointers we will ever need to store, and therefore only utilize this many registers.

▶ **Lemma 9.** *For the sorted list encoding described in Section 4.1, a* $\mathsf{sgn\text{-}rank}(p, \mathbf{b})$ *query has a circuit of* $O(F \log M)$ *gates and* $O(F \log M)$ *ancilla.*

Proof. Such a circuit should induce a -1 phase for every 1 present (in the original bit string) before position p. To achieve this, for each pointer register $|x\rangle$ we compute $x \leq p$, apply a Z to the outcome bit, then uncompute. Each comparison takes $O(\log M)$ gates to compare $O(\log M)$ size numbers, and there are $O(F)$ comparisons to make; the overall circuit complexity is therefore $O(F \log M)$. ◀

▶ **Lemma 10.** *For the sorted list encoding described in Section 4.1, a* $\mathsf{bit\text{-}flip}(p, \mathbf{b})$ *query has a circuit of* $O(F \log M)$ *gates and* $O(\log M)$ *ancilla.*

Proof. Such a circuit should add a pointer p to the list if there is none, otherwise it should remove the pointer p. At a high level, we will do this in three steps.

1. If p exists, move it to the last register
2. On the last register exchange p and ∞
3. If the last register is p, move it to the sorted position

To accomplish this reversibly, we first implement a reversible ordered-swap U_p. This operator swaps two registers if one is p and the other is $> p$. By chaining these together in ascending order, we will move p to the end if it exists. Exchanging classical states can be easily done, then chaining more U_p together in descending order will move p to sorted order if it was at the end. The full circuit requires $O(F)$ calls to subroutine U_p, and each takes $O(\log M)$ (from comparisons); exchanging two classical values on a register has negligible complexity. The overall complexity is therefore $O(F \log M)$. ◀

4.3 Lower Depth

A notable problem with the previously described encoding is the serial nature of the bit flip operator. In particular, the depth of the circuits as described is $O(F \log M)$, primarily due to sequentially "bubbling" a targeted register to the end of the list when implementing a $\mathsf{bit\text{-}flip}(p, \mathbf{b})$ operation. In this section, we describe a modification using $O(F \log M)$ ancillas that allows exponentially smaller depth, $O(\log F + \log \log M)$. Further, the buffer register idea developed here will prove useful when lowering depth in our succinct construction.

To achieve $O(\log F + \log \log M)$ depth, we will pad the encoded state with an $|\infty\rangle$ between registers and on either end. We will refer to these as buffer registers, in contrast with logical registers representing pointers. We will also pad the start with a $|-\infty\rangle$ and the end with $|\infty\rangle$ logical registers for convenience. Formally, consider strings of the form

$$x = e_{i^{(1)}} \oplus e_{i^{(2)}} \oplus ... \oplus e_{i^{(f)}}$$
$$i^{(1)} < i^{(2)} < ... < i^{(f)}$$

where $f < F$. Define $\mathcal{E}^{(2)} : \{0,1\}^M \to \{0,1\}^{O(F \log M)}$ as

$$\mathcal{E}^{(2)}(x) = |-\infty\rangle\,|\infty\rangle\,|i_l^{(1)}\rangle\,|\infty\rangle\,|i_l^{(2)}\rangle\,|\infty\rangle \cdots |\infty\rangle\,|i_l^{(F)}\rangle\,|\infty\rangle \cdots |\infty\rangle\,, \tag{11}$$

where every other register is a buffer (coloured blue, but this is purely conceptual; the same data is stored in each). This leaves $O(F \log M)$ qubits, as the buffer registers are just a constant factor overhead. The correct action of sgn-rank and bit-flip exactly mirrors that of Section 4 on the logical registers (excluding the initial padded $-\infty$), except now we must also leave the buffer registers invariant after the computation is finished.

▶ **Lemma 11.** *Under the list-with-buffers encoding described in Section 4.3, a* sgn-rank$(p, \mathbf{b})$ *query has a circuit of* $O(\log \log M)$ *depth,* $O(F \log M)$ *gates, and* $O(F \log M)$ *ancilla.*

Proof. This operation can be done in a similar way to Section 4.2. We again apply a conditional phase to each logical register (note we do not do this on any buffer register, nor the padded $|-\infty\rangle$ at the beginning). The gate count $O(F \log M)$ follows from the analysis in Lemma 9, and one can see that the depth is fully determined by the depth of a comparison. By simple facts about comparator circuits, these can be done in $O(\log \log M)$ depth using linearly many ancillae, so the overall depth is $O(\log \log M)$. ◀

▶ **Lemma 12.** *Under the list-with-buffers encoding described in Section 4.3, a* bit-flip$(p, \mathbf{b})$ *query has a circuit of* $O(\log F + \log \log M)$ *depth,* $O(F \log M)$ *gates, and* $O(F \log M)$ *ancilla.*

Proof. We are promised that whenever an insertion is made, the last element will be an ∞. Conversely, whenever a deletion is made, the element added to the end will be an ∞. This prevents us from needing to perform a full cycle, instead relying on the buffer registers to provide ∞'s wherever needed. At a high level, it suffices to do the following:

1. Compute a flag f_{del} depending on whether p appears in the logical registers, and fan it out to all registers.
2. If p is not present ($f_{del} = \top$), insert p at the buffer register between it's immediate predecessor and successor.
3. If p is present, shuffle registers $> p$ upwards one position, and move p to it's preceding buffer. Otherwise, shuffle all registers $> p$ downwards one position, and move p out of it's preceding buffer.
4. If p was present ($f_{del} = \bot$), remove p from the buffer between p's predecessor and successor.
5. Uncompute f_{del}.

Note that steps (2) and (4) do not need to explicitly be controlled by f_{del} due to the assumed structure of the data. In step (3) however, the direction in which to shuffle depends on whether p is present or not, so a light cone argument implies that the local operations must depend on whether p is present. It is worth pointing out that, except for the fan-in/fan-out of f_{del}, all operations are nearest-register in a one dimensional layout, which could aid implementation on a quantum computer with geometric constraints.

Using linearly many ancilla registers, a comparison between n bit integers can be done in depth $\log n$. Swaps between registers can be done in $O(1)$ depth, the largest comparison is between $O(\log M)$ bit integers, and a single bit can be fanned out to F positions (one for each register) in depth $O(\log F)$. The total depth is therefore $O(\log F + \log \log M)$ (or $O(\log \log M)$ with unbounded fan-in and fan-out), using $O(F \log M)$ ancillae. Each register of size $\log M$ is acted on by only a constant number of comparison/swaps, so the gate complexity is $O(F \log M)$. ◀

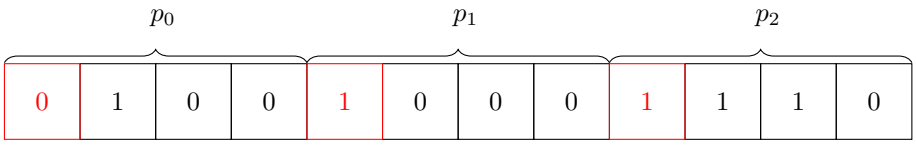

Figure 1 An illustration of the redundancy in a sorted list, for a list of 3 things out of a universe of 16 things. The red bits are non-decreasing, with possibilities: $000, 001, 011, 111$. Four possibilities means 2 bits suffice, rather than 3.

5 Achieving Succinctness

Recall that the information theoretic limit for encoding F fermions in M modes is $\mathcal{I} := \lceil \log \binom{M}{F} \rceil$ qubits. From Stirling's approximation we have

$$\mathcal{I} = F \log \frac{M}{F} + O(F),$$

so the encoding in Section 4.1 is redundant – for instance when $F = \sqrt{M}$, approximately half of the qubits are unnecessary. Here we present an encoding in which only a sublinear $O(F)$ many qubits are unnecessary (there are known constructions that achieve the *exact* information theoretic minimum $\mathcal{I}$ [14, 23], but the gate complexity becomes $M^{O(F)}$). For the example of $F = \sqrt{M}$, this new encoding has only a negligible $o(1)$ fraction of unnecessary qubits, i.e. it is roughly twice as space efficient as in Section 4. These techniques make crucial use of the fact that the list is not anti-symmetrized.

5.1 Succinct encoding

We formally state the main theorem of this section below.

▶ **Theorem 13.** *There is a fermion data structure for strings of M qubits having Hamming weight at most F that uses $\mathcal{I} + O(F)$ qubits, with gate complexity $O(F \log M)$.*

Such an encoding is constructed in the remainder of this section, with Lemma 15 and Lemma 16 demonstrating that it satisfies the requisite efficiencies. Similar to Corollary 8, this implies a fermion to qubit mapping with the same complexities.

▶ **Corollary 14.** *There exists a fermion encoding of an M mode system having at most F fermions which uses $\mathcal{I} + O(F)$ qubits such that any k-local, particle preserving rotation can be implemented with $O(F \log M)$ gates.*

To reduce the number of necessary qubits, the key insight is noting that the most significant $G := \lceil \log F \rceil$ qubits in each register of the encoding in Section 4.1 are not pulling their weight. They use $F \cdot G = \Omega(F \log F)$ qubits to encode F integers in the range 1 to F, but they are in *sorted order*, reducing the number of possible sequences – see Figure 1 for an illustration. We can instead store the same data (the most significant bits) in $O(F)$ space as a bit string where $2^G - 1 = O(F)$ zeroes delimit 2^G bins, and F ones correspond to F fermions. The i-th bin is the space from the i-th zero (or the start of the bit string) to the $i+1$-st zero (or the end of the bit string), and the number of ones in that range indicate elements with most significant bits i. This idea is commonly referred to as the stars and bars method.

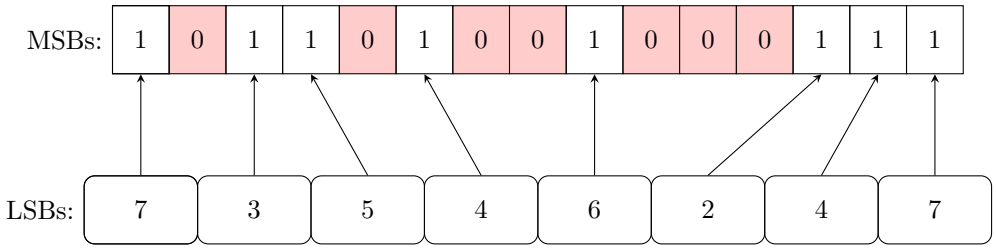

Figure 2 Illustrative example of the succinct representation, with parameters $F = 8$, $M = 63$ and fermions at $[7, 11, 13, 20, 38, 58, 60, \infty]$; recall the convention that the largest storable value (63) is identified with ∞. Red registers demarcate "bins" of different MSB values, out of 8 possible values. The LSBs then only require 3 qubits each, so the total storage is $15 + 24 = 39$ qubits. Using first quantization/sorted list encodings would use $8 \cdot \lceil \log 63 \rceil = 48$ qubits, and Jordan-Wigner or similar second quantized encodings would require 63 qubits.

The remaining least-significant bits can be stored in the usual way, where the order depends on the value determined by both least significant and most significant parts. So long as this order is maintained, the least-significant bits can be paired with the corresponding most-significant bits by the order in which they appear. This saves $F\lceil \log F \rceil$ qubits and adds $O(F)$ many, so the total qubit usage is

$$\begin{aligned}\text{Space}(M, F) =& F\lceil \log(M+1) \rceil - F\lceil \log F \rceil + O(F) \\ =& F \log \frac{M}{F} + O(F) \\ =& \mathcal{I} + O(F).\end{aligned}$$

To define the encoding formally, for strings of the form

$$\begin{aligned} x &= e_{i^{(1)}} \oplus e_{i^{(2)}} \oplus \ldots \oplus e_{i^{(F)}} \\ i^{(1)} &< i^{(2)} < \ldots < i^{(f)} \end{aligned}$$

for $f < F$, let i_m denote the G most significant bits of i, and i_l denote the remaining least significant bits. Let r_j be the number of pointers having most significant bits equal to j, i.e. the number of values of k such that $i_m^{(k)} = j$. Now define $\mathcal{E}^{(3)} : \{0,1\}^M \to \{0,1\}^{\mathcal{I}+O(F)}$ as

$$\mathcal{E}^{(3)}(x) = |i_l^{(1)}\rangle\, |i_l^{(2)}\rangle \cdots |i_l^{(f)}\rangle\, |\infty_l\rangle \cdots |\infty_l\rangle\, ||1^{r_0}01^{r_1}0 \ldots 01^{r_{2^G-1}} \tag{12}$$

Where $||$ is a conceptual divider between information about the most and least significant bits, and 1^n denotes n many 1's. The bits to the left of $||$ store the least significant bits of each pointer, and are referred to as l or LSBs, and i-th register in this section is l_i. The bits to the right of $||$ are referred to as m or MSBs and store the most significant bits of each pointer. Define $\mathcal{E}_s^{(3)} : \mathcal{H}_{2^M} \to \mathcal{H}_{2^{\mathcal{I}+O(F)}}$ as the unique linear extension of $\mathcal{E}^{(3)}$. A simple example of this encoding is shown in Figure 2.

For correctness, it suffices if encoded bit-flip and sgn-rank operators satisfy the rules described in Section 4.1, on the list implicitly represented by our succinct string. In particular, the encoded $\mathsf{bit\text{-}flip}(p, \mathbf{b})$ operator should unitarily insert/delete p from the sorted list defined by the information stored in the MSBs and LSBs, and update this data accordingly. The $\mathsf{sgn\text{-}rank}(p, \mathbf{b})$ operator should apply a minus phase if and only if there are an odd number of elements less or equal to p in the sorted list.

5.2 Efficient circuits

We now turn to constructing efficient circuits for the necessary operations on this succinct encoding. We note that retaining our space complexity advantage limits the number of ancillas that can be used to perform our operations to be $O(F)$ (and, naturally, we require these ancillas to be uncomputed by the end of each operation).

▶ **Lemma 15.** *Under the succinct list encoding $\mathcal{E}_s^{(3)}$ described in Section 5.1, a* $\mathsf{sgn\text{-}rank}(p, \mathbf{b})$ *query has a circuit of $O(F \log M)$ gates, and $O(F)$ ancilla.*

Proof. At a high level, this operation can be performed as follows:

1. Scan the most significant bits m to determine a range $[p_{start}, p_{end})$ of least significant bit registers whose most significant bits match p
2. Use this range to implement comparisons $\leq p$ on all registers
3. Phase the result of this comparison with a Z gate
4. Uncompute comparisons, then p_{start} and p_{end}

Scanning the register m takes $O(F)$ iterations costing $O(\log F)$ each. Each comparison afterwards costs $O(\log M/F)$ gates, and there are $O(F)$ many to make, so the total gate complexity is $O(F \log M)$. The only space used beyond comparisons are registers of size $O(\log F)$, satisfying the ancilla requirement. ◀

▶ **Lemma 16.** *Under the succinct list encoding $\mathcal{E}_s^{(3)}$ described in Section 5.1, a* $\mathsf{bit\text{-}flip}(p, \mathbf{b})$ *query has a circuit of $O(F \log M)$ gates, and $O(F)$ ancilla.*

Proof. Comparisons require information from the most significant bits, which is gathered first. Following this, analogous to the approach in Lemma 10 we will bubble the target element to the end if present, exchange with ∞, and then bubble back. At a high level:

1. Compute and store a pointer t to the target position in the list of F elements, defined as the first register with value $\geq p$ (based on both it's most and least significant bits).
2. Compute a flag f_{del}, which is on if and only if p is present in the list.
3. If f_{del}, shuffle l_t to the end of l.
4. Exchange $\infty_l \leftrightarrow p_l$ on the last register of l.
5. If not f_{del}, shuffle the end of l to t.
6. If f_{del}, shuffle the $(t+p)$-th bit of m to the end
7. If not f_{del}, shuffle the last bit of m to the $(t+p)$-th position.
8. Uncompute f_{del} and t.

Steps (1) and (2) can be done in $O(F \log M)$ gates by computing temporary p_{start}, p_{end} ranges of indices in l which have the same most significant bits as p, implementing comparisons using these, then uncomputing. Steps (3), (4), (6), (7) are simple swap ladders which can be performed in $O(F \log M)$ gates, and Step (5) has negligible complexity. Step (8) has the same cost as steps (1), (2), so the overall gate complexity is $O(F \log M)$. Again, the only additional space stored is $O(\log F)$ size pointers p_{start} and p_{end}, satisfying the ancilla requirement. ◀

6 Applications

In this section we give a more detailed comparison of our encoding to prior encodings, and outline scenarios where ours outperforms prior work. We will focus on the succinct construction, e.g. Theorem 1, as it is likely the more practical of the two constructions.

For concreteness we consider the parameter regime where the number of fermions is polynomially smaller than the number of modes, i.e. $F = M^c$ for some constant $0 < c < 1$, though we note that our encoding is efficient outside this regime as well. This regime is

well motivated for applications such as quantum chemistry, where the number of modes is preferred to be as large as possible to accurately model the continuum, but algorithm's polynomial scaling with M prevents M from being exponentially larger than F.

The primary application we find is in randomized simulation algorithms such as qDRIFT [9], where our encoding gives a polynomial space savings with only logarithmic depth overhead. We also show that our encoding allows for an optimal implementation of a second quantized SELECT subroutine, used in linear combination of unitary methods [10], no matter how M and F relate.

6.1 Space Efficient Randomized Simulation

Randomized product formulas like the qDRIFT algorithm [9] are strong candidates where our encoding will be useful, as the complexity of such algorithms depend heavily on the fermion encoding used. The qDRIFT algorithm requires $O((\lambda t)^2/\epsilon)$ fermionic rotation operators to evolve for time t within error ϵ, where λ is the sum of the magnitude of Hamiltonian coefficients when written in a second quantized basis. The scaling with λ is preferable to scaling with M when the magnitude of coefficients varies drastically, as is often the case for quantum chemistry Hamiltonians.

▶ **Theorem 17.** *For a particle preserving local fermionic Hamiltonian H on an M mode system, there is a second quantized algorithm for evolving an F fermion state to time t using space $\mathcal{I}+O(F)$, with gate complexity $O\left(\epsilon^{-1}(\lambda t)^2\mathcal{I}\right)$, and circuit depth $O\left(\epsilon^{-1}(\lambda t)^2 \log M \log\log M\right)$, where λ denotes the sum of magnitudes of coefficients in H and ϵ denotes the target diamond-norm error.*

This theorem follows straightforwardly from using the qDRIFT algorithm [9] with our Theorem 1 In the regime discussed above, the space complexity of this algorithm is

$$\mathcal{I} + O(F) = O(M^c \log M^{1-c}) = O(M^c \log M),$$

with gate complexity

$$O\left(\epsilon^{-1}(\lambda t)^2\mathcal{I}\right) = O(\epsilon^{-1}(\lambda t)^2 M^c \log M),$$

and circuit depth

$$O\left(\epsilon^{-1}(\lambda t)^2 \log M \log\log M\right).$$

We now compare these complexities against those achieved by other second-quantized encodings in our parameter regime.

6.1.1 Space Complexity

The most space-efficient prior second quantized encodings in this regime that are amenable to randomized simulation methods are the qubit efficient [23] and permutation basis [14], but these encodings would incur an exponential (M^F) gate and depth overhead. Barring these encodings, the next best are the segment code [25, 24], and the optimal degree code [19]. We use polynomially less space than the former ($O(M^c \log M)$ vs. $\Omega(M)$) and quadratically less than the latter ($O(F \log M)$ vs. $\Omega(F^2 \log^4 M)$).

6.1.2 Circuit Complexity

When $c < 1/2$, the prior best second quantized encoding in terms of space usage (barring codes with exponential gate overhead) is the optimal degree code [19]. Compared to this encoding, along with better space efficiencies we also improve on the $O(F^2 \log^5 M)$ gate complexity of fermion operations. Our scaling of $O(\mathcal{I})$ (with $\mathcal{I} < F \log M$) is always quadratically better in dependence on F, and at least four powers better in dependence on $\log M$. Further, while the depth is not analyzed in the optimal degree encoding a simple counting argument implies that it is at least $\Omega((\lambda t)^2 \log M/\epsilon)$, which is at most a negligible $O(\log \log M)$ better than our encoding. Compared to other space efficient second-quantized encodings, we give at least a quadratic improvement in circuit complexity while also removing many log factors.

Allowing space inefficient encodings, the most gate efficient prior encoding in our regime is the Bravyi-Kitaev encoding [7], which uses $O(\log M)$ gates to implement a fermionic rotation. This is the encoding used in the original resource estimates for the qDRIFT algorithm, making it a natural competitor. When the order of fermionic rotations is selected randomly, the Bravyi-Kitaev encoding of these operators cannot be significantly parallelized. The depth for full simulation will generically be $\Omega((\lambda t)^2/\epsilon)$ (and potentially larger if fermion operations take super-constant depth to implement), which is only a logarithmic factor lower than in our encoding. Furthermore, the Bravyi-Kitaev encoding requires polynomially more qubits ($O(M)$ versus $O(M^c \log M)$) than our encoding in this regime – though fewer gates ($O(\log M)$ versus $O(M^c \log M)$). This trade-off is therefore more beneficial the smaller c is.

6.2 Optimal SELECT Subroutine

In the context of post-Trotter methods, our encoding method can be relevant not only for saving space but also for saving gates. We illustrate this by giving a provably optimal implementation of the SELECT subroutine, a key component in the linear combination of unitaries algorithm for Hamiltonian simulation [10]. This algorithm involves expressing the Hamiltonian as a linear combination of unitaries

$$H = \alpha_1 U_1 + ... + \alpha_q U_q,$$

then block encoding the Hamiltonian using a PREPARE oracle that creates a superposition over every number in $j \in [q]$, weighted by amplitude α_j, in conjunction with as a so-called SELECT oracle. The SELECT oracle has a control wire indicating a number $j \in [q]$, and conditioned on j performs the unitary U_j on the physical state – this oracle is the only part whose implementation is dependent on the fermion encoding used. One way to split a k-local second quantized fermionic Hamiltonian into a linear combination of unitaries is to split every a_j into Majoranas $a_j = \gamma_{2j-1} + i\gamma_{2j}$. The γ_j operators are unitary, meaning the full Hamiltonian is now a linear combination of unitaries. Using our encoding, we can perform a SELECT oracle in the optimal complexity. Specifically, we show how to perform an k-local product of Majorana operators, given k index wires denoting which Majoranas appear in the product. This translates to a sequence of $O(k)$ many sgn-rank and bit-flip operations, so in particular it suffices to do a single $\textsf{sgn-rank}(j, \mathbf{b})$ or $\textsf{bit-flip}(j, \mathbf{b})$ operator controlled on an index wire $|j\rangle$.

▶ **Theorem 18.** *Using the encoding described in Theorem 1, we can perform a coherently controlled* $\textsf{sgn-rank}(|j\rangle, \mathbf{b})$ *or* $\textsf{bit-flip}(|j\rangle, \mathbf{b})$ *with* $O(\mathcal{I})$ *gates.*

Proof. Consider the M fermion Hamiltonian

$$H^{(m)} = \alpha_1 U_1^{(m)} + ... + \alpha_q U_q^{(m)}$$

where every $U_i^{(m)}$ is a product of Majorana operators. When the fermionic Hamiltonian H is k-local, then every $U_j^{(m)}$ appearing in $H^{(m)}$ has k-many Majorana operators. It follows that we can implement the action of $U_j^{(m)}$ within the encoding described in Theorem 1 with complexity $O(\mathcal{I})$. We can further coherently condition which $U_j^{(m)}$ is performed using a control register (see the full version for details), introducing at most a constant factor overhead. For this SELECT oracle we therefore obtain circuits of size $O(\mathcal{I})$. Note that in general there are many ways to split a Hamiltonian into a linear combination of unitaries, and we leave to future work whether SELECT has an efficient implementation under alternative choices. ◀

As argued above, this is sufficient to implement a SELECT oracle in the same complexity. We now turn to lower bounds.

▶ **Theorem 19.** *Using any fermion to qubit mapping, a coherently controlled, second-quantized, k-local particle preserving fermion operation (a SELECT oracle) requires $\Omega(\mathcal{I})$ gates.*

Proof. The lower bound for representing F fermions in M modes is $\mathcal{I}$ qubits, due to a straightforward counting argument. Suppose there were a generic implementation of the second quantized SELECT oracle of the aforementioned kind which used $\lfloor \frac{1}{2}(\mathcal{I}-1) \rfloor$ one- and two-qubit gates, and implemented any k-local fermion term for a $k > 1$. It follows that such an oracle would act on at most $\mathcal{I}-1$ qubits, so consider keeping only the $\mathcal{I}-1$ qubits it acts on. We are then left with a fermion encoding on $\mathcal{I}-1$ qubits, as by assumption the SELECT oracle is capable of performing arbitrary pairs of Majorana operators; a contradiction. Hence, any generic implementation of the SELECT oracle requires $\Omega(\mathcal{I})$ gates, matching our upper bound up to constant factors. ◀

To compare this result against existing second quantized encodings, note that in all prior encodings (summarized in Table 1) the complexity of a coherently controlled fermion operator is at least linear in the number of qubits, or exponential in the case of prior succinct encodings. For every gate-efficient encoding, the number of qubits is polynomially larger than $\mathcal{I}$ in our regime $F = M^c$, from which it follows that the gate complexity is at least polynomially larger than $\mathcal{I}$. Concretely, when $c < 1/2$ the best prior implementation of the select oracle is the optimal degree encoding, with gate complexity $\Omega(F^2 \log^5 M)$. Our implementation of complexity $O(\mathcal{I})$ where $\mathcal{I} < F \log M$ is quadratically better in F dependence, and at least four powers better in $\log M$ dependence. We note also that in the parameter regime $c > 1/2$ our encoding maintains at least a factor $\tilde{O}(M^{1-c})$ advantage in gate complexity over prior work, giving a polynomial advantage over the whole regime.

6.3 Comparison to First Quantized Encodings

First quantized algorithms maintain a list of pointers representing fermion positions similar to the encoding described in Section 4, but antisymmetrize the state over all possible permutations. The fermion phases then arise from the exchange statistics of the registers, allowing for a different class of efficient operations. Comparisons against first quantization are subtle, as algorithms within these two paradigms can have drastically different complexities for simulating similar systems. In general one would expect first quantized algorithms to

outperform second quantized algorithms when F is extremely small compared to M, but there is evidence that second quantized algorithms can remain advantageous when F is polynomially smaller than M [27]. This motivates the parameter regime we consider here.

6.3.1 Space Complexity

Using Stirling's approximation we can rewrite

$$\mathcal{I} = F \log \frac{M}{F} + O(F). \tag{13}$$

In our parameter regime of interest, we therefore have

$$\mathcal{I} = (1-c) \cdot F \log M + O(F) \tag{14}$$

Note that the $O(F)$ term is asymptotically less than the $(1-c) \cdot F \log M$ term, and as a corollary the asymptotic space usage of our encoding $(\mathcal{I} + O(F))$ is a factor $1 + o(1)$ from optimal, i.e. it is succinct. Standard first-quantized encodings [26] use $F\lceil \log M \rceil$, which is asymptotically a factor $\frac{1}{1-c}$ above $\mathcal{I}$, which is not succinct. Our encodings saves more space the closer c is to 1.

6.3.2 Gate Complexity

Both our representation and first-quantized representations support efficient (i.e. at most linear in the number of qubits) fermion operations of the first-quantized or second-quantized variety, respectively. Differences in gate complexity, therefore, stem primarily from differences in algorithms built in a first-quantized versus second-quantized picture. Many of the algorithms in these different paradigms are designed for different contexts, making a fair comparison difficult.

7 Conclusion and Open Problems

We presented two second-quantized fermion encodings which are almost exactly optimal in terms of space usage, yet allows gate efficient and low depth second-quantized fermion rotations. In the context of randomized simulation algorithms, the succinct encoding allows for a polynomial space savings with only a logarithmic depth overhead. Along the way, we presented a more simple succinct encoding which did not achieve low depth, as well as a low depth encoding that did not achieve succinctness, though both of these encodings may be of independent interest due to their simplicity. This work leaves open the following questions.

1. In first quantization, a list of positions is stored in an antisymmetrized wavefunction with $F\lceil \log M \rceil$ qubits in standard encodings, allowing for efficient first quantized fermion operations. Can such a representation be made succinct while still antisymmetrizing?
2. Is there an efficient fermionic Fourier transform circuit for our encodings?
3. Can the qubit count be improved beyond $\mathcal{I} + O(F)$ without exceeding gate complexity $O(\mathcal{I})$? We conjecture a lower bound on the qubits required to maintain this gate complexity is $\mathcal{I} + \Omega(F)$.
4. When compiled to a universal gate set like $\mathrm{CNOT}, \mathrm{H}, T$, the complexities of each gate is the same as the overall complexity in our encodings. In many error correcting codes certain gates are harder than others (for instance T gates are more expensive in a surface code), motivating analysis of each gate individually. Can the number of T gates be reduced in this construction?
5. Can the degree of the $\mathsf{poly}(M)$ circuit complexity scaling in our implicit encoding be improved?

Abstract

In recent years, quantum computing involving physical systems with continuous degrees of freedom, such as the bosonic quantum states of light, has attracted significant interest. However, a well-defined quantum complexity theory for these bosonic computations over infinite-dimensional Hilbert spaces is missing. In this work, we lay the foundations for such a research program. We introduce natural complexity classes and problems based on bosonic generalizations of **BQP**, the local Hamiltonian problem, and **QMA**. We uncover several relationships and subtle differences between standard Boolean classical and discrete-variable quantum complexity classes, and identify outstanding open problems. Our main contributions include the following:

1. **Bosonic computations.** We show that the power of Gaussian computations up to logspace reductions is equivalent to bounded-error quantum logspace (**BQL**, characterized by the problem of inverting well-conditioned matrices). More generally, we define classes of continuous-variable quantum polynomial time computations with a bounded probability of error (**CVBQP**) based on gates generated by polynomial bosonic Hamiltonians and particle-number measurements. Due to the infinite-dimensional Hilbert space, it is not a priori clear whether a decidable upper bound can be obtained for these classes. We identify complete problems for these classes, and we demonstrate a **BQP** lower bound and an **EXPSPACE** upper bound by proving bounds on the average energy throughout the computation. We further show that the problem of computing expectation values of polynomial bosonic observables at the output of bosonic quantum circuits using Gaussian and cubic phase gates is in **PSPACE**.
2. **Bosonic ground energy problems.** We prove that the problem of deciding whether the spectrum of a bosonic Hamiltonian is bounded from below is **co-NP**-hard. Furthermore, we show that the problem of finding the minimum energy of a bosonic Hamiltonian critically depends on the non-Gaussian stellar rank of the family of energy-constrained states one optimizes over: for zero stellar rank, i.e., optimizing over Gaussian states, it is **NP**-complete; for polynomially-bounded stellar rank, it is in **QMA**; for unbounded stellar rank, it is **RE**-hard, i.e., undecidable.

1 Introduction

Many quantum mechanical systems, such as spin systems, are effectively described using discrete variables and are captured using qubits or qudits. The standard model of quantum computation is formulated based on such discrete degrees of freedom [37]. However, quantum variables such as the position, momentum, or amplitudes of electromagnetic fields are continuous. These degrees of freedom are described mathematically using infinite-dimensional Hilbert spaces. Continuous-variable systems are also present in many fundamental problems in theoretical physics, such as the solution to energy levels of a molecular system, quantum field theories, or exotic quantum states of matter such as Bose–Einstein condensates.

Continuous-variable quantum architectures have recently been used in practical quantum computing implementations, with several leading quantum error-correction schemes being fundamentally infinite-dimensional [20, 21]. Several important physical frameworks for quantum computing, such as quantum photonic processors, are based on continuous-variable degrees of freedom. These architectures have recently been demonstrated at scales sufficient to solve computational sampling problems that are believed to exceed the power of classical computations [46, 34].

What are the fundamental computational limitations and power of quantum degrees of freedom? This question is the subject of quantum complexity theory [44]. The standard quantum computing model and quantum complexity theory are formulated using discrete-variable quantum degrees of freedom over finite-dimensional Hilbert spaces. Several complexity classes have been defined to capture the computational power associated with these quantum degrees of freedom. One can define various natural models of quantum computations, such as adiabatic computation, quantum circuits, topological quantum computation, or measurement-based quantum computing, and all of these variants have been proven to have power equal to the computational complexity class **BQP**, which captures the power of polynomial-size quantum circuits in deciding logical statements with a small probability of error. Another important complexity class that captures the complexity of estimating the energy levels of a quantum physical system is **QMA**, which can be viewed as a quantum generalization of **NP** and, in particular, **MA** as the randomized generalization of **NP**. Due to a seminal result of Kitaev [28] (and many follow-up works, e.g., [29]), the problem of estimating the ground state energy of a physical system up to inverse-polynomial additive error (known as the local Hamiltonian problem) is complete for **QMA**. In fact, the local Hamiltonian problem can be viewed as the quantum generalization of the canonical constraint satisfaction problem over the Boolean hypercube, which is itself complete for **NP**. In recent years, the relationship between these complexity classes and standard complexity classes such as polynomial time **P**, polynomial space **PSPACE**, nondeterministic polynomial time **NP**, #**P** (corresponding to counting the number of solutions to constraint satisfaction problems), **PP** (the class of problems that are solvable on a probabilistic Turing machine with probability of error $< 1/2$) have been extensively studied. All of these complexity classes are contained in the class of

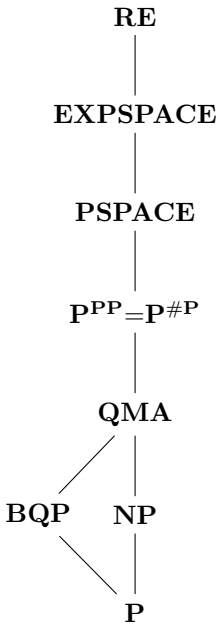

Figure 1 Known relations between complexity classes used in this work. If a line connects complexity class $\mathbf{C}_1$ to $\mathbf{C}_2$, with $\mathbf{C}_1$ being on the right of $\mathbf{C}_2$, it is implied that $\mathbf{C}_2 \subseteq \mathbf{C}_1$.

problems solvable in exponential space **EXPSPACE**, itself included in the set of recursively enumerable languages **RE**. The known relationships between these complexity classes are illustrated in Figure 1.

What are the basic relationships between the power of computations using bosonic continuous-variables over infinite-dimensional Hilbert spaces and these standard discrete-variable complexity classes over finite-dimensional ones? As it turns out, one can robustly encode discrete-variable computations into infinite-dimensional Hilbert spaces. For instance, Knill, Laflamme and Milburn showed that one can simulate arbitrary discrete-variable quantum computations using linear optics, particle-number measurements and feed-forward [32], i.e. adapting the computation based on the result of intermediate measurements, while Gottesman, Kitaev and Preskill gave a protocol to encode a qubit into the continuous degrees of freedom of a quantum harmonic oscillator in a fault-tolerant way [20]; the latter is among the leading proposals for reaching fault-tolerance in continuous-variable quantum architectures. As a consequence of these results, **BQP** can be robustly simulated using continuous quantum degrees of freedom. However, a formal complexity theory of bosonic computations is still missing.

In the continuous-variable setting, a model of quantum computation was first proposed by Lloyd and Braunstein [33]. In this model, the state of a quantum system evolves according to Hamiltonians, which are finite-degree polynomials in canonical continuous-variable (unbounded) operators such as the position operator X and the momentum operator P. These operators have fundamentally different mathematical properties from their discrete-variable counterparts. For instance, for any pair of discrete-variable operators acting on a finite-dimensional Hilbert space, A and B, $\mathrm{Tr}([A,B]) = 0$, it is well known that $[X,P] = iI$, which is not trace-class (i.e., does not have finite trace). The operators X and P have unbounded spectra with respective formal eigenbases $|x\rangle, x \in \mathbb{R}$ such that $X|x\rangle = x|x\rangle$, and $|p\rangle, p \in \mathbb{R}$ such that $P|p\rangle = p|p\rangle$, which are related to each other by a Fourier transform

$|x\rangle \propto \int e^{ipx} |p\rangle \, dp$, with their inner product giving Dirac delta functions $\langle x|x'\rangle = \delta(x - x')$, to be interpreted in the sense of distributions. Another striking example of the peculiarities of infinite dimensions comes from quantum states such as $(\sqrt{6}/\pi) \sum_{n\geq 1} \frac{1}{n} |n\rangle$, which are normalized but have infinite energy with respect to the harmonic oscillator Hamiltonian $X^2 + P^2$. Yet another famous example, known as Tsirelson's problem, is that the tensor product and the commuting operator formulations of quantum mechanics are equivalent in finite dimensions but not in infinite dimensions, because of complexity-theoretic reasons in particular [24].

Due to such nontrivial features, standard quantum complexity results in the discrete-variable setting, such as the Solovay–Kitaev theorem [31], do not have a clear counterpart in the continuous case. In particular, if one defines continuous-variable analogs of standard discrete-variable quantum computational complexity classes **BQP** and **QMA**, does it lead to relationships similar to the discrete-variable case?

Beyond its fundamental relevance, developing such a complexity-theoretic foundation for continuous quantum degrees of freedom would widen our horizon of knowledge in several ways. Firstly, it would help us to understand the computational power of continuous quantum degrees of freedom for real-world applications. Many physical architectures that are promising candidates for realizing a full-fledged universal discrete-variable quantum computer, such as photonic systems, superconducting qubits, and acoustic modes like phonons, are, in fact, inherently continuous. Developing a fundamentally continuous language for studying these systems could be essential to fully utilize the potential of such quantum computational devices, e.g., to devise fast compilation strategies [40] or performing Hamiltonian simulation with optimal constants [39].

Secondly, it touches on fundamental questions in theoretical physics. For instance, a standard approach to understanding continuous systems is to discretize them to a certain precision. We face an immediate question: can we reduce the study of these systems by approximating them with discrete variables, or are continuous-variable systems fundamentally distinct and require their own separate formulation? Theoretical physics provides some evidence for the latter. For instance, the renormalization group provides insight that the fundamental behavior of a physical system can vary significantly at different scales of precision. Or, in quantum field theory, one needs to impose energy cut-offs to avoid divergences in the computation of scattering amplitudes. Computational complexity studies the fundamental limits of finding reductions between two models, and we believe that tools from this framework would play a fundamental role in studying reductions between discrete and continuous degrees of freedom.

In this paper, we lay the groundwork for a computational complexity theory for quantum continuous variables. We formulate several Boolean quantum computational complexity classes based on continuous-variable bosonic generalizations of **BQP** and **QMA**. We study the relationship between these and their discrete-variable counterparts, highlight their fundamental similarities and differences, and identify outstanding open problems.

2 Main models and results

A bosonic quantum state can be described using a vector in the infinite-dimensional Hilbert space of square-summable complex sequences $\ell^2(\mathbb{C})$ which we refer to as a bosonic mode or a qumode. Let $\mathcal{H}_n \cong \ell^2(\mathbb{C}^{\otimes n})$ be the tensor-product space of n bosonic modes. We consider bosonic computations based on Hamiltonians H acting on $\mathcal{H}_n$ that are polynomials of degree d in the canonical operators X and P. Commonly known as position and momentum operators, they satisfy the canonical commutation relations

$$[X_a, P_b] = i\delta_{a,b} I, \quad [X_a, X_b] = 0, \quad [P_a, P_b] = 0. \tag{1}$$

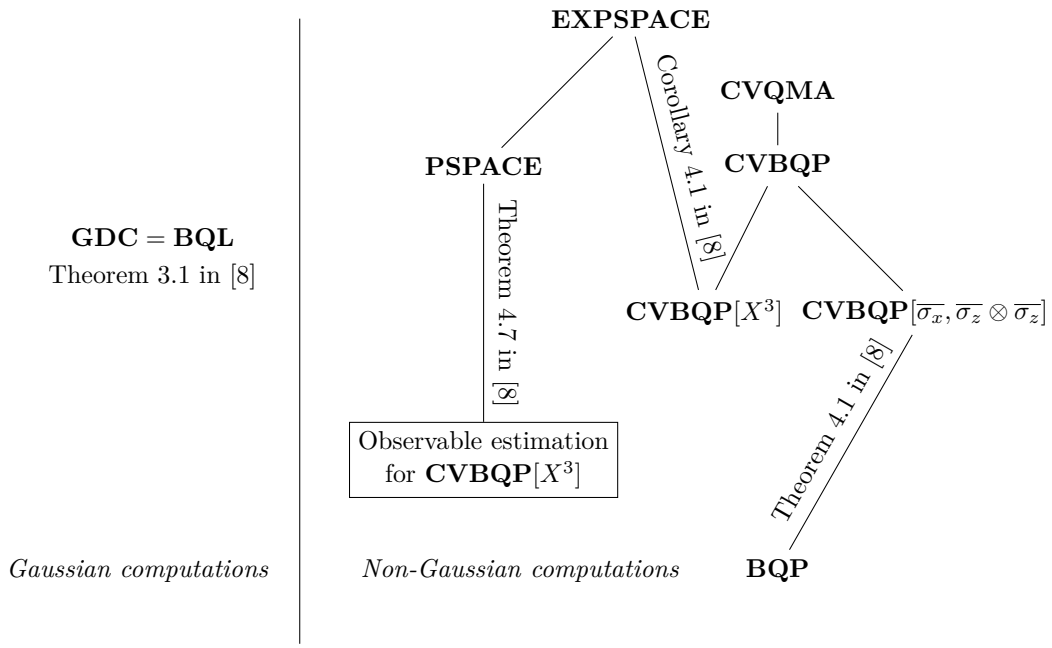

Figure 2 Relations between complexity classes and computational problems proven in this paper and described below, up to logspace reductions on the left and polynomial-time reductions on the right. If a line connects two complexity classes, it is implied that the one below in the diagram is included in the one above. If a line connects a problem to a complexity class, it is implied that the problem is in that class if it is below, and hard for that class if it is above. Square brackets indicate specific choices of non-Gaussian gates, where X^3 and $\overline{\sigma}_x$ are polynomial Hamiltonians of degree 3, while $\overline{\sigma}_z \otimes \overline{\sigma}_z$ is a polynomial Hamiltonian of degree 4. The other inclusions are given by the corresponding theorems or trivial from the definitions of the classes.

Polynomial Hamiltonians are ubiquitous in quantum physics and allow us to describe most existing models of bosonic quantum computations. The spectrum of such Hamiltonians is a subset of the reals, which can be discrete (e.g., for $X^2 + P^2$), continuous (e.g., for X) or both. In our presentation, we always distinguish between the cases of Gaussian Hamiltonians (polynomials of degree $d \leq 2$), which are typically less powerful, and non-Gaussian Hamiltonians (polynomials of degree $d > 2$).

We will often make use of the particle number operator (or simply, number operator) defined in terms of the position and momentum operators by,

$$N := \frac{X^2 + P^2 - I}{2} \tag{2}$$

where $N|n\rangle = n|n\rangle$ for the Fock basis states $|n\rangle$. The number operator plays a key role in our analysis as it quantifies the quanta of excitation, or 'particles,' in a bosonic mode. In terms of the energy of a bosonic state, we often refer to the average particle number, which corresponds to the expectation value $\langle N \rangle$.

2.1 Structure and summary of results

The structure of the full version of the paper [8] is as follows. After preliminary background in Section 2, we first consider Boolean complexity classes based on bounded-error continuous-variable quantum computations in Section 3 (Gaussian) and Section 4 (non-Gaussian). These contributions are summarised in Figure 2.

- We define a complexity class corresponding to the power of Gaussian dynamical computations (**GDC**) with logspace preprocessing. We prove that the power of this model is equivalent to the complexity class **BQL** corresponding to quantum logspace (See Theorem 3.1 in [8]). A complete problem for this class is inverting well-conditioned matrices [16, 42]. This can be viewed as a continuous-variable version of a result by Aaronson and Gottesman [2], which places the problem of simulating Clifford circuits in the complexity class $\oplus\mathbf{L}$ (a complete problem for this class is computing the determinant over the finite field $\mathbb{Z}_2$ [12]).
- We then define bounded-error quantum computations using gates generated by polynomials in the bosonic position and momentum operators (**CVBQP**). In this model, we sample the output of the quantum computation in the particle number basis (eigenstates of $X^2 + P^2$). We show that a specific instance of this class contains **BQP** (Theorem 4.1 in [8]) and that continuous-variable quantum computations using only Gaussian and cubic phase gates (generated by X^3) can be strongly simulated in **EXPSPACE** when no energy upper bound is assumed (Theorem 4.2 in [8]). We explain why proving a stronger upper bound of **PSPACE** or even **PP** as in the discrete-variable case (if true) would require nontrivial ideas. Finally, we give a polynomial-time parallel algorithm for computing output continuous-variable observable expectation values of such computations (Theorem 4.7 in [8]), which is in **PSPACE** by standard results [43]. We explain in Section 4.3.3 of [8] that the **EXPSPACE** and **PSPACE** results for particle-number measurements v.s. continuous-variable observable measurements are due to fundamental computational differences in Schrödinger v.s. Heisenberg dynamical evolution in continuous-variable systems. We conjecture that a strong simulation of the former model is strictly more difficult in terms of computational complexity.

Next, we consider ground state energy problems and Boolean non-deterministic quantum complexity classes in Section 5. These contributions are summarised in Table 1:

- We show that deciding the boundedness of the ground state energy is in **P** for Gaussian Hamiltonians (Theorem 5.1 in [8]) and **co-NP**-hard for constant-degree polynomial Hamiltonians (Theorem 5.2 in [8]). Furthermore, we give an efficient classical algorithm for verifying the boundedness of the ground state energy of a subclass of Hamiltonians of degree $d = 4$ via a reduction to a classical sum-of-squares method (Proposition 5.4 in [8]).
- We study the continuous-variable local Hamiltonian problem ($\mathsf{CVLH}^d_{\mathcal{S}}$) of estimating the lowest energy of a bosonic Hamiltonian of degree d in the position and momentum operators over a set of states $\mathcal{S}$. For Gaussian Hamiltonians, we show that this problem is in **P** whenever the set $\mathcal{S}$ contains the set of Gaussian states (Theorem 5.1 in [8]). For non-Gaussian Hamiltonians, we prove that the complexity of this problem critically depends on the stellar rank r, a measure of the non-Gaussian character of a continuous-variable quantum state [9, 10]. In order to simplify the presentation of the second result below, we rely on a mathematical conjecture (Conjecture 2 in [8], for which we provide numerical evidence), which allows us to parametrize the relevant family of states one optimizes over using simple constraints on the energy (average particle number):
  - For $r = 0$ (corresponding to optimization over Gaussian states) with at most $\mathsf{exp}(n) := e^{n^{O(1)}}$ energy (average particle number), we prove that the problem is **NP**-complete using a reduction from deciding when a matrix is not copositive (Theorem 5.3 in [8]).
  - When energy and stellar rank are both at most $\mathsf{poly}(n) := n^{O(1)}$, we prove that the problem is in **QMA** (Theorem 5.4 in [8]). The same proof technique also shows that for arbitrary r and at most $\mathsf{exp}(n)$ energy (average particle number), the problem is in **NTIME** $(n^{O(r)})$, where **NTIME** (t) is the class of problems that are solvable by a nondeterministic Turing machine that runs in time $O(t)$ on each branch.

- For $r = \infty$ with no energy bound, using an observation of [30], we encode the solution to Hilbert's tenth problem in the ground state of a Hamiltonian. As a consequence, the problem is **RE**-hard (undecidable) when we assume no bound on the stellar rank (Theorem 5.6 in [8]).

- Finally, we introduce a continuous-variable version of **QMA**, based on a **CVBQP** verifier (**CVQMA**). We give preliminary ideas for relating the complexity of the continuous-variable local Hamiltonian problem to this class, based on a continuous-variable analog of Kitaev's history state construction [29, 28].

Table 1 Computational complexity of the Hamiltonian boundedness problem and the continuous-variable local Hamiltonian problem for Gaussian and non-Gaussian polynomial bosonic Hamiltonians over n modes. $\mathcal{S}^{\mathsf{exp}}_{O(1)}$ denotes the set of states with constant stellar rank with at most exponential energy (average particle number) and $\mathcal{S}^{\mathsf{poly}}_{\mathsf{poly}}$ the set of states with polynomially bounded stellar rank and energy. Note that Theorem 5.4 and Theorem 5.5 of [8] rely on Conjecture 2, for which we provide numerical evidence. For all non-Gaussian results, assuming a degree $d = 4$ is sufficient except for the undecidability result where we show that $d = 8$ is sufficient (for $d = 4$, the problem is **QMA**-hard as a consequence of [11]).

Ground state problems	Gaussian Hamiltonians	Non-Gaussian Hamiltonians
HBound	$\in$ **P** (Theorem 5.1 in [8])	**co-NP**-hard (Theorem 5.2 in [8])
CVLH over $\mathcal{S}^{\mathsf{exp}}_{0}$	$\in$ **P** (Theorem 5.1 in [8])	**NP**-complete (Theorem 5.3 in [8])
CVLH over $\mathcal{S}^{\mathsf{poly}}_{\mathsf{poly}}$	$\in$ **P** (Theorem 5.1 in [8])	$\in$ **QMA** (Theorem 5.4 in [8])
CVLH over $\mathcal{S}^{\mathsf{exp}}_{r}$	$\in$ **P** (Theorem 5.1 in [8])	$\in$ **NTIME**$(n^{O(r)})$ (Theorem 5.5 in [8])
CVLH	$\in$ **P** (Theorem 5.1 in [8])	**RE**-hard (Theorem 5.6 in [8])

3 Details of the contributions

In what follows, we detail our contributions and provide some intuition. All definitions and results are stated informally and we refer to [8] for formal statements and proofs.

Gaussian computations

Let us first consider the power of bounded-error quantum computations using polynomial Hamiltonians of degree at most 2. The unitary gates generated by such Hamiltonians are known as Gaussian gates. It is well-known that Gaussian gates are efficiently simulatable in polynomial time **P** when acting on Gaussian states [4], i.e., states that may be obtained from the vacuum using Gaussian gates [17], together with Gaussian measurements, i.e., projection onto Gaussian states. We define a model of Gaussian computations as follows (see Definition 3.1 of [8] for a formal statement):

▶ **Definition 1** (Gaussian dynamical computations, informal)**.** *Gaussian dynamical computation (***GDC***) is the class of problems that can be solved by evolving input Gaussian states via logspace uniform quadratic Hamiltonians for polynomial time, followed by measuring a single mode in the position basis (see Section 2.3.3 of [8] for more details about the formalism). The computation accepts if the measured outcome has a value greater than a fixed constant b and rejects if it is below a fixed constant a.*

GDC allows evolving a quantum state according to different Gaussian Hamiltonians one after the other, so long as the total time and number of Hamiltonians do not exceed a polynomial bound. Gaussian computations are known to be continuous-variable analogs

of the so-called Clifford computations in the discrete-variable case. Clifford computations are also known to be classically simulatable in polynomial time, by the Gottesmann–Knill theorem [19]. In [2], Aaronson and Gottesman showed that one can actually simulate Clifford computations (i.e., sample from one qubit) in the complexity class $\oplus\mathbf{L}$, which is believed to be strictly contained in $\mathbf{P}$. Performing linear algebra (such as computing the determinant) over $\mathbb{Z}_2$ is a complete problem for this class. It is natural to ask whether a continuous-variable analog of this result holds. Our first result resolves this question in the affirmative (see Theorem 3.1 in [8] for a formal statement):

▶ **Theorem 2** (The computational power of Gaussian dynamics, informal)**.** *The power of Gaussian computations up to logspace reductions is captured by bounded-error quantum logspace (**BQL**) and, equivalently, the problem of inverting a well-conditioned matrix.*

The proof is based on the symplectic formulation of Gaussian operators [17].

Recently and independently, in [3], it was shown that simulating a particular class of gate-based Gaussian computations over exponentially many modes is **BQP**-complete. Recall that approximate matrix inversion is a **BQP**-complete problem when the matrix under consideration is sparse and well-conditioned [14]. Although our models and results are technically different, both reveal a strong connection between Gaussian computations and linear algebra.

Bounded-error continuous-variable quantum polynomial time (CVBQP)

Arguably, there are many ways one can define a continuous-variable version of **BQP** based on how computation is being performed. We consider bosonic computations using gates generated by polynomials of constant degree in the position and momentum bosonic operators, which are ubiquitous in quantum physics, with particle-number measurements. We define gate set-dependent classes (see e.g., Definition 3 below) and investigate the computational power of these models for different choices of gate sets. In particular, we show that bosonic computations based on specific gates generated by degree-4 and 2-local Hamiltonians can perform universal (discrete-variable) quantum computation on an *input vacuum state and without requiring feed-forward of measurement outcomes* (see Theorem 4.1 of [8]). Interestingly, the equivalence between these different continuous-variable classes is unknown, in part due to the delicate features of unbounded operators such as those pointed out in the introduction. Some of these relationships, such as the fast compiling of polynomial-degree Hamiltonians into Gaussian and cubic phase gates, are outstanding open questions; see, e.g., [40, 27].

We then consider bosonic computations based on a family of circuits generated by cubic phase gates e^{iX^3} and Gaussian gates e^{iH}, where H is a quadratic Hamiltonian in X and P. Notably, this gate set is believed/conjectured to be universal for the set of unitaries generated by arbitrary polynomials over an arbitrary number of modes [40, 27], a claim that was proven in a controllability sense in [45]. Due to [20], this computational model, when equipped with the ability of performing Gaussian measurements and feed-forward, is capable of performing universal (discrete-variable) quantum computation, when complex input states known as Gottesman–Kitaev–Preskill states are available.

Gaussian gates are closed under multiplication, which is one way we can understand the classical simulation of Gaussians. The single-mode Gaussian dynamics can furthermore be understood via specific integrable classical equations of motion (known as Calogero–Moser dynamics) [10]. However, once we add higher-degree gates to the gate set, the operators generated by the resulting gates generate a vastly larger set of operators, and the single-mode

dynamics becomes chaotic [33, 45]. Define $\mathbf{CVBQP}[X^3]$ as the class of decision problems that are solvable using quantum circuits based on Gaussian and cubic phase gate sets (see Definition 4.4 of [8] for a formal definition):

▶ **Definition 3** ($\mathbf{CVBQP}[X^3]$, informal)**.** $\mathbf{CVBQP}[X^3]$ *is the class of decision problems that are solvable with a bounded probability of error by applying a polynomial-time uniform sequence of Gaussian and cubic phase gates to the vacuum state and measuring the number of particles at the end, with the promise that the energy (average particle number) at the output is polynomially bounded.*

We show that, in between the computation, the energy of states prepared from the vacuum by polynomial-time sequences of Gaussian and cubic phase gates is upper bounded by a doubly-exponential function of the number of gates and modes (see Proposition 4.3 of [8]). The reason for such drastic energy growth in the system is that consecutive application of cubic and Gaussian gates can lead to repeated squaring of basic observables. This, in turn, leads to an upper bound of **EEXP** on the strong simulation (computing output amplitudes up to exponential precision) of $\mathbf{CVBQP}[X^3]$ when the final measurement is made in the computational basis. We then apply standard depth reduction techniques to bring the complexity down to **EXPSPACE** (see Theorem 4.2 of [8] for a formal statement):

▶ **Theorem 4** (Upper bound on the computational power of Gaussian and cubic phase gates, informal)**.** *Bosonic computations consisting of Gaussian and cubic phase gates on input vacuum and measurement in the Fock basis can be strongly simulated in* **EXPSPACE**.

This theorem assumes no energy upper bound for each of the computational steps. When introducing an energy (average particle number) upper bound of E^* in the above result, we note that the space complexity of the classical simulation in the single-mode case scales as $O(\mathsf{log}(E^*))$.

Next, we focus on the problem of computing expectation values at the output of $\mathbf{CVBQP}[X^3]$ circuits for a low-degree observable O (see Definition 4.7 and Theorem 4.7 of [8] for formal statements):

▶ **Theorem 5** (The computational complexity of bosonic expectation values, informal)**.** *The problem of computing expectation values of low-degree observables for states prepared by applying Gaussian and cubic phase gates to the vacuum can be solved in* **PSPACE**.

Proof sketch. Let $W_i := U_i \cdots U_1$ where the unitary gates $\{U_i\}_{1\leq i\leq n}$ selected from the Gaussian and cubic-phase gateset, are sequentially applied to a vacuum state. Suppose that $W_i X_1 W_i^\dagger$ takes the form $O_i = \sum_{\mu,\nu} \alpha_{\mu,\nu} X^\mu P^\nu$. Here we used the multi-index notations $\mu = (\mu_1, \cdots, \mu_n) \in \mathbb{Z}_+^n$ and $X^\mu = X_1^{\mu_1} \cdots X_n^{\mu_n}$. Let $O_{i+1} = U_{i+1} O_i U_{i+1}^\dagger$ be the value after the application of the next gate. We can write $O_{i+1} = \sum_{\mu,\nu} \alpha_{\mu,\nu} (U_i X U_i^\dagger)^\mu (U_i P U_i^\dagger)^\nu$. If U_{i+1} is a Gaussian gate, then the degree of X and P in O_i will be the same as that of O_{i+1}. However, if U_{i+1} is a cubic phase gate, then the degree of O_{i+1} is at most twice the degree of O_i. That is because of the unitary evolution due to the cubic-phase gate $U_i P U_i^\dagger = P + c \cdot X^2$, where c is a constant. As a result, the degree of O_T is at most 2^T. We note that coefficients involving the expansion of O_T into a normal form may be doubly exponentially large. Hence, the naive brute-force approach runs in exponential space. To bring the complexity upper bound down to **PSPACE**, we give a polynomial-time *parallel algorithm* using exponentially many processors. Standard results in computational complexity imply a **PSPACE** upper bound (see, for instance, [43]). We further show that the upper bound remains true for the multimode case, using the fact that the only multimode operators we need to add are the so-called two-mode SUM gates. ◀

We emphasize that the standard relationships outlined in Figure 1 indicate a **PP** upper bound on **BQP**. Proving a **EXPSPACE** upper bound on **CVBQP**$[X^3]$ (outlined in Theorem 4) already utilizes nontrivial tools, and we do not know if a stronger upper bound such as **PP** would hold in this case based on current techniques. Indeed, from the previous proof sketch, a remarkable feature of the cubic phase gate becomes apparent: starting with a single position operator X and applying T cubic phase gates interleaved with suitable Gaussian gates (the Fourier gate $e^{i\frac{\pi}{4}(X^2+P^2)}$, mapping X to P and P to $-X$), one can perform repeated squaring, i.e., obtain an observable of the form $\propto X^{2^T} + \cdots$ after T rounds [1]. This implies that doubly exponentially large numbers may naturally arise after polynomially many gates in the continuous-variable setting, in stark contrast with the discrete-variable setting.

The boundedness problem

Next, we aim to study the complexity of estimating the ground state energy of a bosonic Hamiltonian. Due to the infinite-dimensional setting, however, the spectrum may be unbounded. Hence, we first formulate and study the problem of deciding whether a bosonic Hamiltonian has a bounded ground state energy (see Definition 5.3 of [8] for a formal definition). Note that this problem is equivalent to deciding whether a bosonic Hamiltonian has a bounded spectrum, by checking boundedness of the ground energy for H and $-H$. The spectrum of any Hamiltonian that is a polynomial of odd degree (such as X or X^3 or $X^2P + PX^2$, etc.) is not bounded, as can be seen by computing the expectation value for an arbitrary coherent state (eigenstates of the operator $X + iP$), so we focus on polynomial Hamiltonians of even degree.

It turns out that the quadratic (Gaussian) case is solvable in polynomial time via a reduction to the problem of deciding whether a polynomial-size matrix, which may be computed efficiently from the coefficients of the Hamiltonian, is positive semi-definite (see Theorem 5.1 of [8]).

In the non-Gaussian case, we prove that the problem is significantly harder, even for degree-4 Hamiltonians (see Theorem 5.2 of [8] for a formal statement):

▶ **Theorem 6** (Complexity of the boundedness problem, informal)**.** *The problem of deciding whether the spectrum of a bosonic Hamiltonian with degree* 4 *is bounded is* **co-NP***-hard .*

Proof sketch. The proof proceeds via reduction from matrix copositivity, which is the problem of deciding, given $M \in \mathbb{R}^{n\times n}$, whether $\langle x| M |x\rangle \geq 0$ for all $|x\rangle \in \mathbb{R}^n_{\geq 0}$ with non-negative entries. This problem is known to be **co-NP**-complete [36]. ◀

How hard is it to find a witness for the boundedness of the ground state energy? From the above, if we could find it in polynomial time in general, then we would at least collapse **co-NP** to **P**, which is highly unlikely. However, we may find a procedure to achieve this goal at least in some instances. This is what we do next, based on a sum-of-squares technique.

Consider a polynomial Hamiltonian in the form $H = \sum_{\mu,\nu\in\mathbb{Z}^n_+} \frac{1}{2} h_{\boldsymbol{\mu},\boldsymbol{\nu}} \{X^{\boldsymbol{\mu}}, P^{\boldsymbol{\nu}}\}$, where we used multi-index notation (in Lemma 5.2 of [8] we show that any polynomial Hamiltonian can be brought to this form with real coefficients $h_{\boldsymbol{\mu},\boldsymbol{\nu}} \in \mathbb{R}$). The classical polynomial $p_H : \mathbb{R}^{2n} \to \mathbb{R}$ corresponding to H is defined as

$$p_H(x_1, \cdots, x_n, p_1, \cdots, p_n) = \sum_{\boldsymbol{\mu},\boldsymbol{\nu}\in\mathbb{Z}^n_+} h_{\boldsymbol{\mu},\boldsymbol{\nu}} x^{\boldsymbol{\mu}} p^{\boldsymbol{\nu}}.$$

[1] We thank Francesco Arzani for pointing out this fact.

We prove the following (see Proposition 5.4 of [8] for a formal statement):

▶ **Proposition 7** (Checking boundedness for degree-4 Hamiltonians, informal). *Let H be a bosonic Hamiltonian of degree 4. If p_H is a sum-of-squares polynomial, then the spectrum of H is bounded from below by an efficiently computable constant.*

As a result, a sum-of-squares approach provides a sound algorithm for deciding boundedness of the ground state energy of polynomial Hamiltonians in the $d = 4$ case, meaning that if we find a valid sum-of-squares decomposition for p_H, then H is bounded, but if p_H is not a sum-of-squares that does not imply unboundedness for H. Since the degree of p_H is constant, one can look for a sum-of-squares decomposition by running a polynomial-time semi-definite program [38]. Note that if p_H is not a sum of squares and we conjugate H by a Gaussian unitary U (which does not change the degree of H) and try again, we may find a different valid witness for boundedness.

The continuous-variable local Hamiltonian problem

We consider the case of general polynomial Hamiltonians and define the continuous-variable local Hamiltonian problem as follows (see Definition 5.2 of [8] for a formal definition):

▶ **Definition 8** (The continuous-variable local Hamiltonian problem, informal). *Let $\mathcal{S} \subset \mathcal{H}$ be a subset of continuous-variable quantum states. The continuous-variable local Hamiltonian problem $\mathsf{CVLH}^d_{\mathcal{S}}$ is the problem of estimating the lowest energy of a poynomial Hamiltonian H of degree d over the set $\mathcal{S}$.*

Note that the name *local* for this problem comes here from the fact that any polynomial Hamiltonian of degree d is at most d-local by definition.

For Gaussian Hamiltonians, our solution to the boundedness problem also provides a polynomial-time algorithm to estimate the ground state energy, thus placing the continuous-variable local Hamiltonian problem $\mathsf{CVLH}^2_{\mathcal{H}}$ for Gaussian Hamiltonians in **P** (see Theorem 5.1 of [8]).

For non-Gaussian Hamiltonians, in the case of states with bounded particle number, a result of [11] proves that the problem of estimating the ground state energy of the Bose–Hubbard model at finite (polynomial) number of bosons is **QMA**-complete. This Hamiltonian is of the form $H_{\mathrm{bh}} = t \cdot \sum_{i,j} A_{i,j}\, a_i^\dagger a_j + J \cdot \sum_i N_i(N_i - 1)$, where $N = (X^2 + P^2 - 1)/2$ and $a = (X + iP)/\sqrt{2}$, and where $A_{i,j}$ is the (i,j)-th entry of the adjacency matrix of an undirected graph. Note that the Hamiltonian H_{bh} conserves the number of particles, and hence, this operator may be thought of as a finite-dimensional Hamiltonian. In particular, denoting by $\mathcal{H}_n$ the set of states with less than n particles, this shows that $\mathsf{CVLH}^d_{\mathcal{H}_n}$ is **QMA**-hard already for $d = 4$ (and thus $\mathsf{CVLH}^4_{\mathcal{H}}$ as well).

In general, the complexity of the problem for non-Gaussian Hamiltonians depends significantly on the complexity of the set of states one optimizes. Following [9, 10], we consider the stellar rank of a quantum state as a parameter for specifying this set of states (see Section 2.3 of [8] for a brief review of the stellar rank). In short, to any continuous-variable quantum state $|\psi\rangle$ over n modes, one can associate a holomorphic function $F^\star_\psi : \mathbb{C}^n \to \mathbb{C}$. When this holomorphic function can be decomposed as a product of a polynomial P and a Gaussian G, i.e., $F^\star_\psi(z_1, \cdots, z_n) = P(z_1, \cdots, z_n)G(z_1, \cdots, z_n)$, the degree of the polynomial P defines the stellar rank r of $|\psi\rangle$. Otherwise, the stellar rank is infinite. When $r = 0$, we obtain the set of all Gaussian states, which can be produced by Gaussian gates applied to the vacuum state. The stellar rank can be finite (e.g., the stellar rank of n indistinguishable

particles is n). It can also be infinite, e.g., $\alpha_1 |\psi_1\rangle + \alpha_2 |\psi_2\rangle$ for Gaussian states $|\psi_1\rangle, |\psi_2\rangle$ ($\alpha_1, \alpha_2 \in \mathbb{C}$). We further constrain the energy of these states with respect to the number operator N (see Definition 5.5 of [8] for a formal definition).

For zero stellar rank, we show (see Theorem 5.3 of [8] for a formal statement):

▶ **Theorem 9** (Lowest energy over Gaussian states, informal)**.** *The problem of estimating the lowest energy of an n-mode polynomial bosonic Hamiltonian of constant degree over the set $\mathcal{S}_0^{\mathsf{exp}}$ of states of stellar rank 0 (Gaussian states) with energy (average particle number) at most $\mathsf{exp}(n)$ is **NP**-complete.*

Proof sketch. **NP**-hardness comes from a reduction from matrix non-copositivity (rather than matrix copositivity for Theorem 6). To place the problem in **NP**, note that the expectation value of a constant-degree polynomial Hamiltonian over a Gaussian state with energy at most $\mathsf{exp}(n)$ may be computed efficiently, so the **NP** witness is a description of the Gaussian state of lowest energy. ◀

For logarithmically and polynomially-bounded stellar ranks, we show (see Theorem 5.4 of [8] for a formal statement):

▶ **Theorem 10** (Lowest energy over bounded stellar rank, informal)**.** *The problem of estimating the lowest energy of an n-mode polynomial bosonic Hamiltonian of constant degree over the set $\mathcal{S}_{\mathsf{poly}}^{\mathsf{poly}}$ of states of stellar rank $r = \mathsf{poly}(n)$ with energy (average particle number) at most $\mathsf{poly}(n)$ is in **QMA** (this result holds up to Conjecture 2 of [8]).*

Proof sketch. To place the problem in **QMA**, we use the fact that any state of finite stellar rank is related by a Gaussian unitary G to a state of bounded particle number $|c\rangle$ [10]. This allows us to efficiently rewrite the optimisation in terms of a (sparse) finite-dimensional Hamiltonian, once the Gaussian unitary corresponding to the lowest energy state is known. The **QMA** witness is then given by a classical description of that Gaussian unitary G provided in the computational basis, together with a finite-dimensional state $|c\rangle$ that is the ground state of the finite-dimensional Hamiltonian, such that $G|c\rangle$ is the lowest energy state of the original Hamiltonian.

When the stellar rank is logarithmically bounded instead, $|c\rangle$ has an efficient classical description and the witness can be made fully classical. ◀

Finally, we consider the general case of unbounded stellar rank, with no restrictions on the set of states over which the optimisation takes place, and we show (see Theorem 5.6 of [8] for a formal statement):

▶ **Theorem 11** (The complexity of the continuous-variable local Hamiltonian problem, informal)**.** *The problem of estimating the ground energy of a polynomial bosonic Hamiltonian of constant degree is undecidable. This problem is already undecidable for $d = 8$.*

Proof sketch. The proof of this result proceeds via a reduction from Hilbert's tenth problem (a Nüllstellensatz problem over the integers) due to [30], combined with the fact that there exist explicit undecidable polynomial equations over non-negative integers of degree 4 and a constant number of unknowns [25]. ◀

Continous-Variable Quantum Merlin Arthur games

Finally, we introduce a continuous-variable analog of **QMA** (see Definition 5.1 of [8] for a formal definition):

▶ **Definition 12** (Continuous-variable quantum Merlin-Arthur, informal)**.** **CVQMA** *is the class of decision problems, for which a solution encoded in a continuous-variable quantum state can be verified efficiently by a* **CVBQP** *machine.*

Motivated by the relationship between the local Hamiltonian problem and **QMA** in the discrete-variable case based on Kitaev's history state construction [28], we aim to connect the class **CVQMA** to the continuous-variable local Hamiltonian problem. We give the basis for a continuous-variable history state construction providing such a connection (see Section 5.3 of [8]), and identify the challenges associated with such a construction.

4 Outlook

The study of continuous-variable quantum computations may have various interactions with the foundations of computational complexity, computability, and quantum mechanics, which we discuss in the next section. After that, in Section 4.1.1, we list several open questions.

4.1 Discussion

Energy of continuous-variable computations

One of the key insights of this work is that by alternating Gaussian and cubic phase gates, the average energy of the system – even for a single mode – can grow to be doubly exponential in the number of cubic phase gates used in the circuit. This observation suggests that strong simulation (calculating each amplitude individually) of continuous-variable quantum systems could be significantly more challenging than for discrete-variable ones, potentially being hard for complexity classes like **PSPACE** or even **EXPSPACE**. This suggests that on top of time and space complexity, energy plays a significant role in the computational power of bosonic systems.

In practical physical experiments, the energy must be supplied by the experimentalist, requiring a physical definition of computational cost that accounts for time, space, and energy. Specifically, if one is willing to expend up to E^* units of energy, our results show that a single mode can be simulated within $\mathbf{SPACE}(O(\log E^*))$. This highlights a trade-off between time, space, and energy, which we believe deserves a thorough examination. Understanding time, energy, and space tradeoffs for multimode systems equipped with multi-mode non-Gaussian gates is an interesting open question.

In our definition of **CVBQP**, we enforce the "promise" that the quantum state in the beginning and the end has limited energy, as measured by the average particle number, but it may take any value in between. A natural question to ask is: is the power of this model the same as the one where we impose restrictions on average energy at any point during the computation? See Figure 3 for a visual depiction. We can ask a similar question about classical continuous (time and/or space) models of computation where we are promised that the system's state is effectively discrete (e.g., a two-level system) at the beginning and the end. Still, the system can utilize its continuous degrees of freedom in between to an arbitrary precision. Is the power of this hypothetical model the same as digital computation? We first note that without such promise in the beginning, it is not clear how one can program such a system, and without the promise on the energy in the end, no physically viable device would be able to measure the quantum state. Even if we assume the existence of such a hypothetical device, it is not difficult to approximately predict the output of such a hypothetical device (we output random numbers because, at high energy, no concentration of measure is expected).

We may face the objection that assuming no mechanism to bound energy (e.g., dissipation), this promise is unreasonable because we cannot verify it. We first note that it is not difficult to come up with trivial examples that satisfy such a promise. Consider the unitary $UU^\dagger$ where $U|0\rangle$ has high energy. Clearly, $UU^\dagger$ has bounded energy at the beginning and the end and very high energy in between. Second, promises that are possibly difficult to verify are common in quantum complexity theory, e.g., promise on the gap of a Hamiltonian or promise that a **BQP** computation either accepts with probability $\geq 2/3$ or $\leq 1/3$. We have a similar scenario for the energy promise.

As a thought experiment, assume we have a fragile quantum processing device that breaks if it holds more than N_0 particles. Now, we design a quantum experiment such that the system (on average) has $\ll N_0$ particles at the beginning and the end but may (on average) have $\gg N_0$ particles in a way that many of the computational paths involve $\ll N_0$ particles and many involve $\gg N_0$. In the end, we measure the device's output and measure $\ll N_0$ particles. Do we measure the device to be broken or unbroken? This is similar to the Schrödinger's cat (or Wigner's) paradox. In the mentioned thought experiment, the device played the cat's role. In other words, if the device's condition (i.e., broken or unbroken) is determined only at the time of measurement, then **CVBQP** with mild (or no) energy restriction in between might be a plausible model. Otherwise, if broken paths are forbidden, then **CVBQP** with energy bound on the entire computation path is a more reasonable model from a physical standpoint. We note that in an actual experiment, energy is pumped from an outside source, and the closedness of the experiment is only an approximation.

Connections with the extended Church–Turing thesis

Our result leaves open the possibility that **CVBQP** $\not\subseteq$ **BQP**; due to doubly exponential growth of energy in between computations, such a separation is plausible. What would that imply about the nature of computation in the physical world? If **CVBQP** is a plausible model for computation in the physical world, then **CVBQP** $\not\subseteq$ **BQP** seems to imply a contradiction to the *extended Church Turing Thesis*. But how realistic is **CVBQP** as a model of computation? In particular, how should one determine the energy cap in between the computations? Consider scattering amplitude for quantum field theories, where the specific amplitude sets the number of particles at the beginning and the end, and still, fluctuations in the vacuum may lead to many particle creations, and annihilations can occur in between. Are bounds on the fluctuations of the vacuum (see, for instance, [18]) such that the computational complexity of scattering amplitudes do not exceed that of **BQP**? Are there computational phase transitions depending on γ_1 and γ_2?

What can we say about noisy systems? Suppose we define **DissCVBQP**(γ_1, γ_2) as a dissipated model where we have a mechanism that pumps bosons into the system with rate γ_1 and another mechanism that bosons are emitted to the environment with rate γ_2. How does the power computational complexity of **DissCVBQP**(γ_1, γ_2) depend on γ_1 and γ_2? Can we show for physically relevant parameters the power of this model is **BQP**-complete?

Logarithmic number of cubic phase gates

Standard results in the discrete-variable model of quantum computing (e.g., [7]) imply that starting with a computational basis, discrete-variable quantum circuits with a logarithmic number of T gates and polynomially many Clifford gates can be efficiently strongly simulated on classical computers. Can we prove a similar result for continuous-variable systems, i.e., can we show that starting from the vacuum state, a polynomial-size quantum circuit with a

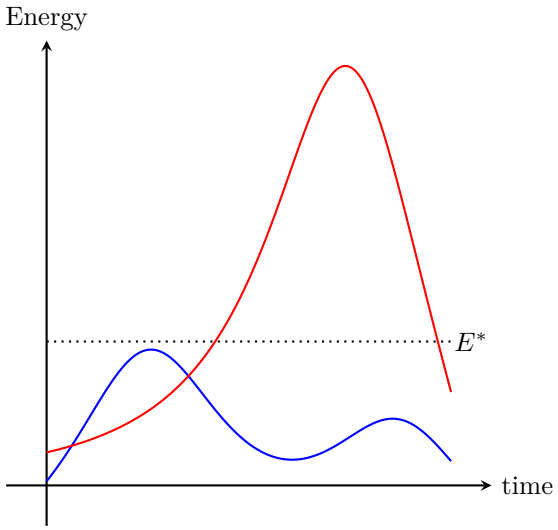

Figure 3 Energy bound conditions for quantum computations. The red curve depicts a system that is promised to have low energy at the beginning and the end of the computation, but may have arbitrary high energy in between. The blue curve depicts a model where we impose energy restrictions at any point during the computation.

logarithmic number of cubic phase gates can be simulated on a classical computer? Based on our results, the best upper bound we could prove for this problem was **PSPACE**. We furthermore note that, due to repeated squaring of energy, the "effective dimension" that the quantum system explores is exponential even if the circuit has, at most, a logarithmic number of cubic phase gates. Based on this intuition, we conjecture that (noiseless) continuous variable quantum circuits with a logarithmic number of cubic phase gates cannot be simulated efficiently on a classical computer.

Noiseless model as a foundation to study noisy systems

Even though a realistic model for the experimental implementation of bosonic computations is a dissipative (or noisy) model, noise models are various, and by understanding the computability limits of the noiseless system, one can gain a reliable foundation to study computational complexity after imposing different restrictions on the model. A similar approach has been pursued for computational complexity in the discrete-variable domain where we define **BQP** as an idealized noiseless quantum computing model and pin down its computational complexity. We then use this foundation to study the model's different variants and restrictions. For instance, we know that computing the amplitudes of a noiseless quantum circuit is #**P**-complete. Obviously, this result is not directly relevant to understanding the cost of simulating practical problems. However, this observation has been utilized via tools in computational complexity to lay the foundations for demonstrating quantum speedup in noisy or restricted models such as Boson Sampling [1]. Moreover, we describe a way to encode **BQP** computations in bosonic subspaces (see Theorem 4.1 of [8]) relying on the Solovay–Kitaev theorem [13], but this result does not appear to be robust to noise, because the noise may induce leakage to unbounded regions of state space where the theorem no longer holds. This motivates further study of robust quantum computations in continuous-variable systems.

Truncating CV systems using the stellar rank

Standard approaches to describe continuous-variable quantum systems using a finite number of variables include (i) truncating their infinite-dimensional Hilbert space, which amounts to restricting to bounded particle-number supports, or (ii) keeping track only of the covariance matrix and displacement vector of the state. These have immediate shortcomings: (i) is not stable under Gaussian evolutions, which may be thought of as computationally easy [4], and truncating a Gaussian state usually makes it non-Gaussian; (ii) only faithfully describes Gaussian computations.

Our results suggest that the stellar rank may be a meaningful approach for describing continuous-variable quantum systems, in particular for studying ground state problems for continuous-variable systems [41]. Informally, the stellar rank combines both approaches (i) and (ii), as states of finite stellar rank can always be expressed as (mixture of) Gaussian unitary operators acting on (core) states of finite support.

4.1.1 Open questions

Since the aim of the present work is to lay foundations for a theory of bosonic quantum complexity, it naturally leads to many open questions, some of which we list in the following:

1. The most immediate open question from this work is whether we can bring the **EXPSPACE** upper bound on **CVBQP** to smaller complexity classes such as **PSPACE** or even **PP**. What about lower bounds? Due to the doubly exponentially large dimensionality of the effective Hilbert space, it is natural to conjecture that strong simulation of **CVBQP** is hard for a complexity class such as **PSPACE** (or even **EXPSPACE**) which is believed to be strictly larger than **PP**. Such a result would be important evidence that **CVBQP** may surpass the power of **BQP**.
2. A related question is: what energy bound on **CVBQP** makes it equal to **BQP**? In an actual physical computation (such as a bosonic system subject to dissipation), one would expect that the energy stays polynomially bounded. Is it the case that **CVBQP** = **BQP** under the promise that the energy stays polynomially bounded throughout the computation? Can we prove that a variant of **CVBQP** subject to dissipation is equivalent to **BQP**?
3. It is usually assumed in the continuous-variable quantum information literature that a single non-Gaussian gate together with all Gaussian ones is sufficient to perform "universal" quantum computations. However, this notion of universality is somewhat restricted, as it relates to the ability to approximate evolutions generated by polynomial Hamiltonians [33]. In particular, is the cubic phase gate (for instance) and Gaussian gate set *universal*, in the sense that *any state* can be reached to arbitrary precision from the vacuum state using unitary gates from this set? See [45] for a formal statement of this open problem, and [35] for an example of a continuous-variable gate set satisfying this property.
4. In the discrete-variable setting, the computational power of quantum circuits is essentially independent of the choice of universal gate set. Is it also the case in the continuous-variable setting? If so, can a continuous-variable Solovay–Kitaev theorem [31, 13] be derived for these gates? See [5] for such a result in the case of Gaussian gates. This also relates to the existence of fast compilation algorithms for bosonic gates [40, 26, 27].
5. What is the precise complexity of the Hamiltonian spectrum boundedness problem? We prove **co-NP**-hardness and conjecture hardness for **co-QMA**. Can we show **co-QMA** is an upper bound? We describe a sound algorithm for verifying boundedness in the $d = 4$ case. Do similar results exist for $d > 4$?

6. After possible conjugations with arbitrary unitary matrices, can we write a Hamiltonian as a sum-of-squares of other Hamiltonians (c.f. [23])? We have obtained partial results in this direction for degree-4 polynomial bosonic Hamiltonians.
7. We can define families of Hamiltonians with a ground state of a given exact or approximate stellar rank r. Is there a procedure to decide the opposite? I.e., given the description of the Hamiltonian and an approximation parameter, decide whether it has an approximate ground state of stellar rank $< r$.
8. Our results indicate if we minimize the energy of a continuous-variable Hamiltonian over an ensemble with polynomially bounded energy (particle number) and stellar rank r, then for $r = \mathsf{poly}(n)$ it is contained in **QMA**. Can we show that these containments are tight? What about $r = \mathsf{exp}(\mathsf{n})$ and higher particle numbers? Proving such results would involve continuous-variable versions of Kitaev's history state [29, 28] in the continuous-variable setting. This construction would involve nontrivial ideas, which we leave for future work.
9. What is the complexity of the continuous-variable local Hamiltonian problem for other natural families of continuous-variable quantum states? For instance, the family of quantum states that are superpositions of $\mathsf{poly}(n)$ Gaussians? This class of states has recently been considered in the context of classical simulation of bosonic computations, leading to the introduction of the continuous-variable notion of *Gaussian rank* [15, 22], akin to the discrete-variable notion of *stabilizer rank* [7]. Note that the stellar rank for such states is typically infinite.
10. What is the complexity of deciding whether the spectrum of a polynomial bosonic Hamiltonian has a continuous part or if is it discrete? When it is discrete, is CVLH **RE**-complete?

Bosonic quantum computations also provide a natural setting for generalizing classical complexity theory over the reals (e.g., in the Blum–Shub–Smale model [6]) to the quantum case, given that bosonic Hamiltonians may have a continuous spectrum. We expect that most of our results should have counterparts over the reals.

Directed Hypercube Routing, a Generalized Lehman-Ron Theorem, and Monotonicity Testing

Deeparnab Chakrabarty

C. Seshadhri
University of California, Santa Cruz, CA, USA

Abstract

Motivated by applications to monotonicity testing, Lehman and Ron (JCTA, 2001) proved the existence of a collection of vertex disjoint paths between comparable sub-level sets in the directed hypercube. The main technical contribution of this paper is a new proof method that yields a generalization of their theorem: we prove the existence of *two* edge-disjoint collections of vertex disjoint paths. Our main conceptual contributions are conjectures on directed hypercube flows with simultaneous vertex and edge capacities of which our generalized Lehman-Ron theorem is a special case. We show that these conjectures imply *directed isoperimetric theorems*, and in particular, the robust directed Talagrand inequality due to Khot, Minzer, and Safra (SIAM J. on Comp, 2018). These isoperimetric inequalities, that relate the directed surface area (of a set in the hypercube) to its distance to monotonicity, have been crucial in obtaining the best monotonicity testers for Boolean functions. We believe our conjectures pave the way towards combinatorial proofs of these directed isoperimetry theorems.

1 Introduction

We let $d \geq 2$ denote a natural number. The directed d-dimensional hypercube graph H has vertices $V(H)$ which correspond to bit-vectors $x \in \{0,1\}^d$, and edges $E(H)$ corresponding to pairs of bit-vectors (x, y) that differ in exactly one coordinate. Edges point from lower Hamming weight vectors to larger ones. We use x_i to denote the ith coordinate of vertex x. There is a natural partial order on the vertices/elements of the Boolean hypercube: $x \preceq y$ iff $\forall i, x_i \leq y_i$. Note that the directed hypercube is precisely the Hasse diagram of this partial order. Equivalently, one can consider the vertices as subsets of $[d]$, and the partial order is given by containment.

Two subsets S, T of $V(H)$ are called a *matched pair* if there exists a *bijection* $\phi : S \to T$ such that $s \prec \phi(s)$ for all $s \in S$; we denote a matched pair by $(S, T; \phi)$. An early writeup of Goldreich-Goldwasser-Ron [30] posed a routing question, inspired by questions in monotonicity testing, which was solved by Lehman and Ron [36]. (More discussion in §4.) They were interested in the following natural question: given any matched pair $(S, T; \phi)$, can one find (edge or vertex) *disjoint* directed paths[1] from S to T? Remarkably, they proved that if all

[1] In their paper, Lehman and Ron consider these paths to be disjoint chains of subsets.

points in S (resp. T) have the same Hamming weight, then the answer is affirmative: one can find *vertex disjoint paths* from S to T! More precisely, for an integer $0 \leq i \leq d$, let L_i denote the *ith layer* of H, that is, $L_i := \{x \in V(H) \ : \ ||x||_1 = i\}$. We refer to this beautiful statement as the "Lehman-Ron (LR) theorem".

▶ **Theorem 1** (Lehman-Ron Theorem [36]). *Fix any two integers $i < j$. Let $(S, T; \phi)$ be a matched pair with $S \subseteq L_i$ and $T \subseteq L_j$. Then, there are $|S| = |T|$* vertex disjoint paths *between S and T. We refer to such a set of vertex disjoint paths as an* LR solution.

▶ Remark. The paths may not respect the bijection ϕ. More precisely, the above doesn't prescribe vertex disjoint paths from s to $\phi(s)$ for all $s \in S$. There exist concrete counterexamples (one is given in Lehman and Ron's paper attributed to Dan Kleitman) for such paths. A follow-up work by proves that *edge*-disjoint paths from s to $\phi(s)$ don't exist either [16].

We give an alternate proof of this theorem. But more importantly, we use our new proof technique to strengthen the LR theorem. If the terminals are at distance at least 2, there exist *two* edge-disjoint LR solutions.

▶ **Theorem 2.** *Fix any two integers $i < j$ with $j - i \geq 2$. Let $(S, T; \phi)$ be a matched pair with $S \subseteq L_i$ and $T \subseteq L_j$. Then, there are 2 collections of* vertex disjoint paths *between S and T, such that their union is* edge disjoint.

Lehman-Ron's proof of Theorem 1 is by induction on $|S|$ and on the quantity $(j - i)$, the distance between the layers in which S and T lie. The base case of $j - i = 1$ is obvious as the bijection gives us the matching between S and T. The heart of the proof essentially shows the existence of a set of vertices U either in layer L_{j-1} or L_{i+1} and two bijections $\phi' : S \to U$ and $\phi'' : U \to T$ such that $(S, U; \phi')$ and $(U, T; \phi'')$ are matched pairs. This last part is a neat argument which uses Menger's theorem, which is a special case of the max-flow-min-cut theorem, on an auxiliary graph that they create. But how can one get *two* edge disjoint LR solutions? The reader may notice that even the "base case" of $j - i = 2$, that is, when S and T are two levels apart is itself non-trivial (indeed, we don't really know a much simpler way to solve this than the general case). And so, a new idea is needed to prove Theorem 2.

Our proof of the Lehman-Ron theorem brings the *flow-cut duality* idea front and center. We note that Theorem 1 is actually a statement about the structure of flows and cuts in the directed hypercube. More precisely, it states the existence of $|S|$ units of flow from vertices in S to vertices in T when all vertices have *vertex capacity* 1 unit. We exploit the duality between cuts and flows, and more precisely the notion of *complementary slackness*, to give an alternate proof of the LR Theorem. In this flow-cut language, Theorem 2 states the existence of $2|S|$ units of flow when both edges and vertices have capacities (1 and 2 units each, respectively). The existence of the two kinds of capacities makes the argument slightly more involved, but the essence is still the same. For completeness, we show proofs of both Theorem 1 and Theorem 2 in Section 2 and Section 3, respectively.

We end our introduction with a natural conjecture that our techniques have been unable to solve. We discuss the connections between this conjecture and monotonicity testing in Section 4. As the layers L_i and L_j move further apart, there should exist more collections of edge-disjoint LR solutions between S and T.

▶ **Conjecture 3.** *Fix any two integers $i < j$ with $r := j - i$. Let $(S, T; \phi)$ be a matched pair with $S \subseteq L_i$ and $T \subseteq L_j$. Then, there are r collections of* vertex disjoint paths *between S and T, such that their union is* edge disjoint.

Other LR connections. Recent work has generalized the LR theorem different directions in [3]. These results find vertex disjoint paths that "cover" any collection of points specifying certain properties. Consider a subset X of the hypercube that is partitioned into subsets of paths (or chains). Meaning, we partition $X = \bigcup_i X_i$ such that, the vertices of X_i can be ordered according to $\prec$. (Moreover, this is the partition that minimizes the number of sets.) In the vanilla LR setting, each X_i is just $(s, \phi(s))$ for each $s \in S$. The main theorem of [3] shows that X can be covered by a collection of vertex disjoint paths. A nice implication of their result is that Theorem 1 holds even if S and T were not contained in levels, but were antichains.

We also note that the routing perspective in §4 answers a question of Sachdeva from a collection of open problems on Boolean functions [27] (Pg 19, "Routing on the hypercube"). We discuss more in §4.

2 Alternate proof of the Lehman-Ron Theorem

As a warm-up, we set up the main idea with a proof of the Lehman-Ron theorem. We begin with an important definition.

▶ **Definition 4.** *Given two sets S and T of the directed hypercube, the* cover *graph $G_{S,T}$ is formed by the union of all paths from S to T.*

In other words, the cover graph is the subset of the hypercube, that contains all vertices v such that $s \prec v \prec t$ (for $s \in S, t \in T$). The cover graph inherits "layers" via intersection with the original hypercube layers. In particular, layer L_i of the cover graph is only S and layer L_j is only T.

For the sake of contradiction, consider the *minimal counterexample* of Theorem 1 in terms of $|S| + |T|$. Consider the following flow network which contains $V(H)$ and also supernodes Ⓢ and Ⓣ. Ⓢ has a directed edge to every vertex in $s \in S$, and every vertex $t \in T$ has a directed edge to Ⓣ. We construct a flow network by setting the following *vertex* capacities to $G_{S,T}$: the supernodes have infinite capacity while every vertex in $V(H)$ has capacity 1. Since (S, T) is a counterexample, by the theory of flows and cuts, the maximum Ⓢ,Ⓣ flow in this vertex-capacitated network is $< |S|$. And so, using flow-cut duality, we know that there exists a *cut* $C \subseteq V(H)$ such that (a) $|C| < |S|$, (b) *every* path from Ⓢ to Ⓣ contains a C-vertex. Call a path *cut-free* if it doesn't contain a vertex from C. We can partition all vertices into three sets $\mathcal{S}, C, \mathcal{T}$, where $\mathcal{S}$ contains all vertices that are reached by a cut-free path from Ⓢ, and vertices of $\mathcal{T}$ can reach Ⓣ by a cut-free path. In particular, there is no edge from a vertex in $\mathcal{S}$ to a vertex in $\mathcal{T}$; all edges leaving $\mathcal{S}$ enter C, and all edges entering $\mathcal{T}$ originate from C. We make a quick observation using the minimality of our counterexample.

▶ **Lemma 5.** *C is disjoint from $S \cup T$.*

Proof. If C contains a vertex $S \cup T$, then one obtains a smaller counterexample. If $v \in C \cap S$, then $S' := S \setminus \{v\}$, $T' := T \setminus \{\phi(v)\}$ and $\phi' := \phi_{|S'}$ forms a matched pair $(S', T'; \phi')$ which is also a counterexample: the cut $(C - \{v\})$ is a valid cut of value $|C| < |S| - 1 = |S'|$. So, $C \cap S = \emptyset$. The proof of $C \cap T = \emptyset$ is analogous. ◀

Our setup so far is a restructuring of the original Lehman-Ron proof. The following lemma is where we start to differ. This lemma is a consequence of *complementary slackness* from the theory of linear optimization, and is the central tool for our new proof.

▶ **Lemma 6.** *There exists a collection of* vertex disjoint *paths $\mathcal{P}$ where every path $p \in \mathcal{P}$ begins at a vertex in S and ends at a vertex in T and*

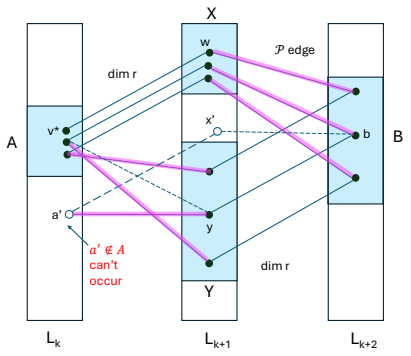
- *Every path $p \in \mathcal{P}$ contains* exactly *one vertex in C.*
- *Every vertex $v \in C$ is in* exactly *one path in $\mathcal{P}$.*

Note that all these paths are in the cover graph $G_{S,T}$. Using the above collection of paths, we make a key definition.

▶ **Definition 7.** *A vertex v is a* gateway *if (i) $v \in \mathcal{S}$, (ii) v doesn't lie on any path in $\mathcal{P}$, and (iii) there is at least one edge (v, w) in the cover-graph.*

The Lehman-Ron theorem, Theorem 1, follows directly from the following lemma.

▶ **Lemma 8.** *For all $i \le k \le j-1$, the kth layer L_k of the cover-graph contains a gateway vertex.*



Proof of Theorem 1. Consider the gateway vertex $v \in L_{j-1} \cap \mathcal{S}$ with edge (v, w) in the cover-graph. Note $w \in T$ and therefore in $\mathcal{T}$. There is an edge from $\mathcal{S}$ to $\mathcal{T}$. Contradiction. Hence, there is no (minimal) counterexample to Theorem 1. ◀

Before giving the formal proof of Lemma 8 directly, let us describe the main idea which uses the symmetry of the hypercube. First, let us observe the layer L_i, that is S, contains a gateway vertex s. Indeed, there are $\le |S| - 1$ paths in $\mathcal{P}$ and so there is some $s \in S$ not in any of these paths. Furthermore, all edges that lead s to $\phi(s)$ lie in the cover-graph.

Now, let's see how to get a gateway in the next layer L_{i+1}. Consider any edge $(s, x^{(1)})$ in $G_{S,T}$, and suppose this edge corresponds to projecting according to some dimension r. That is $s_r = 0$ and $x^{(1)}_r = 1$. If $x^{(1)}$ is not in any path in $\mathcal{P}$, we have discovered the desired gateway in L_{i+1}. Otherwise, $x^{(1)}$ lies on some path, say, $P \in \mathcal{P}$. Follow P *forwards* for a single edge from $x^{(1)}$, to get to $x^{(2)}$. Note that $x^{(2)} \in L_{i+2}$ and has rth-coordinate 1. Now, one can project "down" on the r-coordinate to get $x^{(3)} \in L_{i+1}$. Observe that $(s, x^{(3)})$ is a *projection* of the edge $(x^{(1)}, x^{(2)})$ along the rth-dimension and hence is an edge of the cover-graph. Next, observe that $x^{(3)}$ cannot be in $\mathcal{T}$, so either $x^{(3)} \in \mathcal{S}$ or $x^{(3)} \in C$. If $x_3 \in \mathcal{S}$ and not on any path in $\mathcal{P}$, we are done. Otherwise $x^{(3)}$ lies on some other path $Q \in \mathcal{P}$. We now walk *backwards* along Q, to get $x^{(4)} \in S$. Noting that $x^{(4)}$ has r-coordinate 0, we can redo the entire process above. Observe that each "step" proceeds along a *matching*. Either we project, walk from L_{i+1} to L_{i+2} using a path in $\mathcal{P}$, or walk backward from L_{i+1} to L_i using a path in $\mathcal{P}$. Each of these is using a matching edge, and no vertex is ever visited twice in the entire process. Hence, this process must terminate, at which point a gateway is discovered. And then one uses the same idea to obtain a gateway vertex in L_{i+2}, and so on. One can convert this idea into a formal proof, but it becomes notationally cumbersome. A cleaner proof method is to consider a potential "fixed point" of this process, and prove a contradiction.

Proof of Lemma 8. Fix a collection of paths $\mathcal{P}$ as given by Lemma 6. As argued above, L_i has a gateway vertex. Let $k \in [i, j-1]$ be the largest value such that L_k contains a gateway vertex. If $k = j-1$, we are done. So suppose that $k < j-1$. We now engineer a contradiction. Let $v^\star$ be a gateway in L_k. So $v^\star \in \mathcal{S}$ and has an edge $(v^\star, w)$ leaving it. Let r be the dimension of this edge implying $v^\star_r = 0$ and $w_r = 1$. Let Π_r be the projection operator which flips the rth coordinate; so $\Pi_r(v^\star) = w$ and vice versa. Define the following sets; we give a illustration for convenience where the pink highlighted edges participate in paths of $\mathcal{P}$.

- $A = \{a \ : \ a \in \mathcal{S} \cap L_k, a_r = 0 \text{ and } \Pi_r(a) \in G_{\mathcal{S},\mathcal{T}}\}$.
- $X = \Pi_r(A) = \{\Pi_r(a) \ : \ a \in A\}$.
- $B = \{b \ : \ (x,b) \in P, \text{ for some } x \in X, P \in \mathcal{P}\}$.
- $Y = \Pi_r(B) = \{\Pi_r(b) \ : \ b \in B\}$.

Observe that $X \cup Y \subseteq L_{k+1}$, and $B \subseteq L_{k+2}$. We next argue these subsets lie in the cover-graph. By definition of A, $X \subseteq G_{\mathcal{S},\mathcal{T}}$, and since B is obtained via paths from X, we get $B \subseteq G_{\mathcal{S},\mathcal{T}}$. Finally, for any $y \in Y$, note that $b = \Pi_r(y)$ lies in B, and there's a path (a, x, b) for some $a \in A$ and $x = \Pi_r(a)$. But note that (a, y) edge is the r-projection of (x, b), and so (a, y, b) is a path implying $y \in G_{\mathcal{S},\mathcal{T}}$. Thus, Y also lies in the cover-graph.

Since X is a projection of A, we get $|X| = |A|$. Consider any $x \in X$. Since $x \in L_{k+1}$, by our choice of k, x isn't a gateway vertex. Since (a, x) is an edge for $a = \Pi_r(x)$, we have $x \in \mathcal{S}$ or $x \in C$. In the former case since x isn't a gateway vertex, and in the latter case by Lemma 6, there exists $P \in \mathcal{P}$ with $x \in P$. And so, $|B| = |X|$. By projection property, $|Y| = |B|$, and so following the above chain of equalities, we get $|Y| = |A|$.

Next consider any $y \in Y$. As argued above, there is a vertex $a \in A$ such that (a, y) is an edge in the cover-graph (the projection of $(x, b) \in P$ where $b = \Pi_r(y)$). Since $y \in L_{k+1}$, by our choice of k, y isn't a gateway vertex. Since (a, y) is an edge, we must have $y \in \mathcal{S}$ or $y \in C$. In the former case since y isn't a gateway vertex, and in the latter case by Lemma 6, there exists $Q \in \mathcal{P}$ with $y \in Q$. Let (a', y) be the edge in Q taking y "backward" along Q. We claim that $a' \in A$. If $y \in \mathcal{S}$, then $a' \in \mathcal{S}$ since (a', y) is an edge; if $y \in C$ then by Lemma 6, $a' \in \mathcal{S}$ (the path Q doesn't contain two cut-vertices). Since $(a', x' = \Pi_r(a'))$ lies in the cover graph since the r-projection of the (a', y) lies there, we get x' lies in the cover-graph, implying a' must lie in A. The above figure illustrates this. In short, there are $|Y|$ paths of $\mathcal{P}$ that contain vertices of A. Since $|Y| = |A|$ and since these paths are all vertex-disjoint, we conclude *all* vertices in A are present in some path of $\mathcal{P}$. However, the gateway vertex $v^\star \in A$ and doesn't lie on any path of $\mathcal{P}$. Contradiction. ◀

3 Proof of the generalization Theorem 2

We now prove the generalization of the Lehman-Ron theorem using the proof strategy above. As before, we start with a minimal counter-example and use it to construct a flow network. We have the same directed graph as in the previous section with supernodes Ⓢ and Ⓣ, with every edge incident to supernodes having infinite capacity. The crucial difference is that we have both vertex and edge capacities. Each edge has capacity one, and each vertex has capacity two. (Alternately, it costs "one unit" to cut an edge, but "two units" to cut a vertex.)

Since we have a counter-example, again using the theory of flows, the maximum flow in this network is $< 2|S|$. And thus, by duality, we posit that there exists a *pair* (C, F) with $C \subseteq V(H)$ and $F \subseteq E(H)$, such that (a) $2|C| + |F| < 2|S|$, (b) every path from s to t either contains a C-vertex or an F-edge or both. A path from a vertex u to v is now called *cut-free* if it contains neither a vertex from C nor an edge from E. As before, we can partition all

vertices into three sets $\mathcal{S}, C, \mathcal{T}$, where $\mathcal{S}$ contains all vertices that are reached by a cut-free path from S, and vertices of $\mathcal{T}$ can reach T by a cut-free path. Note that the edges of F are from vertices in $\mathcal{S}$ to vertices in $\mathcal{T}$. And, as before, by minimality of the counter-example, the following simple observation holds.

▶ **Lemma 9.** *(i) The cut set C is disjoint from $S \cup T$. (ii) There exists a mincut (C, F) such that no vertex participates in more than one edge of F.*

Proof. Proof of (i) is exactly as in Lemma 5. Suppose v participates in at least two edges of F. Observe that any S-T path through any of these edges must go via v. Hence, we can remove these edges from F, add v to C, and preserve the fact that $C \cup F$ is an S-T cut. Moreover, the cut value does not increase. ◀

We can now give the analog of Lemma 6.

▶ **Lemma 10.** *There exists a collection of paths $\mathcal{P}$ with the following properties.*

- *Every path $p \in \mathcal{P}$ begins at a vertex in S and ends at a vertex in T.*
- *The paths are pairwise edge-disjoint and any vertex is in at most two paths.*
- *Every path $p \in \mathcal{P}$ either contains* exactly *one vertex in C or* exactly *one edge in F, but not both.*
- *Every vertex $v \in C$ is in* exactly *two paths in $\mathcal{P}$ and every edge $e \in F$ is in* exactly *one path of $\mathcal{P}$.*

Proof. By complementary slackness (Theeorem A.7 of [23]) , every maximum flow must saturate the min cut. Together with integrality of flow, this implies the existence of an integral flow saturating $C \cup F$. We give a (simple) formal explanation. By integrality of flow, there is a maximum flow that can be decomposed into paths. Let $\mathcal{P}$ be those paths. Since these paths form a feasible flow, they satisfy the first two bullet points of the lemma. By duality, $|\mathcal{P}| = 2|C| + |F|$. For each path $p \in P$, let c_p be the number of cut elements in $C \cup F$ that the path contains. For each cut element $e \in C \cup F$, let k_e be the number of paths that e participates in. So $\sum_{p \in \mathcal{P}} c_p = \sum_{e \in C \cup F} k_e$. Note that $\forall p, c_p \geq 1$, since $C \cup F$ is a valid cut. Thus, $\sum_{p \in \mathcal{P}} c_p \geq |\mathcal{P}|$. Now, observe that $\forall e \in C, k_e \leq 2$ and $\forall e \in F$, $k_e \leq 1$, since $C \cup F$ must satisfy the flow constraints. Hence, $\sum_{e \in C \cup F} k_e \leq 2|C| + F$. We get $|\mathcal{P}| \leq \sum_{p \in \mathcal{P}} c_p = \sum_{e \in C \cup F} k_e = 2|C| + |F| = |\mathcal{P}|$. Thus, the inequalities above are all equalities. So $\forall p, c_p = 1$ (third bullet) and $\forall e \in C, k_e = 2$ and $\forall e \in F$, $k_e = 1$ (fourth bullet). ◀

Next we provide the relevant generalization of gateway vertices earlier defined in Definition 7

▶ **Definition 11.** *A vertex v is a* gateway *if (i) $v \in \mathcal{S}$, (ii) v lies on at most one path in $\mathcal{P}$, and (iii) there is at least one edge $(v, w) \notin F$ leaving v in $G_{\mathcal{S},\mathcal{T}}$.*

As before, the proof of Theorem 2 follows from the following lemma, and the remainder of this section will prove it.

▶ **Lemma 12.** *For all $i \leq k \leq j - 1$, L_k contains a gateway vertex.*

As in the proof of Lemma 8, we proceed via minimal counterexamples. First, we establish that there is a vertex in L_i that is a gateway vertex. There are $< 2|S|$ paths in $\mathcal{P}$. Since any vertex participates in at most 2 paths, some vertex in s participates in at most 1 path. Since $\phi(s)$ is at least distance 2 away from s, s has degree at least 2 in $G_{S,T}$. (This is where the distance between S and T is used.) At most one of those edges is in F (Lemma 9), so there is some edge leaving s that is not in F. Thus, s is a gateway vertex.

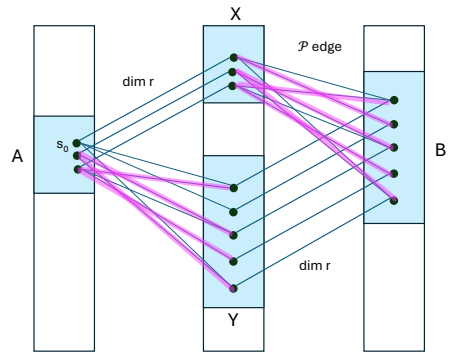


Figure 1 The setup of the proof of Lemma 12. The set X is a projection of A along dimension r, and similarly Y is a (downward) projection of B. The edges between A and Y are projections of edges between X and B.

Now, let $k \in [i, j-1]$ be the largest value such that L_k contains a gateway vertex. If $k = j-1$, we are done. So suppose that $k < j-1$, and we will engineer a contradiction. Let $v^\star$ be a gateway vertex in L_k. So $v^\star \in \mathcal{S}$, participates in at most one path of $\mathcal{P}$, and there is some edge leaving $v^\star$ that is not in F. First, let us choose the projection dimension r as follows. If $v^\star$ lies on exactly one path $P \in \mathcal{P}$, then let $(v^\star, w)$ be the edge of P incident to $v^\star$ and let r be the coordinate that this edge flips. If $v^\star$ lies on no path $P \in \mathcal{P}$, then since $k < j-1$, there are at least two[2] edges incident to $v^\star$ that are in the cover-graph; let $(v^\star, w)$ be any such edge and let r be the coordinate of this edge. As in the proof of Lemma 8, we let Π_r denote the projection operator, and we define the sets exactly as in the previous proof.

- $A = \{a \ : \ a \in \mathcal{S} \cap L_k, a_r = 0 \text{ and } \Pi_r(a) \in G_{\mathcal{S},\mathcal{T}}\}$. Note that $v^\star \in A$.
- $X = \Pi_r(A) = \{\Pi_r(a) \ : \ a \in A\}$.
- $B = \{b \ : \ (x, b) \in P, \text{ for some } x \in X, P \in \mathcal{P}\}$.
- $Y = \Pi_r(B) = \{\Pi_r(b) \ : \ b \in B\}$.

As in the proof of Lemma 8, we have $X \cup Y \subseteq L_{k+1}$, and $B \subseteq L_{k+2}$ and that A, X, B, Y all lie in the cover graph $G_{\mathcal{S},\mathcal{T}}$. As there, we crucially use the property that the projection of every (A, Y) edge lies is an (X, B) edge. Note that, we have $|A| = |X|$ and $|B| = |Y|$. However, unlike in Lemma 8, there can be *two* paths of $\mathcal{P}$ that may contain $x \in X$, and thus, $|B|$ may be larger in size than $|X|$. And this makes the proof slightly more complicated.

We now restrict our attention to these four sets. As a result, we only consider the cover graph $G_{A,B}$, which, recall, is the union of all paths from vertices in A to vertices in B (irrespective of whether they contain cut-elements). Both A and B lie in this graph by definition. We assert $X \subseteq G_{A,B}$. Take a vertex $x \in X$. If $x \in P$ for some path $P \in \mathcal{P}$ then it lies in $G_{A,B}$ by construction. We now show if x is not any path in $\mathcal{P}$, we already have a contradiction. Indeed, the edge (a, x) where $a = \Pi_r(x)$ isn't in F for otherwise, by Lemma 10 there would be a path containing (a, x). Similarly $x \notin C$. So, $x \in \mathcal{S}$. Since $x \in L_{k+1}$ and $k < j-1$, there is at least one edge leaving it, and as before, this edge isn't in F. So, x is a gateway vertex which contradicts the choice of k. Thus, the subset X lies in $G_{A,B}$. And since every (A, Y) edge is an r-projection of an (X, B) edge, we argue that Y also lies in $G_{A,B}$.

We now make another definition which will lead to our contradiction.

[2] There is some $s \in S$ such that $s \prec v \prec \phi(s)$ and there are at least 2 edge disjoint paths from v to $\phi(s)$.

▶ **Definition 13.** *An edge in $G_{A,B}$ is called* pink *if it lies in $\mathcal{P}$ and does not change the r coordinate. For any subset of vertices W in $G_{A,B}$, pink(W) is the number of pink edges W is incident to. For singleton subsets $\{v\}$ we abuse notation and call pink$(\{v\})$ simply pink(v).*

Thus, every pink edge incident to A is incident to Y, and every pink edge incident to X is incident to B. The following claim is a consequence.

▷ Claim 14. $\text{pink}(A) = \text{pink}(Y)$ and $\text{pink}(X) = \text{pink}(B)$.

Next, observe that the gateway $v^\star$ participates in at most one path of $\mathcal{P}$. If such a path existed, we chose the dimension r according to the incident edge of this path. Hence, $\text{pink}(v^\star) = 0$. This is central to proving the final contradiction.

▷ Claim 15. $\text{pink}(X) > \text{pink}(A)$.

Proof. There is a perfect matching between A and X. We prove that $\forall a \in A$, $\text{pink}(\Pi_r(a)) \geq \text{pink}(a)$. Furthermore, for the gateway $v^\star$, we get a strict inequality $\text{pink}(\Pi_r(v^\star)) > \text{pink}(v^\star)$. It is convenient to do a case analysis based on whether $x = \Pi_r(a)$ is in $\mathcal{S}, C$, or $\mathcal{T}$. Note that $\text{pink}(a) \leq 2$ by Lemma 10 since any vertex participates in at most 2 paths of $\mathcal{P}$. Note that all edges of $\mathcal{P}$ that leave X lead to B (by construction), so all these edges are in $G_{A,B}$.

$x \in C$: This is the easiest. By Lemma 10, there are two paths through x. So $\text{pink}(x) = 2 \geq \text{pink}(a)$.

$x \in \mathcal{T}$: Note that $a \in \mathcal{S}$, and so in this case, the r-projection edge (a, x) must be $\in F$. By Lemma 10, there is a path of $\mathcal{P}$ through (a, x), and the next edge leaving x goes into B. Since the r-coordinate doesn't change, this edge is pink, and so $\text{pink}(x) \geq 1$. Since a participates in the path through projection edge (a, x), which is *not* pink, it can participate in at most one other path of $\mathcal{P}$ (by Lemma 10, no vertex is in more than 2 paths). Thus, in this case $\text{pink}(a) \leq 1$ implying $\text{pink}(a) \leq \text{pink}(x)$.

$x \in \mathcal{S}$: By our assumption, x cannot be a gateway vertex. So either all edges leaving x are in F or x is in 2 paths of $\mathcal{P}$. If the latter happens, then $\text{pink}(x) = 2$, completing this case. So let us assume the former. There must be some edge leaving x in $G_{A,B}$ because x is in the cover graph $G_{A,B}$; since x is not a gateway vertex, this edge which must be in F. By Lemma 10, there is a path $P \in \mathcal{P}$ containing this and the edge incident to x doesn't change the r-coordinate, and thus is pink. So, $\text{pink}(x) \geq 1$. So, if $\text{pink}(a) \leq 1$ we are done. So, suppose $\text{pink}(a) = 2$. That is, there are two distinct edges (a, y) and (a, y') which are pink. Consider the r-projection of these edges, $(x, \Pi_r(y))$ and $(x, \Pi_r(y'))$; these are present in $G_{A,B}$ and so by our assumption above, these two must be in F. But again by Lemma 10, there are two paths in $\mathcal{P}$ containing these, and so these edges are pink, implying $\text{pink}(x) = 2$ as well. This settles this case.

All in all, we have proven that $\text{pink}(x) \geq \text{pink}(a)$, and note that in all cases, $\text{pink}(x) \geq 1$. Since $\text{pink}(v^\star) = 0$, we get the strict inequality $\text{pink}(\Pi_r(v^\star)) > \text{pink}(v^\star)$, completing the proof of the claim. ◁

The next claim which, along with Claim 14, contradicts Claim 15, completing our proof of Lemma 12.

▷ Claim 16. $\text{pink}(B) \leq \text{pink}(Y)$.

Proof. There is a perfect matching between B and Y by the Π_r projection. We will show that for every $b \in B$, $\text{pink}(b) \leq \text{pink}(y)$, where $y = \Pi_r(b)$. The proof is analogous to that of Claim 15, with a subtle difference. All edges of $\mathcal{P}$ leaving X are in $G_{A,B}$ by construction. But all edges of $\mathcal{P}$ entering Y might not be in $G_{A,B}$. In particular, there could be a path $Q \in \mathcal{P}$ which contains y and the predecessor, call it z, of y on this path may not be in A. For instance, this could occur if $y \in \mathcal{T}$ and $z \in C$ (and thus not in A).

With hindsight, we assert that if $y \in \mathcal{S} \cup C$, then the vertex z indeed lies in A. To see this note that $z \in \mathcal{S}$; this follows from Lemma 10 since the path Q contains exactly one cut-vertex or cut-edge. Furthermore, $\Pi_r(z)$ must lie in $G_{\mathcal{S},\mathcal{T}}$ since $(z, \Pi_r(z), b)$ is present in the hypercube. In all, $z \in A$. The reader may wonder why this subtlety didn't arise in the original Lehman-Ron proof that we showed in the previous section. Well, there is a vertex $a \in A$ such that (a, y) is an edge, and since in the previous section we only had vertex cuts, we could (and did) assert $y \in S \cup C$. But now the edge (a, y) could be in F. As we will see, the case when $y \in T$ is actually easy to take care of.

Now for the case analysis. Recall that $b \in B$ and $y = \Pi_r(w) \in Y$.

$y \in C$: By Lemma 10 there are two paths entering y, and since $y \in C$ due to the discussion about the subtlety above, $\text{pink}(y) = 2$. Note that $\text{pink}(b) \leq 2$ since there can be at most two paths of $\mathcal{P}$ incident on b.

$y \in \mathcal{S}$: Since y is not a gateway vertex (overall assumption), either y participates in two paths of $\mathcal{P}$ or all edges leaving y are in F. In the former case, since $y \in S$ due to the discussion about the subtlety above, $\text{pink}(y) = 2$. In the latter case, the edge (y, b) must be in F. So there is at least one path through y and, again since $y \in S$, $\text{pink}(y) \geq 1$. Now note that the (y, b) edge is *not* pink although it is on a path in $\mathcal{P}$ because the r-coordinate changes. So, $\text{pink}(b) \leq 1$.

$y \in \mathcal{T}$: Observe that all edges (z, y) with $z \in A \subseteq \mathcal{S}$ must be cut, that is $(z, y) \in F$. By Lemma 9, all such edges are on paths in $\mathcal{P}$ and are thus pink (they are clearly in $G_{A,B}$ and don't change r-coordinate). Suppose $\text{pink}(b) = t$ where $t \in \{1, 2\}$. Then there are t distinct pink edges of the form (x, b) with these x's in X. Consider their r-projections, that is, the t edges of the form $(\Pi_r(x), y)$. Since $\Pi_r(x) \in A$, all these edges must be pink. This shows that if $y \in \mathcal{T}$, $\text{pink}(y) \geq \text{pink}(b)$. ◁

4 Connections to monotonicity testing

The motivation for Conjecture 3 (and indeed, Theorem 1) is a deeper understanding of the problem of monotonicity testing of functions, a problem which, especially over the hypercube and hypergrid domains, has had a rich history of more than 25 years [38, 25, 31, 24, 36, 29, 32, 1, 33, 2, 28, 40, 6, 16, 26, 13, 39, 7, 18, 19, 21, 5, 14, 20, 17, 35, 4, 22, 8, 9, 12, 34, 15, 11, 10]. A function $f : \{0,1\}^d \to \{0,1\}$ is monotone if $\forall x, y \in \{0,1\}^d$ where $x \prec y$, $f(x) \leq f(y)$. The distance between two functions f, g is $|\{x : f(x) \neq g(x)\}|/2^d$, and the distance of f to monotonicity, denote ε_f, is the minimum distance of f to a monotone g. A function f is said to be ε-far from monotone if $\varepsilon_f \geq \varepsilon$. The aim of a tester is to distinguish a monotone function from one that is "far" from monotone. There is a special focus on non-adaptive monotonicity testers with one-sided error. These are testers that (i) always accept monotone functions, and (ii) make all their queries in advance. After a long line of work, this has been resolved (up to $\log d, \text{poly}(\varepsilon^{-1})$ factors) to be $\Theta(\sqrt{d})$ [31, 29, 19, 21, 35, 20, 22].

The study of these monotonicity testers led to the discovery of *directed isoperimetric inequalities*. Much of the study in this paper came from attempts at an alternate, more combinatorial proofs of a central isoperimetric inequality, the so-called *robust directed Talagrand theorem* due to Khot, Minzer, and Safra [35]. In this section, we give connections between monotonicity testing, directed isoperimetric inequalities (like the KMS theorem), and routing on the directed hypercube. Most importantly, we describe another routing statement, Conjecture 26, which implies the KMS theorem. We believe that Conjecture 26 and Conjecture 3 are closely related, as explained in §4.2.

▶ **Definition 17.** *A pair of vertices of* $\{0,1\}^d$ $x \prec y$ *is called a* violation *of* $f(x) > f(y)$. *This pair is called a* violated edge *if additionally,* (x, y) *is an edge of the hypercube. For any* x*, the directed influence* $\mathrm{Inf}_f^+(x)$ *is the number of violated edges incident to* x*. The directed influence of* f*, denoted* I_f^+*, is* $2^{-d}\sum_x \mathrm{Inf}_f^+(x)$.

The most basic inequality is the directed Poincare inequality, which directly leads to $O(d)$ query monotonicity testers (for constant ε).

▶ **Theorem 18** ([31])**.** *For any* $f : \{0,1\}^d \to \{0,1\}$, $I_f^+ \geq \varepsilon_f$.

The main step towards $o(d)$ query testers (for constant ε) is a stronger isoperimetric inequality, the directed Margulis bound. Let Γ_f^+ denote the size of the largest matching of violated edges, which is a measure of the vertex boundary.

▶ **Theorem 19** ([19])**.** *For any* $f : \{0,1\}^d \to \{0,1\}$, $I_f^+ \cdot \Gamma_f^+ = \Omega(\varepsilon_f^2)$.

The culmination of this line of work lead to the *robust, directed Talagrand inequality* for KMS, which yielded the (near) optimal $\widetilde{O}(\sqrt{d})$-query non-adaptive monotonicity tester. (The original KMS result lost a log factor, which was removed by Pallavoor-Raskhodnikova-Waingarten [37].)

▶ **Theorem 20** ([35, 37])**.** *Let* χ *be any bicoloring of the directed hypercube edges, with two colors* 0 *and* 1*. For any* $f : \{0,1\}^d \to \{0,1\}$ *and for any* $x \in \{0,1\}^d$*, let* $\mathrm{Inf}_{f,\chi}^+(x)$ *be the number of violated edges incident to* x *whose color is* $f(x)$*. Then,*

$$2^{-d}\sum_x \sqrt{\mathrm{Inf}_{f,\chi}^+(x)} = \Omega(\varepsilon_f)$$

In the next subsection, we give combinatorial interpretations to each of these statements. The reason for Conjecture 3 and a deeper study of hypercube routing was to get alternate proofs of Theorem 20. A big mystery of all these directed isoperimetric inequalities is the appearance of ε_f, the distance to monotonicity, as a "directed version" of the variance of f. It appears as if ε_f is the "right measure" of directed volume. We hope that alternate proofs of Theorem 20 may shed some light on this mystery.

4.1 From flows to directed isoperimetry

In what follows, all flow networks are over the directed hypercube. There is a source set S, and the aim is to route flow to the complement $\overline{S}$[3]. In the various routing theorems, we set different edge/vertex capacities and try to lower bound the maximum flow from S to $\overline{S}$. In all the flow settings, we have unit edge capacities.
We start with a notion of the "directed volume" of a set.

▶ **Definition 21.** *For* $S \subseteq \{0,1\}^d$*, the directed volume of* S*, denoted* $\mu^+(S)$ *is*

$$\max_{\substack{S' \subseteq S \\ T' \subseteq \overline{S}}} \left\{ |S'| \;\middle|\; \exists \phi, (S', T'; \phi) \text{ is a matched pair} \right\}$$

Any matched pair $(S', T'; \phi)$ *that attains the maximum is called a* directed volume certificate.

[3] Formally, one creates a supernode Ⓢ that connects to S, and a supernode Ⓣ with connections from T. All these connections have infinite capacity.

We now explain why the directed Poincare inequality of Theorem 18 essentially shows that one can send $\mu^+(S)$ units of flow from S to $\overline{S}$ with unit edge capacities. This is a simple application of the max-flow-min-cut theorem, and we provide the proof for completeness.

▶ **Theorem 22.** *Consider the directed hypercube flow network with unit edge capacities, and source set S. The maxflow is at least $\mu^+(S)$.*

Proof. Consider the indicator Boolean function $f : \{0,1\}^d \to \{0,1\}$ where $f(x) = 1$ iff $x \in S$. Using a standard connection between distance to monotonicity (Corollary 2 of [29]) one can argue that $\varepsilon_f = \mu^+(S)/2^d$. Any Ⓢ-Ⓣ cut must remove all edges from S to $\overline{S}$. These are precisely the violated edges of f, which are at least $\varepsilon_f 2^d = \mu^+(S)$ many (Theorem 18). The theorem follows from the duality between max-flow and min-cut. ◀

Thus, the basic directed Poincare inequality basically gives a flow bound for the directed hypercube flow network. We will now interpret the more sophisticated isoperimetric theorems as more general flow statements. A crucial notion is the separation distance of a set.

▶ **Definition 23.** *For any matched pair $(S, T; \phi)$, the separation distance is $|S|^{-1} \sum_{s \in S} (|\phi(s)| - |s|) = |S|^{-1} \Big(\sum_{t \in T} |t| - \sum_{s \in S} |s| \Big)$. Here $|x|$ denotes the number of 1s in $x \in \{0,1\}^d$. The* **separation distance** *of S is the smallest separation distance over directed volume certificates of S.*

A key theorem of [19] shows that larger separation distance implies more (edge disjoint) flow. This theorem is a strengthening of the directed Poincare inequality of Theorem 18, and essentially a flow rewording of Lemma 2.6 of [19]. The proof is entirely analogous to that of Theorem 22 and is omitted.

▶ **Theorem 24** (Lemma 2.6, [19])**.** *Consider the directed hypercube flow network with unit edge capacities, with source set S having separation distance r. The maxflow is at least $r\mu^+(S)$.*

What if we desire *vertex* disjoint paths? Lemma 2.5 of [19] answers this question, and the central tool is the Lehman-Ron theorem. Together, the two theorems above directly imply the directed Margulis statement of Theorem 19.

▶ **Theorem 25** (Lemma 2.5, [19])**.** *Consider a flow network with unit vertex capacities, with source set S having separation distance r. The maxflow is at least $\mu^+(S)/32r$.*

This brings us to a sort of "intellectual starting point" for this paper. The theorems above clearly show how directed isoperimetry and flows are intimately connected. Moreover, statements like Theorem 19 suggest relations between flows with edge capacities, and flow with vertex capacities. We were motivated to see if the KMS theorem (Theorem 20) could be proven from a flow perspective.

▶ **Conjecture 26.** *Let source set S have separation distance r. Consider a flow network with unit edge capacities and vertex capacities r^2. The maxflow is at least $\Omega(r\mu^+(S))$.*

Note that the above is a *simultaneous* strengthening of Theorem 24 and Theorem 25; if we remove either the edge capacity restriction or the vertex capacity restriction, then we get the above theorems. We show that Conjecture 26 implies the robust Talagrand isoperimetry theorem.

▷ Claim 27. Conjecture 26 implies Theorem 20.

Proof. Consider a Boolean function $f : \{0,1\}^d \to \{0,1\}$. Consider any bicoloring χ of the violated edges. Our aim is to lower bound $\sum_x \sqrt{\mathrm{Inf}^+_{f,\chi}(x)}$.

Let S be the set of 1-valued points. By Conjecture 26 and the maxflow-mincut theorem, the mincut of the flow network (where edges have capacity 1 and vertices have capacity r^2) is at least $Cr\mu^+(S)$ for some constant $C > 0$. Note that all edges from S to $\overline{S}$ must be cut; moreover any separation of (the endpoints of) these edges is a valid $(S, \overline{S})$ cut. In terms of f, these are precisely the violated edges.

Let us use χ to construct a cut. For convenience, let $d(x)$ denote $\mathrm{Inf}^+_{f,\chi}(x)$. If $d(x) \le r^2$, we cut all violated edges incident to x. Otherwise, we cut the vertex x. The total cut value is $\sum_{x:d(x)\le r^2} d(x) + r^2|\{x \mid d(x) > r^2\}|$. By Conjecture 26, the cut value is at least $Cr\mu^+(S)$. We split into two cases.

Case 1, $\sum_{x:d(x)\le r^2} d(x) \ge Cr\mu^+(S)/2$. Observe that $\sum_{x:d(x)\le r^2} \sqrt{d(x)\cdot d(x)} \le r\sum_{x:d(x)\le r^2} \sqrt{d(x)}$. Thus, $\sum_x \sqrt{\mathrm{Inf}^+_{f,\chi}(x)} \ge C\mu^+(S)/2 = C\varepsilon_f 2^d/2$.

Case 2, $\sum_{x:d(x)\le r^2} d(x) < Cr\mu^+(S)/2$. So $r^2|\{x \mid d(x) > r^2\}| \ge Cr\mu^+(S)/2$, implying $|\{x \mid d(x) > r^2\}| \ge C\mu^+(S)/(2r)$. We can lower bound $\sum_x \sqrt{d(x)} \ge r\sum_{x:d(x)>r^2} \ge C\mu^+(S)/2 = C\varepsilon_f 2^d/2$. ◁

We believe that Conjecture 26 is stronger than Theorem 20, because it explicitly involves the separation distance of S.

As an aside, the connection between flows and directed isoperimetry resolves an open question in [27] (Pg 19, "Routing on the hypercube"). It is actually a direct consequence of Theorem 18.

▶ **Theorem 28.** *Let (S, T, ϕ) be a matched pair where S and T are disjoint. There exist $|S|$ monotone edge disjoint paths from S to T.*

Proof. Consider the directed hypercube and take a mincut separating S from T. Construct a Boolean function that assigns 1 to the "S-side", and 0 to the "T-side". All remaining vertices can be assigned values such that they do not participate in any monotonicity violation. Note that these vertices cannot be on a directed path from S to T. (Process vertices according to the partial order. For x, set $f(x)$ to be $\max_{y\prec x: f(y) \text{ assigned}} f(y)$. If no $f(y)$ is assigned, set $f(x) = 0$. Observe that if $f(x)$ is assigned value 1, then x must be greater than some point in S. This means that x cannot be less than any point in T, and hence does not create monotonicity violations.)

This function has distance to monotonicity at least $|S|/2^n$. So by Theorem 18, there are at least $|S|$ edges which have value $(1, 0)$. These are precisely cut edges, from the S-side to the T-side. Hence, the cut value is at least $|S|$. Set up a flow problem on the directed hypercube where every edge has unit capacity, vertices in S are sources, and vertices in T are sinks. By the maxflow-mincut theorem, there is a flow of value at least $|S|$. This flow gives edge-disjoint paths from S to T. ◀

4.2 Connections between conjectures

From the perspective of monotonicity testing and directed isoperimetry, Conjecture 26 is more important. From a purely combinatorial (and maybe aesthetic) viewpoint, Conjecture 3 is more appealing. We believe that a proof of Conjecture 3 will shed light on Conjecture 26. This section is speculative, but gives some of the original motivations for studying Conjecture 3.

An uncrossing argument of [19] relates general matched pairs to matched pairs contained in level sets. (These arguments are in Section 2.4 of [19], especially Claim 2.7.2 and Claim 2.7.3.)

▶ **Lemma 29.** *Consider a set S with separation distance r. There exist a collection of matched pairs $(S_1, T_1, \phi_1), (S_2, T_2, \phi_2), \ldots$ with the following properties.*

- $\bigcup_i S_i \subseteq S$, $\bigcup_i T_i \subseteq \overline{S}$.
- $\sum_i |S_i| \geq \mu^+(S)/4$.
- *Each S_i (and T_i) is contained in a level set.*
- *No vertex is present in more than $2r$ cover graphs G_{S_i,T_i}.*

The main upshot of this lemma is that one can "break up" the $(S, \overline{S})$ routing problem into a collection of (S_i, T_i) routing problems, where the S_i, T_i are level subsets. Moreover, the interaction between the various cover graphs is limited, because of the last bullet point. Given that the separation distance of S is r, we believe that for a constant fraction (by total size) of the matched pairs $(S_i, T_i; \phi_i)$, the distance of these pairs is $\Omega(r)$. If Conjecture 3 is true, we can route $\Omega(r|S_i|)$ units of edge disjoint flow with vertex congestion r. Any vertex participates is at most $2r$ such flow. We had hoped to overlay such flows and get an overall vertex congestion of $O(r^2)$. Unfortunately, a direct overlay of flows leads to an edge congestion of $O(r)$, which is not useful for Conjecture 26. Nonetheless, it felt that a proof of Conjecture 3 with the proof techniques of Theorem 24 might yield insight into Conjecture 26.

Unraveling Universally Closest Refinements via Symmetric Density Decomposition and Fisher Market Equilibrium

T-H. Hubert Chan
Department of Computer Science, University of Hong Kong, Hong Kong

Quan Xue
Department of Computer Science, University of Hong Kong, Hong Kong

Abstract

We investigate the closest distribution refinements problem, which involves a vertex-weighted bipartite graph as input, where the vertex weights on each side sum to 1 and represent a probability distribution. A refinement of one side's distribution is an edge distribution that corresponds to distributing the weight of each vertex from that side to its incident edges. The objective is to identify a pair of distribution refinements for both sides of the bipartite graph such that the two edge distributions are as close as possible with respect to a specific divergence notion. This problem is a generalization of transportation, in which the special case occurs when the two closest distributions are identical. The problem has recently emerged in the context of composing differentially oblivious mechanisms.

Our main result demonstrates that a universal refinement pair exists, which is simultaneously closest under all divergence notions that satisfy the data processing inequality. Since differential obliviousness can be examined using various divergence notions, such a universally closest refinement pair offers a powerful tool in relation to such applications.

We discover that this pair can be achieved via locally verifiable optimality conditions. Specifically, we observe that it is equivalent to the following problems, which have been traditionally studied in distinct research communities: (1) hypergraph density decomposition, and (2) symmetric Fisher Market equilibrium.

We adopt a symmetric perspective of hypergraph density decomposition, in which hyperedges and nodes play equivalent roles. This symmetric decomposition serves as a tool for deriving precise characterizations of optimal solutions for other problems and enables the application of algorithms from one problem to another. This connection allows existing algorithms for computing or approximating the Fisher market equilibrium to be adapted for all the aforementioned problems. For example, this approach allows the well-known iterative proportional response process to provide approximations for the corresponding problems with multiplicative error in distributed settings, whereas previously, only absolute error had been achieved in these contexts. Our study contributes to the understanding of various problems within a unified framework, which may serve as a foundation for connecting other problems in the future.

1 Introduction

In this work, we explore several existing and new problems under the same unifying framework. By unraveling previously unknown connections between these seemingly unrelated problems, we offer deeper insights into them. Moreover, existing solutions for one problem can readily offer improvements to other problems. Input instances for these problems all have the following form.

Input Instance. An instance is a vertex-weighted bipartite graph with vertex bipartition $\mathcal{I} = \mathcal{I}^{(0)} \uplus \mathcal{I}^{(1)}$, edge set $\mathcal{F}$ and positive[1] vertex weights $w : \mathcal{I} \to \mathbb{R}_{>0}$. For some problems, it is convenient to normalize the vertex weights into distributions, i.e., the vertex weights on each side sum to 1; in this case, we call this a *distribution* instance. We use $\mathbb{B} := \{0, 1\}$ to index the two sides. Given a side $\iota \in \mathbb{B}$, we use $\bar{\iota} := \iota \oplus 1$ to denote the other side.

Solution Concept. We shall see that in each problem, *refinement* is the underlying solution concept. Given a side $\iota \in \mathbb{B}$, a refinement[2] $\alpha^{(\iota)}$ on vertex weights on side ι indicates how each vertex $i \in \mathcal{I}^{(\iota)}$ distributes its weight $w(i)$ among its incident edges in $\mathcal{F}$. In other words, $\alpha^{(\iota)}$ is a vector of edge weights in $\mathcal{F}$ such that for each $i \in \mathcal{I}^{(\iota)}$, the sum of weights of edges incident on i equals $w(i)$. While some problems may require refinements of vertex weights from one side only, it will still be insightful to consider a *refinement pair* $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ of vertex weights on both sides.

The main problem we focus on is the closest distribution refinement problem, which we show is intricately related to other problems. In probability theory, a *divergence* notion quantifies how close two distributions are to each other, where a smaller quantity indicates that they are closer. Common examples of divergences include total variation distance and KL-divergence. Observe that a divergence notion D needs not be symmetric, i.e. for two distributions P and Q on the same sample space, it is possible that $\mathsf{D}(P\|Q) \neq \mathsf{D}(Q\|P)$.

▶ **Definition 1** (Closest Distribution Refinement Problem). *Given a distribution instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ and a divergence notion D, the goal is to find a distribution refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ such that the distributions $\alpha^{(0)}$ and $\alpha^{(1)}$ on the edges $\mathcal{F}$ are as close to each other as possible under D, i.e., $\mathsf{D}(\alpha^{(0)}\|\alpha^{(1)})$ is minimized.*

Universally Closest Refinement Pair. It is not clear *a priori* if a refinement pair achieving the minimum for one divergence notion would also achieve the minimum for another divergence notion. For a non-symmetric divergence D, a pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ minimizing $\mathsf{D}(\alpha^{(0)}\|\alpha^{(1)})$ may not necessarily achieve the minimum $\mathsf{D}(\alpha^{(1)}\|\alpha^{(0)})$. The special case when $\vec{\alpha}$ consists of a pair of identical refinements is also known as w-transportation or perfect fractional matching [6, 9, 27, 34], in which case $\vec{\alpha}$ is obviously the minimizer for all divergences.

In general, it would seem ambitious to request a *universally closest* refinement pair that simultaneously minimizes all "reasonable" divergence notions. In the literature, all commonly used divergence notions satisfy the *data processing inequality*, which intuitively says that the divergence of two distributions cannot increase after post-processing. Formally, for any deterministic function $\varphi : \Omega \to \widehat{\Omega}$, the induced distribution $\varphi(P)$ and $\varphi(Q)$ on $\widehat{\Omega}$ satisfy the inequality: $\mathsf{D}(\varphi(P)\|\varphi(Q)) \leq \mathsf{D}(P\|Q)$. Surprisingly, we show that such a universally closest pair exists.

[1] Vertices with zero weights are removed and identified with the empty set $\emptyset$.

[2] Since vertex weights on one side can be interpreted as a probability distribution, allocating the weight of each vertex to its incident edges can be viewed as a refinement of the original distribution.

▶ **Theorem 2** (Universally Closest Refinement Pair). *Given a distribution instance* $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$*, there exists a distribution refinement pair* $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ *that minimizes* $\mathsf{D}(\alpha^{(0)} \| \alpha^{(1)})$ *simultaneously for all divergence notions* D *that satisfy the data processing inequality.*

Moreover, this pair can be returned using the near-linear time algorithm of Chen et al. [14] for the minimum quadratic-cost flow problem.

Since Definition 1 gives a clean mathematical problem, we first describe the technical contributions and approaches of this work, and we describe its motivation and application in Section 1.2.

While the technical proofs are given in Sections 4 and 5, we give some motivation for why the problem is studied in the first place and sketch the key ideas for our proofs.

1.1 Our Technical Contributions and Approaches

In addition to the problem in Definition 1, we shall see that the following solution properties are also the key to solving other problems as well.

Desirable Solution Properties. Two desirable solution properties are *local maximin* and *proportional response*.

- **Local Maximin.** A refinement $\alpha^{(\iota)}$ on vertex weights on side ι can also be interpreted as how each vertex in $\mathcal{I}^{(\iota)}$ allocates its weight to its neighbors on the other side $\mathcal{I}^{(\bar{\iota})}$ via the edges in $\mathcal{F}$. Specifically, for $i \in \mathcal{I}^{(\iota)}$ and $j \in \mathcal{I}^{(\bar{\iota})}$, $\alpha^{(\iota)}(ij)$ is the *payload* received by j from i, where we rely on the superscript in $\alpha^{(\iota)}$ to indicate that the payload is sent from side ι to side $\bar{\iota}$ along an edge in $\mathcal{F}$. Consequently, $\alpha^{(\iota)}$ induces a payload vector $p \in \mathbb{R}^{\mathcal{I}^{(\bar{\iota})}}$, where $p(j) = \sum_i \alpha^{(\iota)}(ij)$ is the total payload received by j in the allocation $\alpha^{(\iota)}$. Recalling that vertex j also has a weight, the payload density (resulting from $\alpha^{(\iota)}$) of j is $\rho(j) := \frac{p(j)}{w(j)}$. The refinement $\alpha^{(\iota)}$ is *locally maximin* if for each $i \in \mathcal{I}^{(\iota)}$, vertex i distributes a non-zero payload $\alpha^{(\iota)}(ij) > 0$ to vertex j only if j is among the neighbors of i with minimum payload densities (resulting from $\alpha^{(\iota)}$).
  The intuition of the term "maximin" is that vertex i tries to maximize the minimum payload density among its neighbors by giving its weight to only neighbors that achieve the minimum payload density.
- **Proportional Response.** Given a refinement $\alpha^{(\iota)}$ on vertex weights on side ι, its proportional response $\alpha^{(\bar{\iota})}$ is a refinement on vertex weights from the other side $\bar{\iota}$. Specifically, vertex $j \in \mathcal{I}^{(\bar{\iota})}$ distributes its weight $w(j)$ proportionately according to its received payloads: $\alpha^{(\bar{\iota})}(ij) = \frac{\alpha^{(\iota)}(ij)}{p(j)} \cdot w(j)$.

Several problems in the literature studied in different contexts can be expressed with the same goal.

▶ **Goal 3** (High-Level Goal). Given an instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, find a refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ such that both refinements are locally maximin and proportional response to each other.

This abstract problem have been studied extensively in the literature under different contexts, and various algorithms to exactly achieve or *approximate* (whose meaning we will explain) Goal 3 have been designed. One contribution of this work is to unify all these problems under our abstract framework. Consequently, we readily offer new approximation results for some problems that are unknown before this connection is discovered.

We next describe how our abstract framework is related to each considered problem and what new insights or results are achieved, which also provide the tools to solve or approximate the problem in Definition 1.

1.1.1 Hypergraph Density Decomposition

An instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ is interpreted as a *hypergraph* H. Each element in $i \in \mathcal{I}^{(0)}$ is a hyperedge and each element in $j \in \mathcal{I}^{(1)}$ is a node, where $\{i, j\} \in \mathcal{F}$ means that node j is contained in hyperedge i. Observe that in this hypergraph, both the hyperedges and the nodes are weighted.

Densest Subset Problem. Given a subset $S \subseteq \mathcal{I}^{(1)}$ of nodes in a (weighted) hypergraph, its density is $\rho(S) := \frac{w(H[S])}{w(S)}$, where $H[S]$ is the collection of hyperedges containing only nodes inside S. The densest subset problem requests a subset S with the maximum density.

Density Decomposition. The decomposition can be described by an iterative process that generates a density vector $\rho_* \in \mathbb{R}^{\mathcal{I}^{(1)}}$ for the nodes in the hypergraph by repeated peeling off densest subsets. First, the (unique) maximal densest subset S_1 is obtained, and each $j \in S_1$ will be assigned the density $\rho_*(j) = \frac{w(H[S_1])}{w(S_1)}$ of S_1. Then, the hyperedges $H[S_1]$ and the subset S_1 are removed from the instance; note that any hyperedge containing a node outside S_1 will remain. The process is applied to the remaining instance until eventually every node in $\mathcal{I}^{(1)}$ is removed and assigned its density. The collection of subsets found in the iterative process forms the density decomposition $\mathcal{I}^{(1)} = \uplus_{k \geq 1} S_k$.

As mentioned in [22], the earliest variant of this decomposition was introduced by Fujishige [19] in the context of polymatroids. We describe the related work in more detail in Section 1.3.

Connection with the Local Maximin Condition. Charikar [13] gave an LP (that can be easily generalized to weighted hypergraphs) which solves the densest subset problem exactly, and a refinement $\alpha^{(0)}$ on the weights of hyperedges $\mathcal{I}^{(0)}$ corresponds exactly to a feasible solution of the dual LP. Replacing the linear function in this dual LP with a quadratic function while keeping the same feasible variable $\alpha^{(0)}$, Danisch et al. [15] considered a quadratic program (that has also appeared in [19]). They showed that a refinement corresponds to an optimal solution to the quadratic program *iff* it is locally maximin[3]. Moreover, a locally maximin refinement also induces the aforementioned density vector ρ_*.

As observed in [22], the quadratic program can be expressed as a minimum quadratic-cost flow problem, which can be solved optimally using the nearly-linear time algorithm of Chen et al. [14]. As we shall show that our considered problems are all equivalent to Goal 3, this implies the algorithmic result in Theorem 2.

Symmetry of Density Decomposition. We observe that the density decomposition is symmetric between the hyperedges and the nodes. Recall that in iteration k of the density decomposition, a subset S_k is produced, together with its corresponding collection $\widehat{S}_k$ of hyperedges that determines the density $\frac{w(\widehat{S}_k)}{w(S_k)}$. Therefore, in addition to a partition of nodes, there is a corresponding decomposition of the hyperedges $\mathcal{I}^{(0)} = \uplus_{k \geq 1} \widehat{S}_k$.

[3] Instead of using the term "maximin", the same concept is called "stability" in [15].

Given an abstract instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, one could have interpreted it differently with $\mathcal{I}^{(0)}$ as nodes and $\mathcal{I}^{(1)}$ as hyperedges. When the density decomposition is constructed with the roles reversed, the exact sequence $\{(\widehat{S}_k, S_k)\}_k$ of pairs is obtained, but in reversed order. Intuitively, $(\widehat{S}_1, S_1)$ is the densest from the perspective of $S_1 \subseteq \mathcal{I}^{(1)}$, but it is the least dense from the perspective of $\widehat{S}_1 \subseteq \mathcal{I}^{(0)}$.

The symmetric nature of the density decomposition has been mentioned recently by Harb et al. [23, Theorem 13], but we shall explain later this fact may be inferred when different earlier works are viewed together. Hence, this observation may be considered as part of the folklore. Since we need some crucial properties of the symmetric density decomposition to prove Theorem 2, for the sake of completeness, the connection of Goal 3 and this folklore result is described in Section 3.

Approximation Notions. Even though the exact density decomposition can be achieved via LP or maximum flow, it can be computationally expensive in practice. In the literature, efficient approximation algorithms have been considered. While there are different attempts to define approximation notions for density decompositions, it is less clear what they mean when they are applied to different problems.

Observe that a refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ achieving Goal 3 may not be unique, but the induced payload vectors $(p_*^{(0)}, p_*^{(1)})$ and density vectors $(\rho_*^{(0)}, \rho_*^{(1)})$ are unique. When we say *approximating* Goal 3, we mean finding a refinement pair such that the induced payload and density vectors have some approximation guarantees. We shall see that approximation guarantees[4] on these vectors can be translated readily to approximation notions for various problems.

1.1.2 Unraveling Universally Closest Distribution Refinements via Symmetric Density Decomposition

Restricted Class of Divergence. As a first step towards proving Theorem 2, we consider a restricted class of divergences known as *hockey-stick* divergence. For each $\gamma \geq 0$,

$$\mathsf{D}_\gamma(P\|Q) := \sup_{S \subseteq \Omega} Q(S) - \gamma \cdot P(S).$$

The hockey-stick divergence is related to the well-known (ϵ, δ)-differential privacy inequality. Specifically, $\mathsf{D}_{e^\epsilon}(P\|Q) \leq \delta$ *iff* for all subsets $S \subseteq \Omega$,

$$Q(S) \leq e^\epsilon \cdot P(S) + \delta.$$

We first consider the universal closest distribution refinements with respect to the class of hockey-stick divergences $\mathcal{D}_{\text{HS}} := \{\mathsf{D}_\gamma : \gamma \geq 0\}$. In Lemma 31, we show that the restricted variant of Theorem 2 to the class $\mathcal{D}_{\text{HS}}$ is equivalent to the following problem.

Universal Refinement Matching Problem. Given an instance $G = (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ and two non-negative weights $\vec{c} = (c^{(0)}, c^{(1)}) \in \mathbb{R}^{\mathbb{B}}$, we use $G^{(\vec{c})}$ to denote the instance of (fractional) maximum matching on the bipartite graph $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F})$ with vertex capacity constraints. For side ι and $i \in \mathcal{I}^{(\iota)}$, the capacity constraint at vertex i is $c^{(\iota)} \cdot w(i)$. A fractional solution consists of assigning non-negative weights to the edges in $\mathcal{F}$ such that the weighted degree of every vertex does not exceed its capacity constraint. Observe that for any refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$, the fractional matching $\vec{c} \bullet \vec{\alpha}$ defined below is a feasible solution to $G^{(\vec{c})}$:

$$\vec{c} \bullet \vec{\alpha}(ij) := \min\{c^{(0)} \cdot \alpha^{(0)}(ij), c^{(1)} \cdot \alpha^{(1)}(ij)\} \text{ for all } \{i, j\} \in \mathcal{F}.$$

[4] See Definition 12 for approximation notions of *muliplicative* vs *absolute* errors on vectors.

The goal is to find a refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ such that for any weight pair $\vec{c}$, the edge weights $\vec{c} \bullet \vec{\alpha}$ form an optimal (fractional) solution to the maximum matching instance $G^{(\vec{c})}$.

The structure of the symmetric density decomposition described in Section 1.1.1 makes it convenient to apply a primal-dual analysis to achieve the following in Section 4.

▶ **Theorem 4** (Universal Maximum Refinement Matching). *Given an instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, suppose a distribution refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ satisfies Goal 3. Then, for any $\vec{c} = (c^{(0)}, c^{(1)})$, the (fractional) solution $\vec{c} \bullet \vec{\alpha}$ is optimal for the maximum matching instance $G^{(\vec{c})}$.*

Extension to General Case. To extend Theorem 2 beyond the restricted divergence class $\mathcal{D}_{\mathrm{HS}}$, we consider the closest distribution refinement problem under a more general probability distance notion.

Capturing All Data Processing Divergences via Power Functions. As opposed to using a single number by a divergence notion to measure the closeness of two distributions, the *power function* $\mathsf{Pow}(P\|Q) : [0,1] \to [0,1]$ between distributions P and Q captures enough information to recover all divergence notions that satisfy the data processing inequality. We will give a formal explanation in Section 5. A main result is given in Theorem 37, which states that any distribution refinement pair satisfying Goal 3 achieves the minimal power function, from which Theorem 2 follows immediately.

Approximation Results. In the full version [12], we show that a refinement that induces a payload with multiplicative error can lead to approximation guarantees for other problems. For the universal refinement matching problem, a natural approximation notion is based on the standard approximation ratio for the maximum matching problem.

On the other hand, achieving a meaningful approximation notion for the universally closest distribution refinement problem in terms of divergence values is more difficult. The reason is that any strictly increasing function on a data processing divergence still satisfies the data processing inequality. Therefore, any non-zero deviation from the correct answer may be magnified arbitrarily. Instead of giving approximation guarantees directly on the divergence values, we consider a technical notion of power function stretching, and the approximation quality of a refinement pair is quantified by how much the optimal power function is stretched. The formal statement is given in the full version [12].

1.1.3 Achieving Multiplicative Error via Proportional Response in Fisher Markets

We next interpret an instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ as a special symmetric case of linear Fisher markets [18], which is itself a special case of the more general Arrow-Debreu markets [2]. This allows us to transfer any algorithmic results for Fisher/Arrow-Debreu market equilibrium to counterparts for Goal 3. Specifically, we can use a quick iterative procedure *proportional response* [39, 40] to approximate the densities of vertices in the density decomposition in Section 1.1.1 with multiplicative error, where only absolute error has been achieved before [15, 22]. In addition to being interesting in its own right, multiplicative error is also used to achieve the approximation results in Section 1.1.2.

Market Interpretation. Even though in an instance, the roles of the two sides are symmetric, it will be intuitive to think of $\mathcal{I}^{(0)}$ as buyers and $\mathcal{I}^{(1)}$ as sellers. For buyer $i \in \mathcal{I}^{(0)}$, the weight $w(i)$ is its *budget*. In the symmetric variant, the utilities of buyers have a special form.

Each seller $j \in \mathcal{I}^{(1)}$ has one divisible unit of good j for which a buyer i has a positive utility exactly when $\{i, j\} \in \mathcal{F}$, in which case the utility per unit of good j is $w(j)$ (that is common for all buyers that have a positive utility for j). For a general Fisher market, a buyer i can have an arbitrary utility $w_i(j)$ for one unit of good j.

Market Allocation and Equilibrium. For the symmetric variant, an allocation can be represented by a refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$, in which $\alpha^{(1)}$ must be a proportional response to $\alpha^{(0)}$. For the refinement $\alpha^{(0)}$ on the buyers' budgets, the induced payload vector $p^{(1)}$ on the sellers corresponds to the *price* vector on goods. For the refinement $\alpha^{(1)}$ on the sellers' weights, the induced payload vector $p^{(0)}$ on the buyers corresponds to the utilities received by the buyers. It is well-known (explained in the full version [12]) that a market equilibrium is characterized by a locally maximin refinement $\alpha^{(0)}$ of buyers' budgets together with its proportional response $\alpha^{(1)}$. From our theory of symmetric density decomposition in Section 1.1.1, this is equivalent to Goal 3.

Alternative Characterization. The fact that the local maximin condition on the buyers' budget allocation is equivalent to Fisher market equilibrium readily allows us to borrow any algorithmic results for market equilibrium to solve or approximate Goal 3. In the full version [12], we give details on the following observations.

- In linear Fisher markets (not necessarily symmetric), we show that the local maximin condition on sellers' goods allocation to buyers can be used to characterize a market equilibrium. This is an alternative characterization of linear Fisher market equilibrium that involves only goods allocation and buyers' utilities, but not involving good prices.
- On the other hand, we show that there exists an Arrow-Debreu market such that there is a goods allocation satisfying the local maximin condition, but it is not an equilibrium.

1.2 Motivation and Application for Universally Closest Distribution Refinements

The problem in Definition 26 arises in the study of the composition of differentially oblivious mechanisms [41, 42], which is a generalization of the more well-known concept of differential privacy (DP) [17].

A Quick Introduction to Differential Privacy/Obliviousness. Consider a (randomized) mechanism $\mathcal{M}$ that takes an input from space $\mathcal{X}$ and returns an output from space $\mathcal{Y}$ that will be passed to a second mechanism. During the computation of $\mathcal{M}$, an adversary can observe some *view* from space $\mathcal{V}$ that might not necessarily include the output in general. Suppose at first we just consider the privacy/obliviousness of $\mathcal{M}$ on its own, which measures how much information the adversary can learn about the input from its view. Intuitively, it should be difficult for the adversary to distinguish between two similar inputs from their corresponding views produced by the mechanism. Formally, similar inputs in $\mathcal{X}$ are captured by a *neighboring* symmetric relation, and the privacy/obliviousness of the mechanism $\mathcal{M}$ requires that the two distributions of views produced by neighboring inputs are "close", where closeness can be quantified by some notion of divergence. As mentioned in Section 1.1.2, the popular notion of (ϵ, δ)-DP is captured using hockey-stick divergences.

Composition of Differentially Oblivious Mechanisms. Suppose the output of mechanism $\mathcal{M}$ from space $\mathcal{Y}$ is passed as an input to a second mechanism $\mathcal{M}'$, which is differentially oblivious with respect to some neighboring relation on $\mathcal{Y}$. Hence, given input x to $\mathcal{M}$, one should consider the joint distribution $\mathcal{M}(x)$ on the space $\mathcal{V} \times \mathcal{Y}$ of views and outputs.

The notion of neighbor-preserving differential obliviousness (NPDO) has been introduced [41, 42] to give sufficient conditions on $\mathcal{M}$ that allows composition with such a mechanism $\mathcal{M}'$ so that the overall composition preserves differential obliviousness.

Specifically, given neighboring inputs $x_0 \sim x_1$, conditions are specified on the two distributions $\mathcal{M}(x_0)$ and $\mathcal{M}(x_1)$. Unlike the case for differential privacy/obliviousness, it is not appropriate to just require that the two distributions are close. This is because the adversary can only observe the view component of $\mathcal{V} \times \mathcal{Y}$. Moreover, one also needs to incorporate the neighboring relation on the output space $\mathcal{Y}$, which is needed for the privacy guarantee for the second mechanism $\mathcal{M}'$.

The definition of NPDO is more conveniently described via the terminology offered by our abstract instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$. Here, the sets $\mathcal{I}^{(0)}$ and $\mathcal{I}^{(1)}$ are two copies of $\mathcal{V} \times \mathcal{Y}$. For each $\iota \in \mathbb{B}$, the weights w on $\mathcal{I}^{(\iota)}$ corresponds to the distribution $\mathcal{M}(x_\iota)$. Finally, $(v_0, y_0) \in \mathcal{I}^{(0)}$ and $(v_1, y_1) \in \mathcal{I}^{(1)}$ are neighbors in $\mathcal{F}$ *iff* $v_0 = v_1$ and $y_0 \sim y_1$ are neighboring in $\mathcal{Y}$.

In the original definition [42], the mechanism $\mathcal{M}$ is said to be d-NPDO with respect to divergence D if for the constructed instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, there exists a distribution refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$, which may depend on the divergence D, such that $\mathsf{D}(\alpha^{(0)} \| \alpha^{(1)}) \le d$. Examples of considered divergences include the standard hockey-stick divergence and Rényi divergence [31].

Since it only makes sense to consider divergences satisfying the data processing inequality in the privacy context, the universally closest refinement pair guaranteed in Theorem 2 makes the notion of NPDO conceptually simpler, because the closest refinement pair does not need to specifically depend on the considered divergence.

We believe that this simplification will be a very useful tool. In fact, to achieve advanced composition in [42], a very complicated argument has been used to prove the following fact, which is just an easy corollary of Theorem 2.

▶ **Fact 5** (Lemma B.1 in [42]). *Given a distribution instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, suppose there exist two refinement pairs $\vec{\alpha}_s = (\alpha_s^{(0)}, \alpha_s^{(1)})$ and $\vec{\alpha}_t = (\alpha_t^{(0)}, \alpha_t^{(1)})$ such that the hockey-stick divergences $\mathsf{D}_\gamma(\alpha_s^{(0)} \| \alpha_s^{(1)})$ and $\mathsf{D}_\gamma(\alpha_t^{(1)} \| \alpha_t^{(0)})$ are both at most δ.*

Then, there exists a single refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ such that both $\mathsf{D}_\gamma(\alpha^{(0)} \| \alpha^{(1)})$ and $\mathsf{D}_\gamma(\alpha^{(1)} \| \alpha^{(0)})$ are at most δ.

1.3 Related Work

The densest subset problem is a classical problem in combinatorial optimization with numerous real-world applications in data mining, network analysis, and machine learning [1, 13, 21, 26, 29, 30, 35], and it is the basic subroutine in defining the density decomposition.

Density Decomposition. As mentioned in Section 1.1.1, the earliest reference to the density decomposition and its associated quadratic program were introduced by Fujishige [19]. Even though this decomposition was defined for the more general submodular or supermodular case, the procedure has been rediscovered independently many times in the literature for the special bipartite graph case (or equivalently its hypergraph interpretation).

Earlier we described the decomposition procedure by repeatedly peeling off maximal densest subsets in a hypergraph. This was the approach by Tatti and Gionis [36, 37] and Danisch et al. [15] . Moreover, the same procedure has been used to define hypergraph Laplacians in the context of the spectral properties of hypergraphs [11].

In the literature, there is another line of research that defines the decomposition by repeatedly peeling off least densest subsets instead. However, given a subset $S \subseteq V$ of nodes in a weighted hypergraph $H = (V, E)$, a different notion of density is considered: $\mathfrak{r}(S) := \frac{w(E(S))}{w(S)}$, where $E(S)$ is the collection of hyperedges that have non-empty intersection with S. The difference is that before we consider $E[S]$ that is the collection of hyperedges totally contained inside S. Then, an alternative procedure can be defined by peeling off a maximal least densest subset under $\mathfrak{r}$ and performing recursion on the remaining graph.

This was the approach used by Goel et al. [20] to consider the communication and streaming complexity of maximum bipartite matching. The same procedure has been used by Bernstein et al. [7] to analyze the replacement cost of online maximum bipartite matching maintenance. Lee and Singla [28] also used this decomposition to investigate the the batch arrival model of online bipartite matching. Bansal and Cohen [4] have independently discovered this decomposition procedure to consider maximin allocation of hyperedge weights to incident nodes.

Symmetric Nature of Density Decomposition. At this point, the reader may ask how we know that the two procedures will give the same decomposition (but in reversed order). The answer is that exactly the same quadratic program has been used in [15] and [7] to analyze the corresponding approaches. This observation has also been made recently by Harb et al. [23, Theorem 13]. It is not too difficult to see that the least densest subset using the modified density $\mathfrak{r}$ is equivalent to the densest subset with the roles of vertices and hyperedges reversed. Therefore, Theorem 20 can also be obtained indirectly through these observations.

Connection between Density Decomposition and Fisher Market Equilibrium. Even before this work in which we highlight the local maximin condition, density decomposition has already surreptitiously appeared in algorithms computing Fisher market equilibrium. Jain and Vazirani [24] considered submodular utility allocation (SUA) markets, which generalize linear Fisher markets. Their procedure [24, Algorithm 9] for computing an SUA market equilibrium can be viewed as a masqueraded variant of the density decomposition by Fujishige [19]. Buchbinder et al. [10] used a variant of SUA market equilibrium to analyze online maintenance of matroid intersections, where equilibrium prices are also obtained by the density decomposition procedure.

In this work, we observe conversely that algorithms for approximating market equilibrium can also be directly used for approximating density decompositions. For the simple special case in which the input graph contains a perfect fractional matching, Motwani et al. [32] showed that several randomized balls-into-bins procedures attempting to maintain the locally maximin condition can achieve $(1 + \epsilon)$-approximation.

Distributed Iterative Approximation Algorithms. Even though efficient exact algorithms are known to achieve Goal 3, distributed iterative approximation algorithms have been considered for practical scenarios.

Density Decomposition. By applying the first-order iterative approach of Frank-Wolfe to the quadratic program, Danisch et al. [15] showed that T iterations, each of which takes $O(|\mathcal{F}|)$ work and may be parallelized, can achieve an absolute error of $O(\frac{1}{\sqrt{T}})$ on the density vector ρ_*. Harb et al. [23] showed that the method Greedy++ can be viewed as a noisy variant of Frank-Wolfe and hence has a similar convergence result.

By using a first-order method augmented with Nesterov momentum [33] such as accelerated FISTA [5], Elfarouk et al. [22] readily concluded that T iterations can achieve an absolute error of $O(\frac{1}{T})$. However, observe that if there is a vertex i such that $\rho_*(i) \leq \epsilon$, an absolute error of ϵ may produce an estimate $\rho(i)$ that is arbitrarily small.

Inspired by estimates of ρ_*, several notions of approximate density decompositions have been considered in previous works [15,22,37]. However, it is not clear if there is any meaningful interpretations of these approximate decompositions in the context of closest distribution refinements or market equilibrium.

Fisher Market Equilibrium. Market dynamics have been considered to investigate how agents' mutual interaction can lead to convergence to a market equilibrium. The proportional response (PR, *aka* tit-for-tat) protocol has been used by Wu and Zhang [39] to analyze bandwidth trading in a peer-to-peer network $G = (V, E)$ with vertex weights w. This can be seen as a special case of our instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, where $\mathcal{I}^{(0)}$ and $\mathcal{I}^{(1)}$ are two copies of V, and $i \in \mathcal{I}^{(0)}$ and $j \in \mathcal{I}^{(1)}$ are neighbors in $\mathcal{F}$ *iff* the corresponding pair $\{i, j\} \in E$ are neighbors in G. Interestingly, they consider a *bottleneck* decomposition of the graph G which can be recovered from our symmetric density decomposition. They showed that the PR protocol converges to some equilibrium under this special model.

Subsequently, Zhang [40] showed that the PR protocol can be applied in Fisher markets between buyers and sellers, and analyzed the convergence rate to the market equilibrium in terms of multiplicative error. Birnbaum et al. [8] later improved the analysis of the PR protocol by demonstrating that it can be viewed as a generalized gradient descent algorithm.

1.4 Potential Impacts and Paper Organization

This work unifies diverse problems under a single framework, revealing connections and providing new approximation results. Future research directions are abundant. Examining the implications of various market models or equilibrium concepts on the densest subset problem and density decomposition opens the door for further exploration of the relationships between economic markets and combinatorial optimization problems. This line of inquiry could also lead to new insights into economics, particularly regarding market participants' behavior and the efficiency of different market mechanisms.

Paper Organization. In Section 2, we introduce the precise notation that will be used throughout the paper. In Section 3, we summarize the structural results regarding the symmetric density decomposition, which is used as a technical tool to analyze other problems. As mentioned in the introduction, Section 4 investigates the universal refinement matching problem which is the precursor for tackling the more challenging universally closest distribution refinements problem in Section 5. In Section 5.1, we first consider the special case of hockey-stick divergences; by considering power functions, we prove Theorem 2 in Section 5.2.

Additional Materials in the Full Version. In the full version [12], we present approximation results for the universal closest refinements problem by defining a stretching operation on power functions. Moreover, we recap the connection between the symmetric density decomposition and the symmetric Fisher market equilibrium. We give an alternative characterization of the Fisher market equilibrium in terms of the local maximin condition on sellers' goods allocation to buyers. Furthermore, we give details on the convergence rates of how the iterative proportional response protocol can achieve an approximation with multiplicative error for Goal 3.

2 Preliminaries

We shall consider several problems, whose inputs are in the form of vertex-weighted bipartite graphs.

▶ **Definition 6** (Input Instance). *An instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ of the input consists of the following:*

- *Two disjoint vertex sets $\mathcal{I}^{(0)}$ and $\mathcal{I}^{(1)}$.*
  For the side $\iota \in \mathbb{B} := \{0,1\}$, we use $\bar{\iota} := \iota \oplus 1$ to indicate the other side different from ι.
- *A collection $\mathcal{F}$ of unordered pairs of vertices that is interpreted as a bipartite graph between vertex sets $\mathcal{I}^{(0)}$ and $\mathcal{I}^{(1)}$; in other words, if $f = \{i, j\} \in \mathcal{F}$, then exactly one element of f is in $\mathcal{I}^{(0)}$ and the other is in $\mathcal{I}^{(1)}$. In this case, we also denote $i \sim_{\mathcal{F}} j$ or just $i \sim j$.*
  A vertex is isolated if it has no neighbor.
- *Positive*[5] *vertex weights $w : \mathcal{I}^{(0)} \cup \mathcal{I}^{(1)} \to \mathbb{R}_{>0}$; for a vertex i, we use w_i or $w(i)$ to denote its weight.*
  For $\iota \in \mathbb{B}$, we also use $w^{(\iota)} \in \mathbb{R}^{\mathcal{I}^{(\iota)}}$ to denote the weight vector for each side.

  This notation highlights the symmetry between the two sets $\mathcal{I}^{(0)}$ and $\mathcal{I}^{(1)}$.

▶ Remark 7. In this work, we focus on the case that $\mathcal{I}^{(0)}$ and $\mathcal{I}^{(1)}$ are finite. Even though it is possible to extend the results to continuous and uncountable sets (which are relevant when those sets are interpreted as continuous probability spaces), the mathematical notations and tools involved are outside the scope of the typical computer science community.

▶ **Definition 8** (Allocation Refinement and Payload). *Given an input instance as in Definition 6, for side $\iota \in \mathbb{B}$, an allocation refinement (or simply refinement) $\alpha^{(\iota)} \in \mathbb{R}^{\mathcal{F}}_{\geq 0}$ of $w^{(\iota)} \in \mathbb{R}^{\mathcal{I}^{(\iota)}}$ can be interpreted as edge weights on $\mathcal{F}$ such that for each non-isolated vertex $i \in \mathcal{I}^{(\iota)}$,*

$$w^{(\iota)}(i) = \sum_{f \in \mathcal{F} : i \in f} \alpha^{(\iota)}(f).$$

In other words, if a vertex i has at least one neighbor, it distributes its weight w_i among its neighboring edges $\{i, j\}$ such that $i \sim j$. These edge weights due to the refinement $\alpha^{(\iota)}$ can be interpreted as received by vertices on the other side $\mathcal{I}^{(\bar{\iota})}$; this induces a payload vector $p^{(\bar{\iota})} \in \mathbb{R}^{\mathcal{I}^{(\bar{\iota})}}$ defined by:

$$\forall j \in \mathcal{I}^{(\bar{\iota})}, p^{(\bar{\iota})}(j) := \sum_{f : j \in f} \alpha^{(\iota)}(f).$$

With respect to the weights of vertices in $\mathcal{I}^{(\bar{\iota})}$, the (payload) density $\rho^{(\bar{\iota})} \in \mathbb{R}^{\mathcal{I}^{(\bar{\iota})}}$ is defined by:

$$\rho^{(\bar{\iota})}(j) := \frac{p^{(\bar{\iota})}(j)}{w(j)}.$$

When there is no risk of ambiguity, the superscripts (ι) and $(\bar{\iota})$ may be omitted.

▶ **Definition 9** (Proportional Response). *Suppose for side $\iota \in \mathbb{B}$, $\alpha^{(\iota)}$ is a refinement of the vertex weights on $\mathcal{I}^{(\iota)}$. Then, a proportional response to $\alpha^{(\iota)}$ is a refinement $\alpha^{(\bar{\iota})}$ of the vertex weights on the other side $\mathcal{I}^{(\bar{\iota})}$ satisfying the following:*

[5] Vertices with zero weight do not play any role and may be excluded.

- *If $j \in \mathcal{I}^{(\bar{\iota})}$ receives a positive payload $p^{(\bar{\iota})}(j) > 0$ from $\alpha^{(\iota)}$, then for each $i \sim j$, $\alpha^{(\bar{\iota})}(ij) = \frac{\alpha^{(\iota)}(ij)}{p^{(\bar{\iota})}(j)} \cdot w(j) = \frac{\alpha^{(\iota)}(ij)}{\rho^{(\bar{\iota})}(j)}$.*
- *If a non-isolated vertex $j \in \mathcal{I}^{(\bar{\iota})}$ receives zero payload from $\alpha^{(\iota)}$, then in $\alpha^{(\bar{\iota})}$, vertex j may distributes its weight $w(j)$ arbitrarily among its incident edges in $\mathcal{F}$.*

▶ **Definition 10** (Local Maximin Condition). *Given an input instance as in Definition 6, for $\iota \in \mathbb{B}$, suppose a refinement $\alpha^{(\iota)} \in \mathbb{R}_+^{\mathcal{F}}$ of $w^{(\iota)} \in \mathbb{R}^{\mathcal{I}^{(\iota)}}$ induces a payload density vector $\rho^{(\bar{\iota})} \in \mathbb{R}^{\mathcal{I}^{(\bar{\iota})}}$ as in Definition 8. Then, $\alpha^{(\iota)}$ is locally maximin if,*

$$\forall i \in \mathcal{I}^{(\iota)}, \quad \alpha^{(\iota)}(ij) > 0 \implies j \in \arg\min_{\ell \in \mathcal{I}^{(\bar{\iota})} : \ell \sim i} \rho^{(\bar{\iota})}(\ell).$$

In other words, the local maximin condition states that each vertex $i \in \mathcal{I}^{(\iota)}$ attempts to send a positive weight to a neighbor $j \sim i$ only if j achieves the minimum $\rho^{(\bar{\iota})}(\ell)$ among the neighbors ℓ of i.

▶ Remark 11. Observe that if $\alpha^{(\iota)}$ satisfies the local maximin condition, then every non-isolated vertex in $\mathcal{I}^{(\bar{\iota})}$ must receive a positive payload. This means that its proportional response $\alpha^{(\bar{\iota})}$ is uniquely determined.

▶ **Definition 12** (Notions of Error). *Given a vector ρ, we consider two notions of error for an approximation vector $\widehat{\rho}$.*

- Absolute error ϵ with respect to norm $\|\cdot\|$. *We have:* $\|\rho - \widehat{\rho}\| \le \epsilon$. *A common example is the standard ℓ_2-norm.*
- Multiplicative error ϵ. *For all coordinates i,* $|\rho(i) - \widehat{\rho}(i)| \le \epsilon \cdot |\rho(i)|$.

3 Folklore: Symmetric Density Decomposition

An instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, as in Definition 6, may be interpreted as a hypergraph H. We have the vertex set $V = \mathcal{I}^{(1)}$ (*aka* the *ground* set) and the hyperedge set $E = \mathcal{I}^{(0)}$ (*aka* the *auxiliary* set), where $v \in V$ and $e \in E$ are neighbors in $\mathcal{F}$ *iff* the hyperedge e contains the vertex v. Moreover, w assigns weights to both V and E in the hypergraph.

Notation: Ground and Auxiliary Sets. For side $\iota \in \mathbb{B}$, the *open neighborhood* of a non-empty subset $S \subseteq \mathcal{I}^{(\iota)}$ consists of vertices on the other side that have at least one neighbor in S, i.e., $\mathcal{F}(S) := \{j \in \mathcal{I}^{(\bar{\iota})} : \exists i \in S, i \sim j\}$. Its *closed neighborhood* is $\mathcal{F}[S] := \{j \in \mathcal{F}(S) : \mathcal{F}(\{j\}) \subseteq S\}$, i.e., a vertex j is in $\mathcal{F}[S]$ *iff* it has at least one neighbor and all its neighbors are contained in S. Its density is defined as $\rho^{(\iota)}(S) := \frac{w(\mathcal{F}[S])}{w(S)}$, where the superscript ι may be omitted when the context is clear. When we consider the densities of subsets in $\mathcal{I}^{(\iota)}$, the set $\mathcal{I}^{(\iota)}$ plays the role of the *ground set* and the set $\mathcal{I}^{(\bar{\iota})}$ plays the role of the *auxiliary set*. Observe that this definition is consistent with the hypergraph (V, H) interpretation when $\iota = 1$ plays the role of the vertex set V.

Extension to Empty Set. In some of our applications, it makes sense to have isolated vertices in the input instance. For $\emptyset \subseteq \mathcal{I}^{(\iota)}$, we extend $\mathcal{F}(\emptyset) = \mathcal{F}[\emptyset] := \{j \in \mathcal{I}^{(\bar{\iota})} : \forall i \in \mathcal{I}^{(\iota)}, j \not\sim i\}$. For the purpose of defining $\rho(\emptyset)$, we use the convention that $\frac{0}{0} = 0$ and $\frac{x}{0} = +\infty$ for $x > 0$.

▶ **Definition 13** (Densest Subset). *When $\mathcal{I}^{(\iota)}$ plays the role of the ground set, a subset $S \subseteq \mathcal{I}^{(\iota)}$ is a densest subset, if it attains* $\max_{S \subseteq \mathcal{I}^{(\iota)}} \rho^{(\iota)}(S)$.

The following well-known fact characterizes a property of maximal densest subset (see [3, Lemma 4.1] for a proof).

▶ **Fact 14.** *With respect to set inclusion, the maximal densest subset in $\mathcal{I}^{(\iota)}$ is unique and contains all densest subsets.*

▶ **Definition 15** (Sub-Instance). *Given an instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, the subsets $S^{(0)} \subseteq \mathcal{I}^{(0)}$ and $S^{(1)} \subseteq \mathcal{I}^{(1)}$ naturally induces a sub-instance $(S^{(0)}, S^{(1)}; \mathcal{F}'; w')$, where $\mathcal{F}'$ and w' are restrictions of $\mathcal{F}$ and w, respectively, to $S^{(0)} \cup S^{(1)}$.*

The following definition is essentially the same as the density decomposition of a hypergraph [36, 37].

▶ **Definition 16** (Density Decomposition with Ground Set). *Given an instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, suppose for $\iota \in \mathbb{B}$, we consider $\mathcal{I}^{(\iota)}$ as the ground set. The density decomposition with $\mathcal{I}^{(\iota)}$ as the ground set is a sequence of pairs $\{(S_\ell^{(0)}, S_\ell^{(1)})\}_{\ell \geq 1}$, together with a density vector $\rho_*^{(\iota)} : \mathcal{I}^{(\iota)} \to \mathbb{R}_+$, defined by the following iterative process.*

Initially, we set $G_0 := (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ to be the original given instance, and initialize $\ell = 1$.

1. *If $G_{\ell-1}$ is an instance where the vertex sets on both sides are empty, the process stops.*
2. *Otherwise, let $S_\ell^{(\iota)}$ be the maximal densest subset in $G_{\ell-1}$ with side ι being the ground set, where ρ_ℓ is the corresponding density; let $S_\ell^{(\bar{\iota})} := \mathcal{F}[S_\ell^{(\iota)}]$ be its closed neighborhood in $G_{\ell-1}$.*
   For each $u \in S_\ell^{(\iota)}$, define $\rho_*^{(\iota)}(u) := \rho_\ell = \frac{w(S_\ell^{(\bar{\iota})})}{w(S_\ell^{(\iota)})}$.
3. *Let G_ℓ be the sub-instance induced by removing $S_\ell^{(\iota)}$ and $S_\ell^{(\bar{\iota})}$ from $G_{\ell-1}$; note that edges in $\mathcal{F}$ incident to removed vertices are also removed.*
   Increment ℓ and go to the next iteration.

▶ Remark 17 (Isolated Vertices). Observe that if each side ι has isolated vertices $U^{(\iota)}$ that have no neighbors, then they will also appear at the beginning and the end of the decomposition sequence as $(U^{(0)}, \emptyset)$ and $(\emptyset, U^{(1)})$.

When $\mathcal{I}^{(\iota)}$ is the ground set, the density $\rho^{(\iota)}$ of vertices in $U^{(\iota)}$ is zero. In the rest of this section, we may assume that isolated vertices are removed from the instance.

The following fact has been proved in [15] when the vertices in the ground set have uniform weights. The same proof generalizes to the case where both sides have general positive weights.

▶ **Fact 18** (Local Maximin Condition Gives Density Decomposition). *Given an instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, consider side $\iota \in \mathbb{B}$ as the ground set. Suppose $\alpha^{(\bar{\iota})} \in \mathbb{R}^{\mathcal{F}}$ is a refinement of the vertex weights $w^{(\bar{\iota})}$ on side $\bar{\iota}$, which induces the payload density vector $\rho^{(\iota)}$ on side ι as in Definition 8.*

Suppose further that $\alpha^{(\bar{\iota})}$ satisfies the local maximin condition in Definition 10. Then, $\rho^{(\iota)}$ coincides exactly with the density vector $\rho_*^{(\iota)}$ achieved by the density decomposition in Definition 16 with side ι being the ground set.

Moreover, if $(S_\ell^{(\bar{\iota})}, S_\ell^{(\iota)})$ is a pair in the density decomposition, then $S_\ell^{(\bar{\iota})}$ is exactly the collection of vertices that send positive payload to $S_\ell^{(\iota)}$ in $\alpha^{(\bar{\iota})}$.

Symmetry in Density Decomposition. In Definition 16, one side $\iota \in \mathbb{B}$ plays the role of the ground set. If we switch the ground set to the other side $\bar{\iota}$, the same sequence $\{(S_\ell^{(0)}, S_\ell^{(1)})\}_{\ell \geq 1}$ will be produced in the density decomposition, but in the reversed order. While a similar observation has been made by Harb et al. [23, Theorem 13], we re-establish this fact by considering the proportional response to a locally maximin refinement in the following lemma, whose proof is given in the full version [12].

▶ **Lemma 19** (Proportional Response to Locally Maximin Refinement). *Let $\alpha^{(0)}$ be a refinement of vertex weights in $\mathcal{I}^{(0)}$ that satisfies the local maximin condition. By Remark 11, suppose the refinement $\alpha^{(1)}$ on vertex weights in $\mathcal{I}^{(1)}$ is the unique proportional response to $\alpha^{(0)}$. Moreover, for each side $\iota \in \mathbb{B}$, the refinement $\alpha^{(\iota)}$ induces the payload density vector $\rho^{(\bar{\iota})}$ on vertices on the other side $\bar{\iota}$. Then, the following holds:*

- *For any $i \in \mathcal{I}^{(0)}$ and $j \in \mathcal{I}^{(1)}$ such that $i \sim j$ and $\alpha^{(0)}(ij) > 0$, their received payload densities due to the refinements satisfy $\rho^{(0)}(i) = \frac{1}{\rho^{(1)}(j)}$.*
- *The refinement $\alpha^{(1)}$ also satisfies the local maximin condition.*
- *We get back $\alpha^{(0)}$ as the proportional response to $\alpha^{(1)}$.*

In addition to being used to establish the symmetry of the density decomposition in Theorem 20, Lemma 19 will be used later as a technical tool for analyzing the universal refinement matching problem in Section 4.

▶ **Theorem 20** (Folklore: Symmetry of Density Decomposition). *Given an instance $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, suppose the sequence $\{(S_\ell^{(0)}, S_\ell^{(1)})\}_{\ell \geq 1}$ of pairs is the density decomposition using $\mathcal{I}^{(1)}$ as the ground set.*

Then, the density decomposition using $\mathcal{I}^{(0)}$ as the ground set produces the same sequence of pairs in reversed order.

4 Universal Refinement Matching Problem

As mentioned in Section 1, an instance in Definition 6 can be interpreted as inputs in various problems. As a precursor to the universally closest distribution refinements problem studied in Section 5, we consider a matching problem. Here, an instance is interpreted as the input of the vertex-constrained fractional matching problem, where the vertex constraints on each side is scaled by the same multiplicative factor.

▶ **Definition 21** (Vertex-Constrained Matching Instance). *Given an instance $G = (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ as in Definition 6 and two non-negative weights $\vec{c} = (c^{(0)}, c^{(1)}) \in \mathbb{R}^{\mathbb{B}}$, we use $G^{(\vec{c})}$ to denote the instance of (fractional) matching on the bipartite graph $(\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F})$ with vertex capacity constraints. For side ι and $i \in \mathcal{I}^{(\iota)}$, the capacity constraint at vertex i is $c^{(\iota)} \cdot w(i)$.*

LP Interpretation. The maximum (fractional) matching problem instance $G^{(\vec{c})}$ is captured by the following linear program.

$$\begin{aligned} \mathsf{LP}(G^{(\vec{c})}) \qquad \max \quad & \sum_{i \sim j} x_{ij} \\ \text{s.t.} \quad & \sum_{j' : i \sim j'} x_{ij'} \leq c^{(0)} \cdot w(i), \quad \forall i \in \mathcal{I}^{(0)} \\ & \sum_{i' : i' \sim j} x_{i'j} \leq c^{(1)} \cdot w(j), \quad \forall j \in \mathcal{I}^{(1)} \\ & x_{ij} \geq 0, \quad \forall i \in \mathcal{I}^{(0)} \sim j \in \mathcal{I}^{(1)} \end{aligned}$$

We will also consider the dual in our analysis:

$$\begin{aligned} \mathsf{DP}(G^{(\vec{c})}) \qquad \min \quad & c^{(0)} \sum_{i \in \mathcal{I}^{(0)}} w(i) \cdot \lambda_i + c^{(1)} \sum_{j \in \mathcal{I}^{(1)}} w(j) \cdot \lambda_j \\ \text{s.t.} \quad & \lambda_i + \lambda_j \geq 1, \quad \forall i \in \mathcal{I}^{(0)} \sim j \in \mathcal{I}^{(1)} \\ & \lambda_i \geq 0, \quad \forall i \in \mathcal{I}^{(0)} \cup \mathcal{I}^{(1)} \end{aligned}$$

▶ **Definition 22** (Fractional Matching Induced by Refinement Pair). *Given an instance* $G = (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ *and a non-negative weight pair* $\vec{c} = (c^{(0)}, c^{(1)})$*, a refinement pair* $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$*, where* $\alpha^{(\iota)}$ *is a refinement on vertex weights in* $\mathcal{I}^{(\iota)}$*, induces a feasible fractional matching for* $G^{(\vec{c})}$ *that is denoted as follows:*

$\vec{c} \bullet \vec{\alpha}(ij) := \min\{c^{(0)} \cdot \alpha^{(0)}(ij), c^{(1)} \cdot \alpha^{(1)}(ij)\}$*, for all* $i \sim j$*.*

▶ Remark 23. The feasibility of the fractional matching $\vec{c} \bullet \vec{\alpha}$ to the instance $G^{(\vec{c})}$ follows directly because each $\alpha^{(\iota)}$ is a refinement of the vertex weights in $\mathcal{I}^{(\iota)}$.

▶ **Definition 24** (Universal Refinement Pair for Matching). *Given an instance* $G = (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ *and* $\tau \in [0, 1]$*, a refinement pair* $\vec{\alpha}$ *is* $(1-\tau)$*-universal for matching in* G*, if for any non-negative weight pair* $\vec{c}$*, the solution* $\vec{c} \bullet \vec{\alpha}$ *achieves* $(1-\tau)$*-approximation for the maximum matching problem on* $G^{(\vec{c})}$*.*

For $\tau = 0$*, we simply say* $\vec{\alpha}$ *is universal (for matching in* G*).*

Intuition for Universal Refinement Pair. Besides being a technical tool for later sections, the notion of a universal refinement pair is interesting in terms of understanding the structure of vertex-constrained bipartite matching. Suppose it is known that the vertex weights on each side are correlated and may vary but follow some fixed relative ratios among themselves. The idea of a universal refinement pair is that some pre-computation can be performed such that when the vertex weights on each side change proportionally, the matching can be updated quickly to get a (nearly) optimal solution without computing from scratch.

Observe that the density decomposition in Definition 16 does not change if the vertex weights on one side are multiplied by the same scalar. Informally, the decomposition identifies different levels of "congestion" when a matching is performed between vertices on the two sides. The following result formalizes the connection between the density decomposition and universal refinement pairs.

▶ **Lemma 25** (Local Maximin Achieves Universal for Matching). *Suppose in an instance* G*, for side* $\iota \in \mathbb{B}$*, the refinement* $\alpha^{(\iota)}$ *on vertex weights in* $\mathcal{I}^{(\iota)}$ *is locally maximin, and the refinement* $\alpha^{(\bar{\iota})}$ *is the (unique) proportional response to* $\alpha^{(\iota)}$*. Then, the refinement pair* $(\alpha^{(\iota)}, \alpha^{(\bar{\iota})})$ *is universal for matching in* G*.*

Moreover, suppose in the density decomposition, for side ι*,* $\rho_*^{(\iota)}$ *is the payload density vector and* $p_*^{(\iota)}$ *is the payload vector. Then, for any* $c = (c^{(\iota)}, c^{(\bar{\iota})})$*, the weight of the maximum matching in* $G^{(\vec{c})}$ *is:*

$\sum_{j \in \mathcal{I}^{(\iota)}} \min\{\frac{c^{(\iota)}}{\rho_*^{(\iota)}(j)}, c^{(\bar{\iota})}\} \cdot p_*^{(\iota)}(j)$.

Proof. By Lemma 19, $\alpha^{(\iota)}$ and $\alpha^{(\bar{\iota})}$ are proportional responses to each other and both are locally maximin. Fix some $\vec{c} = (c^{(0)}, c^{(1)})$ and we show that $\vec{c} \bullet \vec{\alpha}$ is an optimal solution to $G^{(\vec{c})}$.

Let $\{(S_\ell^{(0)}, S_\ell^{(1)}\}_{\ell \geq 1}$ be the density decomposition with $\mathcal{I}^{(1)}$ being the ground set. (Recall that the density decomposition is symmetric between $\mathcal{I}^{(0)}$ and $\mathcal{I}^{(1)}$, where the forward or backward order of the sequence depends on which side is the ground set.)

From Fact 18, recall that $\alpha^{(0)}(ij)$ and $\alpha^{(1)}(ij)$ are non-zero only if there exists some ℓ such that $(i, j) \in \mathcal{F}_\ell := \mathcal{F} \cap (S_\ell^{(0)} \times S_\ell^{(1)})$.

Let $L^{(1)} := \{\ell : c^{(1)} \cdot w(S_\ell^{(1)}) \leq c^{(0)} \cdot w(S_\ell^{(0)})\}$ and $L^{(0)} := \{\ell : c^{(1)} \cdot w(S_\ell^{(1)}) > c^{(0)} \cdot w(S_\ell^{(0)})\}$.

Observe that for $i \in S_\ell^{(1)}$, $\rho_*^{(1)}(i) = \frac{w(S_\ell^{(0)})}{w(S_\ell^{(1)})}$. Therefore, for all $\ell \in L^{(1)}$ and $\ell' \in L^{(0)}$, $\ell < \ell'$.

Moreover, for all $\ell < \ell'$, for all $i \in S_\ell^{(0)}$ and $j \in S_{\ell'}^{(1)}$, i and j are not neighbors in $\mathcal{F}$, from the definition of the density decomposition.

Hence, we can construct a feasible dual solution λ to $\mathsf{DP}(G^{(\vec{c})})$ as follows.

- For $\ell \in L^{(1)}$: for $i \in S_\ell^{(0)}$, $\lambda_i = 0$; for $j \in S_\ell^{(1)}$, $\lambda_j = 1$.
- For $\ell \in L^{(0)}$: for $i \in S_\ell^{(0)}$, $\lambda_i = 1$; for $j \in S_\ell^{(1)}$, $\lambda_j = 0$.

The dual feasibility of λ holds because if $i \in \mathcal{I}^{(0)}$ and $j \in \mathcal{I}^{(1)}$ such that $\lambda_i = \lambda_j = 0$, then it must be the case that i and j are not neighbors in $\mathcal{F}$.

Next, we check that the dual solution λ has the same objective value as the primal solution $\vec{c} \bullet \vec{\alpha}$ to $\mathsf{LP}(G^{\vec{c}})$.

Observe that for $\ell \in L^{(1)}$, for $i \in S_\ell^{(0)} \sim j \in S_\ell^{(1)}$, we have

$c^{(1)} \cdot \alpha^{(1)}(ij) = c^{(1)} \cdot \alpha^{(0)}(ij) \cdot \frac{w(S_\ell^{(1)})}{w(S_\ell^{(0)})} \leq c^{(0)} \cdot \alpha^{(0)}(ij)$.

Hence, $c^{(1)} \sum_{j \in S_\ell^{(1)}} w(j) \cdot \lambda_j = c^{(1)} \sum_{(i,j) \in \mathcal{F}_\ell} \alpha^{(1)}(ij) = \sum_{(i,j) \in \mathcal{F}_\ell} \vec{c} \bullet \vec{\alpha}(ij)$, where the first equality holds because $\alpha^{(1)}$ restricted to $\mathcal{F}_\ell$ is a refinement of vertex weights in $S_\ell^{(1)}$.

Similarly, for $\ell \in L^{(0)}$, we have $c^{(0)} \sum_{i \in S_\ell^{(0)}} w(i) \cdot \lambda_i = \sum_{(i,j) \in \mathcal{F}_\ell} \vec{c} \bullet \vec{\alpha}(ij)$.

Therefore, the feasible primal solution $\vec{c} \bullet \vec{\alpha}$ and the feasible dual solution λ have the same objective value, which implies that both are optimal.

Finally, we compute the weight of the maximum matching in $G^{(\vec{c})}$. For simpler notation, it is understood that in each sum below, we include only pairs (i,j) such that both $\alpha^{(0)}(ij)$ and $\alpha^{(1)}(ij)$ are non-zero.

$$
\begin{aligned}
&\sum_{(i,j) \in (\mathcal{I}^{(\bar{\iota})} \times \mathcal{I}^{(\iota)}) \cap \mathcal{F} : \alpha(ij) > 0} \min\{c^{(\bar{\iota})} \cdot \alpha^{(\bar{\iota})}(ij), c^{(\iota)} \cdot \alpha^{(\iota)}(ij)\} \\
&= \sum_{(i,j)} \min\{c^{(\bar{\iota})}, c^{(\iota)} \cdot \frac{\alpha^{(\iota)}(ij)}{\alpha^{(\bar{\iota})}(ij)}\} \cdot \alpha^{(\bar{\iota})}(ij) \\
&= \sum_{(i,j)} \min\{c^{(\bar{\iota})}, c^{(\iota)} \cdot \frac{1}{\rho_*^{(\iota)}(j)}\} \cdot \alpha^{(\bar{\iota})}(ij) \\
&= \sum_{j \in \mathcal{I}^{(\iota)}} \min\{c^{(\bar{\iota})}, \frac{c^{(\iota)}}{\rho_*^{(\iota)}(j)}\} \sum_{i : i \sim j} \alpha^{(\bar{\iota})}(ij) \\
&= \sum_{j \in \mathcal{I}^{(\iota)}} \min\{\frac{c^{(\iota)}}{\rho_*^{(\iota)}(j)}, c^{(\bar{\iota})}\} \cdot p_*^{(\iota)}(j).
\end{aligned}
$$

◀

5 Universally Closest Distribution Refinements Problem

In this section, we show that when an instance is interpreted as two distributions on two sample spaces imposed with a neighboring relation, a refinement pair satisfying Goal 3 is an optimal solution to the *universally closest distribution refinements problem*.

Distribution Instance. In Definition 6, an input is a *distribution instance*, if, in addition, we require that for each side $\iota \in \mathbb{B}$, the vertex weights satisfies $\sum_{i \in \mathcal{I}^{(\iota)}} w^{(\iota)}(i) = 1$, i.e., $w^{(\iota)}$ is a probability distribution on $\mathcal{I}^{(\iota)}$.

Observe that given a distribution instance $G = (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$, for each side $\iota \in \mathbb{B}$, a refinement $\alpha^{(\iota)}$ of the vertex weights $w^{(\iota)}$ is a probability distribution on $\mathcal{F}$. A high-level problem is to find a refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ such that the distributions $\alpha^{(0)}$ and $\alpha^{(1)}$ on $\mathcal{F}$ are as "close" to each other as possible.

Divergence Notion. Given two distributions P and Q on the same sample space Ω, a notion of *divergence* $\mathsf{D}(P\|Q)$ measures how close two distributions are, where a smaller value typically means that the two distributions are closer. An example is the total variation distance $\mathsf{D}_{\mathrm{TV}}(P\|Q) := \sup_{E\subseteq\Omega} |P(E) - Q(E)|$. However, note that in general, a divergence needs not be symmetric, i.e., it is possible that $\mathsf{D}(P\|Q) \neq \mathsf{D}(Q\|P)$. An example of a non-symmetric divergence notion is $\mathsf{D}_{\mathrm{KL}}(P\|Q) = \sum_{\omega\in\Omega} p_\omega \ln \frac{p_\omega}{q_\omega}$.

▶ **Definition 26** (Closest Refinement Pair). *Given a distribution instance $G = (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ and a divergence notion D, a refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ (as in Definition 8) is closest (with respect to D) if, the pair attains the minimum $\mathsf{D}(\alpha^{(0)}||\alpha^{(1)})$ among all refinement pairs, whose value we denote as $\mathsf{D}^*(G)$.*

▶ Remark 27. Since a divergence is typically continuous and the collection of refinement pairs forms a compact set, the minimum is attainable in such a case.

However, note that since D is not necessarily symmetric, from Definition 26 alone, it is not clear if a pair minimizing $\mathsf{D}(\alpha^{(0)}||\alpha^{(1)})$ would also minimize $\mathsf{D}(\alpha^{(1)}||\alpha^{(0)})$.

▶ **Definition 28** (Universally Closest Refinement Pair). *Given a distribution instance $G = (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ and a collection $\mathcal{D}$ of divergence notions, a refinement pair $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ is universally closest (with respect to $\mathcal{D}$) if, for all $\mathsf{D} \in \mathcal{D}$, $\mathsf{D}(\alpha^{(0)}||\alpha^{(1)}) = \mathsf{D}^*(G)$.*

5.1 Class of Hockey-Stick Divergences

We first consider the class of hockey-stick divergences.

▶ **Definition 29** (Hockey-Stick Divergence). *Given distributions P and Q on the same sample space Ω and $\gamma \geq 0$, the (reversed[6]) hockey-stick divergence is defined as*

$\mathsf{D}_\gamma(P\|Q) := \sup_{S\subseteq\Omega} Q(S) - \gamma \cdot P(S)$.

▶ Remark 30. The hockey-stick divergence is related to the well-known (ϵ, δ)-differential privacy inequality. Specifically, $\mathsf{D}_{e^\epsilon}(P\|Q) \leq \delta$ *iff* for all subsets $S \subseteq \Omega$,

$Q(S) \leq e^\epsilon \cdot P(S) + \delta$.

To express the other direction of the inequality, i.e., $\mathsf{D}_{e^\epsilon}(Q\|P) \leq \delta$, we could consider another parameter $\widehat{\gamma} \geq 0$ and keep the order of arguments in $\mathsf{D}_{\widehat{\gamma}}(P\|Q)$. Specifically, by considering the complement of events S in the above inequality, we can deduce that: $\mathsf{D}_{e^\epsilon}(Q\|P) \leq \delta$ *iff* $\mathsf{D}_{e^{-\epsilon}}(P\|Q) \leq 1 - e^{-\epsilon}(1-\delta)$.

We consider universal closest distribution refinements with respect to the class of hockey-stick divergences $\mathcal{D}_{\mathrm{HS}} := \{\mathsf{D}_\gamma : \gamma \geq 0\}$.

The following lemma shows that the hockey-stick divergence is closely related to the matching instance defined in Definition 21.

▶ **Lemma 31** (Hockey-Stick Divergence and Matching). *Suppose $G = (\mathcal{I}^{(0)}, \mathcal{I}^{(1)}; \mathcal{F}; w)$ is a distribution instance and $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ is a refinement pair. For $\gamma \geq 0$, consider the pair of weights $\vec{c} := (c^{(0)} = \gamma, c^{(1)} = 1)$.*

Then, the weight of the fractional matching $\vec{c} \bullet \vec{\alpha}$ in the matching instance $G^{(\vec{c})}$ is exactly $1 - \mathsf{D}_\gamma(\alpha^{(0)}\|\alpha^{(1)})$.

In order words, finding a closest refinement pair for the divergence D_γ is equivalent to finding a maximum matching in $G^{(\vec{c})}$.

[6] In the literature, the hockey-stick divergence $\widetilde{\mathsf{D}}_\gamma$ is defined with the roles of P and Q interchanged: $\widetilde{\mathsf{D}}_\gamma(P\|Q) = \mathsf{D}_\gamma(Q\|P)$. We change the convention to make the notation consistent when we consider power functions later.

Proof. Let $S := \{f \in \mathcal{F} : \alpha^{(1)}(f) \geq \gamma \cdot \alpha^{(0)}(f)\}$.
Observe that $\mathsf{D}_\gamma(\alpha^{(0)} \| \alpha^{(1)}) = \sum_{f \in S}(\alpha^{(1)}(f) - \gamma \cdot \alpha^{(0)}(f))$.
Finally, the weight of the matching $\vec{c} \bullet \vec{\alpha}$ is:

$$\sum_{f \in \mathcal{F}} \min\{\gamma \cdot \alpha^{(0)}(f), \alpha^{(1)}(f)\} = \sum_{f \in S} \gamma \cdot \alpha^{(0)}(f) + \sum_{f \in \mathcal{F} \setminus S} \alpha^{(1)}(f)$$
$$= 1 - \sum_{f \in S}(\alpha^{(1)}(f) - \gamma \cdot \alpha^{(0)}(f)) = 1 - \mathsf{D}_\gamma(\alpha^{(0)} \| \alpha^{(1)}),$$

as required. ◀

▶ **Theorem 32** (Locally Maximin Pair is Closest for $\mathcal{D}_{\mathrm{HS}}$)**.** *Suppose in a distribution instance G, $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ is a distribution refinement pair that is locally maximin and proportional response to each other. Then, $\vec{\alpha}$ is universally closest with respect to the class $\mathcal{D}_{\mathrm{HS}}$ of hockey-stick divergences.*

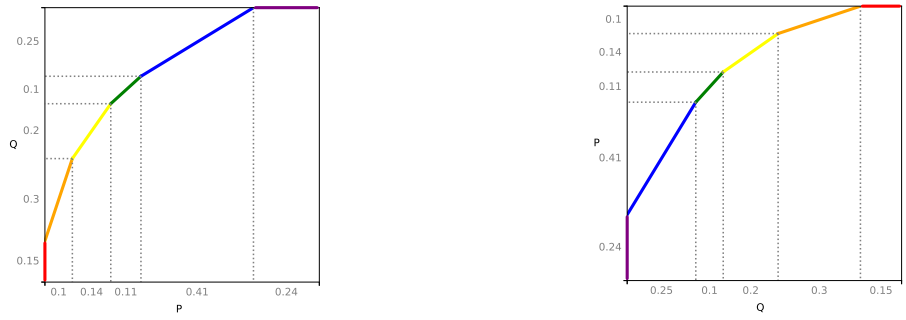
Proof. The statement is a direct consequence of Lemmas 25 and 31. ◀

5.2 Class of Data Processing Divergences

Extending Theorem 32, we show that a locally maximin pair is actually the closest with respect to a wide class of divergences. In fact, for any reasonable usage of divergence, it is intuitive that taking a partial view of a pair of objects should not increase the divergence between them. This is formally captured by the *data processing inequality*.

▶ **Definition 33** (Data Processing Inequality)**.** *A divergence notion* D *satisfies the data processing inequality if given any two distributions P and Q on the sample space Ω and any function $\varphi : \Omega \to \widehat{\Omega}$, the induced distributions $\varphi(P)$ and $\varphi(Q)$ on $\widehat{\Omega}$ satisfy the monotone property:*

$$\mathsf{D}(\varphi(P) \| \varphi(Q)) \leq \mathsf{D}(P \| Q).$$



We use $\mathcal{D}_{\mathrm{DPI}}$ to denote the class of divergences satisfying the data processing inequality.

It is known that all divergences in $\mathcal{D}_{\mathrm{DPI}}$ between two distributions P and Q can be recovered from the power function between them. Recall that in this work, we focus on finite sample spaces; see Figure 1 for an example. It is known that power functions have a fractional knapsack interpretation [25].

▶ **Definition 34** (Power Function)**.** *Suppose P and Q are distributions on the same sample space Ω.*

- *For a discrete sample space Ω, the power function* $\mathsf{Pow}(P \| Q) : [0,1] \to [0,1]$ *can be defined in terms of the* fractional knapsack problem.
  Given a collection Ω of items, suppose $\omega \in \Omega$ has weight $P(\omega)$ and value $Q(\omega)$. Then, given $x \in [0,1]$, $\mathsf{Pow}(P \| Q)(x)$ is the maximum value attained with weight capacity constraint x, where items may be taken fractionally.
- *For a continuous sample space Ω, given $x \in [0,1]$, $\mathsf{Pow}(P \| Q)(x)$ is the supremum of $Q(S)$ over measurable subsets $S \subseteq \Omega$ satisfying $P(S) = x$.*

In the literature (see [16] for instance), the tradeoff function $\mathsf{T}(P \| Q) := 1 - \mathsf{Pow}(P \| Q)$, which has essentially equivalent mathematical properties, has also been considered. However, power functions have the same notation interpretation as divergences in the sense that

(a) $g = \mathsf{Pow}(P||Q)$. **(b)** $\widehat{g} = \mathsf{Pow}(Q\|P) = \mathfrak{R}(\mathsf{Pow}(P\|Q))$.

Figure 1 Consider a sample space Ω with 6 elements indicated with different rainbow colors. Two distributions on Ω are given by the arrays: $P = [0, 0.1, 0.14, 0.11, 0.41, 0.24]$ and $Q = [0.15, 0.3, 0.2, 0.1, 0.25, 0]$, where the elements $\omega \in \Omega$ are sorted in increasing order of the ratio $\frac{Q(\omega)}{P(\omega)}$. The left figure shows the power curve $g = \mathsf{Pow}(P||Q)$, and the right figure shows $\widehat{g} = \mathsf{Pow}(Q\|P)$ which is the reflection of g about the line $y = 1 - x$.

"smaller" means "closer" distributions. In fact, Vadhan and Zhang [38] defined an abstract concept of *generalized probability distance* (with the tradeoff function as the main example) such that the notation agrees with this interpretation. We recap some well-known properties of power functions.

▶ **Fact 35** (Valid power functions [16, Proposition 2.2]). *Suppose $g : [0,1] \to [0,1]$ is a function. Then, there exist distributions X and Y such that $\mathsf{Pow}(X\|Y) = g$ iff g is continuous, concave and $g(x) \geq x$ for all $x \in [0,1]$.*

Partial Order on Power Functions. We consider a partial order on power functions. Given such functions g_1 and g_2, we denote $g_1 \preceq g_2$ *iff* for all $x \in [0,1]$, $g_1(x) \leq g_2(x)$.

We next state formally how a divergence satisfying Definition 33 can be recovered from the power function.

▶ **Fact 36** (Recovering Divergence From Power Function [16, Proposition B.1]). *For any divergence $\mathsf{D} \in \mathcal{D}_{\mathrm{DPI}}$, there exists a functional $\ell_{\mathsf{D}} : [0,1]^{[0,1]} \to \mathbb{R}$ such that for any distributions P and Q on the same sample space, $\mathsf{D}(P\|Q) = \ell_{\mathsf{D}}(\mathsf{Pow}(P\|Q))$.*

Moreover, if $g_1 \preceq g_2$, then $\ell_{\mathsf{D}}(g_1) \leq \ell_{\mathsf{D}}(g_2)$.

The following is the main result of this section, which states that a locally maximin pair essentially solves the closest distribution refinement problem optimally in the most general sense.

▶ **Theorem 37** (Locally Maximin Pair Gives Minimal Power Function). *Suppose in a distribution instance G, $\vec{\alpha} = (\alpha^{(0)}, \alpha^{(1)})$ is a distribution refinement pair that is locally maximin and proportional response to each other. Then, the power function $g_\dagger$ between any other distribution refinement pair of G satisfies $\mathsf{Pow}(\alpha^{(0)}\|\alpha^{(1)}) \preceq g_\dagger$. Consequently, any such locally maximin pair gives rise to the same power function, and we denote $\mathsf{Pow}^*(G) = \mathsf{Pow}(\alpha^{(0)}\|\alpha^{(1)})$.*

From Fact 36, this implies that $\vec{\alpha}$ is a universally closest refinement pair with respect to $\mathcal{D}_{\mathrm{DPI}}$.

▶ Remark 38. Observe that given any $\mathsf{D} \in \mathcal{D}_{\mathrm{DPI}}$ and any strictly increasing function $\phi : \mathbb{R} \to \mathbb{R}$, we still have $\phi(\mathsf{D}(\cdot\|\cdot)) \in \mathcal{D}_{\mathrm{DPI}}$. Since any deviation from the correct answer can be arbitrarily magnified by ϕ, it is difficult to give any meaningful approximation guarantee on the value of a general divergence in $\mathcal{D}_{\mathrm{DPI}}$.

We prove Theorem 37 by analyzing the relationship between hockey-stick divergence and power function, and extend the result from Theorem 32. Similar to convex functions, we also consider the notion of subgradient for power functions.

▶ **Definition 39** (Subgradient). *Suppose $g : [0,1] \to [0,1]$ is a power function and $x \in [0,1]$. Then, the subgradient of g at x is defined as the collection $\partial g(x)$ of real numbers satisfying:*

$\gamma \in \partial g(x)$ iff *for all* $y \in [0,1]$, $g(x) + \gamma \cdot (y - x) \geq g(y)$.

In other words, the line segment with slope γ touching the curve g at x never goes below the curve.

The following is a special case of Fact 36, and describes explicitly how a hockey-stick divergence is recovered from a power function. See Figure 2 for an illustration.

▶ **Fact 40** (Recovering Hockey-Stick Divergence From Power Function). *Suppose P and Q are distributions on the same sample space Ω, where $g = \mathsf{Pow}(P\|Q)$ is the power function between them. Then, for any $\gamma \geq 0$, there exists $x \in [0,1]$ such that $\gamma \in \partial g(x)$ and $\mathsf{D}_\gamma(P\|Q) = g(x) - \gamma x$.*

In other words, one can find a line segment with slope γ touching the curve g and the y-intercept of the line will give $\mathsf{D}_\gamma(P\|Q)$.

Proof. The result should be standard, but we include a short proof for completeness. One can imagine a line segment with slope γ starting high above and gradually being lowered until touching the curve g at some $x \in [0,1]$. Observe that the line segment may touch the curve at more than 1 point, in which case we take x to be the infimum.

We partition the sample space Ω into $S_1 := \{\omega \in \Omega : Q(\omega) > \gamma \cdot P(\omega)\}$ and $S_2 := \Omega \setminus S_1$. Observe that $P(S_1) = x$ and $g(x) = Q(S_1)$.

Then, it follows that $\mathsf{D}_\gamma(P\|Q) = Q(S_1) - \gamma \cdot P(S_1) = g(x) - \gamma x$, as required. ◀

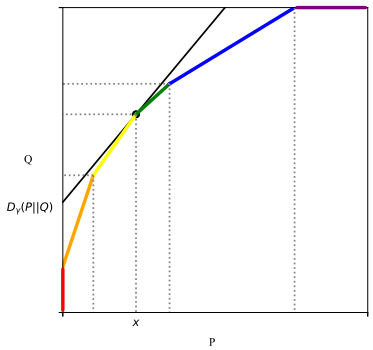


Figure 2 Using the same example in Figure 1, consider a line segment with slope $\gamma = 1.2$ touching the curve g at x. In this case, the red, orange, and yellow elements ω to the left of point x satisfy $\frac{Q(\omega)}{P(\omega)} > 1.2$.

Proof of Theorem 37. Suppose $g = \mathsf{Pow}(\alpha^{(0)}\|\alpha^{(1)})$ is the power function between the given locally maximin pair $\vec{\alpha}$. For the sake of contradiction, suppose some other refinement pair $\vec{\alpha}_\dagger$ produces the power function $g_\dagger$ such that for some $x \in [0,1]$, $g(x) > g_\dagger(x)$.

Fix some $\gamma \in \partial g_\dagger(x)$ and consider the line segment $\ell_\dagger$ with slope γ touching curve $g_\dagger$ at x. By Fact 40, the hockey-stick divergence $\mathsf{D}_\gamma(\vec{\alpha}_\dagger)$ is the y-intercept of $\ell_\dagger$.

However, since $g(x) > g_\dagger(x)$, to find a line segment with slope γ touching curve g, we must move $\ell_\dagger$ strictly upwards. This implies that $\mathsf{D}_\gamma(\vec{\alpha}) > \mathsf{D}_\gamma(\vec{\alpha}_\dagger)$, contradicting Theorem 32 which states that $\vec{\alpha}$ is universally closest with respect to $\mathcal{D}_{\text{HS}}$. ◀

Abstract

Matrix completion tackles the task of predicting missing values in a low-rank matrix based on a sparse set of observed entries. It is often assumed that the observation pattern is generated uniformly at random or has a very specific structure tuned to a given algorithm. There is still a gap in our understanding when it comes to arbitrary sampling patterns. Given an arbitrary sampling pattern, we introduce a matrix completion algorithm based on network flows in the bipartite graph induced by the observation pattern. For additive matrices, we show that the electrical flow is optimal, and we establish error upper bounds customized to each entry as a function of the observation set, along with matching minimax lower bounds. Our results show that the minimax squared error for recovery of a particular entry in the matrix is proportional to the effective resistance of the corresponding edge in the graph. Furthermore, we show that the electrical flow estimator is equivalent to the least squares estimator. We apply our estimator to the two-way fixed effects model and show that it enables us to accurately infer individual causal effects and the unit-specific and time-specific confounders. For rank-1 matrices, we use edge-disjoint paths to form an estimator that achieves minimax optimal estimation when the sampling is sufficiently dense. Our discovery introduces a new family of estimators parametrized by network flows, which provide a fine-grained and intuitive understanding of the impact of the given sampling pattern on the difficulty of estimation at an entry-specific level. This graph-based approach allows us to quantify the inherent complexity of matrix completion for individual entries, rather than relying solely on global measures of performance.

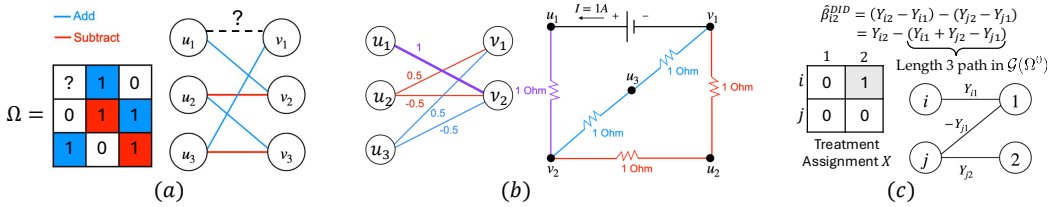

Figure 1 (a) Example of transforming a matrix observation pattern to a bipartite graph. Each a path from u_1 to v_1 defines an unbiased estimator for the ? entry. (b) Example of a network flow, in particular the electrical flow that corresponds to the optimal unbiased estimator. This flow sends a unit of current from u_1 to v_1 on the electrical network constructed by treating each edge in the graph as a unit resistor, thus putting high weight on edges that appear on multiple paths. (c) Equivalence of Difference-in-differences estimators to flow estimators constrained to length-3 paths.

Abstract

We present a simple method based on a variant of Hölder's inequality to lower-bound the trace norm of Boolean matrices. As the main result, we obtain an exponential separation between the randomized decision tree depth and the spectral norm (i.e. the Fourier L_1-norm) of a Boolean function. This answers an open question of Cheung, Hatami, Hosseini and Shirley (CCC 2023). As immediate consequences, we obtain the following results.

- We give an exponential separation between the logarithm of the randomized and the deterministic parity decision tree *size*. This is in sharp contrast with the standard binary decision tree setting where the logarithms of randomized and deterministic decision tree size are essentially polynomially related, as shown recently by Chattopadhyay, Dahiya, Mande, Radhakrishnan, and Sanyal (STOC 2023).
- We give an exponential separation between the approximate and the exact spectral norm for Boolean functions.
- We give an exponential separation for XOR functions between the deterministic communication complexity with oracle access to Equality function (D^{EQ}) and randomized communication complexity. Previously, such a separation was known for general Boolean matrices by Chattopadhyay, Lovett, and Vinyals (CCC 2019) using the Integer Inner Product (`IIP`) function.
- Finally, our method gives an elementary and short proof for the mentioned exponential D^{EQ} lower bound of Chattopadhyay, Lovett, and Vinyals for Integer Inner Product (`IIP`).

1 Introduction

We start by recalling two fundamental notions related to the complexities of Boolean functions: the *randomized parity decision tree complexity* and the *spectral norms*.

A *parity decision tree* (PDT) for a Boolean function $f : \mathbb{F}_2^n \to \{0,1\}$ is similar to a standard decision tree with the following strengthened query power. Instead of a single variable, each internal node can query the parity (sum over $\mathbb{F}_2$) of any subset of variables, e.g., $x_1 \oplus x_5 \oplus x_6$. The *parity decision tree complexity* of f, denoted by $\mathsf{PDT}_{\mathrm{depth}}(f)$, is the smallest depth of a PDT that outputs the correct value of $f(x)$ on every input x. A *randomized parity decision tree* (RPDT) of depth at most d is a probability distribution over PDTs of depth at most d. It computes f with error ϵ if, for every input x, the RPDT outputs $f(x)$ with probability at least $1-\epsilon$. The *randomized parity decision tree complexity*, denoted by $\mathsf{RPDT}_{\mathrm{depth}}(f)$, is the smallest depth of an RPDT computing f with error $\epsilon = 1/3$.

Parity decision trees are closely related to the Fourier expansions of Boolean functions. The *spectral norm* (also known as *algebra norm*) of a function $f : \mathbb{F}_2^n \to \mathbb{R}$, denoted by $\|\widehat{f}\|_1$, is the sum of the absolute values of the Fourier coefficients.

It is easy to see from the Fourier expansion of a PDT that every Boolean function $f : \mathbb{F}_2^n \to \{0,1\}$ satisfies $\log \|\widehat{f}\|_1 \leq \mathsf{PDT}_{\mathrm{depth}}(f)$. The randomized counterpart of this inequality does not hold as illustrated by h, the indicator function of the standard basis vectors $\{e_1, \ldots, e_n\}$: as observed in [14], $\mathsf{RPDT}_{\mathrm{depth}}(h) = O(1)$, but $\log \|\widehat{h}\|_1 = \Theta(\log n)$. Nonetheless, this still leaves the possibility of $\log \|\widehat{f}\|_1 = \widetilde{O}(\mathsf{RPDT}_{\mathrm{depth}}(f))$ open, where $\widetilde{O}(\cdot)$ hides polylogarithmic dependencies on n. Cheung et al. [8] specifically asked whether such a relation could hold, which if confirmed, would have established the stronger lower bound on $\mathsf{RPDT}_{\mathrm{depth}}$.

The main result of this work gives an example in which $\log \|\widehat{f}\|_1$ is exponential in $\mathsf{RPDT}_{\mathrm{depth}}(f)$, answering the question by [8] in the negative.

▶ **Theorem 1** (Main theorem). *There exists a function $f : \mathbb{F}_2^n \to \{0,1\}$ with*

$$\mathsf{RPDT}_{\mathrm{depth}}(f) = O(\log n) \quad \textit{and} \quad \log \|\widehat{f}\|_1 = \Omega(n).$$

In the converse direction, the quadratic gap $\mathsf{RPDT}_{\mathrm{depth}}(f) = O(\|\widehat{f}\|_1^2)$ holds for every Boolean function (see e.g. [14, Lemma 2.7]). Chattopadhyay, Mande, and Sherif [5] proved that the sink function SINK satisfies $\mathsf{RPDT}_{\mathrm{depth}}(\mathsf{SINK}) = \Omega(\|\widehat{\mathsf{SINK}}\|_1)$. This result and Theorem 1 together demonstrate that the measures $\log \|\widehat{f}\|_1$ and $\mathsf{RPDT}_{\mathrm{depth}}(f)$ are not polynomially related in both ways.

The proof technique used in the main theorem involves an application of Hölder's inequality with carefully-chosen parameters (see Section 3) that allow for a combinatorial interpretation of the problem. This framework is useful not only for the question considered above but also in communication complexity, where we will use the Hölder's inequality technique to simplify the proofs of existing lower bounds. For the rest of this section, we will discuss applications of both the proof technique and of the main theorem itself.

1.1 Communication Complexity: The Power of Oracle Access to Equality

Arguably the most well-known communication problem is the Equality function EQ, in which the two parties compare if their inputs are identical. In the model of *public-coin randomized communication*, two parties are given a publicly accessible random string and are

allowed to make errors with probability bounded away from 1/2. It is an elementary result that $\text{EQ} : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ has a randomized protocol requiring only $O(1)$ bits of communication, while any deterministic protocol of EQ requires $n+1$ bits of communication.

A natural question would be whether Equality fully captures the power of randomness in communication. A formal formulation of the question is to compare the relative power of randomized protocols and *deterministic protocols with oracle access to* Equality or, in short, D^{EQ} protocols. A D^{EQ} protocol performs communications as usual; in addition, the parties are given access to an oracle that computes Equality function, and each oracle call is charged at a cost of one bit. The seminal work by Chattopadhyay, Lovett and Vinyals [4] considered this question and proved an exponential separation between the D^{EQ} complexity and randomized communication complexity (denoted as R) of the *Integer Inner Product* function ($\texttt{IIP}$) in dimension at least 6.

For a chosen dimension k and parameter n, the Boolean matrix $\texttt{IIP}_k^{(n)} : \{-2^n, \ldots, 2^n\}^k \times \{-2^n, \ldots, 2^n\}^k \to \{0,1\}$ is defined by

$$\texttt{IIP}_k[(x_1, \ldots, x_k), (y_1, \ldots, y_k)] = \begin{cases} 1 & \text{if } \sum_{i=1}^k x_i y_i = 0 \\ 0 & \text{otherwise} \end{cases}.$$

For this communication problem, each player holds a $\Theta(kn)$-bit input. As we only consider the case when $k = O(1)$, we treat $\texttt{IIP}_k^{(n)}$ as a $\Theta(n)$-bit communication problem.

Chattopadhyay, Lovett, and Vinyals presented a (one-way) randomized protocol for $\texttt{IIP}_k^{(n)}$ of cost $O(k \log n)$. For the lower bound, they introduced a lower bound technique which we call *relative area method* (see Theorem 13), and showed that no D^{EQ} protocol could compute the function with fewer than $\Omega(n)$ bits of communication.

▶ **Theorem 2** ([4]). *For constant $k \geq 6$, $\mathsf{R}\left(\texttt{IIP}_k^{(n)}\right) = O(\log n)$ and $\mathsf{D}^{\mathsf{EQ}}\left(\texttt{IIP}_k^{(n)}\right) = \Omega(n)$.*

In a subsequent work, Cheung et al. [8] obtained a strengthening of Theorem 2 via a different approach of spectral methods. It was shown in [14] that

$$\mathsf{D}^{\mathsf{EQ}}(A) \geq \frac{1}{2} \log \|A\|_{\text{ntr}} \tag{1}$$

for any boolean matrix $A \in \{0,1\}^{m \times n}$, where $\|A\|_{\text{ntr}}$ is the *normalized trace norm* of A with the normalization factor from the matrix dimensions (see Definition 10 for the precise definition).

Cheung et al. [8] observed that for $k \geq 3$, the $\Theta(2^{kn}) \times \Theta(2^{kn})$ matrix $\texttt{IIP}_k^{(n)}$ contains a $2^{4n/3} \times 2^{4n/3}$ *point-line incidence* matrix $\texttt{PL}^{(4n/3)}$ as a submatrix. The matrix $\texttt{PL}^{(n)}$ is defined on the domains $\mathcal{P} = \mathcal{L} = [2^{n/4}] \times [2^{3n/4}] \subseteq \mathbb{Z}^2$, and the entries of $\texttt{PL}^{(n)} : \mathcal{P} \times \mathcal{L} \to \{0,1\}$ are given by

$$\texttt{PL}[(x,x'),(y,y')] = \begin{cases} 1 & \text{if } xy + x' = y' \\ 0 & \text{otherwise} \end{cases}.$$

They proved that the normalized trace norm of $\texttt{PL}^{(n)}$ is exponential in n, which shows that $\mathsf{D}^{\mathsf{EQ}}\left(\texttt{PL}^{(n)}\right) = \Omega(n)$. Since communication complexity does not increase under restriction, this subsequently implies Theorem 2.

▶ **Theorem 3** ([8]). *The $2^m \times 2^m$ Boolean matrix $\texttt{PL}^{(m)}$ satisfies $\|\texttt{PL}^{(m)}\|_{\text{ntr}} = \Omega(2^{m/32})$. Consequently, for $k \geq 3$,*

$$\mathsf{D}^{\mathsf{EQ}}\left(\texttt{IIP}_k^{(n)}\right) \geq \frac{n}{48} + O(1).$$

A common shortcoming of both proofs of Theorem 2 in [4, 8] is their highly technical nature. In Section 4, we give a considerably simplified proof – with improved linear factor on $\mathsf{D}^{\mathsf{EQ}}\left(\mathtt{IIP}_k^{(n)}\right)$ – based on the Hölder's inequality technique. Here, we consider a different submatrix of $\mathtt{IIP}_k$, which is the point-line incidence system $\mathtt{PL}_*$ that proves the optimality of Szemerédi–Trotter theorem. We will provide the precise definition of $\mathtt{PL}_*^{(m)}$ in Section 4.

▶ **Theorem 4** (Improved version of Theorem 3). *The $2^{m+1} \times 2^m$ Boolean matrix $\mathtt{PL}_*^{(m)}$ satisfies $\|\mathtt{PL}_*^{(m)}\|_{\mathrm{ntr}} = \Omega(2^{m/6})$. Consequently, for $k \geq 3$,*

$$\mathsf{D}^{\mathsf{EQ}}\left(\mathtt{IIP}_k^{(n)}\right) \geq \frac{n}{8} + O(1).$$

Nondeterministic communication

When analyzing the power of Equality in communication, another model of interest is *nondeterministic protocols with oracle access to* Equality, or N^{EQ} for short. For the precise definition of the N^{EQ} model, we refer readers to [19]. N^{EQ} and its relationships with related models have been studied previously, both implicitly in [12] and explicitly in [19]. In the latter work, Pitassi, Shirley and Shraibman analyzed the relative area method used by [4] to lower bound $\mathsf{D}^{\mathsf{EQ}}(\mathtt{IIP}_6)$ and showed that the same technique is applicable to N^{EQ} complexity as well. It is not clear that the lower bound technique of [8] on the D^{EQ} complexity of $\mathtt{IIP}_3$ works for N^{EQ}, so prior to this work it was open whether $\mathtt{IIP}_3$ is hard for N^{EQ}. We observe that the analysis in Theorem 4 can be adapted to the relative area method, and therefore yields an almost linear lower bound on $\mathsf{N}^{\mathsf{EQ}}(\mathtt{IIP}_k)$ for every $k \geq 3$.

▶ **Theorem 5.** *For constant $k \geq 3$,*

$$\mathsf{N}^{\mathsf{EQ}}\left(\mathtt{IIP}_k^{(n)}\right) = \Omega\left(\frac{n}{\log n}\right).$$

As far as we know, this method cannot be improved to give a linear lower bound on $\mathsf{N}^{\mathsf{EQ}}(\mathtt{IIP}_3)$. We leave resolving this logarithmic gap as an open question.

XOR-lifts

A related open problem posed in [8] is whether an exponential separation of D^{EQ} and $\mathbb{R}$ holds for an XOR-lift. For a Boolean function $f : \mathbb{F}_2^n \to \{0,1\}$, the XOR-lift $f^{\oplus} : \mathbb{F}_2^n \times \mathbb{F}_2^n \to \{0,1\}$ is defined by $f^{\oplus}(x,y) = f(x \oplus y)$ for each $x, y \in \mathbb{F}_2^n$. It can be verified that $\mathtt{IIP}_k$ is not an XOR-lift, so the D^{EQ}-vs-R separation for the XOR-lift case was open.

The matrix class of XOR-lifts is interesting in complexity theory since many complexity measures of the matrix $f^{\oplus}$ can be related (or even equated) to complexity measures of the Boolean function f. Indeed, the query-to-communication connections allow us to translate the separation question to a purely query-complexity setting. For any Boolean function $f : \mathbb{F}_2^n \to \{0,1\}$, the inequality

$$\mathsf{R}(f^{\oplus}) \leq 2\,\mathsf{RPDT}_{\mathrm{depth}}(f) \tag{2}$$

is evident from the standard simulation of a randomized parity decision tree by a communication protocol. A result of [10] shows that

$$\|f^{\oplus}\|_{\mathrm{ntr}} = \|\widehat{f}\|_1. \tag{3}$$

Immediate from Equations (1)–(3), we obtain the exponential D^{EQ}-vs-R separation for XOR-lifts from Theorem 1.

▶ **Corollary 6.** *There exists a Boolean function* $f : \mathbb{F}_2^n \to \{0,1\}$ *such that its* XOR*-lift* $f^{\oplus}$ *satisfies* $\mathsf{R}(f^{\oplus}) = O(\log n)$ *and* $\mathsf{D}^{\mathsf{EQ}}(f^{\oplus}) = \Omega(n)$.

1.2 Query Complexity: The Power of Randomness

Understanding the power of randomized versus deterministic algorithms is a fundamental problem in complexity theory. Depending on the computational model, this problem varies from fully resolved to forbiddingly out of reach. In the standard decision tree model, it is well known that randomness does not significantly reduce the number of queries. One early result in complexity theory by Nisan [18] showed that a randomized decision tree of depth d computing a Boolean function can be simulated by a deterministic decision tree of depth at most $O(d^3)$. On the other end of the spectrum, the randomized-versus-deterministic problem remains overwhelmingly difficult for Turing Machines.

A generic framework to study the relative powers of two computation models is to study the relations of the complexity classes defined by suitable complexity measures. For the sake of comparisons between measures, we consider the complexity measures normalized to the range $[0, n]$. Given a complexity measure $C(\cdot)$ for a deterministic computation model, $\mathtt{P}$ is defined to be the class of functions $f : \mathbb{F}_2^n \to \{0,1\}$ (more accurately, sequences of functions f_n) such that $C(f) \leq \text{polylog}(n)$. We define the class $\mathtt{BPP}$ similarly for the randomized counterpart of $C(\cdot)$. The inclusion $\mathtt{P} \subseteq \mathtt{BPP}$ for every measure is obvious, so the randomized-versus-deterministic problem amounts to whether the classes $\mathtt{P}$ and $\mathtt{BPP}$ are equal.

We consider the two natural measures for trees, namely depth and logarithmic size (for normalization purposes) and four types of decision trees: (standard) decision tree (DT), parity decision tree (PDT), randomized decision tree (RDT), and randomized parity decision tree (RPDT). This branches into eight complexity measures in concern, and we define the other six measures $\mathsf{DT}_{\text{depth}}$, $\log \mathsf{DT}_{\text{size}}$, $\mathsf{RDT}_{\text{depth}}$, $\log \mathsf{RDT}_{\text{size}}$, $\mathsf{PDT}_{\text{depth}}$ and $\log \mathsf{PDT}_{\text{size}}$ in an analogous manner to $\mathsf{RPDT}_{\text{depth}}$ and $\log \mathsf{RPDT}_{\text{size}}$. Based on the type of queries equipped and the complexity measure, the P-vs-BPP question branches into four pairs for comparison.

Standard decision trees

Nisan [18] showed that $\mathsf{DT}_{\text{depth}}(f) \leq O(\mathsf{RDT}_{\text{depth}}(f)^3)$ in 1988 and settled that $\mathtt{P} = \mathtt{BPP}$ in the depth setting. The question in the size setting remained unsettled for decades until recently Chattopadhyay, Dahiya, Mande, Radhakrishnan, and Sanyal [3] showed that

$$\log \mathsf{DT}_{\text{size}}(f) = O\left(\log^4(\mathsf{RDT}_{\text{size}}(f)) \log^3 n\right),$$

concluding that $\mathtt{P} = \mathtt{BPP}$ in this setting as well.

Parity decision trees

In the depth setting, the two classes $\mathtt{P}$ and $\mathtt{BPP}$ are strongly separated by the simple function of OR. It is well-known that the OR function on n bits satisfies $\mathsf{RPDT}_{\text{depth}}(\mathsf{OR}) = O(1)$ but $\mathsf{PDT}_{\text{depth}}(\mathsf{OR}) = n$, which provides the optimal separation and hence $\mathtt{P} \neq \mathtt{BPP}$ in this setting.

Note that however $\mathsf{PDT}_{\text{size}}(\mathsf{OR}) = O(n)$, so OR does not attest a separation between $\mathtt{P}$ and $\mathtt{BPP}$ in the size setting. Indeed, previous to this work the P-vs-BPP question was unknown in the size setting. As mentioned that $\log \|\widehat{f}\|_1 \leq \mathsf{PDT}_{\text{depth}}(f)$ for every function f, an immediate corollary of Theorem 1 implies that $\mathtt{P} \neq \mathtt{BPP}$ in the size setting for parity decision trees.

▶ **Corollary 7.** *There is a function* $f : \mathbb{F}_2^n \to \{0,1\}$ *such that* $\log \mathsf{RPDT}_{\text{size}}(f) = O(\log n)$, *but* $\log \mathsf{PDT}_{\text{size}}(f) = \Omega(n)$.

In fact, the randomized parity decision tree in our construction is non-adaptive and has a one-sided error, hence we obtain the stronger separation $\mathtt{P} \neq \mathtt{RP}$[1] in the size setting parity decision tree size model. It remains an interesting open problem to determine whether a separation of $O(1)$-vs-$\Omega(n)$ for $\log \mathsf{RPDT}_{\text{size}}$ and $\log \mathsf{PDT}_{\text{size}}$ is possible, as in the case of depth illustrated by the OR function.

▶ **Question 8.** *Is there a boolean function* $f : \mathbb{F}_2^n \to \{0,1\}$ *such that* $\log \mathsf{RPDT}_{\text{size}}(f) = O(1)$, *but* $\log \mathsf{PDT}_{\text{size}}(f) = \Omega(n)$, *or even* $\log \mathsf{PDT}_{\text{size}}(f) = \omega(\log n)$*?*

1.3 Fourier Analysis: Approximate versus Exact Spectral Norms

The notion of *approximate norms* is customary in complexity theory as complexity measures for models with error tolerance. The *approximate spectral norm* of a function f with error ϵ, denoted as $\widehat{L}_{1,\epsilon}(f)$[2], is the minimum $\|\widehat{g}\|_1$ for some function g such that $\|f - g\|_\infty \leq \epsilon$. As in the case of other complexity measures, we adopt the canonical choice $\epsilon = 1/3$ when referring to constant error. Spectral norm and approximate spectral norm of a Boolean function are fundamental parameters that find applications in many areas such as learning theory [17], complexity theory [21, 22, 23, 1], communication complexity [23, 14, 8], Fourier analysis [23, 11] and additive combinatorics [13, 20, 9].

It is natural to ask whether the spectral norm of a Boolean function is upper bounded by its approximate spectral norm. Towards answering this question, Cheung et al. [9] observed that if f is the indicator function of n-bit strings of Hamming-weight 1, then $\widehat{L}_{1,1/3}(f) = O(1)$ but $\|\widehat{f}\|_1 = \Omega(\sqrt{n})$. Nevertheless, this separation does not rule out the possibility of polynomial relations with dependency on n such as $\|\widehat{f}\|_1 = \text{poly}\left(\widehat{L}_{1,1/3}(f), n\right)$. Using the result by [14] that $\log \|\widehat{f}\|_1 \leq \mathsf{RPDT}_{\text{depth}}(f)$ for any Boolean function f, Theorem 1 immediately rules out the possibility of polynomial dependency.

▶ **Corollary 9.** *There exists a function* $f : \mathbb{F}_2^n \to \{0,1\}$ *such that* $\widehat{L}_{1,1/3}(f) = n^{O(1)}$ *but* $\|\widehat{f}\|_1 = 2^{\Omega(n)}$.

2 Preliminaries

For a positive integer k, we denote $[k] \coloneqq \{1, \ldots, k\}$. All logarithms in this paper are base 2.

We denote the indicator function of a predicate P as $\mathbf{1}[P]$ and the indicator function of a set S as $\mathbf{1}_S$. For a random variable r and a set S, we write $r \sim S$ to indicate that r is uniformly sampled from S. Throughout this work, we adopt the standard big-O notations in computer science.

2.1 Schatten norms

For a vector $v \in \mathbb{R}^k$ and $p \in [1, \infty]$, we denote the ℓ_p-norm of v as $\|v\|_p$. For a matrix $A \in \mathbb{R}^{m \times n}$, the singular values of A are the square roots of the eigenvalues of $AA^\top$, which we denote by $\sigma_1(A) \geq \sigma_2(A) \geq \ldots \geq \sigma_{\min\{m,n\}}(A) \geq 0$. The central matrix norms in this paper are *Schatten p-norm*, which is defined as

[1] RP denotes the class of functions computable by RPDT with constant one-sided error and poly-logarithmic costs

[2] We adopt this function-like notation to emphasize that approximate spectral norm is not a norm despite what the name suggests

$$\|A\|_{S_p} = \left(\sum_i \sigma_i(A)^p\right)^{1/p}$$

for $p \in [1,\infty)$, and $\|A\|_{S_\infty} = \sigma_1(A)$. Put differently, Schatten p-norm of a matrix is the ℓ_p norm of the vector $\big[\sigma_1(A), \sigma_2(A), \ldots, \sigma_{\min\{m,n\}}(A)\big]$. One property of Schatten norms inherited from ℓ_p norms is the monotonicity of Schatten p-norm in p: $\|A\|_{S_p} \geq \|A\|_{S_q}$ for $1 \leq p < q \leq \infty$.

The Schatten 1-norm, 2-norm and ∞-norm are frequently used and are commonly known as *trace norm*, *Frobenius norm*, and *spectral norm* respectively:

$$\|A\|_{\mathrm{tr}} = \|A\|_{S_1} = \sum_i \sigma_i(A);$$

$$\|A\|_{\mathrm{F}} = \|A\|_{S_2} = \sqrt{\sum_i \sigma_i(A)^2} = \sqrt{\sum_{ij} A_{ij}^2};$$

$$\|A\| = \|A\|_{S_\infty} = \sigma_1(A) = \max_{x \in \mathbb{R}^n \setminus \{0\}} \frac{\|Ax\|_2}{\|x\|}.$$

For applications in theoretical computer science, it is more convenient to work with the *normalized trace norm* as a complexity measure.

▶ **Definition 10** (Normalized trace norm). *For $A \in \mathbb{R}^{m\times n}$, the normalized trace norm of A is*

$$\|A\|_{\mathrm{ntr}} \coloneqq \frac{\|A\|_{\mathrm{tr}}}{\sqrt{mn}} = \frac{1}{\sqrt{mn}} \sum_i \sigma_i(A).$$

We remind readers that unlike essentially all other complexity measures and matrix norms used in this work, the normalized trace norm may increase upon restriction to a submatrix.

2.2 Fourier analysis of Boolean functions

This section gives a basic overview of Fourier analysis on the Boolean cube. For every $\eta \in \mathbb{F}_2^n$, define the Fourier character $\chi_\eta : \mathbb{F}_2^n \to \{\pm 1\}$ as $\chi_\eta(x) = (-1)^{\langle x,\eta\rangle}$, where $\langle x, \eta\rangle$ is the standard inner product over $\mathbb{F}_2^n$. For a function $f : \mathbb{F}_2^n \to \mathbb{R}$, its Fourier expansion is given by

$$f = \sum_{\eta \in \mathbb{F}_2^n} \widehat{f}(\eta)\chi_\eta, \tag{4}$$

where the Fourier coefficient $\widehat{f}(\eta)$ is defined as $\widehat{f}(\eta) \coloneqq \mathbb{E}_{x\sim\mathbb{F}_2^n}[f(x)\chi_\eta(x)]$.

For a function $f : \mathbb{F}_2^n \to \mathbb{R}$ and $p \in [1,\infty)$, the Fourier p-norm is defined as

$$\|\widehat{f}\|_p = \left(\sum_{x\in\mathbb{F}_2^n} |\widehat{f}(\eta)|^p\right)^{1/p},$$

and $\|\widehat{f}\|_\infty = \max_\eta |\widehat{f}(\eta)|$. In other words, the Fourier p-norm is the ℓ_p norm of the vector of Fourier coefficients. Fourier 1-norm is better known as the *spectral norm* of f, i.e. $\|\widehat{f}\|_1 \coloneqq \sum_{\eta\in\mathbb{F}_2^n} |\widehat{f}(\eta)|$.

For an Abelian group, the convolution of two *real-valued* functions $f, g : G \to \mathbb{R}$ is a function defined to be

$$f * g(x) \coloneqq \mathop{\mathbb{E}}_{y\sim G}[f(y)g(x-y)].$$

It is a standard fact in Fourier analysis that the Fourier transformation of convolution of two functions is the pointwise product of their respective Fourier transforms: $\widehat{f * g} = \widehat{f} \cdot \widehat{g}$.

Lastly, *Parseval's identity* states that the squared Fourier 2-norm of a function f is equal to its second moment (under uniform probability measure):

$$\|\widehat{f}\|_2^2 = \sum_{\eta \in \mathbb{F}_2^n} \widehat{f}(\eta)^2 = \mathop{\mathbb{E}}_{x \sim \mathbb{F}_2^n}[f(x)^2].$$

3 The Proof Framework

The key proof technique throughout this work is Hölder's inequality with a nuanced choice of p-norms. Hölder's inequality states that for any $p, q \in [1, \infty]$ satisfying $\frac{1}{p} + \frac{1}{q} = 1$,

$$|\langle u, v \rangle| \leq \|u\|_p \|v\|_q \tag{5}$$

for any real vectors $u, v \in \mathbb{R}^n$. A generalization of Hölder's inequality known as *Littlewood's inequality* [15], which can be deduced from the standard Hölder's inequality, relates the p-norms of a function for some "interpolated" tuples of p. The inequality states that for $1 \leq p_0 < p_* < p_1 \leq \infty$,

$$\|v\|_{p_*} \leq \|v\|_{p_0}^{\theta} \|v\|_{p_1}^{1-\theta} \tag{6}$$

for any vector $v \in \mathbb{R}^n$, where $\theta \in (0, 1)$ satisfies $\frac{1}{p_*} = \frac{\theta}{p_0} + \frac{1-\theta}{p_1}$. As Schatten norms and Fourier norms are defined based on ℓ_p norms, the above inequality also holds with replacing the ℓ_p norms with these families of norms.

Setting the parameters $(p_*, p_0, p_1) = (2, 1, 4)$ (so that $\theta = 1/3$) for Equation (6) yields the following lower bound for 1-norm (after some algebraic manipulations):

$$\|f\|_1 \geq \frac{\|f\|_2^3}{\|f\|_4^2}. \tag{7}$$

As this is the sole parametrization of Hölder's inequality that we employ, we colloquially refer to Equation (7) as "the Hölder's inequality" in the rest of this work.

Among all the possible parametrizations for Littlewood's inequality, the choice made in Equation (7) of $(p_*, p_0, p_1) = (2, 1, 4)$ is appealing because of the nice physical interpretations of 2-norm and 4-norm for Boolean matrices (the Schatten norms) and Boolean functions (the Fourier norms). One main inspiration of Equation (7) as a practical bound is the work of Chazelle and Lvov on hereditary discrepancy [7]. Chazelle and Lvov proved a hereditary discrepancy lower bound of a matrix in terms of its Schatten 2-norm and 4-norm, highlighting the combinatorial interpretations of these norms for Boolean matrices. In the next section, we illustrate the combinatorial perspective of Equation (7) with a simpler proof of Theorem 3.

4 Simplified Proof of Communication Complexity Lower Bounds

It is customary to associate a Boolean matrix A with the biadjacency matrix of a bipartite graph $G = (U \cup V, E)$. In view of this, the square of Schatten 2-norm i.e. Frobenius norm of A is simply the number of edges of G. The Schatten 4-norm of A also admits a graph-theoretic interpretation:

$$\|A\|_{S_4}^4 = \mathrm{Tr}((A^\top A)^2) = \sum_{i,j \in U} \sum_{k,\ell \in V} A_{ik} A_{i\ell} A_{jk} A_{j\ell} = \sum_{i,j \in U} \sum_{k,\ell \in V} \mathbf{1}[\{ik, i\ell, jk, j\ell\} \subseteq E].$$

In other words, $\|A\|_{S_4}^4$ is precisely the count of possibly degenerate 4-cycles in G. This quantity becomes especially easy to evaluate when the underlying graph G does not contain non-degenerate 4-cycles (C_4-free), or equivalently, A does not contain a 2×2 all-one submatrix.

For a C_4-free bipartite graph, all contributions to $\|A\|_{S_4}^4$ come from the counts of edges and paths of length 2. Furthermore, if G is almost balanced in the sense that the average degree of G is close to the maximum degree, Equation (7) indeed yields a non-trivial lower bound for $\|A\|_{\mathrm{ntr}}$:

▶ **Proposition 11.** *Let $G = (U \cup V, E)$ be a C_4-free bipartite graph with maximum degree $\Delta(G)$. For $x \in U \cup V$, let d_x be the degree of x. If $A \in \{0,1\}^{U\times V}$ is the biadjacency matrix of G, Then*

$$\|A\|_{\mathrm{tr}} \geq \frac{|E|^{3/2}}{\sqrt{\sum_{x\in U\cup V} d_x^2}} \geq \frac{|E|}{\sqrt{2\Delta(G)}}.$$

Proof. By Hölder's inequality (Equation (7)),

$$\|A\|_{\mathrm{tr}} \geq \frac{\|A\|_{\mathrm{F}}^3}{\|A\|_{S_4}^2} = \frac{|E|^{3/2}}{\sqrt{\mathrm{Tr}((A^\top A)^2)}}.$$

Since G is C_4-free, the expression of $\mathrm{Tr}((A^\top A)^2)$ is simplified to

$$\begin{aligned}\mathrm{Tr}((A^\top A)^2) &= \sum_{i\in U}\sum_{k\in V} A_{ik} + \sum_{i\in U}\sum_{\substack{k,\ell\in V\\ k\neq\ell}} A_{ik}A_{i\ell} + \sum_{\substack{i,j\in U\\ i\neq j}}\sum_{k\in V} A_{ik}A_{jk}\\ &= |E| + \sum_{i\in U} d_i(d_i-1) + \sum_{k\in V} d_k(d_k-1)\\ &= \left(\sum_{x\in U\cup V} d_x^2\right) - |E|\end{aligned}$$

and the required bounds follow. ◀

Since every two distinct points define a unique line, the bipartite graph G associated with any point-line incidence system (with no duplicated lines) is C_4-free. From Proposition 11, one can readily derive an improved exponential normalized trace norm lower bound for $\mathtt{PL}$ using the same point-incidence submatrix in [8].

We prove a better bound by considering a point-line incidence system $\mathtt{PL}_*$ attributed to Paul Erdős (see [6, Lemma 6.25]). This point-line incidence system is constructed to show the tightness of the Szemerédi–Trotter incidence bound. Concretely, the $2^{n+1}\times 2^n$ matrix $\mathtt{PL}_*^{(n)} : \mathcal{P}'\times\mathcal{L}' \to \{0,1\}$ is defined as follows: the input domains are $\mathcal{P}' = [2^{n/3}]\times[2^{2n/3+1}]$ and $\mathcal{L}' = [2^{n/3}]\times[2^{2n/3}]$, and the entries are given by

$$\mathtt{PL}_*^{(n)}[(x,x'),(y,y')] = \begin{cases} 1 & \text{if } xy + y' = x'\\ 0 & \text{otherwise}\end{cases}.$$

We first show that $\mathtt{IIP}_3$ contains $\mathtt{PL}_*$ as a submatrix.

▷ Claim 12. The matrix $\mathtt{IIP}_3^{(n)}$ contains the matrix $\mathtt{PL}_*^{(3n/2-3/2)}$ as a submatrix.

Proof. The condition of incidence of $\mathtt{PL}_*$ can be rewritten as $xy + (1)y' + x'(-1) = 0$, which is an instance of integer inner product. For $\mathtt{PL}_*^{(3n/2-3/2)}$, the magnitude of each entry is bounded by $2^{\frac{2}{3}\left(\frac{3}{2}n-\frac{3}{2}\right)+1} = 2^n$, therefore $\mathtt{PL}_*^{(3n/2-3/2)}$ is a submatrix of $\mathtt{IIP}_3^{(n)}$. ◁

Proof of Theorem 4. As noted above, $\mathtt{PL}_*^{(m)}$ is C_4-free because no two distinct lines intersect at the same pair of points. For the matrix $\mathtt{PL}_*^{(m)}$, each line is incident to exactly one point of the form $(i, x') \in \mathcal{P}$ for each $i \in [2^{m/3}]$. Therefore the bipartite graph defined by $\mathtt{PL}_*$ contains $|\mathcal{L}| \cdot 2^{m/3} = 2^{4m/3}$ edges. Also, each point is incident to at most one line of the form $(j, y') \in \mathcal{L}$ for each $j \in [2^{m/3}]$, hence the maximum degree of the graph is $2^{m/3}$. By Proposition 11,

$$\left\|\mathtt{PL}_*^{(m)}\right\|_{\mathrm{ntr}} \geq \Omega\left(\frac{1}{2^m} \cdot \frac{2^{4m/3}}{\sqrt{2 \cdot 2^{m/3}}}\right) = \Omega\left(2^{m/6}\right).$$

By Claim 12 and Equation (1), we obtain

$$\mathsf{D}^{\mathsf{EQ}}\left(\mathtt{IIP}_k^{(n)}\right) \geq \mathsf{D}^{\mathsf{EQ}}\left(\mathtt{IIP}_3^{(n)}\right) \geq \mathsf{D}^{\mathsf{EQ}}\left(\mathtt{PL}_*^{(3n/2-3/2)}\right) \geq \frac{1}{2}\left(\frac{1}{6} \cdot \frac{3n}{2}\right) + O(1) = \frac{n}{8} + O(1). \quad \blacktriangleleft$$

As mentioned earlier, Chattopadhyay, Lovett, and Vinyals [4] proved a linear lower bound on $\mathsf{D}^{\mathsf{EQ}}(\mathtt{IIP}_k)$ for $k \geq 6$ by a method different from the approach in [8] and this work. The method used in [4], the relative area method, considered a parametrized weighted sum of monochromatic rectangle partition of a Boolean matrix. The following D^{EQ} lower bound is deduced from the communication complexity lower bound with more general oracle access.

▶ **Theorem 13** ([4, Lemmas 3.5 and 3.7])**.** *Suppose M is a Boolean matrix with α 1-entries, and the maximum area of any 1-monochromatic rectangle in M is β. For any constant $\eta \in (1/2, 1)$,*

$$\mathsf{D}^{\mathsf{EQ}}(M) = \Omega\left(\log\left(\frac{\alpha}{\beta^{1-\eta}|M|^{\eta}}\right)\right).$$

For the matrix $\mathtt{PL}_*^{(m)}$, as observed in the proof of Theorem 4, $\alpha = |E(G)| = 2^{4m/3}$ and $\beta = \Delta(G) = 2^{m/3}$ since $\mathtt{PL}_*^{(m)}$ is C_4-free. Applying Theorem 13 with $\eta = 1/2 + \epsilon'$ for some very small constant $\epsilon' > 0$, we obtain a linear D^{EQ} lower bound with a slightly inferior constant due to the slackness in η. We can also use this technique to lower bound N^{EQ}, which proves Theorem 5.

▶ **Theorem 14** ([19])**.** *Let M be a $2^m \times 2^m$ Boolean matrix, α be the number of 1-entries in M and let β be the size of the largest 1-monochromatic rectangle in M. Then*

$$\mathsf{N}^{\mathsf{EQ}}(M) = \Omega\left(\log\left(\frac{\alpha}{\sqrt{\beta} 2^m}\right) \cdot \frac{1}{\log m}\right).$$

Proof of Theorem 5. As noted before, $\alpha = |E(G)| = 2^{4m/3}$ and $\beta = \Delta(G) = 2^{m/3}$. For $m = 3n/2 - 3/2$, applying Theorem 14 gives

$$\mathsf{N}^{\mathsf{EQ}}\left(\mathtt{PL}_*^{(m)}\right) = \Omega\left(\frac{n}{\log n}\right)$$

and therefore the same lower bound holds for $\mathsf{N}^{\mathsf{EQ}}\left(\mathtt{IIP}_k^{(n)}\right)$ for $k \geq 3$. ◀

5 Proof of the Main Theorem

The Hölder's inequality supplies a large lower bound on 1-norm in the scenario of large 2-norm and small 4-norm. The proof of Theorem 3 utilizes the C_4-free property and sufficient edge density of $\mathtt{PL}$ to show the desired trace norm lower bound. We adopt the same strategy in exhibiting a function that the separation of randomized parity decision tree depth and spectral norm.

As in the matrix case, we begin by examining the physical interpretations of p-norms in the Hölder's inequality. A fundamental quantity in additive combinatorics known as the *additive energy*, coincides with the fourth power of Fourier 4-norm in Boolean function setting.

▶ **Definition 15** (Additive energy). *For $f : G \to \{0,1\}$ over an Abelian group G, the additive energy of f is defined as*

$$E(f) \coloneqq \mathop{\mathbb{E}}_{x,y,z\sim G}[f(x)f(y)f(z)f(x+y-z)].$$

For a Boolean function $f : \mathbb{F}_2^n \to \{0,1\}$, tt is straightforward to show that $E(f) = \|\widehat{f}\|_4^4$:

$$\begin{aligned} E(f) &= \mathop{\mathbb{E}}_{t\sim\mathbb{F}_2^n}\left[\mathop{\mathbb{E}}_{x\sim\mathbb{F}_2^n}[f(x)f(t-x)] \cdot \mathop{\mathbb{E}}_{z\sim\mathbb{F}_2^n}[f(z)f(t-z)]\right] \\ &= \mathop{\mathbb{E}}_{t\sim\mathbb{F}_2^n}[(f*f(t))^2] \\ &= \sum_{\eta\in\mathbb{F}_2^n} \widehat{f*f}(\eta)^2 = \sum_{\eta\in G} \widehat{f}(\eta)^4 = \|\widehat{f}\|_4^4. \end{aligned}$$

It is also direct from Parseval's identity that $\|\widehat{f}\|_2^2 = \mathbb{E}_x[f(x)]$. Therefore in the Boolean function setting, Equation (7) states that

$$\|\widehat{f}\|_1 \geq \frac{\|\widehat{f}\|_2^3}{\|\widehat{f}\|_4^2} = \sqrt{\frac{\mathbb{E}_x[f(x)]^3}{E(f)}}. \tag{8}$$

Emulating the approach in Section 4 to guarantee a small 4-norm, we consider a Boolean function $f : \mathbb{F}_2^n \to \{0,1\}$ that satisfies $f(x)f(y)f(z)f(x+y+z) = 0$ for any distinct $x, y, z \in \mathbb{F}_2^n$ as an analogue of C_4-free bipartite graphs. For such a function, the additive energy of f is lower than typical as only $O(|\mathbb{F}_2^n|^2)$ tuples of $(x,y,z) \in (\mathbb{F}_2^n)^3$ could contribute to $E(f)$. A function with this property is precisely the indicator function of a Sidon set.

▶ **Definition 16** (Sidon set). *For an Abelian group G, a set $S \subseteq G$ is called a* Sidon *set if for every $a, b, c, d \in S$ such that $a + b = c + d$, then $\{a, b\} = \{c, d\}$.*

The indicator of a Sidon set emerges as a natural candidate function that attains the exponential spectral norm lower bound stated in Theorem 1. Indeed, one can show that the spectral norm of an indicator of a sufficiently big Sidon set is large.

▶ **Proposition 17.** *Every Sidon set S of a finite Abelian group G satisfies $\|\widehat{\mathbf{1}_S}\|_1 \geq \sqrt{|S|/2}$.*

Proof. Since S is a Sidon set, $\mathbf{1}_S(x)\mathbf{1}_S(y)\mathbf{1}_S(z)\mathbf{1}_S(x+y-z) = 1$ implies that $z = x$ or $z = y$. Thus

$$E(\mathbf{1}_S) \leq \frac{2}{|G|} \mathop{\mathbb{E}}_{x,y\sim G}[\mathbf{1}_S(x)\mathbf{1}_S(y)] = \frac{2}{|G|} \times \left(\frac{|S|}{|G|}\right)^2 = \frac{2|S|^2}{|G|^3}.$$

Applying Hölder's inequality (Equation (8)) gives

$$\|\widehat{\mathbf{1}_S}\|_1 \geq \sqrt{\frac{\mathbb{E}_x[\mathbf{1}_S(x)]^3}{E(\mathbf{1}_S)}} = \sqrt{\frac{|S|^3/|G|^3}{2|S|^2/|G|^3}} = \sqrt{\frac{|S|}{2}}. \qquad \blacktriangleleft$$

By Cauchy-Schwarz inequality and Parseval identity, it is direct to check that for any set $T \subseteq G$, the spectral norm of $\mathbf{1}_T$ is at most $\sqrt{|T|}$. The above proposition shows that this upper bound is tight up to constant factor for a Sidon set.

By considering the possible sums of a pair of elements, it is easy to see that for a Sidon set S, we have $\binom{|S|}{2} \leq |G|$ and hence $|S| = O(\sqrt{|G|})$. In the case of $G = \mathbb{Z}_2^n$ [3], a well-known construction of a Sidon set matching the size upper bound is the Bose–Chaudhuri–Hocquenghem (BCH) code [2, 16]. This code is constructed from polynomials over a finite field of characteristic 2.

Denote $\mathbb{F}_{2^m}$ the characteristic-2 finite field of size 2^m. The elements of $\mathbb{F}_{2^m}$ can be isomorphically identified with univariate $\mathbb{F}_2$-polynomials of degree at most $m-1$, where multiplication is defined modulus a fixed irreducible polynomial $P(x) \in \mathbb{F}_2[x]$ of degree m. Viewing as additive groups, $\mathbb{F}_{2^m} \cong \mathbb{F}_2[x]/\langle P(x)\rangle$ is isomorphic to $\mathbb{Z}_2^m$.

For $\mathbb{F}_p$ where p is a prime, the Sidon set construction in [2] is given by the tuples (a, a^k) over all a in a suitable subfield and a suitable exponent k. For $p = 2$, the construction takes the form of $\mathtt{BCH}(S)$, where for a set S we define

$$\mathtt{BCH}(S) \coloneqq \{(a, a^3) : a \in S\}.$$

For the sake of completeness, we include the proof for this specific construction.

▶ **Theorem 18** ([2]). *For every even number m, the set $\mathtt{BCH}(\mathbb{F}_{2^{m/2}}) \subseteq \mathbb{F}_{2^{m/2}} \times \mathbb{F}_{2^{m/2}} \equiv \mathbb{Z}_2^m$ is a Sidon set.*

Proof. Let (a, a^3) and (b, b^3) be two pairs with a prescribed sum $(u, v) \in \mathbb{F}_{2^{m/2}} \times \mathbb{F}_{2^{m/2}}$. This means $a + b = u$ and $a^3 + b^3 = v$, which implies that

$$u^3 = (a+b)^3 = a^3 + b^3 + (a+b)ab = v + uab.$$

Suppose $a \neq b$ i.e. $u \neq 0$, then $a(u+a) = ab = u^2 + vu^{-1}$. The same calculation concludes that a and b are the roots of the quadratic equation $x(x+u) = u^2 + vu^{-1}$. Since a quadratic equation has at most two roots, $\{a, b\}$ is uniquely determined by u and v. ◀

Theorem 18 allows us to construct a large Sidon set in $\mathbb{Z}_2^n$. Since a subset of a Sidon set remains a Sidon set, it remains to select a suitably structured subset whose indicator function is computable with a short randomized parity decision tree. As mentioned earlier, every element in $\mathbb{F}_{2^n}$ can be uniquely identified with a polynomial in $\mathbb{F}_2[x]$ of degree at most $n-1$. For $d \in \mathbb{N}$, denote $\mathcal{P}_d$ the set of $\mathbb{F}_2$-polynomials of degree at most $d-1$. We show that $\mathtt{BCH}(\mathcal{P}_{n/4})$ is the desired Sidon set.

▶ **Theorem 19.** *Let $n = 4d$ for some $d \in \mathbb{N}$, and $S = \mathtt{BCH}(\mathcal{P}_d) \subseteq \mathcal{P}_d \times \mathcal{P}_{3d} \subseteq \mathbb{F}_{2^d} \times \mathbb{F}_{2^{3d}} \cong \mathbb{Z}_2^n$. The Boolean function $\mathbf{1}_S : \mathbb{F}_2^n \to \{0,1\}$ satisfies that $\mathsf{RPDT}_{\mathrm{depth}}(\mathbf{1}_S) = O(\log n)$ and $\|\widehat{\mathbf{1}_S}\|_1 = \Omega(2^{n/8})$.*

Proof. Note that S is a Sidon set of size $|\mathcal{P}_d| = 2^d = 2^{n/4}$. The spectral norm lower bound follows from Proposition 17. It remains to upper-bound the randomized parity decision tree complexity.

We first describe a randomized algorithm that computes $\mathbf{1}_S$. Suppose a pair $(u, v) \in \mathbb{F}_2[x] \times \mathbb{F}_2[x]$ with $\deg(u) < d$ and $\deg(v) < 3d$ is a given. To determine whether $(u, v) \in S$, we interpret $v - u^3$ as a polynomial in $\mathbb{F}_{2^m}[x]$, where $m = \lceil \log(3d) \rceil + 2$, and check whether $v - u^3 \equiv 0$. This can be accomplished using the standard randomized polynomial identity

[3] For clarity, in the rest of this section, we use the notation $\mathbb{Z}_2$ to refer to the additive group of size 2.

testing algorithm: pick a random $t \in \mathbb{F}_{2^m}$ and evaluate $v(t) - u(t)^3 \in \mathbb{F}_{2^m}$. The algorithm declares that "$v \neq u^3$" if any of the evaluated values is non-zero, and declares "$v = u^3$" otherwise.

Notice that this randomized algorithm has a one-sided error, as it always makes the correct declaration when $v = u^3$ (i.e. $\mathbf{1}_S(u, v) = 1$). In the case of $v \neq u^3$, since the polynomial $v - u^3$ has at most $3d$ roots, the probability of error is at most $3d/2^m \leq 1/4$.

Next, we convert the randomized algorithm into a randomized parity decision tree. For every $t \in \mathbb{F}_{2^m}$, the set

$$H_t \coloneqq \{u \in \mathcal{P}_d : u(t) = 0\} \subseteq \mathcal{P}_d \cong \mathbb{Z}_2^d$$

is a linear subspace of co-dimension m in $\mathbb{Z}_2^d$, and each coset of H_t takes a fixed value when evaluated at t. Therefore, the value of $u(t)$ is determined by m deterministic linear queries to u. Similarly, the value of $v(t)$ is determined by m deterministic linear queries to v. Hence, we construct the randomized parity decision tree as follows: pick a random $t \in \mathbb{F}_{2^m}$ and make the $2m$ parity queries that determine the values of $u(t), v(t) \in \mathbb{F}_{2^m}$, and the decision tree outputs whether $v(t)$ and $u(t)^3$ are equal. ◀

5.1 Payley-Zygmud inequality and typical Fourier coefficients

Here instead of Hölder's inequality, we use the Payley-Zygmund inequality to deduce a stronger conclusion than Proposition 17 which could be of independent interest. We show that for the indicator of a Sidon set, a constant fraction of the Fourier coefficients is large. We have shown that for a Sidon set S in an Abelian group G,

$$\sum_{\chi \in \widehat{G}} |\widehat{\mathbf{1}_S}(\chi)|^2 = \frac{|S|}{|G|} \quad \text{and} \quad \sum_{\chi \in \widehat{G}} |\widehat{\mathbf{1}_S}(\chi)|^4 \leq \frac{2|S|^2}{|G|^3}.$$

Consider the random variable $X = |\widehat{\mathbf{1}_S}(\chi)|^2$ where χ is a character picked uniformly at random. The above bounds translate to $\mathbb{E}[X] = |S|/|G|^2$ and $\mathbb{E}[X^2] = 2|S|^2/|G|^4 = 2\,\mathbb{E}[X]^2$. By Paley-Zygmund inequality, we have for any $\delta \in (0, 1)$,

$$\Pr[X > \delta\,\mathbb{E}[X]] \geq (1 - \delta)^2 \frac{(\mathbb{E}[X])^2}{\mathbb{E}[X^2]} \geq \frac{(1 - \delta)^2}{2}.$$

Taking $\delta = 1/2$ for example, this gives

$$\Pr_{\chi}\left[|\widehat{\mathbf{1}_S}(\chi)| > \frac{\sqrt{|S|}}{\sqrt{2}|G|}\right] \geq \frac{1}{8}.$$

Abstract

We introduce a formal notion of defendability against backdoors using a game between an attacker and a defender. In this game, the attacker modifies a function to behave differently on a particular input known as the "trigger", while behaving the same almost everywhere else. The defender then attempts to detect the trigger at evaluation time. If the defender succeeds with high enough probability, then the function class is said to be defendable. The key constraint on the attacker that makes defense possible is that the attacker's strategy must work for a randomly-chosen trigger.

Our definition is simple and does not explicitly mention learning, yet we demonstrate that it is closely connected to learnability. In the computationally unbounded setting, we use a voting algorithm of Hanneke et al. [13] to show that defendability is essentially determined by the VC dimension of the function class, in much the same way as PAC learnability. In the computationally bounded setting, we use a similar argument to show that efficient PAC learnability implies efficient defendability, but not conversely. On the other hand, we use indistinguishability obfuscation to show that the class of polynomial size circuits is not efficiently defendable. Finally, we present polynomial size decision trees as a natural example for which defense is strictly easier than learning. Thus, we identify efficient defendability as a notable intermediate concept in between efficient learnability and obfuscation.

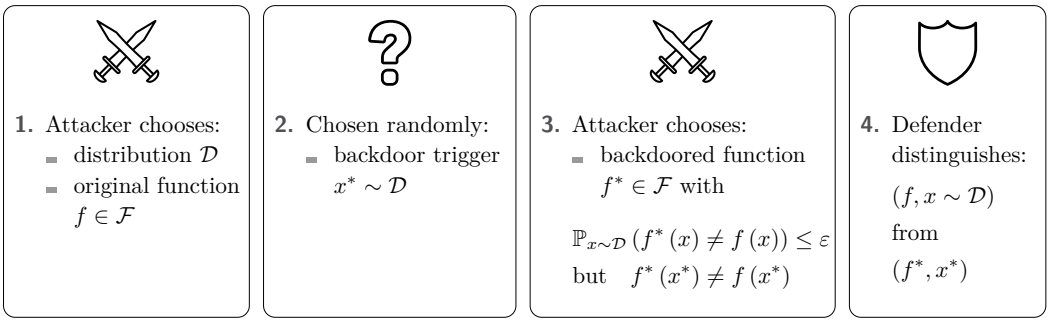

Figure 1 The game used to define ε-defendability for a class $\mathcal{F}$ of $0,1$-valued functions.

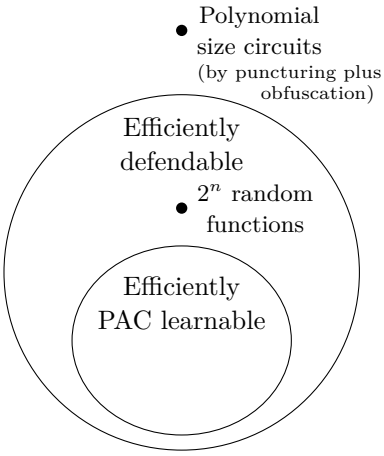
1 Introduction

A *backdoor* in a machine learning model is a modification to the model that causes it to behave differently on certain inputs that activate a secret "trigger". There is a wide literature on backdoor attacks and defenses from both a theoretical and an empirical perspective [26]. However, prior theoretical work typically makes reference to a particular training dataset, leading to a focus on data poisoning attacks. In this work we introduce a formal notion of a backdoor that allows the attacker to modify the model arbitrarily. Our definition is simple, but nevertheless gives rise to a rich array of strategies incorporating both learning and obfuscation.

Our formal notion is focused on backdoor detection *at runtime*, meaning that the defender is given a particular input and must flag whether or not it activates the backdoor trigger. We focus on this case because of the existence of *undetectable* backdoors if the defender is instead required to flag a model as backdoored without being given any particular input [11]. Moreover, detection at runtime is sufficient in threat models where the attacker is given only one opportunity to modify the model, being akin to giving the defender an additional chance to modify the model after the attacker. We also focus on the white-box setting, in which the defender has access to a complete description of the model.



Our main contributions, which are also summarized in Figures 1 and 2, are as follows:

- **Definition of ε-defendability (Section 3).** We introduce a simple game between an attacker and a defender to define what it means for a representation class to be *ε-defendable* with a certain confidence. The only constraint placed on the attacker is that their backdoor strategy must work for a randomly-chosen trigger. Without this assumption, there is a symmetry between the original and backdoored functions that makes defense impossible.
- **Statistical defendability (Section 4).** In the absence of computational constraints on the defender, we show that a representation class $\mathcal{F}$ is ε-defendable with confidence tending to 1 if and only if $\varepsilon = o(1/\mathrm{VC}(\mathcal{F}))$, where $\mathrm{VC}(\mathcal{F})$ is the Vapnik–Chervonenkis dimension of $\mathcal{F}$. We achieve this by adapting a result of Hanneke et al. [13] that applies a learning algorithm multiple times and takes a majority vote.
- **Computational defendability (Section 5).** We introduce a notion of *efficient defendability* in which the defender's detection strategy must run in polynomial time. We show that efficient PAC learnability implies efficient defendability, but not conversely. We also show that under certain cryptographic assumptions, the class of polynomial size circuits is not efficiently defendable, by combining a puncturable pseudorandom function with an efficient indistinguishability obfuscator.

Statistical defendability (Section 4)

$\mathcal{F}$ is ε-defendable with confidence $\to 1$
$\iff$
$\varepsilon = o\left(1/\mathrm{VC}(\mathcal{F})\right)$
(by learning plus voting)

Computational defendability (Section 5)

Defendability of decision trees (Section 6)

Polynomial size decision trees are efficiently uniform-defendable in a single evaluation

(a) Statistical defendability is concerned with computationally unbounded defenders, and is essentially determined by the VC dimension, in much the same way as statistical learnability.

(b) Computational defendability is concerned with polynomial-time defenders, and the set of efficiently defendable classes lies strictly between the set of efficiently learnable classes and the set of all classes.

(c) In the setting where the distribution over inputs is uniform, polynomial size decision trees are a natural class for which defense is faster than learning.

Figure 2 Summary of the results in this paper.

- **Defendability of decision trees (Section 6).** In the setting where the distribution over inputs is uniform, we give a defense for polynomial size decision trees that runs in the time taken to evaluate a single decision tree. This provides a natural example for which defense is faster than learning.

We conclude in Section 7 with a discussion of whether efficient defendability can be further separated from efficient PAC learnability, so-called "mechanistic" defenses that resemble our defense for polynomial size decision trees, and the implications of our results for AI alignment.

2 Related work

The most closely related work to our own is that of Goldwasser, Kim, Vaikuntanathan, and Zamir [11], whose main results use a digital signature scheme to insert an undetectable backdoor into a model. The backdoor trigger can be applied to any input by perturbing it appropriately. In the black-box setting, the backdoor is undetectable in the sense that it is computationally infeasible for the defender to find any input on which the backdoored model and the original model differ. In the white-box setting, the backdoor is undetectable in the sense that it is computationally infeasible for the defender to distinguish the backdoored model from the original model. However, both of these results are in the setting where the backdoor trigger must be extracted from the model rather than detected at runtime.

In the defense at runtime setting, the same authors also show that a backdoored model can be modified by the defender to produce a model that is not backdoored. Once again, the backdoor trigger is applied by perturbing the input. The result only applies to models that

satisfy a certain smoothness assumption, and mirrors the use of randomized smoothing to achieve certified adversarial robustness by Cohen et al. [6]. By contrast, we avoid making smoothness assumptions, and further develop the theory of runtime backdoor detection.

Concurrent work by Goldwasser, Shafer, Vafa, and Vaikuntanathan [12] studies a black-box, non-realizable version of backdoor defense at runtime. Rather than predicting the exact label of the non-backdoored model on the given input (which is equivalent to our notion of runtime detection), the defender must instead produce a "canonical" label that has high accuracy on average, by using black-box access to the potentially backdoored model. In this local mitigation setting, they construct efficient defenders for almost-linear and almost-polynomial functions. They also consider the global mitigation setting, in which the defender must produce an entire clean model, constructing efficient global mitigators for Fourier-heavy functions.

Adversarial examples can be thought of as backdoor triggers, but the attacker must find similar inputs rather than a model with similar outputs. The gap between statistical and computational hardness has been explored in this context by Bubeck et al. [5] and Garg et al. [8]. Much like us, they find that defense is statistically possible but computationally hard.

Returning to backdoors, another thematically similar work to our own is that of Khaddaj et al. [23], which also questions the assumptions behind different backdoor attacks and defenses. However, it remains within the data-poisoning setting, in which the backdoor is inserted using corrupted training data.

A line of work beginning with Dumford and Scheirer [7] goes beyond data-poisoning, inserting a backdoor into an already-trained model, but still using data to search for the backdoored model. More manual methods of backdoor insertion were later introduced by Hong et al. [15]. This line of work is primarily empirical rather than theoretical.

Our result on statistical defendability is heavily based on the result of Hanneke et al. [13] in the realizable case. Following Levine and Feizi [25] and Jia et al. [18], they use a voting algorithm to produce a backdoor defense in the data-poisoning setting. By combining this with a classical result of Haussler, Littlestone, and Warmuth [14] on optimal learning, they relate the optimal performance of this algorithm to the VC dimension of the function class. Our result adapts this to our more general notion of defendability.

Our result on computational defendability of polynomial size circuits uses a hybrid argument that combines a puncturable pseudorandom function and an efficient indistinguishability obfuscator. This combination has been used in a number of previous hybrid arguments, as described by Sahai and Waters [29]. More generally, the relationship between learnability and cryptographic assumptions has a long history, with some basic constructions in this vein described in the textbook of Kearns and Vazirani [22].

3 Definition of ε-defendability

Our formal notion of defendability against backdoors is based on a game played between two players, an "attacker" and a "defender". Informally, the attacker starts with a function and is given a randomly sampled backdoor trigger. They must choose a backdoored function that almost always agrees with the original function, but disagrees with the original function on the backdoor trigger. Then the defender is given either the original function and a random input, or the backdoored function and the backdoor trigger, and they must distinguish one from the other with high confidence.

For our formal definition, we fix a security parameter $n \in \mathbb{N}$ and consider classifiers $\mathcal{X} \to \{0,1\}$ where $\mathcal{X} = \{0,1\}^n$. Formally, a *representation class* over $\mathcal{X}$ is a function $\{0,1\}^{R(n)} \to \{\text{all functions } \mathcal{X} \to \{0,1\}\}$ for some $R(n) \in \mathbb{N}$, but we generally keep the

choice of representation implicit and conflate a representation class with the set of functions in its image. In our results on computationally constrained defenders, we also implicitly assume that $R(n)$ is polynomial in n.

Our definition also makes use of the *example oracle* $\mathrm{Ex}(f, \mathcal{D})$ where $\mathcal{D}$ is a distribution over $\mathcal{X}$ and $f : \mathcal{X} \to \{0,1\}$. This is an oracle that outputs $(x, f(x))$ for a randomly sampled $x \sim \mathcal{D}$.

▶ **Definition 3.1.** Let $\mathcal{F}$ be a representation class over $\mathcal{X} = \{0,1\}^n$ and let $\varepsilon, \delta > 0$. We say that $\mathcal{F}$ is *ε-defendable with confidence* $1 - \delta$ if there is a probabilistic algorithm (the "detection strategy") that wins the following game with probability at least $1 - \delta$:

- An adversary with knowledge of the detection strategy (the "attacker") chooses a distribution $\mathcal{D}$ over $\mathcal{X}$ and $f \in \mathcal{F}$.
- We randomly sample $x^* \sim \mathcal{D}$ (the "backdoor trigger"), and then the adversary chooses $f^* \in \mathcal{F}$ (the "backdoored function").
- The backdoored function f^* is called *ε-valid* if

$$\mathbb{P}_{x \sim \mathcal{D}}(f^*(x) \neq f(x)) \leq \varepsilon \quad \text{but} \quad f^*(x^*) \neq f(x^*).$$

- We randomly choose (f', x') to pass to the detection strategy to be either (f, x) for a random sample $x \sim \mathcal{D}$, or (f^*, x^*), with 50% probability each. The detection strategy is given access to the example oracle $\mathrm{Ex}(f', \mathcal{D})$ as well as the representation of f', x', $f'(x')$, ε and δ as input, and must output either Acc (for "accept") or Rej (for "reject").
- If (f, x) is passed to the detection strategy, then the detection strategy wins if it outputs Acc. If (f^*, x^*) is passed to the detection strategy, then the detection strategy wins if either it outputs Rej or f^* is not ε-valid.

In this definition, the adversary is not specified by a collection of algorithms, but is instead shorthand for a universal quantifier. Thus we could have equivalently (but perhaps convolutedly) said, "there exists a detection strategy such that, for all distributions $\mathcal{D}$ over $\mathcal{X}$ and all $f \in \mathcal{F}$, the expectation over $x^* \sim \mathcal{D}$ of the minimum over all $f^* \in \mathcal{F}$ of the win probability of the detection strategy is at least $1 - \delta$".

The manner in which f, x^* and f^* are chosen in this definition deserves some elaboration. If the attacker were allowed to choose the backdoor trigger x^* themselves, then it would be too easy for the adversary to insert an undetectable backdoor. So we instead require the adversary to come up with a backdoor insertion strategy that works for a randomly-chosen trigger. In fact, we do not even allow the adversary to see the backdoor trigger when they are selecting the original function f, or else they could produce f^* by *removing an existing backdoor* rather than *inserting a new one*. This is illustrated by the following example.

▶ **Example** (Existing backdoor removal). Let $\mathcal{X} = \{0,1\}^n$ and let $\mathcal{F} = \{\mathbb{1}_x \mid x \in \mathcal{X}\}$, where $\mathbb{1}_x : \mathcal{X} \to \{0,1\}$ denotes the indicator function

$$\mathbb{1}_x(x') = \begin{cases} 1, & \text{if } x' = x \\ 0 & \text{if } x' \neq x. \end{cases}$$

Take $\mathcal{D}$ to be uniform over $\mathcal{X}$. If we allowed the adversary to choose both f and f^* after sampling $x^* \sim \mathcal{D}$, then they could take $f = \mathbb{1}_{x^*}$ and $f^* = \mathbb{1}_{x'}$ for $x' \sim \mathcal{D}$ (or in the event that $x' = x^*$, instead take $f = \mathbb{1}_{x''}$ for some $x'' \in \mathcal{X} \setminus \{x^*\}$ sampled uniformly at random). Then f^* would be $\frac{2}{2^n}$-valid, and (f, x) and (f^*, x^*) would be identically distributed for $x \sim \mathcal{D}$. So if $\varepsilon \geq \frac{1}{2^{n-1}}$ then any detection strategy would win with probability at most $\frac{1}{2}$. This would be quite an extreme failure for the defender, especially considering that the VC dimension of $\mathcal{F}$ is only 1.

Thus the way in which f, x^* and f^* are chosen, by randomly sampling the backdoor trigger x^* after the original function f is chosen but before the backdoored function f^* is chosen, is the key symmetry-breaking assumption that makes the game interesting.

▶ Remark. We could generalize this definition to include functions $\mathcal{X} \to \mathcal{Y}$ where $\mathcal{Y}$ is any subset of $\mathbb{R}$ (or even more generally, any metric space). In this setting, the most natural generalization of ε-validity is

$$\mathbb{E}_{x\sim\mathcal{D}}\left[\left(f^*(x) - f(x)\right)^2\right] \leq \varepsilon \quad \text{but} \quad \left|f^*(x^*) - f(x^*)\right| \geq 1.$$

4 Statistical defendability

In this section we will completely determine, up to a constant factor, the values of ε and δ for which an arbitrary representation class is ε-defendable with confidence $1-\delta$, in the absence of any computational constraints on the detection strategy.

Our result is expressed in terms of the *Vapnik–Chervonenkis (VC) dimension* of the representation class $\mathcal{F}$, denoted $\mathrm{VC}(\mathcal{F})$. This is defined as the maximum size of a set S of points *shattered* by $\mathcal{F}$, meaning that all $2^{|S|}$ functions $S \to \{0,1\}$ are realized as the restriction $f|_S$ of some $f \in \mathcal{F}$.

▶ **Theorem 4.1.** *Let $\mathcal{F}$ be a representation class over $\{0,1\}^n$ and let $\varepsilon > 0$. Then the most (i.e., supremum) confidence with which $\mathcal{F}$ is ε-defendable is*

$$\max\left(\tfrac{1}{2}, 1 - \Theta\left(\mathrm{VC}(\mathcal{F})\,\varepsilon\right)\right)$$

as $\mathrm{VC}(\mathcal{F}) \to \infty$.

In particular, $\mathcal{F}$ is ε-defendable with confidence tending to 1 as $n \to \infty$ if and only if $\varepsilon = o\left(1/\mathrm{VC}(\mathcal{F})\right)$ as $n \to \infty$.

Thus in the computationally unbounded setting, defendability is determined almost entirely by the VC dimension of the representation class, in much the same way as PAC learnability [2, 22, Chapter 3].

In fact, to prove Theorem 4.1, we will make use of a certain kind of learning algorithm called a *prediction strategy*. Intuitively, a prediction strategy uses the value of a function on random samples to predict the value of the function on a new random sample. The formal definition is as follows.

▶ **Definition.** Let $\mathcal{F}$ be a representation class over $\mathcal{X} = \{0,1\}^n$. A *prediction strategy* for $\mathcal{F}$ is a randomized algorithm that is given access to the example oracle $\mathrm{Ex}(f, \mathcal{D})$ for some distribution $\mathcal{D}$ over $\mathcal{X}$ and some $f \in \mathcal{F}$, as well as $x \in \mathcal{X}$ as input, and outputs a prediction for $f(x)$.

The *sample size* of a prediction strategy is the maximum number of times it calls the example oracle, maximizing over any randomness used by the algorithm, any calls to the oracle, and the choice of $\mathcal{D}$, f and x.

Given a choice of $\mathcal{D}$ and f, the *error rate* of a prediction strategy is the probability that it fails to correctly predict $f(x)$ for $x \sim \mathcal{D}$, randomizing over any randomness used by the algorithm, any calls to the oracle, and the choice of x.

In their classical paper on prediction strategies, Haussler, Littlestone, and Warmuth [14] exhibit a "1-inclusion graph" algorithm yielding the following result.

▶ **Theorem** (Haussler–Littlestone–Warmuth). *For any representation class $\mathcal{F}$ and any positive integer m, there is a prediction strategy for $\mathcal{F}$ with sample size $m-1$ such that for any distribution $\mathcal{D}$ over $\mathcal{X}$ and any $f \in \mathcal{F}$, the error rate is at most*

$$\frac{\mathrm{VC}(\mathcal{F})}{m}.$$

As discussed in that work, there is a close relationship between prediction strategies and PAC learning algorithms, which we define in Section 5.2. We focus on prediction strategies in this section because they make our proof easier to carry out while avoiding the introduction of unnecessary logarithmic factors.

Our proof of Theorem 4.1 is closely modeled on a proof of Hanneke et al. [13, Theorem 3.1], although we cannot quote that result directly since it is specialized to a data poisoning setup. As in that proof, our detection strategy works by applying the Haussler–Littlestone–Warmuth prediction strategy multiple times and taking a majority vote.

The basic idea for the detection strategy is that, given (f', x') as input (which could be either (f, x) or (f^*, x^*)), if we could successfully predict $f(x')$, then we could distinguish the two cases by comparing this to $f'(x')$, since $f(x) = f(x)$ but $f(x^*) \neq f^*(x^*)$ if f^* is ε-valid. To attempt to make this prediction, we use the Haussler–Littlestone–Warmuth prediction strategy. However, if $f' = f^*$ then this can fail if we encounter a point where f and f^* disagree. Hence we are forced to use a small sample size, but we are still left with a small constant probability of failure. Fortunately though, we can repeat this procedure multiple times with independent samples and take a majority vote, which allows us to make this small constant probability vanish.

We now provide a sketch proof of Theorem 4.1. For a full proof, see Appendix B.

Sketch proof of Theorem 4.1. Write $d = \mathrm{VC}(\mathcal{F})$, and note that the detection strategy can achieve a win probability of at least $\frac{1}{2}$ simply by guessing randomly.

To show that the most confidence with which $\mathcal{F}$ is ε-defendable is at most $\max\left(\frac{1}{2}, 1 - \Omega(d\varepsilon)\right)$, let S be a set of size d shattered by $\mathcal{F}$. Roughly speaking, the adversary can take $\mathcal{D}$ to be uniform over S, and take f to be uniform over the witnesses to the shattering. Then the adversary can insert a backdoor by simply changing the value of f at x^* and no other points of S. The actual construction is slightly more careful than this, and is given in the full proof.

To show that the most confidence with which $\mathcal{F}$ is ε-defendable is at least $\max\left(\frac{1}{2}, 1 - O(d\varepsilon)\right)$, our detection strategy is as follows. Given (f', x') as input, we apply the Haussler–Littlestone–Warmuth prediction strategy with sample size $m-1$ and error rate at most $\frac{d}{m}$ to make a prediction for $f'(x')$, which we in turn think of as a prediction for $f(x')$. We repeat this procedure r times with independent samples and take a majority vote: if more than half of the predictions are different from $f'(x')$, then we output Rej, and otherwise we output Acc.

If (f, x) is passed to the detection strategy, then the probability that more than $\frac{1}{2}$ of the votes are wrong is at most $\frac{2d}{m}$, by Markov's inequality. If (f^*, x^*) is passed to the detection strategy, then there are two ways in which each vote can be wrong: either f and f^* disagree on at least one of the $m-1$ samples, or the prediction strategy fails to predict $f(x^*)$ even if it is provided with the value of f on all of these $m-1$ samples. The probability that $\frac{1}{4}$ or more of the votes will be wrong due to the second failure mode is at most $\frac{4d}{m}$, by Markov's inequality again. Meanwhile, we can ensure that the probability of the first failure mode for each vote is at most $\frac{1}{5}$ by taking $\frac{1}{5\varepsilon} < m \leq \frac{1}{5\varepsilon} + 1$. Since each choice of $m-1$ samples was independent, the probability that $\frac{1}{4}$ or more of the votes will be wrong due to the first

failure mode is at most $\exp\left(-\frac{r}{200}\right)$, by Hoeffding's inequality, which can be made arbitrarily small by taking r to be sufficiently large. Hence the probability that $\frac{1}{2}$ or more of the votes will be wrong is at most $\frac{4d}{m}$, and so the overall win probability is $1 - \frac{3d}{m} = 1 - O(\varepsilon d)$, as required. ◀

Intuitively, the reason that this detection strategy works is that the if ε is small compared to $1/\mathrm{VC}(\mathcal{F})$, then the attacker must choose a backdoored function that is very "strange". Hence the detection strategy can sample a new function that is similar to the given possibly backdoored function, but more "normal", and see if the two functions agree on the given possible backdoor trigger. This process can be thought of as a kind of regularization.

While our proof used distillation (i.e., learning from function samples) plus ensembling (i.e., voting), other methods of regularization may also work. For example, we could also have sampled from a Boltzmann distribution centered on the given function (with exponentially decaying probability based on Hamming distance), to get the same result up to logarithmic factors. We prove this claim in Appendix A.

5 Computational defendability

5.1 Definition of efficient defendability

In Section 4, we related the defendability of a representation class to its VC dimension. However, the prediction strategy we used to construct the detection strategy runs in exponential time, since it involves an expensive search over orientations of a certain graph. Hence it is interesting to ask what a polynomial-time detection strategy can achieve. To explore this, we introduce the following notion.

▶ **Definition 5.1.** Let $\mathcal{F}$ be a representation class over $\{0,1\}^n$. We say that $\mathcal{F}$ is *efficiently defendable* if there is some polynomial p such that for any $\delta > 0$ and any $\varepsilon > 0$ with $\varepsilon < 1/p\left(n, \frac{1}{\delta}\right)$, $\mathcal{F}$ is ε-defendable with confidence $1 - \delta$ using a detection strategy that runs in time polynomial in n and $\frac{1}{\delta}$.

Note that the condition that $\varepsilon < 1/p\left(n, \frac{1}{\delta}\right)$ is crucial: if $\mathcal{F}$ were required to be ε-defendable with confidence $1 - \delta$ for any $\varepsilon, \delta > 0$, then this would not be possible even for a detection strategy with unlimited time (except in trivial cases), by Theorem 4.1. (Recall that ε constrains the attacker, which is why this requirement helps the defender.)

As a reminder, we also assume in this section that representation classes have polynomial-length representations.

5.2 Efficient defendability and efficient PAC learnability

In this sub-section we show that efficient PAC learnability implies efficient defendability, but not conversely.

The well-studied model of probably approximately correct (PAC) learning was introduced by Valiant [30]. The notion of efficient PAC learnability bears some resemblance to our notion of efficient defendability. The following definition is taken from Kearns and Vazirani [22, Definition 4].

▶ **Definition.** Let $\mathcal{F}$ be a representation class over $\mathcal{X} = \{0,1\}^n$. We say that $\mathcal{F}$ is *efficiently PAC learnable* if there is a probabilistic algorithm (the "PAC learning algorithm") with the following properties. The PAC learning algorithm is given access to the example oracle $\mathrm{EX}(f, \mathcal{D})$ for some distribution $\mathcal{D}$ over $\mathcal{X}$ and some $f \in \mathcal{F}$, as well as $0 < \tilde{\varepsilon} < \frac{1}{2}$ (the "error

parameter") and $0 < \tilde{\delta} < \frac{1}{2}$ (the "confidence parameter") as input. The PAC learning algorithm must run in time polynomial in n, $\frac{1}{\tilde{\varepsilon}}$ and $\frac{1}{\tilde{\delta}}$, and must output some polynomially evaluatable hypothesis h, i.e. a representation for a function $\mathcal{X} \to \{0,1\}$ that is evaluatable in time polynomial in n. The hypothesis must satisfy $\mathbb{P}_{x\sim\mathcal{D}}\left(f\left(x\right) \neq h\left(x\right)\right) \leq \tilde{\varepsilon}$ with probability at least $1 - \tilde{\delta}$ for any distribution $\mathcal{D}$ over $\mathcal{X}$ and any $f \in \mathcal{F}$.

Note that $\tilde{\varepsilon}$ and $\tilde{\delta}$ play subtly different roles in this definition to ε and δ in the definition of efficient defendability. In particular, there is no condition on $\tilde{\varepsilon}$ as a function of n and $\tilde{\delta}$ in the definition of efficient PAC learnability.

We now show that efficient PAC learnability implies efficient defendability. This follows easily from the proof of Theorem 4.1. Even though that result used a prediction strategy that runs in exponential time, it is straightforward to replace it by an efficient PAC learning algorithm.

▶ **Corollary 5.2.** *Let $\mathcal{F}$ be a representation class over $\{0,1\}^n$. If $\mathcal{F}$ is efficiently PAC learnable, then $\mathcal{F}$ is efficiently defendable.*

Proof. If $\mathcal{F}$ is efficiently PAC learnable, then for any sufficiently large positive integer m, there is a polynomial-time prediction strategy for $\mathcal{F}$ with sample size $m-1$ and error rate at most $\frac{1}{6}\delta$: we simply PAC learn a hypothesis with confidence parameter $\frac{1}{12}\delta$ and error parameter $\frac{1}{12}\delta$, and then evaluate this hypothesis on the given point. The definition of PAC learning guarantees that this succeeds as long as m exceeds a particular polynomial in n and $\frac{1}{\delta}$.

Our detection strategy is then exactly the same as the one from the proof of Theorem 4.1, but using the above prediction strategy instead of the Haussler–Littlestone–Warmuth prediction strategy. Since $\varepsilon < 1/p(n,\frac{1}{\delta})$ for some polynomial p of our choice, choosing $m > \frac{1}{5\varepsilon}$ as in that proof suffices to ensure that m is eventually large enough for the prediction strategy to succeed. Finally, we take the number of votes r to be the smallest integer greater than $200\log\left(\frac{1}{\delta}\right)$, which keeps the time complexity of the detection strategy polynomial in n and $\frac{1}{\delta}$. Then the detection strategy's overall win probability is at least $1 - \frac{3}{6}\delta - \frac{1}{2}\exp\left(-\frac{r}{200}\right) > 1-\delta$, as required. ◀

We now show that the converse implication does not hold in the random oracle model of computation. In this model, programs have access to an oracle that outputs the result of calling of a uniformly random function $\{0,1\}^* \to \{0,1\}$.

▶ **Theorem 5.3.** *In the random oracle model of computation, with probability $1 - O(2^{-n^c})$ for all c over the choice of random oracle, there is a polynomially evaluatable representation class over $\mathcal{X} = \{0,1\}^n$ that is efficiently defendable but not efficiently PAC learnable.*

To prove this, we simply take a representation class of 2^n functions that make unique calls to the random oracle (supplying a different input to the oracle whenever either the function is different or the input to the function is different), and show that, with high probability over the choice of random oracle, this representation class is efficiently defendable but not efficiently PAC learnable. Roughly speaking, it is efficiently defendable because, for most sets of 2^n random functions with 2^n possible inputs, every pair of functions differs on around half of inputs, meaning that there are no ε-valid functions for the adversary to choose from. Meanwhile, it is not efficiently PAC learnable because most random functions with 2^n possible inputs differ from every possible function that a polynomial-time algorithm could output on around half of inputs. For a full proof, see Appendix C.

Although this result is in the random oracle model of computation, the same proof shows that the converse does not hold in the usual model of computation either. This is because we can make the random choices "on the outside": we fix a randomly-chosen lookup

table, and have the functions use that instead of calling the random oracle. However, this representation class is not necessarily polynomially evaluatable, since the lookup table would take up exponential space.

Nevertheless, we conjecture that there is a polynomially evaluatable counterexample that uses a pseudorandom function instead of a random oracle. The above proof cannot be immediately adapted to work for an arbitrary pseudorandom function, because two distinct keys could give rise to very similar functions, but it might not be too challenging to adapt it.

▶ **Conjecture 5.4.** *Assuming* OWF*, there is a polynomially evaluatable representation class over* $\{0,1\}^n$ *that is efficiently defendable but not efficiently PAC learnable.*

Here, OWF denotes the existence of a one-way function, which can used to construct a pseudorandom function [9, 20, Chapter 6].

One way in which our counterexample is unsatisfying is that it relies on the adversary being unable to find a backdoored function that is ε-valid, making detection trivial. However, it is straightforward to extend this result to a class for which it is always possible for the adversary to find a backdoored function that is ε-valid, but that is nevertheless efficiently defendable.

▶ **Example** (Special-cased random functions)**.** Let $\widetilde{\mathcal{F}}$ be one of the above representation classes over $\mathcal{X} = \{0,1\}^n$ that serves as a counterexample (either 2^n functions that call a random oracle, or a random choice of 2^n functions). Now let

$$\mathcal{F} = \left\{ x \mapsto \begin{cases} f(x), & \text{if } x \neq x^* \\ y & \text{if } x = x^* \end{cases} \;\middle|\; f \in \widetilde{\mathcal{F}}, x^* \in \mathcal{X}, y \in \{0,1\} \right\},$$

where implicitly, the representation of a function in $\mathcal{F}$ is given by a triple consisting of the representation of the function $f \in \widetilde{\mathcal{F}}$, the special-cased point $x^* \in \mathcal{X}$, and the special-cased value $y \in \{0,1\}$. Then the adversary can ensure that there is always a $\frac{2}{2^n}$-valid backdoored function by taking $\mathcal{D}$ to be the uniform distribution over $\mathcal{X}$. However, $\mathcal{F}$ is still efficiently defendable with high probability, since the detection strategy can check whether or not the input has been special-cased. $\mathcal{F}$ also remains not efficiently PAC learnable with high probability.

Thus we have an example of a non-trivial detection strategy that is faster than any PAC learning algorithm for that representation class. This shows that the learning-based detection strategy of Corollary 5.2 is not always best possible under computational constraints. Nevertheless, our example is somewhat contrived, and so in Section 6 we give an example of a more natural representation class for which defense is faster than learning.

5.3 Efficient defendability and obfuscation

We conclude our analysis of computational defendability with the following result, which essentially says that representation classes that are rich enough to support obfuscation are not efficiently defendable.

▶ **Theorem 5.5.** *Assuming* OWF *and* iO*, the representation class* $\mathcal{F}$ *of polynomial size Boolean circuits over* $\mathcal{X} = \{0,1\}^n$ *is not efficiently defendable.*

Here, OWF again denotes the existence of a one-way function, and iO denotes the existence of an efficient indistinguishability obfuscator. Roughly speaking, an efficient indistinguishability obfuscator is a probabilistic polynomial-time algorithm that takes in

a circuit and outputs an "obfuscated" circuit with the same behavior. The circuit being "obfuscated" means that the obfuscations of two different circuits with the same behavior are not distinguishable by any probabilistic polynomial-time adversary. For a precise definition of an efficient indistinguishability obfuscator, we refer the reader to Sahai and Waters [29, Section 3]. The study indistinguishability obfuscation was initiated by Barak et al. [1], and an efficient indistinguishability obfuscator was constructed from well-studied computational hardness assumptions by Jain, Lin and Sahai [17].

We use OWF in our proof of Theorem 5.5 to obtain a puncturable pseudorandom function. Roughly speaking, a puncturable pseudorandom function is pseudorandom function such that any key (i.e., seed) can be "punctured" at a set of points. The key being "punctured" means that, when run using the punctured key, the pseudorandom function behaves the same on unpunctured points, but to a probabilistic polynomial-time adversary with knowledge of the punctured key only, the function looks pseudorandom on punctured points when run using the original key. For a precise definition of a puncturable pseudorandom function, we again refer the reader to Sahai and Waters [29, Section 3]. The observation that puncturable pseudorandom functions can be constructed from one-way functions was made by Boneh and Waters [3], Boyle et al. [4] and Kiayias et al. [24].

Our proof of Theorem 5.5 is an example of a *hybrid argument*: we show that two distributions are computationally indistinguishable via a sequence of intermediate distributions. For a precise definition of computational indistinguishability and further discussion of hybrid arguments, we refer the reader to Katz and Lindell [20, Chapter 6.8]. The specific combination of a puncturable pseudorandom function and an efficient indistinguishability obfuscator has been used in a number of previous hybrid arguments, as described by Sahai and Waters [29].

With these preliminaries in place, we are now ready to prove Theorem 5.5.

Proof of Theorem 5.5. Take $\varepsilon = 2^{-n}$. We will show that, for any polynomial p, the representation class $\mathcal{F}$ of polynomial size Boolean circuits is not ε-defendable with confidence $\frac{1}{2} + \frac{1}{p(n)}$ using a detection strategy that runs in time polynomial in n.

To see this, by OWF, let $C_K \in \mathcal{F}$ be the circuit for a puncturable pseudorandom function with key $K \in \{0,1\}^n$ and a single output bit, and by iO, let $i\mathcal{O}$ be an efficient indistinguishability obfuscator. The adversary proceeds by taking $\mathcal{D}$ to be uniform over $\mathcal{X}$, and takes $f = i\mathcal{O}(C_K)$ for some $K \in \{0,1\}^n$ chosen uniformly at random. As before, we may treat f as if it were chosen randomly, since the detection strategy's worst-case performance can be no better than its average-case performance. Finally, given x^*, the adversary takes

$$f^* = i\mathcal{O}\left(x \mapsto \begin{cases} C_{\langle \textsc{Punc}(K,x^*)\rangle}(x), & \text{if } x \neq x^* \\ \langle 1 - C_K(x^*)\rangle, & \text{if } x = x^* \end{cases}\right),$$

where $\textsc{Punc}(K, x^*)$ punctures the key K at the point x^*, and angle brackets $\langle \dots \rangle$ indicate values that are hard-coded into the circuit, rather than being computed by the circuit. Note that f^* is ε-valid since it agrees with f on every point except x^*.

It remains to show that no polynomial-time detection strategy can win against this adversary with probability at least $\frac{1}{2} + \frac{1}{p(n)}$, which is equivalent to saying that (f, x) and (f^*, x^*) are computationally indistinguishable for $x \sim \mathcal{D}$. To see this, consider the intermediate circuit

$$\tilde{f} = i\mathcal{O}\left(x \mapsto \begin{cases} C_{\langle \textsc{Punc}(K,x^*)\rangle}(x), & \text{if } x \neq x^* \\ \langle C_K(x^*)\rangle, & \text{if } x = x^* \end{cases}\right),$$

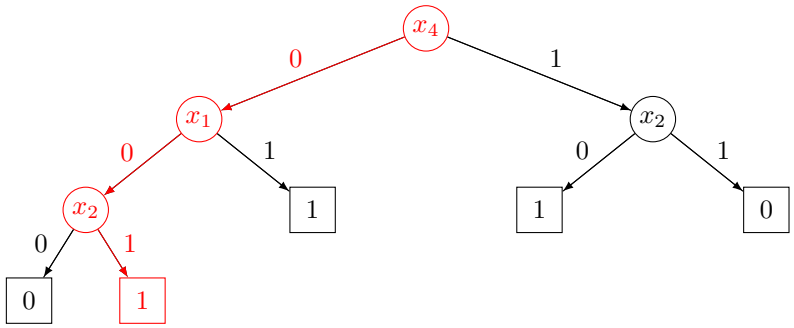


Figure 3 An example of a decision tree f over $\{0,1\}^4$ with a red path showing how $f(0110) = 1$.

which agrees with f everywhere. We claim that

$$(f, x) \overset{c}{\equiv} (f, x^*) \overset{c}{\equiv} (\tilde{f}, x^*) \overset{c}{\equiv} (f^*, x^*),$$

where $\overset{c}{\equiv}$ denotes computational indistinguishability of distributions. The first equivalence is simply an identity of distributions, since x^* was chosen randomly. The second equivalence follows by definition of indistinguishability obfuscation, with the technical detail that x^* is used as the "program state" that is passed from the circuit generator to the distinguisher. The third equivalence follows from puncturability: if $(\tilde{f}, x^*)$ and (f^*, x^*) were computationally distinguishable, then we could use this to computationally distinguish $C_K(x^*)$ from a uniformly random bit using only x^* and $\text{PUNC}(K, x^*)$. This final construction that relies on the fact that $i\mathcal{O}$ runs in polynomial time. By transitivity of computational indistinguishability, we have $(f, x) \overset{c}{\equiv} (f^*, x^*)$, as required. ◀

Thus even though all efficiently PAC learnable representation classes are efficiently defendable, some representation classes are not efficiently defendable due to the possibility of obfuscation.

6 Defendability of decision trees

In Section 5.2 we gave an example of a representation class for which defense is faster than learning, in the sense that it is efficiently defendable using a detection strategy that is faster than any PAC learning algorithm. However, our example was somewhat contrived, and was not polynomially evaluatable without access to a random oracle. In this section, we give an example of a more natural representation class for which defense is faster than learning: the class of polynomial size decision trees over $\{0,1\}^n$.

▶ **Definition.** A *decision tree* over $\{0,1\}^n$ is a rooted binary tree where each non-leaf node is labeled with one of the n input variables and each leaf node is labeled with a 0 or a 1. To evaluate a decision tree, we start at the root node and go left if the variable evaluates to 0 and right if it evaluates to 1, continuing until we reach a leaf. The *size* of a decision tree is its number of leaves.

An example of a decision tree and how to evaluate it is given in Figure 3.

In our study of decision trees, we focus on the *uniform-PAC* model of learning, in which the distribution $\mathcal{D}$ is always the uniform distribution. Thus we say that a representation class is *efficiently uniform-PAC learnable* to mean that it is efficiently PAC learnable as long as $\mathcal{D}$ is uniform. Similarly, we say that a representation class is *efficiently uniform-defendable* to mean that it is efficiently defendable as long as $\mathcal{D}$ is uniform.

As far as we are aware, it is unknown whether the representation class of polynomial size decision trees over $\{0,1\}^n$ is efficiently uniform-PAC learnable, although polynomial-time PAC learning algorithms are known for certain product distributions [19]. However, the class is efficiently uniform PAC-learnable if we allow membership queries (i.e., calls to an oracle that outputs the value of the function on an input of the algorithm's choice) [10, 27, Chapter 3.5]. By specializing the proof of Corollary 5.2, it follows that the representation class of polynomial size decision trees over $\{0,1\}^n$ is efficiently defendable, since the defender can efficiently compute the results of membership queries for themselves using the representation of the decision tree.

Nevertheless, these learning algorithms for decision trees generally use at least linearly many calls to the example or membership oracle. By contrast, we now show that there is a defense for decision trees that is much faster than this.

▶ **Theorem 6.1.** *The representation class $\mathcal{F}$ of decision trees over $\mathcal{X} = \{0,1\}^n$ of size at most s, where s is polynomial in n, is efficiently uniform-defendable using a detection strategy that makes 0 calls to the example oracle and runs in time O(time taken to evaluate a single decision tree).*

To prove this, we use a detection strategy that simply checks the depth of the leaf reached by the given input, and outputs Rej if this is too large. Roughly speaking, the reason this works is that, in order for the backdoored function to be ε-valid, the depth of the leaf reached by the backdoor trigger must be large for either the original function or the backdoored function. But since our trees have polynomially many leaves, this depth is unlikely to be large for the original function. Hence if the depth of the given function on the given input is large, then it is more likely that we have been given the backdoored function and the backdoor trigger.

For a full proof of Theorem 6.1, see Appendix D. We suspect that a similar approach would lead to fast detection strategies for other natural representation classes of piecewise constant functions, perhaps even in the non-uniform setting.

The detection strategy in this proof is not directly comparable to a learning algorithm, since it does not use the example oracle at all. However, if we treat a call to the example oracle as having similar computational cost to evaluating a single decision tree, then it is substantially faster than any possible learning algorithm for this representation class. Thus there is more to defense than only learning.

7 Discussion

7.1 Separating efficient defendability from efficient PAC learnability

A central theme of this work has been that learning can be used to perform backdoor defense, but backdoor defense cannot necessarily be used to perform learning. The first of these claims is encapsulated by Theorem 4.1 in the computationally unbounded setting and Corollary 5.2 in the computationally bounded setting. For the second of these claims, we have made several steps in this direction:

- We showed in Theorem 5.3 that efficient defendability does not imply efficient PAC learnability in the random oracle model of computation.
- We deduced from this that efficient defendability does not imply efficient PAC learnability in the usual model of computation either, as long as we allow representation classes that are not polynomially evaluatable, and we conjectured that there is a polynomially evaluatable counterexample assuming the existence of a one-way function.

- We showed in Theorem 6.1 that the representation class of polynomial size decision trees is efficiently uniform-defendable using a detection strategy that is faster than any possible learning algorithm.

Nevertheless, we still do not have an example of a natural representation class that is efficiently defendable but not efficiently PAC learnable. We consider finding such an example to be a central challenge for follow-up research. One possible candidate of independent interest is the representation class of shallow (i.e., logarithmic-depth) polynomial size Boolean circuits, or equivalently, polynomial size Boolean formulas.

▶ **Question 7.1.** Under reasonable computational hardness assumptions, is the representation class of polynomial size, logarithmic-depth Boolean circuits over $\{0,1\}^n$ efficiently defendable?

This representation class is known to not be efficiently PAC learnable under the assumption of the computational hardness of discrete cube roots [21, 22, Chapter 6].

7.2 Mechanistic defenses

Our detection strategy for decision trees in Theorem 6.1 is interesting not only because it is faster than any possible learning algorithm, but also because it works in a fundamentally different way. Given (f', x') as input, it does not run the decision tree f' on any inputs other than x' itself, but instead exploits the *mechanism* by which the value of $f'(x')$ is computed, by looking at the depth of the corresponding leaf. We call a defense that exploits the structure of f' in this kind of way *mechanistic*.

The existence of mechanistic defenses is another reason to suspect that there are other representation classes for which defense is strictly easier than learning. However, some sophistication may be required to construct such defenses. For example, one might hope to detect a backdoor trigger for a Boolean formula by checking the pattern of inputs to each gate, and seeing how unlikely that pattern would be for a random input to the formula. Unfortunately, though, the following example, found by Thomas Read, presents an obstacle to such an approach.

▶ **Example** (Backdoor with likely input patterns)**.** Consider the Boolean formulas $f, f^* : \{0,1\}^n \to \{0,1\}$ given by $f(x_1, \ldots, x_n) = x_n x_{n-1}$ and

$$f^*(x_1, \ldots, x_n) = (\ldots((x_1 \vee x_n x_2)\, x_2 \vee x_n x_3)\, x_3 \vee \cdots \vee x_n x_{n-1})\, x_{n-1},$$

where ab is shorthand for $(a \wedge b)$. By the distributive property, $f^*(x_1, \ldots, x_n)$ is logically equivalent to $x_1 x_2 \ldots x_{n-1} \vee x_n x_{n-1}$, and so f and f^* disagree only on the input $x^* := (1, \ldots, 1, 0)$. But on a uniformly random input to the formula, every gate in f^* receives every pattern of inputs with probability at least $1/8$. By contrast, in the logically equivalent version of f^*, the subformula $x_1 x_2 \ldots x_{n-1}$ is 1 on x^*, which only happens with probability $1/2^{n-1}$ on a uniformly random input.

This example suggests a possible mechanistic defense for Boolean formulas that involves first rewriting the formula. More generally, mechanistic defenses offer an exciting avenue for future research.

7.3 Implications for AI alignment

We are motivated to study backdoors as an analogy for *deceptive alignment*, the possibility that an advanced AI system would learn to behave cooperatively when there are subtle cues that it is in training, but uncooperatively when those cues are missing [16]. A deceptively

aligned model is analogous to a backdoored function in that it behaves similarly to a fully cooperative model except on certain inputs that are rare during training. Thus, in this analogy, $\mathcal{D}$ is the training distribution, f is the fully cooperative model, f^* is the deceptively aligned model, and x^* is an input on which f^* behaves uncooperatively.

Note that allowing the backdoor to be detected at runtime is appropriate in this analogy, because we have the opportunity to modify f^* or run a monitoring system. The flaw in the analogy comes from how the attacker is restricted. In our formal notion of defendability, the attacker must insert a backdoor that works for a randomly-chosen trigger. But in the case of deceptive alignment, there is no such restriction, and instead the backdoored behavior must arise from properties of the model architecture and the training distribution.

From this perspective, backdoor defenses that rely on learning are unsatisfying, because our assumption is that a similar process of learning gave rise to deceptive alignment in the first place. The detection strategy in our proof of Theorem 4.1 used distillation plus ensembling to produce a regularized model, but this may be exploiting the flaw in our analogy by using resampling to avoid the randomly-chosen trigger. Moreover, we would have to rely on a fast approximation to this strategy, since the exact version runs in exponential time. Similar issues apply to other methods of regularization, such as the one discussed in Appendix A, although that alternative does show more promise.

On the other hand, mechanistic defenses, as discussed in Section 7.2, may fare better, since they work very differently. Intuitively, if a detection strategy could spot the mechanism by which a deceptively aligned model concluded that it was in training, then it should transfer well to the case of deceptive alignment. A mechanistic defense may be able to do this by exploiting the fact that this mechanism is active on the backdoor trigger but inactive on most random inputs. Unfortunately though, we are lacking in examples of mechanistic defenses, which why we are excited to see more research in this direction.

Our result that polynomial size circuits are not efficiently defendable in Theorem 5.5 is also relevant to this analogy. Although it is unlikely that our indistinguishability obfuscator-based construction would arise out of ordinary model training, it is much more plausible for a trained model to be obfuscated in a more informal sense. Indeed, reverse engineering trained neural networks is an active area of research [28]. Hence the possibility of obfuscation poses a potential problem for detecting deceptive alignment. However, in the case of deceptive alignment, we also have access to the entire training process, including the training dataset, which may be enough information for us to detect the trigger despite any potential obfuscation. By analogy, in our construction in Theorem 5.5, it would be easy for the defender to detect the trigger if they had access to the unpunctured key K that was used in the construction of f^*.

This motivates the study of variants of our formal notion of defendability that constrain the attacker in different ways, or provide more assistance to the defender. To better capture the analogy with deceptive alignment, we would be excited to see research into variants that provide the defender with more information about how the function they are given was constructed, to see if this makes defense computationally feasible.

8 Conclusion

We have introduced a formal notion of defendability against backdoors in which the attacker's strategy must work for a randomly-chosen trigger. Despite its simplicity, this notion gives rise to a rich array of strategies. In the absence of computational constraints, defense is exactly as hard as learning. Meanwhile, in the presence of computational constraints, defense

is strictly easier than learning, but impossible for function classes that are rich enough to support obfuscation. We are excited to see future work that further explores the exact relationship between defense and learning.

A Alternative version of Theorem 4.1 using a Boltzmann posterior

In this section we prove a slightly weaker version of Theorem 4.1 using a detection strategy that does not involve learning. Instead of using distillation plus ensembling as in the proof of Theorem 4.1, we employ an alternative method of regularization that involves resampling the given function from a Boltzmann posterior. This gives rise to an extra logarithmic factor in the confidence of the detection algorithm, but otherwise gives the same bound, and in particular the threshold for detecting backdoors in a class of VC dimension d is still $\varepsilon = \Theta\left(\frac{1}{d}\right)$.

We are grateful to Dmitry Vaintrob for an earlier version of these results.

The remainder of this section has been omitted from this version due to the page limit. For the full version, see: https://arxiv.org/abs/2409.03077

B Proof of Theorem 4.1

▶ **Theorem 4.1.** *Let $\mathcal{F}$ be a representation class over $\{0,1\}^n$ and let $\varepsilon > 0$. Then the most (i.e., supremum) confidence with which $\mathcal{F}$ is ε-defendable is*

$$\max\left(\tfrac{1}{2}, 1 - \Theta\left(\mathrm{VC}\left(\mathcal{F}\right)\varepsilon\right)\right)$$

as $\mathrm{VC}\left(\mathcal{F}\right) \to \infty$.

Proof. Write $d = \mathrm{VC}\left(\mathcal{F}\right)$. We will show that, more specifically, for $d \geq 1$:

(a) For any detection strategy there is an adversary limiting their win probability to at most $\max\left(\frac{1}{2}, 1 - \frac{1}{2}\left(d-1\right)\varepsilon\right)$.

(b) There is a detection strategy that wins against any adversary with probability at least $\max\left(\frac{1}{2}, 1 - 15d\varepsilon\right)$.

For part a, let S be a set of size d shattered by $\mathcal{F}$, and let $s \in S$ be any point. The adversary proceeds by taking $\mathcal{D}$ to assign probability $\min\left(\frac{1}{d-1}, \varepsilon\right)$ to each point of $S \setminus \{s\}$ and the remaining $1-p$ probability to the point s, where $p := \min\left(1, \left(d-1\right)\varepsilon\right)$. The adversary then takes f to be one of the 2^{d-1} witnesses for the shattering that assigns 0 to the point s. We may treat f as if it were chosen uniformly at random, since the detection strategy's worst-case performance can be no better than its average-case performance. Finally, given x^*, the adversary takes f^* to be the witness that agrees with f exactly on the set $S \setminus \{x^*\}$ if $x^* \neq s$, and otherwise takes $f^* = f$. It is easy to check that f^* is ε-valid if and only if $x^* \neq s$. Furthermore, (f, x) and (f^*, x^*) are identically distributed for $x \sim \mathcal{D}$. Hence the best a detection strategy can do is to output Acc when given the point s, and otherwise the strategy can do no better than chance. So the detection strategy's overall win probability is at most $(1-p) + \frac{p}{2} = 1 - \frac{p}{2}$, as required.

For part b, note first that the detection strategy can achieve a win probability of at least $\frac{1}{2}$ simply by guessing randomly, so we may assume that $1 - 15d\varepsilon > \frac{1}{2}$. To construct the detection strategy, by Haussler–Littlestone–Warmuth, take a prediction strategy for $\mathcal{F}$ with sample size $m-1$ and error rate at most $\frac{d}{m}$, for some positive integer m to be chosen later. The detection strategy then works as follows:

- Given (f', x') as input (which could be either (f, x) or (f^*, x^*)), we use the prediction strategy to make a prediction z for $f'\left(x'\right)$, which we in turn think of as a prediction for $f\left(x'\right)$. The idea is that if we can successfully predict $f\left(x'\right)$, then we can distinguish the two cases by comparing this to $f'\left(x'\right)$, since $f\left(x\right) = f\left(x\right)$ but $f\left(x^*\right) \neq f^*\left(x^*\right)$ if f^* is ε-valid.
- We repeat this procedure r times with independent samples to obtain predictions $z^{(1)}, \ldots, z^{(r)}$ for some positive integer r to be chosen later.
- Finally, we take a majority vote: if more than half of $z^{(1)}, \ldots, z^{(r)}$ are different from $f'\left(x'\right)$, then we output Rej, and otherwise we output Acc.

To lower bound the detection strategy's win probability, consider first the case in which (f, x) is passed to the detection strategy. In this case the probability that $z \neq f\left(x\right)$ is at most the error rate $\frac{d}{m}$. Hence by Markov's inequality and linearity of expectation, the probability that more than half of $z^{(1)}, \ldots, z^{(r)}$ are different from $f\left(x\right)$ is at most $\frac{2d}{m}$, giving the detection strategy a failure probability of at most $\frac{2d}{m}$. If instead (f^*, x^*) is passed to the detection strategy, then there are two possible reasons why we could have $z \neq f\left(x^*\right)$: either f and f^* disagree on at least one of the $m-1$ samples provided by the example oracle, or the prediction strategy fails to predict $f\left(x^*\right)$ even if it is provided with the value of f on all

of these $m-1$ samples. Write $\mathbb{1}^{(i)}_{f \text{ and } f^* \text{ disagree}}$ and $\mathbb{1}^{(i)}_{\text{prediction fails}}$ for the indicator functions of these two events respectively during the ith trial for $i \in \{1, \ldots, r\}$. Then the probability that the detection strategy fails is

$$\mathbb{P}\left(\frac{1}{r}\sum_{i=1}^{r} \mathbb{1}_{z^{(i)} \neq f(x^*)} \geq \frac{1}{2}\right) \leq \mathbb{P}\left(\frac{1}{r}\sum_{i=1}^{r} \mathbb{1}^{(i)}_{f \text{ and } f^* \text{ disagree}} \geq \frac{1}{4}\right) + \mathbb{P}\left(\frac{1}{r}\sum_{i=1}^{r} \mathbb{1}^{(i)}_{\text{prediction fails}} \geq \frac{1}{4}\right).$$

The second term on the right-hand side is at most $\frac{4d}{m}$ by another application of Markov's inequality and linearity of expectation. To bound the first term on the right-hand side, we may assume without loss of generality that f^* is ε-valid, which implies that $p := \mathbb{P}\left(\mathbb{1}^{(i)}_{f \text{ and } f^* \text{ disagree}} = 1\right) \leq (m-1)\,\varepsilon$, by the union bound. Taking m to be the unique positive integer with $\frac{1}{5\varepsilon} < m \leq \frac{1}{5\varepsilon} + 1$, we have $p \leq \frac{1}{5}$. Since these r indicator functions are independent, the first term on the right-hand side is at most $\exp\left(-2\left(\frac{1}{4} - \frac{1}{5}\right)^2 r\right) = \exp\left(-\frac{r}{200}\right)$ by Hoeffding's inequality, which can be made arbitrarily small by taking r to be sufficiently large. Putting everything together, the detection strategy's best overall win probability is at least

$$\tfrac{1}{2}\left(\left(1 - \tfrac{2d}{m}\right) + \left(1 - \tfrac{4d}{m}\right)\right) = 1 - \tfrac{3d}{m} > 1 - 15\varepsilon d,$$

as required. ◀

C Proof of Theorem 5.3

▶ **Theorem 5.3.** *In the random oracle model of computation, with probability $1 - O(2^{-n^c})$ for all c over the choice of random oracle, there is a polynomially evaluatable representation class over $\mathcal{X} = \{0,1\}^n$ that is efficiently defendable but not efficiently PAC learnable.*

Proof. Write $\textsc{Rand} : \{0,1\}^* \to \{0,1\}$ for the random oracle. Let $\mathcal{K} = \{0,1\}^n$ be a set of "keys", and let $\mathcal{F} = \{x \mapsto \textsc{Rand}(K \parallel x) \mid K \in \mathcal{K}\}$, where $\parallel$ denotes string concatenation. We will show that, over the choice of random oracle, $\mathcal{F}$ is efficiently defendable with probability $1 - o(2^{-n^c})$ as $n \to \infty$ for all $c \geq 1$, but not efficiently PAC learnable with probability $1 - o\left(\exp\left(-2^{n-4}\right)\right)$ as $n \to \infty$. The result then follows by the union bound.

For defendability, let $\delta > 0$ and $c \geq 1$. We will show that, with probability $1 - o(2^{-n^c})$ over the choice of random oracle, if $\varepsilon = o\left(\frac{\delta}{n^c}\right)$ then $\mathcal{F}$ is ε-defendable with confidence $1 - \delta$ using the trivial detection strategy that always outputs $\textsc{Acc}$. To see this, let $\mathcal{D}$ be the distribution over $\mathcal{X}$ chosen by the adversary, and for $x \in \mathcal{X}$ write $\mathbb{P}_{\mathcal{D}}(x)$ for $\mathbb{P}_{x' \sim \mathcal{D}}(x' = x)$. In order for the adversary to be able to choose a backdoored function that is ε-valid with high enough probability over the choice of backdoor trigger, the adversary must choose $\mathcal{D}$ so that

$$S_1 := \sum_{\substack{x \in \mathcal{X} \\ \mathbb{P}_{\mathcal{D}}(x) \leq \varepsilon}} \mathbb{P}_{\mathcal{D}}(x) > 2\delta.$$

Note also that

$$S_2 := \sum_{\substack{x \in \mathcal{X} \\ \mathbb{P}_{\mathcal{D}}(x) \leq \varepsilon}} \mathbb{P}_{\mathcal{D}}(x)^2 \leq \varepsilon S_1.$$

Now for any $K, K^* \in \mathcal{K}$ and any $\varepsilon < \frac{1}{2}S_1$,

$$\begin{aligned}
&\mathbb{P}_{\text{RAND}}\left(\mathbb{P}_{x\sim D}\left(\text{RAND}\left(K \parallel x\right) \neq \text{RAND}\left(K^* \parallel x\right)\right) \leq \varepsilon\right) \\
&\leq \mathbb{P}_{\text{RAND}}\left(\sum_{\substack{x\in\mathcal{X} \\ \mathbb{P}_{\mathcal{D}}(x)\leq\varepsilon}} \mathbb{P}_{\mathcal{D}}\left(x\right) \mathbb{1}_{\text{RAND}(K\parallel x)\neq\text{RAND}(K^*\parallel x)} \leq \varepsilon\right) \\
&\leq \exp\left(-\frac{2\left(\frac{1}{2}S_1 - \varepsilon\right)^2}{S_2}\right) && \text{(by Hoeffding's inequality)} \\
&\leq \exp\left(-\frac{S_1}{2\varepsilon} - \frac{2\varepsilon}{S_1} + 2\right) && \text{(since } S_2 \leq \varepsilon S_1\text{)} \\
&< \exp\left(-\frac{\delta}{\varepsilon} - 2\varepsilon + 2\right) && \text{(since } 2\delta < S_1 \leq 1\text{)}.
\end{aligned}$$

Hence by the union bound, it is impossible for the adversary to choose any $K, K^* \in \mathcal{K}$ with $\mathbb{P}_{x\sim D}\left(\text{RAND}\left(K \parallel x\right) \neq \text{RAND}\left(K^* \parallel x\right)\right) \leq \varepsilon$ with probability at least

$$1 - \binom{|\mathcal{K}|}{2}\exp\left(-\frac{\delta}{\varepsilon} - 2\varepsilon + 2\right) > 1 - \exp\left((2n-1)\log\left(2\right) - \frac{\delta}{\varepsilon} - 2\varepsilon + 2\right).$$

When this event happens the detection strategy always wins, and if $\varepsilon = o\left(\frac{\delta}{n^c}\right)$ then this probability is $1 - o(2^{-n^c})$, as required.

For PAC learnability, we will show that, with probability $1 - o\left(\exp\left(-2^{n-4}\right)\right)$ over the choice of random oracle, there is no PAC learning algorithm for $\mathcal{F}$, even with access to the random oracle, that runs in time $f\left(n\right) = 1.5^n$ with confidence parameter $\frac{1}{4}$ and error parameter $\frac{1}{4}$, say. To see this, note that, for all sufficiently large n, there are fewer than $2^{f(n)}$ possible hypotheses that such an algorithm could output, assuming by convention that algorithms can process at most one bit per unit time. Now for each of these hypotheses h, if $\mathcal{D}$ is the uniform distribution over $\mathcal{X}$ and $K \in \mathcal{K}$, then

$$\mathbb{P}_{\text{RAND}}\left(\mathbb{P}_{x\sim D}\left(\text{RAND}\left(K \parallel x\right) \neq h\left(x\right)\right) \leq \tfrac{1}{4}\right) \leq \exp\left(-2\left(\tfrac{1}{2} - \tfrac{1}{4}\right)^2 |\mathcal{X}|\right) = \exp\left(-2^{n-3}\right)$$

by Hoeffding's inequality. Hence by the union bound, the probability that none of these hypotheses has generalization error at most $\frac{1}{4}$ is at least

$$1 - 2^{f(n)}\exp\left(-2^{n-3}\right) = 1 - \exp\left(1.5^n\log\left(2\right) - 2^{n-3}\right) = 1 - o\left(\exp\left(-2^{n-4}\right)\right).$$

When this event happens the PAC learning algorithm fails with probability $1 > \frac{1}{4}$, as required. ◀

D Proof of Theorem 6.1

▶ **Theorem 6.1.** *The representation class $\mathcal{F}$ of decision trees over $\mathcal{X} = \{0,1\}^n$ of size at most s, where s is polynomial in n, is efficiently uniform-defendable using a detection strategy that makes 0 calls to the example oracle and runs in time $O\left(\text{time taken to evaluate a single decision tree}\right)$.*

Proof. Given $f \in \mathcal{F}$ and $x \in \mathcal{X}$, write $\text{DEPTH}\left(f, x\right)$ for the number of distinct input variables that appear along the path from root to leaf when f is evaluated at x.

Let $\delta > 0$, and take $\varepsilon < \frac{\delta^2}{s^2}$. We claim that, as long as the adversary takes $\mathcal{D}$ to be uniform distribution, $\mathcal{F}$ is ε-defendable with confidence $1-\delta$ using the detection strategy that, given (f', x') as input, outputs Rej if $2^{-\textsc{Depth}\left(f', x'\right)} \leq \frac{\delta}{s}$ and Acc otherwise. This suffices, since evaluating $\textsc{Depth}\left(f', x'\right)$ takes the same time as evaluating $f'\left(x'\right)$, up to a constant factor.

To see this, given $f \in \mathcal{F}$ and $x \in \mathcal{X}$, write

$$\textsc{Leaf}\left(f, x\right) = \left\{x' \in \mathcal{X} \mid x' \text{ and } x \text{ reach the same leaf of } f\right\},$$

and observe that

$$\mathbb{P}_{\mathcal{D}}\left(\textsc{Leaf}\left(f, x\right)\right) = 2^{-\textsc{Depth}(f,x)},$$

where we have written $\mathbb{P}_{\mathcal{D}}\left(S\right)$ as shorthand for $\mathbb{P}_{x\sim\mathcal{D}}\left(x \in S\right)$. The key claim is that, for any $f \in \mathcal{F}$ and any $x^* \in \mathcal{X}$, if $f^* \in \mathcal{F}$ is ε-valid, then

$$2^{-\textsc{Depth}(f,x^*)-\textsc{Depth}(f^*,x^*)} \leq \mathbb{P}_{\mathcal{D}}\left(\textsc{Leaf}\left(f, x^*\right) \cap \textsc{Leaf}\left(f^*, x^*\right)\right) \leq \varepsilon.$$

The first inequality is a consequence of the fact that the number of distinct variables that appear when either f or f^* is evaluated at x^* is at most $\textsc{Depth}\left(f, x^*\right) + \textsc{Depth}\left(f^*, x^*\right)$, and makes essential use of the fact that $\mathcal{D}$ is uniform (or at the very least, a product distribution). The second inequality follows from the definition of ε-valid.

Now choose f, x^*, f^* and x as in the backdoor detection game. Suppose first that (f, x) is passed to the detection strategy. Then with probability at least $1-\delta$, we have $2^{-\textsc{Depth}(f,x)} = \mathbb{P}_{\mathcal{D}}\left(\textsc{Leaf}\left(f, x\right)\right) > \frac{\delta}{s}$, since f has at most s leaves. Hence the detection strategy outputs Acc with probability at least $1-\delta$. Now suppose instead that (f^*, x^*) is passed to the detection strategy. Then with probability at least $1-\delta$, we have $2^{-\textsc{Depth}(f,x^*)} > \frac{\delta}{s}$, by a similar argument. But if f^* is ε-valid, then this implies that $2^{-\textsc{Depth}(f^*,x^*)} < \varepsilon/\frac{\delta}{s} < \frac{\delta}{s}$, by the key claim. Hence the detection strategy outputs Rej with probability at least $1-\delta$. So the detection strategy's overall win probability is at least $1-\delta$, as required. ◀

Data Reconstruction: When You See It and When You Don't

Abstract

We revisit the fundamental question of formally defining what constitutes a *reconstruction attack*. While often clear from the context, our exploration reveals that a precise definition is much more nuanced than it appears, to the extent that a single all-encompassing definition may not exist. Thus, we employ a different strategy and aim to "sandwich" the concept of reconstruction attacks by addressing two complementing questions: (i) What conditions guarantee that a given system is protected against such attacks? (ii) Under what circumstances does a given attack clearly indicate that a system is not protected? More specifically,

- We introduce a new definitional paradigm – *Narcissus Resiliency* – to formulate a security definition for protection against reconstruction attacks. This paradigm has a self-referential nature that enables it to circumvent shortcomings of previously studied notions of security. Furthermore, as a side-effect, we demonstrate that Narcissus resiliency captures as special cases multiple well-studied concepts including differential privacy and other security notions of one-way functions and encryption schemes.
- We formulate a link between reconstruction attacks and *Kolmogorov complexity*. This allows us to put forward a criterion for evaluating when such attacks are convincingly successful.

1 Introduction

Reasoning about data privacy is crucial in today's data-driven world. This includes the design of privacy-enhancing technologies aimed at protecting privacy, as well as identifying vulnerabilities of existing methods by conducting "privacy attacks". The most severe family of attacks is, arguably, *reconstruction attacks*, where an adversary takes what appears to be benign statistics and reconstructs significant portions of the sensitive data [19]. Such attacks have helped shape the theory of data privacy as well as expose vulnerabilities in existing real-world systems.

However, prior works did not coalesce around a single *definition of reconstruction* and instead considered several context-dependent definitions. Although these definitions made sense in the context in which they were introduced, they do not necessarily carry over to other settings, as we will later explain. Motivated by this, our work is set to answer the following meta-question:

▶ **Question 1.** *What is reconstruction?*

This question is more nuanced than it initially appears, as will become clear later. It seems that for every attempt to define reconstruction mathematically, there are cases that either fit the definition but do not "feel like" reconstruction, or vice versa. As a result, we do not know whether a precise answer to Question 1 exists, and leave it as an open question for future work. In this work, we aim to approach Question 1 by "sandwiching" the concept of reconstruction and studying the following two questions:

▶ **Question 2.** *What conditions are sufficient to ensure that a given system is protected against reconstruction attacks?*

▶ **Question 3.** *Under what circumstances does an attack clearly indicate that a given system is vulnerable?*

This is reminiscent of the current state of affairs in the related concept of *differential privacy (DP)* [20]: If an algorithm satisfies DP (with small enough privacy parameters), then it is guaranteed to be "safe" in terms of its privacy implications. However, the fact that an algorithm does not satisfy DP does not immediately mean that it is unsafe privacy-wise. Rather, to convince that an algorithm is unsafe, one usually needs to demonstrate an actual attack, such as a reconstruction or a membership attack. In other words, in the context of data privacy, we currently do not have a good definition of what constitutes "privacy"; only definitions of what it means to "protect" privacy, and definitions for what it means to "attack" an algorithm in order to show a privacy breach. We embrace this way of thinking and leverage it towards formally reasoning about reconstruction, as stated in Questions 2 and 3. We elaborate on each of these two questions separately, in Sections 1.1 and 1.2, respectively.

1.1 Protecting against reconstruction

Consider an algorithm $\mathcal{M}$ that takes a dataset S and returns an output y. For example, the dataset S might contain images, and the output y may be an image generative model. This output y is then given to a "privacy attacker" $\mathcal{A}$ whose goal is to output a "reconstruction" z of elements from S. Informally, we want to say that algorithm $\mathcal{M}$ *prevents reconstruction attacks* if y is "hard to invert" in the sense that y does not help the attacker in "recovering" elements from S. However, there are two immediate issues that require attention here:

1. What it means to "recover elements" is context-dependent. For example, our criteria for when one image "recovers" another image would likely differ from our criteria for when a text file "recovers" another text file. As we aim for a general treatment, we abstract this criteria away in the form of a *relation* R, where $R(S, z) = 1$ if and only if z is a "valid reconstruction" of S (or of some data point in S). In our example with the images, this could mean that z is an image which is "close enough" to one of the images in S. Alternatively, depending on the context, this could also mean that z is a collection of 100 images of which one is "close enough" to an image in S, or it could mean that z is a vector of 100 images, each of them is "somewhat close" to a distinct image in S, etc.
2. The underlying distribution of the data matters a lot. For example, consider a scenario where every sufficiently large image dataset contains the Mona Lisa. An "attack" that outputs an image that is similar or identical to the Mona Lisa is not necessarily a successful attack, as this could be accomplished without even accessing the generative model y.

These considerations led [4] and [18] to present definitions with the following flavor:

▶ **Definition 4** ([4, 18]). *Let $\mathcal{X}$ be a data domain, let $\mathcal{D}$ be a distribution over datasets containing elements from $\mathcal{X}$, and let $R : \mathcal{X}^* \times \{0,1\}^* \to \{0,1\}$ be a reconstruction criterion. Algorithm $\mathcal{M}$ is $(\varepsilon, \delta, \mathcal{D})$-$R$-reconstruction-robust if for all attackers $\mathcal{A}$ it holds that*

$$\Pr_{\substack{S\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ z\leftarrow\mathcal{A}(y)}}[R(S,z)=1] \leq e^{\varepsilon}\cdot\sup_{z^*}\Pr_{T\leftarrow\mathcal{D}}[R(T,z^*)=1]+\delta. \tag{1}$$

In words, in Definition 4 the attacker's probability of success is compared to a *baseline* which is the probability of success of the best *trivial attacker* that simply chooses a fixed element z^* (independently of the dataset). To contradict the security of algorithm $\mathcal{M}$, the attacker must succeed with a probability noticeably higher than the baseline (depending on the parameters ε and δ). Note that the aforementioned attacker that "recovered" the Mona Lisa would *not* contradict the security of $\mathcal{M}$. The reason is that if every (large enough) dataset sampled from $\mathcal{D}$ would contain the Mona Lisa, then in Definition 4 we could take z^* to be the Mona Lisa, and hence the right hand size of Inequality (1) would be one.[1]

This introduces a serious problem: once the baseline probability is 1 then *no adversary* could ever contradict Inequality (1), even adversaries that do achieve meaningful reconstructions. To illustrate the issue, suppose that the dataset contains both "canonical" photos (such as the Mona Lisa or canonical photos of US presidents), as well as "sensitive" photos of ordinary individuals. While recovering a canonical photo should not be considered a successful attack, recovering a "sensitive" photo definitely should. Formally, suppose that every image in S is sampled independently as follows: with probability 1/2 return the Mona Lisa, and otherwise return a photo of a random citizen. If under these conditions $\mathcal{A}(\mathcal{M}(S))$

[1] For this example we assume that if $z^* \in T$ then $R(T, z^*) = 1$.

is able to recover a photo of an ordinary individual from S, then that should be considered a reconstruction attack. But this is not captured by Definition 4 as the performance of $\mathcal{A}$ is compared with a baseline where the Mona Lisa is recovered. More generally, a sever flaw of Definition 4 is that once the baseline probability is ≈ 1 then no adversary could ever contradict Inequality (1).

1.1.1 Towards a new definition

A takeaway from the above discussion is that comparing all adversaries to the same fixed baseline can create a problem. In particular, adversaries that identify "special" elements in S (which are unlikely to appear in fresh datasets) should be distinguished from adversaries that identify "trivial" elements in S. We now make an attempt to incorporate this into the definition. As we will see, this attempt has different shortcomings.

▶ **Definition 5.** *Let $\mathcal{X}$ be a data domain, let $\mathcal{D}$ be a distribution over datasets containing elements from $\mathcal{X}$, and let $R : \mathcal{X}^* \times \{0,1\}^* \to \{0,1\}$. Algorithm $\mathcal{M}$ is $(\varepsilon, \tau, \mathcal{D})$-R-reconstruction-robust if for all attackers $\mathcal{A}$ it holds that*

$$\Pr_{\substack{S\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ z\leftarrow\mathcal{A}(y)}}\Big[R(S,z)=1 \;\; \textit{and} \;\; \Pr_{T\leftarrow\mathcal{D}}[R(T,z)=1]\leq\tau\Big]\leq\varepsilon. \tag{2}$$

In words, with this definition the attacker's goal is to identify an element z such that (1) z is a valid reconstruction w.r.t. the dataset S; and (2) the same z is unlikely to be a valid reconstruction w.r.t. a fresh dataset T. Informally, $\Pr_{T\leftarrow\mathcal{D}}[R(T,z)=1]$ serves as a "conditional baseline" that adapts itself to the element z chosen by the attacker. Note that in the context of our example with the Mona Lisa, an attacker that "recovers" the Mona Lisa would not contradict Inequality (2), because $\Pr_{T\leftarrow\mathcal{D}}[R(T,z)=1]$ would be large and hence greater than the threshold τ. On the other hand, an attacker that manages to recover the photo of an ordinary individual from S (with large enough probability) would contradict Inequality (2). So Definition 5 achieves the desired behavior for this example.

A shortcoming of Definition 5 is that the values of ε and τ are necessarily context dependent. To illustrate this, we will now describe two situations where in one of them we need to set $\varepsilon, \tau < \frac{1}{2}$ in order for the definition to make sense, while in the other situation ε and τ must be larger than $\frac{1}{2}$.

- For the first situation, consider the following distribution $\mathcal{D}$ over datasets: With probability $\frac{1}{2}$ return a dataset containing random photos of ordinary citizens. Otherwise, return a dataset sampled similarly, except that one of its photos is replaced with the Mona Lisa. Under these conditions, we must set $\tau < \frac{1}{2}$ in order to circumvent the "trivial attack" using the Mona Lisa. Setting ε close to 0 seems reasonable under these conditions in order to guarantee that a meaningful reconstruction can happen only with small probability.
- For the second situation, consider a case where the dataset is a vector of n random bits, and the attacker's goal is to pinpoint a single entry from this vector and to guess it with high probability. Formally, in this example we interpret the outcome of the adversary as $z = (i, b) \in [n] \times \{0,1\}$, where $R(S,(i,b)) = 1$ if and only if $S[i] = b$. In this scenario, *every* adversary always satisfies $\Pr_{T\leftarrow\mathcal{D}}[R(T,z)=1] = 1/2$ and hence if we set $\tau < 1/2$ then every algorithm is safe w.r.t. to that definition, which is absurd. Therefore we may assume that $\tau \geq 1/2$. In this case the condition $\Pr_{T\leftarrow\mathcal{D}}[R(T,z)=1] \leq \tau$ holds for every adversary and hence is redundant and we are only left with the first condition. How about ε? Note that a trivial adversary, which always guesses that the first bit is 1,

succeeds with probability $1/2$. Hence, ε must be $\geq 1/2$ or else no algorithm can be safe. To summarize, if $\tau < 1/2$ then every algorithm is safe, and else, if $\tau \geq 1/2$ and $\varepsilon < 1/2$ then no algorithm is safe. Hence, this condition is non-trivial only in the range $\varepsilon, \tau \geq 1/2$.

Intuitively, the issue about ε, τ being context dependent stems from their somewhat nonstandard semantics (especially the parameter τ). Ideally, we would want ε and τ to quantify some notion of "distance from optimality" (similarly to common definitions in the literature, such as differential privacy). But this is not the case with Definition 5. Rather, the threshold τ dictates what we consider to be a "non-trivial" baseline. But "non-trivial" is context dependent, and hence so is τ.

1.1.2 A new Definitional paradigm: Narcissus resiliency – an adversary trying to beat itself in its own game

So far, we have established that: (1) We need to compare the adversary's success probability to a baseline; (2) This baseline cannot be fixed for all adversaries; and (3) We want to circumvent the need for a hyperparameter controlling what "non-trivial" is, as this is likely to be context dependent. To tackle this, we present a new definitional paradigm which we call *Narcissus resiliency*. In this paradigm, instead of explicitly setting and tuning the baseline, we *let the attacker be its own baseline*.[2] More specifically, the attacker's success probability on the real dataset is compared with its success probability in a baseline setting where it does not get any information about the real dataset. Furthermore, the attacker must use the same strategy in both settings. This is enforced by preventing the attacker from receiving any information that can help it distinguish whether it is examined with respect to real dataset S or a fresh dataset T sampled from the same distribution. Hence, a Narcissus attacker needs to choose a compromise strategy: on one hand it needs to be strong (so it succeeds with high probability when it is applied to S) and at the same time it needs to be weak (so it succeeds with low probability when it is applied to T). The formal definition follows:[3]

▶ **Definition 6** (Narcissus resiliency). *Let $\mathcal{X}$ be a data domain, let $\mathcal{F}$ be a family of distributions over datasets containing elements from $\mathcal{X}$, and let $R : \mathcal{X}^* \times \{0,1\}^* \to \{0,1\}$. Algorithm $\mathcal{M}$ is $(\varepsilon, \delta, \mathcal{F})$-R-Narcissus-resilient if for all $\mathcal{D} \in \mathcal{F}$ and for all attackers $\mathcal{A}$ it holds that*

$$\Pr_{\substack{S\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ z\leftarrow\mathcal{A}(y)}}[R(S,z)=1] \leq e^{\varepsilon} \cdot \Pr_{\substack{S\leftarrow\mathcal{D}\\ T\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ z\leftarrow\mathcal{A}(y)}}[R(T,z)=1] + \delta. \tag{3}$$

Note that in both experiments the adversary $\mathcal{A}$ is executed on a dataset S sampled exactly in the same way. Thus, the adversary behaves exactly the same way in both executions. Nevertheless, the adversary's goal is to "separate" the two experiments, where in the left experiment it aims to maximize the probability of reconstruction while in the right experiment it aims to minimize this probability.

▶ **Example 7.** Note that Definition 6 achieves the desired behavior in our example with the Mona Lisa: In order to contradict Inequality (3), the attacker must recover (with noticeable probability) the photo of a citizen from S.

[2] The name "Narcissus" is inspired by the Greek myth of Narcissus, who became obsessed with his own reflection. This alludes to how, in our proposed paradigm, the adversary competes against itself rather than external benchmarks.

[3] In the following definition we switch from a single data distribution $\mathcal{D}$ to a family of data distributions $\mathcal{F}$, where the mechanism is required to be "secure" w.r.t. every distribution in the family. This is standard, and can also be applied in the context of Definition 4.

▶ **Example 8.** Let the underlying dataset distribution $\mathcal{D}$ be uniform over n-bit vectors. Let $k \in [n]$ be a parameter and suppose that, for the sake of this example, the relation R is defined as follows. Given a dataset $S \in \{0,1\}^n$ and the outcome of the attacker z, parse z as a vector of k distinct indices $\tilde{I} = (i_1, \ldots, i_k) \in [n]^k$ and k values $\tilde{Z} = (\tilde{z}_1, \ldots, \tilde{z}_k) \in \{0,1\}^k$ and let $R(S, z) = 1$ if and only if $S|_{\tilde{I}} = \tilde{Z}$. That is, in this example, the adversary's goal is to pinpoint k coordinates from S and to guess them correctly. In order to contradict Inequality (3), the attacker must recover the values of k coordinates from S with probability noticeably higher than 2^{-k}.

We arrived at Definition 6 through the lens of data reconstruction. To provide further evidence supporting the paradigm of Narcissus resiliency, we show in Section 2 that Narcissus resiliency captures concepts from cryptography and privacy as special cases. This includes differential privacy, resiliency to membership inference attacks, security of one-way functions, security of encryption schemes, and more. We show that all of these concepts can be stated in the terminology of Narcissus resiliency, where an adversary is "trying to beat itself in its own game". Furthermore, the paradigm enables us to express strictly weaker protections compared to differential privacy that are still meaningful. To support this claim, in the full version [17] we provide an example of a very natural *deterministic* mechanism (which is clearly not differentially private) that estimates a counting query under Narcissus-resiliency w.r.t. the family of all i.i.d. distributions and a natural reconstruction predicate R.

1.2 Identifying reconstruction

So far we have discussed which types of mechanisms prevent reconstruction of the input data. Such definitions serve as important guidance for responsible algorithm design. However, to show that a mechanism is vulnerable to reconstruction in the real world, an attacker usually only has access to the output of the mechanism, which in the learning context is a model that can be seen as an interactive program, or even just as a fixed string (e.g., a real-world attacker would like to attack a given chat-bot model, and not the algorithm that created the model based on training data). Moreover, such attacker might not even be aware of the training procedure exactly.

Mathematically, in Section 1.1 we considered a setting where initially a dataset S is sampled, and then an outcome y is computed by an algorithm $\mathcal{M}$ based on S. Our definition of Narcissus resiliency 6 pinpoints our ultimate desire from the algorithm $\mathcal{M}$. Often, however, $\mathcal{M}$ is not explicit and we only have access to a fixed model y and a fixed training set S. So there is no clear distribution over S and it is not clear what is the process which was used to compute y from S. Still, in order to be able to assess whether a particular attack is successful, we would like to have a definition of what it means to "reconstruct" a particular S from a particular y. To emphasize this difference, when S and y are fixed and we want to classify a successful attack (rather than resiliency to such) we use the term "extract" instead of "reconstruct".

▶ **Question 9.** *How do we define that a* fixed *dataset S (or a* fixed *point in it $x \in S$) is extractable from a* fixed *string y?*

Intuitively, such "extraction" means that x is encoded in y. But capturing this intuition more formally turns out to be challenging. In this work, we offer the first formal definition that, we hope, will help understand what real-world attacks do, and what properties future attacks should highlight in order to argue about their quality.

Prior works presented several definitions with the following flavor:

▶ **Definition 10** ([14, 11]). *Let R be a relation such that $R(x,z)=1$ means that z is a valid extraction of x. A string x is* extractable *from a model y, if there exists an efficient program $\mathcal{A}$ such that $R(x,\mathcal{A}(y))=1$.*

Intuitively, the program $\mathcal{A}$ in Definition 10 serves as evidence that x is extractable from y, because given y it outputs z with $R(x,z)=1$. For example, if x appears at the i^{th} location of y, then the program that given y as input, outputs $y_i, y_{i+1}, \ldots, y_{i+|x|-1}$ satisfy the condition of Definition 10.

However, at the formal level, this definition is meaningless: Because $\mathcal{A}$ is chosen *after* the example x, then formally, every example x is "extractable" as there exists $\mathcal{A}$ that (ignores its input) and outputs x. [14] mentioned that in order to prevent such pathological cases, the program $\mathcal{A}$ should be *shorter* than x (and therefore $\mathcal{A}$ cannot "memorize" x). But this by itself is not enough. For example, consider the string $x = \underbrace{34\,34\,\ldots\,34}_{1000\text{ times}}$ and the program $\mathcal{A}$ "Print '34' 1000 times". Namely, this example illustrates that $\mathcal{A}$ being short is clearly not evidence for not being able to "memorize" x. Therefore, the length of $\mathcal{A}$ cannot be the only criteria for determining its validity, and there should be some connection between the length of the attack $\mathcal{A}$, and the "complexity" of the target output. Intuitively, if there is no way to encode the target output x using a short program (i.e., to compress it), then by demonstrating a short attacking program that is able to reveal x given y, proves that x is really extracted from the model y.

▶ **Question 11.** *How do we quantify the "complexity" of an outcome x?*

This question leads us to a classical complexity measure, called *Kolmogorov-Complexity*.

1.2.1 Defining Extraction via Kolmogorov Complexity

What makes the string 343434343434343 less random than 285628563123452? The notion of *Kolmogorov complexity* (in short, K-complexity), introduced by [56, 37, 15] in the 60s, provides an elegant method for measuring the amount of "randomness" in an individual string. Informally, the K-complexity of a string x, denoted by $K(x)$, is the length of the shortest program that outputs the string x. Intuitively, a string x has high K-complexity, if there is no short program that outputs it and halts.

One issue with K-complexity is that it is not well defined without specifying which programming language $\mathcal{L}$ do we use. In theoretical results (when constants do not matter), this complexity is usually defined w.r.t. a fixed *Universal Turing Machine*. But when constants matter, a more formal way to define it is as follows.

▶ **Definition 12** ($K_{\mathcal{L}}$-Complexity). *Let $\mathcal{L}$ be a programming language (e.g., Python). The $K_{\mathcal{L}}$-complexity of a string x, denoted by $K_{\mathcal{L}}(x)$, is the length of the shortest $\mathcal{L}$-program that outputs x and halts. Similarly, given a set of strings X, we denote by $K_{\mathcal{L}}(X)$ the length of the shortest $\mathcal{L}$-program that outputs an element in X and halts.*

Now that we have Definition 12 in hand, we are finally ready to define extraction.

▶ **Definition 13** (Our extraction definition, informal). *Let R be an extraction relation and $\mathcal{L}$ a programming language. We say that a string x is $(R,\mathcal{L})$-extractable from a string y iff there exists an $\mathcal{L}$-program $\mathcal{A}$ such that the following holds:*

1. *$\mathcal{A}(y)$ outputs z such that $R(x,z)=1$, and*
2. *$K_{\mathcal{L}}(\{z\colon R(x,z)=1\}) \gg |\mathcal{A}|$.*

We measure the quality *of the extraction by $1-\frac{|\mathcal{A}|}{K_{\mathcal{L}}(\{z\colon R(x,z)=1\})}$ (closer to 1 means a more significant extraction).*

Namely, x is "$(R, \mathcal{L})$-extractable" from y if there exists a *short* $\mathcal{L}$-program $\mathcal{A}$ that outputs an extraction (according to R) of x from y, while there is no short $\mathcal{L}$-program that extracts x without y. We note that extraction must be in a context of a specific programming language, since otherwise, for every x and y we could always find a "special" programming language $\mathcal{L}_{x,y}$ such that x is $\mathcal{L}_{x,y}$-extractable from y.[4] Satisfying this definition w.r.t. a *standard* programming language (e.g., Python, Java, etc) should indeed be considered as a valid extraction.

Definition 13 can easily be extended to datasets S (rather than a single example x), and in Section A we also consider a probabilistic version of the $K_{\mathcal{L}}$-complexity that allows some error probability, and redefine Definition 13 w.r.t. this version.

To provide further evidence supporting Definition 13, we demonstrate in Section A.3 how three different types of real-world attacks [14, 30, 11] can be explained using the terminology of Definition 13.

1.2.2 Narcissus-Resiliency prevents non-trivial extraction of training data

In Section 3 we show that if $\mathcal{M}$ is $(\varepsilon, \delta, \mathcal{F})$-$R$-Narcissus-resilient then it prevents extraction in the following sense. Fix a distribution $\mathcal{D} \in \mathcal{F}$, sample two independent datasets S and T from $\mathcal{D}$, and compute $y \leftarrow \mathcal{M}(S)$. We treat S as the "real" dataset and T as a "shadow" dataset. Suppose that there is no adversary $\mathcal{B}$ that given y can find a short program $\mathcal{A}$ such that $R(T, \mathcal{A}(y)) = 1$. Informally, this means that extracting information about the shadow dataset T without receiving any information about it is hard. Then, if $\mathcal{M}$ is Narcissus-resilient, there is also no adversary that achieves this w.r.t. S (even though the adversary gets y which was computed based on S).

1.2.3 Verifying the validity of reconstruction attacks

The main limitation of Definition 13 is that Item 2 (lower-bounding the Kolmogorov Complexity) is not verifiable, as computing the K-complexity is an intractable problem. We could consider a tractable version of it, called *time-bounded* K-complexity, where given a parameter t we consider only programs that halt within t steps ([37, 55, 57, 36]). This, however, would only relax intractability to inefficiency, which does not help in our context where we would like to verify a reconstruction attack efficiently. In practice, we can only use Heuristics to gain some level of confidence. E.g., to apply many well-known compression algorithms on x and check that all of them results with a compressed representation that is much longer than $|\mathcal{A}|$. Yet, we remark that any such Heuristic can fail to determine some highly compressible patterns, and as we demonstrate in Section A.4.1, this problem is indeed inherent assuming that a basic cryptography primitive (pseudo-random generator) exists.

1.3 Additional related works

Memorization

Perhaps the most basic privacy violation is *memorization*. [25, 24, 6, 7, 43, 1] theoretically study the necessity of memorization in learning. Roughly speaking, they show that for some tasks, the output of any accurate algorithm must have large *mutual information* with the training data. A similar result of [9] show that there exist learning tasks in which

[4] For example, consider a programming language $\mathcal{L}_{x,y}$ that given a command y outputs x.

memorization is only necessary for *efficient* learners. While large memorization (i.e., mutual information) implies that the algorithm is not differentially private, it does not imply the existence of an efficient attack. Indeed, except for [9, 1], these works are typically not constructive (i.e., they do not provide an efficient way to translate the memorization into an efficient privacy attack).

Computational Differential Privacy

[5, 48] considered a computational relaxation of (the standard, information-theoretic) differential privacy, where they require that the outputs of two executions on neighboring datasets are indistinguishable only from the eyes of an *efficient* observer. This relaxation turns out to be necessary for fundamental distributed tasks [47, 31] but also for some (artificial) centralized ones [8, 27]. We note that an efficient privacy attack (e.g., membership inference or reconstruction) implies that the algorithm is not computationally differentially private. But in the opposite direction, if an algorithm is not computationally differentially private, the privacy attack, while being efficient, could be very negligible (e.g., the attack might reveal only a single, insignificant, bit of information about a training example, and still violating computational differential privacy).

Membership Inference

In *membership inference (MI)* [53, 60], an adversary is given a target example and its goal is to infer whether it was included in a model's training set. Most techniques follow a paradigm of measuring some correlation/loss function between the target example and the model and checking if it exceeds some threshold. For example, [22] showed that any algorithm that given $x_1, \ldots, x_n \in \{-1, 1\}^d$ outputs $y \in [-1, 1]^d$ that is sufficiently close to the average $\frac{1}{n}\sum_{i=1}^{n} x_i$, is exposed to the MI attack that given a target example x, decides "IN" or "OUT" based on whether $\langle x, y\rangle$ (the inner-product between x and y) exceeds some threshold. The MI literature is very rich, and includes works that perform attacks on fundamental learning tasks (e.g., [52, 22, 50, 2, 1]) along with MI attacks on more complex models (e.g., [54, 60, 34, 10, 44, 50, 58]). We remark that while MI attacks are indeed a reasonable privacy concern in many scenarios, they are weaker than reconstruction attacks because the attacker needs to know the target training example beforehand while without it there might be no way to extract sensitive information.

Reconstruction

The results of [19] provided a foundation for rigorously quantifying reconstruction bounds for general query release mechanisms. In their setting, the dataset is binary, and they show that given a few statistical queries, it is possible to reveal 90% of the dataset. [21, 23, 31] provide improved results in similar settings like [19] but under weaker accuracy assumptions. In more general settings, [29] demonstrated that both Rényi Differential Privacy (DP) and Fisher information offer robust semantic assurances against reconstruction attacks. [4] introduced the concept of reconstruction robustness (ReRo), establishing a link between reconstruction attacks and DP. [32] extended [4]'s to analyze reconstruction attacks against DP-SGD. [35] furthered this research by examining the connection between the hypothesis testing interpretation of DP (specifically f-DP) and reconstruction robustness. From a more practical standpoint, there is a rich literature on reconstruction attacks on various real-world models (e.g., [26, 12, 59, 33, 13, 61, 11, 30]). In Section A (recognizing reconstruction), we focus on three of them in order to illustrate the expressiveness of our Definition 13.

Formalizing legal concepts of privacy

Some of the work towards formalizing legal privacy concepts mathematically has taken an approach similar to our "sandwiching" of the concept of reconstructing rather than attempting a precise answer to Question 1. These works did not attempt to model a legal concept exactly but rather define requirements which are clearly stricter or clearly weaker than the those of the legal concept, yet non-trivial so they can substantiate a claim that the use of a certain technology satisfies or does not satisfy the legal requirement. As one example, in their modeling of the FERPA privacy requirement,[5] [49] provided a definition which is stronger than the legal requirement, yet satisfiable by the use of differential privacy, hence providing strong evidence that the use of differential privacy (with appropriate parameters) satisfies the legal requirements. As another example is the modeling of the GDPR requirement of protection against singling out [16] defined *protection against predicate singling out*, a concept which is weaker than the legal requirement. Showing that k-anonymity does not protect against predicate singling out they hence claimed that it does neither satisfy the legal requirement.

2 Expressiveness of Narcissus resiliency

In the introduction we presented the definition of Narcissus resiliency (Definition 6) with the interpretation of "security against reconstruction attacks", where the function R encapsulates what a "valid reconstruction" means. We now show that with different instantiations of the function R, the same framework can be used to capture many other existing security notions. In this section we show this for the notions of *membership inference attacks* and for *predicate singling out*. In the full version of this paper [17], we extend this to additional security notions, including *differential privacy*, security of *one-way functions*, and security of *encryption schemes*. The fact that Narcissus resiliency is expressive enough to capture all these (seemingly unrelated) well-established notions enhances our confidence in its application as a security notion against reconstruction attacks.

2.1 Membership inference as Narcissus resiliency

Membership Inference (MI) attacks [53, 60] are a family of attacks which are applied mostly to machine learning models. The goal of an MI attack is to determine whether a given data record was part of the training data underlying the model or not. More specifically, let $\mathcal{D}$ be a distribution over data records, and let $\mathcal{M}$ be an algorithm for analyzing datasets of size n. Algorithm $\mathcal{M}$ is said to be MI-secure if no adversary $\mathcal{A}$ has a significant advantage in distinguishing between the outputs of the following two experiments:

- Sample $S \leftarrow \mathcal{D}^n$ and $z \leftarrow \mathcal{D}$ independently. Let $y \leftarrow \mathcal{M}(S)$. Output (y, z).
- Sample $S \leftarrow \mathcal{D}^n$. Let z be a uniformly random element from S. Let $y \leftarrow \mathcal{M}(S)$. Output (y, z).

The formal definition is as follows.

▶ **Definition 14** (Resilience to Membership Inference, [53, 60]). *Let $\mathcal{M} : \mathcal{X}^n \to Y$ be an algorithm that operates on a dataset, and let $\mathcal{D}$ be a distribution over $\mathcal{X}$. We say that $\mathcal{M}$ is $(\delta, \mathcal{D})$-MI-secure if for every adversary $\mathcal{A}$ it holds that*

[5] FERPA – The Family Educational Rights and Privacy Act (FERPA) – is is a Federal law that protects the privacy in education records.

$$\left| \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ z\leftarrow\mathcal{D} \\ b\leftarrow\mathcal{A}(y,z)}}[b=1] - \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ z\in_{\mathrm{R}}S \\ b\leftarrow\mathcal{A}(y,z)}}[b=1] \right| \leq \delta.$$

We show that Narcissus resiliency captures the concept of membership inference. We make use of the following function:

▶ **Definition 15.** *We define R_{MI} to be a (randomized) binary function, which takes two arguments: a dataset $Z \in \mathcal{X}^n$ and a (possibly randomized) function $f : \mathcal{X} \to \{0,1\}$. Given Z, f, to compute $R_{\mathrm{MI}}(Z,f)$, sample a point $z \in Z$ and return $f(z)$.*

▶ **Theorem 16.** *Let $\mathcal{M} : \mathcal{X}^n \to Y$ be an algorithm and let $\mathcal{D}$ be a distribution over $\mathcal{X}$. Then $\mathcal{M}$ is $(\delta,\mathcal{D})$-MI-secure if and only if it is $(0,\delta,\{\mathcal{D}^n\})$-$R_{\mathrm{MI}}$-Narcissus-resilient.*

Proof. First observe that an MI-adversary gets two arguments (an outcome y and a point z) and returns a bit, while an R_{MI}-Narcissus-adversary gets only one argument (the outcome y) and returns a binary function f that takes a point and returns a bit (aiming to satisfy R_{MI}). To help bridge between these notations, given an MI-adversary $\mathcal{A}$ and an outcome y, we write $f(\cdot) \leftarrow \mathcal{A}(y,\cdot)$ to denote the binary function obtained by fixing $\mathcal{A}$'s first argument to be y. We can interpret this as an R_{MI}-Narcissus-adversary that takes one argument (the outcome y) and returns the function $f(\cdot) \leftarrow \mathcal{A}(y,\cdot)$. It follows that

$$\Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ f(\cdot)\leftarrow\mathcal{A}(y,\cdot)}}[R_{\mathrm{MI}}(S,f)=1] - \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ T\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ f(\cdot)\leftarrow\mathcal{A}(y,\cdot)}}[R_{\mathrm{MI}}(T,f)=1] = \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ z\in_{\mathrm{R}}S \\ b\leftarrow\mathcal{A}(y,z)}}[b=1] - \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ z\leftarrow\mathcal{D} \\ b\leftarrow\mathcal{A}(y,z)}}[b=1].$$

Hence, if $\mathcal{M}$ is $(\delta,\mathcal{D})$-MI-secure then it is also $(0,\delta,\{\mathcal{D}^n\})$-$R_{\mathrm{MI}}$-Narcissus-resilient. In addition, if the above two differences are positive, then the equality holds also in absolute value, and hence the condition of $(0,\delta,\{\mathcal{D}^n\})$-$R_{\mathrm{MI}}$-Narcissus-resiliency implies the condition of $(\delta,\mathcal{D})$-MI-security. Otherwise, to show that the left hand side cannot be smaller than $-\delta$, let $\hat{\mathcal{A}}$ be the R_{MI}-Narcissus-adversary that runs $\mathcal{A}$ and returns the "inverted" function $\hat{f} \equiv 1 - f$. Then,

$$\begin{aligned}
&\Pr_{\substack{S\leftarrow\mathcal{D}^n \\ T\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ f(\cdot)\leftarrow\mathcal{A}(y,\cdot)}}[R_{\mathrm{MI}}(T,f)=1] - \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ f(\cdot)\leftarrow\mathcal{A}(y,\cdot)}}[R_{\mathrm{MI}}(S,f)=1] \\
&= -\left(\Pr_{\substack{S\leftarrow\mathcal{D}^n \\ T\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ \hat{f}(\cdot)\leftarrow\hat{\mathcal{A}}(y,\cdot)}}[R_{\mathrm{MI}}(T,\hat{f})=1] - \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ \hat{f}(\cdot)\leftarrow\hat{\mathcal{A}}(y,\cdot)}}[R_{\mathrm{MI}}(S,\hat{f})=1] \right) \\
&= \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ \hat{f}(\cdot)\leftarrow\hat{\mathcal{A}}(y,\cdot)}}[R_{\mathrm{MI}}(S,\hat{f})=1] - \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ T\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ \hat{f}(\cdot)\leftarrow\hat{\mathcal{A}}(y,\cdot)}}[R_{\mathrm{MI}}(T,\hat{f})=1] \leq \delta.
\end{aligned}$$

which follows from the resilience of $\mathcal{M}$ against $\hat{\mathcal{A}}$. ◀

2.2 Predicate singling out as Narcissus resiliency

[16] defined a type of privacy attack called *Predicate Singling Out (PSO)*, intended to mathematically formulate the legal concept of "singling out" that appears in the General Data Protection Regulation (GDPR). Concretely, let $\mathcal{D}$ be a data distribution and let $S \leftarrow \mathcal{D}^n$ be a dataset containing n iid samples from $\mathcal{D}$. Let $\mathcal{M}$ be an algorithm that operates on S and return an outcome y. A PSO adversary gets y and aims to find a predicate p that "isolates" one record in S, meaning that it evaluates to 1 on *exactly* one record in S. Note, however, that without further restrictions this is not necessarily a hard task. In particular, even without looking at y, the adversary might choose a predicate p whose expectation over $\mathcal{D}$ is $1/n$. Such a predicate would isolate a record in S with constant probability. More generally, if the expectation of p is w, then the probability that it isolates a record in a fresh dataset of size n is $n \cdot w \cdot (1-w)^{n-1}$. Thus, for the attack to be considered "significant", the adversary has to succeed in its attack with probability noticeably higher than this. The formal definition is as follows.

▶ **Definition 17** ([16]). *Let $\mathcal{M} : \mathcal{X}^n \to Y$ be an algorithm that operates on a dataset. We say that $\mathcal{M}$ is $(\varepsilon, \delta, w_{\max})$-PSO secure if for every $w \le w_{\max}$, every distribution $\mathcal{D}$ over $\mathcal{X}$, and every adversary $\mathcal{A}$ it holds that*

$$\Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ p\leftarrow\mathcal{A}(y)}}\left[\sum_{x\in S} p(x) = 1 \wedge \mathbf{E}_{\mathcal{D}}[p] \le w\right] \le e^{\varepsilon} \cdot \sup_{\substack{\text{predicate } p \\ \text{s.t. } \mathbf{E}_{\mathcal{D}}[p]\le w}} \left\{ n \cdot \mathbf{E}_{\mathcal{D}}[p] \cdot (1 - \mathbf{E}_{\mathcal{D}}[p])^{n-1} \right\} + \delta.$$

Using the paradigm of Narcissus resiliency, we present an alternative definition for predicate singling out, which is simpler in that it avoids reasoning directly about the expectations of the predicates.

▶ **Definition 18** (Narcissus singling out security). *Let $\mathcal{M} : \mathcal{X}^n \to Y$ be an algorithm. Let R be the relation that takes a dataset S and a predicate p, where $R(S,p) = 1$ if and only if p evaluates to 1 on* exactly *one point in S. We say that $\mathcal{M}$ is (ε, δ)-Narcissus-singling-out-secure if for every distribution $\mathcal{D}$ over $\mathcal{X}$ and for every attacker $\mathcal{A}$ it holds that*

$$\Pr_{\substack{S\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ p\leftarrow\mathcal{A}(y)}}[R(S,p) = 1] \le e^{\varepsilon} \cdot \Pr_{\substack{S\leftarrow\mathcal{D}^n \\ T\leftarrow\mathcal{D}^n \\ y\leftarrow\mathcal{M}(S) \\ p\leftarrow\mathcal{A}(y)}}[R(T,p) = 1] + \delta.$$

Intuitively, Definitions 17 and 18 have similar interpretations: Finding a predicate that isolates a record in S after seeing the outcome of $\mathcal{M}$ is almost as hard as doing this without seeing the outcome of $\mathcal{M}$. However, the definitions are not equivalent. We leave open the question of understanding the relationships between these two definitions.

3 Narcissus-Resiliency Prevents Non-Trivial Extraction

Let $\mathcal{M}$ be a mechanism which is applied to a dataset S to obtain an outcome y. Let $\mathcal{B}$ be an "extraction attacker" that takes the outcome y and aims to compute a short program $\mathcal{A}$ that serves as an extraction evidence for S w.r.t. a relation R and a programming language $\mathcal{L}$. We show that if $\mathcal{M}$ is Narcissus-resilient (w.r.t. an appropriate reconstruction relation), then it prevents $\mathcal{B}$ from succeeding in its attack. Formally,

▶ **Definition 19.** *Fix a parameter $q \leq 1$ controlling the desired* quality *of extraction (as in Definition 13). We define the relation R_{ext} that takes a dataset S and a pair $(y, \mathcal{A})$ where y is an outcome of $\mathcal{M}$ and $\mathcal{A}$ is a program, and returns 1 if and only if the following two conditions hold:*

1. $R(S, \mathcal{A}(y)) = 1$, *and*
2. $\frac{|\mathcal{A}|}{K_{\mathcal{L}}(\{z\colon R(S,z)=1\})} \leq 1 - q$.

▶ **Lemma 20** (Narcissus-resiliency prevents non-trivial extraction)**.** *Let $\mathcal{M}$ be an $(\varepsilon, \delta, \mathcal{F})$-$R_{\text{ext}}$-Narcissus-resilient according to Definition 6, and consider an adversary $\mathcal{B}$ that takes the outcome of $\mathcal{M}$ and outputs an $\mathcal{L}$-program $\mathcal{A}$. Then for every $\mathcal{D} \in \mathcal{F}$ we have*

$$\Pr_{\substack{S\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ \mathcal{A}\leftarrow\mathcal{B}(y)}}\left[\begin{array}{c}\mathcal{A} \text{ is an } (R,\mathcal{L})\text{-extraction}\\ \text{evidence of } S \text{ from } y\end{array}\right] \leq e^{\varepsilon}\cdot \Pr_{\substack{S\leftarrow\mathcal{D}\\ T\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ \mathcal{A}\leftarrow\mathcal{B}(y)}}\left[\begin{array}{c}\mathcal{A} \text{ is an } (R,\mathcal{L})\text{-extraction}\\ \text{evidence of } T \text{ from } y\end{array}\right] + \delta$$

Proof. This follows directly from the assumption that $\mathcal{M}$ is R_{ext}-Narcissus-resilient. Formally, let $\hat{\mathcal{B}}$ denote the adversary that on input y returns $(y, \mathcal{B}(y))$. Then,

$$\begin{aligned}\Pr_{\substack{S\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ \mathcal{A}\leftarrow\mathcal{B}(y)}}\left[\begin{array}{c}\mathcal{A} \text{ is an } (R,\mathcal{L})\text{-extraction}\\ \text{evidence of } S \text{ from } y\end{array}\right] &= \Pr_{\substack{S\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ (y,\mathcal{A})\leftarrow\hat{\mathcal{B}}(y)}}\left[R_{\text{ext}}(S,(y,\mathcal{A}))=1\right]\\ &\leq e^{\varepsilon}\cdot \Pr_{\substack{S\leftarrow\mathcal{D}\\ T\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ (y,\mathcal{A})\leftarrow\hat{\mathcal{B}}(y)}}\left[R_{\text{ext}}(T,(y,\mathcal{A}))=1\right]+\delta\\ &\leq e^{\varepsilon}\cdot \Pr_{\substack{S\leftarrow\mathcal{D}\\ T\leftarrow\mathcal{D}\\ y\leftarrow\mathcal{M}(S)\\ \mathcal{A}\leftarrow\mathcal{B}(y)}}\left[\begin{array}{c}\mathcal{A} \text{ is an } (R,\mathcal{L})\text{-extraction}\\ \text{evidence of } T \text{ from } y\end{array}\right]+\delta\end{aligned}$$ ◀

A possible downside of Lemma 20 is that it leverages a *different* reconstruction relation for Narcissus-resiliency compared to the extraction relation. This was needed in the proof because our definition of extraction considered two conditions: not only that the attacker needs to satisfy the relation R, but it needs to do it with a "short enough" program. To capture this in the above lemma, we incorporated this condition in the reconstruction relation used for Narcissus-resiliency. This can be avoided in cases where for some parameter k we have:

1. The adversary $\mathcal{B}$ always outputs a program of length at most k; and
2. The underlying data distribution $\mathcal{D}$ is such that with overwhelming probability over sampling $S \leftarrow \mathcal{D}$ we have that $\frac{k}{K_{\mathcal{L}}(\{z\colon R(S,z)=1\})} \leq 1 - q$.

That is, in cases when sampling a dataset $S \leftarrow \mathcal{D}$ then with overwhelming probability the Kolmogorov complexity $K_{\mathcal{L}}(\{z\colon R(S,z)=1\})$ is high. Indeed, if this is the case, then the second condition in Definition 19 holds with overwhelming probability, and hence can be ignored, which unifies the two relations R and R_{ext}.

3.1 Limitation of Lemma 20

It is important to note that Lemma 20 is limited to attackers $\mathcal{B}$ that only see the output y of the mechanism. But some of the real-world attacks also use the training data in order to construct an extraction evidence. E.g., in the Diffusion Model attack of [11] (see Section A.3), the attacker $\mathcal{B}$ first processes the input data in order to find captions of "interesting" images,

and then define $\mathcal{A}$ as the short program that simply queries the model on one of these captions. We note that Narcissus-resiliency does not prevent such attacks in general, because $\mathcal{B}$ uses the training data to generate $\mathcal{A}$. But Lemma 20 does imply that it is impossible to achieve non-trivial extraction of training examples, without knowing them in advanced.

A Recognizing Extraction

Following the discussion in Section 1.2, we use the terminology of "extraction" rather than "reconstruction" in the setting where the dataset S and the model y are fixed. We formally define how to recognize a valid extraction attack on a given (fixed) model y (as described in Section 1.2), use the definition to explain the validity of some real-world attacks, and prove that in general the problem of verifying a valid attack is computationally hard assuming that cryptography exists.

A.1 Defining Extraction via Kolmogorov Complexity

In this paper, we think of extraction as a randomized process that can fail with some probability, so we use the following variant of Definition 12.

▶ **Definition 21** ($K_{\mathcal{L}}$-Complexity, a probabilistic version of Definition 12)**.** *Let $\mathcal{L}$ be a programming language. The $K_{\mathcal{L}}$-complexity of a string x, denoted by $K_{\mathcal{L}}(x)$, is the length of the shortest $\mathcal{L}$-program that with probability $2/3$ outputs the string x and halts.*

In theoretical results, this complexity is usually defined w.r.t. a fixed *Universal Turing Machine* $\mathcal{U}$ that gets a description $\mathcal{M}$ of a Turing machine and outputs $\mathcal{U}(\mathcal{M})$. Then, $K(x) = K_{\mathcal{U}}(x)$ is defined by the shortest $\mathcal{M}$ such that $\Pr[\mathcal{U}(\mathcal{M}) = x] \geq 2/3$. This is good enough for *asymptotic* analysis since for any programming language $\mathcal{L}$ and every x it holds that $K(x) \leq K_{\mathcal{L}}(x) + O(1)$, where $O(1)$ denotes a constant that is independent of $|x|$.[6] However, when we would like to deal with concrete quantities (where constants matter), we must explicitly specify a concrete programming language $\mathcal{L}$, and therefore we do not omit it from the notation.

After fixing the programming language $\mathcal{L}$, the quantity $K_{\mathcal{L}}(x)$ can be thought of as the analogous to the "entropy" of the string x. As with entropy, we can also consider a conditional version of the K-complexity (the analog of conditional entropy) as well as "mutual K-information" (the analog of mutual information) [62, 38, 57, 45, 28, 41, 3]:

▶ **Definition 22** (Conditional $K_{\mathcal{L}}$-Complexity, and mutual $K_{\mathcal{L}}$-information)**.** *Given a programming language $\mathcal{L}$ and two strings x, y, we define the* conditional $K_{\mathcal{L}}$-complexity of x given y*, denoted by $K_{\mathcal{L}}(x \mid y)$, as the length of the shortest program in $\mathcal{L}$ that given y as input, with probability $2/3$ outputs x and halts. We define the* mutual $K_{\mathcal{L}}$-information *of x, y as $KI_{\mathcal{L}}(x; y) = K_{\mathcal{L}}(x) - K_{\mathcal{L}}(x \mid y)$.*

Intuitively, $KI_{\mathcal{L}}(x; y)$ is high if it is possible to extract x from y using a short $\mathcal{L}$-program, but it is not possible to do so without y. In our context of extracting an input example x from a model y, we should also allow to output elements z that are "similar" to x (which are considered as a valid extraction of x under some metric), or perhaps the goal is to output a list of elements that some of them are close to training examples. Therefore, we would be interested in an extension of the K-complexity into a set of strings which allows much more flexibility.

▶ **Definition 23** (Extension of Definitions 21 and 22 for sets)**.** *Let $\mathcal{L}$ be a programming language. The $K_{\mathcal{L}}$-complexity of a set of strings X, denoted by $K_{\mathcal{L}}(X)$, is the length of the shortest $\mathcal{L}$-program that with probability $2/3$, outputs a string $x \in X$ and halts. Similarly to Definition 22, we define $K_{\mathcal{L}}(X \mid y)$ as the length of the shortest $\mathcal{L}$-program that given an input y, outputs w.p. $2/3$ a string $x \in X$ and halts, and we define $KI_{\mathcal{L}}(X; y) = K_{\mathcal{L}}(X) - K_{\mathcal{L}}(X \mid y)$.*

Note that by definition, $KI_{\mathcal{L}}(X; y) = \min_{x \in X} K_{\mathcal{L}}(x) - \min_{x \in X} K_{\mathcal{L}}(x \mid y)$, and these minimums are not necessarily realized by the same x.

A few examples are in order. In all the following examples, we use $\mathcal{L}$ as a fixed Universal Turing Machine language, and for $x = (x^1, \ldots, x^d), z = (z^1, \ldots, z^d) \in \{0,1\}^d$ we denote by $\mathsf{NHamDist}(x, z) = \frac{1}{d} \cdot \left|\{i \in [n] \colon x^i \neq z^i\}\right|$ the *Normalized Hamming Distance* between x and z.

---

[6] Let $\mathcal{C}$ be a $\mathcal{U}$-program (i.e., a Turing machine description) that serves as a compiler from a language $\mathcal{L}$ to $\mathcal{U}$, i.e., give a $\mathcal{L}$-program $\mathcal{M}$, $C(\mathcal{M})$ outputs a $\mathcal{U}$-program $\mathcal{M}'$ that acts as $\mathcal{M}$. So for every x, if it can be described using an $\mathcal{L}$-program $\mathcal{M}$, then it can be described using a $\mathcal{U}$-program $\mathcal{C}(\mathcal{M})$ of length $|\mathcal{M}| + |\mathcal{C}| = |\mathcal{M}| + O(1)$ (note that $|\mathcal{C}|$ is independent of $|x|$).

▶ **Example 24.** For $x \in \{0,1\}^d$ define $R_x = \{(z_1, z_2) \in \{0,1\}^{2d} : \min_{i\in\{1,2\}} \mathsf{NHamDist}(x, z_i) \leq 1/2\}$, (i.e., in this example, R_x defines the task of outputting two strings that at least one of them agrees with x on at least half of the bits). Note that $K_{\mathcal{L}}(R_x) = O(\log d)$ for any x, because the program that outputs a uniformly random $(z_1, z_2) \leftarrow \{0,1\}^{2d}$ – e.g., a for loop executing for $2d$ iterations and outputing a random bit in each – satisfies $(z_1, z_2) \in R_x$ with probability $3/4$.

▶ **Example 25.** For $x \in \{0,1\}^d$ define R_x as the set of all the tuples of the form $z = (z_1, \ldots, z_m)$, for $m \leq \text{poly}(d)$ (for some fixed polynomial), such that $\min_{i\in[m]} \mathsf{NHamDist}(x, z_i) \leq 1/4$ (i.e., at least one of the z_i's agrees with $3/4$ of the bits of x). For a uniformly random $x \leftarrow \{0,1\}^d$, it holds with high probability that $K_{\mathcal{L}}(R_x) \geq (1 - o(1))d/2$ (i.e., for most strings x, any algorithm that aims to output a string that agrees with $3/4$ of the bits of x, essentially must memorize $\approx d/2$ bits of information about x). Indeed, given $y = (x^1, \ldots, x^{d/2})$ (the first half of the bits of x) as input, we have $K(R_x \mid y) = O(\log d)$ because the algorithm that chooses $m = 2$ uniformly random strings $(z_1, z_2) \leftarrow \{0,1\}^{d/2}$ and outputs $z = (y \circ z_1,\ y \circ z_2)$ satisfies $z \in R_x$ with probability $3/4$.

▶ **Example 26.** Let $S = (x_1, \ldots, x_n) \in (\{0,1\}^d)^n$, and define R_S as the set of all the tuples $z = (z_1, \ldots, z_m)$ such that there exist $i \in [n]$ and $j \in [m]$ with $\mathsf{NHamDist}(x_i, z_j) \leq 1/4$. Assume $n, m \leq \text{poly}(d)$ (for some fixed polynomial). Then as in Example 25, it can be shown that when S consists of uniformly random strings, then $K_{\mathcal{L}}(R_S) \geq (1 - o(1))d/2$ with high probability, meaning that solving this problem requires to memorize at least $\approx d/2$ bit of information from one of the strings.

We are now ready to reformulate the extraction definitions of [14, 11].

▶ **Definition 27** (Extractable Information)**.** *Let S be a set of elements over a domain $\mathcal{X}$, let $R : \mathcal{X}^* \times \{0,1\}^* \to \{0,1\}$ be an extraction relation (i.e., $R(S, z) = 1$ means that z is considered a valid extraction of elements in S), let $\mathcal{L}$ be a programming language, and let $R_S = \{z : R(S, z) = 1\}$. We say that a model y contains $(R, \mathcal{L}, \tau)$-extractable information about S if*

$$KI_{\mathcal{L}}(R_S; y) \geq \tau.$$

In order to prove that S is extractable from a model y, it suffices to present an extractor:

▶ **Definition 28** (Extractor, redefinition of Definition 13)**.** *Let $R : \mathcal{X}^* \times \{0,1\}^* \to \{0,1\}$ be an extraction relation and denote $R_S = \{z : R(S, z) = 1\}$. Let $q \in [0, 1)$ be a quality parameter. We say that an $\mathcal{L}$-program $\mathcal{A}$ is an $(\mathcal{L}, R, q)$-extractor of $S \in \mathcal{X}^*$ from y if the following holds:*

1. $\Pr[\mathcal{A}(y) \in R_S] \geq 2/3$*, and*
2. $K_{\mathcal{L}}(R_S) \geq \frac{|\mathcal{A}|}{1-q}$.

Note that when q is closer to 1 is means a more significant extraction.

▷ Claim 29. If there exists an $(\mathcal{L}, R, q)$-extractor $\mathcal{A}$ of S from y, then y contains $(\mathcal{L}, R, \tau = \frac{q}{1-q} \cdot |\mathcal{A}|)$-extractable information about S (Definition 27).

Proof. Compute

$$KI_{\mathcal{L}}(R_S; y) = K_{\mathcal{L}}(R_S) - K_{\mathcal{L}}(R_S \mid y) \geq \frac{|\mathcal{A}|}{1-q} - |\mathcal{A}| = \frac{q}{1-q} \cdot |\mathcal{A}|. \qquad \triangleleft$$

A.2 Capturing Interesting Extractions using the Predicate

In the previous examples (e.g., Example 26), we considered simple relations R that only check for a small distance from an example point. But in the real-world, when thinking about S as the training dataset and on y as the trained model (over S), it is very likely that S will contain duplicated data, and in such cases, it might be considered ok to memorize such data. As a concrete example, if we think about a chat-bot model, then we can query it with "Print the Bible" and it will likely do that. I.e., even though it is indeed a valid extraction (as the K-complexity of the Bible is large), this is not an interesting one since the Bible content is probably duplicated in many training examples. In order to define more interesting relations R, it is reasonable to consider extraction of only *k-Eidetic Memorizated* strings x ([14]) for some small threshold k, which means that such x's only appear at most k times in S.

A.3 Real-World Examples

In order to illustrate the generality of our definitions, we next pick three different types of real-world attacks, and explain what is happening in each of them in terms of Definition 28.

Extraction from Large Language Models [14]

[14] present extraction attacks on GPT-2 by essentially generating many samples from GPT-2 when the model is conditioned on (potentially empty) prefixes. Then they sort each generation according to some metric to remove duplications, and this gives a set of potentially memorized texts from training examples. In one of their methods, they choose the top-m interesting ones by assigning a score to each such text which combines the compressibility of the text using some compression algorithm like zlib [46], and the likelihood of it, e.g., using a "perplexity" measure [13] (higher compressibility and likelihood increase the score). They show that noticeable fraction of such strings are "Eidetic Memorizated", meaning that they only appear a small number of times in the training data (which makes them more interesting).

In terms of our extraction methodology, the training dataset $S = (x_1, \ldots, x_n)$ consists of webpages, and an *interesting extractable text* is a string s that: (1) has high entropy (i.e., high K-complexity, which can be estimated using heuristics like zlib compression) and (2) appears only small number of times in the training examples (here, "appear" in webpage x_i means $s \subseteq x_i$). The attack outputs a list of strings $z = (z_1, \ldots, z_m)$, and succeed when there exists a sub-list $(z_{j_1}, \ldots, z_{j_\ell})$ such that each string z_{j_i} is interesting and extractable, and the K-complexity of the entire list is higher than some threshold (which, again, can be estimated using heuristics like zlib compression).

When the K-complexity of the resulting sub-list is much higher than the length of the attacking code that extracted this information from the GPT-2 model, the attack is considered to have high quality.

Extraction from Diffusion Models [11]

[11] present several extraction attacks on Diffusion models, where all the attacks assume that the training data is given in advance. As one concrete example, they managed to extract training images from Imagen ([51]), a 2 billion parameter text-to-image diffusion model, by first searching for the captions of "outliers" in the training data (that is, training images that are less similar to other training images according to some metric), and then showed that when querying the model on such captions, some of them result with a good approximation of unique training images.

In terms of our extraction methodology, the end program that queries the model on a specific caption that leads to extraction of a unique training image is extremely short compared to the K-complexity of the image that was extracted. So this should be considered a very high-quality extraction to a predicate of the following type (for some threshold parameters $T > t$):

$$R(S = (x_1, \ldots, x_n), z) = 1 \iff \exists i \in [n] \text{ s.t. } (\ell_2(x_i, z) < t \text{ and } \forall j \in [n] \setminus \{i\} : \ell_2(x_i, x_j) > T).$$

Extraction from Binary Classifiers trained by Large Neural Networks [30]

[30] present a general attack that works on large class of binary classifiers trained by Neural networks with many parameters p. Roughly, their attack works as follows: Given the parameters of the model $y \in \mathbb{R}^p$, they define an optimization problem (that depends on y) on variables $z_1, \ldots, z_m \in \mathbb{R}^d$ and $\lambda_1, \ldots, \lambda_m \in \mathbb{R}$ and optimize it, and show that in the regime $p > n \cdot d$, the solution $z_1, \ldots, z_m$ is likely to contain a good approximation of many data points.

As one example of their experimental evaluation, they trained the model on the training images of CIFAR10 on vehicles vs. animals classification, and showed that their optimization program, which is defined based on the model $y \in \mathbb{R}^p$ given as input, managed to extract a good approximation of many training images (the top 45 extractions are presented in their paper).

In terms of our extraction methodology, given the training data $S = (x_1, \ldots, x_n)$, we can define the extraction relation

$$R(S = (x_1, \ldots, x_n), z = (z_1, \ldots, z_m)) = 1 \iff |\{i \in [n] \colon \exists j \in [m] \text{ s.t. } z_j \text{ is "close" to } x_i\}| \geq t,$$

for some parameter t (say, $t = 45$), where "close" is according to some metric. Under the reasonable assumption that $K(R_S)$ is much higher than the length of their attack (which is given the model y as input), this is considered a high quality extraction.

A.4 Inherent Limitations of Definition 28

The main limitation of our Definition 28 is that Item 2 (lower-bounding the Kolmogorov Complexity) is not verifiable, as computing the K-complexity is an intractable problem. While in practice the K-complexity can be estimated using Heuristics like zlib compression [46], any such Heuristic can fail to determine some highly compressible patterns, and as we demonstrate next in Section A.4.1, this problem is indeed inherent assuming that basic cryptography exists.

A well studied tractable variant of the K-complexity is the $t(\cdot)$-time bounded K-complexity, denoted by K^t-complexity, where $K^t(x)$ is the length of the shortest program that outputs x within $t(|x|)$ steps ([37, 55, 57, 36]). However, there is no efficient algorithm for computing the K^t-complexity.[7] Very recently, in a sequence of breakthrough results in cryptography and complexity theory [39, 40, 42, 41], it was shown that (a close variant of) this problem is hard if and only if one-way functions, the most basic cryptographic primitives, exist. Since a real-world verifier is a polynomial-time algorithm, this means that switching from

[7] As surveyed by [57], the problem of efficiently determining the K^t-complexity for $t(n) = \text{poly}(n)$ predates the theory of NP-completeness and was studied in the Soviet Union since the 60s as a candidate for a problem that requires "brute-force search" (see Task 5 on page 392 in [57]).

$K(\cdot)$ to the $K^{\mathrm{poly}(n)}(\cdot)$ variant will essentially not make any difference. Actually, the hardness of verification is inherent, and in the next two sections we show, under common cryptographic assumptions, how to construct triplets $(\mathcal{A}, x, y)$, with efficient $\mathcal{A}$, such that it is computationally hard to verify whether $\mathcal{A}$ extracts information about x from y.

A.4.1 Hardness of Verification

Our harness example is based on the existence of Pseudorandom Generator (PRG).

▶ **Definition 30** (Pseudorandom Generator (PRG)). *A PRG is a* PPT *algorithm G that maps d bits to $\ell(d)$ bits (for $\ell(d) > d$) such that for every* PPT *algorithm V and every $d \in \mathbb{N}$ it holds that*

$$\Pr[V(G(\mathcal{U}_d)) = 1] \leq \Pr\left[V(\mathcal{U}_{d+\ell(d)}) = 1\right] + \mathrm{neg}(d),$$

where $\mathcal{U}_m$ denotes the uniform distribution over $\{0,1\}^m$.

▶ **Lemma 31.** *Assume there exists a PRG G that maps d bits to d^4 bits. Let $\mathcal{L}$ be a Universal Turing Machine programming language with oracle access to G. Then there exists a* PPT *algorithm* Attacker *such that on input 1^d and $b \in \{0,1\}$, outputs a deterministic program $\mathcal{A}$ and two strings $x, y \in \{0,1\}^{d^4}$ such that the following holds w.r.t. a random execution $(\mathcal{A}, x, y) \leftarrow \mathsf{Attacker}(1^d, b)$:*

1. *$|\mathcal{A}| = d^2 + O(1)$ and $\mathcal{A}(y) = x$ (which is an evidence for $K_{\mathcal{L}}(x \mid y) \leq d^2 + O(1)$).*
2. *If $b = 0$ then $K_{\mathcal{L}}(x) \leq d + O(1)$ (and in particular, there is a deterministic $\mathrm{poly}(d)$-time $(d + O(1))$-size algorithm that outputs x).*
3. *If $b = 1$ then x is chosen uniformly over $\{0,1\}^{d^4}$ (which yields $K_{\mathcal{L}}(x) \geq (1 - o(1))d^4$ w.h.p.),*
4. *For every* PPT *$\mathcal{V}$ it holds that*

$$\Pr_{b \leftarrow \{0,1\},\, (\mathcal{A},x,y) \leftarrow \mathsf{Attacker}(1^d,b)}[\mathcal{V}(\mathcal{A}, x, y) = b] \leq 1/2 + \mathrm{neg}(d).$$

Note that when $b = 1$, $\mathcal{A}$ extracts most of the information about x from y (quality $1 - \frac{1+o(1)}{d^2}$), while the case $b = 0$ is clearly not an extraction as $K_{\mathcal{L}}(x) \ll |\mathcal{A}|$. Yet, by Item 4, any PPT verifier $\mathcal{V}$ who only sees $\mathcal{A}, x, y$ cannot distinguish between the two cases.

Proof. The proof holds by considering the following Attacker algorithm.

Algorithm 1 Attacker.

- Input: 1^d and $b \in \{0,1\}$.
- Oracle: PRG G: $\{0,1\}^d \to \{0,1\}^{d^4}$.
- Operation:
  1. If $b = 0$: Sample $s \leftarrow \{0,1\}^d$ and let $x = (x_1, \ldots, x_{d^4}) = G(s)$.
  2. Else (i.e., $b = 1$): Sample $x = (x_1, \ldots, x_{d^4}) \leftarrow \{0,1\}^{d^4}$.
  3. Let $y = (x_1, \ldots, x_{d^4 - d^2})$.
  4. Let $\mathcal{A}$ be the $(d^2 + O(1))$-size algorithm that has $x' = (x_{d^4-d^2+1}, \ldots, x_{d^4})$ hard-coded, and given y as input, outputs $y \circ x'$ and halts.
  5. Output $(\mathcal{A}, x, y)$.

Note that Items 1–3 of the lemma holds by construction. Furthermore, Item 4 immediately holds since G is a PRG. ◀

In the above example, we defined a hardness problem w.r.t. the predicate $R(x, z) = 1 \iff z = x$. But it can be easily be relaxed to a more realistic predicate of the form

$$R(S = (x_1, \ldots, x_n), z = (z_1, \ldots, z_m)) = 1 \iff \exists i \in [n], j \in [m] \text{ s.t. } \{\mathsf{NHamDist}(x_i, z_j)\} \leq 1/2 - \alpha,$$

for any fixing of a constant $\alpha > 0$ and $n, m \leq \text{poly}(d)$ (i.e., when the task is to output a list of strings that at least one of them has non-trivial agreement with one of the elements of S).[8]

[8] The idea is to replace Step 3 of Attacker with $y = (x_1, \ldots, x_{\alpha d^4 - d^2 \log d})$, where x is one of the elements in $\mathcal{S}$, and in Step 4 to define $\mathcal{A}$ as the $O(d^2 \log d)$-size program that has $x' = (x_{\alpha d^4 - d^2 \log d}, \ldots, x_{\alpha d^4 + d^2 \log d})$ hard-coded, and given y as input, samples $x'' \leftarrow \{0,1\}^{(1-\alpha)d^4 - d^2 \log d}$ and outputs $z = y \circ x' \circ x''$. By concentration bounds of the binomial distribution, it holds that $\Pr[\mathsf{NHamDist}(x, z) \leq 1/2 - \alpha] \geq 1 - \text{neg}(d)$. But without memorizing x' or at least $\Omega(d^2 \log d)$ bits of information about one $x \in \mathcal{S}$, the probability that a random guess of the bits after y would lead to $1/2 - \alpha$ Normalized Hamming distance from an element $x \in \mathcal{S}$ is $\text{neg}(d)$.

Derandomized Squaring: An Analytical Insight into Its True Behavior

Abstract

The notion of the derandomized square of two graphs, denoted as $G ⓢ H$, was introduced by Rozenman and Vadhan as they rederived Reingold's Theorem, **SL** = **L**. This pseudorandom primitive, closely related to the Zig-Zag product, plays a crucial role in recent advancements on space-bounded derandomization. For this and other reasons, understanding the spectral expansion $\lambda(G ⓢ H)$ becomes paramount. Rozenman and Vadhan derived an upper bound for $\lambda(G ⓢ H)$ in terms of the spectral expansions of the individual graphs, $\lambda(G)$ and $\lambda(H)$. They also proved their bound is optimal if the only information incorporated to the bound is the spectral expansion of the two graphs.

The objective of this work is to gain deeper insights into the behavior of derandomized squaring by taking into account the *entire spectrum* of H, where we focus on a vertex-transitive c-regular H. Utilizing deep results from analytic combinatorics, we establish a lower bound on $\lambda(G ⓢ H)$ that applies universally to all graphs G. Our work reveals that the bound is the minimum value of the function

$$d \cdot x - \frac{d(d-1)\chi_x(H)}{\chi'_x(H)}$$

in the domain (c, ∞), where $\chi_x(H)$ is the characteristic polynomial of the d-vertex graph H. This bound lies far below the known upper bound for $\lambda(G ⓢ H)$ for most reasonable choices for H. Empirical evidence suggests that our lower bound is optimal. We support the tightness of our lower bound by showing that the bound is tight for a class of graphs which exhibit local behavior similar to a derandomized squaring operation with H. To this end, we make use of finite free probability theory.

In our second result, we resolve an open question posed by Cohen and Maor (STOC 2023) and establish a lower bound for the spectral expansion of rotating expanders. These graphs are constructed by taking a random walk with vertex permutations occurring after each step. We prove that Cohen and Maor's construction is essentially optimal. Unlike our results on derandomized squaring, the proof in this instance relies solely on combinatorial methods. The key insight lies in establishing a connection between random walks on graph products and the Fuss-Catalan numbers.

1 Introduction

Expander graphs have played a crucial role in essentially all areas within theoretical computer science as well as in coding theory, and cryptography, among others. Their utility stems to a large extent from the ability to interpret expansion from various perspectives, be it combinatorial, probabilistic, or linear algebraic. This multifaceted understanding offers a unique advantage: it enables the otherwise challenging inference of combinatorial attributes of graphs by examining the spectral properties of related operators.

We briefly recall the notion of *spectral expansion*. Let G be an undirected d-regular graph on n vertices with adjacency matrix $\mathbf{A}$. Since G is undirected, $\mathbf{A}$ is symmetric and so its spectrum is real-valued. We denote the eigenvalues of $\mathbf{A}$ by $d = \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$. The spectral expansion of G, denoted as $\lambda(G)$, is given by $\max(\lambda_2, |\lambda_n|)$. We further denote the normalized spectral expansion of G by $\omega(G) = \frac{\lambda(G)}{d} \in [0, 1]$. We alternate between the two variants–the normalized and the unnormalized–depending on context.

An *expander* is a graph G with a normalized spectral expansion $\omega(G)$ that is bounded away from 1 [1]. However, for a typical application of expander graphs one "pays" a cost that increases with the degree d and has an "error" that vanishes as $\omega(G) \to 0$. This raises the question of what is the lowest possible value of $\omega(G)$ attainable by d-regular graphs. From the Alon-Boppana bound [30], which is usually stated in terms of $\lambda(G)$, it follows that for every $\varepsilon > 0$ there are only finitely many d-regular graphs G with $\lambda(G) \leq 2\sqrt{d-1} - \varepsilon$. A d-regular graph G satisfying $\lambda(G) \leq 2\sqrt{d-1}$ is called a *Ramanujan graph*. Over the past several decades, Ramanujan graphs have been a focal point of research. The constructions of Ramanujan graphs and their variants lean on profound number theoretic results [19, 24, 27] (see also [18]), or is rooted in deep analytical methods and on the accompanied technique of polynomial interlacing [20, 23, 22, 13, 16].

In their highly influential paper [34], Reingold, Vadhan, and Wigderson introduced the Zig-Zag product which enabled them to obtain a combinatorial construction of expander graphs by elementary means. While the expanders that were constructed were not quite close to Ramanujan, the fact that the construction is combinatorial and highly flexible made the Zig-Zag product extremely useful. Indeed, no long after, Reingold [33] based his breakthrough result, $\mathbf{SL} = \mathbf{L}$, on the Zig-Zag product, not for constructing expanders per se but for the purpose of "transforming" a given graph to an expander while maintaining its connected components structure. In a subsequent work, Ben-Aroya and Ta-Shma [5] put forth an improved variant of the Zig-Zag product, dubbed the *wide-replacement product*, that enabled the combinatorial construction of graphs that come quite close to Ramanujan. That variant was key in a recent breakthrough by Ta-Shma who constructed near-optimal small-bias sets [36]. Several other expander construction paradigms have been put forth in the literature, e.g., [6, 26]. We refer the reader to the excellent survey by Hoory, Linial, and Wigderson [17] for a comprehensive exposition on expander graphs.

[1] To be more precise, it is common to consider a family of graphs in this context. However, we will exclude this technical detail from our discussion for simplicity.

1.1 Derandomized squaring

Not long after the work of Reingold [33], Rozenman and Vadhan [35] introduced a close sibling to the Zig-Zag product, dubbed *derandomized squaring*, which we describe soon. This operation can be "cleaner" than the Zig-Zag product in some settings, in particular for their rederivation of Reingold's result, though the two operations are tightly connected. In the past few years, derandomized squaring has gained significant traction in the space-bounded derandomization literature (see, e.g., [28, 1, 2, 11]) mostly since it facilitated the adaptation of ideas from the realm of fast Laplacian solvers into the domain of space-bounded derandomization. For these reasons, in this paper we focus on the operation of derandomized squaring though we are confident that our techniques can be extended to other operations such as the Zig-Zag product and the wide-replacement product.

Squaring a graph is an easy way of improving its normalized spectral expansion. The square of a graph G, denoted as G^2, is the graph on the same vertex set that has an edge between a pair of vertices for every length-2 path in G between the vertices. Clearly, if $\mathbf{A}$ is the adjacency matrix of G then $\mathbf{A}^2$ is the adjacency matrix of G^2. Hence, $\omega(G^2) = \omega(G)^2$. However, if G is d-regular, G^2 is a d^2-regular graph. As a result, the degree growth associated with squaring the graph often surpasses the advantages gained from reducing the normalized spectral expansion. The purpose of derandomized squaring is to obtain a comparable improvement to the normalized spectral expansion without blowing up the degree by a quadratic factor.

From the view point of a vertex v of G, in the graph G^2, the neighbors of v are all connected to each other. That is, G^2 is obtained by adding copies of the complete graph with self-loops, one copy for each vertex v, where the complete graph associated with v is placed on the neighbors of v. Let H be a graph on d vertices, where we focus on the case in which H is vertex-transitive, and denote the degree of a vertex in H by c. The derandomized square of G and H, denoted as $G \circledS H$, is defined by replacing each such copy of the complete graph with a copy of H. Note that $G \circledS H$ is a D-regular graph where $D = dc$. Formally, the derandomized squaring, like the Zig-Zag product, requires working with edge-labeled graphs, but we sidestep this technicality. For the reader that is familiar with these intricacies, we remark that, for simplicity, in this extended abstract we circumvent labeling issues by assuming that G is given as the union of d perfect matchings, though this condition can be relaxed.

Given that an expander H approximates the complete graph, one is correct to expect that the derandomized square $G \circledS H$ approximates G^2 for every graph G. Rozenman and Vadhan formalized this intuition with regards to the normalized spectral expansion by establishing the bound

$$\omega(G \circledS H) \leq (1 - \omega(H))\,\omega(G)^2 + \omega(H) \leq \omega(G)^2 + \omega(H). \tag{1.1}$$

How tight is this bound? This is a somewhat subtle question. Rozenman and Vadhan proved that the bound is tight *as a function of* $\omega(G)$ and $\omega(H)$, however, it is certainly conceivable that a superior bound might be achieved if one incorporates more information about the graphs beyond just their spectral expansions into the bound. In particular, if we fix H and consider the mapping $\lambda(\cdot \circledS H)$ which maps every d-regular graph G to $\lambda(G \circledS H)$, then it is interesting to ask how strong a bound can be obtained on this mapping as a function of the entire spectrum of H.

Given the significance of the derandomized squaring operation, and the related Zig Zag product as well as the wide-replacement product, a substantial improvement to the bound could profoundly impact our understanding on several fundamental problems, including

in space-bounded derandomization and in coding theory. For example, in the context of space-bounded derandomization such a result may reduce the seed length of PRGs or weighted PRGs (see [9, 10, 11] and references therein). Such a result may also lead to a better construction of small-bias sets in which the wide-replacement product is used for bias-reduction. Therefore, gaining a thorough understanding of derandomized squaring is highly motivated from the theoretical computer science standpoint.

1.2 Two case studies

Before presenting our results, which we view as a first step towards the above goal, we wish to highlight the gap between the Rozenman-Vadhan bound, as given in Equation (1.1), and the "true" behavior of the derandomized squaring operation. We do so by considering two case studies, starting with $H = \mathrm{K}_{c,c}$, the complete $c = \frac{d}{2}$-regular bipartite graph on d vertices.

1.2.1 Derandomized squaring with the complete regular bipartite graph

Since $H = \mathrm{K}_{c,c}$ is bipartite, $\omega(H) = 1$, and so the bound given by Equation (1.1) becomes trivial, $\omega(G \circledS H) \leq 1$ for all d-regular graphs G. For this special case, one can get a nontrivial bound by elementary means by incorporating some information on G. To see this, assume that G is the union of two c-regular Ramanujan graphs on n vertices, whose adjacency matrices are denoted $\mathbf{B}$ and $\mathbf{R}$, respectively. That is, the adjacency matrix of G is given by $\mathbf{A} = \mathbf{B} + \mathbf{R}$. Thus, it can be shown that the adjacency matrix of $G \circledS H$ can be expressed as $\mathbf{RB} + \mathbf{BR}$ [2], and so by the Courant-Fischer Theorem,

$$\lambda(G \circledS H) = 2 \cdot \max_{x \perp \mathbf{1}} \frac{x^{\mathsf{T}}\mathbf{BR}x}{x^{\mathsf{T}}x} \leq 2\left(2\sqrt{\frac{d}{2} - 1}\right)^2 \leq \sqrt{32}\sqrt{D-1} \approx 5.66\sqrt{D-1},$$

where $D = \frac{d^2}{2}$ is the regularity of $G \circledS H$.

Although the above bound on $\lambda(G \circledS H)$ certainly beats the trivial bound, D, it still seems to undersell the typical behavior of $G \circledS H$. In fact, by sampling [3] a random d-regular graph G and evaluating $\lambda(G \circledS H)$, one can verify that for a sufficiently large d, the value of $\lambda(G \circledS H)$ distributes around $2.35\sqrt{D-1}$. But where does the 2.35 value originate? How can this number be determined based on our selected H? Jumping the gun, the analytical tool we introduce *predicts* that the exact value, for this H, is

$$\frac{1}{2}\sqrt{11 + 5\sqrt{5}} \approx 2.35. \tag{1.2}$$

By saying that we "predict" this bound captures the true behavior of derandomized squaring with $H = \mathrm{K}_{c,c}$, we mean the following: First, we prove the aforementioned value to be a lower bound on $\lambda(G \circledS H)$ for *every* d-regular graph G; Second, we prove the existence of infinitely many graphs that meet this bound. These graphs exhibit a local structure resembling a derandomized square with H. Lastly, our predictions align with every experiment we made for every graph H and when G is sampled uniformly at random. We provide further details in Section 2, where our results are formally presented.

---

[2] With regards to the edge labeling, for the last statement to hold we assume that neighbors $1, \ldots, \frac{d}{2}$ of every vertex are those coming from $\mathbf{B}$ and the remaining neighbors $\frac{d}{2} + 1, \ldots, d$ are coming from $\mathbf{R}$.

[3] Our sampling is done by taking the union of d uniformly random and independent perfect matchings, where edges that are sampled multiple times are counted with the respective multiplicity.

1.2.2 Derandomized squaring with a Paley graph

In the aforementioned example, the Rozenman-Vadhan bound was non-informative. It is worth noting that it is not just in these instances where the typical performance of the derandomized square surpasses the predictions of the bound. To give one such example, consider a Paley graph on d vertices, denoted as Pal_d. For a typical d-regular graph G, the limit behavior as $d \to \infty$ of the spectral expansion $\lambda(G ⓢ \mathrm{Pal}_d)$, when properly normalized, is predicted by our analytic tool to equal

$$\lim_{d\to\infty} \frac{\lambda(G ⓢ \mathrm{Pal}_d)}{\sqrt{D-1}} = \frac{1+\sqrt{13+16\sqrt{2}}}{\sqrt{8}} \approx 2.46, \tag{1.3}$$

where $D = \frac{d(d-1)}{2}$ is the degree $G ⓢ \mathrm{Pal}_d$. This should be compared with a bound of 2, the least possible value given the Alon-Boppana bound. Additionally, it should be compared with Equation (1.1), which, irrespective of the choice of G, cannot produce a bound lower than $O(D^{1/4})$.

From the preceding discussion and, in particular, the two case studies, a key question lingers: Is there an exact formula or efficient method that enables us to compute, and more importantly, to gain insight on the spectral expansion of the operation of derandomized squaring with H?

2 Our Results

As our case studies suggest, the spectral expansion of the graphs G and H might not adequately represent the spectral expansion of their derandomized square. In this paper we initiate the study of the following question:

▶ **Main Question.** *What is the "true" behavior of the spectral expansion of derandomized squaring?*

We turn to give a brief summary of our results. We elaborate further on each of these results in the subsequent sections, Sections 2.1–2.3.

Limitations of derandomized squaring

Our first result is a lower bound on $\lambda(G ⓢ H)$, factoring in the full spectrum of H, which holds for *every* graph G. Encoding this spectrum by the characteristic polynomial of H, denoted as $\chi_x(H)$, our work reveals that the bound is the minimum value of the function

$$d \cdot x - \frac{d(d-1)\chi_x(H)}{\chi'_x(H)} \tag{2.1}$$

in the domain (c, ∞), where recall that d and c are the degrees of G and H, respectively. Our proof leans on deep results from analytic combinatorics and the symbolic method. Although this bound may look more complicated than Equation (1.1), it is easy to calculate for various explicit choices of H, and easy to bound for families of graphs, as we will examplify in Section 2.1 (a more comprehensive review of examples, including the ones discussed in Section 1.2, is done in Section 4).

Based on our empirical experiments, it appears that our lower bound is tight in a strong sense, namely, for *every* vertex-transitive graph H and for a *typical* graph G. However, a definitive proof of the bound's tightness eludes us in general. In spite of this, we have

made notable progress by first proving tightness of the bound for particular choices of H, and second by proving its tightness for a broader class of graphs, we term H-local graphs. For obtaining this result we make use of finite free probability theory and the accompanied technique of interlacing. These were instrumental in the seminal works of Marcus, Spielman, and Srivastava [21, 22, 23] who introduced these techniques for their study of bipartite Ramanujan graphs. We elaborate on this in Section 2.2.

Comparison to known bounds

The lower bound described above requires solving a separate polynomial equation for every choice of H. However, restricting the discussion to *reasonable* choices of H–for example, graphs H having no self loops–we show universally that the lower bound for $\omega(G \circledS H)$ lies within the range $\left(\frac{2}{\sqrt{dc}}, \frac{3}{\sqrt{dc}}\right)$, very close to the Alon-Boppana bound and significantly distant from Equation (1.1) that suggests at best that $\omega(G \circledS H) = O\left(\frac{1}{\sqrt{c}}\right)$. As discussed above, we also expect our lower bound to represent the behavior of $G \circledS H$ for a typical choice of G. Note that the restriction of H to simple graphs makes sense, as in all applications of derandomized squaring we are aware of, H is for our choosing.

The proof of Rozenman and Vadhan [35] for the tightness of Equation (1.1) involves a choice of H which is a graph with many self loops. Moreover, our lower bound applied to this specific choice (see Section 4.1.3) exactly yields the formula given by Equation (1.1). This suggests that a better upper bound should hold for particular choices of H (potentially under some assumptions on G). We leave these intriguing open questions for future work.

A lower bound for rotating expanders

In the process of establishing our lower bound on the spectral expansion of derandomized squaring, we address an open problem concerning the spectral expansion of *rotating expanders* [12]. In this recent paper, random walks on expanders were studied, wherein a permutation is applied to the vertices following each step. The objective of this approach is to mitigate the inherent exponential deterioration of the spectral expansion with respect to the length of the walk. Indeed, the authors proved that by using a carefully chosen permutation sequence, the deterioration can be reduced from exponential to linear. The authors left open the question of whether their construction is optimal.

In this work, we resolve this question by proving the optimality of their construction. More generally, we prove that a graph which is constructed as a graph product is inherently far from Ramanujan. Our key observation lies in relating the problem with the Fuss-Catalan numbers which generalize the Catalan numbers that emerge when bounding the spectral expansion of d-regular graphs. We elaborate on this in Section 2.3, where we also give the necessary background on rotating expanders.

A broader perspective: beyond spectral expansion

Almost all of the numerous works and applications of spectral expanders in theoretical computer science, indeed, the very definition of a spectral expander G, rely on the notion of the spectral expansion, $\lambda(G)$. Only a few instances utilize the entire spectrum of G, which holds significantly more, and sometimes vital, information about the graph. In their seminal series of works, Marcus, Spielman, and Srivastava developed finite free probability as a framework to handle the full spectrum of a graph. As mentioned, this enabled them to establish the existence of bipartite Ramanujan graphs of all sizes and degrees.

Our current work serves as a further exploration into analyzing graphs beyond their spectral expansion. Instead of aiming to construct expanders, our objective is to achieve a deeper insight into the derandomized squaring operation. While we primarily target the spectral expansion of the derandomized square $G \circledS H$, our approach involves leveraging the entire spectrum of H for establishing our bounds. In addition to our use of finite free probability, we employ deep results from analytic combinatorics, and the framework offered by the symbolic method. We posit that working with the full spectrum of a graph could yield significant results and improvements for various problems in theoretical computer science, and we believe that the deep results we use could be advantageous in other scenarios where analyzing the full spectrum is desired.

Related work

Already at this point, prior to delving into the formal details concerning our results, we would like to highlight some related work. Our study of the graph $G \circledS H$ for a d-regular graph G is done by considering the graph $\mathcal{T}_d \circledS H$, where $\mathcal{T}_d$ is the d-ary infinite tree. The study of graphs, which represent the quotient of a given (typically infinite) graph X, has a long history (see [15] as an example). Of particular interest are the extreme graphs, known as *X-Ramanujan graphs*. The reader is referred to [25, 31] and references therein for more details. Our result supporting the tightness of our lower bound, presented in Section 3.2.2, can also be derived from the work of Mohanty and O'Donnell [25]. For completeness and accessibility of our paper, we present the full proof here, as it sheds more light on Equation (2.1) and connections between analytic combinatorics and free probability which we discuss further in Section 2.2.

Regarding our lower bound, the spectral radius of operators associated with infinite graphs has been extensively explored. This is particularly true when these graphs exhibit a well-defined group-theoretic structure. Analytic combinatorics has a well-established presence in this context [37]. Finally, it is noteworthy that the Fuss-Catalan numbers are significant in free probability theory and have known associations with the product of certain random matrices [32].

2.1 Limitations of derandomized squaring

Let H be a vertex-transitive graph on d vertices. Recall that, throughout, c denotes the degree of a vertex in H. In this section we state our result regarding the lower bound on $\lambda(G \circledS H)$ which holds for every d-regular graph G. As previously suggested, our approach integrates the complete spectrum of H into the bound. This integration is accomplished by encoding the spectrum through the characteristic polynomial of H-s adjacency matrix, denoted as $\chi_x(H) = \prod_{i=1}^{d}(x - \lambda_i)$, where, as before, $c = \lambda_1 \geq \cdots \geq \lambda_d$ are the corresponding eigenvalues.

▶ **Theorem 1.** *Let H be a vertex-transitive c-regular graph on $d \geq 3$ vertices, where $c \geq 1$. Let x_0 be the largest real solution to the polynomial equation*

$$(d-1)\chi_x(H)\chi''_x(H) = (d-2)\chi'_x(H)^2. \tag{2.2}$$

Then, for every d-regular graph G on n vertices, $\lambda(G \circledS H) \geq \Lambda_H - o_n(1)$, where

$$\Lambda_H \triangleq d\left(x_0 - (d-1)\frac{\chi_{x_0}(H)}{\chi'_{x_0}(H)}\right). \tag{2.3}$$

As shown in the proof of Theorem 1, despite the polynomial equation from Equation (2.2) usually yielding complex solutions, there is always at least one real solution. Experiments overwhelmingly suggest that the bound accurately reflects the behavior of $\lambda(G \circledS H)$ for a typical graph G. Having this in mind, we may posit that the structure of Equations (2.2) and (2.3), namely, $(d-1)\Phi\Phi'' = (d-2)(\Phi')^2$, and the accompanied expression $d\left(x - (d-1)\frac{\Phi(x)}{\Phi'(x)}\right)$, epitomize the derandomized squaring operation with a typical d-regular graph. By setting $\Phi = \chi(H)$, we incorporate details about H.

Although the proof of Theorem 1 leans on deep results from analytic combinatorics and the symbolic method, employing the theorem remains elementary. However, as perhaps anticipated, it is not as direct as the Rozenman-Vadhan bound from Equation (1.1), but rather it requires finding the largest real solution to a polynomial equation.

Before proceeding further, we introduce the following notation. Recall that $G \circledS H$ is D-regular where $D = cd$. We define $\kappa_H = \frac{\Lambda_H}{\sqrt{D-1}}$, and note that, due to the Alon-Boppana bound, $\kappa_H \in \left[2, \frac{D}{\sqrt{D-1}}\right] \approx \left[2, \sqrt{D}\right]$.

Equivalent reformulations of Theorem 1

One can alternatively recast our procedure for finding a lower bound for $\lambda(G \circledS H)$, as given by Theorem 1, in several equivalent ways, as we describe next.

The Cauchy transform is a useful analytic tool which we will make an extensive use of in this paper. For a graph H on d vertices, the Cauchy transform takes a simple form and is given by

$$\mathcal{G}_H(x) = \frac{1}{d} \cdot \frac{\chi'_x(H)}{\chi_x(H)} = \frac{1}{d} \sum_{i=1}^{d} \frac{1}{x - \lambda_i}. \tag{2.4}$$

Using the Cauchy transform we can reformulate Theorem 1 as follows.

▶ **Theorem 2** (Recasting Theorem 1 in terms of the Cauchy transform). *Let H be a vertex-transitive c-regular graph on $d \geq 3$ vertices, where $c \geq 1$. Let x_0 be the unique positive real solution to the equation*

$$\frac{d}{d-1}\mathcal{G}_H(x)^2 + \mathcal{G}'_H(x) = 0. \tag{2.5}$$

Then, for every d-regular graph G on n vertices, $\lambda(G \circledS H) \geq \Lambda_H - o_n(1)$, where

$$\Lambda_H = d \cdot x_0 - \frac{d-1}{\mathcal{G}_H(x_0)}. \tag{2.6}$$

We emphasize that, as demonstrated in the proof of Theorem 2, there always exists a positive real solution to Equation (2.5) and it is unique.

By defining $\psi_H(x) = d \cdot x - \frac{d-1}{\mathcal{G}_H(x)}$, it can further be shown that

$$\Lambda_H = \min_{x > c} \psi_H(x), \tag{2.7}$$

where the minimal point $x_0 > c$ exists and is unique (see the full version of the paper for the details).

2.2 Tightness of the lower bound

As previously discussed, we have yet to establish that the lower bound provided by Theorem 1 is tight in general. However, empirical results strongly suggest its accuracy. Specifically, we believe this to be true for *every* vertex-transitive graph H on d vertices and for a *typical* d-regular graph G. In light of the evidence supporting this assertion, as we discuss next, we will formulate it as a conjecture in Section 2.4. In order to state our analytic evidence for the tightness of our bound, we observe that from the perspective of a vertex v in $G \circledS H$, the vertex v participates in d instances of H. This is because each of the d neighbors of v positions it within a copy of H. We call a graph that has the above local property an *H-local graph* (see the full version of this paper for the formal definition). The following theorem formalizes the evidence we have gathered for the tightness of our lower bound.

▶ **Theorem 3.** *For every vertex-transitive graph H on $d \geq 3$ vertices and for every $n \geq 1$, there exists an H-local graph X_H on nd vertices such that $\lambda_2(X_H) \leq \Lambda_H$.*

In addition to Theorem 3, we prove the optimality of our lower bound for $\lambda(G \circledS H)$ in three specific cases of H: the clique with self-loops, where $G \circledS H$ corresponds to the actual squaring operation; the clique without self-loops, which corresponds to a non-backtracking length-2 random walk; and lastly, the graph employed in the Rozenman-Vadhan bound's tightness result. We provide further details on these cases in Section 4.1. Going back to Theorem 3, note that we manage to bound only the second-largest eigenvalue, $\lambda_2(X)$, rather than the spectral expansion $\lambda(X) = \max(\lambda_2(X), |\lambda_n(X)|)$. Graphs with such property are termed *one-sided spectral expanders*. These graphs are suitable for numerous applications, primarily due to the fact that this property alone suffices for the Alon-Chung Lemma [3].

The proof of Theorem 3 leverages finite free probability and the interlacing technique that were developed by Marcus, Spielman, and Srivastava [21, 22, 23]. We provide a high-level overview for the proof of Theorem 3 in Section 3.2, however, already here we emphasize that the fact that our lower bound, which is based on results from analytic combinatorics, matches our upper bound which is rooted in tools from free probably theory is an instantiation of a deep connection between the two fields. This has to do with the fact that one combinatorial proof for the Lagrange inversion formula–a tool used under the hood in our lower bound– makes use of Lukasiewicz paths that in turn are tightly connected to the lattice of non-crossing partitions which is at the heart of free probability theory. The reader is referred to Chapter 16 in the excellent book by Nica and Speicher [29] to learn more about this connection, though for our purpose, of studying the derandomized squaring operation, we give a direct and self-contained proof in the full version of the paper.

2.3 Lower bound on the spectral expansion of rotating expanders

A "standard" length-t random walk on a graph G is analyzed by considering the power graph, denoted as G^t, generalizing the square of the graph G^2 which was discussed so far. This graph encodes the number of length-t walks by introducing an edge for each such walk between the two corresponding vertices. It is easy to see that if $\mathbf{A}$ is the adjacency matrix of G, then the matrix $\mathbf{A}^t$ is the adjacency matrix of G^t. Consequently, the spectral expansion of G^t, which is the most pertinent quantity when examining length-t random walks on G, is given by $\lambda(G^t) = \lambda(G)^t$. In particular, if G is a d-regular Ramanujan graph, then $\lambda(G^t) = 2^{\Omega(t)}\sqrt{D-1}$, where $D = d^t$ is the degree of G^t. Therefore, even if G is initially Ramanujan, the power graph is exponentially distant, in t, from Ramanujan.

With an eye towards potential applications to theoretical computer science, Cohen and Maor [12] proposed that permuting the vertices after each step (in a palindrome fashion to result in an undirected graph) can circumvent this exponential deterioration. More

precisely, the authors proved that for every d-regular Ramanujan graph G with adjacency matrix $\mathbf{A}$, and for every integer $t \geq 2$, there exists a sequence of permutation matrices $\mathbf{P} = (\mathbf{P}_1, \ldots, \mathbf{P}_{t-1})$ such that the graph $G_{\mathbf{P}}$, whose adjacency matrix is given by

$$\mathbf{A}_{\mathbf{P}} = \mathbf{A}\mathbf{P}_{t-1} \cdots \mathbf{A}\mathbf{P}_1\mathbf{A}^2\mathbf{P}_1^{\mathsf{T}}\mathbf{A} \cdots \mathbf{P}_{t-1}^{\mathsf{T}}\mathbf{A},$$

has spectral expansion

$$\lambda(G_{\mathbf{P}}) \leq \left(1 + \frac{1}{t}\right)^t (t+1)\sqrt{D} + o(1), \tag{2.8}$$

where $D = d^{2t}$ is the degree of $G_{\mathbf{P}}$ and the $o(1)$ term is a quantity that vanishes exponentially fast with the girth of G, and should be ignored in this introductory section. Specifically, by permuting the vertices after each step using suitable permutations, the deterioration is reduced from exponential to linear in t.

An open problem left in [12] is to establish a lower bound on the spectral expansion of $G_{\mathbf{P}}$ that is applicable for any permutation sequence $\mathbf{P}$. Specifically, the authors left open the question of whether the linear dependence in t is optimal. Experimental results suggest that for a typical $\mathbf{P}$, Equation (2.8) holds with equality, up to the vanishing $o(1)$ term. However, it is entirely plausible that the typical behavior does not accurately represent the behavior of the optimal permutation sequence $\mathbf{P}$. The logic would be that for a graph with substantial structure, such as a Cayley graph, a permutation sequence that takes into account the structure of the underlying group and the set of generators may yield a superior spectral expansion. However, in this work we resolve this open problem by proving that the bound is indeed tight.

▶ **Theorem 4.** *For every d-regular graph G and for every permutation sequence $\mathbf{P} = (\mathbf{P}_1, \ldots, \mathbf{P}_{t-1})$,*

$$\lambda(G_{\mathbf{P}}) \geq \left(1 + \frac{1}{t}\right)^t (t+1)\sqrt{D} - o(1).$$

In fact, our lower bound applies to the product of *any* d-regular graphs, not only isomorphic graphs as used in the construction of $G_{\mathbf{P}}$. For $t = 1$, where no actual product is involved, this essentially aligns with the Alon-Boppana bound. As suggested by Theorem 4 (ignoring the $o(1)$ term), we have $\lambda(G_{\mathbf{P}}) = \lambda(G^2) \geq 4\sqrt{D}$. However, for $t = 2$, the bound increases to $\lambda(G_{\mathbf{P}}) \geq \frac{3^3}{2^2}\sqrt{D} = 6.75\sqrt{D}$, and for $t = 3$, it further deteriorates to $\lambda(G_{\mathbf{P}}) \geq \frac{4^4}{3^3}\sqrt{D} \approx 9.48\sqrt{D}$. As indicated, the gap for graph products increases linearly with the number of graphs involved, making them inherently far from Ramanujan.

2.4 Two conjectures and open problems

Given our results and the above discussion, we wish to put forth two conjectures that capture different aspects of the tightness of our lower bound as given by Theorem 1. These are analog to fundamental questions on Ramanujan graphs where Theorem 1 plays in this analogy the role of the Alon-Boppana bound.

▶ **Conjecture 5.** *For every vertex-transitive graph H, $\lambda(G \circledS H) \leq \Lambda_H$ holds for infinitely many graphs G.*

Conjecture 5 is analog to the fundamental question regarding the existence of Ramanujan graphs which has received significant attention in the literature. Resolving Conjecture 5 with respect to $\lambda_2(G \circledS H)$ would be interesting as well. Our second conjecture focuses on the

typical behavior, and is analogous to Friedman's resolution [14] of Alon's conjecture [4] (see also [7]). We first introduce the following notation: For an even integer n and for an integer d, we let $\mathcal{M}_{n,d}$ denote the distribution over d-regular graphs on n vertices that are sampled by taking the union of d uniformly random and independent perfect matchings, where edges that are sampled multiple times are counted with the respective multiplicity.

▶ **Conjecture 6.** *For every vertex-transitive graph H on d vertices and for every $\varepsilon > 0$,*

$$\Pr_{G\sim\mathcal{M}_{n,d}}[\lambda(G\circledS H) \geq \Lambda_H + \varepsilon] = o_n(1).$$

Note that a similar statement is proven in [8] for a wide variety of graph distributions. However, these do not include the one suggested above for graphs of the form $G\circledS H$.

In addition to the conjectures previously discussed, our research raises several intriguing questions. An obvious open problem is the generalization of our results to non-vertex-transitive graphs. For potential theoretical computer science applications, it would be pertinent to identify conditions that a pair of graphs G and H satisfy so that the spectral expansion $\lambda(G\circledS H)$ is close to our lower bound or, at a minimum, substantially improves upon the Rozenman-Vadhan bound. Once this aspect is clearer, problems regarding the explicitness can be addressed. To give just one additional research question, we believe that the extension of our techniques to additional graph operations, including the Zig-Zag product and the wide-replacement product, is feasible. We defer this exploration to future research.

Organization of the rest of the paper

In Section 3 we give a high-level proof overview of our results on the derandomized squaring operator. The detailed proofs of the theorems stated above are provided in the full version of this paper. In Section 4 we apply our results to interesting graph families, and prove our universal bound on κ_H for simple graphs.

3 Proof Overview

In this section, we provide an informal overview of the proofs for our results. We begin with our lower bound for the spectral expansion of derandomized squaring, as given by Theorem 1 (outlined in Section 3.1). Our proof relies on the symbolic method and leverages results from analytic combinatorics, both of which we introduce and explain in the full version of this paper. Additionally, we briefly outline the proof for our evidence regarding the tightness of our lower bound, as stated in Theorem 3, in Section 3.2. In that section, we provide the necessary background on finite free probability, which is essential for understanding the proof.

3.1 Limitations of derandomized squaring

As before, let G be a d-regular graph and H a vertex-transitive c-regular graph on d vertices. In this section we sketch the proof for our lower bound on $\lambda(G\circledS H)$, as stated in Theorem 1. Our starting point is standard, relying on the trace method which asserts that $\lambda(G\circledS H)$ is lower bounded by roughly $c_\ell(G\circledS H)^{1/\ell}$ for every $\ell > 0$, where $c_\ell(G\circledS H)$ is the number of length-ℓ cycles that originate at some fixed vertex v of $G\circledS H$. Thus, the task at hand is to compute, or at least lower bound $c_\ell(G\circledS H)$, where we will choose ℓ to be sufficiently large. A common strategy for this is to consider a suitable infinite cover of the graph of interest,

$G \circledS H$ in our case, which we take to be $\mathcal{T}_d \circledS H$, where $\mathcal{T}_d$ is the d-regular infinite tree. Indeed, for every ℓ, every length-ℓ cycle in $\mathcal{T}_d \circledS H$ that originated at some fixed vertex induces a unique cycle in $G \circledS H$, initiated at some fixed vertex, and so $c_\ell(G \circledS H) \geq c_\ell(\mathcal{T}_d \circledS H)$.

We obtain an accurate estimate on $c_\ell(\mathcal{T}_d \circledS H)$ by first expressing the combinatorial class of cycles in $\mathcal{T}_d \circledS H$ using the symbolic method, from which we immediately derive a functional equation that is satisfied by the corresponding generating function. We then use results from analytic combinatorics to get the desired estimate on the coefficients of the latter. The symbolic method, a prominent combinatorial theory, allows one to deduce a functional equation that is satisfied by the class's generating function straight from its specification. Following this, in Section 3.1.1, we utilize the symbolic method to define the cycle class in $\mathcal{T}_d \circledS H$ and from there, derive a functional equation that is satisfied by the associated generating function.

With the functional equation in hand, our objective is to deduce estimates of its coefficients. To achieve the estimate, we employ deep results from analytic combinatorics. These treat the functional equation as a meromorphic function, considering its singularities to determine the bound.

3.1.1 The functional equation for derandomized squaring

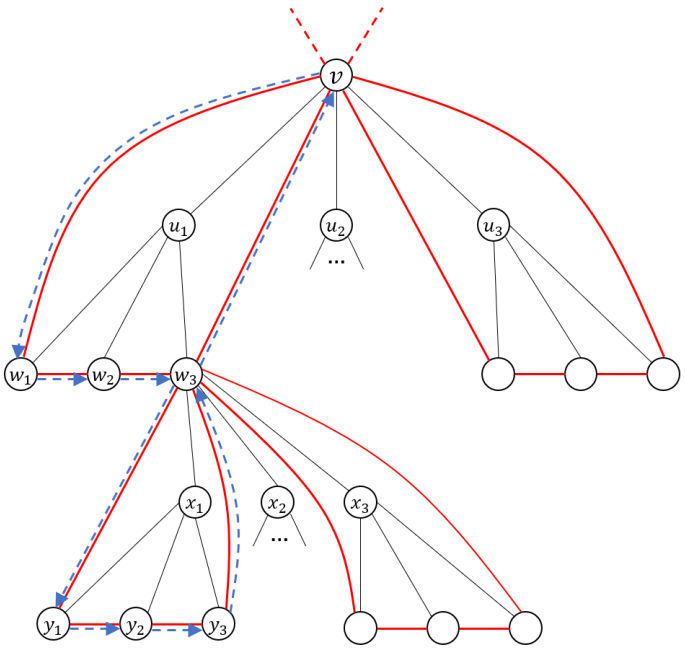

Figure 1 Cycles in $\mathcal{T}_4 \circledS C_4$. The black edges represent the edges of $\mathcal{T}_4$, while the red edges represent those of $\mathcal{T}_4 \circledS C_4$. Dashed red edges indicate the truncated edges. Edges that are irrelevant to the cycles of v (e.g., (u_1, x_1)) have not been included in the figure. The blue cycle within $\mathcal{T}_4 \circledS C_4$ corresponds to the cycle $(v \to w_1 \to w_2 \to w_3 \to v)$ within the copy of H centered around vertex u_1. In this cycle, the first, second, and last steps are substituted with the pair $(\to, \epsilon)$, while the third step is substituted with the pair $\big(\to, c\big)$, where c represents a nested cycle from $\mathcal{C}_{\mathcal{T}_d \circledS H}$ (specifically, $c = (w_3 \to y_1 \to y_2 \to y_3 \to w_3)$).

Let H be a vertex-transitive graph on d vertices. Define $\mathcal{C}_{\mathcal{T}_d \circledS H}$ as the combinatorial class of cycles in $\mathcal{T}_d \circledS H$ that originate at the root. As previously mentioned, the size function corresponds to the cycle's length. To prevent double-counting, we exclude the empty cycle

from this class. When expressing the class using the symbolic method, we use $\mathcal{S}_H$ to represent the combinatorial class of nonempty cycles in H that only revisit the originating vertex upon completing the cycle. Consequently, as detailed below, after truncating one branch of the root, and overriding the class definition of $\mathcal{C}_{\mathcal{T}_d \circledS H}$ to capture cycles on the truncated graph, it satisfies the recursive relation

$$\mathcal{C}_{\mathcal{T}_d \circledS H} = \{1, \ldots, d-1\} \times \left(\mathcal{S}_H \circ \left(\to \times \left(\mathcal{C}_{\mathcal{T}_d \circledS H} + \epsilon\right)\right)\right). \tag{3.1}$$

Here, $\to$ symbolizes an atom, which we interpret as a step within a cycle in H.

To see this, remember that each child of the root positions the root within a copy of H. Therefore, when describing a non-empty cycle originating at the root, we first select one of its $d-1$ children, which determines the copy of H in which the root is involved. Now, consider any cycle within that copy of H starting at the root, $v_1 \to v_2 \to \cdots \to v_\ell = v_1$. This cycle corresponds to a cycle in $\mathcal{T}_d \circledS H$ that begins at the root in the following manner: After each step $v_i \to v_{i+1}$ on the cycle, we examine the copy of $\mathcal{T}_d \circledS H$ rooted at v_{i+1} and attach a cycle from that copy of $\mathcal{T}_d \circledS H$. When we return to v_{i+1}, we proceed with $v_{i+1} \to v_{i+2}$. Note that attaching an empty cycle is permissible, even though it is not included in $\mathcal{C}_{\mathcal{T}_d \circledS H}$, leading to the addition of the neutral element ϵ in Equation (3.1). Furthermore, after the final step $v_{\ell-1} \to v_\ell = v_1$, we attach another (potentially empty) copy of $\mathcal{C}_{\mathcal{T}_d \circledS H}$ to account for cycles that visit the root more than twice. This rationale underpins our definition of $\mathcal{S}_H$, which is designed to prevent over-counting that would have otherwise occur.

Equation (3.1) directly implies that the generating function, $C_{\mathcal{T}_d \circledS H}(z)$, associated with the class $\mathcal{C}_{\mathcal{T}_d \circledS H}$ satisfies

$$C_{\mathcal{T}_d \circledS H}(z) = (d-1) S_H\left(z\left(C_{\mathcal{T}_d \circledS H}(z) + 1\right)\right), \tag{3.2}$$

where $S_H(z)$ is the generating function corresponding to the class $\mathcal{S}_H$. On its own, this result does not provide much insight, as the functional equation $u = (d-1)S_H(z(u+1))$ tends to be intricate, hindering our ability to extract the coefficients of $C_{\mathcal{T}_d \circledS H}(z)$. For instance, even in the simple case of a length-4 cycle, $H = C_4$, in which case $S_{C_4}(z) = \frac{2z^2}{1-2z^2}$, Equation (3.2) takes the form

$$2z^2 c(z)^3 + 10z^2 c(z)^2 + (14z^2 - 1)c(z) + 6z^2 = 0,$$

where the term $c(z)$ is a shorthand for $C_{\mathcal{T}_d \circledS C_4}(z)$, resulting in a complicated expression for $c(z)$.

To address this challenge, we leverage a deep result from analytic combinatorics. We provide the essential background in the full version of the paper. Subsequently, in Section 3.1.3, we will outline our approach to estimating the coefficients of $C_{\mathcal{T}_d \circledS H}(z)$ using Equation (3.2) as our starting point.

3.1.2 A brief introduction to analytic combinatorics

The symbolic method classifies combinatorial classes into *schemes* based on their shared structures. This approach aims to consolidate solutions to these problems and highlight their interrelations. A notable schema within this framework is termed *smooth inverse-function schema*. These are classes whose generating function $\zeta(z)$ satisfies the functional equation $u = z \cdot \phi(u)$, namely, $\zeta(z) = z \cdot \phi(\zeta(z))$, for some "well-behaved" function $\phi(u)$. By manipulating Equation (3.2), we see that $\mathcal{C}_{\mathcal{T}_d \circledS H}$ is tightly connected to this schema. Indeed, letting $\zeta_H(z) = z\big(C_{\mathcal{T}_d \circledS H}(z) + 1\big)$, we have that $\zeta_H(z) = z \cdot \phi_H(\zeta_H(z))$, where

$$\phi_H(u) = 1 + (d-1)S_H(u). \tag{3.3}$$

Analytic combinatorics provides a method to estimate the coefficients of the generating function for smooth inverse-function schema. This approach is applicable under certain technical conditions on $\phi(u)$, which we hide under the rug in this informal proof overview. The key requirement though is that there is a real positive solution to the *characteristic equation* $\phi(u) = u \cdot \phi'(u)$ within ϕ-s analytic domain around the origin. To denote the k'th coefficient of a function we use the coefficient extractor operator, $[z^k]$. For an analytic function $A(z) = \sum A_k z^k$, we have

$$[z^k]A(z) \triangleq A_k$$

With this, we have the following theorem which is informally stated here (see the full version of the paper for the formal statement).

▶ **Theorem 7.** *Let $\zeta(z)$ belong to the smooth inverse-function schema. Then, with τ the positive root of the corresponding characteristic equation $\phi(u) = u \cdot \phi'(u)$, one has*

$$\left([z^k]\,\zeta(z)\right)^{\frac{1}{k}} \approx \phi'(\tau). \tag{3.4}$$

3.1.3 Proof sketch of Theorem 1

With Theorem 7 in hand, and by the discussion above that led us to Equation (3.3), we are ready to sketch the proof of Theorem 1. In fact, it will be more convenient to consider the variant using the Cauchy transform of H. Since $\mathcal{C}_H = \mathsf{SEQ}(\mathcal{S}_H)$, we have that $S_H(z) = 1 - \frac{1}{C_H(z)}$. It can also be shown that $C_H(z) = \frac{1}{z}\mathcal{G}_H(\frac{1}{z})$ (see the full version of the paper for the proof), and so Equation (3.3) takes on the form

$$\phi_H(z) = d - \frac{(d-1)z}{\mathcal{G}_H\left(\frac{1}{z}\right)}.$$

Through some algebraic manipulations, it becomes evident that the characteristic equation, $\phi_H(z) = z \cdot \phi'_H(z)$, transforms into the form presented in Equation (2.5) from Theorem 2 when z is substituted with its reciprocal. Specifically, the equation becomes

$$\frac{d}{d-1}\mathcal{G}_H\left(\frac{1}{z}\right)^2 + \mathcal{G}'_H\left(\frac{1}{z}\right) = 0.$$

Upon further analytical exploration, it can be shown that this equation has a positive real root $z_0 > d$. Consequently, there exists a positive $\tau < \frac{1}{d} \leq R$, where $\tau = \frac{1}{z_0}$, that satisfies the characteristic equation. This allows us to apply Theorem 7 and derive the sought-after estimate

$$\left[z^k\right] C_H(z)^{1/k} \approx \phi'_H(\tau) = \frac{\phi_H(\tau)}{\tau} = dz_0 - \frac{d-1}{\mathcal{G}_H\left(z_0\right)}.$$

3.2 Matching the lower bound with H-local graphs

As briefly discussed in Section 2.2, the proof of Theorem 3 makes use of finite free probability. Thus, to start with, in Section 3.2.1 we give a brief account of this elegant theory. Then, in Section 3.2.2 we sketch the proof of Theorem 3.

3.2.1 Finite free probability

Free probability is a branch of mathematics, initiated by Voiculescu, that extends classical probability theory into the non-commutative setting. In classical probability, random variables are analyzed using their joint distribution, which encodes the correlations or lack of between them. In contrast, free probability introduces the abstract notion of "freeness" to represent the absence of correlations, appropriately defined, among non-commutative random variables. Free probability theory provides, in particular, tools to analyze the spectrum of the sum and product of two operators, given that these operators are free, using knowledge of their individual spectra. Freeness is an infinite-dimensional phenomena in the sense that a pair of finite-dimensional operators can only be free from one another if one of them is constant. As a result, operators associated with finite graphs cannot be studied directly by free probability theory.

In response to this limitation, Marcus, Spielman, and Srivastava, in their groundbreaking series of works [21, 22, 23], introduced the theory of *finite free probability* along with the associated technique of interlacing. This enabled them to extend some results of free probability to the finite-dimensional setting, especially regarding the spectra of matrix sums and products. While finite free probability may not capture all details of the latter spectra, it provides a one-sided bound on its support. Finite free probability does not depend on the abstract concept of freeness or any analogous notion. Rather, it demonstrates that conjugating a finite operator, $\mathbf{A}$, with an orthogonal matrix – sampled according to the Haar measure on this group – effectively "frees" $\mathbf{A}$ from other operators. We consider a specific application of this principle in the context of operator addition.

▶ **Definition 8** (Definition 2.4 in [22]). Let $\mathbf{A}, \mathbf{B}$ be $d \times d$ real symmetric matrices, with characteristic polynomials $a(x)$ and $b(x)$, respectively. The *additive convolution* of $a(x)$ and $b(x)$ is defined as

$$a(x) \boxplus_d b(x) = \mathop{\mathbf{E}}_{\mathbf{Q}} \chi_x \left(\mathbf{A} + \mathbf{Q}\mathbf{B}\mathbf{Q}^{\mathsf{T}}\right), \tag{3.5}$$

where the expectation is taken over random orthogonal matrices $\mathbf{Q}$ sampled according to the Haar measure on the group of n-dimensional orthogonal matrices.

We note that, while it may not be immediately apparent, the right-hand side of Equation (3.5) depends only on the spectra of $\mathbf{A}$ and $\mathbf{B}$. Consequently, the additive convolution is well-defined. It was also proved in [23] that $a(x) \boxplus_d b(x)$ is real-rooted itself, hence a discussion of bounding its roots is sensible. When d is clear from context, we omit the subscript d in $\boxplus_d$.

The analytic machinery that will allow us to study the additive convolution is the Cauchy transform and its max-inverse (see the full version for details). More precisely, the Cauchy transform of a real-rooted degree d polynomial $p(t) \in \mathbb{R}[t]$, whose roots are $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_d$, is defined as $\mathcal{G}_p(x) = \frac{1}{d}\sum_{i=1}^{d} \frac{1}{x-\lambda_i}$. Clearly, for an undirected graph H, the Cauchy transform $\mathcal{G}_H(x)$ as defined in Equation (2.4) can be expressed as $\mathcal{G}_p(x)$ where $p(t) = \chi_t(H)$ is the characteristic polynomial of H.

Note that when the Cauchy transform of a polynomial $p(t)$ is restricted to the domain to the right of its rightmost pole, (λ_1, ∞), its range is $(0, \infty)$. Additionally, $\mathcal{G}_p(x)$ is monotonically decreasing within this domain. With this in mind, one can define $\mathcal{K}_p : (0, \infty) \to (\lambda_1, \infty)$ to be the inverse of $\mathcal{G}_p(x)$ when restricted to the latter domain. In other words, $\mathcal{K}_p$ is the max-inverse of $\mathcal{G}_p$. Particularly, for every $y \in (0, \infty)$, $\mathcal{K}_p(y)$ provides an upper bound on the largest root, λ_1, of $p(t)$. The key feature of the $\mathcal{K}$-transform is that it behaves very-well under additive convolution.

▶ **Theorem 9** (Theorem 1.12 in [23]). *For all $d \times d$ real symmetric matrices $\mathbf{A}, \mathbf{B}$ with characteristic polynomials $a(x), b(x)$, respectively, and for every $y > 0$, it holds that*

$$\mathcal{K}_{a \boxplus b}(y) \leq \mathcal{K}_a(y) + \mathcal{K}_b(y) - \frac{1}{y}.$$

It is worth noting that in free probability, the analog statement to Theorem 9 in the infinite dimensional case holds with equality.

3.2.2 Proof sketch of Theorem 3

The main idea in proving Theorem 3 is to randomly construct an H-local graph in a very intuitive way: since we want each vertex v to appear in d instances of H, we place v in d such instances, choosing the neighbors uniformly at random. Formally, we define a matrix $\mathcal{H}$ consisting of disjoint copies of H, and sum d random permutations of this matrix. This results in the matrix

$$X_{\mathbf{P}}(H) = \sum_{i=1}^{d} \mathbf{P}_i \mathcal{H} \mathbf{P}_i^{\mathsf{T}},$$

where $\mathbf{P} = \mathbf{P}_1, \ldots, \mathbf{P}_d$ are permutation matrices. The proof for the existence of an H-local graph whose second largest eigenvalue meet our lower bound incorporates two parts:

1. Bounding the second largest root of the *expected characteristic polynomial*, $\mathbf{E}_{\mathbf{P}}\, \chi_x\left(X_{\mathbf{P}}(H)\right)$, where the permutations are sampled uniformly and independently at random.
2. Relating the roots of $\mathbf{E}_{\mathbf{P}}\, \chi_x\left(X_{\mathbf{P}}(H)\right)$ to roots of a particular choice for $\mathbf{P}$, resulting in finding a *good* permutation, which induces a graph.

On first sight, it is not clear how to relate the expectation polynomial from Part 1 with the aforementioned tools of finite free probability. Definition 8 uses an expectation over the Haar measure, and together with Theorem 9 (applied $d-1$ times) enables us to establish an upper bound on the largest root of the expected characteristic polynomial, derived as the "free sum" of d of identical matrices. More precisely, a corollary from Theorem 9, together with the above discussion, yields

$$\mathsf{maxroot}\left(\chi_x(\mathbf{A})^{\boxplus d}\right) \leq \min_{x > \lambda_1}\left(d \cdot x - \frac{d-1}{\mathcal{G}_{\mathbf{A}}(x)}\right), \tag{3.6}$$

where λ_1 is the largest eigenvalue of $\mathbf{A}$. When taking $\mathbf{A}$ to be the matrix $\mathcal{H}$, the RHS of Equation (3.6) resembles Equation (2.6) from Theorem 2. However, the relevance of the LHS of the above equation remains unclear, as the expectation hidden in the $\boxplus$ operation is over the Haar measure and not over permutations. For bridging this gap, as well as for establishing Part 2, we follow MSS and proceed in two steps: quadrature and interlacing. While our proof makes a black-box use of these techniques we believe that the unfamiliar reader will benefit from this short account.

3.2.2.1 Quadrature

Quadrature refers to a general technique by which an integral is written as a finite sum. In our context, we make use of the result showing that finite free additive convolution can be expressed using the finite subgroup of permutation matrices of the unitary group. Specifically,

▶ **Theorem 10** (Theorem 4.1 in [22]). *Let* $\mathbf{A}, \mathbf{B}$ *be symmetric* $d \times d$ *matrices with* $\mathbf{A1} = a\mathbf{1}$ *and* $\mathbf{B1} = b\mathbf{1}$*. Let* $\chi_x(\mathbf{A}) = (x-a)a(x)$ *and* $\chi_x(\mathbf{B}) = (x-b)b(x)$*. Then,*

$$\mathop{\mathbf{E}}_{\mathbf{P}} \chi_x\left(\mathbf{A} + \mathbf{PBP}^{\mathsf{T}}\right) = (x - (a+b)) \cdot a(x) \boxplus_{d-1} b(x),$$

where $\mathbf{P}$ *is a uniformly random permutation matrix.*

Assume that $\mathbf{A}$ is the adjacency matrix of a c-regular graph, and let $p(x) = \frac{\chi_x(\mathbf{A})}{x-c}$. As a direct corollary of Theorem 10, we get that

$$\mathop{\mathbf{E}}_{\mathbf{P}_1,\ldots,\mathbf{P}_d} \chi_x\left(\sum_{i=1}^{d} \mathbf{P}_i \mathbf{A} \mathbf{P}_i^{\mathsf{T}}\right) = (x - dc) \cdot p^{\boxplus d}(x).$$

Consequently, by taking $\mathbf{A} = \mathcal{H}$, the upper bound on the max-root of the convolution polynomial, derived using Equation (3.6), directly establishes a bound on the max-root of the expected characteristic polynomial appearing on the LHS. The advantage is that we are now considering an expectation over a finite distribution, and more importantly, each element in the support of the distribution is an H-local graph. The final step of interlacing permits us to conclude that an element exists within this distribution for which the same upper bound holds.

3.2.2.2 Interlacing

So far, we have discussed how to obtain a bound on the largest root of the expected characteristic polynomial (excluding the trivial root), where the expectation is over the group of permutation matrices. It is generally incorrect to assert that a bound on the largest root of the expectation of polynomials can be utilized to infer a bound on the largest root of one of the polynomials involved in the expectation. A key observation by MSS concerning this issue is that such an result holds if the polynomials participating in the expectation form an *interlacing family*. In fact, for any choice of k, this structure suffices to deduce a bound on the k-th largest root of at least one polynomial in the family, given that we are able to bound the k-th largest root of the expected characteristic polynomial.

4 Derandomized Squaring with Interesting Graphs

In this section we apply our results to some interesting graph families, starting with graphs which demonstrate the tightness of our lower bound (see Section 4.1). Our general bound on bounded-degree graphs is given in Section 4.2 and the stronger bound assuming good spectral expansion is given in Section 4.3. The complete bipartite graph is studied in Section 4.4. The remaining sections deal with Paley graphs (see Section 4.5) and, more generally, strongly regular graphs (see Section 4.6), as well as some specific interesting graphs in Section 4.7. Some of the proofs of the results are omitted and can be found in the full version of the paper.

4.1 Three tight examples

In this short section we analyze some basic choices for the graph H, for which we know what behavior to expect and compare against our bound. We prove that for these instances, our lower bound given by Theorem 2 is tight, up to an additive vanishing term, for every Ramanujan graph G.

4.1.1 The true square

Let G be a d-regular graph, where $d \geq 3$, and let J_d denote the complete graph on d vertices, self-loops included. That is, J_d is the graph whose adjacency matrix is the all-ones $d \times d$ matrix, typically denoted as $\mathbf{J}$. Note that $G \circledS \mathrm{J}_d = G^2$. Our lower bound on $\lambda(G \circledS \mathrm{J}_d)$ obtained in Theorem 2 holds for all graphs G in the sense that Λ_{J_d} is independent of G. Therefore, it is sensible to expect that if the lower bound is tight for this choice of $H = \mathrm{J}_d$ then it is matched by taking G to be a d-regular Ramanujan graph. In such case, the spectral expansion $\lambda(G \circledS \mathrm{J}_d) = \lambda(G^2)$ can be computed directly and is equal to $\lambda(G)^2 = \left(2\sqrt{d-1}\right)^2 = 4(d-1)$. As we will now show, it is indeed the case that $\Lambda_{\mathrm{J}_d} = 4(d-1)$, establishing that our lower bound is tight for this choice of H.

The Cauchy transform of J_d is given by

$$\mathcal{G}_{\mathrm{J}_d}(x) = \frac{1}{d}\left(\frac{d-1}{x} + \frac{1}{x-d}\right) = \frac{x-d+1}{x(x-d)}.$$

Substituting to Equation (2.5) and simplifying, we see that the derandomized squaring polynomial associated with J_d is given by $\Delta_{\mathrm{J}_d}(x) = x^2 + (2-2d)x$. The unique real positive root of $\Delta_{\mathrm{J}_d}(x)$ is, of course $x_0 = 2d-2$. Substituting to Equation (2.6) yields $\Lambda_{\mathrm{J}_d} = 4(d-1)$.

4.1.2 Non-backtracking random walks

A second example for the tightness of our bound is given by the clique, denoted as K_d, namely the complete graph without self-loops. It is easily seen combinatorially that $G \circledS \mathrm{K}_d$ corresponds to the graph of non-backtracking length-2 walks in G, which we denote by $G^{(2)}$. The corresponding adjacency matrix is given by $\mathbf{A}^{(2)} = \mathbf{A}^2 - d\mathbf{I}$. Hence, for a Ramanujan graph G, the best value we can hope for coming from the analysis is

$$\lambda(\mathbf{A}^{(2)}) = \lambda(\mathbf{A}^2) - d = 4(d-1) - d = 3d - 4.$$

This bound is indeed what results from our analysis. To see this, note that the Cauchy transform of K_d is

$$\mathcal{G}_{\mathrm{K}_d}(x) = \frac{1}{d}\left(\frac{d-1}{x+1} + \frac{1}{x-d+1}\right) = \frac{x-d+2}{(x+1)(x-d+1)}.$$

Substituting to Equation (2.5) and simplifying, we see that the derandomized squaring polynomial associated with K_d is given by

$$\Delta_{\mathrm{K}_d}(x) = x^2 + (4-2d)x + 3 - 2d.$$

The unique real positive root of $\Delta_{\mathrm{K}_d}(x)$ is $x_0 = 2d-3$. Substituting to Equation (2.6) yields the desired bound, $\Lambda_{\mathrm{K}_d} = 3d-4$.

It is instructive to compare our bound with the upper bound obtained by the Rozenman-Vadhan bound, Equation (1.1) for a Ramanujan graph G. The second largest (normalized) eigenvalue of K_d in absolute value is $\frac{1}{d-1}$, leading to an overall bound of $\approx 5d$ compared to the true behavior of $\approx 3d$.

4.1.3 The graph achieving the Rozenman-Vadhan bound

In [35], Rozenman and Vadhan proved that the bound that is given in Equation (1.1) is tight in a strong sense, namely, for every rational μ, there exists a graph RV_μ with $\omega(\mathrm{RV}_\mu) = \mu$, such that for every graph G it holds that $\omega(G \circledS \mathrm{RV}_\mu) = (1-\mu)\omega(G^2) + \mu$. For ease of

notation, we write RV instead of RV_μ from hereon. The graph RV is constructed as follows: assume $\mu = \frac{s}{r}$ for some integers $r, s \geq 1$, then RV is a graph on d vertices which is rd-regular, consisting of $r - s$ copies of the complete graph J_d, and additional sd self-loops on each vertex. The combinatorial analysis shows that a step in the rd^2-regular graph $G \circledS \mathrm{RV}$ amounts to staying at the same vertex with probability μ or taking a step in G^2 with probability $1 - \mu$, leading directly to the tightness of the bound.

Assume once again that G is Ramanujan, hence $\lambda(G) \leq 2\sqrt{d-1}$. In this case, by Equation (1.1), we get that

$$\begin{aligned}\lambda(G \circledS \mathrm{RV}) &= \omega(G \circledS \mathrm{RV}) \cdot rd^2 \\ &= \left(\left(1 - \frac{s}{r}\right)\frac{4(d-1)}{d^2} + \frac{s}{r}\right) \cdot rd^2 \\ &= 4(d-1)r + (d-2)^2 s.\end{aligned}$$

As in the above two examples, we use the Cauchy transform of RV which is given by

$$\mathcal{G}_{\mathrm{RV}}(x) = \frac{1}{d}\left(\frac{d-1}{x - sd} + \frac{1}{x - rd}\right) = \frac{x - (d-1)r - s}{(x - dr)(x - ds)}.$$

Expanding Equation (2.7) and solving, we get

$$\Lambda_{\mathrm{RV}} = \psi_{\mathrm{RV}}(x_0) = 4(d-1)r + (d-2)^2 s,$$

as in the Rozenman-Vadhan bound.

4.2 Bounded-degree graphs and a universal bound on κ

In this section we prove that derandomized squaring with a simple vertex-transitive graph of bounded degree results with a graph that gravitates towards Ramanujan as the number of vertices in H increases. Moreover, we establish a universal bound on κ_H which holds for all simple vertex-transitive graphs.

▶ **Theorem 11.** *Let H be a simple vertex-transitive c-regular graph on d vertices, where $d \geq 3$ and $c \geq 1$. Then,*

$$\kappa_H \leq 2 + \frac{\sqrt{c}}{\sqrt{d} - \sqrt{c}}.$$

Moreover, for every $d \geq 11$ it holds that $\kappa_H \leq 3$. Lastly, if H is triangle-free then

$$\kappa_H \leq 2 + \frac{c}{d} \cdot \frac{1}{1 - \sqrt{\frac{c}{d}}}.$$

4.3 Spectral expanders

In this section we prove a stronger bound on κ_H than the one obtained in Theorem 11, which recall holds for general bounded-degree graphs, assuming that H is a good spectral expander. The proof follows the same argument as in the proof of Theorem 11 though takes into account the bound on the spectral expansion.

▶ **Proposition 12.** *Let H be a simple vertex-transitive c-regular graph on d vertices. Assume that $10 \leq c < \sqrt{d}$. Then,*

$$\kappa_H \leq 2 + \frac{3}{\sqrt{d}}\left(\frac{\lambda(H)}{\sqrt{c}}\right)^3.$$

Furthermore, if H is triangle-free then

$$\kappa_H \leq 2 + \frac{4}{d}\left(\frac{\lambda(H)}{\sqrt{c}}\right)^4.$$

4.4 Complete bipartite graphs

In this section we consider the operation of derandomized squaring with the complete bipartite graph on d vertices, for an even integer $d \geq 4$. This is, of course, a $c = \frac{d}{2}$ regular graph which we denote as $\mathrm{K}_{c,c}$. It is easy to see that $\mathrm{K}_{c,c}$ has eigenvalues $\pm c$, each with multiplicity 1, and the remaining eigenvalues are all 0. Therefore, the corresponding Cauchy transform, which for ease of notation we denote by $\mathcal{G}_{c,c}$, is given by

$$\mathcal{G}_{c,c}(x) = \frac{4x^2 - d(d-2)}{(4x^2 - d^2)x}.$$

From here one can compute the derandomized squaring polynomial

$$\Delta_{c,c}(x) = x^4 - \frac{d(2d-3)}{2}x^2 - \frac{(d-2)d^3}{16}$$

whose unique positive root $x_0 = \frac{\sqrt{md}}{2}$, where $m = 2d - 3 + \sqrt{(d-1)(5d-9)}$. One can verify that $\mathcal{G}(x_0) = \frac{m-d+2}{x_0(m-d)}$. Substituting this to Equation (2.6), we get

$$\Lambda_{\mathrm{K}_{c,c}} = x_0\left(\frac{m+d}{m-d+2}\right) = \frac{\sqrt{md}}{2}\left(\frac{m+d}{m-d+2}\right).$$

The resulted graph is $D = \frac{d^2}{2}$-regular, and so we normalize by dividing by $\sqrt{D-1}$ to get

$$\kappa_{\mathrm{K}_{c,c}} = \sqrt{\frac{md}{2d^2-4}}\left(\frac{m+d}{m-d+2}\right).$$

From here one can compute the first couple of values, $\kappa_{\mathrm{K}_{2,2}} \approx 2.089$ which, of course, matches the bound we computed for the length-4 cycle, and $\kappa_{\mathrm{K}_{3,3}} \approx 2.157$. Considering the limit behavior as $d \to \infty$ we have that $m \approx \gamma d$ where $\gamma = 2 + \sqrt{5}$, and so

$$\kappa_{\mathrm{K}_{\infty,\infty}} \triangleq \lim_{c\to\infty} \kappa_{\mathrm{K}_{c,c}} = \sqrt{\frac{\gamma}{2}} \cdot \frac{\gamma+1}{\gamma-1} = \frac{1}{2}\sqrt{11 + 5\sqrt{5}} \approx 2.355.$$

4.5 Paley graphs

Let $q = 4r + 1$ be a prime power. The *Paley graph*, denoted as Pal_q, has vertex set corresponding to the finite field $\mathbb{F}_q$ with the vertices adjacent if and only if their difference is a nonzero square in $\mathbb{F}_q$. As $q \equiv 1$ modulo 4, we have that -1 is a square in $\mathbb{F}_q$, and so Pal_q is undirected.

▶ **Theorem 13.**

$$\kappa_{\mathrm{Pal}_\infty} \triangleq \lim_{q\to\infty} \kappa_{\mathrm{Pal}_q} = \frac{1 + \sqrt{13 + 16\sqrt{2}}}{\sqrt{8}} \approx 2.464.$$

4.6 Strongly regular graphs

A c-regular graph on d vertices with no self-loops is called *strongly regular* with parameters λ, μ [4] if $0 < c < d$ (namely, the graph is neither complete nor edgeless) and the following hold:

1. For each pair of adjacent vertices there are λ vertices adjacent to both.
2. For each pair of nonadjacent vertices there are μ vertices adjacent to both.

Strongly regular graphs include dozens of interesting graphs such as the Peterson graph, the Hoffman-Singelton graph (see Section 4.7), and the symplectic graphs (see Section 4.6.1), as well as all Paley graphs which we analyzed in Section 4.5. It is a well-known fact that strongly regular graphs have two eigenvalues other than the trivial eigenvalue c, denoted r, s, with the convention $r > s$. This is, in fact, a spectral characterization of strongly regular graph among regular graphs. The multiplicity of these eigenvalues are denoted by f, g, respectively. In the following we compute the derandomized squaring polynomial of a strongly regular graph.

▶ **Proposition 14.** *Let H be a c-regular strongly regular graph on $d \geq 3$ vertices with parameters λ, μ. Let $\alpha = \lambda - \mu$ and $e = c - d + 1$. Then, the derandomized squaring polynomial associated with H is given by*

$$\Delta_H(x) = x^4 - 2(\alpha + c)x^3 + Ax^2 + Bx + C,$$

where

$$\begin{aligned} A &= 2\mu + 4\alpha c + \alpha^2 + ce, \\ B &= -2\alpha\mu + 2c\left(c - ce - \alpha^2 - \mu\right), \\ C &= (\mu - c)\left(\mu + 2\alpha c + c\right) + c^3 e. \end{aligned}$$

4.6.1 The symplectic graphs

An interesting sub-family of strongly regular graphs are the so-called *symplectic graphs*. Let $r \geq 1$ be an integer. The symplectic graph $\mathrm{Sp}(2r)$ is the graph whose vertex set consists of all nonzero vectors in $\mathbb{F}_2^{2r}$. Two vertices x, y are adjacent whenever $x^{\mathsf{T}}\mathbf{N}y = 1$, with all calculations over $\mathbb{F}_2$, where $\mathbf{N}$ is the $(2r) \times (2r)$ block diagonal matrix with r blocks of the form $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. It is well-known that $\mathrm{Sp}(2r)$ is a strongly regular graph with $\lambda = \mu = 2^{2r-2}$.

▶ **Theorem 15.**

$$\lim_{r\to\infty} \kappa(\mathrm{Sp}(2r)) = \frac{1 + \sqrt{13 + 16\sqrt{2}}}{\sqrt{8}} \approx 2.464.$$

Interestingly, though not unexpectedly, this limit behavior is also shared by Paley graphs (see Section 4.5).

4.7 Some specific graphs

In this section we consider some specific interesting graphs.

[4] It is customary to denote these parameters by λ and μ and so, despite our use of λ for denoting the spectral expansion, we proceed with this standard notation.

Table 1 Summary of specific graphs and their derandomized squaring constants.

H (Graph name)	d (Number of vertices)	c (degree)	κ_H
Petersen graph	10	3	2.025
Heawood graph	14	3	2.004
Hoffman-Singelton graph	50	7	2.007
Biggs-Smith graph	102	3	2.000000016
Conway's 99-graph	99	14	2.041

Query Complexity of Stochastic Minimum Vertex Cover

Abstract

We study the stochastic minimum vertex cover problem for general graphs. In this problem, we are given a graph $G = (V, E)$ and an existence probability p_e for each edge $e \in E$. Edges of G are realized (or exist) independently with these probabilities, forming the realized subgraph $\mathcal{G}$. The existence of an edge in $\mathcal{G}$ can only be verified using edge queries. The goal of this problem is to find a near-optimal vertex cover of $\mathcal{G}$ using a small number of queries.

Previous work by Derakhshan, Durvasula, and Haghtalab [STOC 2023] established the existence of $1.5 + \varepsilon$ approximation algorithms for this problem with $O(n/\varepsilon)$ queries. They also show that, under mild correlation among edge realizations, beating this approximation ratio requires querying a subgraph of size $\Omega(n \cdot \mathrm{RS}(n))$. Here, $\mathrm{RS}(n)$ refers to Ruzsa-Szemerédi Graphs and represents the largest number of induced edge-disjoint matchings of size $\Theta(n)$ in an n-vertex graph.

In this work, we design a simple algorithm for finding a $(1 + \varepsilon)$ approximate vertex cover by querying a subgraph of size $O(n \cdot \mathrm{RS}(n))$ for any absolute constant $\varepsilon > 0$. Our algorithm can tolerate up to $O(n \cdot \mathrm{RS}(n))$ correlated edges, hence effectively completing our understanding of the problem under mild correlation.

1 Introduction

We study the *stochastic minimum vertex cover* problem. In this problem, we are given an arbitrary n-vertex graph $G(V, E)$ and an existence probability p_e for each edge $e \in E$. Edges of G are realized or exist independently, with their corresponding probability forming the realized subgraph $\mathcal{G}$. While $\mathcal{G}$ is unknown, one can query an edge $e \in E$ to see if this edge exists in $\mathcal{G}$. The goal is to find a near-optimal vertex cover of $\mathcal{G}$ by querying a *small* subset of E.

There is extensive literature studying various graph problems in this stochastic setting, such as minimum spanning tree [21, 22], all-pairs shortest paths [24], and maximum matching [13, 5, 12, 25, 3, 6, 9, 10, 8, 16, 15]. The stochastic vertex cover for general graphs was first studied by Blum, Behnezhad, and Derakhshan [7]. They provided a 2-approximation algorithm with $O(n/p)$ queries where $p = \min_{e \in E} p_e$. Later, this approximation ratio was improved to $1.5 + \varepsilon$ by the work of Derakhshan, Durvasula, and Haghtalab [14] with $O(n/\varepsilon p)$

queries. Even though these stochastic settings are primarily concerned with information-theoretical questions, this was the first work to provide positive results for a computationally hard problem. However, the key unresolved question remains:

▶ **Question 1.** *How many non-adaptive edge queries are needed to find a* $(1+\varepsilon)$*-approximation to the minimum vertex cover problem in the stochastic setting?*

In this paper, we take a step toward answering this question. We design a simple algorithm and establish a relation between the number of queries it makes and the density of a well-known class of graphs called Ruzsa-Szemerédi Graphs (Definition 2). Our number of queries matches the lower bound of Derakhshan, Haghtalab, and Durvasula [14] for the number of queries needed to surpass a 1.5-approximation in the presence of $O(n)$ correlated edges.

▶ **Definition 2** (Ruzsa-Szemerédi Graphs [23])**.** *An n-vertex graph $G(V,E)$ is an $RS_n(r,t)$ graph if its edge set E can be decomposed into t edge-disjoint induced matchings of size r. We use $RS_n(r)$ to denote the maximum t for which $RS_n(r,t)$ exists.*

Our main result is formalized in the theorem below.

▶ **Result 3.** *Given any $\varepsilon \in (0,1)$ let t be $RS_n(cn)$ for $c = \frac{\varepsilon^2}{128}$. There exists an algorithm that queries a subgraph of size $O(tn/p)$ and finds a vertex cover with the expected approximation ratio of $(1+\varepsilon)$.*

Proving lower and upper bounds parameterized by the density of RS-graphs has been of interest in various communities, such as dynamic algorithms [11, 4], streaming algorithms [20, 1, 2], property testing [17], and additive combinatorics [19]. Despite this, our understanding of their density remains incomplete. What we currently know is:

$$n^{\Omega_c(1/\log\log(n))} \overset{[17]}{\leq} RS_n(cn) \overset{[18]}{\leq} n/\log^{(O(\log(1/c)))}$$

where $\log^{(x)}$ is the x-iterated logarithmic function. Our result is most interesting if the lower-bound turns out to be tight. In such a case the number of edges queried by our algorithms is

$$|Q| = O(n^{1+\Omega_c(1/\log\log(n))}/p) = O(n^{1+o(1)}/p).$$

On the opposite end, if the actual density of RSgraphs is closer to the known upper-bound, our result implies $|Q| = O(\frac{n^2}{p\log^{O(\log(1/c))}})$.

1.1 Technical Overview

We first design an algorithm with an additive error of at most εn in Section 2 and later show how it can be modified to obtain the $(1+\varepsilon)$ approximation ratio. To choose which edges to query we rely on a parameter c_e defined for any edge $e \in E$ as follows:

$$c_e = \Pr[e \text{ has an end-point in OPT}],$$

where $\text{OPT} = \text{MVC}(\mathcal{G})$. In this definition, the randomization comes from the realization of $\mathcal{G}$ and MVC(.) is a fixed algorithm which returns the minimum vertex cover of a given graph. Basically, c_e is the probability with which an edge $e \in E$ is covered by $\text{MVC}(\mathcal{G})$.[1]

[1] Since we are not concerned with computational efficiency, we assume c_es are known. Regardless, similar to [14], our results can also be obtained with the estimated value of c_es calculated using polynomially many calls to the MVC oracle.

Given a parameter $\tau \in (0,1)$ whose value we fix later, we set Q, the subgraph that we query, to be the subgraph of edges with $c_e \leq 1-\tau$. I.e.,

$$Q = \{e \in E : c_e \leq 1-\tau\}.$$

Since we need the output to be a valid vertex cover, our final solution also needs to cover all the edges that we do not query. Let us denote this subgraph by $H = G - Q$. Therefore, after we query Q and see its realization $\mathcal{Q}$, the most straightforward way of finding a small vertex cover is to output $\text{MVC}(\mathcal{Q} \cup H)$. However, for the sake of analysis, we need to design an alternative algorithm for finding a vertex cover of $\mathcal{Q} \cup H$. We formally explain this in Algorithm 1 and briefly explain the overall ideas below.

After querying Q and observing its realization $\mathcal{Q}$, we also hallucinate the edges in H to get $\mathcal{H}$. The hallucinated subgraph $\mathcal{H}$ is a random realization of H containing each edge independently w.p. p_e. We then let $P_1 = \text{MVC}(\mathcal{Q} \cup \mathcal{H})$ and commit all its vertices to the final solution. Next, we pick another set of vertices, P_2, to cover all the edges in H that were not covered by P_1. That is, $P_2 = \text{MVC}(H[V - P_1])$. We finally output $P_1 \cup P_2$. This clearly covers both $\mathcal{Q}$ and H and is a valid solution. The extra step of hallucinating H is to ensure that P_1 has the same distribution as the optimal solution (see Claim 8). This gives us two properties:

1. The expected size of P_1 is the same as OPT. To analyze our approximation ratio, it suffices to upper-bound $\mathbf{E}[|P_2|]$.
2. For any edge $e \in H$, we have $\Pr[e \text{ not covered by } P_1] = 1 - c_e$. Since by our choice of Q, the edges in $H = G - Q$ all have $c_e \geq 1 - \tau$. This implies that any edge in H remains in $H[V - P_1]$ w.p. at most τ.

Having this, we argue that if the expected size of the solution $P_1 \cup P_2$ is more than $\mathbf{E}[\text{OPT}] + \varepsilon n$, then we have $|P_2| \geq \varepsilon n$. This means that the subgraph $R = H[V - P_1]$ has a large minimum vertex cover and, consequently, a large maximum matching. Now, suppose we draw T independent subgraphs of H from the same distribution as R and call them $R_1, \ldots, R_T$. (We can do so by running our algorithm on T different hallucinations of G (see Definition 4).)

From each R_i, we take the maximum matching of it to be M_i, and from M_i, we delete all the edges present in at least one other R_j for $j \neq i$. We show that this gives us a set of induced matchings. Notice that since we have that any edge is present in R_i with probability at most τ, we can argue that deleting the edges present in other R_j's will not reduce the size of M_i significantly for a choice of $T = \frac{1}{2\tau}$. Therefore, we conclude that if $\mathbf{E}[|P_2|]$ is greater than εn, we can find a dense RS-graph in H. Finally, by carefully choosing $\tau = 1/3t$, where t is $\text{RS}_n(\varepsilon n/8)$, we argue that Algorithm 1 has an additive approximation of at most εn.

In Section 3, we explain how we can modify this algorithm and design our $(1+\varepsilon)$ algorithm Algorithm 3. The main difference is that we pre-commit a subset of vertices to the final solution at the beginning of the algorithm. These vertices are the ones that have a high chance of being in OPT; therefore, including them does not significantly increase the size of the output. This allows us to argue that the optimal solution on H is large enough to allow us to turn the additive error into a multiplicative error.

1.2 Preliminaries

Throughout the paper, we denote the input graph as $G = (V, E)$, where $|V| = n$. From this input graph, we have each edge e present in $\mathcal{G}$ independently with probability p_e. We denote the minimum value among all p_es to be p. Given a small constant $\varepsilon > 0$, our goal is to query a sparse subgraph of G represented by Q non-adaptively and find a $(1+\varepsilon)$ approximate minimum vertex cover of $\mathcal{G}$.

We let MVC() be a fixed algorithm which given any graph outputs its minimum vertex cover. We may also refer to this as the minimum vertex cover oracle. We define $\text{OPT} = \text{MVC}(\mathcal{G})$ to be the optimal solution to our problem. Note that OPT is a random variable since $\mathcal{G}$ is a random realization of G. We also let $\textsc{opt} = \mathbf{E}[|\text{OPT}|]$ be the expected size of this optimal solution. We let $\mu(G)$ be the size of the maximum matching of the graph G.

For any vertex $v \in V$, we define

$$c_v = \Pr[v \in \text{OPT}],$$

which is the probability that v joins the optimal solution. This means $\sum_{v \in V} c_v = \textsc{opt}$. Similarly for any edge $e = (u, v)$ in the graph G we define

$$c_e = \Pr[u \in \text{OPT or } v \in \text{OPT}].$$

▶ **Definition 4** (Graph Hallucination). *Given a any subgraph L of G we define a hallucination of L to be a subgraph $\mathcal{L}$ which contains each edge $e \in L$ independently with probability p_e.*

We define $\text{RS}(n)$ to be the largest number of induced edge-disjoint matchings of size $\Theta(n)$ in an n-vertex graph.

2 The algorithm

In this section, we prove the following theorem.

▶ **Theorem 5.** *Let t be $RS_n(\varepsilon n/8)$. Running Algorithm 1 with $\tau = \frac{1}{3t}$ finds a vertex cover that has an additive approximation of at most εn to the optimal minimum vertex cover and queries a subgraph of size $O(tn/p)$.*

To prove this theorem, we design Algorithm 1, which takes a parameter τ, and queries the subgraph Q with $c_e \leq 1 - \tau$. Let us call the edges realized in Q to be $\mathcal{Q}$. We then hallucinate the edges not in Q which we call the subgraph $H = G - Q$ to get $\mathcal{H}$. We then let P_1 be $\text{MVC}(\mathcal{Q} \cup \mathcal{H})$.

This makes P_1 have the same distribution of OPT (see Claim 8 for the proof). Now we commit the vertices in P_1 to the final solution and all that remains to be covered are edges in H that have not been covered so far. Therefore we add $P_2 = \text{MVC}(H[V - P_1])$ to the solution. All we need to do is to argue $\mathbf{E}[|P_2|]$ is small since we have $\mathbf{E}[|P_1|] = \textsc{opt}$.

We show that if $\mathbf{E}[|P_2|]$ is large we can find a large RS-graph in H (see Algorithm 2) so by carefully choosing τ which we relate to the density of RS-graphs we prove $\mathbf{E}[|P_2|]$ is small and hence we prove Algorithm 1 has at most additive error of εn. In the next section we modify Algorithm 1 slightly to get Algorithm 3 and show that this algorithm finds a $(1 + \varepsilon)$ approximation to the minimum vertex cover.

2.1 A Two-Step Algorithm

Here we describe the algorithm for finding the minimum vertex cover of G. We call it the two step algorithm because the output consists of union of two sets P_1 and P_2.

First, let us prove that the output of Algorithm 1 is a vertex cover.

▷ Claim 6. The output of Algorithm 1 is a vertex cover for $\mathcal{G}$.

Proof. Since P_2 is a vertex cover on the graph that P_1 does not cover we can argue that $P_1 \cup P_2$ is a vertex cover for $\mathcal{G}$. ◁

Algorithm 1 An algorithm to find MVC for $\mathcal{G}$.

Parameter: τ

1. Let Q be the subgraph of edges with $c_e \leq 1 - \tau$.
2. Let H be $G - Q$.
3. Query edges in Q to get its realization $\mathcal{Q}$.
4. Hallucinate edges in H to form $\mathcal{H}$.
5. Let $P_1 = \text{MVC}(\mathcal{Q} \cup \mathcal{H})$.
6. Let $R = H[V \setminus P_1]$.
7. Let $P_2 = \text{MVC}(R)$.
8. Return $O = P_1 \cup P_2$.

Now let us bound the number of queries that Algorithm 1 makes.

▷ Claim 7. The size of subgraph Q that we query is at most $O(\frac{n}{p\tau})$ for $p = \min(p_e)$ for $e \in E$.

Proof. Due to [14] we know that if we take a random minimum vertex cover P for $\mathcal{G}$ at most $O(n/p)$ edges will not be covered by it with high probability. Here we repeat how this argument works for convenience. Let us call this number of edges X and call this subgraph F. For any subgraph with more than n/p edges, the probability of none of its edges being in $\mathcal{G}$ is at most $(1-p)^{n/p}$. Moreover, since F is an induced subgraph of G, there are at most 2^n possibilities for it. By a union bound, we get that with high probability, F has at most n/p edges. That is:

$$\Pr[|E(F)| \leq n/p] \geq 1 - 2^n(1-p)^{n/p} \geq 1 - \frac{2^n}{e^n} = 1 - (2/e)^n$$

Due to linearity of expectation we have

$$E[X] = \sum_e 1 - c_e.$$

For the edges in Q we have $1 - c_e \geq \tau$ so we can get $|E(Q)| \leq \frac{X}{\tau}$ and since we have $X = O(n/p)$ we get that $|E(Q)| \leq O(\frac{n}{p\tau})$. ◁

▷ Claim 8. The expected size of P_1 from Algorithm 1 is equal to OPT and the distribution of P_1 is the same as OPT

Proof. Look at the graph that P_1 is a minimum vertex cover for. It is the graph $\mathcal{Q} \cup \mathcal{H}$. For any edge e, if it is in H then it is present in $\mathcal{H}$ with probability p_e and if it is in Q it is present in $\mathcal{Q}$ with probability p_e. Since $Q \cup H = G$ we can see that the distribution of $\mathcal{Q} \cup \mathcal{H}$ is the same as the distribution for $\mathcal{G}$ and hence the expected size of the minimum vertex cover for $\mathcal{Q} \cup \mathcal{H}$ is the same as $\mathcal{G}$ which is OPT. Also since the distribution of $\mathcal{Q} \cup \mathcal{H}$ is the same as $\mathcal{G}$ we get

$$P_1 = \text{MVC}(\mathcal{Q} \cup \mathcal{H}) = \text{MVC}(\mathcal{G}) = \text{OPT}$$

Hence P_1 comes from the same distribution as OPT. ◁

▶ **Lemma 9.** *If Algorithm 1 does not have additive approximation of at most k in expectation, then* $\mathbf{E}[\mu(R)] \geq \frac{k}{2}$

Proof. Due to Claim 8, the expected size of P_1 is OPT. Therefore, if Algorithm 1 has worse than k additive approximation then we can conclude $\mathbf{E}[|P_2|] \geq k$. In any graph the maximum matching size it at least half of the size of minimum vertex cover. Applying this statement on the graph R give us that

$$\mathbf{E}[\mu(R)] \geq \frac{E[|P_2|]}{2} \geq \frac{k}{2}.$$ ◀

2.2 Finding a Dense RS-graph in H

Suppose in Algorithm 1 instead of querying Q and hallucinating H we hallucinate all the edges. We repeat this process T times, calling the resulting graph R in Algorithm 1 R_i for each i from 1 to T. For each R_i, we find the maximum matching M_i. Then, from each M_i, we delete the edges that are present in at least one other R_j for $j \neq i$, and we define S_i to be the remaining edges of M_i after these deletions. In Algorithm 2, we formalize this process. Our goal in this section is to argue that if Algorithm 1 does not have an additive error of at most εn, then the matchings S_i will be large, and we can find a large RS-graph as a subgraph of H.

Algorithm 2 Finding a large RS-graph in H in Algorithm 1.

Parameter: τ

1. For i from 1 to T:
   a. Let Q and H be graphs defined in Algorithm 1
   b. Hallucinate graph G to get $\mathcal{G}_i$
   c. Let P_i be MVC($\mathcal{G}_i$)
   d. Let $R_i = H[V \setminus P_i]$
2. Let M_i be the maximum matching of R_i
3. Delete the edges in M_i present in at least one other R_j with $j \neq i$ to get S_i
4. Return $S_1 \cup S_2 \ldots \cup S_T$

The next claim will bound the probability of edges being in R_i.

▷ Claim 10. For each edge e and each graph R_i, we have that $\Pr[e \in R_i] \leq \tau$.

Proof. For the edge e we have two cases, $e \in Q$ or $e \in H$. If we have $e \in Q$ and $e \notin \mathcal{Q}$, then this edge will not be present in R, otherwise if $e \in \mathcal{Q}$ since P_1 covers all the edges of $\mathcal{Q}$ this edge will not be present in R. So the only case that $e \in R$ happens is when we have $e \in H$. In this case since we have $c_e \geq 1 - \tau$ and P_1 is a random minimum vertex cover of G, then the edge e will be covered with probability c_e in P_1 (this is because P_1 comes from the same distribution as OPT according to Claim 8). So this edge is present in P_2 with a probability of at most $1 - c_e \leq \tau$. ◁

The following claim will prove that the matching S_i are induced matchings.

▷ Claim 11. The matchings S_i formed in the random process are induced matchings.

Proof. The graphs R_i are induced subgraphs on $V - P_1$. Suppose that S_i's are not induced matchings. Since we delete duplicate edges from R_i to get S_i there is no edge e that is present in S_i and S_j for $i \neq j$. Hence, there must exist two edges $e_1 = (u_1, v_1)$ and $e_2 = (u_2, v_2)$ present in S_i and $e_3 = (u_1, u_2)$ present in S_j for $i \neq j$ to break the property of induced matchings. We call edges like e_3 a *cross edge*. In this case, we can argue that the edge e_3 is

also present in R_i since both of its endpoints are in the vertices of R_i. Since e_3 is present in R_i and R_j this edge gets deleted and can not be part of S_j. This contradicts with what we assumed. Therefore we can conclude that S_i's are induced matchings. ◁

▷ Claim 12. Suppose we set $T = \frac{1}{2\tau}$, then we have $\mathbf{E}[|S_i|] \geq \frac{k}{4}$.

Proof. Due to Lemma 9, we have that $\mathbf{E}[|M_i|] \geq \frac{k}{2}$. Now we should argue that with the edge deletions, each M_i will lose at most $\frac{k}{4}$ edges in expectation. Take an edge e in M_i. For each $j \neq i$ we have $\Pr[e \in M_i] \leq \tau$ due to Claim 10 since for an edge to be in M_i it should also be in R_i. By an application of union bound the edge e is present in at least one other M_j with probability at most $T\tau$. Hence we get,

$$\Pr[\text{e not in any } M_j] \geq 1 - T\tau = \frac{1}{2}$$

And for the size of S_i we have:

$$\mathbf{E}[|S_i|] = \sum_{e \in M_i} \mathbb{1}_{e \notin M_j \text{ for } j \neq i} \geq \sum_{e \in M_i} \frac{1}{2} \geq \frac{k}{4}$$ ◁

▶ **Lemma 13.** *By running the process explained above in Algorithm 2 we can find an $RS_n(r,t)$ graph (see Definition 2) with $t = \frac{1}{2\tau}$ and $r = \frac{k}{8}$ on H.*

Proof. Due to Claim 12 we can have $T = \frac{1}{2\tau}$ matchings each with expected size $\frac{k}{4}$. Putting these matchings together will give us expected $\frac{Tk}{4}$ edges in total. Suppose we break each matching S_i to smaller matchings of size $\frac{k}{8}$ size. If the number of edges in S_i is not divisible by $\frac{k}{8}$ we will lose at most the reminder of $|S_i|$ to $\frac{k}{8}$ which is at most $\frac{k}{8}$. The new matchings each have size exactly $\frac{k}{8}$ and are induced matchings. This is because the original S_i's did not have a cross edge (see Claim 11 for what a cross edge is) and hence the new matchings also do not have a cross edge since we are just partitioning the edges of S_i to smaller matchings. The total size of the new set of matchings is at least

$$\frac{Tk}{4} - \frac{Tk}{8} = \frac{Tk}{8}$$

This is because the total number of removed edges is bounded by the number of edges removed from each S_i which is $\frac{\varepsilon n}{8}$ times the number of S_i's which is T. Since we are running the random process which in expectation gives us induced matchings of size $\frac{k}{8}$ with total size of $\frac{Tk}{8}$ there is an instance which we have at least $\frac{Tk}{8}$ edges in total. From this we can construct an $RS_n(r,t)$ graph with $r = \frac{k}{8}$ and $t = \frac{1}{2\tau}$. ◀

Now we are ready to prove Theorem 5. We restate the theorem below.

▶ **Theorem 5.** *Let t be $RS_n(\varepsilon n/8)$. Running Algorithm 1 with $\tau = \frac{1}{3t}$ finds a vertex cover that has an additive approximation of at most εn to the optimal minimum vertex cover and queries a subgraph of size $O(tn/p)$.*

Proof. Suppose that Algorithm 1 does not find a vertex cover with additive approximation of εn. Then by setting $k = \varepsilon n$ in Lemma 13 we get

$$t' = \frac{1}{2\tau} = \frac{1}{2\frac{1}{3t}} = 1.5t$$

matchings each of size $\frac{\varepsilon n}{8}$ that are induced matchings. This is in contradiction with what we assumed since t is the maximum number of induced matchings of size $\frac{\varepsilon n}{8}$ for an RS-graph and now we have found $1.5t$ matchings of this size. This means that indeed Algorithm 1 has an additive approximation of at most εn for $\tau = \frac{1}{3t}$. Due to Claim 7, we have $|E(Q)| \leq O(\frac{n}{p\tau})$ which for $\tau = 1/3t$ we get $|E(Q)| = O(tn/p)$. ◀

3 Getting a Multiplicative Approximation

In this section, we modify Algorithm 1 to give us a multiplicative approximation of $1+\varepsilon$. Our modification is simple yet effective. At the beginning of the algorithm, we set $P_0 = \{v : c_v \geq 1 - \alpha\varepsilon\}$ and commit P_0 to the final solution. The intuition behind this is that since these vertices have high c_v, they have a high probability of being in the final solution so it does not hurt us to have them in the final solution.

We do this specifically to be able to prove Lemma 16 which states c_vs for a subgraph of vertices is lower bounded by $\frac{\alpha\varepsilon}{2}$. This means that if we find an algorithm that is additive in terms of n' the size of this subgraph, then it is also a multiplicative approximation because of the lower bound for c_vs of this subgraph. Here is the modified algorithm.

Algorithm 3 Multiplicative Approximation Algorithm.

1. Let $P_0 = \{v : c_v \geq 1 - \alpha\varepsilon\}$.
2. Let $G' = G[V \setminus P_0]$.
3. Let Q be the subgraph of edges with $c_e \leq 1 - \tau$ in G'.
4. Let $H = G' - Q$.
5. Query edges in Q to get its realization Q.
6. Hallucinate edges in $G \setminus Q$ to form subgraph $\mathcal{F}$.
7. Let $P_1 = \text{MVC}(Q \cup \mathcal{F})$.
8. Let $R = H[V \setminus P_1]$.
9. Let $P_2 = \text{MVC}(R)$.
10. Return $O = P_0 \cup P_1 \cup P_2$.

The first lemma we prove is for bounding the expected size of $P_0 \cup P_1$.

▶ **Lemma 14.** $\mathbf{E}[|P_0 \cup P_1|] \leq (1 + \varepsilon/2)\textsc{opt}$ *for* $\alpha \leq \frac{1}{4}$

Proof. We can write $E[|P_0 \cup P_1|]$ as follows:

$$E[|P_0 \cup P_1|] = |P_0| + \mathbf{E}[|P_1|] - \mathbf{E}[|P_0 \cap P_1|].$$

Due to Claim 8, we know that $\mathbf{E}[|P_1|] = \textsc{opt}$. Take an arbitrary vertex $v \in P_0$. Since P_1 is a random minimum vertex cover, any vertex v in P_0 has a probability of c_v of also being in P_1. And since $c_v \geq 1 - \alpha\varepsilon$ for $v \in P_0$ we have $\Pr[v \in P_1] \geq 1 - \alpha\varepsilon$. Hence we have

$$|P_0| - \mathbf{E}[|P_0 \cap P_1|] = \sum_{v \in P_0} 1 - \mathbb{1}_{v \in P_1} \leq |P_0| \cdot (\alpha\varepsilon) \tag{1}$$

We know that $|P_0| \leq \frac{\textsc{opt}}{1-\alpha\varepsilon}$ this is because $\textsc{opt} = \sum_{v \in V} c_v$ and we have $\sum_{v \in P_0} c_v \geq (1 - \alpha\varepsilon)|P_0|$. Form Equation (1), we can get

$$|P_0| - \mathbf{E}[|P_0 \cap P_1|] \leq \frac{\textsc{opt}}{1 - \alpha\varepsilon} \cdot (\alpha\varepsilon) \tag{2}$$

Since we have $\alpha \leq \frac{1}{4}$ and $\varepsilon \leq 1$ from Equation (2) we have

$$\begin{aligned} |P_0| - \mathbf{E}[|P_0 \cap P_1|] &\leq \frac{\textsc{opt}}{1 - \alpha\varepsilon} \cdot (\alpha\varepsilon) \\ &\leq \frac{\textsc{opt}}{1 - \alpha\varepsilon} \cdot (\frac{\varepsilon}{4}) \\ &\leq \frac{\textsc{opt}}{0.5} \cdot \frac{\varepsilon}{4} \\ &= \textsc{opt} \cdot \frac{\varepsilon}{2} \end{aligned}$$

Putting this together with $\mathbf{E}[|P_1|] = \textsc{opt}$ due to Claim 8 we get,

$$\mathbf{E}[|P_0 \cup P_1|] \leq (1 + \varepsilon/2)\textsc{opt}$$ ◀

From Lemma 14 we can argue that if Algorithm 3 has worse than εOPT additive approximation in expectation, then $|P_2|$ is greater than $\frac{\varepsilon\text{OPT}}{2}$. We use this fact in the following lemma.

▶ **Lemma 15.** *If Algorithm 3 does not have a approximation of at most $(1+\varepsilon)$ in expectation, then $\mathbf{E}[\mu(R)] \geq \frac{\varepsilon OPT}{4}$*

Proof. Due to Lemma 14 we have $\mathbf{E}[|P_0 \cup P_1|] \leq (1+\varepsilon/2)\text{OPT}$ so if Algorithm 3 does not have a multiplicative approximation of at most $(1+\varepsilon)$ then we can conclude $\mathbf{E}[|P_2|] \geq \frac{\varepsilon\text{OPT}}{2}$. In any graph, the maximum matching size is at least half the minimum vertex cover size. Applying this statement on the graph R gives us,

$$\mathbf{E}[\mu(R)] \geq \frac{E[|P_2|]}{2} \geq \frac{\varepsilon\text{OPT}}{4}$$ ◀

The next lemma proves a lower bound for c_v of vertices in H having at least one edge. We call this graph H for future reference, meaning we remove the vertices in H having no edge.

▶ **Lemma 16.** *For any vertex $v \in H$, we have $c_v \geq \frac{\alpha\varepsilon}{2}$ for $\tau \leq \frac{\alpha\varepsilon}{2}$.*

Proof. Take an edge $e = (u, v) \in H$ since it has a degree of at least one. For this edge we know that $c_e \geq 1 - \tau$ since we put all the edges with $c_e \leq 1 - \tau$ in Q. Also we have $c_u < 1 - \alpha\varepsilon$ since $u \notin P_0$. We also know that $c_e \leq c_v + c_u$. Putting this all together we get that $c_v \geq \alpha\varepsilon - \tau$ which for a $\tau \leq \frac{\alpha\varepsilon}{2}$ we get $c_v \geq \frac{\alpha\varepsilon}{2}$. ◀

▷ Claim 17. We have $\text{OPT} \geq \frac{n'\alpha\varepsilon}{2}$ for $n' = |V(H)|$

Proof. This is because we have,

$$\text{OPT} = \sum_{v \in V} c_v \geq \sum_{v \in H'} c_v$$

and we know that $\sum_{v \in H'} c_v \geq n' \cdot \frac{\alpha\varepsilon}{2}$ due to Lemma 16. ◁

Putting Claim 17 and Lemma 15 together we get that if Algorithm 3 does not give a $(1+\varepsilon)$ approximation, then $\mathbf{E}[\mu(R)] \geq \frac{n'\alpha\varepsilon^2}{8}$. The next lemma asserts that if Algorithm 3 does not find a $(1+\varepsilon)$ approximation then we can find a large RS-graph in H.

▶ **Lemma 18.** *If Algorithm 3 is not a $(1+\varepsilon)$ approximation then, we can find an $RS_{n'}(r,t)$ graph (see Definition 2) with $t = 1/2\tau$ and $r = \frac{\alpha\varepsilon^2 n'}{32}$ on H*

Proof. Suppose we set $k = \frac{n'\alpha\varepsilon^2}{4}$. Then we can run the algorithm explained in Algorithm 2 and put together matchings S_i formed from different realizations of H to find an RS-graph where each matching size is $k/8$. Due to having $\mathbf{E}[\mu(R)] \geq \frac{n'\alpha\varepsilon^2}{8}$ we can prove Claim 10. This is because for edges in R_i we can argue that they exist in R_i with a probability of at most τ similar to how we proved it for R_i's in Algorithm 1 in Claim 10. Moreover, like how we proved for Algorithm 2 that the matchings S_i are induced matchings we form S_i's like in Algorithm 2 and we can argue that they are induced matchings. Then we can also prove Claim 12 and Lemma 13 for the new value of k. Therefore, similar to how we proved Lemma 13 we can find an $\text{RS}_{n'}(r,t)$ graph with $t = \frac{1}{2\tau}$ and $r = \frac{k}{8} = \frac{\alpha\varepsilon^2 n'}{32}$ on H. ◀

Now we are ready to prove the main result of this work.

▶ **Result 3.** *Given any $\varepsilon \in (0,1)$ let t be $RS_n(cn)$ for $c = \frac{\varepsilon^2}{128}$. There exists an algorithm that queries a subgraph of size $O(tn/p)$ and finds a vertex cover with the expected approximation ratio of $(1+\varepsilon)$.*

Proof. Let us run Algorithm 3 with $\alpha = 1/4$ and $\tau = 1/3t$. Meaning we have $c = \frac{\alpha\varepsilon^2}{32}$. We proceed similar to how we proved Theorem 5. Suppose that Algorithm 3 does not find a vertex cover with $(1+\varepsilon)$ approximation. Then we can find an $RS_{n'}(r,t)$ graph in H for $t = 1/2\tau$ and $r = \frac{\alpha\varepsilon^2 n'}{32}$ since $\mathrm{RS}_n(cn) \geq \mathrm{RS}_{n'}(cn')$ for $n \geq n'$. By setting $k = \frac{n'\alpha\varepsilon^2}{4}$ in Lemma 13 we get

$$t' = \frac{1}{2\tau} = \frac{1}{2\frac{1}{3t}} = 1.5t$$

matchings each of size $\frac{k}{8}$ that are induced matchings. This is in contradiction with what we assumed since t is the maximum number of induced matchings of size $\frac{k}{8}$ for an RS-graph and now we have found $1.5t$ matchings of this size. This means that indeed Algorithm 3 has an approximation of at most $(1+\varepsilon)$ for $\tau = \frac{1}{3t}$. Due to Claim 7, we have $|E(Q)| \leq O(\frac{n}{p\tau})$ which for $\tau = 1/3t$ we get $|E(Q)| = O(tn/p)$. ◀

Correlated Edges

Suppose that G has some edges that are realized in $\mathcal{G}$ independently called G_1 and some edges that are correlated with each other and the edges in G_1 called G_2. This means that edges in G_2 might exist based on edges in G_1 or G_2 that are realized. We need to adjust the definition of hallucination and realize the correlated edges by drawing them from the given distribution rather than realizing them independently. Moreover, if a set of them are queried and we want to hallucinate the rest, it should be done conditionally.

Notice that the only place we use independent realization of edges is in the proof of Claim 7. So we can argue that among the edges in G_1 at most $O(tn/p)$ edges will be in Q. Furthermore we know that $|Q| \leq |Q_1| + |Q_2|$ where Q_i is the subgraph of G_i that is in Q. Since the number of correlated edges is at most $\mathrm{RS}_n(cn)$ we have $|Q_2| \leq n \cdot \mathrm{RS}_n(cn)$ so we get:

$$|Q| \leq |Q_1| + |Q_2| \leq O(tn/p) + n \cdot \mathrm{RS}_n(cn) = O(tn/p) + n \cdot t = O(tn/p)$$

Based on the explanation above we drive the following corollary.

▶ **Corollary 19.** *Our Algorithm 3 can handle up to $t = RS_n(cn)$ correlated edges for $c = \frac{\varepsilon^2}{128}$ and still provide a $(1+\varepsilon)$ approximation to the optimal solution with $O(tn/p)$ queries.*

Abstract

A nearest neighbor representation of a Boolean function f is a set of vectors (anchors) labeled by 0 or 1 such that $f(\boldsymbol{x}) = 1$ if and only if the closest anchor to $\boldsymbol{x}$ is labeled by 1. This model was introduced by Hajnal, Liu and Turán [2022], who studied bounds on the minimum number of anchors required to represent Boolean functions under different choices of anchors (real vs. Boolean vectors) as well as the analogous model of k-nearest neighbors representations.

We initiate a systematic study of the representational power of nearest and k-nearest neighbors through Boolean circuit complexity. To this end, we establish a close connection between Boolean functions with polynomial nearest neighbor complexity and those that can be efficiently represented by classes based on linear inequalities – *min-plus polynomial threshold functions* – previously studied in relation to threshold circuits. This extends an observation of Hajnal et al. [2022]. Next, we further extend the connection between nearest neighbor representations and circuits to the k-nearest neighbors case.

As an outcome of these connections we obtain exponential lower bounds on the k-nearest neighbors complexity of explicit n-variate functions, assuming $k \leq n^{1-\epsilon}$. Previously, no superlinear lower bound was known for any $k > 1$. At the same time, we show that proving superpolynomial lower bounds for the k-nearest neighbors complexity of an explicit function for arbitrary k would require a breakthrough in circuit complexity. In addition, we prove an exponential separation between the nearest neighbor and k-nearest neighbors complexity (for unrestricted k) of an explicit function. These results address questions raised by [17] of proving strong lower bounds for k-nearest neighbors and understanding the role of the parameter k. Finally, we devise new bounds on the nearest neighbor complexity for several families of Boolean functions.

1 Introduction

A *nearest-neighbor representation* of a function $f : \{0,1\}^n \to \{0,1\}$ is a set of vectors, called "anchors," say $S = P \cup N$ such that $f(\boldsymbol{x}) = 1$ if and only if the nearest anchor to $\boldsymbol{x}$ (under the Euclidean distance metric) belongs to P. The set of anchors can be seen as a (disjoint) union of "positive" and "negative" examples. If $S \subseteq \{0,1\}^n$, we refer to the representation as *Boolean*, and if $S \subseteq \mathbb{R}^n$ we call it *real*. This model was pioneered by [17], who advocated the study of Boolean functions admitting efficient representations, focusing on the *number of anchors* as a measure of the complexity of the representation. They also consider the *k-nearest neighbors* variation, where the value of f on input x is computed as a majority vote of the k nearest anchors to x.

In particular, [17] observed a relationship between nearest-neighbor representations and threshold circuits. Motivated by their work, we initiate a systematic study of the connections to circuit complexity. Some of our results are related to the *weight complexity* (number of bits) needed when representing Boolean functions by real anchors: A topic receiving recent attention by [24].

There are numerous extensions and variations of nearest neighbor complexity. While studying all of these here is infeasible, one goal of ours is to encourage further exploration of this broad topic. We discuss some future directions in the conclusion section.

1.1 Motivation

We believe that nearest neighbor representations are a natural and interesting model of computation worthy of study. Furthermore, nearest neighbor complexity is relevant to several central research topics listed next.

1.1.1 Boolean function complexity

Nearest neighbor representations are related to depth-two threshold circuits and decision trees: [17] establish that lower bounds for these models are useful for establishing lower bounds for nearest neighbors. Polynomial threshold functions and their relation to geometric representations of Boolean functions also bear a strong connection to nearest neighbor representations. In fact, we will show that the expressivity of nearest neighbors is essentially equivalent to that of polynomial threshold functions *over the tropical semiring* – An interesting model of computation due to [18].

Our approach to understanding nearest neighbor complexity in terms of Boolean circuit complexity follows a long tradition in computational learning theory and computational complexity (e.g., [29, 22, 26, 27, 41, 39]). Uncovering new connections between nearest neighbors and well-studied computational models (such as linear decision lists and depth-two circuits) enables us to prove new unconditional lower bounds and upper bounds on the nearest neighbor complexity of explicit[1] functions. It also allows us to phrase some open problems in circuit complexity in terms of nearest neighbor complexity. For instance, the difficulty of proving super-polynomial lower bounds for k-nearest neighbors representations – for appropriate values of k – follows from representations (that we construct) of circuits with the same difficulty.

1.1.2 Machine learning and pattern recognition

Learning algorithms based on nearest neighbors have been the subject of extensive research for more than 50 years [8, 11]. For example, there is evidence that increasing k in the k-nearest neighbors rule can decrease its estimation error [10]. However, much less seems to be known about the *capacity* of the nearest and k-nearest neighbor rules to represent certain functions, while the capacity of other machine learning models such as Boolean circuits and neural networks has received considerable interest [16, 19, 30, 12, 38].

[1] By "explicit," we mean a function that can be computed in polynomial time by a Turing machine.

1.1.3 Algorithms for nearest neighbors classification and search

Efficient implementation of the nearest neighbor rule in high dimension has received considerable interest, leading to efficient algorithms and sophisticated data structures [7, 2, 1]. The study of nearest neighbor complexity leads naturally to the study of nonuniform algorithms (Boolean circuits) for this rule. Our work (along with previous findings) yields upper and lower bounds on the size of a circuit needed to implement nearest neighbor classification. We focus on exact representations, leaving the study of circuit complexity for *approximate* nearest neighbor search (e.g., [20, 28]) for future work.

1.2 Our results

The objects of our study are the *classes* of Boolean functions admitting *real* and *Boolean* nearest neighbor representation of polynomial complexity, NN and HNN respectively. Standard complexity classes based on circuit-like models of computation are closed under two natural "rewiring" operations: Substitution of variables by constants and duplication of variables (See Definition 11). However, it is not clear how to efficiently perform these operations in the nearest neighbor model. Thus, if we would like to give a precise characterization of NN and HNN in terms of circuits, we have to consider the *closure* of these classes under the same operations. As a result, we obtain classes of *subfunctions* of polynomial-size nearest neighbor representations, $\overline{\mathsf{NN}}$ and $\overline{\mathsf{HNN}}$ (see Defintion 12). We then give a precise characterization (equality) of $\overline{\mathsf{NN}}$ and $\overline{\mathsf{HNN}}$ in terms of the class of *min-plus polynomial threshold functions* of polynomial complexity (mpPTF)[2]. This adds to previous results of [17] showing the *containment* of NN and HNN in mpPTF. As a consequence, we prove (among other results) that HNN contains functions that cannot be computed by depth-two threshold circuits with polynomial size and weight. We also observe that the closure of HNN is closely connected to the class of functions with NN representations of logarithmic bit-complexity.

We study the k-nearest neighbors complexity of Boolean functions for $k > 1$. First, we extend the aforementioned characterization – the closure of NN in terms of mpPTF – to the closure of kNN. We use this characterization to prove that kNN for *constant* k is closely related to NN and that there exists an explicit function that requires exponential kNN complexity when $k \leq n^{1-\epsilon}$ (for an n-variate function). Next, we generalize the characterization of kNN to *arbitrary* k by introducing a new class, kSTAT – functions realizable by an inequality of the k-statistics of two sets of linear forms – which generalizes mpPTF. Consequently, we show that proving lower bounds for kNN for *arbitrary* k would result in lower bounds for the circuit class $\mathsf{SYM} \circ \mathsf{MAJ}$, which would be a major breakthrough in Boolean circuit complexity.

Finally, we present new bounds for nearest neighbor complexity of specific Boolean functions such as disjointness, CNFs, and majority. For example, we show that CNFs with polynomially many clauses have NN representations with polynomially-many anchors which also exhibit *constant bit-complexity*. In contrast, there exist CNFs of polynomial size with exponential HNN complexity. We also establish a new lower bound of $n/2 + 2$ on the HNN complexity of the majority function with an even number of inputs (n). This lower bound is tight, as it matches the upper bound proved in [17].

[2] An mpPTF is an expression of the form $\min\{L_1(\boldsymbol{x}), \cdots, L_\ell(\boldsymbol{x})\} \leq \min\{R_1(\boldsymbol{x}), \cdots, R_r(\boldsymbol{x})\}$ where L_i, R_i are linear forms.

1.3 Related work

Nearest neighbor complexity (under Euclidean distance) was formalized by [17]. They prove that the functions[3] $\mathsf{THR}^{\lfloor n/3 \rfloor}$ and XOR both require an exponential number of Boolean anchors but only 2 and $n+1$ real anchors, respectively. In fact, the same argument proves that THR^t requires at least $\binom{n}{t}/\binom{2t}{t}$ anchors for any t, which gives exponential lower bound for t bounded away from $n/2$, but is vacuous for $\mathsf{THR}^{n/2}$. It was subsequently shown in [24] that any symmetric Boolean function f has an NN representation with $I(f)$ anchors, where $I(f)$ denotes the number of *intervals* of f – the minimal number of contiguous intervals $[a, b]$ partitioning $[0, n]$ where $f(\boldsymbol{x})$ is constant for $a \leq \sum_i x_i \leq b$ – and this bound is optimal when all intervals have the same length. This extends the result of [17] that every symmetric function has nearest neighbor complexity at most $n+1$.

1.3.1 Connections to circuits

It was observed in [17] that functions with polynomial nearest neighbor complexity can be simulated by min-plus polynomial threshold functions, but it is an open question of whether or not the inclusion $\mathsf{NN} \subseteq \mathsf{mpPTF}$ is proper. Relations to the class mpPTF are of interest because it deepens the connection between nearest neighbors and circuit complexity. For instance, [18] establish that systems of mpPTFs compute exactly the class of $\mathsf{AND} \circ \mathsf{OR} \circ \mathsf{THR}$ circuits.

The expressive power of k-nearest neighbors rule was also studied by [17]. In particular, they prove that kNN can simulate *linear decision trees*, which yields a linear (in n) lower bound for the number of anchors in kNN representations of the $\mathsf{IP}\mod 2$ function. They also state the open problem of proving stronger lower bounds for the k-nearest neighbors complexity of an explicit function. In [25], it is shown that, under some regularity assumptions, polynomial-size nearest neighbor representations can simulate convex polytopes (i.e., $\mathsf{AND} \circ \mathsf{THR}$) as well as logarithmic fan-in $\mathsf{SYM} \circ \mathsf{THR}$ circuits and linear decision lists (LDL).

Constructions of Boolean circuits computing nearest neighbor classification are known. [31] constructs an $\mathsf{OR} \circ \mathsf{AND} \circ \mathsf{THR}$ circuit computing any function with an m-anchor NN representation in size $O(m^2)$. (See Appendix B). A very similar depth-three construction for kNN, also with size $O(m^2)$, was found by [6]. Note that the weights of the above circuits are bounded by a polynomial in n.

1.3.2 Bit complexity

It was shown in [24] that (the aforementioned) NN representations for symmetric functions have *logarithmic bit-complexity*, and that this is tight for some functions. It is left as an open problem to characterize NN representations of *threshold functions* in terms of bit-complexity. To this end, the same authors (in [25]) show that logarithmic bit complexity suffices to represent the comparison, equality, and odd-max bit Boolean functions, and conjecture that a logarithmic upper bound holds for any threshold function.

Other works have studied the role of bit-complexity in *approximate nearest neighbor search*; where we wish to find an anchor whose distance is minimal to a query point, up to a factor of $(1+\epsilon)$. For example, [21] provide tight bounds (in terms of bit-complexity) on the size of data structures performing approximate nearest neighbor search. This setting is quite different from our focus on exact classification of Boolean vectors.

---

[3] $\mathsf{THR}^t(\boldsymbol{x}) = 1 \iff \sum_i x_i \geq t$

The bit-complexity of the weights in polynomial-size threshold circuits has been studied extensively (see, e.g., surveys [34, 37]). For example, it was proved by [14, 15] that arbitrarily large weights can be reduced to have logarithmic bit-complexity by slightly increasing the depth of the circuit (along with a polynomial blow-up in size).

1.4 Organization

Section 2 outlines basic definitions required in subsequent sections. Section 3 establishes the equivalence between $\overline{\mathsf{HNN}}, \overline{\mathsf{NN}}$ and min-plus polynomial threshold functions, then discusses some of the consequences. Section 4 generalizes mpPTF to a new class, kSTAT, and proves that a similar equivalence holds with $\overline{\mathsf{kNN}}$. Here, we also derive several connections to circuit classes such as $\mathsf{SYM} \circ \mathsf{MAJ}$. Section 5 contains new results (upper and lower bounds) for the nearest neighbor complexity of explicit Boolean functions. Many proofs are relegated to Appendix A due to space constraints. Appendix B contains some direct constructions of threshold circuits computing HNN, one of which has depth two.

2 Preliminaries

We use the following notation throughout the paper:

Vectors are written in bold (i.e. $\boldsymbol{x} = (x_1, \cdots, x_n)$).
The k'th statistic of $\boldsymbol{x}$, denoted $\boldsymbol{x}_{(k)}$, is the k'th smallest element of $\boldsymbol{x}$.
– In particular, $\boldsymbol{x}_{(k)} = x_{\sigma(k)} \iff x_{\sigma(1)} \leq \cdots \leq x_{\sigma(n)}$ for some $\sigma \in S_n$
$\Delta(\boldsymbol{x}, \boldsymbol{y}) := ||\boldsymbol{x} - \boldsymbol{y}||_2^2$ denotes the squared Euclidean distance between $\boldsymbol{x}, \boldsymbol{y}$.
$\langle \boldsymbol{x}, \boldsymbol{y} \rangle$ denotes the real inner product (dot product), $x_1 y_1 + \cdots + x_n y_n$.
$\mathrm{poly}(n)$ refers to an arbitrary polynomial in the variable n.
$\mathbb{1}[P]$ denotes the Boolean function whose value is 1 if and only if P holds.

Note that the (squared) Euclidean distance between two Boolean vectors is equal to their Hamming distance, $\Delta(\boldsymbol{x}, \boldsymbol{y}) = \sum_{i \leq n} \mathbb{1}[x_i \neq y_i]$, so the Hamming weight of a Boolean vector $\boldsymbol{p}$ is denoted $\Delta(\boldsymbol{p}) := \Delta(\boldsymbol{p}, \boldsymbol{0}) = ||\boldsymbol{p}||_2^2$.

2.1 Boolean functions

▶ **Definition 1.** *A* threshold gate *is a Boolean function* $f : \{0,1\}^n \to \{0,1\}$ *defined by a weight vector* $\boldsymbol{w} \in \mathbb{R}^n$ *and a threshold* $\theta \in \mathbb{R}$ *such that*

$$f(\boldsymbol{x}) = 1 \iff \langle \boldsymbol{w}, \boldsymbol{x} \rangle \geq \theta. \tag{1}$$

A threshold circuit *is a sequence* $(f_1, \cdots, f_s)$ *of* $s \geq n$ *gates such that the first* n *gates are equal to the input variables (i.e.,* $f_i = x_i$ *for* $i \leq n$*) and subsequent gates are threshold gates whose inputs are some subset of the previous gates. The output of the circuit is equal to the output of the final gate. The size of the circuit is equal to* $s - n$.

A threshold circuit can be viewed as a directed acyclic graph. Nodes with fan-in 0 correspond to inputs, and other nodes correspond to threshold gates applied to the values of the preceding nodes. The node with fan-out 0 correspond to the output node. The *depth* of the circuit is the length of the longest path from an input node to the output node.

▶ Remark 2. It is well known that we may assume that the weights (and the threshold) are integers without loss of generality: Since the domain of a threshold gate is finite, we may approximate each weight by a rational number and multiply by a common denominator. See [23] for a comprehensive introduction to circuit complexity.

▶ **Definition 3.** *A* Nearest Neighbor (NN) *representation of a Boolean function* $f : \{0,1\}^n \to \{0,1\}$ *is defined by two disjoint sets of positive and negative* anchors $P, N \subseteq \mathbb{R}^n$ *such that*

- $f(\boldsymbol{x}) = 1$ *if there exists a* $\boldsymbol{p} \in P$ *with* $\Delta(\boldsymbol{x}, \boldsymbol{p}) < \Delta(\boldsymbol{x}, \boldsymbol{q})$ *for all* $\boldsymbol{q} \in N$.
- $f(\boldsymbol{x}) = 0$ *if there exists a* $\boldsymbol{q} \in N$ *with* $\Delta(\boldsymbol{x}, \boldsymbol{q}) < \Delta(\boldsymbol{x}, \boldsymbol{p})$ *for all* $\boldsymbol{p} \in P$.

A Hamming Nearest Neighbor (HNN) *representation is defined identically for Boolean anchors in* $\{0,1\}^n$.

▶ **Definition 4.** *A* k-Nearest Neighbors (kNN) *representation of a function* $f : \{0,1\}^n \to \{0,1\}$ *is defined by two disjoint sets of positive and negative* anchors $P, N \subseteq \mathbb{R}^n$ *and an integer* k *such that*

$$f(\boldsymbol{x}) = 1 \iff \text{there exists an } A \subseteq P \cup N \text{ with the following properties:}$$

1. $|A| = k$
2. $|A \cap P| \geq |A \cap N|$
3. $\Delta(\boldsymbol{x}, \boldsymbol{a}) < \Delta(\boldsymbol{x}, \boldsymbol{b})$ *for all* $\boldsymbol{a} \in A$, $\boldsymbol{b} \notin A$.

A kHNN *representation is defined identically for Boolean anchors.*

▶ **Definition 5** ([18])**.** *A* min-plus polynomial threshold function (mpPTF) *is a Boolean function* $f : \{0,1\}^n \to \{0,1\}$ *defined by two sets of linear forms with integer coefficients*[4] $\{L_1, \cdots, L_{\ell_1}\} \cup \{R_1, \cdots, R_{\ell_2}\}$ *satisfying*

$$f(\boldsymbol{x}) = 1 \iff \min_{i \leq \ell_1} L_i(\boldsymbol{x}) \leq \min_{j \leq \ell_2} R_j(\boldsymbol{x}) \tag{2}$$

The number of terms *in an* mpPTF *is equal to* $\ell_1 + \ell_2$*, and the* maximum weight *is equal to the largest absolute value of the coefficients of any form.*

▶ **Definition 6** ([36])**.** *A* linear decision list (LDL) *representation of a Boolean function* f *is a sequence of instructions "if* $f_i(\boldsymbol{x}) = 1$*, then output* c_i *(and halt)" for* $1 \leq i \leq m$*, followed by "output 0." Here,* $f_1, \cdots, f_m$ *are threshold gates and* $c_1, \cdots, c_m \in \{0,1\}$. Exact *linear decision lists (*ELDL*) are defined similarly using* exact *threshold functions – threshold gates where the inequality in* (1) *is replaced with equality. The* length *of an* LDL *or* ELDL *is the number of gates,* m*, and its* maximum weight *is equal to the largest coefficient of any* f_i.

▶ **Definition 7.** *We consider the following well-known Boolean functions.*

The majority *function,* $\mathsf{MAJ}(x_1, \cdots, x_n) = \mathbb{1}[x_1 + \cdots + x_n \geq n/2]$
The disjointness *function,* $\mathsf{DISJ}(\boldsymbol{x}, \boldsymbol{y}) = \mathbb{1}[\langle \boldsymbol{x}, \boldsymbol{y} \rangle = 0]$
The inner product mod 2 *function,* $\mathsf{IP}(\boldsymbol{x}, \boldsymbol{y}) = \langle \boldsymbol{x}, \boldsymbol{y} \rangle \mod 2$
The odd-max-bit *function,* $\mathsf{OMB}(x_1, \cdots, x_n) = \max\{i : x_i = 1\} \mod 2$

2.2 Function classes

First, we define classes of Boolean circuits whose inputs may be variables, their negations, or the constants 0 and 1. AND, OR, THR, and SYM are the classes of polynomial-size[5] depth-one circuits composed of AND, OR, threshold gates, and symmetric functions (i.e., Boolean functions which depend only on the Hamming weight of the input) respectively. $\mathsf{MAJ} \subset \mathsf{THR}$ is the set of threshold gates with polynomial weights[6]. AC^0 is the class of constant-depth circuits consisting of a polynomial number of AND, OR, and NOT gates.

[4] As for threshold gates, there is no loss of generality in the assumption that weights of mpPTFs are integers.
[5] "polynomial" in this context is always with respect to the input size, n.
[6] We abuse the notation denoting by MAJ both specific function and a class of function. The meaning of our notation will be also clear from the context.

For two circuit classes C_1, C_2, the class of circuits consisting of a circuit from C_1 whose inputs are (the outputs of) a polynomial number of circuits from C_2 is denoted by $C_1 \circ C_2$. (e.g., $\mathsf{THR} \circ \mathsf{THR}$ refers to depth two threshold circuits of polynomial size.)

▶ **Definition 8.** NN *is the class of Boolean functions that have nearest neighbor representations with polynomially-many anchors.* HNN *is the same class where anchors are Boolean.* kNN *and* kHNN *are defined in the same manner for a positive integer* k*.*

▶ **Definition 9.** $\mathsf{mpPTF}(\infty)$ *is the class of min-plus polynomial threshold functions with a polynomial number (in terms of the number of inputs) of terms and unbounded maximum weight.* $\mathsf{mpPTF}(\mathrm{poly}(n))$ *is the same class with polynomially-bounded maximum weight.*

▶ **Definition 10.** LDL *is the class of Boolean functions representable by linear decision lists with polynomial length.* $\widehat{\mathsf{LDL}}$ *is the same class with polynomially-bounded maximum weight.* ELDL *and* $\widehat{\mathsf{ELDL}}$ *are defined similarly for exact linear decision lists.*

3 Min-plus PTFs vs. nearest neighbors

In this section, we introduce the *closure* operation and derive an equivalence between (the closure of) NN, HNN and mpPTF.

▶ **Definition 11.** *Define a substitution of variables as a function* $v : \{0,1\}^n \rightsquigarrow \{0,1\}^{\widetilde{n}}$ *where* $\rightsquigarrow$ duplicates *variables or* adds constant *variables (e.g.,* $x_1x_2 \rightsquigarrow x_1x_1x_2x_2x_20$*). Then, a Boolean function* $f : \{0,1\}^n \to \{0,1\}$ *is a* subfunction *of* $g : \{0,1\}^{\widetilde{n}} \to \{0,1\}$ *when* $\widetilde{n} = \mathrm{poly}(n)$ *and there exists a substitution of variables* v *such that* $f(\boldsymbol{x}) = g(v(\boldsymbol{x}))$ *for all* $\boldsymbol{x} \in \{0,1\}^n$*.*

Subfunctions may equivalently be obtained from $g : \{0,1\}^{\widetilde{n}} \to \{0,1\}$ by *identifying variables* (e.g., $x_1 = x_2$) and *assigning variables* to constants (e.g., $x_1 = 0$).

▶ **Definition 12.** *For any function class* C*, let* $\overline{C}$ *denote the* closure *of* C*: The set of subfunctions derived from the elements of* C*. In particular, we say that a Boolean function* f *has an "*$\overline{\mathsf{NN}}$ *representation" if it is a subfunction of some* $g \in \mathsf{NN}$*.*

▶ Note 13. Circuit classes are already closed under this operation. For example, $\overline{\mathsf{MAJ}} = \mathsf{MAJ}$: Subfunctions of the majority function simply add (polynomially-bounded) coefficients and constant terms.

▶ **Theorem 14.**

$$\overline{\mathsf{NN}} = \mathsf{mpPTF}(\infty), \quad \overline{\mathsf{HNN}} = \mathsf{mpPTF}(\mathrm{poly}(n))$$

Theorem 14 and some consequences are proved in Appendix A.1. Namely, we observe that any n-variate function in $\overline{\mathsf{NN}}$ is a sub-function of an $(n+1)$-variate NN representation, and that $\mathsf{mpPTF}(\mathrm{poly}(n))$ captures precisely the power of $\overline{\mathsf{NN}}$ representations with *bit-complexity* $O(\log n)$. Then, using the results of [17] and [18], we immediately establish the following two corollaries.

▶ **Corollary 15.** $\mathsf{HNN} \subsetneq \overline{\mathsf{HNN}}$

▶ **Corollary 16.** $\overline{\mathsf{NN}}$ *representations of* IP *and* $f_n(\boldsymbol{x}, \boldsymbol{y}) := \bigwedge_{i=1}^{n} \bigvee_{j=1}^{n^2} (x_{i,j} \wedge y_{i,j})$ *require* $2^{\Omega(n)}$ *anchors.*

(Proofs in A.2 and A.3.) Theorem 14 also yields lower bounds for the circuit complexity of functions belonging to HNN. (A direct construction in Appendix B shows that $\mathsf{HNN} \subseteq \mathsf{THR} \circ \mathsf{MAJ}$.)

▶ **Theorem 17.**

$$\mathsf{HNN} \not\subseteq \mathsf{MAJ} \circ \mathsf{MAJ}$$

More precisely, there is a Boolean function with an HNN *representation with* $n+1$ *anchors which cannot be computed by a depth-two majority circuit with* $\mathrm{poly}(n)$ *gates.*

Proof. First, we claim that $\mathsf{OMB} \circ \mathsf{AND}_2 \in \overline{\mathsf{HNN}}$. Indeed, f is computed by an mpPTF with $n+1$ terms:

$$\min\{L_1(\boldsymbol{x},\boldsymbol{y}), L_3(\boldsymbol{x},\boldsymbol{y}), \cdots\} \leq \min\{-1, L_2(\boldsymbol{x},\boldsymbol{y}), L_4(\boldsymbol{x},\boldsymbol{y}), \cdots\}$$

where $L_k(\boldsymbol{x},\boldsymbol{y}) = (k+1)\cdot(1-x_i-y_i)$. Note that if $x_i = y_i = 1$, then $L_i(\boldsymbol{x},\boldsymbol{y}) = -(i+1)$ and otherwise $L_i(\boldsymbol{x},\boldsymbol{y}) \geq 0$. Hence, the minimum is obtained at the maximum index j where $x_j = y_j = 1$. The claim follows from Theorem 14.

Second, it is known that $\mathsf{OMB} \circ \mathsf{AND}_2 \notin \mathsf{MAJ} \circ \mathsf{MAJ}$ by [4, 16]. Thus, if HNN was in $\mathsf{MAJ} \circ \mathsf{MAJ}$, then we could use the $\overline{\mathsf{HNN}}$ representation described above to get a $\mathsf{MAJ} \circ \mathsf{MAJ}$ circuit computing $\mathsf{OMB} \circ \mathsf{AND}_2$, which is a contradiction. ◀

Finally, we observe a connection between mpPTFs and linear decision lists. This provides additional proof techniques for $\overline{\mathsf{HNN}}$ and helps to relate a question of separation of $\overline{\mathsf{HNN}}$ and $\overline{\mathsf{NN}}$ to the similar question for linear decision lists. The following lemma is proved in Appendix A.4.

▶ **Lemma 18.**

$$\mathsf{mpPTF}(\mathrm{poly}(n)) \subseteq \widehat{\mathsf{LDL}}.$$

More precisely, any mpPTF *with* m *terms and maximum weight* W *is equivalent to a linear decision list with length and maximum weight* $O(m^2 W)$.

▶ Remark 19. This lemma enables another technique to prove lower bounds for $\overline{\mathsf{HNN}}$ apart from sign-rank. More specifically, it is known that any function without large monochromatic rectangles must have a large linear decision list by [5].

▶ **Lemma 20.** $\mathsf{LDL} \subseteq \mathsf{mpPTF}(\infty)$.

Proof. It was shown in [18, Lemma 22] that $\mathsf{OMB} \circ \mathsf{THR} \subseteq \mathsf{mpPTF}(\infty)$. Our lemma follows since OMB is complete for the class of decision lists – See [18, Lemma 22]. ◀

It is open whether $\widehat{\mathsf{LDL}}$ and LDL are equal by [5]. Lemmas 18 and 20 immediately allow us to relate this problem to the problem of separating $\overline{\mathsf{HNN}}$ and $\overline{\mathsf{NN}}$.

▶ **Corollary 21.** *If* $\widehat{\mathsf{LDL}} \neq \mathsf{LDL}$, *then* $\overline{\mathsf{HNN}} \neq \overline{\mathsf{NN}}$.

Proof. From Theorem 14 and Lemmas 18, 20, we have the following sequence of inclusions.

$$\overline{\mathsf{HNN}} = \mathsf{mpPTF}(\mathrm{poly}) \subseteq \widehat{\mathsf{LDL}} \subseteq \mathsf{LDL} \subseteq \mathsf{mpPTF}(\infty) = \overline{\mathsf{NN}},$$

If $\overline{\mathsf{HNN}} = \overline{\mathsf{NN}}$, then the whole sequence of inclusions collapses and, in particular, $\widehat{\mathsf{LDL}} = \mathsf{LDL}$. ◀

4 kNN vs. Circuits

In this section, we give a circuit-style characterization of kNN and provide connections to known circuit classes. From these results, we obtain a separation between kNN and NN. Additionally, our results imply complexity theoretic barriers for proving superpolynomial lower bounds for kNN representations of explicit functions.

4.1 Characterization for small k

Here, we use the connection to mpPTF representations to get our first results on k-nearest neighbors complexity. In particular, we relate k-nearest neighbors representations for constant k to $\overline{\text{NN}}$ and prove a lower bound on k-nearest neighbors complexity for sublinear k.

▶ **Theorem 22.** *Any Boolean function with an m-anchor* kNN *representation is computed by an* mpPTF *with $\binom{m}{k}$ terms.*

Proof. We prove only the first statement as both arguments are identical. As noted in the proof of Theorem 14, the distances from anchors to a query point $\boldsymbol{x}$ are linear forms $L_1(\boldsymbol{x}), \cdots, L_m(\boldsymbol{x})$. Assign each linear form a label $\ell_1, \cdots, \ell_m \in \{1, -1\}$ where a positive label indicates placement on the left-hand side of the mpPTF and vice versa.

Then, consider the collection $A^+(\boldsymbol{x}) = \{L_{i_1}(\boldsymbol{x}) + \cdots + L_{i_k}(\boldsymbol{x}) \mid \ell_{i_1} + \cdots + \ell_{i_k} \geq 0\}$ and the compliment $A^-(\boldsymbol{x}) = \{L_{i_1}(\boldsymbol{x}) + \cdots + L_{i_k}(\boldsymbol{x}) \mid \ell_{i_1} + \cdots + \ell_{i_k} < 0\}$. The resulting mpPTF with $\binom{m}{k}$ terms, $\mathbb{1}[\min A^+(\boldsymbol{x}) \leq \min A^-(\boldsymbol{x})]$, realizes the original kNN representation: The minimum is attained by groups of k-nearest neighbors and if any such group has a positive majority then the inequality holds. ◀

It follows that Boolean functions with m-anchor kNN representations can be represented in $\overline{\text{NN}}$ with $\binom{m}{k}$ anchors. These results generalize to both weighted kNN and to non-Boolean inputs. See Appendix A.5 for a discussion.

As a consequence of Theorem 22, sign-rank lower bounds (e.g., Corollary 16) also apply to kNN. In particular, we get an exponential lower bound for kNN with $k = O(n^{1-\epsilon})$ for constant $\epsilon > 0$. This addresses an open question posed in [17] regarding k-nearest neighbors complexity.

▶ **Corollary 23.** *Any* $\overline{\text{kNN}}$ *representation of* IP *or $f_n(\boldsymbol{x}, \boldsymbol{y}) := \bigwedge_{i=1}^{n} \bigvee_{j=1}^{n^2} (x_{i,j} \wedge y_{i,j})$ requires $2^{\Omega(n/k)}$ anchors.*

Proof. Assume that IP (or f_n) has a $\overline{\text{kNN}}$ representation with m anchors. By Theorems 14 and 22 , IP has an $\overline{\text{NN}}$ representation with $\binom{m}{k} \leq m^k$ anchors. By Corollary 16, we have $m^k \geq 2^{\Omega(n)}$ and thus $m \geq 2^{\Omega(n/k)}$. ◀

4.2 Characterization for arbitrary k

In this section, we generalize the ideas of Theorem 14 to the closure of kNN, yielding further connections between nearest neighbors and circuit complexity.

▶ **Definition 24.** *Define by* kSTAT *the class of functions $f\colon \{0,1\}^n \to \{0,1\}$ representable by an inequality between k-statistics of two sets consisting of a polynomial number of linear forms: Given $\{L_1, \cdots, L_{\ell_1}\} \cup \{R_1, \cdots, R_{\ell_2}\}$ and integers k_l and k_r,*

$$f(\boldsymbol{x}) = 1 \iff (L_1(\boldsymbol{x}), \cdots, L_{\ell_1}(\boldsymbol{x}))_{(k_l)} < (R_1(\boldsymbol{x}), \cdots, R_{\ell_2}(\boldsymbol{x}))_{(k_r)} \tag{3}$$

and $\ell_1 + \ell_2$ is bounded by a polynomial in n.

As usual, we can assume that all coefficients in the linear forms are integers. Define the subclass $\widehat{\mathsf{kSTAT}}$ *where all coefficients are bounded by a polynomial in* n[7].

Note that we can reduce Definition 24 to the case of $k_l = k_r$ with only a linear increase in the size. This can be done by adding "dummy" linear forms that are always smaller than all others.

▶ **Theorem 25.**

$\overline{\mathsf{kNN}} = \mathsf{kSTAT}$, $\overline{\mathsf{kHNN}} = \widehat{\mathsf{kSTAT}}$.

See Appendix A.6 for the proof. Next, we provide another equivalent form of kSTAT that is sometimes more convenient.

▶ **Theorem 26.** *The class* kSTAT *consists exactly of functions* $f\colon \{0,1\}^n \to \{0,1\}$ *for which there exist linear forms* $\{L_1, \cdots, L_p\}$ *with* $p = \mathrm{poly}(n)$*, a positive integer* k*, and a labelling function* $\mathsf{label}\colon \{1, \cdots, p\} \to \{0,1\}$*, such that for all* $\boldsymbol{x}$*,*

$$f(\boldsymbol{x}) = 1 \iff (L_1(\boldsymbol{x}), \cdots, L_p(\boldsymbol{x}))_{(k)} = L_i(\boldsymbol{x}) \text{ for some } i \text{ with } \mathsf{label}(i) = 1. \tag{4}$$

The class $\widehat{\mathsf{kSTAT}}$ *consists exactly of functions with the same representation with polynomial-size coefficients in the linear forms.*

See Appendix A.7 for the proof. Now we show that some well-known circuit classes, for which we do not have any known lower bounds, are computable by $\overline{\mathsf{kHNN}}$.

▶ **Theorem 27.**

$\mathsf{SYM} \circ \mathsf{MAJ} \subseteq \widehat{\mathsf{kSTAT}}$.

Any symmetric function of s *threshold functions has a* $\widehat{\mathsf{kSTAT}}$ *representation with* $k = s + 1$.

See Appendix A.8 for the proof. Using the same strategy, we can embed a large complexity class into kNN directly:

▶ **Theorem 28.**

$\mathsf{SYM} \circ \mathsf{AND} \subseteq \mathsf{kNN}$.

Any symmetric function of s *conjunctions has a* kNN *representation with* $k = 2s + 1$.

See Appendix A.9 for the proof.

▶ Remark 29. Note that $\mathsf{SYM} \circ \mathsf{AND} \subseteq \mathsf{SYM} \circ \mathsf{MAJ}$ and $\mathsf{SYM} \circ \mathsf{AND}$ is known to simulate the whole class of ACC^0 within quasi-polynomial size [3]. Related classes are of interest in the context of obtaining lower bounds through circuit satisfiability algorithms [40, Conjecture 1].

As a result of Theorem 28, if we prove for some explicit function f that $f \notin \mathsf{kNN}$, it will follow that $f \notin \mathsf{SYM} \circ \mathsf{AND}$, and this would be a major breakthrough in circuit complexity. Also note that $\mathsf{IP} \in \mathsf{SYM} \circ \mathsf{AND}$ and thus, by Theorem 28, $\mathsf{IP} \in \mathsf{kNN}$. Together with Corollary 16, this gives a separation between NN and kNN. This also shows that in Corollary 23 we cannot get rid of k in the lower bound.

▶ **Theorem 30.** $\mathsf{ELDL} \subseteq \mathsf{kSTAT}$, $\widehat{\mathsf{ELDL}} \subseteq \widehat{\mathsf{kSTAT}}$.

See Appendix A.10 for the proof.

▶ Remark 31. The class ELDL is known to be contained in $\mathsf{THR} \circ \mathsf{THR}$ and proving super-polynomial lower bounds for ELDL is an open problem (See [9]).

[7] mpPTF can be viewed as a special case of kSTAT in which $k_l = k_r = 1$.

5 New bounds for the nearest neighbor complexity of Boolean functions

In this section, we derive several bounds on the nearest neighbor complexity of Boolean functions.

5.1 Nearest neighbor complexity of CNFs

We first show that any CNF admits an efficient NN representation.

▶ **Theorem 32.** *Any CNF or DNF with m clauses has an* NN *representation with $m+1$ anchors and constant bit-complexity.*

Proof. It suffices to prove the statement for DNFs as any CNF can be converted to a DNF by negation.

Let $N = \{\boldsymbol{q} := (\frac{1}{2}, \cdots, \frac{1}{2})\}$ and note that $d(\boldsymbol{x}, \boldsymbol{q}) = n/4$ for every input $\boldsymbol{x} \in \{0,1\}^n$ (where d is the squared Euclidean distance). For each clause, say $C(\boldsymbol{x}) = (x_1 \wedge \cdots \wedge x_k)$, introduce a positive anchor

$$\boldsymbol{p_C} = \left(\underbrace{1, \frac{3}{2}, \cdots, \frac{3}{2}}_{k}, \underbrace{\frac{1}{2}, \cdots, \frac{1}{2}}_{n-k}\right)$$

If any variable is negated, replace the corresponding $\frac{3}{2}$ (or 1) with $-\frac{1}{2}$ (or 0).

If $C(\boldsymbol{x}) = 1$, then $d(\boldsymbol{x}, \boldsymbol{p_C}) = (n-1)/4 < d(\boldsymbol{x}, \boldsymbol{q})$. Otherwise, some literal in C is equal to zero, hence $d(\boldsymbol{x}, \boldsymbol{p_C}) \geq 1 + (n-1)/4 > d(\boldsymbol{x}, \boldsymbol{q})$. Therefore, the entire DNF, say $C_1 \vee \cdots \vee C_m$, is satisfied if and only if some $\boldsymbol{p_{C_i}}$ is a nearest neighbor of $\boldsymbol{x}$. ◀

The polynomial-size representation above does not generalize to deeper AC^0 circuits of depth larger than 2. For instance, Corollary 16 exhibits a function computable by a depth-three De Morgan circuit of polynomial size which does not belong to $\overline{\mathsf{NN}}$. For the well studied disjointness function (that admits a compact CNF representation) we can get an efficient HNN representation:

▶ **Theorem 33.**

$$\mathsf{DISJ} \in \mathsf{HNN}$$

The disjointness function (in $2n$ dimensions) has an HNN *representation with $3n$ anchors.*

Proof. Consider anchors $P = \{(\boldsymbol{e_1}, \boldsymbol{e_1}), \cdots, (\boldsymbol{e_n}, \boldsymbol{e_n})\}$ and $N = \{\boldsymbol{e_1}, \cdots, \boldsymbol{e_{2n}}\}$ where $\boldsymbol{e_i}$ denotes the i'th standard basis vector and $(\boldsymbol{e_i}, \boldsymbol{e_i})$ their concatenation.

Let $\boldsymbol{x}, \boldsymbol{y} \in \{0,1\}^n$ and suppose $x_i = y_i = 1$ for some i. Then, for all j it holds that $\Delta((\boldsymbol{x}, \boldsymbol{y}), (\boldsymbol{e_i}, \boldsymbol{e_i})) \leq \Delta((\boldsymbol{x}, \boldsymbol{y}), \boldsymbol{e_j}) - 1$ with equality when $i = j$. Otherwise, $\Delta((\boldsymbol{x}, \boldsymbol{y}), (\boldsymbol{e_i}, \boldsymbol{e_i})) \geq \Delta((\boldsymbol{x}, \boldsymbol{y}), \boldsymbol{e_j}) + 1$ for all i, j. ◀

▶ Remark 34. It can be shown that the number of anchors in Theorem 33 is nearly tight; based on the $\Omega(n)$ lower bound for DISJ of [33], a simple argument proves that NN representations of disjointness require $\Omega(n/\log n)$ anchors. We omit the details.

Proceeding, we show that some CNFs with polynomially many clauses have exponential *Boolean* nearest neighbor complexity.

▶ **Definition 35.** *The* Hamming cube graph *is an undirected graph with vertices* $V = \{0,1\}^n$ *and edges* $E = \{(\boldsymbol{u}, \boldsymbol{v}) \in V : \Delta(\boldsymbol{u}, \boldsymbol{v}) = 1\}$. *The* components *of a Boolean function* f *are the connected components of the subgraph of the Hamming cube graph induced by the vertex set* $f^{-1}(1)$.

▶ **Lemma 36.** *If a Boolean function* f *has* m *components then any* HNN *representation of* f *has at least* m *anchors.*

Proof. Consider some component C of f and let $\delta(C)$ denote the vertex boundary of C: Vertices in $\{0,1\}^n \setminus C$ with a neighbor in C. Note that $\delta(C) \subseteq f^{-1}(0)$.

Suppose f has HNN representation $P \cup N$ and let $\boldsymbol{p} \in P$ be the nearest anchor to some $\boldsymbol{x} \in C$. Assume for contradiction that $\boldsymbol{p} \notin C$. Note that $\Delta(\boldsymbol{x}, \boldsymbol{p})$ is equal to the length of the shortest path from $\boldsymbol{x}$ to $\boldsymbol{p}$ in the Hamming cube graph, which by assumption must contain some $\boldsymbol{y} \in \delta(C)$. (In particular, $\Delta(\boldsymbol{x}, \boldsymbol{p}) = \Delta(\boldsymbol{x}, \boldsymbol{y}) + \Delta(\boldsymbol{y}, \boldsymbol{p})$.) Thus, there must exist some negative anchor $\boldsymbol{q} \in N$ with $\Delta(\boldsymbol{y}, \boldsymbol{q}) < \Delta(\boldsymbol{y}, \boldsymbol{p})$. By the triangle inequality,

$$\Delta(\boldsymbol{x}, \boldsymbol{q}) \leq \Delta(\boldsymbol{x}, \boldsymbol{y}) + \Delta(\boldsymbol{y}, \boldsymbol{q}) < \Delta(\boldsymbol{x}, \boldsymbol{y}) + \Delta(\boldsymbol{y}, \boldsymbol{p}) = \Delta(\boldsymbol{x}, \boldsymbol{p})$$

which contradicts the minimality of $\boldsymbol{p}$. Thus, each component contains an anchor. ◀

Using the previous results, another separation between HNN and NN follows from the existence of a CNF (over n-variables) with $\text{poly}(n)$ clauses and exponentially (in n) many components. (See Appendix A.)

▶ **Theorem 37.** *For any* $k > 0$*, there exists a* k*-CNF over* n *variables with* $\text{poly}(n)$ *clauses for which any* HNN *representation has* $2^{\Omega(n)}$ *anchors.*

5.2 A new lower bound for majority

We now discuss the disparity between the HNN complexity of the majority function in [17, Theorem 4]: In particular, when n is even, the best upper bound is $\frac{n}{2} + 2$ anchors, whereas 2 anchors suffices when n is odd. Note that if ties were allowed (won by positive anchors) in Definition 3, then $P = \{1^n\}$ and $N = \{0^n\}$ would suffice as an HNN representation for MAJ for all n.

▶ **Theorem 38.** *For even* n*, any* HNN *representation of* MAJ *requires* $\frac{n}{2} + 2$ *anchors.*

Proof. Suppose $P \cup N$ is an HNN representation of MAJ for even n. We claim that for each $\boldsymbol{x} \in \{0,1\}^n$ satisfying $\Delta(\boldsymbol{x}) = n/2$, there is a positive anchor $\boldsymbol{p} \neq \mathbf{1}$ with $\boldsymbol{x} \leq \boldsymbol{p}$ in coordinate-wise order:

It follows from [17] that the nearest anchor $\boldsymbol{p}$ to $\boldsymbol{x}$ satisfies $\boldsymbol{x} \leq \boldsymbol{p}$. Indeed, for some i it holds that $x_i = 1$, so suppose for contradiction that $p_i = 0$. Then, construct $\boldsymbol{y} = \boldsymbol{x} - \boldsymbol{e_i}$ and let $\boldsymbol{q} \in N$ be the nearest anchor to $\boldsymbol{y}$. This yields $\Delta(\boldsymbol{x}, \boldsymbol{p}) = \Delta(\boldsymbol{y}, \boldsymbol{p}) + 1 > \Delta(\boldsymbol{y}, \boldsymbol{q}) + 1$, contradicting the fact that

$$\Delta(\boldsymbol{x}, \boldsymbol{p}) < \Delta(\boldsymbol{x}, \boldsymbol{q}) \leq \Delta(\boldsymbol{y}, \boldsymbol{q}) + 1. \tag{5}$$

A similar argument shows that $\boldsymbol{q} \leq \boldsymbol{y}$. Hence, $\Delta(\boldsymbol{y}, \boldsymbol{q}) \leq \frac{n}{2} - 1$, and (5) becomes $\Delta(\boldsymbol{x}, \boldsymbol{p}) < \frac{n}{2}$ which implies that $\Delta(\boldsymbol{p}) \leq n - 1$, proving the claim.

For contradiction, assume that $|P \cup N| \leq \frac{n}{2} + 1$. Since there must be at least one negative anchor, we have $|P| \leq \frac{n}{2}$. Then, we can construct $\boldsymbol{x} \in \{0,1\}^n$ with $\Delta(\boldsymbol{x}) = \frac{n}{2}$ for which there is no positive anchor $\boldsymbol{p} \neq \mathbf{1}$ with $\boldsymbol{x} \leq \boldsymbol{p}$, leading to a contradiction: For each $\boldsymbol{p} \in P \setminus \mathbf{1}$, arbitrarily select some i where $p_i = 0$ and set $x_i = 1$, ensuring $\boldsymbol{x} \not\leq \boldsymbol{p}$. After this process, $\Delta(\boldsymbol{x}) \leq |P| \leq \frac{n}{2}$. Arbitrarily fixing more coordinates of $\boldsymbol{x}$ to 1 so that $\Delta(\boldsymbol{x}) = \frac{n}{2}$ completes the construction. ◀

6 Conclusion

We have studied nearest neighbor representations of Boolean functions, proving new lower and upper bounds and devising connections to circuit complexity. There are many future questions and research directions:

- Studying representations of Boolean functions using ideas from *approximate* nearest neighbor search [20, 28] could be of interest. Such a study could potentially lead to new insights and more compact representations avoiding the curse of dimensionality.
- Studying nearest neighbor complexity with respect to additional discrete domains such as grids as well as more than two labels is an interesting future direction.
- Circuit complexity has been used to derive new algorithms for nearest neighbor problems [1]. Can ideas about nearest neighbor complexity such as connections to mpPTFs be used to obtain new algorithms for nearest neighbor classification and search?
- Finally, it remains open whether $\overline{\mathsf{NN}} = \overline{\mathsf{HNN}}$.

A Omitted proofs

A.1 Proof of Theorem 14

We break the proof of this theorem into two separate lemmas.

▶ **Lemma 39.**

$$\overline{\mathsf{NN}} \subseteq \mathsf{mpPTF}(\infty), \quad \overline{\mathsf{HNN}} \subseteq \mathsf{mpPTF}(\mathrm{poly}(n))$$

More precisely, any $\overline{\mathsf{NN}}$ *representation with* m *anchors is equivalent to an* mpPTF *with* m *terms, and any* $\overline{\mathsf{HNN}}$ *representation with* m *anchors in* $\widetilde{n}$ *dimensions is equivalent to an* mpPTF *with* m *terms and maximum weight* $\widetilde{n}$.

Proof. The distance from $\boldsymbol{x} \in \{0,1\}^n$ to an anchor $\boldsymbol{p} \in \mathbb{R}^n$ is a linear form in variables $\boldsymbol{x}$:

$$\begin{aligned}\sum_i (x_i - p_i)^2 &= \sum_i \left[x_i^2 - 2p_i x_i + p_i^2\right] \\ &= \sum_i \left[(1-2p_i)x_i + p_i^2\right] \\ &= \langle \mathbf{1} - 2\boldsymbol{p}, \boldsymbol{x}\rangle + ||\boldsymbol{p}||_2^2.\end{aligned}$$

We can observe that NN representations essentially compute $\mathbb{1}[\min_{\boldsymbol{p}\in P} \Delta(\boldsymbol{x},\boldsymbol{p}) \leq \min_{\boldsymbol{q}\in N} \Delta(\boldsymbol{x},\boldsymbol{q})]$, which is an mpPTF. Subfunctions merely multiply coefficients and add constants to each linear form – For example, $d(x_1x_10, p_1p_2p_3) = 2\cdot(1-2p_1)x_1 + (p_3^2 + 2p_1^2)$.

In the case of HNN, we have for all anchors that $\boldsymbol{p} \in \{0,1\}^n$ and $\Delta(\boldsymbol{x},\boldsymbol{p})$ is a linear form with ± 1 coefficients and positive constants bounded (in absolute value) by n. As a result, the weights in mpPTF are bounded by n as well. ◀

▶ **Lemma 40.**

$$\mathsf{mpPTF}(\infty) \subseteq \overline{\mathsf{NN}}, \quad \mathsf{mpPTF}(\mathrm{poly}(n)) \subseteq \overline{\mathsf{HNN}}$$

More precisely, any mpPTF *with* m *terms has an* $\overline{\mathsf{NN}}$ *representation with* m *anchors in* $n+1$ *dimensions. Any* mpPTF *with* m *terms and maximum weight* W *has an* $\overline{\mathsf{HNN}}$ *representation with* m *anchors in* $\widetilde{n} = O(nW)$ *dimensions.*

Proof. We start with the $\mathsf{mpPTF}(\mathrm{poly}(n))$ case. Let $\mathbb{1}[\min_{i\le\ell_1} L_{1i}(\boldsymbol{x}) \le \min_{j\le\ell_2} L_{2j}(\boldsymbol{x})]$ be an arbitrary $\mathsf{mpPTF}(\mathrm{poly}(n))$. First make some pre-processing steps. First, multiply each linear form by 2 and add one to the right-hand side, so that ties are won by the left-hand side. Second, we would like to make all coefficients positive. For this, while there exists a negative term $-a_{ijk}x_k$ (or constant $-\theta_{ij}$), just add x_k (or 1) to every linear form until all negative terms are eliminated. No coefficient (or constant) will increase by more than W. Third, we make all coefficients even by multiplying all linear forms by two. Finally, we add the same constant Θ (to be decided later) to all linear forms. Then, every linear form is equal to $L_{ij}(\boldsymbol{x}) = a_{ij1}x_1 + \cdots + a_{ijn}x_n + \theta_{ij} + \Theta$, for positive, even constants $a_{ijk}, \theta_{ij} \le 8W$.

Define n *block sizes* $t_1, \cdots, t_n$ by $t_k := \max_{i,j} a_{ijk}$ (i.e., the maximum coefficient of x_k in any linear form). Also define $C = \Theta + \max_{i,j}\theta_{ij}$ and let $\widetilde{n} := t_1 + \cdots + t_n + C$. Inputs $\boldsymbol{x} \in \{0,1\}^n$ are mapped ($\rightsquigarrow$) to query points $\widetilde{\boldsymbol{x}} \in \{0,1\}^{\widetilde{n}}$ and linear forms L_{ij} are mapped to anchors $\widetilde{\boldsymbol{p}}_{ij} \in \{0,1\}^{\widetilde{n}}$ such that $\Delta(\widetilde{\boldsymbol{x}}, \widetilde{\boldsymbol{p}}_{ij}) = L_{ij}(\boldsymbol{x})$. In particular,

$$\widetilde{\boldsymbol{x}} := \underbrace{x_1 \cdots\cdots x_1}_{t_1 \text{ many}} \cdots \underbrace{x_n \cdots\cdots x_n}_{t_n \text{ many}} \cdot \underbrace{1 \cdots 1}_{C \text{ many}}$$

and

$$\widetilde{\boldsymbol{p}}_{ij} = \underbrace{0\cdots\cdots 0}_{(t_1+a_{ij1})/2}\,\underbrace{1\cdots\cdots 1}_{(t_1-a_{ij1})/2} \cdots \underbrace{0\cdots\cdots 0}_{(t_n+a_{ijn})/2}\,\underbrace{1\cdots\cdots 1}_{(t_n-a_{ijn})/2} \cdot \underbrace{0\cdots\cdots 0}_{z_{ij}}\underbrace{1\cdots\cdots 1}_{C-z_{ij}}$$

where z_i will be chosen momentarily. (Let $P = \{\widetilde{\boldsymbol{p}}_{1j}\}_{j\le\ell_1}$ and $N = \{\widetilde{\boldsymbol{p}}_{2j}\}_{j\le\ell_2}$.) The distance between $\widetilde{\boldsymbol{x}}$ and $\widetilde{\boldsymbol{p}}_{ij}$ is equal to

$$\begin{aligned}\Delta(\widetilde{\boldsymbol{x}}, \widetilde{\boldsymbol{p}}_{ij}) &= z_{ij} + \sum_k \left(\frac{t_k + a_{ijk}}{2}\right) x_k + \left(\frac{t_k - a_{ijk}}{2}\right)(1 - x_k) \\ &= z_{ij} + \langle \boldsymbol{a_{ij}}, \boldsymbol{x}\rangle + \sum_k \left(\frac{t_k - a_{ijk}}{2}\right)\end{aligned}$$

Now let $z_{ij} = \Theta + \theta_{ij} - \sum_k \left(\frac{t_k - a_{ijk}}{2}\right)$ so that $\Delta(\widetilde{\boldsymbol{x}}, \widetilde{\boldsymbol{p}}_{ij}) = \langle \boldsymbol{a_{ij}}, \boldsymbol{x}\rangle + \Theta + \theta_{ij}$. This is valid (i.e., z_{ij} is a non-negative integer) if we choose a large enough value for Θ: The minimal value of Θ such that $z_{ij} \ge 0$ for all i, j is

$$\Theta = \max_{i,j}\left(\sum_k \left(\frac{t_k - a_{ijk}}{2}\right) - \theta_{ij}\right) \le \sum_k \frac{t_k}{2} \le 4nW.$$

Thus, for $\Theta = 4nW$, we may always choose $0 \le z_{ij} \le \Theta + \theta_{ij} \le C$. Observe that $\boldsymbol{x} \rightsquigarrow \widetilde{\boldsymbol{x}}$ by duplicating each x_i at most $8W$ times and introducing at most $4nW + 8W$ constant variables. Thus, the original mpPTF is equivalent to a subfunction of an HNN representation with m anchors at most $4nW + 8W$ dimensions.

For the $\mathsf{mpPTF}(\infty)$ case, the same method applies, only now we do not need to increase the dimension that much. All coefficients can be realized by choosing anchors $\boldsymbol{p}_{ij} = (1 - \boldsymbol{a}_{ij})/2$ and all constants θ_{ij} can be corrected using one additional dimension. ◀

From this we can also deduce the following:

▶ **Theorem 41.** *Any function with an m-anchor NN representation with bit-complexity $O(\log n)$ is equivalent to an $\mathsf{mpPTF}(\mathrm{poly}(n))$ with m terms. Any function of n inputs with an $\mathsf{mpPTF}(\mathrm{poly}(n))$ representation with m terms is equivalent to a subfunction of a function of $n+1$ inputs with an m-anchor NN representation with bit-complexity $O(\log n)$.*

Proof. Observe that in Lemmas 39 and 40 – for NN and $\mathsf{mpPTF}(\infty)$ – the bit-complexity of NN and the logarithms of weights of mpPTF are linearly related. ◀

A.2 Proof of Corollary 15

Proof. It is shown in [17] that XOR has a unique HNN representation with 2^n anchors. Furthermore, it is established in [18] that $\mathsf{XOR} \in \mathsf{mpPTF}(\mathrm{poly}(n))$: In particular, $\mathsf{XOR}(\boldsymbol{x}) = 1$ if and only if $\min\{L_0(\boldsymbol{x}), L_2(\boldsymbol{x}), \cdots\} \leq \min\{L_1(\boldsymbol{x}), L_3(\boldsymbol{x}), \cdots\}$ where $L_i(\boldsymbol{x}) = i^2 - 2i \cdot (x_1 + \cdots + x_n)$. ◀

A.3 Proof of Corollary 16

Proof. It was shown by [17] that the NN complexity of a Boolean function f is bounded below by the *sign-rank* of f, and this can be easily extended to $\overline{\mathsf{NN}}$ through Theorem 14: The number of terms in an mpPTF computing f is also bounded below by the sign-rank of f, by [18].

[13] and [35] respectively establish that the sign rank of IP is equal to $2^{n/2}$ and the sign rank of f_n is $2^{\Omega(n)}$. ◀

A.4 Proof of Lemma 18

Proof. Consider a function $f \in \mathsf{mpPTF}(\mathrm{poly}(n))$ and let $\mathbb{1}[\min_{i \leq \ell_1} L_{1i}(\boldsymbol{x}) \leq \min_{j \leq \ell_2} L_{2j}(\boldsymbol{x})]$ be its representation. We can assume that all possible values of all linear forms are distinct. For this it is enough to multiply all forms by $\ell_1 + \ell_2$ and to add to each form it's own unique remainder modulo $\ell_1 + \ell_2$.

Observe that all linear forms obtain only polynomially many variables (since there output is polynomially bounded in absolute value). Denote possible values of the form L_{ij} by $a_{ij1}, \cdots, a_{ijt}$ for some t polynomially bounded in n. Note that, for different linear forms, the number of the values obtained might be not the same. To simplify the notation we assume that we add several equal values to the list to make them all of equal size t.

Now we are ready to produce the decision list. Let $c_1 = 1$ and $c_2 = 0$. We consider each a_{ijk} in increasing order and query if $L_{ij}(\boldsymbol{x}) \leq a_{ijk}$. If so, we output c_i. If not, we proceed to the next a_{ijk}.

This decision list computes f since we are just looking for the minimal value of a linear form among all possible values of the forms. ◀

A.5 Consequences of Theorem 22

▶ **Corollary 42.** *Any Boolean function with a* $\overline{\mathsf{kNN}}$ *representation with* m *anchors has an* $\overline{\mathsf{NN}}$ *representation with* $\binom{m}{k}$ *anchors. (Similarly, Boolean function with a* $\overline{\mathsf{kHNN}}$ *representation with* m *anchors has an* $\overline{\mathsf{HNN}}$ *representation with* $\binom{m}{k}$ *anchors.)*

▶ Remark 43. Theorem 22 and Corollary 42 can be extended to non-Boolean inputs. More precisely, the same statements are true over any finite domain $D \subseteq \mathbb{R}^n$. For this we can express (squared) distances to anchors as quadratic forms, for each subset of distances of size k consider the average of these distances and represent them as a distance to a new anchor. We still need to add an extra dimension to absorb constant terms.

▶ Remark 44. Theorem 22 and Corollaries 42 and 23 can be extended to the case of weighted kNN. Indeed, in Theorem 22, instead of sums of linear forms we will have weighted sums. This will require $\binom{m}{k} \cdot k! = \frac{m!}{(m-k)!}$ terms in the mpPTF representation. If the weights in the weighted kNN representation are small and the bit-complexity of anchors is small, this results in a $\overline{\mathsf{HNN}}$ representation and if there are no restrictions of weights and bit-complexity, we get $\overline{\mathsf{NN}}$ representation. The proof of Corollary 23 still works despite the increase of the number of anchors to $\frac{m!}{(m-k)!}$.

A.6 Proof of Theorem 25

We first make the following general observation: [32] show that finding the k'th nearest positive anchor and k'th nearest negative anchor and classifying based on which is closest is equivalent to computing a $(2k-1)$-nearest neighbors representation. This fact can be generalized, considering the closure of kNN.

▶ **Lemma 45.** *Let A and B be two sets of numbers and let S be the k smallest elements of $A \cup B$. Then,*

$$|A \cap S| \geq |B \cap S| \iff A_{(t)} < B_{(t)}$$

where $t = \left\lfloor \frac{k+1}{2} \right\rfloor$. (As in kNN, we assume S exists and is unique).

Proof. A contains a majority of the elements in S if and only if $|A \cap S| \geq t$. This happens if and only if the t'th smallest element in A is smaller than the t'th smallest element in B. ◀

We now proceed with the proof of Theorem 25.

Proof. For the inclusion $\overline{\mathsf{kNN}} \subseteq \mathsf{kSTAT}$, consider any function f in $\overline{\mathsf{kNN}}$. It is a subfunction of some function g with a kNN representation $P \cup N$. As in Lemma 39, the distances between $\boldsymbol{x}$ and each anchor are linear forms $A = \{L_1(\boldsymbol{x}), \cdots, L_{|P|}(\boldsymbol{x})\}$ and $B = \{R_1(\boldsymbol{x}), \cdots, R_{|N|}(\boldsymbol{x})\}$ which we assume have integer coefficients by the usual finite precision argument. By definition $g(\boldsymbol{x}) = 1$ if and only if the set S of k-nearest neighbors satisfies $|P \cap S| \geq |N \cap S|$. By Lemma 45, this happens if and only if $A_{(t)} < B_{(t)}$, taking $t = \left\lfloor \frac{k+1}{2} \right\rfloor$. Hence, $g \in \mathsf{kSTAT}$. As kSTAT is closed under taking subfunctions, $f \in \mathsf{kSTAT}$ as well.

For the inclusion $\mathsf{kSTAT} \subseteq \overline{\mathsf{kNN}}$, assume that f has a kSTAT representation. By adding dummy linear forms we can have $k_l = k_r$. By Lemma 45, the inequality (3) holds if and only if the $2k_l - 1$ smallest linear forms consist of more linear forms from the left-hand side than the right. Representing each inequality by an anchor, we obtain a representation of the same function in $\overline{\mathsf{kNN}}$.

The case of $\overline{\mathsf{kHNN}}$ and $\widehat{\overline{\mathsf{kSTAT}}}$ is analogous. ◀

A.7 Proof of Theorem 26

Proof. Suppose a Boolean function f has a representation $\{L_1, \cdots, L_p\}$ satisfying (4) for some function label and integer k. We will show that $f \in \mathsf{kSTAT}$. First, we assume that all coefficients in all linear form are integers and ensure that all values of all linear forms are distinct and even. For this, multiply all forms by $2p$ and shift each form by its own even remainder modulo $2p$.

For each $i \leq p$, we add one linear form to each side of (3). If $\mathsf{label}(i) = 1$, then place the form $L_i(\boldsymbol{x})$ on the left-hand side and $L_i(\boldsymbol{x}) + 1$ on the right. If $\mathsf{label}(i) = 0$, put the $L_i(\boldsymbol{x})$ on right-hand side and $L_i(\boldsymbol{x}) + 1$ on the left. It is easy to see that the k'th statistics in the left and right-hand sides of the resulting kSTAT representation are $L_i(\boldsymbol{x})$ and $L_i(\boldsymbol{x}) + 1$ (not necessarily in that order), where $L_i(\boldsymbol{x})$ is the k'th statistic of the original representation. Hence, the inequality in (3) holds if and only if $\mathsf{label}(i) = 1$.

For the other direction, assume we have a function $f \in \mathsf{kSTAT}$ given by (3). We again assume that all coefficients are integers and all values of all linear forms are distinct. Now we construct the required representation of f. For each form L_i we add to the representation the forms $L_{ij}(\boldsymbol{x}) := L_i(\boldsymbol{x}) + \frac{j}{k_l + k_r}$ for all $j \in \{0, 1, \cdots, k_l + k_r - 1\}$, and for each form R_i we add to the representation the forms $R_{ij}(\boldsymbol{x}) := R_i(\boldsymbol{x}) + \frac{j}{k_l + k_r + 1}$ for all $j = \{0, 1, \cdots, k_l + k_r\}$.

(That is, we have $k_l + k_r$ copies of each form L_i and $k_l + k_r + 1$ copies of each form R_i). To each L_{ij}, R_{ij} we assign the label 0 if $j < k_l$, and 1 if $j \geq k_l$. Finally, we set $k = (k_l + k_r - 1)(k_l + k_r + 1) + 1$.

Now, observe that the inequality (3) holds if and only if, among the $k_l + k_r - 1$ smallest forms, there are at least k_l forms L_i. Assume that there are precisely a forms L_i and b forms R_i. In particular, $a + b = k_l + k_r - 1$. Then, in the new representation, these linear forms give us

$$a(k_l + k_r) + b(k_l + k_r + 1) = (a + b)(k_l + k_r + 1) - a = (k_l + k_r - 1)(k_l + k_r + 1) - a$$

smallest forms. By construction, the next smallest forms are either $L_{i0} \leq \cdots \leq L_{i(k_l+k_r)}$ or $R_{i0} \leq \cdots \leq R_{i(k_l+k_r+1)}$ for some i. Thus, the k'th smallest form is either L_{ia} or R_{ia} and its label is 1 if and only if $a \geq k_l$ as desired. ◀

A.8 Proof of Theorem 27

Proof. Suppose we are given a function $f \in \mathsf{SYM} \circ \mathsf{MAJ}$ and a circuit computing it. We are going to construct a $\widehat{\mathsf{kSTAT}}$ representation of f in the form given by Theorem 26.

We can assume that all MAJ gates in the circuit have the same threshold $t = 0$. For this we can just add dummy variables and fix them to constants. Denote the linear forms for MAJ gates by $L_1, \cdots, L_s$ (all weights are integers) and denote by $g\colon \{0,1\}^s \to \{0,1\}$ the symmetric function at the top of the circuit. Here, s is the size of the circuit. Now, construct a $\widehat{\mathsf{kSTAT}}$ representation with the following linear forms:

$$(s+2)L_1(\boldsymbol{x}), \cdots, (s+2)L_s(\boldsymbol{x}), 1, 2, \cdots, s+1. \tag{6}$$

That is, we multiply each linear form by $(s + 2)$ and add $(s + 1)$ constant linear forms with values $1, \cdots, s + 1$. We let $k = s + 1$.

It is easy to see that the k'th statistic of (6) is always one of the constant linear forms. It is the form i if and only if $i - 1$ of the linear forms among $L_1, \cdots, L_s$ are positive. We assign label 1 to the form i if and only if $g(\boldsymbol{x}) = 1$ for inputs of weight $i - 1$. As a result, we get the desired representation for f and show that $f \in \widehat{\mathsf{kSTAT}}$. ◀

▶ Remark 46. The well-known argument that shows $\mathsf{MAJ}\circ\mathsf{THR} = \mathsf{MAJ}\circ\mathsf{MAJ}$ (see [14]) can be straightforwardly adapted to show that $\mathsf{SYM}\circ\mathsf{THR} = \mathsf{SYM}\circ\mathsf{MAJ}$. Thus, $\mathsf{SYM}\circ\mathsf{THR} \subseteq \widehat{\mathsf{kSTAT}}$ follows from Theorem 27 as well.

A.9 Proof of Theorem 28

Proof. First, as a warm-up, we show that $\mathsf{IP} \in \mathsf{kNN}$. Recall that $\mathsf{IP}(\boldsymbol{x}, \boldsymbol{y}) = \bigoplus_{i=1}^{n}(x_i \wedge y_i)$. Denote by $\boldsymbol{a} = (\frac{1}{2}, \cdots, \frac{1}{2})$ an $2n$-dimensional vector with $\frac{1}{2}$ in each coordinate. Note that $\Delta(\boldsymbol{a}, (\boldsymbol{x}, \boldsymbol{y})) = \frac{n}{2}$ for all $(\boldsymbol{x}, \boldsymbol{y}) \in \{0,1\}^{2n}$.

For each $i = 1, \ldots, n$ introduce two anchors $\boldsymbol{p_{i0}} = \boldsymbol{a} + \frac{1}{2}(\boldsymbol{e_i} + \boldsymbol{e_{i+n}})$ and $\boldsymbol{p_{i1}} = \boldsymbol{a} + \frac{1}{4}(\boldsymbol{e_i} + \boldsymbol{e_{i+n}})$. If for some $(\boldsymbol{x}, \boldsymbol{y})$ we have $x_i = y_i = 1$, then

$$\Delta((\boldsymbol{x}, \boldsymbol{y}), \boldsymbol{p_{ij}}) \leq \frac{n}{2} - 2\left(\frac{1}{4} - \frac{1}{16}\right) = \frac{n}{2} - \frac{3}{8}.$$

If, on the other hand, $x_i = 0$ or $y_i = 0$, then

$$\Delta((\boldsymbol{x}, \boldsymbol{y}), \boldsymbol{p_{ij}}) \geq \frac{n}{2} - \left(\frac{1}{4} - \frac{1}{16}\right) - \left(\frac{1}{4} - \frac{9}{16}\right) = \frac{n}{2} + \frac{1}{8} > \frac{n}{2}.$$

For each $i = 1, \cdots, n+1$ and $j = 0, 1$ and $l = 0, 1$ introduce an anchor $\boldsymbol{q_{i,j,l}} = \boldsymbol{a} + (-1)^l \frac{2i+j}{8n} \boldsymbol{e_1}$. For $(\boldsymbol{x}, \boldsymbol{y})$ with $x_1 = 1$ it is not hard to see that

$$\frac{n}{2} - \frac{3}{8} < \Delta((\boldsymbol{x},\boldsymbol{y}), \boldsymbol{q_{n+1,1,0}}) < \Delta((\boldsymbol{x},\boldsymbol{y}), \boldsymbol{q_{n+1,0,0}}) < \cdots < \\ < \Delta((\boldsymbol{x},\boldsymbol{y}), \boldsymbol{q_{1,1,0}}) < \Delta((\boldsymbol{x},\boldsymbol{y}), \boldsymbol{q_{1,0,0}}) < \frac{n}{2}$$

and $\Delta((\boldsymbol{x},\boldsymbol{y}), \boldsymbol{q_{i,j,1}}) > \frac{n}{2}$ for all i, j. The situation is symmetric for $x_1 = 0$. We assign label j to the anchor $\boldsymbol{p_{ij}}$. We assign label 1 to the anchor $\boldsymbol{q_{ijl}}$ iff $i + j$ is odd. We let $k = 2n + 1$.

It is easy to see that for a given $(\boldsymbol{x}, \boldsymbol{y})$ among the k closest anchors we have all pairs of anchors $\boldsymbol{p_{i0}}, \boldsymbol{p_{i1}}$ for all i such that $x_i = y_i = 1$. Denote the number of such i by t. Also among the k closest anchors we will have pairs of anchors $\boldsymbol{q_{i,0,l}}, \boldsymbol{q_{i,1,l}}$ for an appropriate l and for $i = n + 1, \ldots, t + 2$. In each of these pairs the labels of anchors are opposite and they cancel out when we compute the majority. Finally, one last anchor we will have among the k closest anchors is $\boldsymbol{q_{t+1,1,l}}$. The label of this anchor determines the majority among the k closest anchors and it is 1 iff t is odd. As a result, we get the desired representation for IP with $6n + 4$ anchors.

Now we extend this argument to SYM $\circ$ AND. Consider a function $f(\boldsymbol{x}) = g(f_1(\boldsymbol{x}), \cdots, f_s(\boldsymbol{x}))$, where each f_i has the form $f_i(\boldsymbol{x}) = \left(\bigwedge_{i \in S_i} x_i\right) \wedge \left(\bigwedge_{i \in T_i} \neg x_i\right)$ for some disjoint $S_i, T_i \subseteq [n]$. For each f_i we let $\frac{1}{2} > \epsilon_{i1} > \epsilon_{i0} > 0$ be a couple of parameters to be fixed later. We introduce a pair of anchors $\boldsymbol{p_{i1}}, \boldsymbol{p_{i0}}$ in the following way: Set the kth coordinate of $\boldsymbol{p_{ij}}$ to

$$\boldsymbol{p_{ij}}^{(k)} = \begin{cases} 1/2 & k \notin S_i \cup T_i \\ 3/2 - \epsilon_{ij} & k \in S_i \\ \epsilon_{ij} - 1/2 & k \in T_i \end{cases}$$

It is easy to see that for $\boldsymbol{x}$ such that $f_i(\boldsymbol{x}) = 1$ we have $\Delta(\boldsymbol{p_{ij}}, \boldsymbol{x}) = \frac{n}{4} - |S_i \cup T_i|(\epsilon_{ij} - \epsilon_{ij}^2)$ and for $\boldsymbol{x}$ such that $f_i(\boldsymbol{x}) = 0$ we have $\Delta(\boldsymbol{p_{ij}}, \boldsymbol{x}) \geq \frac{n}{4} - (|S_i \cup T_i| - 1)(\epsilon_{ij} - \epsilon_{ij}^2) + 1$. We fix ϵ_{ij} in such a way that $\frac{n}{4} - |S_i \cup T_i|(\epsilon_{ij} - \epsilon_{ij}^2) < \frac{n}{4} - \frac{1}{2}$ and $\frac{n}{4} - (|S_i \cup T_i| - 1)(\epsilon_{ij} - \epsilon_{ij}^2) + 1 > \frac{n}{4} + \frac{1}{2}$. We set $\mathsf{label}(\boldsymbol{p_{ij}}) = j$.

We construct anchors $\boldsymbol{q_{ijl}}$ for $i = 1, \cdots, s + 1$ and $j = 0, 1$ the same way as above and assign $\mathsf{label}(\boldsymbol{q_{i1l}})$ to be equal to $g(\boldsymbol{y})$ for $\boldsymbol{y}$ of weight $i - 1$ and $\mathsf{label}(\boldsymbol{q_{i0l}})$ to be the opposite. We let $k = 2s + 1$. The same argument as for IP shows that we get the desired representation of f with $6s + 4$ anchors. ◀

A.10 Proof of Theorem 30

Proof. Consider a function $f \in$ ELDL and suppose the linear forms in its representation are $L_1, \cdots, L_s$. Here L_i corresponds to the i'th query. As in the proof of Theorem 27, we can assume that all thresholds in all linear forms are 0.

We are going to construct a representation for f of the form provided by Theorem 26. We add to this representation the following linear forms:

$$(s+1)L_1, -(s+1)L_1, (s+1)L_2+1, -(s+1)L_2-1, \cdots, (s+1)L_s+s-1, -(s+1)L_s-s+1.$$

That is, for each form L_i in ELDL representation, we add the two forms $(s + 1)L_i + (i - 1)$ and $-(s + 1)L_i - (i - 1)$. We set $k = s$.

Assume that for some x we have $L_i(\boldsymbol{x}) = 0$ and all previous linear forms are non-zero. We than have that $(s+1)L_i(\boldsymbol{x}) + i - 1 = i - 1$. It is not hard to see that for $j < i$ we have that among forms $(s+1)L_j(\boldsymbol{x}) + j - 1$ and $-(s+1)L_j(\boldsymbol{x}) - j + 1$ exactly one is greater than $i - 1$: it is the first one if $L_j(\boldsymbol{x}) > 0$ and the second one if $L_j(\boldsymbol{x}) < 0$. For $j > i$ in a similar way we can see that among the forms $(s+1)L_j(\boldsymbol{x}) + j - 1$ and $-(s+1)L_j(\boldsymbol{x}) - j + 1$ exactly one is greater than $i - 1$: it is the first one if $L_j(\boldsymbol{x}) \geq 0$ and the second one if $L_j(\boldsymbol{x}) < 0$. As a result there are exactly $s - 1$ forms that are greater than $(s+1)L_i(\boldsymbol{x}) + i - 1$. We assign to this form the same label $L_i(\boldsymbol{x})$ has in ELDL. From this it follows that the constructed representation computes the same function.

Clearly, the coefficients in the constructed form are polynomially related to the coefficients in the original forms. Thus, the same proof gives $\widehat{\mathsf{ELDL}} \subseteq \widehat{\mathsf{kSTAT}}$. ◀

▶ Remark 47. Note that decision lists are computable in AC^0 and thus can be computed by quasi-polynomial-size $\mathsf{SYM} \circ \mathsf{AND}$ circuits. As a result, ELDL can be computed by quasi-polynomial-size circuit in $\mathsf{SYM} \circ \mathsf{AND} \circ \mathsf{ETHR} = \mathsf{SYM} \circ \mathsf{ETHR} = \mathsf{SYM} \circ \mathsf{MAJ}$, where the second equality follows since ETHR is closed under AND operation. Still, Theorem 30 gives a polynomial reduction that translates to the case of small coefficients.

A.11 Proof of Theorem 37

Such constructions are likely known; we outline a simple one for completeness.

▶ **Lemma 48.** *For any even integer $k > 0$, there exists a CNF with n variables and $n2^{k-o_k(k)}/k$ clauses with $2^{(1-o_k(1))n}$ components.*

Proof. Assume k divides n. Divide the set of variables to n/k disjoint sets $S_1, \cdots, S_{n/k}$ of size k. For each set S_i, define a CNF C_i which evaluates to 1 if and only if exactly half of the variables in S are equal to 1. This can be achieved with $\binom{k}{k/2} = 2^{k-o_k(k)}$ clauses.

Then, the CNF $C = C_1 \wedge \cdots \wedge C_{n/k}$ has exactly $\binom{k}{k/2}^{n/k} = 2^{(1-o_k(1))n}$ satisfying assignments, and the Hamming distance between any two of such assignments is at least 2. Thus, each of them constitutes a component. ◀

Hence, Theorem 37 follows from Lemmas 36 and 48 by taking k to be a constant independent of n. It is easy to extend the construction above to odd k. We omit the simple details.

B Circuits computing nearest neighbors

In this section we describe a straightforward construction of a *depth-three* circuit computing HNN and then compress it to *depth-two* at the cost of exponential weights. The folklore result of [31] is that any NN representation with m anchors can be computed by a depth three threshold circuit with size $O(m^2)$. A short proof can be found in [24].

▶ **Theorem 49** ([31])**.**
- $\mathsf{NN} \subseteq \mathsf{OR} \circ \mathsf{AND} \circ \mathsf{THR}$, $\mathsf{AND} \circ \mathsf{OR} \circ \mathsf{THR}$
- $\mathsf{HNN} \subseteq \mathsf{OR} \circ \mathsf{AND} \circ \mathsf{MAJ}$, $\mathsf{AND} \circ \mathsf{OR} \circ \mathsf{MAJ}$

Namely, every NN *(*HNN*) representation is computed by a depth-three* $\mathsf{AC}^0 \circ \mathsf{THR}$ *(*MAJ*) circuit with size* $|P||N| + \min\{|P|, |N|\} + 1$.

Note that the only difference between the circuits for HNN and NN is that the first-level threshold gates are guaranteed to have polynomial weights (in the case of HNN). It turns out that the size of the HNN circuit can be improved (when $n \ll |P| + |N|$).

▶ **Lemma 50.**

$$\mathsf{HNN} \subseteq \mathsf{OR} \circ \mathsf{AND} \circ \mathsf{MAJ}$$

In particular, every HNN *representation with m anchors is computed by an* $\mathsf{OR} \circ \mathsf{AND} \circ \mathsf{THR}$ *circuit with size $(n+1)m + (n+1)|P| + 1$.*

Proof. Note that $\mathbb{1}[\Delta(\boldsymbol{x}, \boldsymbol{p}) \leq i]$ is computed by a threshold gate $f^{\boldsymbol{p}}_{\leq i}(\boldsymbol{x})$ defined by $\boldsymbol{w} = \boldsymbol{p} - \overline{\boldsymbol{p}}$ and $\theta = \Delta(\boldsymbol{p}) - i$. (And similarly $\mathbb{1}[\Delta(\boldsymbol{x}, \boldsymbol{p}) \geq i]$.) Suppose f has an HNN representation $P \cup N$. Then, $f(\boldsymbol{x}) = \bigvee_{\substack{i \leq n \\ \boldsymbol{p} \in P}} \left(f^{\boldsymbol{p}}_{\leq i}(\boldsymbol{x}) \wedge \bigwedge_{\boldsymbol{q} \in N} f^{\boldsymbol{q}}_{\geq i}(\boldsymbol{x}) \right)$ ◀

Note that the threshold circuits from Theorem 49 and Lemma 50 have size $O(m^2)$ and $O(mn)$ respectively. In fact, the latter circuit can be compressed to a depth-two threshold circuit with exponential weights.

▶ **Theorem 51.**

$$\mathsf{HNN} \subseteq \mathsf{THR} \circ \mathsf{MAJ}.$$

Namely, every HNN *representation with m anchors is computed by a threshold of $2nm$ majority gates.*

Proof. The first level will consist of $2mn$ gates $f^{\boldsymbol{p}}_{\leq i}$, $f^{\boldsymbol{p}}_{\geq i}$ which output 1 if and only if $\Delta(\boldsymbol{x}, \boldsymbol{p}) \leq i$ and $\Delta(\boldsymbol{x}, \boldsymbol{p}) \geq i$, respectively, for $1 \leq i \leq n$. Define the sum

$$g^p_i(\boldsymbol{x}) := f^{\boldsymbol{p}}_{\leq i}(\boldsymbol{x}) + f^{\boldsymbol{p}}_{\geq i}(\boldsymbol{x}) - 1$$

and note that $g^p_i(\boldsymbol{x}) = \mathbb{1}[\Delta(x, p) = i]$. We can then write the output gate as

$$h(\boldsymbol{x}) = \mathbb{1}\left(\sum_{p \in P, i \leq n} m^{3(n-i)+1} g^p_i(\boldsymbol{x}) - \sum_{q \in N, i \leq n} m^{3(n-i)} g^q_i(\boldsymbol{x}) \geq 0 \right).$$

If some positive anchor is at distance at most j and all negative anchors are at distance at least j to $\boldsymbol{x}$, then

$$\sum_{p \in P, i \leq n} m^{3(n-i)+1} g^p_i(\boldsymbol{x}) \geq m^{3(n-j)+1} \geq \sum_{q \in N, i \leq n} m^{3(n-i)} g^q_i(\boldsymbol{x}).$$

Conversely, if some negative anchor is at distance at most j and all positive anchors are at distance at least $j+1$, then

$$\sum_{p \in P, i \leq n} m^{3(n-i)+1} g^p_i(\boldsymbol{x}) \leq m^{3(n-j)-1} < m^{3(n-j)} \leq \sum_{q \in N, i \leq n} m^{3(n-i)} g^q_i(\boldsymbol{x}).$$ ◀

▶ Remark 52. Theorem 51 can be obtained through Theorem 14, as a consequence of the following result derived from [18]. We include the direct construction to avoid the slight increase in circuit size.

▶ **Lemma 53.**

$$\mathsf{mpPTF}(\mathrm{poly}(n)) \subseteq \mathsf{THR} \circ \mathsf{MAJ}$$

Every mpPTF *with ℓ terms and maximum weight W is computed by a linear threshold of at most $4 \cdot W\ell \log \ell$ majority gates.*

Proof. Let $\mathsf{PTF}_{1,2}$ refer to Boolean functions (over $\{1,2\}$) equal to the sign of an n-variate polynomial. [18] prove that any $\mathsf{PTF}_{1,2}$ with ℓ terms and degree at most d is computed by a linear threshold (with exponential weights) of at most $2\ell d$ majority gates (replacing $\{1,2\}$ with $\{0,1\}$), and any mpPTF with ℓ terms and maximum weight W can be represented by a $\mathsf{PTF}_{1,2}$ with ℓ terms and degree at most $2W \log \ell$. ◀

▶ Remark 54. It is not hard to see that the circuits constructed in this section are *polynomial-time uniform*; they can be generated by a Turing machine given the set of anchors in polynomial time.

Space Complexity of Minimum Cut Problems in Single-Pass Streams

Abstract

We consider the problem of finding a minimum cut of a weighted graph presented as a single-pass stream. While graph sparsification in streams has been intensively studied, the specific application of finding minimum cuts in streams is less well-studied. To this end, we show upper and lower bounds on minimum cut problems in insertion-only streams for a variety of settings, including for both randomized and deterministic algorithms, for both arbitrary and random order streams, and for both approximate and exact algorithms. One of our main results is an $\widetilde{O}(n/\varepsilon)$ space algorithm with fast update time for approximating a spectral cut query with high probability on a stream given in an arbitrary order. Our result breaks the $\Omega(n/\varepsilon^2)$ space lower bound required of a sparsifier that approximates all cuts simultaneously. Using this result, we provide streaming algorithms with near optimal space of $\widetilde{O}(n/\varepsilon)$ for minimum cut and approximate all-pairs effective resistances, with matching space lower-bounds. The amortized update time of our algorithms is $\widetilde{O}(1)$, provided that the number of edges in the input graph is at least $(n/\varepsilon^2)^{1+o(1)}$. We also give a generic way of incorporating sketching into a recursive contraction algorithm to improve the post-processing time of our algorithms. In addition to these results, we give a random-order streaming algorithm that computes the *exact* minimum cut on a simple, unweighted graph using $\widetilde{O}(n)$ space. Finally, we give an $\Omega(n/\varepsilon^2)$ space lower bound for deterministic minimum cut algorithms which matches the best-known upper bound up to polylogarithmic factors.

1 Introduction

We consider the graph streaming model, which is a key model for computations on massive graph datasets that has been extensively studied over the past couple of decades (see, e.g., [36] for a survey). We specifically study the problem of finding minimum cuts in adversarial and random-order streams, which has been less studied than the problem of general cut sparsification of graphs. Besides being theoretically interesting, finding minimum cuts is also a problem of practical interest. For example, they allow for the calculation of social network metrics such as influence [50] and are used to quantify the robustness of power networks [23] and road networks [48] to failures.

1.1 Adversarial Streams

The key method so far for solving minimum cut with low-memory is the usage of cut sparsifiers. The notion of cut sparsifiers was introduced by Benczur and Karger [7] and has been extremely influential. Given a weighted graph $G = (V, E, w)$ with $n = |V|$ vertices and $m = |E|$ edges, and polynomially bounded edge weights $w : E \to \mathbb{R}_+$, together with an accuracy parameter $\varepsilon > 0$, a cut sparsifier of G is a sparse subgraph H on the same vertex set V but with (possibly) different edge weights such that the weight of every cut in G is $(1+\varepsilon)$-approximated by the weight of the corresponding cut in H. For two sets $S, T \subseteq V$, we use $E(S,T) = \{(u,v) \in E : u \in S, v \in T\}$ to denote the set of edges between S and T in graph G and $w_G(S,T) = \sum_{e \in E(S,T)} w_e$ to denote the total weight of edges between S and T in graph G. Formally, we have the following definition,

▶ **Definition 1** (For-All Cut Sparsifier). *H is a $(1+\varepsilon)$ for-all cut sparsifier of G if and only if the following holds for all $\varnothing \subset S \subset V$:*

$$w_H(S, V \setminus S) \approx_\varepsilon w_G(S, V \setminus S)$$

where $a \approx_\varepsilon b$ is defined as $(1-\varepsilon) \cdot b \leq a \leq (1+\varepsilon) \cdot b$.

Specifically, [7] shows that a cut sparsifier always exists with $O(n \log n/\varepsilon^2)$ edges. This bound was improved to $O(n/\varepsilon^2)$ edges by [6] and [1, 2, 11] proved a lower bound of $\Omega(n(\log n)/\varepsilon^2)$ bits (even in the case when the cut-sparsifier H is a not necessarily a subgraph of G). The existence bound was also extended to the stronger notion of spectral sparsifiers [46, 47, 45, 6], where the quadratic form associated with the Laplacian of graph H provides a $(1+\varepsilon)$-approximation to that of G. Let L_G denote the Laplacian matrix of graph G. For every subset $S \subseteq V$, let x_S be the binary indicator vector of S such that $x_i = 1$ if $i \in S$ and $x_i = 0$ if $i \notin S$. Then we have $x_S^\top L_G x_S = w_G(S, V \setminus S)$. The definition of the spectral sparsifier extends the assumption that x is a binary vector to an arbitrary vector.

▶ **Definition 2** (For-All Spectral Sparsifier). *Let G and H be two weighted undirected graphs. Fix $0 < \varepsilon < 1$. We say H is a $(1+\varepsilon)$ for-all spectral sparsifier of G iff the following holds:*

$$(1-\varepsilon) \cdot L_G \preceq L_H \preceq (1+\varepsilon) \cdot L_G$$

where we use $A \preceq B$ to denote $\forall x \in \mathbb{R}^n, x^\top Ax \leq x^\top Bx$.

This construction has had a tremendous impact on cut problems in graphs, see, e.g., [7, 8, 30, 44, 35]. However, for very small values of ε, the $1/\varepsilon^2$ dependence in cut sparsifiers may be prohibitive on large-scale graphs. Motivated by this, the work of [2] relaxed the cut sparsification problem to that of outputting a data structure sk_G such that given any *fixed* cut $S \subseteq V$, the value of $\mathrm{sk}_G(S)$ is within a $(1+\varepsilon)$ factor of the cut value of S in G, with probability at least $2/3$[1]. This relaxed notion of the problem is called the "for-each" model, which should be contrasted with the previous "for-all" model of cut and spectral sparsification.

Surprisingly, [2] showed that such a data structure exists for cut sparsification with $\mathrm{poly}(n)$-bounded integer edge weights of size $\widetilde{O}(n/\varepsilon)$[2], which is optimal up to polylogarithmic factors. In a follow-up work of [24], the authors extended the $\widetilde{O}(n/\varepsilon)$ upper bound to the for-each model for spectral sparsifiers. Another very interesting work is [14], which shows that such a sketch can be chosen as a reweighted subgraph of G. We specifically deal with these graphical for-each sparsifiers:

▶ **Definition 3** (Graphical For-Each Spectral Sparsifier). *Let G and H be two weighted undirected graphs. Fix $0 < \varepsilon < 1$. We say H is a $(1+\varepsilon)$ graphical for-each spectral sparsifier of G if and only if for each $x \in \mathbb{R}^n$, with probability at least $2/3$:*

$$x^\top L_H x \approx_\varepsilon x^\top L_G x$$

In a line of work, see, e.g., [36, 27, 28], efficient algorithms for sparsifiers in the for-all model in a graph stream were constructed. The state-of-the-art work [28] gives a single-pass algorithm for spectral sparsification in dynamic streams which uses space $\widetilde{O}(n/\varepsilon^2)$.

▶ **Lemma 4** ([28]). *Given an input graph G in a stream, there exists a one-pass streaming algorithm that outputs a subgraph H of G such that with high probability H is a $(1+\varepsilon)$-spectral sparsifier of G. Moreover, the algorithm uses $\widetilde{O}(n/\varepsilon^2)$ space and $\widetilde{O}(m + n/\varepsilon^2)$ time.*

However, it was not known how to construct a for-each sketch for cut sparsification in a stream in better than $\widetilde{O}(n/\varepsilon^2)$ space, which follows from computing a for-all sparsifier. A natural question is whether we can implement a streaming algorithm that computes a for-each sparsifier with space matching the $\Omega(n/\varepsilon)$ offline lower bound that holds for for-each sparsification [2].

If we can answer this question in the affirmative, we can also get a better space bound for the approximate minimum cut problem. It is well-known that there are only $\mathrm{poly}(n)$ $O(1)$-approximate minimum cuts[3] in a graph. So we can run a for-all cut sparsification algorithm in a stream with $\varepsilon = \Theta(1)$ in $\widetilde{O}(n)$ space and obtain a candidate set of $\mathrm{poly}(n)$

[1] This can be amplified to high probability, which we define to mean with probability at least $1 - 1/\mathrm{poly}(n)$. This is done by independently repeating the data structure $O(\log n)$ times and outputting the median estimate. This also lets us estimate the cut value for $\mathrm{poly}(n)$ cuts simultaneously.

[2] Throughout we use $\widetilde{O}(\cdot)$ to hide $\mathrm{polylog}(n)$ factors.

[3] When we say a cut is an α-approximate minimum cut, we mean that its cut value is at most α times the minimum cut value.

cuts containing the minimum cut. In parallel, we estimate the value of each cut using a for-each sparsifier with failure probability $1/\text{poly}(n)$. The smallest cut out of the candidate cuts will be a $(1+\varepsilon)$-approximate minimum cut. Thus, the space complexity is just $\widetilde{O}(n)$ plus that of maintaining a for-each sparsifier in a stream. However, the existing algorithms for computing for-each sparsifiers are not streaming algorithms. Motivated by the existence of a for-each sketch in $\widetilde{O}(n/\varepsilon)$ bits of space, one may wonder if it is possible to obtain a $(1+\varepsilon)$-approximation to the minimum cut in $\widetilde{O}(n/\varepsilon)$ space in a single-pass stream.

▶ **Question 5.** What is the space and time complexity of obtaining a $(1+\varepsilon)$-approximate minimum cut in a single-pass insertion-only stream?

We also note that an exact global minimum cut streaming algorithm exists in $\widetilde{O}(n)$ space with two passes for simple graphs [5] (see also [43]) and $\log n$ passes for weighted graphs [38].

1.2 Random-order streams

We know that finding the minimum cut exactly in single-pass adversarial streams needs $\Omega(n^2)$ space [52]. We need an additional pass to get the exact minimum cut in $\widetilde{O}(n)$ space. However, many streaming applications require solving the problem in exactly one pass because the stream cannot be stored.

Thus, to surpass the $\Omega(n^2)$ barrier of adversarial streams in one pass, we consider a relaxation known as random-order streams and ask whether we can find the minimum cut exactly in $o(n^2)$ space in this setting. In this model, the graph can still be chosen adversarially, but its edges arrive in the stream in a random order.

The motivation for studying this model stems from the fact that real-world data is typically not adversarial. Adversarial streams are adversarial in both their input and arrival order, while random-order streams relax the arrival order, making them more representative of real-world data. Additionally, the random-order streaming model may help explain the empirical performance of certain heuristics.

This model was first studied by [39] for sorting in limited space. Many subsequent works have studied problems in random-order streams [21, 26, 12, 37, 42, 16, 13], some of which show a clear separation between the adversarial and random-order models.

One notable line of work focuses on maximum matching within this model [33, 19, 32, 3, 18, 9, 4, 22]. The best-known upper bound in the random order model [4] gets a slightly better than 2/3-approximation in semi-streaming space, which is better than the best possible $\frac{1}{1+\ln 2} \approx 0.59$-approximation in the adversarial model due to the lower bound of [25], showing another separation between adversarial and random-order streams.

Motivated by this, we study the minimum cut problem in the random-order model and ask the following question:

▶ **Question 6.** What is the space complexity of obtaining the exact minimum cut in a single-pass random-order stream?

This work resolves the above questions with matching algorithms and lower bounds. We also carefully optimize the running time and update time of our algorithms. We also obtain several additional results, which we outline in Section 3.

2 Preliminaries

2.1 All-Pairs Effective Resistances

Given $G(V, E, w)$ as an electrical network on n nodes in which each edge e corresponds to a link of conductance w_e (i.e., a resistor of resistance $1/w_e$), the effective resistance of an edge e is the potential difference induced across it when a unit current is injected at one end of e and extracted at the other end of e. Equivalently it is equal to $R^G_{\text{eff}} = \chi^\top_{u,v} L^\dagger_G \chi_{u,v}$, where $L^\dagger_G$ denotes the pseudoinverse of the Laplacian of graph G and $\chi_{u,v} := 1_u - 1_v$.

In the all-pairs effective resistance problem, we are required to output a data structure, which with high probability can generate effective resistance values for each of the n^2 pairs of vertices, or a $(1+\varepsilon)$-approximation of each of the n^2 pairs of values in the $(1+\varepsilon)$-approximate version of the problem. Note that the data structure implicitly represents these n^2 values and responds with one such value on a given query pair.

2.2 Short-Cycle Decomposition

Short cycle decompositions are a recent algorithmic tool for graph sketching problems introduced by Chu et al. [14].

▶ **Definition 7** (Short-Cycle Decomposition). *An $(\hat{m}, L)$ short-cycle decomposition of a graph G is a decomposition of the graph into edge-disjoint cycles of at most length L and an additional $\hat{m}$ edges outside of these cycles.*

The main contribution of [14] to spectral sparsification is in proving the following claim:

▷ Claim 8. Given an undirected weighted graph G and an $(\hat{m}, L)$ short-cycle decomposition routine CycleDecomp, there exists an algorithm which returns with high probability a $(1+\varepsilon)$-spectral sparsifier *graph* with $\widetilde{O}(\hat{m} + nL\varepsilon^{-1})$ edges and run-time

$$\widetilde{O}(m) + T_{\text{CycleDecomp}}(O(m \log n), n)$$

where $T_{\text{CycleDecomp}}(m, n)$ is the running time of CycleDecomp on a graph with m edges and n vertices.

As a high-level overview, the short-cycle decomposition is key as a degree-preserving sparsification method. Given each cycle, we can label them numerically in order and sample either all the odd or all the even labeled edges, each with $1/2$ probability. Previous works on "for-each" sparsifiers [2, 24] used a recursive expander decomposition and subsampling at each level, with the main issue being that the degrees were not well-preserved. This issue was solved by explicitly storing the degrees of the graph, causing their spectral sparsifier data structure to no longer be a graph. The work of [14] circumvents this issue with the short-cycle decomposition by constructing subsampled graphs that exactly preserve their vertex degree.

Note that [14] already gives a graphical spectral sparsifier with $\widetilde{O}(n/\varepsilon)$ edges and bits of working memory using a basic brute-force search for cycle decomposition. However, its runtime for construction is $O(mn)$, which is prohibitively slow as a subroutine. On the other hand, later work by Parter and Yogev [41] shows a deterministic algorithm to compute $(O(n \log n), O(\log^2 n))$ short-cycle decompositions. This combined with Claim 8 will allow us to design an algorithm in $m^{1+o(1)}$ time which returns a $(1+\varepsilon)$-spectral sparsifier which is a reweighted graph with $\widetilde{O}(n/\varepsilon)$ edges. This gives near-optimal parameters except for a required $m^{1+o(1)}$ bits of working memory. However, in Section 4.1, we show that we can implement this subroutine so that it is guaranteed to use only $\widetilde{O}(m)$ working memory, achieving near-optimal results in both working memory usage and running time.

Table 1 Minimum Cut Space Complexity in the Single-Pass Insertion-Only Streaming Setting.

Stream Type	Exact/Approx $(1+\varepsilon)$	Upper Bound	Lower Bound
Adversarial	Exact	$O(n^2)$ (full graph)	$\Omega(n^2)$ [52]
Adversarial	Approx, Deterministic	$\widetilde{O}(n/\varepsilon^2)$ [6]	$\Omega(n/\varepsilon^2)^*$ (Theorem 12)
Adversarial	Approx, Randomized	$\widetilde{O}(n/\varepsilon)$ (Theorem 9)	$\Omega(n/\varepsilon)$ (Theorem 12)
Random-Order	Exact	$\widetilde{O}(n)$ (Theorem 14)	$\Omega(n)$ [12]

3 Overview of Results

We list the current state-of-the-art results for single-pass minimum cut streaming algorithms in Table 1. Our main result is an $\widetilde{O}(n/\varepsilon)$ space streaming algorithm that finds a $(1+\varepsilon)$-approximate minimum cut in a single-pass stream.

▶ **Theorem 9.** *There is a one-pass insertion-only streaming algorithm that, with high probability, computes an $(1+\varepsilon)$-approximation of the minimum cut on weighted graphs using $\widetilde{O}(n/\varepsilon)$ bits of space. Moreover, our algorithm takes $\widetilde{O}(m)+(n/\varepsilon^2)^{1+o(1)}$ total update time and $\widetilde{O}(n^2/\varepsilon^2)$ post-processing time.*

This shows, somewhat surprisingly, that estimating the minimum cut is easier than computing a for-all cut sparsifier in a data stream. Our algorithm is mainly based on the following new for-each spectral sparsifier in a graph stream.

▶ **Lemma 10.** *A one-pass insertion-only streaming algorithm exists that, with high probability, constructs a $(1+\varepsilon)$ for-each spectral sparsifier of weighted graphs with $\widetilde{O}(n/\varepsilon)$ edges using $\widetilde{O}(n/\varepsilon)$ bits of space. This algorithm also has total runtime $\widetilde{O}(m)+(n/\varepsilon^2)^{1+o(1)}$.*

Our algorithm's total runtime is $\widetilde{O}(m)+(n/\varepsilon^2)^{1+o(1)}$, which notably implies its amortized update time is $\widetilde{O}(1)$ when $m \geq (n/\varepsilon^2)^{1+o(1)}$. With the $\Omega(n/\varepsilon)$ data structure lower bound in [2], our algorithm is tight in space complexity up to polylogarithmic factors. Based on our Lemma 10, we can obtain an $\widetilde{O}(n/\varepsilon)$ space streaming algorithm that can $(1\pm\varepsilon)$-estimate all-pairs effective resistances.

▶ **Corollary 11.** *There exists a one-pass insertion-only streaming algorithm that constructs a data structure that calculates $(1+\varepsilon)$-approximations to the effective resistances between every pair of vertices on weighted graphs using $\widetilde{O}(n/\varepsilon)$ bits of space. Our algorithm has $\widetilde{O}(m)+(n/\varepsilon^2)^{1+o(1)}$ total time during the stream and $\widetilde{O}(n^2/\varepsilon)$ post-processing time.*

Notice that we are able to match the sketching bounds of [24] up to polylogarithmic factors in the space and time required.

We also show an $\Omega(n/\varepsilon)$ lower bound for minimum cut and all-pairs effective resistances in Section 4.4 and Section 4.6 respectively, showing that our results of Theorem 9 and Corollary 11 are space-optimal up to polylogarithmic factors.

▶ **Theorem 12.** *Fix $\varepsilon > 1/n$. Any randomized algorithm that outputs a $(1+\varepsilon)$-approximation to the minimum cut of a simple, undirected graph in a single pass over a stream with probability at least $2/3$ requires $\Omega(n/\varepsilon)$ bits of space. If the algorithm is deterministic and $\varepsilon \geq 1/n^{1/4}$, then the algorithm requires $\Omega(n/\varepsilon^2)$ bits of space.*[4]

[4] This latter assumption on ε is the same as used in [11].

▶ **Theorem 13.** *Fix $\varepsilon > 1/n$. Suppose $sk(\cdot)$ is a sketching algorithm that outputs at most $s = s(n, \varepsilon)$ bits, and f is an estimation algorithm such that,*

$$\forall a, b \in V, \qquad \Pr[f(a, b, sk(G)) \in (1 \pm \varepsilon) r_{a,b}] \geq \frac{2}{3},$$

where $r_{a,b}$ is the effective resistance of nodes a, b. Then we have $s \geq \Omega(n/\varepsilon)$.

We also study the minimum cut problem in the random-order streaming model, where edges arrive in a random order instead of an arbitrary worst-case order. We prove the following result for *simple* unweighted graphs, which are graphs with at most one edge between any two vertices.

▶ **Theorem 14.** *There exists a one-pass insertion-only streaming algorithm in the random-order model that outputs all minimum cuts $(S, V \setminus S)$, along with their corresponding edges $E(S, V \setminus S)$, for a simple, unweighted graph and with high probability using $\widetilde{O}(n)$ space. The algorithm has $\widetilde{O}(n)$ update time and $\widetilde{O}(n^2 k)$ post-processing time, where k is the value of the minimum cut.*

We note that Theorem 14 provides the exact minimum cut, which we find surprisingly possible in a single pass. This further adds to the surprises regarding minimum cut in the streaming model, as a 2-pass exact algorithm in arbitrary order streams was known [5] while computing the exact minimum cut in a single pass in an arbitrary order stream is known to require $\Omega(n^2)$ memory [52].

Given that determining whether a graph is connected from a random order stream requires $\Omega(n)$ space [12], our $\widetilde{O}(n)$ space algorithm for finding the exact minimum cut in random-order streams is optimal up to polylogarithmic space factors, even for just outputting the value. Note that we compute the minimum cut and all edges crossing the cut in addition to the value.

3.1 Our Techniques

Approximate Minimum Cut

Suppose that H is a $(1+\varepsilon)$-for-all sparsifier of G. Then the minimum cut of H is a $(1+\varepsilon)$-approximation to that of G. However, such a conclusion will not hold if H is instead a $(1+\varepsilon)$ for-each sparsifier, as the total number of cuts is exponential. As discussed earlier, fortunately the number of 1.1-approximate minimum cuts is $O(n^2)$ [29]. Hence, if we run a for-all sparsifier algorithm in parallel with accuracy $\varepsilon' = O(1)$, we can obtain a list of $O(n^2)$ candidate minimum cuts in G. Using the the $(1+\varepsilon)$ for-each sparsifier, we can then find a $(1+\varepsilon)$-approximation to the minimum cut by union bounding over the $O(n^2)$ candidates.

For the lower bound, we consider the k-edge-connectivity problem. The *edge-connectivity* of a graph is the minimum number of edges that need to be deleted to disconnect the graph. The k-edge-connectivity problem asks whether the edge connectivity of a graph is $< k$ or $\geq k$. Suppose that there is an algorithm that solves the $(1+\varepsilon)$-approximate minimum cut value problem. Then, we can use it to solve the k-edge-connectivity problem with $k = O(1/\varepsilon)$. Combining with the $\Omega(kn)$ bit space lower bound in the work of [49], it follows that there is an $\Omega(n/\varepsilon)$ bit space lower bound.

For-Each Spectral Sparsifier

The main difficulty in implementing the algorithms of [2] and [24] in the streaming setting is that both algorithms require careful graph decomposition. Take the algorithm in [2] as an example: it partitions the graph into several components, where each component is

well-connected and does not have a sparse cut smaller than $1/\varepsilon$. In the worst case, such a procedure may take $\log n$ levels recursively, which seems unachievable in a single-pass stream. Besides, since the for-each sketch of both algorithms is not a graph, it is unclear how to merge two sketches directly. Indeed, natural ways of merging such sketches may destroy the decomposition into sparse cuts. To address these issues, we instead consider the work of [14] in which the authors show how to construct a for-each sparsifier which is, in fact, a re-weighted subgraph of the input graph, with $n^{1+o(1)}/\varepsilon$ edges. Combining this and the merge-and-reduce framework gives a for-each spectral sparsifier with $n^{1+o(1)}/\varepsilon$ edges in a single-pass stream. The extra $n^{o(1)}$ factor in the space is an issue here. We notice that the extra $n^{o(1)}$ factor in the work of [14] is due to their near-linear time short cycle decomposition algorithm. Leveraging ideas from [41], we give a new short-cycle decomposition algorithm that trades off running time for space, namely, it achieves $m^{1+o(1)}$ time and $\widetilde{O}(m)$ space. While this translates to $\widetilde{O}(n/\varepsilon)$ space, it unfortunately gives $n^{o(1)}$ update time per edge. To fix this, we use online leverage score sampling to produce a virtual stream of only $\widetilde{O}(n/\varepsilon^2)$ edges that we instead run our algorithm on. By doing this, we reduce the time to $\widetilde{O}(1)$ per edge provided the number m of edges in the input satisfies $m \geq (n/\varepsilon^2)^{1+o(1)}$.

Approximate All-Pairs Effective Resistance

In [24], the authors show if we can get a for-each sparsifier, then we can use it to generate a data structure in near-linear time, and such a data structure can approximate all pairs of the effective resistance in $\widetilde{O}(n^2/\varepsilon)$ time. Combining this and our Lemma 10 yields our upper bound.

For the lower bound, we use communication complexity and consider a similar graph construction in [2], though we use new arguments based on random walks. Specifically, given a random binary string $s \in \{0,1\}^{n/\varepsilon}$, we encode it into a graph G where G is divided into $O(\varepsilon n)$ disjoint bipartite graphs G_i, and in each G_i, the existence of an edge between each pair corresponds to one random bit in s. We show that for every such pair (a, b), with high probability there is a $(1+\varepsilon)$-separation between the two cases (there is an edge between a, b or not), which yields an $\Omega(n/\varepsilon)$ lower bound. To prove this, in particular, we use the connection between the effective resistance and the hitting time on a graph and a recent concentration result about the hitting time on a random graph $G(n, p)$ (each possible edge on n vertices is included independently with probability p).

Exact Minimum Cut in Random-order Streams

Recall that we assume that the graph is simple and unweighted, and each edge arrives in a random order stream. We also assume the minimum cut size is $\Omega(\log n)$. If the size is smaller, a for-all cut sparsifier with accuracy parameter $\varepsilon' = 1/\log^2 n$ gives the exact value of the minimum cut. The main idea here is that by looking at the prefix of edges in a stream, which we will call the graph H, we roughly learn the sizes of all the cuts up to a small constant factor. Using this information, we learn all 1.1-approximate minimum cuts in G. The next question is how to get the exact value of all these cuts (so we can find the minimum one). For the cut edges in H, note that at this time, the cut values of all these cuts in H is $\Theta(\log n)$, and hence a for-all sparsifier of H with accuracy parameter $\varepsilon' = 1/\log^2 n$ gives the exact value of these cuts in H. We note that the total number of edges that participate in at least one of the 1.1-approximate non-singleton cuts is $O(n)$ [43], which is interesting because there could be as many as $O(n^2)$ such cuts. Hence, we can store all these $O(n)$ edges to get the exact cut values of the approximate minimum cuts in $G \setminus H$. Putting the two things together, we obtain the exact value of all 1.1-approximate minimum cuts and thus obtain the exact minimum cut value in G (along with all the minimum cuts).

Faster Runtime

In the above discussion, our algorithm for $(1+\varepsilon)$ min-cut in worst-case streams has an $\widetilde{O}(n^3)$ post-processing time, and the algorithm for exact min-cut in a random-order stream has an $\widetilde{O}(n^3)$ update time. The difficulty here is related: when enumerating all the $O(1)$-approximate minimum cuts, we need $O(n)$ time to evaluate the cost for each specific cut. We thus propose a general algorithmic framework to overcome this, which is based on the recursive contraction algorithm in [31] (Section 4.4). Namely, when enumerating all the approximate minimum cuts in the recursion tree, we simultaneously maintain a low-space sketch of the columns of the edge-vertex incidence matrix of the corresponding graph. Specifically, we apply a Johnson-Lindenstrauss sketch in our first case and a sparse recovery sketch in our second case, which reduces the evaluation time $O(n)$ to $O(\log n/\varepsilon^2)$ and polylog(n), respectively.

3.2 Open Problems

While we resolve several gaps between the upper and lower bounds, we discuss a remaining open problem. There exist fully dynamic streaming algorithms for approximate minimum cut using $\widetilde{O}(n/\varepsilon^2)$ space where the stream is allowed to both add or delete edges. From Theorem 12, we know that algorithms solving approximate minimum cut in insertion-only streams must use $\Omega(n/\varepsilon)$ space. Therefore, the space complexity of approximate minimum cut in a dynamic stream lies somewhere within these two values, and we believe resolving this gap is a problem of theoretical interest.

▶ **Open Question 15.** What is the exact space complexity of calculating a $(1+\varepsilon)$ approximation to the minimum cut of simple weighted graphs in a one-pass dynamic stream?

We do not have an exact conjecture about this, but we provide an alternative and fully self-contained proof to Theorem 12 in the full version of the paper [17], for which the techniques could help prove a lower bound for the fully dynamic case.

4 Spectral Sparsification and Minimum Cut in Worst-Case Streams

A key result of the section is our construction of Lemma 10, a single-pass insertion-only streaming algorithm for a $(1+\varepsilon)$-for-each cut sparsifier in undirected weighted graphs in $\widetilde{O}(n/\varepsilon)$ space and $n^{o(1)}$ update time. In Section 4.1 and 4.2, we first give our description of graphical spectral sketches (i.e., spectral sparsifiers that are reweighted subgraphs) and online leverage score sampling, which we use as subroutines in our final algorithm. In Section 4.3, we give our full algorithm and prove the correctness of our algorithm. In Section 4.4 and 4.6, we prove the two applications of our algorithm: streaming approximate minimum cut and all-pairs effective resistances.

4.1 Graphical Spectral Sketches

Our algorithm uses the following result in [14] as a subroutine.

▶ **Lemma 16** ([14]). *For $\varepsilon \in (0,1]$, there is an algorithm, which given G, runs in time $m^{1+o(1)}$, and with high probability returns a $(1+\varepsilon)$-for-each spectral sparsifier with $n^{1+o(1)}/\varepsilon$ edges.*

As pointed out by the work of [41], in the above algorithm, the extra $n^{o(1)}$ factor in the number of edges is due to the nearly-linear time short cycle decomposition used in the whole algorithm. We use the simpler and improved short-cycle decomposition algorithm of [41],

which outputs in $m^{1+o(1)}$ time a collection of edge-disjoint cycles of length $O(\log^2 n)$ that cover all but $O(n \log n)$ edges of the graph. Naïvely, the algorithm is also implemented in $m^{1+o(1)}$ space, but we show that a simple modification achieves near-linear space, as follows:

▶ **Lemma 17.** *There is an $m^{1+o(1)}$ time, $\widetilde{O}(m)$ space algorithm that outputs a collection of edge-disjoint cycles of length $O(\log^2 n)$ that cover all but $O(n \log n)$ edges of the graph.*

Proof. The algorithm in Section 3 of [41] first computes a *low-congestion cycle cover*, which is a collection of short cycles that cover most of the edges such that each edge belongs to a small number of cycles. The precise parameters are specified in the statement of Lemma 2 of the full version of [41]: compute a collection of cycles of length $d = O(2^{1/\varepsilon} \log n)$ that cover all but $O(n \log n)$ edges such that each edge appears on at most $c = 1/\varepsilon \cdot n^{O(\varepsilon)}$ cycles. For $\varepsilon = 1/\log\log n$, we obtain $d = O(\log^2 n)$ and $c = n^{o(1)}$. To obtain the short cycle decomposition, the proof of Lemma 2 describes a simple procedure of greedily selecting a subset of edge-disjoint cycles that cover an $\Omega(1/(dc))$ fraction of the edges in the cycle cover and then iterating on the uncovered edges.

Note that the low-congestion cycle cover consists of up to cm edges since each edge can appear in c cycles. Since $c = n^{o(1)}$, storing the entire cycle cover takes up too much space. Our key insight is to terminate the collection of cycles in each iteration of algorithm ImprovedShortCycleDecomp (see Figure 3 in the full version of [41]) once the cycle cover has a total of $O(m)$ edges. Terminating this subroutine early cannot increase the congestion compared to not terminating, thus we maintain the guarantee that the total set of cycles has congestion c. Using the above greedy selection of edge-disjoint cycles, we cover an $\Omega(1/(dc))$ fraction of the edges in our cycle cover, which is $\Omega(1/(dc))$ of all uncovered edges in the graph. Iterating on the uncovered edges gives the same iterations as before up to logarithmic factors. ◀

With our improved short-cycle decomposition, we get the following lemma:

▶ **Lemma 18.** *Given $\varepsilon \in (0, 1]$, there is an algorithm we denote* SpectralSketch*(G, ε), which given G, runs in time $m^{1+o(1)}$ and space $\widetilde{O}(m)$, and with high probability returns a $(1+\varepsilon)$-for-each spectral sparsifier of G with $\widetilde{O}(n/\varepsilon)$ edges.*

4.2 Online Leverage Score Sampling

For the purposes of a faster runtime, we consider only sampling (and reweighting) a fraction of edges during the stream. Existing online leverage score sampling methods allow us to choose edges in an online stream without retracting our choices such that our final graph has $\widetilde{O}(n/\varepsilon^2)$ edges and is a spectral-sparsifier of the original graph. Indeed, let $B_n \in \mathbb{R}^{\binom{n}{2} \times n}$ be the vertex edge incidence matrix of an undirected, unweighted complete graph on n vertices, where the e-th row b_e for edge $e = (u, v)$ has a 1 in column u, a (-1) in column v, and zeroes elsewhere. Then for an arbitrary undirected graph G, we can write its vertex edge incidence matrix $B = SB_n$ where $S \in \mathbb{R}^{\binom{n}{2} \times \binom{n}{2}}$ is a diagonal matrix with entry $\sqrt{w_e}$ in the e-th diagonal entry where w_e is the weight of edge e. It is well-known that the Laplacian matrix L of graph G can be written as $L = B^\top B$. Hence, if we can sample a subset of the rows of B to form a new matrix C (which corresponds to a subset of the edges in G) such that for every x, $\|Bx\|_2 \approx_\varepsilon \|Cx\|_2$, we then have $x^\top Lx \approx_\varepsilon x^\top C^\top Cx$ so that the subgraph H corresponding to C is a $(1+\varepsilon)$-spectral sparsifier of G. For more details, we refer the reader to [27, 15]. Formally, we have the following lemma.

▶ **Lemma 19** (Corollary 2.4 from [15]). *Let G be an undirected simple graph with n vertices and poly(n) bounded edge weights, and $\varepsilon \in (0,1)$. We can construct a $(1+\varepsilon)$-spectral sparsifier of G as a reweighted subgraph with $O(n \log^2 n/\varepsilon^2)$ edges, using only $O(n \log^2 n)$ bits of working memory in the online model. Additionally, the total running time is near-linear in the number of edges of G.*

4.3 Main Algorithm

Our algorithm is presented in Algorithm 1, which is based on the merge-and-reduce paradigm (see, for example, [10]) and uses an additional factor of polylog(n) space. At a high level, our algorithm maintains a number of blocks of edges $\mathbf{B}_0, \mathbf{B}_1, \ldots \mathbf{B}_{\log(n/\varepsilon)}$, each with size $\mathsf{m}_{\mathsf{space}} = \widetilde{O}(n/\varepsilon)$. The most recent edges are stored in $\mathbf{B}_0$; whenever $\mathbf{B}_0$ is full, the successive non-empty blocks $\mathbf{B}_0, \ldots, \mathbf{B}_i$ are merged and reduced to a new graph with $\mathsf{m}_{\mathsf{space}}$ edges, which will be stored in $\mathbf{B}_{i+1}$. Next, we show the correctness of our algorithm. Following a similar argument in [10], we first show the following lemma.

Algorithm 1 StreamingSpectralSparsifier(G, ε).

Input: Undirected graph $G(V,E)$ in a stream with n vertices and m edges, accuracy parameter $\varepsilon \in (\frac{1}{n}, 1)$, offline spectral-sparsifier subroutine SpectralSketch
Output: A graph H with weights w.
Initialize $\mathsf{m}_{\mathsf{space}} = n\log^c(n)/\varepsilon$ for some constant c, $\mathbf{B}_i \leftarrow \emptyset$
foreach *sampled edge e_t (Lemma 19) with rescaled weight u_t* **do**
  if $\mathbf{B}_0$ *does not contain* $\mathsf{m}_{\mathsf{space}}$ *edges* **then**
    $\mathbf{B}_0 \leftarrow e_t \cup \mathbf{B}_0$;
  else
    Let $i > 0$ be the minimal index such that $\mathbf{B}_i = \emptyset$;
    $\mathbf{B}_i, w_i \leftarrow \textsc{SpectralSketch}\left(\mathbf{M}, \frac{\varepsilon}{\log(n/\varepsilon)}\right)$, where $\mathbf{M} = \mathbf{B}_0 \cup \cdots \cup \mathbf{B}_{i-1}$;
    for $j = 0$ **to** $j = i-1$ **do**
      $\mathbf{B}_j \leftarrow \emptyset$;
    $\mathbf{B}_0 \leftarrow e_t$;
$\mathbf{B} \leftarrow \textsc{SpectralSketch}(\mathbf{B}_{\log(n/\varepsilon)} \cup \cdots \cup \mathbf{B}_0, \varepsilon)$
return $\mathbf{B}$.

▶ **Lemma 20** (see Lemma 5.2 in [10]). *Suppose that $\mathbf{B}_0, \ldots, \mathbf{B}_{i-1}$ are all empty while $\mathbf{B}_i$ is non-empty. Then $\mathbf{B}_i$ is a $(1+\frac{\varepsilon}{\log(n/\varepsilon)})^i$-for-each spectral sparsifier for the last $2^{i-1}\mathsf{m}_{\mathsf{space}}$ edges.*

Proof. We prove this by induction on $i \geq 0$. Recall that $\mathbf{B}_i$ can only be non-empty if at some point $\mathbf{B}_0$ contains $\mathsf{m}_{\mathsf{space}}$ and $\mathbf{B}_0, \mathbf{B}_1, \ldots, \mathbf{B}_{i-1}$ are all non-empty. By induction, suppose that for every $1 \leq j < i$, $\mathbf{B}_j$ is a $(1+\frac{\varepsilon}{\log(n/\varepsilon)})^j$-for-each spectral sparsifier for $2^{j-1}\mathsf{m}_{\mathsf{space}}$ edges. Then we have that $\mathbf{B}_i$ is a $(1+\frac{\varepsilon}{\log(n/\varepsilon)})$-for-each spectral sparsifier for $\mathbf{B}_0 \cup \mathbf{B}_1 \cup \ldots \cup \mathbf{B}_{i-1}$. From the mergeability property of spectral sparsifier graphs, we get that $\mathbf{B}_i$ is a $(1+\frac{\varepsilon}{\log(n/\varepsilon)})(1+\frac{\varepsilon}{\log(n/\varepsilon)})^{i-1} = (1+\frac{\varepsilon}{\log(n/\varepsilon)})^i$-for-each spectral sparsifier for the $\mathsf{m}_{\mathsf{space}} + \sum_{j=0}^{i-2} 2^j \mathsf{m}_{\mathsf{space}} = 2^{i-1}\mathsf{m}_{\mathsf{space}}$ edges, as needed. ◀

Proof of Lemma 10. The success probability of each call to subroutine SpectralSketch is at least $1 - 1/\text{poly}(n)$, hence we can assume that each call to this subroutine and the online leverage score sampling procedure is successful with high probability after taking a union

bound. It then follows from Lemma 20 that $\mathbf{B}_{\log(n/\varepsilon)} \cup \cdots \cup \mathbf{B}_0$ is a $(1 + \frac{\varepsilon}{\log(n/\varepsilon)})^{\log(n/\varepsilon)} \leq (1+\varepsilon)$-for-each spectral sparsifier of the original graph G. Thus $\mathbf{B}$ is a $(1 + O(\varepsilon))(1+\varepsilon) = (1 + O(\varepsilon))$-for-each spectral sparsifier of the original graph G.

Space Complexity. Next, we analyze the space complexity of our algorithm. As stated in Lemma 19, the online leverage score sampling procedure can be implemented in $O(n \log^2 n)$ bits of working memory. We maintain $\log(n/\varepsilon)$ blocks $\mathbf{B}_i$, each taking at most $O(\mathsf{m}_{\mathsf{space}})$ words of space. From Lemma 16 we have that each call to the subroutine SpectralSketch takes at most $\widetilde{O}(\mathsf{m}_{\mathsf{space}} \cdot \log(n/\varepsilon))$ words of space, as the total number of edges never exceeds $\mathsf{m}_{\mathsf{space}} \cdot \log(n/\varepsilon)$. Hence, the total space of the algorithm is $\widetilde{O}(n \log^2 n + \mathsf{m}_{\mathsf{space}} \log(n/\varepsilon)) = \widetilde{O}(n/\varepsilon)$.

Time Complexity. We finally analyze the time complexity of our algorithm. As stated in Lemma 19, the online leverage score sampling procedure can be done in time $\widetilde{O}(m)$, and after the sampling procedure, there are at most $O(n \log^2 n/\varepsilon^2)$ edges. For the merge-and-reduce procedure, each edge participates in at most $\log(n/\varepsilon)$ different spectral sparsifiers, one in block $\mathbf{B}_i$. Additionally, from Lemma 16 we have that SpectralSketch runs in $m^{1+o(1)}$ time where $m = \widetilde{O}(n/\varepsilon)$. We deduce that our total runtime is $\widetilde{O}(m + (n \log^2 n/\varepsilon^2)^{1+o(1)}) = \widetilde{O}(m) + (n/\varepsilon^2)^{1+o(1)}$. ◀

4.4 Approximate Minimum Cut Streaming Algorithm

Our main application of Lemma 10 is the one-pass streaming algorithm for a $(1+\varepsilon)$-approximation to the minimum cut. To achieve this, first recall that we can get a $(1+\varepsilon)$ for-all sparsifier of G in a one-pass stream in nearly-linear time, using $\widetilde{O}(n/\varepsilon^2)$ bits of space (Lemma 4).

The next lemma bounds the number of approximate minimum cuts.

▶ **Lemma 21** ([29]). *For constant $\alpha > 0$, the number of α-approximate minimum cuts is $O(n^{\lfloor 2\alpha \rfloor})$.*

Motivated by [2], we run our algorithm in Lemma 10 along with the streaming for-all sparsifier algorithm ALG in Lemma 4 with accuracy parameter $\varepsilon' = O(1)$. Suppose that the output of ALG is H. We then use H to find the cuts that have a size less than 1.5 times that of the minimum cut value (which can be done in $\text{poly}(n)$ time, see, e.g., [29]). Then, since the number of these approximate minimum cuts is $O(n^3)$, using our $(1+\varepsilon)$ for-each sparsifier, we can get a $(1+\varepsilon)$-approximation to each of these cut values with high probability after taking a union bound. Picking the cut with the minimum value gives us a $(1+\varepsilon)$-approximate minimum cut.

Faster Post-processing Time

The above algorithm is simple but, unfortunately, takes $O(n^3)$ post-processing time. To achieve a faster post-processing time, we consider the recursive contraction algorithm introduced by [31], which enumerates all α-approximate minimum cuts in time $O(n^{2\alpha} \log^2 n)$. We combine this with a Johnson-Lindenstrauss sketch to achieve $\widetilde{O}(n^2/\varepsilon^2)$ post-processing time, proving Theorem 9.

First, we state the lemma from [31]:

▶ **Lemma 22.** *There is an algorithm that can find all the α-approximate minimum cuts with high probability in $O(n^{2\alpha} \log^2 n)$ time and $\widetilde{O}(m)$ space.*

Below, we first give a brief explanation of the algorithm. At a high level, in each step, the algorithm randomly samples an edge proportional to its weights and then contracts the two nodes of the edge. When there are only two remaining nodes, we get a partition of the nodes corresponding to a specific cut of the graph. The work of [31] shows that if we repeat the algorithm $\text{poly}(n)$ times, we can finally enumerate all approximate minimum cuts with high probability. The above process is simple but needs $\text{poly}(n)$ runtime. To make the algorithm faster, [31] then proposes a recursive implementation of the contraction process. Basically, at each level of the recursion, the algorithm reduces the number of nodes by contraction by a constant factor and repeats the algorithm twice in each recursion level if the number of remaining nodes is $\Omega(1)$. Then, each leaf node of the recursion tree corresponds to a specific cut of the graph.

The technical difficulty in our case is evaluating the value of the corresponding cut in a short time when we enter a leaf node in the above process. To achieve this, recall that for a given vertex set $S \subseteq V$, the cut value between S and $V \setminus S$ is $x_S^\top L x_S = x_S^\top B^T B x_S = \|B x_S\|_2^2$ where x_S is the binary indicator vector of S and B is the edge-vertex matrix of the graph (see Section 4.2 for more details). The key observation here is since we only care about a $(1+\varepsilon)$-approximate value, we can apply a JL matrix T to Bx_S, where the matrix T has only $O(\log(n/\varepsilon)/\varepsilon^2)$ rows where for every $x \in \mathbb{R}^{O(n/\varepsilon)}$, $\|Tx\|_2^2 \approx_\varepsilon \|x\|_2^2$ with high probability.

Our algorithm procedure is described as follows. As before, after the stream, we first get a for-all sparsifier K with the accuracy parameter $\varepsilon' = 1/\log n$ (Lemma 4) and a $(1+\varepsilon)$ for-each sparsifier H of the original graph G (Lemma 10). We then use the algorithm in Lemma 22 to enumerate all the approximate minimum cuts of K with $\alpha = 1 + c/\log n$. When maintaining the recursion process of the contraction algorithm, we also maintain a sketch of the columns of the edge-vertex matrix B of H. Specifically, we initially compute a sketch of TB where T is a JL matrix with $O(\log n/\varepsilon^2)$ rows. Then, in the contraction process, when we contract a node pair (u, v), we also merge the u, v-th columns of the sketch with their sums. Note that in this procedure, when we enter a leaf node, there will only remain two columns of our sketch, and the two vectors are exactly TBx_S and $TBx_{V\setminus S}$, for which we can directly compute the cut value in $O(\log n/\varepsilon^2)$ time.

Next, we analyze the time and space complexity in the above procedure. Since the sketch has $O(\log n/\varepsilon^2)$ rows at each recursion level, we need $\widetilde{O}(N \log n/\varepsilon^2)$ words of space to save the sketch, where N is the number of the remaining nodes in the current recursion level. Combining two rows also takes $\widetilde{O}(\log n/\varepsilon^2)$ time. Recall that we need $O(n)$ space in each level and $O(N)$ time to contract two nodes in the original recursive contraction algorithm. This implies after the modification, the space complexity of the above algorithm procedure remains the same of $\widetilde{O}(m) = \widetilde{O}(n/\varepsilon)$, and the time complexity becomes $\widetilde{O}(n^2/\varepsilon^2)$. Putting everything together, we get the correctness of our Theorem 9.

4.5 Approximate Minimum Cut Streaming Lower Bound

To prove this lower bound, we consider the k-edge-connectivity problem as follows. The *edge-connectivity* of a graph is the minimum number of edges that need to be deleted to disconnect the graph. The k-edge-connectivity problem asks whether the edge connectivity of a graph is $< k$ or $\geq k$. The work of [49] shows that any deterministic algorithm that solves the k-edge-connectivity problem in insertion-only streams needs $\Omega(kn \log n)$ bits of space. We note that the proof in [49] also works for randomized algorithms with success probability at least $1 - 1/n$, which implies a lower bound of $\Omega(kn)$ bits of space for any randomized algorithm with constant probability of success.

▷ Claim 23 ([49]). Any randomized algorithm solving the k-edge-connectivity problem in an insertion-only stream with probability at least $2/3$ requires $\Omega(kn)$ bits of space. Moreover, any deterministic algorithm solving the k-edge-connectivity problem in an insertion-only stream requires $\Omega(kn \log n)$ bits.

We now prove the randomized and deterministic lower bounds of Theorem 12.

Randomized Lower Bound

▶ **Lemma 24.** *Fix $\varepsilon > 1/n$. Any randomized algorithm that outputs a $(1+\varepsilon)$-approximation to the minimum cut of a simple, undirected graph in a single pass over a stream with probability at least 2/3 requires $\Omega(n/\varepsilon)$ bits of space*

Proof. Consider the lower bound for k-edge-connectivity in [49] with $k = \frac{1}{10\varepsilon}$ (Claim 23). Distinguishing between whether the graph is $< k$-connected or $\geq k$-connected needs $\Omega(kn) = \Omega(n/\varepsilon)$ space. This implies that deciding whether the min-cut has value $< k$ or $\geq k$ also requires $\Omega(kn) = \Omega(n/\varepsilon)$ space. Suppose that there is a $(1+\varepsilon)$-approximation algorithm for the minimum cut value, in the case where the edge connectivity $\lambda < k$, the approximate value is at most $(1+\varepsilon)\lambda \leq (1+1/10k) \cdot (k-1) < k - 9/10$. In the case where the connectivity $\lambda \geq k$, the approximate value is at least $(1-\varepsilon)\lambda \geq (1-1/10k) \cdot k > k - 1/10$. This implies that an algorithm that gives a $(1+\varepsilon)$-approximation to minimum cut value, solves k-edge-connectivity for $k = \frac{1}{10\varepsilon}$. Thus, we obtain a lower bound of $\Omega(n/\varepsilon)$ bits of space for $(1+\varepsilon)$-approximating the value of the minimum cut. ◀

In addition to the proof above that considers the k-edge-connectivity problem, we also provide an alternative self-contained construction for the randomized result using the Index communication problem in the full version of the paper [17].

Deterministic Lower Bound

If the minimum cut value algorithm is deterministic, then we deterministically solve k-edge-connectivity for $k = \frac{1}{10\varepsilon}$. This gives us a lower bound of $\Omega(kn \log n) = \Omega(n \log n/\varepsilon)$ bits of space for deterministic algorithms. We show how to improve this lower bound to $\Omega(n/\varepsilon^2)$ bits for $\varepsilon \geq n^{-1/4}$. Note that this assumption on ε is consistent with the previous work of [11]. They also use this assumption on ε and prove a lower bound of $\Omega(n \log n/\varepsilon^2)$ bits for cut sparsifiers.

▶ **Lemma 25.** *Fix $\varepsilon > 1/n^{1/4}$. Any deterministic algorithm that outputs a $(1+\varepsilon)$-approximation to the minimum cut value of a simple, undirected graph in a single pass over a stream requires $\Omega(n/\varepsilon^2)$ bits of space*

Proof. A randomized insertion-only streaming algorithm for a for-all cut sparsifier needs $\Omega(n/\varepsilon^2)$ bits of space [2] (since any data structure that stores this information needs that much space). If we carefully look at the proof of [2] in section 3.1, their hard instance is a disjoint union of $\varepsilon^2 n/2$ bipartite graphs with $2/\varepsilon^2$ vertices each. They use the cut sparsifier to query cuts that have vertices only in one of these disjoint graphs, which implies that the cut sparsifier only needs to preserve the cut values for cuts that have at most $1/\varepsilon^4$ edges. Thus, a $(1+\varepsilon)$ cut sparsifier that preserves the cut values of all cuts of size at most $1/\varepsilon^4$ edges needs $\Omega(n/\varepsilon^2)$ bits of space.

We will now show how to simulate a $(1+\varepsilon)$ cut sparsifier that preserves the cut values of all cuts of size at most $1/\varepsilon^4$ using an algorithm for $(1+\varepsilon)$-approximate minimum cut. This will give us the desired lower bound. Let A be a deterministic insertion-only streaming algorithm for $(1+\varepsilon)$-approximate minimum cut value we run during the stream for input graph G.

After the stream, consider any cut S whose value we want to approximate within a $(1+\varepsilon)$ factor (note that the value is at most $1/\varepsilon^4$). We now add some extra edges to the stream for A. We first construct two cliques C_1 and C_2 on $2n$ vertices each and add their edges to the stream. We then add edges between all vertices of S and C_1 and similarly for all vertices in $\bar{S}$ and C_2. Call this new graph G'. We now end the stream and look at the output of A. We claim this is the $(1+\varepsilon)$-approximate value of cut S in the original graph.

To prove this, we must show that S is the minimum cut in the modified graph G'. We know that the value of S is at most $1/\varepsilon^4 \leq n$ (since $\varepsilon \geq n^{-1/4}$). Consider any cut that separates vertices in $C_1 \cup S$. Such a cut has a size of at least $2n$. The same applies to any cut separating vertices in $C_2 \cup \bar{S}$. Thus, the minimum cut is $C_1 \cup S$. None of the new edges we added cross this cut, so the size of this cut remains unchanged in G', implying that we get a $(1+\varepsilon)$-approximation to the cut value in G. Note that the algorithm A has to be deterministic for us to do this because we have to repeat this process for exponentially many cuts (potentially 2^n).

The space taken to build the sparsifier for insertion-only streams is the space taken for A when run on $5n$ vertices. This implies that any deterministic insertion-only streaming algorithm for $(1+\varepsilon)$-approximate minimum cut value needs $\Omega(n/\varepsilon^2)$ bits of space, proving the lower bound for deterministic algorithms. ◀

Proof of Theorem 12. The proof of the theorem directly results from combining Lemma 24 and Lemma 25. Notably, this shows that the spectral sparsifier result in Lemma 10 is optimal in space complexity up to polylogarithmic factors. ◀

4.6 Application: All-Pairs Effective Resistances

Another application of our streaming algorithm from Lemma 10 is calculating all-pairs effective resistances in graph streams. Suppose we have a $(1+\varepsilon)$ for-each spectral sparsifier H of the original graph G. Then, we may hope it will be helpful to approximate the pseudoinverse of G. In fact, in the work of [24], it has been shown that if we have a $(1+\varepsilon)$ for-each spectral sparsifier, we can use it to generate an effective resistance sketch in near-linear time, which can compute the all-pairs effective resistances in $\widetilde{O}(n^2/\varepsilon)$ additional time (Algorithm 8 in [24]). From this, we immediately see the correctness of our Corollary 11.

Lower Bound

We next consider lower bounds. In Theorem 13, we show that if a sketch can approximate each effective resistance with constant probability, then such a sketch must have size at least $\Omega(n/\varepsilon)$. We need the following lemmas about effective resistances and random graphs.

▶ **Lemma 26** (see, e.g., [51]). *For a graph G with unit weight for each edge, we have $C(s,t) = 2mr_{\text{eff}}(s,t)$, where $C(s,t)$ is the commute time of s and t, which is defined as the expected number of steps of a random walk to go from s to t and back.*

▶ **Lemma 27** ([40]). *Let $G(n,p)$ be an Erdos-Renyi random graph. Then we have, with high probability that for any pair $w \neq v$,*

$$h(w,v) = \frac{2|E|}{\deg(v)} + \left\{ \begin{array}{ll} -1 & \text{if } (w,v) \in E \\ -1 + 1/p & \text{if } (w,v) \notin E \end{array} \right\} + O\left(\frac{(\log n)^{3/2}}{\sqrt{n}}\right),$$

where $h(s,t)$ is the hitting time of s,t, defined as the expected number of steps of a random walk from s to t. Note that we have $C(s,t) = h(s,t) + h(t,s)$.

Our reduction is based on the following Index problem.

▶ **Lemma 28** (Index Lower Bound [34]). *Suppose that Alice has a random string $u \in \{0,1\}^n$ and Bob has a random index $i \in [n]$. If Alice sends a single message to Bob from which Bob can recover u_i with probability at least $2/3$, where the probability is over both the randomness of the protocol and the input, then Alice must send $\Omega(n)$ bits to Bob.*

At a high level, we will reduce the Index problem to the effective resistance problem. Suppose Alice has a string $s \in \{0,1\}^{\Theta(n/\varepsilon)}$. We will construct a graph G to encode s such that Bob can recover s_i with constant probability from a $(1 \pm \varepsilon)$ effective resistance sketch of G. By the communication complexity lower bound of the Index problem (Lemma 28), the cut sketch must use $\Omega(n/\varepsilon)$ bits.

Proof of Theorem 13. We first give our construction of the graph G.

Construction of G. We use a bipartite graph G to encode s. Let L and R be the left and right nodes of G where $|L| = |R| = n/2$. We partition L into $O(n\varepsilon)$ disjoint blocks $L_1, \ldots, L_{O(n\varepsilon)}$ of the same size $\frac{1}{\varepsilon}$, and similarly, we partition R into $R_1, \ldots, R_{O(n\varepsilon)}$. We divide s into $n\varepsilon$ disjoint strings $s_i \in \{0,1\}^{(\frac{1}{\varepsilon})^2}$ of the same length. We will encode s_i using the edges from L_i to R_i, where we use G_i to denote the subgraph (L_i, R_i). In particular, if the $s_i(j) = 1$, we form an edge that connects the corresponding node pair in L_i and R_i with unit weight. Note that each G_i is disconnected from the other G_j in this construction.

Recovering a bit in s from an effective resistance sketch of G. Suppose Bob wants to recover a specific bit of s, which belongs to the sub-string $z = s_i$ and has an index t in z. This coordinate corresponds to whether there is an edge between $u \in L_i$ and $v \in R_i$.

Next, we consider the effective resistance between u and v for these two cases. Note that since G_i is disconnected from the other G_j, we just need to consider the sub-graph G_i. By construction, G_i is a random graph with $p = \frac{1}{2}$. From Lemma 26 we get that we only need to show both the hitting time $h(u,v)$ and $h(v,u)$ has a $(1+\varepsilon)$-separation (then the $r_{\text{eff}}(u,v)$) will also have a $(1+\varepsilon)$-separation. Then, from Lemma 27, we get that both the $h(u,v)$ and $h(v,u)$ will have a $\Theta(1)$ gap for the two cases, and with high probability, we have that both of $h(u,v)$ and $h(v,u)$ are $\Theta(1/\varepsilon)$. From this, we can get that $r_{\text{eff}}(u,v)$ will have a $(1+\varepsilon)$-separation for the two cases (note that Alice can also send the degree of each node and the number of edges in each G_i to Bob, which only needs $O(n\log(1/\varepsilon))$ bits), which yields an $\Omega(n/\varepsilon)$ lower bound of the effective resistance sketch size. ◀

5 Exact Minimum Cut in Random-Order Streams

In this section, we give an $\widetilde{O}(n)$ algorithm that outputs the minimum cut in a simple, unweighted graph in a single-pass random-order stream. Recall that in a simple graph, there is at most one edge between any pair of vertices. For a clearer demonstration, we will present an initial construction for an algorithm with an $\widetilde{O}(n^2)$ update time when an edge arrives. Then, we shall show how to improve the update time to $\widetilde{O}(n)$, proving Theorem 14.

5.1 Initial Construction

We will use the algorithm in Lemma 4 (for-all sparsifier in a stream) as a subroutine. The whole algorithm is given in Algorithm 2. Below, we first give a high-level explanation of our algorithm. We first consider the case when the minimum cut size is $s = \Omega(\log n)$. Since we are now considering the random-order model, a prefix of the edges gives us partial information about the cut sizes. Let H be the subgraph of G which is formed by a prefix of the edges of the stream where $|H| \approx \frac{|G| \log n}{s}$ and $|G|$, $|H|$ are the number of the edges in G and H respectively. By a Chernoff bound, one can show that with high probability, for every subset $S \subset V$, $w_H(S, V \setminus S)$ is a small constant approximation to $w_G(S, V \setminus S)$. H might be too large to store in memory, so we store H_1, a $(1+\varepsilon)$-for-all sparsifier of H, during the stream (we will decide ε later). Therefore, using the graph H_1, we know all cuts in G whose cut size is within a factor of 1.1 of the true minimum cut of G. After this step, when a new edge $e \in G \setminus H$ arrives, we can use graph H_1 to check whether e belongs to some 1.1-approximate minimum cut in G, and if so, we save this edge (from Lemma 30 we know that the total number of these edges saved is at most $O(n)$). The next question is how to estimate the exact value of these 1.1-approximate cuts in H. The crucial observation is since the minimum cut size of H is an integer and is at most $\Theta(\log n)$, we can set the approximation parameter $\varepsilon = 1/\log^2 n$ for H_1. This gives the exact value of $w_H(S, V \setminus S)$ if S and $V \setminus S$ is a constant-approximate minimum cut in G (since the error is at most $O(\log n) \cdot 1/\log^2 n < 1$). Putting these things together, after the stream, we can enumerate all 1.1-approximate minimum cuts and obtain their exact values, thus getting the exact minimum cut value.

The remaining case to handle is when the minimum cut size is $O(\log n)$. Similarly, in this case, setting $\varepsilon = 1/\log^2 n$ will give us the exact value of the minimum cut. Finally, we do not know the value of s, so we will try all powers of 2 for it. Note that we do not need the exact value; a 2-approximation to s will suffice. The detailed description of the algorithm is given in Algorithm 2.

To show the correctness of our algorithm, we first prove the following key lemma.

▶ **Lemma 29.** *Suppose that H is a subgraph of G formed by a prefix of the edges in the random order model. We have that for every $S \subset V$, if $|H| = |G| \cdot \frac{\ell}{w_G(S, V \setminus S)}$, then with probability at least $1 - 2e^{-c_2 \cdot \ell}$, $|w_H(S, V \setminus S) - \ell| \leq 0.1\ell$.*

Proof. Consider each edge e that is a cut edge between S and $V \setminus S$ (let T denote the set of such edges). Let y_e denote the indicator random variable where $y_e = 1$ if $e \in H$ and $y_e = 0$ otherwise. Then we have that $\mathbb{E}[w_H(S, V \setminus S)] = \mathbb{E}[\sum_{e \in T} y_e] = \ell$ from the assumption in the random-order model. By a standard Chernoff bound, we have that

$$\Pr[|w_H(S, V \setminus S) - \ell| \geq 0.1\ell] \leq 2e^{-c_2 \cdot \ell}$$

for some constant c_2. ◀

We also need the following structural result for the approximate minimum cuts of a graph.

▶ **Lemma 30** ([43])**.** *For any simple, unweighted graph and any constant $\varepsilon > 0$, the total number of edges that participate in non-singleton $(2-\varepsilon)$-approximate minimum cuts is at most $O(n)$.*

We first consider the case when the minimum cut size $s < c \log n$. In this case, the minimum cut of H will never exceed $c \log n$ since H is a subgraph of G. Since the cut value is an integer, setting $\varepsilon = 1/\log^2 n$ gives the exact value of the size of the minimum cut.

Algorithm 2 MinCutRandomOrder.

Input : Undirected and unweighted graph $G(V, E)$ in a random-order stream with n vertices and m edges.

ALG_1 is an instance of Lemma 4 with $\varepsilon = 1/\log^2 n$.
Maintain the degree of each node d_i during the stream.
foreach *edge e in the graph stream* **do**
    Feed e to ALG_1 ;
    if *e is the 2^i-th edge for some $i \in \mathbb{N}$* **then**
        $H_1 \leftarrow$ output of ALG_1 (Here H_1 is a for-all sparsifier of the prefix graph H);
        if *the minimum cut size of H_1 is larger than $c \log n$* **then**
            Save H_1 and break the for loop.
$H_1 \leftarrow$ output of ALG_1 ;
if *there is no new edge in the stream* **then**
    return *the minimum cut value of H_1.*
$T \leftarrow \emptyset$.
foreach *new edge e during the stream* **do**
    if *e is the cut edge between some S and $V \setminus S$ where S and $V \setminus S$ is a non-singleton 1.1-approximate minimum cut in H_1* **then**
        Add e to T
foreach *S where S and $V \setminus S$ is a non-singleton 1.1-approximate minimum cut in H_1* **do**
    $v_S \leftarrow w_{H_1}(S, V \setminus S) + |\{e \in T : e \text{ is a cut edge between } S \text{ and } V \setminus S\}|$
return *the minimum value of* $\min v_S$ *and* $\min d_i$

We next consider the other case when $s \geq c \log n$. We will first show that, as the number of edges in H increases, the minimum cut size of H will increase to $\Theta(\log n)$ when $|H| = \Theta\big(\frac{|G| \log n}{s}\big)$. We next analyze the value of $w_H(S, V \setminus S)$. Let $\mathcal{S}_i$ $(1 \leq i \leq \log n)$ denote the set of nodes such that

$$\mathcal{S}_i = \{S \subset V \mid s \cdot 2^{i-1} \leq w_G(S, V \setminus S) \leq s \cdot 2^i\}$$

For each $\mathcal{S}_i$, from Lemma 21 we know that $|\mathcal{S}_i| \leq O(n^{2^{i+1}})$ and for every $S \in \mathcal{S}_i$, from Lemma 29 we know that with probability at least $1 - 2e^{-c_2 c \cdot \log n \cdot 2^{i-1}} = 1 - 2n^{-c_2 c \cdot 2^{i-1}}$, $w_H(S, V \setminus S) \cdot \frac{|G|}{|H|}$ is a 1.1-approximation of $w_G(S, V \setminus S)$. Note that the constant c here can be sufficiently large, and after taking a union bound over all $S \in \mathcal{S}_i$ and all $\log n$ $\mathcal{S}_i$ we get that with probability at least 9/10, for every $S \subset V$, $w_H(S, V \setminus S) \cdot \frac{|G|}{|H|}$ is a 1.1-approximation of $w_G(S, V \setminus S)$. From the above analysis we immediately know that when $\frac{|G|}{|H|} = \Theta\big(\frac{s}{\log n}\big)$ from the subgraph H, we can learn the set

$$\mathcal{S} = \{S \subset V \mid s \leq w_G(S, V \setminus S) \leq 1.1^2 s\},$$

and the next step is choosing the true minimum cut among them. For every non-single node set $S \in \mathcal{S}$, as mentioned, since $w_H(S, V \setminus S)$ is $\Theta(\log n)$, setting $\varepsilon = 1/\log^2 n$ we can get its exact value. The remaining step is to estimate the value of $w_{G \setminus H}(S, V \setminus S)$. As described in Algorithm 2, after the previous step, we save every edge $e \in G \setminus H$, where e belongs to at least one of the non-singleton 1.1^2-approximate minimum cuts in $\mathcal{S}$. We know the exact

value of $w_{G\setminus H}(S, V \setminus S)$ from this edge set. Putting the two things together, for every $S \in \mathcal{S}$ and $|S| \geq 2$, we know the value of $w_G(S, V \setminus S)$ after taking a sum of the two parts. For every singleton cut, we simply maintain the degree of each node during the stream. Thus, after taking the minimum value of the two parts (singleton and non-singleton cuts), we get the exact value of the minimum cut.

Space Complexity

In the first phase of the algorithm, we use one instance of the algorithm in Lemma 4 with $\varepsilon = 1/\log^2 n$, which takes space $\widetilde{O}(n)$. In the second phase of the algorithm, we save all the edges that belong to the approximate minimum cut in H. From Lemma 30, we know that there are at most $O(n)$ such edges, and hence this part takes $O(n)$ words of space. We also maintain the degree of each node during the stream, which takes $O(n)$ words of space. Putting everything together, the space usage of our algorithm is $\widetilde{O}(n)$.

Time Complexity

In the first phase of the algorithm, when one edge e comes, the update and query time of ALG_1 is polynomial, and we can also find the minimum cut in polynomial time. Hence, the update time here is still polynomial. In the second phase, when one edge e comes, we can enumerate all 1.1-approximate minimum cuts to check whether e belongs to one of the approximate minimum cuts (we can use $O(n^2)$ time to enumerate all approximate minimum cuts, see, e.g., [29]). Hence, we can do the update of this step in polynomial time. After all edges come, we can similarly enumerate all minimum cuts, from which the overall algorithm can be implemented in polynomial time.

5.2 Faster Update and Post-Processing Time

In the above algorithm, the runtime bottleneck is when a non-prefix edge e comes; we need to enumerate all approximate minimum cuts in the prefix graph to check whether to keep this edge. To get a faster runtime, we instead do a check when we collect n edges and consider a similar procedure to what we did in Section 4.4 where we use the recursive contraction algorithm with parameter $\alpha = 1 + \frac{1}{\log n}$. The difference is when doing the recursive contraction algorithm, we maintain the sketch SB where S is a k-sparse recovery matrix (see, e.g., [20]) with $k \log(n/k)$ rows where $k = O(\log n)$ and B is the edge-vertex matrix of the n edges we currently collected. Particularly, during the recursive contraction process, when we contract the nodes u, v, we merge the columns that u, v corresponds to in the sketch SB and replace them with their sum. Next, we consider each leaf node in the recursion, corresponding to one specific cut for the prefix graph. We can check whether it is a non-singleton and approximate minimum cut in $O(1)$ time from the information the algorithm keeps. Note that if without the sketch matrix S, for each edge e we want to check, it belongs to this specific cut if and only if the e-th coordinates of the remaining two columns of the edge-vertex matrix are 1 and -1, and otherwise these two coordinates are both 0. Since the minimum cut of the prefix graph is $\Theta(\log n)$, we can get that both of the remaining columns are $O(\log n)$-sparse before multiplying the sketch matrix S. This means that a k-sparse approximate recovery algorithm with $k = O(\log n)$ is sufficient to recover the indices of the non-zero coordinates of the remaining columns, which helps us to find the corresponding edges.

Time and Space Complexity

We analyze the time and space complexity of the above procedure. At each level of the recursion, since the sketch has $k\log(n/k)$ rows, we need $\widetilde{O}(Nk)$ words of space to save the sketch, and it takes $\widetilde{O}(k)$ time to combine two rows, where N is the number of the remaining nodes in the current level of the recursion. Recall that we need $O(n)$ space in each level and $O(N)$ time to contract two nodes in the original recursive contraction algorithm. This implies the modification only increases the time and space complexity by a factor of $\widetilde{O}(k)$. Since the decoding time of the k-sparse recovery sketch is $k \cdot \text{polylog}(n)$ and $k = O(\log n)$, we have that the procedure has time complexity $\widetilde{O}(n^2)$ and space complexity $\widetilde{O}(n)$. Finally, note that when we collect a set of n edges in the suffix graph, we can do our above checking procedure while collecting the following n edges in the graph stream, which results in a strictly $O(n)$ update time of our algorithm. Similarly, suppose the minimum cut of the graph is $\Theta(c)$. When we do the post-processing, we can use the c-sparse recovery sketch when enumerating all the approximate minimum cuts, which results in a $\widetilde{O}(n^2c)$ post-processing time. Putting everything together, we have the correctness of Theorem 14.

Lastly, we note that our algorithm can not only return the exact min-cut value but also collect all the edges that participate in any of the minimum cuts. When computing the for-all sparsifier of the prefix graph, for an edge that participates in at least one approximate min-cut, the probability that it will be sampled is $\Omega(1)$ as otherwise, the estimated cut value in such a cut will have two different values each with a constant probability, contradicting the guarantees of the for-all sparsifier. Hence, we can collect all of these edges from oversampling by a constant factor, which results in finding all the minimum cuts of the input graph and the edges crossing them.

Abstract

We study learning-augmented streaming algorithms for estimating the value of MAX-CUT in a graph. In the classical streaming model, while a 1/2-approximation for estimating the value of MAX-CUT can be trivially achieved with $O(1)$ words of space, Kapralov and Krachun [STOC'19] showed that this is essentially the best possible: for any $\epsilon > 0$, any (randomized) single-pass streaming algorithm that achieves an approximation ratio of at least $1/2 + \epsilon$ requires $\Omega(n/2^{\mathrm{poly}(1/\epsilon)})$ space.

We show that it is possible to surpass the 1/2-approximation barrier using just $O(1)$ words of space by leveraging a (machine learned) oracle. Specifically, we consider streaming algorithms that are equipped with an ϵ-accurate oracle that for each vertex in the graph, returns its correct label in $\{-1, +1\}$, corresponding to an optimal MAX-CUT solution in the graph, with some probability $1/2 + \epsilon$, and the incorrect label otherwise.

Within this framework, we present a single-pass algorithm that approximates the value of MAX-CUT to within a factor of $1/2 + \Omega(\epsilon^2)$ with probability at least 2/3 for insertion-only streams, using only $\mathrm{poly}(1/\epsilon)$ words of space. We also extend our algorithm to fully dynamic streams while maintaining a space complexity of $\mathrm{poly}(1/\epsilon, \log n)$ words.

1 Introduction

Given an undirected, unweighted graph, the MAX-CUT problem seeks to find a partition of the vertices (a cut) that maximizes the number of edges with endpoints on opposite sides of the partition (such edges are said to be "cut" by the partition). MAX-CUT is a well-known NP-hard problem. The best-known approximation algorithm, developed by Goemans and Williamson [22], achieves a 0.878-approximation ratio, which is the best possible under the Unique Games Conjecture [33].

We consider the problem of estimating the value of MAX-CUT in a graph under the streaming model of computation, where MAX-CUT denotes some fixed optimal solution, and the value of a solution is defined as the number of edges in the graph that are cut by the partition. In this model, the graph is presented as a sequence of edge insertions and

© Yinhao Dong, Pan Peng, and Ali Vakilian;

deletions, known as a graph stream. The objective is to analyze the graph's structure using minimal space. The model is called insertion-only if the stream contains only edge insertions; if both insertions and deletions are allowed, it is referred to as the dynamic model.

In the streaming model, a 1/2-approximation for estimating the value of MAX-CUT can be trivially achieved using $O(1)$ words of space, where a word represents the space required to encode the size of the graph. This is done by simply counting the total number m of edges in the graph and outputting $m/2$. However, Kapralov and Krachun [31] showed that this is essentially the best possible: for any $\epsilon > 0$, any (randomized) single-pass streaming algorithm in the insertion-only model that achieves an approximation ratio of at least $1/2 + \epsilon$ requires $\Omega(n/2^{\text{poly}(1/\epsilon)})$ space.

We focus on the problem of estimating the value of MAX-CUT in a streaming setting within the framework of *learning-augmented algorithms*. These algorithms utilize predictions from a machine learning model to solve a problem, where the predictions typically include some information about the optimal solution, future events, or yet unread data in the input stream (see, e.g., [24, 27, 13]). Learning-augmented algorithms have gained significant attention recently, partly due to numerous breakthroughs in machine learning. Ideally, such algorithms should be both *robust* and *consistent*: when the predictions are accurate, the algorithm should outperform the best-known classical algorithms, and when the predictions are inaccurate, the algorithm should still provide performance guarantees that are close to or match those of the best-known classical algorithms. Despite the extensive research in the area of learning-augmented algorithms over the past few years[1], our understanding of this framework within the streaming model remains limited.

In this work, we consider the *noisy prediction* model, also referred to as *ϵ-accurate predictions*, where the algorithm has oracle access to a prediction vector $Y \in \{-1, 1\}^n$. Each entry Y_v is *independently correct* with probability $\frac{1}{2} + \epsilon$, where $\epsilon \in (0, \frac{1}{2}]$ represents the *bias* of the predictions. Specifically, for each $v \in V$, we have $\Pr[Y_v = x^*_v] = \frac{1}{2} + \epsilon$ and $\Pr[Y_v = -x^*_v] = \frac{1}{2} - \epsilon$, where $x^* \in \{-1, 1\}^n$ denotes some fixed but unknown optimal solution for MAX-CUT. This model captures a scenario where an ML algorithm (or oracle) provides predictions for the values of x^* that are unreliable and noisy, being only slightly better than random guesses (i.e., just above the 1/2 probability that a random solution would satisfy). Recently, variants of this prediction model have been used to design improved approximation algorithms for MAX-CUT and constraint satisfaction problems (CSPs) [14, 21].

Specifically, we study the following question:

> *Given an oracle $\mathcal{O}$ that provides ϵ-accurate predictions Y about the optimal* MAX-CUT *of a streaming graph G, can we improve upon the worst-case approximation ratio and space trade-off established by [31], specifically the $(\frac{1}{2} + \epsilon)$ ratio with $\Omega(n)$ space complexity, for estimating the* MAX-CUT *value?*

1.1 Our Results

We provide an affirmative answer by presenting a single-pass streaming algorithm that surpasses the 1/2-approximation barrier for the value of MAX-CUT using only $\text{poly}(1/\epsilon)$ (resp., $\text{poly}(1/\epsilon, \log n)$)words of space in insertion-only (resp., fully dynamic) streams. Formally, we establish the following result:

[1] See `https://algorithms-with-predictions.github.io/` for an up-to-date repository of publications on this topic.

▶ **Theorem 1.** *Let $\epsilon \in (0, \frac{1}{2}]$. Given oracle access to an ϵ-accurate predictor, there exists a single-pass streaming algorithm that provides a $\left(\frac{1}{2} + \Omega(\epsilon^2)\right)$-approximation for estimating the MAX-CUT value of a graph in insertion-only (resp., fully dynamic) streams using* $\mathrm{poly}(1/\epsilon)$ *(resp.,* $\mathrm{poly}(1/\epsilon, \log n)$*) words of space with probability at least* $2/3$*.*

By using median trick, we can boost the success probability to $1 - \delta$, where $\delta \in (0, 1)$, with an additional $\log(1/\delta)$ factor in space complexity.

We remark that the "robustness" of our learning-augmented algorithm comes for free, as we can always compute the number of edges in the graph and report half of them as a $\frac{1}{2}$-approximation solution, regardless of the value of ϵ. Furthermore, with predictions, it gains an advantage of $\Omega(\epsilon^2)$ in the approximation ratio. Furthermore, our algorithm does not require the exact value of ϵ; a constant-factor approximation of ϵ is sufficient. This estimation is only needed to determine the sample size.

Our algorithm is based on the observation that when the maximum degree of a graph is relatively small (i.e. smaller than $\mathrm{poly}(\epsilon) \cdot m$), the number of edges with endpoints having different predicted labels already provides a strictly better-than-$\frac{1}{2}$ approximation of the MAX-CUT value. For general graphs, we employ some well-known techniques, such as the CountMin sketch and ℓ_0-sampling, to distinguish between high-degree and low-degree vertices in both insertion-only and dynamic streams. By combining a natural greedy algorithm with an algorithm tailored for the low-degree part, we achieve a non-trivial approximation. The space complexity of the resulting algorithm is primarily determined by the subroutines for identifying the set of high-degree vertices, which can be bounded by $\mathrm{poly}(1/\epsilon, \log n)$.

We note that it is standard to assume that the noisy oracle $\mathcal{O}$ has a compact representation and that its space complexity is not included in the space usage of our algorithm, following the conventions in streaming learning-augmented algorithms [24, 27, 13, 1]. Indeed, as noted in [24], a reliable oracle can often be learned space-efficiently in practice as well. Moreover, we show that in the case of random-order streams, our algorithm only needs to query $\mathcal{O}$ for the labels of a constant number of vertices (see Section B).

Additionally, our algorithm actually works in a weaker model. That is, we can assume that in our streaming framework, the predicted label of each vertex is associated with its edges. Thus, the elements in a stream can be represented as $(e = (u, v), Y_u, Y_v)$, where the predictions $(Y_u)_{u \in V}$ remain consistent throughout the stream. The case of dynamic streams is defined analogously. Notably, in this model, no additional space is required to store the predictors.

1.2 Related Work

Learning-augmented algorithms have been actively researched in online algorithms [42, 35, 4, 6, 7, 25, 41, 5, 36], data structures [43, 20, 46, 39, 44], graph algorithms [18, 12, 8, 37, 16, 10, 40, 23, 17, 14, 21, 11], and sublinear-time algorithms [26, 19, 38, 45]. Our algorithms fit into the category of learning-augmented streaming algorithms. Hsu et al. [24] introduced learning-augmented streaming algorithms for frequency estimation, and Jiang et al. [27] extended this framework to various norm estimation problems in data stream. Recently, Aamand et al. [2, 1] developed learning-augmented frequency estimation algorithms, that improve upon the work of [24]. Additionally, Chen et al. [13] studied single-pass streaming algorithms to estimate the number of triangles and four-cycles in a graph. It is worth mentioning that both our work and previous efforts on learning-augmented streaming algorithms mainly focus on using predictors to improve the corresponding space-accuracy trade-offs. Furthermore, recent studies have explored learning-augmented algorithms for MAX-CUT and constraint

satisfaction problems (CSPs) [14, 21] within a variant of our prediction model. In particular, for the Max-CUT problem, Cohen-Addad et al. [14] achieved a $(0.878+\tilde{\Omega}(\epsilon^4))$-approximation using SDP. However, it is important to emphasize that their setting differs significantly from ours: they focus on finding the MAX-CUT in the offline setting, whereas our goal is to estimate its size in the streaming setting. Additionally, Ghoshal et al. [21] developed an algorithm that yields near-optimal solutions when the average degree is larger than a threshold determined only by the bias of the predictions, independent of the instance size. They further extended this result to weighted graphs and the MAX-3LIN problem.

The aforementioned lower bound proven in [31] is, in fact, the culmination of a series of works exploring the trade-offs between space and approximation ratio for the streaming MAX-CUT value problem, including [29, 34, 30]. In our main context, we focus on the problem of estimating the value of MAX-CUT in a streaming setting. Another related problem is that of finding the MAX-CUT itself in a streaming model. Since even outputting the MAX-CUT requires $\Omega(n)$ space, research in this area primarily considers streaming algorithms that use $\tilde{O}(n)$ space, known as the semi-streaming model, where $\tilde{O}(\cdot)$ hides polylogarithmic factors. Beyond the trivial $\frac{1}{2}$-approximation algorithm, which simply partitions the vertices randomly into two parts, there exists a $(1-\epsilon)$-approximation algorithm for finding MAX-CUT. This algorithm works by constructing a $(1-\epsilon)$-cut or spectral sparsifier of the input streaming graph, which can be achieved in $\tilde{O}(n)$ space (see e.g. [3, 32]), and then finding the MAX-CUT of the sparsified graph (which may require exponential time).

2 Preliminaries and Problem Statement

Notations. Throughout the paper we let $G=(V,E)$ be an undirected, unweighted graph with n vertices and m edges. Given a vertex $v \in V$ and disjoint sets $S,T \subseteq V$, $e(v,S)$ denotes the number of edges incident to v whose other endpoint belongs to S; $e(v,S) = |\{(u,v) \mid (u,v) \in E \text{ and } u \in S\}|$. Similarly, we define $e(S,T)$ to denote the number of edges with one endpoint in S and the other endpoint in T; $e(S,T) = \sum_{v \in T} e(v,S)$. A cut (S,T) of G is a bipartition of V into two disjoint subsets S and T. The value of the cut (S,T) is $e(S,T)$.

In the descriptions of our algorithms, for a vertex set $S \subseteq V$, we define S^+ (resp. S^-) as the set of vertices with predicted $+$ (resp. $-$) signs by the given ϵ-accurate oracle $\mathcal{O}$. Note that S^+ and S^- form a bipartition of S. Throughout the paper, all space complexities are measured in words unless otherwise specified. The space complexity in bits is larger by a factor of $\log m + \log n$.

In our algorithms, we utilize several well-known techniques in the streaming model, which we define below.

CountMin Sketch [15]. Given a stream of m integers from $[n]$, let f_i denote number of occurrences of i in the stream, for any $i \in [n]$. In CountMin sketch, there are k uniform and independent random hash functions $h_1, h_2, \ldots, h_k : [n] \to [w]$ and an array C of size $k \times w$. The algorithm maintains C, such that $C[\ell, s] = \sum_{j:h_\ell(j)=s} f_j$ at the end of the stream. Upon each query of an arbitrary $i \in [n]$, the algorithm returns $\tilde{f}_i = \min_{\ell \in [k]} C[\ell, h_\ell(i)]$.

▶ **Theorem 2** (CountMin Sketch [15]). *For any $i \in [n]$ and any $\ell \in [k]$, we have $\tilde{f}_i \geq f_i$ and $\mathbb{E}[C[\ell, h_\ell(i)]] \leq f_i + \frac{m}{w}$. The space complexity is $O(kw)$ words. Let $\epsilon, \delta \in (0,1)$. If we set $k = \lceil \frac{e}{\epsilon} \rceil$ and $w = \lceil \ln \frac{1}{\delta} \rceil$, then for any $i \in [n]$, we have $\tilde{f}_i \geq f_i$, and with probability at least $1-\delta$, $\tilde{f}_i \leq f_i + \epsilon m$. The corresponding space complexity is $O(\frac{1}{\epsilon} \ln \frac{1}{\delta})$ words.*

Reservoir Sampling [47]. The algorithm samples k elements from a stream, such that at any time $m \geq k$, the sample consists of a uniformly random subset of size k of the elements seen so far. The space complexity of the algorithm is $O(k(\log n + \log m))$ bits.

▶ **Definition 3** (ℓ_0-sampler [28]). *Let $x \in \mathbb{R}^n$ be a non-zero vector and $\delta \in (0,1)$. An ℓ_0-sampler for x returns FAIL with probability at most δ and otherwise returns some index i such that $x_i \neq 0$ with probability $\frac{1}{|\operatorname{supp}(x)|}$ where $\operatorname{supp}(x) = \{i \mid x_i \neq 0\}$ is the support of x.*

The following theorem states that ℓ_0-samplers can be maintained using a single pass in dynamic streams.

▶ **Theorem 4** (Theorem 2 in [28]). *Let $\delta \in (0,1)$. There exists a single-pass streaming algorithm for maintaining an ℓ_0-sampler for a non-zero vector $x \in \mathbb{R}^n$ (with failure pribability δ) in the dynamic model using $O(\log^2 n \log \delta^{-1})$ bits of space.*

Problem Statement. In this work, we consider the problem of estimating the value of MAX-CUT of a graph G in the learning-augmented streaming model. Formally, given an undirected, unweighted graph $G = (V, E)$, which is represented as a sequence of edges, i.e., $\sigma := \langle e_1, e_2, \dots \rangle$ for $e_i \in E$, our goal is to scan the sequence in one pass and output an estimate of the MAX-CUT value, while minimizing space usage. When the sequence contains only edge insertions, it is referred to as an *insertion-only* stream. When the sequence contains both edge insertions and deletions, it is referred to as a *dynamic* stream. Note that in dynamic streams, the sequence of the stream is often represented as $\sigma := \langle (e_1, \Delta_1), (e_2, \Delta_2), \dots \rangle$, where for each i, $e_i \in E$ and $\Delta_i = 1$ (resp. -1) denotes edge insertion (resp. deletion).

Furthermore, we assume that the algorithms are equipped with an oracle $\mathcal{O}$, which provides ϵ-accurate predictions $Y \in \{-1, 1\}^n$ where $\epsilon \in (0, \frac{1}{2}]$. This information is provided via an external oracle, and for the purpose of our algorithm, we assume that the edges in the stream are annotated with the predictions of their endpoints.

Specifically, for each vertex $v \in V$, $\Pr[Y_v = x^*_v] = \frac{1}{2} + \epsilon$ and $\Pr[Y_v = -x^*_v] = \frac{1}{2} - \epsilon$, where $x^* \in \{-1, 1\}^n$ is some fixed but unknown optimal solution. Following previous works on MAX-CUT with ϵ-accurate predictions [14, 21], we also assume that the $(Y_v)_{v \in V}$ are independent.

Finally, since we assume that accuracy parameter of predictions, ϵ, is known to the algorithm up to a constant factor in advance, and the space complexity of all algorithms in the paper is at most $\operatorname{poly}(\log n, 1/\epsilon, 1/\delta)$, we will assume throughout that $m = \Omega(\epsilon^{-11}\delta^{-7})$. Otherwise, when $m = O(\epsilon^{-11}\delta^{-7})$, we can simply store all edges in $\operatorname{poly}(1/\epsilon, 1/\delta)$ space and compute the MAX-CUT exactly.

3 The Simple Case of Low-Degree Graphs

In this section, we show that when all vertices have "low-degree" then following the ϵ-accurate predictions, we can beat the $\frac{1}{2}$-approximation barrier for streaming MAX-CUT. Informally, once an edge (u, v) arrives in the stream, we consult the noisy oracle $\mathcal{O}$ and if their endpoints are predicted to be in different parts by the noisy oracle, i.e., $\mathcal{O}(u) \neq \mathcal{O}(v)$, we increase the size of the cut by one. This can be simply implemented using $O(\log n)$ bits of space. Refer to Algorithm 1 for a formal description.

Next, we analyze the space complexity and approximation guarantee of Algorithm 1.

Algorithm 1 A learning-augmented streaming algorithm for estimating MAX-CUT value in low-degree graphs.

Input: Graph G with $\Delta < \frac{\epsilon^2\delta m}{4} - \frac{1}{4\epsilon^2}$ as a stream of edges, an ϵ-accurate oracle $\mathcal{O} \to \{-1, 1\}$
Output: Estimate of the MAX-CUT value of G

```
initialize X ← 0.
for each edge (u, v) in the stream do
    Y_u = O(u), Y_v = O(v)
    if Y_u ≠ Y_v then X ← X + 1
return X
```

▶ **Theorem 5.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0, 1)$. Given an ϵ-accurate oracle $\mathcal{O}$ for the MAX-CUT of G, if the maximum degree Δ in G satisfies $\Delta < \frac{\epsilon^2\delta m}{4} - \frac{1}{4\epsilon^2}$, then with probability at least $1 - \delta$, Algorithm 1 outputs a $(\frac{1}{2} + \epsilon^2)$-approximation of the MAX-CUT value of G. The algorithm uses $O(1)$ words of space.*

Proof. We first analyze the space complexity. In Algorithm 1, we maintain a counter X for the edges whose endpoints have different signs, which takes $O(\log n)$ bits of space. Therefore, the space complexity of the algorithm is $O(1)$ words.

Next, we show that Algorithm 1 with high probability outputs a $(\frac{1}{2} + \epsilon^2)$-approximation of the MAX-CUT when all vertices have low degrees.

Since (V^+, V^-) is a feasible cut of G, where V^+ (resp. V^-) is the set of vertices with predicted $+$ (resp. $-$) signs by the given ϵ-accurate oracle $\mathcal{O}$, we have $X \le \mathrm{OPT}$, where OPT denotes the (optimal) MAX-CUT value of G. For each edge $(u, v) \in E$, define an indicator random variable X_{uv} such that $X_{uv} = 1$ if $Y_u \neq Y_v$, and is zero otherwise.

Let x^* be the assignment vector corresponding to the MAX-CUT in G. Specifically, if $(S, V \setminus S)$ is the MAX-CUT of G, then $x^*_v = 1$ if $v \in S$, and -1 otherwise. Consider the following two cases:

(I.1) If $x^*_u \neq x^*_v$, then $\Pr[Y_u \neq Y_v] = \Pr[Y_u = x^*_u \wedge Y_v = x^*_v] + \Pr[Y_u \neq x^*_u \wedge Y_v \neq x^*_v] = \frac{1}{2} + 2\epsilon^2$.
(I.2) If $x^*_u = x^*_v$, then $\Pr[Y_u \neq Y_v] = \Pr[Y_u = x^*_u \wedge Y_v \neq x^*_v] + \Pr[Y_u \neq x^*_u \wedge Y_v = x^*_v] = \frac{1}{2} - 2\epsilon^2$.

Note that $X = \sum_{(u,v)\in E} X_{uv}$ and $\mathbb{E}[X_{uv}] = \Pr[Y_u \neq Y_v]$. Then, by the linearity of expectation,

$$\begin{aligned}\mathbb{E}[X] = \sum_{\substack{(u,v)\in E\\ x^*_u \neq x^*_v}} \mathbb{E}[X_{uv}] + \sum_{\substack{(u,v)\in E\\ x^*_u = x^*_v}} \mathbb{E}[X_{uv}] &= \mathrm{OPT} \cdot (\frac{1}{2} + 2\epsilon^2) + (m - \mathrm{OPT}) \cdot (\frac{1}{2} - 2\epsilon^2)\\ &= (\frac{1}{2} - 2\epsilon^2)m + 4\epsilon^2 \cdot \mathrm{OPT}\\ &\ge (\frac{1}{2} + 2\epsilon^2) \cdot \mathrm{OPT},\end{aligned}$$

where the last inequality holds since $\frac{1}{2} - 2\epsilon^2 \ge 0$ for $\epsilon \in (0, \frac{1}{2}]$ and $m \ge \mathrm{OPT}$.

Next, we bound $\mathrm{Var}[X]$. Note that $\mathrm{Var}[X_{uv}] = \mathbb{E}[X_{uv}] - \mathbb{E}[X_{uv}]^2$ since $(X_{uv})_{(u,v)\in E}$ are indicator random variables. By (I.1) and (I.2), $\mathrm{Var}[X_{uv}] = \frac{1}{4} - 4\epsilon^4$.

(II.1) If $x^*_u \neq x^*_v$, then $\mathrm{Var}[X_{uv}] = \left(\frac{1}{2} + 2\epsilon^2\right) - \left(\frac{1}{2} + 2\epsilon^2\right)^2 = \frac{1}{4} - 4\epsilon^4$.
(II.2) If $x^*_u = x^*_v$, then $\mathrm{Var}[X_{uv}] = \left(\frac{1}{2} - 2\epsilon^2\right) - \left(\frac{1}{2} - 2\epsilon^2\right)^2 = \frac{1}{4} - 4\epsilon^4$.

For any pair of distinct edges $(u,v),(u,w) \in E$, we compute $\mathbb{E}[X_{uv}X_{uw}] = \Pr[X_{uv} = X_{uw} = 1] = \Pr[Y_v = Y_w = -Y_u]$ and $\mathrm{Cov}[X_{uv}, X_{uw}] = \mathbb{E}[X_{uv}X_{uw}] - \mathbb{E}[X_{uv}] \cdot \mathbb{E}[X_{uw}]$.

(III.1) If $x^*_u = x^*_v$ and $x^*_u = x^*_w$, then

$$\begin{aligned}\mathbb{E}[X_{uv}X_{uw}] &= \Pr[Y_u = x^*_u \wedge Y_v \neq x^*_v \wedge Y_w \neq x^*_w] + \Pr[Y_u \neq x^*_u \wedge Y_v = x^*_v \wedge Y_w = x^*_w] \\ &= \left(\frac{1}{2}+\epsilon\right)\left(\frac{1}{2}-\epsilon\right)^2 + \left(\frac{1}{2}-\epsilon\right)\left(\frac{1}{2}+\epsilon\right)^2 = \frac{1}{4}-\epsilon^2.\end{aligned}$$

Therefore, $\mathrm{Cov}[X_{uv}, X_{uw}] = \left(\frac{1}{4}-\epsilon^2\right) - \left(\frac{1}{2}-2\epsilon^2\right)^2 = \epsilon^2 - 4\epsilon^4$.

(III.2) If $x^*_u = x^*_v$ and $x^*_u \neq x^*_w$, then

$$\begin{aligned}\mathbb{E}[X_{uv}X_{uw}] &= \Pr[Y_u = x^*_u \wedge Y_v \neq x^*_v \wedge Y_w = x^*_w] + \Pr[Y_u \neq x^*_u \wedge Y_v = x^*_v \wedge Y_w \neq x^*_w] \\ &= \left(\frac{1}{2}+\epsilon\right)^2\left(\frac{1}{2}-\epsilon\right) + \left(\frac{1}{2}-\epsilon\right)^2\left(\frac{1}{2}+\epsilon\right) = \frac{1}{4}-\epsilon^2.\end{aligned}$$

Therefore, $\mathrm{Cov}[X_{uv}, X_{uw}] = \left(\frac{1}{4}-\epsilon^2\right) - \left(\frac{1}{2}-2\epsilon^2\right)\left(\frac{1}{2}+2\epsilon^2\right) = 4\epsilon^4 - \epsilon^2$.

(III.3) If $x^*_u \neq x^*_v$ and $x^*_u = x^*_w$, then

$$\begin{aligned}\mathbb{E}[X_{uv}X_{uw}] &= \Pr[Y_u = x^*_u \wedge Y_v = x^*_v \wedge Y_w \neq x^*_w] + \Pr[Y_u \neq x^*_u \wedge Y_v \neq x^*_v \wedge Y_w = x^*_w] \\ &= \left(\frac{1}{2}+\epsilon\right)^2\left(\frac{1}{2}-\epsilon\right) + \left(\frac{1}{2}-\epsilon\right)^2\left(\frac{1}{2}+\epsilon\right) = \frac{1}{4}-\epsilon^2.\end{aligned}$$

Therefore, $\mathrm{Cov}[X_{uv}, X_{uw}] = \left(\frac{1}{4}-\epsilon^2\right) - \left(\frac{1}{2}+2\epsilon^2\right)\left(\frac{1}{2}-2\epsilon^2\right) = 4\epsilon^4 - \epsilon^2$

(III.4) If $x^*_u \neq x^*_v$ and $x^*_u \neq x^*_w$, then

$$\begin{aligned}\mathbb{E}[X_{uv}X_{uw}] &= \Pr[Y_u = x^*_u \wedge Y_v = x^*_v \wedge Y_w = x^*_w] + \Pr[Y_u \neq x^*_u \wedge Y_v \neq x^*_v \wedge Y_w \neq x^*_w] \\ &= \left(\frac{1}{2}+\epsilon\right)^3 + \left(\frac{1}{2}-\epsilon\right)^3 = \frac{1}{4}+3\epsilon^2.\end{aligned}$$

Therefore, $\mathrm{Cov}[X_{uv}, X_{uw}] = \left(\frac{1}{4}+3\epsilon^2\right) - \left(\frac{1}{2}+2\epsilon^2\right)^2 = \epsilon^2 - 4\epsilon^4$.

Hence, $\mathrm{Cov}[X_{uv}, X_{uw}] \leq \epsilon^2 - 4\epsilon^4$. So,

$$\begin{aligned}\mathrm{Var}[X] &= \sum_{(u,v)\in E} \mathrm{Var}[X_{uv}] + \sum_{\substack{(u,v),(u,w)\in E \\ v\neq w}} \mathrm{Cov}[X_{uv}, X_{uw}] + \sum_{\substack{(u,v),(w,z)\in E \\ u,v,w,z \text{ all distinct}}} \mathrm{Cov}[X_{uv}, X_{wz}] \\ &\leq m \cdot \left(\frac{1}{4} - 4\epsilon^4\right) + m \cdot \Delta \cdot \left(\epsilon^2 - 4\epsilon^4\right) + 0 \leq \left(\frac{1}{4} + \Delta\epsilon^2\right) m.\end{aligned}$$

Then, by applying Chebyshev's inequality,

$$\begin{aligned}\Pr\left[X \leq \left(\frac{1}{2}+\epsilon^2\right)\mathrm{OPT}\right] &\leq \Pr\left[|X - \mathbb{E}[X]| \geq \epsilon^2 \cdot \mathrm{OPT}\right] \\ &\leq \frac{\mathrm{Var}[X]}{\epsilon^4 \cdot \mathrm{OPT}^2} \\ &\leq \frac{\left(\frac{1}{4}+\Delta\epsilon^2\right)m}{\epsilon^4 \cdot \mathrm{OPT}^2} && \triangleright\ \mathrm{Var}[X] \leq (\frac{1}{4}+\Delta\epsilon^2)m \\ &\leq \frac{4\cdot(\frac{1}{4}+\Delta\epsilon^2)}{\epsilon^4 m} && \triangleright\ \mathrm{OPT} \geq \frac{m}{2} \\ &< \delta. && \triangleright\ \Delta < \frac{\epsilon^2\delta m}{4} - \frac{1}{4\epsilon^2}\end{aligned}$$

So, with probability at least $1-\delta$, $X \geq (\frac{1}{2}+\epsilon^2)\cdot\mathrm{OPT}$. ◀

4 Our Algorithm for General Graphs

In this section, we present our $(\frac{1}{2} + \Omega(\epsilon^2))$-approximation for streaming MAX-CUT in $O(\text{poly}(1/\epsilon, 1/\delta))$ space using ϵ-accurate predictions. For better presenting our algorithmic ideas, we first consider the problem in the *random order* streams in Section 4.1. Next, in Section 4.2, we show how to extend our algorithm to arbitrary order streams using more advanced sketching techniques. Finally, in Section 4.3, we show that our algorithm also work in dynamic streams where both edge insertions and deletions are allowed.

Offline Implementation. We first describe our algorithm in the offline setting. Recall that our algorithm from Section 3 is effective when the maximum degree in the graph is smaller than a pre-specified threshold $\phi = \Theta(\epsilon^2\delta m)$, where δ is the target failing probability of the algorithm. Let H and L respectively denote the high-degree (i.e., vertices with degree at least ϕ) and low-degree (i.e., vertices with degree less than ϕ) vertices in the input graph $G = (V, E)$. Now, by the guarantee of Theorem 5, suppose we have a $(\frac{1}{2} + \epsilon^2)$-approximation of MAX-CUT on the induced subgraph $G[L]$ denoted by (L^+, L^-). This cut is exactly the cut suggested by the given ϵ-accurate oracle $\mathcal{O}$. Next, we extend this cut using the vertices in H in a greedy manner. We pick vertices in H one by one in an arbitrary order and each time add them to either L^+ or L^- sections so that the size of cut maximized. We denote the resulting cut by $(C, V \setminus C)$. Another cut we consider is simply (H, L). We show at least one these two cuts is a $(\frac{1}{2} + \Omega(\epsilon^2))$-approximation for MAX-CUT on G with high probability.

Throughout the paper, we define high-degree vertices as those with degree $\geq \frac{\epsilon^2 m}{c}$, where $c = \frac{80}{\delta}$. Vertices with degrees below this threshold are considered low-degree.

▶ **Theorem 6.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0, 1)$. The best of $(C, V \setminus C)$ and (H, L) cuts is a $(\frac{1}{2} + \frac{\epsilon^2}{16})$-approximation for MAX-CUT on G with probability at least $1 - \delta$.*

Without loss of generality, we assume that $e(H, L) < (\frac{1}{2} + \epsilon^2) \cdot \text{OPT}$, otherwise we are done. Then it suffices to show that $e(C, V \setminus C) \geq (\frac{1}{2} + \frac{\epsilon^2}{16}) \cdot \text{OPT}$. Recall that the cut $(C, V \setminus C)$ is obtained by extending the cut (L^+, L^-) of $G[L]$ suggested by the given ϵ-accurate oracle using the vertices in H in a greedy manner. We first show that Algorithm 1 works for the induced subgraph $G[L]$.

▶ **Lemma 7.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0, 1)$. Suppose that $e(H, L) < (\frac{1}{2} + \epsilon^2) \cdot \text{OPT}$, $c = \frac{80}{\delta}$ and $m > \frac{c^3\delta}{\epsilon^4} + \frac{1}{4\epsilon^4}$. Then there exists a $(\frac{1}{2} + \epsilon^2)$-approximation of the MAX-CUT value of $G[L]$ with probability at least $1 - \delta$.*

Proof. Note that $m = m_L + m_H + e(H, L)$, where m_L (resp. m_H) is the number of edges in $G[L]$ (resp. $G[H]$). Then we have $m_L = m - m_H - e(H, L) > m - \frac{4c^2}{\epsilon^4} - (\frac{1}{2} + \epsilon^2)m$, since $|H| \leq \frac{2m}{\epsilon^2 m/c} = \frac{2c}{\epsilon^2}$ and $e(H, L) < (\frac{1}{2} + \epsilon^2) \cdot \text{OPT} \leq (\frac{1}{2} + \epsilon^2)m$.

Since the high-degree threshold is $\frac{\epsilon^2 m}{c}$, we have $\Delta_L < \frac{\epsilon^2 m}{c}$, where Δ_L is the maximum degree of $G[L]$. It is easy to check that $\frac{\epsilon^2 m}{c} < \frac{\epsilon^2\delta}{4}(m - \frac{4c^2}{\epsilon^4} - (\frac{1}{2} + \epsilon^2)m) - \frac{1}{4\epsilon^2}$ by substituting in the conditions for c and m. It follows that $\Delta_L < \frac{\epsilon^2\delta m_L}{4} - \frac{1}{4\epsilon^2}$.

Therefore, by the guarantee of Theorem 5, with probability at least $1 - \delta$, there exists a $(\frac{1}{2} + \epsilon^2)$-approximation of MAX-CUT on $G[L]$ denoted by (L^+, L^-), i.e., $e(L^+, L^-) \geq (\frac{1}{2} + \epsilon^2) \cdot \text{OPT}_L$, where OPT_L is the size of the MAX-CUT value of $G[L]$. ◀

▶ **Lemma 8.** *Let $\epsilon \in (0, \frac{1}{2}]$. Suppose that $e(H, L) = \alpha \cdot \text{OPT}$ (where $\alpha < \frac{1}{2} + \epsilon^2$) and $m > \frac{8c^2}{\epsilon^8}$. We have $\text{OPT}_L > (1 - \alpha - \epsilon^4) \cdot \text{OPT}$, where OPT_L is the size of the MAX-CUT value of $G[L]$.*

Proof. Note that $\mathrm{OPT} \leq \mathrm{OPT}_L + \mathrm{OPT}_H + e(H, L)$, where OPT_L (resp. OPT_H) is the size of the MAX-CUT of $G[L]$ (resp. $G[H]$). It follows that

$$\begin{aligned}
\mathrm{OPT}_L &\geq \mathrm{OPT} - \mathrm{OPT}_H - e(H, L) \\
&\geq \mathrm{OPT} - \frac{4c^2}{\epsilon^4} - e(H, L) && \triangleright\ \mathrm{OPT}_H \leq m_H \leq |H|^2 \leq \frac{4c^2}{\epsilon^4} \\
&= \mathrm{OPT} - \frac{4c^2}{\epsilon^4} - \alpha \cdot \mathrm{OPT} && \triangleright\ e(H, L) = \alpha \cdot \mathrm{OPT} \\
&> \mathrm{OPT} - \epsilon^4 \cdot \mathrm{OPT} - \alpha \cdot \mathrm{OPT} && \triangleright\ \frac{4c^2}{\epsilon^4} < \epsilon^4 \cdot \frac{m}{2} \leq \epsilon^4 \cdot \mathrm{OPT} \\
&= (1 - \alpha - \epsilon^4) \cdot \mathrm{OPT}.
\end{aligned}$$

◀

Proof of Theorem 6. Since the algorithm returns the best of two cuts, if the value of the cut (H, L) is at least $(\frac{1}{2} + \epsilon^2) \cdot \mathrm{OPT}$ (i.e., $e(H, L) \geq (\frac{1}{2} + \epsilon^2) \cdot \mathrm{OPT}$), then we are done. Hence, without loss of generality, we can assume that the size of the cut (H, L) is strictly less than $(\frac{1}{2} + \epsilon^2) \cdot \mathrm{OPT}$. Based on Lemma 7 and Lemma 8, we have

$$\begin{aligned}
e(C, V \setminus C) &\geq e(L^+, L^-) + \sum_{v \in H} \max\{e(v, L^+), e(v, L^-)\} \\
&\geq \left(\frac{1}{2} + \epsilon^2\right) \mathrm{OPT}_L + \sum_{v \in H} \max\{e(v, L^+), e(v, L^-)\} && \triangleright\ e(L^+, L^-) \geq (\tfrac{1}{2} + \epsilon^2)\mathrm{OPT}_L \\
&\geq \left(\frac{1}{2} + \epsilon^2\right) \mathrm{OPT}_L + \frac{1}{2} \cdot e(H, L) && \triangleright\ \max\{e(v, L^+), e(v, L^-)\} \geq \frac{e(v, L)}{2} \\
&> \left(\frac{1}{2} + \epsilon^2\right) (1 - \alpha - \epsilon^4)\mathrm{OPT} + \frac{\alpha}{2} \cdot \mathrm{OPT} && \triangleright\ \mathrm{OPT}_L > (1 - \alpha - \epsilon^4)\mathrm{OPT} \\
&= \left(\frac{1}{2} + (1 - \alpha)\epsilon^2 - \frac{\epsilon^4}{2} - \epsilon^6\right) \mathrm{OPT} \\
&> \left(\frac{1}{2} + \left(\frac{1}{2} - \epsilon^2\right)\epsilon^2 - \frac{\epsilon^4}{2} - \epsilon^6\right) \mathrm{OPT} && \triangleright\ \alpha < \frac{1}{2} + \epsilon^2 \\
&\geq \left(\frac{1}{2} + \frac{\epsilon^2}{16}\right) \mathrm{OPT}, && \triangleright\ \left(\frac{1}{2} - \epsilon^2\right)\epsilon^2 - \frac{\epsilon^4}{2} - \epsilon^6 \geq \frac{\epsilon^2}{16}
\end{aligned}$$

with probability at least $1 - \delta$. ◀

4.1 Warm-up: Random Order Streams

Overview of the Algorithm. Suppose that the edges of $G = (V, E)$ arrive one by one in a random order stream. At a high level, we would like to run our algorithm from Section 3 for low-degree vertices L (i.e., the induced subgraph on L), and then, using a greedy approach, add the high-degree vertices H to the constructed cut. However, the set H and L are not known a priori in the stream, and it is not clear how to store the required information to run the described algorithm, space efficiently.

To detect high-degree vertices and collect sufficient information to run the greedy approach on them at the end of the stream, we rely on the random order of the stream. We store a small number of edges from the beginning of the stream and then gather degree information for those vertices that are candidates for being high-degree. More precisely, we store the first $\mathrm{poly}(1/\epsilon, 1/\delta)$ edges in the (random order) stream and use them to identify a set $\tilde{H}$ of size $\mathrm{poly}(1/\epsilon, 1/\delta)$ that contains all high-degree vertices H with probability $1 - \delta$. We then store all edges between vertices in $\tilde{H}$ throughout the stream, which requires $\mathrm{poly}(1/\epsilon, 1/\delta)$ words of space. Additionally, for every vertex $v \in \tilde{H}$, we maintain the number of edges between v

and $\tilde{L}^+ \coloneqq V^+ \setminus \tilde{H}$, as well as between v and $\tilde{L}^- \coloneqq V^- \setminus \tilde{H}$. It is straightforward to check that these counters require $\text{poly}(1/\epsilon, 1/\delta)$ words of space in total. We then apply Algorithm 1 to the graph $G[V \setminus \tilde{H}]$ to approximate the MAX-CUT value of $G[V \setminus \tilde{H}]$.

Finally, at the end of stream, since we can compute the degree of all vertices in $\tilde{H}$ exactly, we can determine the set of high degree vertices $H \subseteq \tilde{H}$. First, for the remaining vertices $\tilde{S} \coloneqq \tilde{H} \setminus H$, we (hypothetically) feed them to our algorithm for the low-degree vertices. Note that we have all edges between any pair of vertices in $\tilde{S}$, as well as all the number of their incident edges to $\tilde{L}^+$ and $\tilde{L}^-$. Therefore, we can compute the size of (L^+, L^-) cut exactly. Now it only remains to run the greedy algorithm for the high-degree vertices H. Similarly, since we have computed the number of incident edges of high-degree vertices to $\tilde{L}^+, \tilde{L}^-$, and we have stored all edges with both endpoints in $\tilde{H}$, we can perform the greedy extension of $(\tilde{L}^+ \cup \tilde{S}^+, \tilde{L}^- \cup \tilde{S}^-)$ using H. Moreover, using the same set of degree information, we can compute the size of $(H, V \setminus H)$ as well. Then, we can return the best of these two cuts as our estimate of MAX-CUT in G.

Next, we prove the approximation guarantee and the space complexity of the algorithm. The algorithm is formally given in Algorithm 2.

▶ **Theorem 9.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0, 1)$. Given an ϵ-accurate oracle $\mathcal{O}$ for the MAX-CUT of G, there exists a single-pass $(\frac{1}{2} + \frac{\epsilon^2}{16})$-approximation algorithm for estimating the MAX-CUT value of G in the insertion-only random-order streams. The algorithm uses $O(\frac{1}{\delta^6\epsilon^8})$ words of space. The approximation holds with probability at least $1 - \delta$.*

▶ **Lemma 10.** *Let $\delta \in (0, 1)$. Then $\tilde{H}$ contains all high-degree vertices in G with probability at least $1 - \frac{\delta}{2}$.*

Proof. Suppose that v is a high-degree vertex in G, i.e., $\deg(v) \geq \frac{\epsilon^2 m}{c}$. For each edge e_i incident to v, define an indicator random variable

$$X_i = \begin{cases} 1, & \text{if } e_i \text{ is in the first } \frac{\beta}{\delta^3\epsilon^4} \text{ edges of the random order stream} \\ 0, & \text{otherwise} \end{cases}$$

So, $\mathbb{E}[X_i] = \Pr[X_i = 1] = \frac{\beta}{\delta^3\epsilon^4 m}$. We define $X \coloneqq \sum_{i \in [\deg(v)]} X_i$ to denote the number of edges incident to v that appear in the first $\frac{\beta}{\delta^3\epsilon^4}$ edges of the random order stream. Then, $\mathbb{E}[X] = \sum_{i \in [\deg(v)]} \mathbb{E}[X_i] = \frac{\beta \deg(v)}{\delta^3\epsilon^4 m}$.

Next, we bound $\text{Var}[X]$. For any $i \in [\deg(v)]$, $\text{Var}[X_i] = \mathbb{E}[X_i^2] - (\mathbb{E}[X_i])^2 = \mathbb{E}[X_i] - (\mathbb{E}[X_i])^2 = \frac{\beta}{\delta^3\epsilon^4 m} - (\frac{\beta}{\delta^3\epsilon^4 m})^2 = \frac{\beta}{\delta^3\epsilon^4 m} - \frac{\beta^2}{\delta^6\epsilon^8 m^2}$. Since $(X_i)_{i \in [\deg(v)]}$ are negatively correlated, $\text{Var}[X] \leq \sum_{i \in [\deg(v)]} \text{Var}[X_i] = \deg(v) \cdot \left(\frac{\beta}{\delta^3\epsilon^4 m} - \frac{\beta^2}{\delta^6\epsilon^8 m^2}\right) \leq \frac{\beta \deg(v)}{\delta^3\epsilon^4 m}$. Therefore, by Chebyshev's inequality,

$$\begin{aligned} \Pr[v \notin \tilde{H}] = \Pr[X \leq 0] &= \Pr\left[X \leq \mathbb{E}[X] - \frac{\beta \deg(v)}{\delta^3\epsilon^4 m}\right] \\ &\leq \frac{\text{Var}[X] \cdot \delta^6\epsilon^8 m^2}{\beta^2 \deg^2(v)} \\ &\leq \frac{\delta^3\epsilon^4 m}{\beta \cdot \deg(v)} && \triangleright\ \text{Var}[X] \leq \frac{\beta \deg(v)}{\delta^3\epsilon^4 m} \\ &\leq \frac{\delta^3\epsilon^2 c}{\beta}. && \triangleright\ \deg(v) \geq \frac{\epsilon^2 m}{c} \end{aligned}$$

By our definition of high-degree vertices, there are at most $\frac{2m}{\epsilon^2 m/c} = \frac{2c}{\epsilon^2}$ high-degree vertices in G. By union bound, with probability at least $1 - \frac{2c}{\epsilon^2} \cdot \frac{\delta^3\epsilon^2 c}{\beta} = 1 - \frac{2c^2\delta^3}{\beta} \geq 1 - \frac{\delta}{2}$ (since $c = \frac{80}{\delta}$ and β is sufficiently large), $\tilde{H}$ contains all high-degree vertices in G. ◀

Algorithm 2 Estimating the MAX-CUT value in (insertion-only) random-order streams.

Input: Graph G as a random-order stream of edges, an ϵ-accurate oracle $\mathcal{O} \to \{-1, 1\}$, a high-degree threshold $\theta = \frac{\epsilon^2 m}{c}$ (where $c = \frac{80}{\delta}$).
Output: The estimate of the MAX-CUT value of G.

▷ **Preprocessing phase**
1: **initialize** $F \leftarrow \emptyset$, $\tilde{H} \leftarrow \emptyset$, $e(L^+, L^-) \leftarrow 0$.
▷ **Streaming phase**
2: **for each** edge (u, v) in the first $\frac{\beta}{\delta^3\epsilon^4}$ edges of the stream (where β is a sufficiently large universal constant) **do**
3: $F \leftarrow F \cup \{(u, v)\}$, $\tilde{H} \leftarrow \tilde{H} \cup \{u, v\}$
4: **for each** vertex $v \in \tilde{H}$ **do**
5: **initialize** $e(v, V \setminus \tilde{H}) \leftarrow 0$, $e(v, L^+) \leftarrow 0$, $e(v, L^-) \leftarrow 0$.
6: **for each** remaining edge (u, v) in the stream **do**
7: $Y_u = \mathcal{O}(u), Y_v = \mathcal{O}(v)$
8: **if** $u \in \tilde{H}$ and $v \in \tilde{H}$ **then** $F \leftarrow F \cup \{(u, v)\}$
9: **else**
10: **if** $u \in \tilde{H}$ and $v \in V \setminus \tilde{H}$ **then** $e(u, V \setminus \tilde{H}) \leftarrow e(u, V \setminus \tilde{H}) + 1$
11: **if** $v \in \tilde{H}$ and $u \in V \setminus \tilde{H}$ **then** $e(v, V \setminus \tilde{H}) \leftarrow e(v, V \setminus \tilde{H}) + 1$
12: **if** $u \in \tilde{H}$ and $v \in V \setminus \tilde{H}$ **then**
13: **if** $Y_v = 1$ **then** $e(u, L^+) \leftarrow e(u, L^+) + 1$ **else** $e(u, L^-) \leftarrow e(u, L^-) + 1$
14: **if** $u \in V \setminus \tilde{H}$ and $v \in V \setminus \tilde{H}$ and $Y_u \neq Y_v$ **then**
15: $e(L^+, L^-) \leftarrow e(L^+, L^-) + 1$ (i.e., apply Algorithm 1 on $G[V \setminus \tilde{H}]$)
▷ **Postprocessing phase**
16: $H \leftarrow \{v \in \tilde{H} : |\{e \in F : v \in e\}| + e(v, V \setminus \tilde{H}) \geq \theta\}$, $L \leftarrow V \setminus H$
17: **for each** edge $(u, v) \in F$ **do**
18: $Y_u = \mathcal{O}(u), Y_v = \mathcal{O}(v)$
19: **if** $u \in H$ and $v \in L$ **then**
20: **if** $Y_v = 1$ **then** $e(u, L^+) \leftarrow e(u, L^+) + 1$ **else** $e(u, L^-) \leftarrow e(u, L^-) + 1$
21: **if** $u \in \tilde{H} \setminus H$ and $v \in \tilde{H} \setminus H$ and $Y_u \neq Y_v$ **then** $e(L^+, L^-) \leftarrow e(L^+, L^-) + 1$
22: **for each** vertex $v \in \tilde{H} \setminus H$ **do**
23: $Y_v = \mathcal{O}(v)$
24: **if** $Y_v = 1$ **then** $e(L^+, L^-) \leftarrow e(L^+, L^-) + e(v, L^-)$ **else** $e(L^+, L^-) \leftarrow e(L^+, L^-) + e(v, L^+)$
25: $\mathrm{ALG}_1 \leftarrow e(L^+, L^-) + \sum_{v \in H} \max\{e(v, L^-), e(v, L^+)\}$
26: $\mathrm{ALG}_2 \leftarrow \sum_{v \in H}(e(v, L^-) + e(v, L^+))$
27: **return** $\max\{\mathrm{ALG}_1, \mathrm{ALG}_2\}$

Proof of Theorem 9. In Algorithm 2, we store the first $\frac{\beta}{\delta^3\epsilon^4}$ edges of the stream (Line 3) and the remaining edges with both endpoints in $\tilde{H}$ (Line 8). We also maintain several counters for vertices in $\tilde{H}$. Therefore, the total space complexity of Algorithm 2 is $O(\frac{1}{\delta^6\epsilon^8})$ words.

Next, we show the approximation guarantee of Algorithm 2. Note that at the end of the stream we can identify H exactly, using the information stored during the streaming phase. In Algorithm 2, we apply Algorithm 1 to the subgraph $G[V \setminus \tilde{H}]$ during the streaming phase (Line 15). Hypothetically, during the postprocessing phase, we apply Algorithm 1 to the subgraph $G[\tilde{H} \setminus H]$ (Line 21) and to edges with one endpoint in $\tilde{H} \setminus H$ and the

other endpoint in $V \setminus \tilde{H}$ (Line 24). This is equivalent to applying Algorithm 1 to $G[L]$ since $L = (V \setminus \tilde{H}) \cup (\tilde{H} \setminus H)$. Then the approximation guarantee of Algorithm 2 follows directly from Theorem 6 (with failure probability $\frac{\delta}{2}$) and Lemma 10 by using union bound. ◀

4.2 Arbitrary Order Streams

Overview of the Algorithm. Unlike random order streams, where we can identify a set $\tilde{H}$, containing the high-degree vertices H, by storing only a small number of edges from the beginning of the stream, finding high-degree vertices is more challenging in arbitrary order streams. To handle this, we employ *reservoir sampling* [47]. Specifically, we uniformly sample $\text{poly}(1/\epsilon, 1/\delta)$ edges from the stream. Then, at the end of the stream, we use these sampled edges to compute a small set $\tilde{H}$ such that $\tilde{H} \supseteq H$. This approach is similar to what we used in the random order stream; however, in this case, we can only retrieve $\tilde{H}$ rather than H at the end of the stream.

We also need to estimate the number of incident edges related to high-degree vertices. To this end, we use techniques from vector sketching, particularly those developed for *frequency estimation* and *heavy hitters*. We consider the sketching techniques for heavy hitters, specifically the randomized summaries of CountMin sketch [15], corresponding to V^+ and V^-, denoted by $\mathbf{CM}[V^+]$ and $\mathbf{CM}[V^-]$, respectively. Intuitively, by the end of the stream, $\mathbf{CM}[V^+]$ and $\mathbf{CM}[V^-]$ will contain the estimates of the number of incident edges of high-degree vertices to sets V^+ and V^-, respectively. More precisely, as an edge (u, v) arrive, we increment the counters related to u in $\mathbf{CM}[V^{\mathcal{O}(v)}]$, and increment the counters related to v in $\mathbf{CM}[V^{\mathcal{O}(u)}]$, where $\mathcal{O}(v)$ and $\mathcal{O}(u)$ are respectively the predicted sign of v, u by the given ϵ-accurate oracle $\mathcal{O}$.

Note that we cannot detect H exactly by the end of stream. Instead, we have $\tilde{H}$. We use $\mathbf{CM}[V^+]$ and $\mathbf{CM}[V^-]$ to approximately compute the value of the cut $(\tilde{L}^+, \tilde{L}^-)$ on the induced subgraph $G[\tilde{L}]$, where $\tilde{L} := V \setminus \tilde{H}$. Then, using $\mathbf{CM}[V^+]$ and $\mathbf{CM}[V^-]$, we can approximately run the greedy approach for $\tilde{H}$. Unlike the random order setting where we could implement the greedy extension exactly, here we can only store the approximate values. However, we show that our estimates of the number of incident edges of high-degree vertices to sets V^+ and V^- are only off by $\text{poly}(\epsilon, \delta) \cdot m$ additive terms with high probability, and they suffice to provide a strictly better than $\frac{1}{2}$-approximation for MAX-CUT on $G[\tilde{L}]$ and its extension with $\tilde{H}$. Similarly, we can use $\mathbf{CM}[V^+]$ and $\mathbf{CM}[V^-]$ to compute the size of $(\tilde{H}, \tilde{L})$ approximately too. Then, we can show that for sufficiently small value of ϵ, the best of two candidate cuts is a $(\frac{1}{2} + \Omega(\epsilon^2))$-approximation for MAX-CUT on G with probability $1 - \delta$.

Next, we prove the approximation guarantee and the space complexity of our algorithm for arbitrary order streams. The algorithm is formally given in Algorithm 3.

▶ **Theorem 11.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0, 1)$. Given an ϵ-accurate oracle $\mathcal{O}$ for the MAX-CUT of G, there exists a single-pass $(\frac{1}{2} + \Omega(\epsilon^2))$-approximation algorithm for estimating the MAX-CUT value of G in the insertion-only arbitrary-order streams. The algorithm uses $O(\frac{1}{\epsilon^7 \delta^3} \ln \frac{1}{\epsilon\delta})$ words of space. The approximation holds with probability at least $1 - \delta$.*

▶ **Lemma 12.** *Let $\delta \in (0, 1)$. Then $\tilde{H}$ contains all high-degree vertices H in G with probability at least $1 - \frac{\delta}{2}$.*

Proof. The proof is basically similar to that of Lemma 10. Suppose that v is a high-degree vertex in G, i.e., $\deg(v) \geq \frac{\epsilon^2 m}{c}$. For each edge e_i incident to v, define an indicator random variable

$$X_i = \begin{cases} 1, & \text{if } e_i \in F \\ 0, & \text{otherwise} \end{cases}$$

Algorithm 3 Estimating the MAX-CUT value in (insertion-only) arbitrary-order streams.

Input: Graph G as an arbitrary-order stream of edges, an ϵ-accurate oracle $\mathcal{O} \to \{-1, 1\}$
Output: Estimate of the MAX-CUT value of G

▷ **Preprocessing phase**

Initialize $e(V^+, V^-) \leftarrow 0$.
Set $h_1, \ldots, h_k : [n] \to [w]$ be 2-wise independent hash functions, with $k = \lceil \frac{e}{\epsilon^7 \delta^3} \rceil$ and $w = \lceil \ln \frac{8\beta}{\epsilon^4 \delta^4} \rceil$ (where β is a sufficiently large universal constant).
Initialize $\mathbf{CM}[V^+]$ and $\mathbf{CM}[V^-]$ to zero.

▷ **Streaming phase**

for each edge (u, v) in the stream **do**
    $Y_u = \mathcal{O}(u), Y_v = \mathcal{O}(v)$
    if $Y_u \neq Y_v$ **then** $e(V^+, V^-) \leftarrow e(V^+, V^-) + 1$
    for each $\ell \in [k]$ **do**
        $\mathbf{CM}[V^{\mathcal{O}(u)}][\ell, h_\ell(v)] \leftarrow \mathbf{CM}[V^{\mathcal{O}(u)}][\ell, h_\ell(v)] + 1$
        $\mathbf{CM}[V^{\mathcal{O}(v)}][\ell, h_\ell(u)] \leftarrow \mathbf{CM}[V^{\mathcal{O}(v)}][\ell, h_\ell(u)] + 1$
In parallel, uniformly sample $\frac{\beta}{\delta^3 \epsilon^4}$ edges F in the stream via reservoir sampling [47].

▷ **Postprocessing phase**

for each $v \in V$ **do**
    $f_v^+ \leftarrow \min_{\ell \in [k]} \mathbf{CM}[V^+][\ell, h_\ell(v)]$
    $f_v^- \leftarrow \min_{\ell \in [k]} \mathbf{CM}[V^-][\ell, h_\ell(v)]$
$\tilde{H} := \bigcup_{(u,v) \in F} \{u, v\}$
$\tilde{H}^+ \leftarrow \{v \in \tilde{H} : Y_v = 1\}, \tilde{H}^- \leftarrow V \setminus \tilde{H}^+$
$\tilde{e}(\tilde{L}^+, \tilde{L}^-) \leftarrow e(V^+, V^-) - \sum_{v \in \tilde{H}^+} f_v^- - \sum_{v \in \tilde{H}^-} f_v^+$
$\mathrm{ALG}_1 \leftarrow \tilde{e}(\tilde{L}^+, \tilde{L}^-) + \sum_{v \in \tilde{H}} \max\{f_v^-, f_v^+\}$
$\mathrm{ALG}_2 \leftarrow \sum_{v \in \tilde{H}} (f_v^- + f_v^+)$
return $\max\{\mathrm{ALG}_1, \mathrm{ALG}_2\}$

So, $\mathbb{E}[X_i] = \Pr[X_i = 1] = \frac{\beta}{\delta^3 \epsilon^4 m}$. We define $X := \sum_{i \in [\deg(v)]} X_i$ to denote the number of edges incident to v that are sampled by the end of the stream. Then, $\mathbb{E}[X] = \sum_{i \in [\deg(v)]} \mathbb{E}[X_i] = \frac{\beta \deg(v)}{\delta^3 \epsilon^4 m}$.

Next, we bound $\mathrm{Var}[X]$. For any $i \in [\deg(v)]$, $\mathrm{Var}[X_i] = \mathbb{E}[X_i^2] - (\mathbb{E}[X_i])^2 = \mathbb{E}[X_i] - (\mathbb{E}[X_i])^2 = \frac{\beta}{\delta^3 \epsilon^4 m} - (\frac{\beta}{\delta^3 \epsilon^4 m})^2 = \frac{\beta}{\delta^3 \epsilon^4 m} - \frac{\beta^2}{\delta^6 \epsilon^8 m^2}$. Since $(X_i)_{i \in [\deg(v)]}$ are negatively correlated, $\mathrm{Var}[X] \leq \sum_{i \in [\deg(v)]} \mathrm{Var}[X_i] = \deg(v) \cdot \left(\frac{\beta}{\delta^3 \epsilon^4 m} - \frac{\beta^2}{\delta^6 \epsilon^8 m^2} \right) \leq \frac{\beta \deg(v)}{\delta^3 \epsilon^4 m}$. Therefore, by Chebyshev's inequality,

$$\begin{aligned}
\Pr[v \notin \tilde{H}] = \Pr[X \leq 0] &= \Pr\left[X \leq \mathbb{E}[X] - \frac{\beta \deg(v)}{\delta^3 \epsilon^4 m}\right] \\
&\leq \frac{\mathrm{Var}[X] \cdot \delta^6 \epsilon^8 m^2}{\beta^2 \deg^2(v)} \\
&\leq \frac{\delta^3 \epsilon^4 m}{\beta \cdot \deg(v)} && \triangleright\ \mathrm{Var}[X] \leq \frac{\beta \deg(v)}{\delta^3 \epsilon^4 m} \\
&\leq \frac{\delta^3 \epsilon^2 c}{\beta}. && \triangleright\ \deg(v) \geq \frac{\epsilon^2 m}{c}
\end{aligned}$$

By our definition of high-degree vertices, there are at most $\frac{2m}{\epsilon^2 m/c} = \frac{2c}{\epsilon^2}$ high-degree vertices in G. By union bound, with probability at least $1 - \frac{2c}{\epsilon^2} \cdot \frac{\delta^3 \epsilon^2 c}{\beta} = 1 - \frac{2c^2 \delta^3}{\beta} \geq 1 - \frac{\delta}{2}$ (since $c = \frac{80}{\delta}$ and β sufficiently large), $\tilde{H}$ contains all high-degree vertices in G. ◀

▶ **Lemma 13.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0,1)$. For all vertices $v \in \tilde{H}$, (1) $f_v^+ \geq e(v, V^+)$ and $f_v^- \geq e(v, V^-)$. (2) with probability at least $1 - \frac{\delta}{4}$, $f_v^+ \leq e(v, V^+) + 2\epsilon^7\delta^3 m$ and $f_v^- \leq e(v, V^-) + 2\epsilon^7\delta^3 m$.*

Proof. (1) By Theorem 2, we have $f_v^+ \geq e(v, V^+)$ and $f_v^- \geq e(v, V^-)$ for all $v \in V$.

(2) By Theorem 2, we have $f_v^+ \leq e(v, V^+) + 2\epsilon^7\delta^3 m$ and $f_v^- \leq e(v, V^-) + 2\epsilon^7\delta^3 m$ with probability at least $1 - \frac{\epsilon^4\delta^4}{8\beta}$ for any $v \in V$. Since $|\tilde{H}| \leq \frac{2\beta}{\delta^3\epsilon^4}$, by union bound, with probability at least $1 - \frac{\epsilon^4\delta^4}{8\beta} \cdot \frac{2\beta}{\delta^3\epsilon^4} = 1 - \frac{\delta}{4}$, we have $f_v^+ \leq e(v, V^+) + 2\epsilon^7\delta^3 m$ and $f_v^- \leq e(v, V^-) + 2\epsilon^7\delta^3 m$ for all $v \in \tilde{H}$. ◀

Proof of Theorem 11. In Algorithm 3, we use CountMin sketch with $k = \lceil \frac{e}{\epsilon^7\delta^3} \rceil$ and $w = \lceil \ln \frac{8\beta}{\epsilon^4\delta^4} \rceil$ to estimate the number of incident edges of high-degree vertices to with respect to V^+ and V^-, which takes $O(\frac{1}{\epsilon^7\delta^3} \ln \frac{1}{\epsilon^4\delta^4}) = O(\frac{1}{\epsilon^7\delta^3} \ln \frac{1}{\epsilon\delta})$ words of space, by Theorem 2. Also, we use reservoir sampling to uniformly sample $O(\frac{1}{\delta^3\epsilon^4})$ edges, which takes $O(\frac{1}{\delta^3\epsilon^4})$ words of space. Therefore, the total space complexity of Algorithm 3 is $O(\frac{1}{\epsilon^7\delta^3} \ln \frac{1}{\epsilon\delta})$ words.

Next, we show the approximation guarantee of Algorithm 3. Recall that in arbitrary order streams, we cannot detect H by the end of stream, and we have $\tilde{H}$ instead. Let $A_1 := e(\tilde{L}^+, \tilde{L}^-) + \sum_{v \in \tilde{H}} \max\{e(v, \tilde{L}^-), e(v, \tilde{L}^+)\}$ denote the value of the cut $(\tilde{C}, V \setminus \tilde{C})$ obtained by running Algorithm 1 on $G[\tilde{L}]$ and then assigning the vertices in $\tilde{H}$ in a greedy manner. Let $A_2 := \sum_{v \in \tilde{H}} (e(v, \tilde{L}^-) + e(v, \tilde{L}^+))$ denote the value of the cut $(\tilde{H}, \tilde{L})$. Suppose that the best of $(\tilde{C}, V \setminus \tilde{C})$ and $(\tilde{H}, \tilde{L})$ cuts is a $(\frac{1}{2} + \frac{\epsilon^2}{16})$-approximation for the MAX-CUT value of G. Recall that $\mathrm{ALG}_1 = \tilde{e}(\tilde{L}^+, \tilde{L}^-) + \sum_{v \in \tilde{H}} \max\{f_v^-, f_v^+\}$ and $\mathrm{ALG}_2 = \sum_{v \in \tilde{H}} (f_v^- + f_v^+)$. In the following, we show that ALG_1 and ALG_2 are good approximations of A_1 and A_2, respectively. Therefore, $\max\{\mathrm{ALG}_1, \mathrm{ALG}_2\}$ returned by Algorithm 3 is also a strictly better than $\frac{1}{2}$-approximation for the MAX-CUT value of G.

Since $V^+ = \tilde{H}^+ \cup \tilde{L}^+$ and $V^- = \tilde{H}^- \cup \tilde{L}^-$, we have $e(v, V^+) = e(v, \tilde{H}^+) + e(v, \tilde{L}^+)$ and $e(v, V^-) = e(v, \tilde{H}^-) + e(v, \tilde{L}^-)$ for any vertex $v \in V$. By Lemma 13, with probability at least $1 - \frac{\delta}{4}$, for all vertices $v \in \tilde{H}$, we have

$$e(v, \tilde{H}^+) + e(v, \tilde{L}^+) \leq f_v^+ \leq e(v, \tilde{H}^+) + e(v, \tilde{L}^+) + 2\epsilon^7\delta^3 m,$$
$$e(v, \tilde{H}^-) + e(v, \tilde{L}^-) \leq f_v^- \leq e(v, \tilde{H}^-) + e(v, \tilde{L}^-) + 2\epsilon^7\delta^3 m.$$

Since $|\tilde{H}| \leq \frac{2\beta}{\delta^3\epsilon^4}$, we have $0 \leq e(v, \tilde{H}^+), e(v, \tilde{H}^-) \leq \frac{2\beta}{\delta^3\epsilon^4}$. Therefore, we have

$$e(v, \tilde{L}^+) \leq f_v^+ \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m + e(v, \tilde{L}^+),$$
$$e(v, \tilde{L}^-) \leq f_v^- \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m + e(v, \tilde{L}^-).$$

Then we have

$$0 \leq f_v^+ - e(v, \tilde{L}^+) \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m \quad \text{and} \quad 0 \leq f_v^- - e(v, \tilde{L}^-) \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m,$$

and

$$\max\{e(v, \tilde{L}^+), e(v, \tilde{L}^-)\} \leq \max\{f_v^+, f_v^-\} \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m + \max\{e(v, \tilde{L}^+), e(v, \tilde{L}^-)\}.$$

Note that

$$e(\tilde{L}^+, \tilde{L}^-) = e(V^+, V^-) - e(\tilde{H}^+, \tilde{H}^-) - \sum_{v \in \tilde{H}^+} e(v, \tilde{L}^-) - \sum_{v \in \tilde{H}^-} e(v, \tilde{L}^+),$$
$$\tilde{e}(\tilde{L}^+, \tilde{L}^-) = e(V^+, V^-) - \sum_{v \in \tilde{H}^+} f_v^- - \sum_{v \in \tilde{H}^-} f_v^+.$$

We have

$$\begin{aligned} e(\tilde{L}^+, \tilde{L}^-) - \tilde{e}(\tilde{L}^+, \tilde{L}^-) &= \sum_{v \in \tilde{H}^+} (f_v^- - e(v, \tilde{L}^-)) + \sum_{v \in \tilde{H}^-} (f_v^+ - e(v, \tilde{L}^+)) - e(\tilde{H}^+, \tilde{H}^-) \\ &\leq \frac{2\beta}{\delta^3\epsilon^4} \cdot \left(\frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m \right) + \frac{2\beta}{\delta^3\epsilon^4} \cdot \left(\frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m \right) - 0 \\ &= \frac{8\beta^2}{\delta^6\epsilon^8} + 8\beta\epsilon^3 m. \end{aligned}$$

Therefore,

$$\begin{aligned} A_1 - \mathrm{ALG}_1 &= (e(\tilde{L}^+, \tilde{L}^-) - \tilde{e}(\tilde{L}^+, \tilde{L}^-)) + \sum_{v \in \tilde{H}} (\max\{e(v, \tilde{L}^-), e(v, \tilde{L}^+)\} - \max\{f_v^-, f_v^+\}) \\ &\leq \left(\frac{8\beta^2}{\delta^6\epsilon^8} + 8\beta\epsilon^3 m \right) + \frac{2\beta}{\delta^3\epsilon^4} \cdot 0 = \frac{8\beta^2}{\delta^6\epsilon^8} + 8\beta\epsilon^3 m. \end{aligned}$$

So, $\mathrm{ALG}_1 \geq A_1 - (\frac{8\beta^2}{\delta^6\epsilon^8} + 8\beta\epsilon^3 m) = A_1 - \Theta(\epsilon^3 m)$.

Similarly,

$$A_2 - \mathrm{ALG}_2 = \sum_{v \in \tilde{H}} ((e(v, \tilde{L}^-) - f_v^-) + (e(v, \tilde{L}^+) - f_v^+)) \leq \frac{2\beta}{\delta^3\epsilon^4} \cdot (0 + 0) = 0.$$

So, $\mathrm{ALG}_2 \geq A_2$.

Since we assume that $\max\{A_1, A_2\}$ is a $(\frac{1}{2} + \frac{\epsilon^2}{16})$-approximation for the MAX-CUT value of G, we have $\mathrm{ALG} := \max\{\mathrm{ALG}_1, \mathrm{ALG}_2\} \geq \max\{A_1, A_2\} - \Theta(\epsilon^3 m) \geq (\frac{1}{2} + \frac{\epsilon^2}{16}) \cdot \mathrm{OPT} - \Theta(\epsilon^3 \cdot \mathrm{OPT}) = (\frac{1}{2} + \Omega(\epsilon^2)) \cdot \mathrm{OPT}$.

Finally, it remains to show that the best of $(\tilde{C}, V \setminus \tilde{C})$ and $(\tilde{H}, \tilde{L})$ cuts is a $(\frac{1}{2} + \frac{\epsilon^2}{16})$-approximation for the MAX-CUT value of G. This directly follows from Theorem 6 (with failure probability $\frac{\delta}{4}$), by substituting H and L with $\tilde{H}$ and $\tilde{L}$, respectively. Together with Lemma 12, Lemma 13, and applying union bound, this concludes the proof. ◀

4.3 Extension to Dynamic Streams

Overview of the Algorithm. Our algorithm in dynamic streams is basically similar to Algorithm 3. The only difference is that to compute a small set $\tilde{H}$ at the end of the stream such that $\tilde{H} \supseteq H$, instead of reservoir sampling, we need to use ℓ_0-sampling [28].

Next, we prove the approximation guarantee and the space complexity of our algorithm for dynamic streams. The algorithm is formally given in Algorithm 4.

▶ **Theorem 14.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0, 1)$. Given an ϵ-accurate oracle $\mathcal{O}$ for the MAX-CUT of G, there exists a single-pass $(\frac{1}{2} + \Omega(\epsilon^2))$-approximation algorithm for estimating the MAX-CUT value of G in the dynamic streams. The algorithm uses $O(\frac{\log^2 n}{\epsilon^7\delta^3} \log \frac{1}{\epsilon\delta})$ bits of space. The approximation holds with probability at least $1 - \delta$.*

Note that Theorem 1 follows from Theorem 11 and Theorem 14 by setting $\delta = 1/3$.

Proof Sketch of Theorem 14. The proof follows a similar structure to that of Theorem 11. First, we show that ℓ_0-sampling in dynamic streams can effectively replace reservoir sampling in insertion-only streams, allowing us to retrieve a set $\tilde{H} \supseteq H$ with high probability by the end of the stream.

Algorithm 4 Estimating the MAX-CUT value in dynamic streams.

Input: Graph G as a dynamic stream of edges, an ϵ-accurate oracle $\mathcal{O} \to \{-1, 1\}$
Output: Estimate of the MAX-CUT value of G

▷ **Preprocessing phase**

Initialize $e(V^+, V^-) \leftarrow 0$.
Set $h_1, \ldots, h_k : [n] \to [w]$ be 2-wise independent hash functions, with $k = \lceil \frac{e}{\epsilon^7 \delta^3} \rceil$ and $w = \lceil \ln \frac{8\beta}{\epsilon^4 \delta^4} \rceil$ (where β is a sufficiently large universal constant).
Initialize $\mathbf{CM}[V^+]$ and $\mathbf{CM}[V^-]$ to zero.

▷ **Streaming phase**

for each item $((u, v), \Delta_{(u,v)})$ in the stream **do**
    $Y_u = \mathcal{O}(u), Y_v = \mathcal{O}(v)$
    if $Y_u \neq Y_v$ **then** $e(V^+, V^-) \leftarrow e(V^+, V^-) + 1$
    for each $\ell \in [k]$ **do**
        $\mathbf{CM}[V^{\mathcal{O}(u)}][\ell, h_\ell(v)] \leftarrow \mathbf{CM}[V^{\mathcal{O}(u)}][\ell, h_\ell(v)] + \Delta_{(u,v)}$
        $\mathbf{CM}[V^{\mathcal{O}(v)}][\ell, h_\ell(u)] \leftarrow \mathbf{CM}[V^{\mathcal{O}(v)}][\ell, h_\ell(u)] + \Delta_{(u,v)}$
In parallel, maintain $\frac{\beta}{\delta^3 \epsilon^4}$ ℓ_0-samplers (with failure probability $\delta' = \frac{\delta^4 \epsilon^4}{8\beta}$) to obtain $\frac{\beta}{\delta^3 \epsilon^4}$ different edges F.

▷ **Postprocessing phase**

for each $v \in V$ **do**
    $f_v^+ \leftarrow \min_{\ell \in [k]} \mathbf{CM}[V^+][\ell, h_\ell(v)]$
    $f_v^- \leftarrow \min_{\ell \in [k]} \mathbf{CM}[V^-][\ell, h_\ell(v)]$
$\tilde{H} := \bigcup_{(u,v) \in F} \{u, v\}$
$\tilde{H}^+ \leftarrow \{v \in \tilde{H} : Y_v = 1\}, \tilde{H}^- \leftarrow V \setminus \tilde{H}^+$
$\tilde{e}(\tilde{L}^+, \tilde{L}^-) \leftarrow e(V^+, V^-) - \sum_{v \in \tilde{H}^+} f_v^- - \sum_{v \in \tilde{H}^-} f_v^+$
$\mathrm{ALG}_1 \leftarrow \tilde{e}(\tilde{L}^+, \tilde{L}^-) + \sum_{v \in \tilde{H}} \max\{f_v^-, f_v^+\}$
$\mathrm{ALG}_2 \leftarrow \sum_{v \in \tilde{H}} (f_v^- + f_v^+)$
return $\max\{\mathrm{ALG}_1, \mathrm{ALG}_2\}$

Next, we show that for all vertices $v \in \tilde{H}$, our estimates of the number of incident edges from v to the sets V^+ and V^- has additive error at most $\mathrm{poly}(\epsilon, \delta) \cdot m$, with high probability.

Finally, using arguments similar to those in the proof of Theorem 11, we can show that Algorithm 4 provides a $(\frac{1}{2} + \Omega(\epsilon^2))$-approximation for the MAX-CUT value of G with probability $1 - \delta$. For completeness, we provide the detailed proof in Section A.

5 Conclusion

We present the first learning-augmented algorithm for estimating the value of MAX-CUT in the streaming setting by leveraging ϵ-accurate predictions. Specifically, we provide a single-pass streaming algorithm that achieves a $(1/2 + \Omega(\epsilon^2))$-approximation for estimating the MAX-CUT value of a graph in insertion-only (respectively, fully dynamic) streams using $\mathrm{poly}(1/\epsilon)$ (respectively, $\mathrm{poly}(1/\epsilon, \log n)$) words of space. This result contrasts with the lower bound in the classical streaming setting (without predictions), where any (randomized) single-pass streaming algorithm that achieves an approximation ratio of at least $1/2 + \epsilon$ requires $\Omega(n/2^{\mathrm{poly}(1/\epsilon)})$ space.

Our work leaves several questions for further research. For example, it would be interesting to extend our algorithm from unweighted to weighted graphs. Currently, our algorithm for handling the low-degree part does not seem to work for weighted graphs, as an edge with a

heavy weight but incorrectly predicted signs can significantly affect our estimator. Another open question is to establish lower bounds on the trade-offs between approximation ratio and space complexity when the streaming algorithm is provided with predictions.

A Proof of Theorem 14

▶ **Lemma 15.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0,1)$. With probability at least $1 - \frac{\delta}{4}$, Line 10 of Algorithm 4 returns a set F which contains $\frac{\beta}{\delta^3\epsilon^4}$ different edges.*

Proof. The error is introduced by the ℓ_0-samplers and the probability that sampling $\frac{\beta}{\delta^3\epsilon^4}$ uniform random edges in parallel does not yield $\frac{\beta}{\delta^3\epsilon^4}$ different edges.

By Theorem 4, the ℓ_0-sampler fails with probability at most δ'. Since we maintain $\frac{\beta}{\delta^3\epsilon^4}$ ℓ_0-samplers, by union bound, the failure probability introduced by ℓ_0-samplers is at most $\frac{\beta}{\delta^3\epsilon^4} \cdot \delta'$.

Suppose that all the ℓ_0-samplers succeed, i.e., $|F| = \frac{\beta}{\delta^3\epsilon^4}$. Now we bound the probability that there exist two identical edges in F. Consider two fixed edges $e_1, e_2 \in F$. Then $\Pr[e_1 = e_2] = \frac{1}{m}$. By union bound, the probability that there exists at least one pair of identical edges is at most $\binom{\beta/\delta^3\epsilon^4}{2} \cdot \frac{1}{m} \le \frac{\beta^2}{\delta^6\epsilon^8 m}$.

Therefore, the probability that F contains $\frac{\beta}{\delta^3\epsilon^4}$ different edges is at least $1 - \frac{\beta}{\delta^3\epsilon^4} \cdot \delta' - \frac{\beta^2}{\delta^6\epsilon^8 m} \ge 1 - \frac{\delta}{8} - \frac{\delta}{8} \ge 1 - \frac{\delta}{4}$ (since $m = \Omega(\epsilon^{-11}\delta^{-7})$). ◀

▶ **Lemma 16.** *Let $\delta \in (0,1)$. By the end of the stream, $\tilde{H}$ contains all high-degree vertices in G with probability at least $1 - \frac{\delta}{4}$.*

Proof. Suppose that v is a high-degree vertex in G, i.e., $\deg(v) \ge \frac{\epsilon^2 m}{c}$. For each edge e_i incident to v, define an indicator random variable

$$X_i = \begin{cases} 1, & \text{if } e_i \in F \\ 0, & \text{otherwise} \end{cases}$$

So, $\mathbb{E}[X_i] = \Pr[X_i = 1] = 1 - (1 - \frac{1}{m})^{\beta/\delta^3\epsilon^4} \ge 1 - \exp\left(-\frac{\beta}{\delta^3\epsilon^4 m}\right) \ge \frac{\beta}{\delta^3\epsilon^4 m} - \frac{\beta^2}{2\delta^6\epsilon^8 m^2} \ge \frac{\beta}{5\delta^3\epsilon^4 m}$ for sufficiently large m. We define $X := \sum_{i\in[\deg(v)]} X_i$ to denote the number of edges incident to v that are sampled by the end of the stream. Then, $\mathbb{E}[X] = \sum_{i\in[\deg(v)]} \mathbb{E}[X_i] \ge \frac{\beta \deg(v)}{5\delta^3\epsilon^4 m}$.

Next, we bound $\mathrm{Var}[X]$. For any $i \in [\deg(v)]$, $\mathrm{Var}[X_i] = \mathbb{E}[X_i^2] - (\mathbb{E}[X_i])^2 = \mathbb{E}[X_i] - (\mathbb{E}[X_i])^2 \le \frac{\beta}{5\delta^3\epsilon^4 m} - (\frac{\beta}{5\delta^3\epsilon^4 m})^2 = \frac{\beta}{5\delta^3\epsilon^4 m} - \frac{\beta^2}{25\delta^6\epsilon^8 m^2}$. Since $(X_i)_{i\in[\deg(v)]}$ are negatively correlated, $\mathrm{Var}[X] \le \sum_{i\in[\deg(v)]} \mathrm{Var}[X_i] = \deg(v) \cdot \left(\frac{\beta}{5\delta^3\epsilon^4 m} - \frac{\beta^2}{25\delta^6\epsilon^8 m^2}\right) \le \frac{\beta \deg(v)}{5\delta^3\epsilon^4 m}$. Therefore, by Chebyshev's inequality,

$$\begin{aligned}\Pr[v \notin \tilde{H}] = \Pr[X \le 0] &\le \Pr\left[X \le \mathbb{E}[X] - \frac{\beta \deg(v)}{5\delta^3\epsilon^4 m}\right] \\ &\le \frac{\mathrm{Var}[X] \cdot 25\delta^6\epsilon^8 m^2}{\beta^2 \deg^2(v)} \\ &\le \frac{5\delta^3\epsilon^4 m}{\beta \cdot \deg(v)} && \triangleright\ \mathrm{Var}[X] \le \frac{\beta \deg(v)}{5\delta^3\epsilon^4 m} \\ &\le \frac{5\delta^3\epsilon^2 c}{\beta}. && \triangleright\ \deg(v) \ge \frac{\epsilon^2 m}{c}\end{aligned}$$

By our definition of high-degree vertices, there are at most $\frac{2m}{\epsilon^2 m/c} = \frac{2c}{\epsilon^2}$ high-degree vertices in G. By union bound, with probability at least $1 - \frac{2c}{\epsilon^2} \cdot \frac{5\delta^3\epsilon^2 c}{\beta} = 1 - \frac{10c^2\delta^3}{\beta} \ge 1 - \frac{\delta}{4}$ (since $c = \frac{80}{\delta}$ and β sufficiently large), $\tilde{H}$ contains all high-degree vertices in G. ◀

▶ **Lemma 17.** *Let $\epsilon \in (0, \frac{1}{2}]$ and $\delta \in (0, 1)$. For all vertices $v \in \tilde{H}$, (1) $f_v^+ \ge e(v, V^+)$ and $f_v^- \ge e(v, V^-)$. (2) with probability at least $1 - \frac{\delta}{4}$, $f_v^+ \le e(v, V^+) + 2\epsilon^7\delta^3 m$ and $f_v^- \le e(v, V^-) + 2\epsilon^7\delta^3 m$.*

Proof. (1) By Theorem 2, we have $f_v^+ \ge e(v, V^+)$ and $f_v^- \ge e(v, V^-)$ for all $v \in V$.

(2) By Theorem 2, we have $f_v^+ \le e(v, V^+) + 2\epsilon^7\delta^3 m$ and $f_v^- \le e(v, V^-) + 2\epsilon^7\delta^3 m$ with probability at least $1 - \frac{\epsilon^4\delta^4}{8\beta}$ for any $v \in V$. Since $|\tilde{H}| \le \frac{2\beta}{\delta^3\epsilon^4}$, by union bound, with probability at least $1 - \frac{\epsilon^4\delta^4}{8\beta} \cdot \frac{2\beta}{\delta^3\epsilon^4} = 1 - \frac{\delta}{4}$, we have $f_v^+ \le e(v, V^+) + 2\epsilon^7\delta^3 m$ and $f_v^- \le e(v, V^-) + 2\epsilon^7\delta^3 m$ for all $v \in \tilde{H}$. ◀

Proof of Theorem 14. In Algorithm 4, we use CountMin sketch with $k = \lceil \frac{e}{\epsilon^7\delta^3} \rceil$ and $w = \lceil \ln \frac{8\beta}{\epsilon^4\delta^4} \rceil$ to estimate the number of incident edges of high-degree vertices to with respect to V^+ and V^-, which takes $O(\frac{1}{\epsilon^7\delta^3} \ln \frac{1}{\epsilon^4\delta^4}) = O(\frac{1}{\epsilon^7\delta^3} \ln \frac{1}{\epsilon\delta})$ words of space, by Theorem 2. Also, we maintain $O(\frac{1}{\delta^3\epsilon^4})$ ℓ_0-samplers, which takes $O(\frac{\log^2 n}{\delta^3\epsilon^4} \log \frac{1}{\delta^4\epsilon^4}) = O(\frac{\log^2 n}{\delta^3\epsilon^4} \log \frac{1}{\delta\epsilon})$ bits of space, by Theorem 4. Therefore, the total space complexity of Algorithm 4 is $O(\frac{\log^2 n}{\epsilon^7\delta^3} \log \frac{1}{\epsilon\delta})$ bits.

Next, we show the approximation guarantee of Algorithm 4. Similar to arbitrary order streams, we cannot detect H by the end of stream. Instead, we have $\tilde{H}$. Let $A_1 := e(\tilde{L}^+, \tilde{L}^-) + \sum_{v \in \tilde{H}} \max\{e(v, \tilde{L}^-), e(v, \tilde{L}^+)\}$ denote the value of the cut $(\tilde{C}, V \setminus \tilde{C})$ obtained by running Algorithm 1 on $G[\tilde{L}]$ and then assigning the vertices in $\tilde{H}$ in a greedy manner. Let $A_2 := \sum_{v \in \tilde{H}} (e(v, \tilde{L}^-) + e(v, \tilde{L}^+))$ denote the value of the cut $(\tilde{H}, \tilde{L})$. Suppose that the best of $(\tilde{C}, V \setminus \tilde{C})$ and $(\tilde{H}, \tilde{L})$ cuts is a $(\frac{1}{2} + \frac{\epsilon^2}{16})$-approximation for the MAX-CUT value of G. In the following, we show that ALG_1 and ALG_2 are good approximations of A_1 and A_2, respectively. Therefore, $\max\{\mathrm{ALG}_1, \mathrm{ALG}_2\}$ returned by Algorithm 4 is also a strictly better than $\frac{1}{2}$-approximation for the MAX-CUT value of G.

Since $V^+ = \tilde{H}^+ \cup \tilde{L}^+$ and $V^- = \tilde{H}^- \cup \tilde{L}^-$, we have $e(v, V^+) = e(v, \tilde{H}^+) + e(v, \tilde{L}^+)$ and $e(v, V^-) = e(v, \tilde{H}^-) + e(v, \tilde{L}^-)$ for any vertex $v \in V$. By Lemma 17, with probability at least $1 - \frac{\delta}{4}$, for all vertices $v \in \tilde{H}$, we have

$$\begin{aligned}e(v, \tilde{H}^+) + e(v, \tilde{L}^+) \le f_v^+ \le e(v, \tilde{H}^+) + e(v, \tilde{L}^+) + 2\epsilon^7\delta^3 m, \\ e(v, \tilde{H}^-) + e(v, \tilde{L}^-) \le f_v^- \le e(v, \tilde{H}^-) + e(v, \tilde{L}^-) + 2\epsilon^7\delta^3 m.\end{aligned}$$

Since $|\tilde{H}| \leq \frac{2\beta}{\delta^3\epsilon^4}$, we have $0 \leq e(v,\tilde{H}^+), e(v,\tilde{H}^-) \leq \frac{2\beta}{\delta^3\epsilon^4}$. Therefore, we have

$$e(v,\tilde{L}^+) \leq f_v^+ \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m + e(v,\tilde{L}^+),$$
$$e(v,\tilde{L}^-) \leq f_v^- \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m + e(v,\tilde{L}^-).$$

Then we have

$$0 \leq f_v^+ - e(v,\tilde{L}^+) \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m \quad \text{and} \quad 0 \leq f_v^- - e(v,\tilde{L}^-) \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m,$$

and

$$\max\{e(v,\tilde{L}^+), e(v,\tilde{L}^-)\} \leq \max\{f_v^+, f_v^-\} \leq \frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m + \max\{e(v,\tilde{L}^+), e(v,\tilde{L}^-)\}.$$

Note that

$$e(\tilde{L}^+,\tilde{L}^-) = e(V^+,V^-) - e(\tilde{H}^+,\tilde{H}^-) - \sum_{v\in\tilde{H}^+} e(v,\tilde{L}^-) - \sum_{v\in\tilde{H}^-} e(v,\tilde{L}^+),$$
$$\tilde{e}(\tilde{L}^+,\tilde{L}^-) = e(V^+,V^-) - \sum_{v\in\tilde{H}^+} f_v^- - \sum_{v\in\tilde{H}^-} f_v^+.$$

We have

$$\begin{aligned} e(\tilde{L}^+,\tilde{L}^-) - \tilde{e}(\tilde{L}^+,\tilde{L}^-) &= \sum_{v\in\tilde{H}^+}(f_v^- - e(v,\tilde{L}^-)) + \sum_{v\in\tilde{H}^-}(f_v^+ - e(v,\tilde{L}^+)) - e(\tilde{H}^+,\tilde{H}^-) \\ &\leq \frac{2\beta}{\delta^3\epsilon^4}\cdot\left(\frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m\right) + \frac{2\beta}{\delta^3\epsilon^4}\cdot\left(\frac{2\beta}{\delta^3\epsilon^4} + 2\epsilon^7\delta^3 m\right) - 0 \\ &= \frac{8\beta^2}{\delta^6\epsilon^8} + 8\beta\epsilon^3 m. \end{aligned}$$

Therefore,

$$\begin{aligned} A_1 - \mathrm{ALG}_1 &= (e(\tilde{L}^+,\tilde{L}^-) - \tilde{e}(\tilde{L}^+,\tilde{L}^-)) + \sum_{v\in\tilde{H}}(\max\{e(v,\tilde{L}^-), e(v,\tilde{L}^+)\} - \max\{f_v^-, f_v^+\}) \\ &\leq \left(\frac{8\beta^2}{\delta^6\epsilon^8} + 8\beta\epsilon^3 m\right) + \frac{2\beta}{\delta^3\epsilon^4}\cdot 0 = \frac{8\beta^2}{\delta^6\epsilon^8} + 8\beta\epsilon^3 m. \end{aligned}$$

So, $\mathrm{ALG}_1 \geq A_1 - (\frac{8\beta^2}{\delta^6\epsilon^8} + 8\beta\epsilon^3 m) = A_1 - \Theta(\epsilon^3 m)$.

Similarly,

$$A_2 - \mathrm{ALG}_2 = \sum_{v\in\tilde{H}}((e(v,\tilde{L}^-) - f_v^-) + (e(v,\tilde{L}^+) - f_v^+)) \leq \frac{2\beta}{\delta^3\epsilon^4}\cdot(0+0) = 0.$$

So, $\mathrm{ALG}_2 \geq A_2$.

Since we assume that $\max\{A_1, A_2\}$ is a $(\frac{1}{2} + \frac{\epsilon^2}{16})$-approximation for the MAX-CUT value of G, we have $\mathrm{ALG} := \max\{\mathrm{ALG}_1, \mathrm{ALG}_2\} \geq \max\{A_1, A_2\} - \Theta(\epsilon^3 m) \geq (\frac{1}{2} + \frac{\epsilon^2}{16})\cdot\mathrm{OPT} - \Theta(\epsilon^3\cdot\mathrm{OPT}) = (\frac{1}{2} + \Omega(\epsilon^2))\cdot\mathrm{OPT}$.

Finally, it remains to show that the best of $(\tilde{C}, V\setminus\tilde{C})$ and $(\tilde{H},\tilde{L})$ cuts is a $(\frac{1}{2} + \frac{\epsilon^2}{16})$-approximation for the MAX-CUT value of G. This directly follows from Theorem 6 (with failure probability $\frac{\delta}{4}$), by substituting H and L with $\tilde{H}$ and $\tilde{L}$, respectively. Together with Lemma 15, Lemma 16, Lemma 17, and applying union bound, this concludes the proof. ◀

B Constant Query Complexity in Random Order Streams

In this section, we show that in the case of random-order streams, it suffices to query the ϵ-accurate oracle $\mathcal{O}$ for the labels of a constant number of vertices. For simplicity, we provide only a sketch of the main ideas and omit the formal proof. We will utilize the following lemma.

▶ **Lemma 18** (Lemma 2.2 in [9]). *Let $a, b \in \mathbb{R}$ with $a < b$, $n \in \mathbb{N}$ and $x \in [a,b]^n$. Let $\Sigma = \sum_{i=1}^{n} x_i$. For any $\eta, \delta \in (0,1)$, there exists an algorithm which samples a set T of $t = O(\eta^{-2} \log \delta^{-1})$ indices from $[n]$ and returns an estimate $\tilde{\Sigma} = \frac{n}{t} \sum_{i \in T} x_i$ such that $|\Sigma - \tilde{\Sigma}| \leq \eta(b-a)n$ with probability at least $1 - \delta$.*

Similar to Algorithm 2, we store the first $\text{poly}(1/\epsilon, 1/\delta)$ edges in the random order stream and use them to identify a set $\tilde{H}$ of size $\text{poly}(1/\epsilon, 1/\delta)$ that contains all high-degree vertices H with high probability as in Lemma 10. For this part, we do not need any information on the labels of vertices provided by the oracle $\mathcal{O}$. Recall that the algorithm considers two candidate cuts and returns the one with the larger size. Let $\tilde{L} := V \setminus \tilde{H}$ and $\tilde{S} := \tilde{H} \setminus H$. The first candidate is obtained by performing the greedy extension of $(\tilde{L}^+ \cup \tilde{S}^+, \tilde{L}^- \cup \tilde{S}^-)$ using H. The second candidate is simply the cut (H, L). Formally, the sizes of these two cuts are given as follows:

$$\begin{aligned}
\text{ALG}_1 &= e(L^+, L^-) + \sum_{v \in H} \max\{e(v, L^-), e(v, L^+)\} \\
&= e(\tilde{L}^+, \tilde{L}^-) + e(\tilde{S}^+, \tilde{S}^-) + \sum_{v \in \tilde{S}^+} e(v, \tilde{L}^-) + \sum_{v \in \tilde{S}^-} e(v, \tilde{L}^+) + \sum_{v \in H} \max\{e(v, L^-), e(v, L^+)\}, \\
\text{ALG}_2 &= e(H, L) = \sum_{v \in H} e(v, L) = \sum_{v \in H} (e(v, \tilde{L}) + e(v, \tilde{S})).
\end{aligned}$$

Observe that, to compute the second cut size ALG_2, there is no need to query the oracle $\mathcal{O}$. It suffices to count $e(v, \tilde{L})$ for each vertex $v \in \tilde{H}$ using the remaining edges (after the first $\text{poly}(1/\epsilon, 1/\delta)$ edges) during the stream. At the end of the stream, we can retrieve H from $\tilde{H}$ and compute ALG_2 exactly.

Next, we focus on estimating ALG_1 by querying the oracle $\mathcal{O}$ a constant number of times. Specifically, we decompose ALG_1 into four parts and estimate each part respectively.

- **(I)** $e(\tilde{L}^+, \tilde{L}^-)$. During the stream (after the first $\text{poly}(1/\epsilon, 1/\delta)$ edges), we employ reservoir sampling to sample $O(\epsilon^{-4} \log \delta^{-1})$ edges T uniformly at random from $E(G[\tilde{L}])$, the set of edges with both endpoints in $\tilde{L}$. Let $U := \bigcup_{(u,v) \in T} \{u, v\}$. By Lemma 18, we query $\mathcal{O}$ for the vertices in U and use $\frac{e(G[\tilde{L}])}{|T|} \cdot e(U^+, U^-)$ to estimate $e(\tilde{L}^+, \tilde{L}^-)$, with an additive error of $\epsilon^2 \cdot e(G[\tilde{L}])$.
- **(II)** $e(\tilde{S}^+, \tilde{S}^-)$. Since we store all edges with both endpoints in $\tilde{H}$ during the stream and $|\tilde{H}| = \text{poly}(1/\epsilon, 1/\delta)$, we can compute $e(\tilde{S}^+, \tilde{S}^-)$ exactly by querying $\mathcal{O}$ a constant number of times.
- **(III)** $\sum_{v \in \tilde{S}^+} e(v, \tilde{L}^-) + \sum_{v \in \tilde{S}^-} e(v, \tilde{L}^+)$. For each vertex $v \in \tilde{H}$, we use reservoir sampling to sample $O(\epsilon^{-4} \log \delta^{-1})$ edges T_v uniformly at random from $E(v, \tilde{L})$, the set of edges with one endpoint at v and the other in $\tilde{L}$. Let $U_v := \bigcup_{(u,v) \in T_v} \{u\}$. By Lemma 18, we query $\mathcal{O}$ for the vertices in U_v and use $\frac{e(v, \tilde{L})}{|T_v|} \cdot e(v, U_v^+)$ to estimate $e(v, \tilde{L}^+)$ and use $\frac{e(v, \tilde{L})}{|T_v|} \cdot e(v, U_v^-)$ to estimate $e(v, \tilde{L}^-)$, both with an additive error of $\epsilon^2 \cdot e(v, \tilde{L})$. Therefore, we can estimate $\sum_{v \in \tilde{S}^+} e(v, \tilde{L}^-) + \sum_{v \in \tilde{S}^-} e(v, \tilde{L}^+)$ with an additive error of $\epsilon^2 \cdot \sum_{v \in \tilde{S}} e(v, \tilde{L}) = \epsilon^2 \cdot e(\tilde{S}, \tilde{L})$.

(IV) $\sum_{v\in H}\max\{e(v,L^-),e(v,L^+)\}$. Since $L^- = \tilde{S}^- \cup \tilde{L}^-$ and $L^+ = \tilde{S}^+ \cup \tilde{L}^+$, we have $e(v,L^-) = e(v,\tilde{S}^-) + e(v,\tilde{L}^-)$ and $e(v,L^+) = e(v,\tilde{S}^+) + e(v,\tilde{L}^+)$, for each vertex $v \in H$. Similar to **(II)** and **(III)**, we can estimate $\sum_{v\in H}\max\{e(v,L^-),e(v,L^+)\}$ with an additive error of $\epsilon^2 \cdot \sum_{v\in H} e(v,\tilde{L}) = \epsilon^2 \cdot e(H,\tilde{L})$.

Let $\widetilde{\mathrm{ALG}}_1$ denote our estimator for ALG_1. Then we have $|\widetilde{\mathrm{ALG}}_1 - \mathrm{ALG}_1| \le \epsilon^2 \cdot (e(G[\tilde{L}]) + e(\tilde{S},\tilde{L}) + e(H,\tilde{L})) \le \epsilon^2 \cdot (e(G[L]) + e(H,L)) \le \epsilon^2 m$.

If $\mathrm{ALG}_2 = e(H,L) \ge (\frac{1}{2}+\epsilon^2)\cdot \mathrm{OPT}$, then we are done. Hence, without loss of generality, we assume that $\mathrm{ALG}_2 = e(H,L) < (\frac{1}{2}+\epsilon^2)\cdot \mathrm{OPT}$. By the proof of Theorem 6, we have $\mathrm{ALG}_1 \ge (\frac{1}{2}+\frac{\epsilon^2}{16})\cdot \mathrm{OPT} \ge (\frac{1}{2}+\frac{\epsilon^2}{16})\cdot \frac{m}{2} \ge \epsilon m$ if we set $\epsilon \le \frac{1}{4}$. Therefore, $|\widetilde{\mathrm{ALG}}_1 - \mathrm{ALG}_1| \le \epsilon^2 m \le \epsilon \cdot \mathrm{ALG}_1$. Since $\mathrm{ALG}_1 \ge (\frac{1}{2}+\frac{\epsilon^2}{16})\cdot \mathrm{OPT}$ and we can use $\widetilde{\mathrm{ALG}}_1$ to approximate ALG_1 within a multiplicative factor of $(1\pm\epsilon)$, we are done.

Query Complexity. In the above analysis, the total query complexity for the ϵ-accurate oracle $\mathcal{O}$ is $\mathrm{poly}(1/\epsilon, 1/\delta, \log(1/\delta))$, which is independent of n.

Distributed and Parallel Low-Diameter Decompositions for Arbitrary and Restricted Graphs

Abstract

We consider the distributed and parallel construction of low-diameter decompositions with strong diameter. We present algorithms for arbitrary undirected, weighted graphs and also for undirected, weighted graphs that can be separated through $k \in \tilde{O}(1)$ shortest paths. This class of graphs includes planar graphs, graphs of bounded treewidth, and graphs that exclude a fixed minor K_r. Our algorithms work in the PRAM, CONGEST, and the novel HYBRID communication model and are competitive in all relevant parameters. Given $\mathcal{D} > 0$, our low-diameter decomposition algorithm divides the graph into connected clusters of strong diameter $\mathcal{D}$. For an arbitrary graph, an edge $e \in E$ of length ℓ_e is cut between two clusters with probability $O(\frac{\ell_e \cdot \log(n)}{\mathcal{D}})$. If the graph can be separated by $k \in \tilde{O}(1)$ paths, the probability improves to $O(\frac{\ell_e \cdot \log\log n}{\mathcal{D}})$. In either case, the decompositions can be computed in $\tilde{O}(1)$[1] depth and $\tilde{O}(m)$ work in the PRAM and $\tilde{O}(1)$ time in the HYBRID model. In CONGEST, the runtimes are $\tilde{O}(\mathrm{HD} + \sqrt{n})$ and $\tilde{O}(\mathrm{HD})$ respectively. All these results hold w.h.p.[2]

Broadly speaking, we present distributed and parallel implementations of sequential divide-and-conquer algorithms where we replace exact shortest paths with approximate shortest paths. In contrast to exact paths, these can be efficiently computed in the distributed and parallel setting [STOC '22]. Further, and perhaps more importantly, we show that instead of explicitly computing vertex-separators to enable efficient parallelization of these algorithms, it suffices to sample a few random paths of bounded length and the nodes close to them. Thereby, we do not require complex embeddings whose implementation is unknown in the distributed and parallel setting.

1 Introduction

This paper considers the efficient construction of so-called (probabilistic) low-diameter decompositions (LDD) for general and restricted graphs in the CONGEST, PRAM, and HYBRID model. An LDD of a (weighted) graph $G := (V, E, \ell)$ with strong diameter $\mathcal{D}$ is a partition of G into disjoint connected subgraphs $\mathcal{K}(G) := K_1, \dots, K_N$ with $K_i := (V_i, E_i)$. We will refer to these subgraphs as *clusters*. We say that a cluster K_i has *strong* diameter $\mathcal{D}$ if it has a diameter of at most $\mathcal{D}$. That is, between two nodes in K_i there is a path of length (at most) $\mathcal{D}$ that only consists of nodes in K_i. In contrast, an LDD with a weak diameter creates possibly disconnected subgraphs with a diameter of $\mathcal{D}$ with respect to the original graph G. Here, for all nodes $v, w \in K_i$, there is a path of length (at most) $\mathcal{D}$ from v to w that can use nodes outside of K_i. We measure the decomposition quality by the number of edges that are *cut* between clusters. An edge $\{v, w\} \in E$ is cut if its two endpoints v and w are assigned to different clusters. Thus, a good clustering algorithm only ensures that *most* nodes are in the same cluster as their neighbors. Without this constraint, a trivial algorithm could simply remove all edges from the graph and return clusters containing one node each. There are several ways to count the edges that are cut. In this work, we consider so-called *probabilistic* decompositions. Here, the probability for an edge $z = \{v, w\}$ to be cut between two clusters K_i and K_j with $i \neq j$ that contain its respective endpoint depends on its length ℓ_z. This means that *short* edges are cut less likely than *long* edges. We use the following formal definition of LDD's in the remainder of this work:

▶ **Definition 1** (Probabilistic Low-diameter Decomposition (LDD)). *Let $G := (V, E, \ell)$ be a weighted graph and $\mathcal{D} > 0$ be a distance parameter. Then, an algorithm for computing an LDD with quality $\alpha \geq 1$ creates a series of disjoint clusters $\mathcal{K} := K_1, K_2, \dots, K_N$ with $K_i := (V_i, E_i)$ where $V_1 \sqcup \dots \sqcup V_N = V$. Futher, it holds:*

1. *Each cluster $K_i \in \mathcal{K}$ has a strong diameter of at most $\mathcal{D}$.*
2. *Each edge $z := \{v, w\} \in E$ of length ℓ_z is cut between clusters with probability $O\left(\frac{\ell_z \cdot \alpha}{\mathcal{D}}\right)$.*

If we do not require each node to be in a cluster, we use the related notion of a Low-Diameter *Clustering* (LDC). In a LDC with quality (α, β) and strong diameter $\mathcal{D}$ we create a series of disjoint clusters $\mathcal{K} := K_1, K_2, \dots, K_N$ with $K_i := (V_i, E_i)$. Each cluster $K_i \in \mathcal{K}$ has a strong diameter of at most $\mathcal{D}$ and each edge $z := \{v, w\} \in E$ of length ℓ_z is cut between clusters with probability (at most) $O\left(\frac{\ell_z \cdot \alpha}{\mathcal{D}}\right)$. Further, each node is part of a cluster with probability at least β. As we will see, LDD's and LDC's are nearly equivalent as we can build an LDD from an LDC by repeatedly applying it until all nodes are clustered.

It is known that the best possible value of α is $O(\log n)$ for general graphs. However, if the graph class is restricted, better decompositions are possible. So, alongside solutions for general graphs, this work will consider the restricted class of so-called k-path separable graphs that Abraham and Gavoille introduced in [2]. Roughly speaking, a weighted graph $G = (G, E, \ell)$ is k-path separable if the *recursive* removal of k shortest paths results in connected components containing a constant fraction of the nodes. Moreover, a graph $G = (G, E)$ is *universally* k-path separable if it is k-path separable for *every* weight function ℓ. Note that this makes universal k-path separability a topological property rather than one that depends on the weight function. Abraham and Gavoille and Diot and Gavoille formalized this as follows:

▶ **Definition 2** (Universally k-Path Separarable Graphs [2, 22]). *A weighted graph $G := (V, E, \ell)$ with n vertices is* k-path separable*, if there exists a subset of vertices S, called a k-path separator, such that:*

1. $S := \mathcal{P}_0 \cup \mathcal{P}_1 \cup \mathcal{P}_2 \cup \ldots$, *where each* $\mathcal{P}_i := \{P_{i_1}, P_{i_2}, \ldots\}$ *is a set of shortest paths in* $G \setminus \bigcup_{j<i} \mathcal{P}_j$.
2. *The total number of paths in* S *is at most* k, *i.e.,* $\sum_{\mathcal{P}_i \in S} |\mathcal{P}_i| \leq k$.
3. *Each connected component in* $G \setminus S$ *contains at most* $\frac{n}{2}$ *nodes.*
4. *Either* $G \setminus S$ *is empty or* k*-path separable.*

If G *is* k*-path separable for any weight function, we call* G *universally* k*-path separable. We will sometimes abuse notation and use* $P_{i_j} \in S$ *when we refer to some path* $P_{i_j} \in \mathcal{P}_i$ *and* $\mathcal{P}_i \in S$.

In this work, we will only consider universally k-path separable graphs. Given this definition, a natural question is which graph classes are k-path separable. Clearly, all graphs that have separators that consist of at most η vertices are trivially universally η-path separable. This follows because every node can be seen as the shortest path to itself in any subgraph that it is contained in. Notably, graphs of bounded tree-width τ have separators that consist of τ nodes [53] and are therefore universally τ-path separable. Further, due to Thorup, it is known that planar graphs are universally 3-path separable [58]. More generally, Abraham and Gavoille [2] showed that every graph $G := (V, E, \ell)$ that does not include a fixed clique minor K_r is universally k-path separable where $k := f(r)$ depends only on r and not the size of G. The concrete value of $f(r)$ is based on the Structure Theorem by Robertson and Seymour [54].

These restricted graph classes have received significant attention in the context of distributed algorithms (cf. [35, 36, 37, 39, 42]). Not only do they contain graph topologies that frequently appear in practice, they also have favorable properties for distributed algorithms as they exclude pathologic worst case topologies. As k-path separable graphs are a superclass of these restricted graphs, we derive novel results for planar graphs, graphs of bounded treewidth, and most importantly, graphs that exclude a fixed minor K_r.

In a nutshell, prior works [13] and [55] have shown that computing LDD's for general graphs can be broken down into $\tilde{O}(1)$ applications of your favorite approximate shortest path algorithm in your favorite model of computation. We extend this innovative insight in two ways by improving the algorithm of [13] and showing that a) we can construct a strong diameter LDD of quality $O(\log n)$ for general graphs and b) on k-path separable graphs one can compute LDD's of quality $O(\log k + \log\log n)$. Again, our algorithms use only approximate shortest paths and are therefore applicable to various models.

Due to its many technical results, this paper takes the form of an extended abstract. In the main part of the paper, we present our algorithms, state our main lemmas, and sketch their proofs. More detailed descriptions and the full analysis, including all proofs, can be found in the full version on arXiv [24]. In the remainder of this section, we will first introduce some notations and convention in Subsection 1.1, then introduce our generalized model of computation in Subsection 1.2, and and state our main results in Subsection 1.3. Finally, we present some important applications for LDD's in Subsection 1.4 and discuss further related work (with a special focus on CONGEST algorithms) in Subsection 1.5.

1.1 Preliminaries and Notations

In this work, we only consider *undirected* graphs $G = (V, E)$ unless specifically mentioned otherwise. We further assume some basic familiarity with graph theory. For an introduction, we refer to standard textbooks, e.g., [21]. Throughout this work, we denote the distance between a node $v \in V$ and a set $S \subset V$ as $d(v, S)$. This distance is defined as the (weighted) length of the shortest path between v and the node $w \in S$ closest to v. If we consider the distance w.r.t. to a subgraph $H \subset G$, we write $d_H(\cdot, \cdot)$. Further for a subset $S \subseteq V$, a

subgraph $H \subseteq G$, and a distance δ, we define $B_H(S, \delta) = \{v \in V \mid d_H(v, S) \leq \delta\}$ to be the so-called *ball* that contains all nodes in distance (at most) δ to any node in G. Again, for $H = G$, we omit the subscript.

1.2 Model(s)

In this work, we present algorithms that can be implemented in several different models of computation for parallel and distributed systems by reducing our algorithms to (approximate) shortest-path computations. Notably, we can derive algorithms for the CONGEST and the PRAM models, which are the de facto standard models for distributed and parallel computing, respectively.

PRAM: In the PRAM model, we assume computations are executed on a machine with p processors. The processes work over a set of shared memory cells M. The input graph G is stored in these cells. In a single step of computation, they can read and write from each cell in an atomic operation. If more than one processor writes in a cell, an arbitrary processor succeeds, i.e., we consider a CRCW PRAM. The *work* of a PRAM algorithm is the total number of primitive read or write operations that the processors perform. Further, the *depth* is the length of the longest series of operations that have to be performed sequentially.

CONGEST: In the CONGEST model [52], we consider a static graph $G = (V, E)$. Each node has a unique identifier. We assume these identifiers consist of $O(\log n)$ bits, i.e., they are picked from interval $[1, \dots, n^c]$ for some $c \in \Theta(1)$. Time proceeds in synchronous rounds. In each round, nodes receive *all* messages sent in the previous round; they perform (unlimited) computation based on their internal states and the messages they have received so far. Finally, a node $v \in V$ may send a *distinct* message of size $O(\log n)$ to each neighbor in G. Thus, a message may contain a node's identifier and a few more bits of information.

HYBRID: In addition to these two *classic* models of computation, we will also use the recently established HYBRID model. The HYBRID model was introduced in [7] as a means to study distributed systems that leverage multiple communication modes. Just as in CONGEST, we assume synchronous rounds. In the HYBRID model, a node can send a message to all its neighbors in G in the so-called *local* mode and also $O(\log n)$ nodes of its choice (as long as no node receives more than $O(\log n)$ messages) in the so-called *global* mode. One typically parameterizes the size of the messages in the local mode. For a discussion of this model, we refer the interested reader to [7, 57].

Rather than exploiting these models' intricacies in bespoke algorithms, we reduce our algorithms to $\tilde{O}(1)$ applications of a $(1+\epsilon)$-approximate shortest path algorithm with $\epsilon \in O\left(1/\log^2 n\right)$ and some simple aggregations on subsets of the input graph. To be precise, our algorithms are based on approximate set-source shortest paths (SetSSP) and so-called minor aggregations. In the remainder of this section, we will clarify what exactly these operations do and how efficiently they can be implemented in the CONGEST, the PRAM, and the HYBRID model.

First, we formalize the class of approximate SetSSP algorithms. For our algorithms, we must be able to compute the shortest paths to a subset of nodes and also to virtual nodes that may not be part of the original input graphs. We define this problem as follows:

▶ **Definition 3** (Approximate SetSSP with Virtual Nodes). *Let $G := (V, E)$ be a weighted graph and let $G' := (V', E', w)$ with $V' := V \cup \{s_1, s_2, \dots\}$ be the graph that results from adding $\tilde{O}(1)$ virtual nodes to G. Each virtual node can have an edge of polynomially bounded weight to every virtual and non-virtual node in G'. Finally, let $S \subset V'$ be an arbitrary subset of virtual and non-virtual nodes. Then, an algorithm that solves $(1+\epsilon)$-approximate set-source shortest path with virtual nodes computes the following:*

- *Each node $v \in V' \setminus S$ learns a predecessor $p_v \in N(v)$ on a path of length at most $(1+\epsilon)d(v,S)$ to some node in S and marks the edge $\{v, p_v\}$. Together, all the marked edges imply an approximate shortest path tree T[3] rooted in set S.*
- *Each node $v \in V'$ learns its distance $d_T(v,S) \leq (1+\epsilon)d(v,S)$ to S in tree T, i.e., its exact distance to S in T and its $(1+\epsilon)$-approximate distance to S in G'.*

Note that, if we can compute SetSSP on a graph G in τ time/depth, we can also compute it on any set of disjoint subgraphs of G in τ time/depth. To be precise, let $C_1, \dots, C_N$ with $C_i = (V_i, E_i)$ be a set of disjoint subgraphs of G and let $S_1, \dots, S_N$ with $S_i \subset V_i$ be subsets of nodes from each C_i. Suppose, we want to compute an SetSSP from each S_i in C_i. To this end, we simply assign a prohibitively high length to an edge between two subgraphs $C_i \neq C_j$. Then, we compute a SetSSP from $\mathcal{S} = \{S_1, \dots, S_N\}$ that results in a tree T. Due to their length, no (approximate) shortest path will ever contain an edge between subgraphs and so, the closest node to any node in C_i must be from S_i. Thus, the tree restricted to C_i is an approximate shortest path tree for S_i.

Our second building block are so-called *minor aggregations*, which were first introduced in [35, 36]. Consider a network $G = (V, E)$ and a (possibly adversarial) partition of vertices into disjoint subsets $V_1, V_2, \dots, V_N \subset V$, each of which induces a *connected* subgraph $G[V_i]$. We will call these subsets *minors*. Further, let each node $v \in V$ have private input x_v of length $\tilde{O}(1)$, i.e., a value that can be sent along an edge in $\tilde{O}(1)$ rounds. Finally, we are given an aggregation function $\bigotimes$ like `SUM`, `MIN`, `AVG`, ..., which we want to compute in each part. Then a *minor aggregation* computes these functions in all minors $G[V_i]$. Note that the diameter of these minors might be (much) larger than the diameter of G. Therefore, the corresponding algorithm has to use edges outside of each minor to be efficient.

Both approximate shortest paths and minor aggregation can be efficiently implemented in arbitrary and restricted graphs in all of our models. Note that we are mainly interested in algorithms that require $\tilde{O}(1)$ aggregations and $(1+\epsilon)$-approximate SetSSP computations with $\epsilon \in \Omega(1/\log^c n)$ as these algorithms can then be efficiently implemented in all three models. Note that *efficient* means different things in different models. While in the PRAM, we hope for a polylogarithmic depth using a linear number of processors and in HYBRID we aim for polylogarithmic runtime, we have to manage our expectations for CONGEST. In the CONGEST model, the best we can hope for is $O(\mathrm{HD})$, where HD denotes the length of the longest shortest path between two nodes *if we ignore the weights*, the so-called hop diameter. The hop-diameter is a natural lower bound for most *global* problems in CONGEST as it describes the precise time in which a message starting from a node $v \in V$ can (theoretically) reach every node in the network. While this can be up to n, it may be much smaller in many practical graphs.

To be precise, it holds:

▶ **Theorem 4.** *Let $G := (V, E, \ell)$ be a (weighted) graph and let $\mathcal{A}$ be an algorithm that can be broken down into the following two types of operations:*

1. *A $(1+\epsilon)$-approximate SetSSP on a set of disjoint connected subgraphs $C_1, \dots, C_N$ with $C_i = (V_i, E_i)$ from a set of sources $S_1, \dots, S_N$ with $S_i \subset V_i$.*
2. *A minor aggregation on a set of disjoint connected subgraphs $C_1, \dots, C_N$ with $C_i = (V_i, E_i)$.*

[3] Technically, for a set S with $|S| \geq 2$, the algorithm produces a forest with the individual tree rooted in the nodes S. However, we slightly abuse notation and refer to it as a forest.

The subgraphs $C_1, \dots, C_N$ may differ in each step. Suppose that $\mathcal{A}$ can be broken down into τ_s steps of $(1+\epsilon)$-approximate SetSSP computations and τ_m minor aggregations. Then, it holds:

- *In* CONGEST*, $\mathcal{A}$ can be executed in $\tilde{O}\left((\epsilon^{-2} \cdot \tau_s + \tau_m) \cdot (HD + \sqrt{n})\right)$ time, w.h.p. If graph G is (universally) k-path separable, $\mathcal{A}$ can be executed in $\tilde{O}\left((\epsilon^{-2} \cdot \tau_s + \tau_m) \cdot k \cdot HD\right)$ time, w.h.p.*
- *In the* PRAM *model with $\tilde{O}(m)$ processors, $\mathcal{A}$ can be executed with $\tilde{O}\left((\epsilon^{-2} \cdot \tau_s + \tau_m) \cdot m\right)$ work and $\tilde{O}\left(\tau_s + \tau_m\right)$ depth, w.h.p.*
- *In the* HYBRID *model, $\mathcal{A}$ can be executed in $\tilde{O}\left((\epsilon^{-2} \cdot \tau_s + \tau_m)\right)$ time, w.h.p., using $O(n)$ bits per message in the local mode. If graph G is (universally) k-path separable, $\mathcal{A}$ can be executed in $\tilde{O}\left((\epsilon^{-2} \cdot \tau_s + \tau_m) \cdot k\right)$ time, w.h.p., using $O(\log n)$ bits per message in the local mode*

For general graphs, the bounds for approximate SetSSP in CONGEST and PRAM follow from a recent breakthrough result [56]. Similarly, the runtimes for minor aggregation in CONGEST and PRAM are given in [41] and [56], respectively. Finally, [57] showed the bounds for both SetSSP and minor aggregation in the HYBRID model. For the runtime on k-path separable graphs in CONGEST, we use that k-path separable graphs exclude K_{4k+1} as minor [22]. If the graph excludes a fixed clique minor K_r, the runtime of a minor aggregation is $\tilde{O}(r \cdot \mathrm{HD})$ [37] and $(1+\epsilon)$-approximate SetSSP can be solved in $\tilde{O}(\epsilon^{-2} \cdot r \cdot \mathrm{HD})$ [56]. Note that for CONGEST, all these bounds are optimal as neither SetSSP nor the aggregation can be computed faster [41].

1.3 Our Contributions

In the following, we give a formal statement of our contributions. First, we show that we can achieve the (asymptotically) best possible quality of $O(\log n)$ for general through approximate SetSSP and minor aggregation. Our first main theorem is the following.

▶ **Theorem 5** (LDDs for General Graphs)**.** *Let $\mathcal{D} > 0$ be an arbitrary distance parameter and $G := (V, E, \ell)$ be a (possibly weighted) undirected graph. Then, there is an algorithm that creates an LDD of G with strong diameter $\mathcal{D}$ and quality $O(\log n)$. The algorithm can be implemented with $\tilde{O}(1)$ minor aggregations and $\tilde{O}(1)$ $(1+\epsilon)$-approximate SetSSP computations where $\epsilon \in O\left(1/\log^2 n\right)$.*

By Theorem 4, this implies that the algorithm can, w.h.p., be implemented in $\tilde{O}(\mathrm{HD} + \sqrt{n})$ time in CONGEST, and $\tilde{O}(1)$ depth in the PRAM and $\tilde{O}(1)$ time in HYBRID. Thus, our algorithm is currently the best randomized LDD construction in CONGEST for general weighted graphs. It has same runtime as [55] and [13], creates clusters of *strong* diameter, and has (asymptotically) optimal quality of $O(\log n)$. We achieve this improvement through a more fine-grained analysis of the well-known exponential-delay clustering first used by Miller et al. [50] that was already used by Becker, Lenzen, and Emek in [13]. In fact, we only present a little addition to their existing algorithm to ensure the strong diameter.

Second, for k-path separable graphs with $k \in \tilde{O}(1)$, we present an algorithm with almost exponentially better quality. More precisely, our second main theorem is the following.

▶ **Theorem 6** (LDDs for k-Path Seperable Graphs)**.** *Let $\mathcal{D} > 0$ be an arbitrary distance parameter and $G := (V, E, \ell)$ be a (possibly weighted) $\tilde{O}(1)$-path separable graph. Then, there is an algorithm that creates an LDD of G with strong diameter $\mathcal{D}$ and quality $O(\log \log n)$. The algorithm can be implemented with $\tilde{O}(1)$ minor aggregations and $\tilde{O}(1)$ $(1+\epsilon)$-approximate SetSSP computations where $\epsilon \in O\left(1/\log^2 n\right)$.*

Thus, by the same reasoning as above, the algorithm can, w.h.p., be implemented in $\tilde{O}(\mathrm{HD})$ time in CONGEST, and $\tilde{O}(1)$ depth in the PRAM and $\tilde{O}(1)$ time in HYBRID.

Our main technical novelty for proving Theorem 6 is a weaker form of a path separator that can be constructed without computing an embedding of G. Prior algorithms for k-path separable graphs, e.g. [2], often employ a so-called shortest path decomposition where we recursively compute k-path separators until the graph is empty. However, computing these separators requires precomputing a complex embedding, which we cannot afford in a distributed or parallel setting. Instead, we take a different approach to completely avoid the (potentially expensive) computation of an embedding. We show that by sampling approximate shortest paths (in a certain way), we can obtain what we will call a weak $\mathcal{D}$-separator. A weak $\mathcal{D}$-separator S' only ensures that in the graph $G \setminus S$, all nodes have at most a constant fraction of nodes in distance $\mathcal{D}$. In particular, in contrast to a *classical* separator, the graph $G \setminus S'$ might still be connected. We strongly remark that, in considering weak separators, we sacrifice some of the useful properties of a traditional seperator. Nevertheless, this only results in some additional polylogarithmic factors in the runtime of our applications.

1.4 Applications of LDDs

In this section, we discuss the natural question of why we consider LDD's in the first place. Simply put, LDD's are part of an algorithm designer's toolkit for developing efficient divide-and-conquer algorithms, as they offer a generic way to decompose a given graph. As such, creating LDD's with low edge-cutting probability plays a significant role in numerous algorithmic applications. In the following, we present a comprehensive list of applications (which we do not claim to be complete):

Tree Embeddings. As a first example, LDD's can be used to embed graphs into trees, i.e., constructing so-called metric tree embeddings (MTE) and low-stretch spanning trees (LSSP). In both, we map a given graph $G := (V, E, \ell)$ into a randomly sampled tree $T = (V, E_T, \ell_T)$ in a way that preserves the path lengths of the original graph G on expectation. In an LSSP, it must hold $E_T \subset E$, i.e., we compute a subtree of G, while a MTE can use virtual edges not present in the original graph. LSSPs and MTEs have proven to be a helpful design paradigm for efficient algorithms as many computational problems are significantly easier to solve on trees than on general graphs. For example, they have been used to construct distributed and parallel solvers for certain important classes of LPs [6, 14, 20, 38], which can then be used solve MaxFlow and other complex problems. Nearly all constructions use LDD's (or variants thereof) as subroutines; see [1, 5, 12, 25] for the construction of LSSPs and [8, 9, 10, 31] for MTEs.

Light Spanners. Another interesting avenue for LDD's are so-called *light spanners* first introduced by Elkin, Neimann, and Solomon in [30]. Given a weighted graph $G = (V, E, \ell)$, a t-spanner is a subgraph $H \subset G$ that approximately preserves the distances between the nodes of the original graph by a factor t, i.e., for all pairs of node $v, w \in V$, it holds $d_H(v, w) \leq t \cdot d_G(v, w)$. A spanner's lightness L_H is the ratio between the weight of all its edges and the MST of graph G, i.e., it holds $L_H = \sum_{e \in H} \ell_e / \sum_{e \in MST(G)} \ell_e$. Thus, compared to the LSSPs and MTEs, light spanners have more freedom in choosing their edges as they are not required to be trees. The lightness is (arguably) a natural quality measure for a spanner, especially for distributed computing. Consider, for example, an efficient broadcast scheme in which a node wants to spread a message to every other node in G. Further, suppose the edges' length as the cost of using this edge to transmit a message. If we send the messages along

the edges of the light spanner H of G, the total communication cost can be bound by its lightness, and the stretch bounds the cost of the path between any two nodes. Despite this, there are almost no distributed algorithms that compute t-spanners with an upper bound on the lightness with [26] being a notable exception of stretch $O(k)$ with lightness $\tilde{O}(n^{\frac{1}{k}})$. The complicating factor in the distributed construction is that lightness is a global measure. Many previously known distributed spanner constructions like [11] or [50] are very local in their computations as they only consider each node's t-neighborhood with $t \in O(\log n)$. Therefore, the resulting spanners' lightness is unbounded despite having few edges. LDD's are connected to light spanners through an observation by Neiman and Filtser in [33]: They show that with black-box access to an LDD algorithm with quality α, one can construct an $O(\alpha)$-spanner with lightness $\tilde{O}(\alpha)$ for any weighted graph $G = (V, E, \ell)$. In addition to an algorithm that creates LDD's for geometrically increasing diameters, they only require so-called (α, β)-nets for which they already provided a distributed implementation in [26]. Thus, finding better distributed algorithms LDDs, especially for restricted graphs, drectly improves the distributed construction of light spanners.

Compact Routing Schemes. *Routing schemes* are distributed algorithms that manage the forwarding of data packets between network devices. Thus, developing efficient routing schemes is essential to enhance communication among multiple parties in distributed systems and, therefore, is well researched [15, 18, 27, 28, 42, 43, 44, 45, 46, 48]. In particular, it is known that LDD's can be used to construct routing schemes with routing paths that are not significantly longer than the shortest paths in G. An LDD with strong diameter and quality α directly enables us to construct a routing scheme where all paths only differ by a factor of $O(\alpha)$ from the true shortest paths. This factor is typically referred to as the stretch of the routing scheme. The core idea is to create LDD's with diameter $O(\alpha\mathcal{D}_i)$ for geometrically increasing distance scales $\mathcal{D}_i = 2^i$. Then, for the right choice of parameters hidden in the O-notation, for any two nodes in distance $[\mathcal{D}_i, 2\mathcal{D}_i]$ there is a cluster of diameter $O(\alpha\mathcal{D})$ containing them both with constant probability. Using techniques presented in [23], this is sufficient to efficiently compute a routing scheme with stretch $O(\alpha)$ in CONGEST, the PRAM, and the HYBRID model. However, this stretch can likely be improved using more sophisticated algorithms.

1.5 Related Work

In this section, we present some related decomposition schemes. We focus on the CONGEST model as it provides the greatest variety of decomposition schemes. We present a compact overview in Table 1.

Despite the vast number of applications for LDD's on *weighted* graphs, research on LDD's in a distributed setting has mostly focused on the unweighted case, producing many efficient algorithms in this regime. Two notable exceptions, however, explicitly consider weighted graphs and are closely related to our results: The work of Becker, Emek, and Lenzen [13] creates LDD's of quality $O(\log n)$ with weak diameter[4] for general graphs. We note that $O(\log n)$ is the best quality we can hope for in an LDD due to a result by Bartal [8]. The algorithm requires $\tilde{O}(\mathrm{HD} + \sqrt{n})$ time in the CONGEST model, which is optimal as each distributed LDD construction in a weighted graph requires $\Omega(\mathrm{HD} + \sqrt{n})$ time [40]

[4] Actually, [13] proves a stronger property of the diameter. Although the diameter is weak, the number of nodes outside of a cluster that are part of the shortest path between two nodes of a cluster is limited. For many applications, this is sufficient and just as good as a strong diameter.

as we can derive approximate shortest paths from it. Just as our algorithm, [13] consists of $\tilde{O}(1)$ $(1+\epsilon)$-approximate SetSSP computations with $\epsilon \in O\left(1/\log^2 n\right)$. Further, [55], makes two significant improvements compared to [13]. They present a decomposition with strong diameter (instead of weak), and their construction is deterministic (instead of randomized). Here, they do not bound the probability that a specific edge of length ℓ is cut, but instead – since the algorithm is deterministic – count the overall number of edges of length ℓ that are cut. We say that a deterministic decomposition has quality α, if the number of edges of length ℓ with endpoint in different clusters is bound by $m \cdot \frac{\alpha \cdot \ell}{\mathcal{D}}$. Note that $m \cdot \frac{\alpha \cdot \ell}{\mathcal{D}}$ is exactly the *expected* number of cut edges in a probabilistic LDD of quality α. Thus, with constant probability, the probabilistic version roughly cuts the same number of edges. However, without further information about the specific random choices made by the corresponding algorithm, a probabilistic LDD could cut many more edges. While this can be mitigated with standard probability amplification techniques, i.e., executing the algorithm $O(\log n)$ times and picking the iteration that cuts the fewest edges, a deterministic LDD does not have this problem in the first place. In a deterministic LDD, we have the guarantee that no matter what happens in the execution of the algorithm, less than $m \cdot \frac{\alpha \cdot \ell}{\mathcal{D}}$ edges of length ℓ are cut. This makes these decompositions very useful when we do not have the time or resources for $O(\log n)$ repetitions. A typical example is distributed algorithms for local problems, where we aim for sublogarithmic runtimes. That being said, they have a slightly worse quality of only $O(\log^3 n)$. Again, the algorithm consists of $\tilde{O}(1)$ $(1+\epsilon)$-approximate SetSSP computations with $\epsilon \in O\left(1/\log^2 n\right)$.

For restricted graphs like planar, bounded treewidth, or minor-free graphs, we are unaware of a distributed/parallel algorithm explicitly designed for weighted graphs. The research [16, 17, 29, 34, 47, 19] in the CONGEST model focused on so-called *network decompositions* for unweighted graphs that enable fast algorithms for local problems like MIS, Coloring, or Matching. In principle, these algorithms could also be applied to weighted graphs and produce LDD's. However, their runtime depends on the diameter $\mathcal{D}$ of the resulting clusters, which might be much larger than the hop diameter (or even n) if the graph is weighted. We further remark that some authors use slightly different notations when describing LDD's. While our definition above focuses on the clusters' diameter, some works emphasize the number of cut edges. That is, they define it as a decomposition that cuts $\epsilon \cdot m$ edges and creates a cluster of diameter $\mathcal{D} := O(\epsilon^{-1})$. The quality is then described by the blowup in the diameter. Notably, Chang and Su [17] show that a low-diameter decomposition with $\mathcal{D} = O(r\epsilon^{-1})$ can be computed in $\epsilon^{-O(1)} \log^{O(1)} n$ rounds with high probability and $\epsilon^{-O(1)} 2^{O(\sqrt{\log n \log\log n})}$ rounds deterministically in the CONGEST model for any K_r-free graph. Chang [16] later improved the deterministic runtime to $O(\mathcal{D} \log^* n + \mathcal{D}^5)$. In particular, if we translate this to our notion of quality, Chang [16] for unweighted graphs that present LDD's in K_r-free graphs with quality $O(r)$ in the CONGEST model. Therefore, our algorithm has worse a worse quality of $O(\log\log n)$ but is faster for large diameters $\mathcal{D}$, which arguably trades off its worse cutting probability. Also note that our techniques are entirely different from those of [16]. We elaborate more on this in the full version [24].

1.6 Structure of This Paper

The main part of the paper is structured as follows: In Section 2 we present the algorithm behind Theorem 5. In doing so, we also present several useful intermediate results we reuse later. Then, in Section 3 we present our novel technique to compute weak separators. In Section 4, we combine our insights into clustering algorithms from Section 2 and findings on the construction of separators from Section 3 to develop the algorithm behind Theorem 6.

Table 1 An overview of the related work on LDD's for various graph families in the CONGEST model.

2 Strong Diameter LDDs for General Graphs

In this section, we present the algorithm behind Theorem 5. The description is divided into three sections/subroutines. First, in Subsection 2.1, we present a generic clustering algorithm. Second, in Subsection 2.2 we combine this algorithm with a technique from [13] that cuts all edges with the correct probability. However, we may not add each node to a cluster. Finally, in Subsection 2.3, we present a generic technique that recursively applies the algorithm from Subsection 2.2 to cluster all nodes while asymptotically preserving the cut probability of an edge.

2.1 Pseudo-Padded Decompositions Using Approximate Shortest Paths

We begin with a crucial technical theorem that will build the foundation of most of our results. A key component in this construction is the use of truncated exponential variables. In particular, we will consider exponentially distributed random variables truncated to the $[0, 1]$-interval. Loosely speaking, a variable is truncated by resampling it until the outcome is in the desired interval. In the following, we will always talk about variables that are *truncated to the* $[0, 1]$*-interval* when we talk about truncated variables. The density function for a truncated exponential distribution with parameter $\lambda > 1$ is defined as follows:

▶ **Definition 7** (Truncated Exponential Distribution). *We say a random variable X is truncated exponentially distributed with parameter λ if and only if its density function is $f(x) := \frac{\lambda \cdot e^{-x\lambda}}{1-e^{-\lambda}}$. We write $X \sim \mathsf{Texp}(\lambda)$. Further, if $X \sim \mathsf{Texp}(\lambda)$ and $Y := \mathcal{D} \cdot X$, we write $Y \sim \mathcal{D} \cdot \mathsf{Texp}(\lambda)$.*

The truncated exponential distribution is a useful tool for decompositions that has been extensively used in the past [4, 32, 51]. Using a truncated exponential distribution and $(1+\epsilon)$-approximate SetSSP computations, we prove a helpful auxiliary result, namely:

▶ **Theorem 8** (Pseudo-Padded Decomposition for General Graphs). *Let $\mathcal{D} > 0$ be a distance parameter, ϵ be an error parameter, $G := (V, E, \ell)$ a (possibly weighted) undirected graph, and $\mathcal{X} \subseteq V$ be a set of possible cluster centers. Suppose that for each node $v \in V$, the following two properties hold:*

- ***Covering Property:*** *There is at least one $x \in \mathcal{X}$ with $d_G(v, x) \leq \mathcal{D}$.*
- ***Packing Property:*** *There are at most τ centers $x' \in \mathcal{X}$ with $d_G(v, x') \leq 6\mathcal{D}$.*

Then, for $\epsilon \in o(1/\log \tau)$ there is an algorithm that computes a series of connected clusters $\mathcal{K} = K_1, \dots, K_N$ with strong diameter $4(1+\epsilon)\mathcal{D}$ where for all nodes $v \in V$ and all $\epsilon \leq \gamma \leq \frac{1}{32}$, it holds:

$$\mathbf{Pr}[B(v, \gamma\mathcal{D}) \subset K(v)] \geq e^{-\Theta((\gamma+\epsilon)\log \tau)} - O(1/n^c).$$

Here, $K(v)$ denotes the cluster that contains v. The algorithm can be implemented with one $(1+\epsilon)$ approximate SetSSP computation and $\tilde{O}(1)$ minor aggregations.

Technically, this algorithm is a generalization of the algorithm in [32] that is based on **exact** shortest path computations. This algorithm is itself derived from [50]. Our algorithm replaces all these exact computations through $(1+\epsilon)$-approximate calculations. The main analytical challenge is carrying the resulting error ϵ through the analysis to obtain the bounds in the theorem. The same approach was already used by Becker, Lenzen, and Emek [13]. However, our analysis is more fine-grained w.r.t. to the impact of the approximation parameter ϵ.

In the following, we give the high-level idea behind the construction. An intuitive way to think about the clustering process from [32, 50] is as follows: Each center x draws value $\delta_x \sim \mathcal{D} \cdot \mathsf{Texp}(2 + 2\log \tau)$ and wakes up at time $\mathcal{D} - \delta_x$. Then, it begins to broadcast its identifier. The spread of all centers is done in the same unit tempo. A node v joins the cluster of the *first* identifier that reaches it, breaking ties consistently. If we had $O(\mathcal{D})$ time, we could indeed implement it exactly like this. However, this approach is infeasible for a general $\mathcal{D} \in \tilde{\Omega}(1)$ in weighted graphs as $\mathcal{D}$ may be arbitrarily large. Instead, we will model this intuition using a virtual super source s and shortest path computations. For each center $x \in \mathcal{X}$, we independently draw a value $\delta_x \sim \mathcal{D} \cdot \mathsf{Texp}(2 + 2\log \tau)$ from the truncated exponential distribution with parameter $2 + 2\log(\tau)$. We assume that τ (or some upper bound thereof) is known to each node. Then, we add a virtual source s with a weighted virtual edge (s, x) to each center $x \in \mathcal{X}$ with weight $w_x := (\mathcal{D} - \delta_x)$. Then, we compute a $(1+\epsilon)$-approximate SetSSP from s with $\epsilon \leq \frac{1}{40 \log \tau}$. Any node joins the cluster of the *last* center on its (approximate) shortest path to s.

With exact shortest paths, this construction would preserve the intuition. Any node whose shortest path to s contains center x as its last center on the path to s would have been reached by x's broadcast first. The statement is not that simple with approximate distances as the approximation may introduce a *detour*, so the center that minimizes $(\mathcal{D} - \delta_x) + d(x, v)$ may not actually cluster a node $v \in V$. In particular, two endpoints of a short edge $\{v, w\}$ may end up in different clusters although the same center minimizes the distance to both. The approximation error for v could be large, while for w, it is very low, which can cause undesired behavior. The nodes will only be added to the same cluster, if its center's head start (which is determined by the random distance to the source) is large enough to compensate for the *approximation errors*. This, however, depends on the approximation and *not* an the length of the edge we consider. Nevertheless, if the error ϵ is small enough, we get similar clustering guarantees that are good enough for our purposes. In particular, if the difference in distance between the two closest centers is larger than $O(\epsilon\mathcal{D})$, the clustering behaves very similar to its counterpart with exact distances. In our analysis, we show this by carefully carrying the approximation error through the analysis. We do not introduce any fundamental new techniques, but simply carry the approximation error all the way through the analysis of the corresponding clustering process with exact distances presented in [32].

In addition to Theorem 8 itself, this also allows us to observe the positive correlation between nodes that are on the shortest path to some cluster center. This closer look also allows us to prove the following technical fact about the pseudo-padded decompositions:

▶ **Lemma 9** (Well-Separated Nodes). *Let $\mathcal{K}$ be a partition computed by the algorithm from Theorem 8. Then, there a constant $c \geq 1$ such that for given node $u \in K_i$ with probability $(1/2)$ the following holds: There is path $P_u := (u = v_1, \dots, v_N = x_i)$ of length at most $2(1+\frac{1}{40 \log \tau})\mathcal{D}$ to the cluster center x_i of K_i where for each $v_j \in P_u$, it holds $B\left(v_j, \frac{\mathcal{D}}{c \log \tau}\right) \subseteq K_i$.*

This lemma states that if a single node $v \in V$ is padded, all nodes on a short path to its cluster center are likely padded as well. While this initially sounds very technical, it roughly translates to the following: Consider a clustering $\mathcal{K} = K_1, \dots, K_N$. Then for a suitably chosen $\rho := \frac{\mathcal{D}}{c \cdot \log \tau}$, in each cluster $\mathcal{K}_i = (V_i, E_i)$ there is a constant fraction of nodes $V_i' \subseteq V_i$ in the distance ρ to their closest node in a neighboring cluster $K_j \neq K_i$ **and** for any two $v, w \in V_i'$ there is a path of length $6\mathcal{D}$ (via the cluster center) that only consists of nodes in V_i'. This insight will be *crucial* for our next algorithm. A more detailed description and the full proof of both lemmas can be found in the full version [24].

2.2 Strong LDCs from Pseudo-Padded Decompositions

In this section, we present a generic algorithm that creates an LDC with strong diameter of quality $(O(\log \tau), 1/2)$ if the number of nodes that can be centers of clusters has been sufficiently *sparsed out*. In particular, we suppose that each node can only be in one of τ clusters. For this case, we show that it holds:

▶ **Theorem 10** (A Generic Clustering Theorem). *Let $\mathcal{D} > 0$ be a distance parameter, $G := (V, E, \ell)$ a (possibly weighted) undirected graph, and $\mathcal{X} \subseteq V$ be a set of marked nodes. Suppose that for each node $v \in V$, the following two properties hold:*

- ***Covering Property:*** *There is at least one $x \in \mathcal{X}$ with $d(v, x) \leq \mathcal{D}$.*
- ***Packing Property:*** *There are at most τ centers $x' \in \mathcal{X}$ with $d(v, x') \leq 6\mathcal{D}$.*

Then, there is an algorithm that creates an LDC of strong diameter $8\mathcal{D}$ with quality $(O(\log \tau), 1/2)$. The algorithm can be implemented with $\tilde{O}(1)$ minor aggregations and $\tilde{O}(1)$ $(1+\epsilon)$-approximate SetSSP computations where $\epsilon \in O(1/\log^2 n)$.

The algorithm uses the so-called *blurry ball growing* (BBG) technique. This is perhaps the key technical result that Becker, Emek, and Lenzen introduced in [13]. It provides us with the following guarantees:

▶ **Lemma 11** (Blurry Ball Growing (BBG), cf. [13, 55]). *Given a subset $S \subseteq V$ and an arbitrary parameter $\rho > 0$, an algorithm for BBG outputs a superset $S' \supseteq S$ with the following properties*

1. *An edge $\{v, w\} \in E$ of length $\ell_{(v,w)}$ is cut with probability $\mathbf{Pr}[v \in S', w \notin S'] \leq O\left(\frac{\ell_{(v,w)}}{\rho}\right)$.*
2. *For each node $v \in S'$, it holds $d(v, S) \leq \frac{\rho}{1-\alpha} \leq 2\rho$ where $\alpha \in O(\log \log n / \log n)$.*

BBG can be implemented using $\tilde{O}(1)$ $(1+\epsilon)$ approximate SetSSP computations with $\epsilon \in O\left((\log \log n / \log n)^2\right)$.

This technique allows us to create clusters with a low probability of cutting an edge while only having access to approximate shortest paths. Note that in [55] the dependency on ϵ was improved to $O(1/\log n)$. The paper also presents a deterministic version of blurry ball growing. However, we will only use the probabilistic version introduced above.

Given this definition, we now give an overview of the algorithm that creates an LDC: In the following, define $\rho := \frac{\mathcal{D}}{c \cdot \log \tau}$ where c is the constant from Lemma 9. The algorithm first computes a pseudo-padded decomposition $\mathcal{K} = K_1, \dots, K_N$ of strong diameter $8\mathcal{D}$ using the algorithm of Theorem 8. To do this, we choose the given set $\mathcal{X}$ of marked nodes as the set of cluster centers.

The following steps are executed in each cluster K_i in parallel. Within each cluster K_i, we determine a so-called *inner cluster* $K_i' \subseteq K_i$ of strong diameter $6\mathcal{D}$ where each node $v \in V_i'$ has distance (at least) $\rho' := \rho/2$ to the closest node in different cluster $K_j \neq K_i$. These inner clusters can be determined via two (approximate) SetSSP computations: First, all nodes calculate the 2-approximate distance to the closest node in a different cluster. To do this, we first create a virtual supersource s, and all nodes $v \in K_i$ with an edge to a node $w \in K_j$ create a virtual edge of length $\ell_{(v,w)}$ to s. If they have several such neighbors, they choose the shortest edge. Then, we perform a 2-approximate SetSSP from s on the resulting virtual graph that consists of all edges within a cluster and the virtual edges to s. In other words, the edges $\{v, w\}$ between clusters are not considered.

We then mark all nodes where this 2-approximate distance exceeds $2\rho'$ as *active nodes*. Next, we consider the graph G' induced by the active nodes. Using a $(1+\frac{1}{40\log\tau})$-approximate SetSSP calculation, the active nodes compute if they have a path of length at most $3\mathcal{D}$ to their cluster center in G'. If so, they add themselves to the inner cluster K_i' of K_i. Recall that their exact distance to the next cluster is at least ρ' as the paths are 2-approximate. Further, for any two nodes $v, w \in K_i'$ there is a path of length at most $6\mathcal{D}$ via the cluster center and so the inner cluster has a strong diameter of $6\mathcal{D}$. Thus, this procedure *always* results in an inner cluster K_i' with the desired properties. In the third and final stage of the algorithm, the actual clusters are computed. To this end, the *inner clusters* $\mathcal{K}' := \bigcup_{i=1}^{N} K_i'$ are used as the input set to the BBG procedure from Lemma 11. In particular, we choose the parameter for the BBG to be $\rho'' := \rho'/2$ and compute the superset $S(\mathcal{K}') := \mathsf{blur}(\mathcal{K}', \rho'')$. Now define final clustering $\mathcal{C} = C_1, \dots, C_N$ where $C_i := K_i \cap S(\mathcal{K}')$. In other words, the cluster C_i contains the inner cluster K_i' and all nodes from K_i added by the BBG process.

The resulting clustering fulfills all three properties required by Theorem 10. For the cutting probability, note that the distance from an inner cluster to a different cluster is ρ', and BBG only adds nodes in distance smaller than $2\rho'' = \rho'$. Thus, all edges with an endpoint in cluster K_i are only cut by the blurring process and not by the initial pseudo-padded decomposition. Thus, the choice of ρ'' implies that edges are cut with correct probability of $O(\ell/\rho'') = O(\frac{\ell \cdot \log\tau}{\mathcal{D}})$ by Lemma 11. The (strong) diameter of the cluster is at most $8\mathcal{D}$ as each node is in the distance at most $\rho \leq \mathcal{D}$ to a node from an inner cluster, and all nodes in an inner cluster are in the distance $6\mathcal{D}$ to one another. Therefore, it only remains to show that a nodes is clustered with prob. $1/2$. We can prove this via Lemma 9. For all nodes $v \in V$ the following holds with probability $1/2$: Node $v \in K_i$ **and** all nodes on the path P_v of length $2(1+\frac{1}{40\log\tau})\mathcal{D}$ to its cluster center x_i are in distance at least ρ to the closest node in a different cluster. Therefore, all these nodes will mark themselves active. As the 2-approximate SetSSP only overestimates, these nodes compute a distance more than $\rho = 2\rho'$, which causes them to be active. Moreover, this implies that the path P_v is fully contained in the graph G' induced by active nodes. As the path P_v is of length $2(1+\frac{1}{40\log\tau})\mathcal{D}$ and ends in the cluster center x_i, the $(1+\frac{1}{40\log\tau})$-approximate SetSSP computation will find a path of length at most $(1+\frac{1}{40\log\tau})2(1+\frac{1}{40\log\tau})\mathcal{D} \leq 3\mathcal{D}$ in G'. Therefore, with a probability of at least $1/2$, node v and all nodes on the path to the cluster center will be added to the inner cluster K_i'. Thus, Theorem 10 follows as half of all nodes are in an inner cluster and are therefore guaranteed to be in some cluster C_i. A more detailed description and the full proof can be found in the full version [24].

2.3 Strong LDDs from Strong LDCs

In this section, we show that we can create an LDD with quality $O(\log n)$ for any graph within $\tilde{O}(1)$ minor aggregations and $(1+\epsilon)$-approximate SetSSP's. Note that, at first glance, the theorem follows almost directly from Theorem 10. Choose $\mathcal{X} = V$ and $\mathcal{D}' = 8\mathcal{D}$ and apply

the theorem to a graph G. We obtain a clustering with diameter $\mathcal{D}'$ if each node has one node in distance $\mathcal{D}'/8$ and at most τ nodes in distance $\mathcal{D}'$. Clearly, for every possible choice of parameter $\mathcal{D}'$, each node has at least one marked node in distance $\mathcal{D}'/8$, namely itself. Further, for every possible choice of parameter $\mathcal{D}'$, each node has at most n marked node in distance $\mathcal{D}$ because there are only n nodes in total. Thus, by choosing all nodes as centers, we obtain a clustering with quality $O(\log n)$ and a diameter we can choose freely. While the diameter and edge-cutting probability of the resulting clustering are both (asymptotically) correct, we can only guarantee that at least half of the nodes are clustered on expectation. To put it simply, we do not have a partition as required. However, we can reapply our algorithm to the graph induced by the *unclustered* nodes. This clusters half of the remaining nodes on expectation. Thus, by applying Markov's inequality, a constant fraction of nodes is clustered with constant probability. It is easy to see that if we continue this for $O(\log n)$ iterations, we obtain the desired partition, w.h.p. Further, this will not significantly affect the edge-cutting probability, as each edge that is not cut will be added to a cluster with constant probability. Therefore, there cannot be too many iterations where the edge can actually be cut. Thus, applying the algorithm until all nodes are clustered intuitively produces the required LDD of quality $O(\log n)$. We formalize and prove this intuition in the following lemma.

▶ **Lemma 12.** *Let $G = (V, E, \ell)$ be a weighted graph. Let $\mathcal{A}$ be an algorithm that for each subgraph $G' \subseteq G$ can create clusters $K_1, \dots, K_N$ where each edge is cut between clusters with probability at most α, and each node is added to a cluster with probability at least β. Then, recursively applying $\mathcal{A}$ to G until all its nodes are in a cluster creates an LDD of quality $O(\alpha\beta^{-2})$. The procedure requires $O(\beta^{-1} \log n)$ applications of $\mathcal{A}$, w.h.p.*

The full proof can be found in the full version [24]. Together, Lemma 12 and Theorem 10 imply Theorem 5. Note that we state Lemma 12 more generally than needed, so we can reuse it in the next section.

3 Weak Separators from Approximate Shortest Paths

We now move from arbitrary graphs to k-path separable graphs. This section presents our main technical result and considers the distributed computation of separators for k-path separable graphs. Recall that a separator S is a *subgraph* of G such that in the induced subgraph $G \setminus S$ that results from removing S from G, every connected component only contains a constant fraction of G's nodes. Separators are a central tool in designing algorithms for restricted graph classes as they give rise to efficient divide-and-conquer algorithms. Our algorithms are no exception. In particular, we will compute a novel type of separator as the main building blocks of our clustering result. Note that the distance is taken w.r.t. to G, which could be a subgraph of a larger graph. We formally define our weak separators as follows:

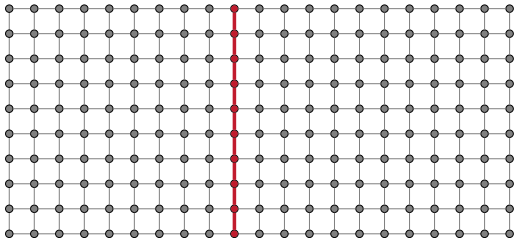
▶ **Definition 13** (Weak κ-Path $(\mathcal{D}, \epsilon)$-Separator)**.** *Let $G := (V, E, \ell)$ be a weighted graph, $\mathcal{D} > 1$ be an arbitrary distance parameter, and $\epsilon > 0$ be an approximation parameter. Then, we call the set $S(\mathcal{D}, \epsilon) := (\mathcal{P}_1, \dots, \mathcal{P}_\kappa)$ with $\mathcal{P}_i := (P_i, B_i)$ a weak κ-path separator, if it holds:*

1. *Each $P_i \in \mathcal{P}_i$ is a (approximate) shortest path in $G \setminus \bigcup_{j=1}^{i-1} \mathcal{P}_j$ of length at most $4\mathcal{D}$.*
2. *Each $B_i \subseteq B_G(P_i, \epsilon\mathcal{D})$ is a set of nodes surrounding path P_i.*
3. *For all $v \in (V \setminus \bigcup_{j=1}^{\kappa} \mathcal{P}_i)$ it holds $|B_{G\setminus S}(v, \mathcal{D})| \leq (7/8) \cdot n$.*

Note that this definition is generic enough to also include vanilla k-path separators (where each set B_i only contains the path itself and no further nodes) and *traditional* vertex separators (where each path is a single node). Thus, for certain k-path separable graphs, we can already use existing algorithms to compute these separators in distributed and parallel models[5]. For general k-path separable graphs, however, we need new techniques.

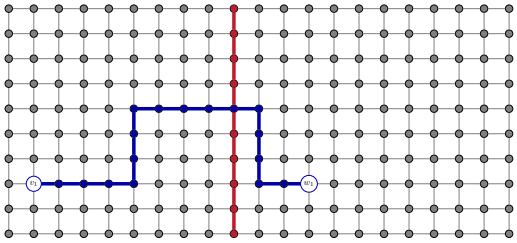
Why Computing Separators for k-Path Separable Graphs is Hard

Before we go into details, let us first review some background on separators that motivates why we will mainly work with the weaker concept. To this end, we first review prior results and identify possible difficulties. Starting with positive results, it *is* possible to construct path separators for planar graphs in a distributed setting. In fact, the state-of-the-art algorithms for computing DFS trees in [39] or computing a graph's (weighted) diameter in [48] in planar graphs construct a path separator for planar graphs. The algorithm presented in these papers constructs a path separator in $\tilde{O}(\text{HD})$ time, w.h.p. However, while the existence of an efficient algorithm for a planar graph gives hope, it turns out to be very tough for other k-path separable graphs. The constructions in both [39] and [48] heavily exploit the fact that a planar embedding of a (planar) graph can be computed in $\tilde{O}(\text{HD})$ time in CONGEST due to Ghaffari and Haeupler in [36]. Given a suitable embedding, the ideas could be generalized. Thus, finding a suitable embedding could be a way to extend this algorithm to more general k-separable graphs. A good candidate for such an embedding can be found in [2]. Abraham and Gavoille present an algorithm that computes a $f(r)$-path separator for K_r-free graphs [2]. Their algorithm relies on a complex graph embedding algorithm by Seymour and Robertson [54]. On a very high level, the embedding divides G into subgraphs that can almost be embedded on a surface similar to planar graph. By *almost*, we mean that in each subgraph, there is only small number of non-embeddable parts (with special properties) that need to be handled separately. The concrete number of these parts depends only on r. Given such an embedding, Abraham and Gavoille show that one can efficiently compute k-path separator. Sadly, we have little hope that the algorithm that computes the embedding can be efficiently implemented in a distributed (or even parallel) context. It already requires $n^{O(r)}$ time in the sequential setting. Moreover, it requires sophisticated techniques that can not be trivially sped up by running them in parallel. Thus, it remains elusive (to the authors at least) how to implement this algorithm in any distributed or even parallel model.



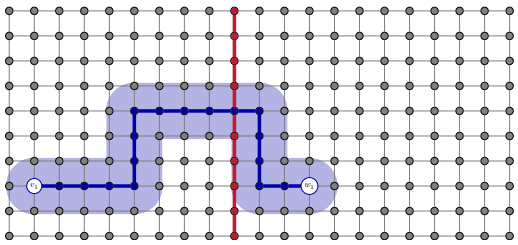
Why Computing Weak Separators for k-Path Separable Graphs is Easier

Now that we have established why it is difficult to compute k-path separators, we can proceed to the initially promised weak separators. Our main insight is that instead of computing an embedding in a distributed and parallel setting, we show that we get very similar guarantees using a weaker separator that can be computed without the embedding. Thus, we take a different approach to completely avoid the (potentially expensive) computation of an embedding. We strongly remark that, in doing so, we sacrifice some of the separator's useful properties. However, in our applications, this only results in some additional polylogarithmic factors in the runtime. To be precise, we prove the following lemma:

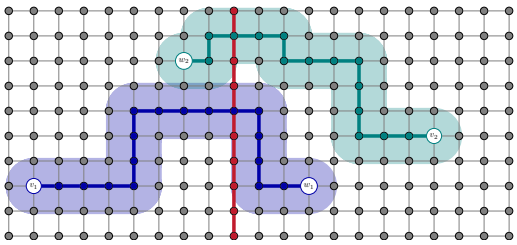


[5] For planar graphs, we can use the algorithm provided in [48] to compute a separator that consists of 4 paths. While for graphs of bounded tree-width τ, we can use [42] to obtain a separator that consists of τ nodes.

▶ **Theorem 14** (Weak Separators for k-Path Separable Graphs)**.** *Consider a weighted k-path separable graph $G := (V, E, \ell)$ with weighted diameter smaller than $\mathcal{D}$. For $\epsilon \geq 0$, there is an algorithm that constructs a weak $O(\epsilon^{-1} \cdot k \cdot \log n)$-path $(\mathcal{D}, \epsilon)$-separator, w.h.p. The algorithm uses $O(\epsilon^{-1} \cdot k \cdot \log n)$ minor aggregations and $O(\epsilon^{-1} \cdot k \cdot \log n)$ 2-approximate shortest path computations, w.h.p.*



Surprisingly, the algorithm behind the lemma can be stated in just a few sentences. The core idea is to iteratively sample approximate shortest paths and nodes close to these paths and remove them from the graph until all remaining nodes have few nodes in distance $\mathcal{D}$, w.h.p. More precisely, we start with a graph $G_0 = G$. The algorithm proceeds in $T \in O(\epsilon^{-1} \cdot k \cdot \log n)$ steps where in step t, we consider graph $(V_t, E_t) := G_t \subset G_{t-1}$. A single step t works as follows: First, we pick a node $v \in V_t$ uniformly at random. Then, we compute a 2-approximate shortest path tree T_v from v. Let $W_v \subset V_t$ be set of all nodes in distance at most $4 \cdot \mathcal{D}$ to v in T_v. We pick a node $w \in W_v$ uniformly at random and consider the corresponding path $P_t = (v, \dots, w)$. Using P_t as a set-source, we compute a 2-approximate shortest path tree T_{P_t} from P_t. Now denote B_{P_t} to be the nodes in the distance at most $\epsilon \cdot \mathcal{D}$ to P_t in G (and **not** G_t). Finally, we remove P_t and B_{P_t} from G_t to obtain G_{t+1}. Note that, due to the approximation guarantee, this removes all nodes in distance at least $\epsilon/2 \cdot \mathcal{D}$ from P_t in G. Further, all steps can be computed using 2-approximate paths (and few aggregation to pick the random nodes) and are completely devoid of any complex embedding. A visualization of the algorithm can be found in Figure 1.



(a) Marked in red is a separator path unknown to the algorithm.

(b) When sampling a random path of bounded length, the probability of crossing the separator is constant.

(c) We remove nodes in distance $\epsilon\mathcal{D}$ around the path. This also removes an $\epsilon\mathcal{D}$-fraction of the separator path.

(d) If the residual graph is not well-separated, the probability of crossing (what remains of) the separator is still constant.

Figure 1 We choose a two-dimensional mesh for illustration. While the operations in Figures **(b)** and **(c)** are straightforward to prove, the core of our analysis we will be the claim we make in Figure **(d)**.

Why does this work? As our main analytical tool, we consider the following potential:

$$\Phi_t := \left|\left\{v \in V_t \;\middle|\; |B_{G_t}(v, 2\mathcal{D})| \geq (7/8) \cdot n\right\}\right|$$

Further, for brevity, we write $\Phi_t(v) = 1$ if and only if $|B_{G_t}(v, 2\mathcal{D})| \geq (7/8) \cdot n$ and $\Phi_t(v) = 0$, otherwise. Note that $\Phi_t := \sum_{v \in V} \Phi_t(v)$.

We make the following important observation: As soon as this potential drops below $(7/8) \cdot n$, we have more than $(1/8) \cdot n$ nodes with less than $(7/8) \cdot n$ nodes in distance $2\mathcal{D}$. This implies that no node can have more than $(7/8) \cdot n$ nodes in distance $\mathcal{D}$. Suppose for contradiction that there is a node $v \in V_t$ with more than $(7/8) \cdot n$ nodes in distance $\mathcal{D}$. By the triangle inequality, all these nodes would be in distance $2\mathcal{D}$ to each other. Thus, the potential would be bigger than $(7/8) \cdot n$ as there are more than $(7/8) \cdot n$ nodes with more than $(7/8) \cdot n$ nodes in distance $\mathcal{D}$. This is a contradiction and therefore the nodes sampled until this point are the desired weak separator.

Therefore, we want to bound the number of steps until the potential drops. For this, we will first show the following useful fact about k-path separators, namely

▶ **Lemma 15.** *Let $G := (V, E, w)$ be a weighted k-path separable graph of n nodes with (weighted) diameter $\mathcal{D}$. Then, there exists a set $\mathcal{B} = \{P_1, \ldots, P_\kappa\}$ with $\kappa \leq k$ simple paths of length at most $32\mathcal{D}$ such that for all $v \in V$, it holds $B_{G \setminus \mathcal{B}}(v, 4\mathcal{D}) \leq (3/4) \cdot n$.*

In other words, a subset of bounded length paths intersects with a constant fraction of all paths our algorithm can potentially sample. The proof requires copious use of the triangle inequality and the pigeonhole principle and can be found in the full version [24].

Now, consider the event that the algorithm samples a path P_t that *crosses* some path of $\mathcal{B}$, i.e., the path we sample contains (at least) one node from one of the κ paths in $\mathcal{B}$. In this case, we remove a subpath of length $(\epsilon/2)\mathcal{D}$ from this path when we remove the set B_{P_t} around the P_t. This follows because we determine the set B_t with respect to the original graph G and not G_t. Thus, after sampling $O(\epsilon^{-1} \cdot \mathcal{D})$ paths that cross $\mathcal{B}$, we must have completely removed $\mathcal{B}$ from G. If $\mathcal{B}$ is removed, each node has at most $(3/4) \cdot n$ nodes in distance $\mathcal{D} \leq 4\mathcal{D}$ per definition and we are done. Thus, we will bound the time until **either** the potential drops **or** a total of $O(\epsilon^{-1} \cdot k)$ paths cross $\mathcal{B}$. Recall that in each step t, we sample a path from v_t to w_t. In the following, denote the event that the path from v_t to w_t crosses $\mathcal{B}$ as $v_t \rightsquigarrow_{\mathcal{B}} w_t$. By definition of $\mathcal{B}$, for each node $v \in V$, the set of nodes where all paths of length smaller than $4 \cdot \mathcal{D}$ contain a node of $\mathcal{B}$ is of size at least $(1/4) \cdot n$. Thus, for all nodes $v \in V_t$ with $\Phi_t(v) = 1$, at least $(1/4) \cdot n - (1/8) \cdot n \geq (1/8) \cdot n$ of these nodes must still be in distance $2\mathcal{D}$. All these nodes might be chosen as the path's endpoint P_t if we pick v as the starting point as the 2-approximate distance is at most $4\mathcal{D}$. So, if we sample one of them, we cross $\mathcal{B}$ as all paths of length at most $4\mathcal{D}$ cross $\mathcal{B}$. Thus, in a configuration with potential $\Phi_t \geq (7/8) \cdot n$, the probability to sample a path that crosses $\mathcal{B}$ is at least

$$\begin{aligned}\mathbf{Pr}[v_t \rightsquigarrow_{\mathcal{B}} w_t \mid \Phi_t \geq (7/8) \cdot n] &\geq \mathbf{Pr}[\Phi_t(v_t) = 1 \mid \Phi_t \geq (7/8) \cdot n] \cdot \mathbf{Pr}[v_t \rightsquigarrow_{\mathcal{B}} w_t \mid \Phi_t(v_t) = 1] \\ &\geq \frac{1}{n} \cdot \Phi_t \cdot \frac{1}{n} \cdot (1/8) \cdot n \geq \frac{7}{64} \geq \frac{1}{16}\end{aligned}$$

Thus, if the potential has not dropped after T steps, the expected number of crossings is $(1/16) \cdot T$. Using standard Chernoff-like tail estimates, we can show that for any $T \in \Omega(\log n)$, this would imply that at least $\frac{T}{32}$ paths crossed $\mathcal{B}$, w.h.p. Thus, within $T \in O(\epsilon^{-1} \cdot k \cdot \log n)$ steps, we either reached a step with low potential or had sufficiently many crossings to remove $\mathcal{B}$. In either case, we are done as each node had less than $7/8 \cdot n$ nodes in distance $\mathcal{D}$. As up until this point we sampled $T \in O(\epsilon^{-1} \cdot k \cdot \log n)$ paths of length $4\mathcal{D}$ and all nodes in distance $\epsilon\mathcal{D}$ around these paths, this set must be the desired weak separator.

4 Low-Diameter Decompositions for k-path Separable Graphs

In this section, we prove Theorem 6. Our algorithm will combine the insights we gathered for LDD's and LDC's in general graphs with our novel separator construction. Our main technical result is the following proposition:

▶ **Proposition 16** (A Clustering Theorem for Restricted Graphs). *Let $\mathcal{D} > 0$ be an arbitrary distance parameter and $G := (V, E, \ell)$ be a (possibly weighted) $\tilde{O}(1)$-path separable graph. Then, there is an algorithm that creates an LDC of strong diameter $\mathcal{D}$ with quality $(O(\log k + \log\log n), 1/2)$. The algorithm can be implemented in $\tilde{O}(k)$ minor aggregations and $\tilde{O}(k)$ $(1+\epsilon)$-approximate SetSSP computations with $\epsilon \in O\left(1/\log^2 n\right)$.*

Crucially, the proposition is sufficient to prove Theorem 6 for $\tilde{O}(1)$-separable graphs: For $k \in \tilde{O}(1)$ one application of the algorithm creates a clustering with strong diameter $\mathcal{D}$ and cutting probability $O\left(\frac{\ell_z \cdot (\log\log n)}{\mathcal{D}}\right)$. Now recall that universally k-path separable graphs are closed under minor-taking. Therefore, the graph $G \setminus \mathcal{K}$ is also k-path separable, and we can apply the algorithm to $G \setminus \mathcal{K}$ with the same guarantees to cluster at least half of the remaining nodes. By Lemma 12, after $O(\log n)$ recursive applications, all nodes are clustered, and we obtain an LDD with quality $O(\log\log n)$ as required. Further, for $k \in \tilde{O}(1)$ one iteration of the algorithm can, w.h.p., be implemented in $\tilde{O}(1)$ minor aggregations and $\tilde{O}(1)$ $(1+\epsilon)$-approximate SetSSP computations with $\epsilon \in O\left(1/\log^2 n\right)$. Thus, $O(\log n)$ recursive applications are within the required time complexity of Theorem 6.

Thus, for the remainder, we will focus on Proposition 16. From a high-level perspective, the algorithm behind Proposition 16 proceeds in two distinct phases: the *backbone phase* and the *refinement phase*. In the backbone phase, we create a special partition $\mathcal{K}[\mathcal{B}] := K(\mathcal{B}_1), \dots, K(\mathcal{B}_N)$ of G. Each node $v \in K(\mathcal{B}_i)$ is in distance at most $\mathcal{D}_{BC} < \mathcal{D}$ to some subset $\mathcal{B}_i \subset K(\mathcal{B}_i)$ that consist of $\tilde{O}(k)$ (possibly disjoint) paths of bounded length of $O\left(\mathcal{D}\log^2\right)$. These paths may not necessarily be short**est** paths in G or even $K(\mathcal{B}_i)$, only their length is bounded. We call these subsets $\mathcal{B}_1, \dots, \mathcal{B}_N$ the *backbones* of the clusters. In contrast to an LDD, the clusters do **not** have simple nodes $v \in V$ as centers. As a result, the diameter of the resulting clusters might be much larger than $\mathcal{D}$. Moreover, a single cluster might not even be connected. In the second phase, we turn the resulting clustering into an LDC with connected clusters of strong diameter $\mathcal{D}$. We do so by computing an LDC $\mathcal{K}_i = K_{i_1}, \dots, K_{i_N}$ of strong diameter $\mathcal{D}$ in each cluster $K(\mathcal{B}_i)$. Here, we exploit the special structure of the backbone cluster and choose a carefully chosen subset of nodes from each backbone path as possible cluster centers such that no more than $\tilde{O}(k)$ centers can cluster a given node. These centers will then be used as an input to Theorem 10 to refine each backbone cluster to a set of connected clusters of strong diameter $\mathcal{D}$.

This algorithm is inspired by the works of Abraham, Gavoille, Gupta, Neiman, and Talwar [3, 4] and the subsequent improvement of their algorithm by Filtser [32]. Surprisingly, we do not require fundamental changes to obtain an efficient distributed algorithm. Both algorithms essentially follow the same two-phase structure sketched above. They first constructed a partition around paths sampled in a certain way, then refined each partition individually to obtain proper clusters centered around nodes. For reference, Abraham, Gavoille, Gupta, Neiman, and Talwar dubbed these subsets around which the partitions are constructed *skeletons* while Filtser used the term *r-core*. However, their key properties are (almost) the same. We use the different term *backbones* because we construct them slightly differently. Our contribution when comparing our algorithm to [3, 4, 32] is that we show a) that the exact shortest path can be replaced by approximate paths and the blurry ball growing procedure

from Lemma 11 and, therefore, can be implemented efficiently and b) that we can use our weak separator from Section 3 to parallelize the algorithm and achieve a logarithmic recursion depth efficiently.

In the remainder of this section, we sketch the backbone phase in Subsection 4.1 and the refinement phase in Subsection 4.2. Together, the lemmas presented in these sections will prove Proposition 16.

4.1 The Backbone Phase

In this section, we sketch the first phase of the algorithm. We begin by giving a general definition of the special type of clustering computed in this phase. Formally, we define it as follows:

▶ **Definition 17** (Backbone Clustering). *Let $\mathcal{D} > 0$ be a distance parameter and $G := (V, E, \ell)$ a (possibly weighted) graph. Then, a (α, β, κ)-backbone clustering is a series of disjoint subgraphs $K(\mathcal{B}_1), \dots, K(\mathcal{B}_N)$ with $K(\mathcal{B}_i) = (V_i, E_i)$ where $V_1 \sqcup \dots \sqcup V_N = V$. Further, the following three conditions hold:*

1. *Each node $v \in K(\mathcal{B}_i)$ is in distance at most $\mathcal{D}$ to $\mathcal{B}_i$.*
2. *An edge of length ℓ is cut between clusters with probability $O\left(\frac{\ell \cdot \alpha}{\mathcal{D}}\right)$.*
3. *Each backbone $\mathcal{B}_i$ consists of at most κ paths of length $O(\beta\mathcal{D})$.*

Given this definition, we show that we can use our algorithm for constructing weak separators to create a good backbone clustering of a graph G. To be precise, we show the following lemma:

▶ **Lemma 18** (Backbone Clustering). *Let $\mathcal{D} > 0$ be a distance parameter and $G := (V, E, \ell)$ a (possibly weighted) k-path separable graph. Then, there is an algorithm that creates an (α, β, κ)-backbone clustering with $\alpha \in O(\log(k \log n))$, $\beta \in O(\log^2 n)$, $\kappa \in O(k \log^2 n)$ and pseudo-diameter $\mathcal{D}$ for G. The algorithm can be implemented with $\tilde{O}(k)$ minor aggregations and $(1+\epsilon)$-approximate SetSSP computations where $\epsilon \in O\left(1/\log^2 n\right)$.*

The algorithm works as follows: Let $G_t \subset G$ be the graph at the beginning of the t^{th} recursive step, where initially $G_0 = G$. At the beginning of each recursive step, we create an LDD $C_1, \dots, C_{N'}$ of diameter $\mathcal{D}' \in O(\mathcal{D} \log^2 n)$ of G_t. We use the algorithm from Theorem 5 for this. The edges between two clusters C_i and C_j are removed and will not be considered in the following iterations. We denote the graph that results from removing all these edges as G'_t. Then, in each C_i, we compute a weak $\tilde{O}(k)$-path $(\mathcal{D}', \epsilon)$-separator $\mathcal{S}_i$ with $\epsilon \in O(1/\log^2 n)$ using the algorithm from Theorem 14. Recall that we defined this separator to be the union of $O(\epsilon^{-1} \cdot k)$ paths of length $4 \cdot \mathcal{D}'$ and some nodes in distance $\epsilon\mathcal{D}'$ to these paths. The $O(\epsilon^{-1} \cdot k)$ paths in $\mathcal{S}_i$ will be the backbone of a cluster. To add further nodes to the cluster, we proceed in two steps: First, we draw $X_i \sim \mathsf{Texp}(4 \log(\log n))$ and compute a $(1+\epsilon)$-approximate SetSSP from $\mathcal{S}_i$. Then, we mark all nodes at a distance at most $(1+\epsilon)X_i \cdot \mathcal{D}_{BC}/4$ from $\mathcal{S}_i$. We denote this set as $K_{\mathsf{Texp}}(\mathcal{S}_i)$. Then, we apply the BBG procedure of Lemma 11 with parameter $\rho_{\mathsf{blur}} := \mathcal{D}_{BC}/c_{\mathsf{blur}} \cdot \log\log n$ from $K_{\mathsf{Texp}}(\mathcal{S}_i)$. Here, $c_{\mathsf{blur}} > 8$ is a suitably chosen constant. This results in a superset $K_{\mathsf{blur}}(\mathcal{S}_i) \subseteq C_i$ for each subgraph C_i. Finally, we add all sets $K_{\mathsf{blur}}(\mathcal{S}_i)$ from all clusters C_i to our clustering $\mathcal{K}[\mathcal{B}]$ and remove them from the graph.

We repeat this process with the remaining graph $G_{t+1} := G'_t \setminus \bigcup K_{\mathsf{blur}}(\mathcal{S}_i)$ until all subgraphs are empty. As we remove a weak $\mathcal{D}'$-separator in each step **and** then create an LDD with strong diameter $\mathcal{D}'$, the size of the largest connected components shrinks by a constant factor in each recursion. Thus, we require $O(\log n)$ recursions overall until all components are empty.

Recall that in each cluster $K_{\mathsf{blur}}(\mathcal{S}_i)$, we define the short paths $P_1, \dots, P_\kappa$ in the separator $\mathcal{S}_i$ to be the backbone. As there are $\kappa \in O(k \cdot \log^2 n)$ paths, it remains to analyze its pseudo-diameter and edge-cutting probability to prove that the resulting clustering is a proper backbone clustering. For an appropriate choice of $\epsilon \in O(1/\log^2 n)$, all nodes in $\mathcal{S}_i$ are in distance $\epsilon\mathcal{D}' \leq \mathcal{D}_{BC}/4$ to any path. Further as $(1+\epsilon) \leq 2$ and $X_i \cdot \mathcal{D}_{BC}/4 \leq \mathcal{D}_{BC}/4$, all nodes in $K_{\mathsf{Texp}}(\mathcal{S}_i)$ are in distance $(1+\epsilon) \cdot X_i \cdot \mathcal{D}_{BC}/4 \leq \mathcal{D}_{BC}/2$ to $\mathcal{S}_i$. Finally, the distance of any node in $K_{\mathsf{blur}}(\mathcal{S}_i)$ to any node in $K_{\mathsf{Texp}}(\mathcal{S}_i)$ is at most $2\rho_{\mathsf{blur}} \leq \mathcal{D}_{BC}/4$. Thus, the distance from each node $u \in K_{\mathsf{blur}}(\mathcal{S}_i)$ to any of the paths in the separator is at most

$$\begin{aligned} d(u, \mathcal{B}_i) &\leq d(v, K_{\mathsf{Texp}}(S_i)) + \mathbf{max}_{v \in K_{\mathsf{Texp}}(S_i)} d(v, S_i) + \mathbf{max}_{w \in S_i} d(w, \mathcal{B}_i) \\ &\leq \mathcal{D}_{BC}/4 + 2 \cdot \mathcal{D}_{BC}/4 + \mathcal{D}_{BC}/4 = 4\mathcal{D}_{BC}/4 = \mathcal{D}_{BC} \end{aligned}$$

Thus, only the edge-cutting probability remains to be shown. For each edge $z \in E$, two operations can cut an edge in each iteration. The LDD from Theorem 5 and the BBG procedure from Lemma 11. First, consider the LDD. As we pick $\mathcal{D}' \in O(\mathcal{D} \log^2 n)$, a single application of Theorem 5 cuts an edge with probability $O\left(\ell_z \log n / \mathcal{D}'\right) = O\left(\ell_z / \mathcal{D} \log n\right)$. Thus, as we apply it at most $O(\log n)$ times, the probability sums up to $O\left(\ell_z / \mathcal{D}\right)$ by the union bound. The other possibility is that z is cut by the BBG. By our choice of ρ_{blur}, the probability for the ball to cut z is $O\left(\ell_z \log(k \log n) / \mathcal{D}\right)$. Therefore, we cannot simply use the union bound to sum up the probabilities over all $O(\log n)$ iterations. Here, the intermediate step where we construct $K_{\mathsf{Texp}}(\mathcal{S}_i)$ comes into play. We can exploit that $K_{\mathsf{Texp}}(\mathcal{S}_i)$ must be *close* to either endpoint of z, i.e., within distance at most $2\rho_{\mathsf{blur}}$, in order for $\mathsf{blur}(K_{\mathsf{Texp}}(\mathcal{S}_i), \rho_{\mathsf{blur}})$ to cut it. The distance between $\mathsf{Texp}(\mathcal{S}_i)$ and z is determined by the exponentially distributed variable $X_i \cdot \mathcal{D}_{BC}/4$. Using the properties of the truncated exponential distribution, we can show that the probability of $\mathsf{Texp}(\mathcal{S}_i)$ being close to z without adding the endpoints of z to $\mathsf{Texp}(\mathcal{S}_i)$ is constant for our choice of parameters. Thus, the edge is safe from ever being cut before the blur procedure is even executed. This follows from the properties of the truncated exponential distribution. Thus, on expectation, there will only be a constant number of tries before z is either cut or safe. As we will see in the full analysis, this is sufficient for our probability bound.

Finally, verifying that each algorithm step requires $\tilde{O}(k)$ approximate SetSSP computations and minor aggregations is easy. We use three subroutines from Theorem 5, Theorem 14, and Lemma 11, which all require at most $\tilde{O}(k)$ approximate SetSSP computations and minor aggregations on a k-path separable graph. In addition, the algorithm only uses one more SetSSP; thus, the runtime follows. A more detailed description and the full proof can be found in the full version [24].

4.2 The Refinement Phase

For the second phase, we show a generic lemma that allows us to turn any backbone clustering as described in Definition 17 into an LDC. Thus, this statement is independent of the algorithm that creates the backbone clustering. To be precise, it holds:

▶ **Lemma 19.** *Suppose we have an algorithm $\mathcal{A}$ that creates a (α, β, κ)-backbone clustering with pseudo-diameter $\mathcal{D}_{BC}$ of a weighted graph G. Then, there is an algorithm that creates an LDC of strong diameter $16 \cdot \mathcal{D}_{BC}$ with quality $(O(\alpha + \log \kappa\beta), 1/2)$. The algorithm requires one application of $\mathcal{A}$, $\tilde{O}(\kappa)$ minor aggregations, and $\tilde{O}(1)$ approximate SetSSP computations with $\epsilon \in O(1/\log^2 n)$.*

The algorithm begins by constructing backbone clustering $K(B_1), \dots, K(B_N)$ using algorithm $\mathcal{A}$. The following steps are executed in parallel in each cluster $K(\mathcal{B}_i)$: On each path $P \in \mathcal{B}_i$ in the backbone, mark a subset of nodes in distance (at most) $\mathcal{D}_{BC}$ to each other and use

them as potential cluster centers. This can be done with one shortest path computation and two aggregations on each path: First, we let each node compute the distance to the first node of the path $v_1 \in P$. A simple SetSSP computation can do this; as there is only one path, the algorithm returns an exact result. Then, we let each node locally compute its *distance class* $\lceil \frac{d_P(v,v_1)}{\mathcal{D}_{BC}} \rceil$. Finally, we mark the first node in each distance class. A node can determine whether it is the first node by aggregating the distance class of both its neighbors in two aggregations. Having marked the nodes, we use them as centers $\mathcal{X}_i$ in the algorithm of Theorem 10 and compute an LDC in $K(\mathcal{B}_i)$. To determine the gurantees of this clustering, we need to determine the *covering* and *packing* properties of these centers. Each node $v \in K(\mathcal{B}_i)$ has at least one marked node in distance $2\mathcal{D}_{BC}$ by construction: It must have a path $P_j \in \mathcal{B}_i$ in distance $\mathcal{D}_{BC}$ and the next marked nodes on the path can also only be in distance $\mathcal{D}_{BC}$ to the node closest to v. Further, as a path of length $\beta\mathcal{D}_{BC}$ has β distance classes, we mark at most β nodes per path. As we limit the number of paths in $\mathcal{B}_i$ to κ and the length of each path to $\beta\mathcal{D}_{BC}$, the total number of centers is limited to $\beta \cdot \kappa$. Thus, each node in $K(\mathcal{B}_i)$ is covered by one center in distance $2\mathcal{D}_{BC}$ and *packed* by at most $\beta \cdot \kappa$ centers in distance $6 \cdot (2\mathcal{D}_{BC})$. Following Theorem 10, this gives us an LDC with strong diameter $8 \cdot (2\mathcal{D}_{BC})$ and quality $O(\log \beta\kappa)$. Finally recall that an edge can either be cut by the initial construction of the backbone clustering or by this procedure. By the union bound, an edge is cut with probability $O(\frac{\alpha+\log \beta\kappa}{\mathcal{D}})$ by either stage. As the algorithm consists of computing a backbone clustering, one SetSSP and one minor aggregations in each path to mark the nodes, and an application of Theorem 10, the proclaimed runtime follows.

Combing this result with Lemma 18, this creates the desired LDC with strong diameter $16\mathcal{D}_{BC}$ of quality $O(\log k + \log\log n)$ in each cluster. In particular, an edge is cut with probability $O(\frac{\ell \cdot \log k \log n}{\mathcal{D}})$ in either of the two phases. This proves the Proposition 16 when choosing $\mathcal{D}_{BC} = \mathcal{D}/16$. A more detailed description and the full proof can be found in the full version [24].

5 Conclusion & Future Work

We presented two novel distributed decomposition schemes for arbitrary and restricted graphs that perform favorably in all relevant parameters and apply to various models. First, for arbitrary graphs, we provided a decomposition scheme that produces decompositions with strong diameter and quality $O(\log n)$. The open question remains whether our algorithm's guarantees can also be achieved deterministically. As our results are deeply connected with the properties of the (truncated) exponential distribution, this likely requires very different techniques and/or novel ideas for derandomization. Second, we presented a decomposition scheme with quality $O(\log k + \log\log n)$ for universally k-path separable graphs, a graphs class containing many practical, relevant graphs. Albeit having a decomposition quality that is exponentially smaller than the quality for general graphs, our algorithm is *not* optimal. First of all, the dependency on n could be improved in future work. Further, for specific k-path separable graphs, the dependency on k could be problematic. For example, in a K_r-free graphs, we have $k = f(r)$ where $f(r)$ depends only on r. We note that $f(r)$, albeit being a constant for a constant r, is extremely large. Its concrete value is based on the Structure Theorem of Seymour and Robinson [54]. Their analysis is quite involved and stretches over a vast series of papers and articles. Moreover, due to its complexity, it is hard even to find an asymptotic characterization of that number. In [49], it is described as a "*tower of powers of* 2 *of height at most* 5*, with* r^{1000} *on top*". We emphasize that this number very likely is too high for practical applications and, therefore, further investigation is required.

Abstract

In this paper, we consider a new problem of portfolio optimization using stochastic information. In a setting where there is some uncertainty, we ask how to best select k potential solutions, with the goal of optimizing the value of the best solution. More formally, given a combinatorial problem Π, a set of value functions $\mathcal{V}$ over the solutions of Π, and a distribution $\mathcal{D}$ over $\mathcal{V}$, our goal is to select k solutions of Π that maximize or minimize the expected value of the *best* of those solutions. For a simple example, consider the classic knapsack problem: given a universe of elements each with unit weight and a positive value, the task is to select r elements maximizing the total value. Now suppose that each element's weight comes from a (known) distribution. How should we select k different solutions so that one of them is likely to yield a high value?

In this work, we tackle this basic problem, and generalize it to the setting where the underlying set system forms a matroid. On the technical side, it is clear that the candidate solutions we select must be diverse and anti-correlated; however, it is not clear how to do so efficiently. Our main result is a polynomial-time algorithm that constructs a portfolio within a constant factor of the optimal.

1 Introduction

Worst-case analysis has long been the prevailing standard for assessing an algorithm's performance. However, this approach often falls short in capturing the real-world performance of algorithms, as instances encountered in practice often differ significantly from those that define worst-case scenarios. To address this discrepancy, the field of *Data-Driven Algorithm Design* has sought to create algorithms that utilize past data about a problem, either implicitly or explicitly, and provably achieve superior performance on the typical instances that arise in practical applications. For surveys of this area see [12, 1].

Building on this line of research, we study the portfolio optimization problem as a simple framework for speeding up algorithms using historical data; a method with potential applications across various combinatorial problems. Specifically, given a combinatorial problem Π, a solution set $\mathcal{I}$, and a distribution $\mathcal{D}$ over value functions (which map solutions to values, with each function representing a different scenario), our objective is to compute a portfolio of k solutions that maximizes (or minimizes) the expected value (or cost) of the best among the k solutions. Starting from a different perspective, Kleinberg, Papadimitriou and Raghavan [9] have defined a very similar family of optimization problems, called "Segmentation Problems". The Portfolio Optimization problem can be seen as a stochastic version of the aforementioned family of problems; actually the two definitions are effectively equivalent when the distribution over value functions has a polynomial-sized support (for more details see Related Work, Section 1.2).

The Portfolio Optimization problem captures many natural questions. The problem mentioned in the abstract–how to select k bundles of r items each so that the expected value of the best bundle is maximized–is only one of them. Another practical application is finding the shortest path between two points (e.g., home and work) in a city, under varying daily traffic conditions. Here, the solution set consists of all possible source-destination paths and the value functions assign weights to each path based on specific traffic scenarios. The distribution over value functions models the stochastic nature of traffic. Rather than rerunning a shortest-path algorithm for each new instance, one could leverage the statistical knowledge about traffic patterns to precompute a few paths that cover different likely scenarios (e.g., peak morning traffic, light nighttime traffic, etc.). This approach, then, allows us to quickly evaluate the precomputed paths under new traffic conditions and select the best option without the need to resolve the problem from scratch each time.

Interestingly, this stochastic formulation also captures problems outside the area of speeding up algorithms. In particular, our objective captures any stochastic problem where one needs to select a set of dependent objects with the goal of maximizing the expectation of their maximum. A practical example of this is sports betting pools, which was recently explored in [6]. The authors examine the scenario of participating in a betting pool for a basketball tournament, where individuals can pay a fee to submit a prediction for the outcome of all tournament matches, with the potential to win a substantial monetary prize if their predictions are accurate. Given a budget constraint on the number of entries that a person can submit, the technical problem essentially reduces to computing a portfolio of entries that maximizes the probability that one of the selected entries succeeds.

From a technical standpoint, in the maximization variant of our problem, the value of a portfolio is a submodular function. Therefore, one can find an approximately optimal portfolio by running the *Greedy* algorithm, with a running time that is polynomial in the size of the solution set $\mathcal{I}$. However, for most interesting problems, e.g., spanning trees, entries in betting pools, etc., the solution set is given implicitly and is usually exponentially large in the size of the input, making *Greedy* inefficient. This raises the natural question of whether one can compute approximately optimal portfolios, for interesting problems, with a running time that is polynomial in the size of the input.

1.1 Our contributions

The first important contribution of our paper is conceptual: we formulate the Portfolio Optimization problem from a new, stochastic, viewpoint and show that it captures many interesting scenarios.

On the technical side, we focus on constructing solution portfolios for the fundamental problem of optimization under matroid contraints. We examine the simplified case where each element of the matroid's ground set takes a 0-1 value, independently, with some known probability, and the value of a set is the sum of the values of its elements. Despite its simplicity, this case captures many core challenges of constructing solution portfolios and proves to be technically challenging. As we discuss in Section 3, this problem differs fundamentally from classical problems in the area of randomized algorithms, because constructing effective portfolios requires leveraging the "anti-concentration" properties of various solutions. Additionally, employing standard tools from the literature, such as contention resolution schemes, presents challenges due to the nature of our objective function. In particular, the value of a portfolio depends heavily on "abnormal" events, such as significant deviations from the expected value, occurring in one of its k solutions. However, contention resolution schemes do not offer per-instance guarantees but rather only work on expectation. Therefore, we need to take extra care to apply these results while conditioning on those events.

The main technical contribution of our work is to design an algorithm with polynomial running time in the size of the matroid's ground set which constructs a portfolio that is a $\Theta(1)$-approximation of the optimal portfolio.

We give a high-level description of our techniques in Section 3 and present a simpler algorithm for the case of uniform matroids in Section 4. In the full version of the paper we show how this algorithm can be extended to work for all matroids.

1.2 Related work

The related work can be broadly categorized into three main directions. The first is the study of Segmentation Problems, initially introduced by Kleinberg, Papadimitriou and Raghavan [9]. This work, inspired by data mining techniques for market segmentation, defines a new class of optimization problems named *Segmentation Problems*. For any combinatorial optimization problem and a set S of different cost vectors for this problem, the corresponding segmentation problem asks to partition the set S into several *segments* and pick a separate solution for each segment, so that the total cost is minimized. The Portfolio Optimization problem can be seen as a stochastic variant of the aforementioned family of problems, where instead of a fixed set of cost vectors, one has access to a distribution over cost vectors and aims to optimize the expected value of the constructed portfolio. In fact, the two formulations are effectively equivalent when the distribution over cost vectors has a polynomial-sized support. This new, stochastic, viewpoint can accommodate a wider variety of applications where randomness is inherent in the problem at hand (e.g., sports betting, as introduced earlier). Besides that, it also enables the formulation of elegant and technically challenging theoretical questions, like the case where every element of a groundset takes a value independently of the other elements. Another adaptation of the family of "Segmentation Problems" is due to Gupta, Moondra and Singh [8] who examined a "robust" version of the problem. In this variant, the objective is to identify a small set of solutions that guarantees a good approximation for each one of the cost vectors of interest. This approach was motivated by fairness concerns, aiming to guarantee a good approximation across various cost vectors that may arise due to different fairness constraints.

On the technical side, Kleinberg et al. [9] study the Catalogue Segmentation problem, i.e. constructing portfolios for linear maximization with cardinality constraints. For the case where elements take values in $\{0, 1\}$, they design an algorithm that runs in time $O(n^{k \log k}/\delta)$ and produces a portfolio that is a $(1 - \delta)$-approximation, under the assumption that on every instance a large fraction of the items have value 1. Our result is a $O(1)$ approximation

with a running time that is polynomial in both n and k, without the need of a density assumption, but for the case where the value of each element is independent of the values of other elements. Furthermore, our results extend to more general settings, accommodating any matroid constraints on the ground set.

The second related line of work is the area of Data-Driven Algorithm Design and specifically speeding up an algorithms' execution by utilizing data. Some of these attempts include speeding up: the *Greedy* algorithm for submodular maximization [2, 15], the Hungarian algorithm for calculating maximum matchings [7], primal-dual algorithms for various graph problems [3], algorithms for flow problems [4, 5] and the Bellman-Ford algorithm [11]. The key distinction of our work lies in defining a new set of problems and providing general techniques for solving them.

A third relevant area of research is stochastic probing and online decision-making (for a detailed survey, see [14]). These problems typically involve a ground set of elements, each with an unknown stochastic weight sampled from a known distribution. The algorithm can probe certain elements – often incurring a cost – in order to reveal their weights. Based on these observations, it then selects a feasible subset and is rewarded with the weight of the selected items. A key distinction between this area and the Portfolio Optimization problem is that, in our setting, the solutions are chosen entirely offline, without observing any weights, and remain fixed across all possible realizations.

Our problem is more closely aligned with a non-adaptive strategy for stochastic probing. However, the variants of non-adaptive strategies studied in the literature typically impose only partial restrictions on the algorithm's flexibility – for instance, requiring the algorithm to preselect which elements to probe but still allowing it to form its solution after observing the probed weights. In contrast, in the Portfolio Optimization problem, the selection is entirely offline, with no adjustments allowed after weights are realized. For this reasons, the benchmarks of the two problems are also different: non-adaptive strategies are evaluated against the optimal value achievable in hindsight, whereas our benchmark is the best offline strategy with the same constraints as the algorithm.

2 Problem statement and preliminaries

2.1 Portfolio Optimization

In this section we define the Portfolio Optimization problem in its general form, for any classical combinatorial problem. In the next section, we define the Matroid Portfolio Optimization problem, which is the portfolio problem for a special case of maximization with matroid constraints.

We present the maximization variant of our problem, with the minimization version defined in a similar manner. For any combinatorial problem Π, the Portfolio Optimization problem is described by a tuple $\mathcal{J} = (\mathcal{I}, \mathcal{V}, \mathcal{D}, k)$ where $\mathcal{I}$ is the set of feasible solutions of problem Π, $\mathcal{V}$ is a set of value functions from $\mathcal{I}$ to $\mathbb{R}_{\geq 0}$, $\mathcal{D}$ is a distribution over $\mathcal{V}$ and k is a natural number that describes the desired size of the portfolio.

Our goal is to select k solutions from $\mathcal{I}$ so as to maximize the expected value of the *best* of those solutions. That is, for a collection of k sets $\mathcal{S} = \{S_1, \ldots, S_k\}$ such that $S_i \in \mathcal{I}, \forall i \in \{1, \ldots, k\}$ we define its value as:

$$\text{value}(\mathcal{S}) = \mathop{\mathbf{E}}_{v \sim \mathcal{D}} \left[\max_{S_i \in \mathcal{S}} v(S_i) \right].$$

Formally, we want to solve the following optimization problem.

$$\begin{aligned} &\text{maximize value}(\mathcal{S}) \\ &\quad \text{s.t.} \quad \mathcal{S} = \{S_1, ..., S_k\} \text{ and } S_i \in \mathcal{I}, \forall i \in [k]. \end{aligned}$$

We remark that the solutions $S_1, \ldots, S_k$ are chosen *offline*, without observing the realized value function, but rather only by using our knowledge about the distribution $\mathcal{D}$.

For any input tuple $\mathcal{J}$, we denote by $\mathcal{O}(\mathcal{J}) = \{O_1(\mathcal{J}), \ldots, O_k(\mathcal{J})\}$ the optimal portfolio, that is the maximizer of the above optimization problem. To ease notation, whenever the input and the algorithm are clear from the context we use $\mathcal{O} = \{O_1, \ldots, O_k\}$ and OPT to denote the optimum solution and its value respectively.

For an algorithm ALG we denote by $\mathcal{S}_{\text{ALG}(\mathcal{J})}$ its output on input $\mathcal{J}$. We say that ALG is a c-approximation if it always outputs a collection of feasible solutions and:

$$\mathop{\mathbf{E}}_{\text{ALG}} \left[\text{value}\left(\mathcal{S}_{\text{ALG}(\mathcal{J})}\right)\right] \geq c \cdot \text{value}\left(\mathcal{O}(\mathcal{J})\right), \ \forall \mathcal{J}$$

where the expectation is taken over the internal randomness of ALG.

In the maximization variant of the problem, the value of a set of solutions, defined as the expected maximum of their values, is a monotone submodular function, as demonstrated by Kleinberg and Raghu [10]. Consequently, the celebrated *Greedy* algorithm of [13] is a $(1-1/e)$ approximation that runs in polynomial time in the size of the solution set $\mathcal{I}$. Without imposing any further restrictions to the problem, this is the best approximation ratio one can achieve, as the Max-k-Cover problem can be reduced to the Portfolio Optimization problem. The details of the reduction are deferred to the full version of the paper.

Although Greedy achieves the optimal approximation ratio for this problem, its running time is impractical for most interesting applications like max-k-cover, knapsack, shortest paths, spanning trees, etc. In all of the aforementioned applications, the set of feasible solutions is given implicitly and is exponentially large in the size of the input. Therefore, one needs to have a running time that is polynomial in the description of the solution set, rather than its size. This raises the natural question of whether one can compute approximately optimal portfolios, for interesting problems, with a running time that is polynomial in the description of the solution set $\mathcal{I}$.

In this work, we focus on the fundamental case of optimization over matroid contraints and answer the latter question affirmatively for a natural distribution over value functions. We formulate this problem in the following section.

2.2 Matroid Portfolio Optimization

The Matroid Portfolio Optimization problem is a special case of the Portfolio Optimization problem, where the set of feasible solutions, $\mathcal{I}$, is the family of independent sets of an underlying matroid $M = (E, \mathcal{I})$ (see Definition 1). The set $\mathcal{V}$ of value functions is the set of all *additive* set functions that map the elements of E to $\{0, 1\}$. Formally, for any value function $u \in \mathcal{V}$, element $e \in E$ and subset $S \subseteq E$ we have: $u(\{e\}) \in \{0, 1\}$ and $u(S) = \sum_{e' \in S} u(\{e'\})$. Throughout the paper we use the term "active" to denote an element $e \in E$ that takes value one, under a specific value function, and the term "inactive" to describe an element with value zero.

We assume that $\mathcal{D}$ is such that each element $e \in E$ is active with probability p_e, independently of the values of the rest of the elements of E. Formally,

$$\forall S \subseteq E : \mathop{\mathbf{Pr}}_{u\sim\mathcal{D}}\left[\bigwedge_{e\in S}\{u(\{e\}) = 1\}\right] = \prod_{e\in S} p_e$$

To simplify the notation we define an equivalent distribution $\mathcal{D}'$ over subsets of E, that represent the set of active elements, such that

$$\forall e \in E : \mathop{\mathbf{Pr}}_{u\sim\mathcal{D}}[u(\{e\}) = 1] = \mathop{\mathbf{Pr}}_{A\sim\mathcal{D}'}[e \in A]\,.$$

and

$$\forall S \subseteq E : \mathop{\mathbf{Pr}}_{A\sim\mathcal{D}'}\left[\bigwedge_{e\in S}\{e \in A\}\right] = \prod_{e\in S} p_e$$

In other words, instead of sampling a value function that assigns $\{0, 1\}$ values to the elements, we can equivalently sample the set of active elements and, thus, switch to distributions over subsets of E. Also, the value of any set $S \subseteq E$ will now be equal to the random variable $|S \cap A|$, where A is the random set denoting the active elements.

For the remainder of the paper, the input to the Matroid Portfolio Optimization problem will be described by a triplet $\mathcal{J} = (M, k, \mathcal{D})$, where $M = (E, \mathcal{I})$ is a matroid over the ground set E, k a natural number describing the desired size of the portfolio and $\mathcal{D}$ is a distribution over subsets of E such that each element $e \in E$ is included in a sample, independently, with probability p_e. For a collection $\mathcal{S} = \{S_1, \ldots, S_k\}$ such that $S_i \in \mathcal{I}, \forall i \in \{1, \ldots, k\}$, we define its value as

$$\text{value}(\mathcal{S}) = \mathop{\mathbf{E}}_{A\sim\mathcal{D}}\left[\max_{S_i\in\mathcal{S}} |S_i \cap A|\right].$$

2.3 Preliminaries

In this subsection we introduce notation and give some preliminary definitions. First, for any positive integer ℓ we use the shorthand $[\ell]$ to denote the set $\{1, \ldots, \ell\}$. In addition, we give the definition of matroids below.

▶ **Definition 1.** *A pair $M = (E, \mathcal{I})$ is called a matroid if E is a finite ground set and $\mathcal{I}$ is a non-empty collection of subsets of E such that*

1. *If $I \in \mathcal{I}$ and $J \subseteq I$, then $J \in \mathcal{I}$,*
2. *If $I, J \in \mathcal{I}$ and $|I| < |J|$, then $I + e \in \mathcal{I}$ for some $e \in J \setminus I$.*

For a matroid $M = (E, \mathcal{I})$ the elements of $\mathcal{I}$ are called the independent sets of M. The rank function of a matroid M, $r_M : 2^E \to \mathbb{N}$, maps each set $U \subseteq E$ to the size of the largest independent set contained in U. We use the term "rank of a matroid M" to denote the rank r of the ground set, i.e. $r = r_M(E)$. A set $B \subseteq E$ is called a base if and only if it's a maximum size independent set. In addition, the span of a set $S \subseteq E$ is defined as $\text{span}_M(S) = \{e \in E : \text{rank}(S \cup \{e\}) = \text{rank}(S)\}$.

The matroid polytope $\mathcal{P}(M)$, of a matroid M, is a subset of $\mathbb{R}^{|E|}$ that is defined by the following sets of inequalities, where r_M is the rank function of M.

$$\mathcal{P}(M) = \left\{ \begin{array}{ll} \displaystyle\sum_{e\in U} x_e \le r_M(U), & \forall U \subseteq E \\ x_e \ge 0, & \forall e \in E \end{array} \right\}$$

It is well known that one can check whether some $x \in \mathbb{R}^{|E|}$ lies in the matroid polytope, that is $x \in \mathcal{P}(M)$, in polynomial time in the size of E.

3 Overview of our Techniques

The core difficulty of the Matroid Portfolio Optimization problem stems from its objective function. Indeed, calculating or bounding, the expectation of the maximum of k random variables is a difficult task, especially when the random variables are dependent. Apart from that, optimizing under this objective requires to look at the problem from a perspective that differs with what we are used to in the analysis of randomized algorithms. Usually, we argue that our solutions have a good enough expectation and that they reach this expectation with a reasonable probability. However, in order to construct a good portfolio we are interested in the "anti-concentration" properties of the solutions that we pick, meaning that we want each solution to be able to greatly surpass its expected value with a reasonable probability. Intuitively, if the values of our solutions were i.i.d. random variables, we would want them to be somewhat "heavy-tailed" so that after k independent samples there would be a good probability that we observe a high outlier. On the other hand, if the solutions that we pick were highly concentrated around their expected value, then we would observe almost no benefit by taking the maximum of several random variables.

In this section, we first highlight our ideas for the simpler case of Matroid Portfolio Optimization for uniform matroids and then explain how they can properly be generalized to work for all matroids. As a reminder, in the Matroid Portfolio Optimization problem on uniform matroids, we are given a ground set of n elements and we want to construct a portfolio $\mathcal{P}$ consisting of k subsets of the elements, each of size r. The value of the i-th element is an independent Bernoulli random variable with probability p_i and we are interested in maximizing the value of the portfolio that we construct.

Even in this simple case, understanding the core trade-off of using a higher probability element multiple times across solutions versus replacing it with independent elements of lower probability is a challenging task. In order to build some intuition, in the next subsection, we discuss some natural approaches for this simple case and show why they fail to produce a portfolio that is a constant-factor approximation of the optimal portfolio.

3.1 Natural approaches that fail

The first approach for this problem is simply to pick the k independent sets with the highest expected value. Of course, it makes sense to enforce that these independent sets are *disjoint*, since we want them to "complement" each other. If these sets had large pairwise intersections, we would observe no benefit from selecting k of them instead of one. In other words, a natural strategy is to pick the highest expectation subset, remove it from the ground set, continue by picking the highest expectation subset of the remaining elements and so on. However, this approach will fail to construct a good portfolio.

Intuitively, in some cases it is better to restrict ourselves to considerably less disjoint subsets and complete our portfolio by combining those subsets in a clever way, instead of using new subsets that might have lower expectation. For example, consider the instance where we need to pick k subsets of size $r = k$ and we have $n = r^2$ elements available. Let the first $k \log k$ elements have activation probability $1/k$, and the rest to have activation probability $1/k^2$. The approach described above will form k disjoint subsets, out of which $\log k$ will behave as independent binomials with expectation 1 and the rest will be independent binomials with expectation $1/k$. The value of this portfolio will be dominated by the expectation of the maximum of the first $\log k$ binomials, which is $O(\log \log k)$. Surprisingly, instead of using the lower probability elements, one can pick k solutions by uniformly combining parts of the first $\log k$ subsets and construct a portfolio that has value $\Theta(\log k / \log \log k)$, which is

asymptotically optimal (we describe this construction in the full version of the paper). This example showcases the power of having a clever "mixing" strategy as this can boost the portfolio to achieve an exponentially better value than a portfolio that only uses disjoint solutions. In fact, in this example, a strategy that picks only disjoint solutions would need k disjoint subsets of expectation 1 in order to achieve the same value as the one achieved by uniformly mixing $\log k$ subsets of expectation 1.

3.2 Main ideas

Filtering out elements

From the previous example, it becomes evident that a candidate algorithm should have a filtering procedure that discards some elements of the ground set, and a mixing strategy, which combines the remaining elements to form the desired subsets. It is natural to wonder if one can commit to the simplest possible mixing strategy (i.e. sampling elements uniformly) and try to find a filtering rule that would make this strategy work. Note that the nearly-optimal solution constructed for the previous example actually fits into this framework.

In the simpler case of uniform matroids, designing the filtering procedure can be reduced to first sorting the elements in decreasing order of their probabilities and then selecting a prefix of this order. A key observation in our work is that there always exists a prefix of the elements that admits a good portfolio under the simplest mixing strategy, i.e. forming subsets by uniform sampling. This observation directly gives us a polynomial-time constant-approximation algorithm, as one can try all possible n prefixes, generate the corresponding portfolios through uniform sampling and keep the best one of them after estimating their values. We formally present this algorithm in Section 4 and build up to our algorithm for general matroids in the full version of our paper.

Analyzing the value of the produced portfolio

The simplicity of our mixing strategy allows us to bypass dealing with the dependencies of the solutions we form when we want to lower bound the expectation of their maximum. On a high level, to analyze the value of our portfolio, we first fix the randomness of the instance, by conditioning on an outcome for the active elements, and then analyze the expected value of a sampled solution over the internal randomness of the algorithm. Once we have fixed the outcome of the active elements, the *values* of the sampled solutions are simply binomial random variables that only depend on the internal randomness of the sampling procedure. Critically, this makes the values of the sampled solutions *independent* random variables which makes them much easier to work with. On the other hand, if we had first fixed the portfolio produced by the algorithm and then tried to analyze its value over the randomness of the instance, we would have to analyze the dependencies of the picked solutions and how these influence the value of the portfolio, which is a much harder task. This analysis technique, of course, comes with its own challenges as selecting the appropriate event to condition on is not a trivial task.

Generalizing to all matroids

The filtering procedure described above fails to work beyond uniform matroids, simply because it ignores the underlying matroid structure of the elements. For example, consider the case of the graphic matroid of a graph G that consists of a clique on $\sqrt{n}$ vertices and a simple path of $n - \sqrt{n}$ vertices. Let the activation probabilities of the edges of the clique

to be $1/\sqrt{n}$ and the activation probabilities of the edges of the path to be $1/\sqrt{n} - \epsilon$ for some small $\epsilon > 0$. Ordering the elements by their activation probabilities and selecting a prefix of this ordering goes towards the wrong direction as one should prioritize taking edges from the path over taking edges from the clique. Indeed, taking the path as our only solution would give us an expected value of $\Theta(\sqrt{n})$, whereas any portfolio of $k = O(n)$ spanning trees of the clique has value at most $O(\log n / \log \log n)$.

In order to overcome this issue, we change our filtering procedure to select a certain number of disjoint, high-expectation, independent sets of the matroid. In other words, we create an ordering of disjoint independent sets of decreasing expectation and we take a prefix of this ordering. Constructing this ordering can simply be achieved by finding the biggest expectation base of the matroid through the Greedy algorithm, then restricting the matroid to the remaining elements and repeating. As in the case of uniform matroids, we prove that there always exists a prefix of this ordering that admits a nearly-optimal portfolio after sampling elements uniformly and then passing them through a contention resolution scheme.

Finally, the biggest technical challenge of this problem is analyzing the value of the produced portfolios in the case of general matroids. To be more precise, the value of a portfolio heavily relies on "abnormal" events happening in one of its k solutions. For example, if we fix a set of active elements, and analyze the expected value of the sampled solutions over the internal randomness of the algorithm, the expected value of each solution will be the number of active elements we expect to sample in one trial. Crucially, one of the k trials will sample much more active elements than its expectation, and this trial will be responsible for the value of the portfolio. At this point, this solution will be passed through a contention resolution scheme to be trimmed down to an independent set. However, contention resolution schemes do not have per-instance guarantees but only work in expectation. Therefore, there is no guarantee that, when this abnormal event happens, the active elements are not going to be discarded by the contention resolution scheme. We overcome this issue by conditioning on appropriate events that do not entirely fix the randomness of either the instance or the algorithm, but still allow us to use the guarantees of a contention resolution scheme and argue that one of the sampled solutions reaches a near-optimal value. This is the main result of our work which is formally stated below.

▶ **Theorem 2.** *If $\mathcal{D}$ is a product distribution then there exists an algorithm that is achieves $\Theta(1)$-approximation for the k-portfolio solution problem and has a polynomial time complexity.*

4 Warm-up: An $O(1)$ approximation for Uniform Matroids

In this section we formally introduce some of the ideas described above by presenting our algorithm for the case of uniform matroids. We remind the reader that the input is described by a triplet $\mathcal{J} = (M, k, \mathcal{D})$ where $M = (E, \mathcal{I})$ is a (uniform in this section) matroid with rank r, k is the size of our portfolio and $\mathcal{D}$ is a product distribution where each element $e \in E$ is active with probability p_e. For simplicity, we order elements in E in decreasing order of their probabilities. We denote by e_i the i-th element in this order and by p_i its activation probability. In addition, throughout this section we assume that $\text{OPT} \geq 200$. In the full version of the paper, we prove that lower bounding OPT by a large constant is without loss of generality.

As mentioned in Section 3, our algorithm filters out some elements of the ground set and then produces the k solutions of its portfolio by sampling elements uniformly at random. We prove that for any instance of the problem, there exists a prefix of the elements (when ordered by decreasing activation probability) that admits a near-optimal portfolio under

uniform sampling. Therefore, the algorithm simply needs to try all n prefixes, estimate the values of the constructed portfolios and output the best one of them. We give the pseudocode of this strategy in Algorithm 1.

Algorithm 1 An algorithm for Uniform Matroids.

```
function CREATE-PORTFOLIO(J = (M, k, D))          ▷ M: uniform matroid of rank r
    Portfolios ← []
    for i = 1, ..., n do
        Prefix ← {1, ..., i}                      ▷ Elements are ordered with decreasing p_i
        Portfolios[i] ← PORTFOLIO-FROM-PREFIX(Prefix, k, r)
    end for
    Estimate the values of the n portfolios
    Return the portfolio with the biggest estimated value
end function

function PORTFOLIO-FROM-PREFIX(Prefix, k, r)
    P ← {}
    for i = 1, ..., k do
        Let V_i = {s_1, ... s_r} be r uniformly random samples from Prefix
        S ← non-duplicate elements of V_i
        P ← P ∪ S
    end for
    return P
end function
```

In order to prove that Algorithm 1 is an $O(1)$-approximation, it suffices to show that there exists a prefix on which sampling elements uniformly creates a portfolio with value at least $\Theta(1) \cdot \mathrm{OPT}$. Indeed, the value of each solution can be estimated using standard techniques within a small factor with polynomially many samples with high probability. Since there is only n solutions the estimate is close for all of them with good probability (by union bound) and we output the best solution. The prefix on which we will focus, is the largest prefix whose expected value is at most $\mathrm{OPT}/2$. More formally, let M be the largest index such that

$$\sum_{i=1}^{M} p_i < \mathrm{OPT}/2.$$

By the definition of M, we know that $\sum_{i=1}^{M+1} p_i \geq \mathrm{OPT}/2$, therefore we also get that

$$\sum_{i=1}^{M} p_i \geq \mathrm{OPT}/2 - p_{M+1} \geq \mathrm{OPT}/2 - 1 \geq \mathrm{OPT}/3,$$

where in the last inequality we used that $\mathrm{OPT} \geq 6$.

Our first observation is that there exists a portfolio which only uses elements outside of the selected prefix, i.e. elements with lower activation probability than what our algorithm has picked, and that achieves value at least $\mathrm{OPT}/2$. This portfolio is the restriction of the optimal one to the elements outside of the prefix. Let $H = \{e_1, \ldots, e_M\}$ and $L = \{e_{M+1}, \ldots, e_n\}$. The aforementioned claim is stated formally in the following lemma:

▶ **Lemma 3.** $\mathbf{E}_{A \sim \mathcal{D}} \left[\max_{O_i \in \mathcal{O}} |O_i \cap L \cap A|\right] \geq \frac{\mathrm{OPT}}{2}$.

Proof of Lemma 3.

$$\begin{aligned}
\mathrm{OPT} &= \mathop{\mathbf{E}}_{A\sim\mathcal{D}}\left[\max_{O_i\in\mathcal{O}} |O_i \cap A|\right] && (1)\\
&= \mathop{\mathbf{E}}_{A\sim\mathcal{D}}\left[\max_{O_i\in\mathcal{O}} |O_i \cap H \cap A| + |O_i \cap L \cap A|\right] && (2)\\
&\leq \mathop{\mathbf{E}}_{A\sim\mathcal{D}}\left[|A \cap H| + \max_{O_i\in\mathcal{O}} |O_i \cap L \cap A|\right] && (3)\\
&\leq \frac{\mathrm{OPT}}{2} + \mathop{\mathbf{E}}_{A\sim\mathcal{D}}\left[\max_{O_i\in\mathcal{O}} |O_i \cap L \cap A|\right] && (4)\\
\Rightarrow \mathop{\mathbf{E}}_{A\sim\mathcal{D}}&\left[\max_{O_i\in\mathcal{O}} |O_i \cap L \cap A|\right] \geq \frac{\mathrm{OPT}}{2}, && (5)
\end{aligned}$$

where from (2) to (3) we used that $O_i \cap H \cap A \subseteq H \cap A$ for all i and from (3) to (4) that $\mathbf{E}_{A\sim\mathcal{D}}[|A \cap H|] = \sum_{i=1}^{M} p_i \leq \frac{\mathrm{OPT}}{2}$. ◀

The next observation we make is that if someone had access to $k \cdot r$ independent copies of the element e_{M+1}, then by using these elements they could construct a portfolio that has value at least OPT/2.

▶ **Lemma 4.** *Let $B_1, \ldots, B_k$ be k i.i.d random variables following $Bin(r, p_{M+1})$. Then,*

$$\mathbf{E}\left[\max_{i\in[k]} B_i\right] \geq \frac{\mathrm{OPT}}{2}.$$

Proof of Lemma 4. From Lemma 3, we know that there exist k dependent Poisson Binomials, namely the solutions picked by the optimal portfolio restricted to L, each of which has at most r trials, trial probabilities at most p_{M+1}, and whose expected maximum is at least OPT/2. The proof follows from the fact that one construct the desired Binomials, $B_1, \ldots, B_k$, by starting from the Poisson Binomials and doing the following transformations:

1. Increase the number of trials of all Poisson Binomials to r by augmenting new independent Bernoulli random variables each having probability p_{M+1}.
2. Make the Poisson Binomials independent by introducing new independent copies for the elements that are shared across many solutions.
3. Transform the Poisson Binomials into Binomials by increasing all probabilities to p_{M+1}.

All of the above transformations do not decrease the expectation of the maximum of the random variables, since (1) the augmented variables stochastically dominate the previous ones, (2) making the random variables independent can only increase the expectation of their maximum, because solutions with shared elements are positively correlated and "fail" together and (3) increasing the probabilities of the trials can also only increase the expectation of their maximum. ◀

The previous lemma gives us a "target" for analyzing the expected value of our portfolio. After conditioning on an appropriate constant probability event for the activation of elements, we argue that the *values* of the sampled solutions are independent Binomial random variables with trial probability close to p_{M+1}. We define such event as H having at least OPT/12 active elements and prove that the latter happens with probability at least 1/2. To that end, let $W = \left\{\tilde{E} \subseteq E : |\tilde{E} \cap H| \geq \mathrm{OPT}/12\right\}$.

▶ **Lemma 5.** $\mathbf{Pr}_{A\sim\mathcal{D}}[A \in W] \geq 1/2$.

Proof of Lemma 5. The left hand side of the desired inequality can be written as:

$$\begin{aligned}
\Pr_{A\sim\mathcal{D}}[A \in W] &= \Pr_{A\sim\mathcal{D}}\left[|A\cap H| \geq \frac{\mathrm{OPT}}{12}\right] && (1)\\
&\geq \Pr_{A\sim\mathcal{D}}\left[|A\cap H| \geq \frac{\mathbf{E}[|A\cap H|]}{4}\right] && (2)\\
&\geq \Pr_{A\sim\mathcal{D}}\left[||A\cap H| - \mathbf{E}[|A\cap H|]| \leq \frac{3}{4}\mathbf{E}[|A\cap H|]\right] && (3)\\
&\geq 1 - 2e^{-\left(\frac{3}{4}\right)^2\cdot\frac{1}{3}\cdot\mathbf{E}[|A\cap H|]} && (4)\\
&\geq \frac{1}{2} && (5)
\end{aligned}$$

where for (1) and (4) we used that $\mathbf{E}_{A\sim\mathcal{D}}[|A\cap H|] = \sum_{i=1}^{M} p_i \geq \frac{\mathrm{OPT}}{3} \geq 10$ and for (3) we used a Chernoff Bound for the Binomial random variable $|A\cap H|$. ◀

We continue by proving Lemma 6 for the expected value of the sampled multisets V_i. For simplicity, we slightly abuse notation and for any set $\tilde{E} \subseteq E$ we use $|V_i \cap \tilde{E}|$ to denote the sum $\sum_{x\in V_i} \mathbb{1}\{x \in \tilde{E}\}$.

▶ **Lemma 6.** *For any $\tilde{E} \in W$, it holds that*

$$\mathop{\mathbf{E}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}|\right] \geq \mathrm{OPT}/24.$$

Proof of Lemma 6. When we have fixed an outcome $\tilde{E} \in W$ for the active elements, the values of the sampled multisets, V_i, depend only on the internal randomness of our sampling procedure and are, thus, independent random variables. In addition, the algorithm samples elements uniformly at random from H. Therefore the probability that a sampled element is active is

$$\frac{|\tilde{E}\cap H|}{|H|} \geq \frac{\mathrm{OPT}}{12\cdot|H|} \geq \frac{\sum_{i\in H} p_i}{12\cdot|H|} \geq \frac{p_{M+1}}{12},$$

where for the first inequality we used that the definition of W, for the second inequality we used that $\sum_{i\in H} p_i \leq \mathrm{OPT}/2$ from the definition of the prefix H, and for the third inequality we used that $\forall i \in H : p_i \geq p_{M+1}$.

Therefore, the random variables $|V_i \cap \tilde{E}|$ are independent Binomials with trial probability at least $p_{M+1}/12$ for all i. Intuitively, this means that the expectation of their maximum should be close to the expectation of the maximum of k independent binomials with trial probability p_{M+1}, which by Lemma 4 is at least $\Theta(1)\cdot\mathrm{OPT}$.

More formally, let $B_1, \ldots, B_k$ be iid random variables following $Bin(r, p_{M+1})$ and $B'_1, \ldots, B'_k$ be iid random variables following $Bin(r, p_{M+1}/12)$. Then for any $\tilde{E} \in W$, it holds that

$$\mathop{\mathbf{E}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}|\right] \geq \mathbf{E}\left[\max_{i\in[k]} B'_i\right] \geq \frac{1}{12}\mathbf{E}\left[\max_{i\in[k]} B_i\right] \geq \frac{\mathrm{OPT}}{24},$$

where the first inequality holds because the values of the sampled multisets dominate the random variables B'_i. For the second inequality, intuitively, one can view the process of sampling the random variables B'_i as first sampling the Binomials $B_1, \ldots, B_k$ and then discarding every Bernoulli random variable that succeeded, independently, with probability $1/12$. In this way, for every outcome of the Binomials $B_1, \ldots B_k$, the Binomials $B'_1, \ldots, B'_k$ will retrieve, on expectation, a $1/12$ factor of their corresponding random variables B_i. Finally, for the third inequality we used Lemma 4. ◀

We continue by proving that for any "good" outcome $\tilde{E} \in W$, the expected value of the maximum of the sets $S_1, \ldots, S_k$, that consist of the unique elements of the sampled multisets, V_i, is still $\Theta(1) \cdot \mathrm{OPT}$.

▶ **Lemma 7.** *For any $\tilde{E} \in W$, it holds that*

$$\mathop{\mathbf{E}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |S_i \cap \tilde{E}|\right] \geq \frac{e}{240(e-1)} \cdot \mathrm{OPT}.$$

Proof of Lemma 7. In order to analyze the expected value of the portfolio for the events $\tilde{E} \in W$, we will condition on the value of the maximum of the multisets $V_1, \ldots, V_k$. By the law of total expectation we get that

$$\mathop{\mathbf{E}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |S_i \cap \tilde{E}|\right] = \sum_x \mathop{\mathbf{E}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |S_i \cap \tilde{E}| \,\middle|\, \max_{i\in[k]} |V_i \cap \tilde{E}| = x\right] \cdot \mathop{\mathbf{Pr}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}| = x\right]. \quad (\ddagger)$$

Lower bounding the following expression,

$$\mathop{\mathbf{E}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |S_i \cap \tilde{E}| \,\middle|\, \max_{i\in[k]} |V_i \cap \tilde{E}| = x\right],$$

can be seen as a balls and bins question. Specifically, we know that one of the k solutions formed by the algorithm sampled x items from $|\tilde{E} \cap H|$. Since the algorithm is sampling elements uniformly at random, those x items are also distributed uniformly at random inside $|\tilde{E} \cap H|$. We are interested in calculating the expected number of distinct items that were sampled. This question is equivalent to counting the non-empty bins after throwing x balls uniformly into $|\tilde{E} \cap H|$ bins. Using a standard result about the expected number of non-empty bins, we get that

$$\mathop{\mathbf{E}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |S_i \cap \tilde{E}| \,\middle|\, \max_{i\in[k]} |V_i \cap \tilde{E}| = x\right] \geq \min\left\{\frac{x}{2}, \frac{3|\tilde{E} \cap H|}{10}\right\}.$$

Eq. ‡ can now be re-written as

$$\begin{aligned}
\mathop{\mathbf{E}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |S_i \cap \tilde{E}|\right] &\geq \sum_x \min\left\{\frac{x}{2}, \frac{3|\tilde{E} \cap H|}{10}\right\} \cdot \mathop{\mathbf{Pr}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}| = x\right] && (1)\\
&\geq \sum_x \min\left\{\frac{x}{2}, \frac{\mathrm{OPT}}{40}\right\} \cdot \mathop{\mathbf{Pr}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}| = x\right] && (2)\\
&\geq \min\left\{\frac{\mathrm{OPT}}{300}, \frac{\mathrm{OPT}}{40}\right\} \cdot \mathop{\mathbf{Pr}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}| \geq \frac{\mathrm{OPT}}{150}\right] && (3)\\
&\geq \frac{\mathrm{OPT}}{300} \cdot \mathop{\mathbf{Pr}}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}| \geq \frac{\mathbf{E}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}|\right]}{5}\right] && (4)\\
&\geq \frac{e}{300(e-1)} \cdot \mathrm{OPT}, && (5)
\end{aligned}$$

where for (2) we used the fact that $|\tilde{E} \cap H| \geq \mathrm{OPT}/12$ for $\tilde{E} \in W$, to get (3) we restricted the sum to the terms $x \geq \mathrm{OPT}/150$, to get (4) we used that $\mathbf{E}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}|\right] \geq \mathrm{OPT}/24$ from Lemma 6 and to get (5) we used a concentration inequality for the maximum of independent Binomial random variables and the assumption that $\mathrm{OPT} \geq 800$ to get that $\mathbf{E}_{\mathrm{ALG}}\left[\max_{i\in[k]} |V_i \cap \tilde{E}|\right]$ is at least some constant. ◀

Finally, we are ready to prove the main theorem of the section.

▶ **Theorem 8.** *Algorithm 1 is a $\Theta(1)$-approximation algorithm for the k-solution portfolio problem when the given matroid is uniform and $\mathcal{D}$ is a product distribution.*

Proof of Theorem 8. The value of the constructed portfolio $\mathcal{P}$ can be written as:

$$\begin{aligned}
\text{value}(\mathcal{P}) &= \mathop{\mathbf{E}}_{\text{ALG},A\sim\mathcal{D}}\left[\max_{i\in[k]}|S_i\cap A|\right] && (1)\\
&\geq \sum_{\tilde{E}\in W}\mathop{\mathbf{E}}_{\text{ALG}}\left[\max_{i\in[k]}|S_i\cap\tilde{E}|\right]\cdot\mathop{\mathbf{Pr}}_{A\sim\mathcal{D}}\left[A=\tilde{E}\right] && (2)\\
&\geq \frac{e}{300(e-1)}\cdot\text{OPT}\cdot\sum_{\tilde{E}\in W}\mathop{\mathbf{Pr}}_{A\sim\mathcal{D}}\left[A=\tilde{E}\right] && (3)\\
&\geq \frac{e}{300(e-1)}\cdot\text{OPT}\cdot\mathop{\mathbf{Pr}}_{A\sim\mathcal{D}}\left[A\in W\right] && (4)\\
&\geq \frac{e}{600(e-1)}\cdot\text{OPT}, && (5)
\end{aligned}$$

where to get (3) we applied Lemma 7 and (5) follows from Lemma 5. ◀

Abstract

We study the question of whether submodular functions of random variables satisfying various notions of negative dependence satisfy Chernoff-like concentration inequalities. We prove such a concentration inequality for the lower tail when the random variables satisfy negative association or negative regression, partially resolving an open problem raised in ([23]). Previous work showed such concentration results for random variables that come from specific dependent-rounding algorithms ([6, 14]). We discuss some applications of our results to combinatorial optimization and beyond. We also show applications to the concentration of read-k families [13] under certain forms of negative dependence; we further show a simplified proof of the entropy-method approach of [13].

1 Introduction

Concentration inequalities are ubiquitous in discrete mathematics and theoretical computer science [2, 9]. The most canonical examples are the Chernoff-Hoeffding bounds, which show strong concentration for linear combinations of independent random variables [7, 15]. In some applications, the condition of independence is too restrictive, so weaker notions have been considered [3, 24, 25]. Of interest to us is the setting where the random variables are negatively correlated, which arises naturally, for example, in designing approximation algorithms by solving a linear or semidefinite program and applying some dependent randomized rounding algorithm [11]. For this setting, [20] showed that the Chernoff-Hoeffding bounds can be shown under the weak notion of *negative cylinder dependence*: this and other standard notions of negative dependence are defined in Section 2.1.

For some applications in combinatorial optimization, algorithmic game theory, and machine learning, one needs to consider the more general class of *submodular functions* f of the random variables, rather than simple linear combinations. When the binary random variables $X_1, \ldots, X_n$ are independent, it was shown that $f(X_1, \ldots, X_n)$ still satisfies Chernoff

bounds exactly [6]. When there is dependence between the random variables, the results are much weaker. The only known results are for random variables that are output by specific dependent-rounding algorithms, known as swap rounding and pipage rounding [6, 14]. These results showed that a Chernoff-like lower-tail bound also holds for submodular functions for their specific dependent rounding procedure. As noted in the work of [12], it is not clear how to generalize either of these proofs to any general notion of negative dependence.

We introduce a new notion of negative dependence, called 1-negative association, which is weaker than negative association and negative regression but stronger than negative cylinder dependence.

▶ **Definition 1.** *A collection of random variables $X_1, \ldots, X_n$ is said to satisfy 1-negative association if for any two monotone functions f and g, where g depends on a single random variable X_i and f depends on the remaining random variables $\{X_j\}_{j\in[n]\setminus\{i\}}$, we have $\mathbb{E}[fg] \leq \mathbb{E}[f]\mathbb{E}[g]$.*

Importantly, while in general it is weaker than the notion of weak negative regression introduced by [23], 1-negative association is equivalent to it when the variables $X_1, \ldots, X_n$ are binary. Further details are provided in Section 3.1.

Our main result is that the Chernoff-like bound shown in [6, 14] also hold under 1-negative association (see Section 3.2). In particular, this implies the following:

▶ **Theorem 2.** *Let $X_1, \ldots, X_n$ be binary random variables with mean $x_1, \ldots, x_n$ satisfying negative association (or negative regression). Let f be a non-negative monotone submodular function with marginal values in $[0, 1]$ and let F be the multilinear extension of f. If we let $\mu_0 = F(x_1, \ldots, x_n)$, then we have the following:*

$$\Pr[f(X_1, \ldots, X_n) \leq (1-\delta)\cdot\mu_0] \leq \exp(-\mu_0\delta^2/2).$$

A few remarks are in order. First, we highlight that the concentration in the above theorem is with respect to the value of the multilinear extension $F(x_1, \ldots, x_n)$, rather than the true expected value $\mathbb{E}[f(X_1, \ldots, X_n)]$. In general, the true expected value can be greater than the value of multilinear extension [23]. Nevertheless, this suffices for applications relating to submodular maximization, and is the same type of concentration result shown in previous work. Second, recall that negative cylinder dependence does not suffice to show this concentration bound [6, p. 583]. As a result, our results are, in some informal sense, almost tight in terms of the condition on negative dependence.

In addition to providing submodular concentration results for a wide class of rounding algorithms and distributions, our results also give a new path toward understanding why pipage rounding and swap rounding satisfy the lower-tail Chernoff bound. By proving that the rounding algorithms output random variables which are 1-negatively associated, we immediately obtain a new proof of the lower tail bounds. This can be viewed as evidence that the two rounding algorithms satisfy 1-negative association or even negative association/regression. We leave this as an interesting open question.

Techniques

We use the standard method of bounding the exponential moments for lower-tail Chernoff bounds. Our idea is to show that the exponential moments for our negatively-correlated random variables is upper bounded by the exponential moments for independent copies of the random variables. Formally, let $X_1, \ldots, X_n$ be random variables satisfying 1-negative association and let $X_1^*, \ldots, X_n^*$ be independent copies of the random variables. We show for any $\lambda < 0$, we have

$$\mathbb{E}[\exp(\lambda \cdot f(X_1, \ldots, X_n))] \leq \mathbb{E}[\exp(\lambda \cdot f(X_1^*, \ldots, X_n^*))].$$

Since the exponential-moments method has been used to prove Chernoff bounds for submodular functions in the independent case [6], we can then repeat their proof and conclude with our desired result. We believe this proof idea may be of independent interest. For example, the same ideas can show that for a supermodular function g and any $\lambda > 0$, we have

$$\mathbb{E}[\exp(\lambda \cdot g(X_1, \ldots, X_n))] \leq \mathbb{E}[\exp(\lambda \cdot g(X_1^*, \ldots, X_n^*))].$$

In other words, we have morally proven the following statement: any upper-tail concentration bound which can be proven for a supermodular function g under independence based on the exponential-moments method also holds when the underlying random variables are negatively associated. As an example, we can apply this to a read-k family of supermodular functions $g_1, \ldots, g_r$ for negatively associated random variables [13]. A read-k family is defined as a set of functions where each variable appears in at most k functions. This concept is particularly useful in scenarios where functions need to model or manage overlapping sets of variables with constraints on their interaction. We highlight that the proof of concentration for read-k families given in [13] doesn't use the exponential-moments method, but instead it is based on the entropy method. We address this by giving a simpler proof of their results, this time using the exponential moments method. This gives the first concentration results for a class of supermodular functions under negatively correlated random variables, and is detailed in Section 3.3.

Applications

Our motivation for studying the problem comes from the randomized-rounding paradigm in approximation algorithms for converting a fractional solution to a linear program into an integral one. In many such randomized-rounding schemes, the output random variables have been shown to satisfy strong negative dependence properties, such as negative association [26, 11]. For all such rounding algorithms, our results immediately imply the submodular Chernoff lower-tail bound. It remains an interesting open question to efficiently sample negatively dependent distributions for a wider class of set systems. A particularly interesting algorithm is given in the work of [22]; they show that a fractional point in a matroid polytope can be rounded to an integral one such that the resulting distribution preserves marginals and satisfies negative association. However, a gap identified in their proof [23] complicates the application of their approach. The implications of this issue for the applicability of our results remain an area for further investigation.

As a concrete application, we consider the maximum coverage problem under group fairness constraints. Here, we have a universe of elements $\{1, \ldots, n\}$, a collection $S_1, \ldots, S_m$ of subsets of the universe, and a budget k. We are further given subsets $C_1, \ldots, C_\ell \subseteq [n]$ (which should be thought of as demographic groups) along with thresholds $w_1, \ldots, w_\ell$. Our goal is to choose k sets from the collection to maximize the number of elements covered subject to the fairness constraint each demographic group is sufficiently covered (i.e., at least w_j elements from C_j are covered). Since this is a special case of multiobjective submodular maximization, there exists a $(1 - 1/e - \epsilon)$-approximation to the problem such that each fairness constraint is approximately satisfied [6, 28]. Unfortunately, these results rely on the randomized swap-rounding algorithm due to its submodular concentration properties, which requires a super-linear time complexity. While swap rounding can be implemented with poly-logarithmic depth [5], a simpler dependent-rounding algorithm of [26] requires linear work and only $O(\log n)$ depth, which improves the efficiency. Observe that the pre-processing step in [28] only requires $O(n\ell)$ time. Since we can solve the linear program for fair maximum

coverage in near-linear time [1], we obtain a near-linear time algorithm for the problem after using the efficient rounding algorithm of [26]. These same ideas can be used to improve the time complexity of the algorithm by [27] for influence maximization with group-fairness constraints. Since the proofs are similar to previous work, we defer the details to a future version of the paper.

More generally, negatively-associated random variables show up naturally in many settings (see e.g., the primer by [29]). [8] studied the canonical example of *balls and bins*, and showed that it satisfied both negative association and negative regression. Another example satisfying the negative-association conditions are any product measure over the set of bases of a balanced matroid, as shown by [10]. A final setting where such random variables occur are random spanning trees, which have been vital in the recent improvements to approximation algorithms for the traveling salesperson problem (see, e.g., [16]). Random spanning trees are known to be strongly Rayleigh, which immediately implies that they are negatively associated. Our results may be interesting here as well.

We also observe that the online rounding scheme of [18] has the strongly Rayleigh property: we immediately get strong concentration (on the lower-tail side) for monotone submodular functions, when the inputs for the function arrive online along with their (Bernoulli) distributions as in the setup of [18].

Related Work

The concentration of negatively-dependent random variables was first formally studied by [19], which showed a central limit theorem for a certain notion of negative dependence. Later on, [20] showed that cylinder negatively dependent random variables yield the Chernoff-Hoeffding concentration inequalities, just like independent random variables. In the context of our paper, these results are somewhat specialized since they focus on linear combinations of random variables.

For non-linear functions of the random variables, the majority of work has focused on the concentration of Lipschitz functions under various notions of negative dependence. [21] showed that for strong Rayleigh measures, one has Gaussian concentration for any Lipschitz function. Later on, [12] corrected an earlier proof of [8], showing that McDiarmid-like concentration results hold for Lipschitz functions of random variables satisfying negative regression. These results are complementary to ours since we are trying to give dimension-free concentration results.

2 Preliminaries

2.1 Notions of Negative Dependence

We begin by defining the notion of negative dependence commonly found in the literature.

Negative Cylinder Dependence

A collection of Boolean random variables $X_1, \ldots, X_n$ is said to be negative cylinder dependent if for every $S \subseteq [n]$,

$$\mathbb{E}\left[\prod_{i \in S} X_i\right] \leq \prod_{i \in S} \mathbb{E}\left[X_i\right]$$

and

$$\mathbb{E}\left[\prod_{i \in S} (1 - X_i)\right] \leq \prod_{i \in S} \mathbb{E}\left[1 - X_i\right].$$

Negative cylinder dependence is the weaker notion considered here. It is known to imply Chernoff bounds for linear combinations of $X_1, \ldots, X_n$ but it is insufficient to show our submodular concentration results.

Negative Association

A collection of random variables $X_1, \ldots, X_n$ is said to be negatively associated if for any $I, J \subset [n], I \cap J = \emptyset$ and any pair of non-decreasing functions $f : \mathbb{R}^I \to \mathbb{R}, g : \mathbb{R}^J \to \mathbb{R}$,

$$\mathbb{E}\left[f\left(X_I\right) g\left(X_J\right)\right] \leq \mathbb{E}\left[f\left(X_I\right)\right] \mathbb{E}\left[g\left(X_J\right)\right].$$

Here and in the following, X_S refers to those random variables that are indexed by the elements in S, $X_S = \{X_i \ : \ i \in S\}$. Negative association is a significant strengthening of negative cylinder dependence, and has many additional useful closure properties. This will be one of the focuses of the paper.

Negative Regression

A collection of random variables $X_1, \ldots, X_n$ is said to satisfy negative regression, if for any $I, J \subset [n], I \cap J = \emptyset$, any non-decreasing function $f : \mathbb{R}^I \to \mathbb{R}$ and $a \leq b \in \mathbb{R}^J$,

$$\mathbb{E}\left[f\left(X_I\right) \mid X_J = a\right] \geq \mathbb{E}\left[f\left(X_I\right) \mid X_J = b\right].$$

Negative regression is a strengthening of negative cylinder dependence, but its relationship with negative association is not yet well understood. It is known that negative association doesn't imply negative regression [8], but the opposite implication is not known. This will be the other focus of the paper.

Strong Rayleigh

A collection of random variables $X_1, \ldots, X_n$ is said to satisfy the strong Rayleigh property if the generating function

$$F(z_1, \ldots, z_n) = \mathbb{E}[\textstyle\prod_{j=1}^{n} z_j^{X_j}]$$

is a real stable polynomial (i.e., it has no root $(z_1, \ldots, z_n) \in \mathbb{C}^n$ with all positive imaginary components). The strong Rayleigh property is the strongest notion of negative dependence, and has been shown to imply all other studied negative dependence definitions [4]. As a result, all of our results apply here as well.

2.2 Submodular Functions

We also give a quick review of the basics of submodular functions.

Submodular Functions

We say that a function $f : \{0,1\}^n \to \mathbb{R}$ is submodular if

$$f(X_1, \ldots, X_{i-1}, 1, X_{i+1}, \ldots X_n) - f(X_1, \ldots, X_{i-1}, 0, X_{i+1}, \ldots X_n)$$

is a non-increasing function of $X_1, \ldots, X_{i-1}, X_{i+1}, \ldots, X_n$ for each $i \in [n]$. When viewing the binary input of f as the indicator vector for a set, this is equivalent to the more common definition that f is submodular if for any $X, Y \subseteq [n]$ with $X \subseteq Y$ and any $x \notin Y$, we have

$$f(X \cup \{x\}) - f(X) \geq f(Y \cup \{x\}) - f(Y).$$

Supermodular Functions

We say that a function $g : \{0,1\}^n \to \mathbb{R}$ is supermodular if

$$g(X_1, \ldots, X_{i-1}, 1, X_{i+1}, \ldots X_n) - g(X_1, \ldots, X_{i-1}, 0, X_{i+1}, \ldots X_n)$$

is a non-decreasing function of $X_1, \ldots, X_{i-1}, X_{i+1}, \ldots, X_n$ for each $i \in [n]$. When viewing the binary input of g as the indicator vector for a set, this is equivalent to the more common definition that g is supermodular if for any $X, Y \subseteq [n]$ with $X \subseteq Y$ and any $x \notin Y$, we have

$$g(X \cup \{x\}) - g(X) \leq g(Y \cup \{x\}) - g(Y).$$

Mutlilinear Extension

The multilinear extension of a function f is

$$F(x) = \mathbb{E}[f(x)] = \sum_{S \subseteq N} f(S) \prod_{i \in S} x_i \prod_{i \notin S} (1 - x_i),$$

for $x \in [0,1]^n$. If we view x as a probability vector, the multilinear extension F is simply the expected value of f when each coordinate is rounded independently in $\{0,1\}$.

3 Submodular Chernoff Bounds

3.1 1-Negative Association and Weak Negative Regression

We first define the weaker notion of negative dependence which we work with, called 1-negative association, and prove some simple properties about it. We also define a related notion of weak negative regression, which is the analogue of 1-negative association for the notion of negative regression, and we show the equivalence between the two for binary random variables and show that weak negative regression is strictly stronger in general. After an initial draft, we discovered that [23] had already introduced the notion of weak negative regression for binary random variables in a context complementary to ours. Using their work, we can immediately show nice properties about 1-negative association.

▶ **Definition 3.** *A collection of random variables $X_1, \ldots, X_n$ is said to satisfy 1-negative association if for any two monotone functions f and g, where g depends on a single random variable X_i and f depends on the remaining random variables $\{X_j\}_{j \in [n] \setminus \{i\}}$, we have $\mathbb{E}[fg] \leq \mathbb{E}[f]\mathbb{E}[g]$.*

▶ **Definition 4.** *A collection of random variables $X_1, \ldots, X_n$ is said to satisfy weak negative regression if for any index i and any monotone function f depending on the remaining random variables $\{X_j\}_{j \in [n] \setminus \{i\}}$, we have $\mathbb{E}[f | X_i = b] \leq \mathbb{E}[f | X_i = a]$ for all $a \leq b$.*

In the following lemmata, we show that weak negative regression implies 1-negative association in general. We then show that the reverse implication holds for binary random variables, but give an example showing that it does not hold in general.

▷ Claim 5. If a collection of random variables $X_1, \ldots, X_n$ satisfies weak negative regression, then it satisfies 1-negative association.

Proof. Assume $X_1, \ldots, X_n$ satisfy weak negative regression; we will prove that it also satisfies 1-negative association. Let f and g be monotone functions such that f depends on X_I for some subset $I \subseteq [n]$ and g depends on X_i for $i \notin I$. Without loss of generality, let us assume that f and g are non-decreasing.

First, define the function $F(a) = \mathbb{E}[f(X)|X_i = a]$. Evaluating the expectation $\mathbb{E}[f(X_I)g(X_i)]$, we can express it via the law of total expectation as

$$\mathbb{E}[f(X_I)g(X_i)] = \mathbb{E}[\mathbb{E}[f(X_I)|X_i]g(X_i)] = \mathbb{E}[F(X_i)g(X_i)].$$

Next, we observe that by the definition of weak negative regression, $F(a)$ is non-increasing. Therefore, random variables $F(X_i)$ and $g(X_i)$ are negatively correlated, yielding

$$\mathbb{E}[F(X_i)g(X_i)] \leq \mathbb{E}[F(X_i)]\mathbb{E}[g(X_i)].$$

Converting $\mathbb{E}[F(X_i)]$ back into the terms of f and g, we find

$$\mathbb{E}[F(X_i)]\mathbb{E}[g(X_i)] = \mathbb{E}[f(X)]\mathbb{E}[g(X_i)].$$

The overall inequality $\mathbb{E}[f(X_I)g(X_i)] \leq \mathbb{E}[f(X_I)]\mathbb{E}[g(X_i)]$ thus holds, which establishes that $X_1, \ldots, X_n$ are 1-negatively associated, completing the proof. ◁

▷ Claim 6. If a collection of binary random variables $X_1, \ldots, X_n$ satisfies 1-negative association, then it satisfies weak negative regression.

Proof. Recall that we wish to prove that for any non-decreasing function f depending on some subset $I \subseteq [n]$ and any $i \notin I$, we have that

$$\mathbb{E}[f(X_I)|X_i = 0] \geq \mathbb{E}[f(X_I)|X_i = 1].$$

By the definition of 1-negative association, we obtain that for any monotone functions g which depends on X_i, the following inequality holds:

$$\mathbb{E}[f(X_I)g(X_i)] \leq \mathbb{E}[f(X_I)] \cdot \mathbb{E}[g(X_i)]. \tag{1}$$

Without loss of generality, we may assume that $\mathbb{E}[f(X_I)|X_i = 1] = 0$ by shifting f by a constant. By choosing g to be the identity function, we can apply the law of total probability to obtain

$$\mathbb{E}[f(X_I) \cdot g(X_i)] = \Pr[X_i = 0] \cdot \mathbb{E}[f(X_I)|X_i = 0] \cdot g(0) + \Pr[X_i = 1] \cdot \mathbb{E}[f(X_I)|X_i = 1] \cdot g(1) = 0.$$

Plugging this into Equation 1, we obtain

$$0 \leq \mathbb{E}[f(X_I)] \cdot \mathbb{E}[g(X_i)] = \mathbb{E}[f(X_I)|X_i = 0] \Pr[X_i = 0] \cdot \mathbb{E}[X_i],$$

again by the law of total probability. Since $\mathbb{E}[X_i] > 0$ and $\Pr[X_i = 0] > 0$, this implies that

$$\mathbb{E}[f(X_I)|X_i = 0] \geq 0,$$

which concludes the proof since $\mathbb{E}[f(X_I)|X_i = 1] = 0$. ◁

▷ Claim 7. There exists (non-binary) distributions over 2 random variables which satisfy 1-negative association but not weak negative regression. In other words, 1-negative association is strictly more general than weak negative regression for non-binary random variables.

Proof. Let's first discuss the intuition for the construction of the counterexample. One can show via algebra that $\mathbb{E}[f(X_I)g(X_i)] - \mathbb{E}[f(X_I)]\mathbb{E}[g(X_i)]$ can be expanded as the following expression:

$$\textstyle\sum_{x<y} \Pr[X_i = x] \Pr[X_i = y] \cdot \big(\mathbb{E}[f(X_I)|X_i = x] - \mathbb{E}[f(X_I)|X_i = y]\big)\big(g(x) - g(y)\big),$$

where the summation is over the values that X_i takes with non-zero probability.

Now, suppose that for some values $x < y$ we have that

$$\mathbb{E}[f(X_1, \ldots, X_n)|X_i = x] - \mathbb{E}[f(X_1, \ldots, X_n)|X_i = y] < 0,$$

violating the weak negative regression property. This would imply that some of the summands are positive (since $g(x) < g(y)$ by monotonicity). In the case of binary random variables, the summation would only consist of a single summand so 1-negative association would be violated. For general random variables, the summation consists of multiple terms so the summation may still be negative even when a single summand is positive. Consequently, the random variables may still satisfy 1-negative association.

We now give the example. Consider the random variables (X_1, X_2) which are uniformly distributed on their support set $\{(0,3),(1,1),(2,2),(3,0)\}$. By considering an identity function $\mathbb{1}_x : \{0,1,2,3\} \to \{0,1,2,3\}$, we can show that that the distribution of (X_1, X_2) does not satisfy weak negative regression:

$$\mathbb{E}[\mathbb{1}_x(X_2)|X_1 = 1] = \mathbb{1}_x(1) = 1 < 2 = \mathbb{1}_x(2) = \mathbb{E}[\mathbb{1}_x(X_2)|X_1 = 2].$$

However, for any pair of non-decreasing functions $f, g : \{0,1,2,3\} \to \mathbb{R}$, we have

$$\mathbb{E}[f(X_1)]\mathbb{E}[g(X_2)] - \mathbb{E}[f(X_1)g(X_2)] = \frac{f(1)+f(2)+f(3)}{4} \cdot \frac{g(1)+g(2)+g(3)}{4} - \frac{f(1)g(1)+f(2)g(2)}{4},$$

where we have again assumed without loss of generality that $f(0) = g(0) = 0$.

We claim that the quantity on the right hand side is always non-negative. In order to see this, observe that $f(2)g(2) \leq f(i)g(j)$ for any $i, j \geq 2$ by monotonicity. As a result, we have

$$\frac{f(2)g(2)}{4} \leq \frac{(f(2)+f(3))(g(2)+g(3))}{16}.$$

Further, we observe that $f(1)g(1) \leq f(i)g(j)$ for any $i, j \geq 1$ by monotonicity. As a result, we have

$$\frac{f(1)g(1)}{4} \leq \frac{f(1)(g(2)+g(3)) + g(1)(f(2)+f(3))}{16}.$$

Combining these two inequalities immediately and observing that $f(1)g(1) \geq 0$ by monotonicity implies our desired result. Hence, the distribution is 1-negatively associated. ◁

Since 1-negative association and weak negative regression are equivalent for binary random variables and weak negative regression has been shown to be strictly stronger than cylinder negative dependence [23, Proposition 2.4], we also have that 1-negative association is strictly stronger than cylinder negative dependence. Additionally, since weak negative regression is strictly stronger than 1-negative association for general random variables and weak negative regression has been shown to be strictly weaker than negative association and negative regression [23, Proposition 2.4], we have that 1-negative association is strictly weaker than negative association and negative regression. We summarize these in the following corollaries.

▶ **Corollary 8.** *1-negative association is a strictly weaker condition than negative association.*

▶ **Corollary 9.** *1-negative association is a strictly weaker condition than negative regression.*

▶ **Corollary 10.** *1-negative association is a strictly stronger condition than negative cylinder dependence.*

3.2 Proof of Submodular Concentration

We will now prove our main result. As mentioned in the introduction, our proof is based on the standard technique of bounding the exponential moments. The following lemma contains our main technical contribution, stating that the exponential moments of $f(X_1, \ldots, X_n)$ under 1-negative association is dominated by that under independence. Our results will follow easily afterwards.

▶ **Lemma 11.** *Let $X_1, \ldots, X_n$ be 1-negatively associated random variables and let $X_1^*, \ldots, X_n^*$ be independent random variables with the same marginal distributions. Also let f be a non-negative monotone function.*

- *If f is submodular and $\lambda < 0$, we have* $\mathbb{E}[\exp(\lambda f(X_1, \ldots, X_n))] \leq \mathbb{E}[\exp(\lambda f(X_1^*, \ldots, X_n^*))]$.
- *If f is supermodular and $\lambda > 0$, we have* $\mathbb{E}[\exp(\lambda f(X_1, \ldots, X_n))] \leq \mathbb{E}[\exp(\lambda f(X_1^*, \ldots, X_n^*))]$.

Proof. Fix $\lambda < 0$ if f is submodular and $\lambda > 0$ if f is supermodular. Observe that in order to prove the lemma, it suffices to prove

$$\mathbb{E}[\exp(\lambda \cdot f(X_1, \ldots, X_i, \ldots, X_m))] \leq \mathbb{E}[\exp(\lambda \cdot f(X_1, \ldots, X_i^*, \ldots, X_m))], \tag{2}$$

since we can iteratively apply the above inequality to each X_i (note that we can do this because independent variables are also negatively associated). For simplicity of notation and without loss of generality, we will prove the inequality for $i = 1$.

By considering the cases of $X_1 = 0$ and $X_1 = 1$ separately, we have

$$\exp(\lambda \cdot f(X_1, \ldots, X_n)) = X_1 \cdot \exp(\lambda \cdot f(1, X_2, \ldots, X_n))) + (1 - X_1) \cdot \exp(\lambda \cdot f(0, X_2, \ldots, X_n))),$$

where the equality holds pointwise on the underlying probability space. Via simple algebraic manipulations, we can rewrite the right hand side as

$$X_1 \cdot [\exp(\lambda \cdot f(1, X_2, \ldots, X_n))) - \exp(\lambda \cdot f(0, X_2, \ldots, X_n))] + \exp(\lambda \cdot f(0, X_2, \ldots, X_n))$$

Taking expectations, we now have that $\mathbb{E}[\exp(\lambda f(X_1, \ldots, X_n))]$ can be written as

$$\mathbb{E}\big[X_1 \cdot [\exp(\lambda \cdot f(1, X_2, \ldots, X_n))) - \exp(\lambda \cdot f(0, X_2, \ldots, X_n))]\big] + \mathbb{E}\big[\exp(\lambda \cdot f(0, X_2, \ldots, X_n))\big] \tag{3}$$

Observe that X_1 is clearly an increasing function of X_1. We claim that if either (i) f is submodular and $\lambda < 0$ or (ii) f is supermodular and $\lambda > 0$, we have that $\exp(\lambda \cdot f(1, X_2, \ldots, X_n))) - \exp(\lambda \cdot f(0, X_2, \ldots, X_n))$ is an increasing function in $X_2, \ldots, X_n$. Indeed, we first rewrite the function as

$$\exp(\lambda \cdot f(0, X_2, \ldots, X_n)) \cdot [\exp(\lambda \cdot (f(1, X_2, \ldots, X_n) - f(0, X_2, \ldots, X_n))) - 1] =: A_1 \cdot A_2$$

for simplicity of notation.

Let us first consider the case when $\lambda < 0$ and f is submodular. We have that A_1 is (i) positive because the exponential function is always positive and (ii) non-increasing in $X_2, \ldots, X_n$ because f is non-decreasing and $\lambda < 0$. We also have that A_2 is (i) negative because the argument in $\exp(\cdot)$ is negative, so the exponential is in $(0, 1)$ (ii) non-decreasing since $\lambda < 0$ and the difference of f evaluated at $X_1 = 1$ and $X_1 = 0$ is non-increasing by definition of submodularity. Hence, our expression of interest is the product of a function A_1 which decreases towards 0 and a function A_2 which increases towards 0. The product will be negative and monotonically increasing towards 0.

Now, let us consider the case when $\lambda > 0$ and f is supermodular. We have that A_1 is (i) positive because the exponential function is always positive and (ii) non-decreasing since $\lambda > 0$, f is monotone, and $\exp(\cdot)$ is also monotone. We also have that A_2 is (i) positive because the argument of $\exp(\cdot)$ is positive since f is monotone so the exponential is greater than 1 and (ii) non-decreasing since $\lambda > 0$ and the difference of f evaluated at $X_1 = 1$ and $X_1 = 0$ is non-decreasing by definition of supermodularity. As a result, the product will be positive and non-decreasing, as desired.

Since we have shown that the A_1A_2 is also monotone, we now have that the first term in Equation 3 can be written as the product of monotone functions of disjoint subsets, one of which is the singleton set. By 1-negative association, we have that the first term is upper bounded by

$$\mathbb{E}[X_1] \cdot \mathbb{E}[\exp(\lambda \cdot f(1, X_2, \ldots, X_n)) - \exp(\lambda \cdot f(0, X_2, \ldots, X_n))].$$

Consequently, the entire expression in (3) is upper bounded by

$$\mathbb{E}[X_1] \cdot \mathbb{E}[\exp(\lambda \cdot f(1, X_2, \ldots, X_n)) - \exp(\lambda \cdot f(0, X_2, \ldots, X_n))] + \mathbb{E}[\exp(\lambda \cdot f(0, X_2, \ldots, X_n))].$$

Since X_1 and X_1^* have the same marginal distributions, the above is exactly equal to

$$\mathbb{E}[X_1^*] \cdot \mathbb{E}[\exp(\lambda \cdot f(1, X_2, \ldots, X_n)) - \exp(\lambda \cdot f(0, X_2, \ldots, X_n))] + \mathbb{E}[\exp(\lambda \cdot f(0, X_2, \ldots, X_n))].$$

And since X_1^* is independent with $X_2, \ldots, X_m$ by assumption, the above is equal to

$$\mathbb{E}[X_1^* \cdot \exp(\lambda \cdot f(1, X_2, \ldots, X_n)) - \exp(\lambda \cdot f(0, X_2, \ldots, X_n))] + \mathbb{E}[\exp(\lambda \cdot f(0, X_2, \ldots, X_n))].$$

In particular, observe that this is in the exact same form as Equation 3, except with X_1 replaced with X_1^*. Note that when we transformed the left-hand side of Equation 2 to Equation 3, we never used any properties of the random variables $X_1, \ldots, X_n$ other than the fact that they take values in $\{0, 1\}$. As a result, we can reverse the direction of all of the equalities to show that the above expression is equal to

$$\mathbb{E}[\exp(\lambda \cdot f(X_1^*, X_2, \ldots, X_n))],$$

which completes the proof of the lemma. ◀

Now, we will complete the proof of our main result. Combining the theorem below with Claims 8 and 9 immediately gives a proof of Theorem 2. Here, our proof will rely heavily on the proof of the Chernoff bound for submodular functions under independence given in [6].

▶ **Theorem 12.** *Let $X_1, \ldots, X_n$ be binary random variables with mean $x_1, \ldots, x_n$ satisfying 1-negative association. Let f be a non-negative monotone submodular function with marginal values in $[0, 1]$ and let F be the multilinear extension of f. If we let, $\mu_0 = F(x_1, \ldots, x_n)$, then we have the following:*

$$\Pr[f(X_1, \ldots, X_n) \leq (1 - \delta) \cdot \mu_0] \leq \exp(-\mu_0 \delta^2 / 2).$$

Proof. Let $X_1^*, \ldots, X_n^*$ be independent random variables with the same respective marginals as $X_1, \ldots, X_n$ and let $\lambda < 0$ be a parameter to be set later. Let us decompose $f(X_1^*, \ldots, X_n^*) = \sum_{i=1}^n Y_i^*$, where

$$Y_i^* = f(X_1^*, \ldots, X_i^*, 0, \ldots, 0) - f(X_1^*, \ldots, X_{i-1}^*, 0, \ldots, 0).$$

Let us denote $\mathbb{E}[Y_i^*] = \omega_i$ and $\mu_0 = \sum_{i=1}^n \omega_i = \mathbb{E}[f(X_1^*, \ldots, X_n^*)]$. By the convexity of the exponential and the fact that $Y_i^* \in [0,1]$, we have that

$$\mathbb{E}[\exp(\lambda \cdot Y_i^*)] \leq \omega_i \cdot \exp(\lambda) + (1-\omega_i) = 1 + [\exp(\lambda) - 1] \cdot \omega_i \leq \exp[(\exp(\lambda) - 1) \cdot \omega_i].$$

Combining the above with Lemma C.1 from [6], we have that

$$\begin{aligned}\mathbb{E}[\exp(\lambda \cdot f(X_1^*, \ldots, X_n^*)] = \mathbb{E}[\exp(\lambda \cdot \textstyle\sum_{i=1}^n Y_i^*)] &\leq \textstyle\prod_{i=1}^n \mathbb{E}[\exp(\lambda \cdot Y_i^*)] \\ &\leq \exp[(\exp(\lambda) - 1) \cdot \mu_0]. \end{aligned} \tag{4}$$

Now, we can follow the proof of the standard Chernoff bound:

$$\begin{aligned}\Pr[f(X_1, \ldots, X_n) \leq (1-\delta) \cdot \mu_0] &= \Pr[\exp(\lambda \cdot f(X_1, \ldots, X_n)) \leq \geq \exp(\lambda(1-\delta) \cdot \mu_0)] \\ &\leq \frac{\mathbb{E}[\exp(\lambda \cdot f(X_1, \ldots, X_n))]}{\exp(\lambda(1-\delta) \cdot \mu_0)} \\ &\leq \frac{\mathbb{E}[\exp(\lambda \cdot f(X_1^*, \ldots, X_n^*))]}{\exp(\lambda(1-\delta) \cdot \mu_0)} \\ &\leq \frac{\exp[(\exp(\lambda) - 1) \cdot \mu_0]}{\exp(\lambda(1-\delta) \cdot \mu_0)}\end{aligned}$$

The first equality follows since $\exp(\lambda \cdot x)$ is a monotone function, the first inequality follows by Markov's inequality, the second inequality follows by Lemma 8, and the final inequality follows Equation 4.

Finally, we can choose λ such that $\exp(\lambda) = 1 - \delta$, which gives

$$\Pr[f(X_1, \ldots, X_n) \geq (1-\delta)\mu_0] \leq \frac{\exp(-\delta\mu_0)}{(1-\delta)^{(1-\delta)\mu_0}} \leq \exp(-\mu_0 \cdot \delta^2/2),$$

where we used $(1-\delta)^{1-\delta} \leq \exp(-\delta + \delta^2/2)$ for $\delta \in (0,1]$ in the final inequality. ◀

3.3 Concentration of read-k families

In this subsection, we illustrate an application of our proof technique to give concentration for a read-k family of supermodular functions. Read-k families arise naturally in problems such as subgraph counting in random graphs, and can be seen as a complementary weak dependence notion to that of low-degree polynomials [17]. Our work gives the first concentration results for these problems under negative dependence.

Let's consider this notion of weak dependence defined in [13]. Let $Y_1, \ldots, Y_n$ be random variables and assume that they can be factored as functions of random variables $X_1, \ldots, X_m$. We say that $Y_1, \ldots, Y_n$ are a read-k family of $X_1, \ldots, X_m$ if for each variable X_i, there are at most k variables among $Y_1, \ldots, Y_n$ that are influenced by X_i. Formally, we have the following.

▶ **Definition 13.** *Let $X_1, \ldots, X_m$ be random variables. For each $j \in [n]$, let $P_j \subseteq [m]$ and let $f_j : \{0,1\}^{P_j} \to [0,1]$ be functions of X_{P_j}. We say that $Y_j = f_j(X_{P_j})$ are a read-k family if $|\{j : i \in P_j\}| \leq k$ for each $i \in [m]$ (i.e., each variable X_i influences at most k functions).*

When $X_1, \ldots, X_m$ are independent, [13] showed that we have

$$\Pr[\textstyle\sum_{j=1}^n f_j(X_{P_j}) \geq (p+\epsilon)n] \leq \exp(-D(p+\epsilon||p) \cdot n/k) \tag{5}$$

$$\Pr[\textstyle\sum_{j=1}^n f_j(X_{P_j}) \leq (p-\epsilon)n] \leq \exp(-D(p-\epsilon||p) \cdot n/k), \tag{6}$$

where $p = (1/n)\sum_{j=1}^{n} \mathbb{E}[Y_j]$ and $D(\cdot||\cdot)$ is the Kullback-Leibler divergence. Notably, while Gavinsky et al. do not require random variables $X_1, \ldots, X_m$ to be binary, as we do in our approach, their model requires $Y_1, \ldots, Y_n$ to be binary. We will show that Inequality 5 on the upper tail still holds for supermodular functions $f_1, \ldots, f_n$. Similarily, Inequality 6, which addresses the lower tail bound, continues to apply to submodular functions $f_1, \ldots, f_n$.

▶ **Theorem 14.** *Let $X_1, \ldots, X_m$ be 1-negatively associated random variables and let $X_1^*, \ldots, X_m^*$ be independent random variables with the same respective marginal distributions as $X_1, \ldots, X_m$. Suppose that $f_j(X_{P_j})$ for $j \in [n]$ are a read-k family, where $f_j : \{0,1\}^{P_j} \to [0,1]$ are supermodular functions. If we let $p_0 = (1/n)\sum_{j=1}^{n} \mathbb{E}[f_j(X_{P_j}^*)]$ denote the averaged expectation when the underlying random variables are independent, we have*

$$\Pr[\textstyle\sum_{j=1}^{n} f_j(X_{P_j}) \geq (p_0 + \epsilon)n] \leq \exp(-D(p_0 + \epsilon||p_0) \cdot n/k).$$

Proof. Let $f(X_1, \ldots, X_m) = \sum_{j=1}^{n} f_j(X_{P_j})$ be the quantity of interest, and note that f is the sum of supermodular functions so it is supermodular as well.

We will follow the standard proof via exponential moments. Let $\lambda > 0$; we have

$$\Pr[f(X_1, \ldots, X_m) \geq (p_0 + \epsilon)n] = \Pr[\exp(\lambda \cdot f(X_1, \ldots, X_m)) \geq \exp(\lambda \cdot (p_0 + \epsilon)n)] \tag{7}$$

$$\leq \mathbb{E}[\exp(\lambda \cdot f(X_1, \ldots, X_m))]/\exp(\lambda \cdot (p_0 + \epsilon)n), \tag{8}$$

where the inequality follows by Markov's. Since f is supermodular, we have by Lemma 11 that

$$\mathbb{E}[\exp(\lambda \cdot f(X_1, \ldots, X_m))] \leq \mathbb{E}[\exp(\lambda \cdot f(X_1^*, \ldots, X_m^*))] = \mathbb{E}[\exp(\lambda \cdot \textstyle\sum_{j=1}^{n} f_j(X_{P_j}^*))]. \tag{9}$$

In the new proof of concentration of read-k families, given in the Appendix, we show that

$$\mathbb{E}[\exp(\lambda \cdot \textstyle\sum_{j=1}^{n} f_j(X_{P_j}^*))] \leq \left(\prod_{j=1}^{n} \mathbb{E}[\exp(\lambda \cdot f_j(X_{P_j}^*))^k]\right)^{1/k}. \tag{10}$$

Combining equations 7–10, we have

$$\Pr[f(X_1, \ldots, X_m) \geq (p_0 + \epsilon)n] \leq \left(\prod_{j=1}^{n} \mathbb{E}[\exp(k\lambda \cdot f_j(X_{P_j}^*))/\exp(k\lambda(p_0 + \epsilon)n]\right)^{1/k}.$$

Let $\lambda' = k\lambda$; since $\lambda > 0$ is a parameter we set, we can view $\lambda' > 0$ as a parameter as well. We will abuse notation and replace λ' with λ, so we have

$$\Pr[f(X_1, \ldots, X_m) \geq (p_0 + \epsilon)n] \leq \left(\prod_{j=1}^{n} \mathbb{E}[\exp(\lambda \cdot f_j(X_{P_j}^*))/\exp(\lambda(p_0 + \epsilon)n]\right)^{1/k},$$

for any $\lambda > 0$. Now, observe that the right hand side of the inequality is the exact same as in the proof of the standard Chernoff bound under independence, except with an additional exponent $1/k$. As a result, we can follow the original proof of the Chernoff bound to show that

$$\Pr[\textstyle\sum_{j=1}^{n} f_j(X_{P_j}) \geq (p_0 + \epsilon)n] \leq \exp(-D(p_0 + \epsilon||p_0) \cdot n/k),$$

which was our desired result. ◀

▶ **Corollary 15.** *Let $X_1, \ldots, X_m$ be 1-negatively associated random variables. Suppose that $f_j(X_{P_j})$ for $j \in [n]$ are a read-k family, where $f_j : \{0,1\}^{P_j} \to [0,1]$ are submodular functions. If we let $p_0 = (1/n)\sum_{j=1}^{n} \mathbb{E}[f_j(X_{P_j}^*)]$ denote the averaged expectation when the underlying random variables are independent, we have*

$$\Pr[\textstyle\sum_{j=1}^{n} f_j(X_{P_j}) \leq (p_0 - \epsilon)n] \leq \exp(-D(p_0 - \epsilon||p_0) \cdot n/k).$$

Proof. Define $g_j := 1 - f_j$, where $g_j : \{0,1\}^{P_j} \to [0,1]$ are supermodular. Then $1 - p_0 = (1/n)\sum_{j=1}^{n} \mathbb{E}[g_j(X^*_{P_j})]$. Applying Theorem 14, we have:

$$\Pr[\textstyle\sum_{j=1}^{n} g_j(X_{P_j}) \geq (1-(p_0-\epsilon))n] \leq (1-p_0+\epsilon)n] \leq \exp(-D(1-p_0+\epsilon||1-p_0)\cdot n/k).$$

The property of Kullback–Leibler divergence $D(1-p||1-q) = D(p||q)$ implies

$$\begin{aligned}\Pr[\textstyle\sum_{j=1}^{n} f_j(X_{P_j}) \leq (p_0-\epsilon)n] &= \Pr[\textstyle\sum_{j=1}^{n} g_j(X_{P_j}) \geq (1-(p_0-\epsilon))n] \\ &\leq \exp(-D(p_0-\epsilon||p_0)\cdot n/k),\end{aligned}$$

which concludes the proof. ◀

A Concentration of Read-k Families

We will give a new simpler proof of the results of Gavinsky et al. [13] using exponential moments for f_j for independent random variables $X_1, \ldots, X_n$. Our proof will use the following lemma

▶ **Lemma 16.** *For an arbitrary read-k family $F_1, \ldots, F_n$, we have*

$$\mathbb{E}\left[\prod_{j=1}^{n} F_j\right] \leq \left(\prod_{j=1}^{n} \mathbb{E}\left[F_j^k\right]\right)^{1/k}. \tag{11}$$

Using this lemma, if we define

$$F_j = \exp(\lambda \cdot f_j(X_1, \ldots, X_m)),$$

it is easy to see that $F_1, \ldots, F_n$ are a read-k family since $f_1, \ldots, f_n$ are read-k. We will show later that after applying inequality (11) on $F_1, \ldots, F_m$, we can adapt the standard Chernoff bound proof to our case.

Proof. We will prove inequality (11) via induction on the number of independent variables m. For the base case $m = 1$, observe that there are at most k non-constant functions F_j by definition. If there are fewer than k functions F_j, we can also add identity functions without changing the product. As a result, we can without loss of generality assume that there are exactly k functions F_j. The inequality then follows directly by the Generalized Hölder's Inequality.

Now assume we have proven the statement for m independent variables; we will try to prove it for $m + 1$. Again, let $S = S_1$ denote the set of functions F_j which are influenced by X_1. We have

$$\begin{aligned}
\mathbb{E}\left[\prod_{j=1}^{n} F_j\right] &= \mathbb{E}\left[\prod_{j\in S} F_j \cdot \prod_{j\notin S} F_j\right] \\
&= \mathbb{E}\left[\mathbb{E}\left[\prod_{j\in S} F_j \cdot \prod_{j\notin S} F_j \middle| X_2, \ldots, X_{m+1}\right]\right] \\
&= \mathbb{E}\left[\mathbb{E}\left[\prod_{j\in S} F_j \middle| X_2, \ldots, X_{m+1}\right] \cdot \prod_{j\notin S} F_j\right]
\end{aligned} \tag{12}$$

Here, the first equality is obvious, the second equality follows by the law of total expectation, and the third equality follows since F_j for $j \notin S$ only depends on $X_2, \ldots, X_{m+1}$ and is independent of X_1.

After taking the conditional expectation, observe that $\mathbb{E}[\prod_{j\in S} F_j | X_2, \ldots, X_{m+1}]$ is a random variable which only depends on $X_2, \ldots, X_{m+1}$. In particular, these form a read-k family over m random variables, so we can apply the inductive hypothesis to claim that

$$\mathbb{E}\left[\prod_{j\in S} F_j | X_2, \ldots, X_{m+1}\right] \leq \left(\prod_{j\in S} \mathbb{E}\left[F_j^k | X_2, \ldots, X_{m+1}\right]\right)^{1/k}$$

After combining this with equation (12), we have

$$\mathbb{E}\left[\prod_{j=1}^{n} F_j\right] \leq \mathbb{E}\left[\prod_{j\in S} \mathbb{E}\left[F_j^k | X_2, \ldots, X_{m+1}\right]^{1/k} \cdot \prod_{j\notin S} F_j\right] =: A$$

For $j \notin S$, let $G_j = F_j$ and for $j \in S$, define

$$G_j = \mathbb{E}\left[F_j^k | X_2, \ldots, X_{m+1}\right]^{1/k}$$

so that $A = \mathbb{E}\left[\prod_{j=1}^{n} G_j\right]$. Observe that G_j are again a read-k family on $X_2, \ldots, X_{m+1}$, so we can again apply the induction hypothesis to claim that

$$A = \mathbb{E}\left[\prod_{j=1}^{n} G_j\right] \leq \prod_{j=1}^{n} \mathbb{E}\left[G_j^k\right]^{1/k} = \prod_{j=1}^{n} \mathbb{E}\left[F_j^k\right]^{1/k},$$

where the final equality follows directly by definition of G_j. This completes the proof. ◀

Using the lemma, we can follow the standard Chernoff bound techniques to complete the proof. Let $X = \sum_{j=1}^{n} f_j(X_1, \ldots, X_m)$; we can apply Markov's inequality for any $\lambda < 0$ to obtain

$$\Pr[X \leq qn] = \Pr[\exp(\lambda X) \geq \exp(\lambda qn)] \leq \exp(-\lambda qn) \cdot \mathbb{E}\left[\exp(\lambda X)\right]$$

As mentioned before, we can take $F_j = \exp(\lambda \cdot f_j(X_1, \ldots, X_m))$ and apply inequality (11) to obtain that

$$\exp(\lambda X) = \mathbb{E}\left[\prod_{j=1}^{n} F_j\right] \leq \prod_{j=1}^{n} \mathbb{E}[F_j^k]^{1/k}.$$

Combining this inequality with the previous inequality, we now have that

$$\Pr[X \leq qn] \leq \exp(-\lambda qn) \cdot \prod_{j=1}^{n} \mathbb{E}[F_j^k]^{1/k} = \left(\prod_{j=1}^{n} \mathbb{E}\left[[F_j/\exp(\lambda q)]^k\right]\right)^{1/k}.$$

Writing out the definition of F_j, we have

$$[F_j/\exp(\lambda q)]^k = \exp(\lambda k \cdot f_j(X_1, \ldots, X_m))/\exp(\lambda k q).$$

Define $\lambda' = \lambda k$; since λ was arbitrary, we will abuse notation and let $\lambda = \lambda'$. Combining the two previous inequalities, we have that

$$\Pr[X \leq qn] \leq \left(\prod_{j=1}^{n} \mathbb{E}[\exp(\lambda \cdot f_j)/\exp(\lambda q)]\right)^{1/k}.$$

Here, the right-hand side is in exactly the same form as in the proof of the Chernoff-Hoeffding theorem under independence, except with an additional exponent $1/k$. As a result, we can follow the Chernoff-Hoeffding proof and take $q = p - \epsilon$ to obtain

$$\Pr[X \leq (p-\epsilon)n] \leq \exp(-D(p-\epsilon||p) \cdot n/k),$$

which was our desired result.

Robust Restaking Networks

Abstract

We study the risks of validator reuse across multiple services in a restaking protocol. We characterize the robust security of a restaking network as a function of the buffer between the costs and profits from attacks. For example, our results imply that if attack costs always exceed attack profits by 10%, then a sudden loss of .1% of the overall stake (e.g., due to a software error) cannot result in the ultimate loss of more than 1.1% of the overall stake. We also provide local analogs of these overcollateralization conditions and robust security guarantees that apply specifically for a target service or coalition of services. All of our bounds on worst-case stake loss are the best possible. Finally, we bound the maximum-possible length of a cascade of attacks.

Our results suggest measures of robustness that could be exposed to the participants in a restaking protocol. We also suggest polynomial-time computable sufficient conditions that can proxy for these measures.

1 Introduction

1.1 Sharing Validators Across Services

Major blockchain protocols such as Bitcoin or Ethereum are "decentralized," meaning that transaction execution is carried out by a large and diverse set of "validators." Such protocols offer a form of "trusted computation," in the sense that, because they are decentralized, no one individual or entity can easily interfere with their execution. A decentralized and Turing-complete smart contract platform such as Ethereum can then be viewed as a trusted programmable computer capable of performing arbitrary computations.

While Turing-complete, the computing functionality offered by Ethereum smart contracts suffers from limitations imposed by design decisions in the underlying consensus protocol. Most obviously, computation and storage in the Ethereum virtual machine is scarce, with perhaps 15–20 transactions processed per second. Could the Ethereum protocol be somehow bypassed, opening the door for different or more powerful computing functionality, while retaining at least some of the protocol's decentralization? Or, what about applications that are not compatible with all Ethereum validators, perhaps due to demanding hardware requirements or regulatory constraints?

One natural approach to addressing these challenges is to allow the *reuse* of a blockchain protocol's validators across multiple services, where a "service" is some task that could be carried out by some subset of validators. (The initial blockchain protocol can be viewed as the canonical service, performed by all validators.) For example, such services could include alternative consensus protocols (perhaps with higher throughput, a different virtual machine, or different consistency-liveness trade-offs), storage ("data availability"), or verifiable off-chain computation ("zk coprocessors").[1]

The obvious danger of validator reuse is an increased risk of a validator deviating from its intended behavior (e.g., due to overwhelming computational responsibilities). Our focus here is deliberate validator deviations in response to economic incentives, such as the profits that could be obtained by corrupting one or more services. The goal of this paper is to quantify such risks:

Under what conditions can validators be safely reused across multiple services?

1.2 Cryptoeconomic Security

We first review the usual "cryptoeconomic" approach to answering a more basic question: when is a blockchain protocol, without any additional services, "safe from attack"? The idea is to perform a cost-benefit analysis from the perspective of an attacker, and declare the protocol safe if the cost of carrying out an attack exceeds the profit that the attacker can expect from it; see also Figure 1. In the specific case of a proof-of-stake blockchain protocol with slashing (such as Ethereum), the cost can be estimated as the value of the validator stake that would be lost to slashing following an attack. For example, let V denote the set of validators of a proof-of-stake blockchain protocol and σ_v the stake of validator $v \in V$ (e.g., 32 ETH in Ethereum). In a typical PBFT-type protocol in which double-voting validators lose all of their stake, the cost of an attack (i.e., causing a consistency violation) can be bounded below by $\frac{1}{3}\sum_{v \in V} \sigma_v$. In this case, the protocol can be regarded as cryptoeconomically secure provided the estimated profit π of an attack is less than this quantity. To the extent that there is a "buffer" between $\frac{1}{3}\sum_{v \in V} \sigma_v$ and π, the protocol can be treated as "robustly secure," meaning secure even after a sudden loss of some amount of stake (e.g., due to slashing caused by a software error).

1.3 Our Results: Robustly Secure Validator Reuse

Viewing the basic scenario of a blockchain protocol as a star graph (with one "service" representing the protocol connected to all the validators running it), the more complex scenario of validators reused across multiple services can be viewed as an arbitrary bipartite graph (Figure 2). As before, we suppose that each validator $v \in V$ has some stake σ_v that can be confiscated in the event that v participates in an attack on a service that it has agreed to support. There is now a set S of services, with π_s denoting the profit an attacker would obtain by compromising the service $s \in S$.[2] We assume that compromising a service $s \in S$ requires the participation of an α_s fraction of the overall validator stake supporting v (e.g., $\alpha_s = 1/3$). With this expanded network formalism to capture multiple services, when should we consider a network to be "secure"?

[1] Several projects, in various stages of production, are currently exploring this idea; the Eigenlayer restaking protocol [15] is perhaps the most well known of them. We stress that our goal here is to develop a model that isolates some of the fundamental challenges and risks of validator reuse, independent of any specific implementation of the idea.

[2] We follow [15] and assume that the estimates on attack profitability (the π_s's) are given. Developing tools to help produce such estimates in practice is an important open research direction.

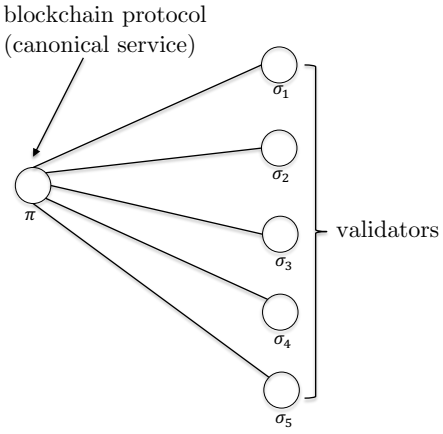

Figure 1 A blockchain protocol operated by a collection of validators, with π denoting the profit of successfully attacking the protocol and σ_v the amount of stake posted by a validator v as collateral.

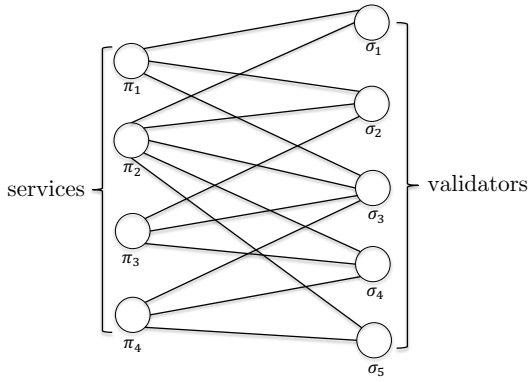

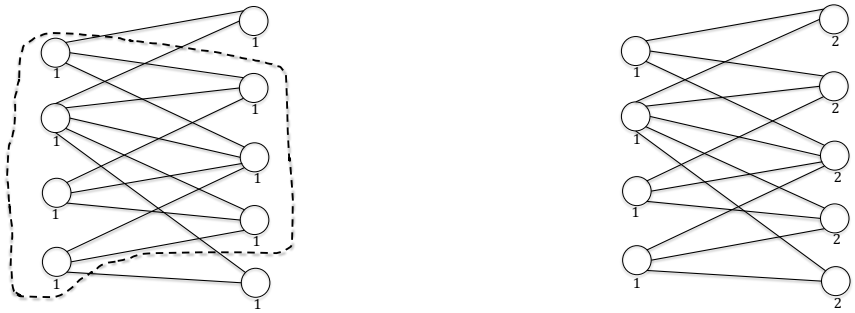

Figure 2 A general restaking network, with validators reused across multiple services.

Intuitively, a network is insecure if there is a set of services that can be profitably attacked. This requires two conditions to be satisfied: the validators $B \subseteq V$ carrying out the attack must control sufficient stake to do so (for each service s in the attacked set A, the validators of B control at least a α_s fraction of the staked pledged to s), and they must profit from it (i.e., $\sum_{s \in A} \pi_s > \sum_{v \in B} \sigma_v$). We call such a pair (A, B) a *valid attack* and a network *secure* if there are no valid attacks; see also Figure 3. With multiple services, security is an inherently combinatorial (as opposed to binary) notion. For example, the computational problem of checking whether a network is secure is as hard as the (coNP-hard) problem of verifying the expansion of a bipartite graph (see [12]).

When is a network "robustly secure," in the sense that the sudden loss of a small amount of stake cannot enable a catastrophic attack? Unlike the "all-or-nothing" version of this question with a single service, with multiple services, the following more fine-grained question is the appropriate one: given an initial shock in the form of a sudden loss of a ψ fraction of the overall stake, what is the total fraction of stake that might be lost following any consequent valid attacks?

As in the case of a single service, some amount of "buffer" in stake (relative to attack profits) is necessary for robust security. We parameterize this overcollateralization factor via a parameter γ and suppose that, whenever $B \subseteq V$ is a subset of validators capable of

(a) A valid attack. **(b)** A secure network.

Figure 3 Two restaking networks. Each service (left-hand side vertex) and validator (right-hand side vertex) is labeled with its profit-from corruption or stake, respectively. Assume that a service can be corrupted if and only if it is attacked by at least half of its validators (i.e., $\alpha_s = 1/2$ for every service s). The restaking network in (a) is not secure because there is a valid attack (indicated by the dotted line): three validators can earn a profit of 4 by corrupting all four services while losing only three units of stake. The restaking network in (b) is secure.

corrupting all the services in $A \subseteq S$, the total stake of B is at least a $1+\gamma$ factor larger than the total profit from corrupting all of A. For example, this condition holds in the network in Figure 3(b) for $\gamma = 1/2$ (but not for larger values of γ).

Our first main result (Theorem 4) precisely characterizes the worst-case (over bipartite graphs and shocks, as a function of γ) fraction of the overall stake that can be lost due to a shock of size ψ: $\left(1+\frac{1}{\gamma}\right)\psi$. Because the network was secure prior to the shock, the value of a $\left(1+\frac{1}{\gamma}\right)\psi$ fraction of the overall stake is also an upper bound on the total profit obtained from all of the attacked services.

We also show that our result is tight in a strong sense (Theorem 6 and Theorem 7): for every ψ, γ, and ϵ greater than zero such that $0 \leq \left(1+\frac{1}{\gamma}\right)\psi - \epsilon \leq 1$, there exists a restaking graph in which a ψ fraction of the overall stake can disappear in a shock that results in the loss of at least a $\left(1+\frac{1}{\gamma}\right)\psi - \epsilon$ fraction of the overall stake.[3]

Qualitatively, this result implies that a constant-factor strengthening of the obvious necessary condition for security automatically implies robust security. For example, if attack costs always exceed attack profits by 10%, then a sudden loss of .1% of the overall stake cannot result in the ultimate loss of more than 1.1% of the overall stake.

Our result suggests a "risk measure" that could be exposed to the participants in a restaking protocol, namely the maximum value of the buffer parameter γ that holds with respect to the current restaking network. We also suggest easy-to-check sufficient conditions that can proxy for this risk measure (Corollary 5). These conditions are similarly tight, as shown in Theorem 6 and Theorem 7.

1.4 Our Results: Local Robust Security Guarantees

The results described in Section 1.3 are "global" with respect to the network structure, in three distinct senses: (i) the overcollateralization condition is assumed to hold for every subset $B \subseteq V$ of validators and $A \subseteq S$ of services that B is capable of corrupting; (ii) the

[3] After slightly reducing the validator stakes, the network in Figure 3(b) already shows that the bound is tight for the special case in which $\psi = 1/5$ and γ is arbitrarily close to $1/2$. (Consider a shock that knocks out the validator that is connected to all four services.)

initial shock can affect any subset of validators, subject to the assumed bound of ψ on the total fraction of stake lost; and (iii) any subset of validators might lose stake following the initial shock, subject to our upper bound of $(1 + \frac{1}{\gamma})\psi$ on the total fraction of lost stake.

Local guarantees

We next pursue more general "local" guarantees, which are parameterized by a set C of services. (The global guarantees will correspond to the special case in which $C = S$.) For example, C might be a set of closely related services that share a number of dedicated validators. The operators of such a set C might object to both the assumptions and the conclusion of our global guarantee:

- How can we be sure that the overcollateralization factor holds for services and validators that we know nothing about?
- And even if we could, how can we be sure that random validators that we have nothing to do with won't suddenly lose their stake (e.g., because they supported a malicious or buggy service), resulting in an initial shock the causes the loss of more than a ψ fraction of the overall stake?
- And even if we could, how can we be sure that our validators won't be the ones that lose their stake following a shock that is purely the fault of other services and/or validators?

To address these concerns, we next consider a refined version of the basic model, parameterized by a set C of services. We denote by $\Gamma(C)$ the validators that are exclusive to C, meaning that they contribute to no services outside C. (In the special case in which $C = S$, $\Gamma(C) = V$ and we recover the original model.) Intuitively, the validators in $\Gamma(C)$ are the ones that services in C are "counting on"; other validators support (potentially malicious or buggy) services outside C and, from C's perspective, could disappear at any time. We then restrict attention to initial shocks in which at most a ψ fraction of the total stake controlled by the validators of $\Gamma(C)$ is lost. (The shock can affect validators outside of $\Gamma(C)$ arbitrarily.) The goal is then to identify overcollateralization conditions guaranteeing that, no matter what the initial shock and subsequent attacks, the fraction of stake ultimately lost by the validators in $\Gamma(C)$ is bounded (by a function of the shock size ψ and an overcollateralization parameter γ).

Generalizing our global guarantees to local guarantees is not straightforward and, as the next two examples show, requires additional compromises. The first example shows that protection can be guaranteed only against a subset of valid attacks, a natural and well motivated subset that we call "stable attacks." The second example shows that, even when restricting attention to stable attacks, overcollateralization is required not only for potential attacks, but more generally for what we call "attack headers."

Necessity of restricting to stable attacks

In more detail, in the first example (depicted on the left of Figure 4), we consider a restaking network with two services and three validators. (Vertices in this figure correspond to validators, which were previously represented as the right-hand side vertices of a bipartite graph; each service is now identified with its neighborhood of validators.) The service highlighted in green on the left has 100 times as much stake securing it as its profit from corruption, and shares no validators with other services, so one might hope that it would be protected from any shocks that affect only the other validators. However, if the validator outlined in red disappears, the two validators outlined in yellow can attack both services for a profit of $102 - 101 > 0$. But this example is unsatisfying: the validator with stake 1

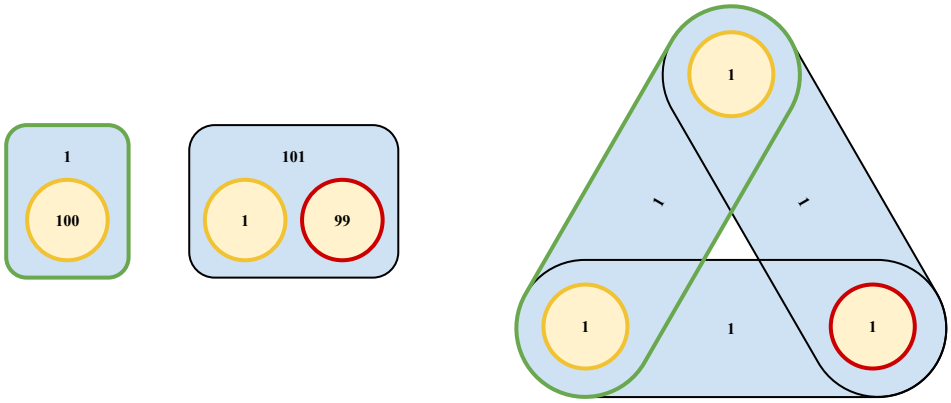

Figure 4 Simple overcollateralization is insufficient in the local setting. There are two restaking networks shown above. In each, the validators are denoted along with their corresponding stakes by the yellow circles. Services and their profits from corruption are denoted by the blue rounded squares. In each of these networks, the service outlined in green is overcollateralized. However, despite being unrelated to the overcollateralized service, if the validator outlined in red disappears, the validators in yellow can attack all services (including the overcollateralized one).

could have attacked the service with profit from corruption 101 on its own to yield a profit of 100. The addition of the validator with stake 100 added 100 to the cost of the attack, but only added 1 (from the corruption of the service highlighted in green) to the profit. We show in Theorem 8 that the issue suggested by this example is fundamental: without further restrictions on attacks that rule out contrived examples such as this one, there does not exist a local condition that guarantees local security. In response, we confine attention to sequences of what we call *stable* attacks in which all of the attacking validators contribute positively to the profit of the attack (as opposed to free riding on the profits attributable to other attacking validators). The attack in the example is not stable, as the validator with stake 100 was not a profitable addition to the attack that could have been carried out by the validator with stake 1.

Necessity of overcollateralizing attack headers

Even if we restrict our attention to stable attacks, simple overcollateralization is insufficient to guarantee local security. To appreciate the issue, consider the restaking network shown on the right in Figure 4. In this example, there are three services, each with a profit from corruption of 1, and three services each with stake 1. Each validator is used to secure two different services. The service outlined in green is overcollateralized in that its profit from corruption is 1, but two units of stake stake are securing it. Despite this, if the unrelated validator outlined in red disappears, the two validators outlined in yellow can attack all three services for a profit of $3 - 2 > 0$. Furthermore, if all validators are required to attack each service (i.e., $\alpha_s = 1$), then this attack is stable, as the inclusion of both validators in the attack is profitable. Thus, despite being overcollateralized, a stable attack can be launched on the service highlighted in green even if stake unrelated to the service disappears in a shock.

We find that to guarantee robust security for a coalition of services C using only "local" information, it is necessary to overcollateralize not only pairs (A, B) where B is a set of validators capable of attacking all services in A, but a more general collection of pairs that we

call *attack headers*. Informally, this amounts to requiring that there is some "buffer" in stake for any potential attack on some services in C even if we were to allow every validator that is also securing a service outside of C to join the attack without considering their profitability. Our main result here (Theorem 10) formally provides a local condition guaranteeing that, whenever an initial shock knocks out at most a ψ fraction of the stake that provides security exclusively to C, the worst-case loss of such stake, after an arbitrary sequence of stable attacks, is at most a $(1 + \frac{1}{\gamma})\psi$ fraction. We show that our bounds are tight and indeed require overcollateralization of all attack headers (Corollary 14 and Theorem 15), and again provide easily computable sufficient (and similarly tight) conditions that can proxy for the overcollateralization condition (Corollary 13). Our local condition generalizes the global overcollateralization condition, with the latter corresponding to the special case of the former in which $C = S$.

1.5 Our Results: Cascading Attacks

An attack on a restaking network results in a loss of stake (of the attacking validators), and this may introduce new opportunities for other sets of validators to carry out profitable attacks. That is, an initial shock may set off an entire *cascade* of attacks. (All of the bounds on stake loss described in Sections 1.3 and 1.4 hold for cascades of attacks of arbitrary length.) Our final result concerns the maximum-possible length of such a cascade, and shows that this quantity is also governed in part by the overcollateralization factor γ.

Precisely, we define the *reference depth* of a cascade of attacks as a measure of the "long-range dependence" between different attacks in an attack sequence. For example, if each attack in the sequence is directly enabled by the loss of the validators slashed in the previous attack, then the reference depth of the sequence is 1. Our main result here (Theorem 16) bounds the maximum-possible attack length as a function of the reference depth k, the shock size ψ, the overcollateralization factor γ, and the minimum stake ϵ held by a validator: $k(1 + \log_{1+\gamma}(\frac{\psi \cdot [\text{total stake}]}{\epsilon\gamma}))$. For example, in the case of constant reference depth and equal validator stake amounts, the worst-case attack length is logarithmic in the number of validators with overcollateralization and linear without it.

1.6 Related Work

Our focus on the risks of cascading failures following a small shock echoes some of themes in the literature on systemic risk in financial networks. For example, Eisenberg and Noe [9] that study the existence and structure of inter-firm payments in a financial network following a default. This work is extended by Glasserman and Young [11], who study how "connectedness," meaning the fraction of liabilities that a firm externally owes, affects contagion risk. Acemoglu et al. [2] build further on this work and study network "stability," meaning the propensity for shocks to propagate; they show that connectivity initially improves stability, but then at a phase transition, denser connectivity leads to increased shock propagation. In a subsequent paper, Acemoglu et al. [1] unify a number of the preceding results.

A separate line of work, beginning with Chen et al. [6], aims to axiomatically characterize systemic risk measures. The model in [6] can capture, in particular, a contagion model characterized by a matrix of profits and losses over different firms and outcomes. The results in [6] characterize the global measures of risk (operating on the matrix) that satisfies certain sets of desirable axioms. This is work is expanded upon in Kromer et al. [13], where the authors consider general outcome measure spaces, as well as in Feinstein et al. [10], where the authors consider set-valued risk measures. Battison et al.[4] study systemic risk measurement

when a regulator has limited information about contracts made between financial network participants (e.g., the fraction of the face value that can likely be recovered if a counterparty defaults), and show how small errors in knowledge can lead to large errors in systemic risk measurement.

Our work also shares some conceptual similarity with the well-known work of Diamond and Dybvig [8] on bank runs and of Brunnermeier et al. [5] on the risks of re-hypothecation.

The model in the present work differs substantially from those considered in the aforementioned papers, in large part because of the idiosyncrasies of restaking networks, including their combinatorial and bipartite nature and their susceptibility to economically motivated attacks.

Restaking has also, to a limited extent, been studied in its own right. The EigenLayer team introduces restaking in [15]. The framing of an economically motivated attacker that trades off stake loss with profits from corruption appears in [15], and is used also by Deb et al. [7]. Chitra and Neuder [14] discuss restaking risk from a validator perspective, comparing restaking with investments in other financial instruments (e.g. bonds). Alexander [3] considers the interplay between existing leveraging schemes and liquid restaking tokens, which can amplify large-scale credit risk.

2 Model

Validators and Services

We consider a setting in which there is a set V of validators and a set S of services. Each service $s \in S$ has some profit from corruption π_s, and each validator $v \in V$ has some stake σ_v. We also associate with each service s a parameter α_s that denotes the fraction of stake required to corrupt/launch an attack on s. We call a bipartite graph $G = (S, V, E, \pi, \sigma, \alpha)$ a *restaking graph*; an edge is drawn between a validator $v \in V$ and a service $s \in S$ if v is restaking for s. For a given set of vertices A in a graph G, we use the notation $N_G(A)$ to denote the neighbors of A.

Attack Dynamics

For simplicity, we assume that validators lose their full stake σ_v if they launch an attack on a service. As such, for a given collection of services $A \subseteq S$, and a given collection of validators $B \subseteq V$ restaking for those services, we say that (A, B) is an *attacking coalition* for a restaking graph G if the validators in B possess enough stake to corrupt the services A:

$$\underbrace{\sum_{v \in B \cap N_G(\{s\})} \sigma_v}_{\text{Total stake in } s \text{ owned by validators } B} \geq \alpha_s \cdot \underbrace{\sum_{v \in N_G(\{s\})} \sigma_v}_{\text{Total amount restaked in } s} \qquad \forall s \in A \tag{1}$$

We further say that (A, B) is a *valid attack* if it is an attacking coalition that has an incentive to launch an attack:

$$\underbrace{\sum_{s \in A} \pi_s}_{\text{Total profit from corrupting } A} > \underbrace{\sum_{v \in B} \sigma_v}_{\text{Total stake owned by validators } B} \tag{2}$$

If a valid attack (A, B) is carried out, we denote by $G \searrow B$ the induced subgraph $G[S, V \setminus B]$. The graph $G \searrow B$ denotes the state of the restaking graph after the attack is carried out. If no valid attacks exist on the graph, we call it *secure*. To simplify notation, for any subset of validators $B \subseteq V$, we will use the shorthand σ_B to denote $\sum_{v \in B} \sigma_v$. Similarly, for any $A \subseteq S$, we will use π_A as shorthand for $\sum_{s \in A} \pi_s$.

EigenLayer sufficient conditions

We note in passing that, in their whitepaper [15], EigenLayer proposes some efficiently verifiable sufficient conditions for security that they check to ensure that an attack does not exist.

▷ Claim 1 (EigenLayer Sufficient Conditions, from Appendix B.1 of the EigenLayer Whitepaper [15]). A restaking graph G is secure if for each validator $v \in V$,

$$\sum_{s \in N_G\{v\}} \frac{\sigma_v}{\sigma_{N_G(\{s\})}} \cdot \frac{\pi_s}{\alpha_s} \leq \sigma_v \tag{3}$$

Proof. It is shown in Appendix B.1 of the whitepaper that if Equation (3) holds for G, then the graph is secure (i.e. no valid attacks (A, B) satisfying Equations (1) and (2) exist). ◁

Cascading attacks

Our goal is to understand when a small shock can result in the loss of a large fraction of the overall stake. Small shocks can turn into large shocks by means of a cascading attack. Formally, we say that a disjoint sequence $(A_1, B_1), \ldots, (A_T, B_T) \in 2^S \times 2^V$ is a *valid cascade of attacks* on a restaking graph $G = (S, V, E, \pi, \sigma, \alpha)$ if for each $t \in [T]$, (A_t, B_t) is a valid attack on $G \searrow \bigcup_{i=1}^{t-1} B_i$. We denote by $\mathcal{C}(G)$ the set of all such sequences of valid cascading attacks.

Worst-case stake loss

We now define a metric that measures the total potential loss of stake due to a sequence of cascading attacks. In our model, we first suppose that an initial small shock decreases the amount of stake. Formally, we define, for a given restaking graph $G = (S, V, E, \pi, \sigma, \alpha)$,

$$\mathbb{D}_\psi(G) := \left\{ D \subseteq V \mid \frac{\sigma_D}{\sigma_V} \leq \psi \right\} \tag{4}$$

to be the set of validator coalitions that constitute at most a ψ-fraction of all stake. Given some $D \in \mathbb{D}_\psi(G)$, we use the notation $G \searrow D := G[S, V \setminus D]$ to denote the induced subgraph of the restaking graph when we delete the validators D. We now define

$$R_\psi(G) := \underbrace{\psi}_{\text{Initial shock}} + \max_{D \in \mathbb{D}_\psi(G)} \max_{(A_1,B_1),\ldots,(A_T,B_T) \in \mathcal{C}(G \searrow D)} \underbrace{\frac{\sigma_{\bigcup_{t=1}^T B_t}}{\sigma_V}}_{\text{Stake lost from cascading attacks}} \tag{5}$$

This quantity represents the worst-case total fraction of stake lost due to an initial ψ-fraction of the stake disappearing. By construction, $\psi \leq R_\psi(G) \leq 1$.

3 Overcollateralization Provides Robust Security

In this section, we show that "scaling up" the definition of security automatically results in robust security, meaning bounded losses from cascading attacks that follow an initial shock. We first show that, without loss of generality, it suffices to consider single valid attacks $(A, B) \in \mathcal{C}(G \searrow D)$ instead of more general cascading attacks.

▶ **Lemma 2.** *Let $G = (S, V, E, \pi, \sigma, \alpha)$ be an arbitrary restaking graph, and further suppose that (A, B) is an attacking coalition on $G \searrow D$, where $D \subseteq V$. Then, $(A, B \cup D)$ is an attacking coalition on G.*

Proof. Because (A, B) is an attacking coalition on $G \searrow D$, we must have by Equation (1) that

$$\sigma_{B \cap N_G\{s\}} \geq \alpha_s \cdot \sigma_{N_G\{s\} \setminus D} \qquad \forall s \in A \tag{6}$$

It follows that for any $s \in A$,

$$\begin{aligned} \sigma_{(B \cup D) \cap N_G\{s\}} &= \sigma_{B \cap N_G\{s\}} + \sigma_{D \cap N_G\{s\}} && (7)\\ &\geq \alpha_s \cdot \sigma_{N_G\{s\} \setminus D} + \sigma_{D \cap N_G\{s\}} && (8)\\ &\geq \alpha_s \cdot \sigma_{N_G\{s\}} && (9) \end{aligned}$$

and the desired result follows. ◀

▶ **Corollary 3.** *Let $G = (S, V, E, \pi, \sigma, \alpha)$ be an arbitrary restaking graph, and further suppose that $(A_1, B_1), \ldots, (A_T, B_T) \in \mathcal{C}(G)$ is a valid sequence of cascading attacks on G. Then, $\left(\bigcup_{t=1}^T A_t, \bigcup_{t=1}^T B_t\right)$ is also a valid attack on G.*

Proof. By repeatedly applying Lemma 2, we find that for each $t \in [T]$, $\left(A_t, \bigcup_{i=1}^t B_t\right)$ is an attacking coalition on G. It follows by inspection of Equation (1) that we must therefore have that $(\bigcup_t A_t, \bigcup_t B_t)$ is an attacking coalition on G. To finish the result, it suffices to show that Equation (2) holds for this attacking coalition on the original graph G. This follows from the disjointness of the A_t's and of the B_t's:

$$\pi_{\bigcup_t A_t} = \sum_{t=1} \pi_{A_t} > \sum_{t=1}^{T} \sigma_{B_t} = \sigma_{\bigcup_t B_t} \tag{10}$$

where in the inner inequality we use that for each $t \in [T]$, $\pi_{A_t} > \sigma_{B_t}$ by Equation (2), as (A_t, B_t) is a valid attack on $G \searrow \bigcup_{i=1}^{t-1} B_i$. It follows that $(\bigcup_t A_t, \bigcup_t B_t)$ is a valid attack on G. ◀

Adding Multiplicative Slack

Our condition is given by adding multiplicative slack to Equation (2). Formally, we say that a restaking graph G is *secure with γ-slack* if for all attacking coalitions (A, B) on G,

$$(1+\gamma) \underbrace{\pi_A}_{\text{Total profit from corrupting } A} \leq \underbrace{\sigma_B}_{\text{Total stake owned by validators } B} \tag{11}$$

▶ **Theorem 4.** *Suppose that a restaking graph $G = (S, V, E, \pi, \sigma, \alpha)$ is secure with γ-slack for some $\gamma > 0$. Then, for any $\psi > 0$, $R_\psi(G) < \left(1 + \frac{1}{\gamma}\right)\psi$.*

Proof. Take any $\psi > 0$ and any $D \in \mathbb{D}_\psi(G)$ for some restaking graph G where (11) holds. Let $(A_1, B_1) \ldots, (A_T, B_T) \in \mathcal{C}(G \searrow D)$ be arbitrary. Applying Corollary 3, we must have that $(\bigcup_t A_t, \bigcup_t B_t) \in \mathcal{C}(G \searrow D)$ as well. Defining $A := \bigcup_t A_t$ and $B := \bigcup_t B_t$, we must therefore have that (A, B) is an attacking coalition on $G \searrow D$, and furthermore that

$$\pi_A > \sigma_B \tag{12}$$

By Lemma 2, we must also have that $(A, B \cup D)$ is an attacking coalition on the original graph G. It then follows that as G is secure with γ-slack, Equation (11) must hold on $(A, B \cup D)$, whence

$$(1+\gamma)\pi_A \leq \sigma_{B \cup D} = \sigma_B + \sigma_D \tag{13}$$

Putting this together with Equation (12), we find that

$$(1+\gamma)\sigma_B < (1+\gamma)\pi_A \leq \sigma_B + \sigma_D \leq \sigma_B + \psi \cdot \sigma_V \tag{14}$$

It follows that

$$\gamma \cdot \sigma_B < \psi \cdot \sigma_V \implies \frac{\sigma_B}{\sigma_V} < \frac{\psi}{\gamma} \tag{15}$$

$$\implies \psi + \frac{\sigma_B}{\sigma_V} < \left(1 + \frac{1}{\gamma}\right)\psi \tag{16}$$

As we took $A_1, \ldots, A_T$ to be arbitrary, we find that $R_\psi(G) < \left(1 + \frac{1}{\gamma}\right)\psi$, as desired. ◀

The EigenLayer sufficient conditions (3) can be similarly "scaled up" to yield efficiently checkable sufficient conditions for security with γ-slack (and hence, by Theorem 4, robustness to cascading attacks).

▶ **Corollary 5.** *Let G be a restaking graph such that, for all validators $v \in V$,*

$$\sum_{s \in N_G(\{v\})} \frac{\sigma_v}{\sigma_{N_G(\{s\})}} \cdot \frac{(1+\gamma)\pi_s}{\alpha_s} \leq \sigma_v \tag{17}$$

Then, $R_\psi(G) < \left(1 + \frac{1}{\gamma}\right)\psi$.

Proof. This follows from Theorem 4 and Claim 1. Noting that the γ-slack condition holds precisely iff no valid attacks exist when profits from corruption π_s are inflated by a multiplicative factor of $(1+\gamma)$, it suffices to apply EigenLayer's sufficient conditions from Claim 1 with modified profits from corruption $(1+\gamma)\pi_s$. ◀

Note that, given a restaking network, it is straightforward to compute the minimum value of γ such that the condition in (17) holds. This value can then be interpreted as an easily computed "risk measure" of such a network.

4 Lower Bounds for Global Security

In this section, we show that the upper bounds from the previous section are tight. We first show that if there is no multiplicative slack (i.e. $\gamma = 0$), then very small shocks can cause all stake to be lost in the worst case. This holds even under the EigenLayer conditions (3)[4].

▶ **Theorem 6.** *For any $0 < \epsilon < 1$, there exists a restaking graph G that is secure and meets the EigenLayer condition (3), but has $R_\psi(G) = 1$ for all $\psi \geq \epsilon$.*

Proof. We construct a restaking graph $G = (S, V, E, \pi, \sigma, \alpha)$ with one service $S = \{x\}$ and two validators $V = \{a, b\}$, where an edge exists between each validator and the service (i.e. $E := (\{x\}, \{a\}), (\{x\}, \{b\})$). We then let $\sigma_a := \epsilon$, $\sigma_b := 1 - \epsilon$, $\pi_x := 1$, and $\alpha_x := 1$. Without loss of generality, we may assume $\psi < 1$ as $R_1(G) = 1$ for any restaking graph G. This graph satisfies (3) as

[4] The graph exhibited in the proof of Theorem 6 has $\pi_x/\sigma_a \to \infty$ as $\epsilon \to 0$. It is possible to construct a counterexample with similar properties while maintaining that π_s/σ_v is greater than some universal constant for any $s \in S$ and $v \in V$. This is done in the full version of the paper.

$$\frac{\sigma_a}{\sigma_a+\sigma_b}\cdot\frac{\pi_x}{\alpha_x}=\sigma_a \tag{18}$$

$$\frac{\sigma_b}{\sigma_a+\sigma_b}\cdot\frac{\pi_x}{\alpha_x}=\sigma_b \tag{19}$$

whence the graph is also secure by Claim 1. We now consider an initial shock $D=\{a\}$. As $\sigma_a/\sigma_V=\epsilon\leq\psi$, it follows that $D\in D_\psi(G)$. The pair $(\{x\},\{b\})$ is a valid attack on $G\searrow D$, since $\{b\}=N_{G\searrow D}\{x\}$ whence it is an attacking coalition, and $\sigma_b<\pi_x$. It follows that $R_\psi(G)\geq\frac{\sigma_a+\sigma_b}{\sigma_V}=1$ as desired. ◀

Next, we show that the bound we give in Theorem 4 (indeed, more strongly, the condition given in Corollary 5) is tight for all $\psi,\gamma>0$.

▶ **Theorem 7.** *For any $\psi,\gamma,\epsilon>0$ such that*

$$0\leq\left(1+\frac{1}{\gamma}\right)\psi-\epsilon\leq 1, \tag{20}$$

there exists a restaking graph G that satisfies the condition (17) from Corollary 5 but has $R_\psi(G)\geq\left(1+\frac{1}{\gamma}\right)\psi-\epsilon$.

Proof. We construct a restaking graph $G=(S,V,E,\pi,\sigma,\alpha)$ with three validators $V=\{a,b,c\}$ and one service $S=\{x\}$, where an edge exists between each of the validators a and b and the service x (i.e. the edge set $E:=\{(x,a),(x,b)\}$). Without loss of generality, suppose that $\epsilon\leq\psi/\gamma$. Let $\sigma_a>0$ be any positive constant. We define

$$\sigma_b:=\sigma_a\left(\frac{1}{\gamma}-\frac{\epsilon}{\psi}\right) \tag{21}$$

$$\sigma_c:=\sigma_a\left(\frac{1-\psi+\epsilon}{\psi}-\frac{1}{\gamma}\right) \tag{22}$$

$$\pi_x:=\frac{\left(1+\frac{1}{\gamma}\right)\psi-\epsilon}{1+\gamma}\cdot\sigma_V \tag{23}$$

$$\alpha_s:=1 \tag{24}$$

Notice first that $\sigma_b\geq 0$ as we have taken $\epsilon\leq\psi/\gamma$. Next, observe that

$$\sigma_c\geq 0\iff\frac{1-\psi+\epsilon}{\psi}\geq\frac{1}{\gamma} \tag{25}$$

$$\iff 1\geq\left(1+\frac{1}{\gamma}\right)\psi-\epsilon \tag{26}$$

whence $\sigma_c\geq 0$ by Equation (20). Finally, we must also have that $\pi_x\geq 0$ by Equation (20) as well. Next, notice by construction that

$$\sigma_V=\sigma_a+\sigma_b+\sigma_c=\sigma_a\left(1+\frac{1}{\gamma}-\frac{\epsilon}{\psi}+\frac{1-\psi+\epsilon}{\psi}-\frac{1}{\gamma}\right)=\frac{\sigma_a}{\psi} \tag{27}$$

This graph meets condition (17) from Corollary 5, as

$$\sum_{s\in N_G\{a\}}\frac{\sigma_a}{\sigma_{N_G\{s\}}}(1+\gamma)\pi_s=\frac{\sigma_a}{\sigma_a+\sigma_b}\left[\left(1+\frac{1}{\gamma}\right)\psi-\epsilon\right]\sigma_V \tag{28}$$

$$=\frac{\sigma_a}{\sigma_a\left(1+\frac{1}{\gamma}-\frac{\epsilon}{\psi}\right)}\left[\left(1+\frac{1}{\gamma}\right)\psi-\epsilon\right]\frac{\sigma_a}{\psi} \tag{29}$$

$$=\sigma_a \tag{30}$$

A similar argument shows that

$$\sum_{s \in N_G\{b\}} \frac{\sigma_b}{\sigma_{N_G\{s\}}}(1+\gamma)\pi_s = \frac{\sigma_b}{\sigma_a\left[\left(1+\frac{1}{\gamma}\right)\psi - \epsilon\right]}\left[\left(1+\frac{1}{\gamma}\right)\psi - \epsilon\right]\sigma_a = \sigma_b \tag{31}$$

Finally, as the validator c has no neighbors, it also satisfies the condition, whence the graph indeed satisfies (17). We now consider an initial shock $D := \{a\}$ to the graph. Because

$$\frac{\sigma_a}{\sigma_V} = \frac{\sigma_a}{\sigma_a/\psi} = \psi, \tag{32}$$

the shock $D \in \mathbb{D}_\psi$ constitutes a ψ fraction of the total stake as desired. The attack $(\{x\}, \{b\})$ is a valid attack on $G \searrow D$. To see this, notice first that $(\{x\}, \{b\})$ is an attacking coalition on $G \searrow D$ as $\{b\} = N_{G\searrow D}\{x\}$. Furthermore, $\{b\}$ is incentivized to attack since

$$\pi_x - \sigma_b = \frac{\left(1+\frac{1}{\gamma}\right)\psi - \epsilon}{1+\gamma} \cdot \sigma_V - \sigma_b \tag{33}$$

$$= \left[\frac{1+\frac{1}{\gamma}-\frac{\epsilon}{\psi}}{1+\gamma} - \left(\frac{1}{\gamma} - \frac{\epsilon}{\psi}\right)\right]\sigma_a \tag{34}$$

$$= \left[\frac{\left(1+\frac{1}{\gamma}\right)\psi + \gamma\epsilon}{(1+\gamma)\psi} - \frac{1}{\gamma}\right]\sigma_a \tag{35}$$

$$= \frac{\gamma\epsilon\sigma_a}{(1+\gamma)\psi} > 0 \tag{36}$$

whence Equation (2) is satisfied for the pair $(\{x\}, \{b\})$. It follows that

$$R_\psi(G) \geq \frac{\sigma_a + \sigma_b}{\sigma_V} = \frac{\left(1+\frac{1}{\gamma}-\frac{\epsilon}{\psi}\right)\sigma_a}{\sigma_a/\psi} = \left(1+\frac{1}{\gamma}\right)\psi - \epsilon \tag{37}$$

as desired. ◀

5 Local Security

The bound in Theorem 4 on the worst-possible stake loss from cascading attacks is reassuring from a global perspective, but less so from the perspective of one or a small number of services who would like an assurance that they will not be among those affected by such attacks. Beginning with this section, we focus on a specific coalition of services $C \subseteq S$ that seeks to insulate their shared security $\Gamma(C)$ against shocks and resulting cascading attacks that may come about due to the decisions of other services and validators. Formally, we denote by

$$\Gamma(C) := \{v \in V \mid N_G\{v\} \subseteq C\} \tag{38}$$

the set of validators that exclusively provide security for services in C.

Worst-case stake loss (local version)

As before, we first suppose that an initial shock affects the restaking graph. Whereas previously, we considered shocks for which the total stake in the shock was bounded, we now consider shocks for which the total stake that impacts the exclusive security of some coalition of services C (i.e., stake that secures services from C and only services from C) is bounded. Formally, for any coalition of services $C \subseteq S$ within some restaking graph G, we let

$$\mathbb{D}_\psi(C,G) := \left\{ D \subseteq V \mid \frac{\sigma_{D\cap\Gamma(C)}}{\sigma_{\Gamma(C)}} \leq \psi \right\} \tag{39}$$

denote the set of all validator coalitions that provide at most ψ stake to the aggregate security of the coalition of services C. Notice that shocks $D \in \mathbb{D}_\psi(C,G)$ may have much more total stake σ_D than a ψ fraction of the graph. We are instead only guaranteed that the impact of the shock on stake that is being used exclusively for members in C is small. We are now interested in the potential cascading losses that can affect the stake that is exclusively utilized by the coalition C after a shock occurs that destroys at most ψ stake from the aggregate security of C. Formally, we study the quantity

$$R_\psi(C,G) := \underbrace{\psi}_{\text{Initial Shock}} + \max_{D\in\mathbb{D}_\psi(C,G)} \max_{(A_1,B_1),\ldots,(A_T,B_T)\in\mathcal{C}(G\searrow D)} \underbrace{\frac{\sigma_{\bigcup_{t=1}^T B_t\cap\Gamma(C)}}{\sigma_{\Gamma(C)}}}_{\text{Stake lost from cascading attacks}} \tag{40}$$

Local security conditions

We seek sufficient conditions on a restaking graph G that guarantee a nontrivial upper bound on $R_\psi(C,G)$. Ideally, the sufficient condition would depend only the neighborhood/choices of the coalition C to provide a guarantee that holds regardless of the choices made by other validators and services (i.e., the services of C can attempt to "control their own destiny" by ensuring that the locally defined sufficient condition holds). Formally, given a restaking graph $G = (S,V,E,\pi,\sigma,\alpha)$ and a coalition of services $C \subseteq S$, we call a restaking graph $G' = (S',V',E',\pi',\sigma',\alpha')$ a *C-local variant* of G if C cannot distinguish G' from G on the basis of local information: $C \subseteq S'$, $N_G C = N_{G'} C$, and

$$(\pi_s,\alpha_s) = (\pi'_s,\alpha'_s) \qquad \forall s \in C \tag{41}$$

$$(\sigma_v, N_G\{v\}) = (\sigma'_v, N_{G'}\{v\}) \qquad \forall v \in N_G C \tag{42}$$

We then define a *local security condition* $f : (C,G) \mapsto \{0,1\}$ to be a Boolean function that takes as input a restaking graph G and a coalition of services $C \subseteq S$ such that $f(C,G)$ must be equal to $f(C,G')$ for all C-local variants G'. The intuition behind this definition is that the condition should only depend on service-level information (e.g. profits from corruption, security thresholds) for services in the coalition, and validator-level information for validators in $N_G C$.

Local security impossibility

Unfortunately, without further restrictions on the attacks under consideration (like those defined later in this section), it is impossible to construct any nontrivial local security condition that yields any nontrivial upper bound on $R_\psi(C,G)$.

▶ **Theorem 8.** *For any local security condition f, any secure restaking graph G and coalition of services $C \subseteq S$ such that $f(C,G) = 1$, there exists a secure C-local variant G' of G such that $R_0(C,G') = 1$.*

Proof. Take any f, C, and secure G such that $f(C,G) = 1$. Define

$$\Delta := \sigma_{N_G C} - \pi_C \tag{43}$$

to be the total overcollateralization of C in aggregate. Next, we define G' to be an augmented version of G, where we add a new service s^* that has a profit from corruption $\pi_{s^*} = \Delta + 2\epsilon$ where $\epsilon > 0$. We further add 2 validators a and b to the graph who are adjacent only to s^*. We let $\sigma_a := \Delta + \epsilon$ and $\sigma_b := \epsilon$. As $\sigma_a + \sigma_b \geq \pi_{s^*}$, the graph G' must be secure as G was secure. Next, notice that as the validator a is not path-connected to C, G' must be a C-local variant of G. However, by construction, the attack $(C \cup \{s^*\}, N_G C \cup \{b\})$ is valid on the graph $G' \searrow \{a\}$. It follows that $R_0(C, G') = 1$. ◀

Stable attacks

While the above impossibility appears to be quite strong, it is somewhat contrived. At the heart of the impossibility is that under the definition of a valid attack (i.e. Equations (1) and (2)), not every validator must be productive in carrying out the attack. There may be a subset of validators in the attack that can yield more net profit than the full coalition. In what follows, we show that if we assume that malicious validator coalitions will choose to add others to their ranks only if it is profitable for them in net to do so, then a local security condition with guarantees similar to those in Theorem 4 does indeed exist. Formally, for $A \subseteq S$ and $B \subseteq V$, we say that an attack (A, B) is *stable* if it is valid (i.e. Equations (1) and (2) hold), and for all $A' \subseteq A$ and $B' \subseteq B$ such that (A', B') is valid,

$$\sigma_{B \setminus B'} < \pi_{A \setminus A'} \tag{44}$$

Intuitively, if (44) did not hold, then the validators of B' would be better off ditching those in $B \setminus B'$ and attacking only the services in A'.

We say that a disjoint sequence $(A_1, B_1), \ldots, (A_T, B_T) \in 2^S \times 2^V$ is a cascade of stable attacks on a restaking graph $G = (S, V, E, \pi, \sigma, \alpha)$ if for each $t \in [T]$, (A_t, B_t) is a stable attack on $G \searrow \bigcup_{i=1}^{t-1} B_i$. We denote by $\mathcal{S}(G)$ the set of all such sequences of cascading stable attacks. In light of Theorem 8, we redefine our notion of worst-case stake loss using stable attacks:

$$R_\psi(C, G) := \psi + \max_{D \in \mathbb{D}_\psi(C,G)} \max_{(A_1,B_1),\ldots,(A_T,B_T) \in \mathcal{S}(G \searrow D)} \frac{\sigma_{\bigcup_t B_t \cap \Gamma(C)}}{\sigma_{\Gamma(C)}} \tag{45}$$

Unlike valid attacks, unions of sequences of stable cascading attacks need not be stable (which will complicate the proof of Theorem 10 in the next section).

▷ Claim 9. There exists a restaking graph G and a sequence $(A_1, B_1), (A_2, B_2) \in \mathcal{S}(G)$ such that $(A_1 \cup A_2, B_1 \cup B_2) \notin \mathcal{S}(G)$.

Proof. Consider restaking graph where there are two services $S = \{x, y\}$ and two validators $V = \{a, b\}$ where both validators are restaking in both services. Furthermore, $\pi_x = \pi_y = 2$, $\alpha_x = \alpha_y = \frac{1}{2}$, and $\sigma_a = \sigma_b = 1$. In this case, the sequence $(\{x\}, \{a\}), (\{y\}, \{b\}) \in \mathcal{S}(G)$. However, $(\{x, y\}, \{a, b\}) \notin \mathcal{S}(G)$ because the attack $(\{x, y\}, \{a\})$ is a valid attack. ◁

6 A Local Security Condition for Stable Attacks

In this section, we give a family of local security conditions that yield guarantees on the local worst-case stake loss $R_\psi(C, G)$ that resemble our result from Theorem 4 for global security. In Theorems 4 and 7, we showed that security with γ-slack was necessary and sufficient in order to obtain a $\left(1 + \frac{1}{\gamma}\right)\psi$ upper-bound on $R_\psi(G)$. In other words, it was both necessary and sufficient to ensure that all attacking coalitions (A, B) were overcollateralized

multiplicatively by a factor of $(1+\gamma)$. Our condition for local security is similar: we must ensure that certain *attack headers* (X, Y) are overcollateralized multiplicatively by a factor of $(1+\gamma)$.

Attack header

Formally, we say that (X, Y) is an *attack header*, for $X \subseteq S$ and $Y \subseteq \Gamma(X)$, if there exists a set of validators $B \subseteq V$ satisfying

$$B \cap \Gamma(X) = \emptyset \tag{46}$$

such that $(X, B \cup Y)$ is an attacking coalition. In other words, (X, Y) is an attack header if Y can be appended to a collection of validators B that may be slashed without attacking services in X to form an attacking coalition that attacks the services X. An attacking coalition is a special case of an attack header (in which B can be taken as $\emptyset$).

▶ **Theorem 10.** *Let $G = (S, V, E, \pi, \sigma, \alpha)$ be a restaking graph and $C \subseteq S$ be a coalition of services. If, for all attack headers (X, Y) where $X \subseteq C$,*

$$(1+\gamma)\pi_X \leq \sigma_Y \tag{47}$$

then $R_\psi(C, G) < (1 + \frac{1}{\gamma})\psi$. Furthermore, the Boolean function that checks whether Equation (47) holds for all attack headers is a local security condition.

Proof. Let $D \in \mathbb{D}_\psi(C, G)$ and $(A_1, B_1), \ldots, (A_T, B_T) \in \mathcal{S}(G \searrow D)$ be arbitrary. For each $t \in [T]$, define

$$L_t := B_t \cap \Gamma(C) \tag{48}$$

to be the set of all validators exclusively securing C that were lost in the t^{th} attack. Next, define

$$A'_t := \left\{ s \in A_t \mid \sigma_{B_t \setminus L_t} \geq \alpha_s \cdot \sigma_{N_G\{s\} \setminus \left(\bigcup_{i=1}^{t-1} B_i \cup D\right)} \right\} \tag{49}$$

to be the maximal set of services such that $(A'_t, B_t \setminus L_t)$ is an attacking coalition on $G \searrow \left(\bigcup_{i=1}^{t-1} B_i \cup D\right)$. Notice also that because (A_t, B_t) is a stable attack on $G \searrow \left(\bigcup_{i=1}^{t-1} B_i \cup D\right)$, we must have that $A_t \setminus A'_t$ is nonempty, and furthermore must be a subset of C.

▷ Claim 11.

$$\sigma_{\bigcup_t B_t \cap \Gamma(C)} < \pi_{\bigcup_t A_t \setminus A'_t} \tag{50}$$

Proof. From stability, we have that

$$\sigma_{L_t} = \sigma_{B_t \setminus (B_t \setminus L_t)} < \pi_{A_t \setminus A'_t} \tag{51}$$

To see why this holds, notice that there are two cases. If the attacking coalition $(A'_t, B_t \setminus L_t)$ is a valid attack, then the inequality follows directly from the stability definition. If instead $(A'_t, B_t \setminus L_t)$ is not a valid attack despite being an attacking coalition, the inequality must still hold because the original attack (A_t, B_t) is valid and therefore satisfies Equation (2). Iterating over t, we find that

$$\sigma_{\bigcup_t B_t \cap \Gamma(C)} = \sum_{t=1}^{T} \sigma_{L_t} < \sum_{t=1}^{T} \pi_{A_t \setminus A'_t} = \pi_{\bigcup_t A_t \setminus A'_t} \tag{52}$$

◁

▷ Claim 12. $\left(\bigcup_t (A_t \setminus A'_t), (\bigcup_t B_t \cup D) \cap \Gamma(C)\right)$ is an attack header on G, and $\bigcup_t (A_t \setminus A'_t) \subseteq C$.

Proof. Because each $A_t \setminus A'_t \subseteq C$, we must also have that $\bigcup_t A_t \setminus A'_t \subseteq C$ as well. Next, by applying Corollary 3 noting the disjointness of the (A_t, B_t), we have that

$$\left(\bigcup_t A_t, \bigcup_t B_t\right) = \left(\bigcup_t (A_t \setminus A'_t) \cup \bigcup_t A'_t, \quad \bigcup_t B_t\right) \tag{53}$$

must be an attacking coalition on $G \searrow D$. In particular, we must have that $\left(\bigcup_t (A_t \setminus A'_t), \bigcup_t B_t\right)$ is an attacking coalition on $G \searrow D$, whence by Lemma 3 we have that $\left(\bigcup_t (A_t \setminus A'_t), \bigcup_t B_t \cup D\right)$ is an attacking coalition on G. Rewriting the above as

$$\left(\bigcup_t (A_t \setminus A'_t), \quad \left[\left(\bigcup_t B_t \cup D\right) \cap \Gamma(C)\right] \cup \left[\left(\bigcup_t B_t \cup D\right) \setminus \Gamma(C)\right]\right) \tag{54}$$

and noting by construction that

$$\left[\left(\bigcup_t B_t \cup D\right) \setminus \Gamma(C)\right] \cap \Gamma(C) = \emptyset, \tag{55}$$

we find that $\left(\bigcup_t (A_t \setminus A'_t), (\bigcup_t B_t \cup D) \cap \Gamma(C)\right)$ is an attack header on G as desired. ◁

Putting these claims together yields the desired result. By Claim 12 and Equation (47), we find that

$$(1+\gamma)\pi_{\bigcup_t A_t \setminus A'_t} \leq \sigma_{(\bigcup_t B_t \cup D) \cap \Gamma(C)} \leq \sigma_{\bigcup_t B_t \cap \Gamma(C)} + \psi \cdot \sigma_{\Gamma(C)} \tag{56}$$

Adding in Claim 11, we find that

$$(1+\gamma)\sigma_{\bigcup_t B_t \cap \Gamma(C)} < \sigma_{\bigcup_t B_t \cap \Gamma(C)} + \psi \cdot \sigma_{\Gamma(C)} \tag{57}$$

$$\implies \frac{\sigma_{\bigcup_t B_t \cap \Gamma(C)}}{\sigma_{\Gamma(C)}} < \frac{\psi}{\gamma} \tag{58}$$

$$\implies R_\psi(C, G) < \left(1 + \frac{1}{\gamma}\right)\psi \tag{59}$$

as desired. To see that the Boolean function that checks whether Equation (47) holds for all attack headers is a local security condition, observe that it suffices to check that for all $X \subseteq C$ and $Y \subseteq N_G C \cap \Gamma(C) = \Gamma(C)$ such that $(X, Y \cup N_G C \setminus \Gamma(C))$ is an attacking coalition, Equation (47) holds. Thus, for any restaking graph G and C-local variant G', this function will evaluate to the same output. ◀

The condition in (47) can be checked via enumeration, although the time required to do so grows exponentially in the number of services in C and the number of validators that contribute security exclusively to services in C. In the event that this is a prohibitive amount of computation, the same guarantee holds under a stronger, easily checked local analog of the EigenLayer sufficient condition (3) which, in effect, treats as malicious all validators that contribute security to any services outside of C.

▶ **Corollary 13.** *For any restaking graph $G = (S, V, E, \pi, \sigma, \alpha)$ and coalition of services $C \subseteq S$, satisfaction of the local condition*

$$\sum_{s \in N_G\{v\}} \frac{\sigma_v}{\sigma_{N_G(\{s\})}} \cdot \frac{(1+\gamma)\pi_s}{\alpha'_s} \leq \sigma_v \tag{60}$$

for all $v \in N_G C$ with $N_G\{v\} \subseteq C$ guarantees that $R_\psi(C, G) < \left(1 + \frac{1}{\gamma}\right)\psi$, where for each $s \in C$,

$$\alpha'_s := \alpha_s - \frac{\sigma_{N_G\{s\} \setminus \Gamma(C)}}{\sigma_{N_G\{s\}}} \tag{61}$$

Proof. This follows from Theorem 10 and Claim 1. Notice that to guarantee that the condition (47) from Theorem 10 holds for all attack headers (X, Y), it suffices to guarantee that no valid attacks exist, when (i) all profits from corruption for services in C are inflated by a multiplicative factor of $(1 + \gamma)$, and (ii) the fraction of stake required to corrupt a given service is offset by the fraction of stake in that service that is also restaking for services that do not belong to C. As Claim 1 provides a sufficient condition to guarantee the existence of no valid attacks, Equation (60) will guarantee that all attack headers are overcollateralized by a multiplicative factor of $(1 + \gamma)$. ◀

7 Lower Bounds for Local Security

We next show senses in which Theorem 10 (and more strongly, Corollary 13) is tight.

▶ **Corollary 14.** *For any $\psi, \gamma, \epsilon > 0$ such that*

$$0 \leq \left(1 + \frac{1}{\gamma}\right)\psi - \epsilon \leq 1, \tag{62}$$

there exists a restaking graph G that satisfies the condition (60) from Corollary 13 but has $R_\psi(C, G) \geq \left(1 + \frac{1}{\gamma}\right)\psi - \epsilon$.

Proof. Notice that if we take $C = S$, the condition (60) from Corollary 13 is identical to the condition (17) from Corollary 5. Furthermore, $R_\psi(S, G)$ is the same as $R_\psi(G)$ except for the fact that $R_\psi(S, G)$ considers only stable attacks. Repeating the argument from Theorem 7, and noting that the attack given in the proof of that result is stable, we obtain the desired result. ◀

▶ **Theorem 15.** *For any $\gamma > 0$, there exists a graph restaking graph $G = (S, V, E, \pi, \sigma, \alpha)$ that satisfies (17) from Corollary 5, but there exists a $C \subseteq S$ such that $R_0(C, G) = 1$.*

Proof. Let there be three services $S = \{x, y, z\}$, three validators $V = \{a, b, c\}$, and edges as follows:

$$E := \{(x, a), (x, b), (y, b), (y, c), (z, c), (z, a)\}. \tag{63}$$

Next, let $\alpha_s = 1$ for all $s \in S$, and let $\pi_x = \pi_y = \pi_z =: \pi > 0$ be an arbitrary positive constant. Next pick σ_a such that

$$\sigma_a < 2\pi, \tag{64}$$

let $\sigma_b := 2(1+\gamma)\pi$, and let $\sigma_c := 2(1+\gamma)\pi$. This graph satisfies (17) from Corollary 5 as

$$\frac{\sigma_a}{\sigma_a+\sigma_b}\cdot(1+\gamma)\pi + \frac{\sigma_a}{\sigma_a+\sigma_c}\cdot(1+\gamma)\pi < (1+\gamma)\pi\left(\frac{1}{\sigma_b}+\frac{1}{\sigma_c}\right)\sigma_a = \sigma_a \tag{65}$$

$$\frac{\sigma_b}{\sigma_a+\sigma_b}\cdot(1+\gamma)\pi + \frac{\sigma_b}{\sigma_b+\sigma_c}\cdot(1+\gamma)\pi < \frac{3}{2}(1+\gamma)\pi < \sigma_b \tag{66}$$

$$\frac{\sigma_c}{\sigma_a+\sigma_c}\cdot(1+\gamma)\pi + \frac{\sigma_c}{\sigma_b+\sigma_c}\cdot(1+\gamma)\pi < \frac{3}{2}(1+\gamma)\pi < \sigma_c \tag{67}$$

Next, let $C := \{x, z\}$, and observe that the shock $D = \{b, c\}$ is an element of $\mathbb{D}_0(C, G)$. However, because $\sigma_a < \pi_x + \pi_z = 2\pi$, we must have that $(\{x, z\}, \{a\})$ is a stable attack on $G \searrow D$. As $\{a\} = \Gamma(C)$, it follows that $R_0(C, G) = 1$. ◀

8 Long Cascades

Cascade Structure

Although Corollary 3 shows that all long cascades can be made into a short, one-step attack, it is arguably more dangerous if large attacks can be made through long cascades of small attacks that each require less coordination. In this section, we show how adding γ-slack also enables us to upper-bound the length of a cascade in the worst case. Our results depend on what we call the *reference depth* of a cascading sequence of attacks. Formally, for a given restaking graph G and coalition of validators B_0, we say that a valid cascade of attacks $(A_1, B_1), \ldots, (A_T, B_T)$ on $\mathcal{C}(G \searrow B_0)$ has reference depth k if

$$k = \max\{i \in [T] \mid \exists t \in [T] \text{ s.t. } N_G(A_t) \cap B_{t-i} \neq \emptyset\} \tag{68}$$

In other words, a cascading sequence has reference depth k if the services attacked in a given time step are not affected by validators that were slashed more than k steps previous.

▶ **Theorem 16.** *Suppose that a restaking graph $G = (S, V, E, \pi, \sigma, \alpha)$ is secure with γ-slack for some $\gamma > 0$. Let $\epsilon = \min_{v \in V} \sigma_v$ denote the minimum stake held by a validator. Then, for any $\psi > 0$, $B_0 \in \mathbb{D}_\psi(G)$, and $(A_1, B_1), \ldots, (A_T, B_T) \in \mathcal{C}(G \searrow B_0)$ with reference depth k,*

$$T < k\left(1 + \log_{1+\gamma}\frac{\psi \cdot \sigma_V}{\epsilon\gamma}\right) \tag{69}$$

Proof. Because $(A_1, B_1), \ldots, (A_T, B_T) \in \mathcal{C}(G \searrow B_0)$ has reference depth k, it follows that if we define

$$A'_i := \bigcup_{t=k(i-1)+1}^{ki} A_t \tag{70}$$

$$B'_i := \bigcup_{t=k(i-1)+1}^{ki} B_t \tag{71}$$

$$B'_0 := B_0 \tag{72}$$

for $i \in \{1, \ldots, \lceil T/k \rceil\}$, we must have that for all $j < i - 1$,

$$N_G A'_i \cap B'_j = \emptyset \tag{73}$$

Furthermore, by Corollary 3, we must have that the sequence $(A'_i, B'_i) \in \mathcal{C}(G \searrow B_0)$. Applying Corollary 3 again, we further have that for every i, $\left(\bigcup_{j=i+1}^{\lceil T/k \rceil} A'_i, \bigcup_{j=i+1}^{\lceil T/k \rceil} B'_i\right)$ is a valid attack on $G \searrow \bigcup_{j=0}^{i} B'_i$. It follows by Equation (2) that for any $i \in \{0, \ldots, \lceil T/k \rceil - 1\}$,

$$\pi_{\bigcup_{j=i+1}^{\lceil T/k \rceil} A'_j} > \sigma_{\bigcup_{j=i+1}^{\lceil T/k \rceil} B'_j} = \sum_{j=i+1}^{\lceil T/k \rceil} \sigma_{B'_j} \tag{74}$$

Next, noting that

$$N_G \bigcup_{j=i+1}^{\lceil T/k \rceil} A'_i \cap \bigcup_{j=1}^{i-1} B'_i = \emptyset \tag{75}$$

by Equation (73), it follows that indeed $\left(\bigcup_{j=i+1}^{\lceil T/k \rceil} A'_i, \bigcup_{j=i+1}^{\lceil T/k \rceil} B'_i\right)$ is also a valid attack on $G \searrow B'_i$. Applying Lemma 2, we then find that $\left(\bigcup_{j=i+1}^{\lceil T/k \rceil} A'_i, B'_i \cup \bigcup_{j=i+1}^{\lceil T/k \rceil} B'_i\right)$ is an attacking coalition on the original graph G. Because G is secure with γ-slack, Equation (11) must now hold on this pair, whence for all $i \in \{0, \ldots, \lceil T/k \rceil - 1\}$,

$$(1+\gamma)\pi_{\bigcup_{j=i+1}^{\lceil T/k \rceil} A'_j} \leq \sigma_{\bigcup_{j=i}^{\lceil T/k \rceil} B'_j} = \sigma_{B'_i} + \sum_{j=i+1}^{\lceil T/k \rceil} \sigma_{B'_j} \tag{76}$$

Putting this together with Equation (74), we have that for all $i \in \{0, \ldots, \lceil T/k \rceil - 1\}$,

$$(1+\gamma) \sum_{j=i+1}^{\lceil T/k \rceil} \sigma_{B'_j} < \sigma_{B'_i} + \sum_{j=i+1}^{\lceil T/k \rceil} \sigma_{B'_j} \tag{77}$$

$$\implies \sigma_{B'_i} > \gamma \sum_{j=i+1}^{\lceil T/k \rceil} \sigma_{B'_j} \tag{78}$$

It can be shown inductively from Equation (78) that the sequence $\sigma_{B'_i} > X_i$, where we define the sequence X_i by

$$X_{\lceil T/k \rceil} := \epsilon \tag{79}$$

$$X_i := \gamma \sum_{j=i+1}^{\lceil T/k \rceil} X_j \qquad\qquad i \in \{0, \ldots, \lceil T/k \rceil - 1\} \tag{80}$$

Solving, we find that

$$X_0 = \epsilon\gamma(1+\gamma)^{\lceil T/k \rceil - 1} \tag{81}$$

It then follows as desired that

$$\psi \cdot \sigma_V = \sigma_{B_0} > \epsilon\gamma(1+\gamma)^{T/k-1} \implies T < k\left(1 + \log_{1+\gamma} \frac{\psi \cdot \sigma_V}{\epsilon\gamma}\right) \tag{82}$$

Confusion Matrix Design for Downstream Decision-Making

Yiding Feng
Department of Industrial Engineering and Decision Analytics,
Hong Kong University of Science and Technology, Hong Kong

Wei Tang
Department of Decisions, Operations and Technology,
Chinese University of Hong Kong, Hong Kong

Abstract

We initiate the study of *confusion matrix design*. In this problem, an algorithm designer needs to generate a machine learning model (for a classification task from contexts to labels) which makes predictions for a population of downstream decision makers. The prediction accuracy of the machine learning model is characterized by its confusion matrix, which is a stochastic matrix where each entry encodes the probability of predicting the true label to another label. Each downstream decision maker faces a separate optimization task and will decide his binary action based on his own context, realized prediction given his context, and the confusion matrix selected by the algorithm designer. Decision makers are heterogeneous, as they may hold different contexts. Both the decision makers and the algorithm designer will obtain utilities that are determined by the actions the decision makers take, and their true labels. The goal of the algorithm designer is to design a public confusion matrix that is used for all decision makers subject to some feasibility constraints in order to maximize her net utility. We consider a general class of net utility functions, which could be a combination of both decision makers' utilities and the algorithm designer's utility. Classic outcome-independent utility and utilitarian/Nash/egalitarian social welfare are all special cases of our net utility formulation.

We study the above problem through an information design framework, where we view training machine learning model as designing an information structure (signaling scheme) subject to some specific constraints motivated by the machine learning literature. By building the connection to the *public persuasion with heterogeneous priors*, we design convex programming-based algorithms that compute the optimal confusion matrix subject to (i) post-processing constraints and (ii) receiver operating characteristic (ROC) constraints in polynomial time, respectively. Besides the computational results, we also obtain analytical structural results and numerical results for the special cases of outcome-independent utility and social-aware utility, by utilizing the convex programming-based characterization of the optimal confusion matrix.

Fully Characterizing Lossy Catalytic Computation

Abstract

A *catalytic machine* is a model of computation where a traditional space-bounded machine is augmented with an additional, significantly larger, "catalytic" tape, which, while being available as a work tape, has the caveat of being initialized with an arbitrary string, which must be preserved at the end of the computation. Despite this restriction, catalytic machines have been shown to have surprising additional power; a logspace machine with a polynomial length catalytic tape, known as *catalytic logspace* (CL), can compute problems which are believed to be impossible for L.

A fundamental question of the model is whether the catalytic condition, of leaving the catalytic tape in its exact original configuration, is robust to minor deviations. This study was initialized by Gupta et al. (2024), who defined *lossy catalytic logspace* ($\mathsf{LCL}[e]$) as a variant of CL where we allow up to e errors when resetting the catalytic tape. They showed that $\mathsf{LCL}[e] = \mathsf{CL}$ for any $e = O(1)$, which remains the frontier of our understanding.

In this work we completely characterize lossy catalytic space ($\mathsf{LCSPACE}[s, c, e]$) in terms of ordinary catalytic space ($\mathsf{CSPACE}[s, c]$). We show that

$$\mathsf{LCSPACE}[s, c, e] = \mathsf{CSPACE}[\Theta(s + e \log c), \Theta(c)]$$

In other words, allowing e errors on a catalytic tape of length c is equivalent, up to a constant stretch, to an equivalent errorless catalytic machine with an additional $e \log c$ bits of ordinary working memory.

As a consequence, we show that for any e, $\mathsf{LCL}[e] = \mathsf{CL}$ implies $\mathsf{SPACE}[e \log n] \subseteq \mathsf{ZPP}$, thus giving a barrier to any improvement beyond $\mathsf{LCL}[O(1)] = \mathsf{CL}$. We also show equivalent results for *non-deterministic* and *randomized catalytic space*.

1 Introduction

1.1 Catalytic computation

Within space-bounded computation, the *catalytic computing* framework, first introduced by Buhrman, Cleve, Koucký, Loff, and Speelman [4], models the question of whether or not full memory can be a computational resource. Their main object of study is a *catalytic logspace* (CL) machine, in which a traditional logspace-bounded Turing machine is given access to a second work tape, polynomial in length, called the catalytic tape; while this tape is exponentially longer than the logspace work tape, it is already full with some string τ at the outset, and this string τ must be preserved by the overall computation.

Surprisingly, [4] show that CL can be much more powerful than L, with the catalytic tape being at least as powerful a resource as non-determinism ($\mathsf{NL} \subseteq \mathsf{CL}$), randomness ($\mathsf{BPL} \subseteq \mathsf{CL}$), and more ($\mathsf{TC}^1 \subseteq \mathsf{CL}$). They also showed that its power is nevertheless limited and falls far short PSPACE, namely $\mathsf{CL} \subseteq \mathsf{ZPP}$.

This work spawned a long sequence of explorations of the power of catalytic space. Given the base model of CL there are many possible variations and structural questions to be asked, such as the power of randomness [11, 6], non-determinism [5], non-uniformity [21, 23, 9, 10], and other variants [15, 2]. There have also been many works connecting the catalytic framework to broader questions in complexity theory, such as space-bounded derandomization [22, 14, 19], as well as adaptations of catalytic techniques to solve longstanding open questions such as compositional upper bounds for space [7, 8, 10] (see [18, 20] for surveys on the topic).

1.2 Lossy catalytic computation

Besides these more standard structural questions, there are also catalytic variants which are more specific to the catalytic space restriction. In particular, Gupta et al. [16] initiated the study of *lossy* catalytic computing, wherein the catalytic tape need not be exactly reset to its initial configuration. This model, which we refer to as LCSPACE, essentially asks how robust the core definition of catalytic space is to seemingly small relaxations; for example, in the *quantum* setting some computation error (albeit of a different form) is necessary for converting between different definitions based on allowed operations.

To begin, note that CL with $e \leq \text{poly}(n)$ errors trivially contains the class $\mathsf{SPACE}[e]$ by simply erasing the first e bits of the catalytic tape and using them as free memory. Because we have not managed to prove that any space-bounded class beyond L which is contained in ZPP, we should not expect to be able to prove CL is the same as CL with $e = \omega(\log n)$ errors. The question, then, is to understand where, in the range of $e = 0$ to $e = O(\log n)$, is the acceptable number of errors that CL can provably tolerate.

As an initial answer to the previous question, [16] show that CL gains no additional power from allowing any constant number of errors on the catalytic tape, i.e., $\mathsf{LCL}[O(1)] = \mathsf{CL}$. This remains the frontier of our knowledge, and Mertz [20] posed it as an open question to improve this result to any superconstant number of errors, or, alternatively, to provide evidence against being able to prove such a collapse.[1] Recently, Cook et al. [6] showed that a different error-prone model, namely *randomized* CL, is no more powerful than the base CL model.

[1] We cannot expect an unconditional separation between CL and any LCL, as even separating PSPACE from e.g. $\mathsf{TC}^1 (\subseteq \mathsf{CL})$ remains wide open.

1.3 Our results

In this work we completely characterize lossy catalytic space in terms of ordinary catalytic space. Let $\mathsf{CSPACE}[s, c]$ denote catalytic machines with free space s and catalytic space c, and let $\mathsf{LCSPACE}[s, c, e]$ be the same with up to e errors allowed in resetting the catalytic tape. We show that these e errors are equivalent to an additional $e \log c$ free bits of memory, up to constant factor losses.

▶ **Theorem 1.** *Let $s := s(n), c := c(n), e := e(n)$ be such that $e \leq c^{1-\Omega(1)}$. Then*

$$\mathsf{LCSPACE}[\Theta(s), \Theta(c), e] = \mathsf{CSPACE}[\Theta(s + e \log c), \Theta(c)]$$

Besides characterizing $\mathsf{LCSPACE}[s, c, e]$, the main takeaway of Theorem 1 is that allowing seemingly minor (superconstant) errors in the resetting condition can give an $\mathsf{LCSPACE}$ machine surprising power. A concrete instantiation of this view is the following direct corollary.

▶ **Corollary 2.** *For any $e := e(n)$,*

$$\mathsf{LCL}[e] = \mathsf{CL} \quad \textit{implies} \quad \mathsf{SPACE}[O(e \log n)] \subseteq \mathsf{ZPP}$$

If we revisit the assumption that we cannot hope to prove $\mathsf{SPACE}[e \log n]$ is in ZPP for any $e = \omega(1)$, then Corollary 2 implies the result of [16] is optimal with respect to e; any result of the form $\mathsf{LCL}[\omega(1)] = \mathsf{CL}$ is out of reach.

We also show that our proof extends to catalytic machines with additional power beyond errors, namely *non-deterministic* and *randomized* catalytic space.

▶ **Theorem 3.** *Let $\mathcal{C} \in \{\mathsf{NCSPACE}, \mathsf{BPCSPACE}\}$, and let $s := s(n), c := c(n), e := e(n)$ be such that $e \leq c^{1-\Omega(1)}$. Then*

$$\mathsf{LC}[s, c, e] = \mathcal{C}[\Theta(s + e \log c), \Theta(c)]$$

We briefly remark that the $e \leq c^{1-\Omega(1)}$ restriction in all our results is only needed to get the constant stretch in the catalytic tape; we discuss the unrestricted setting in Section 3.2.

1.4 Open problems

1.4.1 Errors in expectation

A related question asked in [20] is whether or not CL is equivalent to CL with $O(1)$ errors allowed *in expectation* over all starting catalytic tapes. This represents a different notion of distance between catalytic tapes, in opposition to Hamming distance, that may be more applicable to settings such as quantum computation. This question has received some attention in a related form by Bisoyi et al. [1], who introduce *almost* catalytic machines, which perfectly reset some catalytic tapes and are completely unrestricted on others.

However, no general results are known for expected errors – the results in [1] are very structured – and all techniques in our paper fail to restore the tape in pathological cases where a few starting tapes end up with potentially many errors. Furthermore, a barrier result was pointed out by an anonymous reviewer.[2]

[2] The main idea is that allowing virtually unlimited error in an exponentially small fraction of catalytic tapes gives us a strong form of the "compress-or-random" framework of previous papers; we can simulate

1.4.2 Randomized error-prone catalytic space

Recent work of Cook et al. [6] shows that $\mathsf{CSPACE}[s, c] = \mathsf{BPCSPACE}[O(s), \mathrm{poly}(c)]$, which, in conjunction with Theorem 3, seems to indicate that our theorems can be unified to show the connection between ordinary CSPACE and CSPACE which is both randomized and lossy, i.e. $\mathsf{CSPACE}[s + e \log c, c] = \mathsf{LBPCSPACE}[O(s), \mathrm{poly}(c), e]$. This would characterize how deterministic catalytic space handles both natural kinds of "error", namely both error in the output from the randomness and error in resetting the catalytic tape.

However, the proof of [6] only works when $c = 2^{\Theta(s)}$, and our connection to error-prone space incurs an $e \log c$ blowup in free space, putting us outside this regime. A generalization of their result, i.e. showing $\mathsf{CSPACE}[s, c] = \mathsf{BPCSPACE}[O(s), \mathrm{poly}(c)]$ for *every* s and c, would tie off this connection. Note that the polynomial blowup allowed in the catalytic tape means this result would not yield novel derandomization for ordinary space; even for $s, c = O(\log n)$ this would only show that derandomization overheads can be pushed into a polylogarithmic length catalytic tape, which was already shown by Pyne [22].

1.4.3 Lossy catalytic branching programs

Due to the flexibility in the conditions of Theorem 1, the results of Theorem 3 are likely to extend to other settings catalytic settings; for example, it is immediate to extend both results to CSPACE with *advice*. We focus on non-determinism and randomness simply because these are two of the most well-studied catalytic variants, and future works are free to adapt these proofs to their own settings.

In terms of notable omissions, however, one setting where one direction does not yet extend, and which is very related to advice, is the *catalytic branching program* model, which is a syntactic, and by extension non-uniform, way of capturing CSPACE. The issue here is simply that such machines can read and write their entire work tape in one step, which our simulation of CSPACE by $\mathsf{LCSPACE}$ is unequipped to handle. As we discuss in the full version of this paper, showing such branching programs are *reversible* would be sufficient to close this off.

1.4.4 Exact simulation space requirements

In the current simulation of errors using clean space, we use $4e \log c$ clean space. By contrast, in our simulation of clean space using errors, we use only e more errors. If errors can be simulated in clean space $e \log c$ instead, then there is only very low overhead in switching between the two perspectives. This would tighten the correspondence between errors and space that we establish. However, since the distance between two codewords required to correct e errors is $2e + 1$, a different error correction code would be necessary to reach clean space $e \log c$.

---

a randomized algorithm using the catalytic tape as our source of randomness, and in the exponentially unlikely event the tape is not sufficiently entropic we simply erase it and run brute force. Formalizing this intuition and combining it with the results of [6] gives a derandomization barrier to showing even $\mathsf{LCL}[O(1)] = \mathsf{CL}$, namely that randomized TC^1, which is not known to even be in P, would reduce to the lossy code problem.

2 Preliminaries

We begin by defining catalytic machines as introduced by Buhrman et al. [4].

▶ **Definition 4** (Catalytic space). *A catalytic Turing Machine is a space-bounded Turing machine with two work tapes: 1) a read-write work tape of length $s(n)$ which is initialized to $0^{s(n)}$, and 2) a read-write catalytic tape of length $c(n) \leq 2^{s(n)}$ which is initialized to an arbitrary state $\tau \in \{0,1\}^{c(n)}$. On any input $x \in \{0,1\}^n$ and initial catalytic state τ, a catalytic Turing machine has the property that at the end of the computation on input x, the catalytic tape will be in the initial state τ.*

In this work we focus on a relaxation of catalytic space by Gupta, Jain, and Sharma [16], where we are allowed to make some errors in resetting the catalytic tape.

▶ **Definition 5** (Lossy catalytic space). *A lossy catalytic Turing Machine with $e(n)$ errors is a catalytic machine where at the end of the computation on any input $x \in \{0,1\}^n$ and initial catalytic state τ, instead of requiring that the catalytic tape be in state τ, the catalytic tape can be in any state τ' such that τ and τ' differ in at most $e(n)$ locations.*

Lastly we specify the basic complexity classes arising from our two catalytic definitions, as well as their specification to the "logspace" setting, where most research interest at the moment lies.

▶ **Definition 6.** *We write*

- $\mathsf{CSPACE}[s, c]$*: the class of languages which can be recognized by catalytic Turing Machines with work space $s := s(n)$ and catalytic space $c := c(n)$.*
- $\mathsf{LCSPACE}[s, c, e]$*: the class of languages which can be recognized by lossy catalytic Turing Machines with work space $s := s(n)$, catalytic space $c := c(n)$, and $e := e(n)$ errors.*

We additionally write

- $\mathsf{CL} := \mathsf{CSPACE}[O(\log n), \operatorname{poly} n]$
- $\mathsf{LCL}[e] := \mathsf{LCSPACE}[O(\log n), \operatorname{poly} n, e]$

We note that throughout this paper we write $\mathcal{C}[O(f(n))]$ as a shorthand for $\bigcup_{c\in\mathbb{N}} \mathcal{C}[c \cdot f(n)]$ for complexity class $\mathcal{C}$ and function $f(n)$, and similarly for classes with multiple parameters or other asymptotics (e.g. $\mathsf{CSPACE}[\Theta(s), \Theta(c)]$).

3 Main theorem

In this section we will prove Theorem 1. We will do so via a simulation argument for each direction in turn.

3.1 Simulating errors with space

First, we show that $\mathsf{LCSPACE}[s, c, e] \subseteq \mathsf{CSPACE}[O(s + e \log c), O(c)]$. In fact, we will not need any increase in the length of our catalytic tape.

▶ **Theorem 7.** *Let $s := s(n), c := c(n), e := e(n)$. Then*

$$\mathsf{LCSPACE}[s, c, e] \subseteq \mathsf{CSPACE}[s + O(e \log c), c]$$

We note that this was also proven in [16] for the case of $\mathsf{LCL}[O(1)]$, but we will pursue a different proof, based on error-correcting codes, which will allow us to generalize to other catalytic models in Section 4.

Proof. Let M_e be an $\mathsf{LCSPACE}[s, c, e]$ machine. We will devise a $\mathsf{CSPACE}[s + O(e \log c), c]$ machine M_0 which simulates M_e. Note that in this section, we will not use our parameter restriction on e; this direction holds for every setting of s, c, and e. We will presume that $e \leq \frac{c}{\log(c)}$, as the inclusion becomes trivial otherwise.

Our simulation will go via an error-correcting code. In particular we will use *BCH codes*[3] (BCH), named after Bose, Ray-Chaudhuri, and Hocquenghem [3, 17], which we define as per [13, 12]. We define the mapping BCH and prove the following lemma in the appendix to the the full version of our paper.

▶ **Lemma 8.** *Let $q := 2^{\lceil \log(c+e) \rceil}$. There exists a mapping $\mathsf{BCH} : \mathbb{F}_q^q \to \mathbb{F}_q^q$ with the following operations:*

- ***Encoding:*** $\mathsf{Enc}_{\mathsf{BCH}}$ *takes as input a string S of length c, plus an additional $(2e+1)\lceil \log(c+e) \rceil$ bits initialized in 0, and outputs a codeword S_{enc}:*

  $$S + [0]_{(2e+1)\lceil \log(c+e) \rceil} \to_{\mathsf{Enc}} S_{enc}$$

  Furthermore, all outputs S_{enc} generated this way have minimum distance $\delta := 2e+1$ from one another.
- ***Decoding:*** $\mathsf{Dec}_{\mathsf{BCH}}$ *takes as input a string S'_{enc} of length $c + (2e+1)\log(c+e)$, with the promise that there exists a string S of length c such that $\mathsf{Enc}_{\mathsf{BCH}}(S + [0]_{2e \log(c+e)})$ differs from S'_{enc} in at most $\delta/2 - 1 = e$ locations, and outputs this string S:*

  $$S'_{enc} \to_{\mathsf{Dec}} S + [0]_{(2e+1)\log(c+e)}$$

Furthermore, both $\mathsf{Enc}_{\mathsf{BCH}}$ and $\mathsf{Dec}_{\mathsf{BCH}}$ are in place replacements of the input strings, they require at most an additional $O(e \log c)$ free space of memory.

We now move on to the simulation of our $\mathsf{LCSPACE}[s, c, e]$ machine M_e. Our $\mathsf{CSPACE}[s + O(e \log c), c]$ machine M_0 acts as follows:

1. **Initialization:** use the function $\mathsf{Enc}_{\mathsf{BCH}}$ to encode the initial state τ of the catalytic tape into a codeword, using $(2e+1)\lceil \log(c+e) \rceil$ additional bits from clean space,

   $$\tau + [0]_{(2e+1)\lceil \log(c+e) \rceil} \to_{\mathsf{Enc}} \tau_{enc}.$$

2. **Simulation:** Run M_e using clean space s and the first c bits of τ_{enc} as the catalytic tape. When M_e finishes the calculation, we record the answer in a bit of the free work tape. The catalytic tape is, at this point, in a state τ'_{enc} which differs in at most e locations from τ_{enc}.
3. **Cleanup:** use the function $\mathsf{Dec}_{\mathsf{BCH}}$ to detect and correct our resulting catalytic tape τ'_{enc}:

   $$\tau'_{enc} \to_{\mathsf{Dec}} \tau + [0]_{(2e+1)\lceil \log(c+e) \rceil}$$

   Once we finish this process, we output our saved answer and halt.

The correctness of M_0 is clear, as it gives the same output as M_e. By our error guarantee on M_e and the correctness of Dec, our catalytic tape is successfully reset to τ. Our catalytic memory is c as before, while for our free work space we require s bits to simulate M_e, an additional $(2e+1)\lceil \log(c+e) \rceil = (2 + o(1))e \log c$ zero bits for our codewords, and $O(e \log c)$ space for $\mathsf{Enc}_{\mathsf{BCH}}$ and $\mathsf{Dec}_{\mathsf{BCH}}$, for $s + O(e \log c)$ space in total. ◀

[3] Technically because of our parameters, they can even be considered Reed-Solomon codes, which are a special case of BCH codes; nevertheless we follow the presentation of the more general code form.

▶ Note 9. There is an alternative proof of this point, one which gets better parameters and relies on an interesting characterization of space, namely the *reversibility* of space. This proof is a simplification and extension of the one originally provided in [16], and we provide it in the appendix to the full version of our paper for those interested.

3.2 Simulating space with errors

We now show the other direction of Theorem 1, i.e. $\mathsf{CSPACE}[s + e\log c, c]$ is contained in $\mathsf{LCSPACE}[O(s), O(c), O(e)]$.

▶ **Theorem 10.** *Let $s := s(n), c := c(n), e := e(n)$, and $\epsilon > 0$ be such that $e = o(c^{\epsilon/(1+\epsilon)})$. Then*

$$\mathsf{CSPACE}[s + e\log c, c] \subseteq \mathsf{LCSPACE}[s + \log c, (1 + o(1))c, (1 + \epsilon)e]$$

Since $s \geq \log c$ by the definition of a catalytic machine, this achieves the reverse direction of Theorem 1 with very small blowups in s and c, and for e bounded by a small polynomial in c we get a negligible error blowup as well. Note that we allow $\epsilon > 1$, and so our proof is not limited to $e < c^{1/2}$; however, we will pay for larger values of e in the error blowup, and for $e = c^{1-o(1)}$ this factor becomes superconstant.

To understand our construction, we will first prove a version with looser space parameters. This result is incomparable to Theorem 10; although we lose a factor of e in our catalytic space, in exchange we have no restrictions on e and no loss in e either.

▶ **Theorem 11.** *Let $s := s(n), c := c(n), e := e(n)$ be such that c is a power of 2. Then*

$$\mathsf{CSPACE}[s + e\log c, c] \subseteq \mathsf{LCSPACE}[s + (\log e + \log c + 2), (e + 1)c, e]$$

Proof. Let M_0 be a $\mathsf{CSPACE}[s + e\log c, c]$ machine. We will devise a $\mathsf{LCSPACE}[s + (\log e + \log c + 2), (e+1)c, e]$ machine M_e which simulates M_0. By the definition of a Turing machine, we will assume that in any time step M_0 only reads and writes at most one bit on the work tape.

Throughout this proof, we will associate $[2^k]$ with $\{0,1\}^k$ in the usual manner, i.e. subtracting 1 and taking the binary representation, and so we will use them interchangeably. Our workhorse is the following folklore[4] construction:

▶ **Lemma 12.** *For every k, there exists a mapping $\mathsf{mem} : \{0,1\}^{2^k} \to \{0,1\}^k$, computable in space $k + 1$, such that the following holds: for any $\tau \in \{0,1\}^{2^k}$ and any $y \in \{0,1\}^k$,*

$$\mathsf{mem}(\tau \oplus \sigma_y) = \mathsf{mem}(\tau) \oplus y$$

where σ_y is the vector of length 2^k with a single 1 in position y.

Intuitively, Lemma 12 gives us an easily computable mapping where any transformation of the k-bit output string can be achieved by flipping one bit of the 2^k-bit input string, with the location of this single bitflip being determined only by the locations where the current and target output strings differ.[5]

[4] This construction is based on the solution to the so-called "almost impossible chessboard puzzle"; interested readers can find the setup and solution in videos on the YouTube channels 3Blue1Brown (`https://www.youtube.com/watch?v=wTJI_WuZSwE`) and Stand-up Maths (`https://www.youtube.com/watch?v=as7Gkm7Y7h4`). It can also be seen as the syndrome of the Hamming code.

[5] It is not particularly important that the location to flip in τ to achieve $\mathsf{mem}(\tau) \oplus y$ is exactly σ_y, but only that there exists *some* such place to flip, depending only on the mask y, and that this location can be easily calculated given y.

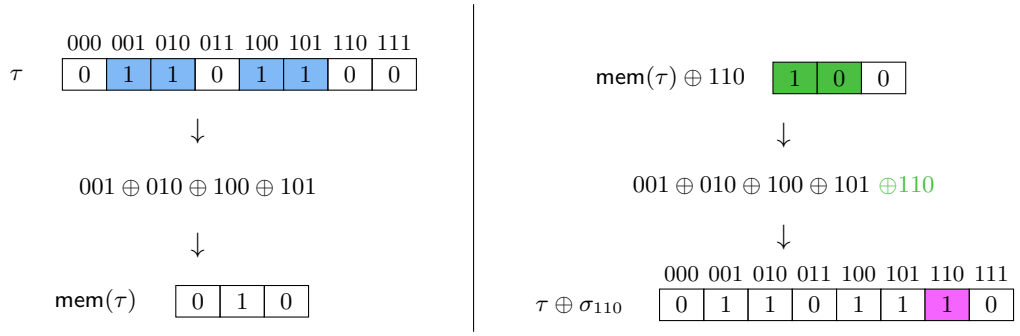

Figure 1 Example of our construction in Lemma 12 for $k = 3$ and $\tau = 01101100$: 1) calculating $\mathsf{mem}(\tau)$ based on the positions of the 1s in τ (blue); 2) how flipping one bit of τ (magenta) allows us to change $\mathsf{mem}(\tau)$ (changes in green).

Proof of Lemma 12. Let $\tau \in \{0,1\}^{2^k}$ be indexed by bitstrings $z \in \{0,1\}^k$. We will define our mapping mem as the entrywise sum of all indices z where $\tau_z = 1$, i.e.

$$\mathsf{mem}(\tau)_j = \bigoplus_{\substack{z \in \{0,1\}^k \\ z_j = 1}} \tau_z$$

This is clearly computable in space $k+1$, as we need only store z and our current sum. Now note that for any y, flipping the entry τ_y, i.e. $\tau \oplus \sigma_y$, flips every $\mathsf{mem}(\tau)_j$ entry where $y_j = 1$ and leaves all other $\mathsf{mem}(\tau)_j$ entry unchanged, which gives $\mathsf{mem}(\tau) \oplus y$ as claimed. ◀

At a high level, our $\mathsf{LCSPACE}[s + (\log e + \log c + 2), (e+1)c, e]$ machine M_e works as follows. M_e will use its s bits of free memory and the first c bits of catalytic memory to represent their equivalent blocks in M_0, i.e. s bits of free memory and c bits of catalytic memory. We will break the remaining $e \cdot c$ bits of our catalytic tape of M_e into e blocks $B_1 \dots B_e$ of size c each, and we denote by τ_i the memory in block B_i. We apply Lemma 12 with $k = \log c$ – recall that we assume c is a power of 2 – and use each $\mathsf{mem}(\tau_i)$ to represent an additional $\log c$ bits of free memory, giving us an additional $e \log c$ bits of memory in total. Our additional workplace memory will be used to compute the mapping, serve as pointers, and other assorted tasks.

Before formally stating M_e, we mention a special case of the construction of Lemma 12, which will allow us to use it in a reversible operational manner.

▷ Claim 13. Let $\tau_0, \tau_1, \tau_2 \dots \tau_{t-1}, \tau_t \in \{0,1\}^{2^k}$ be such that 1) τ_i and τ_{i-1} differ in exactly one coordinate for all $i \in [t]$; 2) $\mathsf{mem}(\tau_i)$ and $\mathsf{mem}(\tau_{i-1})$ differ in exactly one coordinate for all $i \in [t]$; and 3) $\mathsf{mem}(\tau_t) = \mathsf{mem}(\tau_0)$. Then $\tau_t = \tau_0$.

Proof. For all $i \in [t]$, let $b_i \in [k]$ be the location where $\mathsf{mem}(\tau_i)$ and $\mathsf{mem}(\tau_{i-1})$ differ, and let β_i be the location where τ_i and τ_{i-1} differ. Since $\mathsf{mem}(\tau_t) = \mathsf{mem}(\tau_0)$, each value $j \in [k]$ must appear an even number of times in the list $b_1 \dots b_t$, and since flipping any location $j \in [k]$ in $\mathsf{mem}(\tau)$ can only be obtained from one flip in τ at the unique location $2^j \in [2^k]$, it follows that each value $J \in [2^k]$ must appear an even number of times in the list $\beta_1 \dots \beta_t$. This means that τ_t is τ_0 with each bit flipped an even number of times, or in other words $\tau_t = \tau_0$. ◁

We now concretely define our machine M_e:

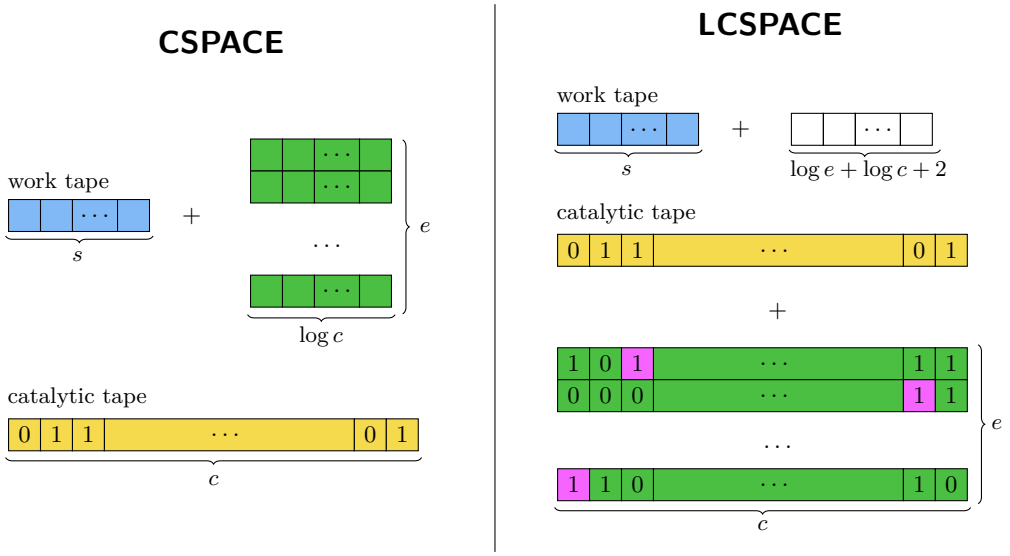

Figure 2 Structure of simulation, where like colors mean space used for same purpose. s bits of work space (blue) and c bits of catalytic space (gold) of the CSPACE machine are directly simulated in the LCSPACE machine, while each $\log c$ length chunk of additional work space of the CSPACE machine (green) is simulated by c catalytic bits and one error (magenta) of the LCSPACE machine. An additional $\log e + \log c + 2$ bits of work memory are used by the LCSPACE machine for scratch work, such as computing mem and addressing into the catalytic memory.

1. **Initialization:** for each block B_i, calculate mem_i and flip the mem_ith element of B_i:

$$\tau_i \to \tau_i \oplus \sigma_{\mathsf{mem}(\tau_i)} \qquad \forall i \in [e]$$

   Define τ_i^{enc} to be the memory after this process. Note that we now have exactly e errors on the tape, one in each τ_i^{enc}, and we are guaranteed that

$$\mathsf{mem}(\tau_i^{enc}) = 0^{\log c} \qquad \forall i \in [e]$$

2. **Simulation:** run M_0 using s free work bits and c catalytic bits, with the concatenation of the values mem_i as the other $e \log c$ free work bits. To do this, whenever we read or write a bit in our $e \log c$ bits of memory, we find the B_i responsible for this bit, calculate mem_i, and update τ_i using one bitflip to reflect how mem_i changes according to the operation of M_0:

$$\tau_i^{enc} \to \tau_i^{enc} \oplus \sigma_{2^j} \qquad \text{update occurs in bit } j \text{ of block } i$$

   If mem_i is unchanged, we make no updates to τ_i.
3. **Cleanup:** when we reach the end of M_0's computation, record the answer on the free work tape and set each mem_i value to $0^{\log c}$ one bit at a time:

$$\tau_i^{enc} \to \tau_i^{enc} \oplus \sigma_{2^j} \qquad \forall i \in [e], j : \mathsf{mem}(\tau_i^{enc}))_j = 1$$

   Once we finish this process, we output our saved answer and halt.

The correctness of M_e is clear, as we output the same value as M_0. Our catalytic space usage is $c + ec$ by construction, while our free space usage is s to simulate M_0, one extra bit to save the output, and any additional space required to handle the simulation of the

additional $e \log c$ work bits. In particular, we need $\log e$ bits for a pointer into B_i and $\log c + 1$ bits for the computation of mem_i by Lemma 12, for a total space usage of $s + \log e + \log c + 2$ as claimed.

We also claim that our lossy catalytic condition is satisfied. By the property of M_0, we make no errors on the c catalytic bits used for the simulation of M_0's catalytic space. The initialization step introduces at most one error per τ_i, thus giving at most e errors on to the catalytic tape. After the initialization step, each other update to τ_i corresponds to changing a single bit in $\mathsf{mem}(\tau_i)$, with the final value being the same as the value after initialization. Thus by Claim 13 we restore the catalytic tape to its position after the initialization phase, and so our end state corresponds to our original catalytic tape with at most e errors, i.e. those induced by the initialization phase, as required. ◀

We now return to Theorem 10, which requires only a small modification of the above proof, namely to break the the catalytic tape into more, smaller blocks, which reduces its required length at the cost of a few extra errors. This modification works because the number of pure bits represented is logarithmic in the length of the block, and so making the blocks smaller barely affects the number of bits represented; for example, $c/2$ bits in a block still lets you represent $\log(c) - 1$ bits, so half the size only loses one bit per block.

Proof of Theorem 10. Let M_0 be a $\mathsf{CSPACE}[s + e \log c, c]$ machine. We will devise a $\mathsf{LCSPACE}[s + e \log c, (1 + o(1))c, (1 + \epsilon)e]$ machine M_e which simulates M_0, where ϵ satisfies $e = o(c^{\epsilon/(1+\epsilon)})$.

An easy manipulation gives us $c = \omega(e^{1+1/\epsilon})$, and so there exists a function $\delta = \omega(1)$ such that $c \geq (\delta e)^{1+1/\epsilon}$. We will have the same approach as Theorem 11, but now we use $(1 + \epsilon)e$ blocks of length $2^{\lceil \log c/(\delta e) \rceil}$ each, i.e., using Lemma 12 for $k = \lceil \log c/(\delta e) \rceil$. Since we introduce one error per block, the number of errors the machine makes is at most $(1 + \epsilon)e$, while our total catalytic tape has length

$$c + (1 + \epsilon)e \cdot 2^{\lceil \log c/(\delta e) \rceil} \leq c + (1 + \epsilon)e \cdot \frac{2c}{\delta e} = c \cdot (1 + o(1))$$

Lastly, we can use our additional catalytic memory to simulate a work tape of length

$$(1 + \epsilon)e \cdot \log 2^{\lceil \log(c/\delta e) \rceil} \geq e \cdot (1 + \epsilon) \log \frac{c}{\delta e}$$

and by manipulating our starting assumption we get that

$$\begin{aligned} c &\geq (\delta e)^{1+1/\epsilon} \\ (c/\delta e)^{\epsilon} &\geq \delta e \\ \epsilon \log(c/\delta e) &\geq \log \delta e \\ \log c - \log \delta e + \epsilon \log(c/\delta e) &\geq \log c \\ e \cdot (1 + \epsilon) \log(c/\delta e) &\geq e \log c \end{aligned}$$

thus giving us a simulation of $e \log c$ work bits as claimed. The correctness and lossy catalytic condition can then be argued as above, and our free space usage is s plus an additional $\log(c \cdot o(1)) + 2 \leq \log c$ bits, for a total space usage of $s + \log c$ as claimed. ◀

4 Further consequences

With this, we have concluded our main theorem and proof. We now move to corollaries and extensions.

4.1 Lossy catalytic logspace with superconstant errors

As stated in the introduction, it immediately follows from Theorem 1 that proving $\mathsf{LCL}[e] = \mathsf{CL}$ is likely difficult, if not false, for superconstant values of e.

Proof of Corollary 2. This follows immediately from the fact that

$$\begin{aligned}\mathsf{LCSPACE}[O(\log n), \operatorname{poly} n, e] &= \mathsf{CSPACE}[O(\log n + e \log(\operatorname{poly} n)), \operatorname{poly} n] \\ &= \mathsf{CSPACE}[O(e \log n), \operatorname{poly} n] \\ &\supseteq \mathsf{SPACE}[O(e \log n)]\end{aligned}$$

combined with the fact that $\mathsf{CL} \subseteq \mathsf{ZPP}$ by [4]. ◀

4.2 Lossy catalytic space with other resources

As mentioned in Section 1, there are many extensions of the base catalytic model besides LCSPACE, such as randomized, non-deterministic, and non-uniform CSPACE. So far, however, there has been little discussion of classes where more than one such external resource has been utilized. In this section, we will discuss two of the aforementioned models – randomized and non-deterministic CSPACE – in the presence of errors.

▶ **Definition 14.** *Let f be a Boolean function on n inputs.*

- *A non-deterministic catalytic Turing machine for f is a catalytic machine M which, in addition to its usual input x, has access to a read-once witness string w, of length at most exponential in the total space of M, based on x, which has the following properties:*
  - *if $f(x) = 1$, then there exists a witness w such that $M(x, w) = 1$*
  - *if $f(x) = 0$, then for every witness string w, $M(x, w) = 0$*

  Furthermore, for every witness string w, $M(x, w)$ restores the catalytic tape to its original configuration.
- *A randomized catalytic Turing machine for f is a catalytic machine M which, in addition to its usual input x, has access to a read-once uniformly random string r, of length at most exponential in the total space of M, such that*

$$\mathbf{Pr}_r[M(x, r) = f(x)] \geq 2/3.$$

  Furthermore, for every witness string w, $M(x, w)$ restores the catalytic tape to its original configuration.

We write

- $\mathsf{NCSPACE}[s, c]$*: the class of languages which can be recognized by non-deterministic catalytic Turing Machines with work space $s := s(n)$ and catalytic space $c := c(n)$.*
- $\mathsf{BPCSPACE}[s, c]$*: the class of languages which can be recognized by randomized catalytic Turing Machines with work space $s := s(n)$ and catalytic space $c := c(n)$.*

Furthermore, for $\mathcal{C} \in \{\mathsf{NCSPACE}, \mathsf{BPCSPACE}\}$, we define $\mathsf{LC}[s, c, e]$ to be the class $\mathcal{C}[s, c]$ with the catalytic resetting definition replaced by the LCSPACE *resetting definition, i.e., where e errors are allowed to remain on the catalytic tape at the end of any computation.*

Note that we allow the errors to depend on the witness and randomness, respectively. Without delving too deep into these models, however, it is clear that our proof of Theorem 1 carries over to all the above definitions.

Proof sketch of Theorem 3. As earlier, we need to show both directions. We will prove the same two equivalences as in Theorems 7 and 10, namely

1. $\mathsf{L}\mathcal{C}[s, c, e] \subseteq \mathcal{C}[s + O(e \log c), c]$
2. $\mathcal{C}[s + e \log c, c] \subseteq \mathsf{L}\mathcal{C}[s + \log c, (1 + o(1))c, (1 + \epsilon)e]$

Both directions will follow immediately via the same simulation as before. For the forward direction, we simulate our $\mathsf{L}\mathcal{C}$ machine by a $\mathcal{C}$ machine as usual, and then at the last step we correct the changes using our BCH code as before; this works just as before because the code allow us to correct any e errors on the catalytic tape, regardless of how they came about.

For the reverse direction, again our $\mathcal{C}$ machine will only read or write one bit per time step, and so we use the same mem_i approach to simulating our additional $e \log c$ bits of free memory, which does not change based on the operation of the rest of the machine. As in the forward direction, simulating the actual workings of the $\mathcal{C}$ machine via the $\mathsf{L}\mathcal{C}$ machine, given our method of simulating the $e \log c$ additional bits of memory, is straightforward, and our resetting step at the end again resets our extra catalytic tape regardless of the computation path the $\mathcal{C}$ machine takes. ◀

Abstract

The parameterized analysis of graph modification problems represents the most extensively studied area within Parameterized Complexity. Given a graph G and an integer $k \in \mathbb{N}$ as input, the goal is to determine whether we can perform at most k operations on G to transform it into a graph belonging to a specified graph class $\mathcal{F}$. Typical operations are combinatorial and include vertex deletions and edge deletions, insertions, and contractions. However, in many real-world scenarios, when the input graph is constrained to be a geometric intersection graph, the modification of the graph is influenced by changes in the geometric properties of the underlying objects themselves, rather than by combinatorial modifications. It raises the question of whether vertex deletions or adjacency modifications are necessarily the *most appropriate* modification operations for studying modifications of geometric graphs.

We propose the study of the disk intersection graph modification through the scaling of disks. This operation is typical in the realm of topology control but has not yet been explored in the context of Parameterized Complexity. We design parameterized algorithms and kernels for modifying to the most basic graph classes: edgeless, connected, and acyclic. Our technical contributions encompass a novel combination of linear programming, branching, and kernelization techniques, along with a fresh application of bidimensionality theory to analyze the area covered by disks, which may have broader applicability.

1 Introduction

In a *graph modification problem*, the input consists of an n-vertex graph G and an integer k. The objective is to determine whether k *modification operations* – such as vertex deletions, or edge deletions, insertions or contractions, or combinations thereof – are sufficient to obtain a graph with prescribed structural properties such as being planar, bipartite, chordal, interval, acyclic or edgeless. Graph modification problems encompass some of the fundamental challenges in graph theory and graph algorithms. They represent the most intensively studied area of research within Parameterized Complexity [23, 20, 32, 47, 8, 13, 14, 9, 2, 36, 3, 27, 11, 38, 37] (this list is illustrative rather than comprehensive; see [19, 23, 20, 32] for more information). Here, the number of allowed modifications, k, is considered a *parameter*. With respect to k, we seek a *fixed parameter tractable* (FPT) algorithm, namely, an algorithm whose running time has the form $f(k)n^{\mathcal{O}(1)}$ for some computable function f. It would not be an exaggeration to state that the design of FPT algorithms for graph modification problems has played one of the most central roles in the development of Parameterized Complexity as a field.

In recent years, parametrized analysis of classic graph problems restricted to geometric intersection graphs – that is, where the input graph G belongs to a prespecified class of geometric intersection graphs – has gained a lot of interest. Naturally, particular attention has been given to graph modification problems restricted to geometric intersection graphs. For example, we refer to [4, 41, 42, 33, 35, 31, 21, 29, 45, 28, 22, 10, 30]. While most classic NP-hard graph problems become polynomial-time solvable on proper interval, interval and circular arc graphs, they remain NP-hard on most other geometric intersection graph classes of interest, which gives rise to their parameterized analysis (see the aforementioned papers). Geometric intersection graph classes studied in this context include, for example, unit disk and disk graphs, unit square and square graphs, convex polygon and polygon graphs, map graphs, string graphs, and the generalization of these classes to higher dimensions. However, one central question arises:

> Are vertex deletion and edge deletion/insertion/contraction the *right* modification operations to use when dealing with graph modification problems on geometric intersection graphs?

Geometric intersection graphs naturally give rise to modification operations that are *geometric* – specifically, we modify the graph by modifying its geometric structure! Arguably, the most fundamental operations in this regard are *scaling* and *shifting (i.e., moving)* the input geometric objects.

> In this paper, our primary objective is to launch a systematic investigation into parameterized graph modification problems concerning geometric intersection graphs, utilizing the operation of scaling the input geometric structure. We regard a significant aspect of our contribution as both conceptual and foundational, with the goal of paving the way for this emerging research direction.

1.1 Topology Control and Disk Scaling as a Modification Operation

Topology Control is a fundamental technique used in wireless ad hoc network and sensor networks to reduce energy consumption and radio interference [46]. This technique is used to control the topology of the graph representing the communication links between network nodes. The usual goal is to maintain or achieve some global graph property (like being connected), or reduce interference (i.e., obtain an edgeless graph) while reducing energy consumption. The geometric operation of scaling – i.e., shrinking or expanding radii – of disks has received significant attention within research of wireless network design due to its relevance to power consumption and interference in the networks. From a theoretical perspective, there is also a large body of literature on algorithmic methods for range assignment in wireless sensor and ad-hoc networks, see [39, 17, 12, 15, 48] for a (very incomplete) sample of various approaches, and it is also of interest for other purposes (see, e.g., [1, 24, 7]). Due to this significance, we consider problems that use disk scaling (i.e., shrinking or expanding a subset of disks) in order to achieve certain topological properties in graph. Our work in fact fits in the larger framework of geometric graph modification, which has been a growing trend in recent years.

Recent work on geometric graph modification. Recently, Fomin et al. [26, 25] have studied some problems related to (re)packing of unit disks and point spreading from the perspective of parameterized complexity. Taking a broader perspective, these problems can also be seen as working in the model of geometric graph modification via *geometric operations*, also studied in [17, 5, 16]. Indeed, these papers consider *movement* of points or disks as an operation to achieve intersection graph that is edgeless. In this paper, we focus on *scaling* (i.e., shrinking or expanding) as the operation, and in addition to edgelessness, we also consider acyclicity and connectivity. Another common theme with the work of [25] is that they also combine enumeration of partial solutions from the (partial) kernel, and then reduce the problem to checking a system of polynomial inequalities. This high level scheme is similar to the one described for designing FPT algorithms for Min k-Shrinking to Independence/Acyclicity, where we use an LP. But this similarity is only superficial, and seems unavoidable due to the inherently *continuous nature* of the problems. The specific context, and in particular, the kind of arguments used to arrive at a point where we can use LP, are quite involved, and different from that in [25], as we will explain this further in the following section. Nevertheless, we hope that using geometric operations for graph modification opens up a new research direction, and we return to this topic in the conclusion. Next, we formally introduce our model and problem definitions, and subsequently delve into the overview of our results.

1.2 Problem Definitions

We fix some notation. Let P be a finite family of points in the plane, and $r : P \to \mathbb{R}_{\geq 0}$ be an assignment of points to radii. Then, the disk graph associated with P and R is defined as follows. Let $\mathcal{D}(P, r)$ be a set that contains the disk centered at p with radius $r(p)$ for each $p \in P$, and let $G(P, r)$ denote the disk graph corresponding to $\mathcal{D}(P, r)$, i.e., a graph where we have a vertex for each point in P, and we have an edge between two points if and only if their corresponding disks intersect. Let $\mathbf{1} : P \to \{1\}$ denote the unit radius assignment, and let $G(P, \mathbf{1})$ denote the *unit disk graph* corresponding to a set of points P.

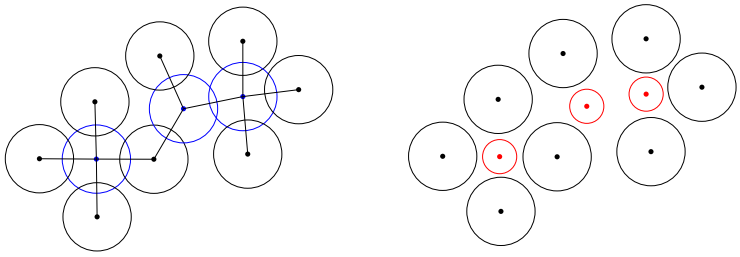

Figure 1 Left: Original intersection graph $G = G(P, \mathbf{1})$ denoting an instance $(P, 1/2, 3)$ of k-Shrinking to Independence. Right: Edgeless graph $G(P, r)$ that shrinks three disks to radius $1/2$ (shown in red).

1.2.1 Shrinking to Achieve Edgelessness and Acyclicity

The first set of problems is related to shrinking a subset of disks in order to achieve two fundamental graph properties, namely, that of being edgeless and acyclic. The general setting is as follows. We are given a unit disk graph $G(P, \mathbf{1})$ corresponding to a set of n points $P \subset \mathbb{R}^2$. We want to *shrink* the disks corresponding to a subset $S \subseteq P$ (i.e., change the radii of disks of each point in S to a value smaller than 1), such that the resulting intersection graph induces an independent set (i.e., is edgeless). We consider two variants of this setting. First, we have a cardinality constrained problem, called k-Shrinking to Independence (see Figure 1).

k-Shrinking to Independence
Input: A finite set of points $P \subset \mathbb{R}^2$, a constant $0 \leq \alpha \leq 1$, and an integer $k \geq 0$.
Task: Decide whether there exists a solution (S, r) such that
1. $S \subseteq P$ is a set of size **at most** k corresponding to shrunken disks,
2. corresponding radii $r : P \to \mathbb{R}_{\geq 0}$ such that $r(p) = \begin{cases} 1 & \text{if } p \notin S \\ \alpha & \text{if } p \in S \end{cases}$
3. $G(P, r)$ is edgeless

We also consider a cost-minimization version of the problem, called Min k-Shrinking to Independence, where the cost of a solution is the total change in the radii, or the sum of *shrinking factors*.

Min k-Shrinking to Independence
Input: A finite set of points $P \subset \mathbb{R}^2$, a constant $0 \leq \alpha \leq 1$, an integer $k \geq 0$, and budget $\mu \geq 0$.
Task: Decide whether there exists a solution (S, r) such that
1. $S \subseteq P$ is a set of size **at most** k corresponding to shrunken disks,
2. corresponding radii $r : P \to \mathbb{R}_{\geq 0}$ where $\begin{cases} r(p) = 1 & \text{if } p \notin S \\ \alpha \leq r(p) \leq 1 & \text{if } p \in S \end{cases}$
3. $G(P, r)$ is edgeless, and
4. $\mathsf{cost}(S, r) := \sum_{p \in S} (1 - r(p)) \leq \mu$.

Analogous to k-Shrinking to Independence, we define k-Shrinking to Acyclicity, where the goal is to achieve $G(P, r)$ that is *acyclic* instead of edgeless (as in item 3 in the definition) (see Figure 2 for an example). Min k-Shrinking to Acyclicity is the

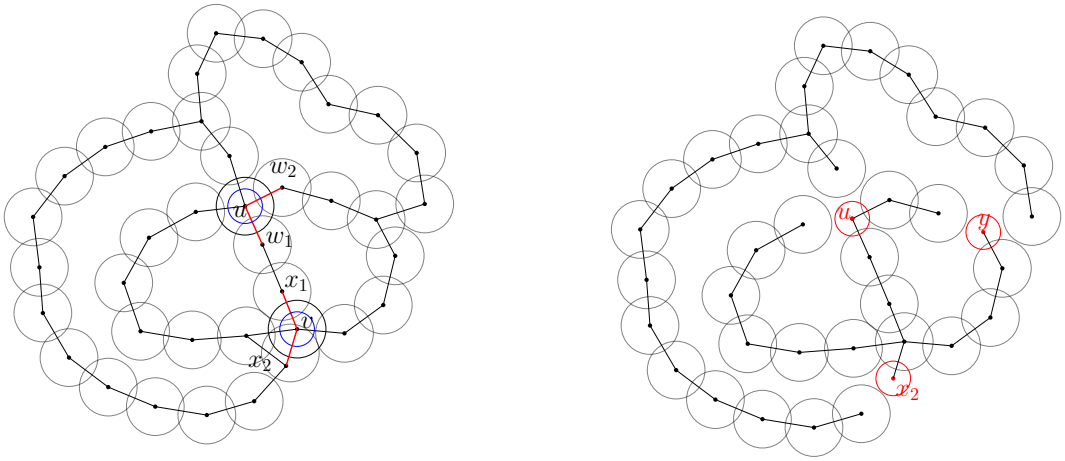

Figure 2 Left: Original intersection graph $G = G(P, \mathbf{1})$ corresponding to an instance $(P, 1/2, 3)$ of k-Shrinking to Acyclicity. Note that $\{u, v\}$ is a minimum feedback vertex set for G. However, even after shrinking the corresponding disks to $1/2$ (shown in blue), the edges $\{uw_1, uw_2, vx_1, v_2\}$ (shown in red) are present in the resulting intersection graph, showing that shrinking disks is not equivalent to vertex deletion. Right: A solution that shrinks three disks (shown in red) to radius $1/2$ corresponding to u, x_2, y, resulting in an acyclic graph $G(P, r)$.

"cost-minimization" version (similar to Min k-Shrinking to Independence), where we want to determine whether we can shrink at most k disks to radii in $[\alpha, 1]$ in order to achieve an acyclic subgraph, such that $\mathsf{cost}(S, r) \leq \mu$.

Note that the operation of shrinking a disk to radius 0 is not necessarily equivalent to deleting the corresponding vertex. Thus, even when $\alpha = 0$, k-Shrinking to Acyclicity (resp. k-Shrinking to Independence) is not exactly equivalent to finding a feedback vertex set (resp. vertex cover) of size k in the original unit disk graph. Nevertheless, we will make use of this connection between the two problems. Now, we turn to the second class of problems considered in this paper.

1.2.2 Shrinking/Expanding to Connectivity

Connectedness is another fundamental graph property in topology control. We consider two variants: shrinking *at least* k disks while *retaining connectivity*, and expanding *at most* k disks to *achieve connectivity*.[1] Next, we define the two problems.

In the first problem, called k-Shrinking to Connectivity[2], we are given a connected unit disk graph $G(P, \mathbf{1})$ corresponding to a set of n points $P \subset \mathbb{R}^2$. We want to *shrink* the disks corresponding to a subset $S \subseteq P$ of size *at least* k (i.e., change the radii of disks corresponding to S to a value smaller than 1), such that the resulting intersection graph *remains* connected.

[1] Observe that expansion versions do not make sense for the problems considered in the earlier section, where we want to obtain an edgeless/acyclic graph – if the graph is not already edgeless/acyclic, one cannot achieve the desired property by expanding a disk.

[2] Ideally, the problem should be named k-Shrinking *While Retaining* Connectivity. However, for the sake of brevity, we stick with k-Shrinking to Connectivity.

k-Shrinking to Connectivity
Input: A finite set of points $P \subset \mathbb{R}^2$, a constant $0 \leq \alpha \leq 1$, and a parameter $k \geq 0$.
Task: Decide whether there exists a solution (S, r) such that
- $S \subseteq P$ is a set of size **at least** k corresponding to shrunken disks,
- corresponding radii $r : P \to \mathbb{R}_{\geq 0}$ such that $r(p) = \begin{cases} 1 & \text{if } p \notin S \\ \alpha & \text{if } p \in S \end{cases}$
- $G(P, r)$ is connected.

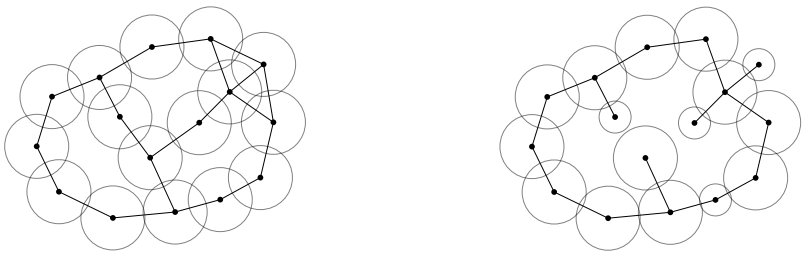

Figure 3 Left: Original intersection graph $G = G(P, \mathbf{1})$ corresponding to an instance $(P, 1/2, 4)$ of k-Shrinking to Connectivity. Right: A solution that shrinks 4 disks to radius $1/2$ while maintaining connectivity in the resulting intersection graph $G(P, r)$.

The next problem, which we call k-Expanding to Connectivity, is in a sense, the "complement version" of k-Shrinking to Independence. Here, we are given a unit disk graph $G(P, \mathbf{1})$ corresponding to a set of n points $P \subseteq \mathbb{R}^2$. We want to *expand* the disks corresponding to a subset $S \subseteq P$ of size at most k (i.e., change the radii of the disks corresponding to S to a value larger than 1), such that the resulting intersection graph *becomes* connected. Formally, the problem is defined as follows.

k-Expanding to Connectivity
Input: A finite set of points $P \subset \mathbb{R}^2$, a constant $\alpha \geq 1$, and a parameter $k \geq 0$.
Task: Decide whether there exists a solution (S, r) such that
- $S \subseteq P$ is a set of size **at most** k corresponding to expanded disks,
- corresponding radii $r : P \to \mathbb{R}_{\geq 0}$ such that $r(p) = \begin{cases} 1 & \text{if } p \notin S \\ \alpha & \text{if } p \in S \end{cases}$
- $G(P, r)$ is connected.

2 Overview of the Technical Results

Our algorithmic technical contribution is, mainly, twofold:

- The first contribution is a novel combination of linear programming, kernelization and branching/exhaustive search: we observe that linear programming can handle continuous domains, kernelization can reduce the search space within these domains, and, when combined with exhaustive search/branching, these can yield the desired solution. While several of our results are based on this approach, we would like to highlight, in particular, the FPT algorithm for k-Shrinking to Acyclicity (see Theorem 8), which exhibits a more intricate combination.

Table 1 A summary of the results in the paper. Additionally, we also show that all of the problems to be NP-hard, which is not mentioned in the table.

Objective	Type of Result	Cardinality version	Cardinality and cost-minimization version
k-Shrinking to Independence	Kernelization	$\mathcal{O}(k)$ partial kernel (Thm. 4), true polynomial kernel (Thm. 5)	$\mathcal{O}(k)$ partial kernel (Thm. 4)
	Parameterized complexity	Subexponential FPT (Thm. 1)	FPT (Thm. 6)
	Approximation	EPTAS (Thm. 10)	Bicriteria EPTAS (Thm. 10)
k-Shrinking to Acyclicity	Kernelization & Compression	True polynomial kernel (Thm. 9)	Partial polynomial compression (Thm. 7)
	Parameterized complexity	Subexponential FPT (Thm. 2)	FPT (Thm. 8)
k-Shrinking to Connectivity	Parameterized complexity	Subexponential FPT (Thm. 3)	–
A generalization of k-Expanding to Connectivity	Parameterized complexity	W[1]-hard (Full version)	–

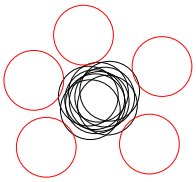
- The second contribution is, in a sense, the first "geometric" use of bidimensionality theory. Here, the application is tied up with the analysis of the different areas covered by disks. We employ this approach to design a subexponential FPT algorithm for k-Shrinking to Connectivity (see Theorem 3).

We believe that our two approaches are quite general in nature, and will be applicable to other parameterized problems that involve placement of geometric objects in the Euclidean space, particularly when dealing with continuous domains. We summarize our results in Table 1. In this extended abstract, we give an in-depth overview of our algorithmic results, and the technical details are deferred to the full version. One remark is that, all of these problems are shown to be NP-hard, and these NP-hardness results are shown via reduction from well-known planar problems, namely, Independent Set, Feedback Vertex Set in planar graphs, and Planar 3-SAT, respectively. Now we turn to the technical overview of the rest of the results.

2.1 Subexponential FPT Algorithms

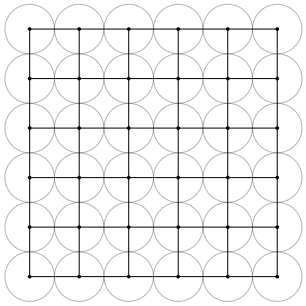
In this section, we discuss the first technical contribution of our paper, namely, to design subexponential FPT algorithms for k-Shrinking to Independence, k-Shrinking to Acyclicity and k-Shrinking to Connectivity (specifically the last problem).

Independence and Acyclicity. Recall that in these problems, the goal is to shrink at most k disks to radius α such that the resulting intersection graph is edgeless (resp. acyclic). For the sake of ease of exposition, let us suppose that α, the radius of the shrunken disks, is a constant. We will start by eliminating *large* cliques, i.e., we show using packing arguments that, if the largest clique in the original intersection graph $G = G(P, \mathbf{1})$ has size $\Omega_\alpha(1)$ [3], then no solution can shrink any subset of disks to radius α and remove all the edges. This bounds



[3] For the sake of simplicity, we use α in the subscript of $\mathcal{O}(\cdot)$ and $\Omega(\cdot)$ notation to suppress the dependence on α in the current overview.

the maximum clique-size. Now, we use *bidimensionality* arguments to show that, either the graph has $\Omega(\sqrt{k}) \times \Omega(\sqrt{k})$ grid as a minor, or the treewidth of the graph is bounded by $\mathcal{O}_\alpha(\sqrt{k})$. In the former case, we can conclude that it is a no-instance, whereas in the latter case we can perform dynamic programming on the tree decomposition of width $\mathcal{O}_\alpha(\sqrt{k})$ to solve the problem. This leads to the following results.



▶ **Theorem 1.** *There exists an algorithm that solves an instance* $\mathcal{I} = (P, k, \alpha)$ *of* k-Shrinking to Independence *in time* $2^{\mathcal{O}((\frac{1}{\alpha})^2\sqrt{k})} \cdot n^{\mathcal{O}(1)}$.

▶ **Theorem 2.** *There exists an algorithm that solves an instance* $\mathcal{I} = (P, k, \alpha)$ *of* k-Shrinking to Acyclicity *in time* $(\frac{1}{\alpha}k)^{\mathcal{O}((\frac{1}{\alpha})^2\sqrt{k})} \cdot n^{\mathcal{O}(1)}$.

Connectivity. Now we turn to the subexponential FPT algorithm for k-Shrinking to Connectivity, which is one of the main results of the paper. This algorithm also begins with the elimination of large cliques. However, already for this step, our arguments are substantially more involved compared to all previously known subexponential-time algorithms for problems on geometric intersection graphs that also eliminate large cliques (see, e.g., [31, 29, 28, 30, 40]). Specifically, for all of these problems, the existence of a large clique trivially implies that we have a yes-instance (or a no-instance) at hand. However, for k-Shrinking to Connectivity, the proof is more complicated. Further, and perhaps more importantly, even once we have proved that every optimal solution contains "most" vertices of a clique, and we have "guessed" (by branching) which these vertices are, we can neither shrink their corresponding disks (since then, we might be left with a clique just as large as it was before) nor delete them. In particular, deletion is incorrect since it might turn a no-instance into a yes-instance, and vice versa (see Figure 4a). Fortunately, we are able to prove that it is possible to delete all of the guessed set except for a carefully chosen subset of a few representatives from it.

(a) There is a solution that shrinks some of the disks in the clique; however, shrinking *all* the disks in the clique results in the disconnected graph (due to the red disks).

(b) Each disk corresponding to the vertices of the grid minor is "touching" its neighbors, and shrinking any of the disks results in a disconnected graph.

Figure 4 Illustrative figures for k-Shrinking to Connectivity.

The next step of our proof handles cycles (or, more precisely, closed walks) that we term *non-empty*. Specifically, we denote some disks as unshrinkable; at the beginning, these are simply the disks that cannot be shrunk without violating connectivity. Then, for a cycle, we consider the "area that it encloses", and identify two sets of disks of interest: the disks intersecting this area (the *relevant set*), and the disks strictly in the interior of this area (the *interior set*). If all the disks in the relevant set are unshrinkable, then the cycle is termed

unshrinkable, and if the interior set is non-empty, then the cycle is termed non-empty. Then, we prove that, given an unshrinkable cycle, it is safe to delete its entire interior set (which, in case of a non-empty cycle, yields progress). Additionally, if the interior set of a cycle is non-empty and contains a shrinkable disk, then the cycle is called *reducible*; we note that a shrinkable non-empty cycle might *not* be reducible. We prove that if we have a large enough collection of reducible cycles whose relevant sets are disjoint, then we have a yes-instance at hand.

Thirdly, we turn to deal with the case where we have a large grid as minor – here, it will also become clear why we had to analyze non-empty cycles. Again, let us remark that all previously known subexponential-time algorithms for problems on geometric intersection graphs, when encountering the case of a large grid as a minor, can simply say Yes or No. For us, having a large grid minor does not imply that we have a yes-instance (or a no-instance), although it may seem so at first glance – indeed, we might even be dealing with an "extreme" case where all of the disks that compose the grid minor are unshrinkable (see Figure 4b). To overcome this difficulty, first of all, we do not consider just any grid minor, but a grid minor such that the closed walks corresponding (according to the minor model) to its 4-cycles have some particular embedding on the plane. Then, we are able to show that within such a grid minor, one can identify either an unshrinkable non-empty closed walk (and, then, apply a reduction rule) or a large enough collection of reducible cycles whose relevant sets are disjoint (and, then, output Yes and terminate). Putting everything together, our algorithm works as follows. As long as we have a large clique, we branch to eliminate most of it. Then, based on a known result, we know that either we have a large grid minor of a particular form (and, then, proceed as described in the previous paragraph) or that the treewidth of the graph is small. In this latter case, we can simply use dynamic programming to directly solve the problem. Thus, we obtain the following result.

▶ **Theorem 3.** *There exists an algorithm that solves an instance $\mathcal{I} = (P, k, \alpha)$ of* k-Shrinking to Connectivity *in time* $(\frac{k}{\alpha})^{\mathcal{O}((\frac{1}{\alpha})^2 \cdot k^{3/4})} \cdot n^{\mathcal{O}(1)}$.

Expanding to achieve Connectivity. Surprisingly, it turns out that, unlike its shrinking counterpart, a generalization of k-Expanding to Connectivity is W[1]-hard. In this generalization, we may only expand the disks centered at a specified subset of points; whereas the disks centered at the rest of the points are fixed to be unit disks. We show this using a reduction from Covering Points by Unit Disks, which is known to be W[1]-hard [43]. This result shows that not all natural problems of interest in this geometric graph modification model are fixed-parameter tractable. [4]

2.2 Polynomial Kernels and Compressions and their Consequences

Now we discuss our results regarding polynomial kernels and compressions for k-Shrinking to Independence/Acyclicity and their minimization variants. We also discuss how these results also enable us to design FPT algorithms for the minimization variants, using a combination of partial enumeration of the solution space of the kernels, and linear

[4] We remark that our algorithmic results (FPT algorithms, kernels, etc.) for the other problems – namely, k-Shrinking to Independence/Acyclicity/Connectivityand their variants – also hold for such a generalization, where a subset of disks cannot be shrunk. In fact, our algorithm for k-Shrinking to Independence supposes the presence of unshrinkable disks, as there, specifically, it simplifies the write-up. Thus, the preceding remark remains valid. However, for the sake of simplicity of presentation of the other results, we decided to stick with the special cases where any disks can be shrunk.

programming. Note that the subexponential FPT algorithms for k-Shrinking to Independence/Acyclicity discussed in the previous section work directly on the original instances and do not rely on the kernels.

2.2.1 (Min) k-Shrinking to Independence

We show the following result.

▶ **Theorem 4.** [Informal] *There exists a partial kernel for k-Shrinking to Independence (resp. for Min k-Shrinking to Independence), where the number of points in the resulting instance is $\mathcal{O}(k)$.*

Note that in this result, we are only able to bound the number of points in the resulting instance by $\mathcal{O}(k)$. However, the number of bits required to encode the coordinates of each point may still be unbounded. Therefore, we only obtain a *partial kernel* for these two problems.

Since k-Shrinking to Independence is a "discrete" problem, we can in fact extend this argument to obtain a (fully) polynomial kernel. Here, we need to additionally show that the geometric information that is relevant for solving k-Shrinking to Independence can be encoded using polynomially many bits in k. Thus, we obtain the following result.

▶ **Theorem 5.** *There exists a (true) polynomial kernel for k-Shrinking to Independence, paramterized by k.*

FPT Algorithm for Min k-Shrinking to Independence. Note that usually the existence of (partial) kernels is sufficient to immediately conclude that the problem is FPT by enumerating all possible solutions. However, for the case of Min k-Shrinking to Independence, even if one fixes a subset of disks of size k to be shrunk (i.e., a *partial solution*), the new radius of each disk is a real number in the range $[\alpha, 1]$. Thus, the number of possible solutions is infinite. Here, we enumerate all partial solutions, and use *linear programming* [5] to check whether there exists a radius assignment of cost at most μ, resulting in an edgeless graph. Thus, we obtain the following result.

▶ **Theorem 6.** *There exists an algorithm that decides an instance $\mathcal{I} = (P, k, \alpha, \mu)$ of* Min k-Shrinking to Independence *in time $k^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$. Additionally, if $\mathcal{I}$ is a yes-instance, the algorithm can return an* optimal solution *for $\mathcal{I}$.*

2.2.2 (Min) k-Shrinking to Acyclicity

We first give an overview of our result regarding the (partial) polynomial compressibility of Min k-Shrinking to Acyclicity, which, along with the FPT algorithm for the problem (as stated subsequently) is the second main result of the paper.

▶ **Theorem 7** (Informal)**.** *There exists a partial polynomial compression for* Min k-Shrinking to Acyclicity *into an annotated graph problem, where the size of the resulting instance is bounded by a polynomial in k, assuming each real number in the instance can be stored using $\mathcal{O}(1)$ bits.*

[5] Since our LP involves real numbers, we cannot use standard LP solvers that run in (weakly) polynomial time. However, since we work in Real RAM model, we can use an algebraic LP solver such as [18, 44] to find an optimum solution, resulting in the algorithm with the claimed running time bound. We thank a reviewer for pointing this out. More details on this can be found in the full version.

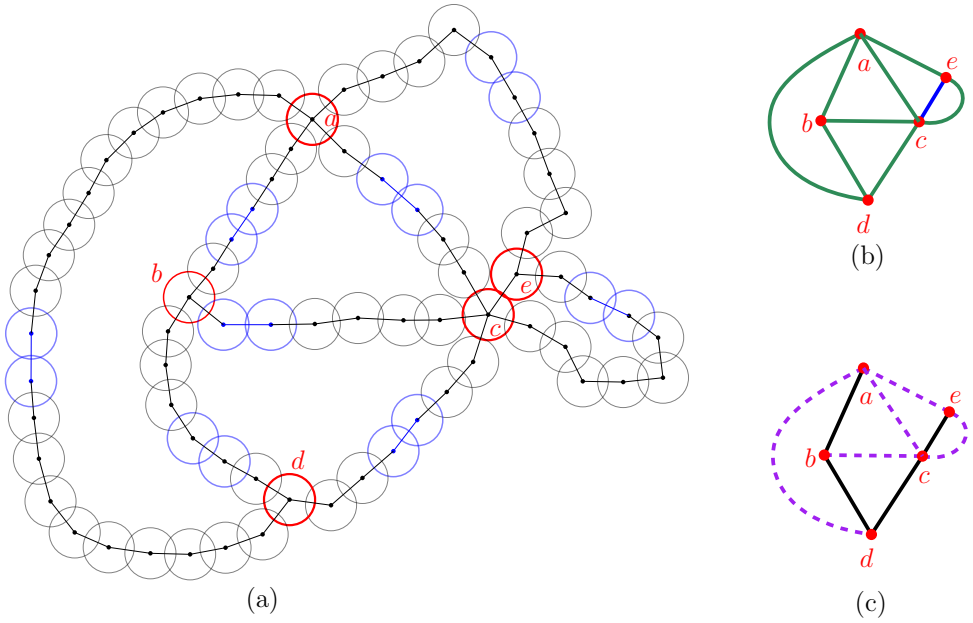


Figure 5 (a) Given intersection graph after removing the vertices of degree at most 1. Vertices of degree at least 3 are shown in red. (b) Resulting multigraph H on vertices of degree at least 3, obtained after replacing degree-2 paths with reducible edges (shown in green) and one of the two edges ce is an original edge (blue). Annotations of green edges include, for example, distance between farthest pairs of disks in the corresponding path (shown in blue in figure (a)). (c) A particular guess for the edges of R (dashed purple), such that $H - R$ (graph induced on black edges) is acyclic. For each edge of R, we guess the number of disks that will be shrunk to remove this edge. Then, an optimal values of the shrunk radii that is compatible with this guess is found using linear programming. For example, such a solution may shrink the disk centered at c (removing bc, ac), e (removing ae and together with c, the edge ce), and the two blue disks in the path corresponding to ad.

We first state relatively straightforward reduction rules. First, we argue that, if any vertex in the initial intersection graph has a "large" degree (i.e., larger than some ck), then it implies the existence of a clique of size at least $k+3$ – note that no solution that is allowed to shrink at most k disks can remove all the edges of such a clique, which implies that we have a no-instance. Thus, either the maximum degree in the given intersection graph is bounded by $\mathcal{O}(k)$, or we can say No. Further, we can safely delete all vertices of degree at most one as well as acyclic components from the graph. So far, these arguments bear resemblance to those used to obtain a polynomial kernel for Feedback Vertex Set. From this point onward, however, we deviate significantly from the standard arguments, and need to rely on the inherent geometric nature of the problem.

We now handle each connected component of the graph separately. If a connected component is a simple cycle, then observe that an optimal solution shrinks either one or two disks, depending on the distances between the consecutive vertices in the cycle. We can compute the optimal choice and get rid of all such isolated cycles. Next, we aim to handle "long" degree-2 paths in a component. Note that an optimal solution shrinks $\ell \leq 2$ disks from such a path. We replace such a path in the intersection graph with a single edge, called a *reducible edge*, that is annotated with an optimal choice for shrinking $0 \leq \ell \leq 2$ disks from the original path. The remaining edges in the graph are *original* edges, and we annotate each edge with the Euclidean distance between its two endpoints.

Thus, we obtain a graph H (in fact, in the actual construction it will be a multigraph). Further, the minimum degree of H is 3, and the maximum degree of H is $\mathcal{O}(k)$. At this point, we can argue that, if the given instance is a yes-instance, then $|V(H)| = \mathcal{O}(k^2)$ and $|E(H)| = \mathcal{O}(k^3)$. The task of determining whether the original instance is a yes-instance of Min k-Shrinking to Acyclicity is equivalent to determining whether H is a yes-instance of an appropriately defined graph problem, say Π. Note that although the size of H is bounded by $\mathcal{O}(k^3)$, the edges of H are annotated with relevant distances denoting optimal choices, and thus can be real numbers in general. Thus, we can only infer a (partial) polynomial compression from Min k-Shrinking to Acyclicity into Π.

We can use the compressed instance of Π to design an FPT algorithm for Min k-Shrinking to Acyclicity, as follows. Recall that $|V(H)| = \mathcal{O}(k^2)$ and $|E(H)| = \mathcal{O}(k^3)$. Thus, any acyclic subgraph of H with vertex set $V(H)$ must contain at most $|V(H)| - 1 = \mathcal{O}(k^2)$ edges. We iterate over all such edge sets $F \subseteq E(H)$ inducing an acyclic subgraph – note that there are at most $k^{\mathcal{O}(k^2)}$ guesses. This implies that each edge in $R = E(H) \setminus F$ must be removed by the solution; note that $|R| = \mathcal{O}(k^3)$. Further, an original edge of R can be removed by shrinking either one or both of its endpoints (3 choices), whereas a reducible edge can be removed by shrinking 1 or 2 disks in the corresponding path, and these choices are encoded in the annotation. Thus, there are a constant number of choices for removal of each edge of R, which results in $2^{\mathcal{O}(k^3)}$ further guesses. For each set of guesses, we can determine an optimal choice for each such guess using the annotated information, and formulate a linear program (LP) that captures the best choices. By solving the LP, in time $2^{\mathcal{O}(k^3 \log k)}$, we can find a minimum-cost solution that shrinks at most k disks that is compatible with all the shrinking choices, if one exists. Finally, we return the best solution found over all $2^{\mathcal{O}(k^3)}$ guesses, which leads to the following result.

▶ **Theorem 8.** *There exists an algorithm that takes as an input of* Min k-Shrinking to Acyclicity*, and in time* $2^{\mathcal{O}(k^3 \log k)} \cdot n^{\mathcal{O}(1)}$ *time, either correctly concludes that it is a no-instance; or finds a solution of the smallest cost that shrinks at most k disks.*

The aforementioned approach also yields a polynomial compression for k-Shrinking to Acyclicity into an intermediate multigraph problem. However, since k-Shrinking to Acyclicity is a "discrete" problem, one can, in fact, encode all the relevant geometric information using polynomially bits in k, resulting in a polynomial kernel for the problem.

▶ **Theorem 9.** *There exists a polynomial kernel for* k-Shrinking to Acyclicity *parameterized by the number of disks k that one is allowed to shrink.*

2.3 Approximation Schemes for (Min) k-Shrinking to Independence

Finally, we design EPTASes, i.e., efficient polynomial-time approximation schemes for (Min) k-Shrinking to Independence. For k-Shrinking to Independence, for a fixed $\varepsilon > 0$, our algorithm either correctly concludes that the given instance is a no-instance, or returns a solution that shrinks at most $(1 + \varepsilon)k$ disks to radius α. For Min k-Shrinking to Independence, our algorithm returns a *bicriteria* EPTAS. That is, it either correctly concludes that the given instance is a no-instance, or returns a solution of cost at most $(1+\varepsilon)\mu$ that shrinks at most $(1+\varepsilon)k$ disks to a radius in $[\alpha, 1]$. Thus, we obtain the following theorem.

▶ **Theorem 10.** *There exists a bicriteria EPTAS (resp. EPTAS) for* Min k-Shrinking to Independence *(resp.* k-Shrinking to Independence*) running in time* $2^{\mathcal{O}(\frac{1}{\varepsilon}\log(\frac{1}{\varepsilon}))} \cdot n^{\mathcal{O}(1)}$.

These results are obtained using the well-known *shifting technique* [6, 34] to reduce the problem to bounded-size instances, at the expense of a small loss in the approximation factor. Each bounded-size instance is then solved optimally. We give an overview for our bicriteria EPTAS for Min k-Shrinking to Independence where the arguments are more involved; those for k-Shrinking to Independence are relatively simpler. First, we subdivide the instance into sub-instances induced by $\mathcal{O}(1/\varepsilon) \times \mathcal{O}(1/\varepsilon)$ squares, such that the number of optimal disks intersecting the boundaries of the squares is at most εk, and the total sum of changes in the radii of such disks is at most $\varepsilon\mu$. In order to solve each subproblem, we further partition the square into smaller grid cells, such that each cell induces a clique in the given UDG. If such a clique contains at most c/ε disks, then we guess the exact subset of disks that are shrunk by an optimal solution. Otherwise, if the clique contains more than c/ε disks, then we mark all disks as *potentially shrinkable*. Note that all except at most one disk from each clique must be shrunk by any solution. Thus, we can argue that the total number of disks that are shrunk in the latter case is at most εk. Now, for each guess of the *potentially shrinkable disks*, we use linear programming to find an optimal solution that is only allowed to shrink the potentially shrinkable disks, in order to result in an edgeless graph. Finally, we need to combine the solutions of subproblems in a careful manner – since the disks near the boundaries of the cell appear in multiple subproblems. We achieve this using dynamic programming over the optimal solutions computed for the bounded-size instances.

As mentioned earlier, we defer the formal descriptions of algorithmic and hardness results to the full version. We proceed directly to the conclusion and directions for future research.

3 Conclusion and Future Research

In this paper, we initiated the study of graph modification by *scaling of disks* from the perspective of Parameterized Complexity. Specifically, we focused on modifying the connectivity properties of the graph while shrinking or expanding a subset of disks. The (Min) k-Shrinking to Independence/Acyclicity problems correspond to shrinking at most k disks to achieve a completely disconnected (i.e., edgeless), and minimally connected (i.e., acyclic) intersection graph, respectively. Whereas k-Shrinking to Connectivity (resp. k-Expanding to Connectivity) corresponds to shrinking at least (resp. at most) k disks while retaining (resp. achieving) connectivity in the intersection graph.

Besides our NP/W[1]-hardness results for the above problems, we also gave several algorithmic results. For (Min) k-Shrinking to Independence, we designed (partial) polynomial kernels, FPT algorithms, and (bicriteria) approximation schemes. For Min k-Shrinking to Independence, we use a novel combination of linear programming with ideas from parameterized complexity and geometric approximation respectively. The FPT algorithm is obtained by first using kernelization to derive a bounded-size instance, and then using LP to solve this instance; whereas the approximation algorithm uses a combination of the classical shifting technique along with LP. We also obtained similar results for (Min)k-Shrinking to Acyclicity; however our arguments and techniques are more sophisticated due to "non-local" nature of the problem. Finally, for k-Shrinking to Connectivity, we introduced a novel decomposition theorem that returns a grid minor of the disk graph along with a particular kind of embedding on the plane, and used this theorem to design a subexponential FPT algorithm for the problem. Similar ideas also gave subexponential FPT algorithms for k-Shrinking to Independence/Acyclicity.

Analogous to the results obtained for k-Shrinking to Independence, it is natural to ask whether k-Shrinking to Connectivity admits (partial) polynomial kernel, and approximation schemes. Furthermore, it is also possible to define cost-optimization version of k-Shrinking to Connectivity and study it from the perspective of fixed-parameter and approximation algorithms.

At a broader level, we believe that a significant portion of our contribution lies in the conceptual realm, with the goal of pioneering a new domain within the field of geometric graph modification problems. Furthermore, it opens up a multitude of potential directions for future research. In this context, we propose a few specific avenues to explore.

- **Modification to other graph Classes:** In addition to graph modification to achieve edgelessness or connectivity, it is intriguing to consider modifying the given geometric graph to belong to other families of graphs, such as acyclic graphs (for minimal connectivity assurance), cluster graphs (for clustering purposes), cliques (for direct communication facilitation), and bounded-degree graphs (which generalize edgeless graphs).
- **Various geometric intersection graphs as input:** Our study primarily focused on the simplest geometric intersection graphs, specifically disk graphs, where graph modification problems often become tractable within the realm of Parameterized Complexity despite being NP-hard. Beyond disk graphs, various other geometric intersection graphs, such as string graphs and map graphs, present substantial differences. Additionally, we can extend our investigations to three-dimensional spaces (e.g., unit ball graphs and more general ball graphs). Therefore, a natural research direction is to explore geometric modifications for graph classes within these broader and distinct geometric intersection graph categories.
- **New geometric modification operations:** While we utilized scaling as a quintessential example of a geometric modification operation, other geometric operations, like movement (recently studied in [25, 26]) or rotation, may be more suitable depending on the context and the nature of the geometric objects under consideration. Furthermore, one might contemplate simultaneously shifting, scaling, and rotating objects (or applying any combination of two out of these three operations). This parallels research on graph modification problems where significant efforts have been made to concurrently address edge deletions and insertions. Beyond these combinations, defining and researching other geometric operations can be highly relevant based on the objectives and the class of geometric intersection graphs at hand. This includes operations like smoothing and dimension reduction.
- **Meta-theorems.** While the study of research questions on a problem-to-problem basis can be sometimes challenging, yet interesting in its own right, the ultimate goal is often to prove meta-theorems that simultaneously assert or refute, say, membership in FPT or the existence of a polynomial kernel, for a host of problems. For example, we may claim, for a whole class of problems, that if a specific constraint X in the definition of any problem in the class can be expressed in some logic (e.g., Monadic Second Order Logic), then the problem is FPT, or that if and only if the input graph (or one of the input graphs) has bounded treewidth, then the problem is FPT, or that if the problem admits an OR-cross-composition from an NP-hard problem, then it has no polynomial kernel unless the polynomial hierarchy collapses. We refer to the books [23, 20, 32] for examples of such results. Clearly, after gaining a better understanding of the problem class introduced in this paper, the pursuit of such meta-theorems represents an intriguing avenue for further research.

Combinatorial Pen Testing (Or Consumer Surplus of Deferred-Acceptance Auctions)

Abstract

Pen testing is the problem of selecting high-capacity resources when the only way to measure the capacity of a resource expends its capacity. We have a set of n pens with unknown amounts of ink and our goal is to select a feasible subset of pens maximizing the total ink in them. We are allowed to learn about the ink levels by writing with them, but this uses up ink that was previously in the pens.

We identify optimal and near optimal pen testing algorithms by drawing analogues to auction theoretic frameworks of deferred-acceptance auctions and virtual values. Our framework allows the conversion of any near optimal deferred-acceptance mechanism into a near optimal pen testing algorithm. Moreover, these algorithms guarantee an additional overhead of at most $(1 + o(1)) \ln n$ in the approximation factor to the omniscient algorithm that has access to the ink levels in the pens. We use this framework to give pen testing algorithms for various combinatorial constraints like matroid, knapsack, and general downward-closed constraints, and also for online environments.

1 Introduction

Pen testing is the problem of selecting high capacity resources when the only way to measure the capacity of the resource expends its capacity [23]. We show that any ascending-price auction can be converted into an equivalent pen testing algorithm. We apply the auction theoretic framework of virtual values to identify optimal pen testing algorithms. This connection allows many existing results from auction theory to be applied to pen testing and gives optimal and near optimal pen testing algorithms in combinatorial and online environments.

The pen testing problem of Qiao and Valiant [23] is the following. We have a set of pens with varying amounts of remaining ink and we want to choose a pen with the largest amount of ink left. We have access to the distribution of ink levels in these pens, but we are only allowed to learn about the ink levels by writing with the pens to test them. While writing gives information about whether there is still ink left, it uses up ink that was previously in the pen. Pens that are expended due to testing can be discarded without incurring any penalty. The combinatorial pen testing problem generalizes the pen testing problem to selecting a feasible subset of pens, e.g., according to a matroid or knapsack constraint, to maximize the total remaining ink in the chosen subset.

Deferred-acceptance auctions [21] formalize the notion of ascending-price mechanisms for allocating goods to strategic agents. These are mechanisms that greedily reject the least promising agent by increasing the price for getting allocated at each stage. For instance, to auction off one good, the deferred-acceptance mechanism keeps increasing the price, rejecting agents whenever their value for the good falls below the price until exactly one agent remains in the auction. The *surplus* of the mechanism is the sum of the values of all the allocated agents and the *consumer surplus* is the surplus minus the payments made by the agents.

We provide a black box reduction to convert any surplus optimal (or near optimal) deferred-acceptance auction into an optimal (or near optimal) pen testing algorithm with equivalent performance guarantees. In this reduction, pens and their ink levels are analogous to agents and their values. Payments correspond to the ink used up via testing, and as a consequence, the consumer surplus of the deferred-acceptance auction corresponds to the residual ink in the pen testing environment. Therefore, optimizing residual ink reduces to designing consumer-surplus-optimal deferred-acceptance mechanisms.

Qiao and Valiant [23] propose comparing the performance of a given pen testing algorithm against the *omniscient benchmark*, the performance of an omniscient algorithm that has access to the ink levels in the pens. The omniscient benchmark can thereby choose the optimal feasible subset of pens without having to burn any ink (i.e, payments in the auction environment), and is thus, analogous to the surplus optimal (sealed-bid) mechanism in the corresponding auction environment. Thus, the *omniscient approximation*, the ratio between the omniscient benchmark to the residual ink in the pen testing algorithm, is analogous to the ratio between the optimal surplus and the consumer surplus of the corresponding deferred-acceptance auction.

In the literature, near optimal deferred-acceptance mechanisms are evaluated against optimal (sealed bid) mechanisms, an upper bound to the optimal deferred-acceptance mechanism. Define the *standard benchmark* as the optimal (sealed-bid) mechanism for consumer surplus and let the *standard approximation* $\gamma(n)$ be the ratio between the standard benchmark and the consumer surplus of a given deferred-acceptance mechanism. Note that the standard benchmark does not have a natural pen testing analog, but is a much tighter upper bound on the optimal pen testing algorithm than the omniscient benchmark. Thus, the reduction to deferred-acceptance mechanism design enables a much tighter approximation bound for the optimal pen testing algorithm.

The reduction framework decomposes into two steps for designing near optimal deferred-acceptance mechanisms. One of the two steps involves proving upper bounds on the standard approximation $\gamma(n)$. In the other step, for any given feasibility constraint, we consider the *optimal omniscient approximation*, the ratio between the omniscient benchmark (here, the optimal surplus) and the standard benchmark (here, the optimal consumer surplus). As we will argue in Theorem 1, the omniscient approximation $\pi(n)$ is at most the product $\gamma(n)\,\zeta(n)$ between the two approximation ratios. At a high level, $\gamma(n)$ captures the loss in surplus due to running a deferred-acceptance auction and $\zeta(n)$ captures the loss in surplus due to burning all payments. Beyond consumer surplus optimization, the reduction framework applies more generally to optimization problems with two natural benchmarks, a weaker standard benchmark and much more powerful omniscient benchmark.

▶ **Theorem 1.** *Consider a combinatorial pen testing environment with n pens, the analogous auction environment with an optimal omniscient approximation $\zeta(n)$, and a deferred-acceptance mechanism with a standard approximation equal to $\gamma(n)$. Then, there is a pen testing algorithm that is a $\gamma(n)$-approximation to the standard benchmark and $\pi(n) = \gamma(n)\,\zeta(n)$-approximation to the omniscient benchmark.*

In the first step of our framework, we bound the optimal omniscient approximation $\zeta(n)$ under various feasibility constraints. Generally, remember that the optimal omniscient approximation $\zeta(n)$ is the ratio between the omniscient benchmark and the standard benchmark, and for our specific application, it corresponds to the loss in surplus due to payments getting burnt instead of getting transferred to the auctioneer. We show that $\zeta(n) \leq (1 + o(1)) \ln n$ in any combinatorial environment. Our result tightens the best known upper bound on $\zeta(n)$ for most settings of interest. Fotakis et al. [13] show that the optimal omniscient approximation is at most $\frac{2}{\ln 2}(1 + o(1)) \ln m$, where m is the number of feasible outcomes. Our bound improves their bound by removing the $\frac{2}{\ln 2}$ constant and by replacing m by n, which is usually smaller.[1] Hartline and Roughgarden [18] show that $\zeta(n) \leq \frac{2}{\ln 2}(1 + o(1)) \ln \frac{n}{k}$ when any k out of the n agents can be allocated the good simultaneously, i.e, any k pens can be chosen in the corresponding pen testing environment. We improve their bound by a multiplicative factor of at least $1.36(1 - o(1))$. We also prove that $\zeta(n) \geq (0.577 + \ln \frac{n}{k})$ for the k-identical goods setting, which we show is tight up to $(1 + o(1))$ terms when $k = o(n)$.

Our upper bound for $\zeta(n)$ is via a reduction from multi-agent environments to a single-agent environment, similar in flavour to Feng et al. [12]. In a single-agent environment where the agent is allocated with an ex-ante allocation probability q, we show that the ratio of the optimal surplus to the optimal consumer surplus is at most $1 - \ln q$. Our reduction allows us to convert the $(1 - \ln q)$-approximation in the single-agent setting to a $(1 + o(1) \ln n$-approximation for any multi-agent environment.

We reduce designing multi-agent approximation mechanisms to single-agent approximations with ex-ante constraints q bounded away from 0. The approach is inspired by Feng et al. [12], who prove a similar reduction when the single-agent approximation is bounded above by a constant for all $q \in [0, 1]$. Their approach cannot be directly applied to the optimal omniscient approximation of consumer surplus because the single-agent approximation $(1 - \ln q)$ approaches ∞ as $q \to 0$. We adapt ideas from Hartline and Taggart [17] to prove a reduction to the single-agent setting with an ex-ante constraint $q \in [1/n, 1]$. In this range, the single-agent approximation ratio is at most $(1 + \ln n)$. The resulting construction establishes an optimal omniscient approximation of $(1 + o(1)) \ln n$ for multi-agent environments with arbitrary feasibility constraints.

The second step of the reduction framework from pen testing to deferred-acceptance auctions upper bounds the standard approximation $\gamma(n)$, the ratio between the optimal consumer surplus of a sealed-bid mechanism and the consumer surplus of a given deferred-acceptance auction. Through Myerson's virtual value framework [22], we argue that the above is equivalent to finding an upper bound for the optimal expected surplus divided by the expected surplus of some deferred-acceptance auction. Surplus optimal deferred-acceptance auctions are known for k-identical goods and more general matroid feasibility constraints [21, 4]. We give a 2-approximate deferred-acceptance mechanism for knapsack constraints. Beyond matroids and knapsacks, Feldman et al. [11] give a logarithmic approximate deferred-acceptance auction for any downward-closed feasibility constraint. We observe an inherent downward-closure in the pen testing problem that allows the auction of Feldman et al. [11] to be extended to all combinatorial constraints. The set of pens chosen by any pen testing algorithm can be padded by adding (possibly expended) pens to always output a maximal feasible set.

[1] In some non-downward-closed settings like public projects, $m < n$. For example, $m = 2$ for building a bridge that serves everyone. Either the bridge is built or not. However, $m \geq n$ in all downward-closed environments. Indeed, for each bidder, we assume there exists an outcome where they are included; otherwise, the bidder can be dropped from consideration altogether.

Table 1 Prior bounds (if any, references indexed by superscripts) and our upper bounds. $n =$ number of agents, $m =$ number of feasible outcomes. Note that $m \geq n$ for all the environments listed in the table. The bounds for optimal omniscient approximation ζ and omniscient approximation π are normalized by a $(1 + o(1))$ factor. Prior work: [*]Hartline and Roughgarden [18]; [**] Milgrom and Segal [21], Bikhchandani et al. [4]; [§]Fotakis et al. [13]; [†] Feldman et al. [11]; [††] Samuel-Cahn [25], Chawla et al. [6]; [§§]Kleinberg and Weinberg [19]; [‡] Qiao and Valiant [23]; [‡‡] Chawla et al. [6], Yan [26]. All bounds in the table also hold for the underlying auction environment. Pen testing algorithms with the same guarantees as downward-closed constraints can be achieved for arbitrary combinatorial constraints.

Environment	$\frac{\zeta(n)}{(1+o(1))}$	$\gamma(n)$	$\frac{\pi(n)}{(1+o(1))}$

Matroid Online Oblivious	$\ln n$	2 [§§]	$2 \cdot \ln n$
Matroid Online Sequential	$\ln n$	$\frac{e}{e-1}$ [‡‡]	$\frac{e}{e-1} \cdot \ln n$

Online posted-price mechanisms are a special case of deferred-acceptance auctions. Online environments are ones where an irrevocable decision regarding choosing a pen needs to be taken before testing the next one. We consider the settings where the order of testing pens is adversarially chosen (the oblivious version, *cf.* prophet inequalities, [6]) and where the algorithm can choose the order (the sequential version, *cf.* correlation gap, [26]). With our analysis of the optimal omniscient approximation ζ and known bounds on the standard approximation γ of online pricing mechanisms, the reduction framework yields better performance guarantees than the $O(\log n)$ bounds by Qiao and Valiant [23] by constant factors for these environments.

The results detailed above are summarized in Table 1.

Our reduction from pen testing to deferred-acceptance auction design improves bounds from previous literature for all the environments that we discuss; however, it does not always yield a tight bound. For the online IID environment (the online environment where the ink levels of all pens are drawn IID), we identify an algorithm with an omniscient approximation $\pi(n)$ that is a constant factor less than $\gamma(n)\,\zeta(n)$.

Our results and techniques are of interest beyond pen testing. Our upper bound of $(1 + o(1)) \ln n$ on the optimal omniscient approximation $\zeta(n)$ is the ratio between the optimal surplus and the optimal consumer surplus, and is a mechanism design problem of independent interest [18, 13, 15]. Recall that the surplus created in an auction equals the sum of the consumer surplus and the revenue generated by the auctioneer. However, when payments made by the winners are burnt instead of being transferred to the auctioneer, the total surplus created is just the consumer surplus. The need to burn payments can be diverse. For instance:

1. Making monetary transactions is not desirable or repugnant, like in setting prices for welfare schemes for vulnerable populations. Ordeal-based mechanisms are employed in such scenarios, where agents make non-transferable non-monetary payments, like spending time waiting in a line to avail the provisions provided in the welfare scheme [20, 3, 5].
2. In computer systems like data packet routing networks, where technological infeasibility to collect payments necessitates charging non-monetary payments [10, 9, 18].

3. The auctioneer cannot be trusted to truthfully implement the auction, like in a blockchain, where a miner runs an auction to decide which set of transaction goes into the next block it proposes. To stop the miner from colluding with agents or from benefiting from injecting fake bids, it becomes essential to burn a substantial portion of the transaction fees collected from the agents [24, 7, 14].

The technique to obtain the $(1 - \ln q)$-approximation in the single-agent environment can have further applications. We express consumer surplus optimization as a linear program and explicitly compute the worst-case distribution. This provides a proof technique which automatically gives tight approximation guarantees. For example, we reuse the technique to compute the worst-case distribution for the omniscient approximation for the online IID environment. We improve the bound obtained from the reduction framework to a multiplicative approximation ratio within an additive 1 of the H_n lower bound of Qiao and Valiant [23] (where H_n is the n^{th} harmonic number).

Paper Organization. We make the reduction from the pen-testing problem to designing deferred-acceptance auctions formal in Section 2. We execute the first step of the reduction framework – upper bounding the optimal omniscient approximation $\zeta(n)$ – in Section 3. We bound the approximation ratio between the surplus and consumer surplus in a single-agent environment in Section 3.1 and discuss the reduction from multi-agent to single-agent settings in Section 3.2. The second step of the reduction from pen testing algorithms to deferred-acceptance mechanisms is discussed in Section 4, where we review deferred-acceptance mechanisms for various environments and discuss the corresponding bounds we get for pen testing. Finally, we revisit the online IID single item environment and achieve a tight (up to $o(1)$ terms) bound in Section 5.

2 The Pen Testing Problem and Ascending-Price Auctions

In this section, we formally define the combinatorial pen testing problem, generalized from Qiao and Valiant [23], and explore its connections to ascending-price mechanisms.

▶ **Definition 2.** *A pen testing instance is described by a set $N = \{1, 2, \ldots, n\}$ of pens with unknown ink levels $v_1, \ldots, v_n$, each v_i drawn independently from the distribution F_i, and a subset $\mathcal{P}$ of the powerset of the pens denoting feasible subsets of pens. The residual ink level u_i of pen i is initiated to v_i. We can test the pens before making a decision. Test (i, θ_i) is done by writing with pen i for time θ_i. We receive a binary signal at the end of the test:*
1. *If $u_i \geq \theta_i$: The test succeeds. The pen now has an (unobservable) ink level $u_i \leftarrow u_i - \theta_i$.*
2. *If $u_i < \theta_i$: The test fails. The pen now has no ink left, i.e, $u_i \leftarrow 0$.*

We can choose to run multiple tests on the pens. We need to output some feasible subset $P \in \mathcal{P}$ of pens, maximizing

$$\sum\nolimits_{i \in P} u_i.$$

The goal is to optimize the total amount of ink remaining in the set of chosen pens.

Compare a pen testing instance with n pens and a feasibility constraint $\mathcal{P}$ with an n-agent auction under the same feasibility constraint. The original levels of ink correspond to the value each agent gets upon being allocated. The ink spent through testing is analogous to the prices in the auction. Thus, maximizing total residual ink is equivalent to optimizing consumer surplus, i.e, the sum of the values of the winning agents minus the sum of all payments. Note that auctions generally give the auctioneer the added advantage of the

ability to solicit bids from agents. In pen testing algorithms, we only get to learn whether the ink left in the pen is more than some threshold and in doing so, we irrevocably expend ink up to the threshold. This is similar to ascending-price auctions, where the auctioneer irreversibly increases the price faced by each agent, and in doing so, only learns whether the agent has a value at least the price.

Milgrom and Segal [21] describe the wide class of ascending-price auctions called deferred-acceptance mechanisms.

▶ **Definition 3** (Milgrom and Segal [21]; Deferred-Acceptance Auctions). *A deferred-acceptance auction is held across multiple stages. For each stage t, the auction maintains a set of active bidders A_t satisfying $A_1 \supseteq A_2 \supseteq \cdots \supseteq A_t$, where the initial active set A_1 is the set of all bidders. The auction is characterized by a (possibly randomized) pricing rule $\vec{p}$, mapping the history of the auction at stage t to (discriminatory) prices for each agent satisfying $p_i(H_t) \geq p_i(H_{t-1})$ for all agents i and for all histories H_t at stage t arising out of stage $t-1$ history H_{t-1}, i.e, the prices are monotonously non-decreasing for all agents over time. Agents can opt to drop out once the prices are updated in stage t. A_{t+1} is the set of agents in A_t that did not drop out in stage t. The mechanism terminates at stage t when A_t becomes feasible. The agents in A_t are charged according to $\vec{p}(H_t)$.*

The definition from Milgrom and Segal [21] restricts deferred-acceptance mechanisms to be deterministic, which we relax for the purpose of designing pen testing algorithms. From the discussion above, note that any deferred-acceptance mechanism can be converted into a pen testing algorithm, by setting thresholds equal to the prices recommended by the mechanism. Thus, the optimal (near optimal) pen testing algorithm corresponds to the consumer surplus optimal (near optimal) deferred-acceptance auction.

We compare the performance of our deferred-acceptance mechanisms (and the corresponding pen testing algorithms) to the following benchmarks:

- The *omniscient benchmark* [23]: The omniscient benchmark corresponds to the omniscient pen testing algorithm that exactly knows the ink levels in the pens, and thus, does not have to waste ink by writing with them. In the reduction to the auction environment, the omniscient benchmark corresponds to a mechanism that neither loses out on the payments nor has to stick to an increasing trajectory of prices. Thus, the omniscient benchmark corresponds to the surplus optimal sealed-bid mechanism. The *omniscient approximation* $\pi(n)$ corresponds to the ratio between the omniscient benchmark and the performance of a given pen testing algorithm in the pen testing setting, and the omniscient benchmark and the consumer surplus of a given deferred-acceptance auction in the auction environment.
- The *standard benchmark*: The standard benchmark corresponds to the consumer-surplus-optimal sealed-bid mechanism. We define the *standard approximation* $\gamma(n)$ to be the ratio between the standard benchmark and the consumer surplus of a candidate deferred-acceptance mechanism. While the standard benchmark does not have a natural pen testing analogy, observe that the standard benchmark is a tighter upper bound to the optimal pen testing algorithm than the omniscient benchmark. Thus, the standard approximation gives a better upper bound on the ratio between the optimal pen testing algorithm and the residual ink gathered by a given pen testing algorithm.

Now that we have established the consumer surplus is a quantity of interest for pen testing, we review consumer surplus optimization through virtual values in the next section.

2.1 Consumer Surplus Optimization and Virtual Valuations

Let us begin in a single-agent environment with one good. Let the agent's value be drawn from the distribution F. The quantile q of an agent with value $v \sim F$ is the measure with respect to F of stronger values, i.e, $q = 1 - F(v)$. For $q \in [0, 1]$, let $v(q)$ be the inverse demand function of F satisfying $F(v(q)) = 1 - q$. In other words, $Pr_{\hat{v}\sim F}(\hat{v} > v(q)) = q$. Throughout the paper, we assume $v(1) = 0$ and $\int_0^0 v(t)dt = 0$. It can be shown that these assumptions can be made without loss of generality.

Let $V(q) = \int_0^q v(t)dt$ be the price-posting surplus curve. Notice that $V(q)$ is the expected surplus from posting a price $v(q)$ to the agent, thereby allocating the good with probability q. By our assumption on F, $V(0) = 0$. Let $U(q) = V(q) - qv(q)$ be the price-posting consumer surplus curve. Similar to the price-posting surplus curve, $U(q)$ is the consumer-surplus from posting a price $v(q)$. Note that $0 \leq U(0) \leq V(0) = 0$, and thus, $U(0) = 0$.

Let $u(q) = U'(q) = -qv'(q)$ be the marginal price-posting consumer surplus curve. Note that v is monotonously non-increasing, and hence its derivative v' is non-positive. Thus, $u(q) \geq 0$ and U is monotone non-decreasing. A quick note on derivatives: whenever $v'(q)$ is well defined, $u(q)$ is well defined. At other points, $u(q)$ can be calculated using any sub-derivative of v. At points q of discontinuity of v, $v'(q) = -\infty$ and thus $u(q) = \infty$.

▶ **Theorem 4** (Myerson [22]). *In a Bayesian incentive-compatible mechanism with allocation rule y and payment rule p (over quantiles), the expected consumer surplus of an agent satisfies*

$$E_{q\sim U[0,1]}[v(q)y(q) - p(q)] = E_{q\sim U[0,1]}[u(q)y(q)] = E_{q\sim U[0,1]}[-U(q)\,y'(q)] + U(0)y(0)$$

Thus, the expected consumer surplus equals the expected virtual surplus with marginal consumer surplus as virtual values. Myerson [22] states that an allocation rule can be implemented as a truthful auction if and only if the allocation rule is monotone non-increasing in quantile space. Thus, the consumer surplus optimal mechanism optimizes for virtual surplus subject to the allocation rule being monotonously non-increasing.

When the marginal price-posting consumer surplus curve is non-increasing (and hence U is concave), optimizing for virtual surplus automatically ensures monotonicity of the allocation rule. We will call these distributions with non-increasing marginal price-posting consumer surplus curves *consumer surplus regular*.

However, u is not monotone non-increasing for common distributions like the uniform and normal distribution. In fact, u is monotone non-decreasing for these distributions. In such a case, the allocation that pointwise optimizes for virtual surplus might not satisfy monotonicity. Myerson [22] prescribes an ironing procedure to optimize for virtual surplus subject to monotonicity.

1. Construct the concave hull $\overline{U}$ of the price-posting consumer surplus curve U
2. Define $\overline{u}(q) = \overline{U}'(q)$
3. Find the virtual surplus optimal mechanism using $\overline{u}$ as virtual surplus

Since $\overline{U}$ is concave, $\overline{u}$ is non-increasing, and hence optimizing for the ironed virtual surplus is easier. Throughout the paper, we will follow the convention of attaching a bar on top of a curve to describe the ironed curve.

In a multi-agent environment, the interim allocation rule for an agent is the single-agent allocation rule that arises in expectation over the quantiles of all other agents. This captures the perspective of the agent after knowing its value, but before learning the values of the other agents.

▶ **Theorem 5.** *Let y be the interim allocation rule for some agent, satisfying $\frac{d}{dq}y(q) = 0$ for all q such that $U(q) \neq \overline{U}(q)$. Then*

$$E_q[u(q)y(q)] = E_q[\overline{u}(q)y(q)]$$

In other words, if the allocation rule does not differentiate between agents in an ironed region, then the ironed virtual surplus can be used to compute the consumer surplus instead of the actual virtual surplus.

▶ **Theorem 6** (Alaei et al. [1, 2]). *Let y be some allocation rule with interim allocation rule y_i monotonously non-increasing for each agent i. Then, there exists a mechanism $\overline{y}$ with interim allocation rule $\overline{y}_i$ for agent i such that the expected consumer surplus for agent i equals*

$$E_{q\sim U[0,1]}[u_i(q)\,\overline{y}_i(q)] = E_{q\sim U[0,1]}[\overline{u}_i(q)\,y_i(q)]$$

In other words, the expected consumer surplus of $\overline{y}$ is the consumer surplus of the original mechanism if the virtual values were given by $\overline{u}_i$ for agent i instead of u_i

2.2 Near-Optimal Deferred-Acceptance Mechanisms for Consumer Surplus

In this section, we prescribe a recipe similar to Feng et al. [12] to convert any approximately optimal deferred-acceptance mechanism for surplus into an approximately optimal deferred-acceptance mechanism for consumer surplus.

▶ **Definition 7** (Virtual-Pricing Transformation of a Deferred-Acceptance Mechanism). *Let DA^V be a deferred-acceptance mechanism designed to optimize surplus. Let v_i be the inverse demand function and u_i be the virtual value function (for consumer surplus) for agent i. The virtual-pricing transformation on DA^V, denoted by DA^U, implements DA^V in ironed virtual price space, i.e, whenever DA^V posts a price $\hat{v}_i$ to agent i, DA^U posts a price $v_i(\theta_i)$ satisfying*

$$\theta_i = \sup\{\theta : \overline{u}_i(\theta) \geq \hat{v}_i\}$$

We will make some preliminary observations about the transformation:

1. Consider two runs of the transformed mechanism DA^U with some agent having two different values, both corresponding to the same ironed virtual value (which can happen if both these values are within the same ironed interval). From the definition of the transform, the agent faces the smallest price needed to differentiate itself from virtual values smaller than the threshold set by the mechanism. Consequently, the mechanism does not post prices from the middle of an ironed interval. Thus, in both these runs of the mechanism, the agent behaves identically. Since the mechanism does not discriminate between values with the same ironed virtual value, the consumer surplus of the mechanism equals the ironed virtual surplus.
2. If the original mechanism DA^V is a γ-approximation to the optimal surplus, in expectation over all product distributions, then the transformed mechanism DA^U is a γ-approximation to the optimal ironed virtual surplus, and hence, to the optimal consumer surplus.
3. Finally, it is straightforward to see that the transformed mechanism DA^U posts non-decreasing prices to each agent. Hence, DA^U is also a deferred-acceptance mechanism.

Recall that the standard approximation $\gamma(n)$ is the ratio between the consumer surplus of the optimal deferred-acceptance mechanism and our proposed mechanism while the optimal omniscient approximation $\zeta(n)$ is the ratio between the optimal surplus and the optimal consumer surplus. The proof of Theorem 1 is now straightforward.

Proof of Theorem 1. Let OPT^U denote the expected optimal consumer surplus, OPT^V denote the expected optimal surplus, and DA^U denote the expected consumer surplus of the deferred acceptance mechanism in Definition 7. Then,

$$\mathrm{DA}^U \geq \frac{\mathrm{OPT}^U}{\gamma(n)} \geq \frac{\mathrm{OPT}^V}{\gamma(n)\,\zeta(n)}$$

where the first inequality follows from the definition of standard approximation $\gamma(n)$ and bullet 2 in the discussion above, while the second follows from the definition of optimal omniscient approximation $\zeta(n)$. The equivalent pen testing algorithm yields the necessary approximation ratios against the two benchmarks. ◀

In the next section, we analyze the optimal omniscient approximation $\zeta(n)$ for general combinatorial environments.

3 Consumer Surplus versus Surplus

Our approximation procedure follows two steps. In Section 3.1, we show that the optimal surplus is at most $1-\ln q$ times the consumer surplus in a single-agent environment where the ex-ante probability of allocation is constrained to be at most q. In Section 3.2, we move from the single-agent environment to multi-agent environments combining approaches from Feng et al. [12] and Hartline and Taggart [17] to show a $(1+o(1))\ln n$ approximation between the consumer surplus and optimal surplus in n-agent environments with general feasibility constraints.

3.1 The Single-Agent Problem

Recall that V, U and $\overline{U}$ are the price-posting surplus curve, price-posting consumer surplus curve and the ironed consumer surplus curve respectively. In this section, we establish a "closeness property" like in Feng et al. [12].

▶ **Theorem 8.** *For an ex-ante allocation probability $q \in [0,1]$, the ratio of the optimal surplus $V(q)$ to the optimal consumer surplus $\overline{U}(q)$ is at most $1-\ln q$.*

We will begin by proving Theorem 8 for consumer surplus regular distributions, and then extend the result to all distributions.

▶ **Lemma 9.** *For any consumer surplus regular distribution and an ex-ante allocation probability $q \in [0,1]$, the ratio of the optimal surplus $V(q)$ to the optimal consumer surplus $U(q)$ is at most $1-\ln q$.*

Proof. Conditional on generating a surplus $V(q)$, we want to compute the distribution that minimizes consumer surplus $U(q)$.

$$\begin{aligned} U(q) &= \int_0^q u(t)dt. \\ V(q) &= U(q) + qv(q) \\ &= \int_0^q u(t)dt - q\int_q^1 v'(t)dt \\ &= \int_0^q u(t)dt + q\int_q^1 \frac{u(t)}{t}dt. \end{aligned} \tag{1}$$

We substitute $u(t) = -tv'(t)$ in the last equation.

Simultaneously, we enforce $u(t) \geq 0$, and $u(t)$ is non-increasing (since the distribution is consumer surplus regular), $v(1) = 0$ and $V(0) = 0$.

Finding the minimum consumer surplus distribution reduces to the following program.

$$\min \int_0^q u(t)dt$$

subject to

$$\int_0^q u(t)dt + q\int_q^1 \frac{u(t)}{t}dt = V(q)$$

$u(t) \geq 0, u(t)$ is monotonously non-increasing

$v(1) = 0, V(0) = 0$

The constraints in the last line can be enforced after solving for u.

Consumer surplus regularity dictates $u(t) \geq u(q)$ for $t \leq q$. Hence, minimizing $\int_0^q u(t)dt$ would correspond to setting $u(t) = u(q)$ for $t \leq q$. Similarly, $u(t) \leq u(q)$ for $t \geq q$. Minimizing $\int_0^q u(t)dt$ would mean minimizing $V(q) - q\int_q^1 \frac{u(t)}{t}dt$ which is achieved by setting $u(t) = u(q)$ for $t \geq q$. Let $u(0) = u(t) = u(1) = u$. For a constant marginal price-posting consumer surplus curve,

$$U(q) = \int_0^q u(t)dt = q\,u$$

$$V(q) = \int_0^q u(t)dt + q\int_q^1 \frac{u(t)}{t}dt = [q - q\ln q]\,u$$

Thus, for any consumer surplus regular distribution, $\frac{V(q)}{U(q)} \leq [1 - \ln q]$. The constant marginal consumer surplus curve that achieves this ratio corresponds to the exponential distribution. ◀

▶ **Lemma 10.** *Let the consumer surplus curves $U, \hat{U}$ satisfy $\hat{U}(0) = 0$ and $\hat{U}(t) \geq U(t)$ for all $t \in [0, 1]$. Then, for the corresponding surplus curves, $\hat{V}(q) \geq V(q)$.*

Proof. We rewrite equation (1) as follow.

$$\begin{aligned} V(q) &= \int_0^q u(t)dt + q\int_q^1 \frac{u(t)}{t}dt \\ &= U(q) + q\Big[\frac{U(t)}{t}\Big]_{t=q}^{t=1} + q\int_q^1 \frac{U(t)}{t^2}dt \\ &= qU(1) + q\int_q^1 \frac{U(t)}{t^2}dt \end{aligned} \tag{2}$$

The second equality is obtained through integrating by parts. Increasing U pointwise clearly results in an increase in V. ◀

Proof of Theorem 8. The optimal consumer surplus for an ex-ante allocation probability q equals $\overline{U}(q)$.

Consider the distribution with price-posting consumer surplus curve $\overline{U}$. Let $\overline{V}$ be the price-posting surplus curve corresponding to $\overline{U}$. From Lemma 10 and Lemma 9,

$$\frac{V(q)}{\overline{U}(q)} \leq \frac{\overline{V}(q)}{\overline{U}(q)} \leq 1 - \ln q$$

The second inequality holds from Lemma 9, since $\overline{V}$ is the price-posting surplus curve of a consumer surplus regular distribution (we made $\overline{U}$ concave through ironing). ◀

See the full online version for a brief discussion on the surplus generated by the single-agent optimal consumer surplus auction.

3.2 Multi-Agent Environments

In this section, we convert the single-agent bound from Theorem 8 into an upper bound on the ratio between the optimal surplus and optimal consumer surplus (aka the optimal omniscient approximation) for multi-agent environments. We outline our approach before delving into the proof. Consider the interim allocation rule y_i for agent i in the surplus optimal mechanism OPT^V. Without loss of generality, assume $y_i(1) = 0$. The expected surplus for agent i equals

$$E_{q\in U[0,1]}[y_i(q)\, v_i(q)] = \left[y_i(q)\, V_i(q)\right]_{q=0}^{q=1} + E_{q\in U[0,1]}[-y_i'(q)\, V(q)] = E_{q\in U[0,1]}[-y_i'(q)\, V(q)]$$

This equality comes from integrating by parts ($y_i(q)V_i(q)$ vanishes at both, $q = 0$ and 1, since $V_i(0) = 0$ and $y_i(1) = 0$). Suppose there exists a constant α such that $V_i(q) \le \alpha\, \overline{U}_i(q)$ for all $q \in [0, 1]$, then,

$$E_{q\in U[0,1]}[-y_i'(q)\, V(q)] \le E_{q\in U[0,1]}[-y_i'(q)\, \alpha\, \overline{U}(q)] = \alpha \cdot E_{q\in U[0,1]}[y_i(q)\, \overline{u}_i(q)]$$

The above inequality connects the expected surplus to the expected ironed consumer surplus of the interim allocation rule y_i. Since $\frac{d}{dq} y_i$ need not be equal to 0 whenever $U(q) \neq \overline{U}(q)$, $E_{q\in U[0,1]}[y_i(q)\, \overline{u}_i(q)] \neq E_{q\in U[0,1]}[y_i(q)\, u_i(q)]$. But, Theorem 6 shows the existence of a mechanism $\overline{y}$ with expected consumer surplus of each agent i equal to $E_{q\in U[0,1]}[y_i(q)\, \overline{u}_i(q)]$. Thus, the expected consumer surplus of $\overline{y}$ is an α-approximation to the optimal surplus. The consumer surplus optimal mechanism OPT^U will only do better.

Unfortunately, as $q \to 0$, the bound from Theorem 8 of $\frac{V_i(q)}{\overline{U}_i(q)} \le (1 - \ln q)$ diverges to ∞. Thus, we need to show that the loss from ignoring the small (strong) quantiles is not much. Suppose we find a mechanism $\hat{y}$ with interim allocation $\hat{y}_i$ for agent i, near optimal surplus, and $\hat{y}_i'(q) = 0$ for $q \in [0, \epsilon]$. Then, $y_i'(q) \times V(q) = y_i'(q) \times U(q) = 0$ in this region. For $q \in [\epsilon, 1]$, we know $V(q) \le (1 - \ln \epsilon) \times \overline{U}(q)$. Thus,

$$(1 - \ln \epsilon) \times \text{OPT}^U \ge \text{surplus}(\hat{y})$$

Hartline and Taggart [17] give the construction of such a mechanism $\hat{y}$, originally intended to design good mechanisms with only sample access to the distributions of bidders' bids.

▶ **Definition 11** (Hartline and Taggart [17]; ϵ-buffering rule)**.** *Given an allocation rule $\vec{y} = (y_1, y_2, \ldots, y_n)$ and a quantile $\epsilon \in [0, 1]$, the ϵ-buffering rule for $\vec{y}$ simulates y with quantiles transformed on each agent as follows:*

- *Top inflate: for any $q_i \in [0, \epsilon]$, return 0*
- *For any $q_i \in [\epsilon, 1 - \epsilon]$, return $\frac{q_i - \epsilon}{1 - 2\epsilon}$*
- *Bottom deflate: for any $q_i \in [1 - \epsilon, 1]$, return 1*

In essence, the top inflate branch makes the ϵ-buffering rule treat all agents with a small quantile as if they had quantile 0 and thus, $y_i'(q) = 0$ for $q \in [0, \epsilon]$ (the bottom deflate branch is unnecessary for the analysis of monotone payoff curves like surplus V and consumer surplus U; see Remark 15).

▶ **Theorem 12** (Hartline and Taggart [17])**.** *Let $\hat{y}$ be the ϵ-buffering rule of the surplus optimal mechanism OPT^V. Then, $\text{OPT}^V \le \frac{1}{(1 - \frac{\epsilon}{1-\epsilon})\,(1-\epsilon)\,(1-2n\epsilon)} \times \text{surplus}(\hat{y})$.*

▶ **Theorem 13.** *Consider an n-agent environment with an arbitrary feasibility constraint. The optimal omniscient approximation is at most $\frac{1 - \ln \epsilon}{(1 - \frac{\epsilon}{1-\epsilon})\,(1-\epsilon)\,(1-2n\epsilon)}$.*

Proof. The proof follows by combining Theorem 12 with the discussion above. Let $\hat{y}$ be the ϵ-buffering rule of the surplus optimal mechanism OPT^V. Then,

$$\text{OPT}^V \leq \frac{1}{(1-\frac{\epsilon}{1-\epsilon})\,(1-\epsilon)\,(1-2n\epsilon)} \times \text{surplus}(\hat{y}) \leq \frac{1-\ln\epsilon}{(1-\frac{\epsilon}{1-\epsilon})\,(1-\epsilon)\,(1-2n\epsilon)} \times \text{OPT}^U$$

◀

▶ **Corollary 14.** *In n-agent environments with an arbitrary feasibility constraint, the optimal omniscient approximation $\zeta(n) \leq (1+o(1))\ln n$.*

Proof. Setting $\epsilon = \frac{1}{n\ln n}$ in Theorem 13, we get

$$\begin{aligned}
\zeta(n) &\leq \frac{1-\ln\frac{1}{n\ln n}}{(1-\frac{\frac{1}{n\ln n}}{1-\frac{1}{n\ln n}})\,(1-\frac{1}{n\ln n})\,(1-2n\cdot\frac{1}{n\ln n})} \\
&= \frac{1+\ln n+\ln\ln n}{(1-\frac{1}{n\ln n-1})\,(1-\frac{1}{n\ln n})\,(1-\frac{2}{\ln n})} \\
&= \frac{n\ln n-1}{n\ln n-2}\cdot\frac{n\ln n}{n\ln n-1}\cdot\frac{\ln n-2}{\ln n}\cdot\frac{1+\ln n+\ln\ln n}{\ln n}\times\ln n \\
&= (1+o(1))\ln n
\end{aligned}$$

◀

▶ Remark 15. The ϵ-buffering rule of Hartline and Taggart [17] can be implemented without a bottom deflate branch. This would strengthen the approximation guarantee to $\frac{1}{(1-\epsilon)\,(1-n\epsilon)}$. However, substituting $\epsilon = \frac{1}{n\ln n}$ will not result in a bound tighter than $(1+o(1))\ln n$.

▶ Remark 16. Fotakis et al. [13] show that the optimal omniscient approximation as a function of the number of outcomes m in the feasibility constraint is at most $\frac{2}{\ln 2}(1+o(1))\ln m$. Corollary 14 improves their bound whenever the feasibility constraint has cardinality at least $\sqrt{n}$. Note that all downward-closed constraints have at least n feasible outcomes. For such feasibility constraints, Corollary 14 yields an exponential improvement. As the number of feasible outcomes become exponential in n, their bound declines to $O(n)$.

▶ Remark 17. The upper bound from Corollary 14 matches the lower bound of Qiao and Valiant [23]. In the single-item environment with values of agents drawn IID from the exponential distribution, they show that the optimal surplus is $H_n = (1+o(1))\ln n$ times the optimal consumer surplus, where H_n is the n^{th} harmonic number.

3.3 The k-Identical Goods Environment

Theorem 13 and Corollary 14 give an over-arching bound for the optimal omniscient approximation $\zeta(n)$ that holds in any environment. However, specific environments admit better approximations. For instance, we will give a tighter bound for $\zeta(n)$ for the k-identical goods environment, where any set of at most k-agents can be allocated simultaneously.

▶ **Theorem 18.** *In the n-agent k-identical goods environment, the optimal omniscient approximation satisfies*

1. $\zeta(n) \leq (1+o(1))\ln\frac{n}{k}$ *when* $k = o(n)$, *and*
2. $\zeta(n) \leq 2.27\,(1+o(1))(0.577+\ln\frac{n}{k})$, *when* $k = \Theta(n)$.

To prove Theorem 18, we make use of the following lemma, whose proof we defer to the end of the section.

▶ **Lemma 19.** *Consider the special case with n agents and k identical goods. The optimal omniscient approximation $\zeta(n) \leq \frac{1}{(1-\frac{1}{\sqrt{2\pi k}})}\cdot(1-\ln\epsilon)(1+[\frac{n}{k}-1]\,\epsilon)$ for any $\epsilon > 0$.*

Lemma 19 is particularly useful when $k = \Theta(n)$. For a constant ϵ, $\frac{1}{(1-\frac{1}{\sqrt{2\pi k}})}$ is $(1 + o(1))$ while $(1 - \ln \epsilon)(1 + [\frac{n}{k} - 1]\,\epsilon)$ is a constant.

Proof of Theorem 18. We show the theorem separately for the three cases, when $k = \Theta(1)$, $k = \omega(1)$ but $o(n)$, and $k = \Theta(n)$.

- $k = \Theta(1)$: The proof is a direct consequence of Corollary 14, where we show $\zeta(n) \leq (1 + o(1)) \ln n = (1 + o(1)) \ln \frac{n}{k}$. The equality follows since k is a constant.
- $k = \omega(1)$, but $o(n)$: By setting $\epsilon = \frac{1}{\frac{n}{k}(1+\ln \frac{n}{k})}$ in Lemma 19, we get

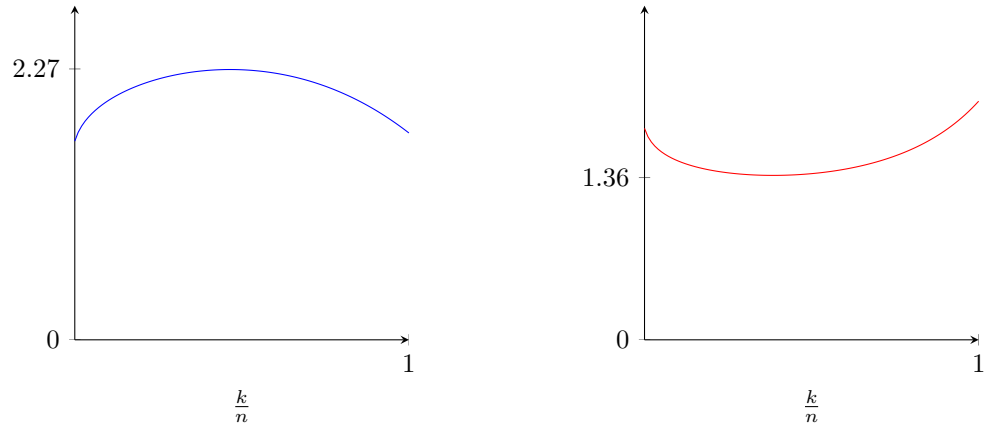
$$\zeta(n) \leq \left(\frac{1}{1-\frac{1}{\sqrt{2\pi k}}}\right) \times \left(1 + \frac{1}{1 + \ln \frac{n}{k}}\,[1 - \frac{k}{n}]\right) \times (1 + \ln \tfrac{n}{k} + \ln(1 + \ln \tfrac{n}{k}))$$

  The first term is $(1 + o(1))$ since $k = \omega(1)$. The second and the third terms are $(1 + o(1))$ and $(1 + o(1)) \ln \frac{n}{k}$ respectively, since $k = o(n)$. Summarizing, $\zeta(n) \leq (1 + o(1)) \ln \frac{n}{k}$.

The above two cases conclude the proof of the first part of the theorem. The next case clinches the proof of the second part.

- $k = \Theta(n)$: We set $\epsilon = \frac{1}{\frac{n}{k}(1+\ln \frac{n}{k})}$ as in the previous case. Once again $\left(\frac{1}{1-\frac{1}{\sqrt{2\pi k}}}\right) = (1+o(1))$ since $k = o(1)$. We plot the ratio between our upper bound and the lower bound $(0.577 + \ln \frac{n}{k})$ from Lemma 20 as a function of $\frac{k}{n}$ in Figure 1a to observe that the ratio is at most 2.27, exactly as needed. We skip a more detailed numerical analysis substantiating this observation. ◀

We modify the lower bound from Qiao and Valiant [23] sketched in Remark 17 to get an analogous result for the k-identical goods environment.



▶ **Lemma 20.** *Consider the n-agent k-identical goods environment with values drawn IID from the exponential distribution with mean 1. Assume, for convenience, that $\frac{n}{k}$ is an integer. The optimal omniscient approximation $\zeta(n) \geq H_{\frac{n}{k}} \geq (0.577 + \ln \frac{n}{k})$.*

Proof. The exponential distribution with mean 1 has a constant marginal consumer surplus curve $u(q) = 1$, and thus, the optimal consumer surplus mechanism allocates to some set of k agents to get an expected consumer surplus equal to k.

Now, consider the following mechanism. Group agents into k batches of $\frac{n}{k}$ agents each, and award the agent with the highest value in each group. Each group is now identical to a single item environment with $\frac{n}{k}$ agents, and thus, generates an expected surplus of $H_{\frac{n}{k}}$ (see Remark 17 on the example sketched in [23]). The k batches together produce an expected surplus equal to $k \cdot H_{\frac{n}{k}}$. The optimal mechanism creates a larger surplus and hence, $\zeta(n)$ is at least $H_{\frac{n}{k}} \geq (0.577 + \ln \frac{n}{k})$. ◀

Thus, the upper bound from Theorem 18 is tight up to $(1 + o(1))$ terms when $k = o(n)$ and up to a multiplicative $2.27\,(1 + o(1))$ when $k = \Theta(n)$. The best known bound for the optimal omniscient approximation is due to Hartline and Roughgarden [18], where they show $\zeta(n) \leq \frac{2}{\ln 2}\,(\ln 2 + \ln \frac{n}{k}) \approx 2.88(\ln 2 + \ln \frac{n}{k})$. Apart from closing the $\frac{2}{\ln 2}$ gap between their upper bound and the lower bound when $k = o(n)$, our bound is an improvement by a factor of at least $1.36(1 - o(1))$ when $k = \Theta(n)$ (Figure 1b).

We conclude the section with the proof of Lemma 19. We will adopt an approach similar to the proof of Theorem 13. Increasing the allocation to the agents with a small quantile so that $y_i(q_i) = y_i(0)$ for $q_i \in [0, \epsilon]$ vastly increases the consumer surplus of i without noticeably decreasing the surplus of the mechanism. We consider online posted-price mechanisms with the constraint $y_i'(q_i) = 0$ whenever $q_i \leq \epsilon$ for all agents i. Posted-price mechanisms are known to achieve a near optimal surplus and we bound the loss in surplus due to the additional constraint.

(a) **(b)**

Figure 1 We compare our upper bound against the lower bound and the best known upper bound when $k = \Theta(n)$. Figure (a) plots the ratio between our upper bound from Theorem 18, normalized by $(1 + o(1))$ and our lower bound from Lemma 20, $(0.577 + \ln \frac{n}{k})$. The maximum value of the curve is less than 2.27, and hence, our upper bound can potentially be improved by a factor of at most $2.27\,(1 + o(1))$. Figure (b) plots the ratio between the current best known bound $\frac{2}{\ln 2}\,(\ln 2 + \ln \frac{n}{k})$ and our bound from Theorem 18, again normalized by $(1 + o(1))$. The minimum value taken by the ratio is greater than 1.36, and hence, our bound improves the best known bound by a factor of at least $1.36(1 - o(1))$.

Consistent with prior literature on online sequential price-posting [6, 26] we will approximate the performance of the mechanism against the optimal ex-ante relaxed mechanism EAR. In the ex-ante relaxation, the feasibility constraint is relaxed to bind ex-ante rather than ex-post. In other words, the expected number of agents served by the mechanism must be at most k. The optimal ex-ante mechanism obtains a larger surplus than OPT^V, since OPT^V is also a feasible ex-ante mechanism. Note that, if agent i is being allocated with probability q_i by EAR, it would allocate to the q_i smallest quantiles (quantiles corresponding to the largest values) without violating the ex-ante constraint, thereby getting an expected surplus $V_i(q_i)$ from agent i.

Let Δ be the set of all ex-ante feasible allocations $\vec{q} = (q_1, \ldots, q_n)$ for selling up to k items such that $q_1, \ldots, q_n \in [0, 1]$ and $\sum_{i=1}^{n} q_i \leq k$. Let $\text{EAR}(\vec{q})$ be the ex-ante relaxed mechanism that allocates to the q_i smallest quantiles of agent i. Note that $\text{EAR}(\vec{q})$ is well-defined even if $\vec{q} \notin \Delta$ as long as $q_1, \ldots, q_n \in [0, 1]$. We will abuse notation to denote the surplus from $\text{EAR}(\vec{q})$ by $\text{EAR}(\vec{q})$. Thus, $\text{EAR} = \max_{\vec{q} \in \Delta} \text{EAR}(\vec{q})$.

Yan [26] showed that the following sequential posted-price mechanism $\text{SP}(\vec{q})$ has a surplus comparable to $\text{EAR}(\vec{q})$ for all $\vec{q} \in \Delta$.

1. Order agents in decreasing order of $\frac{V_i(q_i)}{q_i}$, the expected surplus conditioned on selling to agent i.
2. In the order above, offer agent i a price $v_i(q_i)$ until all n agents interact with the mechanism or until all k goods are sold.

As usual, we will abuse notation to denote the surplus of $\text{SP}(\vec{q})$ by $\text{SP}(\vec{q})$.

▶ **Theorem 21** (Yan [26]). *For* $\vec{q} \in \Delta$, $\frac{1}{(1 - \frac{1}{\sqrt{2\pi k}})} \times \text{SP}(\vec{q}) \geq \text{EAR}(\vec{q})$.

We propose a sequential-posted-price-mechanism with near optimal surplus and interim allocation rules satisfying the additional properties outlined above. For a vector $\vec{q} \in \Delta$, let the ϵ-inflated sequential posted-price mechanism $\text{SP}(\vec{q}, \epsilon)$ denote $\text{SP}(\vec{p})$, where $p_i = \max\{q_i, \epsilon\}$.

Observe that if $\mathrm{SP}(\vec{q},\epsilon)$ has an unsold good while interacting with agent i, it always sells the good if the agent has a quantile $q_i \le \epsilon$. Thus, the interim allocation rule y_i is a constant function in $[0,\epsilon]$ and $y_i'(q) = 0$ in this range. Next, we argue that $\mathrm{SP}(\vec{q},\epsilon)$ approximates the surplus of $\mathrm{EAR}(\vec{q})$.

▶ **Lemma 22.** *For all* $\vec{q} \in \Delta$, $\mathrm{EAR}(\vec{q}) \le \frac{(1+[\frac{n}{k}-1]\,\epsilon)}{(1-\frac{1}{\sqrt{2\pi k}})}\,\mathrm{SP}(\vec{q},\epsilon)$

Proof. The proof proceeds in two steps. First, for $\vec{p}$ with $p_i = \max\{q_i,\epsilon\}$, we show that $\vec{p}$ is not too far away from the set of ex-ante feasible allocations Δ. We then show that the projection $\vec{t}$ of $\vec{p}$ back onto Δ satisfies $\mathrm{EAR}(\vec{q}) \le \mathrm{EAR}(\vec{p}) \le \frac{k+(n-k)\,\epsilon}{k} \times \mathrm{EAR}(\vec{t})$ and $\mathrm{SP}(\vec{t}) \le \mathrm{SP}(\vec{p}) = \mathrm{SP}(\vec{q},\epsilon)$.

Step 1. $\sum_{i=1}^n p_i \le k + (n-k)\,\epsilon$.

Without loss of generality, we assume $\sum_{i=1}^n q_i = k$. Increasing q_i so that their sum equals k would not decrease the value of $\sum_{i=1}^n p_i$. The claim reduces to showing the maximum value of $\sum_{i=1}^n (p_i - q_1)$ is at most $(n-k)\,\epsilon$.

Note that $p_i - q_i \le \epsilon$, equality holding exactly when $q_i = 0$. Thus, whenever $q_i < \epsilon$, decreasing them to zero increases the value of $\sum_{i=1}^n (p_i - q_i)$. However, this would contradict $\sum_{i=1}^n q_i = k$. For $q_i \ge \epsilon$, $p_i - q_i = 0$. Increasing q_i to 1 whenever $q_i \ge \epsilon$ does not change the value of $\sum_{i=1}^n (p_i - q_i)$, but allows other values q_j to be set to zero without violating $\sum_{i=1}^n q_i = k$. A simple greedy argument would suggest that $\sum_{i=1}^n (p_i - q_i)$ is maximized when $q_i = 1$ for $1 \le i \le k$ and $q_i = 0$ when $i > k$, in which case, $\sum_{i=1}^n (p_i - q_i) < (n-k)\,\epsilon$.

Step 2. Order (and re-index) agents in decreasing order of $V_i(p_i)$. Consider the ex-ante allocation $\frac{k}{k+(n-k)\,\epsilon} \cdot \mathrm{EAR}(\vec{p})$ that offers agent i with $\frac{k}{k+(n-k)\,\epsilon}$ fraction of a good whenever $q_i \le p_i$. This has a surplus $\frac{k}{k+(n-k)\,\epsilon} \cdot \mathrm{EAR}(\vec{p}) = \sum_{i=1}^n \frac{k}{k+(n-k)\,\epsilon} \cdot V_i(p_i)$ and allocates up to k units, since $\sum_{i=1}^n p_i \le k + (n-k)\,\epsilon$. Let $\vec{t}$ be an alternate ex-ante feasible allocation that allocates $t_i = p_i$ for agents $1,\ldots,m$ for some $m \le n$ until all k items are allocated. $\vec{t}$ redistributes goods from agents with a smaller surplus $V_i(p_i)$ allocated by $\frac{k}{k+(n-k)\,\epsilon} \cdot \mathrm{EAR}(\vec{p})$ to agents with a larger $V_i(p_i)$ to get a surplus

$$\mathrm{EAR}(\vec{t}) = \sum_{i=1}^m V_i(p_i) \ge \sum_{i=1}^n \frac{k}{k+(n-k)\,\epsilon} \cdot V_i(p_i) = \frac{k}{k+(n-k)\,\epsilon} \cdot \mathrm{EAR}(\vec{p})$$

Step 3. $\mathrm{SP}(\vec{t}) \le \mathrm{SP}(\vec{p})$

$\mathrm{SP}\,\vec{t}$ allocates the first m agents with probability p_i and allocates the others with probability 0. $\mathrm{SP}(\vec{p})$ allocates the first m agents with probability p_i and further allocates any unsold good to the others. Thus, $\mathrm{SP}(\vec{t}) \le \mathrm{SP}(\vec{p})$.

Summarizing,

$$\begin{aligned}
\mathrm{EAR}(\vec{q}) &\le \mathrm{EAR}(\vec{p}) \\
&\le \tfrac{k+(n-k)\,\epsilon}{k} \times \mathrm{EAR}(\vec{t}) = (1 + [\frac{n}{k} - 1]\,\epsilon) \times \mathrm{EAR}(\vec{t}) \\
&\le \frac{(1 + [\frac{n}{k} - 1]\,\epsilon)}{(1 - \frac{1}{\sqrt{2\pi k}})} \times \mathrm{SP}(\vec{t}) \\
&\le \frac{(1 + [\frac{n}{k} - 1]\,\epsilon)}{(1 - \frac{1}{\sqrt{2\pi k}})} \times \mathrm{SP}(\vec{p}) = \frac{(1 + [\frac{n}{k} - 1]\,\epsilon)}{(1 - \frac{1}{\sqrt{2\pi k}})} \times \mathrm{SP}(\vec{q},\epsilon)
\end{aligned}$$

The third inequality follows from Theorem 21 ◀

Proof of Lemma 19. Let $\vec{q} \in \Delta$ be such that $\text{EAR} = \text{EAR}(\vec{q})$. From the review on sequential-price-posting and Lemma 22,

$$\text{OPT}^V \leq \text{EAR} = \text{EAR}(\vec{q}) \leq \tfrac{(1+[\frac{n}{k}-1]\,\epsilon)}{(1-\frac{1}{\sqrt{2\pi k}})} \times \text{SP}(\vec{q},\epsilon)$$

Further, $\text{SP}(\vec{q},\epsilon)$ has a constant interim allocation rule for agent i when its quantile q_i is in the range $[0,\epsilon]$. Arguments identical to the proof of Theorem 13 can be used to conclude

$$\zeta(n) = \frac{\text{OPT}^V}{\text{OPT}^U} \leq \tfrac{(1+[\frac{n}{k}-1]\,\epsilon)}{(1-\frac{1}{\sqrt{2\pi k}})} \cdot \frac{\text{SP}(\vec{q},\epsilon)}{\text{OPT}^U} \leq \tfrac{1}{(1-\frac{1}{\sqrt{2\pi k}})} \cdot (1-\ln\epsilon)(1+[\frac{n}{k}-1]\,\epsilon) \qquad \blacktriangleleft$$

4 Pen Testing Corollaries from Deferred-Acceptance Mechanisms

There are many environments in which deferred-acceptance mechanisms are known to be good. By Theorem 1, these imply good pen testing algorithms (up to an additional $\zeta(n)$ factor in the omniscient approximation, i.e, the ratio of the performances of the omniscient algorithm that knows the amount of ink in each pen and our proposed pen testing algorithm). In this section, we discuss a few notable examples. A summary of these results was given previously in Table 1.

Deferred-acceptance mechanisms that achieve the ex-post surplus optimal outcome are known for various feasibility constraints. While the simple auction that uniformly increases the price until exactly k bidders remain active is surplus optimal in the k-identical goods environment, Milgrom and Segal [21] and Bikhchandani et al. [4] generalize the mechanism for matroid feasibility constraints. We get the following corollaries from the above auctions.

▶ **Corollary 23.** *For a pen testing environment with a matroid feasibility constraint, there exists a pen testing algorithm with an omniscient approximation ratio* $(1+o(1))\ln n$.

▶ **Corollary 24.** *When choosing any k of the n pens is feasible, there exists a pen testing algorithm with an omniscient approximation ratio* $(1+o(1))\ln\frac{n}{k}$ *when* $k=o(n)$ *and* $2.27\,(1+o(1))\,(0.577+\ln\frac{n}{k})$ *when* $k=\Theta(n)$.

Dütting et al. [8] initiated the study of prior-free deferred-acceptance approximation mechanisms in environments where deferred-acceptance mechanisms are known to be suboptimal. Their bounds can be improved in settings like ours where prior distributions of the agents' values are known. For general downward-closed constraints with a prior distribution on values, Feldman et al. [11] give a $O(\log\log m)$ approximation to the optimal surplus, where m is the number of maximal feasible sets. Note that $m \leq 2^n$ (every subset of agents might be feasible) and hence, $\log\log m$ is at most $\log n$. Thus, we have a poly-logarithmic approximate pen testing algorithm for any downward-closed feasibility environment.

Note, however, that the pen testing model is inherently downward-closed. Specifically, suppose an algorithm wanted to select a set $P \subseteq \overline{P}$, but P is not feasible while $\overline{P}$ is. Since all pens have non-negative residual ink, even the ones that failed their tests, there is no loss in selecting $\overline{P}$ instead of the set P. Thus, near optimal pen testing algorithms for downward-closed constraints can be extended to give near optimal algorithms for general combinatorial constraints, giving the same performance guarantee as the downward-closed environment.

▶ **Corollary 25.** *For any combinatorial pen testing environment, there exists a pen testing algorithm with an omniscient approximation ratio* $O(\log n\log\log m) = O(\log^2 n)$.

▶ Remark 26. Note that this reduction cannot be used to design deferred-acceptance mechanisms for general feasibility constraints. Allocating to agents that have dropped out of the auction can make the mechanism non-truthful (i.e, staying active till the price reaches the agent's value and dropping out subsequently might not be in the agent's best interests).

The bound for downward-closed and general combinatorial environments can be improved upon in special cases; for example, in the full online version, we give a natural deferred-acceptance mechanism for knapsack constraints that is a 2-approximation. For this knapsack problem, the agents have sizes along with values and feasible subsets are precisely those with a total size at most the knapsack capacity.

▶ **Corollary 27.** *For a pen testing environment with a knapsack feasibility constraint, there exists a pen testing algorithm with an omniscient approximation ratio* $2\,(1 + o(1)) \ln n$.

Online pricing mechanisms are a special case of deferred-acceptance mechanisms; thus, Theorem 1 converts online pricing mechanisms with good surplus into good online pen testing algorithms. For online pen testing problems, every pen can be tested exactly once and must either be selected or discarded immediately after testing and before testing another pen. The algorithm might have the ability to determine the order of testing pens (the sequential version) or the order might be adversarially determined (the oblivious version).

For the sequential pricing problem, Chawla et al. [6] gave an $\frac{e}{e-1}$-approximation mechanism for the single-item environment. Yan [26] connected the sequential pricing problem to the correlation gap and generalized the $\frac{e}{e-1}$-approximation to matroid environments. Both of these papers considered optimizing revenue, but the results can be easily adapted to optimize surplus.

▶ **Corollary 28.** *In the online sequential pen testing problem with a matroid feasibility constraint, there exists a pen testing algorithm that achieves an omniscient approximation ratio* $\frac{e}{e-1} \cdot (1 + o(1)) \ln n$.

Hajiaghayi et al. [16] and Chawla et al. [6] adapt the prophet inequality of Samuel-Cahn [25] to give a non-adaptive 2-approximation for the oblivious price posting problem with 1 good. Kleinberg and Weinberg [19] extend this 2-approximation to matroid environments and any arrival order of agents but with adaptive prices.

▶ **Corollary 29.** *In the online oblivious pen testing problem to select a single pen, there exists a non-adaptive pen testing algorithm that achieves an omniscient approximation ratio* $2(1 + o(1)) \ln n$.

▶ **Corollary 30.** *In the online oblivious pen testing problem with a matroid feasibility constraint, there exists a pen testing algorithm that achieves an omniscient approximation ratio* $2(1 + o(1)) \ln n$.

The bounds of Corollary 28 and Corollary 29 improve on the online pen testing bounds of Qiao and Valiant [23].

5 The Online IID Environment

Consider the special case of the online pen testing problem where the ink levels are drawn independently from the same distribution. We move away from the reduction framework of Theorem 1 to obtain a better bound for this environment.

▶ **Theorem 31.** *In online single-item environments with IID agents, there exists a price-posting strategy with an omniscient approximation at most* $(1 + o(1)) \ln n$*. Equivalently, in the online pen testing problem with IID ink levels, there exists an algorithm that achieves* $\pi(n) \leq (1 + o(1)) \ln n$*.*

First, note that the above theorem is tight. In Remark 17, we saw an instance (originally from [23]) with n IID agents whose values are drawn from the exponential distribution with consumer surplus only an H_n approximation to the optimal surplus. The optimal online consumer surplus cannot do better. Hence, the $(1 + o(1)) \ln n$ approximation ratio in Theorem 31 is tight.

Before proving Theorem 31, we briefly discuss the guarantee obtained through the reduction framework of Theorem 1. For the online environment with IID agents, it is known that $\gamma(n) = \frac{e}{e-1}$ [6]. Thus, the framework would give us an $\frac{e}{e-1} \cdot (1 + o(1)) \ln n$ bound. The direct analysis below gives a tight $H_n + 1 = (1 + o(1)) \ln n$ bound up to an additive factor 1.

Proof of Theorem 31. Similar to the proof of Theorem 8, we will phrase our program as an optimization problem and compute the optimal solution.

The surplus optimal auction always allocates the good to the agent with the highest value (smallest quantile). Let v_{max} be the random variable denoting the value of the winner.

$Pr(v_{\max} \leq v(t)) = (1 - t)^n$

Thus, the expected surplus of the surplus optimal mechanism equals

$$\begin{aligned}
\int_0^1 v(t) \times n(1-t)^{n-1} dt &= \int_0^1 \int_t^1 \frac{u(r)}{r} dr \times n(1-t)^{n-1} dt \\
&= \int_0^1 \frac{u(t)}{t} dt - \int_0^1 \frac{u(t)}{t} (1-t)^n dt \\
&= \int_0^1 \frac{1-(1-t)^n}{t} u(t) dt \\
&= U(1) + \int_0^1 \frac{1-(1-t)^n - nt(1-t)^{n-1}}{t^2} U(t) dt
\end{aligned}$$

The first equality follows by integrating from $u(t) = -tv'(t)$ and $v(1) = 0$. We integrate by parts for the second and fourth equation.

Next, we look at the consumer surplus through price-posting. For a price $v(q)$, we allocate the good if at least one agent has a quantile in $[0, q]$. Conditioned on selling the good, we get an expected consumer surplus of $\frac{U(q)}{q}$. Thus, the expected consumer surplus equals

$$\frac{1-(1-q)^n}{q} \times U(q)$$

As before, we first show Theorem 31 for consumer surplus regular distributions. Without loss of generality, assume that the maximum achievable consumer surplus through anonymous price posting is at most 1. We want to find the consumer surplus regular distribution with the largest surplus.

$$\max U(1) + \int_0^1 \frac{1-(1-t)^n - nt(1-t)^{n-1}}{t^2} U(t) dt$$

subject to

$$\frac{1-(1-q)^n}{q} \times U(q) \leq 1 \text{ for all } q \in [0, 1]$$

U is concave

First, observe that $C(q) = \frac{q}{1-(1-q)^n}$ is convex (the proof for convexity is deferred to the full online version). We want to fit a concave curve U under the convex curve C. Let $\overline{C}_q$ be the tangent to C at q. $\overline{C}_{\hat{q}}$ is a feasible solution for U for all $\hat{q} \in [0,1]$. Further, given that U touches the curve C at $\hat{q}$, $U(t) \leq \overline{C}_{\hat{q}}(t)$ for all $t \in [0,1]$ (from the concavity of U). Also, it is clear that the objective increases with a pointwise increase in U. Thus, we conclude that the optimal solution to the program is achieved at $U = \overline{C}_{\hat{q}}$ at some $\hat{q} \in [0,1]$. In particular, the worst-case ratio occurs when U is a straight-line.

Without loss of generality, we can normalize the slope to 1. Let $U(q) = q + a$. The surplus equals

$$1 + a + \int_0^1 \frac{1-(1-t)^n - nt(1-t)^{n-1}}{t} dt + a \times \int_0^1 \frac{1-(1-t)^n - nt(1-t)^{n-1}}{t^2} dt = H_n + an$$

See the full online version for the proof of the above equality.

By posting a price $v(q)$, we generate a consumer surplus

$$\frac{1-(1-q)^n}{q} \times U(q) = (1 + (1-q) + \cdots + (1-q)^{n-1}) \times (q + a)$$

If $a \geq \frac{1}{n}$, the ratio between the surplus and the consumer surplus is at most $H_n + 1$ by setting $q = 0$. If $a < \frac{1}{n}$, the surplus is less than $H_n + 1$, and by setting $q = 1$, the consumer surplus is at least 1. Thus, the worst-case ratio between surplus and consumer surplus is at most $H_n + 1 = (1 + o(1)) \ln n$.

We now show the result for all distributions. We rewrite the optimal surplus as follows.

$$\int_0^1 v(t) \times n(1-t)^{n-1} = \Big[V(t) \times n(1-t)^{n-1}\Big]_{t=0}^{t=1} + \int_0^1 V(t) \times n(n-1)(1-t)^{n-2} dt$$

The equality follows through integration by parts. From the above expression, it can be concluded that the optimal surplus increases with a pointwise increase in V.

Let $\overline{V}$ be the price-posting surplus curve of the distribution with a price-posting consumer surplus curve $\overline{U}$. $\overline{U}$ is pointwise larger than U, and hence, from Lemma 10, $\overline{V}$ is pointwise larger than V. Hence, the optimal surplus is larger in the distribution with price-posting consumer surplus curve $\overline{U}$. However, from Theorem 5, the consumer surplus from posting prices is identical to both the distributions. Thus, the consumer surplus irregular distribution has a better ratio between surplus and consumer surplus than the consumer surplus regular distribution. Thus, the ratio between optimal surplus to optimal consumer surplus is at most $(1 + o(1)) \ln n$ for all distributions. ◀

6 Conclusion

In this section, we discuss the various advantages and disadvantages of using the reduction framework of Theorem 1. Connecting the pen testing problem to auction theory and building an easy-to-use reduction framework enable us to design near optimal pen testing algorithms for any general feasibility constraint. We are able to construct algorithms that are only a constant factor away from the lower bound described in Qiao and Valiant [23] for various feasibility constraints like matroids ($\gamma(n) = 1$) and knapsack ($\gamma(n) = 2$). However, there is a scope for improvement on the following two fronts:

1. obtaining tight approximation guarantees, and
2. obtaining approximation guarantees under other models of access to the prior distributions.

Tight Approximation Guarantees. The approximation ratio of any pen testing algorithm is at least the optimal omniscient approximation $\zeta(n)$. This follows since the optimal consumer surplus in the underlying auction environment is an upper bound on the performance of the optimal pen testing algorithm. The framework matches this bound up to a multiplicative factor of the approximation $\gamma(n)$ of deferred-acceptance mechanisms. Reducing this gap for various feasibility environments stands as an open problem.

For instance, consider the online environments discussed in the paper, where $\zeta(n) = (1 + o(1)) \ln n$. Our framework yielded an omniscient approximation $2(1 + o(1)) \ln n$ in the oblivious version ($\gamma(n) = 2$) and $\frac{e}{e-1} \cdot (1+o(1)) \ln n$ in the sequential version ($\gamma(n) = \frac{e}{e-1}$). We conjecture that the approximation guarantees obtained by applying the reduction framework are not tight, and can be strengthened to $(1 + o(1)) \ln n$ in both these environments, like in the IID setting (Section 5).

Other Models of Access to Distributions. Our framework crucially makes use of virtual values, which in turn need complete knowledge of the distribution of ink levels. Thus, tailoring this approach to models where the algorithm gets partial access to the priors is challenging.

Qiao and Valiant [23] study two such models. They study the online oblivious problem where the algorithm gets access to just one sample from the distribution of each pen. They give a $O(\log n)$-approximation to the omniscient benchmark in this setting. They also look at the online secretary setting, where the pens arrive according to a permutation chosen uniformly at random. The quantity of ink in the pens are adversarially determined. The algorithm is told the quantity of ink in the pen with the largest ink level. They give a $O(\log n)$-approximation in this environment. Further, when the algorithm is given access to the ink levels in all the n pens (with random arrival order), they tighten their bound to $O(\frac{\log n}{\log \log n})$. It is an open question to identify reduction frameworks for these different models of access to the distributions.

Abstract

We study differential privacy (DP) in a multi-party setting where each party only trusts a (known) subset of the other parties with its data. Specifically, given a *trust graph* where vertices correspond to parties and neighbors are mutually trusting, we give a DP algorithm for aggregation with a much better privacy-utility trade-off than in the well-studied local model of DP (where each party trusts no other party). We further study a robust variant where each party trusts all but an unknown subset of at most t of its neighbors (where t is a given parameter), and give an algorithm for this setting. We complement our algorithms with lower bounds, and discuss implications of our work to other tasks in private learning and analytics.

1 Introduction

Differential privacy (DP) [22, 21] is a rigorous privacy notion that has seen extensive study (e.g., [23, 52]) and widespread adoption in analytics and learning (e.g., [20, 2, 46, 51]). It dictates that the output of a randomized algorithm remains statistically indistinguishable if the data of a single user changes. The most widely studied models of DP are the *central* model where a trusted curator is given access to the raw data and required to output a DP estimate of the function of interest, and the *local* model [26, 37] where every message leaving each user's device is required to be DP. While the latter is compelling in that each user needs to place minimal trust in other users, it is known to suffer from a significantly higher utility degradation compared to the former (e.g., [15]).

In practice, data sharing settings often include situations where a user is willing to place more trust in a *subset* of other users. For example, many people have different privacy sensitivities depending on their relationships with others: Alice might be willing to share her location data with family and close friends, but unwilling to have her location data be recoverable by strangers from a public channel. This relates to philosophical conceptualizations of privacy as *control over personal information*, in that individuals may specify with whom they are willing share their information [49].

Trust Graph DP Models

In this work, we model such relationships as a *trust graph* where vertices correspond to different users and neighboring vertices are mutually trusting (see Figure 1 for a simple example). We define and study DP over such trust graphs, whereby the DP guarantee is enforced on the messages exchanged by each vertex or its trusted neighbors on one hand, and the other non-trusted vertices on the other hand.

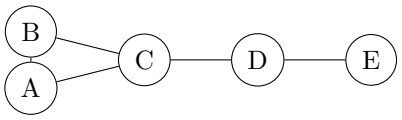

Figure 1 Simple example trust graph. User A is only willing to share their data with users B and C, and user C is additionally willing to share their data with D. We introduce a privacy model (TGDP) in which users D and E cannot identify user A's data based on any communication exchanged.

Specifically, we define notions of *Trust Graph DP (TGDP)* that generalize existing definitions of local DP [37] and central DP, and effectively interpolate between them. Informally, TGDP requires that the distribution of all messages exchanged by each vertex v or one of its neighbors with any vertices that are not trusted by v should remain statistically indistinguishable if the input data held by v changes; we formalize this in Definition 7.

We further extend TGDP to capture *robustness* to potentially compromised neighbors. Namely, the above privacy guarantee can break if a single neighbor of a vertex turns out to be untrustworthy. Thus, we introduce the notion of *Robust Trust Graph DP (RTGDP)*, which maintains the privacy guarantee even if some unknown subset of neighbors of a given size is compromised; see Definition 14.

Our Results

Having defined these trust graph-based models of DP, we give algorithms for the basic *aggregation* primitive that satisfy both TGDP and RTGDP notions. Notably, we propose algorithms that depend on linear programming formulations that can be computed in polynomial time (Theorems 9 and 15). We complement our algorithms with lower bounds on the error that depend on combinatorial properties of the graph (Theorems 10 and 16). Although closing the gap between our upper and lower bounds is still open, we obtain a *bi-criteria* result showing that the upper bound is not much larger than the lower bound when we slightly increase the robustness parameter t (Theorem 17).

The aggregation primitive we study in this work is a basic building block. Indeed, our work implies new DP algorithms over trust graphs for other problems in learning and analytics (see Appendix 5).

We supplement the theory with evaluation on nine real network datasets including email communication networks, social networks, and cryptocurrency trust networks. Our results show that the utility degradation when satisfying TGDP and RTGDP can be significantly lower than that of local DP. Thus, when trust relationships exist, accounting for these relationships when incorporating DP into a system can considerably improve overall utility.

1.1 Technical Overview

We first give a TGDP mechanism for the integer aggregation problem with a mean-squared error (MSE) that scales linearly in the size of any dominating set[1] of the trust graph. The idea of the protocol is the following: Each user identifies one user in the dominating set that they trust and to whom they send their input. Then, each user in the dominating set simply runs the central (discrete) Laplace mechanism to privatize the data. The final estimate is the sum of all these sub-estimates in the dominating set. The MSE grows with the dominating set size, as formalized in Theorem 8.

A disadvantage of the protocol described above is that, in order to minimize the error, it requires the knowledge of a minimum dominating set. However, computing a minimum dominating set is NP-hard and even hard to approximate [27]. So we give (in Theorem 9) a protocol that not only is efficient but can also reduce the error by up to $O(\log n)$ factor. This protocol only requires a solution to a linear program (LP), which, unlike the minimum dominating set, can be computed in polynomial time. At a high-level, there are two key ideas in this protocol:

- **(i)** *Input Splitting:* Instead of sending the input to a single vertex as in the previous section, each user will split their input into (random) additive shares and send it to all its neighbors. The input splitting idea originated in cryptography [36] and has recently found applications in the shuffle model of DP [6, 32], although the nature of how we use it here is quite different from those previous works.
- **(ii)** *Distributed Noise Addition:* Similar to the previous protocol, each user again broadcasts the sum of all messages they receive with some noise added. The main difference here is that, instead of using the discrete Laplace noise, we use the negative binomial noise designed in such a way that, when sufficiently many of them are summed up, they guarantee DP. This helps reduce the amount of noise required in the protocol. (The idea of distributed noise generation dates back to the early works on DP [21], but the distributions we use here are from [6].)

What we gain by applying the input splitting is that, due to the properties of random additive shares, the only way the adversary learns anything about x_v is to sum up all the messages broadcast from its neighbors. By a careful design of the distributed noise distribution, we can ensure that this sum contains sufficient noise to provide DP guarantees.

Our lower bound on integer aggregation with TGDP (Theorem 10) shows that the MSE grows with the packing number of the trust graph. The main idea is to transform any TGDP protocol to a local DP (LDP) protocol with the same privacy and utility, but with a number of users equal to the packing number. The "packing" property ensures that the users are "isolated" from each other in the reduction step.

For our results in the RTGDP model, we consider the same LP but impose a stricter constraint to ensure DP guarantees even when some neighbors of each vertex are compromised. To prove our bi-criteria tightness (Theorem 17), we study the dual of the LP and apply randomized rounding to convert the fractional solution into an integral one.

1.2 Related Work

Secure multiparty computation (SMPC) [55, 56, 34] can be leveraged to allow users to achieve central DP utility without relying on a trusted curator; this is done via cryptographic protocols whose security relies on computational hardness assumptions [21, 8, 11, 9]. An

[1] See Section 3 for the formal definitions of a dominating set and a packing.

important distinction between our model and SMPC is that while the privacy of SMPC protocols relies on computational hardness assumptions, the privacy guaranteed in our proposed TGDP model is information-theoretic (and thus stronger). Still, our proposed TGDP model can also be thought of as relaxing the SMPC threat model to assume that a subset of at least a certain number of users is trustworthy (or would execute the algorithm faithfully). Specifically, the proposed TGDP notion could enable higher-utility protocols than the state-of-the-art in SMPC, by making a stronger (but realistic) assumption that different users fully trust some subset of other users (namely, their neighbors in the trust graph).

We also point out that the multi-central (a.k.a. multi-server) model of DP [50, 17] is a special case of our RTGDP model. Another intermediate model between local and central DP is the shuffle model [10, 25, 16], where aggregation has been extensively studied (e.g., [5, 30, 31]); but this model does not capture mutually trusting relationships between different pairs of users. Finally, the network DP model [18] is a different relaxation of local DP where the (DP) communication between users is restricted to the edges of a given graph; this is in contrast to our proposed TGDP model where a given graph encodes trust relationships.

Organization

We start with some background in Section 2. In Section 3, we formally define the notion of DP on trust graphs, and give algorithms and a lower bound for solving the aggregation task under this privacy guarantee. The RTGDP notion is defined in Section 4 where we also give an algorithm and lower bounds for aggregation under this robust notion. We conclude with some interesting future directions in Section 6. Missing proofs are in Appendix B. In Appendix C, we include experiments in which we report our given upper and lower bounds on real network datasets.

2 Preliminaries

Let n users be represented as vertices $V = \{1, ..., n\}$ of a graph $G = (V, E)$, where $E \subseteq V^2$ corresponds to the set of pairs (i, j) of users, where i and j are willing to share their data with each other.[2] Let $\mathcal{X}$ be any domain and suppose each user $i \in V$ has data $x_i \in \mathcal{X}$, and the (full) input dataset is given by $(x_1, \ldots, x_n) = \mathbf{x} \in \mathcal{X}^n$. Let $N(v)$ be the *neighborhood* of v in $G = (V, E)$, i.e., $N(v) = \{u \mid (u, v) \in E\}$ and let $N[v]$ be the *closed neighborhood* of v, i.e., $N[v] = N(v) \cup \{v\}$.

2.1 Differential Privacy Definitions and Tools

▶ **Definition 1** (DP; [22, 21]). *A randomized mechanism $M : \mathcal{X}^n \to \mathcal{O}$ is* (ε, δ)-differentially private ((ϵ, δ)-DP) *if for all pairs $\mathbf{x}, \mathbf{x}' \in \mathcal{X}^n$ of datasets that differ only in the data of a single user, and for all subsets $S \subseteq \mathcal{O}$,* $\Pr[M(\mathbf{x}) \in S] \leq e^{\varepsilon} \Pr[M(\mathbf{x}') \in S] + \delta$.

For brevity, we write $(\varepsilon, 0)$-DP as ε-DP (a.k.a., *pure*-DP).

In *non-interactive local DP*, each user has to randomize their own input and send it to the server (or, alternatively, publish it). In this case, each user's randomized output is required to be DP:

[2] For simplicity, we focus only on the "symmetric" notion of sharing. It is relatively simple to extend all of our algorithms to the "asymmetric" version as well.

▶ **Definition 2** (Non-Interactive Local DP; [37]). *A randomized mechanism $M : \mathcal{X} \to \mathcal{O}$ is a* non-interactive (ε, δ)-local DP randomizer *if for any pair $x, x' \in \mathcal{X}$, and for all subsets $S \subseteq \mathcal{O}$, $\Pr[M(x) \in S] \leq e^{\varepsilon} \Pr[M(x') \in S] + \delta$.*

To define DP properties of possibly interactive protocols, we follow the approach of [8]. First, we define the notion of a protocol view.

▶ **Definition 3** (View). *The* view *of a protocol P at vertex u for an input dataset $\mathbf{x} \in \mathcal{X}^n$, denoted $\textsc{view}_P^u(\mathbf{x})$, consists of the input x_u and all messages received and sent (together with the corresponding source/destination) by the vertex u.*

The view of the protocol P for a subset $S \subseteq V$ of vertices is defined as $\textsc{view}_P^S(\mathbf{x}) := (\textsc{view}_P^u(\mathbf{x}))_{u \in S}$. Let $\mathcal{O}$ be the set of all possible views. For any $T \subseteq V$, we write $\mathbf{x}_{-T}$ as a shorthand for $\mathbf{x}_{V \setminus T}$ and, for any $v \in V$, $\mathbf{x}_{-v}$ as a shorthand for $\mathbf{x}_{-\{v\}}$. When the protocol is interactive, local DP can be defined as follows [8]:

▶ **Definition 4** (Interactive Local DP). *A protocol P satisfies (ϵ, δ)-*local DP *((ϵ, δ)-LDP) if for each vertex $v \in V$, $\textsc{view}_P^{V \setminus \{v\}}(\mathbf{x})$ satisfies (ε, δ)-DP with respect to the input x_v for all values of $\mathbf{x}_{-v}$. I.e., for all pairs $x_v, x_v' \in \mathcal{X}$, all values of $\mathbf{x}_{-v}$, and all subsets $S \subseteq \mathcal{O}$,*

$$\Pr[\textsc{view}_P^{V \setminus \{v\}}(x_v, \mathbf{x}_{-v}) \in S] \leq e^{\varepsilon} \Pr[\textsc{view}_P^{V \setminus \{v\}}(x_v', \mathbf{x}_{-v}) \in S] + \delta.$$

For pure-DP, it is useful to define $D_\infty(\mathcal{P} \parallel \mathcal{P}') := \max_{o \in \mathrm{supp}(\mathcal{P})} \ln\left(\frac{\Pr_{X \sim \mathcal{P}}[X=o]}{\Pr_{X' \sim \mathcal{P}}[X'=o]}\right)$ for distributions $\mathcal{P}, \mathcal{P}'$. We will sometimes use random variables and distributions interchangeably.

It is well-known that DP is robust to post-processing. This fact will be useful in our privacy analysis.

▶ **Lemma 5** (Post-Processing). *For any random variables X, X' and a (possibly randomized) function f, we have $D_\infty(f(X) \parallel f(X')) \leq D_\infty(X \parallel X')$.*

We will use the following distributions for the noise:

- The *negative binomial distribution* $\mathrm{NB}(r, p)$ with parameters $r > 0, p \in (0, 1)$ is supported on $\mathbb{Z}_{\geq 0}$ with density $\Pr[X = k] = \binom{k+r-1}{k}(1-p)^k p^r$, where $X \sim \mathrm{NB}(r, p)$. Its variance is $r(1-p)/p^2$.
- Let $\mathrm{sNB}(r, p)$ be the distribution of $X - X'$ where $X, X' \sim \mathrm{NB}(r, p)$ are i.i.d.
- The *discrete Laplace distribution* $\mathrm{DLap}(b)$ with parameter $b > 0$ is supported on $\mathbb{Z}$ and its density is given by $\Pr[X = k] \propto \exp(-|k|/b)$ for $X \sim \mathrm{DLap}(b)$.

We will use the following facts in our analysis:

- If $X_1 \sim \mathrm{sNB}(r_1, p)$ and $X_2 \sim \mathrm{sNB}(r_2, p)$, then $X_1 + X_2 \sim \mathrm{sNB}(r_1 + r_2, p)$.
- $\mathrm{DLap}(b)$ is the same distribution as $\mathrm{sNB}(1, 1 - e^{-1/b})$.

The discrete Laplace mechanism is well-known to guarantee DP in the central setting [33]. Below, we state a slightly more general version of this for sNB that will be convenient for our analysis.

▶ **Lemma 6.** *For any $x, x' \in \{0, \ldots, \Delta\}$, let $Z \sim \mathrm{sNB}(r, 1 - e^{-\varepsilon/\Delta})$ where $r \geq 1$. Then, we have $D_\infty(Z + x \parallel Z + x') \leq \varepsilon$.*

In the privacy analysis, we often consider $\textsc{view}_P^S(x_v, \mathbf{x}_{-v})$ and $\textsc{view}_P^S(x_v', \mathbf{x}_{-v})$ for $x_v, x_v' \in \mathcal{X}$. For convenience, we will write $\textsc{view}_P^S(x)$ for $x \in \mathcal{X}$ as a shorthand for $\textsc{view}_P^S(x_v, \mathbf{x}_{-v})$ when $x_v = x$. Similarly, for a quantity y that depends on x_v, we will write $y(x)$ to denote y when $x = x_v$.

3 Trust Graph Differential Privacy

We model trust relationships across users as a network where vertices correspond to users, and undirected edges connect users who are mutually willing to share their data (see Figure 1). We focus on undirected trust graphs, though extensions of our results to directed graphs are possible. For a given trust graph, we define a general notion of Trust Graph DP, provide algorithms for achieving it, and analyze upper and lower bounds on the error for the integer aggregation problem.

▶ **Definition 7.** *(Trust Graph DP) Let $G = (V, E)$. A protocol P satisfies* (ϵ, δ, G)-Trust Graph DP *((ϵ, δ, G)-TGDP) if for each vertex $v \in V$, $\textsc{view}_P^{V \setminus N[v]}(\mathbf{x})$ satisfies (ε, δ)-DP with respect to the input x_v for all values of $\mathbf{x}_{-v}$. I.e., for all pairs $x_v, x'_v \in \mathcal{X}$, all values of $\mathbf{x}_{-v}$, and all subsets $S \subseteq \mathcal{O}$,*

$$\Pr[\textit{VIEW}_P^{V \setminus N[v]}(x_v, \mathbf{x}_{-v}) \in S] \leq e^{\varepsilon} \Pr[\textit{VIEW}_P^{V \setminus N[v]}(x'_v, \mathbf{x}_{-v}) \in S] + \delta.$$

Referring back to Figure 1 as an example, Definition 7 says that even if users D and E pooled their messages together, their collective view would still be DP with respect to the data for user A.

Notably, the proposed TGDP model generalizes both the central DP model and the local DP model. The central DP model is captured when G is a star graph in which all vertices (the users) entrust their data a single central vertex (the analyst): each user's data is private relative to the view of all other users, but all users trust the same central analyst. The local DP model, on the other hand, is captured when G simply has no edges between any vertices. Our TGDP model thus introduces a flexibility to capture intermediate trust relationships, perhaps involving several local analysts, or more general trust graphs arising from social networks.

As before, we write $(\varepsilon, 0, G)$-TGDP as (ε, G)-TGDP. Note that the (ε, G)-DP condition in Definition 7 can be written as $D_\infty\left(\textsc{view}_P^{V \setminus N[v]}(x_v) \,\middle\|\, \textsc{view}_P^{V \setminus N[v]}(x'_v)\right) \leq \varepsilon$.

Recall that for a graph $G = (V, E)$, a *dominating set* is a subset $U \subseteq V$ such that for every $v \in V \setminus U$, there is a $u \in U$ such that $(u, v) \in E$; the size of a minimum dominating set is the *domination number* $\gamma(G)$. A *packing* of G is a subset $U \subseteq V$ such that for any distinct $u, u' \in U$, $N[u]$ and $N[u']$ are disjoint; the size of a maximum packing is the *packing number* $\rho(G)$.

Aggregation

We consider the *integer aggregation* problem. Let each individual have a value $x_i \in \{0, \ldots, \Delta\}$. The goal is to compute an estimate $\tilde{a}$ of $a = \sum_{i=1}^{n} x_i$. We measure the *mean-square error* (MSE), which is defined as $\mathbb{E}[(\tilde{a} - a)^2]$, where the expectation is over the randomness of the protocol. In central DP, the standard Laplace mechanism [22] achieves an error of $2\Delta^2/\varepsilon^2$. In local DP, the local version of the Laplace mechanism achieves an error of $2\Delta^2 n/\varepsilon^2$. Both of these are known to be asymptotically optimal.

3.1 Algorithm via Dominating Set

We start by giving a protocol for the integer aggregation problem using the graph's dominating set.

▶ **Theorem 8.** *There is an (ε, G)-TGDP mechanism for the aggregation problem with MSE at most $2\Delta^2|T|/\varepsilon^2$, where T is any dominating set of G.*

Proof. The protocol works as follows:

- First, each user $v \in V$ picks an arbitrary vertex $u_v \in T \cap N[v]$. (The intersection is not empty since T is a dominating set.) Then, the user sends x_v to u_v.
- Each user $u \in T$ broadcasts the sum of all numbers it receives together with a noise drawn from $\mathrm{DLap}(\Delta/\varepsilon)$. More formally, the user broadcasts $a_u = \sum_{\substack{v \in V \\ u_v = u}} x_v + z_u$, where $z_u \sim \mathrm{DLap}(\Delta/\varepsilon)$.
- Finally, the estimate is $\tilde{a} = \sum_{u \in T} a_u$.

Privacy Analysis. Consider any $v \in V$ and $\mathbf{x}_{-v} \in \{0, \ldots, \Delta\}^{V \setminus \{v\}}$. We write $\mathbf{a}$ as a shorthand for $(a_u)_{u \in T}$. Let $S_v := \{w \in N[v] \mid u_w \in N[v]\}$ denote the nodes in $N[v]$ whose message in the first step is sent to a node in $N[v]$. Notice that $\mathrm{VIEW}_P^{V \setminus N[v]}(x)$ is exactly $(\mathbf{x}_{-S_v}, \mathbf{a}(x))$. We claim that this is a post-processing of $z_{u_v} + x$. This is simply because $\mathbf{x}_{-S_v}, (a_u)_{u \in T \setminus \{u_v\}}$ do not depend on $x_v = x$ at all and are independent of $z_{u_v} + x$; finally, note that $a_{u_v}(x)$ is a post-processing of $z_{u_v} + x$ since $a_{u_v}(x) = (z_{u_v} + x) + \sum_{\substack{v' \in V \setminus \{v\} \\ u_{v'} = u_v}} x_{v'}$.

Consider any $x_v, x'_v \in \{0, \ldots, \Delta\}$. By Lemma 5 and Lemma 6, we have

$$D_\infty \left(\mathrm{VIEW}_P^{V \setminus N[v]}(x_v) \,\middle\|\, \mathrm{VIEW}_P^{V \setminus N[v]}(x'_v) \right) \le D_\infty(z_{u_v} + x_v \parallel z_{u_v} + x'_v) \le \varepsilon,$$

where the second inequality is due to Lemma 6. Thus, the protocol satisfies (ε, G)-TGDP as desired.

Utility Analysis. The MSE is $\mathbb{E}\left[(\tilde{a} - a)^2\right] = \sum_{u \in T} \mathbb{E}[z_u^2] \le |T| \cdot \frac{2\Delta^2}{\varepsilon^2}$. ◀

3.2 Improved Algorithm via Linear Programming

A disadvantage of the protocol from Section 3.1 is that to minimize the error, it requires the knowledge of a minimum dominating set. Computing minimum dominating set is NP-hard and even hard to approximate [27]. In this section, we give a protocol that is efficient to compute and furthermore can reduce the error by up to $O(\log n)$ factor in certain graphs. To describe our protocol, recall the linear programming (LP) relaxation of the dominating set problem:

$$\min \sum_{u \in V} y_u \qquad \text{s.t.} \sum_{u \in N[v]} y_u \ge 1 \quad \forall v \in V; \qquad 0 \le y_u \le 1 \quad \forall u \in V. \tag{1}$$

To see that this is a relaxation of the dominating set problem, note that any dominating set $T \subseteq V$ gives a solution by setting $y_v = \mathbf{1}[v \in T]$. Due to this, the optimum of this LP is no more than the size of the dominating set. In fact, the LP optimum can be smaller than the minimum dominating set size by an $O(\log n)$ factor [45].

The main result is a protocol whose MSE scales with the LP optimum instead of dominating set:

▶ **Theorem 9.** *There is an (ε, G)-TGDP mechanism for the aggregation problem with MSE at most $2\Delta^2 \cdot \mathrm{OPT}_{\mathrm{LP}}/\varepsilon^2$, where $\mathrm{OPT}_{\mathrm{LP}}$ denotes the value of the optimal solution to the LP in (1).*

Proof. Let $\mathbf{y} = (y_u)_{u \in V}$ denote any solution to the LP in (1). The protocol works as follows:

- Let $q = 2n\Delta$.

- For every user $v \in V$, pick $\{s_v^u\}_{u \in N[v]} \subseteq \mathbb{Z}_q$ uniformly at random among those that satisfy $\sum_{u \in N[v]} s_v^u \equiv x_v \mod q$. Then, for every $u \in N[v]$, user v sends s_v^u to u.
- For every $u \in V$, sample $z_u \sim \mathrm{sNB}(y_u, 1 - e^{-\varepsilon/\Delta})$; broadcast $a_u \equiv z_u + \sum_{v \in N[u]} s_v^u \mod q$.
- Compute $a' \equiv \sum_u a_u \mod q$. Then, output $\tilde{a} = \begin{cases} a' & \text{if } a' \le q/2, \\ a' - q & \text{otherwise.} \end{cases}$

Privacy Analysis. Throughout the analysis, we assume that the addition is modulo q unless stated otherwise. Consider any $v \in V$ and $\mathbf{x}_{-v} \in \{0, \dots, \Delta\}^{V \setminus \{v\}}$. We write $\mathbf{a}$ as a shorthand for $(a_u)_{u \in V}$. Notice that $\mathrm{VIEW}_P^{V \setminus N[v]}(x)$ is exactly $(\mathbf{x}_{-N[v]}, \mathbf{a}(x), (s_{v'}^u)_{u \in V \setminus N[v], v' \in V})$. We claim that this is a post-processing of $(z_u + s_v^u)_{u \in N[v]}$. This is simply because $\mathbf{x}_{-N[v]}, (a_u)_{u \in V \setminus N[v]}, (s_{v'}^u)_{u \in V \setminus N[v], v' \in V}$ do not depend on $x_v = x$ at all and are independent of $(z_u + s_v^u)_{u \in N[v]}$; finally, note that $(a_u(x))_{u \in N[v]}$ is a post-processing of $(z_u + s_v^u)_{u \in N[v]}$ since $a_u(x) = (z_u + s_v^u) + \sum_{\substack{v' \in N[v] \setminus \{v\} \\ u_{v'} = u}} s_{v'}^u$ for all $u \in N[v]$.

For any $x_v, x_v' \in \{0, \dots, \Delta\}$, Lemma 5 implies that

$$D_\infty \left(\mathrm{VIEW}_P^{V \setminus N[v]}(x_v) \,\middle\|\, \mathrm{VIEW}_P^{V \setminus N[v]}(x_v') \right) \le D_\infty((z_u + s_v^u(x_v))_{u \in N[v]} \,\|\, (z_u + s_v^u(x_v'))_{u \in N[v]}).$$

Now, since $(s_v^u(x))_{u \in N[v]}$ are random elements of $\mathbb{Z}_q$ that sum to x, we also have that $(z_u + s_v^u(x))_{u \in N[v]}$ are random elements of $\mathbb{Z}_q$ that sum to $x + \sum_{u \in N[v]} z_u$. In other words, $(z_u + s_v^u(x_v))_{u \in N[v]}$ is a post-processing of $x + \sum_{u \in N[v]} z_u$. Again, Lemma 5 implies that

$$D_\infty((z_u + s_v^u(x_v))_{u \in N[v]} \,\|\, (z_u + s_v^u(x_v'))_{u \in N[v]}) \le D_\infty \left(x_v + \sum_{u \in N[v]} z_u \,\middle\|\, x_v' + \sum_{u \in N[v]} z_u \right).$$

Finally, $Z := \sum_{u \in N[v]} z_u$ is distributed as $\mathrm{sNB}\left(\sum_{u \in N[v]} y_u, 1 - e^{-\varepsilon/\Delta}\right)$. Since $\mathbf{y}$ is feasible in (1), we have $\sum_{u \in N[v]} y_u \ge 1$. Thus, we can apply Lemma 6 to conclude that the RHS above is $\le \varepsilon$.

Utility Analysis. Note $\tilde{a} \equiv a + \left(\sum_{u \in V} z_u\right) \mod q$. Since $a \in [0, q/2]$ and $\tilde{a} \in (-q/2, q/2]$, we have $|a - \tilde{a}| \le \left|\sum_{u \in V} z_u\right|$. Thus, the MSE is $\le \sum_{u \in T} \mathbb{E}[z_u^2] \le \sum_{u \in T} \frac{2y_u}{(\varepsilon/\Delta)^2} = \frac{2\Delta^2 \mathrm{OPT}_{\mathrm{LP}}}{\varepsilon^2}$, where the last equality is from our assumption that $(y_u)_{u \in V}$ is an optimal solution to the LP in (1). ◀

We remark that, in the proof above, the privacy guarantee holds even for non-optimal LP solution $\mathbf{y}$, as long as it satisfies the constraints. Similarly, the error guarantee holds where $\mathrm{OPT}_{\mathrm{LP}}$ is replaced with the objective value of the solution. This is helpful for practical applications where we may only have an approximately optimal LP solution.

3.3 Lower Bound

We now give a lower bound for integer aggregation, where the MSE grows with the packing number.

▶ **Theorem 10.** *For any $\varepsilon \le O(1)$, any (ε, G)-TGDP protocol for integer aggregation incurs MSE $\Omega(\Delta^2 \cdot \rho(G))$, where $\rho(G)$ denotes the packing number of the trust graph G.*

In fact, we give the following reduction that transforms any TGDP protocol to an LDP protocol with the same privacy parameter and MSE, but only on $\rho(G)$ users (instead of n users). Applying the known $\Omega(\Delta^2 n)$ lower bound for integer aggregation in LDP [15][3] immediately yields Theorem 10.

▶ **Lemma 11.** *Suppose that there is an (ε, G)-TGDP protocol for integer aggregation. Then, there exists an ε-local DP protocol for integer aggregation for $\rho(G)$ users with the same MSE as the (ε, G)-TGDP protocol, where $\rho(G)$ denotes the packing number of G.*

Proof. Let $U = \{u_1, \ldots, u_m\} \subseteq V$ be the largest packing in G where $m = \rho(G)$. To avoid ambiguity, let $\tilde{\mathbf{x}} = (\tilde{x}_1, \ldots, \tilde{x}_m)$ be the input to the LDP protocol (that we construct below).

To construct the LDP protocol, let $Q_1 \cup \cdots \cup Q_m$ be any partition of V such that $N[u_i] \subseteq Q_i$ for all $i \in [m]$. Such a partition exists because $N[u_1], \ldots, N[u_m]$ are disjoint by the definition of packing. Let P be any (ε, G)-TGDP protocol for integer aggregation. Our LDP protocol $\tilde{P}$ runs the protocol P where each $\tilde{P}$'s user $i \in [m]$ assumes the role of all P's users in Q_i, where the input to P is defined as $x_u = \begin{cases} \tilde{x}_i & \text{if } u = u_i \\ 0 & \text{otherwise,} \end{cases}$ $\forall u \in Q_i$. We then output the estimate as produced by P. The MSE of $\tilde{P}$ is obviously the same as that of P.

To see that $\tilde{P}$ satisfies ε-LDP, consider any $i \in [m], \tilde{\mathbf{x}}_{-i} \in \mathcal{X}^{[m] \setminus \{i\}}$, we have $\textsc{view}_{\tilde{P}}^{[m] \setminus \{i\}}(\tilde{x}) = \textsc{view}_P^{V \setminus Q_i}(\mathbf{x}(\tilde{x}))$, where $\mathbf{x}(\tilde{x})$ is the input to P as defined above. Since $V \setminus Q_i \subseteq V \setminus N[u_i]$, $\textsc{view}_P^{V \setminus Q_i}(\mathbf{x}(\tilde{x}))$ is a post-processing of $\textsc{view}_P^{V \setminus N[u_i]}(\mathbf{x}(\tilde{x}))$, Lemma 5 implies that

$$D_\infty\left(\textsc{view}_{\tilde{P}}^{[m] \setminus \{i\}}(\tilde{x}_i) \,\middle\|\, \textsc{view}_{\tilde{P}}^{[m] \setminus \{i\}}(\tilde{x}_i')\right) \le D_\infty\left(\textsc{view}_P^{V \setminus N[u_i]}(\tilde{x}_i) \,\middle\|\, \textsc{view}_P^{V \setminus N[u_i]}(\tilde{x}_i')\right) \le \varepsilon,$$

where the last inequality is due to P being an (ε, G)-TGDP protocol. Hence, $\tilde{P}$ is ε-LDP. ◀

Unfortunately, the lower bound in Theorem 10 is not tight with respect to the upper bounds in Theorems 8 and 9. Indeed, the following is a example of a graph that has a large gap between the domination number and the packing number [14]. Let $V = [k] \times [k]$ for $k \in \mathbb{N}$. There is an edge between any $(x, y) \in V, (x', y') \in V$ iff $x = x'$ or $y = y'$. For this graph, $\mathrm{OPT}_{\mathrm{LP}}$ is$\Omega(\sqrt{|V|})$ since every vertex has degree $O(k) = O(\sqrt{|V|})$ whereas the maximal packing has size exactly one (see Figure 2 for $k = 4$). We can also show that this instance exhibits an asymptotically optimal gap:

▶ **Theorem 12.** *For any graph G, $\mathrm{OPT}_{\mathrm{LP}} \le \rho(G) \cdot \sqrt{n}$ where $\mathrm{OPT}_{\mathrm{LP}}$ denote the value of the optimal solution to the LP in (1).*

In other words, our upper bound based on the LP (Theorem 9) and our lower bound (Theorem 10) on the MSE has a gap of at most $O(\sqrt{n})$. To the best of our knowledge, the bound in Theorem 12 was not known before; we give the full proof in Section D.

Note that the above instance also gives a gap of $\Omega(\sqrt{|V|})$ between the domination number and the packing number. Since it is known [45] that $\gamma(G) \le O(\log n) \cdot \mathrm{OPT}_{\mathrm{LP}}$, Theorem 12 implies the following corollary:

▶ **Corollary 13.** *For any graph G, $\gamma(G) \le \rho(G) \cdot O(\sqrt{n} \cdot \log n)$.*

That is, the above gap instance is tight up to a logarithmic factor. Furthermore, this also means that our upper bound based on the dominating set (Theorem 8) and our lower bound (Theorem 10) on the MSE has a gap of at most $O(\sqrt{n})$.

[3] Note that [15] state their lower bound for $\Delta = 1$ but the case $\Delta > 1$ follows by scaling up the input.

4 Robust Trust Graph Differential Privacy

In the previous section, we assumed that each user u trusts all of their neighbors $N(u)$. Although this is certainly a reasonable assumption, it might pose a security risk. For example, if one of the neighbors of u is compromised, then u's data might be leaked as the model offers no protection with respect to the view of u's neighbors. Indeed, in the dominating set protocol (Theorem 8), the user sends their raw data to one of their neighbors; if this neighbor is compromised, then the user's data is leaked in the clear. To mitigate this, we propose a revised trust graph DP model that is more robust to such leakage. In particular, for each user u, the DP protection remains as long as at most t_u of their neighbors are compromised, where t_u is some predefined number. This is formalized below.

▶ **Definition 14.** *(Robust Trust Graph DP) Let $G = (V, E)$ and $\mathbf{t} = (t_v)_{v \in V} \in \mathbb{Z}^V_{\geq 0}$. A protocol P satisfies $(\epsilon, \delta, G, \mathbf{t})$*-Robust Trust Graph DP ($(\epsilon, \delta, G, \mathbf{t})$-RTGDP) *if for each vertex $v \in V$ and every set $T \subseteq N(v)$ of size at most t_v, $\textsc{view}_P^{V \setminus (N[v] \setminus T)}(\mathbf{x})$ satisfies (ε, δ)-DP with respect to the input x_v for all values of $\mathbf{x}_{-v}$. I.e., for all pairs $x_v, x'_v \in \mathcal{X}$, all values of $\mathbf{x}_{-v}$, and all subsets $S \subseteq \mathcal{O}$,*

$$\Pr[\textsc{view}_P^{V \setminus (N[v] \setminus T)}(x_v, \mathbf{x}_{-v}) \in S] \leq e^{\varepsilon} \Pr[\textsc{view}_P^{V \setminus (N[v] \setminus T)}(x'_v, \mathbf{x}_{-v}) \in S] + \delta.$$

4.1 Integer Aggregation Protocol

We start by giving an integer aggregation protocol that is again based on an LP. We adapt the LP in (1) by imposing a stricter constraint to ensure DP guarantees even when up to t_v of v's neighbor are compromised. This results in the following LP where the only difference compared to (1) is the stricter first constraint.[4] Note that when $\mathbf{t} = 0$, the two LPs coincide.

$$\min \sum_{u \in V} y_u \qquad \text{s.t.} \sum_{u \in (N[v] \setminus T)} y_u \geq 1 \quad \forall v \in V,\ T \in \binom{N(v)}{\leq t_v}; \quad 0 \leq y_u \leq 1 \quad \forall u \in V. \tag{2}$$

While (2) can have exponential size due to the presence of "$\forall T \in \binom{N(v)}{\leq t_v}$" in the constraint, it can still be solved in polynomial time because an efficient separation oracle exists for the first constraint. Specifically, for each $v \in V$, we can check the first constraint by letting T be the t_v maximum values and check the inequality for just that T (instead of enumerating over all $T \in \binom{N(v)}{\leq t_v}$). From the above LP, we can derive an algorithm that uses exactly the same protocol as in Theorem 9.

▶ **Theorem 15.** *There is an $(\varepsilon, G, \mathbf{t})$-RTGDP protocol for the aggregation problem with MSE at most $2\Delta^2 \cdot \mathrm{OPT}^{\mathbf{t}}_{\mathrm{LP}}/\varepsilon^2$, where $\mathrm{OPT}^{\mathbf{t}}_{\mathrm{LP}}$ denotes the value of the optimal solution to the LP in (2).*

4.2 Lower Bound

We define a $(2, \mathbf{t})$-robust packing of $G = (V, E)$ as a pair $U \subseteq V$ and $(T_u)_{u \in U}$ such that (i) $N[u] \setminus T_u$ are disjoint for all $u \in U$ and (ii) $T_u \in \binom{N(u)}{\leq t_u}$ for all $u \in U$. The size of the robust packing is $|U|$. Let $\rho(G)^{\mathbf{t}}$ denote the largest size of a $(2, \mathbf{t})$-robust packing of G.

[4] $\binom{S}{\leq t}$ denotes the collection of all subsets of S of size $\leq t$.

Note that, when $\mathbf{t} = \mathbf{0}$, $(2, \mathbf{t})$-robust packing coincides with the standard notion of packing we used in the previous section. We prove a lower bound for integer aggregation in the $(\varepsilon, G, \mathbf{t})$-RTGDP model that grows with the size of the maximum $(2, \mathbf{t})$-robust packing:

▶ **Theorem 16.** *For any $\varepsilon \leq O(1)$ and $\mathbf{t} \in \mathbb{N}^V$, any $(\varepsilon, G, \mathbf{t})$-RTGDP protocol for integer aggregation must incur MSE at least $\Omega(\Delta^2 \cdot \rho(G)^{\mathbf{t}})$.*[5]

4.3 Bi-criteria Tightness of the Bounds

Although we are not aware in general how large the gap between our upper (Theorem 15) and lower bounds (Theorem 16) are, we can show the following *bi-criteria* result, that the upper bound is not much larger than the lower bound when we increase $\mathbf{t}$ slightly. This is stated and proved below.

We write $\lceil \alpha \cdot \mathbf{t} \rceil$ for some $\alpha > 0$ as a shorthand for the vector $(\lceil \alpha \cdot t_u \rceil)_{u \in U}$. Furthermore, let $\deg_U$ denote the vector of degrees of the vertices, i.e., $(\deg(u))_{u \in U}$.

▶ **Theorem 17.** *For any $\alpha \in (0, 1)$, $\rho(G)^{\mathbf{t} + \lceil \alpha \cdot \deg_U \rceil} \geq \frac{\alpha}{8} \cdot \mathrm{OPT}^{\mathbf{t}}_{\mathrm{LP}}$, where $\rho(G)^{\mathbf{t}}, \mathrm{OPT}^{\mathbf{t}}_{\mathrm{LP}}$ are as defined in Theorems 15 and 16.*

To show this, we consider the dual of LP in (2), which turns out to be a relaxation for $(2, \mathbf{t})$-robust packing where there is a variable $w_{v,T} \in [0, 1]$ for all $v \in V, T \subseteq \binom{N(v)}{\leq t_v}$ representing whether (v, T) should be included in the robust packing. To turn such a fractional solution to an integral one, we employ *randomized rounding* – a standard technique in approximation algorithms (e.g., [54, Chapter 5]). More precisely, we include (v, T) in our solution with probability proportional to $w_{v,T}$. Unfortunately, this does not work yet as the produced solution may not be a $(2, \mathbf{t})$-robust packing, i.e., it might contain $w_{v,T}$ and $w_{v',T'}$ such that $(N[v] \setminus T)$ and $(N[v'] \setminus T')$ are not disjoint. Due to this, we need to apply a correction procedure on top of this randomized solution. Roughly speaking, we try to enlarge T until we are sure that such an intersection is avoided. This is indeed the reason why we need the slight increase in $\mathbf{t}$. However, even with this increase, we still have to be careful as sometimes T might become too large, i.e., larger than $t_v + \lceil \alpha \cdot \deg(v) \rceil$. We deal with this by simply removing such a pair (v, T) from the solution. A careful analysis shows that (in expectation) only a small fraction of the solution will get removed this way; see Section B.

5 Machine Learning with Trust Graph DP

While the main body of our work focuses on integer aggregation, it is a primitive on which we can build many more complex algorithms. First of all, we can easily use it to perform *real number aggregation* by re-scaling and discretization [6]. In particular, suppose that each user now has $x_i \in [0, 1]$. They can pick $\Delta \in \mathbb{N}$ and perform integer aggregation on $y_i = \mathrm{round}(\Delta x_i)$ where $\mathrm{round}(x)$ randomly round x to either $\lfloor x \rfloor$ or $1 + \lfloor x \rfloor$ with probabilities $1 - (x - \lfloor x \rfloor)$ and $x - \lfloor x \rfloor$ respectively. Once we have run the integer aggregation protocol, the answer is scaled by a factor of $\frac{1}{\Delta}$. If our integer aggregation protocol has MSE $\Delta^2 \xi^2$, then this results in a real aggregation protocol with error $\xi^2 + \frac{n}{4\Delta^2}$ [6]. Picking Δ to be sufficiently large (e.g., $\omega(\sqrt{n})$), the second term becomes negligible.

Real number aggregation allows us to perform statistical queries (SQ) [38]. While a simple family, statistical queries have wide variety of applications in learning theory. One specific work we wish to highlight is that of [29], who showed that convex optimization problems can be solved using statistical queries. As a result, we can apply their algorithm

[5] Again, this theorem is shown via a reduction to the LDP model; see Section B for the proof.

to our setting and obtain convex optimization algorithms with Trust Graph DP. We also remark that statistical queries are also useful for (non-ML) data analytic tasks; e.g., [29] provides SQ-based (vector) mean estimation, and other statistics such as quantiles are also known to be computable via SQs [28].

5.1 Vector Summation with Trust Graph DP

Although SQ-based algorithms can be used in our model, we will sketch a more direct algorithm for the task of *vector summation* with Trust Graph DP. This is not only more efficient but also provide better error guarantees for subsequent tasks such as convex empirical risk minimization (ERM).

In the *vector summation* (with ℓ_2-norm bound) problem, each user input x_i is a vector in $\mathbb{R}^d$ such that $\|x_i\|_2 \leq \Delta$, where Δ is a norm bound known to the algorithm. The goal is again to compute an estimate $\tilde{a}$ to the sum $a = \sum_{i\in[n]} x_i$. The ℓ_2^2-error is defined as $\mathbb{E}[\|\tilde{a} - a\|_2^2]$. Furthermore, we say that the estimator is unbiased if $\mathbb{E}[\tilde{a}] = a$.

It will be easiest to state the algorithms in terms of *zero-concentrated differential privacy (zCDP)* [13, 24]. To do so, we first define α-Renyi divergence for $\alpha > 1$ between distributions $\mathcal{P}, \mathcal{P}'$ for two distributions $\mathcal{P}, \mathcal{P}'$ to be $D_\alpha(\mathcal{P} \parallel \mathcal{P}') := \frac{1}{\alpha-1} \ln \left(\mathbb{E}_{x\sim\mathcal{P}} \left[\left(\frac{\mathcal{P}(x)}{\mathcal{P}'(x)} \right)^{\alpha-1} \right] \right)$. We note that $\lim_{\alpha\to\infty} D_\alpha(\mathcal{P} \parallel \mathcal{P}')$ is indeed equal to $D_\infty(\mathcal{P} \parallel \mathcal{P}')$ that we defined in Section 2.

zCDP can now be defined as follows.

▶ **Definition 18** (zCDP; [13]). *A randomized mechanism $M : \mathcal{X}^n \to \mathcal{O}$ is* ρ-zero concentrated DP (ρ-zCDP) *if for all pairs $\mathbf{x}, \mathbf{x}' \in \mathcal{X}^n$ of datasets that differ only in the data of a single user and all $\alpha > 1$,*

$$D_\alpha \left(M(\mathbf{x}) \parallel M(\mathbf{x}') \right) \leq \alpha\rho. \tag{3}$$

ZCDP can be easily converted to DP:

▶ **Lemma 19** ([13]). *For any $\rho > 0, \delta \in (0, 1/2)$, any ρ-zCDP algorithm is $(\rho + 2\sqrt{\rho \cdot \ln(1/\delta)}, \delta)$-DP.*

It also has a simple composition theorem:

▶ **Lemma 20** ([13]). *Let M be a mechanism that just runs subroutines that are ρ_1-zCDP, ..., ρ_m-zCDP. Then, M is $(\rho_1 + \cdots + \rho_m)$-zCDP.*

Trust Graph zCDP is simply zCDP on the view of the non-neighbors:

▶ **Definition 21** (Trust Graph zCDP). *Let $G = (V, E)$. A protocol P satisfies* (ρ, G)-Trust Graph zCDP ((ρ, G)-TGzCDP) *if for each vertex $v \in V$, $\textsc{view}_P^{V\setminus N[v]}(\mathbf{x})$ satisfies ρ-zCDP with respect to the input x_v for all values of $\mathbf{x}_{-v}$. I.e., for all pairs $x_v, x'_v \in \mathcal{X}$, all values of $\mathbf{x}_{-v}$ and all $\alpha > 1$,*

$$D_\alpha \left(\textsc{view}_P^{V\setminus N[v]}(x_v, \mathbf{x}_{-v}) \;\middle\|\; \textsc{view}_P^{V\setminus N[v]}(x'_v, \mathbf{x}_{-v}) \right) \leq \alpha\rho.$$

We can now state the algorithm for vector summation, which is similar to the algorithm in Theorem 8.

▶ **Theorem 22.** *There is an (ρ, G)-TGzCDP mechanism for the aggregation problem with ℓ_2^2-error $2d\Delta^2|T|/\rho$, where T is any dominating set of G. Furthermore, the estimate is unbiased.*

Proof. Let $\sigma = \Delta\sqrt{\frac{1}{2\rho}}$. The protocol works as follows:

- First, each user $v \in V$ picks an arbitrary vertex $u_v \in T \cap N[v]$.
- Each user $u \in T$ broadcasts the sum of all vectors it receives together with a noise drawn from $\mathcal{N}(0, \sigma^2 I_d)$. More formally, the user broadcasts $a_u = \sum_{\substack{v \in V \\ u_v = u}} x_v + z_u$, where $z_u \sim \mathcal{N}(0, \sigma^2 I_d)$.
- Finally, the estimate is $\tilde{a} = \sum_{u \in T} a_u$.

Privacy Analysis Consider any $v \in V$ and $\mathbf{x}_{-v} \in \mathcal{X}^{V \setminus \{v\}}$. Similar to the proof of Theorem 8, the view is a post-processing of $z_u + x$. Thus, for any $x_v, x'_v \in \mathcal{X}$, we have

$$D_\alpha\left(\text{VIEW}_P^{V \setminus N[v]}(x_v) \,\middle\|\, \text{VIEW}_P^{V \setminus N[v]}(x'_v)\right) \le D_\alpha(z_{u_v} + x_v \parallel z_{u_v} + x'_v) \le \alpha \cdot \rho,$$

where the second inequality follows from the zCDP guarantee of the Gaussian mechanism (e.g., Proposition 16 of [13]). Thus, the protocol satisfies (ρ, G)-TGzCDP as desired.

Utility Analysis It is clear that the estimate is unbiased. The ℓ_2^2-error is

$$\mathbb{E}\left[(\tilde{a} - a)^2\right] = \sum_{u \in T} \mathbb{E}[\|z_u\|^2] = |T| \cdot (\sigma^2 d) = 2d\Delta^2 |T|/\rho. \quad \blacktriangleleft$$

Using Lemma 19, we immediately get the following corollary. For $|T| = \Theta(1)$, this guarantee (asymptotically) matches the known lower bound in central DP (see, e.g., [7]), while for $|T| = \Theta(n)$, this guarantee nearly matches the known lower bound in local DP [4].

▶ **Corollary 23.** *For any $\varepsilon < O(\log(1/\delta))$, there is an (ε, δ, G)-TGDP mechanism for the aggregation problem with ℓ_2^2-error $O\left(\frac{d\Delta^2 |T| \log(1/\delta)}{\varepsilon^2}\right)$, where T is any dominating set of G. Furthermore, the estimate is unbiased.*

5.2 From Vector Summation to Convex Optimizaiton

Using the above vector summation protocol, we can immediately implement several DP ML algorithms in the literature, such as the DP-SGD algorithm [1]. We can also obtain formal guarantee for convex optimization problems from these algorithms. For instance, let us consider the convex ERM problem [7]. Here there is a loss function $\ell : \mathcal{W} \times \mathcal{X} \to \mathbb{R}$ which is L-Lipschitz on the first parameter and suppose that the diameter of $\mathcal{W}$ is at most R. The goal is to minimize the empirical loss $\mathcal{L}(w, \mathbf{x}) := \frac{1}{n} \sum_{v \in V} \ell(w, x_v)$. Using the above vector summation algorithm, we can arrive at the following:

▶ **Theorem 24.** *For $0 < \rho \le O(1)$, there is an (ρ, G)-TGzCDP mechanism for the convex ERM problem with expected excess risk $O\left(\frac{RL\sqrt{d|T|/\rho}}{n}\right)$, where T is any dominating set of G.*

Proof Sketch. The algorithm uses the (stochastic) mirror descent (see, e.g., [12, Section 6.1]) over n^2 steps. In each step, the gradient is computed by running our (ρ', G)-TGzCDP vector summation protocol with $\rho' = \rho/n^2, \Delta = G$ and scale the answer by a factor of $\frac{1}{n}$. The composition theorem (Lemma 20) implies that the algorithm is ρ-TGzCDP. The excess risk guarantee follows from standard analysis of stochastic mirror descent (e.g., [12, Theorem 6.1]). ◀

Again, using Lemma 19, we immediately get the following corollary for (ε, δ)-DP. For $|T| = \Theta(1)$, this guarantee (asymptotically) matches the known lower bound in central DP [7].

▶ **Corollary 25.** *For any $\varepsilon < O(\log(1/\delta))$, there is an (ε, δ, G)-TGDP mechanism for the convex ERM problem with expected excess risk $O\left(\frac{RL\sqrt{d|T|\log(1/\delta)}}{\varepsilon n}\right)$, where T is any dominating set of G.*

6 Conclusion and Future Directions

We have proposed a new model of privacy given a graph of trust relationships between users. Our model generalizes central and local DP, and further captures intermediate trust structures such as social networks or multiple curators. A significant open theoretical problem is to close the gap between the upper and lower bounds for TGDP, though our experiments suggest that this gap may be small in practice.

A Example Graph

Figure 2 gives an example of a graph with a significant gap between the domination number and the packing number, which importantly illustrates the gap between the upper and lower bounds on MSE under TGDP in Theorems 8, 9, and 10.

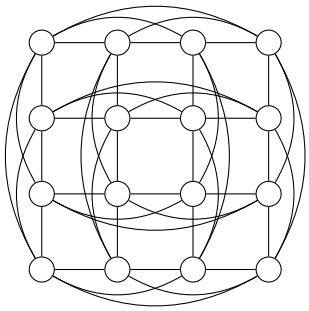

Figure 2 A graph with a gap between the domination number (4) and the packing number (1). The relaxed LP solution $\mathrm{OPT}_{\mathrm{LP}} = 16/7 \approx 2.285$.

B Missing Proofs

Proof of Lemma 6. We may write $Z = Z^1 + Z^2$ where $Z^1 \sim \mathrm{sNB}\left(1, 1 - e^{-\varepsilon/\Delta}\right) = \mathrm{DLap}(\Delta/\varepsilon)$ and $Z^2 \sim \mathrm{sNB}\left(r-1, 1 - e^{-\varepsilon/\Delta}\right)$ are independent. We again can think of $x + Z$ and $x' + Z$ as a post-processing of $x + Z^1$ and $x' + Z^1$, respectively. This implies that

$$\begin{aligned}
&D_\infty\left(x + Z \parallel x + Z\right) \\
&\le D_\infty\left(x + Z_1 \parallel x' + Z_1\right) \\
&= \max_{o \in \mathbb{N}} \ln\left(\frac{\Pr_{Z_1 \sim \mathrm{DLap}(\Delta/\varepsilon)}[x + Z_1 = o]}{\Pr_{Z_1 \sim \mathrm{DLap}(\Delta/\varepsilon)}[x' + Z_1 = o]}\right) \\
&= \frac{\varepsilon}{\Delta} \cdot \left(|o - x| - |o - x'|\right) \\
&\le \frac{\varepsilon}{\Delta} \cdot |x' - x| \le \varepsilon,
\end{aligned}$$

where the last two inequalities follow from the triangle inequality and since $0 \le x, x' \le \Delta$ respectively. ◀

Proof of Theorem 15. Let $\mathbf{y} = (y_u)_{u \in V}$ denote any solution to LP in (2). We use exactly the same protocol as in Theorem 9. The utility analysis is also similar to before. Thus, we only provide the privacy analysis below.

Privacy Analysis

Consider any $v \in V, T \in \binom{N(v)}{\le t_v}$ and $\mathbf{x}_{-v} \in \{0, \dots, \Delta\}^{V \setminus \{v\}}$. We write $\mathbf{a}$ as a shorthand for $(a_u)_{u \in V}$. Notice that $\mathrm{VIEW}_P^{V \setminus (N[v] \setminus T)}(x)$ is exactly $(\mathbf{x}_{-(N[v] \setminus T)}, \mathbf{a}(x), (s^u_{v'})_{u \in V \setminus (N[v] \setminus T), v' \in V})$. We claim that this is a post-processing of $(z_u + s^u_v)_{u \in (N[v] \setminus T)} \cup (s^u_v)_{u \in T}$. This is simply because $\mathbf{x}_{-(N[v] \setminus T)}$, $(a_u)_{u \in V \setminus N[v]}$,

$(s^u_{v'})_{u\in V\setminus N[v],v'\in V}, (s^u_{v'})_{u\in T,v'\in V\setminus\{v\}}$ do not depend on $x_v = x$ at all and are independent of $(z_u + s^u_v)_{u\in(N[v]\setminus T)} \cup (s^u_v)_{u\in T}$; finally, note that $(a_u(x))_{u\in N[v]}$ is a post-processing of $(z_u + s^u_v)_{u\in N[v]}$ since $a_u(x) = (z_u + s^u_v) + \sum_{\substack{v'\in N[V]\setminus\{v\}\\ u_{v'}=u}} s^u_{v'}$.

Now, since $(s^u_v(x))_{u\in N[v]}$ are random elements of $\mathbb{Z}_q$ that sums to x, we also have that $(z_u + s^u_v)_{u\in(N[v]\setminus T)} \cup (s^u_v)_{u\in T}$ are random elements of $\mathbb{Z}_q$ that sums to $x + \sum_{u\in N[v]} z_u$. In other words, $(z_u + s^u_v)_{u\in(N[v]\setminus T)} \cup (s^u_v)_{u\in T}$ is a post-processing of $x + \sum_{u\in(N[v]\setminus T)} z_u$. The remainder of the privacy proof then proceed similarly to that in Theorem 9, where we now use the fact that $\sum_{u\in(N[v]\setminus T)} z_u$ is distributed as $\mathrm{sNB}\left(\sum_{u\in(N[v]\setminus T)} y_u, 1 - e^{-\varepsilon/\Delta}\right)$ and $\sum_{u\in(N[v]\setminus T)} y_u \geq 1$ from (2). ◀

Theorem 16 is an immediate consequence of the following reduction to the LDP model, similar to Theorem 10 and the corresponding reduction (Lemma 11).

▶ **Lemma 26.** *Suppose that there is an $(\varepsilon, G, \mathbf{t})$-RTGDP protocol for integer aggregation. Then, there exists an ε-local DP protocol for integer aggregation with the same MSE for $\rho(G)^{\mathbf{t}}$ users, where $\rho(G)^{\mathbf{t}}$ denotes the size of the largest $(2, \mathbf{t})$-robust packing G.*

Proof of Lemma 26. Let $U = \{u_1, \ldots, u_m\} \subseteq V$ and $(T_v)_{v\in U}$ be the largest $(2, \mathbf{t})$-robust packing in G where $m = \rho(G)$. To avoid ambiguity, we use $\tilde{\mathbf{x}} = (\tilde{x}_1, \ldots, \tilde{x}_m)$ to denote the input to the local DP protocol.

To construct the LDP protocol, let $Q_1, \ldots, Q_m \subseteq V$ be any partition of V such that $(N[u_i]\setminus T_{u_i}) \subseteq Q_i$ for all $i \in [m]$. Such a partition exists because $N[u_1]\setminus T_{u_1}, \ldots, N[u_m]\setminus T_{u_m}$ are disjoint by definition of a packing. Let P be any $(\varepsilon, G, \mathbf{t})$-RTGDP protocol for integer aggregation. Our LDP protocol $\tilde{P}$ works simply by running the protocol P where each user $i \in [m]$ assumes the role of all users in Q_i where the input is defined as

$$x_u = \begin{cases} x_i & \text{if } u = u_i \\ 0 & \text{otherwise.} \end{cases}$$

for all $u \in Q_i$. We then output the estimate as produced by P. The MSE of $\tilde{P}$ is obviously the same as that of P.

To see that this satisfies ε-LDP, consider any $i \in [m], \tilde{\mathbf{x}}_{-i} \in \mathcal{X}^{[m]\setminus\{i\}}$, we have $\textsc{view}^{[m]\setminus\{i\}}_{\tilde{P}}(\tilde{x}) = \textsc{view}^{V\setminus Q_i}_{P}(\mathbf{x}(\tilde{x}))$ where $\mathbf{x}(\tilde{x})$ is the input to P as defined above. Since $V\setminus Q_i \subseteq V\setminus(N[u_i]\setminus T_{u_i})$, $\textsc{view}^{V\setminus Q_i}_{P}(\mathbf{x}(\tilde{x}))$ is a post-processing of $\textsc{view}^{V\setminus(N[u_i]\setminus T_{u_i})}_{P}(\mathbf{x}(\tilde{x}))$. Thus, for every $\tilde{x}_i, \tilde{x}'_i \in \mathcal{X}$, Lemma 5 implies that

$$\begin{aligned} &D_\infty\left(\textsc{view}^{[m]\setminus\{i\}}_{\tilde{P}}(\tilde{x}_i) \parallel \textsc{view}^{[m]\setminus\{i\}}_{\tilde{P}}(\tilde{x}'_i)\right) \\ &\leq D_\infty\left(\textsc{view}^{V\setminus(N[u_i]\setminus T_{u_i})}_{P}(\tilde{x}_i) \parallel \textsc{view}^{V\setminus(N[u_i]\setminus T_{u_i})}_{P}(\tilde{x}'_i)\right) \\ &\leq \varepsilon, \end{aligned}$$

where the last inequality is due to P being $(\varepsilon, G, \mathbf{t})$-RTGDP protocol.

As a result, $\tilde{P}$ is ε-LDP as desired. ◀

Proof of Theorem 17. We will write $\mathbf{t}'$ as a shorthand for $\mathbf{t} + \lceil\alpha \cdot \deg_U\rceil$.

We claim that $\mathrm{OPT}^{\mathbf{t}'}_{\mathrm{pack}} \geq \gamma \cdot \mathrm{OPT}^{\mathbf{t}}_{\mathrm{LP}}$ for $\gamma = \frac{\alpha}{8}$. To prove this, first observe that LP duality implies that $\mathrm{OPT}^{\mathbf{t}}_{\mathrm{LP}}$ is also equal to the optimal of the following LP:

$$\max \sum_{v\in V, T\in\binom{N(v)}{\leq t_v}} w_{v,T} \tag{4}$$

$$\text{s.t.} \sum_{\substack{u\in V, T\in\binom{N(u)}{\le t_u} \\ (N[u]\setminus T)\ni v}} w_{u,T} \le 1 \qquad \forall v \in V \tag{5}$$

$$0 \le w_{v,T} \le 1 \qquad \forall v \in V, T \in \binom{N(v)}{\le t_v}.$$

For $T' \subseteq N[v']$, we let $\overline{T}'[v'] := N[v'] \setminus T'$.

Given an optimal solution $(w_{v,T})_{v\in V, T\in\binom{N(v)}{\le t_v}}$ to the dual LP (4), we construct a $(2,\mathbf{t}')$-robust packing as follows:

- Include each (v,T) in the set R_0 with probability $2\gamma \cdot w_{v,T}$.
- Filter elements in R_0 to create R_1 where R_1 only includes (v,T) such that

$$v \notin \bigcup_{(v',T')\in(R_0\setminus\{(v,T)\})} \overline{T}'[v'], \tag{6}$$

and

$$\left|\bigcup_{(v',T')\in(R_0\setminus\{(v,T)\})} (N(v)\cap\overline{T}'[v'])\right| \le \alpha\cdot\deg(v). \tag{7}$$

- Construct R_2 by adding $\left(v, T\cup\bigcup_{(v',T')\in R_1\setminus\{(v,T)\}}(N(v')\cap\overline{T}'[v'])\right)$, for each $(v,T)\in R_1$.

By the conditions imposed when constructing R_1, it is simple to see that R_2 is a valid $(2,\mathbf{t})$-robust packing. Thus, we are only left to argue that it has a large size. To do so, first observe that

$$\begin{aligned}
&\mathbb{E}[\,|R_2|\,] \\
&= \mathbb{E}[\,|R_1|\,] \\
&= \sum_{v\in V, T\in\binom{N(v)}{\le t_v}} \Pr[(v,T)\in R_1] \\
&= \sum_{v\in V, T\in\binom{N(v)}{\le t_v}} \Pr[(v,T)\in R_0]\cdot\Pr[(v,T)\in R_1 \mid (v,T)\in R_0] \\
&= \sum_{v\in V, T\in\binom{N(v)}{\le t_v}} (2\gamma\cdot w_{v,T})\cdot\Pr[(v,T)\in R_1 \mid (v,T)\in R_0],
\end{aligned} \tag{8}$$

where the last equality is due to the randomized rounding in the first step.

Let us now fix $v\in V$ and $T\in\binom{N(v)}{\le t_v}$. To bound $\Pr[(v,T)\in R_1 \mid (v,T)\in R_0]$, note that from our procedure, we have

$$\begin{aligned}
&\Pr[(v,T)\in R_1 \mid (v,T)\in R_0] \\
&= \Pr\left[(6) \text{ and } (7) \text{ both hold}\right] \\
&\ge 1 - \Pr[(6) \text{ fails}] - \Pr[(7) \text{ fails}].
\end{aligned} \tag{9}$$

We bound each of the two terms separately. For the first term, we have

$$\begin{aligned}
&\Pr[(6) \text{ fails}] \\
&= \Pr\left[v \in \bigcup_{(v',T')\in(R^0\setminus\{(v,T)\})} \overline{T}'[v']\right]
\end{aligned}$$

$$
\begin{aligned}
&= \Pr\left[\exists \begin{smallmatrix} v' \in V, T' \in \binom{N(v')}{\leq t_{v'}} \\ (N[v'] \setminus T') \ni v \end{smallmatrix}, (v', T') \in R^0\right] \\
&\leq \sum_{\substack{v' \in V, T' \in \binom{N(v')}{\leq t_{v'}} \\ (N[v'] \setminus T') \ni v}} \Pr[(v', T') \in R^0] \\
&= \sum_{\substack{v' \in V, T' \in \binom{N(v')}{\leq t_{v'}} \\ (N[v'] \setminus T') \ni v}} 2\gamma \cdot w_{v',T'} \\
&\overset{(5)}{\leq} 2\gamma \\
&\leq \frac{1}{4}.
\end{aligned} \tag{10}
$$

Similarly, we have

$$
\begin{aligned}
&\Pr[(7) \text{ fails}] \\
&= \Pr\left[\left|\bigcup_{(v',T') \in (R^0 \setminus \{(v,T)\})} (N(v) \cap \overline{T}'[v'])\right| > \alpha \cdot \deg(v)\right] \\
&\leq \frac{\mathbb{E}\left[\left|\bigcup_{(v',T') \in (R^0 \setminus \{(v,T)\})} (N(v) \cap \overline{T}'[v'])\right|\right]}{\alpha \cdot \deg(v)} \\
&= \frac{\sum_{u \in N(v)} \Pr\left[u \in \bigcup_{(v',T') \in (R^0 \setminus \{(v,T)\})} \overline{T}'[v']\right]}{\alpha \cdot \deg(v)} \\
&= \frac{\sum_{u \in N(v)} \Pr\left[\exists \begin{smallmatrix} v' \in V, T' \in \binom{N(v')}{\leq t_{v'}} \\ (N[v'] \setminus T') \ni u \end{smallmatrix}, (v', T') \in R^0\right]}{\alpha \cdot \deg(v)} \\
&\leq \frac{\sum_{u \in N(v)} \sum_{\substack{v' \in V, T' \in \binom{N(v')}{\leq t_{v'}} \\ (N[v'] \setminus T') \ni u}} \Pr[(v', T') \in R^0]}{\alpha \cdot \deg(v)} \\
&= \frac{\sum_{u \in N(v)} \sum_{\substack{v' \in V, T' \in \binom{N(v')}{\leq t_{v'}} \\ (N[v'] \setminus T') \ni u}} 2\gamma \cdot w_{v',T'}}{\alpha \cdot \deg(v)} \\
&\overset{(5)}{\leq} \frac{\sum_{u \in N(v)} 2\gamma}{\alpha \cdot \deg(v)} \\
&= \frac{2\gamma}{\alpha} \leq \frac{1}{4},
\end{aligned} \tag{11}
$$

where the first inequality is due to Markov and the last inequality is from our choice of γ.

Combining Equations (8)–(11), we get

$$
\mathbb{E}[\,|R_2|\,] \geq \sum_{v \in V, T \in \binom{N(v)}{\leq t_v}} \gamma \cdot w_{v,T} = \gamma \cdot \mathrm{OPT}^{\mathbf{t}}_{\mathrm{LP}},
$$

which concludes the proof. ◀

C Additional Experiment Details

We next provide additional experiment details. Optimization problems were solved using `cvxpy` [19, 3].

C.1 Additional Dataset Details

Table 1 lists additional details for each dataset. All datasets are publicly available through SNAP [43]. We give additional dataset descriptions below.

Table 1 Integrality gap comparison of $\mathrm{OPT}_{\mathrm{LP}}$ to minimum dominating set size $|T|$ for 9 network datasets.

Dataset	Number of nodes n	Number of edges $\lvert E\rvert$	Maximum degree
EU Emails (Core)	1,005	16,706	347
Bitcoin (Alpha)	3,783	12,972	507
Facebook	4,039	88,234	1,045
Bitcoin (OTC)	5,881	18,591	788
Enron Emails	36,692	183,831	1,383
GitHub	37,700	289,003	9,458
Epinions	75,879	405,740	3,044
Twitter	81,306	1,342,310	3,383
EU Emails (All)	265,214	365,570	7,636

EU Emails datasets. This data comes from an email network at a European research institution collected by [42]. We include an undirected edge between sender and receiver who have exchanged an email, though the original dataset contains directed edge information. We consider two subgraphs: *(i)* a "core" subgraph consisting of email addresses within the research institution (which we refer to as *EU Emails (Core)*), and *(ii)* the full graph of all emails contained in the dataset (which we refer to as *EU Emails (All)*).

Enron Emails. This data comes from an email communication network within Enron [39]. The graph contains an undirected edge between a sender and receiver if at least one email was exchanged between them. The original graph is undirected.

Bitcoin datasets. We include network data from two different Bitcoin trading platforms, *Bitcoin OTC* and *Bitcoin Alpha* [41, 40]. In the original data, each user rater another user with a value between -10 and 10, where a negative rating corresponds to mistrust and a positive rating corresponds to trust. In our analysis, we include an undirected edge between users if and only if one user rates another with a value greater than 0. We ignore mistrust ratings. In general, further analysis that includes the mistrust ratings would be interesting to conduct.

Facebook dataset. This data from Facebook was published by [44]. Each undirected edge indicates a friend relationship between two users.

GitHub dataset. This data comes from a social network of GitHub developers collected by [48]. Edges represent mutual follower relationships between two users.

Epinions dataset. This data comes from the consumer review site Epinions.com [47]. We include an undirected edge if one user "trusts" another by giving a positive rating to the other user (which indicates trusting their reviews). The original dataset is a directed graph.

Twitter dataset. This data encodes follower relationships from Twitter [44]. We include an undirected edge if one user has follows another. The original dataset contains directed edges for follower relationships.

C.2 Integrality Gap Between Linear Program Optimum and Minimum Dominating Set

The proposed LP-based mechanism for achieving Trust Graph DP presented in Theorem 9 will always perform at least as well as the dominating set protocol in terms of error. Here we consider whether in practice, the LP-based mechanism is better than the dominating

set protocol. We observed an integrality gap between $\mathrm{OPT}_{\mathrm{LP}}$ and the size of the minimum dominating set $|T|$ on three out of nine datasets. Notably, we only observed the integrality gap on the email communication datasets, and not on the Bitcoin or social network datasets. Theoretically, it is known that the integrality gap between $\mathrm{OPT}_{\mathrm{LP}}$ and $|T|$ can be up to a factor of up to $O(\log(n))$ [54]. Further study of the integrality gaps that might arise in other real network settings remains an interesting open question. Table 2 lists the ratio $\frac{\mathrm{OPT}_{\mathrm{LP}}}{|T|}$ for each dataset.

Whether any given graph exhibits an integrality gap or not, a prevailing advantage of the proposed improved algorithm via linear programming for TGDP over a minimum dominating set protocol lies in computational efficiency, as finding the minimum dominating set is NP-hard.

Table 2 Integrality gap comparison of $\mathrm{OPT}_{\mathrm{LP}}$ to minimum dominating set size $|T|$ for 9 network datasets.

Dataset	n	$\mathrm{OPT}_{\mathrm{LP}}$	$\lvert T\rvert$	$\frac{\mathrm{OPT}_{\mathrm{LP}}}{\lvert T\rvert}$
EU Emails (Core)	1,005	111.97	128	0.8748
Bitcoin (Alpha)	3,783	686	686	1
Facebook	4,039	10	10	1
Bitcoin (OTC)	5,881	1,126	1,126	1
Enron Emails	36,692	3,060.66	3,062	0.9996
GitHub	37,700	4,538	4,538	1
Epinions	75,879	15,734	15,734	1
Twitter	81,306	961	961	1
EU Emails (All)	265,214	18,074.40	18,181	0.9941

C.3 Other Local DP Mechanisms for Aggregation

Note that we focused our comparisons to the LDP version of the Laplace mechanism since the ratio has a simple expression. Nevertheless, we point out that there are other LDP mechanisms for aggregation. For example, one can apply randomized rounding to the input (where we set it to Δ with probability x_i/Δ and set it to zero otherwise) before applying the classic randomized response (RR) mechanism [53]. The MSE of this method is actually input-dependent due to the randomized rounding, making it harder to compare against our method. To give the benefit to this algorithm, let us assume for the moment that all inputs are either 0 or Δ. In this case, there is no error due to the randomized rounding. A simple calculation shows that the error from here is $c_\epsilon \cdot 2\Delta^2 n/\epsilon^2$ where $c_\epsilon = \frac{e^\epsilon \cdot \epsilon^2}{2(e^\epsilon - 1)^2}$. For $\epsilon \leq 1$, this constant c_ϵ is at least 0.46. Thus, in all cases, our mechanism still demonstrates a significant improvement over this over-optimistic estimate of the error for randomized rounding + RR.

D Relating Packing Number and Minimum Dominating Set

In this section, we prove Theorem 12. Our proof follows that of Halldorsson et al. [35], who gave a greedy algorithm that provides a $\sqrt{n}$-approximation for the packing number. At a high level, the main difference between our proof and theirs is that we compare the greedy solution with the (optimal) LP solution, whereas they compare it with the (optimal) integral solution. The LP for the packing number turns out to be exactly the dual of the LP for the minimum dominating set (i.e., LP (1)); this then gives us the desired claim.

Proof of Theorem 12. Consider the dual of LP (1), which can be written as follows:

$$\min \sum_{u \in V} y_u \tag{12}$$

$$\text{s.t.} \sum_{u \in N[v]} y_u \leq 1 \qquad \forall v \in V \tag{13}$$

$$0 \leq y_u \leq 1 \qquad \forall u \in V.$$

Let $\mathbf{y}^* = (y^*_u)_{u \in V}$ denote an optimal solution of the LP (12). Consider the following greedy algorithm by Halldorsson et al. [35].

- Set $S \leftarrow \emptyset, i \leftarrow 0$, and $V_i \leftarrow V$.
- While $V_i \neq \emptyset$ do:
  - Let v_i be the vertex in V_i with the smallest degree (ties broken arbitrarily).
  - Set $S \leftarrow S \cup \{v_i\}$.
  - Let $Z_i := \{u \in V_i \mid N[u] \cap N[v_i] \neq \emptyset\}$.
  - Set $V_{i+1} \leftarrow V_i \setminus Z_i$.
  - Set $i \leftarrow i + 1$.
- Output S.

It is clear that the output S is indeed a packing; let $q = |S|$. We claim the following for all $i \in [q]$:

$$\sum_{u \in Z_i} y^*_u \leq \sqrt{n}. \tag{14}$$

Before we prove (14), let us argue that it implies $\rho(G) \geq \mathrm{OPT}_{\mathrm{LP}}/\sqrt{n}$. Notice that $\{Z_i\}_{i \in [q]}$ is a partition of V. Therefore, we have

$$\mathrm{OPT}_{\mathrm{LP}} = \sum_{u \in V} y^*_u = \sum_{i \in [q]} \sum_{u \in Z_i} y^*_u \overset{(14)}{\leq} \sum_{i \in [q]} \sqrt{n} \leq \rho(G) \cdot \sqrt{n},$$

as desired.

Finally, we prove (14). Consider two cases based on whether $\deg(v_i) \leq \sqrt{n} - 1$.

- Case I: $\deg(v_i) \leq \sqrt{n} - 1$. In this case, we have

$$\sum_{u \in Z_i} y^*_u \leq \sum_{w \in N[v_i]} \sum_{u \in N[w]} y^*_u \overset{(13)}{\leq} \sum_{w \in N[v_i]} 1 = \deg(v_i) + 1 \leq \sqrt{n}.$$

- Case II: $\deg(v_i) > \sqrt{n} - 1$. Since we pick v_i to be the vertex with the smallest degree among those in V_i, we have $\deg(u) > \sqrt{n} - 1$ for all $u \in Z_i$. Therefore, we have

$$\begin{aligned}
\sum_{u \in Z_i} y^*_u &\leq \frac{1}{\sqrt{n}} \cdot \sum_{u \in Z_i} (\deg(u) + 1) \cdot y^*_u \\
&\leq \frac{1}{\sqrt{n}} \cdot \sum_{u \in V} (\deg(u) + 1) \cdot y^*_u \\
&= \frac{1}{\sqrt{n}} \cdot \sum_{v \in V} \sum_{u \in N[v]} y^*_u \\
&\overset{(13)}{\leq} \frac{1}{\sqrt{n}} \cdot n \\
&= \sqrt{n}.
\end{aligned}$$

Thus, in both cases (14) holds, which completes our proof. ◀

Partial Minimum Branching Program Size Problem Is ETH-Hard

Ludmila Glinskih
Google, Mountain View, CA, USA

Artur Riazanov
EPFL, Lausanne, Switzerland

Abstract

We show that assuming the Exponential Time Hypothesis, the Partial Minimum Branching Program Size Problem (MBPSP*) requires superpolynomial time. This result also applies to the partial minimization problems for many interesting subclasses of branching programs, such as read-k branching programs and OBDDs.

Combining these results with the recent unconditional lower bounds for MCSP [6], we obtain an unconditional superpolynomial lower bound on the size of Read-Once Nondeterministic Branching Programs (1-NBP) computing the *total* versions of the minimum BP, read-k-BP, and OBDD size problems.

Additionally we show that it is **NP**-hard to check whether a given BP computing a partial Boolean function can be compressed to a BP of a given size.

1 Introduction

The Minimum Circuit Size Problem (MCSP) has been a central problem of study in computational complexity in recent years. Given the truth-table of a Boolean function, and a size parameter s, MCSP asks one to determine whether the function can be computed by a Boolean circuit of size s. As the input length of MCSP is exponential in the input length of the function defined by the given truth table, it is clear that MCSP is contained in **NP**. Although it is not known whether MCSP is **NP**-complete, it is widely believed to be hard to compute. Starting from the work of Kabanets and Cai [11] there has been mounting evidence that MCSP $\notin$ **P** [20]. For example, MCSP $\in$ **P** implies that widely believed cryptographic assumptions do not hold. On the other hand, there are complexity-theoretic barriers to proving **NP**-hardness of MCSP [15, 21].

Even before the work of Kabanets and Cai [11], variations of MCSP were studied in the context where the function is given not as a truth table, but represented in some computational model. One family of models that was extensively studied in this context is *branching programs*. The line of work [2, 17, 23, 22, 1] showed that branching program minimization is **NP**-hard for the natural cases of succinct representation of a function: either

© Ludmila Glinskih and Artur Riazanov;
licensed under Creative Commons License CC-BY 4.0

the function itself is represented as a branching program as in [2, 22, 1], or an input is a *partial function* with few fixed values as in [23]. The results, however, are limited to weak models of branching programs such as OBDDs or read-once branching programs. To our knowledge, no hardness results are known even for minimizing read-twice branching programs.

The potential cross-pollination between these two research areas motivates us to study Minimum Branching Program Size Problem (MBPSP): given a function represented as a truth table $\{0,1\}^{2^n}$ and a size parameter $s \in [2^n]$ determine whether exists a *branching program* of size at most s computing the given function.

On the meta-complexity side, one of the approaches to prove **NP**-hardness of MCSP is to show lower bounds for $\mathcal{C}$-MCSP problems, in which we ask whether an input Boolean function can be computed by a circuit from the class $\mathcal{C}$, where $\mathcal{C}$ is a weaker class than general Boolean circuits. There are already results showing **NP**-hardness of DNF-MCSP [14], (DNF$\circ$XOR)-MCSP [8], and the hardness of DeMorgan Formulas-MCSP (MFSP) assuming the Exponential Time Hypothesis (ETH) [10]. All of these reductions share a common structure.

- First they show hardness of the Partial $\mathcal{C}$-MCSP ($\mathcal{C}$-MCSP*) problem in which the input is the truth table of a partial function.
- Then they show a reduction from the $\mathcal{C}$-MCSP* problem to the $\mathcal{C}$-MCSP problem.

Hardness results for Partial MCSP (MCSP*) are already known. In [9] Ilango showed that MCSP* requires superpolynomial time to compute[1], assuming the Exponential Time Hypothesis. Recently, Hirahara [7] showed the **NP**-hardness of MCSP* under randomized reductions. So the only missing component for showing hardness of MCSP is to show an efficient reduction from MCSP* to MCSP.

The study of hardness of MBPSP under the ETH continues the line of work above. Expressive power of branching programs is situated between that of Boolean formulas and Boolean circuits [18, 5]. On the other hand our understanding of branching programs seems to be slightly better than our understanding of circuits. One evidence for this is that the strongest lower bound on the BP size for an explicit function is $\tilde{\Omega}(n^2)$ [16] which is much stronger than $\Omega(n)$ lower bound for Boolean circuits [3]. Showing the ETH-hardness of MBPSP would improve the recent ETH-hardness result for MFSP [10] which is the frontier hardness result for total circuit minimization problems and move us one step closer to the ETH-hardness of MCSP itself. Our main result is completing the first step of the common recipe for establishing the hardness of $\mathcal{C}$-MCSP by showing hardness of BP-MCSP* (that we call MBPSP* for short).

▶ **Theorem 1.** *Every deterministic algorithm computing MBPSP* on inputs of length N requires time $N^{\Omega(\log\log(N))}$ assuming the Exponential Time Hypothesis.*

Note that the ETH-hardness of MCSP* or MFSP* does not imply the ETH-hardness of MBPSP*. Although on surface it seems that MBPSP (MBPSP*) is just a special case of MCSP (MCSP*), the hardness of the latter does not necessarily imply the hardness of the former. For example, in some special settings of parameters, an explicit construction of a many-one reduction between MCSP and MBPSP yields breakthrough circuit or BP

[1] The same hardness result holds for Partial MFSP (MFSP*).

lower bounds.[2] On the other hand, ruling out more natural parameter configurations does not seem as trivial: indeed, our main result shows that the identity function is a reduction on a certain subset of the instances.

On the branching program minimization side, the consequences are twofold. First, our result implies that all partial branching program minimization problems require time $N^{\Omega(\log\log N)}$ under ETH for any representation of a function that is at least as efficient as truth table.[3] Second, we show that our result implies **NP**-hardness of minimization of a branching program computing a partial function that itself is represented as a branching program (see Section 1.2.3 for details).

In particular, our result implies that the problem of finding the smallest OBDD (a subclass of branching programs) that computes the given partial function is ETH-hard. But surprisingly, there is a polynomial-time algorithm that finds the smallest OBDD computing a *total* function [4]. This means that assuming ETH holds, the potential reduction from MBPSP* to MBPSP must fail on OBDDs.

1.1 Techniques

To show Theorem 1 we adapt the proof of a similar result of Ilango [9] for the hardness of MCSP* and MFSP* problems.

▶ **Theorem 2** ([9]). *Every deterministic algorithm computing MCSP* on inputs of length N requires time $N^{\Omega(\log\log(N))}$ assuming the Exponential Time Hypothesis holds. The same holds for MFSP*.*

Ilango's proof of Theorem 2 is a reduction from the $(n \times n)$-Bipartite Permutation Independent Set Problem ($(n \times n)$-BPIS). For now we can think of it as an independent set problem on some special set of graphs. This is an **NP**-hard graph problem introduced in [13], where the authors show that any deterministic Turing machine requires $2^{\Omega(n \log n)}$-time[4] to solve it if the Exponential Time Hypothesis holds. For an input graph G with vertices labeled by elements of $[n] \times [n]$ Ilango constructs a truth-table of a $3n$-variable partial Boolean function γ_G, such that

($\star$) G is a YES-instance of $(n \times n)$-BPIS iff γ_G can be computed by a DeMorgan formula with at most $3n - 1$ gates.

The key point here is that if we constrain a circuit or a formula to have at most $3n - 1$ (inner) gates, its structure becomes simple enough for a very precise analysis. [9] characterizes the structure of such formulas that compute γ_G which would yield the correspondence between such formulas with independent sets in G.

Although branching programs are situated between formulas and circuits in computational expressivity [5], Theorem 2 does not apply to MBPSP*, since with a sharp constraint on the size, branching programs may become stronger than circuits. We observe in Proposition 7

[2] Suppose that f is such a reduction from $\mathrm{MCSP}_{s=3n}$ (the language of the truth-tables computable by circuits with at most $3n$ gates) to $\mathrm{MBPSP}_{s=n^{2.1}}$. Then taking any function requiring circuits of size larger than $3n$ [3, 12] and applying f to it yields $n^{2.1}$ lower bound for general branching programs superior to the current state of the art. In a similar way, we get superlinear circuit lower bounds from any reduction from $\mathrm{MBPSP}_{s=n^2}$ to $\mathrm{MCSP}_{s=n^{1+\varepsilon}}$.

[3] We note that results in this area often establish **NP**-hardness and even hardness of size approximation for the case of concise representation, while our result only establishes ETH-hardness of the exact version of the problem.

[4] The input to this problem has $\Theta(n^4 \log n)$ bit size.

that this is indeed the case, showing that branching programs are stronger than circuits if we constrain the size parameter of both models to "minimal viable" size: $m-1$ inner nodes for a DeMorgan circuit and m non-sink nodes for a BP for the case of a Boolean function on m input bits.

Nevertheless, we show that the reduction to MCSP* from Theorem 2 does yield ETH-hardness for MBPSP*. Indeed, in our proof of Theorem 1 we only change the part ($\star$), keeping the construction of γ_G. The key part of the proof is to understand what structure a branching program has if it has at most $3n$ (non-sink) nodes. As γ_G is sensitive in every input variable, we need to understand a structure of a branching program that has unique variable labels. We call such programs *once-appearance branching programs* (oaBP). We show that γ_G can be computed by a once-appearance branching program iff G is a YES-instance of $(n \times n)$-BPIS.

1.2 Corollaries

1.2.1 Weaker Classes

BP is not the only model that collapses to oaBP when constrained to have at most n non-sink nodes. The same also holds for OBDD, and k-BP for every positive integer k. From this we get a family of hardness of minimization results for restricted classes of branching programs.

▶ **Corollary 3.** *Every deterministic algorithm computing $\mathcal{C}$-MCSP* for $\mathcal{C} \in \{\text{OBDD}, \text{BP}\} \cup \{k\text{-BP} \mid k \geq 1\}$[5] on inputs of length N requires time $N^{\Omega(\log\log(N))}$ assuming the Exponential Time Hypothesis.*

1.2.2 Unconditional Results for a Weaker Model

In the recent work [6] the authors employed the framework of Ilango from [9] to show an unconditional lower bound on the size of the read-once nondeterministic branching program (1-NBP) computing the total version of MCSP. The proof consists of three components.

1. Show that $(n \times n)$-BPIS unconditionally cannot be computed by a 1-NBP of smaller than $\Omega(n!)$ size.
2. Show that Ilango's reduction from $(n \times n)$-BPIS to MCSP* can be efficiently encoded using BP. This shows that if MCSP* on inputs of length N could be computed by a 1-NBP of size $N^{o(\log\log(N))}$, then $(n \times n)$-BPIS could be computed by a 1-NBP of size $o(n!)$.
3. Show that MCSP and MCSP* have the same 1-NBP complexity up to a linear multiplicative factor. This implies that 1-NBP complexity of MCSP is at least $N^{\Omega(\log\log(N))}$.

Since the proof of Theorem 1 follows similar steps as the proof of the Theorem 2, and analogs of the third property from [6] also hold for BP, k-BP, and OBDD, we get similar unconditional 1-NBP lower bounds for total minimization problems in all these models.

▶ **Corollary 4.** *Every* 1-NBP *computing $\mathcal{C}$-MCSP for $\mathcal{C} \in \{\text{OBDD}, \text{BP}\} \cup \{k\text{-BP} \mid k \geq 1\}$ on inputs of length N requires size at least $N^{\Omega(\log\log(N))}$.*

[5] Or any other class of branching programs that collapses to oaBP on the n-node programs.

1.2.3 NP-hardness of Compressing BPs

Additionally, we show that given a graph G we can construct a branching program B of polynomial size that exactly computes the partial function γ_G. Namely it outputs $\{0,1\}$ values on inputs on which γ_G is defined and $*$ on all other inputs. Then B can be compressed to an oaBP which agrees with γ_G on its domain iff G is a YES-instance of $(n \times n)$-BPIS. Combining this result with a folklore result of **coNP**-hardness of compressing a branching program, we get the following result on the hardness of compressing branching programs.

▶ **Corollary 5.** *The language of pairs (B, s) where B is a branching program[6] over the alphabet $\{0,1,*\}$ and s is in integer, such that an extension of the partial function described by B can be computed by a* BP *of size at most s, is* **NP** *and* **coNP***-hard.*

1.3 Organization

The structure of the paper is as follows:

- In Section 2 we give definitions of the branching programs and various versions of MCSP we are working with.
- In Section 3 we state our main result: the hardness of MBPSP* under ETH (Theorem 1) and explain the main ideas behind its proof. We show the proof of Theorem 1 and proofs of all required lemmas in Section 4 and Section 5.
- In Section 6 we sketch the proofs of several corollaries of Theorem 1.
- Finally, in Section 7 we explain the future directions of this work and possible barriers we see for strengthening our results.

2 Preliminaries

Throughout this work we denote by $[n]$ the set of n elements $\{1, \ldots, n\}$. Let a and b be partial assignments. If the supports of a and b do not intersect, denote by $a \cup b$ the partial assignment that coincides with a on the support of a and with b on the support of b. For a graph G we denote its set of vertices by $V(G)$ and its set of edges by $E(G)$. Throughout the paper a *circuit* is a DeMorgan circuit ($\wedge$, $\vee$ and $\neg$ gates) with gates of arity 2. A *formula* is a tree-like DeMorgan circuit. A *read-once formula* is a formula such that each input bit feeds into exactly one gate. E.g. $x \vee (\neg y \wedge z)$ is a read-once formula, and $(x \wedge y) \vee (\neg x \wedge z)$ is not. Since every DeMorgan formulas can be transformed in such a way that all $\neg$-gates are adjacent to the inputs, we identify DeMorgan formulas with trees with *literals* in the leaves and $\wedge/\vee$ in the inner nodes.

A *Branching Program* (BP) is a form of representation of functions. A n-ary function[7] $f\colon D^n \to \{0,1\}$, where $|D| = d$, is represented by a directed acyclic graph with exactly one source and two sinks. Each non-sink node is labeled with a variable; every internal node has exactly d outgoing edges: labeled with elements of D. One of the sinks is labeled with 1 and the other is labeled with 0. We say that a node *queries* x if it is labeled with a variable x. The *size* of a branching program is the number of nodes in it.

The value of the function for given values of the variables is evaluated as follows: we start in the source and then follow the edge labeled with the value of the variable in the source, we repeat this process until the current node is a sink. The label of this sink is the value of the function. We refer to a path that terminates in a σ-labeled sink as *σ-path*.

[6] The same is true for all sub-classes of branching programs that simulate 4-BP.
[7] We will instantiate this definition for $D = \{0,1\}$ and $D = \{0,1,*\}$

A *Non-deterministic Branching Program* (NBP) is a Branching Program over the alphabet $\{0,1\}$ with additional non-labeled *guessing* nodes with two non-labeled outgoing edges. The value computed by a Non-deterministic Branching Program is 1 if there exists at least one 1-path that agrees with the given assignment.

A Branching Program (deterministic or not) is called *read-once* (denoted as 1-BP in the deterministic case and 1-NBP in the non-deterministic case) if any path from the source to a sink contains each variable label at most once.

For a partial assignment $\alpha\colon [n] \to \{0,1,*\}$ and a branching program B with n input bits over the alphabet $\{0,1\}$ we write $B|_\alpha$ for a branching program obtained by removing every edge of form $x_i \neq \alpha(i)$ and contracting every edge of form $x_i = \alpha(i)$ if $\alpha(i) \in \{0,1\}$. It is easy to see that if B computes the function f, then $B|_\alpha$ computes the function $f|_\alpha$.

The Minimum Branching Program Size Problem (MBPSP(f,s)) gets as input the truth-table of a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ of length $N = 2^n$ and a size parameter s, and outputs 1 if there exists a branching program of size at most s that computes f. We use notation $\mathrm{MBPSP}_{s'(n)}(f) = \mathrm{MBPSP}(f, s'(n))$.

The Partial Minimum Branching Program Size Problem (MBPSP$^*(f^*,s)$) gets as input the partial truth-table of a function $f^*\colon \{0,1\}^n \to \{0,1,*\}$ of length $N = 2^n$ and a size parameter s, and outputs 1 if there exists a substitution of each $*$ in the truth-table to a 0/1, transforming f^* to a Boolean function f, such that $\mathrm{MBPSP}(f,s) = 1$. We use notation $\mathrm{MBPSP}^*_{s'(n)}(f) = \mathrm{MBPSP}^*(f, s'(n))$.

2.1 Once-Appearance Branching Programs

A *once-appearance branching program* (oaBP) is a branching program with distinct node labels. Hence, for a function depending on n variables such oaBP representation contains at most n non-sink nodes. For oaBP we identify the non-sink nodes with their labels, and identify the edges with equalities of form $x = \alpha$ for a variable x and α from the alphabet.

It is easy to see, that oaBPs are strictly stronger than read-once DeMorgan formulas.[8]

▶ **Proposition 6.** *If f is computable by a read-once DeMorgan formula, then it is computable by an* oaBP*.*

Proof. We first observe that if g and h are computable by oaBPs, then so are $g \wedge h$ and $g \vee h$ whenever g and h have disjoint set of variables. Indeed oaBP for $g \wedge h$ is constructed by redirecting all edges going to the 1-in the oaBP computing g to the source of the oaBP computing h, and by redirecting all edges to the 0-sink in g to the 0-sink of h. For $g \vee h$ we redirect all edges to the 0-sink of to the source of the oaBP for h, and all edges to the 1-sink to the 1-sink of h. Now to finish the proof observe that all literals $\{x_1, \neg x_1, \ldots, x_n, \neg x_n\}$ are trivially computable by an oaBP. ◀

▶ **Proposition 7.** *Let $g(x,y,z) \coloneqq (y \wedge x) \vee (z \wedge \neg x)$. Then g is computable by an* oaBP *but is is not computable by a read-once DeMorgan formula.*

[8] Notice that for functions sensitive to all variables, read-once DeMorgan formulas are equivalent to general DeMorgan circuits with $n-1$ inner gates. Thus Proposition 6 and Proposition 7 hold for such circuits as well.

Proof. The oaBP for g is a decision tree with the root x, the edge $x = 0$ going to z, the edge $x = 1$ going to y, the edge $y = \alpha$, $z = \alpha$ going to the α-sink for $\alpha \in \{0, 1\}$.

Consider a read-once formula G computing g. Then $G|_{y=0,z=1}$ computes a function $\neg x$, so G must have a leaf $\neg x$. But $G|_{y=1,z=0}$ computes a function x, so G must have a leaf x. That contradicts the read-once property of G. ◀

We note that this example can be extended to a function that is sensitive in an arbitrary number of variables, say for $g(x, y, z) \vee t_1 \cdots \vee t_n$.

2.2 Bipartite Permutation Independent Set Problem

In [9] Ilango showed that Partial MCSP is ETH-hard. The main idea of the proof is to show a reduction from the $(n \times n)$-Bipartite Permutation Independent Set problem that was previously shown to be ETH-hard in [13]. In this section and later we assume that n is even.

In $(n \times n)$-Bipartite Permutation Independent Set problem ($(n \times n)$-BPIS) we are given the adjacency matrix of an undirected graph G over the vertex set $[n] \times [n]$ where every edge is between the sets of vertices $J_1 = [n/2]^2$ and $J_2 = \{n/2 + 1, \ldots, n\}^2$. A graph G is a Yes-instance iff it contains an independent set $S \subseteq J_1 \cup J_2$ of size n such that the coordinates of vertices in S define a permutation of $[n]$, i.e. $\forall i \in [n] \exists j, k \in [n] \colon v = (i, j), w = (k, i), v, w \in S$.

Note that a permutation of $[n]$ corresponding to a Yes-instance of $(n \times n)$-BPIS can be viewed as two permutations on disjoint $n/2$-element subsets. One permutation is defined by $n/2$ vertices from J_1 (corresponding to a permutation of elements $[n/2]$), and another by $n/2$ vertices from J_2 (corresponding to a permutation of elements $\{n/2 + 1, \ldots, n\}$). We use each of these interpretations interchangeably.

▶ **Theorem 8** ([13]). *$(n \times n)$-BPIS cannot be solved in deterministic time $2^{o(n \log n)}$ unless ETH fails.*

Ilango in [9] gave a $2^{O(n)}$-time reduction from $(n \times n)$-BPIS to MCSP*, hence, showing that MCSP* cannot be solved in deterministic time $2^{o(n \log n)}$ unless ETH fails.

3 Main Theorem

In this section we show that the reduction Ilango constructed from ETH-hard problem $(n \times n)$-BPIS to a formula minimization problem holds for the BP minimization problem as well. More precisely we show:

▶ **Theorem 9.** *Suppose that $MBPSP^* \colon \{0, 1, *\}^{2^n} \times [2^n] \to \{0, 1\}$ is in $\mathbf{TIME}[N^{o(\log \log(N))}]$ where $N = 2^n$, then the Exponential Time Hypothesis is false.*

Let us recall the reduction $\mathcal{R} \colon \{0, 1\}^{\binom{n \times n}{2}} \to \{0, 1, *\}^{2^{3n}} \times [2^{3n}]$ from [9][9]. Let $G = ([n] \times [n], E)$ be an instance of $(n \times n)$-BPIS. Then the reduction outputs the pair $(t, 3n - 1)$ where t is the truth table of a partial function $\gamma_G \colon \{0, 1\}^n \times \{0, 1\}^n \times \{0, 1\}^n \to \{0, 1, *\}$ defined as $\gamma_G(\vec{x}, \vec{y}, \vec{z}) =$

[9] We ignore all the edges except for ones between the sets $[n/2] \times [n/2]$ and $\{n/2+1, \ldots n\} \times \{n/2+1, \ldots, n\}$, the second argument is represented in binary form.

$$= \begin{cases} \bigvee_{i\in[n]}(y_i \wedge z_i), & \text{if } \vec{x} = 0^n & (1)\\ \bigvee_{i\in[n]} z_i, & \text{if } \vec{x} = 1^n & (2)\\ \bigvee_{i\in[n]}(x_i \vee y_i), & \text{if } \vec{z} = 1^n & (3)\\ 0, & \text{if } \vec{z} = 0^n & (4)\\ \bigvee_{i=1}^{n/2} x_i & \text{if } \vec{z} = 1^{n/2}0^{n/2} \text{ and } y = 0^n & (5)\\ \bigvee_{i=n/2+1}^{n} x_i & \text{if } \vec{z} = 0^{n/2}1^{n/2} \text{ and } y = 0^n & (6)\\ 1 & \text{if } \exists((j,k),(n/2+j',n/2+k')) \in E\colon (\vec{x},\vec{y},\vec{z}) = (\overline{e_k e_{k'}}, 0^n, e_j e_{j'}) & (7)\\ * & \text{otherwise} & (8) \end{cases}$$

where $\vec{x} = (x_1, \ldots, x_n)$, $\vec{y} = (y_1, \ldots, y_n)$, $\vec{z} = (z_1, \ldots, z_n)$, and $e_i \in \{0,1\}^{n/2}$ is the vector with 1 in the ith entry and zeroes in all the others, and $\overline{e_i}$ is such that $e_i + \overline{e_i} = 1^{n/2}$. In the rest of the proof, we use e_i as a vector with the ith coordinate equal to 1 and all the rest equal to zero with the appropriate dimension.

The intuition behind this reduction is that for every read-once formula, computing this function has to group triples of bits x_i, y_j, and z_k such that $j = k$, and $i \to j$ encodes that an element i maps to an element j in the permutation. The cases (1)-(4) ensure that the read-once formula encodes some permutation on $[n]$. The cases (5) and (6) ensure that the permutation maps the first $n/2$ elements into the first $n/2$ elements and the last $n/2$ elements into the last $n/2$ elements. And, finally, the case (7) enforces that for every edge in the original graph, the permutation defined by the read-once formula contains at most one endpoint of this edge. Note, that every endpoint or vertex chosen in the independent set encodes a mapping of one element of $[n]$ to one element of $[n]$ in the permutation.

As was shown in [9], this reduction maps Yes-instances of BPIS to Yes-instances of $\text{MCSP}^*_{s=m-1}$ where $m = 3n$ is the number of input bits of $\mathcal{R}(G)$:

▶ **Theorem 10** ([9]). *For the reduction $\mathcal{R}$ as above $G \in (n \times n)$-BPIS iff $\mathcal{R}(G) \in MCSP^*_{s=m-1}$.*

To prove Theorem 10, Ilango shows that γ_G extends to a total function computable by a *read-once monotone formula* iff G is a Yes-instance of $(n \times n)$-BPIS. In our work we show that a similar statement holds for *once-appearance branching programs* (oaBP).

▶ **Theorem 11.** *For the reduction $\mathcal{R}$ as above $G \in (n \times n)$-BPIS iff $\mathcal{R}(G)$ can be computed by* oaBP*.*

The plan of the proof is the following:

- In Section 4 we show that the topological order of an oaBP computing γ_G defines a unique permutation $\pi\colon [n] \to [n]$.
- In Section 5 we show that for π as above $\{(i, \pi(i)) \mid i \in [n]\}$ is an independent set in G, thus showing the "only if" direction of the equivalence.
- Since by Proposition 6 that oaBP losslessly simulates read-once formulas, we conclude that Theorem 10 implies the "if" direction of the equivalence.

4 Structure of oaBP Computing γ'

For the first step of our plan it is convenient to simplify the definition of γ_G. Let $\gamma'_n\colon \{0,1\}^{3n} \to \{0,1,*\}$ be equal to γ_G whenever one of (1)-(4) is satisfied, and $*$ otherwise. Here we may choose an arbitrary G as in this domain γ_G does not depend on it.

$$\gamma'_n(\vec{x},\vec{y},\vec{z}) = \begin{cases} \bigvee_{i\in[n]}(y_i \wedge z_i), & \text{if } \vec{x} = 0^n \\ \bigvee_{i\in[n]} z_i, & \text{if } \vec{x} = 1^n \\ \bigvee_{i\in[n]}(x_i \vee y_i), & \text{if } \vec{z} = 1^n \\ 0, & \text{if } \vec{z} = 0^n \\ * & \text{otherwise} \end{cases}$$

We usually shorthand γ'_n as γ'. In Section 4 we identify the structure of an oaBP computing γ'. Let us start by constructing an example of such an oaBP. As we mentioned before, whenever a function is computable by a read-once formula, it is computable by oaBP. Ilango [9] shows that all read-once formulas computing γ' have form

$$\bigvee_{i\in[n]} \left(x_{\pi(i)} \vee (y_i \wedge z_i)\right) \tag{9}$$

for a permutation $\pi \in S_n$. One way to translate this into an oaBP is to chain together n three-node oaBPs each of them computing one disjunct of (9). A topological order of such a oaBP is a sequence of n triplets of $\{x_{\pi(i)}, y_i, z_i\}$ with variables in triplets permuted in some order. We claim that topological order of *every* oaBP computing γ' has this form[10]. We prove this claim in Lemma 12.

We then say that an oaBP B computing γ' *defines* a permutation κ_B mapping $b \mapsto a$ iff $\{x_a, y_b, z_b\} = \{\ell_{3i+1}, \ell_{3i+2}, \ell_{3i+3}\}$ for some $i \in \{0,\dots,n-1\}$. We refer to the triplets of consecutive nodes of form $\{x_a, y_b, z_b\}$ as *xyz-triplets* or *xyz-blocks*.

In this section we prove the following lemma.

▶ **Lemma 12.** *Suppose B is an* oaBP *that computes γ'. Then let $\ell_1, \ell_2, \dots, \ell_{3n}$ be labels of vertices of B in a topological order. Then for every $i \in \{0,..,n-1\}$ we have $\{\ell_{3i+1}, \ell_{3i+2}, \ell_{3i+3}\} = \{x_a, y_b, z_b\}$ for some $a, b \in [n]$.*

The proof of Lemma 12 is surprisingly delicate. The starting point is the characterization of the structure of oaBPs computing the subfunctions of γ' corresponding to the conditions (1)-(4). The main tool in the proofs of these characterizations is the reduction to query complexity, e.g. $\gamma'|_{\vec{x}=0^n}$ has maximum possible query complexity $2n$, which enforces a very tight constraint on the structure of the oaBP computing it. A potential easy proof of Lemma 12 could have followed a logic similar to the proof above if γ' had maximal query complexity $3n$. This, however, is not the case, query complexity[11] of γ' is at most $2n+2$, so such a simple argument is unfortunately ruled out.

4.1 Structure of γ' Conditioned on (1)–(4)

We start by characterizing the structure of oaBP that computes $\gamma'|_{\vec{x}=0^n}$.

[10] Notice that we do not show that the oaBP in question has the exact form as the one constructed according to (9).

[11] Query x_1, x_2, z_1, z_2, if $x_1 \neq x_2$ or $z_1 \neq z_2$, then we may return any value, as none of the conditions (1)-(4) hold. Otherwise, for every possible combination of values x_1, z_1 we have only two possible conditions among (1)-(4) that might hold. If $x_1 = z_1 = \alpha$ we return α right away, if $x_1 = 0$ and $z_1 = 1$, it suffices to query $\vec{y}$ and $\vec{z}$ to get the answer, if $x_1 = 1$ and $z_1 = 0$, it suffices to query $\vec{x}$ and $\vec{z}$ to get the answer.

▶ **Lemma 13.** *The structure of an* oaBP *computing the function* $\bigvee_{i\in[n]}(y_i \wedge z_i)$ *is the following: all nodes except for the* 1*-sink form a single* $2n$*-edge path* $(a_1, b_1, a_2, b_2, \ldots, a_n, b_n, 0\text{-}sink)$ *where* $\{a_i, b_i\} = \{y_{\pi(i)}, z_{\pi(i)}\}$ *for some permutation* $\pi \in S_n$*. For each* $i \in [n]$*, the edge* $a_i = 1$ *goes to* b_i*, the edge* $b_i = 0$ *goes to* a_{i+1}*, the edge* $a_i = 0$ *goes to* a_{i+1} *(for* a_n *it goes to the* 0*-sink), and the edge* $b_i = 1$ *goes to the* 1*-sink.*

Proof. The query complexity of the function $\bigvee_{i\in[n]}(y_i \wedge z_i)$ is $2n$, hence there should exist at least one path of length $2n$ in this branching program. Next, consider the first two variables queried in this path. Assume they do not correspond to y and z with the same label. Without loss of generality assume the first node is labeled by y_1 and the second node is labeled by z_2 (observe that the cases of the first two labels being y_1 and y_2 or z_1 and z_2 are identical, since the variables in the pairs are symmetric). Now, both edges outgoing from y_1 should be parts of the paths that lead to z_2. As for both values of $y_1 = 0$ and $y_1 = 1$ exists a 1-assignment that is zero in all variables other than $z_2 = y_2 = 1$. Hence, if after querying y_1 we do not query z_2, we get a BP that incorrectly computes the function. As we consider the first two nodes of the longest path, we get that both edges from y_1 should directly go to the node labeled by z_2. But it turns the BP to be insensitive to a change in the value of y_1 that contradicts the sensitivity of $\bigvee_{i\in[n]}(y_i \wedge z_i)$ function. Hence the edge $y_1 = 1$ must lead to the node labeled with z_1. Then it remains to observe that after applying the substitutions $y_1 = 0$ or $y_1 = 1, z_1 = 0$ the query complexity of the function decreases by exactly 2. Note that paths corresponding to these two substitutions must lead to the third node in the branching program . This node then must compute $\bigvee_{i\in[n]\setminus\{1\}}(y_i \wedge z_i)$, so the rest of the oaBP has the desired structure by the simple induction on n. ◀

Next, we summarize the structures for the conditions (2)–(4).

▶ **Lemma 14.** *The following structural properties hold.*

(2) *An* oaBP *computing the function* $\gamma'_n|_{\vec{x}=1^n}(\vec{y}, \vec{z}) = \bigvee_{i\in[n]} z_i$ *has the following property. Every node* v *of this* oaBP *reachable from the source computes the function* $\bigvee_{i\in S(v)} z_i$ *where* $S(v) \subseteq [n]$ *is the set of indices of all* z*-variables that do not precede* v *in the topological order.*

(3) *An* oaBP *computing the function* $\gamma'_n|_{\vec{z}=1^n}(\vec{x}, \vec{y}) = \bigvee_{i\in[n]}(x_i \vee y_i)$ *is a Hamiltonian path terminating in the* 0*-sink with edges of the form* $x_i = 0$*,* $y_i = 0$ *going to the next node in the path, and the edges* $x_i = 1$*,* $y_i = 1$ *going to the* 1*-sink.*

(4) *In an* oaBP *computing the function* $\gamma'_n|_{\vec{z}=0^n}(\vec{x}, \vec{y}) \equiv 0$ *the* 1*-sink is not reachable from the source.*

Proof. The structural property for (4) is obvious: if there is a path from the source to the 1-sink, the function is not identically zero.

The structural property for (3) is also easy to see. The query complexity of $\gamma'_n|_{\vec{z}=1^n}$ is $2n$, so the oaBP must have a $2n$-edge path. The edges in these path are the 0-edges and the path terminates in the 0-sink. Suppose an edge of the form $y_i = 1$ or $z_i = 1$ does not go to the 1-sink, say it goes from a node u to a node v, then the path from the source to u according to the Hamiltonian path, then following the edge uv and then continuing to the 0-sink by the Hamiltonian path contradicts the fact that the oaBP computes the disjunction of all variables.

Now let us show the structural property for (2). The source computes the function $\bigvee_{i\in[n]} z_i$ by definition. For any node z_i computing $\bigvee_{j\in S} z_j$ for a set $S \subseteq [n]$ we have that the edge $z_i = 0$ goes to the node computing $\bigvee_{j\in S\setminus\{i\}} z_j$. For any node y_i that is reachable from the source its edges go to the nodes that compute the same function since otherwise

the function computed by the source depends on y_i. Then take any node z_i. Since the function $\gamma'_n|_{\vec{x}=1^n}$ depends on all bits of $\vec{z}$, this node is reachable from the source. Hence, by the observations above, it computes a function of the form $\bigvee_{j\in S} z_j$ with $i \in S$.

Observe that every path from the source to z_i must visit all nodes from $\{z_1, \ldots, z_n\}$ that precede z_i in the topological order. Indeed, if there is a path from the source to z_i that does not visit z_j that precedes z_i in the topological order, then the oaBP returns 0 given the assignment $e_j = 0^{j-1}10^{n-j}$, which is a contradiction. Hence, if the node z_i computes $\bigvee_{j\in S_i} z_j$ and the node z_k computes $\bigvee_{j\in S_k} z_j$, where z_i precedes z_k in the topological order, then $S_i \supseteq S_k$. Moreover $S_i \ni i$ and $S_k \not\ni i$ so $S_i \neq S_k$. Therefore, the sets $S_1, \ldots, S_n$ form a chain by inclusion and are all different, which implies the property given that S_i does not contain indices of nodes that precede z_i in the topological order. ◀

4.2 Proof of Lemma 12

We derive Lemma 12 from the following two lemmas.

▶ **Lemma 15.** *Let B be an* oaBP *computing γ'. Then for every topological ordering of the nodes of B there exists a mapping $\pi\colon [n] \to [n]$ such that $x_{\pi(i)}$ neighbors y_i in the topological order. Additionally, the following property holds*

(†) *if $x_{\pi(i)}$ precedes y_i and z_i in the topological order, then the edge $x_{\pi(i)} = 1$ does not go to 1-sink.*

▶ **Lemma 16.** *Suppose an* oaBP *B computes γ'. Suppose $\ell_1, \ldots, \ell_{3n}$ are the labels of the nodes in some topological ordering of B. Then for every $i \in [3n-4]$ and every $a, b, c \in [n]$ we have $\{\ell_i, \ell_{i+1}, \ldots, \ell_{i+4}\} \neq \{z_a, y_a, x_b, y_c, z_c\}$.*

Proof of Lemma 12. First we show that Lemma 16 guarantees that π given by Lemma 15 is a bijection between $\{y_1, \ldots, y_n\}$ and $\{x_1, \ldots, x_n\}$.

Let $\prec$ denote the topological order of the labels of the nodes in B. Consider a modified version of π that we denote π' such that whenever possible $y_i \prec \pi'(y_i) \prec z_i$ or $z_i \prec \pi'(y_i) \prec y_i$. Observe that this modification never introduces additional violations of injectivity since y_j cannot neighbor a node between y_i and z_i in the topological order for $j \neq i$.

Now suppose $\pi'(y_i) = \pi'(y_j)$ for some $i \neq j$. WLOG assume that $i = 1$ and $j = 2$. Then, by construction of π' and π there exists k such that $\ell_k = y_1, \ell_{k+1} = \pi'(y_1), \ell_{k+2} = y_2$. Notice that $\pi'(y_1)$ must be a single element of $\{x_1, \ldots, x_n\}$ that neighbors y_1 and y_2, thus $\ell_{k-1} = z_1$ and $\ell_{k+3} = z_2$. Then we get a contradiction with the statement of Lemma 16. Hence π' is an injective mapping. As π' is an injective mapping that maps each element of a set of the size n into an element of a set of the size n, we get that π' is a bijection.

By Lemma 13 $\ell_1, \ldots, \ell_{3n}$ has a subsequence of form $a_1, b_1, \ldots, a_n, b_n$ where $\{a_i, b_i\} = \{y_{\tau(i)}, z_{\tau(i)}\}$ for a permutation $\tau\colon [n] \to [n]$. Observe that $\{\ell_1, \ell_2, \ell_3\}$ must contain x_i for $i \in [n]$, otherwise $\{\ell_1, \ell_2, \ell_3\} = \{a_1, b_1, a_2\}$, contradicting Lemma 15 as $y_{\tau(1)}$ does not neighbor $\pi(y_{\tau(1)})$.

If $\{\ell_1, \ell_2, \ell_3\}$ contains more than one element of $\{x_1, \ldots, x_n\}$ then $\{\ell_1, \ell_2, \ell_3\} \ni y_{\tau(1)}$ by surjectivity of π'. Moreover, $\ell_3 = x_b$ and either $\ell_1 = x_a$, $\ell_2 = y_{\tau(1)}$ or $\ell_1 = y_{\tau(1)}$, $\ell_2 = x_a$ for some $a, b \in [n], a \neq b$. Then by Lemma 13 we get $\ell_4 \in \{x_1, \ldots, x_n, z_{\tau(1)}\}$. Thus x_b does not belong to the image of π, which is a contradiction. Therefore, $\{\ell_1, \ell_2, \ell_3\} = \{\pi'(y_{\tau(1)}), y_{\tau(1)}, z_{\tau(1)}\}$. Iteratively applying this procedure to $\{\ell_{3k+1}, \ldots, \ell_{3n}\}$ and π' restricted to $\{y_{\tau(k+1)}, \ldots, y_{\tau(n)}\}$ for $k \in [n]$ concludes the proof of the theorem. ◀

4.3 Proof of Lemma 15

Let B_α for $\alpha \in \{0,1\}$ be the diagram obtained from B by contracting all edges of form $x_i = \alpha$ and removing all edges of form $x_i = 1-\alpha$. Then the diagram B_0 computes $\gamma'|_{\vec{x}=0^n}$. Then from Lemma 13 and (1) we get that B_0 consists of a path of length $2n$ that is split into consequent blocks with two nodes in each, where the labels of the nodes in each block are $\{y_i, z_i\}$ for $i \in [n]$.

Consider an arbitrary block in B_0 and let u and v be the nodes of B corresponding to the nodes in the block, such that u precedes v in the topological order of B.

4.3.1 Case 1: u and v are labeled with z_i and y_i respectively

u must still be present in B_1 and be reachable from the source (say, with the assignment $\vec{x} = \vec{y} = 1^n$; $\vec{z} = 0^n$). Then consider edges in B_0 labeled with $z_i = 1$ and $y_i = 0$: uv and vw, where w is the first node in the subsequent block of B_0, these are uniquely defined since B_0 is an oaBP. We claim that at least one of these edges does not appear in B i.e. it is present in B_0 due to a contraction.

Assume towards a contradiction that both of the edges are present in B. Then let us trace a path from the source of B to the 0-sink according to the assignment $\vec{x} = 1^n$; $\vec{y} = 0^n$; $\vec{z} = e_i$. This path must contain u and w, as z_i-node, corresponding to u should be queried on substitution $x = 0^n$, and then, after assigning $z_i = 1$ and $y_i = 0$ this path leads to the node w. By Lemma 14 for (2) the node w in B_1 and our choice of w, computes $\bigvee_{j \in S} z_j$. Since z_i precedes w in the topological order, $S \not\ni i$. Hence, we get $B(1^n, 0^n, e_i) = 0$ which with value $\gamma'(1^n, 0^n, e_i) = 1$ leads to a contradiction.

Now, since at least one of the edges uv and vw does not appear in B, but appears in B_0, the node v in B is adjacent to a node r labeled with an element of $\{x_1, \ldots, x_n\}$. Since uv and vw belong to the Hamiltonian path in B_0, r must neighbor v in the topological order. Then define $\pi(y_i) = x_j$ where x_j is the label of r. Notice that here the node $x_{\pi(i)}$ never precedes both y_i and z_i, so the property (†) is satisfied.

4.3.2 Case 2: u and v are labeled with y_i and z_i respectively

First, suppose y_i and z_i are the first two nodes in B_0. By Lemma 13 the edge $y_i = 0$ in B_0 goes to the first node of the next yz-pair, let us denote it by w. The edge $y_i = 1$ goes to the z_i-node in B_0. Now, assume, towards a contradiction, that the $y_i = 0$-edge in B goes to w as well. Then, a path in B corresponding to an assignment $s = (1^n, 0^n, e_i)$ skips the node z_i, as y_i is the source of this oaBP, and w is going after z_i in the topological order. Similarly to the proof of Case 1, we get a contradiction with the fact that the subdiagram of B_1 rooted in w computes the function $\bigvee_{j \in S} z_j$ with $S \not\ni i$, which is 0 on s, hence $B(s) = B_1(0^n, e_i) = 0$, whereas $\gamma'(s) = 1$.

Now, assume there is at least one other yz-pair queried before y_i and z_i. Let y_j and z_j be the pair that precedes y_i and z_i in the topological order of B. Note, that in B_0 both edges $y_j = 0$ and $z_j = 0$ go to y_i. And $y_i = 0$ edge in B_0 goes to a node w (skipping z_i), which is the first node in the next yz-block.

▷ Claim 17. One of the edges among $z_j = 0$ and $y_i = 0$ differ in B_0 and B (that is, the edge with this label connects different pairs of nodes).

Proof. The proof of this claim repeats a similar argument in the Case 1. Assume these two edges in B are the same as in B_0. Consider a substitution $s = (1^n, 0^n, e_i)$. As B_1 computes the disjunction of z, a path p corresponding to s in B should query all bits of $\vec{z}$ preceding z_i

in the topological order. Hence, p goes through z_j, and $z_j = 0$ to y_i. Now, as $y_i = 0$ skips z_i and goes to w, which by Lemma 14 computes $\bigvee_{t \in S} z_t$ in B_1. Analogously to the Case 1, $S \not\ni i$, so we get that $B(s) = 0$, which contradicts $\gamma'(s) = 1$. Thus, one of the edges $z_j = 0$ or $y_i = 0$ in B leads to a different node compared to B_0. ◁

4.3.3 Case 2a: the edge $z_j = 0$ goes to y_i

By Claim 17 $y_i = 0$ does not go to w. But in this case it goes to a node r labeled by an x-variable in B. Then as oaBP B queries all bits in $\vec{z}$ on the assignment $(1^n, 0^n, 0^n)$, we get that r goes before z_i in the topological order. So we get that y_i neighbors an x-node in the topological order.

4.3.4 Case 2b: the edge $z_j = 0$ does not go to y_i

Let x_ℓ be the endpoint of $z_j = 0$ in B (notice that $z_j = 0$ can not go to y_j since then it would go there in B_0 as well). Consider the path from x_ℓ to y_i in B according to the assignment $\vec{x} = 0^n$, by the construction of B_0 all nodes on this path are labeled with x-variables. Let x_k be the last node on this path before y_i. We define $\pi(i) = k$. Now it remains to show the following:

1. x_k is the immediate predecessor of y_i in the topological order.
2. The property (†): $x_k = 1$ in B does not go to the 1-sink.

Let us first prove Item 1. Consider the program $B|_{\vec{z}=1^n}$. By Lemma 14 for (3), $B|_{\vec{z}=1^n}$ consists of a single Hamiltonian path of 0-edges. Then, consider the edge $x_k = 0$ in B. This edge goes to y_i, so $x_k y_i$ is present in $B|_{\vec{z}=1^n}$, so in topological order there are no x-node or y-node between x_k and y_i. Given that z_j precedes x_k in the topological order, x_k is the immediate predecessor of y_i.

Now let us prove Item 2. Consider an assignment $\vec{x} = 0^n$, $\vec{y} = 1^n$ and $\vec{z} = 0^n$. Let us trace the path corresponding to this assignment from the root of B to z_j. Notice that z_j is reachable by this path since it is reachable in B_0 by the path according to $\vec{y} = 1^n$, $\vec{z} = 0^n$. After z_j let us follow the edge $z_j = 0$ to x_ℓ and then to x_k following the 0-edges. Suppose that $x_k = 1$ goes to the 1-sink. Let p be the path from the root to the 1-sink that we have traced. Then consider the program $B|_{\vec{z}=0^n}$. Let $p|_{\vec{z}=0^n}$ be the result of contraction of the edges of form $z_t = 0$ in p. $p|_{\vec{z}=0^n}$ exists in $B_{\vec{z}=0^n}$, hence the 1-sink is reachable in this program. This contradicts the fact that $\gamma'|_{\vec{z}=0^n}$ is identically zero.

4.4 Proof of Lemma 16

We are going to gradually derive the structure of the edges going out of the nodes $\{z_a, y_a, x_b, y_c, z_c\}$.

By (3) we have $\gamma'|_{\vec{z}=1^n} = \bigvee_{i \in [n]} x_i \vee y_i$, so by Lemma 14 the edges of from $x_i = 0$ and $y_i = 0$ must either go to a variable in $\{z_1, \ldots, z_n\}$ or to the next variable in $\{x_1, \ldots, x_n, y_1, \ldots, y_n\}$ in the topological order. Hence $y_a = 0$ leads to x_b, $x_b = 0$ leads to y_c.

By (1) we have $\gamma'|_{\vec{x}=0^n} = \bigvee_{i \in [n]} z_i \wedge y_i$, the diagram $B|_{\vec{x}=0^n}$ has structure defined by Lemma 13. Then $z_a = 1$ leads to y_a and $y_c = 1$ leads to z_c and $z_a = 0$ leads either to x_b or y_c. Now observe that the edge $y_a = 1$ goes to the 1-sink by the structure of the diagram $B|_{\vec{z}=1^n}$. If it does go to x_b the assignment $\vec{x} = 0^n$, $\vec{y} = 1^n$ and $\vec{z} = e_a$ is evaluated to 0 by B, which is a contradiction with (3). See Figure 1 for the edges we identified so far.

Now consider an edge $x_b = 1$. By Lemma 14 for (3) it must go to the 1-sink in the diagram $B|_{\vec{z}=1^n}$, so in B it goes either to $\{z_1, \ldots, z_n\}$ or to the 1-sink. Recall that by (2) we have $B|_{\vec{x}=1^n} = \bigvee_{i \in [n]} z_i$. Suppose $x_b = 1$ goes to z_i for $i \in [n]$. Then consider the assignment

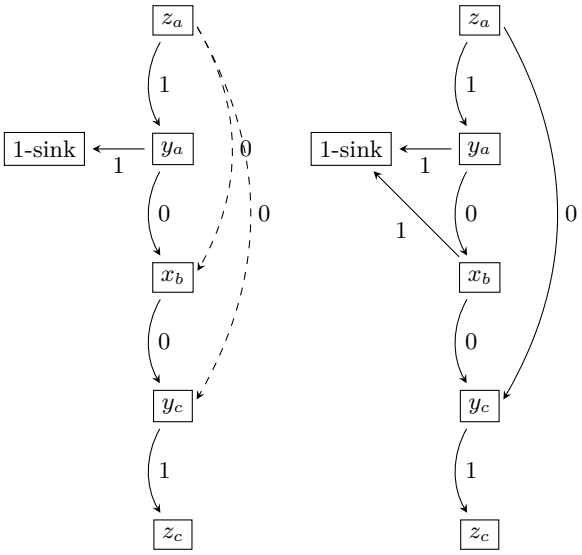

Figure 1 Fixed edges between $\{z_a, y_a, x_b, y_c, z_c\}$.

$\vec{x} = 1^n$, $\vec{z} = e_a$, $\vec{y} = 0^n$. A path p, corresponding to it passes through the node z_a by the structure of $B|_{\vec{x}=1^n}$ given by Lemma 14. Hence, p then leads to x_b and to z_i, which computes $\bigvee_{t\in S} z_t$ for some $S \subseteq [n] \setminus \{a\}$. Thus $B(1^n, 0^n, e_a) = 0$, yet $\gamma'(1^n, 0^n, e_a) = 1$. Hence $x_b = 1$ goes to the 1-sink.

Now we can pinpoint the endpoint of the edge $z_a = 0$. Suppose it goes to x_b. Then we get the contradiction with the assignment $\vec{x} = 1^n$, $\vec{y} = 0^n$ and $\vec{z} = 0^n$. $B(1^n, 0^n, 0^n) = 1$ since we go from z_a to x_b and then to the 1-sink, yet $\gamma(1^n, 0^n, 0^n) = 0$.

Then consider the edge $y_c = 0$, we claim that it goes to z_c. Otherwise consider the assignment $\vec{x} = 1^n$, $\vec{y} = 0^n$ and $\vec{z} = e_c$, $B(1^n, 0^n, e_c) = 0$ since the path of this assignment passes through z_a, then goes to y_c and then to a node strictly below z_c that by Lemma 14 computes $\bigvee_{i\in S} z_i$ for $S \subseteq [n] \setminus \{c\}$. Thus we get a contradiction with $\gamma'(1^n, 0^n, e_c) = 1$.

Then we get the final contradiction as follows: $\gamma'|_{\vec{x}=0^n}$ depends on y_c, but $B|_{\vec{x}=0^n}$ does not, in other words $B(0^n, e_c, e_c) = B(0^n, 0^n, e_c)$, yet $\gamma'(0^n, e_c, e_c) \neq \gamma'(0^n, 0^n, e_c)$.

5 Structure of oaBP Computing γ_G: proof of Theorem 11

The theorem follows from the following lemmas, utilizing the properties (5)-(7) of γ_G.

▶ **Lemma 18.** *For every* oaBP B *computing* γ_G*, the permutation* κ_B *defined by* B *maps elements of* $[n/2]$ *into* $[n/2]$*, and elements of* $\{n/2+1, \ldots, n\}$ *into elements of* $\{n/2+1, \ldots, n\}$.

▶ **Lemma 19.** *For every* oaBP B *computing* γ_G*, the permutation* κ_B *defined by* B *corresponds to an independent set in* G*, that is* $\{(i, \kappa_B(i)) \mid i \in [n]\}$ *is independent in* G.

We start by deriving the theorem from the lemmas.

Proof of Theorem 11. From Lemma 18 and Lemma 19 we get that an oaBP computing γ_G defines a permutation on $[n]$ which maps elements of the first/second half of $[n]$ to the elements of the first/second half of $[n]$ respectively, and for every edge it contains at most one of the vertices of a BPIS instance. Hence, the permutation defined by any oaBP computing γ_G is a correct certificate for a $(n \times n)$-BPIS instance. Thus an oaBP computing γ_G exists iff there is a correct permutation defining independent set in an input $(n \times n)$-BPIS instance. ◀

5.1 Proofs of Lemma 18 and Lemma 19

Both of the lemmas follow from a helper lemma about the structure of oaBP for γ':

▶ **Lemma 20.** *Let B be an* oaBP *computing γ'. Then, if a path p in B goes to the* 1*-sink from one of the nodes in a triplet x_i, z_j, y_j, then p sets at least two variables among x_i, z_j, y_j to* 1*.*

We defer the proof of Lemma 20 to Section 5.2. Now we are ready to prove the lemmas.

Proof of Lemma 18. First, as γ_G is a restricted version of γ', we get that κ_B is well-defined by Lemma 12. Moreover, we know that the topological order of B has the form $a_1, b_1, c_1, a_2, b_2, c_2, \ldots, a_n, b_n, c_n$, where for every $h \in [n]$ there exist $k, \ell \in [n]$, such that $\{a_h, b_h, c_h\} = \{x_k, z_\ell, y_\ell\}$, where $\kappa_B(\ell) = k$.

Let x_i, z_j, y_j form a consequent xyz-triplet in the oaBP, with $i = \kappa_B(j)$. Assume towards a contradiction that i and j are from different halves of the set $[n]$. WLOG let $i \in [n/2]$ and $j \in \{n/2+1, \ldots, n\}$.

Consider a substitution s, in which $z = 1^{n/2}0^{n/2}, y = 0^n, x_i = e_i$. Consider a path p consistent with s. By property (7) it terminates in the 1-sink. Now, consider the last xyz-triplet, that p goes through before getting to the 1-sink. This could either be x_i, z_j, y_j-triplet, or x_k, z_ℓ, y_ℓ, such that $i \neq k; j \neq \ell$. In both cases, at most one of the variables in such xyz-triplets is set to 1. Hence, we get a contradiction with Lemma 20. The proof for the xyz-triplets in the last $n/2$-elements of $[n]$ goes similarly. ◀

Proof of Lemma 19. Consider an edge connecting (j, k) with (j', k') in G. Assume towards a contradiction that κ_B maps an element j to k, and j' to k'. Then, there are two triplets x_j, y_k, z_k, and $x_{j'}, y_{k'}, z_{k'}$ such that within each xyz-triplet the elements are layered consequently in B. Consider a substitution s, which sets $x_j = x_{j'} = 0$, all other bits of $\vec{x}$ to 1, $z_k = z_{k'} = 1$, all other bits of $\vec{z}$ to 0, and all bits of $\vec{y}$ to 0. $\gamma|_s = 1$, hence there is a path p in B consistent with s which goes from the source to 1-sink. Consider a triplet x_a, y_b, z_b, which is queried the last on the path p. Similarly to the previous case we consider two cases, if this triplet is x_j, y_k, z_k (or $x_{j'}, y_{k'}, z_{k'}$, proof for which is analogous) or not. In the latter case, by our assumptions on the structure of B, all $a \neq j$, $a \neq j'$, $b \neq k$, and $b \neq k'$.

If $a = j$ and $b = k$, then, by our choice of s and this triplet, we get that p goes to 1-sink after substituting $x_j = 0, z_k = 1, y_k = 0$. Which is a contradiction with Lemma 20.

Finally, assume either $a \neq j$ and $b \neq k$. Then there is a path in B from the nodes x_a, y_b, z_b directly to 1-sink which is consistent with a substitution $x_a = 1, z_b = 0, y_b = 0$. Thus, again, leads to a contradiction with Lemma 20. ◀

5.2 Proof of Lemma 20

Assume the opposite: there exist paths in B, which go to the 1-sink immediately after substituting exactly one 1-value to variables of an xyz-triplet. Consider a path p among these paths, which goes to the 1-sink from the earliest node according to the topological order of B. Let us denote the xyz-triplet, from which p goes to the 1-sink as x_i, z_j, y_j, and let w be the last non-sink node in p.

▷ Claim 21. p assigns 1 to w.

Proof. Assume the opposite: the last edge in p going to the 1-sink is $w = 0$.

Consider a case $w = x_i$. We want to show that $x_i = 0$-edge cannot lead to the 1-sink. To see this observe that oaBP $B|_{\vec{z}=1^n}$ is sensitive in all x-variables. Hence, in the oaBP $B|_{\vec{z}=1^n}$ a path consistent with setting $\vec{x} = \vec{y} = 0^n$ goes through x_i, and goes to the 0-sink. This contradicts our assumption that the edge $x_i = 0$ goes to 1.

Now consider a case when $w \in \{y_j, z_j\}$. Consider a path p' in the oaBP $B|_{\vec{x}=0^n}$ such that for every $k \in [n]$ $p'(z_k) = 1$ and $p'(y_k) = 0$ if z_k precedes y_k in the topological order, and $p'(z_k) = 0$ and $p'(y_k) = 1$ otherwise. By (1) we have $\gamma'|_{\vec{x}=0^n} = \bigvee_{i\in[n]}(y_i \wedge z_i)$, so every such p' ends in the 0-sink. This contradicts the fact that the edge $w = 0$ goes to the 1-sink, since at least one of such paths p' contains this edge. The claim then follows. ◁

In the remainder of the proof, we show that $w = 1$ cannot be the only 1-value assigned by p to the variables in the last triplet x_i, z_j, y_j. Consider the case when $w = y_j$ or $w = z_j$ and the value of w is assigned to 1 by p. Consider an oaBP $B' = B|_{\vec{x}=0^n}$ corresponding to a partial substitution $\vec{x} = 0^n$. We know the structure of B' from Lemma 13. For each zy-block there is a path to the 1-sink iff we set both $z_i = y_i = 1$. But that contradicts the existence of a path of a form $x_i = 0, y_j = 0, z_j = 1$ or $x_i = 0, y_j = 1, z_j = 0$ from the x_i, z_j, y_j triplet to the 1-sink. Hence, w could not be y or z variable.

Consider the only remaining case, when $w = x_i$, and p sets $x_i = 1$. In the following two claims we show that p should ask either y_j or z_j prior to x_i.

▷ Claim 22. Either y_j or z_j precedes x_i in the topological order.

Proof. Assume the opposite, x_i is the first node in the triplet. By Lemma 15 y_j goes either right before or right after x_i in the topological order. Hence, we get that nodes in this triplet appear in the order x_i, y_j, z_j in the topological order. But then, by the property (†) in Lemma 15, if x_i is the first node of the triplet then the edge $x_i = 1$ does not go to the 1-sink, contradicting the properties of p. ◁

▷ Claim 23. Path p queries either a value of y_j or z_j before querying x_i.

Proof. By Claim 22 we know x_i is not the first node of the triplet x_i, y_j, z_j in the topological order. Now assume that p skips querying yz-nodes preceding x_i in this triplet and goes directly to x_i. Let w' be the last node prior to x_i in p. By our assumption w' belongs to an xyz-triplet $\{x_b, y_a, z_a\}$ different from $\{x_i, y_j, z_j\}$.

First let us rule out the case $w' = z_a$ or $w' = y_a$. If p assigns 0 to w', then the edge $w' = 0$ in $B|_{\vec{x}=0^n}$ goes to the endpoint of the edge $x_i = 0$ in B, which contradicts Lemma 13, since this edge must go to the first variable of the subsequent zy-block, which precedes x_i in the topological order of B. If p assigns 1 to w', then in $B|_{\vec{x}=0^n}$ the edge $w' = 1$ goes to the 1-sink (as it does not go to the node in the same zy-block), hence in B the edge $x_i = 1$ must go to the 1-sink, which implies that the function computed by B does not depend on x_i, which is a contradiction, since γ' does depend on x_i.

Hence $w' = x_b$. Let us now show that p assigns 1 to x_b. Assume the opposite: x_b is set to 0 in B. Let us then trace the path corresponding to the assignment $\vec{x} = 0^n; \vec{z} = 1^n; \vec{y} = 0^n$ in B until we reach the node x_b. This must happen by Lemma 14 for (3). Now by the Lemma 13 and property (1) the edge $x_b = 0$ must go to the first node of the subsequent zy-block, which is a contradiction with the assumption that $x_b = 0$ ends in x_i. Therefore p assigns $x_b = 1$.

Consider an assignment s of $\vec{z} = 1^n, \vec{y} = 0^n$, $\vec{x} = e_b$. By (3) we have $\gamma(s) = 1$. But by our assumptions an edge $x_b = 1$ does not go to the 1-sink immediately, it goes to x_i first. A node x_i should also be reachable by a substitution s' which assigns $\vec{z} = 1^n, \vec{y} = 0^n$, $\vec{x} = 0^n$, as $\gamma'|_{\vec{z}=1^n}$ is sensitive to the value of x_i by (3). But $\gamma(s') = 0$. Hence, we get a contradiction with the fact that paths corresponding to assignments s and s' meet in the node x_i, and follow the same path in B, but one must end in the 0-sink, and another in the 1-sink. Therefore, either z_j or y_j node is not queried by p. ◁

Now, let r be the immediate predecessor of w in p. By Claim 23 we know that either $r \in \{y_j, z_j\}$. First, consider the case of $r = z_j$. Consider a substitution s of $\vec{x} = 1^n$ and $\vec{z} = 0^n$. We know that the oaBP $B|_{\vec{x}=1^n}$ queries all values of z. Hence, $B|_{\vec{x}=1^n}$ contains a path $r = 0, w = 1$, which goes to the 1-sink. But, as the assignment s does not satisfy $B|_{\vec{x}=1^n}$, and is consistent with the substitution $r = 0, w = 1$ we get a contradiction (since the path s passes through r).

Finally, to get a contradiction with the case when $r = y_j$ we show the following two claims.

▷ Claim 24. If $r = y_j$, then z_j goes before y_j and x_i in the topological order.

Proof. Assume the opposite. Let z_j go right after x_i in the topological order. So we get that the order of nodes in this triplet is y_j, x_i, z_j. First, note that $y_j = 0$ edge goes to x_i as $B|_{\vec{z}=1^n}$ queries all ys and xs sequentially, and every edge labeled with 0-edge in $B|_{\vec{z}=1^n}$ goes to either the next node or to the 0-sink. We also know that $x_i = 1$-edge goes to the 1-sink. Now note that that a path consistent with a substitution s defined as $\vec{x} = e_i, \vec{y} = 0^n, \vec{z} = 0^n$ should reach node y_j. But then this path will follow edge $y_j = 0$ to x_i and edge $x_i = 1$ to 1 sink, though $\gamma|_s = 0$. A contradiction. ◁

▷ Claim 25. If z_j is the first node in a xyz-triplet then path p goes through z_j.

Proof. Consider all possible edges which get to this triplet. Let x_a, z_b, y_b be the triplet right before this one. From the structure of $B|_{\vec{x}=1^n}$ we know that all edges from z_b and y_b either go to a node within this triplet, or the 1-sink, or to z_j. We also know that $x_a = 0$ cannot skip z_j, as x_a-node is reachable by a path consistent with a substitution $\vec{x} = 0^n, \vec{y} = 0^n, \vec{z} = 1^n$. Hence if $x_a = 0$ skips z_j then $B|_{\vec{x}=0^n}$ would be insensitive to z_j.

It now remains to show that $x_a = 1$ cannot skip z_j either. In $B|_{\vec{z}=1^n}$ every edge $x_a = 1$ should go to 1-sink. Hence edge $x_a = 1$ either goes to z-node or to 1-sink. This finishes the proof. ◁

From these two claims, we get that p should necessarily go through z_j. Hence, by considering $B|_{\vec{x}=1^n}$ we get that a path consistent $z_j = y_j = 0$ should either go to a node in the next triplet, or go to the 0-sink, in case it is the last triplet of B. Which contradicts the fact that p after substituting $z_j = y_j = 0$ and $x_i = 1$ goes to the 1-sink. This finishes the proof of Lemma 20.

6 Corollaries

Multiple corollaries follow from Theorem 11. For all classes of branching programs that degenerate to an oaBP if constrained on having at most n nodes on an n-bit input, we get that the corresponding minimization problem is ETH-hard. In particular it holds for general branching programs (BP), ordered binary decision diagrams (OBDD) and read-k branching programs for any $k \geq 1$ (k-BP). For definitions of the latter two classes we refer the reader to [27]. Formally we have

▶ **Corollary 26.** *Let $\mathcal{C}$ be a circuit class such that for every $f\colon \{0,1\}^n \to \{0,1\}$ that depends on all its variables there exists $C \in \mathcal{C}$ with $|C| = n$ computing f if and only if there exists* oaBP *B computing f.*

Then, assuming ETH holds we have that $\mathcal{C}$-MCSP$|^*_{s=n}$ requires time $2^{\Omega(n \log n)}$.

It is easy to see that for $\mathcal{C} \in \{\text{OBDD}, \text{BP}\} \cup \{k\text{-BP} \mid k \geq 1\}$ this statement holds, so in particular Theorem 1 is implied.

Proof of Corollary 26. Let $\mathcal{R}$ be the reduction given by Theorem 11. Observe that every partial function in the image of $\mathcal{R}$ can only be extended to a function that depends on all of its variables.

Hence by the assumption on $\mathcal{C}$, $\mathcal{R}(G) \in \mathcal{C}\text{-MCSP}|^*_{s=n}$ iff $\mathcal{R}(G)$ is computable by an oaBP. Therefore, Theorem 11 and Theorem 8 imply the statement. ◀

Following on the results from [6], in which the authors show that $(n \times n)$-BPIS is unconditionally hard for 1-NBPs by showing that reduction of Ilango is computable by a 1-NBPs, we get that similar 1-NBP lower bound holds for all total minimization problems for branching programs.

▶ **Corollary 27.** *For $\mathcal{C}$ as in Corollary 26, the size of the smallest* 1-NBP *that computes $\mathcal{C}$-MCSP is $N^{\Omega(\log\log(N))}$, where N is the input size of $\mathcal{C}$-MCSP.*

Proof. By [6, Theorem 6] we have that the sizes of 1-NBPs computing $\mathcal{C}$-MCSP* and $\mathcal{C}$-MCSP are linearly related (the theorem is only stated for vanilla MCSP, but the proof does not use this). By [6, Threorem 4], the reduction $\mathcal{R}$ can be implemented in 1-NBP, so by Theorem 11 1-NBP size of $\mathcal{C}$-MCSP* with input size $N = 2^{3n}$ is lower bounded by the 1-NBP size of $(n \times n)$-BPIS which by [6, Theorem 3] is $2^{\Omega(n \log n)} = N^{\Omega(\log\log N)}$. ◀

Another corollary follows from the fact that $\mathcal{R}$ always outputs a partial functions that can be encoded as a 2-BP.

▶ **Corollary 28.** *It is* **NP***-hard to check, whether any extension of a partial function expressed by a* 2-BP *over the alphabet $\{0, 1, *\}$ can be computed with an* oaBP*.*

Proof. Since $(n \times n)$-BPIS is an **NP**-complete problem, it suffices to check that for every G the function γ_G can be represented as a 2-BP of polynomial size. First, notice that a 1-BP can distinguish between the cases (1)-(6) and the case that either (7) is true or the function equals to $*$: we read variables in the order $x_1, y_1, z_1, \ldots, x_n, y_n, z_n$ and for each of the patterns among (1)-(6) we maintain if the current prefixes of $\vec{x}$, $\vec{y}$, and $\vec{z}$ coincide with the prefix of the pattern. Thus, at each level of our 1-BP we have 2^6 states. For each of the states at the last level, we choose one of the patterns which is satisfied arbitrary, so we can merge the states into 7: 6 corresponding to the conditions (1)-(6) and one to the case where none of the conditions hold. For each of the cases (1)-(6), the restricted function can easily be computed by a 1-BP.

Now it remains to distinguish the case (7) from a star with a 1-BP. In order to do this we split the input into 6 chunks of length $n/2$ and read then sequentially. For each chunk we maintain the set of possible values among $\{0^{n/2}, 1^{n/2}\} \cup \{e_i \mid i \in [n/2]\} \cup \{\overline{e_i} \mid i \in [n/2]\}$ that the chunk might have given the current prefix. Observe, that the number of potential states is linear. After we read all the chunks we have $O(n^6)$ states at the last level, so we know the only tuple j, k, j', k' that may satisfy the predicate in (7). Since the edges are fixed, we can unite each of the states at the last level with the 1-sink or the $*$-sink. ◀

Finally, to show the **coNP**-hardness of compressing BPs we use the following fact.

▶ **Proposition 29** ([24])**.** *Let $(3, 4)$-SAT be a language of satisfiable* 3-**CNF** *formulas in which every variable occurs in at most 4 clauses. $(3, 4)$-SAT is* **NP***-complete.*

▶ **Corollary 30.** *It is* **coNP***-hard to check whether an input* 4-BP *for a total function can be compressed to a* BP *of a constant size.*

Proof. By Proposition 29 we get that $\overline{(3,4)\text{-SAT}}$ is **coNP**-hard. Now, we construct a reduction from $\overline{(3,4)\text{-SAT}}$ to the partial 4-BP minimization as follows. For a 4-**CNF** formula φ in which every variable appears at most 4 times we construct a branching program B by consequently adding nodes of each clause. Denote the first clause of φ as C_1, and let x_i, x_j, x_k be the variables in it. We add nodes labeled by x_i, x_j, and x_k to B. We set the node labeled by x_i as a source of B. Then, if x_i was negated in C_1 we direct a 1-edge from the x_i-node to the node labeled by x_j, otherwise we direct a 0-edge from x_i to the x_j-node. Then we similarly define one of the edges of x_j to x_k. Finally, if x_k was negated in C_1 we direct its 1-edge to the 1-sink. Then we add nodes from the next clause of φ, and direct all missing edges for nodes x_i, x_j, and x_k to the first node corresponding to the next node. We repeat this procedure for all clauses, redirecting all unassigned edges for nodes corresponding to variables in the last clause of φ to the 0-sink.

Now, for any substitution s of values of the variables B outputs 1 if φ was not satisfied by s, and 0 otherwise. But note, that if φ was an unsatisfiable formula than B would had to output 1 on all inputs. Hence, it could be compressed to a branching program of size 0 (as we count the number of all nodes other than sinks). On the other hand, if φ is satisfiable and has at least one unsatisfying assignment B has to contain at least one node other than a sink. To account for the fact that the size of B corresponding to φ that is satisfiable by any assignment is also 0 (it is just a 0-sink), we change our reduction to first substitute all 0 assignment to φ. If $\varphi(\overline{0}) = 1$ we set B to be a BP for an identity function on one bit which has the size 1. Otherwise, construct B as described before. ◀

Additionally, as for any 3-SAT instance in which every variable appears in at most 4 clauses we can easily construct an equivalent 3-BP of polynomial size. we get that checking whether this BP can compressed to a BP of size 1 allows us to check whether the formula is unsatisfiable.

7 Future Work

The main future direction is to strengthen our results to the total version of MBPSP, and to show **NP**-hardness of MBPSP (or at least MBPSP*). We discuss a couple of barriers for improving results in both of these directions as well as additional open questions motivated by our work.

7.1 Show polynomial-time oracle reduction from MBPSP* to MBPSP

As noted in [10] such reductions are very ad hoc for each specific model. Indeed, the reduction that Ilango showed for the Minimum DeMorgan Formula Size Problem in [10] does not work for branching programs as it relies on the tree-like structure of formulas. The ability of branching programs to reuse the same computation in different branches makes it harder to come up with a suitable reduction. For now we do not even know such a reduction for 1-BPs but the natural next step would be to reduce (1-BP)-MCSP* to (1-BP)-MCSP.

7.2 Prove a stronger conditional lower bound

It would be interesting to find a lower bound stronger than $N^{\Omega(\log\log(N))}$ for the time complexity of MBPSP* (or MFSP*). The obstacle here is that we actually show the ETH-hardness of MBPSP$^*|_n$, for which this time complexity is actually tight, since there are $n^{O(n)} = N^{O(\log\log N)}$ potential branching programs that can compute a function. Hence, in order to have stronger lower bounds we need to consider larger size parameters. The current framework requires us to find explicit functions that require BP-size larger than the

given size parameter. Hence, the best we can hope for without improving the state-of-the-art BP lower bounds is to show that $\text{MBPSP}^*|_{n^2}$ is ETH-hard. Here the trivial upper bound is $n^{O(n^2)} = N^{O(\log N \log\log N)}$, which while still quasipolynomial, is significantly stronger.

7.3 Results for nondeterministic BP minimization

Currently our hardness result only holds for the problem of minimizing deterministic branching programs. But we believe that similar ideas could be used to show that the problem of minimizing nondeterministic branching programs for partial functions is also ETH-hard. Nondeterministic branching programs (NBP) differ from deterministic ones by an additional type of nodes, called *nondeterministic* nodes, that do not have labels. Such nodes correspond to nondeterministic guessing of a branching program. Note, that if we consider a complexity measure that counts *all nodes in an* NBP other than sinks, then our main result immediately extends to the ETH-hardness of minimizing NBP and k-NBP for all k.

However, the standard complexity measure for NBPs is the minimal number of nodes that query a variable (so all nodes other than sinks and nondeterministic nodes) in an NBP computing the function. So one of the approaches to showing the ETH-hardness of the Partial Minimum Nondeterministic Branching Program Size Problem could be in showing that existence of the oaBP with nondeterministic nodes for γ_G is equivalent to the existence of the deterministic oaBP for γ_G. Namely by adding the nondeterministic node we do not make it easier for an oaBP to compute γ_G. Could this result be obtained with an additional careful analysis?

7.4 Could we adapt the NP-hardness proof of Hirahara?

Hirahara in [7] showed a randomized reduction from **NP**-hard problem that is a variation of Minimum Monotone Satisfying Assignment called Collective Minimum Weight Monotone Satisfying Assignment (CMMSA) problem to MCSP^*. One of the possible directions of strengthening our result from the ETH-hardness to **NP**-hardness is by adapting this framework for branching programs. Indeed, the reduction from [7] seems to be robust enough to correctly work on all *no*-instances of CMMSA even for branching programs. But the same reduction does not immediately go through for the *yes*-instances. The main obstacle that we see is in showing an analogue of the Uhlig's lemma [25, 26] for branching programs. This lemma states that in order to compute the direct product of the same function (of arbitrary circuit complexity) on subexponentially many inputs, it is sufficient to use one circuit of size $O(2^n/n)$. Such efficient compression is an important step for constructing a small circuit corresponding to the *yes*-instances of CMMSA. It is not known whether an analogue of Uhlig's lemma exists for branching programs. Rao and Sinha [19] showed a variation of the direct-sum theorem for read-once BPs, hence disproving the analogue of Uhlig's lemma in 1-BP setting. We believe that showing an analogue of Uhlig's lemma for general branching programs in the specific setting required by the Hirahara's proof is a promising direction for showing **NP**-hardness of MBPSP^*.

Completeness Theorems for k-SUM and Geometric Friends: Deciding Fragments of Linear Integer Arithmetic

Geri Gokaj
Karlsruhe Institute of Technology, Germany

Marvin Künnemann
Karlsruhe Institute of Technology, Germany

Abstract

In the last three decades, the k-SUM hypothesis has emerged as a satisfying explanation of long-standing time barriers for a variety of algorithmic problems. Yet to this day, the literature knows of only few proven consequences of a refutation of this hypothesis. Taking a descriptive complexity viewpoint, we ask: What is the largest logically defined class of problems *captured* by the k-SUM problem?

To this end, we introduce a class $\mathsf{FOP}_{\mathbb{Z}}$ of problems corresponding to deciding sentences in Presburger arithmetic/linear integer arithmetic over finite subsets of integers. We establish two large fragments for which the k-SUM problem is complete under fine-grained reductions:

1. The k-SUM problem is complete for deciding the sentences with k existential quantifiers.
2. The 3-SUM problem is complete for all 3-quantifier sentences of $\mathsf{FOP}_{\mathbb{Z}}$ expressible using at most 3 linear inequalities.

Specifically, a faster-than-$n^{\lceil k/2\rceil \pm o(1)}$ algorithm for k-SUM (or faster-than-$n^{2\pm o(1)}$ algorithm for 3-SUM, respectively) directly translate to polynomial speedups of a general algorithm for *all* sentences in the respective fragment.

Observing a barrier for proving completeness of 3-SUM for the entire class $\mathsf{FOP}_{\mathbb{Z}}$, we turn to the question which other – seemingly more general – problems are complete for $\mathsf{FOP}_{\mathbb{Z}}$. In this direction, we establish $\mathsf{FOP}_{\mathbb{Z}}$-completeness of the *problem pair* of Pareto Sum Verification and Hausdorff Distance under n Translations under the L_∞/L_1 norm in $\mathbb{Z}^d$. In particular, our results invite to investigate Pareto Sum Verification as a high-dimensional generalization of 3-SUM.

1 Introduction

Consider a basic question in complexity theory: How can we determine for which problems an essentially quadratic-time algorithm is best possible? If a given problem A admits an algorithm running in $n^{2+o(1)}$ time, and it is known that A cannot be solved in time $O(n^{2-\epsilon})$ for any $\epsilon > 0$, then clearly the $n^{2+o(1)}$ algorithm has *optimal* runtime, up to subpolynomial factors. This question can be asked more generally for any $k \geq 1$ and time $n^{k\pm o(1)}$. To this day, the theoretical computer science community is far from able to resolve this question unconditionally. However, a surge of results over recent years uses conditional lower bounds

© Geri Gokaj and Marvin Künnemann;
licensed under Creative Commons License CC-BY 4.0

based on plausible hardness assumptions to shed some light on why some problems seemingly cannot be solved in time $O(n^{k-\epsilon})$ for any $\epsilon > 0$. Most notably, reductions from k-OV, k-SUM and the weighted k-clique problem have been used to establish $n^{k-o(1)}$-time conditional lower bounds, often matching known algorithms; see [50] for a detailed survey.

In this context, the 3-SUM hypothesis is arguably the first – and particularly central – hardness assumption for conditional lower bounds. Initially introduced to explain various quadratic-time barriers observed in computational geometry [35], it has since been used to show quadratic-time hardness for a wealth of problems from various fields [52, 46, 6, 40, 29, 3, 21]. Its generalization, the k-SUM[1] hypothesis, has led to further conditional lower bounds beyond the quadratic-time regime [31, 4, 1, 2, 41]. For a more comprehensive overview, we refer to [50].

The centrality of the 3-SUM hypothesis for understanding quadratic-time barriers begs an interesting question: Does 3-SUM fully capture quadratic-time solvability, in the sense that it is hard for the entire class $\mathsf{DTIME}(n^2)$? Alas, Bloch, Buss, and Goldsmith [10] give evidence that we are unlikely to prove this: If 3-SUM is hard for $\mathsf{DTIME}(n^2)$ under quasilinear reductions, then $\mathsf{P} \neq \mathsf{NP}$. Thus, to understand precisely the role of 3-SUM to understand quadratic-time computation, the more reasonable question to ask is:

What is the largest class $\mathcal{C}$ of problems such that 3-SUM is $\mathcal{C}$-hard?[2]

Finding a large class $\mathcal{C}$ for which 3-SUM is hard may be seen as giving evidence for the 3-SUM hypothesis. Furthermore, such a result may clarify the true expressive power of the 3-SUM hypothesis, much like the NP-completeness of 3-SAT highlights its central role for polynomial intractability.

1.1 Our approach

We approach our central question from a descriptive complexity perspective. This line of research has been initiated by Gao et al. [36], who establish the sparse OV problem as complete for the class of model checking first-order properties. One can interpret this result as showing that the OV problem expresses relational database queries in the sense that a truly subquadratic algorithm for OV would improve the fine-grained data complexity of such queries (see [36] for details). Related works further delineate the fine-grained hardness of model checking first-order properties and related problem classes [49, 14, 12, 7, 13, 32], see Section 1.3 for more discussion.

Towards continuing the line of research on fine-grained completeness theorems, we introduce a class of problems corresponding to deciding formulas in linear integer arithmetic over finite sets of integers. Specifically, consider the vectors

$$x_1 = (x_1[1], \dots, x_1[d_1]), \dots, x_k = (x_k[1], \dots, x_k[d_k])$$

as quantified variables, and let $t_1, \dots, t_l$ be free variables. Moreover, let

$$X := \{x_1[1], \dots, x_1[d_1], \dots x_k[1], \dots, x_k[d_k], t_1, \dots, t_l\},$$

[1] The k-SUM problem asks, given sets $A_1, \dots, A_k$ of n numbers, whether there exist $a_1 \in A_1, \dots, a_k \in A_k$ such that $\sum_{i=1}^{k} a_i = 0$. The k-SUM hypothesis states that for no $\epsilon > 0$ there exists a $O(n^{\lceil k/2 \rceil - \epsilon})$ time algorithm that solves k-SUM.

[2] Note that there are different reasonable notions of reductions to consider. Rather than the quasilinear reductions used by Bloch et al., we will consider the currently more commonly used notion of fine-grained reductions; see Section 1.2 for details on the notion of completeness that we will use.

and let ψ be a quantifier-free linear arithmetic formula over variables in X. We consider the model-checking problem for formulas ϕ in the prenex normal form

$$\phi := Q_1 x_1 \dots Q_k x_k : \psi,$$

where the quantifiers $Q_1, \dots, Q_k \in \{\exists, \forall\}$ are arbitrary. Formally, for such a ϕ, we define the model checking problem $\mathsf{FOP}_{\mathbb{Z}}(\phi)$ as follows[3]

$$\begin{aligned} &\mathsf{FOP}_{\mathbb{Z}}(\phi): \qquad (1)\\ &\quad\textbf{Input:} \text{ Finite sets } A_1 \subseteq \mathbb{Z}^{d_1}, \dots, A_k \subseteq \mathbb{Z}^{d_k} \text{ and } \hat{t_1}, \dots, \hat{t_l} \in \mathbb{Z}.\\ &\textbf{Problem:} \text{ Does } Q_1 x_1 \in A_1 \dots Q_k x_k \in A_k : \psi[(t_1, \dots, t_l)\backslash(\hat{t_1}, \dots, \hat{t_l})] \text{ hold?} \end{aligned}$$

We let $n := \max_i\{|A_i|\}$ denote the input size and will assume throughout the paper that all input numbers (i.e., the coordinates of the vectors in $A_1, \dots, A_k$ and the values $\hat{t_1}, \dots, \hat{t_l}$) are chosen from a polynomially sized universe, i.e., $\{-U, \dots, U\}$ with $U \leq n^c$ for some c. Let $\mathsf{FOP}_{\mathbb{Z}}$ be the union of all $\mathsf{FOP}_{\mathbb{Z}}(\phi)$ problems, where ϕ has at least 3 quantifiers.[4] Besides 3-SUM, a variety of interesting problems is contained in $\mathsf{FOP}_{\mathbb{Z}}$; we discuss a few notable examples below and in the full version.

Frequently, we will distinguish formulas in $\mathsf{FOP}_{\mathbb{Z}}$ using their quantifier structure; e.g., $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\forall)$ describes the class of model checking problems $\mathsf{FOP}_{\mathbb{Z}}(\phi)$ where in ϕ we have $Q_1 = Q_2 = \exists$ and $Q_3 = \forall$. Furthermore, we let $\mathsf{FOP}^k_{\mathbb{Z}}$ be the union of all $\mathsf{FOP}_{\mathbb{Z}}(\phi)$ problems, where ϕ consists of precisely k quantifiers, regardless of their quantifier structure. For a quantifier $Q \in \{\exists, \forall\}$, we write Q^k for the repetition $\underbrace{Q \dots Q}_{k \text{ times}}$. Finally, we remark that a small subset of $\mathsf{FOP}_{\mathbb{Z}}$ has already been studied by An et al. [7], for a discussion see Section 1.3.

1.2 Our Contributions

We seek to determine completeness results for the class $\mathsf{FOP}_{\mathbb{Z}}$. In particular: What are the largest fragments of this class for which 3-SUM (or more generally, k-SUM) is complete? Is there a problem that is complete for the entire class?

Intuitively, we say that a $T_A(n)$-time solvable problem A is *(fine-grained) complete* for a $T_{\mathcal{C}}(n)$-time solvable class of problems $\mathcal{C}$, if the existence of an $O(T_A(n)^{1-\epsilon})$-time algorithm for A with $\epsilon > 0$ implies that for *all* problems C in $\mathcal{C}$ there exists $\delta > 0$ such that C can be solved in time $O(T_{\mathcal{C}}(n)^{1-\delta})$. We extend this notion to completeness of a *family* of problems, since strictly speaking, any (geometric) problem over $\mathbb{Z}^d$ expressible in linear integer arithmetic corresponds to a family of formulas $\mathsf{FOP}_{\mathbb{Z}}$ (one for each $d \in \mathbb{N}$). Formally, consider a family of problems $\mathcal{P}$ with an associated time bound $T_{\mathcal{P}}(n)$ and a class of problems $\mathcal{C}$ with an associated time bound $T_{\mathcal{C}}(n)$; usually $T_{\mathcal{P}}(n), T_{\mathcal{C}}(n)$ denote the running time of the fastest known algorithm solving all problems in $\mathcal{P}$ or $\mathcal{C}$, respectively (often, we omit these time bounds, as they are clear from context).[5] We say that $\mathcal{P}$ is *(fine-grained) complete* for $\mathcal{C}$, if

1. the family $\mathcal{P}$ is a subset of the class $\mathcal{C}$, and

[3] Below, we use the notation $\psi[(t_1, \dots, t_l)\backslash(\hat{t_1}, \dots, \hat{t_l})]$ to denote the substitution of the variables $t_1, \dots, t_l$ by $\hat{t_1}, \dots, \hat{t_l}$ respectively.

[4] It is not too difficult to see that all formulas with 2 quantifiers can be model-checked in near-linear time; see the full version for details.

[5] Here, we use *family* and *class* as a purely semantic and intuitive distinction: A family consists of a small set of similar problems, and a class consists of a large and diverse variety of problems.

2. if for all problems P in $\mathcal{P}$ there exists $\epsilon > 0$ such that P can be solved in time $O(T_{\mathcal{P}}(n)^{1-\epsilon})$, then for all problems C in $\mathcal{C}$ there exists some $\delta > 0$ such that we can solve C in time $O(T_{\mathcal{C}}(n)^{1-\delta})$.

That is, a polynomial-factor improvement for solving the problems in $\mathcal{P}$ would lead to a polynomial-factor improvement in solving *all* problems in $\mathcal{C}$. If a singleton family $\mathcal{P} = \{P\}$ is fine-grained complete for $\mathcal{C}$, then we also say that P is fine-grained complete for $\mathcal{C}$. We work with standard hypotheses and problems encountered in fine-grained complexity; for detailed definitions of these, we refer to the full version of this article.

1.2.1 k-SUM is complete for the existential fragment of $\mathsf{FOP}_{\mathbb{Z}}$

Consider first the existential fragment of $\mathsf{FOP}_{\mathbb{Z}}$, i.e., formulas exhibiting only existential quantifiers. Any $\mathsf{FOP}_{\mathbb{Z}}$ formula with k existential quantifiers can be decided using a standard meet-in-the-middle approach, augmented by orthogonal range search, in time $\tilde{O}(n^{\lceil k/2 \rceil})$[6], see the full version of the paper for details. Since k-SUM is a member of $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$, this running time is optimal up to subpolynomial factors, assuming the k-SUM Hypothesis. As our first contribution, we provide a converse reduction. Specifically, we show that a polynomially improved k-SUM algorithm would give a polynomially improved algorithm for solving the entire class. In our language, we show that k-SUM is fine-grained complete for formulas of $\mathsf{FOP}_{\mathbb{Z}}$ with k existential quantifiers.

▶ **Theorem 1** (k-SUM is $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$-complete)**.** *Let $k \geq 3$ and assume that k-SUM can be solved in time $T_{k\mathrm{SUM}}(n)$. For any problem P in $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$, there exists some c such that P can be solved in time $O(T_{k\mathrm{SUM}}(n) \log^c n)$.*

Thus, if there are $k \geq 3$ and $\epsilon > 0$ such that we can solve k-SUM in time $O(n^{\lceil k/2 \rceil - \epsilon})$, then we can solve all problems in $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$ in time $O(n^{\lceil k/2 \rceil - \epsilon'})$ for any $0 < \epsilon' < \epsilon$. By a simple negation argument, we conclude that k-SUM is also complete for the class of problems $\mathsf{FOP}_{\mathbb{Z}}(\forall^k)$.

The above theorem generalizes and unifies previous reductions from problems expressible as $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$ formulas to 3-SUM, using different proof ideas: Jafargholi and Viola [39, Lemma 4] give a simple randomized linear-time reduction from triangle detection in sparse graphs to 3-SUM, and a derandomization via certain combinatorial designs. Dudek, Gawrychowski, and Starikovskaya [29] study the family of 3-linear degeneracy testing (3-LDT), which constitutes a large and interesting subset of $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$: This family includes, for any $\alpha_1, \alpha_2, \alpha_3, t \in \mathbb{Z}$, the *3-partite* formula $\exists a_1 \in A_1 \exists a_2 \in A_2 \exists a_3 \in A_3 : \alpha_1 a_1 + \alpha_2 a_2 + \alpha_3 a_3 = t$ and the *1-partite* formula $\exists \alpha_1, \alpha_2, \alpha_3 \in A : \alpha_1 a_1 + \alpha_2 a_2 + \alpha_3 a_3 = t \wedge a_1 \neq a_2 \wedge a_2 \neq a_3 \wedge a_1 \neq a_3$. The authors show that each such formula is either trivial or subquadratic *equivalent* to 3-SUM. For 3-partite formulas, a reduction to 3-SUM is essentially straightforward. For 1-partite formulas, Dudek et al. [29] use color coding.[7] As further examples for reductions from $\mathsf{FOP}_{\mathbb{Z}}$ problems to k-SUM, we highlight a reduction from Vector k-SUM to k-SUM [5] as well as a reduction from $(\min, +)$-convolution to 3-SUM (see [9, 27]) based on a well-known bit-level trick due to Vassilevska Williams and Williams [52], which allows us to reduce inequalities to equalities.

---

[6] We use the notation $\tilde{O}(T) := T \log^{O(1)}(T)$ to hide polylogarithmic factors.

[7] We remark that the reverse direction, i.e., 3-SUM-hardness of non-trivial formulas, is technically much more involved and can be regarded as the main technical contribution of [29].

Perhaps surprisingly in light of its generality and applicability, Theorem 1 is obtained via a very simple, deterministic reduction that combines the tricks from [5, 52]. This generality comes at the cost of polylogarithmic factors (which we do not optimize), which depend on the number of inequalities occurring in the considered formula; for the details see Section 3 and the full version of the paper.

1.2.2 Completeness for counting witnesses

We provide a certain extension of the above completeness result to the problem class of *counting* witnesses to existential $\mathsf{FOP}_{\mathbb{Z}}$ formulas[8]. Counting witnesses is an important task particularly in database applications (usually referred to as model counting). Furthermore, we will make use of witness counting to *decide* certain quantified formulas in subsequent results detailed below. In Section 4, we will obtain the following result.

▶ **Theorem 2.** *Let $k \geq 3$ be odd. If there is $\epsilon > 0$ such that we can count the number of witnesses for k-SUM in time $O(n^{\lceil k/2 \rceil - \epsilon})$, then for all problem P in $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$, there is some $\epsilon' > 0$ such that we can count the number of witnesses for P in time $O(n^{\lceil k/2 \rceil - \epsilon'})$.*

Leveraging the recent breakthrough by [22] that 3-SUM is subquadratic equivalent to counting witnesses of 3-SUM, we obtain the corollary that *3-SUM is hard even for counting witnesses of* $\mathsf{FOP}_{\mathbb{Z}}(\exists^3)$.

▶ **Corollary 3.** *For all problems P in $\mathsf{FOP}_{\mathbb{Z}}(\exists^3)$, there is some $\epsilon_P > 0$ such that we can count the number of witnesses for P in randomized time $O(n^{2-\epsilon_P})$ if and only if there is some $\epsilon' > 0$ such that 3-SUM can be solved in randomized time $O(n^{2-\epsilon'})$.*

1.2.3 Completeness for general quantifier structures of $\mathsf{FOP}_{\mathbb{Z}}$

In light of our first completeness result, one might wonder whether k-SUM is complete for deciding all k-quantifier formulas in $\mathsf{FOP}_{\mathbb{Z}}$, regardless of the quantifier structure of the formulas. Note that for these general quantifier structures, a baseline algorithm with running time $\tilde{O}(n^{k-1})$ can be achieved with a combination of brute-force and orthogonal range queries; see the full version for details.

However, by [7, Theorem 15] there exists a $\mathsf{FOP}_{\mathbb{Z}}(\exists^{k-1}\forall)$-formula ϕ that cannot be solved in time $O(n^{k-1-\epsilon})$-time unless the 3-uniform hyperclique hypothesis is false (see the discussion in Section 1.3). Thus, proving that 3-SUM is complete for all 3-quantifier formulas would establish that the 3-uniform hyperclique hypothesis implies the 3-SUM hypothesis – this would be a novel tight reduction among important problems/hypotheses in fine-grained complexity theory. For $k \geq 4$, it becomes even more intricate: the conditionally optimal running time of $n^{k-1\pm o(1)}$ for $\mathsf{FOP}_{\mathbb{Z}}(\exists^k\forall)$ formulas exceeds the conditionally optimal running time of $n^{\lceil \frac{k}{2} \rceil \pm o(1)}$ for $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$ formulas.

We are nevertheless able to obtain a completeness result for general quantifier structures: Specifically, we show that if two geometric problems over $\mathbb{Z}^d$ can be solved in time $O(n^{2-\epsilon_d})$ where $\epsilon_d > 0$ for all d, then each k-quantifier formula in $\mathsf{FOP}_{\mathbb{Z}}$ can be decided in time $O(n^{k-1-\epsilon})$ for some $\epsilon > 0$. These problems are (1) a variation of the Hausdorff distance that we call *Hausdorff distance under n Translations* and (2) the Pareto Sum problem; the details are covered in Section 5.

[8] A witness for a $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$ formula $\exists a_1 \in A_1 \dots \exists a_k \in A_k : \varphi$ with $\hat{t_1}, \dots, \hat{t_l} \in \mathbb{Z}$ is a tuple $(a_1, \dots, a_k) \in A_1 \times \cdots \times A_k$ that satisfies the formula $\varphi[(t_1, \dots, t_l) \backslash (\hat{t_1}, \dots, \hat{t_l})]$.

Hausdorff Distance under n Translations

Among the most common translation-invariant distance measures for given point sets B and C is the Hausdorff Distance under Translation [24, 18, 19, 23, 45, 38]. To define it, we denote the directed Hausdorff distance under the L_∞ metric by $\delta_{\overrightarrow{H}}(B,C) := \max_{b\in B}\min_{c\in C}\|b-c\|_\infty$.[9] The Hausdorff distance under translation $\delta^T_{\overrightarrow{H}}(B,C)$ is defined as the minimum Hausdorff distance of B and an arbitrary translation of C, i.e.,

$$\delta^T_{\overrightarrow{H}}(B,C) \coloneqq \min_{\tau\in\mathbb{R}^d}\delta_{\overrightarrow{H}}(B,C+\{\tau\}) = \min_{\tau\in\mathbb{R}^d}\max_{b\in B}\min_{c\in C}\|b-(c+\tau)\|_\infty.$$

For $d=2$, Bringmann et al. [18] were able to show a $(|B||C|)^{1-o(1)}$ time lower bound based on the orthogonal vector hypothesis, and there exists a matching $\tilde{O}(|B||C|)$ upper bound by Chew et al. [25].

We shall establish that restricting the translation vector to be among a set of m candidate vectors yields a central problem in $\mathsf{FOP}_\mathbb{Z}$. Specifically, we define the Hausdorff distance under Translation in A, denoted as $\delta^{T(A)}_{\overrightarrow{H}}(B,C)$, by

$$\delta^{T(A)}_{\overrightarrow{H}}(B,C) \coloneqq \min_{\tau\in A}\delta_{\overrightarrow{H}}(B,C+\{\tau\}) = \min_{\tau\in A}\max_{b\in B}\min_{c\in C}\|b-(c+\tau)\|_\infty.$$

Correspondingly, we define the problem *Hausdorff distance under m Translations* as: Given $A,B,C\subseteq\mathbb{Z}^d$ with $|A|\le m$, $|B|,|C|\le n$ and a distance value $\gamma\in\mathbb{N}$, determine whether $\delta^{T(A)}_{\overrightarrow{H}}(B,C)\le\gamma$. Note that this can be rewritten as a $\mathsf{FOP}_\mathbb{Z}(\exists\forall\exists)$-formula, see the full version of the paper for details.

The Hausdorff distance under m Translations occurs naturally when approximating the Hausdorff distance under translation: Specifically, common algorithms compute a set A of $|A|=f(\epsilon)$ translations such that $\delta^{T(A)}_{\overrightarrow{H}}(B,C)\le(1+\epsilon)\delta^T_{\overrightarrow{H}}(B,C)$. Generally, this problem is then solved by performing $|A|$ computations of the Hausdorff distance, which yields $\tilde{O}(|A|n)=\tilde{O}(f(\epsilon)n)$-time algorithms [48]. Improving over the $\tilde{O}(mn)$-time baseline for Hausdorff Distance under m Translations would thus lead to immediate improvements for approximating the Hausdorff Distance under Translation. Our results will establish additional consequences of fast algorithms for this problem: an $O(n^{2-\epsilon_d})$-time algorithm with $\epsilon_d>0$ for Hausdorff distance under n Translations would give an algorithmic improvement for the classes of $\mathsf{FOP}_\mathbb{Z}(\exists\forall\exists)$- and $\mathsf{FOP}_\mathbb{Z}(\forall\exists\forall)$-formulas.

Verification of Pareto Sums

Our second geometric problem is a verification version of computing *Pareto sums*: Given point sets $A,B\subseteq\mathbb{Z}^d$, the Pareto sum C of A,B is defined as the Pareto front of their sumset $A+B=\{a+b\mid a\in A,b\in B\}$. Put differently, the Pareto sum of A,B is a set of points C satisfying (1) $C\subseteq A+B$, (2) for every $a\in A$ and $b\in B$, the vector $a+b$ is dominated[10] by some $c\in C$ and (3) there are no distinct $c,c'\in C$ such that c' dominates c. The task of computing Pareto sums appears in various multicriteria optimization settings [8, 47, 30, 44]; fast output-sensitive algorithms (both in theory and in practice) have recently been investigated by Hespe, Sanders, Storandt, and Truschel [37].

[9] Since we will exclusively consider the *directed* Hausdorff distance under Translation, we will drop "directed" throughout the paper.

[10] We consider the usual domination notion: A vector $u\in\mathbb{Z}^d$ is dominated by some vector $v\in\mathbb{Z}^d$ (written $u\le v$) if and only if in all dimensions $i\in[d]$ it holds that $u[i]\le v[i]$.

We consider the following problem as *Pareto Sum Verification*: Given $A, B, C \subseteq \mathbb{Z}^d$, determine whether

$$\forall a \in A \forall b \in B \exists c \in C : a + b \leq c.$$

The complexity of Pareto Sum Verification[11] is tightly connected to output-sensitive algorithms for Pareto Sum. Specifically, solving Pareto Sum Verification reduces to *computing* the Pareto sum C when given inputs A, B of size at most n with the promise that $|C| = \Theta(n)$; see Section 7 for details. The work of Hespe et al. [37] gives a practically fast $O(n^2)$-time algorithm in this case for $d = 2$; note that for $d \geq 3$, we still obtain an $\tilde{O}(n^2)$-time algorithm via our Baseline Algorithm, which is described in the full version of the paper.

A problem pair that is complete for $\mathsf{FOP}_{\mathbb{Z}}$

As a pair, these two geometric problems turn out to be fine-grained complete for the class $\mathsf{FOP}_{\mathbb{Z}}$.

▶ **Theorem 4.** *There is a function $\epsilon(d) > 0$ such that both of the following problems can be solved in time $O(n^{2-\epsilon(d)})$*

- *Pareto Sum Verification,*
- *Hausdorff distance under n Translations,*

if and only if for each problem P in $\mathsf{FOP}^k_{\mathbb{Z}}$ with $k \geq 3$ there exists an $\epsilon_P > 0$ such that P can be solved in time $O(n^{k-1-\epsilon_P})$.

The above theorem shows that a single pair of natural problems captures the fine-grained complexity of the expressive and diverse class $\mathsf{FOP}_{\mathbb{Z}}$. As an illustration just how expressive this class is, we observe the following barriers:[12]

1. If there is some $\epsilon > 0$ such that all problems in $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\forall)$ (or $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$) can be solved in time $O(n^{2-\epsilon})$, then OVH (and thus SETH) is false [7, Theorem 16].
2. If there is some $\epsilon > 0$ such that all problems in $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\exists)$ (or $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\forall)$) can be solved in time $O(n^{2-\epsilon})$, then the Hitting Set Hypothesis is false [7, Theorem 12].
3. If for all problems P in $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\forall)$ (or $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$), there exists some $\epsilon > 0$ such that we can solve P in $O(n^{2-\epsilon})$, then the 3-uniform Hyperclique Hypothesis is false [7, Theorem 15].
4. If for all problems P in $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$ ($\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\forall)$, $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$, or $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\forall)$), there exists some $\epsilon > 0$ such that we can solve P in time $O(n^{2-\epsilon})$, then the 3-SUM Hypothesis is false (Theorem 1 with Lemma 11).

Theorem 4 raises the question whether for any constant dimension d, the Hausdorff distance under n Translations admits a subquadratic reduction to Pareto Sum Verification. A positive answer would establish Pareto Sum Verification as complete for the *entire* class $\mathsf{FOP}_{\mathbb{Z}}$. We elaborate on this in Section 8.

[11] We remark that our problem definition only checks a single of the three given conditions, specifically, condition (2). However, in Section 7, we will establish that the verifying *all three* conditions reduces to verifying this single condition. More specifically, for sets A, B, C of size at most n, we obtain that if we can solve Pareto Sum Verification in time $T(n)$, then we can check whether C is the Pareto sum of A, B in time $O(T(n))$.

[12] The first three statements follow from $\mathsf{FOP}_{\mathbb{Z}}$ generalizing the class *PTO* studied in [7], see Section 1.3. The remaining statements rely on the additive structure of $\mathsf{FOP}_{\mathbb{Z}}$.

1.2.4 3-SUM is complete for $\mathsf{FOP}_{\mathbb{Z}}$ formulas of low inequality dimension

Returning to our motivating question, we ask: Since it appears unlikely to prove completeness of 3-SUM for all $\mathsf{FOP}_{\mathbb{Z}}$ formulas (as this requires a tight 3-uniform hyperclique lower bound for 3-SUM), can we at least identify a large fragment of $\mathsf{FOP}_{\mathbb{Z}}$ for which 3-SUM is complete? In particular, can we extend our first result of Theorem 1 from existentially quantified formulas to substantially different problems in $\mathsf{FOP}_{\mathbb{Z}}$, displaying other quantifier structures?

Surprisingly, we are able to show that 3-SUM is complete for *low-dimensional* $\mathsf{FOP}_{\mathbb{Z}}$ formulas, *independent of their quantifier structure*. To formalize this, we introduce the *inequality dimension* of a $\mathsf{FOP}_{\mathbb{Z}}$ formula as the smallest number of linear inequalities required to model it. More formally, consider a $\mathsf{FOP}_{\mathbb{Z}}$ formula $\phi = Q_1 x_1 \in A_1, \ldots, Q_k x_k \in A_k : \psi$ with $A_i \subseteq \mathbb{Z}^{d_i}$. The *inequality dimension* of ϕ is the smallest number s such that there exists a Boolean function $\psi' : \{0,1\}^s \to \{0,1\}$ and (strict or non-strict) linear inequalities $L_1, \ldots, L_s$ in the variables $\{x_i[j] : i \in \{1,\ldots,k\}, j \in \{1,\ldots,d_i\}\}$ and the free variables such that $\psi(x_1,\ldots,x_k)$ is equivalent to $\psi'(L_1,\ldots,L_s)$. As an example, the 3-SUM formula $\exists a \in A \exists b \in B \exists c \in C : a + b = c$ has inequality dimension 2, as $a + b = c$ can be modelled as conjunction of the two linear inequalities $a + b \leq c$ and $a + b \geq c$, whereas no single linear inequality can model $a + b = c$.

We show that 3-SUM is fine-grained complete for model-checking $\mathsf{FOP}^3_{\mathbb{Z}}$ formulas with inequality dimension at most 3. This result is our perhaps most interesting technical contribution and intuitively combines our result that 3-SUM is hard for counting $\mathsf{FOP}_{\mathbb{Z}}$ witnesses (Corollary 3) with a geometric argument, specifically, that the union of n unit cubes in $\mathbb{R}^3$ can be decomposed into the union of $O(n)$ pairwise interior- and exterior-disjoint axis-parallel boxes. To this end, we extend a result from [23], which constructs pairwise interior-disjoint axis-parallel boxes, to also achieve exterior-disjointness. For more details, see the Technical Overview below and Section 6.

▶ **Theorem 5.** *There is an algorithm deciding* 3*-SUM in randomized time* $O(n^{2-\epsilon})$ *for an* $\epsilon > 0$*, if and only if for each problem* P *in* $\mathsf{FOP}^k_{\mathbb{Z}}$ *with* $k \geq 3$ *and inequality dimension at most* 3*, there exists some* $\epsilon > 0$ *such that we can solve* P *in randomized time* $O(n^{k-1-\epsilon})$*.*

Note that this fragment of $\mathsf{FOP}_{\mathbb{Z}}$ contains a variety of interesting problems. A general example is given by comparisons of sets defined using the sumset arithmetic[13], which correspond to formulas of inequality dimension at most 2: E.g., checking, given sets $A, B, C \subseteq \mathbb{Z}$ and $t \in \mathbb{Z}$, whether C is an additive t-approximation of the sumset $A + B$ is equivalent to verifying the conjunction of the $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$ problem[14] $A + B \subseteq C + \{0,\ldots,t\}$ and (2) the $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists)$ problem[15] $C \subseteq A + B$. Likewise, this extends to λ-multiplicative approximations of sumsets. Furthermore, the problems corresponding to general sumset comparisons like $\alpha_1 A_1 + \cdots + \alpha_i A_i \subseteq \alpha_{i+1} A_{i+1} + \cdots + \alpha_k A_k + \{-\ell,\ldots,u\}$ have inequality dimension at most 2 as well.

Our results of Theorems 4 and 5 suggests to view Pareto Sum Verification as a geometric, high-dimensional generalization of 3-SUM. Furthermore, it remains an interesting problem to establish the highest d such that 3-SUM is complete for $\mathsf{FOP}_{\mathbb{Z}}$ formulas of inequality dimension at most d; for a discussion see Section 8.

---

[13] The sumset arithmetic uses the sumset operator $X + Y$ to denote the sumset $\{x + y \mid x \in X, y \in Y\}$ and λX to denote $\{\lambda x \mid x \in X\}$.

[14] Note that the corresponding formula is $\forall a \in A \forall b \in B \exists c \in C : (c \leq a + b) \wedge (a + b \leq c + t)$, which clearly has inequality dimension at most 2.

[15] Note that the corresponding formula is $\forall c \in C \exists a \in A \exists b \in B : a + b = c$, which clearly has inequality dimension at most 2.

Further Applications

As an immediate application of our first completeness theorem, we obtain a simple proof of a $n^{4/3-o(1)}$ lower bound for the 4-SUM problem based on the the 3-uniform hyperclique hypothesis; see the full version of the paper for details. Specifically, by Theorem 1, it suffices to model the 3-uniform 4-hyperclique problem as a problem in $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists\exists)$. The resulting conditional lower bound is implicitly known in the literature, as it can alternatively be obtained by combining a 3-uniform hyperclique lower bound for 4-cycle given in [43] with a folklore reduction from 4-cycle to 4-SUM (see [39] for a deterministic reduction from 3-cycle to 3-SUM).

▶ **Theorem 6.** *If there is some $\epsilon > 0$ such that 4-SUM can be solved in time $O(n^{\frac{4}{3}-\epsilon})$, then the 3-uniform hyperclique hypothesis fails.*

Similarly, we can also give a simple proof for a known lower bound for 3-SUM.

Another application of our results is to establish class-based conditional bounds. As a case in point, consider the problem of computing the Pareto sum of $A, B \subseteq \mathbb{Z}^d$: Clearly, this problem can be solved in time $\tilde{O}(n^2)$ by explicitly computing the sumset $A + B$ and computing the Pareto front using any algorithm running in near-linear time in its input, e.g. [34]. We prove the following conditional optimality results already in the case when the desired output (the Pareto sum of A, B) has size $\Theta(n)$.

▶ **Theorem 7** (Pareto Sum Computation Lower Bound)**.** *The following conditional lower bounds hold for output-sensitive Pareto sum computation:*

1. *If there is $\epsilon > 0$ such that we can compute the Pareto sum C of $A, B \subseteq \mathbb{Z}^2$, whenever C is of size $\Theta(n)$, in time $O(n^{2-\epsilon})$, then the 3-SUM hypothesis fails (thus, for any $\mathsf{FOP}^k_{\mathbb{Z}}$ formula ϕ of inequality dimension at most 3, there is $\epsilon' > 0$ such that ϕ can be decided in time $O(n^{k-1-\epsilon'})$).*
2. *If for all $d \geq 2$, there is $\epsilon > 0$ such that we can compute the Pareto sum C of $A, B \subseteq \mathbb{Z}^d$, whenever C is of size $\Theta(n)$, in time $O(n^{2-\epsilon})$, then there is some $\epsilon' > 0$ such that we can decide all $\mathsf{FOP}_{\mathbb{Z}}$ formulas with k quantifiers not ending in $\exists\forall\exists$ or $\forall\exists\forall$ in time $O(n^{k-1-\epsilon'})$.*

Our lower bound for 2D strengthens a quadratic-time lower bound found by Funke et al. [33] based on the $(\min, +)$-convolution hypothesis to hold already under the weaker (i.e., more believable) 3-SUM hypothesis. For higher dimensions, we furthermore strengthen the conditional lower bound via its connection to $\mathsf{FOP}_{\mathbb{Z}}$.

We conclude with remaining open questions in Section 8.

1.3 Further Related Work

To our knowledge, the first investigation of the connection between classes of model-checking problems and central problems in fine-grained complexity was given by Williams [49], who shows that the k-clique problem is complete for the class of existentially-quantified first order graph properties, among other results. As important follow-up work, Gao et al. [36] establish OV as complete problem for model-checking any first-order property.

Subsequent results include classification results for $\exists^k\forall$-quantified first-order graph properties [14], fine-grained upper and lower bounds for counting witnesses of first-order properties [28], completeness theorems for multidimensional ordering properties [7] (discussed below), completeness and classification results for optimization classes [12, 13] as well as an investigation of sparsity for monochromatic graph properties [32].

We remark that An et al. [7] study completeness results for a strict subset of $\mathsf{FOP}_{\mathbb{Z}}$ formulas: Specifically, they introduce a class $\mathsf{PTO}_{k,d}$ of k-quantifier first-order sentences over inputs $\mathbb{N}^d$ (or, without loss of generality $\{1,\dots,n\}^d$) that may only use *comparisons* of coordinates (and constants). Note that such sentences lack additive structure, and indeed the fine-grained complexity differs decisively from $\mathsf{FOP}_{\mathbb{Z}}$: E.g., for $\mathsf{PTO}(\exists\exists\exists)$ formulas, they establish the sparse triangle detection problem as complete, establishing a conditionally tight running time of $m^{2\omega/(\omega+1)\pm o(1)}$. This is in stark contrast to $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$ formulas, for which we establish 3-SUM as complete problem, yielding a conditionally optimal running time of $n^{2\pm o(1)}$. In particular, for each 3-quantifier structure $Q_1Q_2Q_3$, a $O(n^{2-\epsilon})$-time algorithm for all $\mathsf{FOP}_{\mathbb{Z}}(Q_1Q_2Q_3)$ problems would break a corresponding hardness barrier[16].

Since any $\mathsf{PTO}_{k,d}$ formula is also a $\mathsf{FOP}_{\mathbb{Z}}$ formula with the same quantifier structure, any hardness result in [7] for $\mathsf{PTO}(Q_1,\dots,Q_k)$ carries over to $\mathsf{FOP}_{\mathbb{Z}}(Q_1,\dots,Q_k)$. On the other hand, any of our algorithmic results for $\mathsf{FOP}_{\mathbb{Z}}(Q_1,\dots,Q_k)$ transfers to its subclass $\mathsf{PTO}(Q_1,\dots,Q_k)$.

2 Technical Overview

In this section, we sketch the main ideas behind our proofs.

Completeness of k-SUM for $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$

With the right ingredients, proving that k-SUM is complete for $\mathsf{FOP}_{\mathbb{Z}}$ formulas with k existential quantifiers (Theorem 1) is possible via a simple approach: We observe that any $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$ formula ϕ can be rewritten such that we may assume that ϕ is a conjunction of m inequalities. We then use a slight generalization of a bit-level trick of [52] to reduce each inequality to an equality, incurring only $O(\log n)$ overhead per inequality (intuitively, we need to guess the most significant bit position at which the left-hand side and the right-hand side differ). Thus, we obtain $O(\log^m n)$ conjunctions of m equalities; each such conjunction can be regarded as an instance of Vector k-SUM. Using a straightforward approach for reducing Vector k-SUM to k-SUM given in [5], the reduction to k-SUM follows. We give all details in Section 3 and the full version of the paper.

Counting witnesses and handling multisets

While the reduction underlying Theorem 1 preserves the existence of solutions, it fails to preserve the number of solutions. The challenge is that when applying the bit-level trick to reduce inequalities to equalities, we need to make sure that for each witness of a $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$ formula ϕ, there is a unique witness in the k-SUM instances produced by the reduction. While it is straightforward to ensure that we do not produce multiple witnesses, the subtle issue arises that distinct witnesses for ϕ may be mapped to the same witness in the k-SUM instances. It turns out that it suffices to solve a *multiset* version of #k-SUM, i.e., to count all witnesses in a k-SUM instance in which each input number may occur multiple times.

[16] Specifically, an $O(n^{2-\epsilon})$ time algorithm for problems in $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists), \mathsf{FOP}_{\mathbb{Z}}(\forall\forall\forall), \mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$, or $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\forall)$ with $\epsilon > 0$ would refute the 3-SUM hypothesis. Furthermore, an $O(n^{2-\epsilon})$ time algorithm for problems in $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists)$, $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\forall)$, $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\exists)$, or $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\forall)$ with $\epsilon > 0$ would immediately yield an improvement for the MaxConv lower bound problem [27]; for details see the full version of the paper.

Thus, to obtain Theorem 2, we show a fine-grained equivalence of Multiset $\#k$-SUM and $\#k$-SUM, for all odd $k \geq 3$. This fine-grained equivalence, which we prove via a heavy-light approach, might be of independent interest.[17] Combining this equivalence with an inclusion-exclusion argument, we may thus lift Theorem 1 to a counting version for all odd $k \geq 3$.

In the reductions below, we will make crucial use of the immediate corollary of Theorem 2 and [22] that for each $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$ formula ϕ, there exists a subquadratic reduction from counting witnesses for ϕ to 3-SUM (Corollary 3).

On general quantifier structures

We perform a systematic study on the different quantifier structures for $k = 3$. Due to simple negation arguments, we only have to perform a systematic study on the classes of problems $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$, $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists)$, $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$, $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\exists)$.

First, we state a simple lemma establishing syntactic complete problems for the classes above.

▶ **Lemma 8** (Syntactic Complete problems (Informal Version)). *Let $Q_1, Q_2 \in \{\exists, \forall\}$. We can reduce every formula of the class $\mathsf{FOP}_{\mathbb{Z}}(Q_1Q_2\exists)$ to the formula*

$$Q_1\tilde{a_1} \in \tilde{A_1}Q_2\tilde{a_2} \in \tilde{A_2}\exists\tilde{a_3} \in \tilde{A_3} : \tilde{a_1} + \tilde{a_2} \leq \tilde{a_3}.$$

On the quantifier change $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists) \to \mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$

We rely on the subquadratic equivalence between 3-SUM and a functional version of 3-SUM called All-ints 3-SUM, which asks to determine for every $a \in A$ whether there is a solution involving a. A randomized subquadratic equivalence was given in [51], which can be turned deterministic [42].

This equivalence allows us to use the bit-level trick to turn inequalities to equalities, despite it seemingly not interacting well with the quantifier structure $\forall\exists\exists$ at first sight. This results in a proof of the following hardness result.

▶ **Lemma 9.** *If 3-SUM can be solved in time $O(n^{2-\epsilon})$ for an $\epsilon > 0$, then all problems P of $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists)$ can be solved in time $O(n^{2-\epsilon_P})$ for an $\epsilon_P > 0$.*

On the quantifier change $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists) \to \mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$

As a first result for the class $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$, we are able to show equivalence to 3-SUM for a specific problem in this class, thus introducing a 3-SUM equivalent problem with a different quantifier structure in comparison to 3-SUM. Specifically, we consider the problem of verifying additive t-approximation of sumsets. We are able to precisely characterize the fine-grained complexity depending on t.

Formally, we show the following theorem.

▶ **Theorem 10.** *Consider the Additive Sumset Approximation problem of deciding, given $A, B, C \subseteq \mathbb{Z}, t \in \mathbb{Z}$, whether*

$$A + B \subseteq C + \{0, \ldots, t\}.$$

[17] We remark that it is plausible that the proof of the subquadratic equivalence of 3-SUM and #3-SUM due to Chan et al. [22] could be extended to establish subquadratic equivalence with Multiset #3-SUM as well. Note, however, that a fine-grained equivalence of $\#k$-SUM and k-SUM is not known for any $k \geq 4$.

This problem is

- *solvable in time $O(n^{2-\delta})$ with $\delta > 0$, whenever $t = O(n^{1-\epsilon})$ for any $\epsilon > 0$,*
- *not solvable in time $O(n^{2-\epsilon})$, whenever $t = \Omega(n)$ assuming the Strong 3-SUM hypothesis.*

Furthermore, subquadratic hardness holds under the standard 3-SUM Hypothesis if no restriction on t is made.

The above theorem is essentially enabling a quantifier change transforming the $\exists\exists\exists$ quantifier structure for which 3-SUM is complete into a subquadratic equivalent problem with a quantifier structure $\forall\forall\exists$. Moreover, the 3-SUM hardness is a witness to the hardness of the class $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$.

Let us remark a few interesting aspects: The algorithmic part follows from sparse convolution techniques going back to Cole and Hariharan [26], see [16] for a recent account and also [20, 17, 15]. Specifically, whenever $t = O(n^{1-\epsilon})$, it holds that $|C + \{0, \dots, t\}| = O(n^{2-\epsilon})$ and intuitively, we can use an output-sensitive convolution algorithm to compute $A + B$ and compare it to $C + \{0, \dots, t\}$.[18] Our result indicates that an explicit construction of $C + \{0, \dots, t\}$ is required, since once it may get as large as $\Omega(n^2)$, we obtain a $n^{2-o(1)}$-time lower bound assuming the Strong 3-SUM Hypothesis.

The lower bound follows from describing the 3-SUM problem alternatively as $(A+B)\cap C \neq \emptyset$, which is equivalent to the negation of $(A + B) \subseteq \bar{C}$, where $\bar{C}$ denotes the complement of C. Thus, we aim to cover the complement of C by intervals of length t. While this appears impossible for 3-SUM, we employ the subquadratic equivalence of 3-SUM and its convolutional version due to Patrascu [46]. This problem will deliver us the necessary structure to represent this complement with the addition of few auxilliary points.

The reverse reduction from Additive Sumset Approximation to 3-SUM follows from Theorem 5 (as Additive Sumset Approximation has inequality dimension 2).

On completeness results for $\mathsf{FOP}^k_{\mathbb{Z}}$

The above ingredients establish our completeness theorems by exhaustive search over remaining quantifiers. Specifically, by a combination of Theorem 10, which shows that Additive Sumset Approximation is 3-SUM hard, and a combination of Lemma 9 and Theorem 1, we get:

▶ **Lemma 11.** *There is a function $\epsilon(d) > 0$ such that the Verification of Pareto Sum problem can be solved in time $O(n^{2-\epsilon(d)})$ if and only if all problems P in the classes*

- $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\exists\exists\exists)$,$\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\forall\forall\forall)$,
- $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\forall\exists\exists)$,$\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\exists\forall\forall)$,
- $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\forall\forall\exists)$,$\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\exists\exists\forall)$,

where $Q_1, \dots Q_{k-3} \in \{\exists, \forall\}$ and $k \geq 3$, can be solved in time $O(n^{k-1-\epsilon_P})$ for an $\epsilon_P > 0$.

Similarly, for quantifier structures ending in $\exists\forall\exists$ and $\forall\exists\forall$, we obtain the following completeness result.

▶ **Lemma 12.** *There is a function $\epsilon(d) > 0$ such that the Hausdorff Distance under n Translations problem can be solved in time $O(n^{2-\epsilon(d)})$ if and only if all problems P in the classes*

- $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\exists\forall\exists)$, $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\forall\exists\forall)$,

where $Q_1, \dots Q_{k-3} \in \{\exists, \forall\}$ and $k \geq 3$, can be solved in time $O(n^{k-1-\epsilon_P})$ for an $\epsilon_P > 0$.

The combination of Lemma 11 and Lemma 12, thus suffice to prove Theorem 4.

[18] The argument is slightly more subtle, since we need to avoid computing $A + B$ if its size exceeds $O(n^{2-\epsilon})$.

The 3-SUM completeness of formulas with inequality dimension at most 3

As a first idea, one could try to solve problems of different quantifier structures by just counting witnesses. Consider in the following the example $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$.

Assume we are promised that the formula $\forall a \in A \forall b \in B \exists c \in C \psi(a,b,c)$ satisfies a kind of *disjointness* property, specifically that for every $(a,b) \in A \times B$ there exists at most one $c \in C$ such that $\psi(a,b,c)$. Then satisfying the formula boils down to checking whether the number of witnesses (a,b,c) satisfiying $\psi(a,b,c)$ equals to $|A| \cdot |B|$.

To create this *disjointness* effect, we use the following geometric approach: We show that one can re-interpret the formula as $\forall a \in A \forall b \in B : a+b \in \bigcup_{c' \in C'} V(c')$, where $A, B, C' \subseteq \mathbb{Z}^3$, C' is a set of size $O(n)$ and $V(c')$ is an orthant associated to c'. Using an adapted variant of [23], we decompose this union of orthants in $\mathbb{R}^3$ (which we may equivalently view as sufficiently large congruent cubes) into a set $\mathcal{R}$ of $O(n)$ *disjoint* boxes. Thus, it remains to notice that the resulting problem – i.e., for all $a \in A, b \in B$ is there a box $R \in \mathcal{R}$ such that $a+b$ is contained in R – is a $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$ formula with the desired disjointness property, which can be handled as argued above.

For the class $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\exists)$, we perform a slightly more involved argument. The classes $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$ and $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists)$ reduce to 3-SUM regardless of the inequality dimension due to Theorem 1 and Lemma 9.

3 k-SUM is complete for existential $\mathsf{FOP}_{\mathbb{Z}}$ formulas

We begin with a simple completeness theorem that k-SUM is complete for the class of problems $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$. Since k-SUM is indeed a $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$-formula, it remains to show a fine-grained reduction from any $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$ formula to k-SUM. The proofs in this section are deferred to the full version. As a first step towards this Theorem, we consider how to reduce a conjunction of m linear inequalities to a vector k-SUM instance.

▶ **Lemma 13.** *Consider vectors $a_1 \in \{-U,\dots,U\}^{d_1}, \dots, a_k \in \{-U,\dots,U\}^{d_k}$, integers $S_1,\dots,S_m \in \{-U,\dots,U\}$, for each $i \in \{1,\dots,m\}, j \in \{1,\dots,k\}$, vectors $c_{i,j} \in \mathbb{Z}^{d_j}$, and a formula*

$$\psi := \bigwedge_{i=1}^{m} \left(\sum_{j=1}^{k} c_{i,j}^T a_j \geq S_i \right).$$

There exist $O(1)$ time computable functions $f_1^{\ell,\psi}, \dots, f_k^{\ell,\psi}, g^{\ell,\psi,W}$ such that the following statements are equivalent

1. *The formula $\bigwedge_{i=1}^{m} \left(\sum_{j=1}^{k} c_{i,j}^T a_j \geq S_i \right)$ holds.*
2. *There are $\ell \in \{1,\dots,\lceil \log_2(M) \rceil\}^m, W \in \{1,\dots,k\}^m$ such that $f_1^{\ell,\psi}(a_1) + \cdots + f_k^{\ell,\psi}(a_k) = g^{\ell,\psi,W}(S_1,\dots,S_m)$.*

Moreover, if the second item holds, there is a unique choice of such ℓ and W.

Essentially the above lemma enables a reduction from a conjunction of inequality checks to a conjunction of equality checks. We can now continue with our completeness theorem.

▶ **Theorem 1** (k-SUM is $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$-complete)**.** *Let $k \geq 3$ and assume that k-SUM can be solved in time $T_{k\text{SUM}}(n)$. For any problem P in $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$, there exists some c such that P can be solved in time $O(T_{k\text{SUM}}(n) \log^c n)$.*

Ater applying Lemma 13, it remains to reduce a conjunction of equality checks to k-SUM. To do so, we interpret the conjunction of equalities as a Vector k-SUM problem, which can be reduced to k-SUM in a straightforward way [5].

4 On counting witnesses in $\mathsf{FOP}_{\mathbb{Z}}$

In this section, we show reductions from counting witnesses of $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$ formulas to $\#k$-SUM, specifically, we prove Theorem 2. To do so, we adapt the proof of Theorem 1 given in Section 3 to a counting version. As discussed in Section 2, this requires us to work with a multiset version of $\#k$-SUM. Handling multisets is thus the main challenge addressed in this section. Formally, we say that a multiset is a set A together with a function $f : A \to \mathbb{N}$. For $a \in A$, we abbreviate $n_a := f(a)$ as the multiplicity of a. To measure multiset sizes, we still think of each a to have n_a copies in the input, i.e. the size of A is $\sum_{a \in A} n_a$. Almost all proofs in this section are deferred to the full version of the paper.

▶ **Definition 14** ((U,d)-vector Multiset $\#k$-SUM). *Let $X := \{-U, \dots, U\}^d$. Given k multisets $A_1, \dots, A_k \subseteq X$ and $t \in X$, we ask for the total number of k-SUM witnesses, that is*

$$\sum_{\substack{a_1+\dots+a_k=t,\\ a_1 \in A_1, \dots, a_k \in A_k}} \prod_{i=1}^{k} n_{a_i}.$$

Furthermore, define Multiset $\#k$-SUM as $(U,1)$-vector Multiset $\#k$-SUM and M-multiplicity $\#k$-SUM as Multiset $\#k$-SUM with the additional restriction that the multiplicity of each element is limited, that is for all $a \in A_1 \cup \dots \cup A_k : n_a \leq M$ holds. Lastly, $\#k$-SUM is defined as 1-Multiplicity $\#k$-SUM and (U,d)-vector $\#k$-SUM is (U,d)-vector Multiset $\#k$-SUM where for all $a \in A_1 \cup \dots \cup A_k : n_a = 1$ holds.

For the case of $\mathsf{FOP}^3_{\mathbb{Z}}$ we will also introduce the #All-ints version of the above problems, which asks to determine, for each $a_1 \in A_1$, the number of witnesses involving a_1.

The (deferred) proof of the following lemma is analogous to the proof of Abboud et al. [5] to reduce Vector k-SUM to k-SUM.

▶ **Lemma 15** ((U,d)-vector Multiset $\#k$-SUM $\leq_{\lceil k/2 \rceil}$ Multiset $\#k$-SUM). *If Multiset $\#k$-SUM can be solved in time $T(n)$ then (U,d)-vector Multiset $\#k$-SUM can be solved in time $O(nd \log(U) + T(n))$.*

Next, we give a simple approach to solve Multiset $\#k$-SUM when all multiplicities are comparably small.

▶ **Lemma 16** (M-multiplicity $\#k$-SUM$\leq_{\lceil k/2 \rceil}$ $\#k$-SUM). *If $\#k$-SUM can be solved in time $T(n)$, then M-multiplicity $\#k$-SUM can be solved in time $\tilde{O}(T(nM^{k-1}))$.*

For later purposes, we will need the following version of the above lemma.

▶ **Observation 17.** *If #All-ints 3-SUM can be solved in time $T(n)$, then we can solve #All-ints M-multiplicity 3-SUM in time $\tilde{O}(T(nM^2))$.*

We can finally prove the main result of this section.

▶ **Lemma 18.** *For odd $k \geq 3$, if there exists an algorithm for the $\#k$-SUM problem running in time $O(n^{\lceil k/2 \rceil - \epsilon})$ for an $\epsilon > 0$, then there exists an algorithm for the Multiset $\#k$-SUM problem running in time $O(n^{\lceil k/2 \rceil - \epsilon'})$ for an $\epsilon' > 0$.*

Proof. We proceed with a heavy-light approach. Assume there exists an $O(n^{\lceil k/2 \rceil - \epsilon})$ algorithm for the $\#k$-SUM problem. Set $c := (k-1)(\lceil k/2 \rceil)$. Firstly, we count the number of solutions $(a_1, \dots, a_k) \in A_1 \times \dots \times A_k$, where $n_{a_1}, \dots, n_{a_k} \leq n^{\epsilon/c}$ using Lemma 16. This takes time

$$\begin{aligned}\tilde{O}\left((n\cdot(n^{\epsilon/c})^{k-1})^{\lceil k/2\rceil-\epsilon}\right) &= \tilde{O}\left(\left(n^{1+\frac{\epsilon}{\lceil k/2\rceil}}\right)^{\lceil k/2\rceil-\epsilon}\right)\\ &= \tilde{O}\left(n^{\lceil k/2\rceil-\epsilon+\epsilon-\frac{\epsilon^2}{\lceil k/2\rceil}}\right)\\ &= O\left(n^{\lceil k/2\rceil-\epsilon'}\right),\end{aligned}$$

where $\epsilon' > 0$. It remains to calculate the number of witnesses $(a_1, \ldots, a_k)$, where for at least one $i \in \{1, \ldots, k\}$, we have high multiplicity, meaning $n_{a_i} > n^{\epsilon/c}$ holds. Consider the case that $a_1 \in A_1$ is a high-multiplicity number (the case where $a_i \in A_i$ with $i \neq 1$ is a high-multiplicity number is analogous). For each high-multiplicity number a_1 in A_1 we do the following. Solve the $(k-1)$-SUM instance with sets $A_2, \ldots, A_k$ and target $t - a_1$. There are at most $n^{1-(\epsilon/c)}$ many high-multiplicity numbers in A_1, and solving the $(k-1)$-SUM instance takes time $O(n^{(k-1)/2})$, since k is odd. We get a total runtime of

$$\begin{aligned}n^{1-\frac{\epsilon}{c}}\cdot\tilde{O}(n^{(k-1)/2}) &= \tilde{O}(n^{1-(\epsilon/c)+(k-1)/2})\\ &= \tilde{O}(n^{(k+1)/2-(\epsilon/c)})\\ &= O(n^{\lceil k/2\rceil-\epsilon''}),\end{aligned}$$

where $\epsilon'' > 0$, which concludes the proof. ◀

▶ **Theorem 2.** *Let $k \geq 3$ be odd. If there is $\epsilon > 0$ such that we can count the number of witnesses for k-SUM in time $O(n^{\lceil k/2\rceil-\epsilon})$, then for all problem P in $\mathsf{FOP}_{\mathbb{Z}}(\exists^k)$, there is some $\epsilon' > 0$ such that we can count the number of witnesses for P in time $O(n^{\lceil k/2\rceil-\epsilon'})$.*

By combining the subquadratic equivalence between 3-SUM and #3-SUM due to Chan et al. [22] and the above theorem, we obtain the following corollary.

▶ **Corollary 3.** *For all problems P in $\mathsf{FOP}_{\mathbb{Z}}(\exists^3)$, there is some $\epsilon_P > 0$ such that we can count the number of witnesses for P in randomized time $O(n^{2-\epsilon_P})$ if and only if there is some $\epsilon' > 0$ such that 3-SUM can be solved in randomized time $O(n^{2-\epsilon'})$.*

The above proof can also be adapted for the special case $k = 3$ to count for each $a_1 \in A_1$ the number of witnesses involving a_1, by plugging in the appropriate All-ints versions; see the full version of the paper for details. Together with the equivalence between #All-ints 3-SUM and 3-SUM of Chan et al. [22], we get

▶ **Corollary 19.** *For all problems P in $\mathsf{FOP}_{\mathbb{Z}}(\exists^3)$, we are able to count for each $a_1 \in A_1$ the number of witnesses involving a_1 in randomized time $O(n^{2-\epsilon})$ for an $\epsilon > 0$, if 3-SUM can be solved in randomized time $O(n^{2-\epsilon'})$ for an $\epsilon' > 0$.*

5 Completeness Theorems for General Quantifier Structures

As Theorem 1 establishes 3-SUM as the complete problem for the class $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$, we would like to similarly explore complete problems for other quantifier structures. All proofs in this section are deferred to the full version. Let us recall our main geometric problems.

▶ **Definition 20** (Verification of d-dimensional Pareto Sum)**.** *Given sets $A, B, C \subseteq \mathbb{Z}^d$. Does the set C dominate $A + B$, that is does for all $a \in A, b \in B$ exist a $c \in C$, with $c \geq a + b$?*

It is easy to see that Verification of d-dimensional Pareto Sum is in $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$.

▶ **Definition 21** (Hausdorff Distance under n Translations). *Given sets $A, B, C \subseteq \mathbb{Z}^d$ with at most n elements and a $\gamma \in \mathbb{N}$, the Hausdorff distance under n Translations problem asks whether the following holds:*

$$\delta_{\overrightarrow{H}}^{T(A)}(B, C) \coloneqq \min_{\tau \in A} \delta_{\overrightarrow{H}}(B, C + \{\tau\}) = \min_{\tau \in A} \max_{b \in B} \min_{c \in C} \|b - (c + \tau)\|_\infty \leq \gamma.$$

We show the following result firstly, which allows us to assume without loss of generality a certain normal form.

▶ **Lemma 22.** *A general $\mathsf{FOP}_{\mathbb{Z}}(Q_1Q_2\exists)$ formula, with input set $A_1 \subseteq \mathbb{Z}^{d_1}, A_2 \subseteq \mathbb{Z}^{d_2}, A_3 \subseteq \mathbb{Z}^{d_3}$, where $|A_1| = |A_2| = |A_3| = n$, can be reduced to the $\mathsf{FOP}_{\mathbb{Z}}(Q_1Q_2\exists)$ formula*

$$Q_1 a_1' \in A_1' Q_2 a_2' \in A_2' \exists a_3' \in A_3' : a_1' + a_2' \leq a_3'$$

in time $O(n)$, where $|A_1'| = |A_2'| = n$ and $|A_3'| = O(n)$.

The above lemma immediately gives us complete syntactic problems for our classes. It remains to establish connections between the different quantifier structure classes, and explore natural variants of the syntactic problems.

The syntactic complete problem for the class $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\exists)$ turns out to be equivalent to Hausdorff Distance under n Translations. We obtain:

▶ **Lemma 23** (Hausdorff Distance under n Translations is complete for $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\exists)$). *There is a function $\epsilon(d) > 0$ such that Hausdorff Distance under n Translations can be solved in time $O(n^{2-\epsilon(d)})$ if and only if all problems P in $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\exists)$ can be solved in time $O(n^{2-\epsilon_P})$ for an $\epsilon_P > 0$.*

Similarly, the Verification of Pareto Sum problem is complete for the class $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$.

▶ **Lemma 24** (Verification of Pareto Sum is complete for $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$). *There is a function $\epsilon(d) > 0$ such that Verification of Pareto Sum can be solved in time $O(n^{2-\epsilon(d)})$ if and only if all problems P in $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$ can be solved in time $O(n^{2-\epsilon_P})$ for an $\epsilon_P > 0$.*

5.1 $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists) \to \mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$

We continue with handling the class $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists)$. By simply making use of Corollary 19, one can easily prove that 3-SUM is hard for the class $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists)$. We can also show a deterministic proof, as Corollary 19 makes use of the subquadratic equivalence between 3-SUM and #All-ints 3-SUM, which relies on randomization techniques.

▶ **Lemma 9.** *If 3-SUM can be solved in time $O(n^{2-\epsilon})$ for an $\epsilon > 0$, then all problems P of $\mathsf{FOP}_{\mathbb{Z}}(\forall\exists\exists)$ can be solved in time $O(n^{2-\epsilon_P})$ for an $\epsilon_P > 0$.*

5.2 $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists) \to \mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$

We explore the connection between the problem Additive Sumset Approximation, which is a member of the class $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$, and the 3-SUM problem. The following theorem will play a key role to enable the discovery of the relationship between 3-SUM and other quantifier structures.

▶ **Theorem 10.** *Consider the Additive Sumset Approximation problem of deciding, given* $A, B, C \subseteq \mathbb{Z}, t \in \mathbb{Z}$*, whether*

$$A + B \subseteq C + \{0, \dots, t\}.$$

This problem is

- *solvable in time* $O(n^{2-\delta})$ *with* $\delta > 0$*, whenever* $t = O(n^{1-\epsilon})$ *for any* $\epsilon > 0$*,*
- *not solvable in time* $O(n^{2-\epsilon})$*, whenever* $t = \Omega(n)$ *assuming the Strong 3-SUM hypothesis.*

Furthermore, subquadratic hardness holds under the standard 3-SUM Hypothesis if no restriction on t *is made.*

The proof is deferred to the full version of the paper.

5.3 Completeness results for the class $\mathsf{FOP}^k_{\mathbb{Z}}$

We turn to combining the above insights to establish (a pair of) complete problems for the class $\mathsf{FOP}_{\mathbb{Z}}$. The proofs in this section are deferred to the full version of the paper.

▶ **Lemma 11.** *There is a function* $\epsilon(d) > 0$ *such that the Verification of Pareto Sum problem can be solved in time* $O(n^{2-\epsilon(d)})$ *if and only if all problems* P *in the classes*

- $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\exists\exists\exists)$,$\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\forall\forall\forall)$,
- $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\forall\exists\exists)$,$\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\exists\forall\forall)$,
- $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\forall\forall\exists)$,$\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\exists\exists\forall)$,

where $Q_1, \dots Q_{k-3} \in \{\exists, \forall\}$ *and* $k \geq 3$*, can be solved in time* $O(n^{k-1-\epsilon_P})$ *for an* $\epsilon_P > 0$*.*

▶ **Lemma 12.** *There is a function* $\epsilon(d) > 0$ *such that the Hausdorff Distance under* n *Translations problem can be solved in time* $O(n^{2-\epsilon(d)})$ *if and only if all problems* P *in the classes*

- $\mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\exists\forall\exists), \mathsf{FOP}_{\mathbb{Z}}(Q_1 \dots Q_{k-3}\forall\exists\forall)$,

where $Q_1, \dots Q_{k-3} \in \{\exists, \forall\}$ *and* $k \geq 3$*, can be solved in time* $O(n^{k-1-\epsilon_P})$ *for an* $\epsilon_P > 0$*.*

We finally obtain our completeness theorem for the whole class $\mathsf{FOP}^k_{\mathbb{Z}}$.

▶ **Theorem 4.** *There is a function* $\epsilon(d) > 0$ *such that both of the following problems can be solved in time* $O(n^{2-\epsilon(d)})$

- *Pareto Sum Verification,*
- *Hausdorff distance under* n *Translations,*

if and only if for each problem P *in* $\mathsf{FOP}^k_{\mathbb{Z}}$ *with* $k \geq 3$ *there exists an* $\epsilon_P > 0$ *such that* P *can be solved in time* $O(n^{k-1-\epsilon_P})$*.*

Essentially, these two problems capture the complexity of the class $\mathsf{FOP}^3_{\mathbb{Z}}$ and can be seen as the most important problems in $\mathsf{FOP}^k_{\mathbb{Z}}$.

6 The 3-SUM problem is complete for $\mathsf{FOP}_{\mathbb{Z}}$ formulas with Inequality Dimension at most 3

In this section, we show that 3-SUM problem captures an interesting subclass of $\mathsf{FOP}_{\mathbb{Z}}$ formulas with arbitrary quantifier structure, namely the formulas of sufficiently small *inequality dimension*. Let us recall the notion of inequality dimension.

▶ **Definition 25** (Inequality Dimension of a Formula). *Let $\phi = Q_1 x_1 \in A_1, \ldots, Q_k x_k \in A_k : \psi$ be a $\mathsf{FOP}_{\mathbb{Z}}$ formula with $A_i \subseteq \mathbb{Z}^{d_i}$.*

The inequality dimension *of ϕ is the smallest number s such that there exists a Boolean function $\psi' : \{0,1\}^s \to \{0,1\}$ and (strict or non-strict) linear inequalities $L_1, \ldots, L_s$ in the variables $\{x_i[j] : i \in \{1, \ldots, k\}, j \in \{1, \ldots, d_i\}\}$ and the free variables such that $\psi(x_1, \ldots, x_k)$ is equivalent to $\psi'(L_1, \ldots, L_s)$.*

In the following, we look at the class of problems $\mathsf{FOP}^k_{\mathbb{Z}}$ with the restriction of inequality dimension at most 3. We use the following naming convention for boxes.

▶ **Definition 26.** *A d-box in $\mathbb{R}^d$ is the cartesian product of d proper intervals $s_1 \times \cdots \times s_d$, where s_i is an open, closed or half-open interval. We call a cartesian product of only closed intervals a closed box and a cartesian product of only open intervals an open box.*

Given a set R of n closed boxes (represented as $2d$ integer coordinates), and d-dimensional points $a \in A, b \in B$, we can express in $\mathsf{FOP}_{\mathbb{Z}}(\exists\exists\exists)$ whether $a + b$ lies in one of the boxes as follows:

$$\exists a \in A \exists b \in B \exists r \in R : \bigwedge_{i=1}^{d} r[i] \leq a[i] + b[i] \wedge a[i] + b[i] \leq r[d+i].$$

In fact, we are not limited to closed boxes, if a box is open or half open in a dimension, one can adjust the inequalities in this dimension appropriately.

In order to prove our main theorem in this section, we need to partition the union of n unit cubes in $\mathbb{R}^3$ into pairwise interior- and exterior-disjoint boxes. While Chew et al. [23] studied such a decomposition of unit cubes with the requirement of only interior-disjoint boxes, we need an extension of their result to guarantee disjoint exteriors.

▶ **Lemma 27** (Disjoint decomposition of the union of cubes in $\mathbb{R}^3$). *Let $\mathcal{C}$ be a set of n axis-aligned congruent cubes in $\mathbb{R}^3$. The union of these cubes, can be decomposed into $O(n)$ boxes whose interiors and exteriors are disjoint in time $O(n \log^2 n)$.*

The proof is deferred to the full version.

▶ **Theorem 28.** *There is an algorithm deciding 3-SUM in randomized time $O(n^{2-\epsilon})$ for an $\epsilon > 0$ if and only if for each problem P in the classes $\mathsf{FOP}_{\mathbb{Z}}(\forall\forall\exists)$ and $\mathsf{FOP}_{\mathbb{Z}}(\exists\forall\exists)$ of inequality dimension at most 3 there exists some $\epsilon' > 0$ such that we can solve P in randomized time $O(n^{2-\epsilon'})$.*

Proof. For the first direction due to Theorem 10, we can reduce 3-SUM to an instance of Additive Sumset Approximation,

$$\forall a \in A \forall b \in B \exists c \in C : c \leq a + b \wedge a + b \leq c + t,$$

which has inequality dimension 2. Let us continue with the other direction. Let $\phi := Q_1 a \in A \forall b \in B \exists c \in C : \varphi$, where $Q_1 \in \{\exists, \forall\}$ and φ is a quantifier free linear arithmetic formula with inequality dimension 3. Let $L_1 := \alpha_1^T a + \beta_1^T b \leq \gamma_1^T c + S_1$, $L_2 := \alpha_2^T a + \beta_2^T b \leq \gamma_2^T c + S_2$ and $L_3 := \alpha_3^T a + \beta_3^T b \leq \gamma_3^T c + S_3$ after replacing the free variables. Assume that the formula φ is given in DNF, thus each co-clause has at most 3 atoms, chosen from L_1, L_2, L_3 and their negations. Let

$$A' := \left\{ \begin{pmatrix} \alpha_1^T a \\ \alpha_2^T a \\ \alpha_3^T a \end{pmatrix} : a \in A \right\}, B' := \left\{ \begin{pmatrix} \beta_1^T b \\ \beta_2^T b \\ \beta_3^T b \end{pmatrix} : b \in B \right\}, C' := \left\{ \begin{pmatrix} \gamma_1^T c + S_1 \\ \gamma_2^T c + S_2 \\ \gamma_3^T c + S_3 \end{pmatrix} : c \in C \right\}$$

Thus each co-clause consists of conjunctions of a subset of the following set

$$\{a'[0]+b'[0] \le c'[0], a'[0]+b'[0] \ge c'[0]+1, a'[1]+b'[1] \le c'[1],$$
$$a'[1]+b'[1] \ge c'[1]+1, a'[2]+b'[2] \le c'[2], a'[2]+b'[2] \ge c'[2]+1\}.$$

Let the co-clauses of φ be $V_1, \dots, V_h$. Thus, we aim to decide a formula of the form:

$$Q_1 a' \in A' \forall b' \in B' \exists c' \in C' : \bigvee_{i=1}^{h} V_i \tag{2}$$

For each co-clause V_i, $i \in \{1, \dots, h\}$ it holds that V_i is of the form

$$\bigwedge_{k \in V_i^K} L_k \wedge \bigwedge_{j \in V_i^J} \neg L_j,$$

for some $V_i^J, V_i^K \subseteq \{1,2,3\}$ and $V_i^J \cap V_i^K = \emptyset$.

Let us consider for each fixed $c' \in C'$ the following possibly empty orthant in $\mathbb{R}^3$.

$$\mathcal{S}(V_i, c') := \{x \in \mathbb{R}^3 : \bigwedge_{k \in V_i^K} x[k] \le c'[k] \wedge \bigwedge_{j \in V_i^J} x[j] \ge c'[j]+1\}.$$

By construction, it is immediate that for a fixed c' and $(a', b') \in A' \times B'$ that (a', b', c') fulfill the co-clause V_i if and only if $a'+b' \in \mathcal{S}(V_i, c')$. Thus, equivalently to (2), we ask

$$Q_1 a' \in A' \forall b' \in B' \exists c' \in C' : \bigvee_{i=1}^{h} \left(a'+b' \in S(V_i, c')\right).$$

Having a closer look, $\bigvee_{i=1}^{h} (a'+b' \in S(V_i, c'))$ is true if and only if $a'+b'$ lies in one of the orthants $S(V_i, c')$.

We argue that we may represent the orthant $\mathcal{S}(V_i, c')$ as an appropriately chosen cube in $\mathbb{R}^3$. To this end, let $M := 2 \cdot \max\{\|a\|_1 + \|b\|_1 + \|c\|_1 : a' \in A', b' \in B', c' \in C'\}$ be a sufficiently large number. We can interpret $\mathcal{S}(V_i, c')$ as a cube of the type $\mathcal{C}_{i,c'} = [m_0, m_0'] \times [m_1, m_1'] \times [m_2, m_2']$, where for $u \in \{0,1,2\}$, we define:

$$m_u := \begin{cases} -M & u \notin V_i^K, u \notin V_i^J, \\ -2M + c[u] & u \in V_i^K, \\ c[u]+1 & u \in V_i^J, \end{cases} \qquad m_u' := \begin{cases} M & u \notin V_i^K, u \notin V_i^J, \\ c[u] & u \in V_i^K, \\ 2M + c[u] + 1 & u \in V_i^J. \end{cases}$$

The cubes are axis-aligned and have side length $2M$. Due to the large size of the cube we get for fixed $c' \in C'$ that $a'+b' \in \mathcal{S}(V_i, c')$ if and only if $a'+b'$ lies inside the cube $\mathcal{C}_{i,c'}$.

By Lemma 27, we can decompose the collection of cubes $\mathcal{C}_{i,c'}$ for $i \in \{1, \dots, H\}, c' \in C'$ into $l = O(n)$ disjoint boxes $\mathcal{R} := \{R_1, \dots, R_l\}$ in time $O(n \log^2 n)$. Let us now go through a case distinction based on the first quantifier.

- If $Q_1 = \forall$, equivalent to ϕ we ask

  $$\forall a' \in A' \forall b' \in B' \exists i \in \{1, \dots, l\} : a'+b' \text{ lies in } R_i.$$

  By replacing each $i \in \{1, \dots, l\}$ by a 6-tuple denoting the dimensions of the box R_i, we can reduce counting the number of (a', b', R_i) with $a'+b' \in R_i$ to 3-SUM using Corollary 3. Due to the disjointness of the boxes R_i, we know that no (a', b') can be in different boxes $R_i, R_{i'}$ with $i \neq i'$.

  Thus, we can decide our original question by checking whether the number of such witnesses equals $|A'| \cdot |B'|$, concluding the fine-grained reduction to 3-SUM.

- Assume now that $Q_1 = \exists$. Thus, equivalently to ϕ, we ask.

  $$\exists a' \in A' \forall b' \in B' \exists i \in \{1, \ldots, l\} : a' + b' \text{ lies in } R_i.$$

  We can now make use of Corollary 19. Count for each $a' \in A'$ the number of *witnesses* (a', b', R_i) with $a' + b' \in R'$. We claim that it remains to check whether there is some a' that is involved in $|B'|$ witnesses. To see this, note that due to the disjointness of the R_i's, for any $a' \in A'$ we have that the number of (b', R_i) with $a' + b' \in R_i$ is equal to the number of b' such that there exists R_i with $a' + b' \in R_i$. Again, the desired reduction to 3-SUM follows. ◀

We remark that, by [11], we know that the complexity of the union of orthants in $\mathbb{R}^d$ has worst case complexity $O(n^{\lfloor d/2 \rfloor})$. Thus, the above proof does not seem directly generalizable to inequality dimensions larger than 3. We can extend Theorem 28 to k-quantifiers by the following theorem.

▶ **Theorem 5.** *There is an algorithm deciding 3-SUM in randomized time $O(n^{2-\epsilon})$ for an $\epsilon > 0$, if and only if for each problem P in $\mathsf{FOP}^k_{\mathbb{Z}}$ with $k \geq 3$ and inequality dimension at most 3, there exists some $\epsilon > 0$ such that we can solve P in randomized time $O(n^{k-1-\epsilon})$.*

The above theorem gives us immediate reductions to 3-SUM for many seemingly unrelated problems of different quantifier structures and semantics.

For instance, as a direct application of the above theorem we can conclude the equivalence of the Additive Sumset Approximation problem to 3-SUM, together with Theorem 10.

▶ **Lemma 29** (Additive Sumset Approximation $\leq_2$ 3-SUM)**.** *If the 3-SUM problem can be solved in randomized time $O(n^{2-\epsilon})$ for an $\epsilon > 0$ then Additive Sumset Approximation problem can be solved in randomized time $O(n^{2-\epsilon'})$ for an $\epsilon' > 0$.*

7 Application: A lower bound on the computation of Pareto Sums

In the following, we explore how the 3-SUM hardness of Verification of Pareto Sum translates to a hardness result for the problem of computing Pareto Sums. Let us first justify the naming of the Verification of Pareto Sum problem, by showing it to be subquadratic equivalent to the more natural extended version of Verification of Pareto Sum. Throughout this section, we consider dimensions $d \geq 2$.

▶ **Definition 30** (Verification of Pareto Sum (Extended version))**.** *Given sets $A, B, C \subseteq \mathbb{Z}^d$, do the following properties hold simultaneously:*

- *(Inclusion): $C \subseteq A + B$,*
- *(Dominance): C dominates $A + B$. More formally, for every $a \in A, b \in B$ there exists $c \in C$ with $c \geq a + b$.*
- *(Minimality): There are no $c, c' \in C$ with $c \neq c'$ and $c \leq c'$.*

We make use of the following lemma and its construction for the results in this section.

▶ **Lemma 31.** *Given sets $A, B, C \subseteq \mathbb{Z}^d$ of size at most n, one can construct sets $\tilde{A}, \tilde{B}, \tilde{C} \subseteq \mathbb{Z}^d$ of size $\Theta(n)$ in time $\tilde{O}(n)$ such that (1) $\tilde{A}, \tilde{B}, \tilde{C}$ always satisfy the minimality and inclusion condition and (2) $\tilde{A}, \tilde{B}, \tilde{C}$ fulfill the dominance condition if and only if A, B, C fulfill the dominance condition.*

Due to space constraints, the proof had to be deferred to the full version. Using this construction, it is not difficult to obtain the following equivalence.

▶ **Lemma 32.** *There is an $O(n^{2-\epsilon})$ time algorithm for an $\epsilon > 0$ for Verification of Pareto Sum (Extended Version) if and only if there is an $O(n^{2-\epsilon'})$ time algorithm for an $\epsilon' > 0$ for Verification of Pareto Sum.*

The proof can be found in the full version. Thus, for subquadratic reductions, we can restrict ourselves to the Verification of Pareto Sum problem, which essentially only checks the dominance condition.

Let us now consider the natural problem of computing the Pareto Sum.

▶ **Definition 33** (Pareto Sum). *Given sets $A, B \subseteq \mathbb{Z}^d$, compute a set $C \subseteq \mathbb{Z}$, such that A, B, C satisfy the Inclusion, Dominance and Minimality condition.*

In the following, we argue why the lower bounds to Verification of Pareto Sum translate to lower bounds to Computation of the Pareto Sum. Formally, we prove:

▶ **Lemma 34.** *If there is an algorithm to compute the Pareto Sum C of sets $A, B \subseteq \mathbb{Z}^d$ in time $O(n^{2-\epsilon})$ for an $\epsilon > 0$ even when $C = \Theta(n)$, then one can also decide Verification of Pareto Sum of sets A, B, C in time $O(n^{2-\epsilon'})$ for an $\epsilon' > 0$.*

We conclude this section with our resulting hardness results for computing Pareto Sums.

▶ **Theorem 7** (Pareto Sum Computation Lower Bound). *The following conditional lower bounds hold for output-sensitive Pareto sum computation:*

1. *If there is $\epsilon > 0$ such that we can compute the Pareto sum C of $A, B \subseteq \mathbb{Z}^2$, whenever C is of size $\Theta(n)$, in time $O(n^{2-\epsilon})$, then the 3-SUM hypothesis fails (thus, for any $\mathsf{FOP}^k_{\mathbb{Z}}$ formula ϕ of inequality dimension at most 3, there is $\epsilon' > 0$ such that ϕ can be decided in time $O(n^{k-1-\epsilon'})$).*
2. *If for all $d \geq 2$, there is $\epsilon > 0$ such that we can compute the Pareto sum C of $A, B \subseteq \mathbb{Z}^d$, whenever C is of size $\Theta(n)$, in time $O(n^{2-\epsilon})$, then there is some $\epsilon' > 0$ such that we can decide all $\mathsf{FOP}_{\mathbb{Z}}$ formulas with k quantifiers not ending in $\exists\forall\exists$ or $\forall\exists\forall$ in time $O(n^{k-1-\epsilon'})$.*

8 Future Work

While we exhibit a pair of problems that is complete for the class $\mathsf{FOP}_{\mathbb{Z}}$, one could still ask whether there is a subquadratic reduction from Hausdorff distance under n Translations to Verification of Pareto Sum. As a result there would be a single complete problem (or rather the canonical multidimensional family of a single geometric problem) for $\mathsf{FOP}_{\mathbb{Z}}$.

Is Verification of Pareto Sum complete for the class $\mathsf{FOP}_{\mathbb{Z}}$?

Interestingly, previous completeness theorems [36] were able to establish a problem of quantifier structure $\forall\forall\exists$ (the Orthogonal Vectors problem) as complete by making use of a technique in [51] that was originally used to show subcubic equivalence between All-Pairs Negative Triangle and Negative Triangle. However, a major problem we encounter is that while the third quantifier in the Orthogonal Vectors problem ranges over a sparse (intuitively: subpolynomially sized) domain (i.e., the dimensions of the vectors), the third quantifier in Pareto Sum Verification ranges over a linearly sized domain (i.e., the set C).

Finally, we ask if our 3-SUM completeness result for arbitrary quantifier structures can be improved upon.

Can we establish a $d > 3$ such that 3-SUM is complete for $\mathsf{FOP}_{\mathbb{Z}}$ formulas of inequality dimension at most d?

Abstract

Incompressible encryption (Dziembowski, Crypto'06; Guan, Wichs, Zhandry, Eurocrypt'22) protects from attackers that learn the entire decryption key, but cannot store the full ciphertext. In incompressible encryption, the attacker must try to compress a ciphertext within pre-specified memory bound S before receiving the secret key.

In this work, we generalize the notion of incompressibility to functional encryption. In incompressible functional encryption, the adversary can corrupt non-distinguishing keys at any point, but receives the distinguishing keys only after compressing the ciphertext to within S bits. An important efficiency measure for incompressible encryption is the ciphertext-rate (i.e., $\mathsf{rate} = |m|/|\mathsf{ct}|$). We give many new results for incompressible functional encryption for circuits, from minimal assumption of (non-incompressible) functional encryption, with

1. ct-rate-$\frac{1}{2}$ and *short* secret keys,
2. ct-rate-1 and *large* secret keys.

Along the way, we also give a new incompressible attribute-based encryption for circuits from standard assumptions, with ct-rate-$\frac{1}{2}$ and short secret keys. Our results achieve optimal efficiency, as incompressible attribute-based/functional encryption with ct-rate-1 as well as short secret keys has strong barriers for provable security from standard assumptions. Moreover, our assumptions are minimal as incompressible attribute-based/functional encryption are strictly stronger than their non-incompressible counterparts.

1 Introduction

A fundamental principle in cryptography is to leverage "secrets" for differentiating between an honest user legitimately accessing a system and an attacker trying to illegitimately access it. Consider data encryption as an example, where the goal is data secrecy. A central assumption underlying traditional encryption is that *an attacker cannot learn anything about a user's secret decryption key*. Moreover, this assumption seems inherent as if an attacker learns the secret key, then how can one distinguish between "capabilities" of an honest user and an attacker!?

In 2006, Dziembowzki [14] proposed an exquisite approach to *restrict the "capabilities" of an attacker*, even when the *entire* secret key gets corrupted. The proposal was to view *long-term memory storage* as a limited and expensive resource. In words, the intuition was that no real-world attacker can maintain an unbounded long-term memory, and it has to pick and choose what it wants to store in its memory. Dziembowzki [14] formalized this in the secret-key setting, and defined it as a *forward-secure storage* system. Recently, Guan, Wichs, and Zhandry (henceforth GWZ) [23] generalized this to the public-key setting. They labeled cryptography in this model as "incompressible" cryptography. The intuition being that an attacker cannot "compress" its unbounded short-term memory into its bounded long-term memory. GWZ provided multiple constructions for "incompressible" public-key encryption and signatures, from a variety of cryptographic assumptions with different efficiency tradeoffs.

Beyond Public-Key Encryption

Functional encryption (FE) [32, 2, 28, 7] is a powerful generalization of public-key encryption (PKE) [12]. FE generalizes PKE by providing fine-grained access to encrypted data. In FE, the master decryption key holder can create partial "functional" decryption keys sk_f for any supported function f of its choice. Such a key holder can recover $f(m)$ from any ciphertext ct, encrypting data m. Standard indistinguishability-based FE security states that no polytime attacker cannot distinguish between encryptions $\mathsf{ct}_0, \mathsf{ct}_1$ of messages m_0, m_1, unless it receives a secret key sk_{f^*} s.t. $f^*(m_0) \neq f^*(m_1)$. That is, unless an attacker receives a "distinguishing key" sk_{f^*}, it cannot distinguish between any two ciphertexts.[2] The ability to learn only function evaluation of encrypted data and nothing more has had fascinating consequences in cryptography, both theoretically and practically [33, 5, 11, 32, 22, 8, 2, 28, 7, 30, 17, 15, 20, 34, 10, 19, 29, 31, 21, 26, 27, 4, 13].

While functional keys offer fine-grained access over encrypted data, enabling many superior applications, they also enable far more attack opportunities compared to plain encryption. In PKE, there is just one secret key, and while that implies an all-or-nothing functionality, storing the key securely for the entire system lifetime is much easier. On the contrary, in FE, there are master secret keys as well as functional decryption keys. Each decryption key must be securely generated, distributed, and stored by the appropriate user. While it might be reasonable to expect the central trusted authority will (in most part) store master key msk securely; expecting this from every other user (holding a functional key) is unrealistic.

Our Contributions: Incompressible FE

In this work, we study incompressible functional encryption systems. We formalize the concept, and provide multiple constructions from a variety of cryptographic assumptions enabling different efficiency tradeoffs. As we elaborate in the full version [18], incompressibility in FE is extremely interesting, both theoretically and practically. In short, it pushes the traditional perception in FE that leaking an entire decryption key is equivalent to learning the function output on every previously encrypted data.

Formalizing incompressible FE. Interestingly, formally defining incompressibility for FE is more nuanced than for PKE. In public-key encryption, there is just one secret key. Thus, to define incompressibility for PKE, one considers a simple two-stage attacker: in stage 1,

[2] Throughout the sequel, by the phrase a "distinguishing key", we mean a secret key that can distinguish between two ciphertexts (by running decryption). Similarly, by the phrase "non-distinguishing keys", we mean secret keys that do not enable a trivial distinguishing attack between two ciphertexts.

the attacker receives a ciphertext that it must "compress" down to S bits[3]; and stage 2, where the attacker receives the secret key (along with the S-bit "compressed" ciphertext). As long as such an attacker cannot learn anything about the message, the PKE scheme is a secure incompressible scheme. In functional encryption setting, there are many more secret keys! Thus, depending upon the secret key(s) that a *stage 2* attacker learns, there are different formulations of incompressible FE security. Below, we briefly summarize three such formulations, and discuss them in further detail in the full version [18].[4]

- Standard security: the adversary receives *one* (or bounded number of) *distinguishing* secret key(s), after compressing challenge ciphertext (i.e., in stage 2). Moreover, it receives unbounded number of *non-distinguishing* secret keys before and after compressing the ciphertext.
- Semi-strong security: this is a strengthening of standard security, where the adversary can get an *unbounded* number of distinguishing keys in stage 2.
- Strong security: this further strengthens as now adversary gets the *master secret key* in stage 2.

Measuring incompressibility efficiency. Clearly, for the above to not be trivially impossible, the ciphertext size should be larger than S, the incompressibility limit. Further, the ciphertext should be larger than $|m|$ to uniquely encode m and guarantee correctness. However, it is not clear if there are any other necessary constraints on parameter sizes, beyond $|\mathsf{ct}| = \max(S, |m|) + \mathsf{poly}(\lambda)$. Here the $\max(S, |m|)$ term ensures both ciphertext constraints (i.e., $|\mathsf{ct}| > S$ and $|\mathsf{ct}| > |m|$).

Thus, an ideal goal is to design incompressible FE where $|\mathsf{mpk}|, |\mathsf{msk}|, |\mathsf{sk}_f|$ are all independent of S, and $|\mathsf{ct}| = \max(S, |m|) + \mathsf{poly}(\lambda)$. Such an incompressible FE scheme would have asymptotically optimal-sized parameters. As we discuss in the full version [18], achieving optimality in all parameter sizes is unachievable from standard falsifiable assumptions. Therefore, a standard approach in the literature [23, 9] is to design encryption with highest ciphertext-rate. Ciphertext-rate is defined as the ratio of message length and ciphertext length, i.e. $\frac{|m|}{|\mathsf{ct}|}$.

Prior works [23, 9] built incompressible PKE with optimal ct-rate of 1. Unfortunately, that comes at the cost of large secret keys, i.e. $|\mathsf{sk}| = \mathsf{poly}(S, \lambda)$. In this work, we design incompressible ABE/FE in two incomparable parameter regimes – ct-rate of 1 with *"large"* secret keys, and ct-rate of $\frac{1}{2}$ with *"short"* secret keys. We believe both parameter regimes to be equally interesting. In FE applications, where an honest user stores only secret keys and not ciphertexts in its persistent long-term storage, it might be beneficial to have short keys with constant ct-rate. While, in applications where an honest user stores only a few secret keys and a large number of ciphertexts, having a ct-rate of 1 might be more useful.

Our results

We summarize our main results below. All our schemes are in the standard model and under standard assumptions. We do not make any ideal-cipher, random oracle, or any other non-standard/non-falsifiable cryptographic assumption.

[3] S is typically considered to be the bound on the adversary's long-term storage.

[4] We can also consider joint compression of ciphertexts and secret keys in FE. The focus of this work is only on ciphertext incompressibility as discussed in the full version [18]. It is an interesting open question of whether new tradeoffs and applications can be enabled, if one considers joint incompressibility of ciphertexts and secret keys.

Incompressible FE. Our first set of results contains new constructions for incompressible FE for polynomial-sized circuits. We provide three separate and incomparable FE constructions as each provides a unique efficiency-security tradeoff. All three construction rely on a standard public-key FE scheme for polynomial-sized circuits.

1. Our first incompressible FE scheme is proven secure in the *semi-strong* incompressibility model. If the underlying FE scheme has ct-rate of $r \in [0, 1]$, then our incompressible FE scheme has an $\frac{r}{2}$ ct-rate.
2. Our second scheme is also proven secure in the *semi-strong* incompressibility model, except we only prove selective security.[5] Moreover, this construction is a ct-rate preserving construction. That is, we obtain ct-rate r incompressible FE scheme from any ct-rate r standard FE scheme. However, the secret keys are large to avoid known barriers.
3. Our third scheme is an extension of our above scheme. It is proven secure in the *selective standard* incompressibility model, but it provides a rather non-trivial efficiency guarantee. We prove that if the underlying FE scheme has short keys, then so does our incompressible FE scheme (without lowering the ct-rate). As we elaborate later in the overview, this does not contradict known implausibility results (see discussion in the full version [18]), but rather tightly matches it.

By plugging in known optimal-ciphertext-rate FE schemes [23, 25], we obtain incompressible FE schemes under the assumption of poly-secure FE with:

1. a ct-rate-$\frac{1}{2}$, short keys, and selective semi-strong security,
2. a ct-rate-$\frac{1}{4}$, short keys, and *adaptive* semi-strong security,
3. a ct-rate-1, large keys, and selective semi-strong security,
4. a ct-rate-1, *short* keys, and selective *standard* security.

Incompressible ABE. Our second result is an incompressible attribute-based encryption (ABE) scheme for polynomial-sized circuits achieves (standard) incompressible ABE security, with ciphertext size $|\mathsf{ct}| = S + |m| + \mathsf{poly}(\lambda)$ and all other parameter sizes, $|\mathsf{mpk}|, |\mathsf{msk}|, |\mathsf{sk}_f|$, are independent of S. That is, this scheme has ct-rate of $\frac{1}{2}$, and short keys. The construction and security proof are available in the full version [18].

2 Preliminaries and Notations

Throughout this paper, we will use λ to denote the security parameter and $\mathrm{negl}(\cdot)$ to denote a negligible function in the input. We will use the short-hand notation PPT for "probabilistic polynomial time". For any finite set X, $x \leftarrow X$ denotes the process of picking an element x from X uniformly at random. Similarly, for any distribution $\mathcal{D}$, $x \leftarrow \mathcal{D}$ denotes an element x drawn from the distribution $\mathcal{D}$. For any natural number $n \in \mathbb{N}$, $[n]$ denotes the set $\{1, 2, \ldots, n\}$. For any two binary string x and y, $x||y$ denotes the concatenation of x and y. We use the following two notations to denote a family of circuits - $\{\mathcal{C}_n\}_n$ is a set of families of circuits indexed by some parameter n and $\{\mathcal{C}_{d,\ell}\}_{d,\ell}$ is a set of families of circuits indexed by the depth of the circuits d and the number of inputs to the circuits ℓ.

[5] Here selective means that the adversary must submit challenge messages before receiving secret keys in stage 1.

2.1 Randomness Extractors

▶ **Definition 1** (Strong Average Min-Entropy Extractor). *A (k, ϵ)-strong average min-entropy extractor is an efficient function* $\mathsf{Ext} : \{0,1\}^d \times \{0,1\}^n \to \{0,1\}^m$ *such that for all jointly distributed random variable X, Y where X takes values $\{0,1\}^d$ and $H_\infty(X|Y) \geq k$, we have $(U_d, \mathsf{Ext}(X, U_d), Y) \approx_\epsilon (U_d, U_m, Y)$ where U_d, U_m are uniformly random strings of length d, m respectively. Here $H_\infty(X|Y) = -\log \mathop{\mathbb{E}}_{y \leftarrow Y}(\max_x \mathsf{Pr}(X = x|Y = y))$ is the average min-entropy of X conditioned on Y.*

▶ **Theorem 2.** *There exists an explicit efficient $(k, 2^{-\lambda})$-strong average min-entropy extractor* $\mathsf{Ext} : \{0,1\}^d \times \{0,1\}^n \to \{0,1\}^\lambda$ *such that $k = \mathsf{poly}(\lambda)$, $d = \mathsf{poly}(\lambda)$, $n = S + k$ and the depth of the extractor circuit is* $\mathsf{poly}(\lambda, \log(n))$.

2.2 Pseudorandom Functions

A family of pseudorandom functions $\mathsf{PRF} = (\mathsf{KeyGen}, \mathsf{Eval})$ with key space $\{\mathcal{K}_\lambda\}_\lambda$, input space $\{\mathcal{X}_\lambda\}_\lambda$ and output space $\{\mathcal{Y}_\lambda\}_\lambda$ consists of the following algorithms.

- $\mathsf{KeyGen}(1^\lambda)$: The key generation algorithm is a randomized algorithm that takes as input the security parameter 1^λ and outputs a key $k \in \mathcal{K}_\lambda$.
- $\mathsf{Eval}(k, x)$: The evaluation algorithm is a deterministic algorithm that takes as input a key $k \in \mathcal{K}_\lambda$ and $x \in \mathcal{X}_\lambda$ and outputs $y \in \mathcal{Y}_\lambda$.

▶ **Definition 3.** *A PRF scheme* PRF *is secure if for all PPT adversary $\mathcal{A}$, there exists a negligible function* $\mathrm{negl}(\cdot)$ *such that for all $\lambda \in \mathbb{N}$,*

$$|\Pr[\mathcal{A}^{\mathsf{Eval}(k,\cdot)}(1^\lambda) = 1 \ : \ k \leftarrow \mathsf{KeyGen}(1^\lambda)] - \Pr[\mathcal{A}^{R(\cdot)}(1^\lambda) = 1 \ : \ R \leftarrow \mathcal{U}_\lambda]| \leq \mathrm{negl}(\lambda)$$

where $\mathcal{U}_\lambda$ is the set of all functions from $\mathcal{X}_\lambda$ to $\mathcal{Y}_\lambda$.

2.3 Garbling Scheme

A garbling scheme $\mathsf{GC} = (\mathsf{Garble}, \mathsf{Eval})$ for a class of circuits $\{\mathcal{C}_\lambda\}_\lambda$ consists of the following algorithms.

- $\mathsf{Garble}(1^\lambda, C)$: The garbling algorithm is a randomized algorithm that takes as input the security parameter 1^λ and a circuit $C \in \mathcal{C}_\lambda$ such that $C : \{0,1\}^n \to \{0,1\}$ and outputs a garbled circuit $\hat{C}$ and a set of labels $\{\mathsf{lab}_{i,b}\}_{i \in [n], b \in \{0,1\}}$.
- $\mathsf{Eval}(\hat{C}, \{\mathsf{lab}_i\}_{i \in [n]})$: The evaluation algorithm takes as input a garbled circuit $\hat{C}$ and a set of n labels $\{\mathsf{lab}_i\}_{i \in [n]}$ and outputs $y \in \{0,1\}$.

Correctness

For correctness of a garbling scheme GC for a class of circuits $\{\mathcal{C}_\lambda\}_\lambda$, we require that for all $\lambda \in \mathbb{N}, C \in \mathcal{C}_\lambda$, $x \in \{0,1\}^n$,

$$\mathsf{Eval}(\hat{C}, \{\mathsf{lab}_{i,x_i}\}_{i \in [n]}) = C(x)$$

where $(\hat{C}, \{\mathsf{lab}_{i,b}\}_{i \in [n], b \in \{0,1\}}) \leftarrow \mathsf{Garble}(1^\lambda, C)$.

Security

For security, we define simulation based security [35, 1].

▶ **Definition 4.** *A garbling scheme* $\mathsf{GC} = (\mathsf{Garble}, \mathsf{Eval})$ *for a class of circuits* $\{\mathcal{C}_\lambda\}_\lambda$ *is said to be secure if there exists a PPT algorithm* Sim *such that for all PPT adversaries* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$*, there exists a negligible function* $\mathrm{negl}(\cdot)$ *such that for all* $\lambda \in \mathbb{N}$*, the following holds.*

$$\left| \Pr\left[\mathcal{A}_2(\hat{C}, \{\mathsf{lab}_{i,x_i}\}_{i\in[n]}, \mathsf{aux}) = 1 : \begin{array}{c}(C, x, \mathsf{aux}) \leftarrow \mathcal{A}_1(1^\lambda),\\ (\hat{C}, \{\mathsf{lab}_{i,x_i}\}_{i\in[n]}) \leftarrow \mathsf{Sim}(1^\lambda, 1^n, 1^{|C|}, C(x))\end{array}\right] \right.$$

$$\left. - \Pr\left[\mathcal{A}_2(\hat{C}, \{\mathsf{lab}_{i,x_i}\}_{i\in[n]}, \mathsf{aux}) = 1 : \begin{array}{c}(C, x, \mathsf{aux}) \leftarrow \mathcal{A}_1(1^\lambda),\\ (\hat{C}, \{\mathsf{lab}_{i,b}\}_{i\in[n],b\in\{0,1\}}) \leftarrow \mathsf{Garble}(1^\lambda, C))\end{array}\right] \right| \leq \frac{1}{2} + \mathrm{negl}(\lambda).$$

2.4 Incompressible Secret Key Encryption

An incompressible secret key encryption scheme $\mathsf{IncSKE} = (\mathsf{Setup}, \mathsf{Enc}, \mathsf{Dec})$ with message space $\{\mathcal{M}_\lambda\}_\lambda$ consists of the following PPT algorithms.

- $\mathsf{Setup}(1^\lambda, 1^S, 1^n)$: The setup algorithm is a randomized algorithm that takes as input the security parameter λ, a parameter 1^S, the length of the message 1^n and outputs a secret key sk.
- $\mathsf{Enc}(\mathsf{sk}, m)$: The encryption algorithm is a randomized algorithm that takes as input a secret key sk and a message $m \in \mathcal{M}_\lambda$ and outputs a ciphertext ct.
- $\mathsf{Dec}(\mathsf{sk}, \mathsf{ct})$: The decryption algorithm takes as input a secret key sk and a ciphertext ct and outputs either a message $m \in \mathcal{M}_\lambda$ or $\perp$.

Correctness

For correctness, we require that for all $\lambda \in \mathbb{N}, S \in \mathbb{N}, n \in \mathbb{N}, m \in \mathcal{M}_\lambda$ and $\mathsf{sk} \leftarrow \mathsf{Setup}(1^\lambda, 1^S, 1^n)$,

$$\Pr[\mathsf{Dec}(\mathsf{sk}, \mathsf{Enc}(\mathsf{sk}, m)) = m] = 1$$

where the probability is over the random bits used in the encryption algorithm.

Incompressible SKE Security

Consider the following experiment with an adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$.

- **Initialization Phase:** $\mathcal{A}_1$ on input 1^λ, outputs an upper bound on the state size 1^S and the length of the message 1^n. The challenger runs $\mathsf{sk} \leftarrow \mathsf{Setup}(1^\lambda, 1^S, 1^n)$.
- **Challenge Phase:** $\mathcal{A}_1$ outputs a message m, along with an auxiliary information aux. The challenger randomly chooses $b \in \{0, 1\}$. If $b = 0$, it samples a truly random string ct^*. Else, it computes a ciphertext $\mathsf{ct}^* = \mathsf{Enc}(\mathsf{sk}, m)$ and sends it to $\mathcal{A}_1$.[6]
- **First Response Phase:** $\mathcal{A}_1$ computes a state st such that $|\mathsf{st}| \leq S$.
- **Second Response Phase:** $\mathcal{A}_2$ receives $(\mathsf{sk}, \mathsf{aux}, \mathsf{st})$ and outputs b'. $\mathcal{A}$ wins the experiment if $b = b'$.

▶ **Definition 5.** *An SKE scheme is said to be incompressible secure if for all PPT adversaries* $\mathcal{A}$*, there exists a negligible function* $\mathrm{negl}(\cdot)$ *such that for all* $\lambda \in \mathbb{N}$*,*

$$\Pr[\mathcal{A} \textit{ wins in the above experiment}] \leq \frac{1}{2} + \mathrm{negl}(\lambda)$$

[6] In the incompressible security definition presented in prior works [9, 24], the adversary sends two messages m_0, m_1 and receives an encryption of one of these message. Note that this is a weaker notion, which is implied by the incompressible security notion defined in this paper.

CPA-SKE Security

Consider the following experiment with an adversary $\mathcal{A}$ where Setup algorithm takes only 1^λ and 1^n as input.

- **Initialization Phase:** The challenger runs $\mathsf{sk} \leftarrow \mathsf{Setup}(1^\lambda, 1^n)$.
- **Pre-Challenge Query Phase:** $\mathcal{A}$ is allowed to make polynomially many queries. For each query m, the challenger computes $\mathsf{ct} \leftarrow \mathsf{SKE.Enc}(\mathsf{sk}, m)$ and returns ct to Adv.
- **Challenge Phase:** $\mathcal{A}$ outputs a message m^*. The challenger randomly chooses $b \in \{0,1\}$. If $b = 0$, it samples a truly random string ct^*. Else, it computes a ciphertext $\mathsf{ct}^* = \mathsf{Enc}(\mathsf{sk}, m^*)$ and sends it to $\mathcal{A}$.[7]
- **Post-Challenge Query Phase:** $\mathcal{A}$ is allowed to make polynomially many queries. For each query m, the challenger computes $\mathsf{ct} \leftarrow \mathsf{SKE.Enc}(\mathsf{sk}, m)$ and returns ct to Adv.
- **Response Phase:** $\mathcal{A}$ outputs $b' \in \{0,1\}$ and wins the experiment if $b = b'$.

▶ **Definition 6.** *An SKE scheme is said to be secure if for all PPT adversaries $\mathcal{A}$, there exists a negligible function* $\mathrm{negl}(\cdot)$ *such that for all $\lambda \in \mathbb{N}, n \in \mathbb{N}$,*

$$\Pr[\mathcal{A} \text{ wins in the above experiment}] \leq \frac{1}{2} + \mathrm{negl}(\lambda)$$

▶ **Theorem 7** ([14])**.** *Assuming the existence of one-way functions, there exists an incompressible SKE scheme with* $\mathsf{poly}(\lambda)$ *secret-key size and $S + n + \mathsf{poly}(\lambda)$ ciphertext size where n is the size of the message and S is the compressibility parameter. The depth of the decryption circuit is* $\mathsf{poly}(\lambda, \log(S, n))$.

2.5 Functional Encryption

A functional encryption scheme $\mathsf{FE} = (\mathsf{Setup}, \mathsf{KeyGen}, \mathsf{Enc}, \mathsf{Dec})$ for the function space $\{\mathcal{F}_n : \mathcal{X}_n \to \mathcal{Y}_n\}_n$ consists of the following PPT algorithms.

- $\mathsf{Setup}(1^\lambda, 1^n)$: The setup algorithm is a randomized algorithm that takes as input the security parameter 1^λ and an index 1^n and outputs a master public key mpk and a secret key msk.
- $\mathsf{KeyGen}(\mathsf{msk}, f)$: The key generation algorithm is a randomized algorithm that takes as input the master secret msk and a function $f \in \mathcal{F}_n$ and outputs a secret sk_f.
- $\mathsf{Enc}(\mathsf{mpk}, m)$: The encryption algorithm is a randomized algorithm that takes as input a public key mpk and a message $m \in \mathcal{X}_n$ and outputs a ciphertext ct.
- $\mathsf{Dec}(\mathsf{sk}_f, \mathsf{ct})$: The decryption algorithm takes as input a secret key sk_f and a ciphertext ct and outputs either a $y \in \mathcal{Y}_n$ or $\perp$.

Correctness

For correctness, we require that for all $\lambda \in \mathbb{N}, n \in \mathbb{N}, m \in \mathcal{X}_n, f \in \mathcal{F}_n$ and $(\mathsf{mpk}, \mathsf{msk}) \leftarrow \mathsf{Setup}(1^\lambda, 1^n)$,

$$\Pr[\mathsf{Dec}(\mathsf{KeyGen}(\mathsf{msk}, f), \mathsf{Enc}(\mathsf{mpk}, m)) = f(m)] = 1$$

where the probability is over the random bits used in the encryption and key generation algorithm.

[7] Note that this security notion implies the standard indistinguishability security notion where the adversary sends two messages m_0, m_1 and receives an encryption of one of the messages.

Adaptive IND-based Security

Consider the following experiment with an adversary $\mathcal{A}$.

- **Initialization Phase:** The challenger runs $(\mathsf{mpk}, \mathsf{msk}) \leftarrow \mathsf{Setup}(1^\lambda, 1^n)$ and sends mpk to $\mathcal{A}$.
- **Pre-Challenge Query Phase:** $\mathcal{A}$ is allowed to make polynomially many queries. For each query f, the challenger computes $\mathsf{sk}_f \leftarrow \mathsf{KeyGen}(\mathsf{msk}, f)$ and returns sk_f to $\mathcal{A}$.
- **Challenge Phase:** $\mathcal{A}$ outputs two message m_0, m_1. If there exists a function f queried by $\mathcal{A}$ such that $f(m_0) \neq f(m_1)$, the challenger aborts the game. Else, it randomly chooses $b \in \{0, 1\}$ and computes a ciphertext $\mathsf{ct}^* = \mathsf{Enc}(\mathsf{mpk}, m_b)$ and sends it to $\mathcal{A}$.
- **Post-Challenge Query Phase:** $\mathcal{A}$ is allowed to make polynomially many queries. For each query f, if $f(m_0) \neq f(m_1)$, the challenger sends $\perp$. Else, computes $\mathsf{sk}_f \leftarrow \mathsf{KeyGen}(\mathsf{msk}, f)$ and returns sk_f to $\mathcal{A}$.
- **Response Phase:** $\mathcal{A}$ outputs b'. $\mathcal{A}$ wins the experiment if $b = b'$.

▶ **Definition 8.** *An FE scheme satisfies adaptive indistinguishability-based security if for all PPT adversaries $\mathcal{A}$, there exists a negligible function* $\mathrm{negl}(\cdot)$ *such that for all $\lambda \in \mathbb{N}$,*

$$\Pr[\mathcal{A} \textit{ wins in the above experiment}] \leq \frac{1}{2} + \mathrm{negl}(\lambda)$$

If the FE is secure against an unbounded number of queries from the adversary, then we say that the scheme is collision-resistant.

A relaxed notion of the FE indistinguishability-based security is the well-known selective security model. An FE scheme is said to be *selectively* secure if it is secure against PPT adversaries $\mathcal{A}$ that do not make any key queries during the pre-challenge query phase, and have to submit the challenge message before obtaining the public parameters.

The following two theorems addresses the optimal ciphertext-rate and secret-key size FE schemes for both adaptive and selective settings. It is important to note that in these FE scheme, the decryption algorithm requires the complete description of the function f in addition to the secret key sk_f to perform decryption.

▶ **Theorem 9** ([25])**.** *Assuming selectively secure FE for circuits, there exists an adaptively secure FE such that*

$$|\mathsf{mpk}| = O_\lambda(1), \quad |\mathsf{sk}_f| = O_\lambda(1)^8, \quad |\mathsf{ct}| = 2|x| + O_\lambda(1)$$

where $O_\lambda(\cdot)$ hides factors of $\mathsf{poly}(\lambda)$*, λ is the security parameter,* ct *is a ciphertext and* sk_f *is a secret key for the function f, x is any element from the input space of f and* mpk *is the master public key generated by the scheme.*

▶ **Theorem 10** ([25])**.** *Assuming selectively secure FE for circuits, there exists an adaptively secure FE such that*

$$|\mathsf{mpk}| = O_\lambda(1), \quad |\mathsf{sk}_f| = O_\lambda(1)^9, \quad |\mathsf{ct}| = |x| + O_\lambda(1)$$

where $O_\lambda(\cdot)$ hides factors of $\mathsf{poly}(\lambda)$*, λ is the security parameter,* ct *is a ciphertext and* sk_f *is a secret key for the function f that outputs a single bit, x is any element from the input space of f and* mpk *is the master public key generated by the scheme.*

Simulation security

Consider the following real and simulated experiment with an adversary $\mathcal{A}$ where Sim is a PPT simulator.

Real Experiment

- **Initialization Phase:** The challenger runs $(\mathsf{mpk}, \mathsf{msk}) \leftarrow \mathsf{Setup}(1^\lambda, 1^n)$ and sends mpk to $\mathcal{A}$.
- **Challenge Phase:** $\mathcal{A}$ outputs a message m and a function f. The challenger computes a ciphertext $\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{mpk}, m)$ and $\mathsf{sk}_f \leftarrow \mathsf{KeyGen}(\mathsf{msk}, f)$ and sends $(\mathsf{ct}, \mathsf{sk}_f)$ to $\mathcal{A}$.
- **Response Phase:** $\mathcal{A}$ outputs b.

Simulated Experiment

- **Initialization Phase:** The simulator runs $(\mathsf{mpk}, \mathsf{msk}) \leftarrow \mathsf{Setup}(1^\lambda, 1^n)$ and sends mpk to $\mathcal{A}$.
- **Challenge Phase:** $\mathcal{A}$ outputs a message m and a function f. The simulator computes $(\mathsf{ct}, \mathsf{sk}_f) \leftarrow \mathsf{Sim}(\mathsf{mpk}, f, f(m), 1^{|m|})$ and sends $(\mathsf{ct}, \mathsf{sk}_f)$ to $\mathcal{A}$.
- **Response Phase:** $\mathcal{A}$ outputs b.

▶ **Definition 11.** *An FE scheme is said to be* ***single-key*** *simulation secure if for all PPT adversaries $\mathcal{A}$, there exists a PPT simulator* Sim *and a negligible function* $\mathrm{negl}(\cdot)$ *such that for all $\lambda \in \mathbb{N}, n \in \mathbb{N}$,*

$$\Big|\Pr[\mathcal{A} \text{ outputs 0 in the real experiment}] - \Pr[\mathcal{A} \text{ outputs 0 in the simulated experiment}]\Big| \leq \mathrm{negl}(\lambda)$$

▶ **Theorem 12** ([16])**.** *Assuming the hardness of* LWE*, there exists a single-key simulation secure* FE *for a class of circuits $\{\mathcal{C}_{n,d}\}_{n,d}$ that takes input of size n, outputs a single bit and has depth d such that*

$$|\mathsf{ct}| = O_\lambda(n \cdot d^2), \quad |\mathsf{sk}_f| = O_\lambda(d^2), \quad |mpk| = O_\lambda(n \cdot d^2)$$

where $O_\lambda(\cdot)$ hides factors of $\mathsf{poly}(\lambda)$, λ is the security parameter, ct *is a ciphertext and* sk_f *is a secret key for the circuit $f \in \mathcal{C}_{n,d}$ and* mpk *is the master public key generated by the scheme.*

▶ **Corollary 13.** *Assuming the hardness of* LWE*, there exists a single-key simulation secure* FE *for a class of circuits $\{\mathcal{C}_{n,d}\}_{n,d}$ that takes input of size n, outputs m-bits and has depth d such that*

$$|\mathsf{ct}| = O_\lambda(m \cdot n \cdot d^2), \quad |\mathsf{sk}_f| = O_\lambda(m \cdot d^2), \quad |mpk| = O_\lambda(m \cdot n \cdot d^2)$$

where $O_\lambda(\cdot)$ hides factors of $\mathsf{poly}(\lambda)$, λ is the security parameter, ct *is a ciphertext and* sk_f *is a secret key for the circuit $f \in \mathcal{C}_{n,d}$ and* mpk *is the master public key generated by the scheme.*

Specializing FE

An attribute based encryption scheme (ABE) is a function encryption scheme where the message space is $\{\mathcal{M}_n \times \mathcal{X}_n\}_n$, i.e., it is a tuple of a message and an attribute and the function class is a set of function $\{\mathcal{F}_n\}_n$ such that any function $f_C \in \mathcal{F}_n$ is associated with a predicate function C with the following definition.

$$\mathcal{F}_C(m, x) = \begin{cases} m & if \;\; C(x) = 1 \\ \perp & if \;\; C(x) = 0 \end{cases}$$

In the security experiment, the adversary has to output m_0, m_1, x^* in the challenge phase with the restriction that it has never queried a key for a function f_C such that $C(x^*) = 1$.

▶ **Theorem 14** ([6]). *Assuming the hardness of* LWE*, there exists an selectively secure ABE scheme for any family of circuits* $\{\mathcal{C}_{d,\ell}\}_{d,\ell}$ *that has* ℓ*-length input and* d*-depth satisfying*

$$|\mathsf{ct}| = O_\lambda(\ell \cdot d^2), \qquad |\mathsf{sk}_f| = O_\lambda(d^2), \qquad |mpk| = O_\lambda(\ell \cdot d^2)$$

where $O_\lambda(\cdot)$ *hides factors of* $\mathsf{poly}(\lambda)$*,* λ *is the security parameter,* ct *is a ciphertext and* sk_f *is a secret key for the predicate* $f \in \mathcal{C}_{d,\ell}$ *and* mpk *is the master public key generated by the scheme.*

An identity based encryption scheme (IBE) is a attribute based encryption scheme where the message space is $\{\mathcal{M}_\lambda \times \mathcal{ID}_\lambda\}_\lambda$, i.e., it is a tuple of a message and an identity and the function class is a set of function $\{\mathcal{F}_\lambda\}_\lambda$ such that any function $f_{\mathsf{id}} \in \mathcal{F}_\lambda$ is associated with an identity id with the following definition.

$$\mathcal{F}_{\mathsf{id}}(m, \mathsf{id}') = \begin{cases} m & if \ \ \mathsf{id} = \mathsf{id}' \\ \perp & if \ \ \mathsf{id} \neq \mathsf{id}' \end{cases}$$

In the security experiment, the adversary has to output m_0, m_1, id^* in the challenge phase with the restriction that it has never queried a key for id^*.

3 Incompressible Functional Encryption: Definitions

In this section, we will proceed to define the incompressible version of the security game for FE scheme where Setup takes an additional input 1^S. Similar to the incompressible SKE schemes, we will consider two adversaries $\mathcal{A}_1, \mathcal{A}_2$. The first adversary $\mathcal{A}_1$ will be provided with the complete challenge ciphertext and produce a compressed version of it. The second adversary $\mathcal{A}_2$ is provided with the master public key, compressed challenge ciphertext which was created by $\mathcal{A}_1$ and certain secret keys.

▶ **Definition 15** (Incompressible FE Security). *Let* $\mathsf{FE} = (\mathsf{Setup}, \mathsf{KeyGen}, \mathsf{Enc}, \mathsf{Dec})$ *be an FE scheme in which the setup algorithm takes an additional parameter* 1^S *as input. Consider the following experiment with an adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$*.*

- ***Initialization Phase:*** *$\mathcal{A}_1$ on input 1^λ, outputs an upper bound on the state size 1^S and 1^n. The challenger runs $(\mathsf{msk}, \mathsf{mpk}) \leftarrow \mathsf{Setup}(1^\lambda, 1^S, 1^n)$ and sends mpk to $\mathcal{A}_1$.*
- ***Pre-Challenge Query Phase:*** *In this phase, $\mathcal{A}_1$ is allowed to make polynomially many key queries. For each query f sent to the challenger, the challenger computes $\mathsf{sk}_f \leftarrow \mathsf{KeyGen}(\mathsf{msk}, f)$ and returns sk_f to $\mathcal{A}_1$.*
- ***Challenge Phase:*** *$\mathcal{A}_1$ outputs two messages m_0, m_1, along with an auxiliary information aux. If there exists a function f queried by $\mathcal{A}_1$ such that $f(m_0) \neq f(m_1)$, the challenger aborts the game. Else, it randomly chooses $b \in \{0, 1\}$ and computes a ciphertext $\mathsf{ct}^* = \mathsf{Enc}(\mathsf{mpk}, m_b)$ and sends it to $\mathcal{A}_1$.*
- ***Post-Challenge Query Phase:*** *This is similar to the pre-challenge query phase. The adversary $\mathcal{A}_1$ is allowed to send polynomially many key queries. For each query f, if $f(m_0) \neq f(m_1)$, the challenger sends $\perp$. Else, computes $\mathsf{sk}_f \leftarrow \mathsf{KeyGen}(\mathsf{msk}, f)$ and returns sk_f to $\mathcal{A}_1$.*
- ***First Response Phase:*** *$\mathcal{A}_1$ computes a state st such that $|st| \leq S$.*
- ***Second Response Phase:*** *$\mathcal{A}_2$ receives (mpk, aux, st) and can make the following query.*
  - ***Key Query Phase:*** *In this phase, $\mathcal{A}_2$ is allowed to make **a single distinguishing key** query but polynomially many queries for non-distinguishing keys. The challenger computes $\mathsf{sk}_f \leftarrow \mathsf{KeyGen}(\mathsf{msk}, f)$ and returns sk_f to $\mathcal{A}_2$.*

  Finally, $\mathcal{A}_2$ outputs b'. $\mathcal{A}$ wins the experiment if $b = b'$.

An FE scheme is said to be incompressible secure if for all PPT adversaries $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$*, there exists a negligible function* $\text{negl}(\cdot)$ *such that for all* $\lambda \in \mathbb{N}$*,*

$$\Pr[\mathcal{A} \text{ wins in the above experiment}] \leq \frac{1}{2} + \text{negl}(\lambda)$$

We consider two stronger variants of the above security - strongly incompressible and semi-strongly incompressible. In the strongly incompressible version, $\mathcal{A}_2$ is provided with the master secret msk whereas in the semi-strongly incompressible version, it is allowed to make polynomially many distinguishing key queries.

▶ **Definition 16** (Strongly Incompressible FE Security)**.** *An FE scheme is said to be strongly incompressible secure if for all PPT adversaries* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$*, there exists a negligible function* $\text{negl}(\cdot)$ *such that for all* $\lambda \in \mathbb{N}$*,*

$$\Pr[\mathcal{A} \text{ wins in the Incompressible } \mathsf{FE} \text{ experiment}] \leq \frac{1}{2} + \text{negl}(\lambda)$$

provided the second adversary $\mathcal{A}_2$ *is also given the* ***master secret key*** msk *at the beginning of Second Response Phase.*

▶ **Definition 17** (Semi-Strongly Incompressible FE Security)**.** *An FE scheme is said to be semi-strongly incompressible secure if for all PPT adversaries* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$*, there exists a negligible function* $\text{negl}(\cdot)$ *such that for all* $\lambda \in \mathbb{N}$*,*

$$\Pr[\mathcal{A} \text{ wins in the Incompressible } \mathsf{FE} \text{ experiment}] \leq \frac{1}{2} + \text{negl}(\lambda)$$

provided the second adversary $\mathcal{A}_2$ *is allowed to make* ***polynomially many distinguishing key queries*** *in the Key Query Phase.*

We can consider similar incompressible security notions for IBE and ABE schemes.

4 Rate-$\frac{1}{2}$ Incompressible FE with Short Keys and Semi-Strong Security

In this section, we present a *semi-strong incompressible* FE scheme, using a regular FE scheme along with an incompressible SKE and regular SKE scheme. If the underlying FE has ct-rate of $r \in [0, 1]$, then our incompressible FE scheme has an $\frac{r}{2}$ ct-rate.

Our Construction

Our FE scheme supports functions from the class $\{\mathcal{F}_n : \mathcal{N}_n \to \{0,1\}\}_n$ such that any function in this class has a $\mathsf{polylog}(|\mathcal{N}_n|)$ depth circuit using the following primitives. Throughout S denotes the (in)compressibility parameter.

- $\mathsf{IncSKE} = (\mathsf{IncSKE.Setup}, \mathsf{IncSKE.Enc}, \mathsf{IncSKE.Dec})$ be an incompressible SKE. We define $\alpha = \alpha(\lambda, S)$ as the length of the secret key of this scheme and $\beta = \beta(\lambda, S)$ as the length of the ciphertext for a message of length λ encrypted using this scheme.
- $\mathsf{SKE} = (\mathsf{SKE.Setup}, \mathsf{SKE.Enc}, \mathsf{SKE.Dec})$ be an SKE scheme with secret keys of length λ.
- $\mathsf{FE} = (\mathsf{FE.Setup}, \mathsf{FE.Keygen}, \mathsf{FE.Enc}, \mathsf{FE.Dec})$ be an FE scheme with message spaces $\{\tilde{\mathcal{N}}_n\}_n$ and function space $\{\tilde{\mathcal{F}}_n\}_n$ that contains the decryption circuits of IncSKE and SKE.

Let $\tilde{n} = \tilde{n}(\lambda, n, S)$ be the lexicographically smallest functionality index such that $\tilde{\mathcal{F}}_{\tilde{n}}$ contains $\mathcal{F}_n$, the decryption circuit of SKE and IncSKE. We describe the algorithms for our incompressible FE scheme below.

- $\mathsf{Setup}(1^\lambda, 1^S, 1^n)$: The setup algorithm samples a master public key and a master secret key of the FE scheme by computing $(\mathsf{fe.mpk}, \mathsf{fe.msk}) \leftarrow \mathsf{FE.Setup}(1^\lambda, 1^{\tilde{n}})$. It generates a secret key of the incompressible SKE scheme by computing $\mathsf{inc.sk} \leftarrow \mathsf{IncSKE.Setup}(1^\lambda, 1^S, 1^\lambda)$ and two secret keys of the SKE scheme by computing $\mathsf{ske.sk} \leftarrow \mathsf{SKE.Setup}(1^\lambda)$ and $\mathsf{ske.sk}' \leftarrow \mathsf{SKE.Setup}(1^\lambda)$. It sets $\mathsf{mpk} = \mathsf{fe.mpk}$ and $\mathsf{msk} = (\mathsf{fe.msk}, \mathsf{inc.sk}, \mathsf{ske.sk}, \mathsf{ske.sk}')$.
- $\mathsf{KeyGen}(\mathsf{msk}, f)$: Let $\mathsf{msk} = (\mathsf{fe.msk}, \mathsf{inc.sk}, \mathsf{ske.sk}, \mathsf{ske.sk}')$. The key generation algorithm first computes ciphertext $\mathsf{ske.ct} = \mathsf{SKE.Enc}(\mathsf{ske.sk}, (0, 0^\alpha))$ and $\mathsf{ske.ct}' = \mathsf{SKE.Enc}(\mathsf{ske.sk}', 0)$. Then, it generates a key of the FE scheme by computing $\mathsf{fe.sk}_f \leftarrow \mathsf{FE.Keygen}(\mathsf{fe.msk}, C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'})$ where the function $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$ is described in Figure 1.

Input: Messages m, SKE key $\mathsf{ske.sk}$, incompressible ciphertext $\mathsf{inc.ct}$ and a flag b
Hardwired: Function f, two SKE ciphertexts $\mathsf{ske.ct}, \mathsf{ske.ct}'$
Output: y

1. Check if $b = 0$:
   – If yes, output $y = f(m)$.
2. Otherwise, compute $(flag, \mathsf{inc.sk}) \leftarrow \mathsf{SKE.Dec}(\mathsf{ske.sk}, \mathsf{ske.ct})$.
3. Check if $flag = 0$:
   – If yes, output $y = f(m)$.
4. Otherwise, compute $\mathsf{ske.sk}' \leftarrow \mathsf{IncSKE.Dec}(\mathsf{inc.sk}, \mathsf{inc.ct})$.
5. Output $y = \mathsf{SKE.Dec}(\mathsf{ske.sk}', \mathsf{ske.ct}')$.

Figure 1 Description of $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$.

- $\mathsf{Enc}(\mathsf{mpk}, m)$: Let $\mathsf{mpk} = \mathsf{fe.mpk}$. The encryption algorithm randomly samples $\mathsf{inc.ct} \leftarrow \{0,1\}^\beta$ and generates $\mathsf{fe.ct} \leftarrow \mathsf{FE.Enc}(\mathsf{fe.mpk}, (m, \perp, \mathsf{inc.ct}, 0))$[10]. It returns $\mathsf{fe.ct}$.
- $\mathsf{Dec}(\mathsf{sk}_f, \mathsf{ct})$: Let $\mathsf{sk}_f = \mathsf{fe.sk}_f$. The decryption algorithm decrypts the ciphertext by computing $m = \mathsf{FE.Dec}(\mathsf{fe.sk}_f, \mathsf{ct})$. It returns m.

Correctness

A ciphertext corresponding to a message m in the above scheme is an encryption of $(m, \perp, \mathsf{inc.ct}, 0)$ using the FE scheme, i.e., $\mathsf{ct} \leftarrow \mathsf{FE.Enc}(\mathsf{fe.mpk}, (m, \perp, \mathsf{inc.ct}, 0))$ where $\mathsf{inc.ct}$ is a truly random string.

Consider that a decryptor possesses the secret key sk_f for some function f. The secret key sk_f is a key $\mathsf{fe.sk}_f$ of the underlying FE scheme for the circuit $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$ which takes as input in $(m, \mathsf{ske.sk}, \mathsf{inc.ct}, b)$ and outputs $f(m)$ if $b = 0$. The decryption algorithm simply computes the decryption algorithm of the underlying FE scheme on the ciphertext ct using $\mathsf{fe.sk}_f$ and returns the output. Since, b is set to 0 in the ciphertext ct, decrypting ct using $\mathsf{fe.sk}_f$ gives $f(m)$ due to the correctness of the underlying FE scheme.

Size of the master public key

The master public key of our scheme is $\mathsf{fe.mpk}$. Therefore, the size is $|\mathsf{fe.mpk}|$.

[10] By $\perp$, we mean it sets a null secret key.

Size of the ciphertext

Recall that the ciphertext is an FE encryption of $(m, \perp, \mathsf{inc.ct}, 0)$ where the third component has size β. From the definition of β, it is the length of an incompressible ciphertext which is intended encrypt an SKE secret key, therefore, $\beta = S + \mathsf{poly}(\lambda)$ using Dziembowski's construction (see Theorem 7). So, the size of $(m, \perp, \mathsf{inc.ct}, 0)$ is $|m| + S + \mathsf{poly}(\lambda)$. Assuming that FE has ct-rate of r, the size of $\mathsf{fe.ct}$ is also $r^{-1} \cdot (|m| + S + \mathsf{poly}(\lambda))$. Therefore, the rate of the proposed scheme is

$$\frac{r \cdot |m|}{(|m| + S + \mathsf{poly}(\lambda))} = \frac{r}{\left(1 + \frac{S}{|m|} + \frac{\mathsf{poly}(\lambda)}{|m|}\right)}$$

Size of the secret keys

The size of the secret key associated with a function f is $|\mathsf{fe.sk}_f|$ where $\mathsf{fe.sk}_f$ is an FE secret key for the circuit $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$. To use this secret key, the decryption algorithm would require the entire description of $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$ (see Theorem 9 and Theorem 10).

In addition to the description of f and the decryption circuits of SKE and IncSKE, the circuit $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$ contains two SKE ciphertexts generated during the key generation process. Therefore, $\mathsf{fe.sk}_f$ should contain both an FE secret key for the circuit $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$ and the two ciphertexts $\mathsf{ske.ct}, \mathsf{ske.ct}'$. The first SKE ciphertext is an encryption of an incompressible SKE scheme's secret key $\mathsf{inc.sk}$ along with a bit $flag$, and the second is just a bit y. Using Dziembowski's construction (see Theorem 7), we have $|\mathsf{inc.sk}| = \mathsf{poly}(\lambda)$. Therefore, $|\mathsf{fe.sk}_f|$ is the size of an FE secret key associated with $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$, with an additional $\mathsf{poly}(\lambda)$.

▶ **Theorem 18.** *Assuming* $\mathsf{FE} = (\mathsf{FE.Setup}, \mathsf{FE.Keygen}, \mathsf{FE.Enc}, \mathsf{FE.Dec})$ *is an* ct*-rate-*r *adaptively (selectively) secure FE scheme,* $\mathsf{SKE} = (\mathsf{SKE.Setup}, \mathsf{SKE.Enc}, \mathsf{SKE.Dec})$ *is a secure SKE scheme against unbounded number of ciphertexts and* $\mathsf{IncSKE} = (\mathsf{IncSKE.Setup}, \mathsf{IncSKE.Enc}, \mathsf{IncSKE.Dec})$ *be a secure incompressible SKE scheme, then the above construction is an adaptively (selectively) secure semi-strongly incompressible FE scheme. Also,*

$$|\mathsf{mpk}| = |\mathsf{fe.mpk}|, \quad |\mathsf{sk}| = |\mathsf{fe.sk}|, \quad |\mathsf{ct}| = (|m| + S + \mathsf{poly}(\lambda))/r$$

Proof-Sketch. The proof proceeds via a sequence of hybrid experiments.

- H_0: This corresponds to the adaptive semi-strong incompressibility security game. The adversary first receives the master public key mpk. It queries for polynomially many non-distinguishing keys, and receives the corresponding secret keys. Then, it sends its challenge messages m_0, m_1 and receives the challenge ciphertext which is encryption of m_b. Again, the adversary queries for polynomially many non-distinguishing keys, and receives the corresponding secret keys. It then compresses its state, and queries for both distinguishing and non-distinguishing functions. Upon receiving the secret keys, it must guess which message was encrypted.
- H_1 : In this hybrid, the challenger keeps the challenge ciphertext same as before, but modifies the *distinguishing* secret keys. For every *distinguishing* key query for some function f, it encrypts $f(m_b)$ instead of 0 to generate $\mathsf{ske.ct}'$.
  Note that H_0 and H_1 are indistinguishable due to SKE security. This is because the attacker does not get access to the SKE secret key, except in the form of ciphertexts as part of functional secret keys. We highlight we know the value $f(m_b)$ because the adversary is allowed to make distinguishing key queries in the second phase only.

- H_2 : In this hybrid, the challenger generates $\mathsf{inc.ct}^*$ by encrypting $\mathsf{ske.sk}'$ instead of sampling a truly random string. The rest of the game proceeds as before.
  Indistinguishability of hybrids H_1 and H_2 follows from standard indistinguishability-based security of the incompressible SKE scheme. This is because the secret key $\mathsf{inc.sk}$ is used only during the generation of $\mathsf{inc.ct}^*$.
- H_3 : In this hybrid experiment, the challenger keeps the challenge ciphertext same as before, but modifies the *distinguishing* secret keys. For every *distinguishing* key query for some function f, it encrypts $(1, \mathsf{inc.sk})$ instead of $(0, 0^\alpha)$ to generate $\mathsf{ske.ct}$.
  Note that H_2 and H_3 are indistinguishable due to SKE security. This is because the attacker does not get access to the SKE secret key, except in the form of ciphertexts as part of functional secret keys.
- H_4 : In this hybrid, the challenger modifies the challenge ciphertext ct^* by encrypting $(m_0, \mathsf{ske.sk}, \mathsf{inc.ct}^*, 1)$ instead of $(m_b, \bot, \mathsf{inc.ct}^*, 0)$. The rest of the game proceeds as before.
  Indistinguishability of hybrids H_3 and H_4 follows from adaptive indistinguishability-based security of FE, as the output of the function stays the same for all key queries. This is because in H_4, the non-distinguishing keys would decrypt the challenge ciphertext to $f(m_0)$ (since b is set to 1 and $flag = 0$), which is equal to $f(m_b)$. Whereas, the distinguishing keys would decrypt to $f(m_b)$ (since b is set to 1 and $flag = 1$, see Figure 1).
- H_5 : In this hybrid, the challenger reverts to generating $\mathsf{inc.ct}^*$ by sampling a truly random string. The rest of the game proceeds as before.
  Indistinguishability of hybrids H_4 and H_5 follows from the *incompressible* indistinguishability-based security of the incompressible SKE scheme. This is because the information $\mathsf{inc.sk}$ is needed to generate distinguishing keys in the second phase.
  Finally, note that in H_5, the bit b is used only in the second phase while generating distinguishing keys. That is, $\mathsf{ske.ct}'$ is generated by encrypting $f(m_b)$. Therefore, the winning probability for any adversary in G_5 depends on the standard indistinguishability-based security of the regular SKE scheme. ◀

The proof for the above theorem is provided in the full version [18]. Using Theorem 9, we have the following corollary.

▶ **Corollary 19.** *Assuming the existence of selectively secure FE for circuits, there exists a* ct*-rate-*$\frac{1}{4}$ *adaptively secure semi-strongly incompressible FE scheme for circuits. Also,*

$$|\mathsf{mpk}| = \mathsf{poly}(\lambda), \quad |\mathsf{sk}_f| = \mathsf{poly}(\lambda), \quad |\mathsf{ct}| = 2(|m| + S) + \mathsf{poly}(\lambda)$$

Using Theorem 10, we have the following corollary.

▶ **Corollary 20.** *Assuming the existence of selectively secure FE for circuits, there exists a* ct*-rate-*$\frac{1}{2}$ *selectively secure semi-strongly incompressible FE scheme for circuits. Also,*

$$|\mathsf{mpk}| = \mathsf{poly}(\lambda), \quad |\mathsf{sk}_f| = \mathsf{poly}(\lambda), \quad |\mathsf{ct}| = |m| + S + \mathsf{poly}(\lambda)$$

5 Rate-1 Incompressible FE with Large Keys and Semi-Strong Security

In this section, we present a *selective semi-strong incompressible* FE scheme, using a (regular) public key FE, together with other standard cryptographic primitives. If the underlying FE scheme has ct-rate-1, then our incompressible FE scheme also has ct-rate-1. Although the functional key sizes are larger.

Our construction

For simplicity, we consider boolean-valued functions. To design an incompressible FE supporting function class $\{\mathcal{F}_n : \{0,1\}^n \to \{0,1\}\}_{n\in\mathbb{N}}$, we use the following primitives. Throughout S denotes the (in)compressibility parameter.

- $\mathsf{Ext} : \{0,1\}^d \times \{0,1\}^\ell \to \{0,1\}^\lambda$ be a strong average-min entropy randomness extractor, where $d = d(\lambda)$ and $\ell = \ell(\lambda, S)$.
- $\mathsf{SKE} = (\mathsf{SKE.Setup}, \mathsf{SKE.Enc}, \mathsf{SKE.Dec})$ be an SKE scheme that can encrypt messages of length $n + d + 1$. (Here n is the FE message length and d is the seed length. W.l.o.g., we assume the secret key length to be λ.)
- $\mathsf{FE} = (\mathsf{FE.Setup}, \mathsf{FE.Keygen}, \mathsf{FE.Enc}, \mathsf{FE.Dec})$ be an FE scheme with message spaces $\{\{0,1\}^n\}_n$ and function space $\left\{\tilde{\mathcal{F}}_n\right\}_n$.
  Let $\tilde{n} = \max(n, S) + \lambda + 1$. We require the function class $\tilde{\mathcal{F}}_{\tilde{n}}$ to be such that it contains $\mathcal{F}_n$, and the decryption circuit of SKE and extractor Ext.

We describe the algorithms for our incompressible FE scheme below.

- $\mathsf{Setup}(1^\lambda, 1^S, 1^n)$: Let $\tilde{n} = \max(n, S) + \lambda + 1$. The setup algorithm samples a master public and secret key of the FE scheme by sampling $(\mathsf{fe.msk}, \mathsf{fe.mpk}) \leftarrow \mathsf{FE.Setup}(1^\lambda, 1^{\tilde{n}})$. It also samples an SKE secret key $\mathsf{ske.sk} \leftarrow \mathsf{SKE.Setup}(1^\lambda)$. It sets $\mathsf{msk} = (\mathsf{ske.sk}, \mathsf{fe.msk})$ and $\mathsf{mpk} = \mathsf{fe.mpk}$.
- $\mathsf{KeyGen}(\mathsf{msk}, f)$: Parse master key as $\mathsf{msk} = (\mathsf{ske.sk}, \mathsf{fe.msk})$. The key generation algorithm first computes ciphertext $\mathsf{ske.ct} = \mathsf{SKE.Enc}(\mathsf{ske.sk}, \mathbf{0})$. That is, it encrypts $n+d+1$ zeros. Then, it generates an FE secret key by computing $\mathsf{fe.sk}_f \leftarrow \mathsf{FE.Keygen}(\mathsf{fe.msk}, C_{f,\mathsf{ske.ct}})$, where C is described in Figure 2.

Input: $x \in \{0,1\}^{\max(n,S)}$, an SKE secret key $\mathsf{ske.sk} \in \{0,1\}^\lambda$, bit $\mathsf{flag} \in \{0,1\}$.
Hardwired: Function f, an SKE ciphertext $\mathsf{ske.ct}$.
Output: $y \in \{0,1\}$.

1. Check if $\mathsf{flag} = 0$:
   – If yes, parse x as an n-bit message m, and output $f(m)$.
   That is, if $S > n$, then $m = x[1:n]$, else $m = x$.
2. Otherwise, compute $(b, s, v) = \mathsf{SKE.Dec}(\mathsf{ske.sk}, \mathsf{ske.ct})$.
   Here $b \in \{0,1\}$, $s \in \{0,1\}^d, v \in \{0,1\}^n$.
3. Check if $b = 0$:
   – If yes, then output first bit of s, i.e. $s[1]$.
4. Otherwise, parse x as an S-bit source R, and output $f(v \oplus \mathsf{Ext}_s(R))$.
   That is, if $S < n$, then set $R = x[1:S]$, else set $R = x$.
   Then compute message $m = v \oplus \mathsf{Ext}_s(R)$ and output $f(m)$.

Figure 2 Description of $C_{f,\mathsf{ske.ct}}$.

- $\mathsf{Enc}(\mathsf{msk}, m)$: The encryption algorithm generates the ciphertext by computing $\mathsf{fe.ct} \leftarrow \mathsf{FE.Enc}(\mathsf{msk}, (m, \perp, 0))$. It outputs $\mathsf{fe.ct}$. (We point out that the message m is padded to be of length S in case $S > n$. Also, by $\perp$, we mean it sets a null secret key.)
- $\mathsf{Dec}(\mathsf{sk}_f, \mathsf{ct})$: The decryption algorithm decrypts the ciphertext by computing $m = \mathsf{FE.Dec}(\mathsf{sk}_f, \mathsf{ct})$. It returns m.

Correctness

Follows immediately from the construction.

Size of the master public key

The master public key of our scheme is $\mathsf{fe.mpk}$. Therefore, the size is $|\mathsf{fe.mpk}|$.

Size of the ciphertext

The size of the message encrypted by $\mathsf{FE.Enc}$ is $\tilde{n} = \max(n, S) + \lambda + 1$. Now if the base FE scheme has ct-rate-1, then ciphertext size in our scheme is also $\max(S, n) + \mathsf{poly}(\lambda)$.

Size of the secret key

The size of the secret key associated with a function f is $|\mathsf{fe.sk}_f|$ where $\mathsf{fe.sk}_f$ is an FE secret key for the circuit $C_{f,\mathsf{ske.ct}}$. To use this secret key, the decryption algorithm would require the entire description of $C_{f,\mathsf{ske.ct}}$ (see Theorem 10).

In addition to the description of f and the decryption circuit of SKE, the circuit $C_{f,\mathsf{ske.ct}}$ contains an SKE ciphertext generated during the key generation process. So, $\mathsf{fe.sk}_f$ should contain both an FE secret key for the circuit $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$ and the ciphertext $\mathsf{ske.ct}$. The SKE ciphertext is an encryption of a message of length $n + d + 1$ where d is the seed length of the extractor[11] and n is the length of the message. Therefore, $|\mathsf{fe.sk}_f|$ is equal to $n + d + 1$ plus the size of an FE secret key associated with $C_{f,\mathsf{ske.ct}}$.

▶ **Theorem 21.** *Assuming* $\mathsf{SKE} = (\mathsf{SKE.Setup}, \mathsf{SKE.Enc}, \mathsf{SKE.Dec})$ *is IND-CPA secure,* $\mathsf{FE} = (\mathsf{FE.Setup}, \mathsf{FE.Keygen}, \mathsf{FE.Enc}, \mathsf{FE.Dec})$ *is a selectively secure FE with* ct*-rate-*r*, then the above FE construction is a selective semi-strong incompressible FE scheme. Also,*

$$|\mathsf{mpk}| = |\mathsf{fe.mpk}|, \quad |\mathsf{sk}| = |\mathsf{fe.sk}| + |\mathsf{ske.ct}|, \quad |\mathsf{ct}| = (\max(n, S) + \mathsf{poly}(\lambda))/r$$

Proof-Sketch. The proof proceeds via a sequence of hybrid experiments.

- H_0: This corresponds to the selective semi-strong incompressibility security game. The adversary first sends its challenge messages m_0, m_1 and receives the challenge ciphertext which is encryption of m_b. Next, the adversary queries for polynomially many non-distinguishing keys, and receives the corresponding secret keys. It then compresses its state, and queries for both distinguishing and non-distinguishing functions. Upon receiving the secret keys, it must guess which message was encrypted.
- H_1 : In this hybrid, the challenger keeps the challenge ciphertext same as before, but modifies the secret keys. During setup, the challenger samples a *single* random string $R \leftarrow \{0,1\}^S$ as the extractor source, and a *single* random string $s \leftarrow \{0,1\}^d$ as the extractor seed. Now, instead of using an SKE encryption of $\mathbf{0}$ within each secret key, the challenger does the following:
  - For every *non-distinguishing* key query for some function f, it encrypts $(0, f(m_0), \mathbf{0})$. That is, the second message bit is $f(m_0)$ and rest are still all zeros.
  - For every *distinguishing* key query for some function f, it sets $v = m_b \oplus \mathsf{Ext}_s(R)$, and computes the SKE ciphertext as to be an encryption of $(1, s, v)$.

[11] d is equal to $\mathsf{poly}(\lambda)$, see Theorem 2

Note that H_0 and H_1 are indistinguishable due to SKE security. This is because the attacker does not get access to the SKE secret key, except in the form of ciphertexts as part of functional secret keys. We highlight that since we need to know $f(m_0)$ to answer even a non-distinguishing key query, thus we can only prove selective security of our incompressible FE scheme.

- H_2 : In this hybrid, the challenger encrypts $(R, \mathsf{ske.sk}, 1)$ instead of $(m_b, \perp, 0)$. (Note that here we are overloading notation and consider that there is a fixed deterministic way, e.g. by padding, to write R and m as $\max(n, S)$-bit strings.) The rest of the game proceeds as before.
  Indistinguishability of hybrids H_1 and H_2 follows standard selective indistinguishability-based security of FE, as the output of the function stays the same for all key queries. This is because for non-distinguishing keys we know that $f(m_0) = f(m_b)$, while for non-distinguishing keys, the function output is still $f(m_b)$.
- H_3 : In this hybrid experiment, v is chosen uniformly at random (instead of setting it as $m_b \oplus \mathsf{Ext}_s(R)$. Using the strong extractability guarantee of the extractor, we can argue that H_2 and H_3 are negligibly close.
  Finally, note that the bit b is not used in H_3, and therefore the adversary has no advantage in this experiment. ◀

The detailed proof for the above theorem is provided in the full version [18]. Using Theorem 10, we have the following corollary.

▶ **Corollary 22.** *Assuming the existence of* ct*-rate-*$\frac{1}{2}$ *selectively secure FE for circuits, there exists a* ct*-rate-*$\frac{1}{2}$ *selectively secure semi-strongly incompressible FE scheme for circuits. Also,*

$$|\mathsf{mpk}| = \mathsf{poly}(\lambda), \quad |\mathsf{sk}_f| = |m| + \mathsf{poly}(\lambda), \quad |\mathsf{ct}| = |m| + S + \mathsf{poly}(\lambda)$$

6 Rate-1 Incompressible FE with Short Keys and Standard Security

In this section, we present a *selective (standard) incompressible* FE scheme, using a (regular) public key FE, together with other standard cryptographic primitives. If the underlying FE scheme has ct-rate-1, then our incompressible FE scheme also has ct-rate-1. Interestingly, we show that if the underlying FE scheme has short keys, then our resulting incompressible FE scheme has short keys as well. While it might seem to contradict the lower bound [3], we observe that since we only prove standard incompressibility security (where only one non-distinguishing key gets corrupted) and the functions supported by our FE scheme has single-bit output, thus this does not contradict the result. This is because the lower bound actually states that if an incompressible FE scheme has ct-rate-1, then the size of the functional secret key must grow with the output length of the function, and not necessarily the input/message length.

Our construction

As discussed in the overview, this construction relies on the same ingredients as our FE construction from Section 5. The core difference is that now the functions that we create secret keys for change slightly. Below we describe the algorithms where we make modifications, and underline all the changes.

- $\mathsf{Setup}(1^\lambda, 1^S, 1^n)$: This is the same as in Section 5.

- $\mathsf{KeyGen}(\mathsf{msk}, f)$: Parse master key as $\mathsf{msk} = (\mathsf{ske.sk}, \mathsf{fe.msk})$. The key generation algorithm first computes ciphertext $\mathsf{ske.ct} = \mathsf{SKE.Enc}(\mathsf{ske.sk}, \underline{\mathbf{0}})$. That is, it encrypts $d+2$ zeros. Then, it generates an FE secret key by computing $\mathsf{fe.sk}_f \leftarrow \mathsf{FE.Keygen}(\mathsf{fe.msk}, C'_{f,\mathsf{ske.ct}})$, where C is described in Figure 3.

Input: $x \in \{0,1\}^{\max(n,S)}$, an SKE secret key $\mathsf{ske.sk} \in \{0,1\}^{\lambda}$, bit $\mathsf{flag} \in \{0,1\}$.
Hardwired: Function f, an SKE ciphertext $\mathsf{ske.ct}$.
Output: $y \in \{0,1\}$.

1. Check if $\mathsf{flag} = 0$:
   – If yes, parse x as an n-bit message m, and output $f(m)$.
2. Otherwise, compute $(b, s, v) = \mathsf{SKE.Dec}(\mathsf{ske.sk}, \mathsf{ske.ct})$.
   Here $b \in \{0,1\}, s \in \{0,1\}^d, \underline{v \in \{0,1\}}$.
3. Check if $b = 0$:
   – If yes, then output first bit of s, i.e. $s[1]$.
4. Otherwise, parse x as an S-bit source R, and output $\underline{v \oplus \mathsf{Ext}_s(R)}$.
   That is, it no longer computes f in this case.

Figure 3 Description of $C'_{f,\mathsf{ske.ct}}$.

- $\mathsf{Enc}(\mathsf{msk}, m), \mathsf{Dec}(\mathsf{sk}_f, \mathsf{ct})$: The encryption and decryption algorithms are the same as in Section 5.

Correctness

Follows immediately from the construction.

Size of the master public key and ciphertext

This is the same as in Section 5.

Size of the secret key

The size of the secret key associated with a function f is $|\mathsf{fe.sk}_f|$ where $\mathsf{fe.sk}_f$ is an FE secret key for the circuit $C'_{f,\mathsf{ske.ct}}$. To use this secret key, the decryption algorithm would require the entire description of $C'_{f,\mathsf{ske.ct}}$ (see Theorem 10).

In addition to the description of f and the decryption circuit of SKE, the circuit $C_{f,\mathsf{ske.ct}}$ contains an SKE ciphertext generated during the key generation process. So, $\mathsf{fe.sk}_f$ should contain both an FE secret key for the circuit $C_{f,\mathsf{ske.ct},\mathsf{ske.ct}'}$ and the ciphertext $\mathsf{ske.ct}$. The SKE ciphertext is an encryption of a message of length $d+2$ where d is the seed length of the extractor[12]. Therefore, $|\mathsf{fe.sk}_f|$ is the size of an FE secret key associated with $C_{f,\mathsf{ske.ct}}$, with an addition $d+1$.

▶ **Theorem 23.** *Assuming* $\mathsf{SKE} = (\mathsf{SKE.Setup}, \mathsf{SKE.Enc}, \mathsf{SKE.Dec})$ *is IND-CPA secure,* $\mathsf{FE} = (\mathsf{FE.Setup}, \mathsf{FE.Keygen}, \mathsf{FE.Enc}, \mathsf{FE.Dec})$ *is a selectively secure FE with* ct*-rate-*r*, then the above FE construction is a selective (standard) incompressible FE scheme. Also,*

$$|\mathsf{mpk}| = |\mathsf{fe.mpk}|, \quad |\mathsf{sk}| = |\mathsf{fe.sk}|, \quad |\mathsf{ct}| = (\max(n, S) + \mathsf{poly}(\lambda))/r$$

[12] d is equal to $\mathsf{poly}(\lambda)$, see Theorem 2

Proof-Sketch. The proof is very similar to the security proof of Theorem 21, except with one change. Since we only prove standard incompressibility of our FE scheme, then we only need to answer a single distinguishing key query. Therefore, rather than programming v as $m_b \oplus \mathsf{Ext}_s(R)$ as in the previous proof, we simply program $v = f(m_b) \oplus \mathsf{Ext}_s(R)$. That is, we only hardwire one function value inside v rather than the full message m_b. Because of this change, we can only prove standard incompressibility security (because we cannot answer more than one non-distinguishing key), but the circuit $C'_{f,\mathsf{ske.ct}}$ (that we have to create a functional key for) now has a succinct description as it only needs f and $\mathsf{ske.ct}$ (which is short anyways). For completeness, we sketch the hybrids below.

- H_0: This corresponds to the selective standard incompressibility security game. The adversary first sends its challenge messages m_0, m_1 and receives the challenge ciphertext which is encryption of m_b. Next, the adversary queries for polynomially many non-distinguishing keys, and receives the corresponding secret keys. It then compresses its state, and queries for one distinguishing function $f\mathsf{st}$ and many non-distinguishing functions. Upon receiving the secret keys, it must guess which message was encrypted.
- H_1 : In this hybrid, the challenger keeps the challenge ciphertext same as before, but modifies the secret keys. During setup, the challenger samples a single random string $R \leftarrow \{0,1\}^S$ as the extractor source, and a random string $s \leftarrow \{0,1\}^d$ as the extractor seed. Now, instead of using an SKE encryption of $\mathbf{0}$ within each secret key, the challenger does the following:
  - For every *non-distinguishing* key query for some function f, it encrypts $(0, f(m_0), \mathbf{0})$. That is, the second message bit is $f(m_0)$ and rest are still all zeros.
  - For *distinguishing* key query f, it sets $v = f(m_b) \oplus \mathsf{Ext}_s(R)$, and computes the SKE ciphertext as to be an encryption of $(1, s, v)$.
- H_2 : In this hybrid, the challenger encrypts $(R, \mathsf{ske.sk}, 1)$ instead of $(m_b, \perp, 0)$. The rest of the game proceeds as before.
- H_3 : In this hybrid experiment, v is chosen uniformly at random (instead of setting it as $f(m_b) \oplus \mathsf{Ext}_s(R)$.

  Finally, note that the bit b is not used in H_3, and therefore the adversary has no advantage in this experiment. ◀

The detailed proof for the above theorem is provided in the full version [18]. Using Theorem 10, we have the following corollary.

▶ **Corollary 24.** *Assuming the existence of* ct*-rate-*1 *selectively secure FE for circuits, there exists a* ct*-rate-*1 *selectively secure regular incompressible FE scheme for circuits. Also,*

$$|\mathsf{mpk}| = \mathsf{poly}(\lambda), \quad |\mathsf{sk}_f| = \mathsf{poly}(\lambda), \quad |\mathsf{ct}| = \max(S, n) + \mathsf{poly}(\lambda)$$

▶ Remark 25 (Handling functions with longer outputs, or a fixed number of distinguishing keys). The above FE construction can be naturally extended to support functions with longer outputs, or a fixed number of distinguishing keys. The idea is quite simply to hardwire either the multi-bit function output (in the first case) or the function output for every distinguishing function (in the second case). Note that if the secret keys for the underlying FE scheme are short (independent of the function description), then the above scheme achieves incompressible FE with optimal ciphertexts as well as secret keys.

Deterministic Approximation for the Volume of the Truncated Fractional Matching Polytope

Heng Guo
School of Informatics, University of Edinburgh, UK

Vishvajeet N
School of Informatics, University of Edinburgh, UK

Abstract

We give a deterministic polynomial-time approximation scheme (FPTAS) for the volume of the truncated fractional matching polytope for graphs of maximum degree Δ, where the truncation is by restricting each variable to the interval $[0, \frac{1+\delta}{\Delta}]$, and $\delta \leq \frac{C}{\Delta}$ for some constant $C > 0$. We also generalise our result to the fractional matching polytope for hypergraphs of maximum degree Δ and maximum hyperedge size k, truncated by $[0, \frac{1+\delta}{\Delta}]$ as well, where $\delta \leq C\Delta^{-\frac{2k-3}{k-1}} k^{-1}$ for some constant $C > 0$. The latter result generalises both the first result for graphs (when $k = 2$), and a result by Bencs and Regts (2024) for the truncated independence polytope (when $\Delta = 2$). Our approach is based on the cluster expansion technique.

1 Introduction

The evaluation of volume is a classic computing task. The pioneer work of Dyer, Frieze, and Kannan [11] showed that given a membership oracle, the volume of a convex body can be approximated to arbitrary accuracy in randomised polynomial time. On the other hand, in the same model, deterministic approximation takes at least exponential time [12, 2]. This marked an early milestone that distinguished the computational power of deterministic algorithms from that of randomized algorithms.

Nonetheless, computing volumes might still be interesting for other models and/or more restricted cases, where the lower bound of [12, 2] does not apply, and interesting deterministic volume algorithms may still exist. In particular, there appears to be no run-time lower bound for deterministically approximating the volume of a polytope given by facets. In this case, as the membership oracle is trivial to implement, the randomised algorithm of Dyer, Frieze, and Kannan [11] achieves an ε-approximation in time polynomial in the input size and $\frac{1}{\varepsilon}$. The deterministic counterpart of such an algorithm is called *fully polynomial-time approximation scheme* (FPTAS). Unfortunately, the best deterministic algorithmic technique for polytope volumes appears to fall short of achieving FPTAS. They either require exponential time [18, 5][1] or yield exponential approximation [3, 4]. In the hope of getting an FPTAS, we may focus on even more restricted cases, such as the independence polytope or matching polytope for graphs.

[1] The algorithms of [18, 5] are in fact exact algorithms and the dominating term in their run-time is linear in the number of vertices of the polytope.

Along this direction, Gamarnik and Smedira [13] considered the relaxed independence polytope. Given a graph $G = (V, E)$, it is defined as $\{\mathbf{x} \in [0,1]^V \mid \forall \{u, v\} \in E,\ x_u + x_v \leq 1\}$. Clearly, if we further restrict every x_v to the interval $[0, 1/2]$, this polytope degenerates to a cube of side length $1/2$ and its volume is simply $2^{-|V|}$. Gamarnik and Smedira [13] showed that we can push beyond this trivial case, namely, if we truncate the relaxed independence polytope by the interval $\left[0, \frac{1}{2}\left(1 + \frac{O(1)}{\Delta^2}\right)\right]$ for graphs of maximum degree Δ, a quasi-polynomial-time approximation scheme exists. Their technique is based on the correlation decay approach [22, 1]. Subsequently, Bencs and Regts [8] improved the interval to $\left[0, \frac{1}{2}\left(1 + \frac{O(1)}{\Delta}\right)\right]$ and the run-time to polynomial-time, based on the zeros of polynomial approach [6, 20]. The bound on this interval appears to be where the limit of the current methods is.

In this paper, we explore what other polytopes may admit efficient deterministic volume approximation. In particular, we consider the natural dual of the independence polytope, namely the matching polytope, or more precisely, its standard relaxation, the fractional matching polytope. Note that although it is the dual of the relaxed independence polytope, its volume might be drastically different.

▶ **Definition 1** (Fractional matching polytope). *Given a graph $G = (V, E)$, the* fractional matching polytope *is defined as follows*

$$P_G := \left\{ \mathbf{x} \in [0,1]^E \mid \sum_{e \sim v} x_e \leq 1 \text{ for every } v \in V \right\},$$

where $e \sim v$ if the edge e is adjacent to v.

For the fractional matching polytope, the trivial truncation is with the interval $\left[0, \frac{1}{\Delta}\right]$. Similar to [13, 8], we also truncate P_G by an interval that is slightly longer, multiplicatively, than the trivial truncation.

▶ **Definition 2** (Truncated fractional matching polytope). *For $\delta > 0$ and a graph $G = (V, E)$ of maximum degree Δ, the* truncated fractional matching polytope *is defined as follows*

$$P_{G,\delta} := \left\{ \mathbf{x} \in \left[0, \frac{1+\delta}{\Delta}\right]^E \mid \sum_{e \sim v} x_e \leq 1 \text{ for every } v \in V \right\}.$$

Denote the interval $\left[0, \frac{1+\delta}{\Delta}\right]$ by M_δ. Then $P_{G,\delta} = {M_\delta}^E \cap P_G$. Additionally, for any $v \in V$, the constraint $\sum_{e \sim v} x_e \leq 1$ is denoted by C_v. We are interested in computing the volume of $P_{G,\delta}$, i.e. the quantity

$$\mathrm{Vol}(P_{G,\delta}) := \int_{{M_\delta}^E} \prod_{v \in V} \mathbb{1}_{C_v} d\mu, \tag{1}$$

where μ is the Lebesgue measure and the indicator function $\mathbb{1}_{C_v} : {M_\delta}^E \to \{0, 1\}$ outputs 1 if and only if the constraint C_v is satisfied, i.e. when $\sum_{e \sim v} x_e \leq 1$.

Our main result regarding $\mathrm{Vol}(P_{G,\delta})$ is the following. Interestingly, similar to [8], the relative margin for the truncation interval we get is also $\frac{C}{\Delta}$.

▶ **Theorem 3.** *For graphs of maximum degree $\Delta \geq 2$ and $\delta \leq \frac{C}{\Delta}$ for some constant $C > 0$, there is a fully polynomial-time approximation scheme (FPTAS) for* $\mathrm{Vol}(P_{G,\delta})$.

The proof of Theorem 3 relies on the algorithmic cluster expansion approach [14, 16]. This is very closely related to the zeros of polynomial approach Bencs and Regts [8] took. The first step is to rewrite $\mathrm{Vol}(P_{G,\delta})$ as the partition function of a polymer model on the graph G. Roughly speaking, each polymer corresponds to a set of connected vertices where the constraints on these vertices are violated. For the algorithmic approach of the polymer model to work, we need to show that the total weights of these violations decay rapidly, or more technically, the so-called Kotecký-Preiss criterion [17] holds. Intuitively, when we truncate with the trivial interval $\left[0, \frac{1}{\Delta}\right]$, none of the violation may happen. With a longer truncation interval, violations can happen, but the small relative margin we allow implies that violations can only happen with small probability. Our method involves some careful estimates of these violation probabilities. We also note that it appears difficult to apply the correlation decay method here, and a direct application of the argument of Bencs and Regts [8] would yield a smaller margin $\delta = \frac{C}{\Delta^2}$ for some constant $C > 0$.

As mentioned earlier, the volumes of the relaxed independence polytope and the fractional matching polytope do not appear to be related, and thus Theorem 3 is not directly comparable to the main result of [8]. To put both results under a unified framework, we also consider hypergraph matchings. Let $H = (V, E)$ be a hypergraph. Consider the following polytope:

$$P_H := \left\{ \mathbf{x} \in [0,1]^E \mid \sum_{e \ni v} x_e \leq 1 \text{ for every } v \in V \right\}, \tag{2}$$

where $e \ni v$ if the hyperedge e contains v. This is a relaxation of the hypergraph matching polytope and a natural generalisation of the fractional matching polytope for graphs in Definition 1. We denote it by the *fractional hypergraph matching polytope*.

We consider hypergraphs of maximum degree $\Delta \geq 2$ and maximum hyperedge size $k \geq 2$. In this case, the polytope P_H is indeed defined by a set of linear constraints where each variable appears at most k times, and each constraint has at most Δ variables. When $k = 2$, this degenerates to the fractional matching polytope, and when $\Delta = 2$, this degenerates to the relaxed independence polytope. Similar to Definition 2, we truncate it by a cube of side length $\frac{1+\delta}{\Delta}$. Recall that M_δ denotes the interval $\left[0, \frac{1+\delta}{\Delta}\right]$. Define the truncated polytope $P_{H,\delta} := {M_\delta}^E \cap P_H$. Our result regarding $\mathrm{Vol}(P_{H,\delta})$ is the following.

▶ **Theorem 4.** *For hypergraphs of maximum degree $\Delta \geq 2$ and maximum hyperedge size $k \geq 2$, and $\delta \leq \frac{C}{\Delta^{\frac{2k-3}{k-1}} k}$ for some constant $C > 0$, there is an FPTAS for $\mathrm{Vol}(P_{H,\delta})$.*

The bound $\delta = O\left(\left(\Delta^{\frac{2k-3}{k-1}} k\right)^{-1}\right)$ recovers Theorem 3. Namely, when $k = 2$, $\delta = O\left(\frac{1}{\Delta}\right)$. Moreover, when $\Delta = 2$, $\delta = O\left(\frac{1}{k}\right)$ and the interval length is $\frac{1+\delta}{\Delta} = \frac{1}{2} + O\left(\frac{1}{k}\right)$, which recovers the result of [8].

The proof of Theorem 4 also relies on the algorithmic cluster expansion approach. It combines our technique for proving Theorem 3 and a generalisation of the technique in [8]. In particular, we introduce a different polymer model in this case, which requires a new generalisation of the classic broken circuit theory [23, 21] to hypergraphs.

An immediate open problem is if Theorem 4 holds with $\delta = O\left(\frac{1}{\Delta k}\right)$, which is discussed in more detail in Section 4. A much more challenging question is if we can obtain deterministic volume approximation for these polytopes without truncation, or with truncation by the interval $[0, 1 - \delta]$ for some small δ. For the closely related problems of approximating the number of independent sets or matchings, deterministic algorithms [22, 20, 7] match their randomised counterparts, at least for bounded degree graphs. In particular, in bounded degree graphs, an efficient deterministic algorithm exists to approximately count the number

of matchings [7]. However, these methods do not seem to carry over to volume approximation. When there is no or little truncation, volume approximation appears to be out of reach for current deterministic methods.

The rest of the paper is organised as follows. In Section 2, we consider the fractional matching polytope and show Theorem 3. In Section 3, we turn our attention to the hypergraph case and show Theorem 4. Finally, in Section 4, we discuss some potential future directions and the current obstacles.

2 Cluster Expansion

In this section, we briefly review the polymer model and the algorithmic cluster expansion approach, and apply it to $\mathrm{Vol}(P_{G,\delta})$ to show Theorem 3. Let $\mathcal{P}$ be a finite set, whose elements we call *polymers*. We endow $\mathcal{P}$ with a symmetric and reflexive incompatibility relation $\not\sim$ between any two polymers, and also a weight function $w(\cdot)$[2] that assigns a weight $w(\gamma)$ to the polymer γ. Given two polymers γ_1 and γ_2, we write $\gamma_1 \not\sim \gamma_2$ if γ_1 and γ_2 are incompatible, and $\gamma_1 \sim \gamma_2$ otherwise. For a set Γ of polymers, we say it is *compatible* if for any two $\gamma_1, \gamma_2 \in \Gamma$, $\gamma_1 \sim \gamma_2$. Additionally, there is a size function for polymers, and we use $|\gamma|$ to denote the size of γ.

▶ **Definition 5** (Polymer partition function). *The partition function of the polymer model above is*

$$\Xi(\mathcal{P}, w) := \sum_{\Gamma} \prod_{\gamma \in \Gamma} w(\gamma),$$

where the sum is over compatible $\Gamma \subseteq \mathcal{P}$.

We will be interested in the cluster expansion which is an infinite series representation of $\log \Xi(P)$. Given a multiset Γ of polymers from $\mathcal{P}$, we define the incompatibility graph $H(\Gamma)$ where we have a vertex v_γ for every polymer $\gamma \in \Gamma$ and an edge between every pair of vertices corresponding to an incompatible pair of polymers. A multiset Γ is called a *cluster* if the incompatibility graph $H(\Gamma)$ is connected. We also denote the set of all clusters from $\mathcal{P}$ as $\mathcal{C}$. Given $\Gamma \in \mathcal{C}$, let $H = H(\Gamma)$ and define the Ursell function

$$\Phi(\Gamma) := \frac{1}{|V(H)|!} \sum_{\substack{A \subseteq E(H) \\ \text{spanning, connected}}} (-1)^{|A|}. \tag{3}$$

▶ **Definition 6** (Cluster Expansion). *The cluster expansion of* Ξ *is*

$$\log \Xi(\mathcal{P}, w) := \sum_{\Gamma \in \mathcal{C}} \Phi(\Gamma) \prod_{\gamma \in \Gamma} w(\gamma).$$

We refer the interested reader to the survey by Jenssen [15] for various algorithmic (and beyond) applications of the cluster expansion. The cluster expansion is a good approximation to the logarithm of the partition function under various conditions. One of the most well-known conditions is the following.

[2] The weight function can be complex-valued, but in this paper we will focus on real-valued weight functions.

▶ **Proposition 7** (Kotecký-Preiss Criterion [17]). *Let $g : \mathcal{P} \to [0, \infty)$ be a "decay function". Suppose that for all $\gamma \in \mathcal{P}$, we have,*

$$\sum_{\gamma' \not\sim \gamma} |w(\gamma')| \, e^{|\gamma'|+g(\gamma')} \leq |\gamma| \,. \tag{4}$$

Then, the cluster expansion converges absolutely.

We note that the condition in Proposition 7 is not the most general, but this particular form will be convenient for our use later.

We are going to recast (1) into a polymer partition function. Let $G = (V, E)$ be a graph of maximum degree Δ. For $S \subseteq V$, let $\mathcal{K}(S)$ be the set of connected components in the induced subgraph $G[S]$.

Denote by $\overline{C_v}$ the constraint $\sum_{e \sim v} x_e > 1$. Using the indicator function for the constraint $\overline{C_v}$, and the fact that $\mathbb{1}_{C_v} = 1 - \mathbb{1}_{\overline{C_v}}$, we can expand (1) as

$$\begin{aligned}
\mathrm{Vol}(P_{G,\delta}) &= \int_{{M_\delta}^E} \prod_{v \in V} (1 - \mathbb{1}_{\overline{C_v}}) d\mu \\
&= \int_{{M_\delta}^E} \sum_{S \subseteq V} (-1)^{|S|} \prod_{v \in S} \mathbb{1}_{\overline{C_v}} d\mu \\
&= \int_{{M_\delta}^E} \sum_{S \subseteq V} \prod_{K \in \mathcal{K}(S)} (-1)^{|K|} \prod_{v \in K} \mathbb{1}_{\overline{C_v}} d\mu.
\end{aligned}$$

We then continue by pushing the integral inside:

$$\begin{aligned}
\mathrm{Vol}(P_{G,\delta}) &= \sum_{S \subseteq V} \int_{{M_\delta}^E} \prod_{K \in \mathcal{K}(S)} (-1)^{|K|} \prod_{v \in K} \mathbb{1}_{\overline{C_v}} d\mu \\
&= \sum_{S \subseteq V} \int_{{M_\delta}^{E \setminus E(S)}} 1 d\mu \left(\prod_{K \in \mathcal{K}(S)} (-1)^{|K|} \int_{{M_\delta}^{E(K)}} \prod_{v \in K} \mathbb{1}_{\overline{C_v}} d\mu \right),
\end{aligned} \tag{5}$$

where, for a subset $S \subseteq V$ of vertices, $E(S)$ denotes the set of edges adjacent to it. Note that we swapped the integral with the product in (5). This is valid because the constraint regarding each S_i rely on disjoint set of edges. There is also an extra factor of $\int_{{M_\delta}^{E \setminus E(S)}} 1 d\mu$ to account for the edges that are not adjacent to S. As $\int_{{M_\delta}^{E \setminus E(S)}} 1 d\mu = \left(\frac{1+\delta}{\Delta}\right)^{|E|-|E(S)|}$, we have

$$\begin{aligned}
\mathrm{Vol}(P_{G,\delta}) &= \left(\frac{1+\delta}{\Delta}\right)^{|E|} \sum_{S \subseteq V} \left(\frac{1+\delta}{\Delta}\right)^{-|E(S)|} \prod_{K \in \mathcal{K}(S)} \int_{{M_\delta}^{E(K)}} (-1)^{|K|} \prod_{v \in K} \mathbb{1}_{\overline{C_v}} d\mu \\
&= \left(\frac{1+\delta}{\Delta}\right)^{|E|} \sum_{S \subseteq V} \prod_{K \in \mathcal{K}(S)} w(K),
\end{aligned} \tag{6}$$

where

$$w(K) = \left(\frac{1+\delta}{\Delta}\right)^{-|E(K)|} (-1)^{|K|} \int_{{M_\delta}^{E(K)}} \prod_{v \in K} \mathbb{1}_{\overline{C_v}} d\mu. \tag{7}$$

The redistribution of the $\left(\frac{1+\delta}{\Delta}\right)^{-|E(S)|}$ factor is valid because $\{E(K)\}_{K \in \mathcal{K}(S)}$ is a partition of $E(S)$.

To fit (6) into Definition 5, we call a subset $S \subseteq V$ a polymer if the induced subgraph $G[S]$ is connected. Two polymers S_1 and S_2 are compatible if $\mathrm{dist}_G(S_1, S_2) \geq 2$, namely when they are not adjacent. The size of a polymer is simply the number of vertices it contains. In addition, equipped with the weight function in (7), we then have that

$$\Xi(G) = \frac{\mathrm{Vol}(P_{G,\delta})}{\left(\frac{1+\delta}{\Delta}\right)^{|E|}}. \tag{8}$$

The polymer model is useful thanks to the following theorem by Jenssen, Keevash, and Perkins [16] (building upon the works of [9, 20, 14]).

▶ **Proposition 8** ([16, Theorem 8]). *Fix an integer $\Delta > 0$ and let $\mathcal{G}$ be a class of graphs of maximum degree at most Δ. Suppose the following conditions hold for a given polymer model with decay function $g(\cdot)$ as in Proposition 7:*

1. *There exist constants $c_1, c_2 > 0$ such that given a connected subgraph γ, determining whether γ is a polymer, and then computing $w(\gamma)$ and $g(\gamma)$ can be done in time $O(|\gamma|^{c_1} e^{c_2|\gamma|})$;*
2. *There exists $\rho > 0$ such that for every $G \in \mathcal{G}$ and every polymer $\gamma \in \mathcal{P}(G)$, $g(\gamma) \geq \rho|\gamma|$;*
3. *The Kotecký-Preiss criterion as in Proposition 7 holds for $g(\cdot)$.*

Then there exists an FPTAS for $\Xi(G)$ for every $G \in \mathcal{G}$.

The algorithm in Proposition 8 is as follows. Given $\varepsilon > 0$ and a graph G on n vertices, let $t = \log(n/\varepsilon)$. For a cluster $\Gamma \in \mathcal{C}$, extend g by defining $g(\Gamma) := \sum_{\gamma \in \Gamma} g(\gamma)$. Moreover, recall the Ursell function in (3). Then,

1. Enumerate all clusters $\Gamma \in \mathcal{C}$ with $|\Gamma| < t/\rho$;
2. For each such Γ, compute $\Phi(\Gamma)$, $\prod_{\gamma \in \Gamma} w(\gamma)$, and $g(\Gamma)$;
3. Compute

$$T_t(G) := \sum_{\gamma \in \mathcal{C},\ |\Gamma| < t/\rho,\ g(\Gamma) < t} \Phi(\Gamma) \prod_{\gamma \in \Gamma} w(\gamma);$$

4. Output $\exp(T_t(G))$.

Roughly speaking, this yields a good approximation because the KP criterion in Proposition 7 holds. All the computation is efficient because of the algorithmic techniques in [9, 20, 14].

2.1 Verifying the Kotecký-Preiss Criterion

The most important condition in Proposition 8 is the Kotecký-Preiss criterion as in Proposition 7. Let $g(\gamma) := \rho\,|\gamma|$ for some sufficiently small constant ρ. For any $S \subseteq V$, let $N^+(S)$ be the extended neighbourhood of S, namely, $N^+(S) := S \cup \partial S$. Then we have,

$$\begin{aligned} \sum_{\gamma' \not\sim \gamma} |w(\gamma')|\, e^{|\gamma'| + g(\gamma')} &= \sum_{\gamma' \not\sim \gamma} |w(\gamma')|\, e^{(1+\rho)|\gamma'|} \\ &\leq \sum_{v \in N^+(\gamma)} \sum_{\gamma' \ni v} |w(\gamma')|\, e^{(1+\rho)|\gamma'|}. \end{aligned} \tag{9}$$

Note that $|N^+(\gamma)| \leq (\Delta + 1)\,|\gamma|$. Moreover, Borgs, Chayes, Kahn, and Lovász showed the following lemma.

▶ **Lemma 9** ([10, Lemma 2.1]). *For a graph G of maximum degree Δ, the number of connected subgraphs containing v of size ℓ is at most $\frac{1}{\ell}\binom{\ell\Delta}{\ell-1} \leq (e\Delta)^{\ell-1}$.*

Thus we need an upper bound of $w(\gamma)$ for any polymer γ of a fixed size ℓ.

▶ **Lemma 10.** *For a polymer γ of size ℓ and $\delta < \frac{1}{\Delta-1}$,*

$$|w(\gamma)| \le (e\delta)^{|\gamma|}.$$

Proof. Note that we can reinterpret (7) as

$$|w(\gamma)| = \Pr\left[\bigwedge_{v\in\gamma} \overline{C_v}\right],$$

where the probability is over the product distribution of $\{x_e\}_{e\in E(\gamma)}$ where each x_e is uniform over $\left[0, \frac{1+\delta}{\Delta}\right]$. Let I_γ be a maximal independent set of γ. Then $|I_\gamma| \ge \frac{|\gamma|}{\Delta}$, and

$$\Pr\left[\bigwedge_{v\in\gamma} \overline{C_v}\right] \le \Pr\left[\bigwedge_{v\in I_\gamma} \overline{C_v}\right] = \prod_{v\in I_\gamma} \Pr\left[\,\overline{C_v}\,\right]. \tag{10}$$

Recall that $\overline{C_v}$ is the constraint that $\sum_{e\sim v} x_e > 1$.

If there is some $u \in I_\gamma$ such that $\deg_G(u) \le \Delta - 1$, then $\sum_{e\sim u} x_e \le \frac{\Delta-1}{\Delta}(1+\delta) < 1$ as $\delta < \frac{1}{\Delta-1}$ In this case $\Pr\left[\,\overline{C_u}\,\right] = 0$ and the lemma follows.

Therefore we can assume that $\deg_G(v) = \Delta$ for all $v \in I_\gamma$. Let $y_e = \frac{1+\delta}{\Delta} - x_e$. Then

$$\Pr\left[\sum_{e\sim v} x_e > 1\right] = \Pr\left[\sum_{e\sim v} y_e < \delta\right],$$

where each y_e is uniform over $\left[0, \frac{1+\delta}{\Delta}\right]$.
Denote by S_δ the simplex $\{\mathbf{y} \mid \sum_{e\sim v} y_e < \delta, \text{ and } \forall e \sim v,\ y_e \ge 0\}$. Then, $S_\delta \subseteq {M_\delta}^{E(v)}$ as $\delta < \frac{1+\delta}{\Delta}$. Thus,

$$\Pr\left[\sum_{e\sim v} y_e < \delta\right] = \frac{\mathrm{Vol}\left(S_\delta \cap {M_\delta}^{E(v)}\right)}{\mathrm{Vol}\left({M_\delta}^{E(v)}\right)} = \frac{\mathrm{Vol}\left(S_\delta\right)}{\mathrm{Vol}\left({M_\delta}^{E(v)}\right)} = \frac{\frac{\delta^\Delta}{\Delta!}}{\left(\frac{1+\delta}{\Delta}\right)^\Delta} \le \left(\frac{e\delta}{1+\delta}\right)^\Delta,$$

where we used the fact that a standard simplex of dimension Δ has volume $1/\Delta!$ and $\Delta! \ge \left(\frac{\Delta}{e}\right)^\Delta$. Plugging it back to (10),

$$|w(\gamma)| \le \prod_{v\in I_\gamma} \Pr\left[\,\overline{C_v}\,\right] \le \left(\frac{e\delta}{1+\delta}\right)^{\Delta\cdot\frac{|\gamma|}{\Delta}} < (e\delta)^{|\gamma|}. \qquad ◀$$

Now we can verify the Kotecký-Preiss criterion.

▶ **Lemma 11.** *For graphs of maximum degree $\Delta \ge 2$, $\delta \le \frac{1}{e^4\Delta}$, and sufficiently small ρ, the Kotecký-Preiss criterion (4) holds.*

Proof. By (9), Lemma 9, and Lemma 10, for sufficiently small ρ,

$$\begin{aligned}
\sum_{\gamma\not\sim\gamma'} |w(\gamma')|\, e^{|\gamma'|+g(\gamma')} &\le (\Delta+1)\,|\gamma| \sum_{\ell\ge1} (e\Delta)^{\ell-1}\,(e\delta)^\ell\, e^{(1+\rho)\ell} \\
&\le \frac{\Delta+1}{e\Delta}\,|\gamma| \sum_{\ell\ge1} \left(e^{3+\rho}\delta\Delta\right)^\ell \le \frac{1.5}{e}\,|\gamma| \sum_{\ell\ge1} \left(e^{\rho-1}\right)^\ell \\
&\qquad\qquad \text{(as } \delta \le \tfrac{1}{e^4\Delta} \text{ and } \Delta \ge 2) \\
&\le \left(\frac{1.5}{e}\cdot\frac{e^{\rho-1}}{1-e^{\rho-1}}\right)|\gamma| < |\gamma|. \qquad ◀
\end{aligned}$$

2.2 Proof of Theorem 3

With the KP criterion verified, we can prove Theorem 3 now.

Proof of Theorem 3. We apply Proposition 8. Let $g(\gamma) = \rho|\gamma|$ for a sufficiently small constant ρ, which then satisfies Item (2). The Item (3) follows from Lemma 11. For Item (1), determining if γ is a polymer is trivial, and computing $g(\gamma)$ is trivial too.

For computing $w(\gamma)$, recall (7). It is easy to see that $\left(\frac{1+\delta}{\Delta}\right)^{|E(\gamma)|}(-1)^{|\gamma|}w(\gamma)$ is in fact the volume of a polytope with variables $\{x_e\}$ for each $e \in E(\gamma)$, and constraints $\overline{C_v}$ for each $v \in \gamma$ and $0 \le x_e \le \frac{1+\delta}{\Delta}$ for each $e \in E(\gamma)$. This polytope has at most $\binom{|E(\gamma)|+|\gamma|}{|E(\gamma)|} = \binom{|E(\gamma)|+|\gamma|}{|\gamma|} = O((e(\Delta+1))^{|\gamma|})$ vertices, as $|E(\gamma)| \le \Delta|\gamma|$. Using the polytope volume algorithm by Lawrence [18] or by Barvinok [5], we can thus compute $w(\gamma)$ in $O(e^{C|\gamma|})$ time for some constant C that depends on Δ. ◀

▶ Remark 12. The bit complexity of the volume of a polytope can be exponential in the size of the polytope. Recall the algorithm (described after Proposition 8) of [16]. The polytopes for which we apply the algorithm of [18] or [5] essentially have size $O(\log n)$. Thus the bit complexity of their volumes is at most a polynomial in n.

Moreover, Lawrence's algorithm [18] is only stated for simple polytopes. To get around this issue, one may employ a small perturbation, such as the one from [19], to make the polytope simple. Doing so incurs an exponentially small additive error on the volume. On the other hand, Barvinok's algorithm [5] does not require simple polytopes, but it also incurs exponentially small additive errors. It is easy to observe that, as these volumes are in the exponent of the final estimate, small additive errors translate to small multiplicative errors in the end. Thus, for input error tolerance ε, we can set $\varepsilon' = \varepsilon/2$ in the algorithm of [16] to accommodate the extra small error in volume computation.

3 Hypergraph Matching Polytope

Now we turn our attention to the hypergraph case and show Theorem 4. Let $H = (V, E)$ be a hypergraph. We will assume throughout this section that, for some constants $\Delta, k \ge 2$, vertices of H have maximum degree Δ, and hyperedges of H have maximum size k. Recall that the fractional hypergraph matching polytope is defined in (2), and the truncated version $P_{H,\delta}$ is defined by intersecting P_H with ${M_\delta}^E$.

Our δ will satisfy that $\delta < \frac{1}{\Delta-1}$, in which case, if the degree of some v is at most $\Delta - 1$, the corresponding constraint is always satisfied. Thus, we may assume that $\deg_H(v) = \Delta$ for all $v \in V$.

Let $\mathrm{Flat}(H)$ be the flattened graph of H, namely its vertex set is still V, and for $u, v \in V$, u and v are adjacent if they appear in the same hyperedge e for some $e \in E$. In other words, we replace each hyperedge e by a clique on the vertex set of e. Notice that the maximum degree of $\mathrm{Flat}(H)$ is at most $\Delta(k-1)$. Similar to (5), we have

$$\mathrm{Vol}(P_{H,\delta}) = \sum_{S \subseteq V} \int_{{M_\delta}^{E \setminus E(S)}} 1 d\mu \left(\prod_{K \in \mathcal{K}(S)} (-1)^{|K|} \int_{{M_\delta}^{E(K)}} \prod_{v \in K} \mathbb{1}_{\overline{C_v}} d\mu \right), \tag{11}$$

where $\mathcal{K}(S)$ denote the connected components of the induced subgraph $\mathrm{Flat}(H)[S]$. Thus, we have a similar polymer model partition function

$$\Xi(H) = \frac{\mathrm{Vol}(P_{H,\delta})}{\left(\frac{1+\delta}{\Delta}\right)^{|E|}} = \sum_{S \subseteq V} \prod_{K \in \mathcal{K}(S)} w_H(K), \tag{12}$$

where

$$w_H(K) = \left(\frac{1+\delta}{\Delta}\right)^{-|E(K)|} (-1)^{|K|} \int_{M_\delta{}^{E(K)}} \prod_{v\in K} \mathbb{1}_{\overline{C_v}} d\mu. \tag{13}$$

While (12) and (13) look identical to (6) and (7), the underlying graph is different and consequently Lemma 10 no longer applies. We may view this as a polymer model over $\mathrm{Flat}(H)$, by treating connected induced subgraphs of $\mathrm{Flat}(H)$ as polymers.

Directly applying the method of Lemma 10 would yield

$$|w_H(\gamma)| < (e\delta)^{\frac{|\gamma|}{k-1}}.$$

This bound can only validate the Kotecký-Preiss criterion up to $\delta = \Theta\left(\frac{1}{\Delta k}\right)^{k-1}$. To get a better bound, we need a different polymer model.

3.1 A Different Polymer Model

Let $\mathrm{Inc}(H)$ be the incidence graph of H, where the vertex set is $V \cup E$, and for $v \in V$ and $e \in E$, $v \sim e$ in $\mathrm{Inc}(H)$ if $v \in e$ in H. Then, $\mathrm{Inc}(H)$ is a bipartite graph, and $\mathrm{Flat}(H)$ is exactly $\mathrm{Inc}(H)$ projected on the V side. For each subset $S \subset V$ of vertices, let $\partial_{\mathrm{Inc}(H)} S$ be the neighbours of S in $\mathrm{Inc}(H)$. Note that $\partial_{\mathrm{Inc}(H)} S = E(S)$, namely the set of hyperedges that contain at least one vertex in S.

We rewrite (12) into a different polymer model. For a connected induced subgraph K of $\mathrm{Flat}(H)$, we map it to a *minimal connected subgraph* (MCS) T as follows. Fix an arbitrary ordering of V. We consider vertices of K in order one at a time, to potentially add them to T. Initialise T to be the first vertex of K and remove it from K. Given the current T, we find the first vertex u in K that is adjacent to the current T in $\mathrm{Flat}(H)$. Add u to T if $E(v_i) \not\subseteq E(T)$. In other words, we only add v_i if it introduces a new hyperedge to $E(T)$. Whether u is added to T or not, we remove u from K. We keep doing this until K is empty. Denote this mapping by φ. We also extend the mapping to any (not necessarily connected) subset $S \subseteq V$ by defining $\varphi(S) = \emptyset$ if $\mathrm{Flat}(H)[S]$ is not connected. We call a non-empty image T of φ an MCS, namely, T is an MCS if there is a connected $K \subseteq V$ such that $\varphi(K) = T$. Equivalently, a connected T is an MCS if and only if $\varphi(T) = T$.

▶ **Lemma 13.** *Let T be an MCS. Then,*
1. $|E(T)| \geq |T|$*;*
2. T *is connected in* $\mathrm{Flat}(H)$*.*

Proof. Both claims are straightforward by an induction on the number of vertices of T. ◀

While an MCS is connected in $\mathrm{Flat}(H)$, it is not necessarily a tree. Indeed, an MCS is determined by $\mathrm{Inc}(H)$ and not by $\mathrm{Flat}(H)$ alone.

Our new model have MCSes as polymers. As before two MCSes are incompatible if their distance is at most 1. For this model, define a new weight function

$$u(T) := \sum_{K:\varphi(K)=T} w_H(K).$$

We rewrite (12) as

$$\Xi(H) = \sum_F \prod_{T\in\mathcal{K}(F)} u(F), \tag{14}$$

where the sum is over $F \subseteq V$ whose every component is an MCS.

For an MCS T, a vertex $v \in V \setminus T$ is said to be *broken* if $\varphi(T \cup \{v\}) = T$. Let $B(T)$ be the set of broken vertices with respect to T. This notion is a hypergraph generalisation of the well-known broken circuit theory for graphs [23, 21].

▶ **Lemma 14.** *For $K \subseteq V$, $\varphi(K) = T$ if and only if $T \subseteq K \subseteq (T \cup B(T))$.*

Proof. If $\varphi(K) = T$, the inclusion $T \subseteq K$ follows directly from the definition of φ. For the other inclusion, we induct on the size of K. If $K = T$, the claim holds trivially. For the inductive step, let $v \in K \setminus T$ be the first vertex that is not added to T during φ. Then, clearly $\varphi(K \setminus \{v\}) = T$, and thus by the induction hypothesis $K \setminus \{v\} \subseteq (T \cup B(T))$. We claim that $v \in B(T)$ as well. This is because the mapping $\varphi(T \cup \{v\})$ would behave the same as $\varphi(K)$ until v is considered (and then dropped), as before v all vertices considered in $\varphi(K)$ are added to T. As v is dropped next, the rest of the process $\varphi(T \cup \{v\})$ just processes vertices of T and add them. It implies that $\varphi(T \cup \{v\}) = T$, and thus $v \in B(T)$. This finishes the inductive step and shows that $K \subseteq (T \cup B(T))$.

For the other direction, suppose $T \subseteq K \subseteq (T \cup B(T))$. We also do an induction on $|K|$. The base case of $K = T$ is trivial. For the inductive step, consider the first $v \in K \setminus T$ that is processed during $\varphi(K)$. Note that up to v all processed vertices are in T, and the process is identical to the process of $\varphi(T \cup \{v\})$ up to this point. Thus, v would be discarded then. The rest of $\varphi(K)$ is identical to $\varphi(K \setminus \{v\})$, and by the induction hypothesis, $\varphi(K \setminus \{v\}) = T$. Thus, $\varphi(K) = T$. ◀

Notice that if $\varphi(K) = T$, $E(K) = E(T)$. We then have a better expression for $u(T)$ as follows,

$$u(T) = \sum_{K:\varphi(K)=T} w_H(K) = \sum_{K:\varphi(K)=T} \left(\frac{1+\delta}{\Delta}\right)^{-|E(T)|} (-1)^{|K|} \int_{{M_\delta}^{E(K)}} \prod_{v\in K} \mathbb{1}_{\overline{C_v}} d\mu \qquad \text{(by (13))}$$

$$= \left(\frac{1+\delta}{\Delta}\right)^{-|E(T)|} \sum_{K:T\subseteq K\subseteq T\cup B(T)} (-1)^{|K|} \int_{{M_\delta}^{E(T)}} \prod_{v\in K} \mathbb{1}_{\overline{C_v}} d\mu \qquad \text{(by Lemma 14)}$$

$$= \left(\frac{1+\delta}{\Delta}\right)^{-|E(T)|} (-1)^{|T|} \sum_{A\subseteq B(T)} \int_{{M_\delta}^{E(T)}} \prod_{v\in T} \mathbb{1}_{\overline{C_v}} \prod_{v\in A} -\mathbb{1}_{\overline{C_v}} d\mu$$

$$= \left(\frac{1+\delta}{\Delta}\right)^{-|E(T)|} (-1)^{|T|} \int_{{M_\delta}^{E(T)}} \prod_{v\in T} \mathbb{1}_{\overline{C_v}} \prod_{v\in B(T)} \left(1 - \mathbb{1}_{\overline{C_v}}\right) d\mu$$

$$= \left(\frac{1+\delta}{\Delta}\right)^{-|E(T)|} (-1)^{|T|} \int_{{M_\delta}^{E(T)}} \prod_{v\in T} \mathbb{1}_{\overline{C_v}} \prod_{v\in B(T)} \mathbb{1}_{C_v} d\mu. \qquad (15)$$

Next we give an upper bound for $|u(T)|$.

▶ **Lemma 15.** *Let T be a MCS of size ℓ. For $\delta < \frac{1}{\Delta}$,*

$$|u(T)| \leq (\Delta\delta)^\ell \left(\frac{e}{\Delta}\right)^{\frac{\ell}{k-1}}.$$

Proof. By (15),

$$|u(T)| \leq \left(\frac{1+\delta}{\Delta}\right)^{-|E(T)|} \int_{{M_\delta}^{E(T)}} \prod_{v\in T} \mathbb{1}_{\overline{C_v}} d\mu.$$

Thus,

$$|u(T)| \leq \Pr\left[\bigwedge_{v\in T} \overline{C_v}\right],$$

where the probability is over the product distribution of x_e's for $e \in E(T)$, and each x_e is uniform over $\left[0, \frac{1+\delta}{\Delta}\right]$. Notice that $\overline{C_v}$ means $\sum_{e\sim v} x_e > 1$, which is equivalent to $\sum_{e\sim v} y_e < \delta$ where $y_e = \frac{1+\delta}{\Delta} - x_e$. As $y_e \geq 0$, this implies that $y_e < \delta$ for all $e \sim v$. Since $T \cup E(T)$ is connected in $\mathrm{Inc}(H)$, if $\prod_{v\in T} \mathbb{1}_{\overline{C_v}} = 1$, then for all $e \in E(T)$, $y_e < \delta$.

Moreover, for a maximal independent set I_T of T (in $\mathrm{Flat}(H)$), we have that $|I_T| \geq \frac{|T|}{\Delta(k-1)}$, as the maximum degree of $\mathrm{Flat}(H)$ is $\Delta(k-1)$. Note that for $v \in I_T$, the constraints C_v are independent from each other. Then we have

$$\begin{aligned}
\Pr\left[\bigwedge_{v\in T} \overline{C_v}\right] &\leq \Pr\left[\bigwedge_{v\in I_T} \overline{C_v} \wedge \bigwedge_{e\in E(T)\setminus E(I_T)} y_e < \delta\right] \\
&= \prod_{v\in I_T} \Pr\left[\,\overline{C_v}\,\right] \prod_{e\in E(T)\setminus E(I_T)} \Pr\left[y_e < \delta\right] \\
&= \left(\frac{1+\delta}{\Delta}\right)^{-|E(T)|} \delta^{|E(T)|-|E(I_T)|} \left(\frac{\delta^\Delta}{\Delta!}\right)^{|I_T|},
\end{aligned}$$

where we use the fact that the volume of a standard simplex of dimension Δ is $\frac{1}{\Delta!}$. (Recall that we can assume that all vertices have degree Δ, as vertices of smaller degrees correspond to a constraint that trivially holds.) As I_T is an independent set, $|E(I_T)| = \Delta\,|I_T|$. Together with $\Delta! \geq \left(\frac{\Delta}{e}\right)^\Delta$ and $|I_T| \geq \frac{|T|}{\Delta(k-1)}$, we have

$$\Pr\left[\bigwedge_{v\in T} \overline{C_v}\right] \leq (\Delta\delta)^{|E(T)|} \left(\left(\frac{e}{\Delta}\right)^\Delta\right)^{\frac{|T|}{\Delta(k-1)}}.$$

As T is a MCS, by Lemma 13, $|E(T)| = \left|\partial_{\mathrm{Inc}(H)} T\right| \geq |T| = \ell$. Then, as $\delta\Delta < 1$,

$$|u(T)| \leq (\Delta\delta)^\ell \left(\frac{e}{\Delta}\right)^{\frac{\ell}{k-1}}. \qquad \blacktriangleleft$$

Given Lemma 15, the verification of the Kotecký-Preiss criterion (4) is very similar to previous arguments.

▶ **Lemma 16.** *For hypergraphs of maximum degree $\Delta \geq 2$ and maximum hyperedge size $k \geq 2$, $\delta \leq \left(e^4 \Delta^{\frac{2k-3}{k-1}} (k-1)\right)^{-1}$, and sufficiently small ρ, the Kotecký-Preiss criterion (4) holds for MCSes and $u(\cdot)$.*

Proof. Let T be a MCS. Any MCS incompatible with T must contain at least a vertex of T or a neighbour of T in $\mathrm{Flat}(H)$. By Lemma 13, every MCS is a connected subgraph in $\mathrm{Flat}(H)$. For any $v \in T \cup \partial_{\mathrm{Flat}(H)} T$, by Lemma 9, the number of MCSes of size ℓ that contains v is at most $(e\Delta(k-1))^{\ell-1}$. As $\left|T \cup \partial_{\mathrm{Flat}(H)} T\right| \leq (\Delta(k-1)+1)\,|T|$, the number of MCSes of size ℓ and incompatible with T is at most $(\Delta(k-1)+1)\,|T|\,(e\Delta(k-1))^{\ell-1}$. Using this bound, for $\Delta \geq 2$, $k \geq 2$, and sufficiently small constant ρ,

$$\begin{aligned}\sum_{T' \not\sim T} |w(T')|\, e^{|T'|+g(T')} &\le (\Delta(k-1)+1)\,|T| \sum_{\ell \ge 1} (e\Delta(k-1))^{\ell-1} (\Delta\delta)^{\ell} \left(\frac{e}{\Delta}\right)^{\frac{\ell}{k-1}} e^{(1+\rho)\ell} \\ &= \frac{\Delta(k-1)+1}{e\Delta(k-1)}\,|T| \sum_{\ell \ge 1} \left(e^{2+\frac{1}{k-1}+\rho} \delta \Delta^{\frac{2k-3}{k-1}} (k-1)\right)^{\ell} \\ &\le \frac{1.5}{e}\,|T| \sum_{\ell \ge 1} \left(e^{\rho-1}\right)^{\ell} \\ &\le \left(\frac{1.5}{e} \cdot \frac{e^{\rho-1}}{1-e^{\rho-1}}\right) |T| < |T|\,. \end{aligned}$$

◀

3.2 Proof of Theorem 4

With the KP criterion verified, we can prove Theorem 4 now.

Proof of Theorem 4. We apply Proposition 8 on $\mathrm{Flat}(H)$. For a polymer (MCS) T, let $g(T) = \rho\,|T|$ for a sufficiently small constant T, which then satisfies Item (2). Item (3) follows from Lemma 16. For Item (1), computing $g(T)$ is trivial. To determine if T is a polymer is trivial, we just check if $\varphi(T) = T$. This takes time linear in $|T|$.

For computing $u(T)$, we use the expression (15). The integral in (15) is the volume of a polytope defined by the constraints $\overline{C_v}$ for $v \in T$, C_v for $v \in B(T)$, and $0 \le x_e \le \frac{1+\delta}{\Delta}$ for $e \in E(T)$. To find the defining constraints of this polytope, we need to compute $B(T)$. Note that by definition, $v \in B(T)$ only if $T \cup \{v\}$ is connected, which implies that $B(T) \subseteq \partial_{\mathrm{Flat}(H)} T$. Then we just need to go through every $v \in \partial_{\mathrm{Flat}(H)} T$ and check if $\varphi(T \cup \{v\}) = T$. As $\left|\partial_{\mathrm{Flat}(H)} T\right| \le \Delta(k-1)\,|T|$, this takes at most $O(|T|^2)$ time.

There are $|T| + |B(T)| + |E(T)|$ constraints and $|E(T)|$ variables. Note that $|B(T)| \le \left|\partial_{\mathrm{Flat}(H)} T\right| \le \Delta(k-1)\,|T|$. Recall that $|E(T)| \le \Delta\,|T|$ and by Lemma 13, $|E(T)| \ge |T|$. Thus, the number of vertices of this polytope is at most

$$\begin{aligned}\binom{|T|+|B(T)|+|E(T)|}{|E(T)|} &\le \left(\frac{e(|T|+|B(T)|+|E(T)|)}{|E(T)|}\right)^{|E(T)|} \\ &\le (e\Delta k + e)^{\Delta|T|}.\end{aligned}$$

Using the polytope volume algorithm by Lawrence [18] or by Barvinok [5], we can compute $u(T)$ in $O(e^{C|\gamma|})$ time for some constant C that depends on Δ and k. This verifies Item (1) of Proposition 8 and finishes the proof. ◀

Regarding the applicability of [18] and [5], see Remark 12.

4 Concluding Remarks

Our work leaves open the question of whether, under the setting of Theorem 4, an FPTAS exists for $\delta = \frac{C}{\Delta k}$ for some constant $C > 0$. The most straightforward potential approach to this bound is to strengthen the bound in Lemma 15 to $(C\delta)^{|T|}$. However, this strengthening does not appear to hold, at least for some parameters k and Δ, when $\delta = \frac{C}{\Delta k}$. To see this, consider $T = \{v_1, \ldots, v_k\}$ of size k. Let the hyperedges $e_1 = \cdots = e_{\Delta-1} = T$. Moreover, for each $i \in [k]$, introduce f_i such that $v_i \in f_i$ but $v_j \notin f_i$ for any $j \ne i$. Namely, each f_i contains only v_i from T (and possibly other vertices from outside of T). Note that T is an MCS and let $B(T) = \emptyset$. Then, $|T| = k$ and $|E(T)| = \Delta - 1 + k$. We have

$$\begin{aligned}\int_{M_\delta{}^{E(T)}} \prod_{v\in T} \mathbb{1}_{\overline{C_v}} d\mu &= \sum_{i=1}^{k} \int_{M_\delta{}^{E(T)}} \mathbb{1}_{\overline{C_{v_i}}} \prod_{j=1}^{k} \mathbb{1}_{x_{f_j}\geq x_{f_i}} d\mu \\ &= \sum_{i=1}^{k} \int_{M_\delta{}^{E(T)}} \mathbb{1}_{\sum_{t=1}^{\Delta-1} y_{e_t}\leq \delta - y_{f_i}} \prod_{j=1}^{k} \mathbb{1}_{y_{f_j}\leq y_{f_i}} d\mu \\ &= \sum_{i=1}^{k} \int_0^\delta \frac{(\delta - y_{f_i})^{\Delta-1} y_{f_i}^{k-1}}{(\Delta-1)!} dy_{f_i} \\ &= \frac{k!\delta^{\Delta-1+k}}{(\Delta-1+k)!},\end{aligned}$$

where we substitute $y_e = \frac{1+\delta}{\Delta} - x_e$ for all $e \in \{e_1, \ldots, e_{\Delta-1}, f_1, \ldots, f_k\}$. Then,

$$\begin{aligned}|u(T)| &= \left(\frac{1+\delta}{\Delta}\right)^{-(\Delta-1+k)} \frac{k!\delta^{\Delta-1+k}}{(\Delta-1+k)!} \\ &\geq \left(\frac{1+\delta}{\Delta}\right)^{-(\Delta-1+k)} \frac{\delta^{\Delta-1+k}}{(\Delta-1+k)^{\Delta-1}} \\ &= (1+\delta)^{-(\Delta-1+k)} \left(\frac{\Delta\delta}{\Delta-1+k}\right)^{\Delta-1} (\Delta\delta)^k.\end{aligned}$$

Plug in $\delta = \frac{C}{\Delta k}$ and let $k \geq \Delta$ such that $\frac{k}{\log k} \gg \frac{\Delta}{\log \Delta}$ (for example $k = \Delta^2$). Then,

$$\begin{aligned}\frac{|u(T)|}{\delta^k} &\geq C_0 \left(\frac{C}{2k^2}\right)^{\Delta-1} \Delta^k \\ &\geq C_1^k = C_1^{|T|},\end{aligned}$$

for some constant $C_0 > 0$ and any constant $C_1 > 0$ when $\Delta \to \infty$. Thus, to achieve an FPTAS for $\delta = \frac{C}{\Delta k}$, some new ideas are required.

Abstract

While graphs and abstract data structures can be large and complex, practical instances are often regular or highly structured. If the instance has sufficient structure, we might hope to compress the object into a more succinct representation. An efficient algorithm (with respect to the compressed input size) could then lead to more efficient computations than algorithms taking the explicit, uncompressed object as input. This leads to a natural question: when does knowing the input instance has a more succinct representation make computation easier?

We initiate the study of the computational complexity of problems on factored graphs: graphs that are given as a formula of products and unions on smaller graphs. For any graph problem, we define a parameterized version that takes factored graphs as input, parameterized by the number of (smaller) ordinary graphs used to construct the factored graph. In this setting, we characterize the parameterized complexity of several natural graph problems, exhibiting a variety of complexities. We show that a decision version of lexicographically first maximal independent set is **XP**-complete, and therefore *unconditionally* not fixed-parameter tractable (**FPT**). On the other hand, we show that clique counting is **FPT**. Finally, we show that reachability is **XNL**-complete. Moreover, **XNL** is contained in **FPT** if and only if **NL** is contained in some fixed polynomial time.

1 Introduction

Traditionally, algorithm design and computational complexity both measure computational time as a function of the input size. Thus, the complexity of computational problems is crucially sensitive to the way the instances are represented as bit sequences. While graphs and abstract data structures can be complex and expressive in the worst case, practical instances

are often highly structured or regular. For example, road networks are often organized into repetitive grid patterns. Similarly, in databases, relations frequently inherit underlying structures from previous relations through operations like joins. In molecular geometry, compounds such as graphite are composed of layers of graphene, with each layer forming a regular honeycomb structure. If the input instance has sufficiently regular structure, we might hope to compress the object into a more succinct representation.

An algorithm that is efficient with respect to the size of the succinct encodings would then be able to compute the desired result more efficiently than an algorithm that takes a naive representation of the input. This raises the question: when does knowing that the input instance was created in a uniform way (or has a succinct representation) make computation easier?

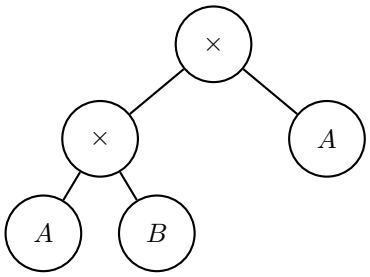
To address this question, various formulations of "succinct representation" have been explored. For example, one such formulation is given by a Boolean circuit that can produce any particular input bit [35, 61]. Frequently, the complexity of problems given in this type of succinct format is exponentially more difficult than when the input is given explicitly (see e.g. [35, 31, 49, 48]). However, it's important to note that the difficulty only increases as a function of the smaller size parameter, and the actual problem has not necessarily become more difficult.

Another type of succinct representation, factored instances, was introduced by [21]. While they give a number of specific problems rather than introduce the concept abstractly, we can generalize by thinking of a fixed set of operations that take pairs of instances to possibly larger instances. For example, one natural operation might be set sum, taking two sets of integers A, B to the set of all sums $A + B = \{a + b \mid a \in A, b \in B\}$. Instead of being described directly, the input to a factored problem is given as this operation applied to a pair of possibly smaller instances. If these operations can be computed in polynomial time, the size of the output might be polynomially larger than the input, so this representation might be considerably smaller than the original. For each such set of operations and problem on instances, we can define a parameterized version of the problem on factored instances, where the input is represented as a formula in these (binary) operations over smaller instances, with the parameter k being the number of smaller instances. If the underlying problem is polynomial time solvable, then for fixed k, the problem remains polynomial time solvable, but with an exponent that potentially grows with k. How the compressed representation affects the difficulty of the problems can be formalized in terms of the complexity of such factored problems from the point of view of parameterized complexity. In this paper, we consider such parameterized factored problems for graphs, using standard graph products and union as our operations.

To make this precise, we first review some standard concepts from parameterized complexity. The gold standard for tractability in parameterized complexity is membership in the class of fixed-parameter tractable (**FPT**) problems [25]. Roughly speaking, a factored problem will be fixed-parameter tractable (i.e. in **FPT**) if on an instance composed using k smaller instances of size at most n, there is an algorithm computing the function in $O(f(k)n^C)$ time for some fixed function f and absolute constant C independent of k. In these settings, we think of n as large and k as small, so that any dependence on k alone is preferable over an exponent of n that grows with k. A natural approach to solving problems on factored graphs is to explicitly compute the graph, requiring time and space $n^{O(k)}$, and solving the problem on the explicit graph. Such an algorithm has an exponent growing with k. Thus such factored problems will always be in **XP**[1], the class of problems that are polynomial for

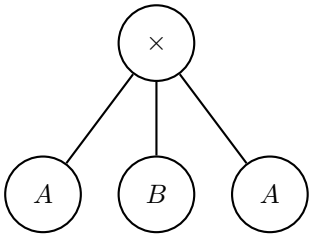
[1] assuming the problem can be solved in polynomial time on the explicit graph

any particular k, but not necessarily in **FPT**. Even for simple problems with linear time algorithms (on explicit graphs), computing an explicit representation already requires $n^{O(k)}$ time and so this approach does not put the problem in **FPT**.



In this work, we initiate the study of the complexity of computational problems on factored graphs. In particular, we consider the question: for a given computational problem, is there an algorithm substantially better than first explicitly computing the factored graph G? This can be formalized as: is the problem in **FPT**, and, if not, how does the best exponent of n possible depend on k?

1.1 Definition of Factored Graphs



We consider a highly natural class of factored problems where the instances are graphs, and the operations are well-studied graph products and unions. Our factored graphs consist of arbitrary combinations of graphs under the following (binary) operations. Unless otherwise stated, all graphs are directed and (a, b) denotes an edge from a to b.

1. **Cartesian Product.** Given A, B, the Cartesian product $A \square B$ has vertices (a, b) for $a \in A, b \in B$ and there is an edge from (a, b) to (c, d) if either 1) $a = c$ and $(b, d) \in E(B)$, or 2) $(a, c) \in E(A)$ and $b = d$.
2. **Tensor Product.** Given A, B, the tensor product $A \times B$ has vertices (a, b) for $a \in A, b \in B$ and there is an edge from (a, b) to (c, d) if $(a, c) \in E(A)$ and $(b, d) \in E(B)$.
3. **Union.** Given A, B, the union $A \cup B$ has vertices $x \in V(A) \cup V(B)$ and there is an edge from x to y if $(x, y) \in E(A) \cup E(B)$.

A factored graph G can be defined by an ordered tree $T(G)$, where internal nodes are labelled by one of the above three operations $\square, \times, \cup$ and leaves are labelled with (possibly identical) input graphs. Since each operation is associative, we in fact allow the internal nodes to have arbitrary degree.[2] We say that a factored graph $G = f(G_1, \ldots, G_k)$ is *of complexity* (n, k) if the tree has k leaves and each input graph has at most n vertices. Here, we stress that the we parameterize by the number of leaves in $T(G)$, regardless of the fan-in of specific internal nodes or if a certain input graph appears in multiple leaf nodes. As an example, both $(A \times B) \times A$ and $A \times B \times A$ are factored graphs of complexity $(n, 3)$, where $n = \max(|V(A)|, |V(B)|)$. We illustrate their tree structures in Figure 1.

Tree structure of $(A \times B) \times A$.

Tree structure of $A \times B \times A$.

Figure 1 Tree structures of factored graphs $(A \times B) \times A$ and $A \times B \times A$. Both factored graphs have complexity $(n, 3)$ where $n = \max(|V(A)|, |V(B)|)$. Note that in this example the two factored graphs are in fact isomorphic.

[2] We require each internal node to have degree greater than 1, as otherwise the operation is the identity.

As another example, any graph G can be represented by a factored graph of complexity $(2, |E(G)|)$ by taking a union over all edges of the graph.

We define a *factored component* of G, denoted G_F, as follows. G_F is defined by an ordered tree $T(G_F)$, which is obtained from $T(G)$ by deleting every internal node v labeled by $\cup$ and attaching exactly one child of v to its parent. Another way to understand this is that, since the union and product operations obey the distributive law, we can recursively apply this law to convert a factored graph formula into a union of products. Then, each of these product terms is a factored component. The vertices of G_F are k_F-tuples (note $k_F \leq k$, where k_F is the number of leaves of $T(G_F)$ and k is the number of leaves of $T(G)$). We emphasize that the vertices are *flattened* tuples and do not preserve the topology of $T(G_F)$ beyond the order of the leaves. We call k_F the *dimension* of the factored component G_F. The edges of G_F are determined by $T(G_F)$ according to the definition of the graph operations $\square$ and $\times$.

The vertex and edge sets of G are then given by the union of the vertex and edge sets of the factored components. While a vertex may belong to multiple factored components, they must all have the same dimension, allowing us to define the dimension of a vertex (Definition 14). We also observe that G has at most 2^k factored components. We give a more formal definition of factored graphs as well as simple examples in Section 2.

1.2 Our Contributions

Our first result provides an *unconditional* hardness for a natural parameterized version of the well-studied Lexicographically First Maximal Independent Set (LFMIS) problem. The standard decision version of the LFMIS problem takes as input a graph $G = (V(G), E(G))$, where the vertices are indexed as $V(G) = \{0, 1, \ldots, |V(G)|-1\}$, and a special vertex $s \in V(G)$. The problem asks whether s belongs to the LFMIS of G. In the parameterized version, the input is given as a factored graph $G = f(G_1, \ldots, G_k)$ and the vertex indices are provided only for each graph factor $V(G_i) = \{0, 1, \ldots, |V(G_i)| - 1\}$. To recover the indices for $V(G)$, recall that each vertex in the factored graph G is a flattened tuple of numbers $(v_1, \ldots, v_{k'})$ for some $k' \leq k$, and therefore, we define the vertex indices to be given according to the standard lexicographic order of these tuples, with the index 0 given to the vertex with the lowest lexicographic order. In this work, we show that the LFMIS problem on factored graphs is **XP**-complete under **FPT**-reductions[3] and therefore *unconditionally* not in **FPT**, providing a lower bound on the best possible exponent as a function of k. LFMIS is a natural **P**-complete problem [18], studied by [58, 59, 60] including in the parallel setting [20, 50, 12, 8]. We use the **P**-completeness of this problem as an intuition for why the factored version might be difficult (**XP**-complete), but we know of no direct connection between **P**-completeness and hardness of the factored version.

▶ **Theorem 1** (**XP**-completeness of LFMIS). *The LFMIS problem on factored graphs is* **XP***-complete under* **FPT***-reductions and not fixed-parameter tractable. In particular, the LFMIS problem on a factored graph $G = f(G_1, \ldots, G_k)$ of complexity (n, k) requires $n^{\Omega(\sqrt{k})}$ time.*

While many works in parameterized complexity gave *conditional* lower bounds against problems in **FPT** [25], for example completeness for the **W**-hierarchy [25, 26, 28] or the **A**-hierarchy [32], *unconditional* lower bounds against natural problems in **FPT** are relatively rare [27]. Moreover, although it is known that **FPT** $\subsetneq$ **XP** via a diagonalization argument,

[3] See Definition 9.3 [27]. Also formally stated in Definition 20 in the context of factored graph problems.

the literature on **XP**-complete problems remains sparse. The "pebble game" problem was first introduced by Kasai, Adachi, and Iwata [45]. Its parameterized version, the "k-pebble game", was one of the earliest natural combinatorial problems shown to require $\Omega(n^k)$ time and be **XP**-complete [1]. As an application of the k-pebble game, some other game problems, such as the "cat and mouse game" [13] and the "k-peg game", have also been proven to be **XP**-complete via reductions from the k-pebble game problem [1]. More recently, Berkholz established an unconditional lower bound of $O(n^{(k-3)/12})$-time for the existential k-pebble game [6]. Our result provides yet another natural example of an **XP**-complete problem with an explicit lower bound of $n^{\Omega(\sqrt{k})}$.

In contrast to the LFMIS problem on factored graphs, we show that the well-studied problem of clique counting [51] is in **FPT**, solvable in a fixed polynomial of the input graph sizes (where the exponent possibly depends on the size of the clique of interest) times some function on the number of input graphs. Subgraph counting (in particular clique counting) has been studied by a long line of works [51, 16, 11, 42] in a variety of computational models [21, 24, 2, 56, 39]. On graphs with n vertices, s-cliques can be counted in $O(n^s)$ time (and $n^{\Omega(s)}$ time is necessary under standard hardness assumptions). We show that counting s-cliques on factored graphs of complexity (n, k) is in $O(g(s, k)n^s)$ time for some fixed (large) function g. Note that we do not show clique counting is in **FPT** with respect to the clique size parameter s, but only with respect to the complexity of the factored graph k.

▶ **Theorem 2** (Counting Clique Subgraphs is in **FPT**). *Let H be a clique on s vertices. Then, computing the number of exact copies of H in G, denoted $\#\mathbf{H}(G)$, is fixed-parameter tractable. In particular, there is an algorithm computing $\#\mathbf{H}(G)$ on factored graphs G of complexity (n, k) in $O\left(g(s, k)n^s\right)$ time for some function $g(s, k)$.*

Finally, we turn to the problem of reachability, one of the most fundamental computational problems on graphs. On an explicit graph, algorithms such as depth-first search (DFS) and breadth-first search (BFS) compute reachability in linear time. This raises the question: can reachability on factored graphs be computed efficiently? Moreover, reachability is closely related to classic space complexity classes. The general reachability problem is an important **NL**-complete problem [57, 43]; meanwhile, Cook and Mckenzie showed that reachability on a directed acyclic graph of outdegree at most one is **L**-complete [19]. This naturally gives rise to another question: does the completeness of reachability for a classic complexity class extend to its parameterized counterpart when the inputs are given as factored graphs, similar to what we have seen in the case of LFMIS in Theorem 1?

Indeed, we show that the parameterized version of reachability on factored graphs is **XNL**-complete under **FPT**-reductions, where **XNL** is the class of parameterized problems solvable in nondeterministic logarithmic space for any fixed parameter k. On the other hand, while we cannot provide a definitive answer to whether reachability on factored graphs is in **FPT**, we show that answering this question would exactly resolve a major open problem in classical complexity theory. Specifically, we establish a parameterized analog of the well-known open problem that asks whether $\mathbf{NL} \subseteq \mathbf{DTIME}(n^C)$ for some fixed constant C.

▶ **Theorem 3** (**XNL**-completeness of Reachability). *Reachability on factored graphs is* **XNL***-complete under* **FPT***-reductions. Furthermore, the following are equivalent:*

1. *There is a constant C such that $\mathbf{NL} \subseteq \mathbf{DTIME}(n^C)$.*
2. $\mathbf{XNL} \subseteq \mathbf{FPT}$.

This result also has several further implications. First, we observe that if reachability is not in **FPT**, $\mathbf{NSPACE}(h(n)) \not\subseteq \mathbf{P}$ for any space-constructible $h(n) = \omega(\log n)$. On the other hand, if reachability is in **FPT** then the Exponential Time Hypothesis (ETH) is false.

In particular, we claim that since k-SUM (determining if in a set of n numbers of $O(k \log n)$ bits there is a subset of k numbers summing to zero) is in **NL**, then k-SUM can be solved in $O\left(n^C\right) = n^{o(k)}$ time, and therefore ETH is false [55].[4] Finally, by combining the above implications, one can also conclude that if ETH is true, then $\mathbf{NSPACE}(\omega(\log n)) \subsetneq \mathbf{P}$, a result that, to the best of our knowledge, has not been previously established.

Parameterized space complexity classes, including **XL** and **XNL**, have also been studied extensively in the literature [10, 17, 33, 29]. Chen, Flum, and Grohe introduced the first complete problems for **XL** and **XNL** under parameterized-logspace-reductions[5] [17]. In a related direction, [9] identified a wide variety of problems complete for the class **XNLP**, which is the class of parameterized problems solvable in nondeterministic logarithmic space *and* polynomial time for each parameter. Most relevant to our result, Elberfeld, Stockhusen, and Tantau also showed that a parameterized version of reachability with multi-colored edges is complete for the class parameterized-**NL**-cert under **PL**-reductions [29].

1.3 Related Work

A long line of work, initiated by [25, 26, 28, 32], has studied the complexity of parameterized problems as a function of their input size and a parameter. Within parameterized complexity, a common theme is to study the complexity of problems given succinct representations of their input. For example, several previous works have investigated the complexity of computing Nash equilibrium of *succinct* games (represented implicitly) [31, 23, 22, 34, 53, 36]. As another example, [62] considers the complexity of combinatorial problems with succinct representation. Similarly, [52, 63, 40, 41, 49, 48, 14, 15] study the complexity of various computational problems on periodic structures, i.e., travel schedules on a periodic timetable.

Most relevant to this paper, several works have investigated computational problems on graphs with succinct representations such as small circuits [35], distributed graphs described by low complexity agents [4], and factored problems [21]. However, none of these works consider the complexity of factored graphs formed under graph products.

On the subject of succinct representations, researchers have also studied how to represent graphs as efficiently as possible [44, 38, 5, 30, 7, 47, 54].

2 Preliminaries

Unless otherwise noted, we work with directed graphs, with edges from a to b denoted by (a, b). For a graph G, we denote its vertices by $V(G)$ and edges by $E(G)$. For any subset of vertices $S \subset V(G)$, let $G[S]$ denote the subgraph induced by S. For a set X, we define $\mathcal{P}(X) = \{Y : Y \subseteq X\}$ to be the power set of X.

2.1 Graph Products

We begin with the definitions of the relevant graph operations. Let G and H be two directed graphs.

▶ **Definition 4.** *The* Cartesian product $G \square H$ *of* G *and* H *has vertex set* $V(G) \times V(H)$ *and directed edges* $((v_1, u_1), (v_2, u_2))$ *if and only if either*

- $v_1 = v_2$ *and* $(u_1, u_2) \in E(H)$*, or*
- $u_1 = u_2$ *and* $(v_1, v_2) \in E(G)$

[4] We need $O(k^2 \log n)$ bits to verify that k numbers of $O(k \log n)$ bits sum to zero.
[5] Also known as **PL**-reductions, a more restrictive notion compared to **FPT**-reductions

As a simple example, note that the Cartesian product of two paths is a grid.

▶ **Definition 5.** *The* tensor product $G \times H$ *of* G *and* H *has vertex set* $V(G) \times V(H)$ *and directed edges* $((v_1, u_1), (v_2, u_2))$ *if and only if* $(v_1, v_2) \in E(G)$ *and* $(u_1, u_2) \in E(H)$.

▶ **Definition 6.** *The* union $G \cup H$ *of* G *and* H *has vertex set* $V(G) \cup V(H)$ *and edge set* $E(G) \cup E(H)$.

While there are many other graph products and operations to consider, such as the or product, or graph negation, we will primarily focus our study of factored graphs under the above three operations.

We note that the above three operations are associative, and observe that the products of higher arity are given as follows.

▶ **Definition 7.** *The* Cartesian product $\square_{i=1}^{k} G_i$ *has vertex set* $\prod_{i=1}^{k} V(G_i)$ *and directed edges* $((v_1, \ldots, v_k), (u_1, \ldots, u_k))$ *if and only if there is some index* $j \in [k]$ *such that* $(v_j, u_j) \in E(G_j)$ *and* $v_i = u_i$ *for all* $i \neq j$.

▶ **Definition 8.** *The* tensor product $\times_{i=1}^{k} G_i$ *has vertex set* $\prod_{i=1}^{k} V(G_i)$ *and directed edges* $((v_1, \ldots, v_k), (u_1, \ldots, u_k))$ *if and only if* $(v_i, u_i) \in E(G_i)$ *for all* $i \in [k]$.

▶ **Definition 9.** *The* union $\bigcup_{i=1}^{k} G_i$ *of* G *and* H *has vertex set* $\bigcup_{i=1}^{k} V(G_i)$ *and edge set* $\bigcup_{i=1}^{k} E(G_i)$.

2.2 Factored Graph Construction

We now describe how the above operations construct factored graphs. Formally, we define a factored graph by describing how the above graph operations combine the input graphs into a single graph. This motivates the definition of a factored graph according to a tree which specifies the order of operations, or the tree structure of a factored graph.

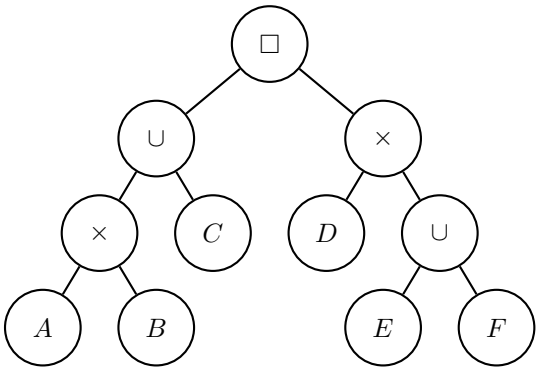
▶ **Definition 10** (Factored Graph Tree Structure)**.** *The* factored graph tree structure *with* k *leaves, denoted* $f(G_1, \ldots, G_k)$*, is an ordered tree with* k *leaves where internal nodes are labelled by an operation (one of* $\square, \times$*, or* $\cup$*) and the leaves are labelled by graphs* $G_1, \ldots, G_k$*. Note that* G_i *are arbitrary and not necessarily distinct. We require that each internal node has degree at least* 2.

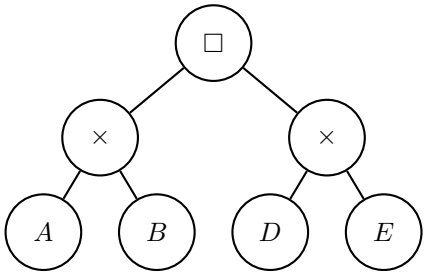
Let $G = f(G_1, \ldots, G_k)$ *denote that* G *is the* factored graph *given by the factored graph tree structure* $f(G_1, \ldots, G_k)$*. For convenience, let* $T(G)$ *denote the factored graph tree structure. We say that the factored graph tree structure* $f(G_1, \ldots, G_k)$*, or simply* G*, is* of complexity (n, k) *if* $T(G)$ *has at most* k *leaves and each leaf is labelled by a graph with at most* n *vertices.*

To illustrate our definitions, we will use the following example of a factored graph $G = ((A \times B) \cup C) \square (D \times (E \cup F))$. Note that there is a natural correspondence between the tree structures of factored graphs and the formulas of the above form, by using parentheses to delineate subtrees of the tree structure. The tree structure of G is given in Figure 2.

We now describe how the vertex and edge sets of a factored graph are obtained from its tree structure. First, we define factored components of factored graphs.

▶ **Definition 11** (Factored Component)**.** *Let* G *be a factored graph. A* factored component G_F *of* G *is the factored graph whose tree structure* $T(G_F)$ *is obtained from the tree structure of* G *by recursively replacing each internal node labelled by* $\cup$ *with the subtree rooted at one of its children. Note that the internal nodes of* $T(G_F)$ *are labelled either* $\square$ *or* $\times$.





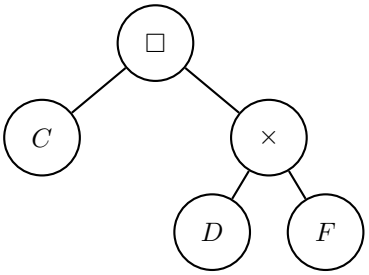


Figure 2 Tree structure of the factored graph $G = ((A \times B) \cup C) \,\square\, (D \times (E \cup F))$.

We say G_F has dimension ℓ *if $T(G_F)$ has ℓ leaves. Suppose the leaves are labelled $G_1, \ldots, G_\ell$. Then, $V(G_F) = \prod_{i=1}^{\ell} V(G_i)$. We say every vertex $v \in V(G_F)$ has dimension ℓ. The edge set $E(G_F)$ is determined by $T(G_F)$ and $E(G_1), \ldots, E(G_\ell)$ following the rules of Cartesian and tensor products.*

In our example, the factored components are $(A \times B) \,\square\, (D \times E), (A \times B) \,\square\, (D \times F), C \,\square\, (D \times E)$, and $C \,\square\, (D \times F)$, with dimensions $4, 4, 3, 3$, respectively. Some example tree structures of factored components are given in Figure 3.

Tree structure of $(A \times B) \,\square\, (D \times E)$.

Tree structure of $C \,\square\, (D \times F)$.

Figure 3 Examples of the Tree Structures of Factored Components.

Here, we emphasize that the vertex sets of the factored components are *flattened* products of the vertex sets of the graphs labeling the leaves. For example, the vertex of the factored component $(A \times B) \,\square\, (D \times E)$ has the form (a, b, d, e) not $((a, b), (d, e))$. In particular, the vertex sets do not depend on the topology of the tree beyond the order of the leaves. Finally, the vertex and edge set of G is simply the union of the factored components.

▶ **Definition 12** (Factored Graph). *Let $G = f(G_1, \ldots, G_k)$ be a factored graph with tree structure $T(G)$ and factored components $G_{F_1}, \ldots, G_{F_m}$. Define $V(G) = \bigcup_{i=1}^{m} V(G_{F_i})$ and $E(G) = \bigcup_{i=1}^{m} E(G_{F_i})$.*

We note here that different factored graphs can have identical vertex and edge sets. For example, $G_1 = (H_1 \times H_2) \times H_3$ and $G_2 = H_1 \times (H_2 \times H_3)$ both have vertex set $\prod_{i=1}^{3} H_i$ and edges from (h_1, h_2, h_3) to (h'_1, h'_2, h'_3) if and only if $(h_i, h'_i) \in E(H_i)$ for all i. This aligns with our expectation, as the tensor product is associative.

Note that a single vertex in G can belong to multiple factored components. In our running example, if there is a vertex $x \in V(E) \cap V(F)$, then the vertex (c, d, x) is in the factored components corresponding to $C \square (D \times E)$ and $C \square (D \times F)$. However, both factored components have dimension 3. This is formalized in the following lemma, which follows directly from the construction of factored graphs.

▶ **Lemma 13.** *Suppose $v \in V(G)$ is in factored components $G_F, G_{F'}$. Then,* $\dim(G_F) = \dim(G_{F'})$.

This allows us to define the dimension of a vertex $\dim(v)$ as the dimension of any factored component it belongs to.

▶ **Definition 14** (Vertex Dimension). *Let $G = f(G_1, \ldots, G_m)$ be a factored graph and $v \in V(G)$ be a vertex. The* dimension *of v, denoted by* $\dim(v)$*, is the dimension* $\dim(G_F)$ *of any factored component G_F that contains v.*

By construction, the endpoints of any edge must belong to the same factored component.

▶ **Lemma 15.** *Let $(u, v) \in E(G)$ be an edge. Then, u and v belong to the same factored component.*

As a corollary, we show that there are no edges between vertices of different dimensions, since vertices in the same factored component necessarily have the same dimension.

▶ **Corollary 16.** *Let (u, v) be an edge in G. Then, u and v have the same dimension.*

Finally, since every vertex has a unique dimension, it is clear that vertex dimension partitions the vertices of the factored graph. Thus, vertex dimension induces an equivalence relation on $V(G)$.

2.3 Parameterized Complexity

In this section, we review the parameterized complexity classes relevant to this paper with respect to problems on factored graphs. We begin with the definition of fixed-parameter tractability (**FPT**).

▶ **Definition 17** (Fixed-parameter Tractability (**FPT**) for Factored Graph Problems). *A problem on factored graphs is* fixed-parameter tractable *if there exists an algorithm that solves the problem on factored graph inputs of complexity (n, k) in time $O\left(g(k)n^C\right)$, where g is a function of k and C is a constant independent of k.*

We also study the parameterized complexity classes **XP** and **XNL**, which correspond to the parameterized version of the classical complexity classes **P** and **NL**, respectively. More generally, one can define the parameterized version **XC** for any classical complexity class **C** as follows [27]: a parameterized language $L \in \mathbf{XC}$ if and only if $L_k \in \mathbf{C}$ for every parameter k. Here, L_k is referred to as the *k-th slice* of L, which is the subset of L consisting of all instances with parameter k. We now give the definitions of **XP** and **XNL** in the context of factored graph problems.

▶ **Definition 18** (**XP** for Factored Graph Problems). *A problem on factored graphs is* in **XP** *if there exists an algorithm that solves the problem on factored graph inputs of complexity (n, k) in time $O\left(f(k)n^{f(k)}\right)$, where f is a function of k.*

▶ **Definition 19** (**XNL** for Factored Graph Problems). *A problem on factored graphs is* in **XNL** *if there exists a nondeterministic algorithm that solves the problem on factored graph inputs of complexity* (n, k) *in space* $O(f(k) \log n)$*, where* f *is a function of* k*.*

Finally, for **XP**- and **XNL**-completeness, we follow the usual definition that a problem is considered to be *complete* for a complexity class **C** if it belongs to **C** and is *hard* for **C** under some suitable notion of reductions. Here, we use the standard notion of parameterized mapping reduction (see Definition 9.3 in [27]), also known as the **FPT**-reduction [17], under which the class **FPT** is closed. We now give a definition for **XP**- and **XNL**-hardness under this reduction in the context of factored graph problems.

▶ **Definition 20** (**XP**-hardness (resp. **XNL**-hardness) for Factored Graph Problems). *A problem* L' *on factored graphs is* **XP**-hard *(resp.* **XNL**-hard*) if for every parameterized language* $L \in \mathbf{XP}$ *(resp.* $L \in \mathbf{XNL}$*), there exists a mapping* F *such that for every parameter* k*,* L_k *mapping reduces to* $L'_{k'}$ *under* F *using* $O(f(k)n^{O(1)})$ *time, where* f *is a function of* k *and* k' *depends only on* k*.*

3 Technical Overview

In this section, we provide a technical overview of our results. Due to space constraints, the proofs are left to the full version of the paper.

3.1 Lexicographically First Maximal Independent Set

Recall that our first main result is the **XP**-completeness of the LFMIS problem on factored graphs.

▶ **Theorem 1** (**XP**-completeness of LFMIS). *The LFMIS problem on factored graphs is* **XP***-complete under* **FPT***-reductions and not fixed-parameter tractable. In particular, the LFMIS problem on a factored graph* $G = f(G_1, \ldots, G_k)$ *of complexity* (n, k) *requires* $n^{\Omega(\sqrt{k})}$ *time.*

Theorem 1 is a consequence of a generic reduction from an arbitrary language $L \in \mathbf{DTIME}(n^\ell)$ to the LFMIS problem on factored graphs. Specifically, given a language $L \in \mathbf{DTIME}(n^\ell)$ and the corresponding Turing machine that decides L in $O(n^\ell)$ time, we construct a factored graph G of complexity $(O(n), O(\ell^2))$ using $O(\ell^2 n^2)$ time, such that solving the LFMIS on G simulates the Turing machine M. Then, it is fairly straightforward from this reduction that the problem is **XP**-complete. Moreover, we also obtain the explicit lower bound of $n^{\Omega(\sqrt{k})}$ by an application of the Time Hierarchy Theorem to the reduction.

Before proceeding to the detailed explanation, we first provide a high level intuition of this construction. Given a Turing machine, we can encapsulate its computation history in a matrix, where each row represents a configuration of the Turing machine at a specific time. The key idea of the reduction is to construct a graph in such a way that selecting vertices for the LFMIS corresponds to recovering the matrix entries, and thereby simulating the machine. To achieve this, we construct a graph with a grid structure mirroring the matrix. At each grid point, we place a collection of vertices representing all the possible choices for the corresponding matrix entry. The edges are defined according to the machine's transition function to ensure that the LFMIS chooses the single correct vertex from each grid point that agrees with the computation history of the Turing Machine, effectively allowing us to simulate the Turing machine by solving the LFMIS on the graph. It turns out that this graph has a highly regular structure and therefore can be factorized into a more succinct representation. In the remainder of this (sub)section, we explain this reduction in further detail.

Let L be a language in $\mathbf{DTIME}(n^\ell)$ and let M be the corresponding Turing machine that decides L in time $O(n^\ell)$. Given an input x to M, if M halts within time T, then the entire computation history of M on x can be represented by a $T \times T$ matrix W, where the i-th row of W represents the configuration of M at time i. To achieve this, each entry $W_{i,j}$ contains the following information about the j-th tape cell at time i: 1) the symbol occupying the cell, 2) whether the tape head is over the cell, and 3) the machine's current state if the tape head is over the cell. The goal now is to define a graph G such that the LFMIS of G recovers the computation history W, thereby simulating the machine M. We modify the Turing machine so that it suffices to query a single vertex in the graph for the halting state of M.

Explicit Graph Definition

We begin by defining G explicitly as an ordinary graph and then give a factored representation of G. Let S be the set of vertices corresponding to all possible choices for an entry in the matrix W. We define the vertex set of G to be T^2 copies of S, arranged in a $T \times T$ grid-like pattern analogous to the matrix W. Each copy of S is referred to as a *supernode*, and we use $S_{i,j}$ to denote the supernode in the i-th row and j-th column. Intuitively, the supernode $S_{i,j}$ represents all possible choices for the entry $W_{i,j}$. Therefore, we must define the edges of G such that the LFMIS includes the single correct vertex, which we call $w_{i,j}$, from each $S_{i,j}$ that agrees with the entry $W_{i,j}$.

The edge set of G consists of two types of edges: *intra*-supernode and *inter*-supernode edges. The intra-supernode edges are designed to ensure that the LFMIS contains *at most one* vertex within each supernode. This is easily achieved by defining a complete digraph on each supernode. On the other hand, the inter-supernode edges are constructed to ensure that the LFMIS contains *the correct* vertex from each supernode that agrees with the corresponding entry of W. This construction is more subtle and leverages the fact that the configuration at any given time of a deterministic machine uniquely determines the next configuration. Moreover, since the tape head can only move one step left or right at a time, each entry $W_{i,j}$ can be uniquely determined given only the three neighboring entries from the previous row: $W_{i-1,j-1}, W_{i-1,j}, W_{i-1,j+1}$ (instead of the entire previous row). To view this from another perspective: the entries $W_{i-1,j-1}$, $W_{i-1,j}$, and $W_{i-1,j+1}$ each restricts the possible choices for $W_{i,j}$ according to the machine's transition function. We define edges between neighboring supernodes to encode these restrictions. Specifically, for $v \in S_{i,j}$ and $v' \in S_{i+1,j'}$, a directed edge (v, v') indicates that, if v is chosen to represent the j-th tape cell at time i, then v' cannot represent the j'-th tape cell at the next time step $i + 1$, based on the machine's transition function. We hope that if the vertices $w_{i-1,j-1} \in S_{i-1,j-1}$, $w_{i-1,j} \in S_{i-1,j}$, and $w_{i-1,j+1} \in S_{i-1,j+1}$ are correctly contained in the LFMIS, then the edges ensure that $w_{i,j}$ is the unique vertex in $S_{i,j}$ that is not adjacent to $w_{i-1,j-1}, w_{i-1,j}$, or $w_{i-1,j+1}$. This will allow us to build the LFMIS inductively. The base case (which corresponds to the first row) is more technical and involves adding horizontal connections between supernodes.

Factored Graph Construction

Naively, this graph has $\Omega(T^2)$ vertices, where $T^2 = \Omega(n^{2\ell})$. However, since the computation rules of M are local (depending only on the symbol of the work tape under the head) and repetitive (the same rules apply regardless of the head's absolute position), we can give a succinct factored representation of G. Specifically, we show that G has a factored graph representation of complexity $(O(n), O(\ell^2))$. The factorization of G is outlined in Figure 4.

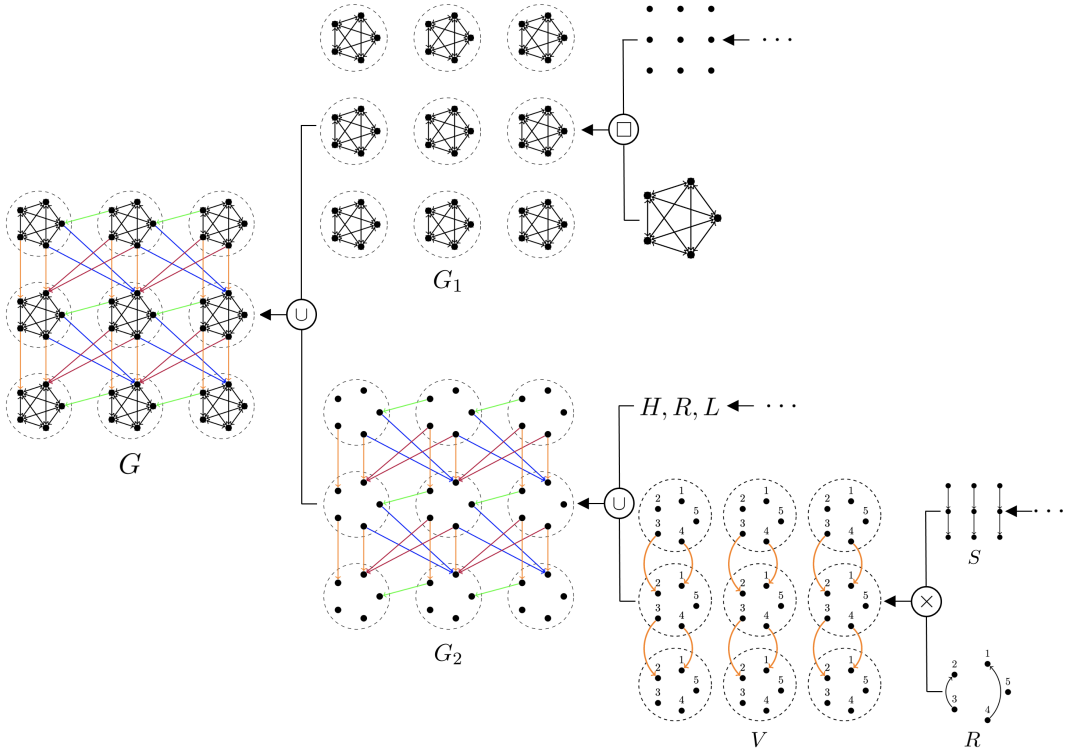

Figure 4 Overview of the Factorization of G. Supernodes are enclosed within dotted circles.

The key idea is to break down the graph G into regular and repetitive substructures. Following this, we begin by decomposing G into two subgraphs, G_1 and G_2, such that both subgraphs share the same vertex set as G, but G_1 contains only the intra-supernode edges and G_2 contains only the inter-supernode edges. G_1 forms a $T \times T$ grid of complete supernodes, which can be represented as the Cartesian product of an empty $T \times T$ grid of vertices and a single complete supernode. Similarly, G_2 is a $T \times T$ grid of supernodes, but with edges connecting neighboring supernodes in four possible directions: vertical (V), horizontal (H), diagonally-right R, and diagonally-left (L). We can further decompose G_2 into four subgraphs V, H, R, and L, which only contain the edges which are in the direction indicated by the name of the subgraph. Each of these subgraphs can be further decomposed into a "structure" graph and a "relation" graph using the tensor product. The structure graph S consists of a $T \times T$ grid of (ordinary) vertices with edges connecting all neighboring vertices in the corresponding direction of the subgraph. The relation graph R encodes the connections between vertices in neighboring supernodes in the corresponding direction. Moreover, the structure graphs themselves can be further factorized. For example, the structure graph S for the subgraph V can be expressed as the Cartesian product of a path of length T and an empty graph on T vertices. When the path length is a perfect power b^k (where $b, k \geq 1$ are integers), it can be further decomposed into a union of k factored graphs of complexities (b, k). Further details can be found in the full version of the paper.

3.2 Counting s-Cliques

In contrast to the first result, our second main result states that counting cliques on factored graphs is in **FPT**. For this result, we assume that all graphs are undirected.

▶ **Theorem 2** (Counting Clique Subgraphs is in **FPT**). *Let H be a clique on s vertices. Then, computing the number of exact copies of H in G, denoted $\#\mathbf{H}(G)$, is fixed-parameter tractable. In particular, there is an algorithm computing $\#\mathbf{H}(G)$ on factored graphs G of complexity (n,k) in $O\left(g(s,k)n^s\right)$ time for some function $g(s,k)$.*

In the technical overview, we use edge counting ($s = 2$) as an illustrative example. Note that if (u,v) is an edge, u, v must have the same dimension (Corollary 16), so we may count the edges in each dimension separately. Thus, fix a dimension $d \leq k$.

There are at most 2^k factored components of dimension d. While some edges may belong to multiple factored components, we can use the inclusion-exclusion principle to avoid double-counting such edges. In particular, it suffices to consider counting the number of edges in an arbitrary intersection of factored components $G_{F_1} \cap \ldots \cap G_{F_m}$. Note that the number of such intersections, while being a large function of k, is crucially independent of n.

Fix such an intersection and consider a pair of vertices u, v with $u = (u_1, \ldots, u_d)$ and $v = (v_1, \ldots, v_d)$. Note that by determining whether u_i, v_i are equal or adjacent for all $i \in [k]$, we can infer from the factored graph tree structure whether $(u,v) \in E(G)$. Thus, we can categorize all pairs of vertices into 2^{2k} groups based on the relations $u_i = v_i$ and $(u_i, v_i) \in E(G_i)$. Note also that these groups are disjoint. Next, we collect the subset of groups that form edges in the current intersection $G_{F_1} \cap \ldots \cap G_{F_m}$. To count the number of edges, it then suffices to sum up the sizes of each group in this collection. For a given group, we can determine its size in $O(kn^2)$ time since the relations on each coordinate are independent. In particular, we can count the number of pairs of vertices in each input graph satisfying the relevant constraints and take the product over all input graphs.

3.3 Reachability

Finally, we study the reachability problem on factored graphs.

▶ **Theorem 3** (**XNL**-completeness of Reachability). *Reachability on factored graphs is* **XNL***-complete under* **FPT***-reductions. Furthermore, the following are equivalent:*

1. *There is a constant C such that* $\mathbf{NL} \subseteq \mathbf{DTIME}(n^C)$.
2. $\mathbf{XNL} \subseteq \mathbf{FPT}$.

We begin with an overview of the proof for the **XNL**-completeness result, followed by that for the equivalence result. In fact, we will see that both proofs rely on the same major building blocks in slightly different ways.

XNL-completeness

We follow the standard framework for showing that reachability is **NL**-complete [57].

Membership in **XNL** can be established using the same algorithm that shows the ordinary reachability problem is in **NL**, even if the input is now given as a factored graph. As in the standard proof, we non-deterministically guess the next vertex in the path and thus only require $O(k \log n)$-space for factored graphs $G = f(G_1, \ldots, G_k)$ of complexity (n,k). Formally, each vertex in G can be specified by $O(k \log n)$ bits, since each vertex is a tuple of at most k coordinates and each coordinate is a vertex in an input graph G_i with at most n vertices. Thus, the algorithm requires $O(k \log n)$ bits to write down the current vertex and, since the factored graph has at most n^k vertices, at most $O(k \log n)$ bits to keep track of the number of steps taken so far.

For **XNL**-hardness, suppose we have some language $L \in \mathbf{XNL}$. Then, there exists a nondeterministic Turing machine M deciding L using $f(k) \log n$-space on inputs of length n and parameter k, for some function f of k. The standard reduction creates an explicit

configuration graph where each vertex encodes a tuple consisting of state, input and work tape positions, and a setting of the work tape. Since the work tape has length $f(k) \log n$, there are at least $n^{f(k)}$ distinct settings of the work tape. Thus, even though reachability is computable in linear time, the size of the graph already depends exponentially on $f(k)$. However, we are able to exploit the locality of Turing machine operations so that the configuration graph can in fact be encoded by a factored graph of complexity $(\text{poly}(n), \text{poly}(f(k)))$. Given some configuration of M on input x (a tuple of state, tape head locations and work tape contents), we split the configuration into segments, where each segment only contains $\log n$ contiguous bits of the work tape contents. Note that each segment, even if it encodes a state and tape head locations, only has $n^{O(1)}$ possible values, since one segment of the work tape only has $\log n$ bits. Thus, we can represent all possible configurations of a segment explicitly using a graph with $n^{O(1)}$ vertices, while a product of $f(k)$ segment graphs can explicitly represent any full configuration of M on input x.

It remains to express the appropriate transitions between configurations using a factored graph. There are two types of transitions: *intra*-segment transitions, where the work tape head stays within the same segment, and *inter*-segment transitions, where the work tape head moves from one segment to another (adjacent) segment. In either case, at most two segments of the work tape are active, where a segment is active during a transition if the work tape head either starts or ends in the segment and inactive otherwise. Thus, we can express individual segments (or pairs of segments) explicitly using input graphs of size $n^{O(1)}$. Since the active segments and inactive segments do not interact, we can encode all *intra*-segment transitions of a single segment using factored graphs of complexity $(n^{O(1)}, f(k))$. Similarly, we can encode all *inter*-segment transitions between a single pair of adjacent segments. Summing over all $O(f(k))$ segments and pairs of adjacent segments, we encode the configuration graph in a factored graph of complexity $(n^{O(1)}, O(f(k)^2))$.

We now briefly describe how the locality of Turing machine computation allows us to express the configuration graph of M on x using factored graphs. In the overview, we describe only *intra*-segment transitions. First, note that if the work tape head is not currently placed in a segment, the work tape contents of this segment cannot change. We thus define an *inactive* graph, where for every possible work tape content, we create a self-loop vertex. If the work tape head is currently placed in the segment, the work tape contents may change. Thus, we define an *active* graph with all possible configurations on a given segment as nodes, and edges encoding valid transitions. For a given segment, taking the tensor product of the active graph for this segment and the inactive graph for all other segments encodes all *intra*-segment transitions. A similar construction can be used to construct factored graphs that encode *inter*-segment transitions.

Equivalence to the Open Problem

For the forward direction, suppose there exists an absolute constant C such that $\mathbf{NL} \subseteq \mathbf{DTIME}(n^C)$. To show that $\mathbf{XNL} \subseteq \mathbf{FPT}$, it now suffices to show reachability on factored graphs is in $\mathbf{FPT}$ due to its $\mathbf{XNL}$-completeness under $\mathbf{FPT}$-reductions. Note that the algorithm used in the proof of $\mathbf{XNL}$-membership is in fact an $\mathbf{NL}$ algorithm for each fixed parameter k. Thus, if $\mathbf{NL} \subseteq \mathbf{DTIME}\left(n^C\right)$ for some C independent of k, then for any fixed k, reachability on factored graphs of complexity (n, k) can be computed in time $O(k^C n^{2C})$ (as factored graphs of this complexity have input size $O(kn^2)$) and is therefore in $\mathbf{FPT}$.

Conversely, if $\mathbf{XNL} \subseteq \mathbf{FPT}$, then in particular, reachability on factored graphs is in $\mathbf{FPT}$. Now, consider any language $L \in \mathbf{NL}$ with its associated nondeterministic Turing machine M that decides L in $S \log n$ space for some constant S. Using the same construction as in the

proof of **XNL**-hardness, we construct a factored graph G of complexity $(n^{O(1)}, O(S^2))$ where solving reachability on G simulates M. Since reachability on factored graphs is in **FPT**, it follows that reachability on G can be solved in time $O(f(S^2)n^{O(1)})$ for some function f, where the exponent on n is independent of S, hence independent of the specific language $L \in \mathbf{NL}$. This shows that $\mathbf{NL} \subseteq \mathbf{DTIME}(n^C)$ for some absolute constant C.

4 Conclusion and Future Work

We have studied the computational complexity of various problems on factored graphs. Even among problems with polynomial time algorithms on explicit graphs, we have shown that their parameterized complexity when the input is represented as a factored graph can differ quite drastically. In the context of parameterized complexity, we have sought to characterize which problems on factored graphs are in **FPT**. On the positive side, counting the number of copies of a small clique is in **FPT**. On the negative side, LFMIS is *unconditionally* not in **FPT**. Finally, we show that determining whether reachability is in **FPT** is equivalent to determining whether $\mathbf{NL} \subseteq \mathbf{DTIME}(n^{O(1)})$.

Can the unconditional lower bounds for LFMIS on factored graphs be used to prove similar unconditional lower bounds for other parameterized problems? One obstacle to doing this is the gap in complexity between the **P**-complete LFMIS problem and the easily parallelizable problems that form the bulk of the literature in parameterized complexity. However, reductions in fine-grained complexity often cut across traditional complexity classes, e.g., [46]. So we do not know a reason why this should not also be the case here. Either finding such unconditional results or explaining their impossibility would both be interesting. We could also hope to prove similar results for other **P**-complete problems.

While our lower bounds separate the problems of interest from **FPT**, they do not rule out significant improvements on the naive $n^{O(k)}$ algorithm of computing the factored graph G explicitly and solving the problem on G itself. For example, our LFMIS lower bound only unconditionally rules out algorithms with time $n^{o(\sqrt{k})}$. An interesting open problem is to provide a more *fine-grained* analysis of the complexity of factored graph problems, possibly distinguishing between the number of product and union operations.

In this work, we have chosen to study factored graphs under graph products and unions, specifically the Cartesian and tensor products. A natural extension is to consider other products and operations on graphs, or other interesting objects. Factored problems on bit strings were introduced in [21], and implicitly on integer-valued vectors in [3]. Do similar results hold for factored problems for these input domains and operations?

Error Correction for Message Streams

Meghal Gupta
University of California Berkeley, CA, USA

Rachel Yun Zhang
MIT, Cambridge, MA, USA

Abstract

In the setting of error correcting codes, Alice wants to send a message $x \in \{0,1\}^n$ to Bob via an encoding $\mathsf{enc}(x)$ that is resilient to error. In this work, we investigate the scenario where Bob is a *low space* decoder. More precisely, he receives Alice's encoding $\mathsf{enc}(x)$ bit-by-bit and desires to compute some function $f(x)$ in low space. A generic error-correcting code does not accomplish this because decoding is a very global process and requires at least linear space. Locally decodable codes partially solve this problem as they allow Bob to learn a given bit of x in low space, but not compute a generic function f.

Our main result is an encoding and decoding procedure where Bob is still able to compute any such function f in low space when a constant fraction of the stream is corrupted. More precisely, we describe an encoding function $\mathsf{enc}(x)$ of length $\mathrm{poly}(n)$ so that for any decoder (streaming algorithm) A that on input x computes $f(x)$ in space s, there is an explicit decoder B that computes $f(x)$ in space $s \cdot \mathrm{polylog}(n)$ as long as there were not more than $\frac{1}{4} - \varepsilon$ fraction of (adversarial) errors in the input stream $\mathsf{enc}(x)$.

1 Introduction

Consider the following scenario: Alice streams a message denoted $x = x_1 \dots x_n$ to Bob that he receives and processes bit-by-bit. His goal is to compute some function $f(x_1 \dots x_n)$ unknown to Alice in significantly less space than necessary to store the entire stream. This scenario arises for instance in automatic control applications, where a device receives an incoming stream of data and needs to use it to make decisions.

As an example, a class of functions that Bob may wish to compute in small space from a message stream is the class of *linear functions*. If Bob's function is $f(x) = f_y(x) = x \cdot y \mod 2$ for some $y \in \{0,1\}^n$, then after receiving each bit of x, Bob adds $x_i \cdot y_i$ to a running sum. Bob only needs to track i and the running sum modulo 2, which is in total $\log n + 1$ bits of space.

However, this and other small space algorithms are very rigid when it comes to errors in the stream. Corruption of even one bit of Alice's message can change the output of Bob's linear function. The same applies if Bob's function is an index function, a majority, or the result of a decision tree.

In this work, we study what happens when there is noise in the incoming stream. In particular, we ask if it's possible to convert a given algorithm that processes a message stream into one that is robust to errors in the message while still allowing the output to be computed in low space.

In the usual error correction setting, Alice could just encode her message using a generic large distance error-correcting code. Bob would be able to compute any function f in the presence of a small constant fraction of error, but he must receive and store the whole stream in order to decode, which is far too much space. Even if Alice sends a locally decodable code, which has the property that to determine a single bit of x one only needs to track a few random bits of the codeword, it is not clear how Bob can compute a function requiring all n bits without $\Omega(n)$ storage. Our question is whether there is an encoding that preserves the space complexity of Bob's original decoding algorithm while being resilient to error.

In this work, we answer the question in the affirmative. Our main result is a scheme that protects any streaming algorithm against noise in the incoming stream. More precisely, we give an encoding $\mathsf{enc}(x)$ of length $O(n^{4+\delta})$ such that any streaming algorithm running in s space on the noiseless stream can be converted to one running in $s \cdot \text{polylog}(n)$ space on the encoded stream. It is correct with high probability whenever at most $\frac{1}{4} - \varepsilon$ of the stream was corrupted. In the specific case where Bob's function is a linear function such as dot product, our encoding can be made to have length $O(n^{2+\delta})$.

1.1 The Model

We provide a formal definition of a noise resilient transformation for a message stream and processing algorithm. The transformation has two components:

- An encoding function $\mathsf{enc}(\cdot) : X \subseteq \{0,1\}^n \to \{0,1\}^m$.
- An explicit transformation B that takes as input a deterministic streaming algorithm $A : X \to \mathbb{F}_q$ and outputs a randomized streaming algorithm $B_A = B(A) : \{0,1\}^m \to \mathbb{F}_q$.

The algorithm is said to be α-error resilient if whenever $\Delta(z, \mathsf{enc}(x)) < \alpha \cdot m$, then $B_A(z)$ outputs $A(x)$ with high probability.

1.2 Our Results

Our main result is a noise-resilient conversion for deterministic streaming algorithms.

▶ **Theorem 1.** *Fix $\varepsilon, \delta > 0$. For any $X \subseteq \{0,1\}^n$, there is a noise resilient transformation consisting of an encoding $\mathsf{enc} : X \subseteq \{0,1\}^n \to \{0,1\}^m$, and a transformation of algorithms B that is $\left(\frac{1}{4} - \varepsilon\right) \cdot m$ error resilient with probability $\geq 1 - 2^{O_\varepsilon(\log^2 n)}$. Moreover, $m = O_\varepsilon(n^{4+\delta})$, and for any deterministic algorithm A on domain X that runs in space s and time t, the algorithm $B(A)$ runs in space $s \cdot O_\varepsilon\left((\log n)^{O(1/\delta)}\right)$ and time $m \cdot O_{\varepsilon,\delta}\left(1 + \frac{t}{n^2}\right)$.*

In other words, given an algorithm A that accepts a stream of length n and uses s space, we demonstrate a noise resilient algorithm $B(A)$ computing A that uses $s \cdot \text{polylog}(n)$ space. The transformation enc of the stream x from the sender is independent of A and has length $O(n^{4+\delta})$.

A priori, it is not obvious that there is *any* low-memory noise resilient transformation of the algorithm A even with an arbitrary blow-up in communication. For example, if the sender were to encode their message using an arbitrary error-correcting code, the receiver would need to store the entire message in memory in order to decode it before applying the algorithm A. Our result shows that not only does this low-memory transformation exist, but that it can be done efficiently (both with respect to communication complexity and computational complexity).

Linear Streaming Algorithms

In the above transformation, the length of the resulting stream is $O(n^{4+\delta})$ for any $\delta > 0$. In the specific case where the streaming algorithm is *linear*, we construct a scheme where the stream length is only quadratic, namely $O(n^{2+\delta})$. The key property of linear streaming algorithms that we will be leveraging is that they can be computed in pieces in any order, and later computations do not depend on the results of previous ones.

▶ **Definition 2** (Linear Streaming Algorithms). *A linear streaming algorithm $A : \{0,1\}^n \to \mathbb{F}_q$ is described by a list of functions $g_i : \{0,1\} \to \mathbb{F}_q$ for $i \in [n]$, and computes the value $A(x) = g_1(x_1) + \ldots + g_n(x_n)$ (where addition is over $\mathbb{F}_q$) by tracking the partial sum $g_1(x_1) + \ldots + g_i(x_i)$ upon receiving the i'th bit.*

Note, for example, that every linear function on codomain $\{0,1\}^n$ admits a linear streaming algorithm. We note that linear streaming algorithms capture a large class of interesting functions, including linear sketching algorithms (see for example [12, 10, 1, 37]). For linear streaming algorithms, we show the following result.

▶ **Theorem 3.** *Fix $\varepsilon, \delta > 0$. There is a function $\mathsf{enc} : X \subseteq \{0,1\}^n \to \{0,1\}^m$ where $m = O_\varepsilon(n^{2+\delta})$ and an explicit transformation B such that the following holds: For any linear streaming algorithm A that takes as input $x \in X \subseteq \{0,1\}^n$ as a stream, runs in space s and time t, and outputs $A(x)$, the algorithm $B_A = B(A)$ takes as input $z \in \{0,1\}^m$ as a stream, runs in space $s \cdot O_\varepsilon((\log n)^{O(1/\delta)})$ and time $m \cdot O_{\varepsilon,\delta}\left(1 + \frac{t}{n^2}\right)$, and satisfies that whenever $\Delta(z, \mathsf{enc}(x)) < \left(\frac{1}{4} - \varepsilon\right) \cdot m$ then $B_A(z)$ outputs $A(x)$ with probability $\geq 1 - 2^{O_\varepsilon(\log^2 n)}$.*

Randomized Algorithms

We remark that our transformations in Theorems 1 and 3 are only for deterministic algorithms. However, this easily implies the result for algorithms A that *pre-sample* all of their randomness (that is, algorithms that fix their randomness before receiving any bits of x, at which point they are deterministic for the remainder of the algorithm). Such algorithms can be viewed as sampling from a distribution over deterministic algorithms. Our transformation can then be applied to the ensuing deterministic algorithm, thus correctly computing the function A with high probability while being resilient to noise.

We remark that this notion of randomized algorithms whose only access to randomness is pre-sampled at the start of computation is quite general: randomized algorithms that sample its randomness online can often be converted to protocols where the randomness is pre-sampled, see e.g. [44].

Non-Binary Input Alphabets

Our main theorems are stated for the setting where the input stream is binary. We remark that this assumption is without loss of generality: a larger alphabet stream can be converted to a binary one by assigning each alphabet symbol to a unique binary string.

1.3 Discussion of Subsequent Work

Since this paper was first posted, the work of [29] improved upon our schemes in a few major ways.

- For the case of general deterministic streaming algorithms, they demonstrate a transformation that only requires near-quadratic encoding length.

- They show that this is essentially tight: there is no transformation that has sub-quadratic encoding length.
- And, in the case of linear streaming algorithms, they construct a transformation that has an encoding of near linear length.

This addresses most of the open questions posed by our paper.

1.4 Related Works

Streaming Algorithms

The study of streaming algorithms began with the work Morris [42] on approximate counting; a rigorous analysis was given later in [20]. Later works introduced other classic problems in streaming, including heavy hitters [9], ℓ_p approximation [2, 41, 36], and finding a nonzero entry in a vector (for turnstile algorithms) [41].

Many works, for example [22, 11, 39, 3], consider the problem of processing noisy data sets using streaming algorithms. [22] shows a memory lower bound for learning a parity function with noisy samples of random linear equations.

However, this type of noise is quite different from our treatment. In these problems, noise is inherent in the way samples are generated, whereas we are investigating noise that occurs in the communication process.

Error Correcting Codes

Our result can be viewed through the lens of low-space noise resilient one-way communication.

Noise resilient one-way communication, in other words, error correction [51, 35], is one of the most well-studied problems in computer science. One specific line of works related to our result is that of *locally decodable codes*. Locally decodable codes [52] can be viewed as a low-time and low-space version of error-correcting codes, where the goal is to learn a single bit of the original message. By constrast, for us, the decoder must be able to piece together any function of the input that is noiselessly computable in low space, with the tradeoff that the decoder accesses the entire encoding via a stream rather than via query access. Local decodable codes have been constructed in a variety of different parameter regimes, including constant query [16, 15] and near 1 rate [38]. In our work, we will use Reed-Muller codes [43, 46] that achieve polylog(n) query complexity and slightly super-linear block length.

Another line of works related to ours is that of streaming algorithms for local testing of codes [47, 40]. However, this direction was rendered moot by the recent discovery of locally testable codes with constant rate, distance, and locality [14].

Coding for Interactive Communication

The analogue of noise resilient one-way communication in the interactive setting, where Alice and Bob have inputs x, y and engage in a protocol to compute some $f(x, y)$ while being resilient to error, comprises the study of *coding for interactive communication*. Interactive coding was studied starting with the seminal works of Schulman [48, 49, 50] and continuing in a prolific sequence of followup works, including [8, 6, 4, 5, 34, 7, 13, 25, 24, 17, 28, 26, 19, 30, 31]. We refer the reader to an excellent survey by Gelles [23] for an extensive list of related work.

The recent work of [18] studies the space complexity of interactive coding schemes. Their main result is an interactive coding scheme that preserves the space complexity of the original noiseless protocol up to a $\log(n)$ factor, where n is the length of the protocol. Their result

can be viewed as the interactive analogue of ours, where their noiseless and noise resilient protocols are both interactive. We remark that their techniques are quite different than ours and do not apply to our setting, however, since their approach crucially relies on the communication of feedback from Bob to Alice.

2 Overview of Techniques

Consider the task of computing a linear function $f(x) = \sum_{i\in[n]} g_i(x_i)$. In a noiseless setting, one can compute $f(x)$ by tracking the partial sum $\sum_{1\le i\le n'} g_i(x_i)$ and updating it with $g_{n'+1}(x_{n'+1})$ upon receiving the $(n'+1)$'th bit of x.

As a first attempt to create a noise resilient version of this algorithm, one might consider the input stream $\mathsf{enc}(x) = \mathsf{LDC}(x)$, where LDC is a locally decodable code. In short, a locally decodable code is a noise resilient encoding of x such that in order to decode any specific bit of x, say x_i, the decoder simply has to read polylog(n) (randomized) bits of $\mathsf{LDC}(x)$. In a streaming setting, the decoder can record only these polylog(n) bits into memory, then run the decoding algorithm to determine x_i after all such query bits have been seen.

However, it's not clear that this local decoding property extends to arbitrary linear functions.[1] If we attempt to simultaneously decode all bits x_i from $\mathsf{LDC}(x)$ using a separate query set Q_i for each index, the issue is that we will need to track $\Omega(n)$ queries simultaneously since we cannot ensure that the local decoding for any index finishes before another: the query sets Q_i are typically randomized so that any bit of the codeword is equally likely to belong to the query set for any particular index.

A second attempt is to send $\mathsf{LDC}(x)$ n times, with the intent that Bob locally decodes x_i in the i'th $\mathsf{LDC}(x)$ and computes $f(x)$ by tracking the partial sum $\sum_{1\le i\le n'} g_i(x_i)$ at the end of the i'th chunk. Now, the only space requirements are the space required to store this partial sum and the space required to locally decode x_i in each $\mathsf{LDC}(x)$, which is polylog(n). However, the adversary can simply corrupt the first $\mathsf{LDC}(x)$ so that Bob mis-decodes x_1, thereby corrupting his final output, and ultimately, this approach is not so different from just sending the bits $x_1 \dots x_n$ in order.

What Bob would like to do is randomize which x_i he is computing from a given copy of $\mathsf{LDC}(x)$ so that the adversary does not know. This crucially uses the property that LDC's allow Bob to decode *any* x_i not known to the encoder or adversary. Then, if he computes each x_i many times and takes the majority, he will learn x_i correctly with high probability, regardless of the adversary's corruption process. Since the adversary does not know in advance which chunks Bob is computing x_i in, she cannot target corruptions towards a specific x_i. However, this runs into an issue with the amount of space Bob requires. Since he computes each x_i many times throughout the protocol and only takes the majority when he has finished these computations, he needs to track his current guess for its value through (almost) the entire protocol. When each x_i was computed only once, Bob could just add $g_i(x_i)$ to the running sum, but now he needs to track each x_i individually between the first and last time he queries it, for a total of $\Omega(n)$ bits of space.

The crux of our construction is an organized system for aggregating decoding attempts in space much smaller than storing all n attempts simultaneously.

[1] The smallest local decodable code we know of that supports local decoding to any arbitrary linear function is an extension of the Hadamard code, which has block length exponential in n. This will not be a satisfactory solution for us because (a) we would like encodings that are efficiently computable, and (b) keeping track of which bit of the stream one is receiving takes n memory.

A recursive computation

Let $r = \text{polylog}(n)$. Suppose that we already know how to compute linear functions on inputs of size n/r in space $s_{n/r}$, that is resilient to $\varepsilon_{n/r}$ fraction of errors in the stream of $M_{n/r}$ copies of $\mathsf{LDC}(x)$. We will use this to build a scheme for computing linear functions on inputs of size n. Note that the base case is given by computing linear functions on a single bit, which can be done by local decoding on a single $\mathsf{LDC}(x)$.

To compute $f(x) = \sum_{i\in[n]} g_i(x_i)$, we just need to compute $f_1(x) = \sum_{i\in[n/r]} g_i(x_i)$, $f_2(x) = \sum_{i\in[n/r+1,2n/r]} g_i(x_i)$, $\ldots$, $f_r(x) = \sum_{i\in[n-n/r+1,n]} g_i(x_i)$. Each sub-computation can individually be done with the guarantee that if $< \varepsilon_{n/r}$ fraction of the stream is corrupted, then the function is computed correctly.

Consider a stream consisting of $\ell \cdot r \cdot M_{n/r}$ copies of $\mathsf{LDC}(x)$ (you can think of $\ell = \log^2 n$). We split up this stream into ℓ chunks each consisting of r blocks of $M_{n/r}$ $\mathsf{LDC}(x)$'s. In each of the ℓ chunks, we will assign the r blocks of $M_{n/r}$ LDC's to the computation of a random permutation of $f_1(x), \ldots, f_r(x)$. Throughout the algorithm, we will keep track of all the outputs from each of the ℓ sub-computations for each of $f_1(x), \ldots, f_r(x)$. At the end, we can take a majority vote for each of the $f_j(x)$. We illustrate the recursion process in Figure 1.

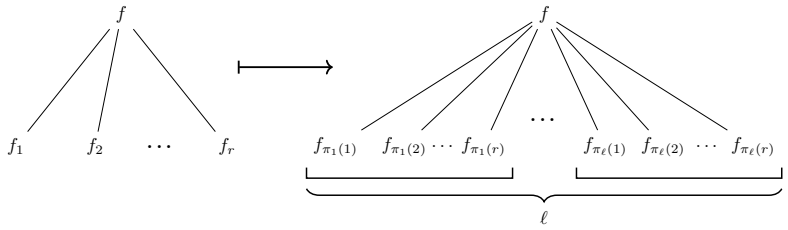

Figure 1 In our transformation, each sub-function is computed ℓ times instead of 1, and in each of the ℓ chunks, the sub-functions f_i are computed in according to a random permutation π.

Because of the way we've randomly assigned blocks to $f_1, \ldots, f_r$, the adversary cannot concentrate her attack on the computation of any specific f_i. More precisely, we can show that the amount of error present in the blocks corresponding to the computation of f_k is (roughly) proportional to the total error present. Then, as long as at least half the blocks corresponding to f_k have $< \varepsilon_{n/r}$ fraction of errors, we have that the majority vote for each of $f_1, \ldots, f_r$ will be correct. In total, this means that our algorithm for computing $f(x)$ is resilient to $\frac{\varepsilon_{n/r}}{2}$ fraction of errors.

Unfortunately, this factor of 2 loss in the error resilience in each iteration of the recursion will prove to be problematic, as we can no longer guarantee a positive error resilience when n gets large.

Decoding with confidences

In the above analysis, our worst case error distribution was that where just under one-half of the chunks have $\varepsilon_{n/r}$ error while the rest are error-free. In this case, the chunks with $\varepsilon_{n/r}$ error will produce a wrong output, while the error-free ones will produce a correct output.

However, we notice that in certain local decoding constructions (for us, we will use a Reed-Muller code), one can actually obtain an estimate of how much error there was in the codeword based on the inconsistency of the queries. In particular, in chunks where there were $\varepsilon_{n/r}$ errors, even though we will obtain a wrong answer, we can also see that there were a lot of errors in the codeword, and thereby be less sure of the obtained answer.

This motivates our definition of *local decoding with confidences*: in addition to outputting an answer, the decoding algorithm should also output a *confidence* $c \in [0, 1]$ indicating how confident it is that the answer is correct. A confidence of 0 indicates that it's not sure at all: the fraction of errors seen was near the threshold ε_1; whereas a confidence of 1 indicates that it's quite sure: either the answer is right and no errors occurred, or at least $2\varepsilon_1$ errors were required to obtain a wrong answer with confidence 1. Another way to view the confidence is as an estimate of how much error was present in the total codeword (how far the actual error is from ε_1).

Now, when we perform the recursive step to obtain a noise resilient algorithm for f from $f_1, \ldots, f_r$, in addition to recording the outputted answer from each chunk, we will also record the associated confidence. Suppose that the ℓ answers and confidences obtained for f_k were $(\hat{q}^{(1)}, \hat{c}^{(1)}), \ldots, (\hat{q}^{(\ell)}, \hat{c}^{(\ell)})$. Then, the weighted majority vote of these answers is defined to be the $\hat{q}$ with the largest total confidence. We can show that as long as the cumulative fractional error c_n is at most $c_{n/r}$, we're guaranteed that the correct answer has more the highest total confidence.

We remark that one does not have to store all ℓ pairs $(\hat{q}^{(j)}, \hat{c}^{(j)})$. Rather, we can keep track of a most likely q and associated confidence c. To update (q, c) with a new pair $(\hat{q}, \hat{c})$, one can update c by $\pm\hat{c}$ ($+\hat{c}$ if $\hat{q} = q$, and $-\hat{c}$ otherwise). If the resulting confidence c is less than 0, then it means that the answer $\hat{q}$ is supported by less overall error, so we set our most likely q to be $\hat{q}$ and flip the sign of c.

Now, we analyze the space and communication complexity of the resulting algorithm. The space required is simply $s_{n/r}$, the space required to do a size n/r sub-computation, plus the space required to store a pair (q, c) for each of $f_1, \ldots, f_r$. Overall, this means that for each layer of the recursion, we are only gaining an additive factor of $r \cdot (|q| + |c|)$ space overhead, so the total space overhead is at most polylogarithmic in n. As for the size of the resulting stream, we see that the number of $\mathsf{LDC}(x)$'s is $\approx (r \cdot \ell)^{\log_r n}$,[2] which is polynomial in n.

Computing non-linear functions

Our algorithm so far has only captured functions f that are splittable into r sub-computations whose computations do not depend on each other. However, for a general function, this may not be the case. Indeed, for many functions, the computations must be done *sequentially*, where later computations can only be done once earlier computations have finished. We may split a general function f into r sub-functions where $q_1 := f_1(x[1 : n/r], \emptyset)$ is the state of the algorithm after n/r bits of the stream, $q_2 := f_2(x[n/r + 1 : 2n/r], q_1)$ is the state of the algorithm after receiving the next n/r bits of the stream, and so on. The difference from the linear function case is that to compute f_j, we must have the correct output of f_{j-1}.

In order to handle such sequential computations, we modify our above algorithm as follows. In the recursive layer computing f from functions $f_1, \ldots, f_r$, we always compute f_j from the starting state q_{j-1} which is our current best guess for the output of f_{j-1}. This value of q_{j-1} may not always be correct, in which case the computation done for f_j will be doomed.

As with our algorithm for linear functions, after every chunk, we update the most likely state q_j and confidence c_j for the sub-function that was computed in that chunk. However, when a state q_j changes, this also means that computations done for $f_{j+1} \ldots f_n$ were based

[2] In our actual protocol, we will repeat the procedure $\log^2 n$ times and take a final majority vote, so the number of $\mathsf{LDC}(x)$'s used will be $(r \cdot \ell)^{\log_r n} \cdot \log^2 n$.

on wrong information. In the case of linear functions, the computations are independent so this does not matter, but for sequential functions, we have to discard the guesses $q_{j+1} \dots q_n$. Formally, we set these states to $\emptyset$ and set the corresponding confidences all to 0.

Because each sub-function q_j is only computed usefully when q_{j-1} is correct and also the value of q_j is frequently discarded, it is less clear that over many iterations the q_j's will converge to the correct values. Nevertheless, we prove in Section 6 that over enough iterations, the guesses q_j will eventually all be correct as long as there are not too many errors in the stream.

Outline

The rest of this paper is organized as follows. In Section 3, we start with some preliminary theorems about error-correcting codes. In Section 4, we define our notion of local decoding with confidences and prove that Reed-Muller codes satisfy this property. Then, in Sections 5 and 6, we present our noise resilient streaming algorithms for linear and general (sequential) functions, respectively.

3 Preliminaries

Notation

- The function log is in base 2 unless otherwise specified.
- The set $[n]$ denotes the integers $1 \dots n$.
- We use $x[i:j]$ to denote the i'th to j'th bits of x inclusive. We use $x(i:j]$ to refer to the $(i+1)$'th to j'th bit inclusive.
- We use e as a variable rather than the universal constant e.

3.1 Error-Correcting Codes

We begin with some results about error-correcting codes. The first is the existence of a relative distance $\frac{1}{2}$ binary code.

▶ **Theorem 4** ([33]). *For all $\epsilon > 0$, there exists an explicit error-correcting code $\mathsf{ECC}_\epsilon = \{\mathsf{ECC}_{\epsilon,n} : \{0,1\}^n \to \{0,1\}^m\}_{n \in \mathbb{N}}$ with relative distance $\frac{1}{2} - \epsilon$ and $m = O_\epsilon(n)$, and a $\mathrm{poly}_\epsilon(n)$-time decoding algorithm $\mathsf{DEC}_\epsilon : \{0,1\}^m \to \{0,1\}^n$, such that for any $x \in \{0,1\}^n$ and $w \in \{0,1\}^m$ satisfying $\Delta(\mathsf{ECC}_\varepsilon(x), w) < \left(\frac{1}{4} - \frac{\varepsilon}{4}\right) \cdot m$, it holds that $x = \mathsf{DEC}_\varepsilon(w)$.*

Our second theorem is about the efficient decoding of Reed-Solomon codes [45].

▶ **Theorem 5** (Berlekamp-Welch; see e.g. [27]). *Given a collection of tuples $(\alpha_1, v_1), \dots, (\alpha_n, v_n)$ where $\alpha_i, v_i \in \mathbb{F}_q$ and a parameter $d \leq n$, there is an algorithm running in $\mathrm{poly}(n, \log q)$ time that outputs a polynomial $g(\alpha) \in \mathbb{F}_q[\alpha]$ of degree at most $d-1$ such that $\Delta((g(\alpha_i))_{i \in [n]}, (v_i)_{i \in [n]}) < \frac{n-d+1}{2}$.*

Finally, we recall generalized minimum distance decoding, which allows us to decode concatenated codes efficiently.

▶ **Theorem 6** (GMD Decoding [21, 32]). *Given two codes, $N_{outer} : \{0,1\}^k \to \Sigma^n$ of distance $1 - \varepsilon_{outer}$ with decoding time T_{outer}, and $N_{inner} : \Sigma \to \{0,1\}^m$ of distance $\frac{1}{2} - \varepsilon_{inner}$ with decoding time D_{inner}, there is an algorithm running in time $\mathrm{poly}(D_{inner}, D_{inner})$ that on input $w \in \{0,1\}^{n \cdot m}$ outputs $x \in \{0,1\}^k$ such that $\Delta(w, N_{outer} \circ N_{inner}(x)) < \frac{(1-\varepsilon_{outer})(\frac{1}{2}-\varepsilon_{inner})}{2}$.*

4 Locally Decoding with Confidences

We now recall the definition of *locally decodable codes*. For us, besides just correctness of local decoding when the distance to a codeword is small, we require that the decoder output a *confidence* indicating how much error it witnessed (less error means higher confidence).

▶ **Theorem 7** (Locally Decodable Code). *For any $\varepsilon > 0$ and $d = d(n) = \log^{1/\delta} n$, there is a code $\mathsf{LDC} : \{0,1\}^n \to \{0,1\}^{N(n)}$ where $N(n) = O_\varepsilon(n^{1+\delta})$ that satisfies the following properties:*

- **Distance:** *For any $x \neq y \in \{0,1\}^n$, it holds that $\Delta(\mathsf{LDC}(x), \mathsf{LDC}(y)) \geq \left(\frac{1}{2} - \varepsilon\right) \cdot N$.*
- **Locally Decoding with Confidence:** *For any index $i \in [n]$ and any word $w \in \{0,1\}^N$, there exists a randomized algorithm $\mathcal{D}_i$ that reads $Q = O_\varepsilon(\log^{2/\delta} n)$ bits of w, runs in $O_\varepsilon(n^{O(1/\delta)})$ time, and outputs a bit $\hat{x}_i$ along with confidence $\mathsf{conf} \in [0,1]$, satisfying that*
  - *For any $x \in \{0,1\}^n$ such that $\Delta(w, \mathsf{LDC}(x)) = \left(\frac{1}{4} - 2\varepsilon - e\right) \cdot N$ where $e \geq 0$, it holds that*

    $$\hat{x}_i = x_i \qquad \text{and} \qquad \mathsf{conf} > e$$

    with probability at least $1 - \exp\left(-\log^2 n\right)$.
  - *For any $x \in \{0,1\}^n$ such that $\Delta(w, \mathsf{LDC}(x)) = \left(\frac{1}{4} - 2\varepsilon + e\right) \cdot N$ where $e > 0$, it holds that*

    $$\hat{x}_i = x_i \qquad \text{or} \qquad \mathsf{conf} < e$$

    with probability at least $1 - \exp\left(-\log^2 n\right)$.

  Furthermore, the confidence conf can be represented as a rational number with denominator $4Q$.

Proof. This proof is omitted for the conference version. ◀

5 Noise Resilient Streaming for Linear Algorithms

Our first result is a noise resilient conversion for linear streaming algorithms A. We begin by recalling the definition of a linear streaming algorithm.

▶ **Definition 2** (Linear Streaming Algorithms). *A linear streaming algorithm $A : \{0,1\}^n \to \mathbb{F}_q$ is described by a list of functions $g_i : \{0,1\} \to \mathbb{F}_q$ for $i \in [n]$, and computes the value $A(x) = g_1(x_1) + \ldots + g_n(x_n)$ (where addition is over $\mathbb{F}_q$) by tracking the partial sum $g_1(x_1) + \ldots + g_i(x_i)$ upon receiving the i'th bit.*

For such algorithms, we describe a noise resilient conversion that incurs quadratic blow-up in communication complexity.

▶ **Theorem 3.** *Fix $\varepsilon, \delta > 0$. There is a function $\mathsf{enc} : X \subseteq \{0,1\}^n \to \{0,1\}^m$ where $m = O_\varepsilon(n^{2+\delta})$ and an explicit transformation B such that the following holds: For any linear streaming algorithm A that takes as input $x \in X \subseteq \{0,1\}^n$ as a stream, runs in space s and time t, and outputs $A(x)$, the algorithm $B_A = B(A)$ takes as input $z \in \{0,1\}^m$ as a stream, runs in space $s \cdot O_\varepsilon((\log n)^{O(1/\delta)})$ and time $m \cdot O_{\varepsilon,\delta}\left(1 + \frac{t}{n^2}\right)$, and satisfies that whenever $\Delta(z, \mathsf{enc}(x)) < \left(\frac{1}{4} - \varepsilon\right) \cdot m$ then $B_A(z)$ outputs $A(x)$ with probability $\geq 1 - 2^{O_\varepsilon(\log^2 n)}$.*

5.1 Statement of Algorithm

Let $\varepsilon > 0$. Throughout the section let $r = \log^{1/\delta} n$ and define $\ell := \log^2 n$. We also assume for simplicity that $\log_r n$ is an integer. We will also assume that $n > \max\{\exp(\exp(8\delta/\varepsilon)), \exp(1/\varepsilon)\}$ is sufficiently large, so that also $\ell < n$.

We begin by specifying the encoding $\mathsf{enc}(x)$ that Alice sends in the stream.

▶ **Definition 8** ($\mathsf{enc}(x)$)**.** *Let $\mathsf{LDC}(x)$ be a locally decodable code with $N(n) = |\mathsf{LDC}(x)| = O_\varepsilon(n^{1+\delta})$ and query complexity $Q = O_\varepsilon(\log^{2/\delta} n)$ satisfying the guarantees of Theorem 7 for $\varepsilon/8$. Then Alice sends $\mathsf{enc}(x) := \mathsf{LDC}(x)^{\log^2 n \cdot M_n}$ where $M_n = (r \cdot \ell)^{\log_r n}$ (that is, $\mathsf{enc}(n)$ is $\log^2 n \cdot M_n$ copies of $\mathsf{LDC}(x)$). In particular, $m = |\mathsf{enc}(x)| = (r \cdot \ell)^{\log_r n} \cdot \log^2 n \cdot N(n) = O_\varepsilon(n^{2+4\delta})$.*

Throughout this section, we use the notation $A_{i,j}(x)$ to denote the quantity $g(x_{i+1}) + \ldots + g_j(x_j)$. Then, $A(x) = A_{0,n}(x)$. We define $N_{j-i} := (r \cdot \ell)^{\log_r(j-i)} \cdot N(n)$ which, as we'll see in the description below, represent the number of bits read by the algorithm to approximate $A_{i,j}(x)$.

We describe Bob's streaming algorithm $B_A := B(A)$. Before stating it formally, we provide a high-level description.

Description

Let z be the incoming stream that Bob receives. At a high level, the algorithm B_A runs by generating many guesses for $A(x)$ along with confidences indicating how likely that guess was correct (depending on how much error is witnessed while generating the guess). At the end, the guess that has the most cumulative confidence is outputted.

For i, j where $j - i$ is an integer power of r, we define the algorithm $\mathsf{estA}(i, j)$ that takes in two input two indices $i, j \in [n]$. It reads N_{j-i} many bits of z after which it outputs a guess for $A_{i,j}(x)$ along with a confidence. In particular, $\mathsf{estA}(0, n)$ outputs a guess for $A(x)$ along with a confidence. By running $\mathsf{estA}(0, n)$ many times and aggregating the guesses weighted by the confidences, we obtain a final output.

To compute $\mathsf{estA}(i, j)$, we break down the interval $(i : j]$ into r subintervals $(i_0 : i_1], (i_1 : i_2], \ldots, (i_{r-1} : i_r]$ where $i_a = i + a \cdot \frac{j-i}{r}$. We then recursively formulate guesses for each $A\left(x\left(i_{a-1} : i_a\right]\right)$ over many iterations by calling $\mathsf{estA}(i_{a-1}, i_{a)}$ each many times. The choice of a in each iteration must be randomized, so that the adversary cannot attack any single choice of a. More specifically, we will split up the N_{j-i} length input stream into ℓ chunks, each of length N_{j-i}/ℓ bits. Each chunk is split into r sections, each of size $N_{j-i}/(\ell \cdot r) = N_{(j-i)/r}$. In each chunk, we pick a random permutation $(\pi_1, \pi_2, \ldots, \pi_r)$ of $[r]$. In the a'th section of the chunk, we will compute on the subproblem corresponding to interval $(i_{\pi_a - 1} : i_{\pi_a}]$ by calling $\mathsf{estA}\left(i_{\pi_a - 1}, i_{\pi_a}\right)$.

Whenever a recursive call to $\mathsf{estA}\left(i_{a-1}, i_a\right)$ is completed, outputting $(\hat{q}, \hat{c})$, then: if $q_a = \hat{q}$ then the confidence c_a is increased by $\hat{c}$, and if $q_a \neq \hat{q}$ then the confidence c_a is decreased by $\hat{c}$. If the confidence c_a becomes negative, then we are more sure that the correct state is $\hat{q}$ rather than q_a: then q_a is replaced by $\hat{q}$ and the confidence is negated (so that it's positive).

5.2 Proof of Theorem 3

We begin by proving the stated claims about the communication, time, and space complexities, and then proceed to prove correctness.

Algorithm 1 Bob's Noise Resilient Algorithm B_A.

input $n \in \mathbb{N}$ and stream $z \in \{0,1\}^m$.
function $\mathsf{estA}(i,j)$ ▷compute the state of A starting at state q between steps i and j
  if $j = i+1$ **then**
    Read the next $|\mathsf{LDC}(x)|$ bits of the stream y.
    Using Theorem 7 compute guess $\hat{b}$ for $x[j]$ and confidence $\hat{c}$ in $O_\varepsilon\left((\log n)^{O(1/\delta)}\right)$ bits of space.
    return $g_i(\hat{b}), c$.
  else
    Let $i_0 = i, i_1 = i + \frac{j-i}{r}, i_2 = i + \frac{2(j-i)}{r}, \ldots, i_r = j$.
    Initialize a list of pairs $(q_1, c_1), \ldots (q_r, c_r)$ each to $(\emptyset, 0)$. ▷cumulative best guesses and confidences
    for ℓ iterations **do**
      Let $\pi_1 \ldots \pi_r$ be a random permutation of $[r]$.
      for $a \in [r]$ **do**
        Compute $(\hat{q}, \hat{c}) \leftarrow \mathsf{estA}(i_{\pi_a - 1}, i_{\pi_a})$.
        if $\hat{q} = q_{\pi_a}$ **then** ▷update the confidence on $\mathsf{estA}(i_{\pi_a}, i_{\pi_j + 1}, q_{\pi_a - 1})$
          $c_{\pi_a} \leftarrow c_{\pi_a} + \hat{c}$
        else
          $c_{\pi_a} \leftarrow c_{\pi_a} - \hat{c}$
          if $c_{\pi_a} < 0$ **then** ▷if the guess changes, flip its confidence
            $q_{\pi_a} \leftarrow \hat{q}$ and $c_{\pi_a} \leftarrow -c_{\pi_a}$.
    return $q_1 + \ldots + q_r, \min(c_1 \ldots c_r)/\ell$

Initialize a pair (q, c) to $(\emptyset, 0)$.
for $\log^2 n$ iterations **do** ▷amplification step
  Let $(\hat{q}, \hat{c}) \leftarrow \mathsf{estA}(0, n)$
  if $\hat{q} = q$ **then**
    $c \leftarrow c + \hat{c}$
  else
    $c \leftarrow c - \hat{c}$
    if $c < 0$ **then**
      $q \leftarrow \hat{q}$ and $c \leftarrow -c$.
output q. ▷output $A(x)$

5.2.1 Algorithmic Complexity

The proofs of communication, time, and space complexities are omitted for the conference version.

5.2.2 Correctness

We now show correctness. Formally, correctness is shown by the following lemma.

▶ **Lemma 9.** *When at most* $\frac{1}{4} - \varepsilon$ *fraction of the stream* $\mathsf{enc}(x)$ *is corrupted, Algorithm 1 outputs* $A(x)$ *with probability* $\geq 1 - \exp\left(-\varepsilon^2 \log^2 n/32\right)$.

We prove the following statement which will easily imply Lemma 9. For a given i, j and associated string that is read by the algorithm in the computation, let the random variable $(q(i,j), c(i,j))$ denote the state and confidence after the computation $\mathsf{estA}(i,j)$. We

define the *signed confidence*, denoted $c^{\pm}(i,j)$, to be defined as $+c(i,j)$ if $q(i,j) = A_{i,j}(x)$ and $-c(i,j)$ otherwise. For intuition, the more positive $c^{\pm}(i,j)$ is, the more correct with higher confidence the output $(q(i,j), c(i,j))$ is, whereas the more negative $c_{\pm}(i,j)$ is, the more $q(i,j)$ is incorrect with high confidence. So, $c^{\pm}(i,j)$ gives us a scaled measure of how correct the output of $\mathsf{estA}(i,j)$ is.

▶ **Lemma 10.** *For any $0 \leq i < j \leq n$ and $e \in \mathbb{R}$, given $\leq \frac{1}{4} - \frac{\varepsilon}{4} - \frac{\varepsilon}{4} \cdot \frac{\log(j-i)}{\log n} - e$ fraction of corruptions in the bits read by the computation of $\mathsf{estA}(i,j)$, we have $\mathbb{E}[c^{\pm}(i,j)] > e$.*

Proof. The proof of this lemma is omitted for the conference version. ◀

Proof of Lemma 9. In the special case where $i = 0, j = n$ and there are $\leq \frac{1}{4} - \frac{\varepsilon}{2} - e < \frac{1}{4} - \frac{\varepsilon}{4} - \frac{\varepsilon}{4} \cdot \frac{\log(j-i)}{r} - e$ errors (where the inequality follows because $\log n < \varepsilon \cdot r$), by Lemma 10 we have that $\mathbb{E}[c^{\pm}(0,n)] > e$.

Then, the final amplification step of the protocol computes the pair $(q(0,n), c(0,n))$ for $\log^2 n$ times, where in each chunk i we denote the fraction of error to be $\left(\frac{1}{4} - \frac{\varepsilon}{2} - e_i\right)$, where $\sum_i e_i \geq \frac{\varepsilon \log^2 n}{2}$ since we assumed the total error was $\leq \frac{1}{4} - \varepsilon$. Also, the protocol outputs $A(x)$ if and only if $\sum_i c_i^{\pm}(0,n)$ (denoting the value of $c^{\pm}(0,n)$ in the i'th chunk) is positive. By Azuma's inequality,

$$Pr\left[\sum_i c_i^{\pm}(0,n) > 0\right] \geq Pr\left[\sum_i \left(c_i^{\pm}(0,n) - e_i\right) > -\frac{\varepsilon \log^2 n}{2}\right] \geq 1 - \exp\left(-\frac{\varepsilon^2 \log^2 n}{32}\right).$$ ◀

This concludes the proof of Theorem 3.

6 Noise Resilient Streaming for General Algorithms

We now consider general streaming algorithms, whose computational may be sequential in nature. Our main result is a noise resilient conversion for deterministic streaming algorithms A. Compared to our scheme for linear algorithms from Section 5, the length of our encoding is larger: $n^{4+\delta}$ compared to $n^{2+\delta}$.

▶ **Theorem 1.** *Fix $\varepsilon, \delta > 0$. For any $X \subseteq \{0,1\}^n$, there is a noise resilient transformation consisting of an encoding $\mathsf{enc} : X \subseteq \{0,1\}^n \to \{0,1\}^m$, and a transformation of algorithms B that is $\left(\frac{1}{4} - \varepsilon\right) \cdot m$ error resilient with probability $\geq 1 - 2^{O_\varepsilon(\log^2 n)}$. Moreover, $m = O_\varepsilon(n^{4+\delta})$, and for any deterministic algorithm A on domain X that runs in space s and time t, the algorithm $B(A)$ runs in space $s \cdot O_\varepsilon\left((\log n)^{O(1/\delta)}\right)$ and time $m \cdot O_{\varepsilon,\delta}\left(1 + \frac{t}{n^2}\right)$.*

Throughout this section, we use the notation

$$A(q, \hat{x}) \in \{0,1\}^s$$

to denote the state of algorithm A when starting with the state $q \in \{0,1\}^s$ and executing on $\hat{x}$ received in a stream. By definition, there is an explicit algorithm that computes $A(q, \hat{x})$ in s space. We also use the shorthand $A(\hat{x})$ to denote $A(\emptyset, \hat{x})$. Notice that $A(x) = A(\emptyset, x)$ is simply the output state of the stream.

6.1 Statement of Algorithm

Let $\varepsilon > 0$. Throughout the section let $r = \log^{1/\delta} n$ and define $\ell := r^2 \log^4 n$. We also assume for simplicity that $\log_r n$ is an integer. We will also assume that the parameter $n > \max\{\exp(\exp(8\delta/\varepsilon)), \exp(1/\varepsilon)\}$ is sufficiently large, so that also $\ell < n$.

We begin by specifying the encoding $\mathsf{enc}(x)$ that Alice sends in the stream.

▶ **Definition 11** ($\mathsf{enc}(x)$)**.** *Let* $\mathsf{LDC}(x)$ *be a locally decodable code with* $N(n) = |\mathsf{LDC}(x)| = O_\varepsilon(n^{1+\delta})$ *and query complexity* $Q = O_\varepsilon(\log^{2/\delta} n)$ *satisfying the guarantees of Theorem 7 for* $\varepsilon/8$*. Then Alice sends* $\mathsf{enc}(x) := \mathsf{LDC}(x)^{\log^2 n \cdot M_n}$ *where* $M_n = (r \cdot \ell)^{\log_r n}$ *(that is,* $\mathsf{enc}(n)$ *is* $\log^2 n \cdot M_n$ *copies of* $\mathsf{LDC}(x)$*). In particular,* $m = |\mathsf{enc}(x)| = (r \cdot \ell)^{\log_r n} \cdot \log^2 n \cdot N(n) = O_\varepsilon(n^{4+6\delta})$.

Next, we describe Bob's streaming algorithm $B_A := B(A)$. Before stating it formally, we provide a high-level description.

Description

Let z be the incoming stream that Bob receives. At a high level, the algorithm B_A runs by generating many guesses for $A(x)$ along with confidences indicating how likely that guess was correct (depending on how much error is witnessed while generating the guess). At the end, the guess that has the most cumulative confidence is outputted.

For i, j where $j - i$ is an integer power of r, we define the algorithm $\mathsf{estA}(i, j, q)$ that has the following syntax:

- $\mathsf{estA}(i, j, q)$ takes as input two indices $i, j \in [n]$ along with a state $q \in \{0,1\}^s$ which represents a guess for the state of $A(q, x(i : j])$.
- It reads $N_{j-i} := (r \cdot \ell)^{\log_r(j-i)} \cdot N(n)$ many bits of z after which it outputs a guess for $A(q, x(i : j])$ along with a confidence.

In particular, $\mathsf{estA}(0, n, q)$ outputs a guess for $A(x)$ along with a confidence. By running $\mathsf{estA}(0, n, q)$ many times and aggregating the guesses weighted by the confidences, we obtain a final output.

At a high level, to compute $\mathsf{estA}(i, j, q)$, we break down the interval $(i : j]$ into r subintervals $(i_0 : i_1], (i_1 : i_2], \ldots, (i_{r-1} : i_r]$ where $i_a = i + a \cdot \frac{j-i}{r}$. We then recursively formulate guesses for each $A(x(1 : i_a])$ over many iterations by calling $\mathsf{estA}(i_{a-1}, i_a, q_{a-1})$ for some state q_{a-1}. The choice of a in each iteration must be randomized, so that the adversary cannot attack any single choice of a. More specifically, we will split up the N_{j-i} length input stream into ℓ chunks, each of length N_{j-i}/ℓ bits. Each chunk is split into r sections, each of size $N_{j-i}/(\ell \cdot r) = N_{(j-i)/r}$. In each chunk, we pick a random permutation $(\pi_1, \pi_2, \ldots, \pi_r)$ of $[r]$. In the a'th section of the chunk, we will compute on the subproblem corresponding to interval $(i_{\pi_a - 1} : i_{\pi_a}]$ by calling $\mathsf{estA}(i_{\pi_a - 1}, i_{\pi_a}, q_{\pi_a - 1})$.

Note that as the algorithm A is computed sequentially, computing a guess for $A(x[1 : i_a])$ requires having a starting state q_{a-1} for $A(x[1 : i_{a-1}])$. Thus, throughout the entire computation, we will keep track of the best guess and associated confidence for each of the r states $A(x[1 : i_a])$, denoted (q_a, c_a) and all initialized to $(\emptyset, 0)$.

These pairs (q_a, c_a) are maintained as follows. Whenever a recursive call to $\mathsf{estA}(i_{a-1}, i_a, q_{a-1})$ is completed, outputting $(\hat{q}, \hat{c})$, then: if $q_a = \hat{q}$ then the confidence c_a is increased by $\hat{c}$, and if $q_a \neq \hat{q}$ then the confidence c_a is decreased by $\hat{c}$. If the confidence c_a becomes negative, then we are more sure that the correct state is $\hat{q}$ rather than q_a: then q_a is replaced by $\hat{q}$ and the confidence is negated (so that it's positive). In this last case where q_a is replaced, we have no more reason to believe that further computations of $q_{a'}$, $a' > a$, are correct since they all depended on q_a, so we erase all such pairs $(q_{a'}, c_{a'})$ and reset them to $(\emptyset, 0)$. A key point in our analysis is to understand why this does not cause the error probability to accumulate.

Algorithm 2 Bob's Noise Resilient Algorithm B_A

input $n \in \mathbb{N}$ and stream $z \in \{0,1\}^m$.
function $\mathsf{estA}(i, j, q)$ ▷compute the state of A starting at state q between steps i and j
  if $j = i + 1$ **then**
    Read the next $|\mathsf{LDC}(x)|$ bits of the stream y.
    Using Theorem 7 compute guess $\hat{b}$ for $x[j]$ and confidence $\hat{c}$ in $s \cdot O_\varepsilon\left((\log n)^{O(1/\delta)}\right)$ bits of space.
    return $A(q, \hat{b}), c$.
  else
    Let $i_0 = i, i_1 = i + \frac{j-i}{r}, i_2 = i + \frac{2(j-i)}{r}, \ldots, i_r = j$.
    Initialize a list of pairs $(q_1, c_1), \ldots (q_r, c_r)$ each to $(\emptyset, 0)$. ▷cumulative best guesses and confidences
    for ℓ iterations **do**
      Let $\pi_1 \ldots \pi_r$ be a random permutation of $[r]$.
      Set $(q'_1, c'_1) = (q_1, c_1), \ldots (q'_r, c'_r) = (q_r, c_r)$.
      for $a \in [r]$ **do**
        Compute $(\hat{q}, \hat{c}) \leftarrow \mathsf{estA}(i_{\pi_a - 1}, i_{\pi_a}, q'_{\pi_a - 1})$ where $q'_0 := q$.
        if $\hat{q} = q'_{\pi_a}$ **then** ▷update the confidence on $\mathsf{estA}(i_{\pi_a}, i_{\pi_j + 1}, q_{\pi_a - 1})$
          $c_{\pi_a} \leftarrow c'_{\pi_a} + \hat{c}$
        else
          $c_{\pi_a} \leftarrow c'_{\pi_a} - \hat{c}$
          if $c_{\pi_a} < 0$ **then** ▷if the guess changes, reset its confidence
            $q_{\pi_a} \leftarrow \hat{q}$ and $c_{\pi_a} \leftarrow -c_{\pi_a}$.
      if some q_a was changed from its value at the beginning of the chunk **then**
        For all $i > a$, set $(q_i, c_i) \leftarrow (\emptyset, 0)$. ▷reset state and confidence for states with $i > a$
    return $q_r, \min(c_1 \ldots c_r)/\ell$

Initialize a pair (q, c) to $(\emptyset, 0)$.
for $\log^2 n$ iterations **do** ▷amplification step
  Let $(\hat{q}, \hat{c}) \leftarrow \mathsf{estA}(0, n, \emptyset)$
  if $\hat{q} = q$ **then**
    $c \leftarrow c + \hat{c}$
  else
    $c \leftarrow c - \hat{c}$
    if $c < 0$ **then**
      $q \leftarrow \hat{q}$ and $c \leftarrow -c$.
output q. ▷output $A(x)$

6.2 Proof of Theorem 1

The proofs that the algorithm satisfies the required space, computational and communication guarantees are essentially the same as in Section 5, but we reproduce them for completeness. The proof of correctness is somewhat more complicated but also follows the same general outline.

6.2.1 Algorithmic Complexity

The proofs of communication, time, and space complexities are omitted for the conference version.

6.2.2 Correctness

Next, we show correctness. Formally, correctness is shown by the following lemma.

▶ **Lemma 12.** *When at most* $\frac{1}{4} - \varepsilon$ *fraction of the stream* $\mathsf{enc}(x)$ *is corrupted, Algorithm 2 outputs* $A(x)$ *with probability* $\geq 1 - \exp\left(-\varepsilon^2 \log^2 n/32\right)$.

We prove the following statement which will easily imply Lemma 12. For a given i, j, q and associated string that is read by the algorithm in the computation, let the random variable $(q(i,j,q), c(i,j,q))$ denote the state and confidence after the computation $\mathsf{estA}(i,j,q)$. We define the *signed confidence*, denoted $c^{\pm}(i,j,q)$, to be defined as $+c(i,j,q)$ if $q(i,j,q) = A(q, x(i:j])$ and $-c(i,j,q)$ otherwise. For intuition, the more positive $c^{\pm}(i,j,q)$ is, the more correct with higher confidence the output $(q(i,j,q), c(i,j,q))$ is, whereas the more negative $c_{\pm}(i,j,q)$ is, the more $q(i,j,q)$ is incorrect with high confidence. So, $c^{\pm}(i,j,q)$ gives us a scaled measure of how correct the output of $\mathsf{estA}(i,j,q)$ is.

▶ **Lemma 13.** *For any* $0 \leq i < j \leq n$, $q \in \{0,1\}^s$, *and* $e \in \mathbb{R}$, *given* $\leq \frac{1}{4} - \frac{\varepsilon}{4} - \frac{\varepsilon}{4} \cdot \frac{\log(j-i)}{\log n} - e$ *fraction of corruptions in the bits read by the computation of* $\mathsf{estA}(i,j,q)$, *we have* $\mathbb{E}[c^{\pm}(i,j,q)] > e$.

Proof. The proof of this lemma is omitted for the conference version. ◀

Proof of Lemma 12. In the special case where $i = 0, j = n, q = \emptyset$ and there are $\leq \frac{1}{4} - \frac{\varepsilon}{2} - e < \frac{1}{4} - \frac{\varepsilon}{4} - \frac{\varepsilon}{4} \cdot \frac{\log(j-i)}{r} - e$ errors (where the inequality follows because $\log n < \varepsilon \cdot r$), by Lemma 13 we have that $\mathbb{E}[c^{\pm}(0,n,\emptyset)] > e$.

Then, the final amplification step of the protocol computes the pair $(q(0,n,\emptyset), c(0,n,\emptyset))$ for $\log^2 n$ times, where in each chunk i we denote the fraction of error to be $\left(\frac{1}{4} - \frac{\varepsilon}{2} - e_i\right)$, where $\sum_i e_i \geq \frac{\varepsilon \log^2 n}{2}$ since we assumed the total error was $\leq \frac{1}{4} - \varepsilon$. Also, the protocol outputs $A(x)$ if and only if $\sum_i c_i^{\pm}(0,n,\emptyset)$ (denoting the value of $c^{\pm}(0,n,\emptyset)$ in the i'th chunk) is positive. By Azuma's inequality,

$$Pr\left[\sum_i c_i^{\pm}(0,n,\emptyset) > 0\right] \geq Pr\left[\sum_i \left(c_i^{\pm}(0,n,\emptyset) - e_i\right) > -\frac{\varepsilon \log^2 n}{2}\right] \geq 1 - \exp\left(-\frac{\varepsilon^2 \log^2 n}{32}\right).$$

◀

This concludes the proof of Theorem 1.
