Preface
Raghu Meka 0:xi

List of Authors
..... 0:xiii

Papers

Simple Is COOL: Graded Dispersal and Its Applications for Byzantine Fault Tolerance
Ittai Abraham, Gilad Asharov, and Anirudh Chandramouli 1:1–1:20

Improved Lower Bounds for 3-Query Matching Vector Codes
Divesh Aggarwal, Pranjal Dutta, Zeyong Li, Maciej Obremski, and Sidhant Saraogi 2:1–2:19

Sparsity Lower Bounds for Probabilistic Polynomials
Josh Alman, Arkadev Chattopadhyay, and Ryan Williams 3:1–3:25

A Bicriterion Concentration Inequality and Prophet Inequalities for k-Fold Matroid Unions
Noga Alon, Nick Gravin, Tristan Pollner, Aviad Rubinstein, Hongao Wang, S. Matthew Weinberg, and Qianfan Zhang 4:1–4:22

Edge-Minimum Walk of Modular Length in Polynomial Time
Antoine Amarilli, Benoît Groz, and Nicole Wein 5:1–5:23

Doubly Sub-Linear Interactive Proofs of Proximity
Noga Amir, Oded Goldreich, and Guy N. Rothblum 6:1–6:25

Simultaneous Haar Indistinguishability with Applications to Unclonable Cryptography
Prabhanjan Ananth, Fatih Kaleoglu, and Henry Yuen 7:1–7:23

Single-Round Proofs of Quantumness from Knowledge Assumptions
Petia Arabadjieva, Alexandru Gheorghiu, Victor Gitton, and Tony Metger 8:1–8:16

The Local Hamiltonian Problem for Quasi-Quantum States: A Toy Model for the Quantum PCP Conjecture
Itai Arad and Miklos Santha 9:1–9:1

Algorithmic Collusion Without Threats
Eshwar Ram Arunachaleswaran, Natalie Collina, Sampath Kannan, Aaron Roth, and Juba Ziani 10:1–10:21

Rank Lower Bounds on Non-Local Quantum Computation
Vahid R. Asadi, Eric Culf, and Alex May 11:1–11:18

Stable Matching with Interviews
Itai Ashlagi, Jiale Chen, Mohammad Roghani, and Amin Saberi 12:1–12:19

16th Innovations in Theoretical Computer Science Conference (ITCS 2025).
Editor: Raghu Meka
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Low Sensitivity Hopsets
Vikrant Ashvinkumar, Aaron Bernstein, Chengyuan Deng, Jie Gao, and Nicole Wein 13:1–13:23

The More the Merrier! On Total Coding and Lattice Problems and the Complexity of Finding Multicollisions
Huck Bennett, Surendra Ghentiyala, and Noah Stephens-Davidowitz 14:1–14:22

Exponential-Time Approximation (Schemes) for Vertex-Ordering Problems
Matthias Bentert, Fedor V. Fomin, Tanmay Inamdar, and Saket Saurabh 15:1–15:18

On Fault Tolerant Single-Shot Logical State Preparation and Robust Long-Range Entanglement
Thiago Bergamaschi and Yunchao Liu 16:1–16:9

Random Restrictions of Bounded Low Degree Polynomials Are Juntas
Sreejata Kishor Bhattacharya 17:1–17:21

Finite Matrix Multiplication Algorithms from Infinite Groups
Jonah Blasiak, Henry Cohn, Joshua A. Grochow, Kevin Pratt, and Chris Umans 18:1–18:23

Differential Privacy and Sublinear Time Are Incompatible Sometimes
Jeremiah Blocki, Hendrik Fichtenberger, Elena Grigorescu, and Tamalika Mukherjee 19:1–19:18

Estimating Euclidean Distance to Linearity
Andrej Bogdanov and Lorenzo Taschin 20:1–20:18

Adjacency Labeling Schemes for Small Classes
Édouard Bonnet, Julien Duron, John Sylvester, and Viktor Zamaraev 21:1–21:22

Round-Vs-Resilience Tradeoffs for Binary Feedback Channels
Mark Braverman, Klim Efremenko, Gillat Kol, Raghuvansh R. Saxena, and Zhijun Zhang 22:1–22:23

Accumulation Without Homomorphism
Benedikt Bünz, Pratyush Mishra, Wilson Nguyen, and William Wang 23:1–23:25

Sampling List Packings
Evan Camrud, Ewan Davies, Alex Karduna, and Holden Lee 24:1–24:15

Locally Private Histograms in All Privacy Regimes
Clément L. Canonne and Abigail Gentle 25:1–25:24

Settling the Complexity of Testing Grainedness of Distributions, and Application to Uniformity Testing in the Huge Object Model
Clément L. Canonne, Sayantan Sen, and Joy Qiping Yang 26:1–26:19

The Randomness Complexity of Differential Privacy
Clément L. Canonne, Francis E. Su, and Salil P. Vadhan 27:1–27:21

Coresets for 1-Center in ℓ_1 Metrics
Amir Carmel, Chengzhi Guo, Shaofeng H.-C. Jiang, and Robert Krauthgamer 28:1–28:20

Extracting Dual Solutions via Primal Optimizers
Yair Carmon, Arun Jambulapati, Liam O'Carroll, and Aaron Sidford 29:1–29:24

Provability of the Circuit Size Hierarchy and Its Consequences
Marco Carmosino, Valentine Kabanets, Antonina Kolokolova, Igor C. Oliveira, and Dimitrios Tsintsilidas 30:1–30:22

Quantum Advantage and Lower Bounds in Parallel Query Complexity
Joseph Carolan, Amin Shiraz Gilani, and Mahathi Vempati 31:1–31:14

Succinct Fermion Data Structures
Joseph Carolan and Luke Schaeffer 32:1–32:21

Bosonic Quantum Computational Complexity
Ulysse Chabaud, Michael Joseph, Saeed Mehraban, and Arsalan Motamedi 33:1–33:19

Directed Hypercube Routing, a Generalized Lehman-Ron Theorem, and Monotonicity Testing
Deeparnab Chakrabarty and C. Seshadhri 34:1–34:15

Unraveling Universally Closest Refinements via Symmetric Density Decomposition and Fisher Market Equilibrium
T-H. Hubert Chan and Quan Xue 35:1–35:23

Entry-Specific Matrix Estimation Under Arbitrary Sampling Patterns Through the Lens of Network Flows
Yudong Chen, Xumei Xi, and Christina Lee Yu 36:1–36:2

A Lower Bound on the Trace Norm of Boolean Matrices and Its Applications
Tsun-Ming Cheung, Hamed Hatami, Kaave Hosseini, Aleksandar Nikolov, Toniann Pitassi, and Morgan Shirley 37:1–37:15

Backdoor Defense, Learnability and Obfuscation
Paul Christiano, Jacob Hilton, Victor Lecomte, and Mark Xu 38:1–38:21

Data Reconstruction: When You See It and When You Don't
Edith Cohen, Haim Kaplan, Yishay Mansour, Shay Moran, Kobbi Nissim, Uri Stemmer, and Eliad Tsfadia 39:1–39:23

Derandomized Squaring: An Analytical Insight into Its True Behavior
Gil Cohen, Itay Cohen, Gal Maor, and Yuval Peled 40:1–40:24

Query Complexity of Stochastic Minimum Vertex Cover
Mahsa Derakhshan, Mohammad Saneian, and Zhiyang Xun 41:1–41:12

Nearest Neighbor Complexity and Boolean Circuits
Mason DiCicco, Vladimir Podolskii, and Daniel Reichman 42:1–42:23

Space Complexity of Minimum Cut Problems in Single-Pass Streams
Matthew Ding, Alexandro Garces, Jason Li, Honghao Lin, Jelani Nelson, Vihan Shah, and David P. Woodruff 43:1–43:23

Learning-Augmented Streaming Algorithms for Approximating MAX-CUT
Yinhao Dong, Pan Peng, and Ali Vakilian 44:1–44:24

Distributed and Parallel Low-Diameter Decompositions for Arbitrary and Restricted Graphs
Jinfeng Dou, Thorsten Götte, Henning Hillebrandt, Christian Scheideler, and Julian Werthmann 45:1–45:26

Data-Driven Solution Portfolios
Marina Drygala, Silvio Lattanzi, Andreas Maggiori, Miltiadis Stouras, Ola Svensson, and Sergei Vassilvitskii 46:1–46:15

Concentration of Submodular Functions and Read-k Families Under Negative Dependence
Sharmila Duppala, George Z. Li, Juan Luque, Aravind Srinivasan, and Renata Valieva 47:1–47:16

Robust Restaking Networks
Naveen Durvasula and Tim Roughgarden 48:1–48:21

Confusion Matrix Design for Downstream Decision-Making
Yiding Feng and Wei Tang 49:1–49:1

Fully Characterizing Lossy Catalytic Computation
Marten Folkertsma, Ian Mertz, Florian Speelman, and Quinten Tupker 50:1–50:13

Parameterized Geometric Graph Modification with Disk Scaling
Fedor V. Fomin, Petr A. Golovach, Tanmay Inamdar, Saket Saurabh, and Meirav Zehavi 51:1–51:17

Combinatorial Pen Testing (Or Consumer Surplus of Deferred-Acceptance Auctions)
Aadityan Ganesh and Jason Hartline 52:1–52:22

Differential Privacy on Trust Graphs
Badih Ghazi, Ravi Kumar, Pasin Manurangsi, and Serena Wang 53:1–53:23

Partial Minimum Branching Program Size Problem Is ETH-Hard
Ludmila Glinskih and Artur Riazanov 54:1–54:22

Completeness Theorems for k-SUM and Geometric Friends: Deciding Fragments of Linear Integer Arithmetic
Geri Gokaj and Marvin Künnemann 55:1–55:25

Incompressible Functional Encryption
Rishab Goyal, Venkata Koppula, Mahesh Sreekumar Rajasree, and Aman Verma 56:1–56:22

Deterministic Approximation for the Volume of the Truncated Fractional Matching Polytope
Heng Guo and Vishvajeet N 57:1–57:14

The Computational Complexity of Factored Graphs
Shreya Gupta, Boyang Huang, Russell Impagliazzo, Stanley Woo, and Christopher Ye 58:1–58:19

Error Correction for Message Streams
Meghal Gupta and Rachel Yun Zhang 59:1–59:18

List Decoding Bounds for Binary Codes with Noiseless Feedback
Meghal Gupta and Rachel Yun Zhang 60:1–60:20

Hardness of Sampling for the Anti-Ferromagnetic Ising Model on Random Graphs
Neng Huang, Will Perkins, and Aaron Potechin 61:1–61:23

A High Dimensional Cramer's Rule Connecting Homogeneous Multilinear Equations to Hyperdeterminants
Antoine Joux and Anand Kumar Narayanan 62:1–62:16

Complexity Classification of Product State Problems for Local Hamiltonians
John Kallaugher, Ojas Parekh, Kevin Thompson, Yipu Wang, and Justin Yirka 63:1–63:32

A Universal Sequence of Tensors for the Asymptotic Rank Conjecture
Petteri Kaski and Mateusz Michałek 64:1–64:24

Online Versus Offline Adversaries in Property Testing
Esty Kelman, Ephraim Linder, and Sofya Raskhodnikova 65:1–65:18

Graph Reconstruction via MIS Queries
Christian Konrad, Conor O'Sullivan, and Victor Traistaru 66:1–66:19

Error-Correcting Graph Codes
Swastik Kopparty, Aditya Potukuchi, and Harry Sha 67:1–67:20

New Pseudorandom Generators and Correlation Bounds Using Extractors
Vinayak M. Kumar 68:1–68:23

Approximate Unitary k-Designs from Shallow, Low-Communication Circuits
Nicholas LaRacuente and Felix Leditzky 69:1–69:2

Facility Location on High-Dimensional Euclidean Spaces
Euiwoong Lee and Kijun Shin 70:1–70:21

Toward the Impossibility of Perfect Complete Quantum PKE from OWFs
Longcheng Li, Qian Li, Xingjian Li, and Qipeng Liu 71:1–71:16

Information Design with Unknown Prior
Tao Lin and Ce Li 72:1–72:1

On White-Box Learning and Public-Key Encryption
Yanyi Liu, Noam Mazor, and Rafael Pass 73:1–73:22

Sublinear Metric Steiner Tree via Improved Bounds for Set Cover
Sepideh Mahabadi, Mohammad Roghani, Jakub Tarnawski, and Ali Vakilian 74:1–74:24

Gadgetless Lifting Beats Round Elimination: Improved Lower Bounds for Pointer Chasing
Xinyu Mao, Guangxu Yang, and Jiapeng Zhang 75:1–75:14

A Quantum Unique Games Conjecture
Hamoon Mousavi and Taro Spirig 76:1–76:16

Sketching, Moment Estimation, and the Lévy-Khintchine Representation Theorem
Seth Pettie and Dingyu Wang 77:1–77:23

Randomized Lifting to Semi-Structured Communication Complexity via Linear Diversity
Vladimir Podolskii and Alexander Shekhovtsov 78:1–78:21

Catalytic Communication
Edward Pyne, Nathan S. Sheffield, and William Wang 79:1–79:24

Diversity in Evolutionary Dynamics
Yuval Rabani, Leonard J. Schulman, and Alistair Sinclair 80:1–80:3

Online Balanced Allocation of Dynamic Components
Rajmohan Rajaraman and Omer Wasim 81:1–81:23

Tight Bounds on List-Decodable and List-Recoverable Zero-Rate Codes
Nicolas Resch, Chen Yuan, and Yihan Zhang 82:1–82:21

Fine-Grained Equivalence for Problems Related to Integer Linear Programming
Lars Rohwedder and Karol Węgrzycki 83:1–83:18

Quantum Communication Complexity of Classical Auctions
Aviad Rubinstein and Zixin Zhou 84:1–84:27

Quantum 2-SAT on Low Dimensional Systems Is QMA_1-Complete: Direct Embeddings and Black-Box Simulation
Dorian Rudolph, Sevag Gharibian, and Daniel Nagaj 85:1–85:24

Eulerian Orientations and Hadamard Codes: A Novel Connection via Counting
Shuai Shao and Zhuxiao Tang 86:1–86:13

When to Give up on a Parallel Implementation
Nathan S. Sheffield and Alek Westover 87:1–87:18

Detecting and Correcting Computationally Bounded Errors: A Simple Construction Under Minimal Assumptions
Jad Silbak and Daniel Wichs 88:1–88:23

Optimal Communication Complexity of Chained Index
Janani Sundaresan 89:1–89:18

Polynomial Size, Short-Circuit Resilient Circuits for NC
Yael Tauman Kalai and Raghuvansh R. Saxena 90:1–90:18

Simple Norm Bounds for Polynomial Random Matrices via Decoupling
Madhur Tulsiani and June Wu 91:1–91:22

Listing 6-Cycles in Sparse Graphs
Virginia Vassilevska Williams and Alek Westover 92:1–92:21

Polynomials, Divided Differences, and Codes
S. Venkitesh 93:1–93:25

New Direct Sum Tests
Alek Westover, Edward Yu, and Kai Zhe Zheng 94:1–94:26

Toward Separating QMA from QCMA with a Classical Oracle
Mark Zhandry 95:1–95:19

Formulations and Constructions of Remote State Preparation with Verifiability, with Applications
Jiayu Zhang 96:1–96:19

Preface

The papers in this volume were presented at the 15th Innovations in Theoretical Computer Science (ITCS 2025) conference. The conference was held from January 7 to January 10, 2025 at Columbia University

ITCS seeks to promote research with innovative or bold agendas, which could be conceptual, technical, or methodological, and whose message will advance and inspire the greater theory community. Some examples of the kind of papers that the conference aims to feature are those introducing a new concept, model or understanding; opening a new line of inquiry within traditional or interdisciplinary areas; introducing new mathematical techniques and methodologies, or new applications of known techniques; putting forth a bold, even if preliminary, vision or line of attack; making interesting progress on traditional research directions; or unearthing novel or surprising connections between different topics.

The conference received 303 submissions of which the program committee accepted 96 papers. The submission pool was strong, which explains the high acceptance rate. The conference format was single-session with the goal of promoting a sense of community, and promoting the exchange of ideas between different areas of theoretical computer science. Given this and the sizable number of accepted papers, each talk at the conference was only about 10 minutes long. The authors of each paper were thus requested to submit a 20–25 minute video, which are linked from the conference website. Among the many strong submissions, two papers *Random Restrictions of Bounded Low Degree Polynomials Are Juntas*, by Sreejata Kishor Bhattacharya (Tata Institute of Fundamental Research) and *Error Correction for Message Streams*, by Rachel Yun Zhang (MIT); Meghal Gupta (UC Berkeley) received the Best Student Paper Award.

The program committee (PC) consisted of 37 fantastic members (excluding the chair): Ittai Abraham (Intel), Sepehr Assadi (University of Waterloo), Andris Ambainis (University of Latvia), Prabhanjan Ananth (University of California, Santa Barbara), Srinivasan Arunachalam (IBM Research), Hadley Black (University of California, San Diego), Adam Bouland (Stanford University), Eshan Chattopadhyay (Cornell University), Lijie Chen (University of California, Berkeley), Rishabh Goyal (University of Wisconsin-Madison), Prahladh Harsha (Tata Institute of Fundamental Research), Aayush Jain (Carnegie Mellon University), Rahul Jain (National University of Singapore), Michael Kapralov (École polytechnique fédérale de Lausanne), Robert Kleinberg (Cornell University), Vasilis Kontonis (University of Texas at Austin), Pravesh Kothari (Princeton University), Ravi Kumar (Google Research), Jason Li (Carnegie Mellon University), Daniel Lokshtanov (University of California, Santa Barbara), Pasin Manurangasi (Google Research), Dor Minzer (Massachussetts Institute of Technology), Chinmay Nikhre (University of Washington, Seattle), Shayan Oveis Gharan (University of Washington, Seattle), Prasad Raghavendra (University of California, Berkeley), Guy Rothblum (Apple), Shubhangi Saraf (University of Toronto), Sushant Sachdeva (University of Toronto), Tselil Schramm (Stanford University), Sahil Singla (Georgia Institute of Technology), Srikanth Srinivasan (University of Copenhagen), Avishay Tal (University of California, Berkeley), Roei Tell (University of Toronto), Christos Tzamos (University of Athens), David Wajc (Technion), Ryan Williams (Massachussetts Institute of Technology), Jiapeng Zhang (University of Southern California).

I am extremely grateful to all members of the PC, who worked really hard under very tight time constraints to produce a fantastic program as well as provide useful feedback to the authors, of accepted and rejected papers alike. The review process was double-blind, and

16th Innovations in Theoretical Computer Science Conference (ITCS 2025).
Editor: Raghu Meka

LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

throughout the review process the PC members did not have access to the identities of the authors on the hotcrp conference review software. The rationale behind the double-blind process was to help PC members and external reviewers come to a judgment about the paper without unconscious bias, but it was not intended to make it impossible for them to discover who the authors are. As such, the authors were free to post their papers or otherwise make them publicly available. In addition, while the conference did not have a formal rebuttal process, the PC engaged in interactive communication with the authors throughout the review process, coordinated by the chair, to address any misunderstandings (e.g., concerns about errors or missing attributions).

The program schedule was divided into sessions, each consisting of 6–7 papers. Following ITCS tradition, the chair of each session was tasked with "ranting" about the papers in the session, emphasizing their contributions and the ways in which they are innovative, and when possible tying all the papers in the session together. The program also continued with the wonderful ITCS tradition of "graduating bits," where students and postdocs looking for academic jobs or postdoc opportunities give a very short (few minutes) presentation. In addition, the local chairs also organized a fun game night during the conference.

I would like to thank Columbia University for hosting the event. Local chairs Josh Alman and Alexander Andoni were outstanding in their organization, smoothly managing the many unexpected issues that arose during the conference. I am also grateful to ITCS Steering Committee chair Guy Rothblum for his guidance, for patiently answering all my questions, and running the event smoothly. Josh, Alexander, and Guy were tremendously helpful in shouldering extra responsibilities during the physical conference, as I was unable to attend due to the emergency situation in Los Angeles at the time. Their efforts were essential to the conference's success.

Simple Is COOL: Graded Dispersal and Its Applications for Byzantine Fault Tolerance

Ittai Abraham

Abstract

The COOL protocol of Chen (DISC'21) is a major advance that enables perfect security for various tasks (in particular, Byzantine Agreement in Synchrony and Reliable Broadcast in Asynchrony). For an input of size L bits, its communication complexity is $O(nL + n^2 \log n)$, which is optimal up to a $\log n$ factor. Unfortunately, Chen's analysis is rather intricate and complex.

Our main contribution is a simple analysis of a new variant of COOL based on elementary counting arguments. Our main consistency proof takes less than two pages (instead of over 20 pages), making the COOL protocol much more accessible. In addition, the simple analysis allows us to improve the protocol by reducing one round of communication and reducing the communication complexity by 40%.

In addition, we suggest a new way of extracting the core properties of COOL as a new primitive, which we call Graded Dispersal. We show how Graded Dispersal can then be used to obtain efficient solutions for Byzantine Agreement, Verifiable Information Dispersal, Gradecast, and Reliable Broadcast (in both Synchrony and Asynchrony, where appropriate). Our improvement of COOL directly applies here, and we improve the state-of-the-art in all those primitives by reducing at least one round and 40% communication.

1 Introduction

Byzantine agreement (BA), introduced by [27, 22], is a fundamental problem in distributed protocol design. It involves n parties, each holding an initial input v_i, who must agree on a common value v. BA requires satisfying two key properties: **Agreement**, where all honest parties must output the same value, and **Validity**, which ensures that if all honest parties begin with the same initial value v, their output should also be v. These security properties must be guaranteed even in the presence of up to t corrupted parties, which may deviate arbitrarily from the protocol's specifications. This work focuses on perfect security with optimal resilience ($t < n/3$).

It is known that agreement on a single bit requires $\Omega(n^2)$ bits of communication when the protocol is deterministic [16], or even randomized, against strongly-adaptive adversaries [3] (for any $t = O(n)$). Moreover, agreeing on an L bit message requires $\Omega(nL)$ communication,

© Ittai Abraham, Gilad Asharov, and Anirudh Chandramouli;
licensed under Creative Commons License CC-BY 4.0

since we might have $O(n)$ parties that do not hold the agreed message as input and to receive that message. Furthermore, it has been shown that for any Byzantine agreement protocol with perfect security, there exists an execution that requires $t+1$ rounds [18]. These impossibilities imply that the best one can hope for is $O(nL + n^2)$ for agreeing on a message of size L. However, achieving this bound has been an elusive goal for extensive research.

The baseline protocol [10] for binary Byzantine agreement has a communication complexity of $O(n^2)$ and runs in $\Theta(n)$ rounds. For messages of size L, this implies a communication complexity of $O(n^2L)$. Liang and Vaidya [23] proposed a protocol with a communication complexity of $O(nL + n^4\sqrt{L} + n^6)$ communication; Ganesh and Patra [19], and Loveless, Dreslinski, and Kasikci [24] introduced protocols with a complexity of $O(nL + n^4 \log n)$ communication; Subsequently, Nayak, Ren, Shi, Vaidya, and Xiang [25] improved on this with a protocol that achieves $O(nL + n^3 \log n)$ communication.

The COOL protocol. The paper of Chen [13] further advanced the state of the art by presenting a *deterministic* byzantine agreement protocol, named COOL (stands for **co**ded BA protoc**ol**), that achieves $O(nL + n^2 \log n)$ communication complexity, which is only a logarithmic factor away from the best possible one can hope for. He shows:

▶ **Theorem 1.1** (Byzantine agreement [13]). *There exists a perfectly secure and deterministic Byzantine agreement protocol over a synchronous network for messages of size L bits with communication complexity of $O(nL+n^2 \log n)$ with $\Theta(n)$ rounds, resilient to $t < n/3$ malicious faults.*

Unfortunately, the analysis in [13] is complex and lengthy, making it difficult to understand. Our goal is to provide a simplified analysis of the protocol, offering new insights into the technique and its limitations. The COOL approach has already been applied to related primitives, such as broadcast and gradecast [30] in the synchronous settings, and reliable broadcast in asynchronous settings [6], and holds promise for broader applications as well.

1.1 Our Contributions

In this paper, we provide the following contributions:

Graded dispersal. The COOL protocol of [13] is tailored for Byzantine agreement, and its core was later adopted for reliable broadcast [6] and gradecast by [30]. We show that this core of COOL is essentially a new variant of dispersal (a part of a Verifiable Information Dispersal protocol [12]). We call this new variant *graded dispersal*. We note that dispersal typically needs a designated sender; in our abstraction, we assume the parties have already received the message from some "virtual sender" and wish to verify that they have enough information to retrieve and agree on it later. Defining this graded dispersal variant allows us to distill the novelty of COOL's protocol consistency check and build applications that are based on COOL in a more modular fashion.

Simple analysis. The analysis in [13] is rather involved and relies on various tools; citing [13] "the proof borrows tools from coding theory, together with graph theory and linear algebra". As mentioned above, this also makes the result hard to verify. We provide a new analysis of our graded dispersal protocol. Notably, our analysis is significantly more concise, much shorter than the original COOL analysis, and uses only simple counting. Given the centrality of the result and its simple analysis, we believe that this protocol will be a good candidate for being part of a curriculum in distributed computing classes as a prime example of the centrality of polynomials in obtaining efficient perfect security.

Applications. We show how to apply graded dispersal to achieve the following (1) gradecast (synchrony); (2) multi-valued Byzantine agreement; (3) broadcast; and (4) reliable broadcast (asynchrony).

Gradecast introduced by Feldman and Micali [17] ("graded-broadcast") is a fundamental primitive used for various consensus algorithms.

Bracha's Reliable Broadcast [11] is a useful building block in asynchronous protocols. The recent paper of Das, Xiang, and Ren [15] has a detailed survey of the usefulness of communication-efficient Reliable Broadcast. In particular, it implies Asynchronous Verifiable Secret Sharing and Asynchronous Distributed Key Generation [4].

One round less. Our new protocol reaches agreement faster than the COOL protocol. Specifically, while COOL requires three rounds of reporting agreements to one another (see more in-depth in Section 2), we show that two rounds suffice. This improvement becomes particularly significant when utilizing the COOL technique in constant round protocols such as reliable broadcast and gradecast - and improves the state-of-the-art for those primitives.

Less communication. Our new protocol improves the communication complexity by 40%. Specifically, the protocol of COOL divides the messages into blocks of polynomials of degree $d = t/5$. Our protocol works when dividing the messages into blocks of degree $d = t/3$. Changing the degree enhances the state-of-the-art in all our applications – multi-valued byzantine agreement, broadcast, gradecast, and reliable broadcast.

We consolidate the costs of gradecast and reliable broadcast in Table 1.

Table 1 The communication complexity (in bits) and round complexity of our gradecast and reliable broadcast compared to previous works. We compare here protocols with perfect security and optimal resilience only (see Section 2.3 for other settings). The reported numbers of rounds are for non-balanced protocols; Making the protocols balanced increases the number of rounds by one (except for [17, 11], which remain the same).

Gradecast (synchrony)

	Communication	Rounds
[17]	$O(n^2L)$	2
[2]	$O(nL + n^3 \log n)$	9
[30]	$O(nL + n^2 \log n)$	8
This work	$O(nL + n^2 \log n)$	5

Reliable Broadcast (asynchrony)

	Communication	Rounds
[11]	$O(n^2L)$	4
[26]	$O(nL + n^4 \log n)$	11
[25]	$O(nL + n^3 \log n)$	7
[6]	$O(nL + n^2 \log n)$	9
This work	$O(nL + n^2 \log n)$	6

2 Technical Overview

In this section, we provide a technical overview of the different primitives. We denote by n the number of parties and by t the number of corrupted parties. We assume a finite field $\mathbb{F}$ of size at least $n + 1$ (and for simplicity, $\mathsf{poly}(n)$). We let $t < n/3$ bound the number of corrupted parties (corresponding to optimal resilience in the plain model, that is, in the absence of a PKI).

We consider both synchronous communication, in which protocols proceed in rounds (Section 2.1), and asynchronous communication networks (Section 2.2). Messages between honest parties in the asynchronous network are guaranteed to be delivered, but the adversary can introduce arbitrary delays.

2.1 Synchrony

The COOL protocol in a nutshell. The protocol of COOL divides the value v_i of size L into blocks, where each block is a polynomial of degree-d over a finite field $\mathbb{F}$. For simplicity of exposition, assume that $L = (d+1)\log|\mathbb{F}|$ (i.e., we have a single block – one polynomial).

Two parties P_i and P_j that wish to check whether their polynomials $f_i(x), f_j(x)$ are identical can do so efficiently using randomization and with a statistical error based on the Schwartz-Zippel lemma [29, 31]. Each pair evaluates its respective polynomials on a random point $r \in \mathbb{F}$ and verify that $f_i(r) = f_j(r)$. This approach was taken in [1] for gradecast and reliable broadcast. The novelty of COOL protocol is that it achieves a similar effect of equality check of polynomials, *deterministically*, and *error free*. Each pair of parties exchange just $O(1)$ points, as in the statistical case. Specifically, P_i sends to P_j the points $f_i(i)$ and $f_i(j)$ only, and P_j verifies that those two points agree with its polynomial $f_j(x)$. If a party agrees with $n-t$ parties - then the party is happy. The protocol proceeds in a few rounds, during which each party reports to others whether it is happy. A party remains happy if at least $n-t$ parties in its agreement set report they are happy. Interestingly, the proof of COOL shows that after three rounds of repeating this process, all parties that report that they are happy must hold the same polynomial.

Graded dispersal. We formalize a variant of dispersal, which, as mentioned, distills the consistency property achieved by COOL. We require the following properties from a graded dispersal protocol. Each party holds some polynomial $f_i(x)$ as input (of degree-d). The parties output $(f'_i(x), g_i)$ where $f'_i(x)$ is a polynomial of degree-d (might be $\perp$), and g_i is a grade in $\{0,1,2\}$. The guarantees are: (1) Validity: If all honest parties start with the same polynomial $f(x)$, then they all must output $(f(x), 2)$; (2) Graded agreement: If some honest party outputs $(f(x), 2)$ then at least $t+1$ honest party output $f(x)$ with a grade at least 1, and all other honest parties output $(\perp, 0)$. Note that we have no guarantee in the case where no honest party outputs grade 2, i.e., in that case, different honest parties might have different polynomials as output (with grade 1). Furthermore, our formalization of graded dispersal allows two honest parties to output grades of 2 and 0, respectively. This is different from the typical definition of graded primitives (such as gradecast), where if an honest party outputs grade 2, then all honest parties output a grade at least 1. However, looking ahead, we show that this weak formalization of graded dispersal suffices for all the applications we consider, including reaching a full byzantine agreement.

We implement graded-dispersal based on the COOL protocol. The crux of our contribution is in providing a simple proof for this construction. Moreover, we show we can achieve it in one round of reporting happiness less than COOL. Specifically, we show that:

1. Initially, only two sets of parties, A and B, holding polynomials $f_A(x)$ and $f_B(x)$, respectively, can report that they are happy after the initial pairwise checks. Since two polynomials might agree on only d common points, three parties holding distinct polynomials cannot have enough agreements and cannot all be happy. See Claim 3.4.
2. We show that if there is one set of parties A, all holding the same polynomial $f_A(x)$ and $|A| \geq t+1$, then only parties from A can output grade at least 1, and all other parties output $(\perp, 0)$. Intuitively, if another set of parties B with $|B| \leq t$ holds polynomial $f_B(x)$, then those parties cannot remain happy due to inconsistencies with the larger set A. See Claim 3.5. Importantly, a party outputs grade 2 if it is happy and it received at least $2t+1$ reports from its agreement set in the last round. This implies that it received at least $t+1$ reports from honest parties. In that case, a party can output grade 2, and the other happy parties must also hold $f_A(x)$, and we have at least $t+1$ parties with the same (and only) output polynomial, $f_A(x)$.

3. If no large set exists, no party outputs grade 2 (no party is happy and received $2t+1$ reports of happiness from its agreed set in the last round). See Claim 3.6.

Our graded dispersal works in three rounds and requires $O(nL+n^2\log n)$ for inputs of size L.

Data dissemination. In Section 3.2, we show a protocol that allows parties to reconstruct the output $f(x)$ once there are at least $t+1$ honest parties that hold the same input $f(x)$ (and other honest parties hold $\perp$). Essentially, this is precisely the guarantee we have once one party outputs 2 in the graded dispersal protocol. Simply, each party that has an input $f(x)$ sends to each party P_i its point $f(i)$. P_i then takes as its point the majority value that it received, and since $t+1$ honest parties that hold $f(x)$ and there are at most t corrupted parties, we are guaranteed that the majority of P_i is $f(i)$. Once each party P_i has a point $f(i)$, the parties reconstruct f by sending their points to one another and using Reed-Solomon decoding.

Given graded dispersal and data dissemination, we provide three applications in synchrony.

Application I: Gradecast. Gradecast is a relaxation of broadcast and involves a sender that holds a message M, and all parties output (M_i, g_i) with $g_i \in \{0,1,2\}$. If the sender is honest, all parties must output $(M,2)$. The guarantee is that if one honest party outputs $(M,2)$, all honest parties must output (M,g_i) with $g_i \geq 1$. We remark that the definition that we provide is a relaxation of Gradecast that was formalized by Katz and Koo [21], which allows the parties to output different messages when there is no honest party with grade 2 (just as in our graded dispersal). We are unaware of any application of gradecast in which the relaxed definition does not suffice.

We show how to implement gradecast using graded dispersal and data dissemination. Specifically, the sender sends its message to all parties, and the parties then run graded-dispersal. After that, they run data dissemination and output the message they received in the data dissemination with their grade in the graded dispersal. It is easy to see that the requirements for gradecast are met.

The last round of graded dispersal can be run parallel to the first round of data dissemination, so we can get a protocol that runs in a total of 5 rounds. This results in an improvement of 3 rounds compared to the state-of-the-art [30]; yet, our guarantee is slightly weaker. We also show how to satisfy the [17] definition at the expense of adding one more round. We then get a strict improvement of 2 rounds with the same security definition (and reduce communication by 40%). The improvement of 2 rounds is due to some redundancy in the protocol of [30].

We emphasize that the "relaxed" gradecast suffice for all the applications we are aware of, specifically to achieve broadcast with an expected constant number of rounds (see Section 2.3). We therefore advocate using the relaxed version.

Application II: Multi-Valued Byzantine Agreement. We compose graded-dispersal, with binary agreement (on whether a party has grade 2), and data dissemination to achieve multi-valued byzantine agreement. As mentioned, our protocol has one less round than the state-of-the-art and 40% less communication. The protocol runs in $O(nL+n^2\log n)$ with $\Theta(n)$ rounds (due to the binary agreement).

Application III: Broadcast. Again, by composing graded-dispersal, binary agreement, and data dissemination, we obtain a broadcast protocol that runs in $O(nL+n^2\log n)$ communication and $\Theta(n)$ rounds.

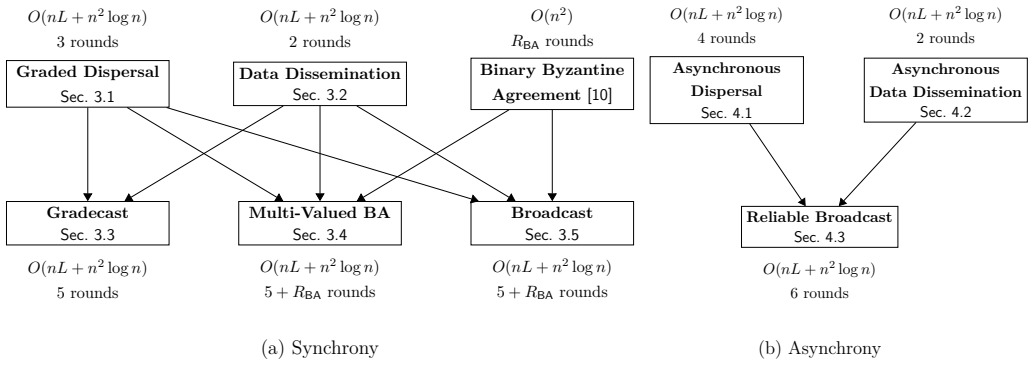

Figure 1 A roadmap of the paper, and the different primitives we construct. Next to each primitive, we report the round complexity and the communication complexity. When reporting the number of rounds – we report for a non-balanced protocol variation. Making each protocol balanced requires one more round of communication.

For gradecast and broadcast, we also show a variant where the protocol is balanced: each party sends or receives $O(L + n \log n)$, and there is no party whose communication load is higher than the others. This comes at the expense of adding an extra round.

2.2 Asynchrony

In reliable broadcast, there is a sender who holds a message M. If the sender is honest, then the protocol always terminates, and all honest parties must output M. If the sender is corrupted and the honest parties terminate, then they must all output the same message M'. Note that the protocol might not terminate if the sender is not honest.

Based upon graded dispersal in synchrony, we show a dispersal protocol in asynchrony (Section 4.1). We show perfect asynchronous data dissemination which has a weak agreement property. Our protocol and formalization is identical to that of [14] and we present it here for completeness of our result.

We have to add one more round than synchrony to guarantee the termination of honest parties for the honest sender case. We also provide an asynchronous variant of data dissemination (Section 4.2). Combining those primitives, we obtain a reliable broadcast.

Our reliable broadcast is deterministic and runs in 6 rounds. This is an improvement of 3 rounds, in addition to 40% reduced communication, compared to [6] that is based on COOL. See Section 4.3 for the protocol, and Table 1 for the improvements over previous protocols.

2.3 Related Work

All our protocols are deterministic and error-free. The applications we are considering (broadcast, multi-valued BA, gradecast, and reliable broadcast) were also studied in different settings.

Protocols with an expected number of rounds. As mentioned, broadcast and byzantine agreement in that setting must incur $\Omega(n)$ rounds [18]. The broadcast and byzantine agreement presented in our paper achieves $O(n)$ rounds in the worst case. Rabin [28] and Ben-Or [8] studied the effect of randomization on round complexity, and Feldman and Micali [17] gave the first protocol with an expected constant round protocol for byzantine agreement with optimal resilience. Many works have improved the communication complexity

of expected constant round Byzantine agreement protocols with optimal resilience [20, 25, 2, 7] where the current state of the art is $O(nL + n^3 \log^2 n)$ with expected constant number of rounds. We remark that in all those protocols, the sender first gradecasts its message, and therefore using our improved gradecast (whose relaxed notion suffices for this application) improves the constant in the "expected constant" of these works.

Gradecast. Gradecast is an important primitive used for various consensus algorithms, e.g., multi-consensus, approximate agreement [9], or Phase-King [5]. Our round complexity is the most efficient in the perfect setting. However, the protocol of Abraham and Asharov [1] is one round better at the expense of introducing some error (i.e., statistical security).

Reliable broadcast. In the computational setting, the protocol of Cachin and Tessaro [12] achieves $O(nL+\kappa n^2 \log n)$ where κ is the computational security parameter. This is improved by Alhaddad et al.[6] to $O(nL + n^2\kappa)$ with 4 rounds of communication. The recent work by Locher and Shoup looks into the constants and obtains $1.5nL + O(\kappa n^2 \log n)$.

Organization

The rest of the paper is organized as follows. The synchronous protocols appear in Section 3, and the asynchronous protocols appear in Section 4. See also Figure 1 for the previous primitives and their interplay.

3 Synchrony

In this section, we provide the protocols for synchronous communication.

Preliminaries. In the analysis, we sometimes use $H \subseteq [n]$ to denote the set of honest parties and $I \subseteq [n]$ to denote the set of corrupt parties. Our protocols also use Reed Solomon decoding. Let $R = \{(i, v_i)\}$ denote a set of evaluations of a degree d polynomial over $\mathbb{F}$ where up to t of the points may be incorrect. If $|R| > 2t + d$, then there exists an efficient algorithm that upon input R, d and t, can recover a degree-d polynomial $f(x)$ such that for $|R| - t$ points $(i, v_i) \in R$, it holds that $f(i) = v_i$. We denote this algorithm as $\mathsf{RSDec}(R)$.

Communication complexity. In each of our protocols, we assume that the input (either of the designated sender or each one of the parties) is a polynomial of degree at most d over the field $\mathbb{F}$. For the general case of an L-bit input, the parties segment the L-bit message into $\ell = \left\lceil \frac{L}{(d+1)\log|\mathbb{F}|} \right\rceil$ blocks of $(d+1)\log|\mathbb{F}|$ bits each (with appropriate padding for the last block if L is not a multiple of $(d+1)\log|\mathbb{F}|$). The parties then execute ℓ instances of the same protocol, where the input for the mth instance is the mth block interpreted as a polynomial of degree at most d. Aggregation over the ℓ different executions is performed in a natural way, e.g., a party P_i agrees with P_j if and only if they agree in all the ℓ instances. We, therefore, omit such details. We report the communication complexity of our protocols over inputs of size L bits while we present the protocols assuming $|L| = (d+1)\log|\mathbb{F}|$. Additionally, note that $\log|\mathbb{F}| \in O(\log n)$ and our communication complexity is reported in that light.

The degree d. We set the degree of our polynomials to be $d = \lfloor t/3 \rfloor$. Looking ahead, we remark that the only place this is necessary (except for requiring $d \leq t$) is in the proof of Claim 3.4.

3.1 Building Block I: Graded Dispersal

We introduce the notion of graded dispersal:

▶ **Definition 3.1** (Graded Dispersal). *A protocol for parties $P_1, \ldots, P_n$ where*

- **Input:** *Each party P_i holds as input some polynomial $f_i(x)$ of degree d over $\mathbb{F}$;.*
- **Output:** *An output $(f_i(x), g_i)$ with grade 2 or 1, or an output $(\perp, 0)$.*

is graded dispersal protocol tolerating t malicious parties *if the following properties hold:*

- **Validity:** *If all honest parties start with the same polynomial $f(x)$, then all output $(f(x), 2)$.*
- **Weak Graded Agreement:** *If an honest party outputs $(f(x), 2)$, then at least $t+1$ honest parties output $(f(x), g_i)$ with $g_i \geq 1$, and all other honest parties output $(\perp, 0)$.*

Note that if there is no honest party with grade 2 then honest parties with non-$\perp$ output and grade 1, may disagree on their output value. Moreover, grade 2 does not imply full agreement among the honest parties.

Nevertheless, we show that this Weak Graded Agreement property is sufficient to work well with the Data Dissemination protocol (see Section 3.2).

Protocol 3.2: Graded Dispersal

Input: Each party P_i holds $f_i(x)$ of degree at most $d = \lfloor t/3 \rfloor$ over $\mathbb{F}$ to encode $d \log n$ bits.
The protocol:

1. **Exchange:**
   a. P_i sends $(f_i(i), f_i(j))$ to each P_j.
2. **Dynamic set A_i^1:**
   a. Let (u_j, v_j) be the two values that P_i receives from P_j. If $f_i(j) = u_j$ and $v_j = f_i(i)$ then add j to A_i^1.
   b. If $|\mathsf{A}_i^1| \geq n - t$ then send OK_1 to all parties.
3. **Dynamic set A_i^2:**
   a. If OK_1 is received from P_j for $j \in \mathsf{A}_i^1$ then add j to A_i^2.
   b. If $|\mathsf{A}_i^2| \geq n - t$ then send OK_2 to all parties.
4. **Output:**
   a. If sent OK_2, and received at least $2t+1$ messages OK_2, then output $(f_i(x), 2)$.
   b. If sent OK_2, but received $\leq 2t$ messages OK_2, then output $(f_i(x), 1)$.
   c. Otherwise, output $(\perp, 0)$.

In the COOL protocol, there is an additional round of OK_3 messages and the degree is $d = \lfloor t/5 \rfloor$. In our protocol, there are just two rounds of OK and the degree is $d = \lfloor t/3 \rfloor$. Hence our protocol reduces the number of rounds from 3 to 2 (by %33) and reduces the overhead per bit from 15 to 9 (by %40). Note that when $L > d \log n$, only the first round is parallelized.

▶ **Theorem 3.3.** *Protocol 3.2 is a graded-dispersal protocol for messages of size $L = d \log n$ bits where $d = \lfloor t/3 \rfloor$ that is resilient to $t = \lfloor (n-1)/3 \rfloor$ malicious parties. The protocol runs in 3 rounds and incurs a total communication of $\leq \binom{n}{2} \log n + 2\binom{n}{2} < n^2 \log n$ bits.*

Proof. We now show that all the properties hold as in Definition 3.1.

Validity. Assume that all honest parties have the same input $f(x)$. For each party P_i, the set A_i^1 will contain the set of all honest parties and therefore $|\mathsf{A}_i^1| \geq n - t$ and P_i sends OK_1. Moreover, it will receive OK_1 from all honest parties; therefore, P_i also sends OK_2. We get that all honest parties send OK_2, and consequently, all receive at least $2t + 1$ OK_2, so all output $(f(x), 2)$.

Weak graded agreement. If one party outputs $(f(x), 2)$, then there are at least $t+1$ honest parties that output $(f(x), g)$ with $g \geq 1$, and all the others output $(\perp, 0)$. This is done in 3 steps:

- Claim 3.4 proves that there cannot be three honest parties that hold different inputs, that all send OK_1. Hence there exists at most two inputs f_a, f_b such that each honest party that sends OK_1 must hold one of these two inputs.
- Given this, Claim 3.5 proves that if there is a set of at least $t + 1$ honest parties that all have the same input, then no honest party holding a different input will send OK_2.
- Claim 3.6 shows that if there is no set with at least $t + 1$ honest parties that have the same input, then no honest party outputs grade 2.

Proof of Weak graded agreement given the Claims 3.4, 3.5, 3.6. If an honest party outputs grade 2, then from Claim 3.6 we must be in the case where there are at least $t + 1$ honest parties as in Claim 3.5 and from that all honest parties that send OK_2 (hence output grade 1) must output the same value.

Proving Claims 3.4, 3.5, 3.6 concludes the proof of the Theorem.

▷ Claim 3.4. There can be at most two distinct inputs, such that there exist honest parties that hold these inputs and send OK_1 messages.

Proof. Seeking a contradiction, assume there exist honest parties P_a, P_b, P_c that hold distinct input polynomials f_a, f_b, and f_c, such that P_a, P_b, P_c all send OK_1 messages.

Let H be the set of all honest parties and let $I = [n] \setminus H$ be the malicious parties.

For any $x \in \{a, b, c\}$ define S_x as the set of all the honest parties that agree with P_x:

$$S_x := \mathsf{A}_x^1 \cap H \ .$$

Observe that:

- For any $x \in \{a, b, c\}, |S_x| \geq n - t - |I|$. Because if P_x sent OK_1, it must agree with at least $n - t$ parties, and thus with at least $n - t - |I|$ honest parties.
- For any $x, y \in \{a, b, c\}, |S_x \cap S_y| \leq d$. Because for any $j \in S_x \cap S_y$ then $f_x(j) = f_j(j) = f_y(j)$. So if $|S_x \cap S_y| \geq d+1$ then f_x and f_y agree on at least $d+1$ points, and therefore, must be identical.

So from inclusion-exclusion:

$$\begin{aligned} |S_a \cup S_b \cup S_c| &= |S_a| + |S_b| + |S_c| - |S_a \cap S_b| - |S_a \cap S_c| - |S_b \cap S_c| + |S_a \cap S_b \cap S_c| \\ &\geq 3(n - t - |I|) - 3d + 0 \ . \end{aligned}$$

Since $d = \lfloor t/3 \rfloor$ so $3d \leq t$:

$$|S_a \cup S_b \cup S_c| \geq 3n - 3t - 3|I| - t = 3n - 4t - 3|I| \ .$$

On the other hand, $(S_a \cup S_b \cup S_c) \subseteq H$, and therefore $|S_a \cup S_b \cup S_c| \leq |H| = n - |I|$:

$$3n - 4t - 3|I| \leq |S_a \cup S_b \cup S_c| \leq n - |I| \ .$$

Using $n \geq 3t+1$ and $|I| \leq t$:

$$\begin{aligned} 2n-4t &\leq 2|I| \\ 2(3t+1)-4t \leq 2n-4t &\leq 2|I| \leq 2t \\ 2t+2 &\leq 2t\ , \end{aligned}$$

which is a contradiction. ◁

So let T_a and T_b be the at most two sets of honest parties with inputs f_a and f_b respectively such that only members in those sets send OK_1. Since $\mathsf{A}_j^2 \subseteq \mathsf{A}_j^1$ for each honest party P_j then only parties in T_a or T_b may send OK_2.

Assume wlog that $|T_a| \geq |T_b|$.

Define:

$$T_{a+} = \{i \in T_a \mid f_a(i) = f_b(i)\}\ , \qquad T_{a-} = T_a \setminus T_{a+} \quad (= \{i \in T_a \mid f_a(i) \neq f_b(i)\})\ ,$$
$$T_{b+} = \{i \in T_b \mid f_a(i) = f_b(i)\}\ , \qquad T_{b-} = T_b \setminus T_{b+} \quad (= \{i \in T_b \mid f_a(i) \neq f_b(i)\})\ .$$

▷ Claim 3.5. If $|T_a| \geq t+1$ then no party in $H \setminus T_a$ sends OK_2.

Proof. From Claim 3.4, honest parties not in $T_a \cup T_b$ do not send OK_1.

Observe that parties in T_{b-} do not send OK_1. This is because $|T_a| \geq t+1$, all $j \in T_{b-}$ have $f_a(j) \neq f_b(j)$ by definition. Therefore, any $j \in T_{b-}$ cannot receive support from T_a and thus

$$|\mathsf{A}_j^1| \leq n - |T_a| \leq n - t - 1 < n - t\ .$$

Given this, parties in in T_{b+} do not send OK_2. This is because the only honest parties that can send OK_1 that will be accepted by T_{b+} are from $T_{a+} \cup T_{b+}$, but $|T_{a+} \cup T_{b+}| \leq d$ because otherwise $f_a = f_b$. So for any party $j \in T_{b+}$ must have

$$|\mathsf{A}_j^2| \leq |T_{a+}| + |T_{b+}| + |I| \leq d + t \leq 2t < n - t\ .$$ ◁

▷ Claim 3.6. If $|T_a| \leq t$ then no party outputs grade 2.

Proof. Observe that the parties in T_{a-} and T_{b-} do not send OK_2. This is because all parties not in T_a, T_b do not send OK_1, and for $x \in \{a, b\}$, a party in T_{x^-} can receive OK_1 only from T_x and the corrupted parties. Thus,

$$|\mathsf{A}_x^2| \leq |T_x| + |I| \leq t + t = 2t < n - t\ .$$

Given this, only parties in T_{a+}, T_{b+} might send OK_2. However, no party can receive $2t+1$ OK_2 messages. This is because $|T_{a+} \cup T_{b+}| \leq d$ so

$$|\mathsf{A}_x^2| \leq |T_{a+}| + |T_{b+}| + |I| \leq d + t \leq 2t < n - t\ .$$ ◁

This concludes the proof of Theorem 3.3. ◀

Note: adding one more round. We are unaware of an application that actually requires this a property, where grade 2 implies that all parties output the same value with grade > 2 (so graded agreement not just weak graded agreement as in Definition 3.1). Nevertheless, we comment here that can be obtained by one more round.

To achieve this, parties that receive $n - t$ OK_2s send OK_3, and then: (1) if P_i sent OK_3 and received $2t+1$ OK_3 it outputs $(f(x), 2)$; (2) otherwise, if it sent OK_3 it outputs $(f(x), 1)$; (3) otherwise, (it did not send OK_3) it outputs $(\perp, 0)$.

If all parties start with the same input $f(x)$ then they all send and receive $n-t$ OK_3s and all output $(f(x), 2)$. In addition, if there is no set $|T_a| \geq t+1$, then all honest parties must output $(\perp, 0)$. In this case, Claim 3.6 shows that no party receives $2t+1$ OK_2; therefore, no honest party sends OK_3.

3.2 Building Block II: Data Dissemination

▶ **Definition 3.7.** *A protocol for parties $P_1, \ldots, P_n$ is where each party P_i has an input $f_i(x)$ (of degree d over field $\mathbb{F}$, might be $\perp$) and an output $f'_i(x)$, is* data dissemination protocol tolerating t malicious parties *if it satisfies the following property:*

- **Output consistency:** *If there exists a polynomial $f^*(x)$ such that there are at least $t+1$ honest parties with the input $f^*(x)$, and all other honest parties start with input $\perp$, then all honest parties output $f^*(x)$.*

Protocol 3.8: Data Dissemination

Input: Each party P_i holds $f_i(x)$ as input, of degree at most d. Some P_i might have input $\perp$.
The protocol:

1. **Round I – Exchange:** If $f_i(x) \neq \perp$, send to each P_j its point $f_i(j)$.
2. **Round II – Set and send your point:** Each party P_i receives messages $(u_1, \ldots, u_n)$. Let u_i be the value received at least $t+1$ times. Send u_i to all parties.

Output: Let $(y_1, \ldots, y_n)$ be the received values. Run Reed Solomon decoding RSDec on $(y_1, \ldots, y_n)$ to find a unique polynomial of degree-d $f'_i(x)$ with at most t errors. Output $f'_i(x)$. If there is no unique decoding, output $\perp$.

▶ **Theorem 3.9.** *Protocol 3.8 is a data-dissemination protocol tolerating $t < n/3$ malicious parties (as per Definition 3.7). The protocol takes two rounds of communication and $O(nL + n^2 \log n)$ communication, where each party starts with an input of size L.*

Proof. Assume that $t+1$ honest parties start with the same input $f(x)$. Each honest party P_j receives $f(j)$ at least $t+1$ times. All other honest parties that hold $\perp$ send nothing in the first message. As such, the majority value of P_j must be $f(j)$, and it sends it to all other parties in the second round. Therefore, all honest parties must receive $(y_1, \ldots, y_n)$ that is of distance at most t from $(f(1), \ldots, f(n))$. Since $n > 2t + d$, the Reed Solomon decoding guarantees that all output $f(x)$.

Protocol 3.8 as described above incurs a total communication of $O(n^2 \log n)$ bits and this corresponds to the case when each party starts with an input of size $(d+1)\log|\mathbb{F}|$ bits. Hence, the communication complexity of Protocol 3.8, where each party starts with inputs of size L bits, is $O(nL + n^2 \log n)$ bits. ◀

3.3 Application I: Gradecast

We now show how the above protocols can be utilized to achieve gradecast.

Gradecast is a relaxation of broadcast introduced by Feldman and Micali in 1988 [17]. Our protocol follows a relaxed notion of Gradecast formalized by Katz and Koo [21].

▶ **Definition 3.10.** *A protocol for parties $P_1, \ldots, P_n$, where a distinguished sender $P^* \in \{P_1, \ldots, P_n\}$ holds an initial input M is* a gradecast protocol tolerating t malicious parties *if the following conditions hold for any adversary controlling at most t parties:*

- *Each honest party P_i outputs a message m_i and a grade $g_i \in \{0, 1, 2\}$.*
- *If the sender is honest, then the output of every honest party P_i satisfies $m_i = M$ and $g_i = 2$.*
- *If there exists an honest party P_i which outputs a message m_i and the grade $g_i = 2$, then the output of every honest party P_j satisfies $m_j = m_i$ and $g_j \geq 1$.*

Protocol 3.11: Gradecast from Graded-Dispersal and Data Dissemination

Input: The sender P^* holds $f(x)$ of degree at most d. Other parties have no input.
The protocol:

1. **The sender:** The sender sends $f(x)$ to all parties.
2. **Each party P_i:** The parties invoke the graded-dispersal protocol (Protocol 3.2) where P_i inputs $f_i^{(1)}(x)$. Let $(f_i^{(2)}(x), g_i)$ be the output of the graded-dispersal protocol.
3. **Each party P_i:** The parties run the data-dissemination protocol (Protocol 3.8) with input $f_i^{(2)}(x)$. Let $f_i^{(3)}(x)$ be the output.
4. **Output:** If $g_i = 2$, then output $(f_i^{(3)}(x), 2)$. Otherwise, if $f_i^{(3)}(x) \neq \perp$, then output $(f_i^{(3)}(x), 1)$. Otherwise, output $(\perp, 0)$.

▶ **Theorem 3.12.** *Protocol 3.11 is a Gradecast protocol tolerating up to $t < n/3$ malicious parties (as per Definition 3.10). The protocol takes 5 rounds and $O(nL + n^2 \log n)$ communication for gradecasting a message of size L.*

Proof. We prove the case of an honest sender and a corrupted sender.

An honest sender. We first show that if the sender is honest and has an input $f(x)$, then all honest parties output $(f(x), 2)$. Specifically, all honest parties start the graded dispersal with the same input $f(x)$. Therefore, from the validity of graded-dispersal, all honest parties output $(f(x), 2)$. Moreover, since more than $t + 1$ honest parties hold the same input $f(x)$ in the data-dissemination protocol, all honest parties output $f(x)$ in that protocol, and output $(f(x), 2)$ in the gradecast protocol.

An honest party with output grade 2. We next consider the case where there exists an honest party P_j with an output grade 2. In that case, P_j must have grade 2 in the graded-dispersal protocol. As such, from the graded agreement, there are at least $t + 1$ honest parties that output the same polynomial $f(x)$ with grade $g_i \geq 1$ from graded dispersal. Moreover, from the properties of graded-dispersal, parties with output that is not $f(x)$ use $\perp$ as their input in the data dissemination protocol. Thus, there are at least $t + 1$ honest parties with input $f(x)$ in the data dissemination protocol, and therefore all honest parties must output $f(x)$ in the data dissemination. All honest parties output $f(x)$ with a grade of at least 1. ◀

Reducing one-round. We can reduce one round of interaction by sending the first round of the data-dissemination protocol together with the last round of the graded dispersal protocol. Specifically, each party that sends OK_2 message to P_j (the last round of the weak dispersal) sends together with it the point $f_i(j)$ to party P_j (the first message of the data dissemination).

We, therefore, get that the total round complexity of the protocol is five rounds (Theorem 3.12 is reported in that light).

Making the protocol balanced. In the protocol as described, the communication complexity of the sender is $O(n(d+1)\log n)$ while the communication complexity of every other party is just $O(n \log n)$. To reduce the communication complexity for the sender, the sender can first send to each party P_i its point $f(i)$. Each party forwards the point it received to all others, and the parties use Reed Solomon decoding to reconstruct the polynomial $f(x)$.

Stronger property. As mentioned, we use the relaxed definition of gradecast as defined in [20]. The definition by [17] requires that in the absence of a party with grade 2, all parties with grade 1 must agree on their message as well. This can be achieved at the expense of adding one round to the graded-dispersal, as discussed in Section 3.1.

3.4 Application II: Multi-Valued Byzantine Agreement

▶ **Definition 3.13** ((Binary/Multi-valued) Byzantine Agreement). *A protocol for parties $P_1, \ldots, P_n$ where each party P_i holds initial input v_i, is a* Byzantine agreement protocol tolerating t malicious parties *if the following conditions hold for any adversary controlling at most t parties:*

- **Agreement:** *All honest parties must output the same value.*
- **Validity:** *If all honest parties begin with the same input value v, then all honest parties output v.*
- **Strong consistency:** *If not all honest parties begin with the same input v, then all honest parties output the same value, which was an input of some honest party.*

For brevity, if the values $\{v_i\}$ are restricted to binary values, then we call the protocol a binary Byzantine agreement.

Protocol 3.14: Multi-Valued Byzantine Agreement from Graded Dispersal, Binary Byzantine Agreement, and Data Dissemination

- **Input:** Each party P_i holds a polynomial $f_i^{(1)}(x)$ of degree at most d over $\mathbb{F}$.
- **The protocol:**
  1. The parties invoke the graded dispersal protocol (Protocol 3.2), where each party P_i inputs $f_i^{(1)}(x)$. Let $(f_i^{(2)}(x), b_i)$ be the output.
  2. The parties run the binary Byzantine agreement protocol (e.g., [10]), where the input of each P_i is the bit b_i. Let b be the output of the Byzantine agreement.
  3. If $b = 1$, then the parties invoke the data dissemination protocol (Protocol 3.8) where each party P_i inputs $f_i^{(2)}(x)$. Let $f_i^{(3)}(x)$ be the output of P_i.
     If $b = 0$, then P_i sets $f_i^{(3)}(x) = \perp$.
- **Output:** Each P_i outputs $f_i^{(3)}(x)$.

We recall that the binary Byzantine agreement of [10] requires $O(n^2)$ communication and $\Theta(n)$ rounds for agreeing on a single bit. We get:

▶ **Theorem 3.15.** *When instantiated with a binary Byzantine agreement protocol with $O(n^2)$ communication and $\Theta(n)$ rounds ([10]), protocol 3.14 is a Byzantine Agreement protocol tolerating $t < n/3$ malicious parties (as per Definition 3.13). The protocol uses $O(nL + n^2 \log n)$ communication and $\Theta(n)$ rounds where each party starts with an input of size L.*

Proof. We first show validity, then agreement.

Validity. If all honest parties have the same input $f(x)$, then from the graded agreement property of graded dispersal (Definition 3.1), we get that all honest parties output $(f(x), 2)$. All honest parties then input 1 to the Binary Byzantine agreement, and then all honest parties receive 1 as output. The parties then invoke the data-dissemination protocol, and since there are more than $t+1$ honest parties with the input $f(x)$, all honest parties receive $f(x)$ as output and output it.

Agreement. The output of the parties is determined by the output of the binary byzantine agreement, b, which is the same for all parties. There are two cases to consider:

- If $b = 0$, then all honest parties output $\perp$, and agreement holds.
- If $b = 1$, then there must exists an honest party P_j with an input $b_j = 1$ to the Binary Byzantine Agreement. By the properties of weak-dispersal (Definition 3.1), this implies that at least $t+1$ honest parties have the same output $f(x)$ from the weak-dispersal protocol, i.e., the input of each honest party to the data-dissemination protocol (Protocol 3.8) is either $\perp$ or $f(x)$, and there are at least $t+1$ honest parties with input $f(x)$. The data-dissemination protocol then guarantees that all parties output $f(x)$. The parties output that value in our Byzantine Agreement protocol, and we again have an agreement.

Strong consistency. The only case that is interesting is when $b = 1$. The graded dispersal guarantees that output was also an input of some honest party. ◀

3.5 Application III: Broadcast

▶ **Definition 3.16** (Broadcast). *A protocol for parties $P_1, \ldots, P_n$ where a distinguished sender P^* holds an initial input M, is a* broadcast protocol tolerating t malicious parties *if the following conditions hold for any adversary controlling at most t parties:*

- **Agreement:** *All honest parties output the same value.*
- **Validity:** *If the sender is honest, then all honest parties output M.*

Protocol 3.17: Broadcast from Graded-Dispersal, Data Dissemination, and Binary Agreement

- **Input:** The sender holds a polynomial $f(x)$ of degree at most d over $\mathbb{F}$.
- **The protocol:**
  1. **The sender:** The sender sends $f(x)$ to all parties.
  2. **Each party P_i:** Let $f_i^{(1)}(x)$ be the received polynomial. The parties invoke graded-dispersal protocol (Protocol 3.2), where each party P_i inputs $f_i^{(1)}(x)$. Let $(f_i^{(2)}(x), g_i)$ be the output.
  3. **Each party P_i:** Run Binary byzantine agreement where each party P_i inputs 1 iff $g_i = 2$. Let b be the output.
  4. **Each party P_i:** If $b = 1$, then the parties run the data-dissemination protocol (Protocol 3.8), where each party P_i inputs $f_i^{(2)}(x)$. Let $f_i^{(3)}(x)$ be the output of the data dissemination protocol.
- **Output:** If $b = 1$, then output $f_i^{(3)}(x)$. If $b = 0$ then output $\perp$.

▶ **Theorem 3.18.** *Protocol 3.17 is a broadcast protocol tolerating $t < n/3$ malicious parties (as per Definition 3.16). The protocol uses $\Theta(n)$ rounds and $O(nL + n^2 \log n)$ communication for broadcasting a message of size L.*

Proof. We show agreement and validity.

Agreement. By the binary byzantine agreement, all parties receive the same bit b. If $b = 0$, then all honest parties output $\perp$ and agreement holds; If $b = 1$, then it must be that some honest party received grade 2 in the graded dispersal. As follows from the guarantees of graded dispersal, this implies that there are at least $t + 1$ honest parties with the same output $f(x)$. Those honest parties input $f(x)$ to the data dissemination, and the output of all honest parties is then $f(x)$. Agreement again holds.

Validity. If the sender is honest and starts with input $f(x)$ of degree-d over $\mathbb{F}$, then from the guarantees of graded-dispersal, all honest parties output $(f(x), 2)$. As such, all honest parties input 1 to the binary byzantine agremeent, and must agree on $b = 1$. Therefore, all run the data-dissemination protocol, and all output $f(x)$. ◀

Making the protocol balanced. In the broadcast protocol as described in Protocol 3.17, the communication complexity of the sender is $n(d + 1) \log n$ bits, whereas the communication complexity of every other party is just $O(n \log n)$ bits. As before, to reduce the communication complexity for the sender, the sender can first send to each party P_i its point $f(i)$. The parties then forward the received point to all others and use Reed Solomon decoding to reconstruct the polynomial $f(x)$.

4 Reliable Broadcast in Asynchrony

We now move to asynchronous communication. Here, when an honest party sends a message it is guaranteed to be delivered, but the adversary can introduce arbitrarily delays.

4.1 Dispersal

▶ **Definition 4.1** (Dispersal). *A protocol for parties $P_1, \ldots, P_n$ where the input of each party P_i is some $v_i \in \mathbb{F}$, is an* asynchronous dispersal protocol tolerating t corrupted parties *if the following properties hold:*

- **Termination:** *If one honest party terminates, then all honest parties terminate.*
- **Weak agreement:** *If one honest party terminates with output $f(x)$, then at least $t + 1$ other honest parties output also $f(x)$. Furthermore, all honest parties that terminate with a non-$\perp$ output, terminate with the same polynomial $f(x)$.*
- **Weak Validity:** *If all honest parties start with the same polynomial $f(x)$ of degree at most d, then termination and weak agreement hold with respect to $f(x)$.*

Our asynchronous dispersal protocol is fairly identical to the synchronous counterpart. However, when executed under asynchrony, a key distinction is in the construction of the dynamic sets, $\mathsf{A}_i^1, \mathsf{A}_i^2$. As the adversary may introduce arbitrary delays, the OK_2 messages may not be delivered after the OK_1 messages. The parties construct the A_i^1 and A_i^2 sets and update them in an online fashion upon receiving any message (OK_1 or OK_2).

Protocol 4.2: Dispersal

Input: Each party P_i holds $f_i(x)$ of degree at most d over $\mathbb{F}$.
The protocol:

1. Initialization: Each party initializes $S_i = \emptyset, \mathsf{A}_i^1 = \mathsf{A}_i^2 = \emptyset$, and $f_i(x) = \perp$.
2. **Exchange:**
   a. P_i sends $(\texttt{Exchange}, f_i(i), f_i(j))$ to each P_j.
3. **Dynamic set A_i^1:**
   a. **Upon** receiving $(\texttt{Exchange}, u_j, v_j)$ from P_j, if $f_i(j) = u_j$ and $f_i(i) = v_j$ then add j to A_i^1 .
   b. **Upon** $|\mathsf{A}_i^1| \geq n - t$, send OK_1 to all.
4. **Dynamic set A_i^2:**
   a. **Upon** receiving message OK_1 from P_j for which $j \in \mathsf{A}_i^1$, then add j to A_i^2.
   b. **Upon** $|\mathsf{A}_i^2| \geq n - t$, send OK_2 to all.
5. **Sending** `Done`**:**
   a. If P_i sent OK_2, and **upon** receiving $2t + 1$ OK_2 messages, send `Done` message to everyone.
   b. **Upon** receiving $t + 1$ `Done` messages from distinct parties, send `Done` to everyone.
   c. **Upon** receiving $2t + 1$ `Done` messages, if P_i sent OK_2 message, then terminate and output $f_i(x)$. If P_i did not send OK_2 message, then terminate and output $\perp$.

▶ **Theorem 4.3.** *Protocol 4.2 is an asynchronous dispersal protocol tolerating $t < n/3$ malicious parties (as per Definition 4.1). The protocol takes 4 rounds and a total communication of $O(nL + n^2 \log n)$ bits where each party starts with an input of size L.*

Proof. We show each one of the properties separately.

Termination. An honest party terminates only after it receives $2t + 1$ `Done` messages. This implies that it received at least $t + 1$ messages `Done` from honest parties (and in particular, it also sent the `Done` message). Eventually, all honest parties will receive those $t + 1$ `Done` messages and, in response, will also send a `Done` message. We obtain that eventually, all honest parties send `Done` message, and therefore each honest party will eventually receive $2t + 1$ `Done` messages, regardless of the messages of the adversary. Therefore, all honest parties must terminate.

Weak agreement. An honest party that terminates with an output $f^*(x) \neq \perp$ must have sent an OK_2 message. Moreover, since it terminated, it must have received at least $2t + 1$ `Done` messages, i.e., it received `Done` messages from at least $t + 1$ honest parties. An honest party sends a `Done` message if it either received $2t + 1$ OK_2 messages or received $t + 1$ `Done` messages. The latter implies that at least one honest party sent a `Done` message due to receiving $2t+1$ OK_2 messages, and at least $t+1$ honest parties sent OK_2 message. As follows from Claim 3.4, there are at most two sets of parties (with the same polynomial) that could have sent OK_1. We have two cases to consider:

- As follows from Claim 3.6, if there is no large set of $t+1$ parties with the same polynomial, then no party receives $2t + 1$ OK_2. This implies that no honest party would have sent the `Done` message, and no party terminates.
- If there is a large set of $t+1$ parties with the same polynomial $f^*(x)$, then no other party sends OK_2.

This implies that if some honest party terminates, then we must have a large set of $t+1$ parties with the same polynomial $f^*(x)$. This implies that at least $t+1$ honest parties terminate with that polynomial $f^*(x)$. Any other honest party that terminates with non-$\perp$ must also output $f^*(x)$.

Weak Validity. If all honest parties start with the same polynomial $f^*(x)$, then eventually, all honest parties will appear in the agreed sets of one another. As such, eventually, all honest parties will send the OK_2 message, send `Done` messages, and terminate. Parties might terminate earlier; as mentioned, if one honest party terminates, it outputs its polynomial, and we are also guaranteed that at least $t+1$ other honest parties terminate with their input polynomials. Therefore, weak validity holds. ◀

4.2 Asynchronous Data Dissemination

▶ **Definition 4.4** (Asynchronous Data Dissemination). *A protocol for parties $P_1, \ldots, P_n$ where each P_i has input $f_i(x)$ (of degree d over $\mathbb{F}$, might be $\perp$) is an* asynchronous data dissemination protocol tolerating t malicious parties *if it satisfies the following property:*

- **Agreement and termination:** *If there exists a polynomial $f(x)$ such that at least $t+1$ honest parties start with the input $f(x)$, and all other honest parties start with input $\perp$, then all honest parties terminate and output $f(x)$.*

Protocol 4.5: Asynchronous Data Dissemination

Input: Each party P_i holds $f_i(x)$ as input, of degree at most d. Some P_i might have input $\perp$.
The protocol:

1. Initialize a multi-set $M_i = \emptyset$ and $S_i = \emptyset$. If $f_i(x) \neq \perp$, send to each P_j its point $(\texttt{YourPoint}, f_i(j))$.
2. **Upon** receiving $(\texttt{YourPoint}, u_j)$ from P_j, add u_j to M_i.
3. **Upon** some u_i appearing $t+1$ times in M_i, send $(\texttt{MyPoint}, u_i)$ to all parties.
4. **Upon** receiving $(\texttt{MyPoint}, u_j)$ from P_j, add (j, u_j) to S_i. **Upon** $|S_i| \geq d+t+1$ execute the following:
   a. Run $\mathsf{RSDec}(S_i)$ and try to decode a polynomial $f_i(x)$ of degree at most d that agrees with S_i on at at least $d+t+1$ values.
   b. If no such polynomial exists, then wait to receive more points in S_i and retry.
   c. If such a polynomial $f_i(x)$ is computed, set $f_i(x)$ to be the resultant value
5. **Upon** unique decoding of $f_i(x)$, terminate and output $f_i(x)$.

▶ **Theorem 4.6.** *Protocol 4.5 is an asynchronous data-dissemination protocol tolerating $t < n/3$ malicious parties. The protocol takes 2 rounds and $O(nL + n^2 \log n)$ communication, where each party starts with an input of size L.*

Proof. Assuming that $t+1$ honest parties hold the input $f(x)$ and the others hold $\perp$, we get that each honest party P_j eventually receives $f(j)$ at least $t+1$ times and therefore sends to everyone the message $(\texttt{MyInput}, f(j))$. As a result, all honest parties eventually send that message. Therefore, all honest parties will eventually succeed in their Reed Solomon decoding and terminate with the polynomial $f(x)$. ◀

4.3 Reliable Broadcast

▶ **Definition 4.7** (Reliable Broadcast). *A protocol for parties $P_1, \ldots, P_n$ where a distinguished party P^* has an input $f(x)$ of degree at most d over $\mathbb{F}$ is a* reliable broadcast tolerating t malicious parties *if the following properties hold:*

- **Validity:** *If the sender P^* is honest then all honest parties terminate and output $f(x)$.*
- **Agreement:** *If two honest parties terminate, their output is the same.*
- **Termination:** *If an honest party terminates, then all honest parties will eventually terminate.*

Protocol 4.8: Reliable Broadcast

Input: The sender holds a polynomial $f(x)$ of degree at most d.
The protocol:

1. **The sender:** Send $f(x)$ to each party P_i.
2. **Each party P_i: Upon** receiving $f_i^{(1)}(x)$ from the sender, participate in Dispersal (Protocol 4.2) with input $f_i^{(1)}(x)$.
3. **Each party P_i: Upon** receiving an output $f_i^{(2)}(x)$ from the dispersal protocol, participate in asynchronous data dissemination protocol (Protocol 4.5) with input $f_i^{(2)}(x)$.
4. **Upon** receiving an output $f_i^{(3)}(x)$ from the data dissemination protocol, terminate and output $f_i^{(3)}(x)$.

▶ **Theorem 4.9.** *Protocol 4.8 is a reliable broadcast protocol tolerating $t < n/3$ malicious parties (as per Definition 4.7). The protocol takes 6 rounds and $O(nL + n^2 \log n)$ bits for reliably broadcasting a message of size L.*

Proof. We show each one of the properties separately.

Validity. If the sender is honest and starts with the input $f(x)$, then eventually all honest parties start the Dispersal protocol with the input $f(x)$. From the weak-validity property of the dispersal protocol (see Definition 4.1), all honest parties terminate with an output which is in $\{\perp, f(x)\}$, and at least $t+1$ honest parties terminate with $f(x)$. All honest parties then eventually continue to the asynchronous data dissemination. According to that protocol, if at least $t+1$ honest parties start with the same input $f(x)$, and all other honest parties start with $\perp$, then all honest parties must terminate, and with output $f(x)$. Therefore, all honest parties eventually terminate the reliable broadcast protocol, with an output $f(x)$.

Agreement and termination. Assume that some honest party terminates. This implies that both the dispersal and the data dissemination protocols must terminate (an honest party does not participate in the data dissemination before terminating the dispersal). If the dispersal protocol terminates, then from its security properties, we must have that at least $t+1$ honest parties terminate with the same polynomial $f(x)$, and all the other honest parties terminate with an output $\perp$. The parties then input those inputs to the data-dissemination protocol, which guarantees that under this exact input – all honest parties terminate with the same output $f(x)$. We conclude that all honest parties terminate with the same output $f(x)$. ◀

Reducing one-round. As in the case of synchrony, we can reduce one round of interaction by sending the first round of the data-dissemination protocol together with the last round of the data-dispersal protocol. Specifically, each party that sends `Done` message to P_j (the last round of the weak dispersal) sends, together with it, the point $f_i(j)$ to party P_j (the first message of the data dissemination).

Making the protocol balanced. In the reliable broadcast protocol as described in Protocol 4.8, the communication complexity of the sender is $n(d+1)\log n$ bits, whereas the communication complexity of every other party is just $O(n \log n)$ bits. As in the case of synchrony, to balance the communication complexity of the sender, the sender can first send to each party P_i its point $f(i)$. The parties then send it to all other parties and execute Reed Solomon decoding repeatedly to reconstruct the polynomial $f(x)$. Specifically, each party waits to receive at least $d+t+1$ points and executes Reed Solomon decoding to recover a polynomial that agrees with at least $d+t+1$ points.

Abstract

A Matching Vector (**MV**) family modulo a positive integer $m \geq 2$ is a pair of ordered lists $\mathcal{U} = (\boldsymbol{u}_1, \cdots, \boldsymbol{u}_K)$ and $\mathcal{V} = (\boldsymbol{v}_1, \cdots, \boldsymbol{v}_K)$ where $\boldsymbol{u}_i, \boldsymbol{v}_j \in \mathbb{Z}_m^n$ with the following property: for any $i \in [K]$, the inner product $\langle \boldsymbol{u}_i, \boldsymbol{v}_i \rangle = 0 \pmod m$, and for any $i \neq j$, $\langle \boldsymbol{u}_i, \boldsymbol{v}_j \rangle \neq 0 \pmod m$. An **MV** family is called *r-restricted* if inner products $\langle u_i, v_j \rangle$, for all i, j, take *at most* r different values. The r-restricted **MV** families are extremely important since the only known construction of constant-query subexponential locally decodable codes (LDCs) are based on them. Such LDCs constructed via matching vector families are called *matching vector codes*. Let $\mathbf{MV}(m, n)$ (respectively $\mathbf{MV}(m, n, r)$) denote the *largest* K such that there exists an **MV** family (respectively r-restricted **MV** family) of size K in $\mathbb{Z}_m^n$. Such a **MV** family can be transformed in a black-box manner to a *good* r-query locally decodable code taking messages of length K to codewords of length $N = m^n$.

For small prime m, an *almost* tight bound $\mathbf{MV}(m, n) \leq O(m^{n/2})$ was first shown by Dvir, Gopalan, Yekhanin (FOCS'10, SICOMP'11), while for general m, the same paper established an upper bound of $O(m^{n-1+o_m(1)})$, with $o_m(1)$ denoting a function that goes to zero when m grows. For any arbitrary constant $r \geq 3$ and composite m, the best upper bound till date on $\mathbf{MV}(m, n, r)$ is $O(m^{n/2})$, is due to Bhowmick, Dvir and Lovett (STOC'13, SICOMP'14).In a breakthrough work, Alrabiah, Guruswami, Kothari and Manohar (STOC'23) implicitly improve this bound for 3-restricted families to $\mathbf{MV}(m, n, 3) \leq O(m^{n/3})$.

In this work, we present an upper bound for $r = 3$ where $\mathbf{MV}(m, n, 3) \leq m^{n/6+O(\log n)}$, and as a result, any 3-query matching vector code must have codeword length of $N \geq K^{6-o(1)}$.

1 Introduction

1.1 Locally Decodable Codes

A code $C : \Sigma^K \to \Sigma^N$ is said to be (r, δ, ε)-locally decodable if for every $i \in [K]$, the i-th coordinate of the message $\boldsymbol{x}_i \in \Sigma$ can be recovered with probability at least $1 - \varepsilon$ by a randomized decoding procedure that makes only r queries to the codeword, i.e., reads the codeword at r positions even if the codeword is corrupted on up to δN locations.

Locally decodable codes were formally introduced in [19] but had already been studied informally in the context of the PCP theorem [3, 4]. Locally decodable codes have found applications in many areas of computer science such as worst-case to average-case reductions, private information retrieval, secure multi-party computation, derandomization, matrix rigidity, data structures, and fault-tolerant computation. See [25] for a detailed survey.

A central research question is to understand the largest possible message length K (as a function of N) that can be achieved by a r-query locally decodable code. For the simplest non-trivial setting of $r = 2$, we have a nearly complete understanding – the Hadamard code achieves $K = \log_2 N$, and it was shown in [20, 12] that this is the best possible up to a constant factor, i.e., $K = O(\log_2 N)$.

Much less is understood about the dependence between K and N for the number of queries $r \geq 3$. In particular, the only known constructions for r-query locally decodable codes for a constant $r \geq 3$ are based on families of matching vector codes [24, 10, 9]. These constructions achieve $K = (\log N)^{\Omega(\log \log N)}$. On the other hand, the known upper bounds on K are very far from what is achieved by these constructions. In a series of works [19, 20, 22, 23, 6], it has been shown that $K = N^{1-2/(r+1)} \operatorname{polylog} N$, when r is odd, and $K = N^{1-2/r} \operatorname{polylog} N$, when r is even. For the special case where $r = 3$, it was shown that $K = O(N^{1/3} \log^2 N)$ in a celebrated recent result [2].

1.2 Matching Vector Families and Application to Locally Decodable Codes

A matching vector (**MV**) family is a combinatorial object that has been used in different contexts such as Ramsey graphs and weak representation of OR polynomials[11, 17, 1, 13], but the most prominent application of matching vector families is in the construction of constant-query locally decodable codes [9, 25]. A matching vector family is defined by two ordered lists $\mathcal{U} = (\boldsymbol{u}_1, \ldots, \boldsymbol{u}_K)$ and $\mathcal{V} = (\boldsymbol{v}_1, \ldots, \boldsymbol{v}_K)$ where for all $i \in [K]$, $\boldsymbol{u}_i, \boldsymbol{v}_i$ are in $\mathbb{Z}_m^n$ for some positive integers $m, n > 1$. An S-matching vector family can be defined as follows.

▶ **Definition 1** (Matching Vector Family). *Let $S \subseteq \mathbb{Z}_m \setminus \{0\}$. An S-matching vector family is a set of vectors $\mathcal{U} = \{u_1, \ldots, u_K\}$, $\mathcal{V} = \{v_1, \ldots, v_K\}$, $\mathcal{U}, \mathcal{V} \subseteq \mathbb{Z}_m^n$ such that:*

- $\forall i \in [K], \langle u_i, v_i \rangle = 0$.
- $\forall i \neq j,\ i, j \in [K], \langle u_i, v_j \rangle \in S$.

An S-matching vector family is often called $(|S| + 1)$-restricted matching vector family, and such a family gives a locally decodable code for messages of block length K, codeword length $N = m^n$, and number of queries $r = |S|+1$. See Theorem 15 ([25]) for the construction of a locally decodable code from a matching vector family.

Finally, we denote $\mathbf{MV}(m, n)$ (respectively $\mathbf{MV}(m, n, r)$), as the *largest* K such that there exists an **MV** family (respectively r-restricted **MV** family) of size K in $\mathbb{Z}_m^n$.

1.3 Upper Bounds for Matching Vector Families

Since the only known approach that has led to constructions of constant-query locally decodable codes is via constructing a large matching vector family, it is natural to ask what is the largest K as a function of m, n for which there is a r-restricted matching vector family of size K. This in particular will give an upper bound for the rate of a r-query locally decodable code via matching vector codes, i.e., any r-query locally decodable code achieving a better rate must be via some novel approach that does not require a matching vector family.

This problem was first studied in [9], where the authors showed that when m is a large prime, $\mathbf{MV}(m, n) \leq O(m^{n/2})$. On the other hand, the same paper established a general upper bound of $O(m^{n-1+o_m(1)})$, with $o_m(1)$ denoting a function that goes to zero when a composite m grows. In [8], the authors improved this bound to $\text{poly}(m) \cdot m^{.625n}$, for a very special case when $m = pq$, for distinct primes p and q such that $p \approx q$, and $n \ll m$. On the other hand, when $m \ll n$ is a prime, it can be shown via linear algebraic methods that $\mathbf{MV}(m, n) \leq O(n^{m-1})$ [5].

Bhowmick, Dvir and Lovett [7] showed how to extend the results of [9] to the case of m being a composite integer. They showed that $\mathbf{MV}(m, n, r) \leq r^{O(r \log r)} m^{n/2}$, i.e., for constant query codes, they showed that $K = O(\sqrt{N})$.

Additionally, in the same paper, Bhowmick, Dvir and Lovett also showed that under the (recently proved) polynomial Freiman Ruzsa (PFR) theorem [16], for m constant, $\mathbf{MV}(m, n) \leq m^{O(n/\log n)}$.

1.4 Our Result

The main contribution of the paper is to give a better upper bound for 3-restricted matching vector families.

▶ **Theorem 2.** *Let $n, m \geq 2$ be positive integers with $n > 10m^3$. Suppose m has atleast two distinct prime factors, then*

$$\mathbf{MV}(m, n, 3) \leq m^{\frac{n+2\log(n+1)}{2q}+2m^2},$$

where q is the second-smallest *prime dividing m.*

We already know a polynomial bound for prime powers due to [15] which we state below and prove for completeness in Section 2.4.

▶ **Theorem 3.** *Suppose $n, m \geq 2$ be positive integers where m is a constant prime power. Then $\mathbf{MV}(m, n, 3) \leq (2emn)^{m-1}$.*

This allows us to conclude an upper bound for arbitrary m:

▶ Remark 4. When m has at least one factor which is not 2, that immediately gives a $m^{n/6+O(\log n)}$ upper bound, while if the constant m is a power of 2, the bound is just $\text{poly}(n)$, as mentioned above.

Finally, we can also derive a lower bound for the 3-query LDCs derived from matching vector families:

▶ **Corollary 5.** *Suppose $C : \Sigma^K \to \Sigma^N$ is a 3-query locally decodable code constructed from a 3-restricted matching vector family in a black-box manner (as in Theorem 15), then $N \geq K^{6-o_K(1)}$ where $o_K(1)$ vanishes as K increases.*

1.5 Concurrent Work

Concurrent to our work, the Polynomial Freiman Ruzsa conjecture was proven by Gowers, Green, Manners and Tao [16] for all abelian groups with bounded torsion! As a corollary (via Theorem 6.4 of [7]), one could conclude that

$$\mathbf{MV}(m,n) \leq 2^{1200c(m)m^{6\log m}n/\log n},$$

where $c(m)$ is some explicit constant depending only on m. Infact, if we plug in the bound of [16] to Lemma 6.3 from [7], we can conclude that $c(m) \geq m^3$. Note that this bound is non-trivial (i.e., less than m^n) only when $n \geq 2^{\frac{1200\cdot 6^{3+6\log 6}}{\log 6}} > 2^{2^{56}}$ (plugging in $m = 6$) and beats our bound only when $n \geq 2^{2^{58}}$.

While this result supersedes ours in many parameter regimes, the techniques and approaches are very different. And our approach might have the potential of breaking the $2^{n/\log n}$ barrier. (See discussions below.)

1.6 Our Techniques

In the discussion below, we want to prove upper bounds for a matching vector family $\mathcal{U}, \mathcal{V}$ of size K over $\mathbb{Z}_m^n$ for some positive integers m and n.

Techniques from [7]. We begin by describing Bhowmick, Dvir, and Lovett's ([7]) approach towards getting an upper bound of $m^{n/2}$. They observe that if we consider the random variables $\boldsymbol{U}, \boldsymbol{V}$ as sampled independently and randomly from $\mathcal{U} = \{\boldsymbol{u}_1, \ldots, \boldsymbol{u}_K\}$ and $\mathcal{V} = \{\boldsymbol{v}_1, \ldots, \boldsymbol{v}_K\}$, respectively, then we have that $\Pr[\langle \boldsymbol{U}, \boldsymbol{V}\rangle = 0] = \frac{1}{K}$, and hence $\langle \boldsymbol{U}, \boldsymbol{V}\rangle \bmod m$ is *far* from uniform.

If m is a prime, then standard properties of the inner product two-source extractor imply that $\mathbf{H}_\infty(\boldsymbol{U}) + \mathbf{H}_\infty(\boldsymbol{V}) = 2\log K$ is not much bigger than $n \log m$, else the inner product extractor's output would be very close to uniform. This straightaway yields the desired bound of $K \lessapprox m^{n/2}$.

For composite m, this approach does not work directly, since $\mathbb{Z}_m$ is *not* a field. In particular, say for $m = 6$, it is possible to have two random variables distributed uniformly over $\{0, 2, 4\}^n$ such that their inner product is *far* from uniform modulo 6, but the sum of the min-entropies is $2n \log_2 3 \gg n \log 6$. The authors overcome this by showing that this is essentially the *only* bad case, i.e., it can be attributed to some "bad" factor $s \mid m$ (in the example above, $s = 2$). Hence, with some careful inductive argument on the modulus m/s, one can still force out the fundamental observation: $\mathbf{H}_\infty(\boldsymbol{U}) + \mathbf{H}_\infty(\boldsymbol{V}) = 2\log K$, which cannot be too large due to the biased behavior of $\langle \boldsymbol{U}, \boldsymbol{V}\rangle$, showing the desired upper bound on K.

Going beyond $m^{n/2}$. A natural attempt towards improving the upper bound for K would be to consider the inner product $\langle \boldsymbol{U}^\dagger, \boldsymbol{V}^\dagger\rangle$ where $\boldsymbol{U}^\dagger = \boldsymbol{U}_1 + \cdots + \boldsymbol{U}_\ell$ for some integer ℓ with each $\boldsymbol{U}_i$ sampled uniformly and independently from $\mathcal{U}$ (and $\boldsymbol{V}^\dagger$ similarly defined), and hope for two nice events:

(a) $\mathbf{H}_\infty(\boldsymbol{U}^\dagger) + \mathbf{H}_\infty(\boldsymbol{V}^\dagger) \approx 2\ell \log K \gg 2\log K$;

(b) $\langle \boldsymbol{U}^\dagger, \boldsymbol{V}^\dagger\rangle$ remains far from uniform just like $\langle \boldsymbol{U}, \boldsymbol{V}\rangle$. And hence $\mathbf{H}_\infty(\boldsymbol{U}^\dagger) + \mathbf{H}_\infty(\boldsymbol{V}^\dagger) \lessapprox m \log n$.

In other words, we are trying to boost the lower bound on min-entropy by adding ℓ independent samples of $\boldsymbol{U}$, and at the same time maintain the upper bound on min-entropy. And if the above is true, one would obtain a substantial improvement on the upper bound (e.g. $K \leq m^{n/4}$ even for the smallest non-trivial $\ell = 2$).

In the rest of this proof overview, we will walk through how we show the two events above are true for any $\{\alpha, \beta\}$-matching vector family. For simplicity, let $m = pq$ for distinct primes p and q, with $q > p$. And one could further assume that $\alpha = 0 \pmod p, \alpha \neq 0 \pmod q$, and $\beta = 0 \pmod q, \beta \neq 0 \pmod p$; see Lemma 25 for more details.

Event (a)

In order to show that $\mathbf{H}_\infty(\boldsymbol{U}^\dagger) \approx \ell \log K$, it is sufficient to show that $\boldsymbol{U}^\dagger = \sum_{i=1}^{\ell} \boldsymbol{U}_i$ *does not* generate too many collisions.

Omitting most technical details, we show that if $\boldsymbol{u}_1 + \ldots + \boldsymbol{u}_\ell = \boldsymbol{u}'_1 + \ldots + \boldsymbol{u}'_\ell$ (i.e. a collision), then it must be the case that $\langle \boldsymbol{u}'_i, \boldsymbol{v}_1 \rangle = \alpha$ for all $1 \leq i \leq \ell \leq q$, where $\boldsymbol{v}_1$ is the matching vector for $\boldsymbol{u}_1$. This is due to the heavy constraint that – (1) any inner product can only take values from $\{0, \alpha, \beta\}$, and (2) inner product with $\boldsymbol{v}_1$ gives an expression of the form $x_1\alpha + x_2\beta$, on the LHS, while $y_1\alpha + y_2\beta$, on the RHS, for nonnegative integers x_i, y_i such that $x_1 + x_2 \leq \ell - 1$. and $y_1 + y_2 \leq \ell$. (Remember $\langle \boldsymbol{u}_1, \boldsymbol{v}_1 \rangle = 0$.)

This anomaly (that there is plausibly 1 less term in the LHS) is sufficient to conclude that if there are too many collisions, one can easily extract a large $\{\alpha\}$-matching vector family, which would contradict a known linear upper bound, since a simple pigeon-hole principle argument shows that $\mathbf{MV}(pq, n, 2) \leq n + 1$; see Lemma 18.

In the actual proof, for technical reasons, we work with a slightly different distribution $\boldsymbol{U}^\star$, which adds up ℓ *distinct* random vectors from $\mathcal{U}$. In other words, one may view $\boldsymbol{U}^\dagger$ as sampling *with replacement* and $\boldsymbol{U}^\star$ as sampling *without replacement* from $\mathcal{U}$. These two distributions are so close to each other that we are able to substitute one with the other without incurring much loss in the final argument. Moreover, this distinction also helps us to argue that the sum of the coefficients in LHS is *exactly* $\ell - 1$, while it is *exactly* ℓ in RHS. For the detailed proof on lower bounding the min-entropy, see Section 3.2.

Event (b)

To show that $\langle \boldsymbol{U}^\dagger, \boldsymbol{V}^\dagger \rangle$ is far from uniform, we directly examine its bias $\left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger, \boldsymbol{V}^\dagger \rangle}]\right|$ in terms of Fourier coefficients (where ω is a primitive m-th root of unity). Via standard Fourier-analytic techniques, and using the "almost" multiplicative property of the bias (Lemma 11), we can *almost* show that

$$\left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger, \boldsymbol{V}^\dagger \rangle}]\right| \gtrapprox \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}, \boldsymbol{V} \rangle}]\right|^{\ell^2} .$$

That is, adding ℓ independent samples of $\boldsymbol{U}$ (and $\boldsymbol{V}$) will *not* smooth out the inner product for not too large ℓ (see Lemmas 11 and 13).

On the other hand, since $\langle \boldsymbol{U}, \boldsymbol{V} \rangle$ takes only 3 possible values with 0 showing up with negligible probability $\frac{1}{K}$, we can show that $\left|\mathbb{E}[\omega^{\langle \boldsymbol{U}, \boldsymbol{V} \rangle}]\right|$ has to be large! And this is essentially all we need. For the detailed proof on upper bounding the min-entropy, see Section 3.1.

Combining all of the above and choosing $\ell = q$, we get $2q \log K \lessapprox \mathbf{H}_\infty(\boldsymbol{U}^\star) + \mathbf{H}_\infty(\boldsymbol{V}^\star) \lessapprox n \log m$ which gives us the desired upper bound of $K \lessapprox m^{n/2q}$. For a general m one can always reduce it to working with $m = p^s q^t$, for primes p and q; see Lemmas 24 and 25. And for $m = p^s q^t$, the argument is similar to the above.

Lastly, it is worth noting that via a more direct analysis on the min-entropy of carefully chosen random variables, we are able to avoid the inductive argument in [7], which was tailored for composite m.

1.7 Conclusions and Open Questions

Our approach can be broadly summarized as considering $\boldsymbol{U}^\dagger := \boldsymbol{U}_1 + \cdots + \boldsymbol{U}_\ell$, and similarly $\boldsymbol{V}^\dagger := \boldsymbol{V}_1 + \cdots + \boldsymbol{V}_\ell$, and then proving that

1. $\omega^{\langle \boldsymbol{U}^\dagger, \boldsymbol{V}^\dagger \rangle}$ is far from uniform, where ω is the m-th root of unity, and
2. $\mathbf{H}_\infty(\boldsymbol{U}^\dagger) \approx \ell \cdot \mathbf{H}_\infty(\boldsymbol{U})$ for $\ell = q$.

The first item implies that $\mathbf{H}_\infty(\boldsymbol{U}^\dagger) + \mathbf{H}_\infty(\boldsymbol{V}^\dagger)$ is not much larger than $m \log n$, and this combined with the second item implies that $\mathbf{H}_\infty(\boldsymbol{U}) = \mathbf{H}_\infty(\boldsymbol{V})$ is small, giving an upper bound on K.

We prove these two items for $\ell = q$, and for r-restricted families for $r = 3$. Notice that the approach is much more general, and it is just a shortcoming of our proof techniques that doesn't allow us to go beyond $\ell > q$, or $r > 3$. In particular, for $r = 3$, the statement (1) above holds for $\ell \gg q$, and we leave it as an open question whether one can prove that for $\ell \gg q$, $\mathbf{H}_\infty(\boldsymbol{U}^\dagger) \gg q\mathbf{H}_\infty(\boldsymbol{U})$. This will immediately imply a better upper bound on K for 3-query matching vector codes.

Similarly, we leave it as an open question whether the same approach can be extended to a larger number of queries.

2 Preliminaries

2.1 Random Variable and Entropy

▶ **Definition 6** (Min-Entropy). *Let X be a random variable over a set $\mathcal{X}$, the Min-Entropy is defined as:*

$$\mathbf{H}_\infty(X) = \min_{x \in \mathcal{X}} -\log(\Pr[X = x]) \ .$$

▶ **Definition 7** (Collision Entropy). *Let X and Y be independent and identically distributed random variables, the Collision Entropy is defined as:*

$$\mathbf{H}_2(X) = -\log \Pr[X = Y] \ .$$

Alternatively,

$$\mathbf{H}_2(X) = -\log \sum_x (\Pr[X = x])^2 .$$

▶ **Observation 8** (Relation Between Collision and Min-Entropy). *For any random variable X, it holds that*

$$\mathbf{H}_2(X) \geq \mathbf{H}_\infty(X) \ .$$

▶ **Lemma 9.** *Let X and Y be independent random variables of the same domain $\mathcal{X}$ closed under addition. It holds that*

$$\mathbf{H}_\infty(X) \leq \mathbf{H}_\infty(X + Y) \ .$$

Proof. For any $z \in \mathcal{X}$, we have:

$$\begin{aligned}
\Pr[X + Y = z] &= \sum_{y \in \mathcal{X}} \Pr[X = z - y | Y = y] \Pr[Y = y] \\
&= \sum_{y \in \mathcal{X}} \Pr[X = z - y] \Pr[Y = y] \\
&\leq \sum_{y \in \mathcal{X}} (\max_x \Pr[X = x]) \Pr[Y = y] \\
&\leq \max_x \Pr[X = x] \ .
\end{aligned}$$

Therefore,

$$\mathbf{H}_\infty(X) \;=\; \log \frac{1}{\max_x \Pr[X=x]} \;\leq\; \log \frac{1}{\max_z \Pr[X+Y=z]} \;=\; \mathbf{H}_\infty(X+Y)\;,$$

as desired. ◀

Let ω be a primitive root of unity of order m. Let X and Y be two probability distributions over $\mathbb{Z}_m^n$. The bias of the output distribution wrt ω, denoted $\mathbb{E}[\omega^{\langle X,Y\rangle}]$, can be defined as follows:

$$\mathbb{E}[\omega^{\langle X,Y\rangle}] \;=\; \mathbb{E}_{x\sim X, y\sim Y}[\omega^{\langle x,y\rangle}] \;=\; \sum_{x,y} X(x)Y(y)\omega^{\langle x,y\rangle}\;.$$

▶ **Lemma 10** (Lemma 2.14 from [7]). *Let ω be a primitive root of unity of order m. Let X and Y be two probability distributions over $\mathbb{Z}_m^n$. If $|\mathbb{E}[\omega^{\langle X,Y\rangle}]| \geq \epsilon$, then $\mathbf{H}_2(X)+\mathbf{H}_2(Y) \leq n\log m + 2\log(1/\epsilon)$.*

▶ **Lemma 11** (Lemma 3.3 from [21]). *Let ω be a primitive root of unity of order m. Let X and Y be two probability distributions over $\mathbb{Z}_m^n$, then $|\mathbb{E}[\omega^{\langle X-X,Y\rangle}]| \geq |\mathbb{E}[\omega^{\langle X,Y\rangle}]|^2$. Here $X-X$ is shorthand for taking the difference of two samples drawn independently according to the distribution X.*

▶ Remark 12. Lemma 11 was stated for distributions over $\mathbb{F}^n$ for any finite field $\mathbb{F}$ in [21], but the proof trivially extends to distributions over $\mathbb{Z}_m^n$. For completeness, we reproduce the proof from [21] in the appendix.

▶ **Lemma 13** ([21]). *Let ω be a primitive root of unity of order m. Let X and Y be two probability distributions over $\mathbb{Z}_m^n$. For any integer $x, y \geq 0$, $|\mathbb{E}[\omega^{\langle 2^x\cdot X - 2^x\cdot X, 2^y\cdot Y - 2^y\cdot Y\rangle}]| \geq |\mathbb{E}[\omega^{\langle X,Y\rangle}]|^{2^{x+y+2}}$. Here $2^x\cdot X$ represents the distribution of adding 2^x independent samples of X.*

Proof. Notice that $(X-X)-(X-X) = 2X-2X$. Hence this follows from applying Lemma 11 $(x+1)+(y+1) = x+y+2$ times. ◀

2.2 Matching Vector Families and Codes

Much of these definitions follow the same notation as Yekhanin's survey [25].

▶ **Definition 14** (Locally Decodable Codes). *A q-ary code $C : \Sigma^K \to \Sigma^N$ with $|\Sigma| = q$ is (r,δ,ε)-locally decodable if there exists a randomized decoding algorithm $\mathcal{A}$ such that*

1. *For all $x \in \Sigma^K$, $i \in [K]$ and all $y \in \Sigma^N$ such that $\Delta(C(x), y) \leq \delta$:*

$$\Pr_{\mathcal{A}}[\mathcal{A}^y(i) = x(i)] \geq 1-\varepsilon$$

2. *$\mathcal{A}$ makes atmost r queries to y.*

The best-known constructions of locally decodable codes are derived from constructions of matching vector families over $\mathbb{Z}_m$ for composite m's. The following theorem demonstrates the parameters of locally decodable codes obtained from given parameters of a matching vector family.

▶ **Theorem 15** ([25]). *Let $\mathcal{U}, \mathcal{V}$ be a S-matching vector family over $\mathbb{Z}_m^n$ with $|\mathcal{U}| = |\mathcal{V}| = K$. Suppose $m \mid q-1$ for some prime power q, then there exists a linear code $C : \mathbb{F}_q^K \to \mathbb{F}_q^{m^n}$ that is $(|S|+1, \delta, (|S|+1)\delta)$-locally decodable for every δ.*

In the low-query complexity regime, $r = O(1)$, the best-known matching vector families are based on Grolmusz's construction of set systems.

▶ **Theorem 16** ([25, Lemma 4.8]). *Let $m = \prod_{i=1}^{t} p_i$ be a product of distinct primes. Let w be a positive integer. Let $\{e_i\}_{i=1}^{t}$ be integers such that $p_i^{e_i} \geq w^{1/t}$ for all i. Let $d = \max_i p_i^{e_i}$ and $h \geq w$ be arbitrary. Then there exists an $\binom{h}{w}$-sized σm-bounded family of matching vectors in $\mathbb{Z}_m^n$ where $n = \binom{h}{\leq d}$ and σ is an arbitrary real larger than $\sum_{i\in[t]} \frac{1}{p_i}$.*

Then, using Theorem 15, this matching vector family construction can be transformed into a linear binary LDC with the following parameters:

▶ **Theorem 17** ([18], as stated in [25], Theorem 3.11). *For every integer $t \geq 2$ and for all $K \geq 2$, there exists an $r = 3 \cdot 2^{t-2}$-query (binary) linear locally decodable code over $\mathbb{F}_{2^t}$ encoding K-long messages to $2^{t(\log K)^{1/t}(\log\log K)^{1-1/t}}$-long codewords and allowing $\delta = O(1/r)$ fraction of errors.*

In particular, when $r = 3$, there exists a code with codeword length $N = 2^{2^{\widetilde{O}(\sqrt{\log K})}}$

2.3 Upper Bounds for 2-restricted Matching Vector Families

In this section, we prove an upper bound on any $\{\alpha\}$-matching vector family over $\mathbb{Z}_m^n$. Without loss of generality, one can assume that m is a prime power p^s, because otherwise if $m = p^s q^t$, then without loss of generality $\alpha \neq 0 \pmod{p^s}$, and therefore the same set of vectors form a matching vector family over $\mathbb{Z}_{p^s}^n$.

▶ **Lemma 18.** *For any prime p and positive integer s, $\mathbf{MV}(p^s, n, 2) \leq ns + 1$.*

Proof. Suppose $\alpha \neq 0 \pmod{p^s}$. Assume towards contradiction that $\mathcal{U}, \mathcal{V}$ is a $\{\alpha\}$-matching vector family over $\mathbb{Z}_{p^s}^n$ with $|\mathcal{U}| = |\mathcal{V}| = K \geq ns + 2$.

Define $\boldsymbol{u}_i' := \boldsymbol{u}_{ns+2} - \boldsymbol{u}_i$ for $\boldsymbol{u}_i \in \mathcal{U}$. By definition of the $\{\alpha\}$-matching vector family, for $i, j \leq ns + 1$ we have:

$$\langle \boldsymbol{u}_i', \boldsymbol{v}_j \rangle = \begin{cases} \alpha, & i = j \\ 0, & i \neq j \end{cases}.$$

We claim that there exist integer coefficients $c_1, \ldots, c_{ns+1}$, not all zero, such that $-(p-1) \leq c_i \leq p - 1$, and

$$\sum_{i=1}^{ns+1} c_i \boldsymbol{u}_i' = 0 \,.$$

To see this, consider all possible sums $\sum_{i=1}^{ns+1} d_i \boldsymbol{u}_i' \in \mathbb{Z}_{p^s}^n$, for $d_i \in \{0, 1, \ldots, p-1\}$. There are p^{ns+1} such sums that can each take one of $(p^s)^n = p^{ns}$ values. By the pigeon-hole principle, there exist two distinct sums that are equal, i.e.,

$$\sum_{i=1}^{ns+1} d_i \boldsymbol{u}_i' = \sum_{i=1}^{ns+1} d_i' \boldsymbol{u}_i' \,,$$

for some tuples $(d_1, \ldots, d_{ns+1}) \neq (d_1', \ldots, d_{ns+1}')$. The claim follows by taking $c_i = d_i - d_i'$ for $i \in \{1, \ldots, ns + 1\}$.

We have that at least one of $c_1, \ldots, c_{ns+1}$ is non-zero. Without loss of generality, let $c_{ns+1} \neq 0$. Notice that $c_{ns+1} \in \{-(p-1), \ldots, -1\} \cup \{1, \ldots, p-1\}$, and hence has a multiplicative inverse modulo p^s. Let $c'_i = c_{ns+1}^{-1} c_i \pmod{p^s}$ for $i \in [ns+1]$. Thus, we have that

$$\boldsymbol{u}'_{ns+1} \;=\; -\sum_{i=1}^{ns} c'_i \boldsymbol{u}'_i \,.$$

Now take the inner product on both sides with $\boldsymbol{v}_{ns+1}$. Note that, $\langle \boldsymbol{u}'_{ns+1}, \boldsymbol{v}_{ns+1} \rangle = \alpha$, while

$$\left\langle \sum_{i=1}^{ns} c'_i \boldsymbol{u}'_i, \boldsymbol{v}_{ns+1} \right\rangle \;=\; \sum_{i=1}^{ns} c'_i \langle \boldsymbol{u}'_i, \boldsymbol{v}_{ns+1} \rangle \;=\; 0 \,.$$

Therefore, we obtain that $\alpha = 0$ which is a contradiction. ◀

▶ Remark 19. By the above lemma, we get $\mathbf{MV}(m, n, 2) \leq n \log m + 1$, since trivially, $s \leq \log m / \log p \leq \log m$.

2.4 Upper Bounds for Prime Powers

In this section, we provide a polynomial upper bound for matching vector families over $\mathbb{Z}_m$ where m is a prime power. The sketch was personally communicated to us by Sivakanth Gopi. To prove this, we need the following lemma from [14]. We state it without proof, but it follows from Lucas' Theorem.

▶ **Lemma 20.** *Let p be a prime and $s \in \mathbb{Z}^+$. There exists a polynomial $f(x_1, \ldots, x_n)$ of degree $p^s - 1$ such that for $x \in \{0,1\}^n$, $f(x) \neq 0 \pmod{p}$ iff $\sum_{i=1}^n x_i$ is divisible by p^s. Specifically, $f(x) = \prod_{j=1}^{s-1} \left(1 - \binom{\sum_{i=1}^n x_i}{p^j}^{p-1}\right)$.*

Here $\binom{\sum_{i=1}^n x_i}{k} = \sum_{i_1 < \ldots < i_k} x_{i_1} \ldots x_{i_k}$ is always a valid integer polynomial for $k \leq n$. Note that in [14], the lemma is technically stated with $1 - f$ as opposed to f. We are now ready to show the upper bound. Also, note that f takes only 2 values 1 and 0 $\pmod{p}$, depending on the divisibility property.

▶ **Theorem 21** (Upper bound for prime-power [15])**.** *Let $m = p^s$ for some prime p and $s \in \mathbb{Z}^+$. Then, for any matching vector family $\mathcal{U}, \mathcal{V} \subseteq \mathbb{Z}_m^n$ of size $t = |\mathcal{U}| = |\mathcal{V}|$ we have that $t \leq (2emn)^{m-1}$.*

Proof. We will first convert the matching vector family $\mathcal{U}, \mathcal{V}$ into a matching vector family consisting of vectors with *only zero or one* coordinates, we stress that the matching vector family is still considered over $\mathbb{Z}_m$ and $0, 1$ are interpreted as elements of $\mathbb{Z}_m$, not $\mathbb{F}_2$. Thereafter, we will argue by showing an upper bound on the rank of a specially constructed matrix, via the polynomial defined in Lemma 20.

Converting into a binary matching vector family. We will transform vectors in $\mathcal{U}, \mathcal{V}$ into vectors in $\{0,1\}^{n'} \subset \mathbb{Z}_m^{n'}$ for $n' = nm^2$, such that the pairwise inner-product $\langle \boldsymbol{u}, \boldsymbol{v} \rangle$ for $\boldsymbol{u} \in \mathcal{U}, \boldsymbol{v} \in \mathcal{V}$ is preserved over $\mathbb{Z}_m$. For any $\boldsymbol{u} \in \mathcal{U}$ (resp. $\boldsymbol{v} \in \mathcal{V}$), map each coordinate $\boldsymbol{u}_i$ (resp. $\boldsymbol{v}_i$) into the $m \times m$ matrix[1] $\boldsymbol{u}'_i$ (resp. $\boldsymbol{v}'_i$) with all 1's in the first $\boldsymbol{u}_i$ rows (resp. first $\boldsymbol{v}_i$ columns). It is easy to see that $\boldsymbol{u}_i \cdot \boldsymbol{v}_i = \langle \boldsymbol{u}'_i, \boldsymbol{v}'_i \rangle$ and

[1] Matrix is interpreted as a vector simply by reading entries of the matrix row by row.

$$\langle \boldsymbol{u}, \boldsymbol{v} \rangle = \sum_{i \in [n]} \boldsymbol{u}_i \cdot \boldsymbol{v}_i = \sum_{i \in [n]} \langle \boldsymbol{u}'_i, \boldsymbol{v}'_i \rangle = \langle \boldsymbol{u}', \boldsymbol{v}' \rangle$$

As a result, we can turn any matching vector family $\mathcal{U}, \mathcal{V} \subseteq \mathbb{Z}_m^n$ into one with only binary vectors in $\mathbb{Z}_m^{mn^2}$. For the rest of the argument, denote $\mathcal{U}, \mathcal{V} \subseteq \mathbb{Z}_m^{n'}$ to be the binary vectors obtained like above from the original $\mathcal{U}, \mathcal{V}$ where $n' = nm^2$.

Constructing a useful matrix. Suppose $\mathcal{U} = \{\boldsymbol{u}^{(1)}, \ldots, \boldsymbol{u}^{(t)}\}, \mathcal{V} = \{\boldsymbol{v}^{(1)}, \ldots, \boldsymbol{v}^{(t)}\}$ where all $\boldsymbol{u}^{(i)}, \boldsymbol{v}^{(j)} \in \{0,1\}^{n'} \subset \mathbb{Z}_m^{n'}$. Recall $m = p^s$, let $f(x)$ be such a polynomial as defined in Lemma 20. By the same lemma, $\langle \boldsymbol{u}, \boldsymbol{v} \rangle = \sum_{i=1}^{n'} \boldsymbol{u}_i \boldsymbol{v}_i = 0 \pmod m$ iff $f(\boldsymbol{u}_1 \boldsymbol{v}_1, \ldots, \boldsymbol{u}_{n'} \boldsymbol{v}_{n'}) \neq 0 \pmod p$. Now, we define a matrix $M \in \mathbb{Z}_p^{t \times t}$ whose rows are indexed by vectors in $\mathcal{U}$ and whose columns are indexed by vectors in $\mathcal{V}$ such that:

$$M_{i,j} = M(\boldsymbol{u}^{(i)}, \boldsymbol{v}^{(j)}) \;:=\; f(\boldsymbol{u}_1^{(i)} \boldsymbol{v}_1^{(j)}, \ldots, \boldsymbol{u}_{n'}^{(i)} \boldsymbol{v}_{n'}^{(j)}) \,.$$

Note that $M(\boldsymbol{u}^{(i)}, \boldsymbol{v}^{(j)}) \neq 0$ iff $i = j$. Hence, M is full rank diagonal matrix (infact, it is the identity matrix!).

On the other hand, by Lucas' Theorem, f has degree at most $p^s - 1 = m - 1$ and n' variables. Notice that there are at most $\binom{n'}{m-1} + \binom{n'}{m-2} + \ldots + \binom{n'}{0} \leq \binom{n'+m-1}{m-1}$ possible monomials up to degree $m-1$. For any polynomial f of degree $m-1$ we can consider the vector $\widetilde{\boldsymbol{f}} \in \mathbb{Z}_m^{\binom{n'+m-1}{m-1}}$, a vector of coefficients of each of $\binom{n'+m-1}{m-1}$ monomials. One can also take any input $x_1, \ldots, x_{n'}$ and consider a vector $\widetilde{\boldsymbol{x}} \in \mathbb{Z}_m^{\binom{n'+m-1}{m-1}}$ consisting of evaluations of each of the monomials on $x_1, \ldots, x_{n'}$. Notice that then $f(x_1, \ldots, x_{n'}) = \langle \widetilde{\boldsymbol{x}}, \widetilde{\boldsymbol{f}} \rangle$. Similarly, for each $\boldsymbol{u} \in \mathcal{U}, \boldsymbol{v} \in \mathcal{V}$ we can find $\widetilde{\boldsymbol{u}}, \widetilde{\boldsymbol{v}} \in \mathbb{Z}_m^{\binom{n'+m-1}{m-1}}$, such that $f(\boldsymbol{u}_1 \boldsymbol{v}_1, \ldots, \boldsymbol{u}_{n'} \boldsymbol{v}_{n'}) = \langle \widetilde{\boldsymbol{u}}, \widetilde{\boldsymbol{v}} \rangle$, for example $\widetilde{\boldsymbol{u}}$ consists of evaluations of monomials on input $u_1, \ldots, u_{n'}$ while $\widetilde{\boldsymbol{v}}$ combines evaluations of monomials on $v_1, \ldots, v_{n'}$ with coefficients of polynomial f. Thus, an obvious counting argument gives the desired upper bound:

$$t \;=\; \operatorname{rank}(M) \;\leq\; \binom{n'+m-1}{n'} \;=\; \binom{nm^2+m-1}{m-1} \;\leq\; (2enm)^{m-1} \,. \qquad \blacktriangleleft$$

Note that the above proof fails immediately for composites. For one, we don't have a version of the Lucas' Theorem. Moreover, there is no unified notion of rank that can be utilized, for example by reducing it to working over a prime field.

▶ Remark 22. For any constant $m = p^s$ for some prime p and positive integer s, Theorem 21 implies $\mathbf{MV}(m, n, r) \leq (2emn)^{m-1} = \operatorname{poly}(n)$ for any $0 < r \leq m$.

2.5 Some properties of 3-restricted matching vector families

We will consider matching vector families in $\mathbb{Z}_m$ where m is a composite positive integer. All algebraic operations in this section, unless otherwise stated, are modulo $\mathbb{Z}_m$.

Let $\alpha, \beta \in \mathbb{Z}_m \setminus \{0\}$. Consider a matching vector family $(\mathcal{U}, \mathcal{V})$ such that $\mathcal{U} = \{u_1, \ldots, u_K\}, V = \{v_1, \ldots, v_K\} \subseteq \mathbb{Z}_m^n$ that satisfy the following properties:

- For all $i \in [K]$, $\langle \boldsymbol{u}_i, \boldsymbol{v}_i \rangle = 0$.
- For all $i, j \in [K]$ with $i \neq j$, we have that $\langle \boldsymbol{u}_i, \boldsymbol{v}_j \rangle \in \{\alpha, \beta\}$.

We call $(\mathcal{U}, \mathcal{V})$ an $\{\alpha, \beta\}$-matching vector family of size K.

▶ Remark 23. For the rest of the paper until the end of Section 3.2, we will assume that $(\mathcal{U}, \mathcal{V})$ is not a matching vector family modulo m' for any $m'|m$. We can make this assumption without loss of generality. This is because we will prove an upper bound on K that increases as a function of m, and we get a better bound if there exists such an m'.

In our argument, it will be useful to work with composites that are exactly the product of two prime powers. This is clearly the first non-trivial case since we have a polynomial upper bound (in n) for the case of prime powers. In fact, for 3-restricted matching vector families, [7] demonstrated that this is the only non-trivial case. We include the proof below for completeness.

▶ **Lemma 24** ([7]). *Let $(\mathcal{U}, \mathcal{V})$ be a $(q+1)$-restricted matching vector family in $\mathbb{Z}_m^n$. Then m has at most q prime factors.*

Proof. Suppose $m = \prod_i p_i^{r_i}$ for some primes p_i's and corresponding positive integers r_i's. Suppose the possible non-zero values of inner products are $\alpha_1, \ldots, \alpha_q \pmod m$. For each α_j, there must exist i such that $\alpha_j \neq 0 \pmod{p_i^{r_i}}$. We can take m' to be the product of atmost q prime powers that satisfy the above condition for the respective α_j's. Thus the $(q+1)$-restricted matching vector family in $\mathbb{Z}_m^n$ induces (via the modulo m' operation) a matching vector family in $\mathbb{Z}_{m'}^n$ of the same size, and with the same number of restrictions. ◀

From the previous lemma, we can assume $m = p^s q^t$ for any $\{\alpha, \beta\}$-matching vector family $(\mathcal{U}, \mathcal{V})$ where p, q are some primes and s, t are some positive integers. In the next lemma, we can show some more restrictions on the values taken by α and β.

▶ **Lemma 25.** *Let $m = p^s q^t$ be a composite positive integer such that for any m' which is a divisor of m, $(\mathcal{U}, \mathcal{V})$ is not a matching vector family modulo m'. Then we have $\alpha = 0 \pmod{p^s q^{t-1}}$, $\alpha \neq 0 \pmod{q^t}$, $\beta = 0 \pmod{p^{s-1} q^t}$, $\beta \neq 0 \pmod{p^s}$.*

Proof. By the same argument as Lemma 24, we can assume without loss of generality that $\alpha \neq 0 \pmod{q^t}$ and $\beta \neq 0 \pmod{p^s}$. Now, suppose for a contradiction $\beta \neq 0 \pmod{p^{s-1} q^t}$. Clearly, $\alpha \neq 0 \pmod{p^{s-1} q^t}$ Then $(\mathcal{U}, \mathcal{V})$ is a $\{\alpha, \beta\}$-matching vector family modulo $m' = p^{s-1} q^t \mid m$ which is a contradiction. Similarly, we can show $\alpha = 0 \pmod{p^s q^{t-1}}$. ◀

3 Upper Bound for 3-restricted Matching Vector Families

Let $\mathcal{U}, \mathcal{V}$ be a matching vector family of size K in $\mathbb{Z}_m^n$ with non-zero residues α and β. By Lemma 24, we have that $m = p^s q^t$ for primes p and q and integers $s, t \geq 1$ with $p < q$. Further, using Lemma 25, we have that $\alpha = 0 \pmod{p^s q^{t-1}}$, $\alpha \neq 0 \pmod{q^t}$, $\beta = 0 \pmod{p^{s-1} q^t}$, $\beta \neq 0 \pmod{p^s}$. Define, a parameter τ (which is a small constant) as follows:

$$\tau := \frac{1}{2pq}.$$

Let $\mathcal{S}_{q,K} = \{A \subset [K] \mid |A| = q\}$ be the set of all subsets of $[K]$ of size q. Let $\omega = e^{\frac{2\pi i}{m}}$ be a primitive root of unity of order m.

For analysis, we define a few random variables as follows: Let $\boldsymbol{U}_i$ be uniform and independent vectors drawn from $\mathcal{U}$. Let ℓ be the *smallest* integer such that $q \leq 2^\ell$. We have:

1. $\boldsymbol{U} := \boldsymbol{U}_i$.
2. $\boldsymbol{U}^{\S} := \sum_{i=1}^{2^\ell} \boldsymbol{U}_i - \sum_{i=2^\ell+1}^{2^{\ell+1}} \boldsymbol{U}_i$. That is, sample *with replacement* $2 \cdot 2^\ell$ independent vectors from $\mathcal{U}$, add up the first 2^ℓ vectors and subtract away the remaining 2^ℓ vectors.

3. $\boldsymbol{U}^{\dagger} := \sum_{i=1}^{q} \boldsymbol{U}_i$. That is, sample *with replacement* q independent vectors from $\mathcal{U}$ and add them up.
4. $\boldsymbol{U}^{\ddagger} := \sum_{i=q+1}^{2^\ell} \boldsymbol{U}_i - \sum_{i=2^\ell+1}^{2^{\ell+1}} \boldsymbol{U}_i$. Here we define $\boldsymbol{U}^{\ddagger}$ such that $\boldsymbol{U}^{\S} = \boldsymbol{U}^{\dagger} + \boldsymbol{U}^{\ddagger}$.
5. $\boldsymbol{U}^{\star}$ is distributed as follows: pick a subset $A \sim \mathcal{S}_{q,K}$ uniformly at random and $\boldsymbol{U}^{\star} := \sum_{i\in A} \boldsymbol{u}_i$. In other words, sample *without replacement* q vectors from $\mathcal{U}$ and add them up. This is in contrast to $\boldsymbol{U}^{\dagger}$ which is sampling *with replacement*.

Random variables for $\mathcal{V}$ are defined similarly.

Sampling without replacement helps in lower bounding the min-entropy of $\boldsymbol{U}^{\star}$. On the other hand, we upper bound the min-entropy of $\boldsymbol{U}^{\dagger}$ where sampling with replacement (and hence full independence) is useful. And we are able to relate these two quantities as these two distributions are really close to each other.

The introduction of $\boldsymbol{U}^{\S}$ (and hence $\boldsymbol{U}^{\ddagger} = \boldsymbol{U}^{\S} - \boldsymbol{U}^{\dagger}$) serves as a tool for lower bounding the bias of $\boldsymbol{U}^{\dagger}$ via Lemma 13 because we are restricted to sums containing powers of 2 elements.

3.1 Upper Bound on Min-Entropy

In the following lemma, we prove that since $\mathcal{U}, \mathcal{V}$ constitute a 3-restriced **MV** family over $\mathbb{Z}_m^n$, then $\langle \boldsymbol{U}, \boldsymbol{V}\rangle$ has to be *far* from uniform. This is captured via Fourier analysis.

▶ **Lemma 26** (Large bias for **MV** family). *Let $K \geq 10pq$. Then, we have that $\left|\mathbb{E}[\omega^{\langle \boldsymbol{U},\boldsymbol{V}\rangle}]\right| \geq \tau$.*

Proof. This proof relies on the fact that the random variable $\omega^{\langle \boldsymbol{U},\boldsymbol{V}\rangle}$ is essentially supported on two values, $\{\omega^\alpha, \omega^\beta\}$, since the mass on ω^0 (corresponding to $\langle \boldsymbol{U}, \boldsymbol{V}\rangle = 0$) is very small. To complete the argument, we show that $\alpha - \beta$ is an integer different from $m/2$, and thus the mass on ω^α doesn't cancel that on ω^β. The detailed argument is given below.

Recall that $\langle \boldsymbol{U}, \boldsymbol{V}\rangle \in \{0, \alpha, \beta\}$ and $\Pr[\langle \boldsymbol{U}, \boldsymbol{V}\rangle = 0] = \frac{1}{K}$. Let $\lambda := \Pr[\langle \boldsymbol{U}, \boldsymbol{V}\rangle = \alpha]$, $\lambda \in \left[0, 1 - \frac{1}{K}\right]$. Then $\Pr[\langle \boldsymbol{U}, \boldsymbol{V}\rangle = \beta] = 1 - \lambda - \frac{1}{K}$. Since $\alpha = 0 \pmod{p^s q^{t-1}}$ and $\beta = 0 \pmod{p^{s-1}q^t}$, let $\frac{\alpha}{m} = \frac{c}{q}$ and $\frac{\beta}{m} = \frac{d}{p}$, for some $0 < c < q$ and $0 < d < p$. By definition of the bias, we have

$$
\begin{aligned}
\left|\mathbb{E}[\omega^{\langle \boldsymbol{U},\boldsymbol{V}\rangle}]\right| &= \left|\sum_{u,v\in\mathbb{Z}_m^n} \boldsymbol{U}(u)\boldsymbol{V}(v)\omega^{\langle u,v\rangle}\right| \\
&\geq \min_{\lambda\in[0,1-\frac{1}{K}]} \left|\frac{1}{K} + \lambda\omega^\alpha + (1 - 1/K - \lambda)\omega^\beta\right| \\
&\geq \min_{\lambda\in[0,1-\frac{1}{K}]} \left|\lambda\omega^\alpha + (1 - 1/K - \lambda)\omega^\beta\right| - \frac{1}{K} \\
&= \min_{\lambda\in[0,1-\frac{1}{K}]} \left|\lambda + (1 - 1/K - \lambda)\omega^{\beta-\alpha}\right| - \frac{1}{K} \\
&= \min_{\lambda\in[0,1-\frac{1}{K}]} \sqrt{\lambda^2 + (1-1/K-\lambda)^2 + 2\lambda(1-1/K-\lambda)\cos\left(2\pi\left(\frac{c}{q} - \frac{d}{p}\right)\right)} - \frac{1}{K} \\
&\geq \min_{\lambda\in[0,1-\frac{1}{K}]} \sqrt{\lambda^2 + (1-1/K-\lambda)^2 + 2\lambda(1-1/K-\lambda)\cos\left(\frac{(pq-1)\pi}{pq}\right)} - \frac{1}{K} \\
&\geq \left(\frac{K-1}{K}\right)\cdot\sin\left(\frac{\pi}{2pq}\right) - \frac{1}{K} \\
&\geq \tau\,.
\end{aligned}
$$

The third equality follows from the identity that for constants c_i, and θ,

$$|c_1 + c_2 e^{i\theta}|^2 = |(c_1 + c_2 \cos\theta) + ic_2 \sin\theta|^2 = c_1^2 + c_2^2 + 2c_1 c_2 \cos\theta \,.$$

The third last inequality follows from the observation (which we discuss below) that $\left|2\pi\frac{cp-dq}{pq} - \pi\right| \geq \frac{\pi}{pq}$, and that cos θ for $\theta \in (0, 2\pi)$ is minimized when $|\theta - \pi|$ is minimized. If pq is odd, the above is trivially true since after multiplying left-hand-side by $\frac{pq}{\pi}$ we obtain $|2(cp - dq) - pq|$ and this is a difference of odd and even number and thus the absolute value has to be at least 1. Now, suppose $p = 2$, via similar argument we have

$$\left|\frac{2c - dq}{q} - 1\right| \geq \frac{1}{q} > \frac{1}{2q} \,,$$

since $c \neq 0 \pmod q$ and q is an odd prime.

The second last inequality follows from taking $\lambda = \frac{K-1}{2K}$ which minimizes the expression, and using $1 - \cos\theta = 2\sin^2(\theta/2)$, giving a value of the square root to be

$$\left(2\left(\frac{K-1}{2K}\right)^2 - 2\cdot\left(\frac{K-1}{2K}\right)^2 \cos\left(\frac{\pi}{pq}\right)\right)^{1/2} = \left(\frac{K-1}{K}\right)\sin\left(\frac{\pi}{2pq}\right) \,.$$

Finally, the last inequality follows from $\sin x \geq \frac{x}{2}$ for $x \in [0, 1]$ and that $K > 10pq$. ◀

Next, we will show that $\boldsymbol{U}^\star$ has low min-entropy.

▶ **Lemma 27.** $\left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger + \boldsymbol{U}^\ddagger, \boldsymbol{V}^\dagger + \boldsymbol{V}^\ddagger\rangle}]\right| \geq \tau^{16q^2}$.

Proof. Recall that ℓ is the *smallest* integer such that $q \leq 2^\ell$. Thus, $2^{\ell-1} < q$, i.e., $2^\ell < 2q$. By Lemma 13, we can control the bias of $\langle \boldsymbol{U}^\S, \boldsymbol{V}^\S\rangle$:

$$\begin{aligned}
\left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger + \boldsymbol{U}^\ddagger, \boldsymbol{V}^\dagger + \boldsymbol{V}^\ddagger\rangle}]\right| &= \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\S, \boldsymbol{V}^\S\rangle}]\right| \\
&\geq \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}, \boldsymbol{V}\rangle}]\right|^{2^{2(\ell+1)}} \\
&\geq \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}, \boldsymbol{V}\rangle}]\right|^{4\cdot(2q)^2} \\
&= \tau^{16q^2} \,.
\end{aligned}$$

◀

Define the event E_U (resp. E_V) where each $\boldsymbol{U}_i$ (resp. $\boldsymbol{V}_i$) is unique when $\boldsymbol{U}^\dagger$ (resp. $\boldsymbol{V}^\dagger$) is sampled. Notice that $\boldsymbol{U}^\dagger | E_U$ is distributed exactly as $\boldsymbol{U}^\star$. Also, $\Pr[\neg E_U] = \Pr[\neg E_V] \leq \frac{q^2}{K}$ and so, by the union bound $\Pr[\neg(E_U \wedge E_V)] \leq \frac{2q^2}{K}$.

▶ **Lemma 28.** $\left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\star + \boldsymbol{U}^\ddagger, \boldsymbol{V}^\star + \boldsymbol{V}^\ddagger\rangle}]\right| \geq \tau^{16q^2} - \frac{2q^2}{K}$.

Proof. The proof uses the above observation that $\boldsymbol{U}^\dagger | E_U$ (resp. $\boldsymbol{V}^\dagger | E_V$) is distributed exactly as $\boldsymbol{U}^\star$ (resp. $\boldsymbol{V}^\star$), and that both E_U and E_V hold simultaneously with probability at least $1 - \frac{2q^2}{K}$. In particular,

$$\begin{aligned}
\left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\dagger+\boldsymbol{V}^\ddagger\rangle}]\right| &= \Big|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\dagger+\boldsymbol{V}^\ddagger\rangle} \mid E_U \wedge E_V] \cdot \Pr[E_U \wedge E_V] \\
&\quad + \mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\dagger+\boldsymbol{V}^\ddagger\rangle} \mid \neg(E_U \wedge E_V)] \Pr[\neg(E_U \wedge E_V)]\Big| \\
&\leq \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\dagger+\boldsymbol{V}^\ddagger\rangle} \mid E_U \wedge E_V]\right| \Pr[E_U \wedge E_V] \\
&\quad + \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\dagger+\boldsymbol{V}^\ddagger\rangle} \mid \neg(E_U \wedge E_V)]\right| \Pr[\neg(E_U \wedge E_V)] \\
&= \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\star+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\star+\boldsymbol{V}^\ddagger\rangle}]\right| \Pr[E_U \wedge E_V] \\
&\quad + \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\dagger+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\dagger+\boldsymbol{V}^\ddagger\rangle} \mid \neg(E_U \wedge E_V)]\right| \Pr[\neg(E_U \wedge E_V)] \\
&\leq \left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\star+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\star+\boldsymbol{V}^\ddagger\rangle}]\right| + \frac{2q^2}{K} \,.
\end{aligned}$$

It follows that $\left|\mathbb{E}[\omega^{\langle \boldsymbol{U}^\star+\boldsymbol{U}^\ddagger,\boldsymbol{V}^\star+\boldsymbol{V}^\ddagger\rangle}]\right| \geq \tau^{16q^2} - \frac{2q^2}{K}$. ◀

▶ **Lemma 29.** $\mathbf{H}_\infty(\boldsymbol{U}^\star) + \mathbf{H}_\infty(\boldsymbol{V}^\star) \leq n \log m - 2\log(\tau^{16q^2} - \frac{2q^2}{K})$.

Proof. By Lemma 28 and Lemma 10, we have that

$$\mathbf{H}_2(\boldsymbol{U}^\star + \boldsymbol{U}^\ddagger) + \mathbf{H}_2(\boldsymbol{V}^\star + \boldsymbol{V}^\ddagger) \leq n \log m - 2\log(\tau^{16q^2} - \frac{2q^2}{K}) \,.$$

Finally, notice that $\boldsymbol{U}^\star$ is independent of $\boldsymbol{U}^\ddagger$ and $\boldsymbol{V}^\star$ is independent of $\boldsymbol{V}^\ddagger$. By Lemma 9, we have:

$$\mathbf{H}_\infty(\boldsymbol{U}^\star) + \mathbf{H}_\infty(\boldsymbol{V}^\star) \leq \mathbf{H}_\infty(\boldsymbol{U}^\star + \boldsymbol{U}^\ddagger) + \mathbf{H}_\infty(\boldsymbol{V}^\star + \boldsymbol{V}^\ddagger) \leq n \log m - 2\log\left(\tau^{16q^2} - \frac{2q^2}{K}\right) \,,$$

where $\mathbf{H}_\infty(X) \leq \mathbf{H}_2(X)$ for any random variable X. ◀

3.2 Lower Bound on Min-Entropy

In this subsection, we will talk about sums of vectors from $\mathcal{U}, \mathcal{V}$. For each $A \subseteq [K]$, we can naturally associate a sum of vectors $\sum_{i \in A} \boldsymbol{u}_i$ from $\mathcal{U}$ (and similarly for $\mathcal{V}$). Note that we only care about *unique* sums where each vector from $\mathcal{U}$ (or $\mathcal{V}$) appears only once. In this view, a *collision* corresponds to pair of sets $A, B, A \neq B$ such that $\sum_{i \in A} \boldsymbol{u}_i = \sum_{j \in B} \boldsymbol{u}_j$ (or similarly for vectors from $\mathcal{V}$). In the following we give a lower bound on the min-entropy of $\boldsymbol{U}^\star$. By symmetry, the statement holds for $\boldsymbol{V}^\star$ as well.

We start with a lemma that discusses the behaviour of a collision.

▶ **Lemma 30.** *Let $m = p^s q^t$ where $q > p$ and $\mathcal{U}, \mathcal{V}$ be a $\{0, \alpha, \beta\}$-restricted matching vector family of size K such that $\alpha = 0 \pmod{p^s q^{t-1}}$, $\alpha \neq 0 \pmod{q^t}$ and $\beta = 0 \pmod{p^{s-1} q^t}$, $\beta \neq 0 \pmod{p^s}$. Let $A, B \in \mathcal{S}_{q,K}, A \neq B$ be such that $\sum_{i \in A} \boldsymbol{u}_i = \sum_{i \in B} \boldsymbol{u}_i$ where each $\boldsymbol{u}_i \in \mathcal{U}$. Then:*

- **(i)** *For each $i \in A, j \in B$, $\boldsymbol{u}_i \neq \boldsymbol{u}_j$ $(A \cap B = \emptyset)$.*
- **(ii)** *For each $i \in A, j \in B$, $\langle \boldsymbol{u}_j, \boldsymbol{v}_i \rangle = \alpha \pmod{q^t}$.*

Proof.

Proof of Part (i). For any $i \in A$, we can write $\sum_{j\in B}\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle - \sum_{j\in A}\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle$ as a linear combination of α's and β's such that

$$a_i\alpha + b_i\beta = \sum_{j\in B}\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle - \sum_{j\in A}\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle = \langle \sum_{j\in B}\boldsymbol{u}_j - \sum_{j\in A}\boldsymbol{u}_j, \boldsymbol{v}_i\rangle = 0 \pmod m \tag{1}$$

for some integers a_i, b_i.

As $\langle \boldsymbol{u}_i, \boldsymbol{v}_i\rangle = 0 \pmod m$, there are q terms in the first sum and $q-1$ terms in the second sum; this is where we use the fact that $\boldsymbol{u}_i$ were picked without replacement. Therefore, we have the obvious inequalities: $-(q-1) \le a_i, b_i \le q$. Since, $\beta = 0 \pmod{q^t}$, and $a_i\alpha + b_i\beta = 0 \pmod m$, it follows that $a_i\alpha + b_i\beta = 0 \pmod{q^t} \implies a_i\alpha = 0 \pmod{q^t}$. Since α is divisible by q^{t-1}, and not q^t, and a_i is between $-(q-1)$ and q, it must happen that either $a_i = 0$ or $a_i = q$.

Suppose for a contradiction that $i \in A \cap B$. Let $k \in A\backslash B$ (non-empty since $A \neq B$). Then,

$$a_k\alpha + b_k\beta = \sum_{j\in B}\langle \boldsymbol{u}_j, \boldsymbol{v}_k\rangle - \sum_{j\in A}\langle \boldsymbol{u}_j, \boldsymbol{v}_k\rangle = \sum_{j\in B\backslash A}\langle \boldsymbol{u}_j, \boldsymbol{v}_k\rangle - \sum_{j\in A\backslash(B\cup\{k\})}\langle \boldsymbol{u}_j, \boldsymbol{v}_k\rangle .$$

By our choice of $\boldsymbol{u}_k$, fact that all inner products on the right-hand side above are non-zero, and since $|A| = |B| = q$, we know that:

1. $|B\backslash A| = |A\backslash(B\cup\{k\})| + 1$, and therefore $a_k + b_k = |B\backslash A| - |A\backslash(B\cup\{k\})| = 1$.
2. $-(q-1) \le -|A\backslash(B\cup\{k\})| \le b_k \le |B\backslash A| \le q-1$

If $a_k = 0$, then $b_k = 1$ implies that $a_k\alpha + b_k\beta = \beta \neq 0 \pmod m$, a contradiction to Equation (1). Also, notice that $a_k \neq q$ since for the same reason as above $a_k \le |B\backslash A| \le q-1$. This completes the proof of Part (i).

Proof of Part (ii). Now, consider any $i \in A$, clearly $i \notin B$ from our proof above. From a similar argument as above, we know $a_i + b_i = 1$. And further $a_i = q$ and $b_i = 1 - a_i = -(q-1)$. However the only way we can have $a_i = q$ is if each term in the sum $\sum_{j\in B}\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle$ is α which completes the proof. Note that we can trivially reduce from mod m to mod q^t, since $\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle = \alpha \neq 0 \pmod{q^t}$. ◀

▶ **Theorem 31.** *Let $m = p^s q^t$ where $q > p$ and let $\boldsymbol{U}^\star$ be defined as in the beginning of this section. Then $\mathbf{H}_\infty(\boldsymbol{U}^\star) \ge q\log\left(\frac{K}{q}\right) - \log(nt+1)$.*

Proof. We will upper bound the probability $\Pr_{\boldsymbol{U}^\star}[\boldsymbol{U}^\star = \boldsymbol{u}]$, where $\boldsymbol{u} \in \mathbb{Z}_m^n$ is an arbitrary vector. Let

$$C_{\boldsymbol{u}} := \left\{ A \in \mathcal{S}_{q,K} \mid \sum_{i\in A}\boldsymbol{u}_i = \boldsymbol{u} \right\},$$

be the set of sums of length q from $\mathcal{S}_{q,K}$ such that its sum is equal to $\boldsymbol{u}$. Note that each term in the sum is unique by how we sample $\boldsymbol{U}^\star$.

Now, consider any pair of collisions $A, B \in C_{\boldsymbol{u}}$. From Lemma 30, we know that for each $i \in A, j \in B$, $i \neq j$ and $\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle = \alpha$, and all the sets in $C_{\boldsymbol{u}}$ are disjoint. In particular, if we pick exactly one vector from each sum in $C_{\boldsymbol{u}}$ (and their corresponding matching vectors in $\mathcal{V}$), the set of vectors form a $\{\alpha\}$-matching vector family in $\mathbb{Z}_{q^t}^n$. Formally, $\mathcal{U}' := \{\boldsymbol{u}_i \mid i = \min(A), A \in C_{\boldsymbol{u}}\} \subseteq \mathcal{U}$, and $\mathcal{V}' \subseteq \mathcal{V}$ with the corresponding matching vectors forms a $\{\alpha\}$-matching vector family in $\mathbb{Z}_{q^t}^n$ of size $|C_{\boldsymbol{u}}|$.

By Lemma 18, we have $|C_{\boldsymbol{u}}| \leq nt + 1$. Therefore, we have

$$\mathbf{H}_\infty(\boldsymbol{U}^\star) \;\geq\; \log\left(\frac{\binom{K}{q}}{nt+1}\right) \;\geq\; q\log\left(\frac{K}{q}\right) - \log(nt+1)\;. \qquad \blacktriangleleft$$

▶ Remark 32. As pointed out by a helpful anonymous reviewer, we can extend Lemma 30 to work for $A, B \in \mathcal{S}_{q',K}$ where $q' > q$ in certain cases. Suppose we again write $\sum_{j\in B}\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle - \sum_{j\in A}\langle \boldsymbol{u}_j, \boldsymbol{v}_i\rangle$ as a linear combination of $a_{i,q'}\alpha + b_{i,q'}\beta = 0 \pmod m$. The proof only requires two properties from q':

1. For the first part, we require that for every $q'' < q'$ the corresponding equation $a_{i,q''}\alpha + b_{i,q''}\beta = 0 \pmod m$ has only trivial solutions ($a_{i,q''} = b_{i,q''} = 0$).
2. For the second part, we require that $a_{i,q'} = q'$.

For $m = 6$, $q' = 3$ but by a calculation it can be shown that for $m = 15$, we can have $q' = 6 > 5 = q$. This implies that we can improve the conclusion of Theorem 31 to $\mathbf{H}_\infty(\boldsymbol{U}^\star) \geq q'\log\left(\frac{K}{q'}\right) - \log(nt+1)$ which eventually gives us a better bound for Theorem 33. However, we omit this for clarity.

3.3 Main Theorem

We are now ready to prove our main theorem.

▶ **Theorem 33.** *Let $n, m \geq 1$ be positive integers with $n > 10m^3$. Suppose $\mathcal{U}, \mathcal{V}$ is a 3-restricted* **MV** *family of size K over $\mathbb{Z}_m^n$. Then $K \leq (2emn)^{m-1}$ if m is a prime power, and otherwise*

$$K \;\leq\; m^{\frac{n+2\log(n+1)}{2q}+2m^2}\;,$$

where q is the second-smallest prime dividing m.

Proof. Let m' be the smallest factor of m such that $\mathcal{U}, \mathcal{V}$ is a 3-restricted **MV** family of size K over $\mathbb{Z}_{m'}^n$. If m' is a prime power, then by Theorem 21,

$$K \;\leq\; (2em'n)^{m'-1} \;\leq\; (2emn)^{m-1}\;.$$

Suppose m is not a prime power, then $K \leq (2emn)^{m-1} \leq m^{\frac{n+2\log(n+1)}{2q}+2m^2}$; the second inequality follows, since $n > 10m^3$.

Now we consider the case when m' is not a prime power. Then, by Lemma 24, we have that $m' = p_1^s \cdot p_2^t$ for primes p_1 and p_2 and integers $s, t \geq 1$ with $p_1 < p_2$. Further, using Lemma 25, we have that $\alpha = 0 \pmod{p_1^s p_2^{t-1}}$, $\alpha \neq 0 \pmod{p_2^t}$, $\beta = 0 \pmod{p_1^{s-1}p_2^t}$, $\beta \neq 0 \pmod{p_1^s}$.

Let q be the *second-smallest* prime dividing m, and we assume that $K > m^{\frac{n+2\log(n+1)}{2q}+2m^2}$, since otherwise we are already done. Also, note that by assumption, $p_2 \geq q$. Since $n \geq 10m^3$, and $2 \leq p_1p_2 \leq m$, this implies that

$$K \;\geq\; m^{7m^2} \;\geq\; m^2\cdot(2m)^{4m^2} \;\geq\; 4p_2^2\cdot(2p_1p_2)^{16p_2^2}\;.$$

By Lemma 29, we have without loss of generality (between $\boldsymbol{U}^\star$ and $\boldsymbol{V}^\star$) that

$$\begin{aligned}
\mathbf{H}_\infty(\boldsymbol{U}^\star) &\leq \frac{n\log m'}{2} - \log\left(\left(\frac{1}{2p_1p_2}\right)^{16p_2^2} - \frac{2p_2^2}{K}\right)\\
&\leq \frac{n\log m}{2} - \log\left(\frac{1}{2}\cdot\left(\frac{1}{2p_1p_2}\right)^{16p_2^2}\right)\\
&\leq \frac{n\log m}{2} + 16p_2^2\cdot\log(2p_1p_2) + 1\\
&\leq \frac{n\log m}{2} + 4m^2\log m + 4m^2 + 1\,.
\end{aligned}$$

Here we used that $2p_2 \leq p_1p_2 \leq m$. On the other hand, by Theorem 31, we know that

$$\mathbf{H}_\infty(\boldsymbol{U}^\star) \geq p_2\log\left(\frac{K}{p_2}\right) - \log(nt+1)\,.$$

Putting them together we have:

$$p_2\log\left(\frac{K}{p_2}\right) - \log(nt+1) \leq \frac{n\log m}{2} + 4m^2\log m + 4m^2 + 1\,.$$

This gives us that

$$\begin{aligned}
K &\leq p_2\cdot m^{\frac{n}{2p_2}}\cdot m^{\frac{4m^2}{p_2}}\cdot 2^{\frac{4m^2+1}{p_2}}\cdot 2^{\frac{\log(nt+1)}{p_2}}\\
&\leq m^{\frac{n}{2p_2}}\cdot m^{\frac{4m^2}{p_2}+1}\cdot m^{\frac{1.9m^2}{p_2}}\cdot 2^{\frac{\log(nt+1)}{p_2}}\\
&\leq m^{\frac{n}{2p_2}}\cdot m^{\frac{6m^2}{p_2}}\cdot 2^{\frac{\log(nt+1)}{p_2}}\\
&\leq m^{\frac{n}{2p_2}}\cdot m^{2m^2}\cdot 2^{\frac{\log(nt+1)}{p_2}}\\
&\leq m^{\frac{n}{2q}}\cdot m^{2m^2}\cdot 2^{\frac{\log(nt+1)}{p_2}}\\
&= m^{\frac{n}{2q}}\cdot m^{2m^2}\cdot m^{\frac{\log(nt+1)}{p_2\cdot\log m}};\\
&\leq m^{\frac{n}{2q}}\cdot m^{2m^2}\cdot m^{\frac{\log(nt+1)}{p_2\cdot t\cdot\log p_2}};\\
&\leq m^{\frac{n}{2q}}\cdot m^{2m^2}\cdot m^{\frac{\log(nt+1)}{p_2\cdot t}}\\
&\leq m^{\frac{n}{2q}}\cdot m^{2m^2}\cdot m^{\frac{\log(nt+1)^{1/t}}{p_2}}\\
&\leq m^{\frac{n}{2q}}\cdot m^{2m^2}\cdot m^{\frac{\log(n+1)}{p_2}}\\
&\leq m^{\frac{n+2\log(n+1)}{2q}}\cdot m^{2m^2}\,.
\end{aligned}$$

In the second inequality, we used $p_2 \leq m$, and also, $2^{4m^2+1} < m^{1.9m^2}$, which is true since $m \geq 6$. In the third inequality, we used the fact that $\frac{6m^2}{p_2} \geq \frac{5.9m^2}{p_2} + 1$, which is equivalent to showing $\frac{m^2}{10p_2} \geq 1$, which is true since $\frac{m^2}{10p_2} = \left(\frac{m}{2p_2}\right)\cdot\left(\frac{m}{5}\right) > 1$, because $m \geq 2p_2 \geq 2q \geq 6$. In the seventh inequality, we used that $m \geq p_2^t$. Finally, the second to last inequality follows from Bernoulli's inequality: $(nt+1) \leq (n+1)^t$.

This is a contradiction to our assumption that $K > m^{\frac{n+2\log(n+1)}{2q}+2m^2}$. This finishes the proof. ◀

▶ **Corollary 34.** *For an arbitrary positive integer m, consider a 3-query matching vector codes $C : \Sigma^K \to \Sigma^N$ constructed from 3-restricted matching vector families using the construction in Theorem 15, then $N \geq \Omega(K^{6-o_K(1)})$.*

The proof follows straightforwardly from the Theorem 15 combined with Theorem 33.

A Proof of Lemma 11

We include the proof of completeness.

Proof.

$$|\mathbb{E}[\omega^{\langle X,Y\rangle}]| = \left|\sum_{y\in\mathbb{Z}_m^n} Y(y) \sum_{x\in\mathbb{Z}_m^n} X(x)\omega^{\langle x,y\rangle}\right|$$
$$\leq \sum_{y\in\mathbb{Z}_m^n} Y(y)\left|\sum_{x\in\mathbb{Z}_m^n} X(x)\omega^{\langle x,y\rangle}\right| .$$

On the other hand, since the square function is convex, by Jensen's inequality, one have

$$|\mathbb{E}[\omega^{\langle X,Y\rangle}]|^2 \leq \sum_{y\in\mathbb{Z}_m^n} Y(y)\left|\sum_{x\in\mathbb{Z}_m^n} X(x)\omega^{\langle x,y\rangle}\right|^2$$
$$= \left|\sum_{y\in\mathbb{Z}_m^n} Y(y) \sum_{x_1,x_2\in\mathbb{Z}_m^n} X(x_1)X(x_2)\omega^{\langle x_1,y\rangle}\omega^{-\langle x_2,y\rangle}\right|$$
$$= \left|\sum_{y\in\mathbb{Z}_m^n} Y(y) \sum_{x_1,x_2\in\mathbb{Z}_m^n} X(x_1)X(x_2)\omega^{\langle x_1-x_2,y\rangle}\right|$$
$$= \left|\mathbb{E}[\omega^{\langle X_1-X_2,Y\rangle}]\right| .$$

Sparsity Lower Bounds for Probabilistic Polynomials

Abstract

Probabilistic polynomials over commutative rings offer a powerful way of representing Boolean functions. Although many degree lower bounds for such representations have been proved, sparsity lower bounds (counting the number of monomials in the polynomials) have not been so common. Sparsity upper bounds are of great interest for potential algorithmic applications, since sparse probabilistic polynomials are the key technical tool behind the best known algorithms for many core problems, including dense All-Pairs Shortest Paths, and the existence of sparser polynomials would lead to breakthrough algorithms for these problems.

In this paper, we prove several strong lower bounds on the sparsity of probabilistic and approximate polynomials computing Boolean functions when 0 means "false". Our main result is that the AND of n ORs of $c \log n$ variables requires probabilistic polynomials (over any commutative ring which isn't too large) of sparsity $n^{\Omega(\log c)}$ to achieve even $1/4$ error. The lower bound is tight, and it rules out a large class of polynomial-method approaches for refuting the APSP and SETH conjectures via matrix multiplication. Our other results include:

- Every probabilistic polynomial (over a commutative ring) for the disjointness function on two n-bit vectors requires exponential sparsity in order to achieve exponentially low error.
- A generic lower bound that any function requiring probabilistic polynomials of degree d must require probabilistic polynomials of sparsity $\Omega(2^d)$.
- Building on earlier work, we consider the probabilistic rank of Boolean functions which generalizes the notion of sparsity for probabilistic polynomials, and prove separations of probabilistic rank and probabilistic sparsity.

Some of our results and lemmas are basis independent. For example, over any basis $\{a, b\}$ for true and false where $a \neq b$, and any commutative ring R, the AND function on n variables has no probabilistic R-polynomial with $2^{o(n)}$ sparsity, $o(n)$ degree, and $1/2^{o(n)}$ error simultaneously. This AND lower bound is our main technical lemma used in the above lower bounds.

1 Introduction

Let R be a ring. The sparsity of a polynomial $p \in R[x_1, \ldots, x_n]$, denoted by $\text{sparsity}(p)$, is the number of monomials of p. A *probabilistic polynomial in n variables* is a distribution $\mathcal{P}$ on n-variate polynomials. Its *degree* and *sparsity* are the maximum degree and sparsity, respectively, of any polynomial in its support. The error of $\mathcal{P}$ on a function $f : \{0,1\}^n \to \{0,1\}$ is the function from $\mathbb{N}$ to $[0,1]$ defined as

$$\text{error}(\mathcal{P}, f)(n) = \max_{x \in \{0,1\}^n} \Pr_{p \sim \mathcal{P}} [p(x) \neq f(x)] .$$

Probabilistic polynomials with low sparsity are the main technical component in a number of recent randomized algorithms for core problems. This includes the best known randomized algorithm for the dense case of All-Pairs Shortest Paths (APSP) [36], the best known randomized algorithm for Orthogonal Vectors (OV) [1], the best known deterministic algorithms for these problems (which *derandomizes* the aforementioned probabilistic polynomials) [11], as well as Constraint Satisfaction problems [37, 15], All-Pairs Nearest Neighbor problems [3, 2], systems of polynomial equations over finite fields [23], online matrix-vector multiplication [22], and Stable Matching [26]. APSP and OV are especially of interest, as substantially faster algorithms for them would have many applications (see the survey of Vassilevska-Williams [38]). Moreover, it has become popular to conjecture that it is impossible to improve the best-known runtimes of these problems by polynomial factors.

For all of these algorithms, the running time improvement is completely determined by the sparsity of a certain probabilistic polynomial: if we can find a sparser polynomial, we would directly improve the runtime. This leads to the main motivating question of this paper:

Is it possible to design sparser probabilistic polynomials to speed up these algorithms further, and in particular, can we design polynomials sparse enough to refute some of the popular conjectures?

In this paper, we prove unconditionally that several known probabilistic polynomial constructions are already optimal, in a broad sense. The particular Boolean functions of interest for APSP and OV are as follows.

For a function $c : \mathbb{N} \to \mathbb{N}$, the Boolean function $OV_c : \{0,1\}^{2 \cdot n \cdot c(n) \log n} \to \{0,1\}$, is defined by:

$$OV_c(x, y) = \bigvee_{i_1, i_2 \in [n]^2} \bigwedge_{j=1}^{c(n) \log n} (\overline{x_{i_1,j}} \vee \overline{y_{i_2,j}}).$$

The best known algorithm for OV [1] uses a probabilistic $\mathbb{F}_2$-polynomial representation of the OV_c function with $n^{O(\log c)}$ sparsity to quickly check the orthogonality of many pairs of vectors. The OV problem for n input vectors of dimension $c \log n$ could be solved in truly sub-quadratic time, if a probabilistic polynomial with sparsity $n^{O(1)}$ could be designed for OV_c. In particular, if there were a polynomial for OV_c with sparsity n^k (for some universal k) that worked for every $c \geq 1$, that would yield a fast enough algorithm for OV to refute the *Strong Exponential Time Hypothesis* (SETH) [18, 10]. For completeness, we prove this in Theorem 27 in Appendix B.

Chan and Williams [36, 11] showed that $OV_{n/\log n}$ can be used to solve APSP as well. Their algorithm, the best known randomized algorithm for APSP in dense graphs, crucially uses a probabilistic $\mathbb{F}_2$-polynomial representation of the $OV_{n/\log n}$ function with $n^{O(\log n)}$ sparsity, in order to get a $n^3/2^{\Omega(\sqrt{\log n})}$ time algorithm. If the sparsity could be improved to $n^{O(1)}$, then APSP would be solvable in truly subcubic time – an algorithmic breakthrough.

Our main result shows that in a broad sense, the sparsities of the known probabilistic polynomials for OV_c are already **optimal**, up to a constant factor in the exponent:

▶ **Theorem 1.** *For every $c : \mathbb{N} \to \mathbb{N}$, every $\varepsilon > 0$ and every finite commutative ring R such that $|R| \leq 2^{O(n^{1/2-\varepsilon})}$, R-probabilistic polynomials with error $1/4$ for OV_c which use the 0 of R to represent "false" require sparsity $n^{\Omega(\log c(n))}$.*

Theorem 1 is quite powerful, as it holds for all *finite commutative rings* rather than just finite fields. For instance, many simple functions like OR are known to have smaller polynomial representations when working modulo a composite number m rather than over a finite field [6], but we rule out a sparsity improvement over such rings as well.

Theorem 1 also rules out sparser representations over larger rings (even infinite rings like $\mathbb{R}$) without very large coefficients. For instance, given a sparse probabilistic polynomial for OV_c over the integers, we could compute all of its coefficients modulo 2 to get a probabilistic polynomial over $\mathbb{F}_2$ with at most the same degree, sparsity, and error. Even if we are working over a commutative ring R where such a trick doesn't work, it takes $n^{1/2-o(1)}$ bits to describe elements of R when $|R| \geq 2^{O(n^{1/2-\varepsilon})}$. Working with such large coefficients is prohibitive when trying to solve OV or APSP, since it would presumably multiply the runtime by such a large polynomial factor, unless polynomial evaluation techniques substantially different from the current known techniques (FFT and fast matrix multiplication) are used.

The (only) caveat of our lower bound in Theorem 1 is that it relies on using the 0 of R for false (which is very natural when working with $\wedge$ and $\vee$). We leave open the problem of proving a "basis independent" lower bound (where false can correspond to any value in R).

A General Lower Bound for AND and OR

Our main technical tool is a general (basis independent) lower bound for probabilistic polynomials representing the AND and OR functions, which is also of independent interest. The celebrated probabilistic polynomial constructions of Razborov and Smolensky, which are the key component behind the aforementioned probabilistic polynomials in many recent algorithms (including APSP and OV) yield:

▶ **Theorem 2** ([29, 32])**.** *For all primes p and integers $t \geq 1$, OR and AND on n variables have $\mathbb{F}_p$-probabilistic polynomials of degree $(p-1)t$, sparsity $O(n^{(p-1)t})$, and error $1/p^t$.*

Using this construction, there are $\mathbb{F}_p$-probabilistic polynomials for AND on n variables with low values for any *two choices* of the sparsity, degree, and error measures:

- Sparsity $(p-1)n$ and degree $p-1$ (but error $\Omega(1/p)$) follows from Theorem 2 with $t = 1$.
- Degree $\log n$ and error $1/p^{(\log n)/(p-1)}$ (but sparsity $n^{\Omega(\log n)}$) follows from Theorem 2 with $t = (\log n)/(p-1)$.
- Sparsity 1 and error 0 (but degree $\Omega(n)$) is achieved by the exact polynomial $x_1 x_2 \cdots x_n$.

A natural question arises: is there a probabilistic polynomial for AND with low degree, low sparsity, and low error *simultaneously*?

▶ **Question 1.** *Is there a probabilistic polynomial for AND on n variables over any commutative ring which has $O(\log n)$ degree, $1/poly(n)$ error, and $poly(n)$ sparsity?*

While Question 1 is fundamental in its own right, a positive answer would also contradict a non-uniform version of SETH, by using it to construct sparse probabilistic polynomials for OV_c; see the discussion in Appendix B for more details. In constructing these polynomials, there is a choice of which values in our ring R map to true and false. We could use $\{0, 1\}$,

or $\{1, -1\}$, or even a basis like $\{1, 2\}$ [16]. While the degrees of polynomials do not change under such transformations, it is known that in general, the sparsity of polynomials can be very sensitive to this map [21]. Could this be exploited to refute SETH?

We unconditionally prove a strong **no** answer to Question 1:

▶ **Theorem 3.** *For every commutative ring R, every distinct $a, b \in R$, and all $d \geq 1$ and $e > 0$, there is a $c \geq 1$ such that for all sufficiently large m, the AND function on m variables does not have a R-probabilistic polynomial, where a represents false and b represents true, of sparsity $2^{dm/c}$, degree m/c, and error $2^{-em/c}$.*

Indeed, a polynomial giving a yes answer to Question 1, upon setting all but $m = \omega(\log n)$ variables to 1 (or whichever element of the ring R corresponds to true), would contradict Theorem 3, since sparsity, degree, and error cannot increase upon setting variables. We emphasize that Theorem 3 holds over *any* commutative ring R and *any* choice of basis $\{a, b\}$.

Further Results

Our technical lemmas can be applied to yield several sparsity lower bounds for various algebraic representations of natural and well-studied Boolean functions. First, we give an exponential sparsity-error tradeoff lower bound for probabilistic polynomials for the disjointness function $DISJ$ and the "complements" function $COMP$. Informally, $DISJ$ determines whether two given bit-vectors have zero inner product, and $COMP$ determines whether two given bit-vectors are binary complements of each other; it is very closely related to the equality function (see Section 2 for formal definitions).

▶ **Theorem 4.** *For every commutative ring R, function $f : \mathbb{N} \to \mathbb{N}$, constants $e > 0$ and $d \geq 1$, there is a $c \geq 1$ such that the disjointness of two n bit vectors does not have a R-probabilistic polynomial of sparsity $f(c)2^{dn/c}$ and error $f(c)/2^{en/c}$ which uses the 0 of R to represent "false".*

▶ **Theorem 5.** *Theorem 4 also holds with disjointness replaced by $COMP$.*

That is, we cannot obtain a probabilistic polynomial for disjointness with subexponential sparsity and subexponential error simultaneously, *regardless* of the degree. (Observe that the exact representation of disjointness of two n-bit vectors has 2^n sparsity and 0 error.)

In the appendices, we also apply the above results in a number of other ways.

In Appendix A, we give a simple equivalence between probabilistic polynomials and certain depth-3 circuits, which makes some prior work relevant. In Appendix B, we discuss how sparse probabilistic polynomials for simple AC^0 functions would refute SETH:

▶ **Theorem 6** (Informal; see Theorems 24 and 27)**.** *For any commutative ring R, either of the following would refute SETH:*

- *A low-degree, low-sparsity, and low-error R-probabilistic polynomial for AND (over 0/1), or*
- *An R-probabilistic polynomial for $OR_n \circ AND_{c \log n} \circ OR_2$ with sparsity n^k and constant error for any fixed integer k.*

In Appendix C, we investigate probabilistic polynomials over the $\{-1, 1\}$ basis instead of $\{0, 1\}$. While the degree of a polynomial does not depend on the basis, the sparsity can be very sensitive to such a change, and we give examples where probabilistic polynomial sparsity lower bounds in the $\{0, 1\}$ setting do not hold in the $\{-1, 1\}$ setting. Building on our lower bound Theorem 5 over the $\{0, 1\}$ basis, we prove:

▶ **Theorem 7.** *Over any commutative ring R which doesn't have characteristic 2, the complements function $COMP$ has a probabilistic polynomial with sparsity poly(n) and error $1/$poly(n) over the basis $\{-1, 1\}$, and does not over the basis $\{0, 1\}$.*

In Appendix D, we consider a notion related to the probabilistic sparsity of a function, introduced by [4], called the *probabilistic rank*. The probabilistic rank of a function f measures the extent to which the truth table matrix, or communication matrix, of f can be probabilistically represented by low rank matrices. Probabilistic sparsity upper bounds give corresponding probabilistic rank upper bounds, a fact which is used by the aforementioned "polynomial method" algorithms to reduce polynomial evaluation to fast matrix multiplication. For some functions, the probabilistic rank could potentially be much smaller than the probabilistic sparsity. This is interesting, both for the prospect of being able to design faster algorithms using rank instead of sparsity, and given the connection between probabilistic rank and the matrix rigidity problem [4]. In Appendix D, we prove a separation between the two notions in a number of settings over $\mathbb{F}_2$, including showing that the two notions can be arbitrarily far apart for a natural function:

▶ **Theorem 8.** *For any $k > \Omega(n/\log(1/\varepsilon))$, the ε-probabilistic sparsity of $MAJ \circ XOR$ over $\mathbb{F}_2$, where MAJ has fan-in n and each XOR has fan-in k, is strictly greater than its ε-probabilistic rank. In particular, as k increases, the ε-probabilistic sparsity grows unboundedly while ε-probabilistic rank remains fixed.*

We note that there are more straightforward constructions of functions f which separate probabilistic sparsity and probabilistic rank, such as any function of large probabilistic sparsity which depends only on the first half of its input bits and thus has rank 1. However, the functions which are most interesting in algorithmic applications typically depend on both the first and second halves of the input variables similarly.

In Appendix E, we observe how bounds on one of the sparsity or degree of probabilistic polynomials for a function can give bounds on the other as well. We notably show that, if a function requires probabilistic degree d, then it must require probabilistic sparsity $\Omega(2^d)$. Hence, probabilistic degree lower bounds, which are more common in the literature, imply probabilistic sparsity lower bounds as well. We also relate probabilistic degree to probabilistic rank in a better-than-trivial way: Any n-variate Boolean function with a probabilistic polynomial of degree d and error ε has ε-probabilistic rank most $O\left(\binom{n/2}{d/2}\right)$, compared to the trivial $O\left(\binom{n/2}{d}\right)$.

Intuition for our Results

Our main proof technique, which we use to prove Theorem 3, and then again in some of our additional results, is a novel combination of two well-known ideas from the literature on lower bounds for Boolean functions and their polynomial representations.

The first idea is *carefully chosen random restrictions*. Random restrictions are convenient for studying probabilistic polynomial sparsity, since we can study each monomial of a probabilistic polynomial separately, and analyze the distribution of its resulting degree after applying a restriction. We give random restrictions that do not restrict too many variables, but that substantially lower the degree of any sparse polynomial.

The second idea is a variant of the *Schwartz-Zippel Lemma* (Lemma 13 below), which roughly says that low degree multivariate polynomials must have many roots on the Boolean hypercube. This is especially interesting, for instance, when applied to the OR function, which has only one Boolean root; it says that low degree probabilistic polynomials for OR must have high error.

Our proof strategy combines these two ideas in a new way. Given a sparse probabilistic polynomial for AND with low degree and error, we design a random restriction so that the restriction of at least one polynomial in the support of the probabilistic polynomial violates the Schwartz-Zippel Lemma, giving a contradiction. Previous work using random restrictions to get sparsity lower bounds for other types of polynomials has typically combined the random restrictions with simple degree lower bounds. Here, we need some novel technical arguments in order to apply the Schwartz-Zippel Lemma with the trade-off between the error and degree of the resulting restriction.

Of course, our description here (necessarily) glosses over many important details. In addition to random restrictions and the Schwartz-Zippel Lemma, our techniques use multi-party communication complexity, algebraic results about commutative rings (especially in our proof that Theorem 3 holds over any basis), and prior work in the area of polynomial representations of Boolean functions. Our proof extending Theorem 3 to any basis, which we give in Section G, is very general, and could be of independent interest for proving basis-independent versions of other results. It shows that for any function f, a simultaneous lower bound on the degree and sparsity of a probabilistic polynomial for f over any one basis implies a sparsity lower bound over any other basis as well.

Prior Work

Work on particular depth-three circuit size lower bounds (namely, $\mathsf{MAJ} \circ \mathsf{SYM} \circ \mathsf{AND}$ circuits) can be seen as lower bounds on the sparsity of probabilistic polynomials (see Appendix A for an overview of the simple connection). For example:

- Razborov and Wigderson [30] showed that a simple depth-three $\mathsf{AC}^0[2]$ function f requires $\mathsf{MAJ} \circ \mathsf{SYM} \circ \mathsf{AND}$ circuits of size $n^{\Omega(\log n)}$. This implies $f \notin \mathbb{F}_p\text{-SDE}_{0,1}[n^{o(\log n)}, n, 1/2 - \varepsilon]$ for any fixed prime p, a sparsity/degree/error lower bound for probabilistic polynomials computing f.
- Chattopadhyay [12] gave an AC^0 function requiring exponential $\mathsf{MAJ} \circ \mathsf{SYM} \circ \mathsf{ANY}$ circuits when the bottom fan-in is $o(\log \log n)$; this corresponds to an $\Omega(\log \log n)$ degree lower bound for probabilistic polynomials computing an AC^0 function.
- Beame and Huynh [8] give a depth-9 AC^0 circuit that needs $\mathsf{MAJ} \circ \mathsf{SYM} \circ \mathsf{AND}$ circuits of size $n^{\Omega(\log n)}$, corresponding to a probabilistic $n^{\Omega(\log n)}$-sparsity lower bound for this AC^0 function.
- Sherstov [31] gives a depth-3 AC^0 circuit with tighter $\mathsf{MAJ} \circ \mathsf{SYM} \circ \mathsf{AND}$ circuit size lower bound. Essentially, if the bottom fan-in is $(1/2 - \varepsilon) \log n$ for some $\varepsilon > 0$, then the circuit size must be exponential.

Our Lemma 20, which we prove on the way to proving Theorem 1, can be viewed as extending this line of work by showing a probabilistic $n^{\Omega(\log n)}$-sparsity lower bound for a depth-2 AC^0 circuit.

Polynomial sparsity has been studied in a stronger setting, where the polynomials in question only need to correlate with a target function f rather than probabilistically represent f, by Lovett and Srinivasan [24]. Their main result is that polynomials over $\mathbb{F}_2$ with $n^{o(\log n)}$ monomials have exponentially low correlation with the $\mathsf{MOD3}$ function. Note that a sparse probabilistic polynomial for a Boolean function f implies the existence of a sparse polynomial with high correlation with f, but not vice versa. Hence, Lovett and Srinivasan's lower bound applies to probabilistic polynomials as well. Their technique has similarities to some of ours – they also use a type of variable restriction to reduce low sparsity polynomials to low degree

polynomials – but their "tree restriction" technique and analysis isn't powerful enough to apply in our setting where, as we will see, we are constrained in how we are allowed to restrict our variables based on the function we are computing.

Sparsity has also been studied in the setting of polynomial threshold functions, where the sign of a polynomial dictates its output (as a Boolean function). Krause and Pudlak [21, 20] give a function f that has exponentially-high sparsity as a polynomial threshold function in the $\{-1, 1\}$ basis, but polynomially-low sparsity over $\{0, 1\}$. Other references on sparsity in the polynomial threshold function setting include Basu *et al.* [7], O'Donnell and Servedio [28], and Hansen and Poldoskii [16]. It should be noted that these polynomial threshold function sparsity lower bounds *do not suffice* to prove probabilistic polynomial sparsity lower bounds: they correspond to lower bounds against depth-2, $\mathsf{MAJ} \circ \mathsf{AND}$ circuits, compared to our lower bounds against probabilistic polynomials which correspond to depth-3, $\mathsf{MAJ} \circ \mathsf{SYM} \circ \mathsf{AND}$ circuits.

The degrees of probabilistic polynomials are more well-studied, starting with the work of Razborov and Smolensky [29, 32], although even some basic questions remain open. For instance, while AND is known to have constant-degree probabilistic polynomials for constant error over any fixed finite field, it is unknown what degree is needed over $\mathbb{R}$: there is a gap between the best upper bound of $O(\log n)$ [9, 34, 5] and the best lower bound of $\tilde{\Omega}(\sqrt{\log n})$ [25, 17]. Our connection between sparsity and degree which we prove in Appendix E makes use of the probabilistic degree of AND, and is thus only (close to) tight over a finite field.

2 Preliminaries

Definitions and Notation

As usual, all logarithms are assumed to be base-two. For gates $\mathcal{G}_1$ and $\mathcal{G}_2$, we write $\mathcal{G}_1 \circ \mathcal{G}_2$ to denote the circuit whose output gate is a $\mathcal{G}_1$ whose inputs are all copies of $\mathcal{G}_2$ on disjoint variables. We write AND_k, OR_k, and XOR_k to denote the AND, OR, and XOR functions on k inputs, respectively, and MAJ is the majority function which computes whether at least half of its inputs are 1.

Let $\mathcal{F} = \{f_n : \{0,1\}^n \to \{0,1\}\}$ be a decision problem, construed as an infinite family of Boolean functions (one for each $n \in \mathbb{N}$). To facilitate the presentation, we define a (non-uniform) complexity class for problems which are computable by sparse, low-degree, and low-error probabilistic polynomials over R:

▶ **Definition 9.** *A decision problem $\mathcal{F}$ is in the class R-**SDE**$[s(n), d(n), e(n)]$ if for all but finitely many n, there is a probabilistic R-polynomial $\mathcal{P}_n$ for $f_n \in \mathcal{F}$ with* **sparsity** *at most $s(n)$,* **degree** *at most $d(n)$, and* **error** *at most $e(n)$. We analogously define R-**SE**$[s(n), e(n)]$ and R-**DE**$[d(n), e(n)]$ when there is no bound on the third parameter, and R-**SDE**$_{a,b}[s(n), d(n), e(n)]$ for probabilistic polynomials over the basis where "false" means $a \in R$ and "true" means $b \in R$ (when omitted, the default is that $a = 0$ and $b = 1$).*

With this notation, we can succinctly state results about probabilistic polynomials for Boolean functions.

Many of our lower bounds concern two different Boolean functions, the *disjointness function*, and the *complements function*.

▶ **Definition 10.** *For vectors $x, y \in \{0,1\}^n$, the* disjointness function*, $DISJ : \{0,1\}^{2n} \to \{0,1\}$, is given by $DISJ(x_1, \ldots, x_n, y_1, \ldots, y_n) = \bigwedge_{i=1}^{n}(x_i \vee y_i)$. (Note that this definition negates the variables compared to how the disjointness function often appears in the literature.)*

▶ **Definition 11.** *For vectors $y \in \{0,1\}^n$, we write $\bar{y}$ to denote the* complement *of y, given by $\bar{y}_i = 1 - y_i$ for each $1 \leq i \leq n$. The* equality function*, $EQ : \{0,1\}^{2n} \to \{0,1\}$, is given by, for $x, y \in \{0,1\}^n$, $EQ(x,y) = 1$ if $x = y$ and $EQ(x,y) = 0$ otherwise. In other words, $EQ(x_1, \ldots, x_n, y_1, \ldots, y_n) := \bigwedge_{i=1}^n (x_i \oplus y_i \oplus 1)$.*

The complements function*, $COMP : \{0,1\}^{2n} \to \{0,1\}$, is given by, for $x, y \in \{0,1\}^n$, $COMP(x,y) = EQ(x,\bar{y})$. In other words, $COMP(x_1, \ldots, x_n, y_1, \ldots, y_n) := \bigwedge_{i=1}^n (x_i \oplus y_i)$.*

Chernoff Bound

In a few of our proofs, we will use a standard Chernoff bound for sums of independent Bernoulli random variables.

▶ **Lemma 12** (Chernoff bound)**.** *If $X_1, \ldots, X_n$ are independent Bernoulli random variables with sum $X = X_1 + \cdots + X_n$, and μ is the expected value of X, then we have:*

$\Pr[X \leq (1-\delta)\mu] \leq \exp\{-\delta^2\mu/2\}$ *for all* $0 < \delta < 1$*, and*

$\Pr[X \geq (1+\delta)\mu] \leq \exp\{-\delta^2\mu/3\}$ *for all* $0 < \delta$*.*

Useful Facts About Polynomials

We state two key facts from past work which we will use in the proofs of our main results. First, we will need the following variant of the Schwartz-Zippel-DeMillo-Lipton Lemma (which appears, for instance, in [27, Lemma 2.6]).

▶ **Lemma 13** (The 0-1 Schwartz-Zippel Lemma)**.** *Let p be a nonzero multilinear n-variate polynomial over any commutative ring R, of total degree at most d. Then $\Pr_{x \sim \{0,1\}^n}[p(x) \neq 0] \geq 1/2^d$.*

A proof can be found in Appendix G for completeness. Note that Lemma 13 is tight for $p(x_1, \ldots, x_d) = \prod_{i=1}^d x_i$. Second, we need a simple lower bound on the probabilistic degree of $AND \circ OR$ circuits which can be derived from a communication complexity lower bound. We refer the reader to the introduction of Sherstov's paper [31] for the relevant definitions (of the number-on-forehead communication model, and the k-party set disjointness problem), as we will only need the statement of Corollary 15 for this paper.

▶ **Theorem 14** ([31] Theorem 1.1)**.** *The number-on-forehead communication complexity of k-party set disjointness on n elements with error $1/3$ is at least $\Omega(\sqrt{n}/(2^k k))$.*

▶ **Corollary 15.** *For every $\varepsilon > 0$ and every $a > 0$, there is a $c > 0$ such that: For every sufficiently large positive integer n, every positive integer k with $k < c \cdot \log n$, and every finite commutative ring R with $|R| \leq 2^{a \cdot n^{1/2-\varepsilon}}$, the function $AND \circ OR$, where the AND has fan-in n and each OR has fan-in k, does not have a probabilistic polynomial of error $1/3$ and degree less than k.*

Proof (sketch). From such a polynomial, we can design a $1/3$ error number-on-forehead communication protocol for k-party set disjointness: draw a polynomial from the probabilistic polynomial, then map each monomial to a player whose variable is not in that monomial. Each player can evaluate their monomials and report the sum, from which they can compute set disjointness with the desired error. Each player only needs to communicate one element of R, using $O(\log(|R|)) = O(a \cdot n^{1/2-\varepsilon})$ bits of communication, so the total communication is $O(a \cdot k \cdot n^{1/2-\varepsilon})$. If $k < c \cdot \log n$ for sufficiently small $c > 0$, then this contradicts Theorem 14. ◀

3 Sparsity Lower Bounds for Probabilistic Polynomials

We begin by proving a probabilistic polynomial lower bound for AND:

▶ **Theorem 16.** *For every commutative ring R, and all $d \geq 1$ and $e > 0$, there is a $c \geq 1$ such that for all sufficiently large m, the AND function on m variables is not in R-**SDE**$[2^{dm/c}, m/c, 2^{-em/c}]$.*

For notational simplicity, we use the substitution $m = c \log n$ in our proof:

▶ **Restatement of Theorem 16.** *For every commutative ring R, and all $d \geq 1$ and $e > 0$, there is a $c \geq 1$ such that for all sufficiently large n, the AND function on $c \log n$ variables is not in R-**SDE**$[n^d, \log n, 1/n^e]$.*

Theorem 16 is a special case of Theorem 3, restricted to when the basis is $\{0, 1\}$. Theorems 4 and 5 will follow from this. We will later prove the more general Theorem 3, which holds for any basis over R, in Appendix G. In other words, *we are currently focusing on the $\{0, 1\}$ basis, but we later generalize this statement to hold over any basis.* Before we give the proof, let us show that Theorem 16 implies Theorems 4 and 5.

Proof of Theorem 4. Let P be an R-**SE**$[f(c)2^{dn/c}, f(c)/2^{en/c}]$ representation of $\text{AND}_n \circ \text{OR}_2$. From each of the OR_2 gates, pick at random one variable feeding into the gate and fix it 0. Thus, for each c', every monomial in P of degree at least $c'n/c$ survives with probability at most $1/2^{c'n/c}$. The probability that P under this restriction has degree greater than $c'n/c$ is therefore at most $f(c)2^{dn/c} \cdot \frac{1}{2^{c'n/c}}$. We set $c > c' > d$.

Note that under this restriction, the disjointness function reduces to AND_n. Thus, we have constructed a probabilistic polynomial for AND_n of degree $c'n/c$ with error $\frac{f(c)2^{dn/c}}{2^{c'n/c}} + \frac{f(c)}{2^{en/c}}$. If c is large enough, this contradicts Theorem 16. Hence our assumption about the existence of P must be false. ◀

Proof of Theorem 5. The proof is identical, since restricting one input of each XOR_2 gate to 0 reduces $COMP$ to AND as well. ◀

We now begin proving Theorem 16. We start with a simple case to illustrate our use of the 0-1 Schwartz-Zippel Lemma (Lemma 13):

▶ **Lemma 17.** *For every commutative ring R, and all $e > 1$, there is a $c > 1$ such that for all sufficiently large n, the AND function on $c \log n$ variables is not in R-**DE**$[\log n, 1/n^e]$.*

Proof. Let $\mathcal{P}$ be a probabilistic R-polynomial with error at most $1/n^e$ computing AND of $c \log n$ bits, such that every polynomial in the distribution has at most $\log n$ degree.

First we claim that, without loss of generality, the support of $\mathcal{P}$ may be assumed to not contain the identically zero polynomial z. Since $\mathcal{P}$ is a polynomial for AND with error at most $1/n^e$, on the point $y = (1, \ldots, 1)$ we must have $\Pr_{p \sim \mathcal{P}}[p(y) = 1] \geq 1 - 1/n^e$. Therefore, if z is in the support of $\mathcal{P}$, it must have probability at most $1/n^e$ of being chosen. Hence if we simply replace z in $\mathcal{P}$ with the polynomial which is identically the constant 1, the new probability of error is at most $2/n^e$.

Next, we prove there is no distribution $\mathcal{P}$ satisfying the above properties, if $e > 1$. Otherwise, by fixing randomness in $\mathcal{P}$ (i.e., by picking any polynomial in the support of $\mathcal{P}$ which achieves at most the average error), we can identify a fixed polynomial p of degree at most $\log n$ which disagrees with the AND function on at most a $1/n^e < 1/n$ fraction of inputs. By the previous paragraph, p is *not identically zero*. Since the AND of $c \log n$ variables is nonzero on only one point in $\{0, 1\}^{c \log n}$, it follows that the polynomial p is nonzero on at most $n^c/n^e + 1$ points in $\{0, 1\}^{c \log n}$. Hence the nonzero degree-$\log n$ polynomial p satisfies

$$\Pr_{x \sim \{0,1\}^{c \log n}}[p(x) \neq 0] \leq 1/n^e + 1/n^c,$$

contradicting Lemma 13 when $e, c > 1$. ◀

Before we turn to the harder part of the proof, where $e \leq 1$, we sketch the main ideas. Our first step is to hit a presumed probabilistic polynomial for AND with a random restriction of 1-inputs. The probabilities are chosen carefully so that the degree of the polynomial decreases considerably, yet the number of variables restricted is not too small, with high probability. That is, we shrink the degree of the polynomial, but we do not force it to a constant. Next, we select a non-zero polynomial from the remaining probabilistic polynomial distribution, and argue that with high probability, its degree has dropped significantly below $e \log n$, but its error on the AND function remains about $O(1/n^e)$. This contradicts Lemma 13, which says that a non-zero polynomial of degree-d must be non-zero on at least $1/2^d$ points. While the general idea of the proof is not too complicated, we need to be careful with the details, and choose parameters very particularly so that all of the required constraints hold. Let us now give the details:

Proof of Theorem 16. Assume there is a probabilistic polynomial $\mathcal{P}$ over R for AND with $d, e > 0$ such that for all $c \geq 1$, the sparsity is at most n^d, the degree is $\log n$, and the error is $1/n^e$. As in the proof of Lemma 17, we may assume that the zero polynomial is not in the support of $\mathcal{P}$. Let $\alpha, \beta, \gamma > 0$ be real-valued parameters to be set later. Define

$$g := (1+\alpha)(\log n)/\gamma, \text{ and } \ell := (1-\beta)(c \log n)/\gamma.$$

Consider the following construction $\mathcal{Q}$ of a probabilistic polynomial for AND on ℓ bits:

- Given $(x_1, \ldots, x_\ell) \in \{0,1\}^\ell$, sample $p(y_1, \ldots, y_{c \log n}) \sim \mathcal{P}$.
- For $i = 1, \ldots, c \log n$, independently and with probability $1 - 1/\gamma$, assign y_i to 1 in the polynomial p. Let p' be the remaining polynomial in $\text{vars}(p') \leq c \log n$ variables.
- If $\text{vars}(p') \geq \ell$ and $\deg(p') \leq g$, then output $p'(x_1, \ldots, x_\ell, 1, \cdots, 1)$ (where the $\cdots$ indicate $\text{vars}(p') - \ell$ ones).
- Otherwise, output a random bit.

Our central claim is that, for appropriate setting of α, β, γ, the probabilistic polynomial $\mathcal{Q}$ has degree at most g and computes the AND of ℓ bits with error at most $O(1/n^e)$. The degree of $\mathcal{Q}$ and AND functionality follow by construction; we need to bound the error. This will follow from positing a series of inequalities in the analysis that imply a small error bound, then proving at the end that the inequalities can be satisfied.

Define $\text{err} := \Pr[(\deg(p') > g) \vee (\text{vars}(p') < \ell)]$, where the probability is over the sampling in $\mathcal{P}$ (of step 1) and the random restriction to p' (of step 2). Observe that err is precisely the probability that case 4 is reached in the above procedure. Further observe that the error of $\mathcal{Q}$ is at most $1/n^e + \text{err}$: we have $1/n^e$ probability of error from $\mathcal{P}$ which is $1/n^e$, and probability err of reaching case 4.

We now claim that $\text{err} \leq 2/n^e$, when $\alpha, \beta, \gamma > 0$ are set appropriately. In particular, provided that

$$\frac{\alpha^2(1+\alpha)}{3\gamma^2} \geq d + e, \quad \text{and} \tag{1}$$

$$\frac{\beta^2 c}{2\ln(2)\gamma} \geq e, \tag{2}$$

we will have that both $\Pr[\deg(p') > g]$ and $\Pr[\text{vars}(p') < \ell]$ are at most $1/n^e$.

Observe that the number of variables $\text{vars}(p')$ in p' can be seen as a sum of independent $0-1$ random variables $Y_1, \ldots, Y_{c \log n}$, such that $\Pr[Y_i] = 1/\gamma$. Hence $\text{vars}(p')$ has expectation $(c \log n)/\gamma$ and by a Chernoff bound (Lemma 12),

$$\Pr[\text{vars}(p') < \ell] = \Pr[\sum_i Y_i < (1-\beta)(c \log n)/\gamma] \leq \exp\{-\beta^2 (c \log n)/(2\gamma)\}.$$

But if (2) holds, then $\Pr[\text{vars}(p') < \ell] < \exp\{-\beta^2 (c \log n)/(2\gamma)\} \leq \exp\{-e \ln n\} = 1/n^e$.

We will analyze $\Pr[\deg(p') > g]$ by considering the monomials of p. Let m be a monomial in $p \sim \mathcal{P}$ of degree $\deg(m) \leq \log n$. If $\deg(m) \leq g$, then the monomial m cannot possibly contribute to the event that $\deg(p') > g$ (the degree cannot increase by setting variables). So we may assume $\deg(m) > g$. There is a corresponding randomly reduced monomial m' in p', obtained by setting each of the variables in monomial m to 1 with probability $1/\gamma$. (Note this is the worst case; in some commutative rings R, the monomial m' could also cancel with another monomial and disappear from p'.) The degree $\deg(m')$ can be seen as a sum of independent 0-1 random variables $Z_1, \ldots, Z_{\deg(m)}$ where $\Pr[Z_i] = 1/\gamma$. By a Chernoff bound (Lemma 12),

$$\begin{aligned}
\Pr[\deg(m') > (1+\alpha)\deg(m)/\gamma] &= \Pr[\sum_i Z_i > (1+\alpha)\deg(m)/\gamma] \\
&\leq \exp\{-\alpha^2 \deg(m)/(3\gamma)\} \\
&< \exp\{-\alpha^2 g/(3\gamma)\} = \exp\{-\alpha^2(1+\alpha)(\log n)/(3\gamma^2)\}.
\end{aligned}$$

Now, if (1) holds, then $(\alpha^2(1+\alpha))/(3\ln(2)\gamma^2) \geq d+e$ and therefore

$$\Pr[\deg(m') > (1+\alpha)\deg(m)/\gamma] < \exp\{-\alpha^2(1+\alpha)(\log n)/(3\gamma^2)\} \leq \exp\{-(d+e)\ln n\} = 1/n^{d+e}.$$

This bound and $\deg(m) \leq \log n$ holds for every monomial m in p, and there are at most n^d monomials, so

$$\begin{aligned}
\Pr[\deg(p') > (1+\alpha)(\log n)/\gamma] &\leq \Pr\left[(\exists \text{ monomial } m')[\deg(m') > (1+\alpha)(\log n)/\gamma]\right] \\
&\leq \Pr\left[(\exists \text{ monomial } m')[\deg(m') > (1+\alpha)\deg(m)/\gamma]\right] \\
&\leq n^d/n^{d+e} = 1/n^e,
\end{aligned}$$

by the union bound.

We have proved that, assuming α, β, γ are set properly, $\mathcal{Q}$ has degree at most g and computes the AND of ℓ bits with error at most $O(1/n^e)$. Finally, suppose that

$$\frac{1+\alpha}{\gamma} < e. \tag{3}$$

Then, $\mathcal{Q}$ is a probabilistic polynomial for the AND on ℓ variables, with degree at most $g = (1+\alpha)(\log n)/\gamma < e \log n$ and error $O(1/n^e)$.

Fixing the randomness in $\mathcal{Q}$, we are in an analogous situation as the earlier case of $e > 1$: we can find a single non-zero degree-g polynomial q that differs from the AND of ℓ variables on an $O(1/n^e)$-fraction of points. Since the AND is nonzero on a $1/2^\ell$ fraction of points, the polynomial q is non-zero on at most an $O(1/n^e) + 1/2^\ell$ fraction of points. Provided that

$$\frac{(1-\beta)c}{\gamma} > e, \tag{4}$$

we will have $\ell = (1-\beta)(c \log n)/\gamma > e \log n$ and $1/n^e > 1/2^\ell$, hence q is non-zero on an $O(1/n^e)$ fraction of points. But then the degree of q is $\deg(q) \leq g \leq (e-\varepsilon)\log n$, for some $\varepsilon > 0$. This contradicts Lemma 13.

It remains to show that (1), (2), (3), and (4) can be simultaneously satisfied to yield the above contradiction, which we do in Lemma 46 in Appendix F. ◀

The full proof of Theorem 3, which generalizes the above Theorem 16 to any basis $\{a, b\}$ over R, can be found in Appendix G. It shows that picking representatives in R for true and false other than 1 and 0 cannot help to overcome the lower bound of Theorem 16. It is unfortunately not so straightforward to prove from here, since our proof of Theorem 16 critically uses the Schwartz-Zippel lemma, Lemma 13, which does not hold for general a, b over any commutative ring R. For a simple example, if $(a, b) = (0, 3)$ over $R = \mathbb{Z}/6\mathbb{Z}$, then the nonzero linear polynomial $p(x) = 2x$ is nonetheless zero on both a and b. We solve this issue by taking any probabilistic polynomial $\mathcal{P}$ over R with a basis $\{a, b\}$ where the Schwartz-Zippel lemma does not hold, and performing a combinatorial transformation to yield a new probabilistic polynomial $\mathcal{Q}$ over R with a different basis where the Schwartz-Zippel lemma does hold, and such that $\mathcal{Q}$ has the same degree and error, and only mildly greater sparsity, than $\mathcal{P}$.

3.1 Probabilistic Sparsity Lower Bounds for Compositions

We next show how probabilistic degree lower bounds for Boolean functions f can lead to probabilistic sparsity lower bounds for compositions of f with simple functions like OR and XOR.

▶ **Theorem 18.** *Let R be any commutative ring, and let $f : \{0,1\}^n \to \{0,1\}$ be any Boolean function such that any probabilistic polynomial of error ε for f over R requires degree d. Then, for every $0 < a < \varepsilon$, every $(\varepsilon - a)$-error probabilistic polynomial over R for the kn-variate function $f \circ OR_k$, the composition of f with ORs of k disjoint variables, requires sparsity at least $a \cdot k^d$ over the $\{0,1\}$ basis.*

Proof. Label the variables of our function of interest, $f \circ OR_k$, by $x_{i,j}$ for $i \in \{1, \ldots, n\}$ and $j \in \{1, \ldots, k\}$, so that our function can be written $f\left(\bigvee_{j=1}^{k} x_{1,j}, \ldots, \bigvee_{j=1}^{k} x_{n,j}\right)$. Consider the following random restriction ρ: for each $i = 1, \ldots, n$, choose one $j \in \{1, \ldots, k\}$ uniformly and independently at random, and set $x_{i,j'}$ to 0 for each $j' \neq j$. Notice in particular that after applying ρ to the inputs of our function $f \circ OR_k$, the result is the function f on the remaining n variables which were not set to 0.

Assume to the contrary that a probabilistic polynomial P exists for $f \circ OR_k$ with sparsity less than $a \cdot k^d$. We construct a probabilistic polynomial for f as follows:

1. Draw a $p \sim P$, and a random restriction ρ as described above.
2. Let p_ρ be the polynomial obtained by substituting 0s chosen by ρ into the variables of p.
3. If $deg(p_\rho) < d$ then output p_ρ, otherwise output a random bit.

Since the restriction ρ transforms $f \circ OR_k$ into f, we know that p_ρ as constructed in step 2 is a probabilistic polynomial for f with error $(\varepsilon - a)$. If we can show that we actually return p_ρ with probability at least $1 - a$ in step 3, then we know our probabilistic polynomial has error at most $(\varepsilon - a) + a = \varepsilon$, and it by definition has degree less than d, which will contradict our assumption about f as desired.

Observe that the monomials of p_ρ are a subset of the monomials of p. Moreover, a monomial of p appears in p_ρ if and only if none of its variables were set to 0. For a monomial m in p of degree at least d, the probability that m appears in p_ρ is at most $1/k^d$: if both x_{i,j_1} and x_{i,j_2} appear in m for some i and $j_1 \neq j_2$, then m is definitely set to zero upon restriction ρ, and otherwise, each variable in m is set to 0 with probability $1 - 1/k$ independently of the rest.

Therefore, if p has sparsity $|p|$, then the expected number of monomials of degree at least d in p_ρ is at most $|p|/k^d \leq a$. Hence, by Markov's inequality, the probability that p_ρ has degree at least d, meaning it has at least one monomial of degree at least d, is at most a, as desired. ◀

▶ **Corollary 19.** *Theorem 18 also holds with $f \circ OR_k$ replaced by $f \circ XOR_k$.*

Applying Theorem 18 and Corollary 15, we can prove that a simple depth-2 AC^0 circuit requires probabilistic sparsity $n^{\Omega(\log n)}$. (Note the lower bound is tight, as mentioned in the introduction.)

▶ **Lemma 20.** *For every $\varepsilon > 0$ and every finite commutative ring R such that $|R| \leq 2^{O(n^{1/2-\varepsilon})}$, and every function $g : \mathbb{N} \to \mathbb{N}$, R-probabilistic polynomials with error $1/4$ for $AND \circ OR$, where the AND has fan-in n and each OR has fan-in $g(n) \cdot \log(n)$, require sparsity $n^{\Omega(\log g(n))}$ over the $\{0,1\}$ basis.*

Proof. Pick a sufficiently small $c > 0$ such that Corollary 15 holds, meaning $f := AND_n \circ OR_{c \log n}$ requires R-probabilistic degree $\Omega(\log n)$ for error $1/3$. Applying Theorem 18 to f with $a = 1/12$ and $k = g(n)$, we see that $f \circ OR_{g(n)}$ requires $\mathbb{F}_2$-probabilistic sparsity $(g(n))^{\Omega(\log n)} = n^{\Omega(\log g(n))}$ for error $1/4$. Collapsing the two bottom layers of ORs, we see that $f \circ OR_{g(n)} = AND_n \circ OR_{c \cdot g(n) \log n}$, which implies the desired result since $c \cdot g(n) \log n < g(n) \log(n)$. ◀

We can finally prove our main theorem:

Proof of Theorem 1. Setting $y_{i,j} = 1$ for all i, j changes OV_g into the negation of the function from Lemma 20. The same lower bounds hold since setting variables does not increase the degree, sparsity, or error. ◀

4 Conclusion

By combining multiple techniques (random restrictions, Schwartz-Zippel, communication complexity lower bounds, known degree lower bounds, etc.), we have shown sparsity lower bounds for probabilistic and approximate polynomials computing several natural functions of interest in algorithm design. Perhaps the main question left open by our work is whether there is a polynomially-sparse constant-error probabilistic polynomial for the depth-three $OR_n \circ AND_n \circ OR_2$ circuit over *some* basis $\{a, b\}$ where $a \neq b$, working in *some* ring R. Even more generally, does this circuit have low *probabilistic rank* over some ring? In this paper, we proved several strong sparsity lower bounds over the basis $\{0, 1\}$ which significantly narrows the search space for such polynomials, but some of steps in our proofs require that the basis contains 0 ("killing" monomials by setting variables to 0).

For the complements ($COMP$) function, there is a nice sparsity upper bound over $\{-1, 1\}$ (compared to the lower bound over $\{0, 1\}$), so it is still possible (but unlikely) that the $\{-1, 1\}$ basis could support sparse probabilistic polynomials for depth-3 AC^0 functions. More basis-independent methods for sparsity lower bounds (such as Theorem 3) would be of great interest, as well as new techniques for constructing sparse polynomial representations.

A Depth-3 Circuits and Probabilistic Polynomials

The study of probabilistic polynomials over $\mathbb{F}_p$ is equivalent to studying depth-three circuits of a certain form; let us recall the simple connection. In the following, let $||x||$ denote the number of 1s in the binary string x.

▶ **Definition 21.** *The* approximate majority of separation δ on n bits, *denoted* MAJ_δ, *is defined only on* $x \in \{0,1\}^n$ *with* $||x|| \notin ((1/2-\delta)n, (1/2+\delta)n)$, *and is given by* $MAJ_\delta(x) = 1$ *when* $||x|| \geq (1/2+\delta)n$, *and* $f(x) = 0$ *when* $||x|| \leq (1/2-\delta)n$.

▶ **Lemma 22.** *If f is computable by a depth-three circuit with an approximate majority of separation δ at the output, PARITY gates with fan-in at most s on the middle layer, and AND gates of fan-in at most d at the bottom layer, then there is an $\mathbb{F}_2$ probabilistic polynomial for f with degree d, sparsity s, and error δ.*

Proof. An $\mathbb{F}_2$ polynomial can be viewed as a $PARITY \circ AND$ circuit, and vice versa: each monomial in such a polynomial is computing the AND of its constituent variables, and then the output of the polynomial is the $\mathbb{F}_2$ sum of these monomials, which is a $PARITY$. We thus get our probabilistic polynomial by selecting a uniformly random $PARITY \circ AND$ subcircuit which feeds into the top MAJ_δ gate of our circuit, and outputting it as an $\mathbb{F}_2$ polynomial. ◀

▶ **Lemma 23.** *For any constant $c > 0$, if there is an $\mathbb{F}_2$ probabilistic polynomial for f with degree d, sparsity s, and error δ, then f is computable by a depth-three circuit with an approximate majority of separation $(1-c)\delta$ and fan-in $O(n/\delta)$ at the output, PARITY gates with fan-in at most s on the middle layer, and AND gates of fan-in at most d at the bottom layer.*

If we didn't bound the fan-in of the approximate majority gate, then the proof would be almost identical to the proof of Lemma 22. In order to bound the fan-in by $O(n)$, we need to use a Chernoff bound:

Proof. Randomly sample t polynomials $p_1, \ldots, p_t$ from the probabilistic polynomial, for a parameter t to be selected later. For each $x \in \{0,1\}^n$, by the Chernoff bound, the probability that less than a $(1-c)\delta$ fraction of the polynomials $p_1, \ldots, p_t$ output the correct answer on x is at most $exp(-c^2\delta t)$. By setting $t = a \cdot n/(c^2\delta)$ for a sufficiently large constant a, this can be made less than 2^{-n}. Then, by the union bound, there is a probability less than 1 that, for any $x \in \{0,1\}^n$, less than a $(1-c)\delta$ fraction of the polynomials $p_1, \ldots, p_t$ output the correct answer on x. Hence, by the probabilistic method, there must be a choice of $p_1, \ldots, p_t$ such that at least a $(1-c)\delta$ fraction give the correct answer on every x. We can convert these polynomials into the desired circuit as in the proof of Theorem 22. ◀

It is interesting to note, via Lemmas 22 and 23, that we may assume that any probabilistic polynomial with constant error over $\mathbb{F}_2$ is the uniform distribution on only $O(n)$ different polynomials.

B SETH Predictions about Probabilistic Polynomials

Several algorithms based on the polynomial method in circuit complexity (such as [36, 37, 1, 3, 2]) have the following form: (a) we identify a "subcircuit" C which, if C could be evaluated on many inputs rapidly, we could solve a desired problem faster, (b) efficiently convert C into a polynomial (probabilistic, approximate, etc.) so that the evaluation task becomes algebraic, and (c) solve the evaluation task rapidly using algebraic algorithms, such as a fast Fourier transform or a matrix multiplication. How far can this approach be pushed? A significant question has been whether this kind of approach can be used to solve CNF-SAT fast enough to refute the pesky Strong Exponential Time Hypothesis (SETH).

We observe in this section that a low-degree, low-sparsity, and low-error probabilistic polynomial for AND would have contradicted SETH (recall that we unconditionally prove in this paper that there is no such polynomial). Along the way, we demonstrate other "predictions" about polynomial representations obtained by assuming SETH.

▶ **Theorem 24.** *For any commutative ring R, a low-degree, low-sparsity, and low-error R-probabilistic polynomial for AND (over 0/1) implies that there is a universal $\varepsilon > 0$ such that for all $k \geq 3$, there is a non-uniform circuit family of size $2^{(1-\varepsilon)n}$ for solving k-SAT on n variables.*[1]

The proof of Theorem 24, follows from a few claims. First, we note that a low-degree/low-sparsity/low-error probabilistic polynomial for AND over 0/1 is equivalent to low-sparsity/low-error probabilistic polynomial for $DISJ$ over 0/1. Let R be any commutative ring.

▶ **Proposition 25.** *For any $n, s, d, e \geq 0$, if $AND_n \in R$-**SDE**$[s, d, e]$ then $AND_n \circ OR_2 \in R$-**SE**$[s \cdot 3^d, e]$.*

Proof. From a probabilistic polynomial for AND_n, substitute the exact OR of two variables, $OR(x, y) = x + y - xy$, to get a probabilistic polynomial of the same error for $AND_n \circ OR_2$. In this substitution, each original monomial is replaced by a product of at most d polynomials, each of which is the OR of two variables and has three monomials; so the new polynomial has at most $s \cdot 3^d$ monomials. ◀

Next, we note that a probabilistic polynomial for disjointness ($AND_n \circ OR_2$) with low sparsity and error implies the probabilistic polynomial needed for refuting SETH:

▶ **Theorem 26.** *For any $n, s \geq 0$, if $AND_{c \log n} \circ OR_2 \in R$-**SE**$[s, 1/(8n)]$ then $OR_n \circ AND_{c \log n} \circ OR_2$ has a R-probabilistic polynomial $\mathcal{P}$ of sparsity $O(n^2 \cdot s^2)$ and error 11/24 which (when there is no error) outputs 0 for false and a nonzero value for true.*

Proof. We define $\mathcal{P}$. Let $\mathcal{Q}$ be the R-**SE**$[s, 1/(8n)]$ probabilistic polynomial for $AND_{c \log n} \circ OR_2$. Draw a $q \sim \mathcal{Q}$. By a union bound, with probability at least 7/8, q correctly computes the 0 or 1 value of $AND_{c \log n} \circ OR_2$ on the n different inputs which we want to compute the OR of. Hence, there are n polynomials $q_1, \ldots, q_n$ which each have at most s monomials, and we want to compute their OR assuming they all evalutate to 0 or 1.

The subring R' of R generated by 1 consists of all integer multiples of 1. It is isomorphic to $\mathbb{Z}/m\mathbb{Z}$ for some nonnegative integer $m \neq 1$. (The $m = 0$ case is when no positive integer multiple of 1 is 0 in R, and hence $R' = \mathbb{Z}$.) We consider three cases depending on whether $m = 0$, $m = 2$, or $m > 2$.

If $m = 0$, then simply $q_1 + \cdots + q_n$ suffices to compute OR over $\mathbb{Z}$. This has sparsity at most $n \cdot s$, and no additional error, for a total error of 1/8.

If $m = 2$, then let $S_1, S_2 \subseteq \{1, \ldots, n\}$ be two uniformly random subsets, and we pick

$$-1 + \prod_{i=1}^{2} \left(1 + \sum_{j \in S_i} q_j\right).$$

This is 0 when all the q_j are 0, and each $\sum_{j \in S_i} q_j$ is 1 with probability 1/2 otherwise, so the entire polynomial is 1 with probability at least 3/4. Hence the total error is 3/8, and the sparsity is $O(n^2 \cdot s^2)$.

If $m > 2$, then pick uniformly and independently random $a_1, \ldots, a_n \in \{1, \ldots, m\}$, and pick the polynomial $\sum_{i=1}^{n} a_i q_i$. If each $q_i = 0$ then this is 0, and otherwise it is 0 with probability at most $1/m$. The sparsity is at most $n \cdot s$, and the error is at most $1/8 + 1/m \leq 11/24$. ◀

[1] Moreover, an efficiently-samplable probabilistic polynomial for AND with these properties would refute the original Strong Exponential Time Hypothesis. All interesting probabilistic polynomial constructions we are aware of, such as those found in the works [29, 32, 9, 5, 19, 33, 3, 2], are efficiently samplable.

Finally, we note that a $n^{O(1)}$-sparse constant-error probabilistic polynomial (in the sense of Theorem 26) for $OR_n \circ AND_{c \log n} \circ OR_2$ for *every* $c \geq 1$ would refute (non-uniform) SETH:

▶ **Theorem 27.** *Suppose there is a fixed $k \geq 1$ such that for all $c \geq 1$, $OR_n \circ AND_{c \log n} \circ OR_2 \in R\text{-}\mathbf{SE}[n^k, 11/24]$. Then there is a universal $\varepsilon > 0$ such that for all $k \geq 3$, there is a non-uniform circuit family of size $2^{(1-\varepsilon)n}$ for solving k-SAT on n variables.*

Proof (sketch). The Orthogonal Vectors problem asks: *given a collection of bit vectors, is there a pair of them which are orthogonal?* We show that the hypothesis implies that for all $c \geq 1$, the Orthogonal Vectors problem with n vectors from $\{0,1\}^{c \log n}$ can be solved in $n^{2-\delta}$ time with $O(n^{2-\delta})$ advice, for a universal $\delta > 0$. The theorem then follows from a (by now) standard reduction (as in [35, 3]).

By our hypothesis, we can store (as non-uniform advice) a probabilistic polynomial $\mathcal{P}$ with sparsity $n^{\alpha k}$ and error $11/24$ for the function $OR_{n^\alpha} \circ AND_{c \log n} \circ OR_2$, where $\alpha \in (0, 1/k)$ is a sufficiently small constant. Note this requires storing a distribution of only $O(n)$ distinct $n^{\alpha k}$-sparse polynomials (see Section A).

To solve Orthogonal Vectors on n vectors, we proceed just as in Abboud-Williams-Yu [1]: partition the set of vectors into $O(n^{1-\alpha/2})$ parts, with each part containing at most $n^{\alpha/2}$ vectors. For all $O(n^{2-\alpha})$ pairs (P_1, P_2) of parts, we want to evaluate the probabilistic polynomial $\mathcal{P}$ on all pairs of vectors in the union $P_1 \cup P_2$ of the two parts. This gives an input of n^α pairs of vectors; feeding this input to a polynomial $p \sim \mathcal{P}$, we can estimate whether there is an orthogonal pair among vectors in $P_1 \cup P_2$.

The problem of solving Orthogonal Vectors now reduces to: *evaluate a random $p \sim \mathcal{P}$ with sparsity $n^{\alpha k}$, on $O(n^{2-\alpha})$ different pairs of input vectors.* When $\alpha k < 0.3$ (for example), this problem can be solved in $n^{2-\alpha+o(1)}$ time, via fast rectangular matrix multiplication. To have a high probability of success, we only need to sample $O(\log n)$ random p from our probabilistic polynomial $\mathcal{P}$. ◀

For similar reasons, many types of low sparsity polynomial representations for depth-3 AC^0, including low sparsity approximate polynomials over $\mathbb{R}$, would refute this form of SETH.

C Sparsity for −1/1 Probabilistic Polynomials

In many settings, the choice of basis (which field element corresponds to "true" and which to "false") can have a large impact on the sparsity of polynomial representations of Boolean functions. For instance, over $\{0,1\}$, computing XOR exactly on n inputs requires $\Omega(2^n)$ monomials, whereas over $\{-1,1\}$ it requires only one monomial.

We will show in this section that the choice of basis can make a big difference in the sparsity of probabilistic polynomials for the complements function (defined in Section 2). Although Theorem 16 holds over any choice of basis for our polynomials, our proof of Theorem 5 relies heavily on the fact that we are working over a basis where "false" corresponded to 0, and hence setting a variable to false eliminated every monomial that it was a part of.

Suppose we look instead at the $\{-1,1\}$ basis, with the standard convention that "true" corresponds to -1. In this setting, the statement of Theorem 5 is no longer true, since we can construct a probabilistic polynomial for the complements function with polynomial sparsity and polynomial error:

▶ **Lemma 28.** *For any $\varepsilon > 0$, and any commutative ring R which doesn't have characteristic 2, the AND of n variables has a probabilistic polynomial over R of sparsity $O(1/\varepsilon)$ and error ε over the basis $\{-1,1\}$.*

Proof. Pick a random subset $S \subseteq \{1, \ldots, n\}$, and consider the polynomial $E(x_1, \ldots, x_n) = 1 + (-1)^{|S|} \prod_{i \in S} x_i$. If $AND(x) = 1$, then some nonempty subset of the x_i's are 1's, and the probability that $\prod_{i \in S} x_i = (-1)^{|S|}$ is $1/2$. Hence, in this case, $E = 0$ with probability $1/2$. If $AND(x) = -1$, then all x_i's are -1, and we always have that $E = 2$. Hence, if we take $k = \lceil \log(1/\varepsilon) \rceil$ independent copies $E_1, \ldots, E_k$ of the above E, then the polynomial $P := 1 - \frac{1}{2^{k-1}} \prod_{i=1}^{k} E_i$ has the desired properties. ◀

▶ **Theorem 29.** *For any $\varepsilon > 0$, and any commutative ring R which doesn't have characteristic 2, $COMP$ has a probabilistic polynomial over R of sparsity $O(1/\varepsilon)$ and error ε over the basis $\{-1, 1\}$.*

Proof. The XOR of two variables is a single monomial over the $\{-1, 1\}$ basis, and so we simply substitute these monomials into the probabilistic polynomial from Lemma 28. ◀

Theorem 29 with $\varepsilon = 1/\text{poly}(n)$ shows that $COMP$ has a probabilistic polynomial with polynomial sparsity and any polynomial error over the $\{-1, 1\}$ basis, whereas Theorem 5 says that no such probabilistic polynomial can exist over the $\{0, 1\}$ basis.

Finally, we remark that just as in the $\{0, 1\}$ case, we can still construct probabilistic polynomials for OR over $\{-1, 1\}$ that achieve any two of the three goals of low sparsity, low degree, and low error:

- Low sparsity and error comes from Theorem 29,
- Low degree and error still follows from Theorem 2 with $t = (\log n)/(p-1)$, since degree and error are unchanged upon changing basis, and
- Low sparsity and degree still follows from Theorem 2 with $t = 1$, since then the degree is still $(p-1)$ and so by exploiting multilinearity, the sparsity must be $O(n^{p-1})$.

D Separation Between Probabilistic Rank and Probabilistic Sparsity

▶ **Definition 30.** *Let $a : [2^{n/2}] \to \{0,1\}^{n/2}$ be the canonical bijection, R be any ring, $f : \{0,1\}^n \to \{0,1\}$ be any Boolean function, and $A \cup B = \{x_1, \ldots, x_n\}$ be any partition of the input variables to f into two sets of size $|A| = |B| = n/2$. For $x, y \in \{0,1\}^{n/2}$, let $f(A|_x, B|_y)$ denote f evaluated at the assignment where the variables in A are set to x and the variables in B are set to y. The* truth table matrix *$M_{f,A,B}$ of f is the $2^{n/2} \times 2^{n/2}$ matrix given by $M_{f,A,B}(i,j) = f(A|_{a(i)}, B|_{b(j)})$.*

For $\varepsilon \geq 0$, and any $2^{n/2} \times 2^{n/2}$ matrix M over R, the ε-probabilistic rank of M is the minimum r for which there is a distribution $\mathcal{D}$ on $2^{n/2} \times 2^{n/2}$ matrices over R of rank at most r such that for all i, j:

$$\Pr_{D \sim \mathcal{D}}[D(i,j) \neq M(i,j)] \leq \varepsilon.$$

The ε-probabilistic rank *of f is the maximum, over all such partitions $A \cup B$, of the ε-probabilistic rank of $M_{f,A,B}$ over R.*

In this section, we compare the probabilistic sparsity of a function with its probabilistic rank. We know that the probabilistic sparsity is always an upper bound on the probabilistic rank:

▶ **Lemma 31** ([4] Corollary 2.1)**.** *For any ring R, if $f \in R$-$\mathbf{SE}[m, \varepsilon]$, then f has ε-probabilistic rank at most m over R.*

Using our probabilistic polynomial sparsity lower bounds, we are able to prove a separation in two different settings.

D.1 Complements

First, by using Theorem 5, we can give a simple explicit function, the *complements function* (defined in Section 2), which has substantially lower probabilistic rank than probabilistic sparsity over $\mathbb{F}_2$.

Recall from Theorem 5 that $COMP$ requires superpolynomial sparsity for any polynomial error over $\mathbb{F}_2$. In contrast, EQ is known to have low probabilistic rank, by simulating a communication complexity protocol for disjointness (similar to our proof of Theorem 29), and it follows that $COMP$ has low probabilistic rank as well:

▶ **Proposition 32** ([4] Lemma D.2)**.** *EQ has ε-probabilistic rank $O(1/\varepsilon)$ over any field, including $\mathbb{F}_2$.*

▶ **Proposition 33.** *$COMP$ has ε-probabilistic rank $O(1/\varepsilon)$ over any field, including $\mathbb{F}_2$.*

Proof. The communication matrix of $COMP$ is the same as that of EQ, up to a permutation of columns that swaps y with $\bar{y}$ for each $y \in \{0,1\}^{\log n}$. ◀

▶ **Corollary 34.** *$COMP$ has polynomial rank for any polynomial error over $\mathbb{F}_2$, whereas it requires superpolynomial sparsity for any polynomial error over $\mathbb{F}_2$.*

Proof. Follows from Corollary 33 and Theorem 5. ◀

D.2 Compositions with high fan-in XORs

Second, we combine Corollary 19 with Lemma 31 and a simple upper bound construction to prove a separation between probabilistic rank and probabilistic sparsity for functions of the form $f \circ XOR_k$, over $\mathbb{F}_2$.

Let $f : \{0,1\}^n \to \{0,1\}$ be any Boolean function, and $\varepsilon > 0$, $k \geq 1$ be any values. Let d be the smallest value such that f has an $\mathbb{F}_2$-probabilistic polynomial of error ε and degree d. We will prove a separation for the nk-variate function

$$f \circ XOR_k(x_{1,1}, \ldots, x_{n,k}) := f\left(\bigoplus_{j=1}^{k} x_{1,j}, \ldots, \bigoplus_{j=1}^{k} x_{n,j}\right).$$

▶ **Proposition 35.** *Over $\mathbb{F}_2$, the function $f \circ XOR_k$ has ε-probabilistic rank at most*

$$r := \sum_{i=0}^{2d} \binom{2n}{i}.$$

Proof. Suppose we have partitioned our nk variables into parts A, B, and for $1 \leq i \leq n$, let $A_i \subseteq A$ and $B_i \subseteq B$ be the corresponding partition of the variables $x_{i,1}, \ldots, x_{i,k}$. Define $y_i := \bigoplus_{x_{i,j} \in A_i} x_{i,j} \in \{0,1\}$ and $z_i := \bigoplus_{x_{i,j} \in B_i} x_{i,j} \in \{0,1\}$, and note that y_i and z_i are each functions of the variables in only one of the parts.

By assumption, f has an $\mathbb{F}_2$-probabilistic polynomial P of error ε and degree d. Suppose we draw a $p \in P$, and consider the expression

$$p(\chi(y_1, z_1), \chi(y_2, z_2), \ldots, \chi(y_n, z_n)), \tag{5}$$

where $\chi : \{0,1\}^2 \to \{0,1\}$ is the exact degree-2 polynomial for computing XOR on two variables. Expression (5) is therefore a probabilistic expression for $f \circ XOR_k$, and it is a degree $2d$ polynomial in the $2n$ variables $y_1, \ldots, y_n$ and $z_1, \ldots, z_n$, where each depends only on the variables in one side of the partition. The probabilistic rank is hence at most r by Lemma 31. ◀

Meanwhile, recall from Corollary 19 that $f \circ XOR_k$ requires $\mathbb{F}_2$-probabilistic sparsity $\varepsilon \cdot k^d$. Combining these two bounds can show a separation, for instance:

▶ **Theorem 36.** *For any*

$$k > \left(\frac{n \cdot e}{d}\right)^2,$$

the ε-probabilistic sparsity of $f \circ XOR_k$ is strictly greater than its ε-probabilistic rank. In particular, as k increases, the ε-probabilistic sparsity grows unboundedly while ε-probabilistic rank remains fixed.

Proof. With this bound on k, we have

$$k^d > \left(\frac{n \cdot e}{d'}\right)^{2d} \geq \sum_{i=0}^{2d} \binom{2n}{i},$$

as desired, where the second inequality is a standard bound on binomial coefficients. We can make the separation arbitrarily big by making k sufficiently large, since increasing k does not change the rank upper bound (the bound from Proposition 35 has no dependence on k), but increases the sparsity lower bound to as large as we would like. ◀

We can now apply known upper and lower bounds to get separations for other explicit functions. Consider, for instance, the majority function:

▶ **Theorem 37** ([29, 32])**.** *$\mathbb{F}_2$-probabilistic polynomials for MAJ on n bits with error ε require degree $\Omega(\sqrt{n \log(1/\varepsilon)})$.*

▶ **Theorem 38** ([3])**.** *There is an $\mathbb{F}_2$-probabilistic polynomial for MAJ on n bits with error ε and degree $O(\sqrt{n \log(1/\varepsilon)})$.*

Combining these with Theorem 36 yields:

▶ **Theorem 39.** *There is a constant $c > 0$ such that, for any*

$$k > \frac{c}{\log(1/\varepsilon)} \cdot n,$$

the ε-probabilistic sparsity of $MAJ \circ XOR$ over $\mathbb{F}_2$, where MAJ has fan-in n and each XOR has fan-in k, is strictly greater than its ε-probabilistic rank. In particular, as k increases, the ε-probabilistic sparsity grows unboundedly while ε-probabilistic rank remains fixed.

E Relationship between Degree, Sparsity, and Rank

Since the degree and sparsity of a probabilistic polynomial are related concepts, we are able to bound one using bounds on the other. Bounding the degree of a probabilistic polynomial will bound the sparsity of the polynomial, since there are only so many monomials of a given degree:

▶ **Proposition 40.** *For any decision problem $\mathcal{F}$, any $d, \varepsilon > 0$, and any prime p, if $\mathcal{F} \in \mathbb{F}_p$-$DE[d, \varepsilon]$, then $\mathcal{F} \in \mathbb{F}_p$-$SDE[m, d, \varepsilon]$, where*

$$m := \sum_{i=0}^{d} \binom{n}{i} \leq (1+n)^d.$$

Proof. Let P be a $\mathbb{F}_p$-DE$[d, \varepsilon]$ representation of $\mathcal{F}$. Since $x_i^2 = x_i$ whenever $x_i \in \{0, 1\}$, we may assume that any polynomial in the support of P is multilinear. Hence, each polynomial in the support of P is a multilinear polynomial of degree at most d, which has at most m monomials. P is therefore a $\mathbb{F}_p$-SDE$[m, d, \varepsilon]$ representation of $\mathcal{F}$. ◀

Perhaps more surprisingly, decision problems with low sparsity probabilistic polynomials must have low degree representations as well:

▶ **Proposition 41.** *For any decision problem $\mathcal{F}$, any $m, \varepsilon > 0$, and any prime p, if $\mathcal{F} \in \mathbb{F}_p$-SE$[m, \varepsilon]$, then $\mathcal{F} \in \mathbb{F}_p$-DE$[d, 2\varepsilon]$, where*

$$d := (p-1)\log_p(m/\varepsilon).$$

Proof. Let P be a $\mathbb{F}_p$-SE$[m, \varepsilon]$ representation of $\mathcal{F}$. We design a new probabilistic polynomial for $\mathcal{F}$, defined as follows:

1. Draw a polynomial $p(x_1, \ldots, x_n)$ from P. We can write p as a sum of monomials as $p(x_1, \ldots, x_n) = \sum_{i=1}^{m'} a_i \cdot m_i$, where $m' \leq m$, each $a_i \in \mathbb{F}_p$, and each m_i is a monomial.
2. Recall by Theorem 2 that AND $\in \mathbb{F}_p$-SDE$[O(n^{(p-1)t}), (p-1)t, 1/p^t]$ for all $t \geq 1$. Draw a polynomial q from the corresponding probabilistic polynomial on n variables with $t = \log_p(m/\varepsilon)$.
3. Each monomial m_i computes the AND of some set $x_{i,1}, x_{i,2}, \ldots, x_{i,n_i}$ of variables. It can therefore be probabilistically computed as $q(x_{i,1}, \ldots, x_{i,n_i}, 1, 1, \ldots, 1)$, where there are $(n - n_i)$ '1's. We can thus output the polynomial

$$\sum_{i=1}^{m'} a_i \cdot q(x_{i,1}, \ldots, x_{i,n_i}, 1, 1, \ldots, 1).$$

This has degree $(p-1)t = d$, and by a union bound over the error of the replacement for each monomial, it has error at most $\varepsilon + m/p^t = 2\varepsilon$. ◀

At most a logarithmic factor is lost when converting between these two bounds; if $\mathcal{F}$ has probabilistic degree d then it can have probabilistic sparsity $\leq n^d$, and if it has probabilistic sparsity n^d then it can have probabilistic degree $\leq d \cdot (p-1) \cdot \log_p(n)$.

Proposition 41 allows us to prove probabilistic sparsity lower bound from probabilistic degree lower bounds, which are much more common in the literature. For instance:

▶ **Corollary 42.** *If $f : \{0,1\}^n \to \{0,1\}$ is any Boolean function which requires $\mathbb{F}_2$-probabilistic degree d for error ε, then f requires $\mathbb{F}_2$-probabilistic sparsity $\varepsilon \cdot 2^d$ for error ε.*

Proof. A lower sparsity representation would yield a probabilistic degree less than d using Proposition 41. ◀

Combining Proposition 40 with Lemma 31, we see that if f has a probabilistic polynomial of degree d, then it has probabilistic rank at most $\sum_{i=1}^{d} \binom{n}{i}$. Applying ideas from the recent breakthrough work of Croot, Lev, and Pach [13] on Roth's theorem over $\mathbb{Z}_4^n$, we can derive an improved bound on the rank from the degree:

▶ **Proposition 43.** *Let n be even. Let $f : \{0,1\}^n \to \{0,1\}$ be any Boolean function with a probabilistic polynomial of degree d and error ε. Then, the ε-probabilistic rank of f is at most $m := 2\sum_{i=0}^{\lfloor d/2 \rfloor} \binom{n/2}{i}$.*

We note that Dvir and Edelman [14] also used this observation when studying the rigidity of a certain family of matrices. Proposition 43 will follow immediately from Theorem 45 below, but first we need a definition.

▶ **Definition 44.** *Let R be and ring, n be an even integer, and $a : [2^{n/2}] \to \{0,1\}^{n/2}$ be any bijection between the two sets. For any function $f : \{0,1\}^n \to R$, the* Boolean rank of f over R *is the minimum r such that there are matrices A, B of dimensions $2^{n/2} \times r$ and $r \times 2^{n/2}$ with $(A \cdot B)[i,j] = f(a(i), a(j))$ for all i, j.*

▶ **Theorem 45.** *Let n be even. Let P be a multilinear polynomial in n variables with degree at most d over a ring R. Then, the Boolean rank of P over R is at most $m := 2\sum_{i=0}^{\lfloor d/2 \rfloor} \binom{n/2}{i}$.*

Proof. Think of P as being over two sets of variables, $\{x_1, \ldots, x_{n/2}\}$ and $\{y_1, \ldots, y_{n/2}\}$. We begin with some notation: For sets $I, J \subseteq [n/2]$, let x^I denote $\prod_{i \in T} x_i$, and let $c_{I,J}$ be the coefficient in P of the monomial $x^I y^J$. Let $I_1, \ldots, I_t$ be a list of all subsets of $[n/2]$ of cardinality at most $\lfloor d/2 \rfloor$. Given a monomial M and a variable assignment $A \in \{0,1\}^{n/2}$, we let $M|_A$ denote the evaluation of M on the assignment A.

We want to prepare two matrices A ($2^{n/2} \times r$) and B ($r \times 2^{n/2}$), and prove for all i, j that

$$(A \cdot B)[i,j] = P(a(i), a(j)).$$

For each $i \in [2^{n/2}]$, we make a $2t$-dimensional vector

$$A[i,:] := \left(x^{I_1}|_{a(i)}, \ldots, x^{I_t}|_{a(i)}, \sum_{J \subseteq [n/2], |J| \leq |I_1|} c_{J,I_1} x^J|_{a(i)}, \ldots, \sum_{J \subseteq [n/2], |J| \leq |I_t|} c_{J,I_t} x^J|_{a(i)} \right).$$

Correspondingly, for all $j \in [2^{n/2}]$ we make an $2t$-dimensional vector

$$B[:,j] := \left(\sum_{J \subseteq [n/2], |J| < |I_1|} c_{I_1,J} y^J|_{a(j)}, \ldots, \sum_{J \subseteq [n/2], |J| < |I_t|} c_{I_t,J} y^J|_{a(j)}, y^{I_1}|_{a(j)}, \ldots, y^{I_t}|_{a(j)} \right).$$

Since every d-set of $\{x_1, \ldots, x_{n/2}, y_1, \ldots, y_{n/2}\}$ contains either at most $\lfloor d/2 \rfloor$ x_i's or at most $\lfloor d/2 \rfloor$ y_i's, we observe as desired that

$$\langle A[i,:], B[:,j] \rangle = \sum_{I,J \in \{I_1, \ldots, I_t\}} a_{I,J} x^I|_{a(i)} y^J|_{a(j)} = P(a(i), a(j)). \qquad \blacktriangleleft$$

F Missing Proof

▶ **Lemma 46.** *There is a setting to α, β, and γ which satisfies equations* (1), (2), (3), *and* (4) *from the proof of Theorem 16.*

Proof. Recall that d, e are fixed, and we may set $c \geq 1$ to be arbitrarily large.

Setting

$$\beta := \sqrt{\frac{2\ln(2)e\gamma}{c}},$$

inequality (2) immediately holds. Setting $\gamma := \alpha + 2$, we have $\frac{\alpha+1}{\gamma} = \frac{\alpha+1}{\alpha+2} < 1$, so (3) holds. To satisfy (1), we need

$$\frac{\alpha^2(1+\alpha)}{3\ln(2)\gamma^2} = \frac{\alpha^2 + \alpha^3}{\ln(2)(3\alpha^2 + 12\alpha + 12)} \geq d + e.$$

Setting $\alpha > 1$ to be sufficiently large satisfies this inequality. Finally, we turn to (4). Substituting in our above solution for β, we have

$$\frac{(1-\beta)c}{\gamma} = \frac{c - \sqrt{2\ln(2)}e^{1/2}\gamma^{1/2}c^{1/2}}{\gamma}.$$

As γ is only a function of d and e which are fixed constants, and c can be made arbitrarily large, the above expression can be made larger than e. This completes the proof. ◀

G Generalization to a-b basis

In this section, we generalize Theorem 16 to hold for a general basis, where we can choose any two elements $a, b \in R$ from our commutative ring R to represent true and false. What we prove is:

▶ **Reminder of Theorem 3.** *For every commutative ring R, every pair of distinct $a, b \in R$, and all $d \geq 1$ and $e > 0$, there is a $c \geq 1$ such that for all sufficiently large m, the AND function on m variables is not in R-$\mathbf{SDE}_{a,b}[2^{dm/c}, m/c, 2^{-em/c}]$.*

We begin by recalling and proving the version of the Schwartz-Zippel Lemma, Lemma 13, which we use in the proof of Theorem 16.

▶ **Reminder of Lemma 13.** *Let p be a nonzero multilinear n-variate polynomial over any commutative ring R, of total degree at most d. Then $\Pr_{x\sim\{0,1\}^n}[p(x) \neq 0] \geq 1/2^d$.*

Proof. Let $d' \leq d$ be the total degree of p. Without loss of generality, we may assume p has the monomial $x_1x_2\cdots x_{d'}$ with a nonzero coefficient. Consider any $\{0,1\}$ assignment to the remaining $n - d'$ variables. The resulting polynomial p' still has the monomial $x_1x_2\cdots x_{d'}$ with the same coefficient, and so it is a nonzero multilinear polynomial of degree d' in d' variables. It remains to show that p' is nonzero on at least one of the $2^{d'}$ assignments to the remaining d' variables, which will imply as desired that $\Pr_{x\sim\{0,1\}^n}[p(x) \neq 0] \geq 1/2^d$.

Let m be a monomial in p' of lowest degree with a nonzero coefficient, let $c \neq 0$ be its coefficient, and let $S \subseteq \{x_1, \ldots, x_{d'}\}$ be the set of variables in m (it may be that m is the constant term, in which case $S = \emptyset$). Then, consider the assignment which sets the variables in S to 1, and the remaining variables to 0. Our polynomial p' must evaluate to c on this assignment, since monomial m will have all variables set to 1, and all other monomials will have at least one variable set to 0 by how we chose m. This is the desired assignment since $c \neq 0$. ◀

By carefully examining our proof of Theorem 16, we see that we only used the fact that we were working with the basis $\{0,1\}$ in three ways:

- We need that substituting a value in for one variable in a monomial decreases the degree of that monomial by at least one; this is true regardless of what basis we are working over.
- We need that the correct output when the AND is false is 0, and that the correct output when AND is true is any nonzero value; by subtracting b from our polynomial we can always assume this is the case, while changing the number of monomials by at most one and leaving the degree unchanged.
- We need the Schwartz-Zippel lemma (Lemma 13) to hold for our choice of basis.

If we could generalize Lemma 13 to hold for any basis $\{a, b\}$, then our same proof would work as stated to prove Theorem 3. Unfortunately this is impossible in general: If $a, b \in R$ are such that $a - b$ is a zero-divisor, then Lemma 13 does not hold when we use the $\{a, b\}$ basis. For example, working over $R = \mathbb{Z}/6\mathbb{Z}$, with $(a, b) = (0, 3)$, the single variable linear polynomial $p(x) = 2x$ is a nonzero polynomial, but is zero on all inputs from the basis.

Although it is possible to salvage this method, at least for most choices of $\{a, b\}$, we will instead proceed in a different way, which does not rely on how our original proof works, except for the fact (as remarked) that Theorem 3 holds when the *input basis* (what values we input to the polynomial for true or false) is $\{0, 1\}$, and the *output basis* (what values the polynomial outputs for true or false) is $\{0, b\}$ for any nonzero $b \in R$.

We begin with the input basis $\{0, b\}$ for any nonzero $b \in R$, where true maps to b but false still maps to 0.

▶ **Lemma 47.** *For every commutative ring R, every nonzero $a \in R$, and all $d \geq 1$ and $e > 0$, there is a $c \geq 1$ such that for all sufficiently large m, the AND function on m variables is not in R-**SDE**$_{0,b}[2^{dm/c}, m/c, 2^{-em/c}]$.*

Proof. For a given d and e, we make the same choice of $c \geq 1$ as in Theorem 16. Assume to the contrary that AND is in R-**SDE**$_{0,b}[2^{dm/c}, m/c, 2^{-em/c}]$, and let p be the corresponding probabilistic polynomial. We will convert p into a R-**SDE**$_{0,1}[2^{dm/c}, m/c, 2^{-em/c}]$ representation, which will contradict Theorem 16.

Draw a polynomial q from p, and consider any nonzero monomial $\mathfrak{m}$ of q, with degree $\mathfrak{d}$ and nonzero coefficient $\mathfrak{a}$. If any of the variables in $\mathfrak{m}$ is assigned to 0, then $\mathfrak{m}$ evaluates to 0, and otherwise it evaluates to $\mathfrak{a} \cdot b^{\mathfrak{d}}$.

Consider the new polynonial q', given by

$$q'(x) = \sum_{\mathfrak{a} \cdot \mathfrak{m} \in q} \mathfrak{a} \cdot b^{\mathfrak{d}} \cdot \mathfrak{m}.$$

In other words, we have multiplied each monomial $\mathfrak{m}$ from q by $b^{\mathfrak{d}}$. Now, for any $x \in \{0, 1\}^n$, let $x' \in \{0, b\}^n$ be given by $x'_i = b \cdot x_i$. Then we always have that $q'(x) = q(x')$. Since x corresponds to the same true/false assignment over the $\{0, 1\}$ basis as x' does over the $\{0, b\}$ basis, this means that the resulting distribution on q' is a probabilistic polynomial with input basis $\{0, 1\}$ and output basis $\{0, b\}$ for AND with the same sparsity, degree, and error as p, as desired. ◀

Finally, we generalize to all input bases $\{a, b\}$.

Proof of Theorem 3. For a given $d \geq 1$ and $e > 0$, let $c(d, e)$ be the choice of c which is made by Lemma 47. We will choose $c = c(d+1, e)$ here. Similar to before, our plan is to convert from a R-**SDE**$_{a,b}[2^{dm/c}, m/c, 2^{-em/c}]$ representation to a R-**SDE**$_{0,b-a}[2^{(d+1)m/c}, m/c, 2^{-em/c}]$ representation, and then to invoke Lemma 47.

Assume to the contrary that AND is in R-**SDE**$_{a,b}[2^{dm/c}, m/c, 2^{-em/c}]$, and let p be the corresponding probabilistic polynomial. Draw a polynomial q from p, and consider the new polynomial q' given by

$$q'(x_1, x_2, \ldots, x_n) = q(x_1 + a, x_2 + a, \ldots, x_n + a).$$

Our desired probabilistic polynomial over the $\{0, b - a\}$ input basis will be the resulting distribution on q'. The polynomial q' clearly has the same degree as q, and errs on the same true/false inputs as q.

Consider any nonzero monomial $\mathfrak{m}$ of q, with degree $\mathfrak{d}$ and nonzero coefficient $\mathfrak{a}$. Each variable in $\mathfrak{m}$ has been replaced by the sum of two terms, and so $\mathfrak{m}$ has been replaced by $2^{\mathfrak{d}}$ monomials when expanded out. Since p had degree at most m/c, we have that $2^{\mathfrak{d}} \leq 2^{m/c}$, and so since q had at most $2^{dm/c}$ monomials, we have that q' has at most $2^{dm/c} \cdot 2^{m/c} = 2^{(d+1)m/c}$ monomials. Our probabilistic polynomial is therefore a R-**SDE**$_{0,b-a}[2^{(d+1)m/c}, m/c, 2^{-em/c}]$ representation, as desired. ◀

We note finally that, although we have been limiting ourselves to the same input basis $\{a, b\}$ for all of the n variables, we could actually choose a different input basis for each variable, and then another output basis like usual, and the above proof still holds.

A Bicriterion Concentration Inequality and Prophet Inequalities for k-Fold Matroid Unions

Abstract

We investigate prophet inequalities with competitive ratios approaching 1, seeking to generalize k-uniform matroids. We first show that large girth does *not* suffice: for all k, there exists a matroid of girth $\geq k$ and a prophet inequality instance on that matroid whose optimal competitive ratio is $\frac{1}{2}$. Next, we show k-fold matroid unions *do* suffice: we provide a prophet inequality with competitive ratio $1 - O(\sqrt{\frac{\log k}{k}})$ for any k-fold matroid union. Our prophet inequality follows from an online contention resolution scheme.

The key technical ingredient in our online contention resolution scheme is a novel bicriterion concentration inequality for arbitrary monotone 1-Lipschitz functions over independent items which may be of independent interest. Applied to our particular setting, our bicriterion concentration inequality yields "Chernoff-strength" concentration for a 1-Lipschitz function that is not (approximately) self-bounding.

1 Introduction

Prophet inequalities are fundamental problems in optimal stopping theory, whose study dates back to seminal work of Krengel and Sucheston [17], and that have wide applications across Economics and Computer Science (e.g., [8, 11]). A prophet inequality instance contains a ground set E of elements, a family $\mathcal{F} \subseteq 2^E$ of feasible sets, and a collection of distributions $\{\mathcal{D}_e\}_{e\in E}$. For one element at a time, a random variable v_e is drawn from distribution $\mathcal{D}_e$ independently and revealed to a gambler, who immediately and irrevocably decides whether to accept or reject e. The gambler must at all times maintain the set of accepted elements $A \in \mathcal{F}$, and gets payoff $\sum_{e\in A} v_e$ at the end of the game. A prophet inequality is c-competitive if it guarantees $\mathbf{E}[\sum_{e\in A} v_e] \geq c \cdot \mathbf{E}[\max_{S\in\mathcal{F}} \sum_{e\in S} v_e]$.[1]

Krengel and Sucheston's seminal result establishes a $\frac{1}{2}$-competitive prophet inequality for any instance where $\mathcal{F}$ is a 1-uniform matroid (i.e. at most one element is feasible to accept), and moreover establish that no better guarantee is possible.[2] For k-uniform matroids, however, a significantly improved guarantee of $1-O(\frac{1}{\sqrt{k}})$ is possible [1, 14, 10]. This motivates the following question: for a given $\varepsilon > 0$, what conditions on $\mathcal{F}$ suffice for a $(1-\varepsilon)$-competitive prophet inequality?

Main Result I: Large Girth does not Suffice

A natural starting point to address this question is to first understand what makes k-uniform matroids "special" in the sense that the canonical hard instance cannot be embedded. One conjecture might be because k-uniform matroids have large *girth*: there are *no infeasible sets of size* $\leq k$. So, a natural first question to ask is whether $\mathcal{F}$ having large girth suffices in order to conclude that any instance over $\mathcal{F}$ admits a c-competitive prophet inequality. Our first main result establishes that large girth does *not* suffice.

▶ **Theorem 1.** *For all $k \geq 1$ and $\varepsilon > 0$, there exists a prophet inequality instance $(E, \mathcal{F}, \{\mathcal{D}\}_{e\in E})$ such that: (a) $(E, \mathcal{F})$ is a graphic matroid with girth k, and (b) $(E, \mathcal{F}, \{\mathcal{D}\}_{e\in E})$ does not admit a $(\frac{1}{2}+\varepsilon)$-competitive prophet inequality.*

Our construction leverages dense graphs of high girth (and a particular construction of [18]) in order to effectively embed multiple copies of the canonical hard 1-uniform instance. See Section 3 for further details.

Main Result II: k-fold Matroid Unions Suffice

Theorem 1 motivates richer generalizations of k-uniform matroids. We next consider *k-fold matroid unions*, observing that k-uniform matroids are the union of k 1-uniform matroids. Given a matroid $\mathcal{M} = (E, \mathcal{F})$ over ground set E with feasible sets $\mathcal{F}$, the *k-fold union of* $\mathcal{M}$ is a new matroid $\mathcal{M}^k$ with ground set E and feasible sets $\mathcal{F}^k := \{F_1 \cup F_2 \cup \cdots \cup F_k : F_1, F_2, \ldots, F_k \in \mathcal{F}\}$. That is, a set is feasible in $\mathcal{M}^k$ if it can be partitioned into k sets that are each feasible in $\mathcal{M}$.

---

[1] The expectation is taken with respect to the random variables $\{v_e\}_{e\in E}$, which in turn makes A a random variable.

[2] That is, there exist prophet inequality instances over 1-uniform matroids for which better than a $\frac{1}{2}$-competitive ratio is impossible. The hard instance is quite simple: $v_1 \sim \mathcal{D}_1$ is a point mass at 1, and $v_2 \sim \mathcal{D}_2$ is equal to $\frac{1}{\varepsilon}$ with probability ε and 0 otherwise. A gambler who sees v_1 first cannot achieve expect reward exceeding 1, but a prophet who always takes the maximum can achieve expected reward of $2-\varepsilon$.

▶ **Theorem 2.** *For every prophet inequality instance $(E, \mathcal{F}^k, \{\mathcal{D}_e\}_{e\in E})$ where $(E, \mathcal{F}^k)$ is the k-fold union of a matroid $(E, \mathcal{F})$, there exists a $(1 - O(\sqrt{\frac{\log k}{k}}))$-competitive prophet inequality.*

Our proof of Theorem 2 follows from a novel Online Contention Resolution Scheme (OCRS). An OCRS is parameterized by a ground set E, a feasibility family $\mathcal{F}$, and a vector of probabilities $\boldsymbol{x} \in \text{ConvexHull}(\{\mathbf{1}_F : F \in \mathcal{F}\}) \subseteq [0,1]^E$ (that is, $\boldsymbol{x}$ can be written as a convex combination of indicator vectors of feasible sets). One at a time, elements of E are revealed and *active* with probability x_e independently. If an element is active, it can be accepted or rejected (if inactive, it must be rejected), and the accepted elements must at all times be in $\mathcal{F}$. An OCRS is c-selectable if every element e is accepted with probability at least $c \cdot x_e$. In this language, Theorem 2 follows from a novel $(1 - O(\sqrt{\frac{\log k}{k}}))$-selectable OCRS for k-fold matroid unions.

To prove our OCRS, we follow a similar framework as [12], and design a recursive decomposition of $\mathcal{F}$ over which to greedily accept active elements. There are two key challenges to applying their framework, which we overview in greater detail in Subsection 4.2. We give a representative example below.

Applied to the 1-uniform matroid, the [12] algorithm simply proposes "accept any active element independently with probability b." Then, linearity of expectation suffices to observe that there are at most b elements in expectation that are both active and accepted,[3] and Markov's inequality suffices to guarantee that with probability at least $1 - b$, no elements are accepted at all. This suffices to guarantee that for all e: (a) with probability at least $1 - b$ it is feasible to accept e when revealed, and (b) independently, we will accept e with probability b conditioned on e being active and feasible. This implies a $b(1 - b)$-selectable algorithm, which is optimized at $b = \frac{1}{2}$.

Applied to the k-uniform matroid, a natural algorithm would again be "accept any active element independently with probability b." Then, linearity of expectation still suffices to observe that there are at most bk elements in expectation that are both active and accepted, but Markov's inequality only guarantees that with probability at least $1-b$, at most k elements are accepted. This would lead to the same $\frac{1}{4}$-selectable OCRS, which is not the desired $1 - O(\sqrt{\frac{\log k}{k}})$. Of course, the obvious fix is to use a significantly stronger concentration inequality than Markov's. E.g., a Chernoff bound suffices to guarantee that with probability at least $1 - \frac{1}{k}$ at most $k - 1$ elements are accepted, when $b = 1 - O(\sqrt{\frac{\log k}{k}})$. This leads to the desired $1 - O(\sqrt{\frac{\log k}{k}})$ selectable OCRS for *k-uniform* matroids. However, Chernoff bounds are insufficient for the general class of k-fold matroid unions – the probability that a particular element is feasible to accept is a highly combinatorial function that depends on the underlying matroid structure. Thus our Theorem 2 has two components: first, a decomposition that reduces the OCRS problem to a concentration inequality and second, a novel concentration inequality, which is our third main result.

Main Result III: A Bicriterion Concentration Inequality

Putting aside prophet inequalities for a moment, concentration inequalities are a core aspect of applied probability with widespread application across many areas of Computer Science. One representative setting is the following: Let $f : \{0,1\}^E \to \mathbb{R}$ be some function, and let $\boldsymbol{X} = \langle X_e \rangle_{e\in E}$ be a vector of independent Bernoulli random variables, where $X_e \sim \text{Ber}(p_e)$. A canonical question asks: what is the probability that $f(\boldsymbol{X})$ exceeds $\mathbf{E}[f(\boldsymbol{X})] + t$?

[3] There are at most 1 elements in expectation that are active, and each active element is accepted with probability b.

On one extreme, McDiarmid's inequality holds whenever f is 1-Lipschitz. On the other, Chernoff bounds are *significantly* stronger, if f is linear (and 1-Lipschitz). In between, "Chernoff-strength" concentration holds whenever f is fractionally-subadditive or (approximately) self-bounding [5, 6, 22, 7, 27], but this provably does not extend even to the case when f is subadditive [27].

Our third main result provides a *bicriterion concentration inequality* for any monotone 1-Lipschitz function. Specifically, if $\boldsymbol{X}$ is a vector of Bernoulli random variables with probability vector $\boldsymbol{p}$, let $\boldsymbol{X}^{(s)}$ denote a vector of Bernoulli random variables with probability vector $e^{-s}\boldsymbol{p}$. That is, each probability p_i has been decreased by a factor of e^{-s}. Our new concentration inequality establishes:

▶ **Theorem 3.** *Let $f : \{0,1\}^E \to \mathbb{R}$ be a monotone 1-Lipschitz function. For any $s \in (0,1]$, $t > 0$:*

$$\mathbf{Pr}\left[f(\boldsymbol{X}^{(s)}) \geq \mathbf{E}[f(\boldsymbol{X})] + t\right] \leq e^{-st}.$$

A helpful comparison point is McDiarmid's inequality, which instead proves the following: $\mathbf{Pr}\left[f(\boldsymbol{X}) \geq \mathbf{E}[f(\boldsymbol{X})] + t\right] \leq e^{-2t^2/|E|}$. The distinctions are: (a) our concentration inequality is bicriterion – we analyze $f(\boldsymbol{X}^{(s)})$ instead of $f(\boldsymbol{X})$, and (b) our concentration has an exponent of $-st$ instead of $-2t^2/|E|$. In particular, McDiarmid's inequality depends on the dimension $|E|$ and cannot possibly kick in for $t \ll \sqrt{|E|}$, whereas our concentration inequality can kick in for any $t > 1/s$. A representative example to have in mind might be $s = \sqrt{\log(1/\varepsilon)/\,\mathbf{E}[f(\boldsymbol{X})]}$ and $t = \sqrt{\log(1/\varepsilon)\,\mathbf{E}[f(\boldsymbol{X})]}$. This results in a tail probability of ε for exceeding $\mathbf{E}[f(\boldsymbol{X})]$ by $\sqrt{\log(1/\varepsilon)}$ multiples of $\sqrt{\mathbf{E}[f(\boldsymbol{X})]}$, which is "Chernoff-strength". *But*, this concentration holds only for $f(\boldsymbol{X}^{(s)})$, rather than $f(\boldsymbol{X})$. This suffices for our application.

To prove Theorem 3, we utilize the entropy method for self-bounding functions [5, 6, 22, 7] in an unconventional way. We give a more detailed technical overview in Subsection 5.1.

1.1 Related Work

There are three strands of related work: prophet inequalities, concentration inequalities, and attempts to generalize k-uniform guarantees.

Prophet Inequalities

Prophet inequalities have a long history in Mathematics, Computer Science, and Operations Research. Representative results include Krengel and Sucheston's initial $\frac{1}{2}$-approximation [17], Samuel-Cahn's elegant thresholding strategy [25], Chawla et al.'s connection to Bayesian mechanism design [8], Kleinberg and Weinberg's extension to matroids [16], and Dutting et al.'s connection to Price of Anarchy [11].

Of particular relevance to our work are prophet inequalities for k-uniform matroids. The first $1 - O(\sqrt{\frac{\log k}{k}})$ approximation was developed by [13], and the first asymptotically tight $1 - O(\frac{1}{\sqrt{k}})$ approximation was developed by [1]. Subsequent works achieve the same $1 - O(\frac{1}{\sqrt{k}})$ approximation with sample access [4], the optimal OCRS [14], or a simpler OCRS [10]. The most technically related paper to our work is [12], whose OCRS framework we leverage. It remains an open question whether the prophet inequality for k-fold matroid unions can be improved to $1 - O(\frac{1}{\sqrt{k}})$.

Concentration Inequalities

The most related concentration inequalities fit the same framework but consider different f. McDiarmid's inequality [21] holds for all 1-Lipschitz f, Schechtman's inequality holds for f that are subadditive [26], Bucheron et al. derive an inequality for f that are self-bounding functions [5], and Vondrák derives an inequality for f that are fractionally subadditive [27]. These inequalities are commonly used across Theoretical Computer Science, and especially within combinatorial prophet inequalities and Bayesian mechanism design [24, 23].

Generalizing k-uniform matroids

Recent work of [9] considers (offline) contention resolution and correlation gap inequalities. Here too, guarantees for k-uniform matroids are significantly stronger than what is achievable for arbitrary matroids. Their work similarly extends guarantees achievable for k-uniform matroids to k-fold matroid unions. In comparison to our work: (a) the general motivation is the same – both works seek to extend stronger guarantees for k-uniform matroids to more general settings, (b) the problems studied and technical aspects are orthogonal,[4] (c) our work also proposes a bicriterion concentration inequality.

Another generalization of k-uniform matroids are *packing constraints*, where each element has a d-dimensional size in $[0,1]^d$ and one can accept a subset of elements if their size vectors sum to at most k in every coordinate. Packing constraints have been studied in various online settings, including secretary model [15], prophet model [2], and mixed model [3].

2 Preliminaries

Prophet Inequalities

In the *prophet inequality* problem, we are given a ground set of elements E, a downward-closed family of feasible sets $\mathcal{F} \subseteq 2^E$, and a distribution $\mathcal{D}_e$ associated with each element $e \in E$. Elements arrive in an adversarial order.[5] As each element e arrives, its value v_e, independently drawn from $\mathcal{D}_e$, is revealed. At this point, an irrevocable decision must be made whether to include e in its output A, while keeping $A \in \mathcal{F}$.

For $c \in [0,1]$, we say an online algorithm implies a *c-competitive* prophet inequality for $\mathcal{F}$, if for any distributions $\{\mathcal{D}_e\}_{e\in E}$,

$$\mathbf{E}\left[\sum_{e\in A} v_e\right] \geq c \cdot \mathbf{E}\left[\max_{S\in\mathcal{F}} \sum_{e\in S} v_e\right]$$

where the expectation is taken with respect to random variables $\{v_e\}_{e\in E}$ and the internal randomness of the algorithm.

Online Contention Resolution Schemes

Given a ground set of elements E and a downward-closed family of feasible sets $\mathcal{F} \subseteq 2^E$, we define the polytope of $\mathcal{F}$ as the convex hull of all characteristic vectors of feasible sets, i.e., $\mathcal{P}_\mathcal{F} = \text{ConvexHull}(\{\mathbf{1}_F : F \in \mathcal{F}\}) \subseteq [0,1]^E$.

[4] While in principle, contention resolution and online contention resolution may appear similar, the relevant techniques are fundamentally different with little overlap. Similarly, while correlation gap inequalities are sometimes a useful tool in prophet inequalities, in this case there is no overlap.

[5] There are various adversarial models. The weakest is the *fixed-order adversary*, which sets the arrival order offline, based solely on the distributions. The strongest is the *almighty adversary*, which sets the arrival order online, with full knowledge of all realizations of randomness and the algorithm's past decisions. Our negative result in Section 3 applies to fixed-order adversary, while our positive result in Section 4 holds against almighty adversary.

An *online contention resolution scheme* (OCRS) takes a vector $\boldsymbol{x} \in \mathcal{P}_{\mathcal{F}}$ as input. Let $R(\boldsymbol{x}) \subseteq E$ be a random set where each element $e \in E$ is in $R(\boldsymbol{x})$ independently with probability x_e. The OCRS sees membership in $R(\boldsymbol{x})$ of elements in E, arriving in an adversarial order; when each $e \in E$ arrives, if $e \in R(\boldsymbol{x})$ (i.e., e is "active"), the scheme must decide irrevocably whether to include e in its output A, while keeping $A \in \mathcal{F}$.

For $c \in [0, 1]$, an OCRS is called *c-selectable* for $\mathcal{F}$, if for any $\boldsymbol{x} \in \mathcal{P}_{\mathcal{F}}$,

$$\mathbf{Pr}[e \in A \mid e \in R(\boldsymbol{x})] \geq c \quad \forall e \in E$$

where $A \in \mathcal{F}$ is the output of the OCRS, and the probability is measured with respect to $R(\boldsymbol{x})$ and internal randomness of the OCRS. As shown in [12], a c-selectable OCRS directly implies a c-competitive prophet inequality.

▶ **Lemma 4** ([12]). *For a ground set E and a family of feasible sets $\mathcal{F} \subseteq 2^E$, a c-selectable OCRS for $\mathcal{F}$ implies a c-competitive prophet inequality for $\mathcal{F}$.*

Matroids

A *matroid* $\mathcal{M} = (E, \mathcal{I})$ is defined by a ground set of elements E and a non-empty downward-closed family of independent sets $\mathcal{I} \subseteq 2^E$ with the *exchange property*, i.e., for every $A, B \in \mathcal{I}$ where $|A| > |B|$, there exists an element $e \in A \setminus B$ such that $B \cup \{e\} \in \mathcal{I}$. Given a matroid $\mathcal{M} = (E, \mathcal{I})$, the following notations are used throughout the paper:

- The *rank* of a set $S \subseteq E$ is the size of the largest independent set contained in S: $\text{rank}(S) = \max\{|I| : I \subseteq S, I \in \mathcal{I}\}$.
- The *span* of a set $S \subseteq E$ is the set of elements that is not independent from S: $\text{span}(S) = \{e \in E : \text{rank}(S) = \text{rank}(S \cup \{e\})\}$.
- The *restriction* of $\mathcal{M}$ to a set $S \subseteq E$ is a matroid $\mathcal{M}|_S = (S, \mathcal{I}|_S) = (S, \{I \in \mathcal{I} : I \subseteq S\})$.
- The *girth* of $\mathcal{M}$ is the size of the smallest dependent set: $\text{girth}(\mathcal{M}) = \min\{|S| : S \subseteq E, S \notin \mathcal{I}\}$.

Following are some special matroids that we will use later.

▶ **Example 5** (Uniform matroid). A *k-uniform matroid* $\mathcal{M} = (E, \mathcal{I})$ is a matroid in which the independent sets are exactly the sets that contains at most k elements for an integer $k \geq 1$, i.e, $\mathcal{I} = \{I \subseteq E : |I| \leq k\}$.

▶ **Example 6** (Graphical matroid). A *graphical matroid* $\mathcal{M} = (E, \mathcal{I})$ is a matroid in which the independent sets are the forests in a given undirected graph $G = (V, E)$, i.e., $\mathcal{I} = \{I \subseteq E : I \text{ is acyclic in } G\}$.

We formally define k-fold matroid union as follows.

▶ **Definition 7** (k-fold matroid union). *Given a matroid $\mathcal{M} = (E, \mathcal{I})$ and an integer $k \geq 1$, the* k-fold union *of $\mathcal{M}$ is defined as $\mathcal{M}^k = \underbrace{\mathcal{M} \vee \mathcal{M} \vee \cdots \vee \mathcal{M}}_{k \text{ times}} = (E, \mathcal{I}^k)$ where*

$$\mathcal{I}^k = \{I_1 \cup I_2 \cup \cdots \cup I_k : I_1, I_2, \ldots, I_k \in \mathcal{I}\}.$$

In other words, a set I is independent in $\mathcal{M}^k$ if and only if I can be partitioned into at most k independent sets in $\mathcal{M}$. Note that $\mathcal{M}^k$ remains a matroid by the closure property of matroid union.

3 Large Girth is Not Sufficient

In this section, we prove that a large girth is not sufficient for matroids (specifically, graphical matroids) to have a prophet inequality with a competitive ratio better than $\frac{1}{2}$.

▶ **Theorem 1.** *For all $k \geq 1$ and $\varepsilon > 0$, there exists a prophet inequality instance $(E, \mathcal{F}, \{\mathcal{D}\}_{e\in E})$ such that: (a) $(E, \mathcal{F})$ is a graphic matroid with girth k, and (b) $(E, \mathcal{F}, \{\mathcal{D}\}_{e\in E})$ does not admit a $(\frac{1}{2} + \varepsilon)$-competitive prophet inequality.*

To construct a hard instance, we start with a dense graph of large girth. We then transform the graph by splitting each edge (v_1, v_2) into two edges (v_1, u) and (v_2, u), where u is a newly introduced vertex. We obtain the final hard instance of the prophet inequality problem by embedding the hard instance of the single-item case into each of these edge pairs $(v_1, u), (v_2, u)$.

The hardness of this instance arises from the following observation: without accepting both edges in a pair, the instance essentially reduces to $|E|$ independent hard instances of the single-item case. On the other hand, one can accept at most $|V| - 1$ extra pairs of edges (in addition to $|E|$ single-item problems) at the same time without forming a cycle, which could not contribute a lot to the final solution because the graph is dense.

Proof of Theorem 1. We employ a construction of [18] which provides dense graphs of large girth. In particular, we will use that for any fixed k there exists some arbitrarily large n such that there is a graph G_n on n vertices with at least $n \log n$ edges and girth at least k.[6] Specifically, consider the graph G_n with vertices $V(G_n) = \{v_1, v_2, \ldots, v_n\}$ and edges $E(G_n) = \{e_1, e_2, \ldots, e_m\}$, where $m \geq n \log n$ and each edge $e_i = (a(i), b(i)) \in E(G_n)$ connects vertices $a(i)$ and $b(i)$ in $V(G_n)$. We construct a new graph H_n with $n + m$ vertices as follows:

- Begin with a set of $n+m$ vertices, labeled $V(H_n) := \{w_1, w_2, \ldots, w_n\} \sqcup \{u_1, u_2, \ldots, u_m\}$.
- For each edge e_i in G_n connecting $v_{a(i)}$ and $v_{b(i)}$, add in H_n an edge between u_i and $w_{a(i)}$ (call it f_i) as well as an edge between u_i and $w_{b(i)}$ (call it f'_i).

Hence H_n has a total of $2m$ edges. For $1 \leq i \leq m$, let the associated random variable X_{f_i} of f_i be a constant 1, and let the associated random variable $X_{f'_i}$ of f'_i follow a distribution which takes a value of $\frac{1}{\varepsilon}$ with probability ε, and a value of 0 with probability $1 - \varepsilon$. We consider an instance of the prophet inequality problem where the online algorithm is presented edges in the order $(f_1, f'_1, f_2, f'_2, \ldots, f_m, f'_m)$.

We first lower bound $\mathrm{OPT}(H_n)$, the expected value the optimal offline algorithm gets on this instance. Note that an offline algorithm could simply look at each pair $\{f_i, f'_i\}$ and take whichever edge has higher realized weight; this cannot create a cycle because every edge selected will be incident to a vertex of degree 1. We hence have the bound

$$\mathrm{OPT}(H_n) \geq \sum_{i=1}^{m} \left(\varepsilon \cdot \frac{1}{\varepsilon} + (1 - \varepsilon) \cdot 1 \right) = m(2 - \varepsilon).$$

Fix an online algorithm $\mathcal{A}$, and we now give an upper bound on its expected performance $\mathcal{A}(H_n)$ on the instance. The lower bound relies on the following observation.

▷ Claim 8. There are at most $n - 1$ values of i in $\{1, 2, \ldots, m\}$ such that $\mathcal{A}$ accepts both f_i and f'_i.

[6] In fact, [18] prove a significantly stronger result, but the weaker version stated above suffices for our purposes.

Proof. Suppose there are at least n such values of i; call them i_1, i_2, …, i_n. As the original graph G has n vertices, and a forest on n vertices has at most $n-1$ edges, we clearly see that there is a cycle among $\{e_{i_1}, e_{i_2}, \ldots, e_{i_n}\}$. That however would imply there is a cycle in H; namely, follow the cycle that existed in G, but replace each edge e_i with the edge f_i followed by the edge f'_i. ◁

For each $1 \le i \le m$, we now consider cases for what $\mathcal{A}$ gets in expectation from $\{f_i, f'_i\}$ right after f_i arrives:

- If $\mathcal{A}$ rejects f_i, then it clearly gets in expectation at most 1 from $\{f_i, f'_i\}$ because $\mathbb{E}[X_{f'_i}] = 1$.
- If $\mathcal{A}$ accepts f_i and rejects f'_i, then it clearly gets weight at most 1 from $\{f_i, f'_i\}$.
- If $\mathcal{A}$ accepts f_i and accepts f'_i, then it clearly gets weight at most $1 + \frac{1}{\varepsilon}$ from $\{f_i, f'_i\}$.

Let C_1 denote the set of all $i \in [m]$ such that $\mathcal{A}$ rejects f_i, let C_2 denote the set of all $i \in [m]$ such that $\mathcal{A}$ accepts f_i and rejects f'_i, and let C_3 denote the set of all $i \in [m]$ such that $\mathcal{A}$ accepts f_i and f'_i. Note C_1, C_2, and C_3 are random (disjoint) sets that may depend on the values realized by $\{X_{f_i}, X_{f'_i}\}_{i=1}^m$ and any randomness in $\mathcal{A}$. By the above cases, we can see that in expectation, $\mathcal{A}$ gets score at most

$$\sum_{i \in C_1} 1 + \sum_{i \in C_2} 1 + \sum_{i \in C_3} \left(1 + \frac{1}{\varepsilon}\right) = |C_1| + |C_2| + |C_3| \cdot \left(1 + \frac{1}{\varepsilon}\right).$$

Although $|C_1|$, $|C_2|$, and $|C_3|$ are random variables, $|C_1| + |C_2| \le m$ always, and by Claim 8 we have $|C_3| \le n - 1$ always. Hence, in expectation (averaging over all possible realizations of C_1, C_2, and C_3), we can bound the performance of $\mathcal{A}$ on H_n by $\mathcal{A}(H_n) \le m + n\left(1 + \frac{1}{\varepsilon}\right)$. As n grows, we can compute

$$\liminf_{n \to \infty} \frac{\mathcal{A}(H_n)}{\mathrm{OPT}(H_n)} \le \lim_{n \to \infty} \frac{m + n\left(1 + \frac{1}{\varepsilon}\right)}{m(2 - \varepsilon)} = \frac{1}{2 - \varepsilon}.$$

Taking $\varepsilon \to 0$ demonstrates the claimed result. ◀

4 k-Fold Unions are Sufficient

Our main goal in the section is to construct a good OCRS for k-fold matroid unions (Theorem 9). Combining with the reduction from prophet inequalities to OCRSs by [12] (Lemma 4), this immediately implies the existence of good prophet inequality for all k-fold matroid unions (Theorem 2).

▶ **Theorem 9.** *There exists a $(1 - O(\sqrt{\frac{\log k}{k}}))$-selectable OCRS for any k-fold matroid union $\mathcal{M}^k$.*

Our OCRS for k-fold matroid unions builds on the chain decomposition approach used in the matroid OCRS by [12], outlined in Subsection 4.1. We overview our approach and highlight main difficulties in Subsection 4.2. The construction is then formally given and analyzed in Subsection 4.3, where the bicriterion concentration inequality in Section 5 is used to bound its selectability.

4.1 Recap: OCRS for general matroids

We briefly describe the idea of the $\frac{1}{4}$-selectable matroid OCRS by [12]. Specifically, they show that for any parameter $b \in (0,1)$, there exists a $(1-b)$-selectable OCRS for any matroid $\mathcal{M} = (E, \mathcal{I})$ and $\boldsymbol{x} \in b \cdot \mathcal{P}_{\mathcal{M}}$. Note that one can "scale down" a vector $\boldsymbol{x}$ from $\mathcal{P}_{\mathcal{M}}$ to $b \cdot \mathcal{P}_{\mathcal{M}}$ by only considering each element independently with probability b. Formally:

▶ **Fact 10.** *For $b, c \in (0,1)$ and any matroid $\mathcal{M}$, a c-selectable OCRS for all $\boldsymbol{x} \in b \cdot \mathcal{P}_{\mathcal{M}}$ implies a bc-selectable OCRS for all $\boldsymbol{x} \in \mathcal{P}_{\mathcal{M}}$.*

Therefore, it follows that a $b(1-b)$-selectable ORCS exists for any matroid $\mathcal{M}$ and $\boldsymbol{x} \in \mathcal{P}_{\mathcal{M}}$. By letting $b = \frac{1}{2}$, they obtain a $\frac{1}{4}$-selectable matroid OCRS.

The greedy algorithm

Let us start with the simple greedy algorithm that always accepts the active element whenever possible. When $\mathcal{M}$ is a 1-uniform matroid, the greedy algorithm is actually $(1-b)$-selectable for $\boldsymbol{x} \in b \cdot \mathcal{P}_{\mathcal{M}}$ (i.e., $\sum_{e \in E} x_e \le b$ since $\mathcal{M}$ is 1-uniform), since the selectability of an element $e \in E$ can be easily lower bounded as

$$\begin{aligned}\mathbf{Pr}[e \text{ is accepted} \mid e \text{ is active}] &\ge \mathbf{Pr}[\text{no other element is active} \mid e \text{ is active}] \\ &\ge \mathbf{Pr}[\text{no element is active}].\end{aligned}$$

The first inequality holds because when there is no active elements besides e, the greedy algorithm can always accept e even if it arrives at the end. The second inequality holds due to the independence between elements. Moreover, by Markov's inequality,

$$\begin{aligned}\mathbf{Pr}[\text{no element is active}] &= 1 - \mathbf{Pr}[|R(\boldsymbol{x})| \ge 1] \\ &\ge 1 - \mathbf{E}[|R(\boldsymbol{x})|] = 1 - \sum_{e \in E} x_e \ge 1 - b.\end{aligned}$$

(Recall that $R(\boldsymbol{x})$ is the set of active elements.)

The first half of argument applies when $\mathcal{M}$ is a general matroid: for every element $e \in E$,

$$\mathbf{Pr}[e \text{ is accepted} \mid e \text{ is active}] \ge \mathbf{Pr}[e \notin \operatorname{span}(R(\boldsymbol{x}))].$$

However, unlike in 1-uniform matroids, the probability that an element $e \in E$ is spanned by active elements $R(\boldsymbol{x})$ could be much smaller than $1-b$, even for a scaled $\boldsymbol{x} \in b \cdot \mathcal{P}_{\mathcal{M}}$. In fact, the selectability of the greedy algorithm can be arbitrarily bad for a general matroid $\mathcal{M}$ (see, e.g., [19]).

Protection

Consider Algorithm 1, a modified greedy algorithm with a *protection set* $S \subsetneq E$ that only handles elements in $E \setminus S$. Intuitively, the algorithm accepts every active element $e \in E \setminus S$ whenever it does not conflict with any element in S. As a result, elements in S are "prioritized" over those in $E \setminus S$: regardless of which independent set from S is accepted, it remains an independent set when combined with the accepted elements in $E \setminus S$.

Algorithm 1 Modified greedy algorithm for $\mathcal{M} = (E, \mathcal{I})$ with a protection set $S \subseteq E$.

$A \leftarrow \emptyset$ ▷ *the set of accepted elements in* $E \setminus S$
for each arriving active element $e \in E \setminus S$ **do**
  if $e \notin \text{span}(A \cup S)$ **then**
    $A \leftarrow A \cup \{e\}$ ▷ *accepts element* e

For the modified greedy algorithm, we can similarly lower bound the selectability for $e \in E \setminus S$:

$$\mathbf{Pr}[e \text{ is accepted} \mid e \text{ is active}] \geq \mathbf{Pr}[e \notin \text{span}(R(\boldsymbol{x}) \cup S)].$$

The good news is that, such probabilities can be further lower bounded by $1 - b$ for the S obtained using Algorithm 2, an iterative algorithm that updates S by adding an element e whenever $\mathbf{Pr}[e \in \text{span}(R(\boldsymbol{x}) \cup S)] > b$.

Algorithm 2 Find a protection set S for $\mathcal{M} = (E, \mathcal{I})$ and $\boldsymbol{x} \in b \cdot \mathcal{P}_{\mathcal{M}}$.

function PROTECT($\mathcal{M}, \boldsymbol{x}, b$)
  $S \leftarrow \emptyset$
  while $\exists e \in E \setminus S,\ \mathbf{Pr}[e \in \text{span}(R(\boldsymbol{x}) \cup S)] > b$ **do**
    $S \leftarrow S \cup \{e\}$
  return S

Note that Algorithm 2 always terminates since E is a finite set, and the modified greedy algorithm with this protection set S guarantees $(1-b)$-selectability for every element $e \in E \setminus S$. More importantly, the protection is non-trivial, i.e., S is a proper subset of E.

▶ **Lemma 11** ([12]). *For any matroid* $\mathcal{M} = (E, \mathcal{I})$ *and* $\boldsymbol{x} \in b \cdot \mathcal{P}_{\mathcal{M}}$, PROTECT$(\mathcal{M}, \boldsymbol{x}, b) \subsetneq E$.

Therefore, it remains to get a good OCRS for $\mathcal{M}|_S$ and $\boldsymbol{x}|_S$, the restriction of the original matroid and vector to the protection set S.

Chain decomposition

The matroid OCRS in [12] starts with an offline prepossessing that finds the following *chain decomposition* of the elements:

$$\emptyset = N_\ell \subsetneq N_{\ell-1} \subsetneq \cdots \subsetneq N_1 \subsetneq N_0 = E$$

where $N_{i+1} = \text{PROTECT}(\mathcal{M}|_{N_i}, \boldsymbol{x}|_{N_i}, b)$ for every $0 \leq i < \ell$. And the OCRS is then operates by invoking Algorithm 1 on matroid $\mathcal{M}|_{N_i}$ with a protection set N_{i+1} for each $e \in N_i \setminus N_{i+1}$.

It is easy to see that these algorithms together produces an independent set of $\mathcal{M}$, and the selectability for each element $e \in N_i \setminus N_{i+1}$ is

$$\mathbf{Pr}[e \text{ is accepted} \mid e \text{ is active}] \geq 1 - \mathbf{Pr}[e \in \text{span}_{\mathcal{M}|_{N_i}}(R(\boldsymbol{x}|_{N_i}) \cup N_{i+1})] \geq 1 - b$$

where the last inequality holds due to the way N_{i+1} is obtained using Algorithm 2. By setting $b = \frac{1}{2}$, the resulting OCRS is $\frac{1}{2}$-selectable given any matroid $\mathcal{M}$ and $\boldsymbol{x} \in \frac{1}{2} \cdot \mathcal{P}_{\mathcal{M}}$.

4.2 Overview of our construction

We now give a high-level overview of our construction and highlight main difficulties. Let us first examine the case when $\mathcal{M}$ is a k-uniform matroid and see why the simple greedy algorithm works better for larger k.

Intuition from k-uniform matroids

When $\mathcal{M}$ is a k-uniform matroid, it turns out that the simple greedy algorithm that always accepts the active element whenever possible yields an OCRS with a selectability of $1 - O(\sqrt{\frac{\log k}{k}})$. To see this, consider the following tighter analysis of selectability for k-uniform matroids: for every element $e \in E$,

$$\mathbf{Pr}[e \text{ is accepted} \mid e \text{ is active}] \geq \mathbf{Pr}[e \notin \text{span}(R(\boldsymbol{x}))] = \mathbf{Pr}[|R(\boldsymbol{x})| < k].$$

Intuitively, $|R(\boldsymbol{x})|$ represents the number of slots occupied by active elements, and we know $|R(\boldsymbol{x})| < k$ indicates $e \notin \text{span}(R(\boldsymbol{x}))$. We want the bad event $|R(\boldsymbol{x})| \geq k$ to occur with a small probability.

Note that $|R(\boldsymbol{x})|$ is a sum of Bernoulli random variables and it concentrates very well: if we consider a slightly scaled-down $\boldsymbol{x} \in (1 - O(\sqrt{\frac{\log k}{k}})) \cdot \mathcal{P}_{\mathcal{M}}$, Chernoff bound (Theorem 27) tells us that $\mathbf{Pr}[|R(\boldsymbol{x})| \geq k] \leq \frac{1}{k}$. By Fact 10, one can further derive an OCRS for k-uniform matroids with a selectability of $(1 - O(\sqrt{\frac{\log k}{k}}))(1 - \frac{1}{k}) = 1 - O(\sqrt{\frac{\log k}{k}})$.

To summarize, the greedy algorithm performs well on k-uniform matroids because of the existence of a **fine-grained occupancy indicator $|R(\boldsymbol{x})|$ that concentrates well**.

Main idea and challenges

For a k-fold matroid union $\mathcal{M}^k = (E, \mathcal{I}^k)$, the simple greedy algorithm could perform very poor due to inherent non-uniformity of $\mathcal{M}^k$. In the matroid OCRS by [12], this is resolved using the idea of chain decomposition. For each level, an iterative procedure (Algorithm 2) is used to find a protection set S that includes all elements that are easily spanned by $R(\boldsymbol{x}) \cup S$. This is done by directly looking at the probability $\mathbf{Pr}[e \in \text{span}(R(\boldsymbol{x}) \cup S)]$.

Our idea is to construct a different chain decomposition based on functions $\omega_e(\cdot) : 2^E \to [0, k]$ that act as a "generalized occupancy indicator" for each element e, such that $\omega_e(\emptyset) = 0$, $\omega_e(S) = k$ if e is spanned by the set S, and we want $\omega_e(\cdot)$ to be as smooth as possible (i.e., 1-Lipschitz). For each level of the chain decomposition, we will add e to the protection set S whenever the expected occupancy $\mathbf{E}[\omega_e(R(\boldsymbol{x}) \cup S)]$ is large.

For k-uniform matroids, a simple occupancy indicator would be $\omega_e(S) = \min(k, |S|)$ (since we require its value to be between 0 and k). However, extending the definition of an occupancy function to a general k-fold matroid union introduces several challenges:

1. (**Compatibility with chain decomposition**) The most crucial part of the chain decomposition in [12] is to show the protection set S is always a proper subset of E (Lemma 11). Similarly, we will need to show that it is always possible to find a protection set $S \subsetneq E$ such that the expected occupancy $\mathbf{E}[\omega_e(R(\boldsymbol{x}) \cup S)]$ for every $e \in E \setminus S$ is smaller than k by a large enough margin.
2. (**Chernoff-strength concentration**) Based on the fact that $\mathbf{E}[\omega_e(R(\boldsymbol{x}) \cup S)]$ is sufficiently smaller than k, we ultimately want to show that $\mathbf{Pr}[\omega_e(R(\boldsymbol{x}) \cup S) = k]$ is very small, which would imply a good selectability for e. This is simple for k-uniform matroids by using Chernoff bound. However, it turns out $\omega_e(\cdot)$ for general k-fold matroid unions does not admit a standard Chernoff-strength concentration inequality, and much more efforts are required to achieve a similar selectability guarantee.

4.3 An OCRS for k-fold matroid unions

In Subsubsection 4.3.1, we define our candidate occupancy functions and show some useful properties. Then, in Subsubsection 4.3.2, we show these functions are compatible with the chain decomposition approach and can be used to get an OCRS for k-fold matroid unions.

Finally, in Subsubsection 4.3.3, we prove the selectability of this OCRS by showing these functions concentrates well enough using Theorem 3. Some proofs in the section are deferred to Appendix B for ease of reading.

4.3.1 The occupancy function

To define the occupancy function, we will instead work with the following *extended k-fold unions* which essentially introduces k parallel copies for each element. They are still matroids, and OCRS for them implies OCRS for k-fold matroid unions. Therefore, it suffices for us to give an OCRS for the extended k-fold union.

▶ **Definition 12** (Extended k-fold union)**.** *Given a matroid $\mathcal{M} = (E, \mathcal{I})$ and an integer $k \geq 1$, let $\mathcal{M}_* = (E_*, \mathcal{I}_*)$ be the matroid that contains k parallel copies $(e,1), \ldots, (e,k)$ of each element $e \in E$. Formally,*

$$E_* = E \times [k] = \{(e,i) : e \in E, i \in [k]\},$$
$$\mathcal{I}_* = \{\{(e_1,i_1), \ldots, (e_t,i_t)\} : \{e_1, \ldots, e_t\} \in \mathcal{I}, i_1, \ldots, i_t \in [k]\}.$$

And we define the extended k-fold union $\mathcal{M}_*^k = (E_*, \mathcal{I}_*^k)$ *of $\mathcal{M}$ to be the k-fold union of $\mathcal{M}_*$.*

▶ **Lemma 13.** *The extended k-fold union $\mathcal{M}_*^k$ of a matroid $\mathcal{M}$ is a matroid. Furthermore, a c-selectable OCRS for $\mathcal{M}_*^k$ implies a c-selectable OCRS for $\mathcal{M}^k$.*

We are now ready to define the following *occupancy function* on $\mathcal{M}_*^k = (E_* = E \times [k], \mathcal{I}_*^k)$. Intuitively, the function indicates the number of "slots" for elements $(e,\cdot) \in E_*$ that are occupied by the elements in S. We then show the occupancy function has good properties: it is monotone and 1-Lipschitz. More importantly, the value of $\omega_e(S)$ can be used to deduce whether $(e,\cdot) \in E_*$ is spanned by other elements in S.

▶ **Definition 14** (Occupancy function)**.** *Given an extended k-fold union $\mathcal{M}_*^k = (E_* = E \times [k], \mathcal{I}_*^k)$, for every $e \in E$, define its* occupancy function $\omega_e : 2^{E_*} \to [0,k]$ *as the function where for all $S \subseteq E_*$,*[7]

$$\omega_e(S) = k - \operatorname{rank}(S \cup (\{e\} \times [k])) + \operatorname{rank}(S).$$

▶ **Lemma 15.** *For any extended k-fold union $\mathcal{M}_*^k = (E_*, \mathcal{I}_*^k)$ and element $(e,i) \in E_*$, ω_e satisfies*

1. (Monotone) *$\omega_e(S) \leq \omega_e(T)$ for every $S \subseteq T \subseteq E_*$;*
2. (1-Lipschitz) *$\omega_e(S \cup \{a\}) - \omega_e(S) \leq 1$ for every $S \subseteq E_*$ and $a \in E_*$.*

▶ **Lemma 16.** *For any extended k-fold union $\mathcal{M}_*^k = (E_*, \mathcal{I}_*^k)$, element $(e,i) \in E_*$, and set $S \subseteq E_*$, $\omega_e(S) < k$ implies $(e,i) \notin \operatorname{span}(S \setminus \{(e,i)\})$.*

▶ **Example 17.** When $\mathcal{M}$ is a 1-uniform matroid of size n, its extended k-fold union $\mathcal{M}_*^k$ is a k-uniform matroid of size kn. For every $e \in E$ and $S \subseteq E_*$, we have

$$\operatorname{rank}(S \cup (\{e\} \times [k])) = \min(k, |S \cup (\{e\} \times [k])|) = k,$$
$$\operatorname{rank}(S) = \min(k, |S|).$$

Therefore, $\omega_e(S) = \min(k, |S|)$, i.e., the number of occupied slots by S.

Also, note that for any $\boldsymbol{x_*} \in (1 - O(\sqrt{\frac{\log k}{k}})) \cdot \mathcal{P}_{\mathcal{M}_*^k}$, the value $\omega_e(R(\boldsymbol{x_*}))$ concentrates very well as a capped sum over Bernoulli random variables. Therefore, the bad event $\omega_e(R(\boldsymbol{x_*})) = k$ rarely happens and the simple greedy algorithm without protection works.

[7] When it is clear from context, we will use rank(·)/span(·) to denote the rank/span of a set of elements in $\mathcal{M}_*^k$ for the ease of notation.

4.3.2 Chain decomposition based on occupancy functions

Similar to the matroid OCRS by [12], our OCRS for extended k-fold union $\mathcal{M}_*^k = (E_*, \mathcal{I}_*^k)$ and $\boldsymbol{x}_* \in b \cdot \mathcal{P}_{\mathcal{M}_*^k}$ starts with an offline prepossessing step that finds the following chain decomposition of elements in E_*,

$$\emptyset = N_\ell \subsetneq N_{\ell-1} \subsetneq \cdots \subsetneq N_1 \subsetneq N_0 = E_*$$

where $N_{j+1} = \textsc{KFoldProtect}(\mathcal{M}_*^k|_{N_j}, \boldsymbol{x}_*|_{N_j}, b)$ for every $0 \le j < \ell$, as described in Algorithm 3. Unlike Algorithm 2, it relies on the occupancy functions which are only defined for extended k-fold unions.

Algorithm 3 Find a protection set S for extended k-fold union $\mathcal{M}_*^k = (E_*, \mathcal{I}_*^k)$ and $\boldsymbol{x}_* \in b \cdot \mathcal{P}_{\mathcal{M}_*^k}$.

function $\textsc{KFoldProtect}(\mathcal{M}_*^k, \boldsymbol{x}_*, b)$
  $S_0, S \leftarrow \emptyset$
  while $\exists e \in E \setminus S_0,\ \mathbf{E}[\omega_e(R(\boldsymbol{x}_*) \cup S)] > bk$ **do**
    $S_0 \leftarrow S_0 \cup \{e\}$
    $S \leftarrow S \cup (\{e\} \times [k])$
  return S

Before introducing our OCRS, we need to make sure the chain decomposition above is well-defined, i.e., Algorithm 3 will always returns a proper subset S of elements, and $\mathcal{M}_*^k|_S$ remains an extended k-fold union. This is formally stated in Lemma 18, which resembles Lemma 11 in [12].

▶ **Lemma 18.** *For any $b \in (0,1)$, any extended k-fold union $\mathcal{M}_*^k = (E_*, \mathcal{I}_*^k)$ and $\boldsymbol{x}_* \in b \cdot \mathcal{P}_{\mathcal{M}_*^k}$, $S \subsetneq E_*$ for $S = \textsc{KFoldProtect}(\mathcal{M}_*^k, \boldsymbol{x}_*, b)$. Moreover, $\mathcal{M}_*^k|_S$ remains an extended k-fold union.*

Having obtained such a chain decomposition for $\mathcal{M}_*^k$ and $\boldsymbol{x}_* \in b \cdot \mathcal{P}_{\mathcal{M}_*^k}$, our OCRS is simply running the modified greedy algorithm, Algorithm 1, for each submatroid $\mathcal{M}_*^k|_{N_j}$ with a protection set N_{j+1} for all $0 \le j < \ell$ together. Note that although the chain decomposition is constructed with $\boldsymbol{x}_*$, an extra scaling factor of $e^{-(1-b)}$ will be applied before invoking Algorithm 1. This will be useful later when we apply the bicriterion concentration inequality.

Algorithm 4 OCRS for extended k-fold union $\mathcal{M}_*^k = (E_*, \mathcal{I}_*^k)$ and $\boldsymbol{x}_* \in b \cdot \mathcal{P}_{\mathcal{M}_*^k}$.

Construct the chain decomposition $\emptyset = N_\ell \subsetneq \cdots \subsetneq N_1 \subsetneq N_0 = E_*$ for $\mathcal{M}_*^k$ and $\boldsymbol{x}_*$
for each arriving active element $(e, i) \in E_*$ **do**
  Sample $r \sim \mathrm{Ber}(e^{-(1-b)})$
  if $r = 0$ **then**
    Reject (e, i)
  else
    ▷ *The set of remaining active elements follows the same distribution as $R(e^{-(1-b)}\boldsymbol{x}_*)$.* ◁
    Find $0 \le j < \ell$ such that $(e, i) \in N_j \setminus N_{i+1}$
    Invoke Algorithm 1 for $\mathcal{M}_*^k|_{N_j}$ with protection set N_{j+1} for (e, i)

The feasibility of such a scheme follows exactly from [12] as running Algorithm 1 on any chain decomposition always produces an independent set. We are left to show the OCRS guarantees a good selectability for any $\mathcal{M}_*^k$ and $\boldsymbol{x}_* \in b \cdot \mathcal{P}_{\mathcal{M}_*^k}$ for some parameter b. In fact, we will set $b = 1 - \sqrt{\frac{\log k}{k}}$ and show the selectability is at least $1 - O(\sqrt{\frac{\log k}{k}})$, proving Theorem 9.

4.3.3 Analyzing the selectability

Without loss of generality, let us focus on the selectability of elements in the first layer $E_* \setminus N_1$, since a same proof would work for all submatroid $\mathcal{M}_*^k|_{N_j}$ as they remains to be extended k-fold unions.

By Lemma 16, for every element $(e,i) \in E_* \setminus N_1$, its selectability can be lower bounded as

$$\begin{aligned}\mathbf{Pr}[(e,i) \text{ is accepted} \mid (e,i) \text{ is active}] &\geq \mathbf{Pr}[(e,i) \notin \operatorname{span}((R(e^{-(1-b)}\boldsymbol{x}_*) \setminus \{(e,i)\}) \cup N_1)] \\ &\geq \mathbf{Pr}[\omega_e(R(e^{-(1-b)}\boldsymbol{x}_*) \cup N_1) < k].\end{aligned}$$

On the other hand, by the way chain decomposition is obtained using Algorithm 3, we know even without the extra scaling of $e^{-(1-b)}$, the expected value of $\omega_e(R(\boldsymbol{x}_*) \cup N_1)$ is not too close to k:

$$\mathbf{E}[\omega_e(R(\boldsymbol{x}_*) \cup N_1)] \leq bk.$$

For the ease of notation, denote $X = R(\boldsymbol{x}_*)$ and $X' = R(e^{-(1-b)}\boldsymbol{x}_*)$. Fixing an element $(e,i) \in E_*$, define the function $f : 2^{E_*} \to [0,k]$ where for every $S \subseteq E_*$,

$$f(S) = \omega_e(S \cup N_1).$$

Then, to lower bound selectability for (e,i), it is equivalent to upper bound $\mathbf{Pr}[f(X') = k]$ given that $\mathbf{E}[f(X)] \leq bk$. Specifically, to get a selectability of $1 - O(\sqrt{\frac{\log k}{k}})$, we will set $b = 1 - \sqrt{\frac{\log k}{k}}$, and it suffices to show the following *bicriterion concentration inequality*:

$$\mathbf{E}[f(X)] \leq k - \sqrt{k \log k} \implies \mathbf{Pr}\left[f(X') \geq \mathbf{E}[f(X)] + \sqrt{k \log k}\right] \leq O\left(\frac{1}{k}\right). \tag{$*$}$$

By Lemma 15, we know f is always monotone and 1-Lipschitz. Then, using Theorem 3 (and recall that $X' = R(e^{-\sqrt{\log k/k}}\boldsymbol{x}_*)$), we have

$$\mathbf{Pr}\left[f(X') \geq \mathbf{E}[f(X)] + \sqrt{k \log k}\right] \leq \exp\left(-\sqrt{\frac{\log k}{k}} \cdot \sqrt{k \log k}\right) = \frac{1}{k}.$$

Therefore, for extended k-fold union $\mathcal{M}_*^k$ and $\boldsymbol{x}_* \in b \cdot \mathcal{P}_{\mathcal{M}_*^k}$, running Algorithm 4 yields

$$\begin{aligned}\mathbf{Pr}[(e,i) \text{ is accepted} \mid (e,i) \text{ is active}] &\geq 1 - \mathbf{Pr}\left[f(X') \geq k\right] \\ &\geq 1 - \mathbf{Pr}\left[f(X') \geq \mathbf{E}[f(X)] + \sqrt{k \log k}\right] \geq 1 - \frac{1}{k}.\end{aligned}$$

Together with Fact 10 and Lemma 13, we prove Theorem 9 by showing the existence of an OCRS for all k-fold union $\mathcal{M}^k$ and $\boldsymbol{x}_* \in \mathcal{P}_{\mathcal{M}^k}$ with a selectability of

$$\left(1 - \frac{1}{k}\right) \cdot b \cdot e^{-(1-b)} = \left(1 - \frac{1}{k}\right) \cdot \left(1 - \sqrt{\frac{\log k}{k}}\right) \cdot e^{-\sqrt{\frac{\log k}{k}}} = 1 - O\left(\sqrt{\frac{\log k}{k}}\right).$$

▶ Remark 19. It might seems bizarre and unnecessary to consider $f(X')$ instead of $f(X)$. Indeed, since f is monotone non-decreasing, the following claim that only contains $f(X)$ would imply $(*)$, and it looks more like a standard concentration inequality:

$$\mathbf{E}[f(X)] \leq k - \sqrt{k \log k} \implies \mathbf{Pr}\left[f(X) \geq \mathbf{E}[f(X)] + \sqrt{k \log k}\right] \leq O\left(\frac{1}{k}\right). \tag{$**$}$$

We know (∗∗) is true when f is a sum over Bernoulli random variables by Chernoff bound, and it is tempting to use more powerful concentration inequalities to prove (∗∗) for general 1-Lipschitz f. Unfortunately, such a bound does not exist for general monotone and 1-Lipschitz set functions (see Section 5 for details), and it turns out to be impossible even for the specific f we use here, as Example 29 shown.

5 A Bicriterion Concentration Inequality

In this section, we assume the ground set $E = [n]$ and consider a function $f : \{0,1\}^n \to \mathbb{R}$ that satisfies the following properties:[8]

1. (**Monotone**) $f(\boldsymbol{x}) \leq f(\boldsymbol{y})$ for all $\boldsymbol{x}, \boldsymbol{y} \in \{0,1\}^n$ where $\boldsymbol{x} \leq \boldsymbol{y}$ (element-wise).
2. (**1-Lipschitz**) $|f(\boldsymbol{x}) - f(\boldsymbol{y})| \leq \|\boldsymbol{x} - \boldsymbol{y}\|_1$ for all $\boldsymbol{x}, \boldsymbol{y} \in \{0,1\}^n$.

Also, let $\boldsymbol{X} = (X_1, X_2, \ldots, X_n)$ be a vector of n independent Bernoulli random variables where $X_i \sim \mathrm{Ber}(p_i)$ for each $i \in [n]$ and $\boldsymbol{p} \in [0,1]^n$. For simplicity, we denote this as $\boldsymbol{X} \sim \mathrm{Ber}(\boldsymbol{p})$.

We are interested in how well $f(\boldsymbol{X})$ concentrates on its upper tail. By McDiarmid's inequality (Theorem 28), for every $t > 0$,

$$\mathbf{Pr}\left[f(\boldsymbol{X}) \geq \mathbf{E}[f(\boldsymbol{X})] + t\right] \leq e^{-\frac{2t^2}{n}},$$

Unfortunately, the bound depends on the dimension n, whereas our application in Section 4 requires a *dimension-free* bound that is independent from n. In fact, it is known that dimension-free concentration inequality does not exist for f in general (see, e.g., [27]).

The good news is that, for our application, it suffices to consider another $\boldsymbol{X'} \sim \mathrm{Ber}(\boldsymbol{p'})$ with slightly smaller parameters $\boldsymbol{p'} < \boldsymbol{p}$ and show $f(\boldsymbol{X'})$ does not exceed $\mathbf{E}[f(\boldsymbol{X})]$ by much, with high probability. Formally, we define $\boldsymbol{X}^{(s)}$ with a scaling factor s as follows:

▶ **Definition 20** (Scaling). *Given n independent Bernoulli random variables $\boldsymbol{X} \sim \mathrm{Ber}(\boldsymbol{p})$, for any* scaling factor *$s \geq 0$, define $\boldsymbol{X}^{(s)} \sim \mathrm{Ber}(e^{-s}\boldsymbol{p})$. In other words, $X_i^{(s)} \sim \mathrm{Ber}(e^{-s}p_i)$ for all $i \in [n]$.*

And we prove Theorem 3, a *bicriterion concentration inequality*, where the bound depends on both the scaling factor s and the deviation size t.

▶ **Theorem 3.** *Let $f : \{0,1\}^E \to \mathbb{R}$ be a monotone 1-Lipschitz function. For any $s \in (0,1]$, $t > 0$:*

$$\mathbf{Pr}\left[f(\boldsymbol{X}^{(s)}) \geq \mathbf{E}[f(\boldsymbol{X})] + t\right] \leq e^{-st}.$$

For our application in Section 4, we basically set $s = \sqrt{\frac{\log k}{k}}, t = \sqrt{k \log k}$ for some $k \approx \mathbf{E}[f(\boldsymbol{X})]$ and the inequality gives us $\mathbf{Pr}[f(\boldsymbol{X}^{(s)}) \geq k + \sqrt{k \log k}] \leq \frac{1}{k}$. Note that this bound is sharp up to a constant factor in the exponent: even in the case where $f(\boldsymbol{x}) = \sum_{i=1}^n x_i$, the Chernoff bound of $f(\boldsymbol{X}^{(s)})$ only yields $\mathbf{Pr}[f(\boldsymbol{X}^{(s)}) \geq k + \sqrt{k \log k}] \leq O(\frac{1}{k^c})$ for some constant c.

[8] Note that f can be equivalently viewed as a function over subsets of a ground set of size n, as we did in Section 4.

5.1 Technical overview

Before getting into the proof, let us first outline our approach and highlight the main difficulty. Our proof utilizes the entropy method for self-bounding functions [5, 6, 22, 7]. Roughly speaking, to prove a exponential concentration inequality for some $Z = f(\boldsymbol{X})$, the plan is to establish a differential inequality for the moment-generating function $\mathbf{E}[e^{\lambda Z}]$ based on the following modified logarithmic Sobolev inequality. If this differential inequality implies strong bounds for $\mathbf{E}[e^{\lambda Z}]$, a concentration inequality can be subsequently obtained.

▶ **Lemma 21** (A modified logarithmic Sobolev inequality [20])**.** *Given n independent Bernoulli random variables $\boldsymbol{X}$ and a function $f : \{0,1\}^n \to \mathbb{R}$. Let $Z = f(\boldsymbol{X})$ and $Z_i = f_i(X_1, \ldots, X_{i-1}, X_{i+1}, \ldots, X_n)$ for an arbitrary function $f_i : \{0,1\}^{n-1} \to \mathbb{R}$. For any $\lambda \in \mathbb{R}$,*

$$\lambda \mathbf{E}\left[Ze^{\lambda Z}\right] - \mathbf{E}\left[e^{\lambda Z}\right] \log \mathbf{E}\left[e^{\lambda Z}\right] \leq \sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z} \phi(-\lambda(Z - Z_i))\right]$$

where $\phi(x) = e^x - x - 1$.

Whether Lemma 21 can be effectively converted into a useful differential inequality for $\mathbf{E}[e^{\lambda Z}]$ depends on the choice of $\{Z_i\}_{i\in[n]}$. For a monotone function f, a typical choice is $Z_i = f(X_1, \ldots, X_{i-1}, 0, X_{i+1}, \ldots, X_n)$, and previous works have demonstrated that such a conversion is possible if f is 1-Lipschitz and the following condition holds almost surely for some constants $a, b \geq 0$: [9]

$$\sum_{i=1}^{n} Z - Z_i \leq aZ + b. \tag{†}$$

Now, given $Z^{(s)} = f(\boldsymbol{X}^{(s)})$ under a scaling factor $s > 0$, one might attempt to similarly derive a differential inequality of $\mathbf{E}[e^{\lambda Z^{(s)}}]$ based on Lemma 21 if the condition (†) can be satisfied. In fact, if we define $Z_i^{(s)} = f(X_1^{(s)}, \ldots, X_{i-1}^{(s)}, 0, X_{i+1}^{(s)}, \ldots, X_n^{(s)})$, the following holds:

$$\mathbf{E}\left[\sum_{i=1}^{n} Z^{(s)} - Z_i^{(s)}\right] = -\frac{\mathrm{d}}{\mathrm{d}s} \mathbf{E}\left[Z^{(s)}\right].$$

Thus, if $-\frac{\mathrm{d}}{\mathrm{d}s} \mathbf{E}[Z^{(s)}] \leq aZ^{(s)} + b$, then (†) holds in expectation for $Z^{(s)}$; otherwise, $E[Z^{(s)}]$ is decreasing rapidly with respect to s at that point.

As a result, either there exists some $s^* \in (0, s)$ such that (†) holds *in expectation* for $Z^{(s^*)}$, or $\mathbf{E}[Z^{(s)}]$ becomes significantly smaller than $\mathbf{E}[Z^{(0)}]$. Intuitively, the latter case should directly imply a bicriterion concentration result, leaving only the former case to be addressed.[10] However, it turns out that such a use of Lemma 21 crucially depends on (†) holding *almost surely*, which is not applicable to such $Z^{(s^*)}$ in the former case.[11]

Given this limitation, rather than working with moment-generating functions directly, we propose an alternative approach. Our key idea is to relate Lemma 21 with the following unconventional function, defined for every $\lambda \geq 0$:

$$F(\lambda) = \mathbf{E}\left[e^{\lambda Z^{(\lambda)}}\right].$$

---

[9] In this case, f is a so-called (a, b)-*self-bounding* function [22, 7].

[10] If we do not aim for an exponential tail bound, these observations indeed suffice to get a Chebyshev-type bicriterion concentration inequality for $Z^{(s)}$, by using Efron-Stein inequality to bound its variance in the former case.

[11] Specifically, applying the entropy method for $\mathbf{E}[e^{\lambda Z}]$ requires $\sum_{i=1}^{n} \mathbf{E}[e^{\lambda Z}(Z - Z_i)] \leq \mathbf{E}[e^{\lambda Z}(aZ + b)]$ for every λ, which might be false even if (†) holds with very high probability.

Note that this is not a moment-generating function, as λ here also serves as the scaling factor of Z, causing the random variable $Z^{(\lambda)}$ to change with it. Surprisingly, we can obtain the following upper bound for the derivative of $F(\lambda)$ that aligns well with Lemma 21.

▶ **Lemma 22.** *Given n independent Bernoulli random variables $\boldsymbol{X}$ and a monotone 1-Lipschitz function $f : \{0,1\}^n \to \mathbb{R}$. For any $\lambda \in (0,1]$,*

$$F'(\lambda) \le \mathbf{E}\left[Z^{(\lambda)} e^{\lambda Z^{(\lambda)}}\right] - \frac{1}{\lambda}\sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z^{(\lambda)}} \phi(-\lambda(Z^{(\lambda)} - Z_i^{(\lambda)}))\right]$$

where $Z^{(\lambda)} = f(\boldsymbol{X}^{(\lambda)})$, $Z_i^{(\lambda)} = f(X_1^{(\lambda)}, \ldots, X_{i-1}^{(\lambda)}, 0, X_{i+1}^{(\lambda)}, \ldots, X_n^{(\lambda)})$, and $F(\lambda) = \mathbf{E}[e^{\lambda Z^{(\lambda)}}]$.

By combining Lemma 22 with Lemma 21, we can conclude that for all $\lambda \in (0,1]$,

$$\lambda F'(\lambda) \le F(\lambda) \log F(\lambda).$$

Solving this differential inequality provides an upper bound for $F(\lambda)$. Theorem 3 then follows by applying Markov's inequality to the random variable $e^{sZ^{(s)}}$.

5.2 Proof of Theorem 3

Let $Z^{(\lambda)} = f(\boldsymbol{X}^{(\lambda)})$ and $Z_i^{(\lambda)} = f(X_1^{(\lambda)}, \ldots, X_{i-1}^{(\lambda)}, 0, X_{i+1}^{(\lambda)}, \ldots, X_n^{(\lambda)})$ throughout the proof. Given Lemma 21 and Lemma 22, it is not hard to show the bicriterion concentration inequality.

Proof of Theorem 3. For any $\lambda > 0$, we apply Lemma 21 to $Z^{(\lambda)}$ and $\{Z_i^{(\lambda)}\}_{i\in[n]}$ and obtain

$$\lambda \mathbf{E}\left[Z^{(\lambda)} e^{\lambda Z^{(\lambda)}}\right] - \mathbf{E}\left[e^{\lambda Z^{(\lambda)}}\right] \log \mathbf{E}\left[e^{\lambda Z^{(\lambda)}}\right] \le \sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z^{(\lambda)}} \phi(-\lambda(Z^{\lambda} - Z_i^{(\lambda)}))\right]$$

where $\phi(x) = e^x - x - 1$. Rearranging the inequality, we have

$$\lambda\left(\mathbf{E}\left[Z^{(\lambda)} e^{\lambda Z^{(\lambda)}}\right] - \frac{1}{\lambda}\sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z^{(\lambda)}} \phi(-\lambda(Z^{\lambda} - Z_i^{(\lambda)}))\right]\right) \le \mathbf{E}\left[e^{\lambda Z^{(\lambda)}}\right] \log \mathbf{E}\left[e^{\lambda Z^{(\lambda)}}\right].$$

Together with Lemma 22, this gives us the following differential inequality for $F(\lambda) = \mathbf{E}[e^{\lambda Z^{(\lambda)}}]$:

$$\lambda F'(\lambda) \le F(\lambda) \log F(\lambda), \quad \forall \lambda \in (0,1].$$

And by letting $G(\lambda) = \log F(\lambda)$, we can rewrite the inequality as

$$\lambda G'(\lambda) \le G(\lambda), \quad \forall \lambda \in (0,1].$$

Note that $G_0(\lambda) = \lambda \mathbf{E}[Z^{(0)}]$ is a solution to $\lambda G'(\lambda) = G(\lambda)$ for $\lambda \in (0,1]$. Define $g(\lambda) = \frac{G(\lambda) - G_0(\lambda)}{\lambda}$ and we have

$$g'(\lambda) = \frac{G'(\lambda) - G_0'(\lambda)}{\lambda} - \frac{G(\lambda) - G_0(\lambda)}{\lambda^2} = \frac{(\lambda G'(\lambda) - G(\lambda)) - (\lambda G_0'(\lambda) - G_0(\lambda))}{\lambda^2} \le 0.$$

Also note that $\lim_{\lambda\to 0^+} \frac{G(\lambda)}{\lambda} = G'(0) = \frac{F'(0)}{F(0)} = \mathbf{E}[Z^{(0)}]$ (where the last equality holds by Lemma 23), therefore $\lim_{\lambda\to 0^+} g(\lambda) = 0$. Combining this with $g' \le 0$, we conclude that g is non-positive on $(0,1]$. In other words, for $\lambda \in (0,1]$,

$$G(\lambda) \le G_0(\lambda) = \lambda \mathbf{E}[Z^{(0)}].$$

Finally, by Markov's inequality, we conclude that for any $\lambda \in (0,1]$ and $t > 0$,

$$\mathbf{Pr}\left[Z^{(\lambda)} \geq \mathbf{E}[Z^{(0)}] + t\right] = \mathbf{Pr}\left[e^{\lambda Z^{(\lambda)}} \geq e^{\lambda(\mathbf{E}[Z^{(0)}]+t)}\right] \leq \frac{\mathbf{E}[e^{\lambda Z^{(\lambda)}}]}{e^{\lambda(\mathbf{E}[Z^{(0)}]+t)}} \leq e^{-\lambda t}. \quad \blacktriangleleft$$

We are left to prove Lemma 22. Let us first compute $F'(\lambda)$ by definition.

▶ **Lemma 23.** *For any $\lambda \geq 0$, $F'(\lambda) = \mathbf{E}[Z^{(\lambda)} e^{\lambda Z^{(\lambda)}}] - \sum_{i=1}^{n} \mathbf{E}[e^{\lambda Z^{(\lambda)}} - e^{\lambda Z_i^{(\lambda)}}]$.*

Proof. Define a function $h : \mathbb{R} \times [0,1]^n \to \mathbb{R}$ as

$$h(t, \boldsymbol{q}) = \mathop{\mathbf{E}}_{\boldsymbol{Y} \sim \mathrm{Ber}(\boldsymbol{q})}\left[e^{tf(\boldsymbol{Y})}\right].$$

For each $i \in [n]$ and $b \in \{0,1\}$, denote $f_{i,b}(\boldsymbol{Y}) = f(Y_1, \ldots, Y_{i-1}, b, Y_{i+1}, \ldots, Y_n)$ and we can compute the partial derivative of h with respect to q_i as

$$\begin{aligned}\frac{\partial}{\partial q_i} h(t, \boldsymbol{q}) &= \frac{\partial}{\partial q_i}\left(q_i \mathop{\mathbf{E}}_{\boldsymbol{Y} \sim \mathrm{Ber}(\boldsymbol{q})}[e^{tf_{i,1}(\boldsymbol{Y})}] + (1 - q_i) \mathop{\mathbf{E}}_{\boldsymbol{Y} \sim \mathrm{Ber}(\boldsymbol{q})}[e^{tf_{i,0}(\boldsymbol{Y})}]\right) \\ &= \mathop{\mathbf{E}}_{\boldsymbol{Y} \sim \mathrm{Ber}(\boldsymbol{q})}[e^{tf_{i,1}(\boldsymbol{Y})} - e^{tf_{i,0}(\boldsymbol{Y})}].\end{aligned}$$

Recall that $\boldsymbol{X} \sim \mathrm{Ber}(\boldsymbol{p})$ and $F(\lambda) = \mathbf{E}[e^{\lambda Z^{(\lambda)}}] = h(\lambda, e^{-\lambda}\boldsymbol{p})$. Therefore,

$$\begin{aligned}F'(\lambda) &= \frac{\mathrm{d}t}{\mathrm{d}\lambda} \cdot \frac{\partial}{\partial t} h(\lambda, e^{-\lambda}\boldsymbol{p}) + \sum_{i=1}^{n} \frac{\mathrm{d}q_i}{\mathrm{d}\lambda} \cdot \frac{\partial}{\partial q_i} h(\lambda, e^{-\lambda}\boldsymbol{p}) \\ &= 1 \cdot \mathbf{E}\left[f(\boldsymbol{X}^{(\lambda)}) e^{\lambda f(\boldsymbol{X}^{(\lambda)})}\right] + \sum_{i=1}^{n} (-e^{-\lambda} p_i) \cdot \mathop{\mathbf{E}}_{\boldsymbol{Y} \sim \mathrm{Ber}(e^{-\lambda}\boldsymbol{p})}\left[e^{\lambda f_{i,1}(\boldsymbol{Y})} - e^{\lambda f_{i,0}(\boldsymbol{Y})}\right] \\ &= \mathbf{E}\left[f(\boldsymbol{X}^{(\lambda)}) e^{\lambda f(\boldsymbol{X}^{(\lambda)})}\right] - \sum_{i=1}^{n} \mathop{\mathbf{E}}_{\boldsymbol{Y} \sim \mathrm{Ber}(e^{-\lambda}\boldsymbol{p})}\left[e^{\lambda f(\boldsymbol{Y})} - e^{\lambda f_{i,0}(\boldsymbol{Y})}\right] \\ &= \mathbf{E}\left[Z^{(\lambda)} e^{\lambda Z^{(\lambda)}}\right] - \sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z^{(\lambda)}} - e^{\lambda Z_i^{(\lambda)}}\right]. \quad \blacktriangleleft\end{aligned}$$

Then we further derive a lower bound to the latter term, $\sum_{i=1}^{n} \mathbf{E}[e^{\lambda Z^{(\lambda)}} - e^{\lambda Z_i^{(\lambda)}}]$.

▶ **Lemma 24.** *For any $\lambda \geq 0$, $\sum_{i=1}^{n} \mathbf{E}[e^{\lambda Z^{(\lambda)}} - e^{\lambda Z_i^{(\lambda)}}] \geq \lambda e^{-\lambda} \sum_{i=1}^{n} \mathbf{E}[e^{\lambda Z^{(\lambda)}}(Z^{(\lambda)} - Z_i^{(\lambda)})]$.*

Proof. We prove the inequality for each term separately and without expectation. For any $i \in [n]$, note that

$$e^{\lambda Z^{(\lambda)}} - e^{\lambda Z_i^{(\lambda)}} = e^{\lambda Z_i^{(\lambda)}}(e^{\lambda(Z^{(\lambda)} - Z_i^{(\lambda)})} - 1) \geq e^{\lambda Z_i^{(\lambda)}} \cdot \lambda(Z^{(\lambda)} - Z_i^{(\lambda)})$$

since $e^x - 1 \geq x$. Meanwhile, we know $Z_i^{(\lambda)} \geq Z^{(\lambda)} - 1$ by 1-Lipschitzness of f. Therefore,

$$e^{\lambda Z^{(\lambda)}} - e^{\lambda Z_i^{(\lambda)}} \geq \lambda e^{-\lambda} \cdot e^{\lambda Z^{(\lambda)}}(Z^{(\lambda)} - Z_i^{(\lambda)}). \quad \blacktriangleleft$$

The following two facts of the function $\phi(x) = e^x - x - 1$ will also be used.

▶ **Fact 25.** *For any $\lambda \in (0,1]$, $\frac{\phi(-\lambda)}{\lambda} \leq \lambda e^{-\lambda}$.*

▶ **Fact 26.** *For any $\lambda \in \mathbb{R}$ and $x \in [0,1]$, $\phi(-\lambda x) \leq \phi(-\lambda)x$.*

Now we are ready to prove the lemma.

Proof of Lemma 22. We upper bound $F'(\lambda)$ step-by-step as follows:

$$F'(\lambda) = \mathbf{E}[Z^{(\lambda)}e^{\lambda Z^{(\lambda)}}] - \sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z^{(\lambda)}} - e^{\lambda Z_i^{(\lambda)}}\right] \qquad \text{(Lemma 23)}$$

$$\leq \mathbf{E}[Z^{(\lambda)}e^{\lambda Z^{(\lambda)}}] - \lambda e^{-\lambda} \sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z^{(\lambda)}}(Z^{(\lambda)} - Z_i^{(\lambda)})\right] \qquad \text{(Lemma 24)}$$

$$\leq \mathbf{E}[Z^{(\lambda)}e^{\lambda Z^{(\lambda)}}] - \frac{\phi(-\lambda)}{\lambda} \sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z^{(\lambda)}}(Z^{(\lambda)} - Z_i^{(\lambda)})\right] \qquad \text{(Fact 25)}$$

$$\leq \mathbf{E}[Z^{(\lambda)}e^{\lambda Z^{(\lambda)}}] - \frac{1}{\lambda} \sum_{i=1}^{n} \mathbf{E}\left[e^{\lambda Z^{(\lambda)}}\phi(-\lambda(Z^{(\lambda)} - Z_i^{(\lambda)}))\right] \qquad \text{(Fact 26)}$$

where in the last step we also use the fact that $Z^{(\lambda)} - Z_i^{(\lambda)} \in [0, 1]$, as f is monotone and 1-Lipschitz. ◀

A Useful Concentration Inequalities

▶ **Theorem 27** (Multiplicative Chernoff bound). *Given n independent Bernoulli random variables $X_1, X_2, \ldots, X_n$, let $X = \sum_{i=1}^{n} X_i$ denote their sum. For any $\delta > 0$, we have*

$$\mathbf{Pr}[X \geq (1+\delta)\,\mathbf{E}[X]] \leq \exp\left(-\frac{\delta^2\,\mathbf{E}[X]}{2+\delta}\right).$$

▶ **Theorem 28** (McDiarmid's inequality). *Given n independent random variables $X_1, X_2, \ldots, X_n \in \mathcal{X}$ and a function $f : \mathcal{X}^n \to \mathbb{R}$. If for every $i \in [n]$ and $x_1, x_2, \ldots, x_n, x_i' \in \mathcal{X}$, the function f satisfies*

$$|f(x_1, \ldots, x_{i-1}, x_i, x_{i+1}, \ldots, x_n) - f(x_1, \ldots, x_{i-1}, x_i', x_{i+1}, \ldots, x_n)| \leq c_i,$$

then for any $t > 0$, we have

$$\mathbf{Pr}[f(X) \geq \mathbf{E}[f(X)] + t] \leq \exp\left(-\frac{2t^2}{\sum_{i=1}^{n} c_i^2}\right).$$

B Missing Proofs and Examples

Proof of Lemma 13. It is straightforward to check $\mathcal{M}_*$ in Definition 12 is a matroid, and hence its k-fold union $\mathcal{M}_*^k$ remains a matroid by the closure property of matroid union. Also, note that the restriction of $\mathcal{M}_*^k$ to $E \times \{1\}$, $\mathcal{M}_*^k\,|_{E\times\{1\}}$, is isomorphic to the k-fold union $\mathcal{M}^k$ of $\mathcal{M}$, as there exists a simple bijection $(e, 1) \mapsto e$ between $E \times \{1\}, \mathcal{I}_*|_{E\times\{1\}}$ and $E, \mathcal{I}$. Therefore, an α-selectable OCRS for $\mathcal{M}_*^k$ can also be used as an α-selectable OCRS for $\mathcal{M}^k$. ◀

Proof of Lemma 15. Note that the rank function for any matroid is a submodular function. Therefore, $\mathrm{rank}(S \cup (\{e\} \times [k])) - \mathrm{rank}(S) \geq \mathrm{rank}(T \cup (\{e\} \times [k])) - \mathrm{rank}(T)$ for every $S \subseteq T$ by a simple induction, and thus $\omega_e(\cdot)$ is monotone.

Also, we know the rank function is monotone, and the rank of a set can increase by at most 1 after adding an element. Therefore, $\mathrm{rank}(S \cup \{a\}) \geq \mathrm{rank}(S)$ and $\mathrm{rank}(S \cup \{a\} \cup (\{e\} \times [k])) \leq \mathrm{rank}(S \cup (\{e\} \times [k])) + 1$ for every $a \in E_*$ and $S \subseteq E_*$. As a result, $\omega_e(\cdot)$ is 1-Lipschitz. ◀

Proof of Lemma 16. When $\omega_e(S) < k$, we have $\mathrm{rank}(S \cup (\{e\} \times [k])) > \mathrm{rank}(S)$ and there exists (at least) one element $(e, j) \in \{e\} \times [k]$ such that $(e, j) \notin \mathrm{span}(S)$. By definition of extended k-fold union, it further implies $(e, i) \notin \mathrm{span}(S \setminus \{(e, i)\})$. ◀

Proof of Lemma 18. It is straightforward to see $S = S_0 \times [k]$ when the algorithm terminates, and thus $\mathcal{M}_*^k|_{S_0\times[k]}$ is the extended k-fold union of $\mathcal{M}|_{S_0}$ by definition. It remains to prove $S \subsetneq E_*$. Since S must be a subset of the universe E_*, it suffices to show $S \neq E_*$. Our plan is to show that S is not full rank in $\mathcal{M}_*^k$, even after combined with all active elements $R(\boldsymbol{x}_*)$ and take the expectation, i.e.,

$$\mathbf{E}[\mathrm{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup S)] < \mathrm{rank}_{\mathcal{M}_*^k}(E_*).$$

This would directly imply $S \neq E_*$ by the monotonicity of the rank function.

Denote $r = \mathrm{rank}_{\mathcal{M}}(S_0)$. Let $e_1, e_2, \ldots, e_r \in S_0$ be the elements from $\mathcal{M}$ that increase the rank of S_0 in $\mathcal{M}$ during the execution of Algorithm 3, and denote e_i (for $1 \leq i \leq r$) as the specific element that increases $\mathrm{rank}_{\mathcal{M}}(S_0)$ from $i-1$ to i. By definition, $\mathrm{span}_{\mathcal{M}}(\{e_1, e_2, \ldots, e_r\}) = S_0$. In fact, we also have

$$\mathrm{span}_{\mathcal{M}_*^k}(\{e_1, e_2 \ldots, e_r\} \times [k]) = S.$$

This is because $\{e_1, e_2, \ldots, e_r\} \times [k] \subseteq S$ is an independent set of size kr in $\mathcal{M}_*^k$ by definition of the extended k-fold union, and we can further show it is a basis of S. Suppose it is not, then there must be another independent set $T \subseteq S$ of size larger than kr. Since one can partition T into k disjoint independent sets $T_1, T_2, \ldots, T_k$ in $\mathcal{M}_*$ where $\sum_{j\in[k]} |T_j| > kr$, we know there exists some T_j of size larger than r, which leads to a contradiction as $T_j \subseteq S_0 \times [k]$ and $\operatorname{rank}_{\mathcal{M}_*}(S_0 \times [k]) = r$.

Also, by the way the algorithm picks elements to be added to S_0, for every $1 \le i \le r$ we have

$$\mathbf{E}[\omega_{e_i}(R(\boldsymbol{x}_*) \cup (\{e_1, e_2, \ldots, e_{i-1}\} \times [k]))] > bk.$$

Equivalently, we have

$$\mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup (\{e_1, e_2, \ldots, e_i\} \times [k])) - \operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup (\{e_1, e_2, \ldots, e_{i-1}\} \times [k]))] < (1-b)k.$$

Together with these observations, we can upper bound $\mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup S)]$ by a telescoping sum as follows:

$$\begin{aligned}
\mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup S)] &= \mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup \{e_1, e_2, \ldots, e_r\} \times [k])] \\
&= \mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*))] + \sum_{i=1}^{r} \mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup (\{e_1, e_2, \ldots, e_i\} \times [k])) \\
&\qquad - \operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup (\{e_1, e_2, \ldots, e_{i-1}\}) \times [k])] \\
&< \mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*))] + (1-b)kr.
\end{aligned}$$

The former term $\mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*))]$ can be trivially upper bounded by $\mathbf{E}[|R(\boldsymbol{x}_*)|]$ and further by $b \operatorname{rank}_{\mathcal{M}_*^k}(E_*)$ due to $\boldsymbol{x}_* \in b \cdot \mathcal{P}_{\mathcal{M}_*^k}$. For the latter term involving kr, we already know $kr = \operatorname{rank}_{\mathcal{M}_*^k}(S) \le \operatorname{rank}_{\mathcal{M}_*^k}(E_*)$. In conclusion, we have

$$\mathbf{E}[\operatorname{rank}_{\mathcal{M}_*^k}(R(\boldsymbol{x}_*) \cup S)] < b \operatorname{rank}_{\mathcal{M}_*^k}(E_*) + (1-b) \operatorname{rank}_{\mathcal{M}_*^k}(E_*) = \operatorname{rank}_{\mathcal{M}_*^k}(E_*). \qquad \blacktriangleleft$$

▶ **Example 29** (A counterexample to $(**)$)**.** Fix parameters n, k where $n \gg k$, and consider the case when $\mathcal{M}$ is an n-uniform matroid of size $2n$. Its extended k-fold union $\mathcal{M}_*^k$ is a kn-uniform matroid of size $2kn$. Similar to Example 17, for every $e \in E$ and $S \subseteq E_*$ we can derive

$$\omega_e(S) = \begin{cases} 0, & |S| \le kn - k \\ |S| - (kn-k), & kn - k < |S| < kn \\ k, & |S| \ge kn. \end{cases}$$

Since no protection is needed for uniform matroids, let $f(\cdot) = \omega_e(\cdot)$ for some fixed $e \in E$. When $\boldsymbol{x}_* = (\frac{1}{2} - \frac{1}{2n}) \cdot \mathbf{1}_{E_*}$ (namely, every element in E_* is active with probability $\frac{1}{2} - \frac{1}{2n}$), $|X|$ will follow a binomial distribution with $kn - k$ as both its mean and median. As a result,

$$\mathbf{E}[f(X)] \le k \, \mathbf{Pr}[f(X) > 0] = k \, \mathbf{Pr}[|X| > kn - k] \le \frac{k}{2},$$

$$\text{while} \quad \mathbf{Pr}[f(X) \ge k] = \mathbf{Pr}[|X| \ge kn] \ge \Omega(1), \qquad (n \gg k)$$

which is a counterexample to the claim $(**)$.

Note that this is not an actual counterexample to Algorithm 4 (even without the extra scaling) since $\boldsymbol{x}_* \notin (1 - O(\sqrt{\frac{\log k}{k}})) \cdot \mathcal{P}_{\mathcal{M}_*^k}$. But it shows that the condition $\mathbf{E}[f(X)] \le k - O(\sqrt{k \log k})$ alone is not enough to derive a good enough upper bound for $\mathbf{Pr}[f(X) \ge k]$, and it is crucial to also rely on the scaling applied to $\boldsymbol{x}_*$.

Edge-Minimum Walk of Modular Length in Polynomial Time

Abstract

We study the problem of finding, in a directed graph, an *st*-walk of length r mod q which is edge-minimum, i.e., uses the smallest number of *distinct* edges. Despite the vast literature on paths and cycles with modularity constraints, to the best of our knowledge we are the first to study this problem. Our main result is a polynomial-time algorithm that solves this task when r and q are constants.

We also show how our proof technique gives an algorithm to solve a generalization of the well-known Directed Steiner Network problem, in which connections between endpoint pairs are required to satisfy modularity constraints on their length. Our algorithm is polynomial when the number of endpoint pairs and the modularity constraints on the pairs are constants.

In this version of the article, proofs and examples are omitted because of space constraints. Detailed proofs are available in the full version [3].

1 Introduction

We begin with a simple question: Given an n-vertex, m-edge directed graph G and terminals s,t, can we efficiently find an odd-length *st*-walk that is "edge-minimum", i.e., has the minimum number of *distinct* edges? This question may appear similar to classical problems from the vast literature on paths and cycles with parity constraints. For instance, one may think of the classical "shortest odd *st*-path" problem, which is well-known to be NP-hard (this is via a simple reduction from the 2-disjoint paths problem of [19], and can be proved in the same way as [37, Proposition 2.1]). However, this hardness result only applies to *simple paths*, whereas the edge-minimum odd *st*-walk may not be a simple path. One may also think of the "shortest odd *st*-walk" problem (i.e., minimizing the length), which is well-known to

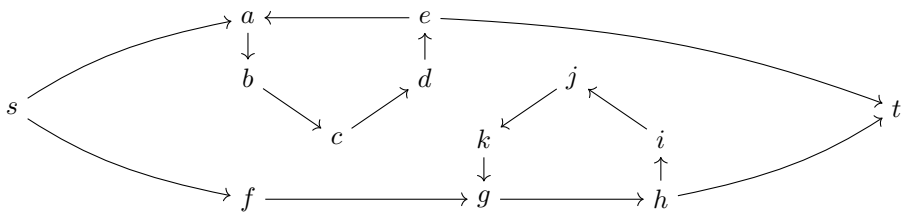

Figure 1 An example of a graph with different answers to the problems of finding the edge-minimum odd st-walk, the shortest odd st-walk, and the shortest odd simple st-path. First, every simple path from s to t is of even length, so there is no shortest odd st-path. Second, the *shortest* odd st-walk uses the bottom cycle $s, f, g, h, i, j, k, g, h, t$: it has length 9 and uses 8 distinct edges. Third, the *edge-minimum* odd st-walk uses the top cycle: $s, a, b, c, d, e, a, b, c, d, e, t$. It has length 11 but uses only 7 distinct edges.

be in polynomial time[1]. However, the *edge-minimum* odd st-walk may be *longer* than the *shortest* odd st-walk while using *fewer distinct edges*. See Figure 1 for an example of a graph in which the solutions to all three of these problems is different.

The focus of this paper is the *Edge-Minimum Walk of Modular Length* problem, which is the above problem generalized to an arbitrary modularity q and remainder r. Let us define it formally:

Edge-Minimum Walk of Modular Length (EWM):
Input: An unweighted directed[2] graph G, terminals s,t, and non-negative integers $r < q$.
Output: An st-walk of length r mod q which is edge-minimum, i.e., uses the minimum number of distinct edges (or $\emptyset$ if no such walk exists).

We stress that the modularity constraint does not apply to the number of distinct edges, but only to the length of the walk. We are most interested in the regime where q, and hence r, are constants; our algorithms will work without this assumption, but they achieve worse complexities.

Despite the vast literature on paths and cycles of given modularities [31, 26, 37, 36, 39, 27, 4, 38, 10, 41, 34, 32, 29, 40, 24, 1, 35, 6, 25, 14, 16, 7, 23] (see [2] for a survey), to the best of our knowledge we are the first to study the EWM problem.

EWM can also be viewed as a problem in the field of *network design*. Network design problems ask questions of the form "find an edge-minimum subgraph with a certain property". Famous network design problems include, for instance, Minimum Spanning Tree, Traveling Salesperson, and st-Shortest Path. We can give an equivalent rephrasing of EWM in this way: find an edge-minimum subgraph that contains an st-walk of length r mod q. The network design problem most related to EWM is the Directed Steiner Network problem (DSN) [17, 18, 8, 20, 15, 9, 33, 21, 13]. In DSN, the input is a directed graph G and a set of k terminal pairs $(s_1,t_1),\ldots,(s_k,t_k)$; the goal is to find an edge-minimum subgraph that

[1] Make two copies of the vertex set, and for every edge $u \to v$ in the original graph, add the edges $u_1 \to v_2$ and $u_2 \to v_1$. Then find the shortest walk from s_1 to t_2. This also trivially generalizes to modularities which are polynomial in n.

[2] One could also ask this question on an undirected graph. However, in this case, one unnatural aspect of the problem is that one can always traverse the same edge back and forth over and over to add any multiple of 2 to the path length. We use this observation to show in the full version [3] that EWM on undirected graphs reduces to EWM on directed graphs.

contains a path $s_i \to t_i$ for all terminal pairs. When k is arbitrary, DSN generalizes Directed Steiner Tree and is therefore NP-hard. When k is constant, Feldman and Ruhl [17] showed that DSN can be solved in polynomial time. In fact, we show in Section 8 that, in the special case where the set of terminal pairs is strongly connected, the DSN problem with constant k can be directly expressed as a special case of EWM with constant q. As a consequence, our main result will imply, as a byproduct, the known result that this special case of DSN is in polynomial time for constant k [17] (albeit with a larger exponent). We also study a problem generalizing both EWM and DSN and give an algorithm that subsumes the tractability of both problems, as we will explain later in the introduction.

EWM is also related to problems from database theory, in particular the evaluation of *regular path queries* (RPQs) on graph databases. More precisely, a graph database is a graph whose edges are labeled with symbols from a fixed alphabet, and an RPQ is a regular expression e over the alphabet. The results of the RPQ are vertex pairs (s, t) such that there is a walk from s to t (or sometimes a simple path or a trail, depending on the variant) whose edge labels from a word that matches e (see e.g. [12, 11, 5, 28]). In particular, RPQs of the form $a^r(a^q)^*$ express walks of length r mod q for constant r and q. The EWM problem then corresponds to the *smallest witness problem* [30, 22] for such queries, which is the problem of finding a sub-database of minimum size that satisfies the query. However, to the best of our knowledge there is no prior work on the smallest witness problem for RPQs enforcing modularity conditions, or indeed for RPQs in general: our work can be seen as a first step towards addressing this problem.

Our results. What is the complexity of EWM for constant q? It is unclear a priori; EWM is related to both polynomial-time solvable problems such as Shortest Modular-Length st-Walk and Directed Steiner Network, as well as NP-hard problems such as Shortest Modular-Length st-Path. Our main result is that EWM is in polynomial time for constant q:

▶ **Theorem 1.1.** *There is an algorithm solving EWM in time:* $n^{O(\log q)} \cdot 2^{O(q \log^2 q)}$.

Specifically, the exponent of n in Theorem 1.1 has reasonable constants: $7 + 3\log_2 q$, though we did not focus on optimizing them.

Generalizations. A natural generalization of EWM is to consider weighted graphs. EWM admits two natural notions of weights: (1) each edge has a *length*, and the length of a walk is the sum of the lengths of the edges, and (2) each edge (or vertex) has a *cost* and the edge-minimum walk is measured in terms of the sum of the costs of the edges (or vertices) that it traverses. We show in Section 7 that our algorithm extends to accommodate costs, and that it can also accommodate lengths provided that their values are polynomial. In the case where lengths and the value q are super-polynomial, we show that the problem is NP-complete by reduction from Subset Sum.

Inspired by Directed Steiner Network, we also extend our results in Section 8 from one walk to multiple walks. The input is a directed graph G, and k endpoint pairs along with modularity constraints: $(s_1, t_1, q_1, r_1), \ldots, (s_k, t_k, q_k, r_k)$, and the goal is to find an edge-minimum subgraph that contains a walk from s_i to t_i of length r_i mod q_i, for all i. Generalizing our main result, we show (Theorem 8.4) that this problem, which subsumes the DSN and EWM problems, also admits a polynomial-time algorithm for constant q_i values and a constant number k of endpoint pairs. Our approach to show the result focuses on the case of strongly connected solutions (in line with the connection to DSN mentioned earlier), before extending the proof to arbitrary solutions by re-using lemmas from [18].

2 Technical Overview

Our work is related to the Directed Steiner Network (DSN) problem studied by Feldman and Ruhl [17], where we must find an edge-minimum subgraph of the input directed graph which satisfies connectivity requirements. Their work shows that the DSN problem is tractable when the number of endpoint pairs in the connectivity requirements is constant. Following their work, Feldmann and Marx [18] have investigated the parameterized complexity of the DSN problem. One key idea of their approach is to show bounds on the *cutwidth* of solutions to the DSN problem. Informally, cutwidth is a parameter that limits how many edges are "cut" when arranging vertices in a well-chosen order $<$. Bounding the cutwidth of a graph ensures that we can go over vertices in the order of $<$ and that, at any cut along $<$, all edges except a constant number will be entirely to one side of the cut. (See Section 3 for the formal definition of cutwidth.)

Feldmann and Marx show that when the number of endpoint pairs is bounded by a constant k, then DSN instances always have a solution of constant *undirected* cutwidth (depending only on k). They further show that bounded-cutwidth solutions can be computed in polynomial time by dynamic programming. We follow the same framework and show that solutions to EWM also have bounded cutwidth. Then we can find the solution by an approach similar to the dynamic programming algorithm of [18], or to the token game of [17].

Thus, our main goal is to solve the purely structural problem of bounding the cutwidth of edge-minimum st-walks of length $r \bmod q$ in arbitrary directed graphs. We only focus on this goal in the rest of the technical overview. To provide intuition, we will begin by considering the case of $q = 2$, $r = 1$ (i.e. odd walks), and then outline the obstacles that arise when generalizing to arbitrary q, r.

Odd walks. Let w denote an edge-minimum odd-length st-walk, and let G_w be the subgraph of G consisting of the union of edges in the walk w. We first observe that, without loss of generality, w does not contain any even cycles: If w contained an even cycle, we could simply delete it, and w would still be of odd length, and still be edge-minimum. (To clarify, we are not referring to even cycles in G_w, but rather even cycles in the walk w itself. After deleting a cycle C from w, edges from C can still appear in G_w if they are traversed at another point of the walk w.)

Now suppose w contains two odd cycles in succession. Again, we could simply delete both cycles, and w would still be of odd length, and still be edge-minimum. So, we can suppose without loss of generality that w has either no cycles (and trivially has small cutwidth), or consists of a simple path P_1, followed by an odd cycle C, followed by a simple path P_2. We assume this latter case in the rest of the discussion, and we define C by looking at first time that the walk re-visits a previously visited vertex: this ensures that, by construction, P_1 is vertex-disjoint from C. However, the graph does not necessarily have small cutwidth, because P_2 could intersect P_1 and C in intricate ways forming an unbounded number of nested cycles. It is a priori conceivable that, e.g., a grid-like structure with high cutwidth could emerge. However, we can show that this does not happen.

First, we can observe that once P_2 leaves C, without loss of generality it does not return. This is because if P_2 leaves C at vertex a and then returns at vertex b, we can delete the subpath of P_2 from a to b, and instead traverse only the edges of C to get from a to b. This way, we can still ensure that w is of odd length since every traversal of C changes the parity of w, and we can traverse C for "free" without adding any extra edges.

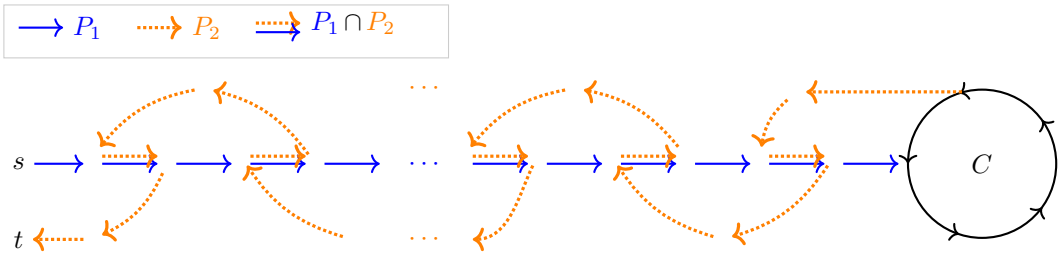

Figure 2 Specific shape of solutions to EWM for $q = 2$. Each "edge" in the figure represents a subpath, not necessarily a single edge. The cycle C is of odd length.

Finally, we consider how P_1 and P_2 can interact. We can observe that without loss of generality P_2 cannot hit a vertex a on P_1, then leave P_1, then return to a *later* vertex b on P_1. In this case we could delete the subpath of P_2 from a to b, and instead traverse P_1 to get from a to b. Again, we can still ensure that w is of odd length since we can always traverse C for free to change the parity of w. We stress that this argument only holds when P_2 re-enters P_1 at a *later* vertex, and in fact, P_2 can re-enter P_1 at an *earlier* vertex an unbounded number of times.

With all of these observations in mind, we conclude that if w has a cycle, then w must have the very specific structure depicted in Figure 2. Then, it is visually clear that any vertical cut only has a constant number of crossing edges, and thus w has constant cutwidth.

This concludes the outline for the case of odd walks. The same argument holds for even walks, and more generally an argument for a particular choice of constants q, r is easily extendable by reduction to other constant values r' with the same q, simply by adding a new source connected to the original source by a path of constant length $r' - r \bmod q$. The challenging part is extending to arbitrary q. Our approach is to define a *segment decomposition* of the walk and prove that each successive segment allows us to expand the reachable set of remainder values, so that the number of segments is bounded as a function of q (Lemma 4.3). We then show that the cutwidth of a walk can be bounded linearly in its number of segments (Proposition 5.1): we do this by defining a suitable ordering of the vertices following the *chunks* of the walk, which refine the segments in the decomposition. These two results imply that solutions to EWM have bounded cutwidth and hence that they can be found in polynomial time.

3 Preliminaries

In this section, we present preliminary notions used throughout the proof of our main result (Theorem 1.1).

Basic definitions. All graphs in the paper are finite and directed. Graphs are not necessarily simple; they may contain self-loops, but they do not contain multi-edges. Given a directed graph $G = (V, E)$, a *walk* w in G is a sequence of edges $w[1], \ldots, w[\ell]$ such that the target vertex of $w[i]$ is equal to the source vertex of $w[i+1]$ for each $1 \leq i < \ell$. Note that an edge e of G may occur at several positions in G: considering a position i for which $w[i] = e$, we write $w[i]$ to refer to that occurrence of e at the i-th position of w. However, when convenient we abuse notation and identify $w[i]$ with e itself; e.g., we talk about the source and target vertices of $w[i]$ to mean those of e. For $1 \leq i \leq \ell$ we call $w[i]$ a *first-visited* edge occurrence if it is the first occurrence of some edge e, i.e., if there is no $j < i$ such that $w[j] = w[i]$. Otherwise, $w[i]$ is a *revisited* edge. Of course, each edge that occurs in w is first-visited at exactly one position.

The *source vertex* s of w is that of $w[1]$, and its *target vertex* t is that of $w[\ell]$: we then call w an *st-walk*. The *length* $|w|$ of w is ℓ. The *set of vertices used by* w, denoted V_w, is simply the set of vertices that occur in w, i.e., occur in some edge of w; in particular the source and target vertices of w are in V_w. The *set of edges used by* w is $E_w := \{w[i] \mid 1 \leq i < \ell\}$. The *subgraph spanned by* w is $G_w = (V_w, E_w)$. Note that G_w is *not* the subgraph induced by V_w, as it only contains the edges that actually occur on the walk. A *subwalk* of w is a contiguous subsequence of w. We denote subwalks of w with the slicing convention, i.e., $w[: i] = w[1] \dots w[i]$ and $w[i : j] = w[i] \dots w[j]$. Note that the right endpoint is included so that, e.g., $w[i : j]$ is empty precisely when $j < i$, and $w[: i]$ is empty precisely when $i \leq 0$. When u and v are walks and when the target vertex of u is the source vertex of v, we write uv to mean the walk obtained by concatenating u and v: it admits u and v as subwalks, and of course $|uv| = |u| + |v|$.

For convenience, throughout the paper we denote by $G_{w,i}$ the graph $G_{w[:i]}$ spanned by the subwalk $w[: i]$ (up to i included); by convention $G_{w,0}$ is always the graph with the single vertex s and no edges.

Strongly connected components. A *strongly connected component* (SCC) of a graph G is a maximal set of vertices C of G such that, for any two distinct vertices $u, v \in C$, there is a directed path from u to v in G. As usual, belonging to the same SCC is an equivalence relation, so that SCCs form a partition of the vertices of G. We say that an SCC C of G is *non-trivial* if the subgraph of G induced by C contains at least one edge. This is the case if and only if C contains more than one vertex, or contains a single vertex on which there is a self-loop.

EWM and solutions. We study the *Edge-Minimum Walk of Modular Length* problem (EWM), as defined in the introduction: given a directed graph $G = (V, E)$, terminals s,t, and non-negative integers $r < q$, we wish to compute a subset E' of E such that (V, E') has an st-walk of $r \bmod q$ and E' is edge-minimum (i.e., the number of edges of G' is minimum). This phrasing is somewhat different from the one given in the introduction, in which we wanted to compute an edge-minimum walk. However, we can easily compute an edge-minimum walk from E' by a product construction, in time $O(|E'| \times q)$.

In the sequel, we only consider the computation of edge-minimum subsets of edges (rather than walks). When fixing inputs $G = (V, E)$, s, t, q, and r, we talk about a *candidate solution* to mean a subset E' of E such that (V, E') has an st-walk of length $r \bmod q$ but E' is not necessarily edge-minimum, and of an *optimal solution* to mean a candidate solution which is additionally edge-minimum.

Cutwidth. The *cutwidth* is a structural parameter of graphs. We show that there always exists an optimal solution to EWM with bounded cutwidth, which suffices to ensure that such solutions can be found with an efficient algorithm. We first recall the definition of cutwidth for undirected graphs. Let $G = (V, E)$ be an undirected graph. An *ordering* of G is a total order over the vertex set V of G. A *cut* (V_-, V_+) of G that respects the ordering $<$ is a partition $V_- \uplus V_+ = V$ such that $v_- < v_+$ for all $(v_-, v_+) \in V_- \times V_+$. We say that an edge e of G *crosses the cut* if it has one endpoint in V_- and one in V_+, i.e., $e \cap V_-$ and $e \cap V_+$ are both nonempty. Note that self-loops never cross cuts. The *cutwidth* of a cut (V_-, V_+) that respects $<$ is the number of edges that cross this cut, and the *cutwidth* of $<$ is the maximum cutwidth of a cut that respects $<$. The *cutwidth* of G is then the minimum cutwidth of an ordering of V.

We now define cutwidth for directed graphs. Let $G = (V, E)$ be a directed graph. Its *underlying undirected graph* is $G' = (V, E')$ where $E' = \{\{u, v\} \mid (u, v) \in E, u \neq v\}$: note that self-loops are not reflected in G'. We then define the *cutwidth* of G to be that of G'. We underscore that our definition of cutwidth for directed graphs is always the undirected cutwidth: we do not consider the directed cutwidth in this paper. We then define the *cutwidth* of a walk w of G as the cutwidth of the directed graph G_w.

4 Segment Decomposition of a Walk

Our proof of our main theorem (Theorem 1.1) consists of three steps, spanning this section and the next two sections. First, in this section we introduce the notion of the *segment decomposition* of a walk, and we show that any walk w can be transformed into a walk w' that satisfies the same modularity conditions (i.e., has the same remainder modulo q), uses a subset of the edges (i.e., $E_{w'} \subseteq E_w$), and has a segment decomposition with $O(\log q)$ segments. Second, in the next section, we will show how the cutwidth of the graph $G_{w'}$ spanned by w' can be bounded linearly in this number of segments, implying that optimal solutions to EWM have bounded cutwidth. Third, in Section 6, we show that this cutwidth bound makes it possible to solve EWM in polynomial time.

Segment decomposition. Let w be a walk. Its *segment decomposition* is a sequence of walks $s_1, \ldots, s_\xi$ such that $w = s_1 \cdots s_\xi$; the number ξ is the *number of segments* of w. The segment decomposition is defined by processing the walk w from left to right as follows. Initially, the segment decomposition is the empty sequence, and the entire walk w remains to be decomposed. At any point of the decomposition, we have already computed the first σ segments $s_1, \ldots, s_\sigma$ for some number $\sigma \geq 0$ of segments, and can write $w = s_1 \cdots s_\sigma w'$. If w' is non-empty, we compute the next segment as a prefix of w'.

Informally, we read w' and terminate the segment whenever we have a first-visited edge $w'[j] = (u, v)$ followed (not necessarily immediately) by an edge $w'[k] = (x, y)$ where y can be reached by a path from u using only edges of w up to $w'[j]$ excluded. The intuition of segments is that they capture a moment where the walk revisits a vertex y from a vertex u via a path that starts with an edge $e = (u, v)$ which had not been previously visited in w, even while there was already a path from u to y in the graph spanned by the walk before e was visited. Formally, we will look for the *segment end* inside the suffix w' of w, according to the following definition:

▶ **Definition 4.1** (Segment end, Segment detour). *Having fixed $w = s_1 \cdots s_\sigma w'$, let $\lambda_\sigma = |s_1 \cdots s_\sigma| = |w| - |w'|$ be the total length of the already-computed segments. For $\lambda_\sigma < k \leq |w|$, we say that segment $s_{\sigma+1}$* ends at *k if k is minimum such that the following hold:*

- *There is $\lambda_\sigma < j \leq k$ such that $w[j]$ is first-visited in w; we write $w[j]$ as (u, v);*
- *Writing the edge $w[k]$ as (x, y), then there is a path from u to y in the graph $G_{w,j-1}$ which contains the edges of the walk w up to $w[j]$ excluded. Note that, in particular, if $u = y$ then this requirement is always satisfied using the empty path from u to y.*

We stress that the path from u to y required by the second item of the definition is a path in the graph spanned *by a certain prefix of w; it may be the case that the path does not occur as a subwalk of w. As for the subwalk $w[j : k]$ from u to y in w, which is a subwalk of w', we call it the* segment detour *of $s_{\sigma+1}$, denoted $\det_{\sigma+1}$. Note that, having chosen the minimal k, there could be multiple valid choices for j, and we pick one arbitrarily.*

Given the definition of a segment end above, the next segment of the decomposition after s_σ is simply $s_{\sigma+1} := w[\lambda_\sigma + 1 : k]$. This means that we terminate the $(\sigma+1)$-th segment right after the edge $w[k]$, and continue the decomposition if $s_1 \cdots s_{\sigma+1}$ does not yet cover the entire walk w. If there is no segment end at any k, then we take all the rest of the walk w' to be the last segment of the decomposition and we finish. Note that for this reason, unlike other segments, the last segment of the decomposition may not feature a segment detour.

Let us formalize which paths are known to exist at the moment when a segment ends:

▶ **Lemma 4.2.** *Let w be a walk and let $w[i:k] = s_\sigma$ be the σ-th segment of the walk. Let y be the ending vertex of $w[i:k]$, and assume that $k < |w|$, i.e., the segment finishes before the end of the walk. Let $w[j] = (u, v)$ in $w[i:k]$ be the first edge of the segment detour $\det_\sigma$. There is:*

- *the segment detour $\det_\sigma$ from u to y in $G_{w,k}$*
- *a path p_σ from u to y in $G_{w,j-1}$.*
- *a path $\overline{p_\sigma}$ from y to u in $G_{w,j-1}$.*

Notice that we may have $y = u$, and then p_σ and $\overline{p_\sigma}$ may be empty; but $\det_\sigma$ is never empty because it contains at least $w[j]$.

In the sequel for each $1 \leq \sigma < \xi$ we denote by p_σ and $\overline{p_\sigma}$ a pair of paths obtained by applying Lemma 4.2 (if there are multiple valid choices for p_σ and $\overline{p_\sigma}$, we choose arbitrarily).

Achievable differences. For a walk w and segment σ, we denote by $\Delta_q(w, \sigma)$ the value $(|\det_\sigma| - |p_\sigma|) \bmod q$ and call this the[3] *difference achievable by σ*. We often drop the subscript q when clear from context. Intuitively, we know that we can modify the walk w to replace the subwalk $\det_\sigma$ from u to y by the existing path p_σ that goes from u to y, and this change subtracts $\Delta_q(w, \sigma)$ from the length of the walk modulo q; we will make this formal in the sequel. It should also be intuitively clear that achievable differences can be assumed to be non-zero in an edge-minimum walk: intuitively, an achievable difference of 0 means that we can replace the detour $\det_\sigma$ by the existing path p_σ that has the same endpoints, without changing the length of the walk modulo q. We know that this change does not harm the edge-minimality of w because p_σ consists of already visited edges. What is more, having too many segments with the same achievable difference is useless, because we can intuitively replace $\det_\sigma$ by p_σ and compensate the effect of this change by doing similar substitutions in earlier segments. Then, thanks to Lagrange's theorem on the additive group $\mathbb{Z}/q\mathbb{Z}$, the number of segments can in fact be bounded by $1 + \log_2 q$. We formalize this in the following lemma, which is the main result of this section:

▶ **Lemma 4.3** (Segment Decomposition Lemma)**.** *For every st-walk w with length $r \bmod q$, there is another st-walk of length $r \bmod q$ using only edges from w whose number of segments is at most $1 + \log_2 q$.*

The rest of this section is devoted to proving the Segment Decomposition Lemma; we will then use it in the next section to bound the cutwidth of some edge-minimum solution.

Recall that a *preorder* over a set is a binary relation that is both reflexive and transitive (this is a weaker requirement than non-strict partial orders which are additionally required to be antisymmetric). To prove the Segment Decomposition Lemma (Lemma 4.3), we define

[3] Note that there could be several choices for the difference achievable by σ depending on the arbitrary choices made earlier, e.g., depending on the first edge j for the segment detour, and on the choice of paths p_σ and $\overline{p_\sigma}$; nevertheless, we fix one single value $\Delta_q(w, \sigma)$ according to the choices made.

a preorder over the edge-minimum walks that are using a specific set of edges. Intuitively, the preorder favors walks which do their first visit of edges as late as possible relative to the end of the walk. More precisely, the preorder criterion asks us to minimize the number of remaining steps of the walk at the moment where the last first-visited edge is visited; then break ties by minimizing the number of remaining edges at the moment where the second-to-last first-visited edge is visited; and so on. This is designed to ensure that replacing a detour $\det_\sigma$ by p_σ improves the walk according to the preorder.

Let us fix from now on the graph $G = (V, E)$, the source s and target t, and the integers r and q. For any subset of edges $E' \subseteq E$, we define an *E'-walk* to mean an st-walk of length r mod q in G which uses precisely the edges of E'. Let us then define the order:

▶ **Definition 4.4.** *Let $E' \subseteq E$ be a subset of edges and let $m := |E'|$. Let w be an E'-walk, and let $i_1, \ldots, i_m$ be the indexes of the first-visited edges in ascending order, i.e., $w[i_1], \ldots, w[i_m]$ are the first-visited edges of w and $i_1 < \cdots < i_m$. The* first-visited timestamp *of w is then the m-tuple $(|w| - i_m, \ldots, |w| - i_1)$.*

We define as follows a preorder relationship $\trianglelefteq$ called the timestamp preorder *on E'-walks. Let w and w' be two E'-walks, and let t_w and t'_w be their first-visited timestamps, respectively. Then we have $w \trianglelefteq w'$ if we have $t_w \leq t'_w$ in lexicographic ordering.*

In other words, the timestamp preorder compares two walks by the number of remaining edges to traverse when visiting the last first-visited edge, then the second-to-last, and so on. Note that the timestamp preorder is not antisymmetric because two different walks on the same set of edges may happen to have the same first-visited timestamp (i.e., they visit first-visited edges at the same positions from the end, even though the identity of these edges and the revisits may be different). We then define:

▶ **Definition 4.5.** *If w is an E'-walk, we say w is* timestamp-minimum *if, for every E'-walk w', we have $w \trianglelefteq w'$.*

Note that, whenever there is an E'-walk, then there is a timestamp-minimum E'-walk, but it is not necessarily unique because the timestamp preorder is not antisymmetric. We are now ready to conclude the section by proving the Segment Decomposition Lemma (Lemma 4.3):

Proof sketch. We show that a timestamp-minimal walk has at most $1 + \log_2 q$ segments. We consider the successive subgroups of $\mathbb{Z}/q\mathbb{Z}$ generated by the achievable differences of the successive segments, and show that these must be a strictly increasing subsequence, so that the bound follows by Lagrange's theorem. To do this, we show as an intermediate claim that walks can be modified to augment their length by any combination of achievable differences of previous segments, while still using the same edges. Thanks to this claim, assuming by contradiction that there is a segment s_σ whose achievable difference is already achievable using the preceding segments, then we rewrite the segment to replace its detour $\det_\sigma$ by the path p_σ from Lemma 4.2, and use the claim to modify the walk and fix its length. We then show that this modification yields a walk which is smaller in the timestamp preorder, contradicting the minimality of w. See the full version [3] for the full proof. ◀

5 Number of Segments and Cutwidth Bounds

In this section, we continue our proof of Theorem 1.1 by showing that, for any walk w, the number of segments in the decomposition of the previous section gives a bound on the cutwidth of G_w up to a constant factor. This result is completely independent from the definition of the EWM problem. Formally, we show:

▶ **Proposition 5.1** (Segment Cutwidth Bound). *For any walk w, letting ξ be the number of segments in its segment decomposition, the cutwidth of G_w is at most 3ξ.*

We remark that there is no converse of this result: a walk formed of a succession of cycles connected by single edges will have an unbounded number of segments but has cutwidth 2. Combining Proposition 5.1 with Lemma 4.3 establishes the following:

▶ **Corollary 5.2.** *For every st-walk w' with length $r \bmod q$, there is another st-walk w of length $r \bmod q$ using only edges from w' such that the cutwidth of G_w is at most $3 + 3\log_2 q$.*

This implies the following bound on the cutwidth of optimal solutions to the EWM problem, on which our algorithm relies:

▶ **Corollary 5.3.** *For any graph $G = (V, E)$, terminals s,t, and non-negative integers $r < q$, every optimal solution to the EWM problem on G, s, t, r, and q has cutwidth at most $3 + 3\log_2 q$.*

To prove Proposition 5.1, we need several intermediate steps. First, we define the notion of *chunk* of a walk, which is a contiguous sequence of first-visited edges whose intermediate vertices are also first-visited. Second, we define the ordering $\prec$ on the vertices of G_w along which the cutwidth bound will be shown: this order is defined using the notion of chunks, intuitively because all vertices of a chunk will be ordered relative to the already-visited vertices that are the endpoints of the chunk (also distinguishing special cases like *cycle chunks* and *tadpole chunks*). Third, we show that the cutwidth along the order $\prec$ is bounded by 3ξ, by showing for each segment that the number of times its first-visited edges can cross the cut is at most 3. Throughout this section, we fix an arbitrary walk w in a graph G, and call s and t its source and target vertices.

Chunks. We define first-visited vertices similarly to first-visited edges: for every vertex $v \in V_w$ occurring in w, we say v is *first-visited at $w[i]$* if $w[i]$ is the first edge in which v occurs. Note that a vertex v which is first-visited at $w[i]$ always occurs as the target vertex of $w[i]$, except in the specific case of the first edge $w[1]$ where both the source s and the target vertex are first-visited at $w[1]$. Of course, every vertex of V_w is first-visited at exactly one position. Further, if a vertex v is the target vertex of an edge $w[i]$ and is first-visited at $w[i]$, then both $w[i]$ and $w[i+1]$ (if it exists) must be first-visited edges.

We can now define *chunks*:

▶ **Definition 5.4.** *A* chunk *of w is a maximal subwalk $w[i : j]$ of w where all edges are first-visited, and where, for every $i \leq k < j$ (if any), the target vertex of $w[k]$ is first-visited at $w[k]$.*

In other words, a chunk is a maximal sequence of one or more consecutive first-visited edges such that the first and last vertex are not first-visited (unless they are extremities of the whole walk) but all intermediate vertices are first-visited. A chunk may consist of a single first-visited edge $w[i]$ between two already-visited vertices, in which case there are no intermediate vertices.

The *first* and *last* vertices of chunk $w[i : j]$ are the source vertex of $w[i]$, and the target vertex of $w[j]$, respectively. Note that two successive chunks in the walk need not be separated by revisited edges and can simply be separated by a revisited vertex: for instance, for the length-2 walk $(s, s), (s, t)$, all edges are first-visited, but there are two chunks of length 1 which are separated by the revisit of the vertex s.

It will be useful to distinguish two special kinds of chunks. First, *tadpole* chunks, which loop back on an intermediate vertex of the chunk:

▶ **Definition 5.5.** *A chunk is a* tadpole *if it consists of at least two edges and if, letting $u_1, \ldots, u_\ell$ be the successive vertices that it visits, with u_1 its first vertex and u_ℓ its last vertex, we have $u_\ell = u_{\ell'}$ for some $1 < \ell' < \ell$.*

In other words, a *tadpole* is a chunk that consists of a path (containing at least one edge), followed by a cycle (possibly a self-loop).

Second, *cycle* chunks, which loop back on the vertex from which they started:

▶ **Definition 5.6.** *A chunk is a* cycle *if its first vertex and last vertex are identical.*

Note that these two cases are mutually exclusive. A chunk which is neither a tadpole nor a cycle, and thus is a simple path, is a *normal chunk*.

The notion of chunk must be distinguished from the notion of segments used in the segment decomposition of the previous section, but we can notice the following connections between the two notions:

- Segment ends never happen within a chunk: indeed, the intermediate vertices y reached within a chunk are first-visited by definition, so there is no way to reach them except by the edge that precedes them, and thus no earlier path can reach y in the walk.
- At the end of a tadpole chunk or cycle chunk, the current segment always ends. Indeed, the last edge $e' = (x, y)$ of the chunk reaches a vertex y which already has an outgoing edge in the chunk: this edge is a first-visited edge $e = (y, v)$, and the empty path from y to itself allows us to finish the segment at the end of the chunk, i.e., just after e'.

In summary, chunks are contiguous subsequences of the walk that never straddle segment boundaries, and the end of a tadpole chunk or cycle chunk always triggers the end of a segment. Also note that, by definition, chunks form a partition of the first-visited edges. This implies that, except possibly for the last segment, every segment must contain at least one chunk, because they contain at least one first-visited edge.

Defining the ordering. Having defined the notion of chunks of the walk w, we now define the ordering $\prec$ along which we will show that the cutwidth is bounded. This definition only depends on chunks; it does not depend on the segment decomposition. We see the total order $\prec$ as a sequence of vertices. Initially, the order is the empty order on the single vertex s. Then, for every chunk $w[i : j]$ successively, we consider the (possibly empty) sequence σ of the intermediate vertices of $w[i : j]$. Recall that the first vertex of $w[i : j]$ is already in the domain of $\prec$: either it is s (for the first chunk), or it is a vertex which is already visited. Then there are four cases:

- Tadpole: If $w[i : j]$ is a tadpole, then we insert all its intermediate vertices at the end of the current ordering $\prec$, in the order in which they were first-visited.
- Cycle: Otherwise, if $w[i : j]$ is a cycle, then, letting v be its first and last vertex, we know that v already occurs in $\prec$, and we insert all its intermediate vertices right after the vertex v, in the order in which they were visited.
- Normal: We consider two subcases:
  - First, suppose that the last vertex t of $w[i : j]$ is first-visited at $w[j]$. This is only possible with $j = |w|$, so that $w[i : j]$ is the last chunk. Then we do the same as in the tadpole case: insert the intermediate vertices and t at the end of the current ordering $\prec$, in the order in which they were first-visited.
  - Otherwise, $w[i : j]$ is a chunk whose last vertex v is first-visited at $w[k]$ with $k < i$ so v already occurs in $\prec$, and as we explained the first vertex u of the chunk also already occurs in $\prec$. Further, we have $v \neq u$ because the chunk is not a cycle. Then, we insert

the intermediate vertices so that the vertices along the chunk are ordered in a monotone fashion in the ordering. In other words, let $x_1, \ldots, x_\ell$ be the successive intermediate vertices of the chunk, so that its edges are $(u, x_1), (x_1, x_2), \ldots, (x_{\ell-1}, x_\ell), (x_\ell, v)$. If $u \prec v$ then we insert $x_1, \ldots, x_\ell$ in order between u and v, and if $v \prec u$ we insert $x_\ell, \ldots, x_1$ in order between v and u. The order $\prec$ between the newly inserted elements and the existing elements between u and v is arbitrary, for instance we can arbitrarily say that we insert the new vertices just after the smallest of u and v in $\prec$.

Note that, in all cases above, the (intermediate) vertices of a chunk are always ordered as a monotone sequence.

SCCs of the segment decomposition. We have defined, from our walk w, the order $\prec$ along which we will bound the cutwidth. To show the cutwidth bound, we establish two results describing the SCCs of the graph generated by the walk and its close relationship with our ordering $\prec$:

▶ **Lemma 5.7.** *At each step $0 \leq i \leq |w|$, the successive SCCs $C^i_1, \ldots, C^i_{\kappa_i}$ of $G_{w,i}$ are linearly ordered by the reachability relationship (i.e., every vertex in C^i_b is reachable from every vertex in C^i_a iff $a < b$), and the target vertex of the last edge $w[i]$ is in the last SCC $C^i_{\kappa_i}$ of $G_{w,i}$.*

▶ **Lemma 5.8.** *For every prefix $w[:i]$ of the walk such that a chunk of w ends at $w[i]$, the ordering $\prec$ induced by $w[:i]$ is consistent with the topological order of the SCCs of $w[:i]$.*

Bounding the cutwidth from the number of segments. We can now turn back to the segment decomposition introduced in the previous section for the walk w, and show how the number of segments of w can be used as a bound on the cutwidth of the graph G_w spanned by w, following the order $\prec$ that we defined. For this, we will consider an arbitrary cut $V_- \uplus V_+$ of V_w following $\prec$, and count how many edges of w cross the cut. As each edge is first-visited once, and first-visited in exactly one segment, it suffices to bound how many edges each segment contributes to the cut, and to count only the first-visited edges of each segment. We want to show:

▶ **Lemma 5.9.** *For each segment $w[i:j]$ of the walk w, the number of first-visited edges in $w[i:j]$ that cross the cut is at most 3.*

This immediately implies the Segment Cutwidth Bound (Proposition 5.1) stated at the beginning of the section. This bound of 3 edges crossing the cut can be proved by a case analysis summarized in the following lemmas:

▶ **Lemma 5.10.** *Let $w[i:j]$ be a segment of w and assume that the last chunk of $w[i:j]$ is a cycle $w[k:j]$. Then $w[k:j]$ crosses the cut at most twice. Further, if it does cross the cut twice then it must be the case that the first and last vertex of $w[k:j]$ is in V_- and that $w[k:j]$ contains some intermediate vertex in V_+.*

▶ **Lemma 5.11.** *Let $w[i:j]$ be a segment of w and assume that the last chunk of $w[i:j]$ is a tadpole $w[k:j]$. Then $w[k:j]$ crosses the cut at most twice. Further, if it crosses the cut twice then it has an intermediate vertex in V_- and an intermediate vertex in V_+.*

▶ **Lemma 5.12.** *Let $w[i:j]$ be a normal chunk of w, then it crosses the cut at most once.*

▶ **Lemma 5.13.** *Let $w[i:j]$ be a normal chunk of w which crosses the cut forwards, i.e., the starting vertex of the chunk is in V_- and its ending vertex is in V_+. Then the segment containing $w[i:j]$ ends at j.*

All that remains is to bound the contribution to the cut of the normal chunks that cross the cut backwards. To this end, let us distinguish the last chunk of a segment which we call the *final* chunk, and the remaining chunks in that segment which we call *non-final* chunks. Non-final chunks must be normal (because the segment ends right after cycle chunks or tadpole chunks), and they cannot cross the cut forward by the previous lemma.

We are ready to conclude the proof of Lemma 5.9:

Proof sketch. We consider a segment and consider the SCC decomposition of the graph of the walk when the segment starts, using Lemma 5.7. By Lemma 5.8 the segment begins in the rightmost SCC according to the order. Now the intuition is the following: if all chunks but the final one stay on the same side of the cut, then only the final chunk can cross the cut and the preceding lemmas (Lemma 5.10, Lemma 5.11 and Lemma 5.12) show that the bound is satisfied.

Otherwise, there is a first non-final chunk which ends on some SCC C_ϕ that contains nodes to the left of the cut and this chunk thus potentially crosses the cut (backwards, by Lemma 5.13). If the next chunk is final, the bound is satisfied, so we may assume the next chunk is not final. This next chunk may also cross the cut, but in any case it has for target an SCC C_ψ which is further left than C_ϕ, a property we exploit to show that the walk cannot return to the right of the cut without terminating the segment. This implies that the cut is crossed at most 4 times in total: once for each of the two non-final chunks considered, and potentially twice for the final chunk. We lower the bound to 3 by showing that in fact the final chunk can only cross the cut once if it is preceded by two chunks that already crossed the cut. See the full version [3] for the full proof. ◀

6 Computing an Edge-Minimum Walk of Bounded Cutwidth

Up to now, we have shown Corollary 5.3: optimal solutions to the EWM problem have cutwidth at most $3 + 3\log_2 q$. In this section, we conclude the proof of Theorem 1.1 by showing that optimal solutions of bounded cutwidth can be efficiently found.

At a high level, our algorithm proceeds by searching for a shortest path in a graph of configurations. The approach is similar to the approaches in [17] and [18]. The intuitive principle of our algorithm is the following. As we follow a path in the graph of configurations and move from one configuration to another, we choose which edges of the original graph to keep in the solution. To be more precise, the path will start on the empty configuration which denotes that no edges have been selected, and will iteratively add vertices and some of their incident edges to the solution.

To make sure that the selected edges do form a solution, we could try to record in the configurations the exact set of edges kept in the solution so far. However, the space of configurations would then be exponential. To avoid this, a configuration does not really store the entire set of chosen edges: instead it concisely represents the possible lengths modulo q of walks between a small subset of vertices of G, whose size is bounded as a function of the cutwidth.

The distance in the configuration graph from the initial configuration to any configuration Ξ will reflect the smallest cardinality of a set of edges that achieve the set of walks witnessed by Ξ. The algorithm therefore looks for a shortest path in the configuration graph from the initial configuration to any configuration which witnesses the st-walk of length r mod q required by the EWM problem.

Formally, fix the input graph $G = (V, E)$, the source $s \in V$ and the target $t \in V$, and the modularity requirement $r \bmod q$. Let $\omega \in \mathbb{N}$ be a *domain size bound*, which is related to the cutwidth, but will be precisely defined later. Let us define the notion of configurations formally:

▶ **Definition 6.1** (Configuration). *A V, ω, q-*configuration *$\Xi = (D, \rho)$ is a subset D of at most ω vertices of V, called the* domain *of the configuration, together with a function ρ mapping each ordered pair (u, v) for $u, v \in D$ to a subset of $\{0, \ldots, q-1\}$. Having fixed the vertex set V of the input graph G, we denote by $\Phi_{\omega,q}$ the set of all possible V, ω, q-configurations, and omit the subscript when clear from context.*

To compute transitions in the configuration graph, our algorithm will need to compute the *closure* of a configuration (D, ρ). The point of the closure is to ensure that, whenever we can achieve a walk from $u \in D$ to $v \in D$ via intermediate vertices of D and using remainders given by ρ, then that walk can be witnessed directly by a value in $\rho(u, v)$. Formally:

▶ **Definition 6.2** (Closure). *Given a configuration $\Xi = (D, \rho)$, an* internal walk *of Ξ is a sequence of vertices of D together with a choice of remainder for each step. Formally, it is a sequence $v_1, \ldots, v_\ell \in D$ and a choice of remainders $0 \leq r_1, \ldots, r_{\ell-1} < q$ such that we have $r_i \in \rho(v_i, v_{i+1})$ for each $1 \leq i < \ell$. The* total length *of the internal walk is the sum of the remainders modulo q, namely, $\sum_{1 \leq i < \ell} r_i \bmod q$.*

The closure *of (D, ρ) is the configuration (D, ρ') where, for each $u, v \in D$, for each $r' \in \{0, \ldots, q-1\}$, we have $r' \in \rho'(u, v)$ iff there is an internal walk of total length r' from u to v in (D, ρ). Note that we always have $\rho'(u, v) \supseteq \rho(u, v)$ because for each $r' \in \rho(u, v)$ we can take the single-edge internal walk u, v with remainder r'.*

We can easily compute the closure of a configuration in polynomial time in q and ω, for instance using a product construction. Specifically, create a graph on vertices $D \times \{0, \ldots, q-1\}$, then add the following edges: for each $u, v \in D$ and each $r' \in \rho(u, v)$, for each $i \in \{0, \ldots, q-1\}$ create an edge from (u, i) to $(v, i + r' \bmod q)$. Then compute the transitive closure and define $\rho'(u, v)$ to be the set of r' such that $(u, 0)$ has a path to (v, r').

We now define the graph over configurations, which we call $\Gamma_{\omega,q}$ and which also depends on the directed graph G given as input to EWM. We omit the subscripts when clear from context.

▶ **Definition 6.3.** *The* graph of configurations $\Gamma_{\omega,q}$ *is a weighted and labeled directed graph: each edge carries an integer cost and is labeled by a subset of edges of the original graph G. The vertex set of Γ is the set Φ of all V, ω, q-configurations. To define the edges, let us choose any configuration $\Xi \in \Phi$ and define the outgoing edges of Ξ. These edges are of two kinds:*

- Forget*: from $\Xi = (D, \rho)$ with D nonempty, for each $v \in D$, letting $D' := D \setminus \{v\}$ be the new domain, we have an edge leaving Ξ which has cost 0, is labeled with the empty set of edges, and leads to $(D', \rho_{|D'})$ where $\rho_{|D'}$ is the restriction of ρ to D'*
- Introduce*: from $\Xi = (D, \rho)$ with $|D| < \omega$, for each $v \in V \setminus D$, let $D' := D \uplus \{v\}$ be the new domain, and let $E_{v,D'}$ be the set of edges of G which are of the form (v, v') or (v', v) with $v' \in D'$; we also add to $E_{v,D'}$ the self-loop edge on v if it exists. Then for each $E' \subseteq E_{v,D'}$, we have an edge leaving Ξ which has cost $|E'|$, is labeled by E', and leads to the closure of the configuration (D', ρ') with ρ' intuitively defined from ρ by adding the edges of E', formally:*
  - *For all $u, u' \in D \cup \{v\}$, we initialize $\rho'(u, u') := \emptyset$.*
  - *For each $(u, u') \in D \times D$, we set $\rho'(u, u') := \rho(u, u')$.*
  - *For each edge $e \in E_{v,D'}$, we set $\rho'(e) := \{1\}$. Note that by definition of $E_{v,D'}$ this case is disjoint from the previous one.*

Note that we may have several Introduce edges with the same source and target configurations but labeled with different sets of edges and with different costs; in this case all of these edges exist in Γ *as defined above, although we could equivalently have decided to keep only one of these edges among those with minimum cost.*

We have now defined the graph Γ of configurations. We will look for shortest paths in this graph from the *initial configuration* to a *final configuration*, namely:

▶ **Definition 6.4.** *The* initial configuration *is simply the configuration with empty domain.*

A configuration is final *if it contains* s *and* t *and features a walk with the requisite remainder, i.e., the configuration* (D, ρ) *is final if* $s, t \in D$ *and* $r \in \rho(s, t)$*.*

We can now define our algorithm to solve the EWM problem, which we call the *EWM algorithm*. We first set the value ω, following the cutwidth bound, to be: $\omega := 6 + 3\log_2 q$, i.e., three more than the cutwidth bound that follows from Corollary 5.3. (Intuitively, we add 2 to make sure that the sources s and t can always be part of the domain of configurations, and we add 1 extra to make sure that we can always perform Introduce steps before Forget steps.) The EWM algorithm then builds explicitly the graph $\Gamma_{\omega,q}$ and computes a shortest path π in Γ from the initial configuration to a final configuration. Once such a shortest path π is found[4], then the algorithm returns the subgraph of G formed of the edges of G obtained as the union of all edge labels in π.

Proving that the EWM algorithm correctly solves the EWM problem is relatively straightforward: we show that whenever the algorithm return a subgraph, this subgraph is indeed a candidate solution. Conversely, we show that for every optimal solution E' there is a path from in the configuration graph from some initial configuration to some final configuration, such that the union of labels along the path is E' without duplicates (hence the path has cost $|E'|$), which guarantees that the algorithm returns the optimal solution. Those properties can be proved by establishing the following invariant:

▷ Claim 6.5. Let $\pi = \Xi_1, \ldots, \Xi_\ell$ be a path in Γ from the initial configuration Ξ_1. Let $G_1 = (V, E_1)$, …, $G_\ell = (V, E_\ell)$ be the sequence of subgraphs of G defined in the following way: we have $E_1 = \emptyset$, and for each $1 < i \leq \ell$ we set $E_i = E_{i-1} \cup E'_i$ where E'_i is the edge set that labels the edge of Γ used to go from Ξ_{i-1} to Ξ_i in Γ. Then the following is true: for any $1 \leq i \leq \ell$, writing $\Xi_i = (D_i, \rho_i)$, for any $u_1, u_2 \in D_i$, for any $r' \in \{0, \ldots, q-1\}$, we have $r' \in \rho_i(u_1, u_2)$ iff there is a u_1u_2-walk in G_i whose length modulo q is r'.

Note that, in the definition of the graphs G_i, we may add the same edge of G multiple times because it occurs in the label of several edges of π; this can happen even if π is a simple path in Γ. As it turns out, this never happens when π is a shortest path (because we are then, in effect, paying twice for the same edge); but the invariant of Claim 6.5 applies to paths π even if they do traverse edges labeled with non-disjoint edge sets.

Altogether, we have explained why the algorithm correctly solves the EWM problem, and the algorithm can be shown to have complexity $n^{\omega+1} \cdot 2^{O(\omega^2 q)}$. Instantiated with our choice of $\omega = 3 + 3\log_2 q$, we get a final complexity of $n^{O(\log q)} \cdot 2^{O(q \log^2 q)}$ for the algorithm. See the full version ([3]) for details. This concludes the proof of our main result (Theorem 1.1).

[4] If there is no path in Γ from an initial configuration to a final configuration, then we return $\emptyset$ to indicate that there is no subgraph of G with an st-walk of length r mod q. Note that this case can be excluded from the outset, simply by checking whether G contains an st-walk of length r mod q: this can be done, e.g., with the product construction.

7 Extension to Weighted Graphs

Having shown our main result (Theorem 1.1), in this section we start exploring variants and extensions of the EWM problem. We first study two extensions of EWM in this section. First, we study the addition of *costs* on edges, meaning that we look for a walk where the total cost is minimum (instead of the number of edges). Second, we study the addition of integer *lengths* on edges.

In this section and the next, the problems that we define and study are always posed on a directed graph G and ask about the existence of a subgraph of G satisfying certain properties and which is optimal according to some criterion (usually, being edge-minimum). We use the same terminology as before: a *candidate solution* is a subgraph which satisfies the properties but is not necessarily edge-minimum, and an *optimal solution* is a candidate solution which is additionally edge-minimum.

Costs on edges and vertices. We first study the extension of the EWM problem with costs on edges. Specifically, the *EWM problem with costs on edges* takes as input a directed graph $G = (V, E)$, a cost function γ giving to each edge $e \in E$ a cost $\gamma(e)$, a pair of a source $s \in V$ and target $t \in V$, and a modularity requirement r mod q for integers q and r. The output to the EWM problem with costs on edges is an st-walk of length r mod q such that the cost $\gamma(E_w) := \sum_{e \in E_w} \gamma(e)$ is minimum. We assume that all costs given by γ are nonnegative. Indeed, in the presence of negative weights, we lose the correspondence explained in Section 3: computing a minimum-weight *subgraph* that contains a walk reduces to the case of positive weights (all negative-weight edges will always be included in the optimal solution subgraph); but computing a minimum-weight *walk* is NP-hard even without modularity constraints:

▶ **Proposition 7.1.** *The following problem is NP-complete: given a directed graph $G = (V, E)$, a cost function $\gamma \colon E \mapsto \mathbb{Z}$, and source and target $s, t \in V$, compute a minimum-weight subset of edges $E' \subseteq E$ such that there is an st-walk using precisely the edges in E'.*

Our tractability result for EWM (Theorem 1.1) can be easily extended to solve the EWM problem with costs on edges. Specifically, the Segment Decomposition Lemma (Lemma 4.3) shows that there must be an optimal solution to EWM with costs on edges that obeys the bound on the number of segments, because the γ function on subset of edges is monotone. Then the Segment Cutwidth Bound (Proposition 5.1) applies as is, and the algorithm to find an optimal solution of bounded cutwidth from the previous section can be easily extended: simply modify the definition of the graph of configurations (Definition 6.3) so that the cost of an edge labeled with a set E' of edges of G is no longer the cardinality $|E'|$ of E but the total cost $\gamma(E')$. Other than that, the algorithm proceeds in the same way, and computes a shortest path which now reflects the subgraph of G satisfying the requirements which has minimum cost instead of minimum cardinality.

We also mention that the EWM problem can be defined to have costs (unit costs or not) on vertices instead of edges. In this case, the cost of a candidate solution is the number of different vertices traversed by the walk (or more generally their total cost). However, this problem is interreducible to the EWM problem with costs on edges:

▶ **Lemma 7.2.** *The EWM problem (with unit costs on edges) reduces to the EWM problem with unit costs on vertices, and the EWM problem with costs on edges reduces to the EWM problem with costs on vertices. Conversely, the EWM problem with unit costs on vertices reduces to the EWM problem with unit costs on edges, and the EWM problem with costs on vertices reduces to the EWM problem with costs on edges.*

Lengths on edges. Having studied the use of costs on edges to change the optimization criterion, we turn to a different problem variant where we annotate edges with integer lengths. Specifically, the *EWM problem with lengths* takes as input a directed graph $G = (V, E)$, a length function $\delta\colon E \to \mathbb{N}$, and a pair of a source $s \in V$ and target $t \in V$ and a modularity requirement $r \bmod q$ for integers q and r. The answer to the EWM problem with lengths is an st-walk w that traverses a minimum number of distinct edges and whose total length is $r \bmod q$, i.e., $\delta(w) := \sum_{1 \leq i \leq |w|} \delta(w[i])$ is $r \bmod q$. (Note that the length of an edge is summed as many times as the edge is traversed.)

The impact of allowing lengths is different depending on the regime. In the case where r and q are constant, or given in unary, then we can rewrite the graph in polynomial time to eliminate edge lengths. Specifically, letting m be the number of edges in the graph, we replace each edge e of length $\delta(e)$ by a path on $(m+1)q + (\delta(e) \bmod q)$ edges (where m is the number of edges in the graph). This ensures that a walk in the new graph has the same modularity as the corresponding walk in the original graph, and the cost of a candidate solution in the rewritten graph is $(m+1)qM + \epsilon$, where M is the number of original edges traversed and $\epsilon \leq mq$. This ensures that an optimal solution in the original graph indeed minimizes the number of edges taken from the original graph.

One different regime is when r and q are written in binary and do not necessarily have polynomial value. In this case, the EWM problem with lengths written in binary can be shown to be NP-hard by an easy reduction from Subset Sum. In fact, just the problem of deciding the existence of a walk of length $q \bmod r$ is NP-hard:

▶ **Proposition 7.3.** *The problem of deciding whether an st-walk of length $q \bmod r$ exists, where q, r and the lengths of δ are written in binary, is NP-hard.*

We do not know whether an analogous hardness result holds for the original EWM problem (without edge lengths) in the setting where q and r can be written in binary and do not necessarily have polynomial value. Indeed, in the proof above, we crucially use the edge lengths to concisely write the numbers given in the Subset Sum instance; writing them in unary as paths of the corresponding length will not give a polynomial-time reduction and indeed the Subset Sum problem can be solved in pseudo-polynomial time.

We last address the question of showing an upper bound on the complexity of EWM with lengths, by showing an NP upper bound. Of course the bound is phrased on the decision version of EWM with lengths, i.e., given an instance of EWM with lengths and a threshold k, we wish to decide whether there exists a candidate solution having at most k different edges. We have:

▶ **Proposition 7.4.** *The following problem is in NP: given a directed graph $G = (V, E)$, a function $\gamma\colon E \to \mathbb{N}$ that assigns lengths (written in unary) to each edge, integers q, r and k (written in binary), source and target $s, t \in V$, decide if there is a subset $E' \subseteq E$ of at most k edges that contains an st-walk of length $r \bmod q$ according to γ.*

8 Connections to DSN and SCSS

We conclude the paper by exploring how EWM relates to the Directed Steiner Network (DSN) problem mentioned in the introduction, and more specifically the *Strongly Connected Steiner Subgraph (SCSS)* problem. We first define the SCSS problem and show that it is subsumed by EWM, in the sense that a polynomial algorithm for EWM (with fixed q and r) gives a polynomial algorithm for SCSS with a constant number of terminals. Then, we introduce a problem generalizing both SCSS and DSN on the one hand, and EWM in the other: we study

how to find the smallest subgraph satisfying connectivity requirements on specified endpoint pairs with specified modularities. We show that we can generalize our results to this problem, and provide a polynomial algorithm for the setting when the number of endpoint pairs and the modularity requirements are constants.

Reducing SCSS to EWM. Let us recall the definition of the SCSS problem [17, 18] before explaining how it can be reduced to EWM. In the SCSS problem, the input simply consists of a directed graph $G = (V, E)$ with an input set $T \subseteq V$ of terminals, and we want to find the smallest subgraph $E' \subseteq E$ that is strongly connected and contains edges incident to each terminal in T. In other words, SCSS is a special case of DSN where the connectivity requirements on the vertices of T require that they are strongly connected. The SCSS problem is NP-hard in general (by an easy reduction from the directed Steiner tree problem) but it can be solved in polynomial time provided that the size of T is bounded by a constant, as shown in [17]. Thus, for $k \in \mathbb{N}$, we write k-SCSS to refer to the SCSS problem where the set T of terminals is required to contain at most k vertices. Following our previous terminology in the paper, when we talk of *candidate solutions* we mean a subgraph satisfying the requirements of a problem (e.g., for k-SCSS, a strongly connected subgraph containing the requisite terminals), and by *optimal solution* we mean a candidate solution which is also edge-minimum.

Let us show that the SCSS problem can be reduced to EWM, which implies that Theorem 1.1 gives an alternative proof of the results of [17] (with worse bounds). More precisely, we show:

▶ **Lemma 8.1.** *For any constant $k > 0$, we can compute constants q and r in $2^{O(k \log k)}$ such that there is a linear-time reduction from k-SCSS to EWM with the constant values q and r.*

The previous reduction shows that our EWM problem is intuitively at least as complicated as SCSS, given that the tractability of EWM for constant q implies that of SCSS for constant k. (This being said, we do not claim that the polynomial algorithm given by our results is as efficient as that of earlier works [17, 18].) Alternatively, instead of this black-box reduction, we can also adapt our techniques to recapture the tractability of SCSS by showing a bound on the cutwidth of optimal solutions, using the segment decomposition. We exemplify below how this is done, and will revisit this afterwards when extending EWM to support multiple paths. Recall the notion of timestamp-minimum walks (Definition 4.5), and let us show the following result; note that it applies to *edge-minimal* solutions (not just optimal solutions).

▶ **Lemma 8.2.** *Let $G = (V, E)$ and $T = \{v_1, \ldots, v_k\}$ be an SCSS instance. Every edge-minimal solution H to the instance has cutwidth at most $3k$.*

What is more, for any terminal v_i, considering all H-walks that start and conclude in v_i and visit all terminals from T, then any timestamp-minimum H-walk among those H-walks has at most k segments.

We remark that the cutwidth bound of $3k$ given by this result is slightly better than the bound of $6k$ shown in [18].

Defining Directed Steiner Network with Modularity constraints. The reduction from SCSS to EWM leads to the natural question of whether there could be a problem which subsumes SCSS and EWM, or even DSN and EWM; and a polynomial-time algorithm that subsumes the tractability of all these problems. We now introduce such a problem, dubbed *Directed Steiner Network with Modularity* (DSNM), and show a polynomial-time algorithm to solve it.

▶ **Definition 8.3.** *For $k > 0$, the* k-Directed Steiner Network with Modularity *problem (k-DSNM) takes as input a graph (V, E) and a* k-requirement specification $\mathcal{R}$ *consisting of k tuples (s_i, t_i, r_i, q_i) for $1 \leq i \leq k$ such that $s_i, t_i \in V$ and $q_i > 0$ and $0 \leq r_i < q_i$. Our goal is to compute an optimal solution, i.e., an edge-minimum subgraph H of G such that H contains a walk from s_i to t_i of length $r_i \bmod q_i$ for every $i \leq k$.*

Our last result in this paper is to show that the k-DSNM problem is in PTIME when k and the modulo values q_i are constants. This result subsumes Theorem 1.1 and the tractability of k-DSN for constant k shown in [17, 18].

▶ **Theorem 8.4.** *We can compute in $n^{O(k+\log q)} \cdot 2^{O(q(k+\log q)^2)}$ time an optimal solution to k-DSNM, where q denotes the least common multiple (LCM) of the q_i in the input k-requirement specification.*

Note that our exponents are given up to constant factors, so we do not claim to recover the same exponents as earlier works on k-DSN without modularity constraints (i.e., for $q = 1$).

The overall strategy to prove Theorem 8.4 is to follow the methodology used for EWM, adjusting the constructions presented so far in the paper. Deviating somewhat from EWM, but following prior work about DSN [17, 18], in our study of DSNM we will focus on the SCCs of an optimal solution and study them separately, instead of studying the entire solution graph. Our main objective is to bound the cutwidth of SCCs in an optimal solution as a function of q and of the number k of endpoint pairs. We can then easily deduce like in [18] that the cutwidth of optimal solutions is bounded as a function of q and k. To compute the solutions of bounded cutwidth, we then modify slightly the algorithm of Section 6.

To study the SCCs of optimal solutions, it will be useful to introduce an analogue of the SCSS problem featuring modularities. Specifically, we call k-SCSSM the problem that takes the same input as k-DSNM and returns a smallest *strongly connected* subgraph H of G such that H contains a walk from s_i to t_i of length $r_i \bmod q_i$ for every $i \leq k$. Note that, unlike the SCSS problem which was simply defined by a set of terminals, in k-SCSSM we specify a set of tuples connecting pairs of vertices, because we need to specify which remainder must be achieved by which endpoint pair. The difference with k-DSNM is only that the solution graph is required to be strongly connected. Our study of k-SCSSM is motivated by the fact that the SCCs of optimal solutions to k-DSNM are optimal solutions to instances of k-SCSSM, as was already known in the setting without modularities [17]. Namely:

▷ Claim 8.5. Let $G = (V, E)$ be a directed graph, and $\mathcal{R}$ be a k-requirement specification. In any optimal solution $H = (V, E')$ to k-DSNM on G for $\mathcal{R}$, for any SCC C of H, there exists a k-requirement specification $\mathcal{R}'$ such that C (as a set of edges) is an optimal solution to k-SCSSM on G for $\mathcal{R}'$.

We next bound the cutwidth of optimal solutions to the k-SCSSM problem specifically. Then we will deduce a cutwidth bound on optimal solutions to k-DSNM using a result of [18]. Finally, we explain how to design an algorithm to compute these solutions.

Bounding the cutwidth of solutions to k-SCSSM Let us start by showing that solutions to k-SCSSM have a small segment number and hence a small cutwidth:

▶ **Lemma 8.6.** *Let G be a graph and $\mathcal{R}$ be a k-requirement specification, denote by $q_1, \ldots, q_k$ the respective modularities of its tuples, and denote by q the least common multiple (LCM) of $q_1, \ldots, q_k$. Then every optimal solution of the k-SCSSM problem on G and $\mathcal{R}$ can be covered with a walk of at most $O(k + \log q)$ segments and therefore has cutwidth at most $O(k + \log q)$.*

Note that this claim only works for the k-SCSSM problem, not the k-DSNM problem, because it assumes the solution can be covered by a single walk which is not true in general for k-DSNM. Let us show the result:

Proof sketch. The proof of this result can be decomposed into three steps. In step 1, we define the notion of a *legal covering walk*, which is a walk that covers the edges of a solution in a prescribed order: first visit all terminals to witness that they are strongly connected in a subwalk w_0 (similarly to Lemma 8.2), then visit all paths with the prescribed modularities in a subwalk w'. In step 2, we carefully impose a variant of timestamp-minimality on legal covering walks towards bounding their number of segments. In step 3, we use Lemma 8.2 (on the first part of the legal covering walk) and an argument adapted from Lemma 4.3 (for the second part) to show that the number of segments is bounded. The point of splitting the walk in two is that w_0 visits enough edges to allow us to move to arbitrary endpoints and ensure strong connectedness: this allows us to replay arbitrary detours in any subwalk no matter where they occur, intuitively "pooling" the achievable differences $\Delta(w, \dots)$ between all the subwalks. See the full version [3] for the full proof. ◀

From k-SCSSM to k-DSNM. We have shown that optimal solutions to the k-SCSSM problem can be assumed to have bounded cutwidth. We now wish to show that the same is true for optimal solutions to the k-DSNM problem. This is simple, using Lemma 8.6 above along with two lemmas from [18]:

▶ **Lemma 8.7.** *Fix a graph G and a k-requirement specification $\mathcal{R}$, and let q be the LCM of the q_i in $\mathcal{R}$. Let H be an optimal solution to k-DSNM on G and $\mathcal{R}$. Then H has cutwidth at most $O(k + \log q)$.*

Computing optimal solutions. We have shown in Lemma 8.7 that optimal solutions to the k-DSNM problem have cutwidth $O(k+\log q)$. The only remaining thing to prove Theorem 8.4 is to adapt the dynamic algorithm from Section 6 to compute solutions to that problem instead of EWM. We explain in the full version [3] how this is done.

9 Future work

We now outline possible directions for future work in light of our results:

Improving our bounds. One natural direction for further research would be to improve the complexity bounds that we show. Our algorithm for EWM runs in time $n^{O(\log q)} \cdot 2^{O(q \log^2 q)}$. Can the factor of q in the exponent be improved, e.g., by getting an algorithm in time $n^{O(\log q)}$? Or, on the other hand, is the problem NP-hard? (We have only shown that the variant of EWM with edge lengths is NP-hard, in Proposition 7.1.)

Intermediate problems between shortest walk and edge-minimum walk. It could be interesting to search for walks that are minimized according to some criterion that is "intermediate" between shortest walk and edge-minimum walk, e.g., if the cost of each edge is expressed as a function of how many times it is traversed by the walk. Such a general framework would capture the two problem variants that we contrast in the introduction: shortest walks are the case where we are charged ℓ when traversing an edge ℓ times, and edge-minimum walks are the case where we are charged 1 when traversing an edge $\ell > 0$ times and charged 0 when we do not traverse it.

Edge-minimum walks satisfying other constraints. Last, one other problem of interest would be to investigate the complexity of finding edge-minimum subgraphs guaranteeing the existence of st-walks satisfying other properties. One very natural example is the following: Given a number ℓ, and a directed graph G with specified vertices s, t, find an edge-minimum st-walk of length exactly ℓ. (This is the same as EWM except the length is exactly ℓ, instead of r mod q.) The trivial algorithm for this problem is in time $O(n^\ell)$, but can we do better? To our knowledge, this problem has not been studied.

Another example is looking for edge-minimum walks that achieve constraints expressed by a finite semigroup. For instance, assume that each edge of the graph is labeled by a semigroup element, and that we want a walk whose evaluation in the semigroup achieves a specific target element of the semigroup, where evaluating the walk means multiplying the labels of its edges in the order that they are traversed. This problem generalizes the EWM problem (with lengths on edges), which uses the semigroup $\mathbb{Z}/q\mathbb{Z}$. An alternative way to phrase this problem is in the language of regular path queries (RPQs) mentioned in the introduction: fixing a regular language L on an alphabet Σ, and given a directed graph G with terminals s and t and with edges labeled by letters of Σ, find an edge-minimum subgraph G with an st-walk which evaluates to a word that belongs to L. For which fixed regular languages L can this problem be solved in polynomial time in G?

Abstract

We initiate a study of *doubly-efficient* interactive proofs of *proximity*, while focusing on properties that can be tested within query-complexity that is significantly sub-linear, and seeking interactive proofs of proximity in which

1. The query-complexity of verification is significantly smaller than the query-complexity of testing.
2. The query-complexity of the honest prover strategy is not much larger than the query-complexity of testing.

We call such proof systems doubly-sublinear IPPs (dsIPPs).

We present a few doubly-sublinear IPPs. A salient feature of these IPPs is that the honest prover does not employ an optimal strategy (i.e. a strategy that maximizes the verifier's acceptance probability). In particular, the honest prover in our IPP for sets recognizable by constant-width read-once oblivious branching programs uses a distance-approximator for such sets.

1 Introduction

This work combines the mind-frames of interactive proofs of *proximity* (i.e., IPPs) and *doubly-efficient* interactive proofs (de-IPs), while giving the notion of doubly-efficient a new meaning that focuses on the *query-complexity* of the honest prover strategy. Specifically, we focus on properties that can be tested by reading a small portion of the input (equiv., have query-complexity that is significantly sub-linear), and seek interactive proofs of proximity in which

1. The query-complexity of verification is significantly *smaller than* the query-complexity of testing.
2. The query-complexity of the honest prover strategy is *not much larger than* the query-complexity of testing.

In addition, we may seek analogous relations for the time-complexities; yet, we recall that, in the context of property testing, time-complexity is secondary to query-complexity (see [4, Sec. 1.3.1]).

A salient feature of (almost all) the IPPs that we present is that the honest prover does not employ an optimal strategy, because it cannot afford to read the entire input (per the second query-complexity condition). In particular, while an optimal prover strategy for the verifiers that we present achieves perfect completeness, our honest provers don't.

1.1 Our focus: query-efficient generation of proofs of proximity

Focusing on properties that can be tested in sub-linear query-complexity, we initiate a study of interactive proofs of proximity in which verification requires less queries than testing whereas proving does not require much more queries than testing. We recall the wider context first.

Property testing. The focus of property testing[6, 22] is on approximate decision procedures that read small portion of their input (see [4] for an introduction to the subject). For a predetermined property (i.e., a set of valid objects), approximate decision means distinguishing between objects that have the property and objects that are far from any object having this property.[1] Such procedures, called testers, are probabilistic and obtain local views of the object by performing queries; that is, the object is seen as a function and the testers get oracle access to this function (and thus may be expected to read only part of the object).

The insistence on procedures that read a small portion of the input reflects envisioning applications in which the input is huge and fetching it entirely is infeasible. In some of these applications, one may afford computation time that is almost linear in the size of the input, although fetching the entire input is still deemed infeasible.

Proofs. A generic question is whether proofs can offer verification that is more efficient than the corresponding decision. In the context of property testing, this refers to interactive proofs of proximity (IPPs)[3, 21]. In such proof systems, *verification should require significantly less queries than testing*, and suitable notions of completeness and soundness should hold.[2] Specifically, *completeness* means that inputs that have the property should be accepted with high probability (when the prover uses an adequate strategy), whereas *soundness* means that inputs that are far from the property should be rejected with high probability (no matter what strategy is employed by the prover). Indeed, in the completeness condition we consider a honest prover, whereas in the soundness condition we consider a cheating one.

Doubly-efficient proofs. Seeking to utilize proof systems in reality prohibits the use of arbitrary honest provers. Such applications require that the honest prover strategy be relatively efficient, a requirement that is captured by the term *double-efficiency*, which refers to the complexities of both the verifier and the honest prover. Given our postulate that it is infeasible to fetch the entire input and our focus on query complexity, this means that the honest prover strategy should also have query complexity that is significantly smaller than linear. We call such proof systems doubly-sublinear IPPs (dsIPPs).

Note that dsIPPs may exist only for properties that can be tested using small query complexity. This is the case because the interaction between the verifier and the honest prover (along with the queries they make) can be emulated by the tester. Hence, we focus on properties that can be tested using small query complexity and ask *for which of these properties we can obtain dsIPPs*?

---

[1] Distances are measured according to the relative Hamming measure; that is, $x \in \{0,1\}^n$ is considered ε-far from $y \in \{0,1\}^n$ if x and y differ on more than $\varepsilon \cdot n$ locations.

[2] In addition, one requires low communication complexity. In particular, this does not allow the prover to send the entire input to the verifier (a possibility that is not relevant in the context of double-efficiency that we consider here).

We stress that the notion of double-efficiency employed here is different from the notion employed in the context of IPs (see[10, 19, 5]) and also in studies of IPPs that made reference to doubly-efficient IPPs (e.g.[20]). In these prior cases, the reference was to polynomial running time of the honest prover, whereas we focus on its query complexity and on the case that it is small (and in particular is sub-linear).

1.2 Our Main Results

We construct doubly-sublinear IPPs (dsIPPs) for several problems. Specifically, for any property that can be decided by a constant-width read-once oblivious branching program (ROOBP), for approximating the input's Hamming weight, for telling whether a given function is a permutation, and for a relaxation of the graph bipartiteness problem in the bounded-degree model.

As mentioned earlier, the honest prover strategies in (almost all) the dsIPPs that we present do not employ an optimal strategy, because they cannot afford to read the entire input. In particular, while optimal prover strategies for these IPPs achieves perfect completeness (i.e., the verifier always accepts inputs that have the property), our honest provers do not achieve perfect completeness.

1.2.1 Protocol for Read-Once Oblivious Branching Programs

We construct a dsIPP for any property that can be decided by constant-width read-once oblivious branching programs (ROOBPs). Recall that in such branching programs, in each layer, all vertices are labelled by the same input variable (which is the one being read), and each input variable labels the vertices of at most one layer. A branching program decides a property Π if it accepts all inputs in the property and rejects all inputs that are not in the property. See Section 4.1 for a fuller discussion on ROOBPs.

Newman [16] showed that any property that can be decided by a constant-width ROOBP has a tester that makes $\mathsf{poly}(1/\varepsilon)$ queries, where the exponent of the polynomial is linear in the width of the branching program. We construct a dsIPP for any such property, where the verifier's query complexity is only $O(1/\varepsilon)$, which is optimal.[3]

▶ **Theorem 1** (dsIPP for ROOBPs, informal). *Let Π be a property that can be decided by a constant-width ROOBP, and let n and ε denote the input length and the proximity parameter. Then, for every $r : \mathbb{N} \to \mathbb{N}$, there exists an $r(n)$-round dsIPP for Π such that the verifier has query complexity $O(1/\varepsilon)$, the honest prover has query complexity $\widetilde{O}(n^{1/r(n)}) \cdot \mathsf{poly}(r(n)/\varepsilon)$, and the communication complexity is $O(n^{1/r(n)} \cdot r(n) \cdot (\log n)/\varepsilon)$.*

See Corollary 20 for a full and formal statement. Evidently, our protocol allows for a trade-off between the number of rounds (on one hand) and the query complexity of the prover and the communication (on the other hand). In particular, a logarithmic number of rounds suffices for getting the prover's query complexity and the communication to depend only poly-logarithmically on n. The verifier's runtime can be linear in the communication complexity assuming access to a suitable procedure specifying the structure of the ROOBP (see below).[4] The prover's runtime depends on the computational complexity of tolerant testing for properties decided by ROOBPs, see below.

[3] Consider the set property $\{0^i 1^{n-i} : i \in [n]\}$, the input $x = 0^{n/2}1^{n/2}$ and a honest prover strategy that refers to the input x but is also invoked as a cheating strategy on a random input r that is at Hamming distance 2ε from x. Then, an $o(1/\varepsilon)$-query verifier cannot distringuish the two cases.

[4] We remark that for a general non-uniform ROOBP no verifier can have a sublinear running time: for example, one layer in the ROOBP might make it go into a state that rejects all inputs. Without reading the entire ROOBP, the verifier has no hope of detecting whether there is a "universal rejection" layer.

Our protocol builds on an IPP of Goldreich, Gur and Rothblum[7], in which the honest prover reads the entire input. On the other hand, the IPP of[7] works also for unbounded width (but its communication complexity grows logarithmically with the width). We note that our dsIPP is actually *tolerant* (see below), whereas this was not the case for the protocol of [7] (or the tester of [16], see below).

A reduction to tolerant testing. An interesting feature of our IPP is that the honest prover strategy is reduced to *tolerant* testing (or distance approximation) for a property that can be decided by an ROOBP of (at most) the same width and length. A *tolerant* tester [17] for a property Π gets proximity parameters $\varepsilon_c < \varepsilon_f$ and is supposed to accept (w.h.p.) if the input is ε_c-close to the property, and to reject (w.h.p.) if the input is ε_f-far from the property. The complexity is usually measured as a function of the gap $\varepsilon_f - \varepsilon_c$ (and possibly also of the input length).

Theorem 1 follows by plugging any tolerant tester for constant-width ROOBPs into our general reduction (which is stated in Theorem 2). While, as noted above, Newman's tester for ROOBPs[16] is not tolerant, we show that that it can be made tolerant. This contribution of the current work is presented in the full version of the article.

Our reduction of the prover's strategy to tolerant testing ROOBPs actually gives a *tolerant* dsIPP of ROOBPs, where *Tolerant IPPs* are defined analogously to tolerant testers.[5] Fixing the ROOBP under consideration, the reduction assumes that the honest prover has access to a distance approximator that gets an ROOBP of (at most) the specified width and length, and approximates the distance of an input from the corresponding property (i.e., the property decided by the ROOBP). We need the deviation of the distance approximation to be $O((\varepsilon_f - \varepsilon_c)/r)$, and its error probability to be sufficiently small. The approximator only needs to operate on "sub-ROOBPs" of the original ROOBP.

Before stating the reduction, we also specify the access the verifier and the prover need to the ROOBP in order to get sublinear *runtimes*. We assume that the prover and the verifier have (unit cost) access to two procedures that *specify the structure of the ROOBP* as follows. The first procedure, given two nodes u and v in the ROOBP, returns a bit indicating whether there is a path from u to v. The second procedure gets as input the index i of a layer and returns the vertices in that layer. (We emphasize that these procedures do not depend on the input to the ROOBP: they ignore edge labels and refer to the ROOBP as a directed graph.)

▶ **Theorem 2** (Reducing tolerant dsIPP to distance approximation for ROOBPs, informal)**.** *For any constant w, let Π_w be a property that can be decided by a width w ROOBP, and let $\varepsilon_c, \varepsilon_f$ denote the proximity parameters. Suppose that there exists a distance approximator for w-width ROOBP (and its subgraphs) with query-complexity $Q_w(\delta, \eta, n)$ and time-complexity $T_w(\delta, \eta, n)$, when δ denotes the approximation parameter, η denotes the error probability bound, and the ROOBP has length n. Then, for every $r : \mathbb{N} \to \mathbb{N}$, there exists an $r(n)$-round tolerant dsIPP for Π_w such that*

- *The verifier's query-complexity is $O(1/\delta)$, and the honest prover's query-complexity is $O(n^{1/r(n)} \cdot Q_w(\delta, \eta)/\delta)$, where $\delta = (\varepsilon_f - \varepsilon_c)/3r(n)$ and $\eta = \delta/O(n^{1/r(n)})$.*
- *The communication complexity is $O(n^{1/r(n)} \cdot r(n) \cdot (\log n)/\delta)$.*

[5] Specifically, if the input is ε_c-close to the property, then the honest prover should convince the verifier to accept (w.h.p.); but if the input is ε_f-far from the property, then the verifier should reject (w.h.p.) regardless of the prover's strategy. We stress that, while in the context of testing, tolerant testing and distance approximation are equivalent (under suitable parameters), this is not the case for dsIPPs (see Section 2 and Remark 8).

- *Assuming that the verifier and the prover have access to procedures specifying the structure of the ROOBP (see above), the verifier's runtime equals the communication complexity (up to constant factors), and the honest prover's runtime is* $O(n^{1/r(n)} \cdot r(n) \cdot \mathsf{T}_w(\delta, \eta, n)) \cdot \widetilde{O}(1/\delta)$.

See Theorem 19 for a full and formal statement. As discussed above, Theorem 1 is obtained from the above reduction by plugging in a distance approximator for constant-width ROOBPs, which we construct based on Newman's (non-tolerant) property tester. While the reduction of Theorem 2 only has polynomial dependence on the width of the ROOBP, Newman's tester and our tolerant version of it have an exponential dependence on the width of the ROOBP (which is the reason that Theorem 1 holds only for constant width).[6] See the details in Section 4.6.

1.2.2 Protocol for Hamming Weight

We construct a dsIPP for the Hamming weight (HW) problem, where the input is a string $x \in \{0,1\}^n$ and a claim about its Hamming weight. Note that Hamming weight cannot be computed by constant-width ROOBP [18], so the results of Section 1.2.1 do not give a dsIPP for HW.

Approximating the (relative) Hamming weight up to distance ε requires $O(1/\varepsilon^2)$ queries in the standalone setting. We construct a dsIPP with $O(1/\varepsilon)$ verifier queries (which is optimal).

▶ **Theorem 3** (dsIPP for Hamming weight, informal)**.** *Let n and ε denote the input length and the proximity parameter for the Hamming weight problem (HW). Then, for every $r : \mathbb{N} \to \mathbb{N}$, there exists an $r(n)$-round dsIPP for HW such that the verifier has query complexity $O(1/\varepsilon)$ and the honest prover's query complexity and its runtime are both $\widetilde{O}(n^{1/r(n)} \cdot r^3(n)/\varepsilon^3)$. Furthermore, the verifier's runtime and the communication complexity are both $O(n^{1/r(n)} \cdot r(n) \cdot \widetilde{O}(1/\varepsilon))$.*

See Theorem 10 for a full and formal statement. This protocol also obtains a trade-off between the number of rounds and the honest prover's runtime. Taking the number of rounds to be logarithmic in n gives a *honest prover with query complexity and runtime that are poly-logarithmic in n*. The honest prover's query complexity and runtime grow cubically with (the reciprocal of) the proximity parameter. We wonder whether this dependence can be improved to quadratic (which would be optimal [1]).

Rothblum, Vadhan and Wigderson [21] also constructed an IPP for Hamming weight, but did not have a sub-linear honest prover. Our HW protocol borrows ideas from the IPP for ROOBP of[7]. Indeed, one can get an IPP for HW directly from their ROOBP protocol, by applying it to the $O(n)$-width ROOBP that computes HW. However, their protocol does not have a sub-linear prover.

1.2.3 Protocol for PERM

For $n \in \mathbb{N}$, the set PERM consists of all permutations over $[n]$. Here we consider the problem of testing (resp., verifying) whether a function $f : [n] \to [n]$ is in PERM. Note that PERM has a tester of complexity $O(\sqrt{n/\varepsilon})$, which we outline below, whereas a query lower bound of $\Omega(\sqrt{n})$ follows from[13].[7] Furthermore, PERM has two different (1-round) IPPs, which were presented in[13] and[7], respectively. We review them next:

[6] In contrast, Theorem 2 holds also for varying width, but in that case the complexities have a multiplicative factor of poly(w).

[7] See also a direct proof in[23, Apdx A].

1. In the IPP of[13] the verifier selects uniformly at random a point $r \in [n]$, and sends r to the prover, who is supposed to return its f-preimage; the verifier accepts if and only if the prover's answer is mapped by f to r.
2. In the IPP of[7], the verifier selects uniformly at random a point $r \in [n]$, queries f on it, and sends $y \leftarrow f(r)$ to the prover, who is supposed to return its f-preimage; the verifier accepts if and only if the prover's answer equals r.
   (This IPP, unlike the previous one, utilizes prover-oblivious queries.)

In both cases, $f \in$ PERM is always accepted, whereas functions that are ε-far from PERM are rejected with probability $\Omega(\varepsilon)$. (In both cases, the protocol is repeated $O(1/\varepsilon)$ times to yield an IPP.)

More importantly, in both cases, the honest prover finds the required f-preimage by querying f on all points (or practically so). Our initial conjecture was that an IPP for PERM cannot have a verifier that uses $o(\sqrt{n})$ queries and an honest prover that makes $o(n)$ queries. Interestingly, this "working conjecture" is wrong.

▶ **Theorem 4** (dsIPP for PERM)**.** *For every $\alpha \in (0, 0.5)$, there exists a 1-round IPP for PERM that has a verifier that uses $O(n/\varepsilon)^{0.5-\alpha}$ queries and an honest prover that uses $O(n/\varepsilon)^{0.5+\alpha}$ queries.*

The communication and time complexity of both parties is $\widetilde{O}((n/\varepsilon)^{0.5+\alpha})$.

Sketch of the proof of Theorem 4. The straightforward tester for PERM consists of selecting $q = O(\sqrt{n/\varepsilon})$ random points in $[n]$, querying the function $f : [n] \to [n]$ on them, and rejecting if and only if collisions are found (among the f-images).

Evidently, any $f \in$ PERM is accepted with probability 1, whereas (as can be seen later) any f that is ε-far from PERM is rejected with high constant probability. A similar analysis for the soundness case implies that for any f that is ε-far from PERM, if we select $O(n/\varepsilon)^{0.5+\alpha})$ random points, then we expect to see $\Omega(n^{2\alpha})$ collisions and that these collisions involve $\Omega(n^{2\alpha})$ disjoint pairs of points. This leads us to the following protocol.

1. The verifier selects $p = O(n/\varepsilon)^{0.5+\alpha}$ (distinct) random points in $[n]$, denoted $s_1, ..., s_p$, and sends them to the prover,
2. The prover queries the input $f : [n] \to [n]$ on these p sample points, and sends the answers $(a_1, ..., a_p) \leftarrow (f(s_1), ..., f(s_p))$ to the verifier.
3. The verifier rejects if it sees a collision (i.e., if $a_i = a_j$ for some $i \neq j$).
4. Otherwise, it sub-samples $m = O(n/\varepsilon)^{0.5-\alpha}$ of the original points, queries f on each of these m samples, and accept if and only if all answers match the prover's answers (i.e., if $f(s_i) = a_i$ for the i's it sub-sampled).

Clearly, $f \in$ PERM is always accepted. Turning to the soundness analysis, we fix an arbitrary function f that is ε-far from PERM and let $C \stackrel{\text{def}}{=} \{x \in [n] : |f^{-1}(f(x))| > 1\}$ denote the set of points that form collisions under f. Then, $|C| > \varepsilon \cdot n$; actually, $|C| - |f(C)| > \varepsilon \cdot n$, because modifying f to a permutation requires changing its value on all but a single point in $f^{-1}(y)$ for every $y \in f(C)$.

An analogous consideration applies to the sample of p points, denoted $S = \{s_1, ..., s_p\}$, that is sent to the prover. Specifically, the answers provided by the prover must disagree with the values of f on at least $|S| - |f(S)|$ points, because for each $s \in S$ the prover must provide different answers to all the other points in S that are in $f^{-1}(f(s))$ (since otherwise the verifier rejects in Step 2). Towards upper-bounding $|f(S)|$, we observe that it is upper-bounded by $|f'(S)|$, where $f' : [n] \to [n]$ is defined such that for every $x, x' \in [n]$ it

holds that (i) $f'(x) \neq f'(x')$ whenever $f(x) \neq f(x')$ and (ii) for each x that forms a collision under f, the restriction of f' to $f^{-1}(f(x))$ is 2-to-1 except on at most one element (in case $|f^{-1}(f(x))|$ is odd). Now, we lower-bound $|S| - |f'(S)|$ by the number of collisions of S under f' (i.e., $|\{\{i,j\} \in \binom{[p]}{2} : f'(s_i) = f'(s_j)\}|$)

First note that the number of collisions of $[n]$ under f' is at least $\sum_{y \in f(C)} \lfloor |f^{-1}(y)|/2 \rfloor$, which is at least $|C|/3 > \varepsilon n/3$. Hence, with high probability over the choice of $S \in \binom{[n]}{p}$, we get $\Omega(\varepsilon \cdot p^2/n) = \Omega((n/\varepsilon)^{2\alpha})$ collisions of S under f'. In this case, there are $\Omega((n/\varepsilon)^{2\alpha})$ disjoint pairs of points in S such that the elements in each pair have the same f'-image (and hence also the same f-image).

Wishing to avoid rejection in Step 2, the prover must cheat on the values of the $\Omega((n/\varepsilon)^{2\alpha})$ foregoing points (in S), but (with high probability) at least one of these points will appear in the sub-sample that the verifier selects in Step 4 (since the sub-sample rate is $m/p = O(\varepsilon/n)^{2\alpha}$). Hence, in Step 4, when quering the function f on this sub-sample, the verifier detects this cheating and rejects (w.h.p.). This completes the proof of Theorem 4.

1.2.4 Protocol for Bipartiteness

We construct a dsIPP for a *relaxation* of graph bipartiteness in the bounded degree model. In this model (see, e.g.,[4, Sec. 9.1]), the input is an undirected n-vertex graph of constant maximum degree d. The input graph is represented by its incidence function $g : [n] \times [d] \to [n] \cup \{0\}$ such that $g(v,i)$ is the i-th neighbor of the vertex v (or 0 if v has less than than i neighbors). The prover and the verifier have query access to this function. The distance between two n-vertex graphs is the ratio (over $dn/2$) of the number of edges on whose presence or absence they disagree.

The promise problem we consider is that the input graphs are rapidly-mixing graphs; that is, graphs in which a random lazy walk of logarithmic length starting at any vertex reaches any other vertex with probability $\Theta(1/n)$. (An ℓ-step lazy walk is described by a ℓ-long sequence over $[2d]$ such that $i \in [2d]$ indicates a step that moves from the current vertex v to its i^{th} neighbor (in case v has at least i neighbors) and staying in place if v has less than i neighbors.)

▶ **Theorem 5** (dsIPP for bipartiteness). *Let n and ε denote the number of vertices and the proximity parameter. Then, there exists a 1-round dsIPP for bipartiteness on rapidly-mixing graphs in the bounded-degree graph model in which the verifier's query complexity is $O(\log(n)/\varepsilon)$, and the honest prover's query and time complexity are $\widetilde{O}(\sqrt{n}/\varepsilon)$. Furthermore, the verifier's runtime is polylog$(n)/\varepsilon$, and the communication complexity is $O(\log(n)/\varepsilon)$.*

Related work. Goldreich and Ron [9] showed a $\Omega(\sqrt{n})$ lower bound on the query complexity of testing bipartiteness.[8] A later work of the same authors[8] shows a tester with $\widetilde{O}(\sqrt{n}) \cdot \mathsf{poly}(1/\varepsilon)$ query complexity. We remark that their tester works for general graphs, without needing the rapidly-mixing condition. Rothblum, Vadhan and Wigderson [21] constructed an IPP for an intermediate relaxation of bipartiteness, where the YES case includes all the bipartite graphs, but the NO case includes only the graphs that are both far from bipartite and rapidly-mixing. In their IPP, the verifier's query complexity is $O(\log(n)/\varepsilon)$, but the

[8] Their lower bound, which is stated for general 3-regular graphs, also holds under the additional promise that the graphs are rapidly-mixing (see the exposition in [4, Sec. 9.3.1]). In particular, the distribution of NO cases is concentrated on expander graphs (see [4, Clm. 9.18.1]). A similar analysis shows that the YES cases are bipartite expanders (w.h.p.)

honest prover is not sub-linear: it has to read the entire graph. Our proof of Theorem 5 uses the [21] protocol, but shows a sublinear-time implementation for the honest prover, where the implementation works for graphs that are both *rapidly-mixing* and bipartite.

Proof of Theorem 5: The sublinear-time honest prover. We first recall the[21] protocol. In the basic test, the verifier picks a random vertex s, and performs a lazy random walk of length $\ell = O(\log(n))$, which is long enough to guarantee the "rapidly-mixing" condition (see above), reaching a vertex t. The verifier sends s and t to the prover, asks the prover to recover the parity of a (simple) path that leads from s to t, and accepts if and only if the answer equals the parity of the number of "real moves" in the lazy walk (i.e., moves in which the walk did not stay in the current vertex). If the graph is bipartite, then the prover, who can read the entire graph, can always answer correctly by checking whether s and t are on the same side of the bipartition. As shown in[21], if the graph is rapidly mixing and ε-far from bipartite, then a cheating prover will fail with probability $\Omega(\varepsilon)$. In order to reduce the soundness error (from $1 - \Omega(\varepsilon)$ to $1/3$), this basic test is repeated $r = O(1/\varepsilon)$ times in parallel (and the verifier accepts if and only if it accepted in all invocations of the basic test).

We construct a sub-linear time honest prover for the basic test. Upon receiving the vertices s and t, the prover performs $w = O(\sqrt{n} \cdot \log(1/\varepsilon))$ independent random walks of length ℓ starting at s, as well as w independent random walks of length ℓ starting at t. Let W_s (resp., W_t) denote the set of vertices traversed in (the union of all) the walks that started at s (resp., t). The prover checks if there is a vertex v in the intersection of W_s and W_t (i.e., a vertex encounted in a walk that started at s as well as in a walk that started at t). If so, then the prover has found a walk from s to t (going through v), and it replies with the parity of the number of real moves on this walk.

Soundness follows directly from the soundness of the [21] protocol (since we did not change the verifier). We now argue for completeness (alas not perfect completeness). If the graph is bipartite, then all paths from s to t have the same parity. Thus, whenever the prover finds a path from s to t (i.e., when the intersection is non-empty), then it returns the correct parity. It remains to show that in each of execution of the basic test (i.e., for each s and t sent by the verifier), the intersection of W_s and W_t is non-empty with probability at least $1 - (1/3r)$. We show this in Claim 6, which is where we use the condition that the graph is rapidly-mixing, and it follows that the verifier accepts in all r repetitions with probability at least $2/3$.

▷ Claim 6. If the graph is rapidly-mixing, then, for every two vertices $s, t \in [n]$, the probability, over the honest prover's random walks, that $W_s \cap W_t = \emptyset$ is at most $1/3r$.

Proof. We focus on the sets $W'_s \subset W_s$ and $W'_t \subset W_t$ of *terminal* vertices reached by the random walks (i.e., the final vertex in each walk), and show that these subsets intersect with probability at least $1 - (1/3r)$. Using the rapidly-mixing condition, observe first that taking $w = O(\sqrt{n} \cdot \log(1/\varepsilon)) = O(\sqrt{n} \log r)$ independent walks from s, with probability at least $1 - (1/6r)$, the number of distinct vertices reached (i.e., the size of the set W'_s) is $\Omega(\sqrt{n})$. Assuming that this event occurs, and recalling that each of the random walks starting at t is rapidly-mixing, we infer that, with probability at least $\Omega(1/\sqrt{n})$, such a walk terminates in a vertex that resides in W'_s. Recalling that there are $O(\sqrt{n} \cdot \log r)$ walks starting at t, the probability that they all land outside of W'_s is thus at most $1/6r$. The claim follows. ◁

1.3 Further Related Work

Goldwasser, Rothblum, Shafer and Yehudayoff [11] studied interactive proofs for approximate verification of the results of a machine-learning computation on an unknown underlying distribution. The verifier and the honest prover both have sampling access to the unknown distribution (in some of their results the honest prover also has membership queries, see also [12]). While their model is quite different from ours, there is a similarity in spirit: if we think of the unknown distribution as a "huge input" to the proof system, then they are also concerned with proof systems where verification is more efficient than the computation being verified (a learning problem), and proving is not much more expensive than performing the same computation. In particular, proving is sub-linear in the size of the "input" (the unknown distribution). The settings, however, are quite different: both in the access to the input (querying an unknown function vs. sampling from an unknown distribution), and in the types of tasks studied (approximate decision vs. machine learning). We stress that other recent works on verifying properties of unknown distributions [2, 14, 15] do *not* study *honest provers with sublinear sample complexity.*

1.4 Technical Overview

In this section provide overviews of our dsIPPs for Hamming Weight and for properties that are decidable by ROOBPs. Recall that the dsIPPs for PERM and for a relaxed version of Bipartiutness were sketched in prior sections.

We start by outlining our IPPs for Hamming Weight (HW), and then extend its underlying ideas to obtain IPPs for ROOBPs. Both IPPs follow an abstract idea that underlies the IPPs of[21, 7], but deviate from it in a significant manner. Loosely speaking, the IPPs of[21, 7] rely on partitioning the original property to sub-properties that refer to parts of the original input. However, while the IPPs of[21, 7] call for an honest prover strategy that finds optimal partitions of the property to sub-properties, we shall use partitions that are sub-optimal, because these sub-optimal partitions can be found more efficiently (by the honest prover).

IPPs for Hamming Weight (HW). Our r-round IPPs proceed by recursion, where for a parameter k (to be set to $n^{1/r}$), the current input x is partitioned to k equal-length blocks, denoted $x_1, ..., x_k$. Clearly, the Hamming weight of x, denoted $\mathtt{wt}(x)$, equals the sum of the Hamming weights of the x_i's (i.e., $\sum_{i\in[k]} \mathtt{wt}(x_i)$). Hence, wishing to prove that $\mathtt{wt}(x)$ equals w, an optimal prover determines the corresponding weights of the x_i's, denoted $w_1, ..., w_k$, sends the w_i's to the verifier, who selects a random i, and the parties proceed to prove that the weight of x_i equals w_i. (Indeed, after r iterations, the verifier can check the claim, which refers to a single bit, by making a single query.) Needless to say, determining these w_i's requires reading the entire input x, which we want to avoid. Instead, we consider a query-efficient honest prover that obtains approximations of the desired w_i's (or obtains the exact value when $|x| = k$, which happens after $r-1$ recursion steps). This requires relaxing the verification procedure so that it does not reject in case the sum $\sum_i w_i$ does not equal w (but is rather only close to it).

As in[21], the soundness analysis relies on the fact that if $|\mathtt{wt}(x) - w| > \Delta$, then, for every sequence of w_i's such that $\sum_{i\in[k]} w_i = w$, it holds that $\sum_{i\in[k]} |\mathtt{wt}(x_i) - w_i| > \Delta$; equivalently, if x is ε-far from having weight w, then, for every sequence of w_i's such that $\sum_{i\in[k]} w_i = w$, on the average, x_i is ε-far from having weight w_i. Note, however, that if we allow $\sum_{i\in[k]} w_i$ to deviate from w by say $\varepsilon' \cdot |x|$, then, on the average, x_i is $(\varepsilon - \varepsilon')$-far from having weight w_i. Hence, at the bottom of the recursion, the expected distance of single bits from their claimed weight is $\varepsilon - r \cdot \varepsilon'$, which means that the verifier rejects with such probability. Using $\varepsilon' = \varepsilon/2r$ and repeating the protocol $O(1/\varepsilon)$ times, we obtain the desired IPP.

IPPs for constant-width ROOBP. As in the case of HW, we wish to proceed by recursion. Indeed, in the r-round IPP of[7], on current input x, an optimal prover determines the path in the current ROOBP that accepts x, which (as before) is partitioned to equal-length strings $x_1, ..., x_k$. This path defines k sub-ROOBPs that each accept the corresponding x_i's. Alas, determining these sub-ROOBPs requires reading the entire input x, which we want to avoid.

Using the fact that the ROOBP has bounded width, it follows that, for each $i \in [k]$, there is a bounded number of sub-ROOBPs (i.e., the square of the width bound) such that x_i is accepted by (at least) one of them. Using a distance approximator for (constant-width) ROOBPs, the honest prover can find, for each $i \in [k]$, a sub-ROOBP such that x_i is close to being accepted by this sub-ROOBP. This means that the foregoing description has to be modified: In subsequent iteration of the recursion it does not necessarily hold that the current x is accepted by the current ROOBP; it is only the case that the current x is close to being accepted by the current ROOBP. But in this case, for $x = (x_1, ..., x_k)$, it does not necessarily hold that each x_i is close to being accepted the corresponding sub-ROOBPs, but it is rather the case that their average distance from these sub-ROOBPs is small; that is, if x is ε-close to the current ROOBP, then for some $\varepsilon_1, ..., \varepsilon_i$ such that $\sum_{i\in[k]} \varepsilon_i/k = \varepsilon$, each x_i is ε_i-close to a corresponding sub-ROOBP, but it is not necessarily the case that $\varepsilon_i \approx \varepsilon$ for each $i \in [k]$.

Recall that the honest prover does not find these ε_i's, but rather finds their approximate values (as well as the corresponding sub-ROOBPs). Specifically, for width bound b, the honest prover considers an auxilary graph G with $k+1$ layers, index $0, 1, ..., k$, such that the i^{th} layer of G contains the vertices that are at the $i \cdot k$ layer of the current ROOBP. Each pair of vertices in adjacent layers of G represents a possible sub-ROOBP, where pairs in layers $i-1$ and i of G represent a sub-ROOBP that reads x_i. For each such pair, the honest prover estimates the distance of x_i from being accepted by the corresponding sub-ROOBP, where these estimates are obtained by invoking the distance-approximator (for ROOBPs). Using a shortest path algorithm, the honest prover finds sequence of intermediate vertices $(v_1, ..., v_{k-1})$ in G such that the average distance of the x_i's from the corresponding sub-ROOBPs, denoted $(B_1, ..., B_k)$, is minimal, and sends $(v_1, ..., v_{k-1})$ to the verifier along with the corresponding distances. (As in the case of HW, the verifier will select $i \in [k]$ uniformly at random, and the parties will proceed to prove the corresponding claim (i.e., that x_i is ε_i-close to being accepted by the corresponding sub-ROOBP).)

2 Preliminaries and Definitions

For strings $x, y \in \{0,1\}^n$, the relative Hamming distance between x and y is the fraction of coordinates in which they disagree (we often refer to this as the *distance* for short). If this distance is at most ε, then we say that x is ε-close to y, and otherwise we say that x is ε-far from y. We define the distance of x from a (non-empty) set $S \subseteq \{0,1\}^n$ as its distance from the closest y in S, and we define the string being ε-close and ε-far from the set analogously. We extend these definitions from strings to functions by identifying a function with its truth table.

A property Π (or a language) is a set of strings of varying lengths (i.e. in $\{0,1\}^*$). The approximate decision problem for Π is deciding, for specified proximity parameters, whether an input string is close or far from the property. See [4] for an introduction to property testing: the field that studies algorithms of sublinear query complexity for such approximate decision problems.

▶ **Definition 7** (Interactive Proof of Proximity (IPP, tolerant)). *An IPP is a protocol between two probabilistic parties, a prover P and a verifier V who both get an input length n and a joint input $x \in \{0,1\}^n$. The verifier has query access to x (and explicit access to the input length n). The parties interact and at the end of the interaction the verifier accepts or rejects. The protocol is a (tolerant) IPP for a property Π and for proximity parameters $\varepsilon_c, \varepsilon_f : \mathbb{N} \to \mathbb{R}$ if for every input length n and every input $x \in \{0,1\}^n$:*

- ***Completeness:*** *If x is $\varepsilon_c(n)$-close to the property Π (in relative Hamming distance), then the verifier, after interacting with the prover P, accepts with probability at least $2/3$ (the probability is over the prover's and the verifier's coin tosses). If the verifier, interacting with the honest prover, accepts every input in the language with probability 1 then we say that the IPP has* perfect completeness.
  In this work we focus on IPPs where the honest prover only has query access to the input x (similarly to the verifier, it gets the input length n as an explicit input).
- ***Soundness:*** *If x is $\varepsilon_f(n)$-far from the property Π, then for every cheating strategy P^*, the verifier V, after interacting with the prover P^*, rejects with probability at least $2/3$ (the probability is over the verifier's coin tosses, w.l.o.g. the cheating prover can be taken to be deterministic, and can have explicit access to the entire input).*

A non-tolerant IPP is one where $\varepsilon_c = 0$. In this case, we refer to a single proximity parameter $\varepsilon = \varepsilon_f$ (the parameter ε_c is implicit). Testers are viewed as a special case of IPPs in which there is no prover (or no interaction with it).

The protocol's complexity measures include the (honest) prover's and the verifier's query complexities and runtimes, the communication complexity and the round complexity (the number of back-and-forth communication rounds). These complexities are typically measured as a function of the gap $(\varepsilon_f(n) - \varepsilon_c(n))$ between the proximity parameters and of the input length.

Our focus in this work is on protocols where the query complexities of the verifier and the honest prover are as small as possible. In particular, we focus on properties that have testers of sublinear query complexity and require that the verifier's query complexity should be smaller than the tester's. The prover's query complexity should be as close as possible to the tester's. We refer to these as *doubly sub-linear* IPPs (dsIPPs, see the discussion in the Introduction).

▶ Remark 8. We emphasize that, while in the context of testing, tolerant testing and distance approximation are equivalent [17] (under suitable parameters), this is not the case for IPPs. The reason for this divergence is that a tolerant IPP only provides a one-sided guarantee: it can affirmatively convince the verifier of *upper bounds* on the input's distance from the property, but it does not convince the verifier of a *lower bound* on the distance.

▶ Remark 9. We remark that in the study of standard IPPs (where the honest prover can read the entire input), if we allow linear communication complexity, then the query complexity can always be tiny. This is because the prover can send the entire input to the verifier. The verifier receives this alleged input and verifies that it is close to the real input by checking consistency for a few random locations (these are the only queries made to the real input). If the alleged input is close to the real input, then the verifier can simply check if the alleged input is in the property (or, for tolerant protocols, that it is at the appropriate distance from the property). For dsIPPs it is not clear that linear communication always allows for a sublinear verifier. In particular, the aforementioned strategy cannot be utilized because the honest prover doesn't know the entire input and cannot send it. Thus, dsIPPs with linear (or even polynomial) communication may be an interesting object for further study.

3 dsIPP for the Hamming Weight Problem

In this section, we present a doubly sub-linear IPP (dsIPP) for the Hamming Weight Problem. Specifically, given a claimed weight $\sigma \in \mathbb{N}$, a proximity parameter $\varepsilon > 0$ and an oracle access to an input $x \in \{0,1\}^n$, we present an r-round IPP, with $r = \log(n)$ and with poly-logarithmic communication complexity, in which V verifies that $\mathtt{wt}(x) = \sigma$ using query complexity of $O(\frac{1}{\varepsilon})$, the honest prover P uses poly-logarithmic query complexity. We note that we use r to represent the number of (pairs) of message exchanges (and not the total number of messages sent).

First, in Section 3.1, we present a standard IPP for the Hamming Weight Problem. This IPP (which is not doubly sub-linear) uses a divide-and-conquer approach, and in it the prover P computes exact weights for sub-sequences of the input x. Then, in Section 3.2, we present a warm-up towards a dsIPP: We amend the standard IPP by allowing P to approximate the Hamming weight of the sub-sequences, and relaxing the accepting conditions of V in a way that doesn't compromise the completeness and soundness of the protocol. Unfortunately, in this IPP the prover P still has query complexity of $\Omega(n)$. Lastly, in Section 3.3, we present the actual dsIPP, which applies the IPP presented in Section 3.2 recursively, thus improving the query complexity of P without compromising the query complexity of V.

3.1 The Standard IPP

Given some σ, we want to verify that $\mathtt{wt}(x) = \sigma$. First, we observe that when we partition x to k consecutive equally-length parts, $x_1, ..., x_k$, the following holds:

- On the one hand, if $\mathtt{wt}(x) = \sigma$, then $\sum_i \mathtt{wt}(x_i) = \sigma$.
- On the other hand, if $|\mathtt{wt}(x) - \sigma| > \varepsilon n$, then for any $(\sigma_1, ..., \sigma_k)$ such that $\sum_i \sigma_i = \sigma$, it holds that $\sum_i |\mathtt{wt}(x_i) - \sigma_i| > \varepsilon n$.

Given the above, we consider the following IPP: P sends $(\sigma_1, ..., \sigma_k) \leftarrow (\mathtt{wt}(x_1), ..., \mathtt{wt}(x_k))$ to V. Then, V verifies that $\sum_i \sigma_i = \sigma$, and if so, selects at random $i \in [k]$, and verifies that $\mathtt{wt}(x_i) = \sigma_i$ (by reading the entire x_i). Note that if $\mathtt{wt}(x) = \sigma$ and V interacts with P, then for every i, it holds that $\mathtt{wt}(x_i) = \sigma_i$, and the verifier always accepts. However, if $|\mathtt{wt}(x) - \sigma| > \varepsilon n$ and $\sum_i \sigma_i = \sigma$, it holds that $\sum_i \frac{\mathtt{wt}(x_i) - \sigma_i}{k} > \varepsilon \cdot \frac{n}{k}$. Then, the average deviation of the claimed weight of x from the actual weight of x translates to a deviation on a corresponding fraction of random i's, hence guarantees that the verifier rejects with probability at least ε. To increase the rejection probability, we can repeat this procedure for $O(\frac{1}{\varepsilon})$ times.

The query complexity of the verifier is the length of a single x_i times the number of repetitions, which gives $O(\frac{n}{\varepsilon \cdot k})$. However, to compute $(\mathtt{wt}(x_1), ..., \mathtt{wt}(x_k))$, the prover must access to the entire input x, which yields query complexity of n.

3.2 A Warm-Up towards a dsIPP

In this section, we aim to achieve poly-logarithmic query complexity for the honest prover P without compromising the query complexity of the verifier V: We amend the interaction described in Section 3.1 by allowing P to *approximate* the Hamming weight of the sub-parts of x. However, at the end of this section, we explain why P still has query complexity of $\Omega(n)$. In Section 3.3, we show how to solve this issue and present the actual dsIPP.

First, we observe that for a deviation parameter $\delta > 0$ and an error probability parameter $\eta > 0$, there exists a (δ, η)-approximator for the Hamming weight of $x \in \{0,1\}^n$ with query complexity $O(\frac{\log(\frac{1}{\eta})}{\delta^2})$ and error probability η: Given the input x and the deviation parameter

δ, the approximator chooses, uniformly at random, $O(\frac{\log(\frac{1}{\eta})}{\delta^2})$ indices of x, and outputs the (normalized) number of indices i for which $x[i] = 1$. Using Chernoff bound, we can show that with probability at least $1 - \eta$, the output of the approximator deviates from $\mathtt{wt}(x)$ by at most δn.

Based on this approximator, we amend the interaction such that the prover provides *approximated* weights to the verifier, by using the approximator with some predefined error probability $\eta > 0$ and deviation parameter $\delta > 0$ (we fix both parameters later). That is, P sends $(\sigma_1, ..., \sigma_k)$ to V, such that for every $i \in [k]$, σ_i is a (δ, η)-approximation for $\mathtt{wt}(x_i)$. We also change the verifier's accepting conditions in the interaction, so that V allows this deviation (and doesn't reject P's approximations). That is, V now verifies that $|\sigma - \sum_i \sigma_i| \leq \delta n$, chooses $i \in [k]$ uniformly at random, and verifies that $|\mathtt{wt}(x_i) - \sigma_i| \leq \frac{\delta \cdot n}{k}$ (by reading the entire x_i). Similar to the standard IPP, we repeat the protocol for $O(\frac{1}{\varepsilon})$ times.

3.2.1 Correctness

The completeness of the protocol still holds (but with a completeness error): If $\mathtt{wt}(x) = \sigma$ and we interact with P, then for a single invocation of the protocol the following holds: For every $i \in [k]$, with probability at least $1 - k \cdot \eta$, it holds that $|\sigma_i - \mathtt{wt}(x_i)| \leq \frac{\delta \cdot n}{k}$, and therefore also $\sum_i |\mathtt{wt}(x_i) - \sigma_i| \leq \delta n$, and the verifier accepts. Since we invoke the protocol for $O(\frac{1}{\varepsilon})$ times, then the verifier accepts in all invocations with probability at least $1 - t \cdot \eta$ where $t = O(\frac{k}{\varepsilon})$. Thus, we can set $\eta \leq 0.01 \cdot \frac{1}{t} = O(\frac{\varepsilon}{k})$, and the verifier accepts with high constant probability in all invocations.

To show the soundness of the protocol also holds, we observe that if $|\mathtt{wt}(x) - \sigma| > \varepsilon n$, then for any $(\sigma_1, ..., \sigma_k)$ such that $|\sigma - \sum_i \sigma_i| \leq \delta n$, it holds that $\sum_i |\mathtt{wt}(x_i) - \sigma_i| > (\varepsilon - \delta)n$. Then, the average deviation of the claimed weight of x from the actual weight of x, beyond the allowed deviation, translates to a deviation on a corresponding fraction of random i's. Since the verifier rejects if $|\mathtt{wt}(x_i) - \sigma_i| > \frac{\delta n}{k}$, we can set $\delta = \frac{\varepsilon}{3} < \frac{\varepsilon}{2}$ and infer that the verifier still rejects with probability at least $\Omega(\varepsilon)$ in a single invocation. Since we invoke the protocol for $O(\frac{1}{\varepsilon})$ times, we get that the verifier rejects with high constant probability in at least one of the invocations.

3.2.2 Query Complexity

Now, let us analyze the query complexity of V and P:

- The query complexity of V is $O(\frac{n}{\varepsilon k})$, because we read a sub-sequence of the input of length $\frac{n}{k}$ for $O(\frac{1}{\varepsilon})$ repetitions.
- The query complexity of P is $O(\frac{k \cdot \log(\frac{k}{\varepsilon})}{\varepsilon \cdot \delta^2})$, since we invoke the approximator with error probability parameter $\eta = O(\frac{\varepsilon}{k})$ for k times in each of the $O(\frac{1}{\varepsilon})$ repetitions.

Since we can $(\delta, 0.1)$-approximate the Hamming weight of x without any interaction using query complexity $O(\frac{1}{\delta^2})$, we can perform ε-test for the Hamming weight of x using query complexity $O(\frac{1}{\varepsilon^2})$. Therefore, for the IPP to be meaningful, we want the query complexity of V to be $o(\frac{1}{\varepsilon^2})$. To achieve this in our setting, we must require $k = \omega(\varepsilon \cdot n)$. However, this causes the query complexity of P to be $\Omega(n)$, whereas we want our IPP to be doubly sub-linear. In the next section, we extend the foregoing IPP by applying it recursively, and show that we can get both query complexity of $o(\frac{1}{\varepsilon^2})$ for V, **and** poly-logarithmic query complexity for P.

3.3 The Actual dsIPP

In Section 3.2, we aim to achieve poly-logarithmic query complexity for the honest prover P, without compromising the query complexity of the verifier V. Unfortunately, for reasons explained at Section 3.2.2, P still has query complexity of $\Omega(n)$.

To solve this, we extend the IPP presented in Section 3.2 by applying it recursively: That is, after V selects at random $i \in [k]$, instead of directly computing the Hamming weight of x_i, both parties recursively run the protocol on x_i with the claimed Hamming weight σ_i, and do it for r rounds. Only in the base of the recursion, V computes the Hamming weight of the input (at this level), and accepts accordingly. This gives us an improvement in the query complexity of the verifier, as the length of the input after r rounds is $(\frac{n}{k^r})$, while the number of times the prover needs to run the approximator grows only to $k \cdot r$ (in every repetition). To make sure that the query complexity of V is $o(\frac{1}{\varepsilon^2})$, we set $k = n^{\frac{1}{r}}$.

Indeed, we now allow the prover to deviate from the claimed weight for r times: At each of the recursion levels, as well as in the base level. Thus, to make sure that soundness still holds (i.e. the total allowed deviation is not too big), we set the verifier's allowed deviation (i.e. δ) to be smaller (by a factor of r).

To make sure that completeness still holds, we first change the error probability parameter of the approximator. P now runs the approximator for a total of $t = O(\frac{k \cdot r}{\varepsilon})$ times, and so we set $\eta = 0.01 \cdot \frac{1}{t} = O(\frac{\varepsilon}{k \cdot r})$. In addition, we observe the following: Assume V interacts with P, with input x and weight parameter σ, such that $\mathtt{wt}(x) = \sigma$. Then, when we are not in the first recursion level, then the weight parameter provided to the protocol is the approximated weight provided by P in the previous recursion level. Therefore, the weight parameter in the current recursion level might deviate from the actual weight of the input in this level. Since P also performs weight approximations in the current recursion level, we need to account for both deviations. Details follow.

▶ **Protocol 1.** *dsIPP for the Hamming Weight Problem*

- ***Query Access Input:*** $x \in \{0,1\}^n$
- ***Deviation Parameter:*** $\varepsilon > 0$
- ***Other Parameters:*** *Weight* $\sigma \in \mathbb{N}$*, initial number of rounds* r_0 *and remaining number of rounds* r

Repeat the protocol for $O(\frac{1}{\varepsilon})$ *times, and accept iff* V *accepts in all repetitions.*

We show that Protocol 1 is a dsIPP for the Hamming Weight Problem: In Section 3.3.1, we show the correctness of the protocol, and in Section 3.3.2, we present the query complexity of the protocol.

3.3.1 Correctness

Completeness. Assume $\mathtt{wt}(x) = \sigma$ and V interacts with P. We observe that at any recursion level (but the base level), the following claim holds: If our input is x' and our weight parameter is σ' such that $|\mathtt{wt}(x') - \sigma'| \leq \frac{\delta|x'|}{2}$, then with probability at least $1 - \eta \cdot k$, the prover P sends $(\sigma'_1, ..., \sigma'_k)$ to V such that the following holds:

1. The verifier doesn't reject in Step $4(a)$ (i.e., $|\sigma' - \sum_i \sigma'_i| \leq \delta|x'|$).
2. The protocol is recursively invoked with some x'_i and σ'_i for which $|\mathtt{wt}(x'_i) - \sigma'_i| \leq \frac{\delta|x'|}{2}$.

The claims follows from the fact that P runs the approximator on every x'_i with deviation parameter $\frac{\delta}{2}$ and error probability parameter η. Then, since we start with $\mathtt{wt}(x) = \sigma$, with probability at least $1 - \eta \cdot k \cdot r_0$, the verifier doesn't reject in Step $4(a)$ in all the r_0 recursion levels. By the second item of the claim, the base of the recursion is also invoked with an input x' and weight parameter is σ' such that $|\mathtt{wt}(x') - \sigma'| \leq \frac{\delta|x'|}{2}$, and the verifier accepts. Since we repeat the protocol for $O(\frac{1}{\varepsilon})$ times, we get that the verifier accepts in all invocations with probability at least $1 - t \cdot \eta$ where $t = O(\frac{k \cdot r_0}{\varepsilon})$. Then, since we set $\eta = 0.01 \cdot \frac{1}{t} = O(\frac{\varepsilon}{k \cdot r_0})$, we get that V accepts with high constant probability in all invocations.

Soundness. Assume $|\mathtt{wt}(x) - \sigma| > \varepsilon n$. We observe that in each recursion level, we lose at most an additive factor of δ. Since we set $\delta = \frac{\varepsilon}{3r_0}$, we get that after r_0 rounds, we are still at distance at least $\frac{\varepsilon}{2}$ from a valid assertion. Thus, the verifier rejects with probability at least $\Omega(\varepsilon)$ *in each invocation*, and therefore rejects with high constant probability in at least one of the $O(\frac{1}{\varepsilon})$ invocations.

3.3.2 Computational Complexity

We present the query, communication and time complexity of Protocol 1. Let us start by analyzing the query complexity of V (denoted Q_V) and P (denoted Q_P):

- $\mathsf{Q}_V = O(\frac{n}{\varepsilon k^{r_0}}) = O(\frac{1}{\varepsilon})$, because we read a sub-sequence of the input of length $\frac{n}{k^{r_0}} = 1$ for $O(\frac{1}{\varepsilon})$ times.
- Q_P is the query complexity of the approximator times the number of calls P makes to the approximator in all repetitions:
  - The query complexity of the approximator is $O(\frac{r_0^2 \cdot \log(\frac{k \cdot r_0}{\varepsilon}))}{\varepsilon^2})$, because P invokes the approximator with error probability parameter $\eta = O(\frac{\varepsilon}{k \cdot r_0})$ and deviation parameter $\delta = O(\frac{\varepsilon}{r_0})$.
  - P calls the approximator for $k \cdot r_0$ times in each of the $O(\frac{1}{\varepsilon})$ repetitions.

  Since we set $k = n^{\frac{1}{r_0}}$, we get that $\mathsf{Q}_P = \tilde{O}(\frac{n^{\frac{1}{r_0}} \cdot r_0^3}{\varepsilon^3})$.

Hence, regardless of how we set r_0, the query complexity of the verifier is $O(\frac{1}{\varepsilon}) = o(\frac{1}{\varepsilon^2})$. Indeed, the larger we set r_0, the smaller Q_P gets, but this causes the round complexity to grow. Specifically, to minimize Q_P, we can set $r_0 = \log(n)$, and we get $\mathsf{Q}_P = \tilde{O}(\frac{\log^3(n)}{\varepsilon^3})$.

Now, the communication of Protocol 1 is $O(\frac{k \cdot r_0}{\varepsilon} \cdot \log(\frac{r_0}{\varepsilon}))$: In each of the $O(\frac{1}{\varepsilon})$ repetitions there are r_0 rounds, and in each round the prover P sends k weight approximations that can be represented by $O(\log(\frac{r_0}{\varepsilon}))$ bits (because the approximations are up to a factor of $\delta = O(\frac{\varepsilon}{r_0})$). Again, since we set $k = n^{\frac{1}{r_0}}$, we can set $r_0 = \log(n)$ and get poly-logarithmic communication complexity.

Lastly, the time complexity of the honest prover (denoted T_P) is the same as its query complexity (i.e., $\mathsf{T}_P = \mathsf{Q}_P$), whereas the time complexity of the verifier (denoted T_V) is $O(\frac{k \cdot r_0}{\varepsilon} \cdot \log(\frac{r_0}{\varepsilon}))$, because in each of the $O(\frac{1}{\varepsilon})$ repetitions there are r_0 rounds, and in each round the verifier performs simple calculations on $O(k)$ values that can be represented by $O(\log(\frac{r_0}{\varepsilon}))$ bits.

We conclude with the following theorem, that summarizes what we achieved in this section.

▶ **Theorem 10.** *For every function $r : \mathbb{N} \to \mathbb{N}$, there exists an $r(n)$-round dsIPP for the Hamming Weight Problem with $Q_V = O(\frac{1}{\varepsilon})$, $Q_P = \tilde{O}(\frac{n^{\frac{1}{r(n)}} \cdot r(n)^3}{\varepsilon^3})$ and communication complexity of $O(\frac{n^{\frac{1}{r(n)}} \cdot r(n) \cdot log(\frac{r(n)}{\varepsilon})}{\varepsilon})$. In addition, the time complxity of the dsIPP is $T_P = Q_P$ and $T_V = O(\frac{n^{\frac{1}{r(n)}} \cdot r(n) \cdot log(\frac{r(n)}{\varepsilon})}{\varepsilon})$.*

4 Tolerant dsIPP for ROOBPs of Constant Width

In this section, we present a tolerant dsIPP for ROOBPs of constant width. Before we review our plan in Section 4.2, let us recall some standard definitions related to ROOBPs.

4.1 Definitions

▶ **Definition 11** (ROOBP). *A **branching program (BP)** on n variables is a directed acyclic graph that has a unique source vertex (denoted s) with in-degree 0 and a unique sink vertex (denoted t) with out-degree 0. Each non-sink vertex is labeled by an index $i \in [n]$, and has 2 outgoing edges, which are labeled by either 0 or 1. An input $x \in \{0,1\}^n$ defines a walk on B starting at the source vertex, such that at every vertex labeled by $i \in [n]$, the step taken is on the edge labeled by x_i. The output of the branching program B on input $x \in \{0,1\}^n$, denoted $B(x)$, is defined as 1 if the walk reached the sink vertex, and 0 if it got "stuck" before reaching it (i.e., the walk reached vertex labeled by $i \in [n]$, and there was no outgoing edge labeled by x_i).*

*An **oblivious BP** is a BP in which the nodes are partitioned into levels, $L_0, ..., L_n$, and edges are going only from one level to nodes in the consecutive level. In addition, all the vertices of some level are associated with the same index. Therefore, we can say that the level itself is associated with some index. A **read-once oblivious BP (ROOBP)** is a BP in which no two levels are associated with the same index. An **ROOBP of constant width** w is an ROOBP in which every level has at most w vertices.*

From now on, let B be an ROOBP with n variables and width at most w.

▶ Remark 12. By the above, there's a 1-1 correspondence between an $s \rightsquigarrow t$ path in B and an **accepting** input for B. In that case, we say that the $s \rightsquigarrow t$ path is **associated** with the accepting input.

▶ Remark 13. We say that two vertices $u \in L_l$ and $v \in L_{l'}$ in B are connected only if they are connected via a **directed** path. If $l < l'$, we say that u is **forwards-connected** to v, and v is **backwards-connected** to u.

▶ Remark 14. Without loss of generality, we assume:

1. For every $i \in \{0, ..., n-1\}$, L_i is associated with the index i. Otherwise, we can change the input x to an input x' by reordering its indices accordingly.
2. B depends on the entire input. Otherwise, we can change the input to $x' \in \{0,1\}^{n'}$, and then B will depend on every index of x'.
3. There exists a path between the source and the sink of B; this is equivalent to assuming there exists an $x \in \{0,1\}^n$ accepted by B.

▶ **Definition 15** (Absolute and Relative Distance). *We denote the **absolute distance** between two strings $x, x' \in \{0,1\}^n$ by $\Delta(x, x') = |\{x[i] \neq x'[i] : i \in [n]|$, and their **relative distance** by $\overline{\Delta}(x, x') = \frac{\Delta(x,x')}{n}$. Assume there exist an accepting input for B, an ROOBP of length n.*

We denote the ***absolute distance*** *of a string $x \in \{0,1\}^n$ from B by $\Delta(x,B) = min\{\Delta(x,x') : x' \in \{0,1\}^n, B(x') = 1\}$. Similarly, the* ***relative distance*** *of x from B is denoted by $\overline{\Delta}(x,B) = min\{\overline{\Delta}(x,x') : x' \in \{0,1\}^n, B(x') = 1\}$.*

4.2 Our Plan

For a fixed ROOBP B of width w, proximity parameters $\varepsilon_f > \varepsilon_c \geq 0$, and oracle access to an input $x \in \{0,1\}^n$, we present an r-round IPP, with $r = \log(n)$ and with poly-logarithmic communication complexity, in which V uses query complexity of $O(\frac{1}{\varepsilon_f - \varepsilon_c})$, the honest prover P uses poly-logarithmic query complexity, and the following holds:

- If $\overline{\Delta}(B,x) \leq \varepsilon_c$, then when communicating with P, with probability at least $2/3$ the verifier V accepts x.
- If $\overline{\Delta}(B,x) > \varepsilon_f$, then when communicating with any prover P^*, with probability at least $2/3$ the verifier V rejects x.

We note that we use r to represent the number of (pairs) of message exchanges (and not the total number of messages sent).

Our plan is as follows: First, in Section 4.3, we present a standard tolerant IPP for the ROOBP Problem. This IPP (which is not doubly sub-linear) uses a divide-and-conquer approach, and in it the prover P partitions the ROOBP to a sequence of k sub-ROOBPs (see Definition 16) according to the accepting path associated with an accepting input that minimizes the distance to x in B (see Definition 17). Then, in Section 4.4, we present a warm-up towards the tolerant dsIPP: We amend the standard tolerant IPP by allowing P to partition the ROOBP according to an approximated path, and relaxing the accepting conditions of V in a way that doesn't compromise the completeness and soundness of the protocol. Unfortunately, in this IPP the prover P still has query complexity of $\Omega(n)$. Lastly, in Section 4.5, we present the actual tolerant dsIPP, which applies the IPP presented in Section 4.4 recursively, thus improving the query complexity of P without compromising the query complexity of V.

4.3 The Standard Tolerant IPP

Given some ROOBP B, and proximity parameters $\varepsilon_f > \varepsilon_c \geq 0$, we want to verify that $\overline{\Delta}(B,x) \leq \varepsilon_c$. In the following tolerant IPP, that adapts the non-tolerant IPP from [7], we decompose B to k consecutive equally-length sub-ROOBPs, $B_1, ..., B_k$. Therefore, we start with defining the notion of a sub-ROOBP.

▶ **Definition 16** (sub-ROOBP). *For $0 \leq i \leq j \leq n$, let $u \in L_i$ and $v \in L_j$. We define $B[u,v]$ as a* ***sub-ROOBP*** *of B, with the following properties:*

- *The source (resp., sink) vertex of $B[u,v]$ is u (resp., v).*
- *$B[u,v]$ is of length $j - i$.*
- *If $x \in \{0,1\}^n$ is the input for B, then $x[i+1,j] = x[i+1] \cdot x[i+2] \cdot \cdots x[j]$ is the input for $B[u,v]$.*

Indeed, there is more than one way we can decompose B to k consecutive equally-length sub-ROOBPs, because for each sub-ROOBP there could be up to w^2 possible source-sink pairs. Therefore, we continue with defining the notion of (what we consider) a valid decomposition of B to k sub-ROOBPs: A decomposition that doesn't cause us to "lose" any distance (i.e. the average distance of x from all the sub-ROOBPs in the decomposition is at least the distance of x from B). We can achieve this by enforcing the decomposition to follow some path associated with some accepting input for B, since for any accepting input x' we have $\overline{\Delta}(x,x') \geq \overline{\Delta}(x,B)$.

▶ **Definition 17** ((k,π)-Decomposition). *Let B be an ROOBP, and let π be an accepting path in B. The **(k,π)-decomposition** of B is a sequence of k sub-ROOBPs of B, denoted $\mathcal{B}_{k,\pi} = (B_1, ..., B_k)$, such that for every $i \in [k]$, the source of B_i is the $\frac{(i-1)\cdot n}{k}$'th vertex in π, and the sink of B_i is the $\frac{i\cdot n}{k}$'th vertex in π.*

Now, we observe that when we partition x to k consecutive equally-length parts, $x_1, ..., x_k$, the following holds:

- On the one hand, if x is ε_c-close to B, then for $(B_1, ..., B_k)$, the (k,π)-decomposition of B constructed according to an accepting input that minimizes the distance to x, it holds that $\sum_i \frac{\overline{\Delta}(B_i,x)}{k} \leq \varepsilon_c$.
- On the other hand, if $\overline{\Delta}(B,x) > \varepsilon_f$, then for any $(B_1, ..., B_k)$, a (k,π)-decomposition of B constructed according to some accepting path in B, it holds that $\sum_i \frac{\overline{\Delta}(B_i,x_i)}{k} > \varepsilon_f$.

Given the above, we consider the following IPP: The prover P finds the (k,π)-decomposition of B constructed according to an accepting input that minimizes the distance to x. Then, P checks the distance of x_i from each of the sub-ROOBPs in the decomposition, and sends V a succinct representation of the decomposition (for example, the sink of every sub-ROOBP), as well as the obtained distances. After V receives some decomposition $(B_1, ..., B_k)$ and claimed distances $(\hat{\varepsilon_1}, ..., \hat{\varepsilon_k})$, V verifies that $(B_1, ..., B_k)$ is a valid (k,π)-decomposition of B, and that the average of the claimed distances is at most ε_c. Lastly, V selects at random $i \in [k]$, and verifies that $\overline{\Delta}(B_i, x_i) = \hat{\varepsilon}_i$ (by reading the entire x_i).

Note that if x is ε_c-close to B and V interacts with P, then $\sum_i \frac{\hat{\varepsilon}_i}{k} \leq \varepsilon_c$, and for every $i \in [k]$, it holds that $\overline{\Delta}(B_i, x_i) = \hat{\varepsilon}_i$, and the verifier always accepts. However, if $\overline{\Delta}(B,x) > \varepsilon_f$, then for any valid decomposition $(B_1, ..., B_k)$ and claimed distances $(\hat{\varepsilon}_1, ..., \hat{\varepsilon}_k)$ sent by some prover P^* such that $\sum_i \frac{\hat{\varepsilon}_i}{k} \leq \varepsilon_c$, it holds that $\sum_i \frac{\overline{\Delta}(B_i,x_i)-\hat{\varepsilon}_i}{k} > \varepsilon_f - \varepsilon_c$. Then, the average deviation of the actual distance of x from B, from the claimed distance of x from B, translates to a deviation on a corresponding fraction of random i's, which guarantees that the verifier rejects with probability at least $\varepsilon_f - \varepsilon_c$. To increase the rejection probability, we can repeat this procedure for $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ times.

We stress that V can verify the validity of a (k,π)-decomposition without any query access to the input x. Thus, the query complexity of the verifier is the length of a single x_i times the number of repetitions, which gives $O(\frac{n}{(\varepsilon_f - \varepsilon_c)\cdot k})$. However, to find an accepting input that minimizes the distance to x, the prover must access to the entire input x, which yields query complexity of $\Omega(n)$.

4.4 A Warm-Up towards a tolerant dsIPP

In this section, we aim to achieve poly-logarithmic query complexity for the honest prover P without compromising the query complexity of the verifier V: We amend the interaction described in Section 4.3 by allowing P to divide the ROOBP B according to an accepting input that *approximates* the distance of x to B. However, at the end of this section, we explain why P still has query complexity of $\Omega(n)$. In Section 4.5, we show how to solve this issue and present the actual tolerant dsIPP.

In the full version of this paper, we show the existence of a δ-distance-approximation algorithm for ROOBPs of constant width with query complexity that is independent of the length of the input, n. That is, we show there exists an algorithm that given an ROOBP B of width w, an input $x \in \{0,1\}^n$, deviation parameter $\delta > 0$ and error probability parameter $\eta > 0$, outputs $\hat{\varepsilon}$ such that with probability at least $1 - \eta$ it holds that $|\hat{\varepsilon} - \overline{\Delta}(B,x)| \leq \delta$, and this algorithms has query complexity of $(\frac{\log(\frac{1}{\eta})\cdot 2^w}{\delta})^{O(w)}$.

Based on this distance-approximation algorithm, we amend the interaction as follows: P performs distance approximation (with parameters δ and η we fix later) for every (k,π)-decomposition (constructed according to every accepting path π). Since P performs distance approximation also for the decomposition of B constructed according to an accepting input that minimizes the distance to x, P can just choose the the (k,π)-decomposition which yields the minimal (average) distance approximation. That is, P chooses $\mathcal{B}_{k,\pi^*} = (B_1^{\pi^*},...,B_k^{\pi^*})$ for which $\sum_i \frac{\hat{\varepsilon}_i^{\pi^*}}{k}$ is minimal.

Even though there could be many possible (k,π)-decompositions, the total number of sub-ROOBPs in all the (k,π)-decompositions is upper-bounded by $w^2 \cdot k$: For every $i \in [k]$, there are at most w^2 possible source-sink pairs for the i't sub-ROOBP. Thus, using the union bound, with probability at least $1 - w^2 \cdot k \cdot \eta$, all approximations deviate from the actual distance by at most δ, and the following holds:

- For every $i \in [k]$, it holds that $\overline{\Delta}(B_i^{\pi^*}, x_i) \leq \hat{\varepsilon}_i^{\pi^*} + \delta$.
- If $\overline{\Delta}(B,x) \leq \varepsilon_c$, then since P chooses the (k,π)-decomposition which yields the minimal (average) distance approximation, we get that $\sum_i \frac{\hat{\varepsilon}_i^{\pi^*}}{k} \leq \varepsilon_c + \delta$.

Lastly, we also change V's accepting conditions in the interaction, so that V allows the deviation. That is, after V receives $(B_1,...,B_k)$ and $(\hat{\varepsilon}_1,...,\hat{\varepsilon}_k)$, in addition to verifying that $(B_1,...,B_k)$ is a valid decomposition, V verifies that $\sum_i \frac{\hat{\varepsilon}_i}{k} \leq \varepsilon_c + \delta$, and after V chooses $i \in [k]$ uniformly at random, V verifies that $\overline{\Delta}(B_i, x_i) \leq \hat{\varepsilon}_i + \delta$ (by reading the entire x_i). Similar to the standard IPP, we repeat the protocol for $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ times.

4.4.1 Correctness

We claim that the completeness of the protocol still holds (but with a completeness error). If V interacts with P, then for a single invocation of the protocol, using the union bound, with probability at least $1 - \eta \cdot k \cdot w^2$, all approximations deviate from the actual distances by at most δ. Then, if $\overline{\Delta}(B,x) \leq \varepsilon_c$, it holds that $\sum_i \frac{\hat{\varepsilon}_i^{\pi^*}}{k} \leq \varepsilon_c + \delta$, and for every $i \in [k]$ it holds that $\overline{\Delta}(B_i^{\pi^*}, x_i) \leq \hat{\varepsilon}_i^{\pi^*} + \delta$, and the verifier accepts. Since we invoke the protocol for $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ times, then for $t = O(\frac{k \cdot w^2}{\varepsilon_f - \varepsilon_c})$, the verifier accepts in all invocations with probability at least $1 - \eta \cdot t$. Thus, we can set $\eta \leq 0.01 \cdot \frac{1}{t} = O(\frac{\varepsilon_f - \varepsilon_c}{k \cdot w^2})$, and the verifier accepts with high constant probability in all invocations.

To show the soundness of the protocol also holds, assume $\overline{\Delta}(B,x) > \varepsilon_f$, and let $(B_1,...,B_k)$ be a decomposition that P^* sends, along with the respective claimed distance approximations $(\hat{\varepsilon}_1,...,\hat{\varepsilon}_k)$. If the decomposition is valid, then $\sum_i \frac{\overline{\Delta}(B_i,x_i)}{k} > \varepsilon_f$. Thus, if $\sum_i \frac{\hat{\varepsilon}_i}{k} \leq \varepsilon_c + \delta$, we get that $\sum_i \frac{\overline{\Delta}(B_i,x_i) - \hat{\varepsilon}_i}{k} > \varepsilon_f - \varepsilon_c - \delta$. Then, the average deviation of the actual distance of x from B, from the claimed distance of x from B, beyond the allowed deviation, translates to a deviation on a corresponding fraction of random i's. Since the verifier rejects if $\overline{\Delta}(B_i,x_i) > \hat{\varepsilon}_i + \delta$, we can set $\delta = \frac{\varepsilon_f - \varepsilon_c}{3}$, and infer that the verifier still rejects with probability at least $\Omega(\varepsilon_f - \varepsilon_c)$ in a single invocation. Since we invoke the protocol for $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ times, we get that the verifier rejects with high constant probability in at least one of the invocations.

4.4.2 Query Complexity

Now, let us analyze the query complexity of V and P:

- Because V can verify that the (k,π)-decomposition that P sends is valid without any query access to the input x, the query complexity of V is $O(\frac{n}{(\varepsilon_f - \varepsilon_c) \cdot k})$: V reads a sub-sequence of the input of length $\frac{n}{k}$ for $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ repetitions.

- The query complexity of P is $k \cdot (\frac{\log(\frac{k}{\varepsilon_f - \varepsilon_c}) \cdot 2^w}{\varepsilon_f - \varepsilon_c})^{O(w)}$, because the distance approximation algorithm with deviation parameter $\delta = O(\varepsilon_f - \varepsilon_c)$ and error probability parameter $\eta = O(\frac{\varepsilon_f - \varepsilon_c}{w^2 \cdot k})$ has query complexity of $(\frac{\log(\frac{k}{\varepsilon_f - \varepsilon_c}) \cdot 2^w}{\varepsilon_f - \varepsilon_c})^{O(w)}$, and P invokes the algorithm for $w^2 \cdot k$ times in each of the $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ repetitions.

Since we can δ-approximate $\overline{\Delta}(B, x)$ without any interaction using query complexity $(\frac{2^w}{\delta})^{O(w)}$, we can perform tolerant $(\varepsilon_f, \varepsilon_c)$-test for ROOBPs using query complexity $(\frac{2^w}{\varepsilon_f - \varepsilon_c})^{O(w)}$. Therefore, for the IPP to be meaningful, we want the query complexity of V to be $o((\frac{2^w}{\varepsilon_f - \varepsilon_c})^{O(w)})$. To achieve this in our setting, we must require $k = \omega((\frac{\varepsilon_f - \varepsilon_c}{2^w})^{O(w)}) \cdot n)$. However, this causes the query complexity of P to be $\Omega(n)$, whereas we want our IPP to be doubly sub-linear. In the next section, we extend the foregoing IPP by applying it recursively, and show that we can get both query complexity of $o((\frac{2^w}{\varepsilon_f - \varepsilon_c})^{O(w)})$ for V, **and** poly-logarithmic query complexity for P.

4.5 The Actual dsIPP

In Section 4.4, we aim to achieve poly-logarithmic query complexity for the honest prover P, without compromising the query complexity of the verifier V. Unfortunately, for reasons explained at Section 4.4.2, the prover P still has query complexity of $\Omega(n)$.

To solve this, we extend the IPP presented in Section 4.4 by applying it recursively: That is, after V selects at random $i \in [k]$, instead of directly checking the distance of x_i from B_i, both parties recursively run the protocol on x_i with B_i, and do it for r rounds. Only in the base of the recursion, assuming the input is x' and the ROOBP is B', V checks the distance of x' from B' and accepts accordingly. This gives us an improvement in the query complexity of the verifier, as the length of the input after r rounds is $(\frac{n}{k^r})$, while the number of times the prover needs to run the distance approximation algorithm grows only to $w^2 \cdot k \cdot r$ (in every repetition). In order to make the query complexity of V independent of the input length, we set $k = n^{\frac{1}{r}}$.

Now, we observe the following: Assume V interacts with P, with input x and ROOBP B, such that $\overline{\Delta}(B, x) \leq \varepsilon_c$. Then, since we are only guaranteed that $\sum_i \frac{\hat{\varepsilon}_i}{k} \leq \varepsilon_c + \delta$, when both parties recursively apply the protocol with input x_i and ROOBP B_i, we can't guarantee that $\overline{\Delta}(B_i, x_i) \leq \varepsilon_c$ (or even guarantee that $\overline{\Delta}(B_i, x_i) \leq \varepsilon_c + \delta$).

Therefore, we amend the protocol as follows: In addition to the input x and the ROOBP B, we add a claimed distance parameter, $\hat{\varepsilon}$, that represents P's claim regarding the distance of x from B. In the first recursion level, we set $\hat{\varepsilon} = \varepsilon_c$, since P claims that $\overline{\Delta}(B, x) \leq \varepsilon_c$. Then, at each recursion level, assume our input x', our ROOBP is B', our (new) claimed distance parameter is $\hat{\varepsilon}'$, and P sends the decomposition $(B_1, ..., B_k)$ and the respective approximations $(\hat{\varepsilon}'_1, ..., \hat{\varepsilon}'_k)$. Then, V verifies that $(B_1, ..., B_k)$ is a valid decomposition and that $\sum_i \frac{\hat{\varepsilon}'_i}{k} \leq \hat{\varepsilon}' + \delta$ (i.e., we replace ε_c in the previous condition with the new parameter $\hat{\varepsilon}'$). Lastly, for some $i \in [k]$ both parties recursively run the protocol on x'_i with B'_i and the claimed distance $\hat{\varepsilon}'_i$, and at the base of the recursion, V verifies that the distance of the input from the ROOBP does not exceed the **claimed distance** by more than δ.

Now, on every recursion level, P only claims that the average distance doesn't grow too much **with respect to the approximated distance in the previous recursion level**. Since P uses a distance approximation algorithm with some error probability parameter $\eta > 0$, and chooses the (k, π)-decomposition of B that yields the minimal average distance approximation from x, the claim holds for all recursion levels with probability at least $1 - \eta \cdot k \cdot w^2 \cdot r_0$, and at the base level, the verifier accepts. Since P invokes the protocol for

$O(\frac{1}{\varepsilon_f-\varepsilon_c})$ times, then for $t = O(\frac{w^2\cdot k\cdot r}{\varepsilon_f-\varepsilon_c})$, the verifier accepts in all invocations with probability at least $1-\eta\cdot t$. Thus, we can set $\eta = 0.01\cdot\frac{1}{t} = O(\frac{\varepsilon_f-\varepsilon_c}{w^2\cdot k\cdot r})$, and the verifier accepts with high constant probability in all invocations. Lastly, we note that at each recursion level, we want V to account for two possible deviations: In the approximation that P provides for the previous recursion level (i.e. $\hat{\varepsilon}$), and in the approximations that P performs in the current recursion level (i.e. $(\hat{\varepsilon}_1,...,\hat{\varepsilon}_k)$).

For soundness, we observe that V allows the prover to exceed from the initial claimed distance (i.e., ε_c) by at most δ for r times: At each of the recursion levels, as well as in the base level. Thus, to make sure that soundness still holds (i.e. V does not allow the prover to exceed too much in distance), we set δ to be smaller (by a factor of r). Details follow.

▶ **Protocol 2.** *Tolerant dsIPP for the ROOBP Problem*

- ***Query Access Input:*** $x\in\{0,1\}^n$
- ***Proximity Parameters:*** $\varepsilon_f > \varepsilon_c \geq 0$
- ***Massive Parameter:*** *ROOBP B of width w*
- ***Other Parameters:*** *Claimed distance $\hat{\varepsilon}$ (initialized to ε_c in the first round), initial number of rounds r_0 and remaining number of rounds r*

1. *Set $k = n^{\frac{1}{r_0}}$, $\delta = \frac{\varepsilon_f-\varepsilon_c}{3r_0}$, and $\eta = O(\frac{\varepsilon_f-\varepsilon_c}{r_0\cdot k\cdot w^2})$.*
2. *V: If $r=0$ then accept iff $\overline{\Delta}(B,x)\leq\hat{\varepsilon}+\frac{\delta}{2}$.*
3. *P:*
   a. *For every $i\in[k]$, and for every $u\in L_{\frac{(i-1)\cdot n}{k}}$ and $v\in L_{\frac{i\cdot n}{k}}$, approximate the distance of x_i from $B[u,v]$ with deviation parameter $\frac{\delta}{2}$ and error probability parameter η.*
   b. *For every (k,π)-decomposition of B, $\mathcal{B}_{k,\pi} = (B_1^\pi,...,B_k^\pi)$, let $(\hat{\varepsilon}_1^\pi,...,\hat{\varepsilon}_k^\pi)$ be the respective distance approximations obtained in the previous step.*
   c. *Find a decomposition $\mathcal{B}_{k,\pi^*}$ for which $\sum_i\hat{\varepsilon}_i^{\pi^*}$ is minimal, and send (a succinct representation of) $\mathcal{B}_{k,\pi^*}$, along with $(\hat{\varepsilon}_1^{\pi^*},...,\hat{\varepsilon}_k^{\pi^*})$, to V.*
4. *V:*
   a. *Verify that $\mathcal{B}_{k,\pi^*}$ is a valid (k,π)-decomposition, and that $\sum_i\frac{\hat{\varepsilon}_i^{\pi^*}}{k}\leq\hat{\varepsilon}+\delta$. Otherwise, reject.*
   b. *Choose uniformly at random $i\in[k]$ and send i to P.*
5. *Both parties recursively invoke the protocol with input x_i, ROOBP $B_i^{\pi^*}$, claimed distance $\hat{\varepsilon}_i^{\pi^*}$, and remaining number of rounds $r-1$.*

Initiate the protocol with $\hat{\varepsilon}=\varepsilon_c$, repeat the protocol for $O(\frac{1}{\varepsilon_f-\varepsilon_c})$ times, and accept iff V accepts in all repetitions.

▶ Remark 18. P can efficiently find a decomposition in Step 3(c) as follows: Construct a graph $G=(V,E)$ with V being all the vertices of B in the levels $(L_0,L_{\frac{n}{k}},L_{\frac{2n}{k}}...,L_{\frac{k\cdot n}{k}})$, and $u,v\in V$ are connected in G with edge-weight $\hat{\varepsilon}_{u,v}$ if P performs distance approximation for $B[u,v]$ in Step 3(a) and it results in $\hat{\varepsilon}_{u,v}$. Then, every (k,π)-decomposition considered in Step 3(b) has a corresponding $s\rightsquigarrow t$ path in G, and the weight of the $s\rightsquigarrow t$ path equals the sum of distance approximations for the sub-ROOBPs in the decomposition. Thus, P can choose the decomposition with the shortest $s\rightsquigarrow t$ path in G.

We show that Protocol 2 is a dsIPP for ROOBPs: In Section 4.5.1, we show the correctness of the protocol, and in Section 4.6.1, we present the query complexity of the protocol.

4.5.1 Correctness

Completeness. Assume $\overline{\Delta}(B,x) \leq \varepsilon_c$ and V interacts with P. We observe that at any recursion level (but the base level), the following claim holds: If our input is x', our ROOBP is B' and our claimed distance parameter is $\hat{\varepsilon}'$ such that $\overline{\Delta}(B',x') \leq \hat{\varepsilon}' + \frac{\delta}{2}$, then with probability at least $1 - \eta \cdot k \cdot w^2$, the prover P sends $(B'_1, ..., B'_k)$ and $(\hat{\varepsilon}'_1, ..., \hat{\varepsilon}'_k)$ to V such that the following holds:

1. The verifier doesn't reject in Step $4(a)$ (i.e., $\sum_i \frac{\hat{\varepsilon}'_i}{k} \leq \hat{\varepsilon}' + \delta$).
2. The protocol is recursively invoked with some x'_i, B'_i and $\hat{\varepsilon}'_i$ for which $\overline{\Delta}(B'_i, x'_i) \leq \hat{\varepsilon}'_i + \frac{\delta}{2}$.

The claims follows from the fact that P runs the distance approximation algorithm with deviation parameter $\frac{\delta}{2}$ and with error probability parameter η. Since we start with $\overline{\Delta}(B,x) \leq \varepsilon_c = \hat{\varepsilon}$, then with probability at least $1 - \eta \cdot k \cdot w^2 \cdot r_0$, the verifier doesn't reject in Step $4(a)$ in all the r_0 recursion levels. By the second item of the claim, the base of the recursion is also invoked with an input x', ROOBP B' and claimed distance parameter $\hat{\varepsilon}'$ such that $\overline{\Delta}(B',x') \leq \hat{\varepsilon}' + \frac{\delta}{2}$, and the verifier accepts. Since we repeat the protocol for $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ times, we get that for $t = O(\frac{k \cdot w^2 \cdot r_0}{\varepsilon_f - \varepsilon_c})$, the verifier accepts in all invocations with probability at least $1 - \eta \cdot t$. Then, since we set $\eta = 0.01 \cdot \frac{1}{t} = O(\frac{\varepsilon_f - \varepsilon_c}{k \cdot w^2 \cdot r_0})$, we get that V accepts with high constant probability in all invocations.

Soundness. Assume $\overline{\Delta}(B,x) > \varepsilon_f$. We observe that in each round, we lose at most an additive factor of δ in distance (i.e. we allow the prover to "exceed" the claimed distance up to an additive δ factor). Since we start with claimed distance ε_c, and since we set $\delta = \frac{\varepsilon_f - \varepsilon_c}{3r_0}$, we get that after r_0 rounds, we are still at distance at least $\frac{\varepsilon_f - \varepsilon_c}{2}$ from a valid assertion. Hence, the verifier rejects with probability at least $\Omega(\varepsilon_f - \varepsilon_c)$ *in each invocation*, and rejects with high constant probability in at least one of the $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ invocations.

4.6 Computational Complexity (of Protocol 2)

The query and communication complexity of our tolerant dsIPP are our main complexity measures. Indeed, the communication complexity is $O(\frac{k \cdot \log(w \cdot n) \cdot r_0}{\varepsilon_f - \varepsilon_c})$, because in each of the $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ repetitions there are r_0 rounds, and in each round the prover P sends k vertices and k distance approximations to V that can be represented by $O(k \cdot \log(w \cdot n))$ bits. Since we set $k = n^{\frac{1}{r_0}}$, we can set $r_0 = \log(n)$ and get poly-logarithmic communication complexity.

We continue in Section 4.6.1, where we calculate the query complexity of both the verifier and the prover. We show that if we set $r_0 = \log(n)$, then V uses query complexity of $O(\frac{1}{\varepsilon_f - \varepsilon_c})$, and the honest prover P uses poly-logarithmic query complexity.

We finish by calculating the time complexity of our tolerant dsIPP. We show that, if we set $r_0 = \log(n)$, and assume both V and P have black-box access to two procedures that refer to the input ROOBP (see Section 4.6.2 for more details), then the verifier V has time complexity of $O(\frac{\log^2(n)}{\varepsilon_f - \varepsilon_c})$. In addition, if the honest prover P uses a distance approximation algorithm for ROOBPs with time complexity T_A, then P has time complexity of $O(\frac{\log^2(n) \cdot \mathsf{T}_A}{\varepsilon_f - \varepsilon_c})$.

4.6.1 Query Complexity

Let us analyze the query complexity of V (denoted Q_V) and P (denoted Q_P):

- Because V can verify that the (k,π)-decomposition P sends in every round is valid without any query access to the input x, we have $\mathsf{Q}_V = O(\frac{n}{(\varepsilon_f - \varepsilon_c) \cdot k^{r_0}}) = O(\frac{1}{\varepsilon_f - \varepsilon_c})$: V reads a sub-sequence of the input of length $\frac{n}{k^{r_0}} = 1$ for $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ times.

- P uses a distance approximation algorithm A with deviation parameter $\delta = O(\frac{\varepsilon_f - \varepsilon_c}{r_0})$ and error probability parameter $\eta = O(\frac{\varepsilon_f - \varepsilon_c}{r_0 \cdot k \cdot w^2})$, with query complexity $\mathsf{Q}_A(\delta, \eta, w)$. Then, the query complexity of Q_P is $\mathsf{Q}_A(\delta, \eta, w)$ times the number of calls P makes to A in all the repetitions. Since P calls the approximator for $w^2 \cdot k \cdot r_0$ times in each of the $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ repetitions, and we set $k = n^{\frac{1}{r_0}}$, we get that $\mathsf{Q}_P = O(\frac{w^2 \cdot n^{\frac{1}{r_0}} \cdot r_0}{\varepsilon_f - \varepsilon_c} \cdot \mathsf{Q}_A(\delta, \eta, w))$.

Hence, regardless of how we set r_0, the query complexity of the verifier is $O(\frac{1}{\varepsilon_f - \varepsilon_c})$. Indeed, the larger we set r_0, the smaller Q_P gets, but this causes the round complexity to grow. To minimize Q_P, we can set $r_0 = \log(n)$, and we get $\mathsf{Q}_P = O(\frac{w^2 \cdot \log(n)}{\varepsilon_f - \varepsilon_c} \cdot \mathsf{Q}_A(\delta, \eta, w))$.

In the full version of this paper, we show the existence of a distance approximation algorithm with query complexity of $\mathsf{Q}_A(\delta, \eta, w) = (\frac{\log(\frac{1}{\eta}) \cdot 2^w}{\delta})^{O(w)}$. If P uses this distance approximation algorithm, we get $\mathsf{Q}_P = \tilde{O}(n^{\frac{1}{r_0}}) \cdot (\frac{r_0 \cdot 2^w}{\varepsilon_f - \varepsilon_c})^{O(w)}$. Again, we can set $r_0 = \log(n)$, and if we assume w is constant, we get poly-logarithmic query complexity.

4.6.2 Time Complexity

Indeed, assuming a standard access to the input ROOBP B (i.e. the "Massive Parameter"), the time complexity of both the verifier (denoted T_V) and the honest prover (denoted T_P) is $\Omega(n)$:

- Given a sub-sequence of vertices $(v_0, ..., v_k)$ in B, the verifier V has to verify that every v_i is in the $\frac{i \cdot k}{n}$'th level of B, and that $v_i \rightsquigarrow v_{i+1}$. Since $v_0 \in L_0$ and $v_k \in L_n$, this requires accessing the entire ROOBP, thus yields time complexity of $\Omega(n)$.
- P approximates the distance of sub-parts of x from sub-ROOBPs of B of length $\frac{n}{k}$ for $w^2 \cdot k$ times. Using the distance approximation algorithm presented in the full version of this paper, this also yields time complexity of $\Omega(n)$.

However, we can take an alternative approach in the analysis: Assume both V and P have black-box access to the following two procedures, that refer to the structure of the input ROOBP, and are independent of the specific input x:

1. Given two vertices u and v, determine whether $u \rightsquigarrow v$ in B.
2. Given $i \in \{0, ..., n\}$, list the (up to w) vertices that are in level i of B.

In addition, assume P uses a distance approximation algorithm A with deviation parameter $\delta = O(\frac{\varepsilon_f - \varepsilon_c}{r_0})$ and error probability parameter $\eta = O(\frac{\varepsilon_f - \varepsilon_c}{r_0 \cdot k \cdot w^2})$, with time complexity $\mathsf{T}_A(\delta, \eta, n, w)$ (where n is the length of the input and w is the width of the ROOBP). Now, for $i \in [r_0]$, we can analyze the time complexity of V and P *in the i'th round of the protocol*:

- V calls the first two procedures for $O(k)$ times, obtains values that can be represented by $O(k \cdot \log(w \cdot n))$ bits, and performs simple calculations on the obtained values.
- P calls the first two procedures for k times, and calls the distance approximation algorithm for at most $w^2 \cdot k$ times on inputs of length $\frac{n}{k^i}$. By doing the foregoing, P obtains values that can be represented by $O(w^2 \cdot k \cdot \log(w \cdot n))$ bits, and performs simple calculations on the obtained values. This yields time complexity of $O(w^2 \cdot k \cdot (\log(w \cdot n) + \mathsf{T}_A(\delta, \eta, \frac{n}{k^i}, w)))$.

Since V and P perform the foregoing for every $i \in [r_0]$ in each of the $O(\frac{1}{\varepsilon_f - \varepsilon_c})$ invocations of the protocol, and since we set $k = n^{\frac{1}{r_0}}$, we get that:

- $\mathsf{T}_V = O(\frac{n^{\frac{1}{r_0}} \cdot r_0 \cdot \log(w \cdot n)}{\varepsilon_f - \varepsilon_c})$
- $\mathsf{T}_P = O(\frac{w^2 \cdot n^{\frac{1}{r_0}} \cdot (r_0 \cdot \log(w \cdot n) + \sum_{i=1}^{r_0} \mathsf{T}_A(\delta, \eta, n^{\frac{r_0 - i}{r_0}}, w))}{\varepsilon_f - \varepsilon_c})$

To minimize the time complexity, we can set $r_0 = \log(n)$, and assuming w is constant, we get $\mathsf{T}_V = O(\frac{\log^2(n)}{\varepsilon_f - \varepsilon_c})$ and $\mathsf{T}_P = O(\frac{\log^2(n)+\log(n)\cdot \mathsf{T}_A(\delta,\eta,n,w)}{\varepsilon_f - \varepsilon_c})$. We conclude with the following theorem and corollary.

▶ **Theorem 19.** *For every function $r : \mathbb{N} \to \mathbb{N}$, there exists an $r(n)$-round tolerant dsIPP for ROOBPs of width w with proximity parameters $\varepsilon_f > \varepsilon_c \geq 0$. In the tolerant dsIPP, the honest prover P uses a distance approximation algorithm A with deviation parameter $\delta = O(\frac{\varepsilon_f - \varepsilon_c}{r(n)})$ and error probability parameter $\eta = O(\frac{\varepsilon_f - \varepsilon_c}{r(n)\cdot n^{\frac{1}{r(n)}}\cdot w^2})$ such that the query complexity of A is $\mathsf{Q}_A(\delta,\eta)$ and the time complexity of A is $\mathsf{T}_A(\delta,\eta,n,w)$. Then, the computational complexity of the tolerant dsIPP is as follows:*

- ***Query Complexity**: $\mathsf{Q}_V = O(\frac{1}{\varepsilon_f - \varepsilon_c})$ and $\mathsf{Q}_P = O(\frac{w^2\cdot n^{\frac{1}{r(n)}}\cdot r(n)}{\varepsilon_f - \varepsilon_c} \cdot \mathsf{Q}_A(\delta,\eta))$.*
- ***Communication Complexity**: $O(\frac{n^{\frac{1}{r(n)}}\cdot r(n)\cdot log(w\cdot n)}{\varepsilon_f - \varepsilon_c})$.*
- ***Time Complexity**: If both V and P have black-box access to procedures that refer to the structure of the input ROOBP, then:*
  - $\mathsf{T}_V = O(\frac{n^{\frac{1}{r(n)}}\cdot r(n)\cdot log(w\cdot n)}{\varepsilon_f - \varepsilon_c})$
  - $\mathsf{T}_P = O(\frac{w^2\cdot n^{\frac{1}{r(n)}}\cdot (r(n)\cdot log(w\cdot n) + \sum_{i=1}^{r(n)} \mathsf{T}_A(\delta,\eta,n^{\frac{r(n)-i}{r(n)}},w))}{\varepsilon_f - \varepsilon_c})$

In the full version of this paper, we show the existence of a distance approximation algorithm with time complexity of $\mathsf{T}_A(\delta,\eta,n,w) = (\frac{\log(\frac{1}{\eta})\cdot 2^w}{\delta})^{O(w)}\cdot n$. If P uses this distance approximation algorithm, we get the following corollary.

▶ **Corollary 20.** *For every function $r : \mathbb{N} \to \mathbb{N}$, there exists an $r(n)$-round tolerant dsIPP for ROOBPs of width w with $\mathsf{Q}_V = O(\frac{1}{\varepsilon_f - \varepsilon_c})$, $\mathsf{Q}_P = \tilde{O}(n^{\frac{1}{r(n)}})\cdot(\frac{r(n)\cdot 2^w}{\varepsilon_f - \varepsilon_c})^{O(w)}$, and communication complexity of $O(\frac{n^{\frac{1}{r(n)}}\cdot r(n)\cdot log(w\cdot n)}{\varepsilon_f - \varepsilon_c})$. If both V and P have black-box access to procedures that refer to the structure of the input ROOBP, then $\mathsf{T}_V = O(\frac{n^{\frac{1}{r(n)}}\cdot r(n)\cdot log(w\cdot n)}{\varepsilon_f - \varepsilon_c})$ and $\mathsf{T}_P = (\frac{r(n)\cdot 2^w\cdot log(n)}{\varepsilon_f - \varepsilon_c})^{O(w)}\cdot n$.*

Simultaneous Haar Indistinguishability with Applications to Unclonable Cryptography

Abstract

We study a novel question about nonlocal quantum state discrimination: how well can non-communicating – but entangled – players distinguish between different distributions over quantum states? We call this task *simultaneous state indistinguishability*. Our main technical result is to show that the players cannot distinguish between each player receiving independently-chosen Haar random states versus all players receiving the same Haar random state.

We show that this question has implications to unclonable cryptography, which leverages the no-cloning principle to build cryptographic primitives that are classically impossible to achieve. Understanding the feasibility of unclonable encryption, one of the key unclonable primitives, satisfying indistinguishability security in the plain model has been a major open question in the area. So far, the existing constructions of unclonable encryption are either in the quantum random oracle model or are based on new conjectures.

We leverage our main result to present the first construction of unclonable encryption satisfying indistinguishability security, with quantum decryption keys, in the plain model. We also show other implications to single-decryptor encryption and leakage-resilient secret sharing. These applications present evidence that simultaneous Haar indistinguishability could be useful in quantum cryptography.

1 Introduction

Quantum state discrimination [40] is a foundational concept with applications to quantum information theory, learning theory and cryptography. In a state discrimination task, a party receives ρ_x from an ensemble $\{\rho_x\}_{x\in\mathcal{X}}$ and has to determine which state it received. A compelling variant of this problem is concerned with the multi-party setting where there are two or more parties and each party receives a disjoint subset of qubits of ρ_x. This multi-party variant of state discrimination has also garnered interest from quantum information-theorists

focused on the LOCC (local operations and classical communication) model and quantum data hiding [50, 14, 29, 25]. Understanding the multi-party state discrimination problem in turn sheds light on the difficulty of simulating global measurements using local measurements [52].

An important aspect to consider when formulating the multi-party state discrimination problem is the resources shared between the different parties. If we allow the parties to share entanglement and also communicate with each other then this is equivalent to the original state discrimination task (against a single party) due to teleportation. Thus, in order for the multi-party setting to be distinct from the single-party setting, we need to disallow either shared entanglement or classical communication. This results in two different settings:

- Parties without shared entanglement: In this setting, the parties are allowed to communicate using classical channels but they cannot share entanglement. The extensive research on quantum data hiding and LOCC [29, 32, 39, 46, 51, 15, 23, 24, 25, 36, 48] are mainly concerned with this setting.
- Parties with shared entanglement: In this setting, the parties are allowed to share entanglement but they cannot communicate. On the contrary, this setting is relatively unexplored with the notable exception being the recent works of [45, 30]. There are good reasons to study multi-party state discrimination with shared entanglement. Firstly, it can be viewed as a subclass of semi-quantum games [18], which are non-local games with quantum questions and classical answers. Secondly, it has connections to unclonable cryptography [54, 1], an emerging area in quantum cryptography, as discussed in [45].

Our Work. We focus on the setting when the parties share entanglement but are not allowed to communicate. We introduce a new concept called *simultaneous state indistinguishability* (SSI). In the two-party version of the problem, we have two parties (say, Bob and Charlie) who receive as input one of two bipartite states $\{\rho_0, \rho_1\}$ and they are supposed to distinguish. The first half of ρ_b is given to Bob and the second half is given to Charlie for $b \in \{0, 1\}$.

We say that ρ_0 and ρ_1 are ϵ-*simultaneous state indistinguishable* if the probability that Bob and Charlie can simultaneously distinguish is at most ϵ. That is, $d_{\mathsf{TV}}(x, x') \leq \epsilon$, where $d_{\mathsf{TV}}(\cdot, \cdot)$ denotes the total variation distance, $x = (x_B, x_C) \leftarrow (\text{Bob, Charlie})(\rho_0)$ denotes the random variable corresponding to the joint outputs of Bob and Charlie given input ρ_0, and similarly $x' = (x'_B, x'_C) \leftarrow (\text{Bob, Charlie})(\rho_1)$ denotes the random variable corresponding to their joint outputs when given input ρ_1.

This is related to a recent concept introduced by [45] who considered the unpredictability (search) version of this problem whereas we are interested in indistinguishability. Looking ahead, for applications, it turns out that the indistinguishability notion is more amenable to carrying out proofs (e.g. in the security of unclonable encryption) compared to the unpredictability definition considered by [45]. This is largely due to the fact that our notion is more compatible with the hybrid technique.

An interesting special case of simultaneous-state-indistinguishability is when Bob and Charlie either receive copies of the same state $|\psi\rangle$ drawn from some distribution $\mathcal{D}$ or receive i.i.d. samples from $\mathcal{D}$, i.e.

$$\rho_0 = \mathop{\mathbb{E}}_{|\psi\rangle\sim\mathcal{D}} \psi^{\otimes t} \otimes \psi^{\otimes t} \quad \text{vs.} \quad \rho_1 = \mathop{\mathbb{E}}_{|\psi_B\rangle,|\psi_C\rangle\sim\mathcal{D}} {\psi_B}^{\otimes t} \otimes \psi_C^{\otimes t}.$$

Observe that if Bob and Charlie were allowed to make global entangled measurements then they can indeed distinguish by performing swap tests. However, it is not clear these two situations are distinguishable using local measurements, even with preshared entanglement between Bob and Charlie.

We study simultaneous state indistinguishability in the case that each party receives (copies of) a state drawn from the *Haar measure*.[1] Specifically, we consider the following definition:

(d, t, ε)-Simultaneous Haar Indistinguishability: We say that (d, t, ε)-simultaneous Haar indistinguishability holds if any two non-communicating and entangled adversaries Bob and Charlie can distinguish the following distributions with probability at most ε:

- Bob and Charlie each receive t copies of $|\psi\rangle$, where $|\psi\rangle$ is a d-dimensional Haar state,
- Bob receives t copies of $|\psi_B\rangle$ and Charlie receives t copies of $|\psi_C\rangle$, where $|\psi_B\rangle, |\psi_C\rangle$ are i.i.d d-dimensional Haar states.

In the default setting, both Bob and Charlie each output 1 bit. We also consider the setting when they output multiple bits.

Variants of this problem have been studied in different contexts before. Independently, two works, namely, Harrow [38] and Chen, Cotler, Huang and Li [22] showed (for the case when $t = 1$) that Bob and Charlie fail, except with probability negligible in the dimension d, in the above distinguishing experiment as long as they don't share any entanglement. In fact, Harrow's result proves something stronger: the indistinguishability holds even if the two parties exchange classical information (i.e., LOCC setting). Both works discuss the applications of this problem to well studied topics such as multiparty data hiding, local purity testing and separations between quantum and classical memory. Neither of the works [38, 22] addresses the setting when Bob and Charlie can share an arbitrary amount of entanglement.

1.1 Our Results

1.1.1 Main Result

We show the following:

▶ **Theorem 1** (Informal). *For any $d, t \in \mathbb{N}$, (d, t, ε)-Simultaneous Haar indistinguishability holds for $\varepsilon = O\left(\frac{t^2}{\sqrt{d}}\right)$.*

Our result complements the works of [38, 22] by showing that it is not possible to distinguish i.i.d versus identical Haar states either using the entanglement resource or using classical communication.

In the case when $t = 1$, we show that $(d, 1, \epsilon)$-simultaneous Haar indistinguishability does not hold for $\epsilon = O\left(\frac{1}{d}\right)$, which suggests that the above bound cannot be improved significantly. Perhaps surprisingly, our attack even holds in the setting when Bob and Charlie do not share any entanglement. This further indicates that for the problem of simultaneous Haar indistinguishability, the gap between the optimal success probabilities in the entangled and the unentangled cases is small.

1.1.2 Applications

Besides being a natural problem, simultaneous Haar indistinguishability has applications to unclonable cryptography [54, 1, 55, 17, 9, 28, 27, 19]. This is an area of quantum cryptography that leverages the no-cloning principle of quantum mechanics to design cryptographic notions for tasks that are impossible to achieve classically.

[1] The Haar measure over states is the unique measure where for all fixed unitaries U, if $|\psi\rangle$ is Haar-distributed then so is $U|\psi\rangle$.

Unclonable Encryption: Unclonable encryption is an encryption scheme with quantum ciphertexts that are unclonable. It was first introduced by Broadbent and Lord [17] and is now considered a fundamental notion in unclonable cryptography. There are two security notions of unclonable encryption, namely search and indistinguishability security, studied in the literature. The search security stipulates that any cloning adversary[2] after receiving a ciphertext of randomly chosen message m should not be able to guess m except with probability negligible in $|m|$. In the challenge phase, the cloning adversary receives as input (k, k), where k is the decryption key. The indistinguishability security imposes a stronger guarantee that any cloning adversary after receiving encryption of m_b, for a randomly chosen bit b and adversarially chosen message pair (m_0, m_1), cannot predict b except with probability negligibly close to $\frac{1}{2}$.

While we have long known that search security is feasible [17], establishing indistinguishability security has remained an important and intriguing open problem. Unclonable encryption satisfying indistinguishability is achievable in the quantum random oracle model [6, 7] or in the plain model (i.e., without oracles) based on new unproven conjectures [3]. Various generic transformations are also known that convert one-time unclonable encryption to the public-key variant [5] or those that convert unclonable encryption for one-bit messages to multi-bit messages [41]. Given that unclonable-indistinguishable encryption has interesting applications to copy-protection [5, 26], it is important we completely settle its feasibility in the plain model. Perhaps embarassingly, we do not how to establish feasibility in the plain model even under strong assumptions such as indistinguishability obfuscation [10, 31]!

We consider the notion of unclonable encryption, where the decryption keys are allowed to be quantum keys. This only affects the challenge phase of the security experiment, where the cloning adversary now receives as input many copies[3] of the quantum decryption key.

We show the following:

▶ **Theorem 2** (Informal). *There is an unclonable encryption scheme, with quantum decryption keys, satisfying indistinguishability security in the plain model.*

Ours is the first work to show that unclonable-indistinguishable encryption exists in the plain model albeit with quantum decryption keys. Our relaxation (i.e. decryption keys being quantum states) is not only natural and interesting, it also respects the essence of unclonable encryption. For a detailed perspective on the above result, we refer the reader to the full version. We leave open the problem of achieving unclonable encryption with *classical* decryption keys to future works; we note that the prior works only mentioned the open problem of constructing unclonable encryption in the plain model without explicitly mentioning the need for classical decryption keys.

Moving Beyond Quantum Decryption Keys: A potential approach to transform this scheme into another scheme where the decryption keys are binary strings is to generate the decryption key to be an obfuscation of the setup algorithm that produces decryption keys. It is an intriguing problem to formalize the requirements of the underlying quantum obfuscation scheme. At the bare minimum, we require that the quantum obfuscation scheme satisfies the property that the obfuscated program can be represented as a binary string. While

[2] A cloning adversary is a tri-partite adversary $(\mathcal{A}, \mathcal{B}, \mathcal{C})$. $\mathcal{A}$ receives as input an unclonable state and produces a bipartite state given to $\mathcal{B}$ and $\mathcal{C}$ who are not allowed to communicate. Then, in the challenge phase, the cloning adversary receives as input $(\mathsf{ch}_{\mathcal{B}}, \mathsf{ch}_{\mathcal{C}})$ and then gives $\mathsf{ch}_{\mathcal{B}}$ to $\mathcal{B}$ and $\mathsf{ch}_{\mathcal{C}}$ to $\mathcal{C}$. Finally, $\mathcal{B}$ and $\mathcal{C}$ output their respective answers. Refer to [7] for an abstract modeling of unclonable security notions.

[3] We consider a security notion where the adversary receives at most t copies of the quantum decryption key and t is fixed ahead of time.

achieving quantum obfuscation has been a difficult open problem [16, 12, 11], obfuscating special classes of quantum algorithms (those that capture the setup algorithm of Theorem 2) could be relatively more tractable.

Our scheme supports one-bit messages and is one-time secure. It is an interesting future direction to extend the works of [5] and [41] to generically achieve unclonable encryption with quantum decryption keys in the public-key setting and for longer messages.

Single-Decryptor Encryption: Single-decryptor encryption [33] is a sister notion of unclonable encryption, where instead of requiring the ciphertexts to be unclonable, we instead require the decryption keys to be unclonable. Constructions of single-decryptor encryption in different settings are known from a variety of assumptions [33, 27, 7, 43]. There are two important security notions considered in the literature. In the *independent* setting, in the challenge phase, the cloning adversary gets two independently generated ciphertexts while in the *identical* setting, it gets copies of the same ciphertext. All the known constructions of single-decryptor encryption [27, 7, 43] are in the independent setting and specifically, there are no known constructions in the identical setting. This should not be surprising in light of [33] who showed the equivalence between single-decryptor encryption with identical ciphertexts and unclonable encryption, which suggests the difficulty in achieving the identical ciphertext setting.

We prove the following.

▶ **Theorem 3** (Informal). *There is a single-decryptor encryption scheme, with quantum ciphertexts, satisfying identical indistinguishability security.*

Ours is the first work to demonstrate the feasibility of single-decryptor encryption in the identical-challenge setting, albeit with quantum ciphertexts.

In addition to its applications to unclonable cryptography, simultaneous Haar indistinguishability can be used to construct leakage-resilient secret sharing.

Leakage-Resilient Secret Sharing: Leakage-resilient cryptography [42] is an area of cryptography that is concerned with the goal of building cryptographic primitives that are resilient to side-channel attacks. We are interested in designing secret sharing schemes that are leakage resilient. In a leakage-resilient secret sharing scheme, a leakage function is applied on each share and we require the guarantee that all the leakages put together are not sufficient enough to compromise the security of the secret sharing scheme. Leakage-resilient secret sharing is a well studied topic [35, 53, 2, 21, 13] with applications to leakage-resilient secure multi-party computation [13].

We consider a notion of leakage-resilient secret sharing, where we allow the parties holding the shares to be entangled with each other. We now require the guarantee that security should still hold even if each share is individually leaked. Moreover, we consider a relaxed requirement where the shares are allowed to be quantum. Just like the works in the classical setting, we consider the bounded leakage model. That is, if the number of qubits of each share is m then we allow for some $\lfloor \frac{c}{n} \rfloor$ fraction of bits of leakage from each share, where c is some constant and n is the number of parties[4].

We show the following:

▶ **Theorem 4** (Informal). *There is a 2-out-n leakage-resilient secret sharing scheme with the following properties: (a) the shares are quantum, (b) the number of bits of leakage on each share is $\lfloor \frac{c \cdot m}{n} \rfloor$, where c is some constant and the size of each share is m qubits, and (c) the parties can share arbitrary amount of entanglement.*

[4] We set $m \gg n$.

In fact, our construction satisfies a stronger security guarantee where the adversary can receive $p(n)$ number of copies of its share, where $p(\cdot)$ is an arbitrary polynomial.

A recent interesting work by [20] also considers leakage-resilient secret sharing schemes with quantum shares. However, there are notable differences. Firstly, they consider the setting when there can be unbounded amount of classical[5] bits of leakage from each quantum share whereas we consider bounded leakage. On the other hand, we allow the parties to be entangled whereas they mainly focus on the LOCC setting. In fact, they show that it is not possible to achieve unbounded amount of leakage in the shared entanglement setting even with two parties; this is the reason we focus on the setting of bounded leakage. However, there seems to be a large gap between the amount of leakage leveraged in the impossibility result in [20][6] and the leakage that we tolerate in our feasibility result. It is an interesting problem to close the gap. Finally, we allow each party to get arbitrary polynomially many copies of its share whereas [20] doesn't satisfy this guarantee.

Paper Organization. We give a technical overview in Section 1.3. In Section 2 we formally define simultaneous state indistinguishability and give basic facts about it. In Section 3, we show SSI for Haar states. In Section 4 we show cryptographic applications of our result. For a full list of preliminaries and a list of missing proofs, please refer to the full version of the paper.

1.2 Subsequent Work

Studying the simultaneous Haar indistinguishabiliy problem could have further implications beyond unclonable cryptography. Indeed, inspired by our work, a recent subsequent work [4] studied a dual problem of simultaneous Haar indistinguishabiliy problem where two parties can communicate using classical channels but cannot share entanglement. They showed similar bounds and demonstrated applications to proving black-box separations in quantum cryptography. The combination of our results implies an interesting fact: entanglement and classical communication are resources that are individually insufficient to non-locally distinguish independent vs. identical Haar states, whereas together they suffice (indeed trivialize the problem) due to quantum teleportation. Exploring the relationship between the resources of entanglement and classical communication for different non-local tasks is an interesting research direction.

1.3 Technical Overview

1.3.1 Simultaneous Haar Indistinguishability

We formally define the notion of simultaneous state indistinguishability (SSI), of which simultaneous Haar indistinguishability is a special case. We consider a non-local distinguisher $(\text{Bob}, \text{Charlie}, \rho)$ where Bob and Charlie are spatially separated quantum parties who share an entangled state ρ. Given two distributions $\mathcal{D}_1, \mathcal{D}_2$ over bipartite states, we can write the distinguishing advantage of $(\text{Bob}, \text{Charlie}, \rho)$ as $d_{\mathsf{TV}}(x, x')$, where $x = (x_B, x_C)$ is the random variable corresponding to the output of Bob and Charlie when they get as input $\rho \otimes \psi$ where $|\psi\rangle$ is sampled from $\mathcal{D}_1$. Here, x_B refers to Bob's output and x_C refers to Charlie's output. Similarly, $x' = (x'_B, x'_C)$ is the random variable corresponding to Bob and Charlie's outputs when they receive $\rho \otimes \psi'$ where $|\psi'\rangle$ is sampled from $\mathcal{D}_2$.

[5] They also consider bounded quantum leakage in addition to the classical leakage.
[6] Their impossibility result seems to require $O(2^m)$ bits of total leakage from all the parties.

For fixed $\mathcal{D}_1, \mathcal{D}_2$ we can ask the question: *What is the maximal distinguishing advantage if Bob and Charlie are restricted to output n classical bits?*. We first limit our attention to a special case of this problem such that $n = 1$ as well as:

1. $\mathcal{D}_1$ outputs two identical Haar random states $|\psi\rangle \otimes |\psi\rangle$.
2. $\mathcal{D}_2$ outputs two independent Haar random states $|\psi_B\rangle \otimes |\psi_C\rangle$.

In both $\mathcal{D}_1$ and $\mathcal{D}_2$, the first half of the state will be given to Bob and the second half will be given to Charlie. Note that if we restrict our attention to Bob (or Charlie) alone, then the two cases are perfectly indistinguishable. Therefore, Bob and Charlie need to work collectively in order to achieve a non-trivial distinguishing advantage.

For now assume that the pre-shared entanglement consists of some arbitrary number (r) of EPR pairs, denoted by $|\mathsf{EPR}\rangle^{\otimes r}$. Let M and N be the measurements (formally POVM elements) applied by Bob and Charlie, respectively. It is without loss of generality to assume that M and N are projective. In this case, we can write the distinguishing advantage of Bob and Charlie as

$$\mathsf{Tr}\left[(M \otimes N)\left\{\mathsf{EPR}^{\otimes r} \otimes \left(\mathop{\mathbb{E}}_{|\psi\rangle} \psi \otimes \psi - \mathop{\mathbb{E}}_{\psi_B,\psi_C} \psi_B \otimes \psi_C\right)\right\}\right].$$

The second expectation equals the maximally mixed state $(\mathsf{id} \otimes \mathsf{id})/d^2$, where d is the dimension of the Haar random states. The first expectation equals the maximally mixed state over the symmetric subspace[7], which is $O(1/d)$ close to $(\mathsf{id} \otimes \mathsf{id} + F)/d^2$, where F is the operator that swaps two registers. Hence, we can approximate the advantage as

$$\frac{1}{d^2}\mathsf{Tr}\left[(M \otimes N)\left\{\mathsf{EPR}^{\otimes r} \otimes F\right\}\right].$$

We examine this expression in terms of tensor network diagrams[8] [49]. Up to normalization, the effect of the EPR pairs (followed by trace) is to connect the entangled registers of M and N in reverse (i.e. after partially transposing one of the projectors), whereas the effect of F (followed by trace) is to connect the registers of M and N containing the Haar states. Overall, we observe that the expression above equals

$$\frac{1}{2^r d^2}\mathsf{Tr}\left[M \cdot N^{\top_P}\right], \tag{1}$$

where $\top_P$ denotes the partial transpose operation. Notice that this is the Hilber-Schmidt inner-product of M and $N^{\top_P}$, hence by Cauchy-Schwarz we can bound it by

$$\frac{1}{2^r d^2}\left\|M\right\|_2 \cdot \left\|N^{\top_P}\right\|_2 = \frac{1}{2^r d^2}\left\|M\right\|_2 \cdot \left\|N\right\|_2 \leq \frac{1}{2^r d^2}\sqrt{2^r d} \cdot \sqrt{2^r d} = \frac{1}{d},$$

where we used the fact that $\|M\|_2^2$ equals the rank of M. Together with the previous approximation error we had, this gives us a bound of $O(1/d)$.

This bound is in fact tight, which can be seen by a simple attack where Bob and Charlie measure and output the first qubit of their input state. Moreover, this attack is unentangled, leading to the interesting conclusion that entangled attacks are no more powerful than unentangled attacks.

[7] See [37] for an introduction to the symmetric subspace.
[8] See [47] for an introduction to tensor network diagrams.

The Case of Many Copies. Now we generalize our argument to the case when Bob and Charlie each get t copies of their input. Similar to the $t = 1$ case, we can write the projection onto the symmetric subspace over t registers as

$$\Pi^t = \frac{1}{t!} \sum_{\sigma \in S_t} P_\sigma,$$

where P_σ is a register-wise permutation operator. Using this identity for Bob's and Charlie's registers alike, the independent case yields a sum of terms of the form $P_{\sigma_B} \otimes P_{\sigma_C}$. On the other hand, the identical case will give us a sum of P_σ for $\sigma \in S_{2t}$. We can match the coefficients up to $O(t^2/d)$ error, and thus we can approximate the advantage as

$$\frac{1}{d^{2t}} \mathsf{Tr} \left[(M \otimes N) \left\{ \mathsf{EPR}^{\otimes r} \otimes \sum_{\sigma \in S^*_{2t}} P_\sigma \right\} \right],$$

where S^*_{2t} is the set of permutations over $2t$ registers that cannot be expressed as a product of two permutations over t registers. A natural idea would be to bound this expression separately for each P_σ, but it would yield a factor of $\mathsf{poly}(t!)$ which blows up very fast. Our idea instead is to group permutations based on how far they are from a product permutation. In more detail, we define $S^{(s)}_{2t}$ as the set of permutations σ which obeys the identity

$$P_\sigma = (P_{\sigma_1} \otimes P_{\sigma_2}) \, P_{\sigma_s} \, (P_{\sigma_3} \otimes P_{\sigma_4})$$

for some permutations $\sigma_1, \sigma_2, \sigma_3, \sigma_4$ over t registers, where σ_s is a fixed permutation that swaps t of Bob's registers with t of Charlie's registers. Indeed, $S^{(s)}_{2t}$ is the set of permutations σ that make s *swaps* across Bob's and Charlie's registers. Moreover, by a combinatorial argument, we can compute the average of P_σ by averaging the identity above over $\sigma_1, \sigma_2, \sigma_3, \sigma_4$, so that

$$\sum_{\sigma \in S^{(s)}_{2t}} P_\sigma = C_s \left(\Pi^t_B \otimes \Pi^t_C \right) P_{\sigma_s} \left(\Pi^t_B \otimes \Pi^t_C \right),$$

where C_s is a constant that depends on s, t, and Π^t_B, Π^t_C are projections onto the symmetric subspace over Bob's and Charlie's t registers, respectively. Using the generalization of Equation (1) we show that

$$\frac{1}{d^{2t}} \mathsf{Tr} \left[(M \otimes N) \left\{ \mathsf{EPR}^{\otimes r} \otimes \sum_{\sigma \in S^{(s)}_{2t}} P_\sigma \right\} \right] \leq \binom{t}{s}^2 s! d^{-s},$$

and summing this over $s = 1, 2, \ldots, t$ gives us a bound of $O(t^2/d)$. Keep in mind that $s = 0$ is excluded from the sum because it corresponds to product permutations.

The Case of General Entanglement. Now suppose the entangled state $|\Omega\rangle$ shared between Bob and Charlie is arbitrary. Intuitively, we don't expect this relaxation to help the adversary a lot since the number of EPR pairs above was unbounded, yet it requires a proof to show this. Recall that $|\Omega\rangle$ can be written as

$$|\Omega\rangle = \sum_i \sqrt{\lambda_i} \, |u_i\rangle \, |v_i\rangle$$

for some choice of bases $(u_i), (v_i)$ for the registers of Bob and Charlie, known as the *Schmidt decomposition*. An equivalent way to write this is[9]

$$|\Omega\rangle = (\sigma^{1/2} \otimes V) \, |\mathsf{EPR}^{\otimes r}\rangle$$

for some density matrix σ, unitary V, and integer r. The unitary V can be safely ignored by changing the basis of Charlie's projection N. Using the cyclicity of trace we can absorb $\sigma^{1/2}$ in M and get a similar expression for the distinguishing advantage as the maximally entangled state, where M is replaced with $(\sigma^{1/2} \otimes \mathsf{id})M(\sigma^{1/2} \otimes \mathsf{id})/2^r$, with d' being the dimension of Bob's share of the entangled state. Following the same analysis as the EPR case results in a bound that scales with $\sqrt{d'}$. In order to get a bound that does not depend on the amount of entanglement we perform a more refined and involved analysis coupled with a more careful application of Cauchy-Schwarz, which yields a bound of $O(t^2/\sqrt{d})$ on the distinguishing advantage. An interesting open question is whether the gap between the EPR and non-EPR cases is inherent.

1.3.2 Applications

Unclonable Encryption. The search (weak) security of unclonable encryption (UE) was known since its formal introduction [17], yet strong (CPA-style/indistinguishability) security has been an open problem. There are fundamental reasons why this problem has been difficult, including the following:

1. Because the adversary learns the secret key in the challenge phase of the unclonable security experiment, it is hard to leverage traditional cryptographic tools – wherein revealing the secret key tantamounts to the compromise of security – in the construction of unclonable encryption.
2. There is a lack of straightforward equivalence between unpredictability and indistinguishability in the unclonability setting. The former is used to define CPA-style security and is not transitive, hence unfriendly to hybrid arguments.
3. Due to the simultaneous nature of the security experiment, extraction techniques that work for a single party often fail against two or more entangled parties.

To elaborate on the third bullet further, one can hope to deploy classical techniques for search-to-decision reductions in this setting. For instance, it has been shown that random oracles can be used to go from weak security to strong security in UE [6, 7]. In the plain model, a common classical tool is the Goldreich-Levin extraction technique [34], using which one can try the following folklore construction of UE:

1. The key consists of (k, r), where k is a key for a weakly secure UE scheme and $r \in \{0,1\}^n$ is a random string.
2. To encrypt a single-bit message $m \in \{0,1\}$, sample a random message $x \in \{0,1\}^n$, then output encryption of x using k, as well as $\langle r, x\rangle \oplus m$.
3. To decrypt, first use k to recover x using the decryption procedure of the weakly secure UE scheme and then recover m.

To prove unclonable security of this construction, one needs the *identical-challenge* version of simultaneous Goldreich-Levin, where Bob and Charlie will get the same r as challenge. This is unknown even though the independent-challenge version is known [44, 7].

[9] Here we are implicitly assuming that the dimensions of Bob and Charlie's registers both equal the same power of 2. This is merely for convenience and does not affect the analysis.

Our main insight is to make the string r in the key come in superposition, i.e. from a quantum state $\sum \alpha_r |r\rangle$. Intuitively, if Bob and Charlie were to measure r in the computational basis, then they would effectively receive independent values of r, meaning that we can hope to use independent-challenge Goldreich-Levin. Accordingly, we look for a state $\sum \alpha_r |r\rangle$ such that (1) Bob and Charlie cannot simultaneously distinguish whether or not this state has been measured in the computational basis, and (2) the computational basis measurement results in a uniform value of r.

Perhaps the most natural candidate for this task is to pick a Haar random state. This allows us to apply our simultaneous Haar indistinguishability result. Nonetheless, there still remain some technical challenges in the application of this concept. To begin with, we need to adapt the construction slightly to incorporate the newly acquired quantumness of r. Our solution is as follows:

1. The key is partially quantum:
   - The (classical) *encryption key* consists of $(k, x, \widetilde{b})$, where x is a random message and $\widetilde{b} \in \{0,1\}$ is a single-bit one-time-pad.
   - The (quantum) *decryption key* consists of k and a state $\sum \alpha_r |r\rangle |\langle r, x\rangle \oplus \widetilde{b}\rangle$, where $\sum \alpha_r |r\rangle$ is a Haar random state.
2. To encrypt a single-bit message $m \in \{0,1\}$, output encryption of x using k, as well as $\widetilde{b} \oplus m$.
3. To decrypt, first use k to recover x, then coherently recover $\widetilde{b}$ followed by m.

Using the simultaneous Haar indistinguishability, we can show that our construction is secure via the hybrid method. Note that we can do this because our notion of simultaneous-state-indistinguishability is strong enough that it is amenable to the use of hybrids.

In more detail, we reach an indistinguishable hybrid experiment where the Bob and Charlie get keys which use independently generated Haar random states. Equivalently, Bob gets $(r, \langle r, x\rangle \oplus \widetilde{b})$ and Charlie gets $(r', \langle r', x\rangle \oplus \widetilde{b})$ for independent r, r'.

Next, we move to a hybrid which is the weak security (i.e. search security) experiment of the underlying unclonable encryption scheme, so that Bob and Charlie need to output x each given the key k. Unfortunately, even though r and r' are independent in the previous hybrid, independent-challenge simultaneous Goldreich-Levin [44, 7] is insufficient due to the correlation between the bits $b = \langle r, x\rangle \oplus \widetilde{b}$ and $b' = \langle r', x\rangle \oplus \widetilde{b}$, namely $b \oplus b' = \langle r, x\rangle \oplus \langle r', x\rangle$. To overcome this issue, we prove exactly what we need, which we call *correlated simultaneous quantum Goldreich-Levin*[10] [11] (Lemma 30), which can be summarized as follows:

> Correlated Goldreich-Levin: Suppose that Bob is given input (r, b) and Charlie is given input (r', b'), where r, r' are independent strings and b, b' are uniform bits satisfying the correlation $b \oplus b' = \langle r, x\rangle \oplus \langle r', x\rangle$. If (Bob, Charlie) can output $(\langle r, x\rangle, \langle r', x\rangle)$ with probability $1/2 + 1/\mathsf{poly}$, then there is an extractor $(\mathrm{ExtBob}, \mathrm{ExtCharlie})$ that extracts (x, x) from (Bob, Charlie) with probability $1/\mathsf{poly}$.

To prove this lemma we first tackle the correlation between b and b'. Consider $\widetilde{\text{Bob}}$ who takes as input r, samples b himself uniformly, and runs Bob on input (r, b) to obtain b_B; similarly consider $\widetilde{\text{Charlie}}$ who takes r' as input, samples b' and runs Charlie on input (r', b') to obtain b_C. Now that the input bits b, b' are uncorrelated, $(\widetilde{\text{Bob}}, \widetilde{\text{Charlie}})$, who output (b_B, b_C), are expected to have worse success probability than (Bob, Charlie). However, we can in turn relax the success criterion for $(\widetilde{\text{Bob}}, \widetilde{\text{Charlie}})$ to merely output bits (b_B, b_C) that

[10] As a side note, this lemma resolves an open question in [44], implying that their construction achieves a more desirable notion of security.

[11] Previously, the work of [3] explicitly stated the correlated Goldreich-Levin problem over large finite fields as a conjecture.

satisfy $b_B \oplus b_C = \langle r, x\rangle \oplus \langle r', x\rangle$ in order to counteract this lack of correlation. In other words, now $(\widetilde{\text{Bob}}, \widetilde{\text{Charlie}})$ are additionally allowed to be *both incorrect*. Indeed, we show that the success probability of $(\widetilde{\text{Bob}}, \widetilde{\text{Charlie}})$ in this case is at least that of (Bob, Charlie), i.e. $1/2 + 1/\mathsf{poly}$. To show this fact, we define E as the event that $b \oplus b' = \langle r, x\rangle \oplus \langle r', x\rangle$. Conditioned on E, Bob and Charlie will output $(\langle r, x\rangle, \langle r', x\rangle)$ with probability $1/2 + 1/\mathsf{poly}$ by our assumption. In addition, the event E is independent of Bob's (or Charlie's) marginal output due to the fact that the players' correlation satisfies no-signalling. To see this, notice that the bits b and b' can each independently control the event E. We utilize this important observation to show the desired result. Another way to interpret this reduction is as follows: the correlation that (Bob, Charlie) require in order to output $(\langle r, x\rangle, \langle r', x\rangle)$ appears as a correlation in the output of $(\widetilde{\text{Bob}}, \widetilde{\text{Charlie}})$, who take uncorrelated bits as input.

After this reduction, it seems that we still cannot use the original independent-challenge simultaneous Goldreich-Levin because of the relaxed success criterion above. Luckily, by examining the proof of [7] we see that this condition is sufficient without additional work for the existence of (ExtBob, ExtCharlie) who can extract (x, x) simultaneously.

Many-Copy Security. For t-copy security, where Bob and Charlie get t copies of the decryption key in the unclonable security experiment, we need t to be at most linear in n, for otherwise Bob and Charlie can learn x using Gaussian elimination. In the proof, we similarly reach a hybrid where the Haar random states given to Bob and Charlie are independent. Then, we need an extra step where we switch to a hybrid in which Bob gets as input $(r_i, \langle r_i, x\rangle \oplus \widetilde{b})$ for independent samples $r_1, \ldots, r_t$ (instead of $(r_1, \ldots, r_t)$ being generated from t copies of a Haar random state) and similarly Charlie gets $(r'_i, \langle r'_i, x\rangle \oplus \widetilde{b})$ for independently generated $r'_1, \ldots, r'_t$. We show that the success probability of Bob and Charlie does not decrease from this change. To show this, we argue that that given $(r_i, \langle r_i, x\rangle \oplus \widetilde{b})$ Bob can prepare

$$\left(\sum_r \alpha_r \left|r\right\rangle \left|\langle r, x\rangle \oplus \widetilde{b}\right\rangle\right)^{\otimes t}$$

where $|\varphi\rangle = \sum_r \alpha_r |r\rangle$ is a Haar random state. In the expression above, $|r\rangle$ corresponds to the register that holds Goldreich-Levin samples, which are generated from t copies of a Haar random state rather than t independent samples. Recall that $\varphi^{\otimes t}$ can be written as a random vector in the *type basis*. Using this fact, Bob can coherently apply a random permutation $\sigma \in S_t$ to the values $|r_i, \langle r_i, x\rangle \oplus \widetilde{b}\rangle$, after which he can uncompute the permutation σ. We can argue similarly for Charlie, since their inputs originate from independent Haar distributions. This argument in fact requires the strings r_i to be distinct, which fortunately holds with high probability by the birthday bound.

Note that the input above given to Bob can be thought of as $(r, \langle r, x\rangle \oplus \widetilde{b})$ alongside $t - 1$ random samples of $(r_i, \langle r_i, x\rangle)$. In the final step, we apply our correlated Goldreich-Levin result in the presence of this extra information to reach the search security experiment for the weakly secure UE scheme. In this experiment, the extra information can be guessed by Bob and Charlie, hence if t is bounded by a linear function of n the security still holds.

Single-Decryptor Encryption. Single-decryptor encryption is a primitive that closely resembles unclonable encryption. It is an encryption scheme in which the decryption key is unclonable. In the security experiment, Alice tries to clone a quantum decryption key and split it between Bob and Charlie, who then try to decrypt a ciphertext they receive using their shares of the key. Depending on the correlation of these ciphertexts, one can

define *identical-challenge* or *independent-challenge* security. We adapt our construction of unclonable encryption with quantum decryption keys to construct single-decryptor encryption with quantum ciphertexts. Our construction can be summarized as follows:

1. The encryption key consists of a key k as well as a random message x for a weakly secure UE scheme. The quantum decryption key contains k and encryption of x using k.
2. To encrypt a one-bit message m, output k as well as $\sum \alpha_r |r\rangle |\langle r, x\rangle \oplus m\rangle$, where $\sum \alpha_r |r\rangle$ is a Haar random state.
3. To decrypt, first recover x and then coherently compute m.

We can show that this construction is secure if Bob and Charlie are given t copies of the same ciphertext for $t = O(|x|)$. The proof is nearly identical to the security proof of our UE construction above. For more clear exposition, in the technical sections we first present our construction of single-decryptor encryption (Section 4.1), followed by that of unclonable encryption (Section 4.2).

Classical-Leakage-Resilient Secret-Sharing. As another application of simultaneous Haar indistinguishability, we construct a 2-out-of-n quantum secret-sharing scheme for a single-bit classical message. The construction is as follows:

1. The shares of bit $b = 0$ are identical Haar random states $|\psi\rangle$ and the shares of $b = 1$ are independent Haar random states $|\psi_i\rangle$. In addition, we give t copies of their share to all parties $1, 2, \ldots, n$.
2. Any two parties i, j can recover the message by applying t SWAP tests between their secrets. If $m = 0$, then all the tests will succeed. On the other hand, if $m = 1$, then with high probability the independent Haar random states held by i and j will be almost orthogonal, therefore the number of SWAP tests that pass will be concentrated near $t/2$ by a Chernoff bound.

Formally, we show that m remains hidden in the presence of ℓ-bits of classical leakage from each party. This amounts to showing a many-party and many-bit generalization of simultaneous Haar indistinguishability (SHI), that is, either all parties get (copies of) the same Haar random state or they get (copies of) independent Haar random states. Firstly, we go from 1-bit SHI to ℓ-bit SHI for 2 parties. This can be achieved by a union bound, which incurs a multiplicative loss of $2^{2\ell}$ in security. And then we show an equivalence between SHI in the cases of (1) 2 parties each getting $O(nt)$ copies and (2) $O(n)$ parties each getting t copies. This can be seen as distributing a fixed number of Haar random states among more parties. In the proof we use $O(\log n)$ hybrids, doubling the number of parties at each hybrid. We show by an additional hybrid argument that we incur a multiplicative loss of $O(1)$ at each step, hence a multiplicative loss of $O(n)$ in total after $O(\log n)$ steps. Putting everything together, we show that we can allow $\ell = O(\log d/n)$ bits of leakage from each party, where $\log d$ is the number of qubits of each copy of a share. The number of copies (t) given to each party can be an arbitrary polynomial, which lets us amplify the correctness of the scheme. An interesting open question is to get rid of the exponential dependence on the number of bits leaked (ℓn), which would imply that our construction tolerates unbounded polynomial leakage.

1.4 Notation

We write $\log := \log_e$ to denote the natural logarithm. We write $[n] := \{1, \ldots, n\}$. We use the notation $\langle \cdot, \cdot \rangle : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ to denote the inner product over $\mathbb{F}_2^n$, i.e. for classical strings $x, y \in \{0,1\}^n$ we have $\langle x, y\rangle := \sum_{i=1}^n x_i y_i \pmod 2$. We denote the set of d-dimensional pure quantum states by $\mathcal{S}(\mathbb{C}^d) := \left\{|\psi\rangle \in \mathbb{C}^d \ : \ \langle\psi|\psi\rangle = 1\right\}$. We sometimes write $\psi := |\psi\rangle\langle\psi|$ for simplicity. For a complex matrix (or operator) A, we write $A^\top$ to

denote its transpose and $\overline{A}$ to denote its entry-wise complex conjugation, both with respect to the computational basis. $d_{\mathsf{TV}}(x, x')$ denotes the total-variation distance between random variables x, x'.

2 Simultaneous State Indistinguishability

Terminology. Below, $\mathcal{D}$ represents a probability distribution over pure states. Particularly, we will consider bipartite pure states $|\psi\rangle_{BC}$ and non-local adversaries $\mathcal{A} = (\mathcal{B}, \mathcal{C}, \rho_{BC})$ as distinguishers, where the B register will be given to $\mathcal{B}$ and the C register will be given to $\mathcal{C}$.

2.1 Definitions

▶ Remark 5. A distribution $\mathcal{D}$ has a unique representation as a quantum mixed state $\rho_{\mathcal{D}}$, whereas a quantum mixed state can represent many distributions. Accordingly, we can apply our results to mixed states ρ for which we can find an appropriate distribution $\mathcal{D}'$ that satisfies $\rho_{\mathcal{D}'} = \rho$.

▶ **Definition 6** (Simultaneous State Indistinguishability)**.** *We say that two distributions $\mathcal{D}_1$ and $\mathcal{D}_2$ are* ε-simultaneous state indistinguishable *(ε-SSI) against a non-local adversary $\mathcal{A} = (\mathcal{B}, \mathcal{C}, \rho_{BC})$ if the following holds for every pair of bits b_1, b_2:*

$$\left| \mathsf{Pr}\left[(b_1, b_2) \leftarrow \mathcal{A}(\psi_{BC}) \ : \ |\psi\rangle_{BC} \leftarrow \mathcal{D}_1\right] - \mathsf{Pr}\left[(b_1, b_2) \leftarrow \mathcal{A}(\psi_{BC}) \ : \ |\psi\rangle_{BC} \leftarrow \mathcal{D}_2\right] \right| \leq \varepsilon$$

Here, $\mathcal{B}$ gets the register B of ψ and $\mathcal{C}$ gets the register C.

Of interest to us is the case when $\mathcal{D}_1 = \mathcal{D}^{\mathsf{id}}$ and $\mathcal{D}_2 = \mathcal{D}^{\mathsf{ind}}$, where we define $\mathcal{D}^{\mathsf{id}}$ and $\mathcal{D}^{\mathsf{ind}}$ as follows[12]:

$(\mathcal{D}^{\mathsf{id}})$: Sample $|\psi\rangle \leftarrow \mathcal{D}$ and output $(|\psi\rangle_B \otimes |\psi\rangle_C)$

$(\mathcal{D}^{\mathsf{ind}})$: Sample $|\psi\rangle, |\psi'\rangle \leftarrow \mathcal{D}$ and output $(|\psi\rangle_B \otimes |\psi'\rangle_C)$, i.e. $\mathcal{D}^{\mathsf{ind}} = \mathcal{D} \times \mathcal{D}$.

In this case, we refer to the above notion as $(\varepsilon, \mathcal{D})$-simultaneous state indistinguishability ($(\varepsilon, \mathcal{D})$-SSI). Note that up to a constant factor this is equivalent to the output distributions of $\mathcal{A}$ with respect to $\mathcal{D}_1, \mathcal{D}_2$ having total variation distance ε. Also note that we can fix the bits b_1, b_2 without loss of generality.

▶ **Definition 7** ($(\varepsilon, \mathcal{D})$-SSI)**.** *We say that* $(\varepsilon, \mathcal{D})$-SSI *holds if $\mathcal{D}^{\mathsf{id}}$ and $\mathcal{D}^{\mathsf{ind}}$ defined above are ε-SSI against all non-local adversaries $(\mathcal{B}, \mathcal{C}, \rho)$.*

▶ Remark 8. When it is clear from the context, we omit the mention of the registers B and C.

2.1.1 SSI as a metric

This notion defines a metric over bipartite states, namely $T_{SSI}(\rho_0, \rho_1)$ is the smallest value of ε such that ρ_0 and ρ_1 are ε simultaneously indistinguishable. Equivalently,

$$T_{SSI}(\rho_0, \rho_1) := \sup_{(\mathcal{B}, \mathcal{C}, \rho)} \left| \Pr\left[(1,1) \leftarrow (\mathcal{B} \otimes \mathcal{C})(\rho \otimes \rho_0)\right] - \Pr\left[(1,1) \leftarrow (\mathcal{B} \otimes \mathcal{C})(\rho \otimes \rho_1)\right] \right|. \quad (2)$$

It is easy to see that this is a valid metric[13].

Since any binary measurement is a linear combination of projective measurements by the Spectral Theorem, we have the following fact.

[12] Here id stands for *identical* and ind stands for *independent*.

[13] Technically, a pseudometric since two different states may have distance 0.

▶ **Lemma 9.** *$T_{SSI}(\cdot,\cdot)$ can be equivalently defined by restricting $\mathcal{B},\mathcal{C}$ to be projective measurements.*

2.1.2 Extending to Many-Bit Output

We can extend the definition of SSI such that the non-local adversary can output many bits in each register. We then require that the total variation distance between the collective outputs of $\mathcal{B}$ and $\mathcal{C}$ for the two distributions is small.

▶ **Definition 10** (($\varepsilon,\mathcal{D},n$)-SSI)**.** *We say that $(\varepsilon,\mathcal{D},n)$-SSI holds if for any nonlocal adversary $\mathcal{A}=(\mathcal{B},\mathcal{C},\rho)$ and any $S\subseteq\{0,1\}^n\times\{0,1\}^n$ we have*

$$\left|\Pr\left[(x_1,x_2)\in S \;:\; \substack{|\psi\rangle\leftarrow\mathcal{D}\\(x_1,x_2)\leftarrow\mathcal{A}(\psi\otimes\psi)}\right]-\Pr\left[(x_1,x_2)\in S \;:\; \substack{|\psi\rangle,|\psi'\rangle\leftarrow\mathcal{D}\\(x_1,x_2)\leftarrow\mathcal{A}(\psi\otimes\psi')}\right]\right|\leq\varepsilon$$

Note that $(\varepsilon,\mathcal{D},2)$-SSI and $(\varepsilon,\mathcal{D})$-SSI are equivalent up to a constant factor on ε. There is a straightforward relation between $(\varepsilon,\mathcal{D})$-SSI and $(\varepsilon,\mathcal{D},n)$-SSI using the union bound, which we formally state below.

▶ **Lemma 11.** *Suppose $(\varepsilon,\mathcal{D})$-SSI holds, then $(2^{2n-1}\varepsilon,\mathcal{D},n)$-SSI holds for all $n\in\mathbb{N}$.*

Proof. For any non-local adversary $\mathcal{A}=(\mathcal{B},\mathcal{C},\rho)$ and any $y,y'\in\{0,1\}^n$, we have

$$\left|\Pr\left[(y,y')\leftarrow\mathcal{A}(\psi\otimes\psi)\;:\;|\psi\rangle\leftarrow\mathcal{D}\right]-\Pr\left[(y,y')\leftarrow\mathcal{A}(\psi\otimes\psi')\;:\;|\psi\rangle,|\psi'\rangle\leftarrow\mathcal{D}\right]\right|\leq\varepsilon$$

by $(\varepsilon,\mathcal{D})$-SSI. This is because $\mathcal{B}$ ($\mathcal{C}$) can associate y (respectively, y') with 0 and every other string with 1. By summing over all y,y' and dividing by 2 we get the desired result. ◀

2.1.3 Extending to Many Copies

For a distribution $\mathcal{D}$, denote by $\mathcal{D}^t$ the distribution that samples $|\psi\rangle\leftarrow\mathcal{D}$ and outputs $|\psi\rangle^{\otimes t}$. Then, we can consider $(\varepsilon,\mathcal{D}^t)$-SSI or $(\varepsilon,\mathcal{D}^t,n)$-SSI as extensions where $\mathcal{B}$ and $\mathcal{C}$ each get t copies of their respective inputs.

2.1.4 Extending to Many Parties

We can consider as the distinguisher a q-party non-local adversary $\mathcal{A}=(\mathcal{A}_1,\ldots,\mathcal{A}_q,\rho_{A_1\cdots A_q})$. By giving every party t copies of a quantum state generated either identically or independently we can generalize Definition 10:

▶ **Definition 12** (($\varepsilon,\mathcal{D},n$)-SSI against q Parties)**.** *We say that $(\varepsilon,\mathcal{D},n)$-SSI holds* against q parties *if for any q-party nonlocal adversary $\mathcal{A}=(\mathcal{A}_1,\ldots,\mathcal{A}_q,\rho_{A_1\cdots A_q})$ and any $S\subseteq\{0,1\}^{nq}$ we have*

$$\left|\Pr\left[(x_1,\ldots,x_q)\in S\;:\;\substack{|\psi\rangle\leftarrow\mathcal{D}\\(x_1,\ldots,x_q)\leftarrow\mathcal{A}(\psi_{A_1}\otimes\cdots\otimes\psi_{A_q})}\right]\right.$$
$$\left.-\Pr\left[(x_1,\ldots,x_q)\in S\;:\;\substack{|\psi_1\rangle,\ldots,|\psi_q\rangle\leftarrow\mathcal{D}\\(x_1,\ldots,x_q)\leftarrow\mathcal{A}((\psi_1)_{A_1}\otimes\ldots\otimes(\psi_q)_{A_q})}\right]\right|\leq\varepsilon$$

In general, SSI against many parties is weaker than regular SSI with the same number of copies and the same total output length, which we state formally below.

▶ **Lemma 13.** *Suppose that $(\varepsilon,\mathcal{D}^{qt},qn)$-SSI holds (against 2 parties), then $(2q\varepsilon,\mathcal{D}^t,n)$-SSI holds against q parties.*

Combining Lemmas 11 and 13 yields the following corollary:

▶ **Corollary 14.** *Suppose that $(\varepsilon,\mathcal{D}^{qt})$-SSI holds, then $(2^{2qn}q\varepsilon,\mathcal{D}^t,n)$-SSI holds against q parties.*

2.2 Distinguishing Bell-States

In this section, we use the Bell basis over a 2-qubit system as a warm-up example to demonstrate some facts about simultaneous state indistinguishability. By the Bell basis we mean

$$\left\{ \frac{1}{\sqrt{2}}\left(|00\rangle + |11\rangle\right), \frac{1}{\sqrt{2}}\left(|00\rangle - |11\rangle\right), \frac{1}{\sqrt{2}}\left(|{+}{+}\rangle + |{-}{-}\rangle\right), \frac{1}{\sqrt{2}}\left(|{+}{+}\rangle - |{-}{-}\rangle\right) \right\}.$$

Note that the Bell basis is symmetric for the purposes of this section, meaning any fact we show about a pair of Bell states will also apply to any other pair of Bell states. We start off by demonstrating that the non-local distance $T_{SSI}(\cdot,\cdot)$ can be strictly less than LOCC distance. Recall that two orthogonal Bell states can be perfectly distinguished using LOCC measurements.

▶ **Lemma 15** (Comparison to LOCC). *Let $|\Phi^+\rangle, |\Phi^-\rangle$ be orthogonal Bell states. Then, $T_{SSI}(|\Phi^+\rangle\langle\Phi^+|, |\Phi^-\rangle\langle\Phi^-|) = 1/2$.*

Proof. It suffices to consider projective $\mathcal{B}, \mathcal{C}$. After that, the only non-trivial case is when they both are rank-1 projections, in which case it is easy to show

$$\mathsf{Tr}\left((\mathcal{B}\otimes\mathcal{C})\left(|\Phi^+\rangle\langle\Phi^+| - |\Phi^-\rangle\langle\Phi^-|\right)\right) \leq \mathsf{Tr}\left((\mathcal{B}\otimes\mathcal{C})|\Phi^+\rangle\langle\Phi^+|\right) \leq 1/2. \qquad \blacktriangleleft$$

Next, we show that a non-local distinguisher with an arbitrary number of EPR pairs is no more powerful than unentangled distinguishers for the same problem.

▶ **Lemma 16** (Entanglement has no effect). *Let $|\Phi^+\rangle, |\Phi^-\rangle$ be orthogonal Bell states and let $|\mathsf{EPR}_n\rangle$ denote n EPR pairs. Then, $T_{SSI}(|\Phi^+\rangle\langle\Phi^+| \otimes |\mathsf{EPR}_n\rangle\langle\mathsf{EPR}_n|, |\Phi^-\rangle\langle\Phi^-| \otimes |\mathsf{EPR}_n\rangle\langle\mathsf{EPR}_n|) = 1/2$.*

2.3 Impossibility Results about SSI

There are many distributions that are simultaneously distinguishable. We give some examples below by identifying $\mathcal{D}$ for which $(\varepsilon, \mathcal{D})$-SSI does not hold for small ε.

▷ Claim 17. Suppose $\mathcal{D}$ is a (classical) distribution on $\{0,1\}^n$ such that $\mathsf{Pr}[y_1 \neq y_2 : y_1, y_2 \leftarrow \mathcal{D}] \geq c$, for some $c = c(n)$. Then, $(\varepsilon, \mathcal{D})$-simultaneous state indistinguishability does not hold for any $\varepsilon < c/2n$.

▷ Claim 18. Let $m, n \in \mathbb{N}$ and $m \geq n$. Let $C \in \mathcal{L}(\mathbb{C}^{2^n}, \mathbb{C}^{2^m})$ be a Clifford circuit. That is, C appends $m-n$ qubits initialized to zeros to its input and applies a sequence of Clifford gates. Define $\mathcal{D}_1$ as follows: sample $r \xleftarrow{\$} \{0,1\}^{n-1}$ and then output $|\psi_r\rangle_{BC} = C|r||0\rangle$. Define $\mathcal{D}_2$ as follows: sample $r \xleftarrow{\$} \{0,1\}^{n-1}$ and then output $|\psi_r\rangle_{BC} = C|r||1\rangle$. Then, the distributions $\mathcal{D}_1$ and $\mathcal{D}_2$ are ε-simultaneous state distinguishable for all $\varepsilon < \frac{1}{2}$.

3 Simultaneous Haar Indistinguishability

We show that SSI can be instantiated using Haar random states.

3.1 Single-Copy Case

▶ **Theorem 19** (Simultaneous Haar Indistinguishability (SHI)). *$(\varepsilon, \mathcal{H}_{2^n})$-simultaneous state indistinguishability holds for $\varepsilon = O(1/2^{n/2})$.*

▶ Remark 20. The entangled state held by $\mathcal{A}$ above can have arbitrary dimension. In particular, the proof shows that an arbitrary number of EPR pairs has no asymptotic advantage in distinguishing identical vs. independent Haar states, for the advantage is $O(1/d)$ in both cases.

3.2 Generalization to Many Copies

We generalize Theorem 19 to show indistinguishability when the non-local distinguisher is given many copies of the input state. The proof has the same overall structure, but requires some additional ideas. We start by listing a useful lemma.

▶ **Lemma 21.** *Let $S_{2t}^{(s)} \subset S_{2t}$ be the set of permutations σ over $[2t]$ such that*

$$|\{i \in [t] \ : \ \sigma(i) \notin [t]\}| = s.$$

Define P_σ as the permutation operator over registers $X_1 \dots X_t Y_1 \dots Y_t$, where we match $[t]$ with $X_1 \dots X_t$ and $[2t] \setminus [t]$ with $Y_1 \dots Y_t$. Then,

$$\sum_{\sigma \in S_{2t}^{(s)}} P_\sigma = (t!)^2 \binom{t}{s}^2 \left(\Pi_{\mathsf{Sym}}(X_1 \dots X_t) \otimes \Pi_{\mathsf{Sym}}(Y_1 \dots Y_t)\right) P_{\sigma_s} \left(\Pi_{\mathsf{Sym}}(X_1 \dots X_t) \otimes \Pi_{\mathsf{Sym}}(Y_1 \dots Y_t)\right),$$

where $\sigma_s \in S_{2t}^{(s)}$ is the permutation that swaps i with $t+i$ for $i \in [s]$.

▶ **Theorem 22** (t-Copy Simultaneous Haar Indistinguishability (SHI))**.** *Let $\varepsilon = o(1)$ and $t = \varepsilon 2^{n/4}$. Let $\mathcal{H}_{2^n}^t$ be the distribution defined by sampling t copies of a state from $\mathcal{H}_{2^n}$. Then, $(O(\varepsilon^2), \mathcal{H}_{2^n}^t)$-simultaneous state indistinguishability holds.*

4 Applications

We present applications of simultaneous Haar indistinguishability (Section 3) to single-decryptor encryption (Section 4.1) and unclonable encryption (Section 4.2). Ordinarily, single-decryptor encryption is defined with classical ciphertexts and quantum decryption keys, whereas unclonable encryption is defined using quantum ciphertexts and classical encryption/decryption keys. We achieve relaxed notions of both primitives above: namely, we additionally allow quantum ciphertexts in single-decryptor encryption and quantum decryption keys in unclonable encryption.

In Section 4.3, we show how to construct leakage-resilient quantum secret sharing of classical messages, which additionally guarantees security against an eavesdropper that learns classical leakage of all the shares.

4.1 Single-Decryptor Encryption with Quantum Cipertexts

4.1.1 Definitions

We adopt the definition of single-decryptor encryption by [33] to the setting where the ciphertexts can be quantum.

▶ **Definition 23** (Single-Decryptor Encryption)**.** *A* single-decryptor encryption *(SDE) scheme is a tuple of QPT algorithms* $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$*:*

- $\mathsf{Gen}(1^\lambda)$ *takes as input a security paramter. It outputs a classical encryption key* ek *and a one-time quantum decryption key* $|🔑\rangle$.
- $\mathsf{Enc}(\mathsf{ek}, m)$ *takes as input an encryption key* ek*, and a classical message m. It outputs a quantum ciphertext* $|\mathsf{CT}\rangle$*. We require that* Enc *is pseudo-deterministic.*
- $\mathsf{Dec}(|🔑\rangle, |\mathsf{CT}\rangle)$ *takes as input a quantum decryption key* $|🔑\rangle$*, a quantum ciphertext* $|\mathsf{CT}\rangle$ *and outputs a classical message m.*

▶ **Definition 24** (Correctness). *A SDE scheme* $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ *with quantum ciphertexts is* correct *if for any security parameter* λ *and any message* m *we have*

$$\Pr\left[m' = m \ : \ \begin{matrix}(\mathsf{ek}, |\mathsf{sk}\rangle) \leftarrow \mathsf{Gen}(1^\lambda) \\ |\mathsf{CT}\rangle \leftarrow \mathsf{Enc}(\mathsf{ek}, m) \\ m' \leftarrow \mathsf{Dec}(|\mathsf{sk}\rangle, |\mathsf{CT}\rangle)\end{matrix}\right] \geq 1 - \mathsf{negl}(\lambda).$$

Before defining security, we introduce a notation $\mathsf{Enc}^T(\mathsf{ek}, m)$, which means sampling randomness r and running $\mathsf{Enc}(\mathsf{ek}, m; r)$ for T times.

▶ **Definition 25** (Security of SDE). *An SDE scheme* $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ *is called* (information-theoretically) secure against identical ciphertexts *if for any cloning adversary* $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ *and any pair of messages* (m_0, m_1) *we have*

$$\Pr\left[b_{\mathcal{B}} = b_{\mathcal{C}} = b \ : \ \begin{matrix}(\mathsf{ek}, |\mathsf{sk}\rangle) \leftarrow \mathsf{Gen}(1^\lambda) \\ \rho_{BC} \leftarrow \mathcal{A}(|\mathsf{sk}\rangle) \\ b \xleftarrow{\$} \{0,1\}, \quad |\mathsf{CT}\rangle^{\otimes 2} \leftarrow \mathsf{Enc}^2(\mathsf{ek}, m_b) \\ b_{\mathcal{B}} \leftarrow \mathcal{B}(|\mathsf{CT}\rangle, \rho_B), \quad b_{\mathcal{C}} \leftarrow \mathcal{C}(|\mathsf{CT}\rangle, \rho_C)\end{matrix}\right] \leq \frac{1}{2} + \mathsf{negl}(\lambda),$$

where ρ_E *denotes the* E *register of the bipartite state* ρ_{BC} *for* $E \in \{B, C\}$.

▶ Remark 26 (Identical Ciphertexts). In Definition 25 we consider security against identical ciphertexts. One can similarly define security against ciphertexts that are independently generated. This alternate definition was achieved in the plain model by [7], and it only requires independent-challenge Goldreich-Levin.

▶ Remark 27. Note that Definition 25 need not be physical for an arbitrary scheme $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ without the requirement that Enc is pseudo-deterministic due to the fact that $|\mathsf{CT}\rangle$ may be unclonable even for the encryptor. Nonetheless, our construction satisfies this condition, with the classical randomness of Enc being used for sampling a Haar random state.

Below, we consider a stronger security definition where many copies of the quantum ciphertext are given to the adversary. This matches the case of classical ciphertext more closely, since classical ciphertexts can be cloned arbitrarily. Another implication of this stronger definition is that security holds against adversaries who can clone the quantum ciphertexts.

▶ **Definition 28** (t-Copy Security of SDE). *An SDE scheme* $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ *is called* (information-theoretically) t-copy secure against identical ciphertexts *if for any cloning adversary* $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ *and any pair of messages* (m_0, m_1) *we have*

$$\Pr\left[b_{\mathcal{B}} = b_{\mathcal{C}} = b \ : \ \begin{matrix}(\mathsf{ek}, |\mathsf{sk}\rangle) \leftarrow \mathsf{Gen}(1^\lambda) \\ \rho_{BC} \leftarrow \mathcal{A}(|\mathsf{sk}\rangle) \\ b \xleftarrow{\$} \{0,1\}, \quad |\mathsf{CT}\rangle^{\otimes 2t} \leftarrow \mathsf{Enc}^{2t}(\mathsf{ek}, m_b) \\ b_{\mathcal{B}} \leftarrow \mathcal{B}(|\mathsf{CT}\rangle^{\otimes t}, \rho_B), \quad b_{\mathcal{C}} \leftarrow \mathcal{C}(|\mathsf{CT}\rangle^{\otimes t}, \rho_C)\end{matrix}\right] \leq \frac{1}{2} + \mathsf{negl}(\lambda),$$

where ρ_E *denotes the* E *register of the bipartite state* ρ_{BC} *for* $E \in \{B, C\}$.

4.1.2 Construction

Let $(\mathsf{Gen}_{\mathsf{UE}}, \mathsf{Enc}_{\mathsf{UE}}, \mathsf{Dec}_{\mathsf{UE}})$ be a one-time unclonable encryption scheme with C^n-weak unclonable security and message space $\mathcal{M} \subseteq \{0,1\}^n$, with $n = \mathsf{poly}(\lambda)$, where $C \in (1/2, 1)$ is a constant. Let $\mathcal{D} = \mathcal{H}_{2^n}$, so that:

1. $(\varepsilon, \mathcal{D}^t)$-SSI holds for some $\varepsilon = \mathsf{negl}(\lambda)$ by Theorem 22 as long as $t^2/2^{n/2}$ is negligible.
2. $\mathbb{E}_{|\psi\rangle \leftarrow \mathcal{D}} |\psi\rangle\langle\psi| = \mathsf{id}_{2^n}$.

We construct SDE for single-bit messages ($m \in \{0,1\}$) secure against identical ciphertexts as follows:

- $\mathsf{Gen}(1^\lambda)$ samples a random message $x \xleftarrow{\$} \mathcal{M}$ and a key $k \leftarrow \mathsf{Gen}_{\mathsf{UE}}(1^\lambda)$. It computes $|\psi\rangle \leftarrow \mathsf{Enc}_{\mathsf{UE}}(k, x)$. It outputs an encryption key $\mathsf{ek} = (k, x)$ and a decryption key $|🔑\rangle = |\psi\rangle$.
- $\mathsf{Enc}(\mathsf{ek}, m)$ samples $|\varphi\rangle = \sum_y \alpha_y |y\rangle \leftarrow \mathcal{D}$. It parses $\mathsf{ek} = (k, x)$ and computes the state $|\phi\rangle = \sum_y \alpha_y |y\rangle |\langle y, x\rangle \oplus m\rangle$. It outputs a quantum ciphertext $|\mathsf{CT}\rangle = (k, |\phi\rangle)$. Note that Enc is pseudo-deterministic given that it can sample from $\mathcal{D}$ using classical randomness.
- $\mathsf{Dec}(|🔑\rangle, |\mathsf{CT}\rangle)$ parses $|\mathsf{CT}\rangle = (k, |\phi\rangle)$. It computes $x \leftarrow \mathsf{Dec}_{\mathsf{UE}}(k, |\phi\rangle)$. It computes $U_x |\psi\rangle$ and measures the second register to obtain m, where U_x is the unitary defined as $U_x |y\rangle |z\rangle = |y\rangle |z \oplus \langle y, x\rangle\rangle$. It outputs m.

▶ Remark 29. Since t is bounded (see Theorem 34), we can use a $2t$-state design to instantiate the Haar random state used in the construction. We can similarly use a $2t$-state design to instantiate our construction of unclonable encryption in Section 4.2.

From the correctness of $(\mathsf{Gen}_{\mathsf{UE}}, \mathsf{Enc}_{\mathsf{UE}}, \mathsf{Dec}_{\mathsf{UE}})$, it follows that Dec recovers m (with probability negligibly close to 1) from $|\mathsf{CT}\rangle$, where $|\mathsf{CT}\rangle$ is an encryption of m.

4.1.3 Security Proof

We first show a lemma that is needed in our security proof:

▶ **Lemma 30** (Simultaneous Quantum Goldreich-Levin with Correlated Input)**.** *Let $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ be a cloning adversary that given*[14] *$(\rho, (\sigma, (y_\mathcal{B}, b_\mathcal{B}), (y_\mathcal{C}, b_\mathcal{C})))$, where $y_\mathcal{B}, y_\mathcal{C} \in \{0,1\}^n$ are i.i.d. uniform strings and $b_\mathcal{B}, b_\mathcal{C} \in \{0,1\}$ are random bits satisfying $b_\mathcal{B} \oplus b_\mathcal{C} = \langle y_\mathcal{B}, x\rangle \oplus \langle y_\mathcal{C}, x\rangle$, can output $(\langle y_\mathcal{B}, x\rangle, \langle y_\mathcal{C}, x\rangle)$ with probability at least $1/2 + \varepsilon$. Then, there is an extractor $(\mathcal{A}', \mathcal{B}', \mathcal{C}')$ that given input (ρ, σ) outputs (x, x) (running $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ as a subprotocol) with probability $\mathsf{poly}(\varepsilon)$.*

▶ Remark 31. Lemma 30 proves a special case of the simultaneous inner product conjecture postulated in [3]. Roughly speaking, the simultaneous inner product conjecture states that if a set of bipartite states $\{\rho_x\}_{x \in \{0,1\}^n}$ is such that any non-local adversary $(\mathcal{B}, \mathcal{C})$ given ρ_x, where $x \xleftarrow{\$} \{0,1\}^n$, cannot recover x (except with negligible probability) then $\mathcal{B}$ and $\mathcal{C}$ cannot distinguish Goldreich-Levin samples versus uniform samples (except with negligible advantage). The conjecture is parameterized by the distribution of the samples and also by the algebraic field associated with the samples. Lemma 30 shows that the conjecture is true for a correlated distribution of samples and when the field in question is $\mathbb{F}_2$.

▶ Remark 32. Lemma 30 resolves an important technical issue we will face in our unclonable security proof, similar to the one faced by [44][15]. Namely, $\mathcal{B}$ and $\mathcal{C}$ seem to get additional information about the hidden values $\langle y_\mathcal{B}, x\rangle, \langle y_\mathcal{C}, x\rangle$ by holding secret shares of their XOR value. Above we show that this is in fact not the case, i.e. the adversary does not get additional power from these shares. In [44], the authors utilized alternative security definitions to overcome this issue.

▶ **Theorem 33.** $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ *above is secure against identical ciphertexts.*

***t*-Copy Security.** We show that our construction remains secure if up to $O(n)$ copies of the quantum ciphertext is given to the adversary in the unclonable security experiment.

[14] Here ρ is given to $\mathcal{A}$ and then a bipartite state σ is given to $\mathcal{B}$, $\mathcal{C}$ in the challenge phase.
[15] See Remark 7 (pp. 53) in [44].

▶ **Theorem 34.** *Let $c > 0$ be a constant and $t \leq (\log_2(1/\sqrt{C}) - c)n$, then* $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ *above is t-copy secure against identical ciphertexts.*

By instantiating $(\mathsf{Gen}_{\mathsf{UE}}, \mathsf{Enc}_{\mathsf{UE}}, \mathsf{Dec}_{\mathsf{UE}})$ with the construction of [17], we can set $C = 0.86$ and thus $t = n/10$. Therefore, by setting $n = 10t$ we get the following corollary:

▶ **Corollary 35.** *For any $t = \mathsf{poly}(\lambda)$, there exists a single-decryptor encryption scheme with quantum ciphertexts t-copy secure against identical ciphertexts (Definition 28) in the plain model.*

▶ Remark 36 (Bounded Number of Copies). Our construction is not t-copy secure against identical ciphertexts if t is an unbounded polynomial due to a simple attack that measures each copy of the ciphertext in the computational basis. Every measurement (except the first) will give a random linear constraint on the bits of x, hence a linear number of copies on average suffice to solve for x entirely. Nonetheless, we can set n accordingly for any fixed polynomial t.

4.2 Unclonable Encryption with Quantum Keys

Using our ideas in Section 4.1, we construct unclonable encryption with quantum keys in the plain model. Besides allowing the decryption key to be quantum, we do not relax the syntax of unclonable encryption. In particular, we achieve identical-challenge security with quantum challenges. Due to its similarity with Section 4.1, we leave the details of this section for the full version.

4.3 Secret Sharing

Definition. Below we formally define a quantum secret sharing scheme for a single-bit message $m \in \{0,1\}$, which is secure against an eavesdropper if only classical strings are leaked from the quantum shares.

▶ **Definition 37** (2-out-of-n Classical-Leakage-Resilient Quantum Secret Sharing)**.** *Let $n = \mathsf{poly}(\lambda)$. A* 2-out-of-$n$ classical-leakage-resilient quantum secret sharing scheme *is a tuple of algorithms* $(\mathsf{Share}, \mathsf{Rec})$ *with the following syntax:*

- $\mathsf{Share}(1^\lambda, m)$ *takes as input a security parameter and a message $m \in \{0,1\}$; it outputs a product state $|\psi_m\rangle = \bigotimes_{i=1}^n |\psi_m^i\rangle$ over registers $S_1, S_2, \ldots, S_n$ with $\mathsf{poly}(\lambda)$ qubits each.*
- $\mathsf{Rec}(i, j, \psi^i, \psi^j)$ *takes as input two indices $i, j \in [n]$ and quantum shares $|\psi^i\rangle, |\psi^j\rangle$ over registers S_i, S_j. It outputs a message $m \in \{0,1\}$.*

It satisfies the following properties:

1. **δ-Correctness:** *For all $m \in \{0,1\}, \lambda \in \mathbb{N}, (i,j) \in [n] \times [n]$ we have*

$$\Pr\left[m \leftarrow \mathsf{Rec}(i, j, \psi_m^i, \psi_m^j) \ : \ |\psi\rangle = \bigotimes_{i=1}^n |\psi_m^i\rangle \leftarrow \mathsf{Share}(1^\lambda, m)\right] \geq \delta.$$

2. **Perfect Secrecy:** *For all $i \in [n]$, we have*

$$\mathop{\mathbb{E}}_{|\psi_0\rangle \leftarrow \mathsf{Share}(1^\lambda, 0)} |\psi_0^i\rangle\langle\psi_0^i| = \mathop{\mathbb{E}}_{|\psi_1\rangle \leftarrow \mathsf{Share}(1^\lambda, 1)} |\psi_1^i\rangle\langle\psi_1^i|.$$

3. **ℓ-bit ε Classical-Leakage-Resilience:** *For any quantum algorithms* $\mathsf{Leak}_1, \ldots, \mathsf{Leak}_n$ *that output* ℓ *classical bits, any* n*-partite state* ρ*, and any distinguisher* $\mathcal{A}$*, we have*

$$\left| \Pr\left[1 \leftarrow \mathcal{A}(y_1, \ldots, y_n) \ : \ \begin{smallmatrix} \psi_0 \leftarrow \mathsf{Share}(1^\lambda, 0) \\ y_i \leftarrow \mathsf{Leak}_i(\psi_0^i, \rho_i),\ i \in [n] \end{smallmatrix}\right] - \Pr\left[1 \leftarrow \mathcal{A}(y_1, \ldots, y_n) \ : \ \begin{smallmatrix} \psi_1 \leftarrow \mathsf{Share}(1^\lambda, 1) \\ y_i \leftarrow \mathsf{Leak}_i(\psi_1^i, \rho_i),\ i \in [n] \end{smallmatrix}\right] \right| \leq \varepsilon,$$

where ρ_i *is the* i*-th register of* ρ*.*

▶ Remark 38. Note that we consider the perfect secrecy and the classical leakage resilience properties separately. It is natural to ask if it is possible to combine the two properties into a stronger property that guarantees security even against adversaries who in addition to receiving one of the shares, also receives as input classical leakage on the rest of the shares. Unfortunately, this stronger property cannot be satisfied due to a simple attack via quantum teleportation. Thus, we need to consider these two properties separately.

▶ Remark 39. The above notion can be generalized in many ways. Firstly, for simplicity, we define the shares to be pure states and we could consider a general notion where the shares could be entangled with each other. Secondly, we can consider sharing schemes guaranteeing security against different adversarial access structures.

4.3.1 Construction

We will construct the primitive above using the Haar distribution $\mathcal{D} = \mathcal{H}_d$ for $d = 2^{4\ell+\lambda}$. This satisfies $(\varepsilon, \mathcal{D}^t, \ell)$-SSI for $\varepsilon = \mathsf{negl}(\lambda)$ by Corollary 14 and Theorem 22. $\mathcal{H}_d$ can in turn be instantiated using a nt-design. We will pick $\omega(\log \lambda) \leq t \leq \mathsf{poly}(\lambda)$, so that the construction is efficient.

- $\mathsf{Share}(1^\lambda, m)$: Set $d = 2^{4n\ell+\lambda}$ and $\mathcal{D} = \mathcal{H}_d$. If $m = 0$, it samples nt copies of $|\psi\rangle \leftarrow \mathcal{D}$ and outputs $|\psi\rangle_{S_1}^{\otimes t} \otimes \ldots \otimes |\psi\rangle_{S_n}^{\otimes t}$. If $m = 1$, it independently samples t copies of $|\psi_i\rangle \leftarrow \mathcal{D}$ for $i \in [n]$ and outputs $|\psi_1\rangle_{S_1}^{\otimes t} \otimes \ldots \otimes |\psi_n\rangle_{S_n}^{\otimes t}$.
- $\mathsf{Rec}(i, j, |\varphi\rangle_{S_i}, |\varphi'\rangle_{S_j})$: It parses $S_i = S_i^{(1)} \ldots S_i^{(t)}$ and $S_j = S_j^{(1)} \ldots S_i^{(t)}$ as t registers. It applies a SWAP test to the registers $S_i^{(k)}$ and $S_j^{(k)}$ for $k \in [t]$. It outputs 0 if at least $\lfloor 3t/4 \rfloor$ of the SWAP tests succeed and outputs 1 otherwise.

4.3.2 Correctness and Secrecy

The construction above has δ-correctness for $\delta \geq 1 - \mathsf{negl}(\lambda)$. Note that for $m = 0$ each SWAP test will succeed with probability 1, so Rec will always output the correct message. If $m = 1$ on the other hand, each SWAP test will succeed with probability negligibly close to $1/2$, so by a Chernoff bound Rec will output 0 with only negligible probability since $t = \omega(\log \lambda)$.

Perfect secrecy is trivial given that each share is distributed according to $\mathcal{D}$.

4.3.3 Classical Leakage Resilience

By Corollary 14 and Theorem 22, the total variation distance between the output distributions of any ℓ-bit leakage functions $\mathsf{Leak}_1, \ldots, \mathsf{Leak}_n$ with respect to shares of $m = 0$ and $m = 1$ is at most

$$O\left(\frac{2^{2n\ell} n^3 t^2}{\sqrt{d}}\right) = O\left(\frac{n^3 t^2}{2^{\lambda/2}}\right) \leq \mathsf{negl}(\lambda).$$

Abstract

A *proof of quantumness* is an efficiently verifiable interactive test that an efficient quantum computer can pass, but all efficient classical computers cannot (under some cryptographic assumption). Such protocols play a crucial role in the certification of quantum devices. Existing single-round protocols based solely on a cryptographic hardness assumption (like asking the quantum computer to factor a large number) require large quantum circuits, whereas multi-round ones use smaller circuits but require experimentally challenging mid-circuit measurements.

In this work, we construct efficient single-round proofs of quantumness based on existing *knowledge assumptions*. While knowledge assumptions have not been previously considered in this context, we show that they provide a natural basis for separating classical and quantum computation. Our work also helps in understanding the interplay between black-box/white-box reductions and cryptographic assumptions in the design of proofs of quantumness. Specifically, we show that multi-round protocols based on Decisional Diffie-Hellman (DDH) or Learning With Errors (LWE) can be "compiled" into single-round protocols using a knowledge-of-exponent assumption [7] or knowledge-of-lattice-point assumption [36], respectively. We also prove an *adaptive hardcore-bit* statement for a family of claw-free functions based on DDH, which might be of independent interest.

1 Introduction

Demonstrating quantum advantage, the point where a quantum computer can solve a problem that no existing classical computer can, is both a theoretical and technological challenge. It requires a problem that is plausibly intractable for classical algorithms and which admits an

© Petia Arabadjieva, Alexandru Gheorghiu, Victor Gitton, and Tony Metger;
licensed under Creative Commons License CC-BY 4.0

efficient quantum algorithm, ideally one that can be performed with noisy intermediate-scale quantum (NISQ) devices [42]. Additionally, the problem's solution should be efficiently verifiable by a classical computer. This is necessary if one wishes to have a convincing and scalable way of proving quantum advantage. Currently, there are three main paradigms for demonstrating quantum advantage.

The most straightforward one is to solve a problem which is believed to be classically hard, such as integer factorization. A quantum computer could efficiently solve this task by running Shor's algorithm [43] and the solution can be efficiently verified by multiplying the factors reported by the prover. But while Shor's algorithm is efficient in the sense of only requiring a polynomial-size quantum circuit, the actual circuit for any reasonably-sized integer to be factored is too large to implement with NISQ devices [22, 25]. Another approach is based on the classical hardness of sampling problems such as *random circuit sampling* [12, 6, 44] or *boson sampling* [1, 48, 37]. While these experiments can be implemented with current hardware, they are not efficiently verifiable.

The work of Brakerski et al. [13] introduced a new approach towards testing for quantum advantage, referred to as a *proof of quantumness* protocol. Akin to the cryptographic notions of proof or argument systems [24, 15, 23], a proof of quantumness is an interactive protocol between a polynomial-time classical *verifier* and an ostensibly quantum polynomial-time *prover*. The verifier issues challenges to the prover and checks the correctness of the prover's responses. The key feature of such a protocol is that there should exist an efficient quantum strategy that allows the prover to correctly answer the verifier's challenges with high probability, whereas any efficient classical strategy can only succeed with low probability (under some plausible cryptographic hardness assumption such as the classical intractability of factoring, Decisional Diffie-Hellman (DDH), or the Learning With Errors (LWE) problem).

In contrast to other paradigms for proving quantum advantage, the cryptographic proofs of quantumness of Brakerski et al. and follow-up works do not require the quantum prover to break the underlying computational hardness assumption. Instead, they leverage the fact that the restriction imposed on the prover through mid-protocol interaction limits a classical prover's capacity for correctly responding to subsequent challenges from the verifier more strongly than it limits a quantum prover.

The advantage of these protocols over an integer factorization-based test is that they have much smaller circuits than Shor's algorithm, making them potentially more suitable for implementation on near-term devices [30, 29, 49, 26, 35, 4]. However, due to their interactive nature, they require the honest quantum prover to perform mid-circuit measurements for each of the verifier's challenges. Mid-circuit measurements on a subset of qubits are difficult to implement on existing quantum devices without disturbing neighboring qubits and can thus degrade the quality of the remaining computation. An experimental implementation of the two-round protocol by Brakerski et al. [49] directly compared the performance of an ion-trap quantum computer running the protocol with and without mid-circuit measurements, revealing a significant difference. Thus, implementing this proof of quantumness protocol at the scale required for quantum advantage seems especially challenging.[1] It would therefore be desirable to have proofs of quantumness with relatively small quantum circuits and which involve only one round[2] of interaction between the verifier and the prover. Beyond the practical motivation, this would also give us a better understanding of the structure required for demonstrating quantum advantage in a way that is efficiently verifiable.

[1] Note that the instance sizes of the underlying cryptographic problem in [49] are so small that they can easily be broken by a laptop. For a convincing demonstration of quantum advantage, one would have to use instance sizes that cannot be broken even by the fastest classical supercomputers.

[2] Throughout the paper, we use the convention that a one-round protocol refers to a protocol with two messages, one message from the verifier to the prover and one message back.

The recent breakthrough work of Yamakawa and Zhandry made progress in this direction by giving a single-round proof of quantumness protocol in the *random oracle model* (ROM) [45]. Prior to their work, Brakerski et al. constructed single-round proofs of quantumness in the ROM that additionally required a structured computational assumption, such as factoring or LWE [14]. However, with both of these approaches the circuits that the prover would have to perform are possibly larger than those in existing multi-round proofs of quantumness [13, 29].

Our main result is a single-round proof of quantumness that only requires the same small circuits as an existing multi-round interactive proof of quantumness and is based on *knowledge assumptions*, a cryptographic idea that turns out to be natural for proofs of quantumness. We achieve this by starting from the two-round protocol of [13] and removing one of the rounds of interaction through the use of a knowledge assumption [17, 40, 16, 36, 32]. As explained in [32], a knowledge assumption is a statement of the form:

> "If an algorithm $\mathcal{A}$ outputs an object of type X, it must know a corresponding witness of the type W, such that the output and the witness are in some relation $\mathcal{R} \subseteq X \times W$."

The rationale behind knowledge assumptions is that certain computational tasks, performed by some probabilistic algorithm $\mathcal{A}$, can only be performed efficiently by following a specific sequence of steps, thus obtaining a series of intermediate values. Informally, we say that $\mathcal{A}$ must have "known" the intermediate values for its specific output. This is made more precise by saying that there exists an efficient *extractor* $\mathcal{A}^*$ that receives as input $\mathcal{A}$'s random coins and outputs (or *extracts*) the relevant intermediate values of $\mathcal{A}$.

Knowledge assumptions have traditionally been used for the design of protocols that require both extractability (like in proof/argument of knowledge protocols) and succinctness [9, 32]. In our case, we are able to leverage knowledge assumptions to construct efficient, single-round proofs of quantumness. As far as we are aware, this is the first time knowledge assumptions are used in this context. We argue that their application here is natural and in some sense necessary, if one wishes to avoid multi-round interaction or working in the ROM. Intuitively, this is because some aspect of the proof of quantumness protocol has to differentiate between classical and quantum provers. In multi-round protocols, this distinction comes from the fact that classical provers can be *rewound*, but quantum provers generally cannot. In a ROM-based protocol, the distinction arises from the ability to *record* classical queries to a random oracle in a way that is not possible quantumly.

In our single-round protocols, the classical-quantum distinction is due to the knowledge assumption: for example, if $f : \mathcal{X} \to \mathcal{Y}$ is a one-way function with a sparse range (i.e. most values in $\mathcal{Y}$ are not in the range of f), it is plausible that a *classical* prover that produces a value in the range of f must have done so by evalating the function on some $x \in \mathcal{X}$, and must therefore also "know" the corresponding preimage; this can be captured formally as a knowledge assumption [16, 8]. However, a *quantum* prover can do the following: first prepare the state $\sum_x |x\rangle|f(x)\rangle$, then measure the second register in the computational basis to obtain an image $y \in \text{range}(f)$, and measure the first register in the Hadamard basis to "erase" any knowledge of the preimage x. Such a prover can be said to produce a value in the range of f without knowledge of a preimage. It is this distinction between classical and quantum computation that our single-round proofs of quantumness exploit. We note that a related idea of oblivious LWE sampling was recently explored in [18]; since a proof of quantumness only requires soundness against classical provers, we do not need to analyse the quantum prover in detail, but it might be interesting to explore the relation between knowledge assumptions used in our work and the (strong) notion of oblivious LWE sampling proposed in [18]. We discuss the classical-quantum distinction and the impossibility of single-round proofs of quantumness with black-box security reductions in more detail in Section 3.

Organsation

The rest of this work is structured as follows: in Section 1.1, we give a brief overview of the two-round proof of quantumness from [13]. This will form the basis for our single-round proof of quantumness. In Section 1.2, we recall two existing knowledge assumptions from [7, 36] that we use in our protocols. In Section 2, we explain how to make use of these knowledge assumptions to obtain different single-round proofs of quantumness. In Section 3 we argue that a white-box assumption (like a knowledge assumption) seems to be necessary for single-round proofs of quantumness. Finally, in Section 4 and Section 5 we discuss additional related works and open questions. For a formal description of our results and proofs, we refer to the full version of this paper [5].

1.1 A two-round proof of quantumness

To explain our results, we first need to outline the two-round (four-message) proof of quantumness protocol from [13]. At the heart of this protocol is a collection of functions known as Trapdoor Claw-free Functions (TCF). TCFs are a type of collision-resistant hash function – they are 2-to-1 functions for which it should be intractable to find a colliding pair of inputs (known as a *claw*), given the description of the function. Additionally, the functions are generated with a trapdoor that allows for efficient inversion. The specific TCFs used in [13] require an additional property known as the *adaptive hardcore-bit* (AHCB) property. Informally, this states that it is not only intractable to find collisions, but given any particular input x_0 and corresponding image under the TCF, denoted $y = f(x_0)$, it should be intractable to recover even a single bit of x_1, the other input with which x_0 forms a claw (i.e. $f(x_1) = f(x_0) = y$). Prior to our work, constructing TCFs with an AHCB had only been achieved from LWE and (non-standard) hardness assumptions of isogeny-based group actions [3]. One of our results shows an AHCB property for a TCF based on DDH.

Algorithm 1 The Proof of Quantumness of [13] (informal).

1. The verifier generates a description of a TCF f, together with its trapdoor, t. It then sends f to the prover.
2. The prover sends the verifier a point y in the image of f. Denote as x_0 and x_1 the associated preimages, so $y = f(x_0) = f(x_1)$.
3. With probability 1/2, the verifier sends the prover one of the following two challenges:
   - **(a) Preimage test.** The verifier asks the prover for a valid preimage of y. Denoting the prover's response as x, the verifier accepts iff $f(x) = y$.
   - **(b) Equation test.** The verifier asks the prover for a non-zero string d, such that $d \cdot (x_0 \oplus x_1) = 0$. The verifier uses the trapdoor, t, to recover x_0 and x_1 from y and then checks whether the equation is satisfied, accepting if it is and rejecting otherwise.

Given a family of TCFs, with the AHCB property, the Brakerski et al. protocol from [13] is described informally in Protocol 1. Brakerski et al. showed that, assuming the AHCB property, no polynomial-time classical prover makes the verifier accept with probability non-negligibly[3] larger than 3/4 (this is referred to as the *soundness* of the protocol). At the same time, they gave a simple quantum strategy which would allow the prover to succeed with probability 1 (referred to as the *completeness* of the protocol). This honest prover first creates an equal superposition over evaluations of f,

[3] A *negligible* function f, denoted by $f = \mathrm{negl}(\lambda)$, is a function $f : \mathbb{N} \to \mathbb{R}$ such that $f(\lambda) = o(\lambda^{-c})$ for every constant $c \in \mathbb{R}$.

$$\sum_x |x\rangle|f(x)\rangle\,.$$

The prover then measures the second register, resulting in a value $y = f(x_0) = f(x_1)$, and collapsing the state in the first register to

$$\frac{|x_0\rangle + |x_1\rangle}{\sqrt{2}}\,. \tag{1.1}$$

We can see that if this state is measured in the computational basis, it results in one of the two preimages of y, thus providing a valid response to the preimage test. Conversely, if the state is measured in the Hadamard basis (i.e. applying Hadamard gates to all qubits and measuring in the computational basis), the result will be a string d such that $d \cdot (x_0 \oplus x_1) = 0$, yielding a valid response to the equation test. Thus, a quantum prover implementing this strategy would make the verifier accept with probability 1.

The intuition for why it is classically intractable to succeed in this protocol is that a classical prover that answers both the preimage and equation tests correctly can be *rewound* so as to obtain both a valid preimage and a valid equation. However, having both would contradict the AHCB property. In contrast, a quantum prover cannot be rewound and can use the state from Equation (1.1) to answer *either of the two challenges* correctly, but not both at the same time. Communication between the two rounds is crucial for the security proof, as a reduction to the AHCB property requires that the prover holds a preimage and equation *for the same* y. This can only be guaranteed if the prover commits to a fixed choice of y before receiving the second challenge.

A natural question is whether the equation test on its own is already classically intractable. Unfortunately, simply removing the preimage test breaks the security proof of [13]: the AHCB property says that it is hard to produce an image, an equation, *and a preimage* together. Therefore, without the preimage test one cannot use a successful classical prover in the proof of quantumness to break the AHCB property, as one does not have access to a preimage[4]. Indeed, it can be shown that no *black-box* reduction can reduce the security of this "equation-test only" proof of quantumness to LWE ([39], see also Section 3).

Our results show that a variation of the "equation-test only" proof of quantumness can be made to work, provided we use a knowledge assumption to replace the role of the preimage test. Intuitively, the knowledge assumption can be used to "extract" a preimage from a successful classical prover without the need for an explicit preimage test. Since a knowledge assumption deals with the inner workings of a prover, our result can be interpreted as a *white-box* reduction from a version of the equation test to the AHCB property.

1.2 Knowledge assumptions

Knowledge assumptions posit the existence of an efficient extractor that is able to produce certain intermediate values that are in some relation with the output of an algorithm. A canonical example is the so-called *knowledge of exponent assumption* (KEA), introduced by Damgård in [17]. Informally, this says that given a generator g of some multiplicative

[4] We remark here that this is actually not the only problem that arises when removing the preimage test. In fact, Urmila Mahadev observed that for both constructions we consider, there exists a classical winning strategy in the equation test which involves evaluating f on an extended domain. In the original Brakerski et al. protocol [13], this strategy is excluded by the preimage test. In our protocols, this strategy is excluded by adding another type of test which does not increase the number of rounds of the protocol and is explained in Section 2.

group $\mathbb{G}$, as well g^α for some random power α, the only way to produce a new pair of the form (h, h^α) is by *exponentiating* the original pair. In other words, any efficient (randomized) algorithm $\mathcal{A}$ which outputs (h, h^α) given (g, g^α) must "know" an exponent k such that $h = g^k$. This is formalized by saying that for every such algorithm $\mathcal{A}$, there exists an efficient extractor $\mathcal{A}^*$ that, given (g, g^α) and the random coins of $\mathcal{A}$ for which $\mathcal{A}$ outputs (h, h^α), will output (or *extract*) the exponent k such that $h = g^k$ with overwhelming probability:

▶ **Assumption 1** (KEA (informal), from [17]). *Let $\mathcal{A}$ be an efficient probabilistic algorithm which receives as input a generator g of a multiplicative group $\mathbb{G}$ and a random group element g^α. Then there exists an efficient extractor $\mathcal{A}^*$, which uses the same input and random coins r as $\mathcal{A}$, and such that*

$$\Pr\left[\begin{array}{c}(h,h') \leftarrow \mathcal{A}(g, g^\alpha, r) \\ h^\alpha = h'\end{array} \wedge \begin{array}{c} k \leftarrow \mathcal{A}^*(g, g^\alpha, r) \\ g^k \neq h\end{array}\right] = \mathrm{negl}(\lambda)\,. \tag{1.2}$$

Variations of this assumption have also been considered, such as the t-KEA, in [7], in which the input to $\mathcal{A}$ is instead of the form $(g^{\mathbf{r}}, g^{\alpha\mathbf{r}})$, where $\mathbf{r}$ is a t-dimensional vector and exponentiation is element-wise.

The rationale behind knowledge of exponent assumptions is that the function that maps k to $(g^k, g^{\alpha k})$ has a sparse image (considered as a subset of $\mathbb{G} \times \mathbb{G}$). Thus, it seems implausible that $\mathcal{A}$ could come up with a valid image simply by cleverly sampling its output from $\mathbb{G} \times \mathbb{G}$ without exponentiating the input.[5]

More recently, similar knowledge assumptions were proposed for lattices. One example, introduced in [36], is known as the *knowledge of lattice point assumption* (denoted as LK-ϵ). This says the following: suppose there is an efficient randomized classical algorithm $\mathcal{A}$ which takes as input a lattice basis $\mathbf{A}$ and outputs a point $\mathbf{c}$ that is ϵ-close to the lattice $\mathcal{L}(\mathbf{A})$. Then $\mathcal{A}$ must "know" the lattice point closest to $\mathbf{c}$.

▶ **Assumption 2** (LK-ϵ (informal), from [36]). *Let ϵ be a fixed constant in $(0, 1/2)$. Denote by $\lambda(\mathcal{L})$ the norm of the shortest vector in a lattice $\mathcal{L}$. Let $\mathcal{A}$ be an efficient probabilistic algorithm which receives as input a basis $\mathbf{A}$ of a lattice $\mathcal{L}$ and outputs a vector $\mathbf{y}$. Then there exists an efficient algorithm $\mathcal{A}^*$ which uses the same input and random coins r as $\mathcal{A}$, and outputs a lattice point $\mathbf{p} \in \mathcal{L}$ such that*

$$\Pr\left[\begin{array}{c}\mathbf{y} \leftarrow \mathcal{A}(\mathbf{A}, r) \\ \exists\ \mathbf{c} \in \mathcal{L}(\mathbf{A})\ s.t.\ ||\mathbf{c} - \mathbf{y}|| \leq \epsilon \cdot \lambda(\mathcal{L}(\mathbf{A}))\end{array} \wedge \begin{array}{c}\mathbf{p} \leftarrow \mathcal{A}^*(\mathbf{A}, r) \\ \mathbf{p} \neq \mathbf{c}\end{array}\right] = \mathrm{negl}(\lambda)\,. \tag{1.3}$$

The motivation for this assumption is similar to that of KEA – the set of points that are close to the lattice (for a suitable choice of ϵ) is sparse in the set of all points, and the only apparent efficient strategy to sample from this sparse set is to pick a random lattice point and perturb it. This lattice knowledge assumption and variants of it have been used to construct efficient FHE and SNARK schemes [19, 27].

For our results, we will use t-KEA and LK-ϵ, which we state formally in [5, Assumption 4] and [5, Assumption 5].

[5] An alternative way of coming up with an image would be if $\mathcal{A}$ could determine α, given g and g^α. However, this would entail solving the discrete logarithm problem, which is believed to be classically intractable.

2 Main results

Our main result is that combining knowledge assumptions with standard cryptographic assumptions, like LWE or DDH, leads to efficient single-round proof of quantumness protocols. To make our results modular, we first show how to construct a general single-round proof of quantumness from a cryptographic primitive that we call Doubly Extended Extractable Noisy Trapdoor Claw-free Functions (abbreviated e^{3}NTCF). Second, we give two constructions of e^{3}NTCF: one from the DDH and t-KEA assumptions, and one from the LWE and LK-ϵ assumptions.

2.1 Single-round proof of quantumness from e^{3}NTCF

Our starting point is the protocol from [13], which we explained in Section 1.1. Recall that there, one uses a TCF with the AHCB property, and argues that if a classical prover could succeed in the preimage and equation tests, by rewinding we could construct a tuple (x, y, d) of a preimage, image, and equation that would contradict the AHCB property.

Now suppose that the TCF family $\mathcal{F} = \{f : \mathcal{X} \to \mathcal{Y}\}$ used in this protocol had an additional extractability property: for any classical prover that produces an image $y \in \text{range}(f)$, there exists an extractor that produces a corresponding preimage x. This is, in essence, a knowledge assumption. With such an extractable TCF, we could simply remove the preimage test from Protocol 1: then, if we had a classical prover that succeeded in this modified protocol, we could use that prover to find an image $y \in \text{range}(f)$ and equation d, and use the extractor to find a corresponding preimage x, such that (x, y, d) break the AHCB property.

Unfortunately, we do not know how to construct such an extractable TCF with AHCB from existing knowledge assumptions such as t-KEA or LK-ϵ[6]. The key difficulty here is that the extractability and AHCB properties have to hold simultaneously.

One way to circumvent this issue would be to introduce an additional function family $\mathcal{H} = \{h : \mathcal{X} \to \mathcal{Y}\}$ that is indistinguishable from the TCF family $\mathcal{F}$ (i.e. given a description of a random choice of either kind of function, it is hard to tell which kind of function it is). This function family $\mathcal{H}$ can be constructed such that it has an extractability property, i.e. if a classical algorithm produces a value y in the image of h, an extractor can find a preimage x (under a standard knowledge assumption such as t-KEA). However, $\mathcal{H}$ itself is not a TCF and has no AHCB property.

We now want to combine the AHCB property of $\mathcal{F}$ with the extractability property of $\mathcal{H}$. For this we leverage that the two function families are computationally hard to distinguish[7]: if we send a description of either $f \in \mathcal{F}$ or $h \in \mathcal{H}$ to a classical prover, the prover cannot tell which kind of function it received. This suggests the following protocol.

1. The verifier generates a description of a TCF $f \in \mathcal{F}$ (with a trapdoor t) or an extractable function $h \in \mathcal{H}$ and sends this function description to the prover.

[6] To be precise, we found that using these knowledge assumptions directly on the known NTCF constructions based on DDH and LWE does not work to infer extractability.

[7] One may ask here why we do not use computational indistinguishability to directly transfer the extractability property of $\mathcal{H}$ to $\mathcal{F}$, given that the extractor is an efficient algorithm. This has to do with the exact form of the extractability property: successful extraction is only guaranteed under the condition $y \in \text{range}(h)$, which cannot be checked efficiently without the trapdoor. Thus, while we can exploit the computational indistinguishability of $\mathcal{F}$ and $\mathcal{H}$ in our protocol, it is not possible to use computational indistinguishability to infer an analogous extractability property for $\mathcal{F}$.

2. The verifier receives (y, d) from the prover.
   - If the verifier sent a TCF f, it uses the trapdoor to recover x_0 and x_1 such that $y = f(x_0) = f(x_1)$ and accepts iff $d \cdot (x_0 \oplus x_1) = 0$.
   - If the verifier sent an extractable function h, it accepts iff $y \in \text{range}(h)$.

Suppose that a classical prover succeeded in this protocol with high probability. We can use this prover (and the corresponding extractor for the extractable function family) to break the AHCB property of f as follows: given a description of $f \in \mathcal{F}$, run the prover to generate (y, d). Then use the extractor on this prover on input $f \in \mathcal{F}$ to generate a preimage x. We claim that (x, y, d) violates the AHCB property.

Note that this reduction runs the extractor for the function family $\mathcal{H}$ on an input $f \in \mathcal{F}$, i.e. it runs the extractor on an input for which it was not designed. However, recall that descriptions of f and h are computationally indistinguishable. On the other hand, the extractor as well as the function that checks whether the extractor produced a correct preimage are efficient. Therefore, since the protocol ensures that on input h, the classical prover produces $y \in \text{range}(h)$, it follows that when we run the extractor for this classical prover on an input $f \in \mathcal{F}$, it will still produce a valid preimage of $y = f(x_0) = f(x_1)$; otherwise, we could distinguish f from h.

When trying to construct such a pair $(\mathcal{F}, \mathcal{H})$ of function families from DDH and t-KEA, we are faced with one additional technical challenge: the only evident construction of an extractable function family $\mathcal{H}$ works by extending the functions $f \in \mathcal{F}$ to a larger domain $\mathcal{X}'$ (on which $\mathcal{F}$ no longer satisfies the AHCB property) and constructing extractable functions $h : \mathcal{X}' \to \mathcal{Y}$, i.e. the extractability property of h only holds with respect to the extended domain $\mathcal{X}'$. This means that the extractor may, on input $y \in f(\mathcal{X})$, produce a $x \in \mathcal{X}' \setminus \mathcal{X}$ that also maps to y. While this is a valid preimage to y, it is not useful for breaking the AHCB property: for that we need a preimage $x \in \mathcal{X}$.

We therefore introduce a third function family, $\mathcal{G} = \{g : \mathcal{X}' \to \mathcal{Y}\}$, that is computationally indistinguishable from both $\mathcal{H}$ and the extension of $\mathcal{F}$. The functions in $\mathcal{G}$ are injective even on the larger domain $\mathcal{X}'$. In our proof of quantumness, the verifier will check that when sent a function g, the prover returns an image $y \in g(\mathcal{X})$, i.e. the image y must be in the range of the restricted domain $\mathcal{X}$. This essentially forces the prover to evaluate any function it receives only on the restricted domain[8] $\mathcal{X}$, since if it evaluated the *injective* function g on an input $x \in \mathcal{X}' \setminus \mathcal{X}$, the verifier would reject the resulting image y.

In summary, our single-round proof of quantumness relies on a triplet of function families $(\mathcal{F}, \mathcal{G}, \mathcal{H})$ with the following properties:[9]

▶ **Definition 1** (e^{3}NTCF, informal)**.** *A tuple of function families $(\mathcal{F}, \mathcal{G}, \mathcal{H})$ is called a* Doubly Extended Extractable Noisy Trapdoor Claw-free Functions *(abbreviated e^{3}NTCF) if*

1. *$\mathcal{F}$ is a TCF family with an AHCB property.*
2. *$\mathcal{G}$ is an injective trapdoor one-way function family.*
3. *$\mathcal{H}$ is an extractable one-way function family, in the sense that for any algorithm that takes the description of $h \in \mathcal{H}$ as input and outputs $y \in \text{range}(h)$, there exists an extractor which outputs a preimage x such that $h(x) = y$.*
4. *The functions are computationally indistinguishable from each other. In other words, given a description of a function from one of the three families, no polynomial-time classical algorithm can determine the function's type with probability non-negligibly greater than $1/3$.*

[8] This also serves to exclude the "extended-domain" attack mentioned in Footnote 4.

[9] As usual, this primitive depends on a security parameter λ, which we suppress for readability.

For the formal statement, see [5, Definition 8].

The notion of an e^{3}NTCF function family is an extension of Injective Invariant Noisy TCFs, which were introduced in [38] to derive a protocol for verifying general quantum computations, and which only use the first two types of families $\mathcal{F}$ and $\mathcal{G}$.

The preceding discussion naturally leads to the single-round Protocol 2 (see [5, Protocol 4] for the formal protocol), based on an e^{3}NTCF. Our main result is that this protocol is a proof of quantumness, i.e. that an efficient quantum prover can succeed with high probability, but no efficient classical prover can.

Algorithm 2 Single-Round Proof of Quantumness based on e^{3}NTCF. (informal)

1. The verifier samples a challenge type $a \leftarrow_U \{\texttt{Eq}, \texttt{sIm}, \texttt{wIm}\}$.
   if $a = \texttt{Eq}$:
2. Verifier samples $f \in \mathcal{F}$ with trapdoor t_f and sends a description of f to the prover.
3. Verifier receives tuple (y, d) and accepts iff $d \cdot (x_0 \oplus x_1) = 0$ (and $d \neq 0$). Here, (x_0, x_1) are the two preimages of y, which the verifier can efficiently compute with t_f.
   else if $a = \texttt{sIm}$:
4. Verifier samples $g \in \mathcal{G}$ with trapdoor t_g and sends a description of g to the prover.
5. Verifier receives tuple (y, d) and accepts iff $y \in g(\mathcal{X})$. This check is efficient using t_g.
   else if $a = \texttt{wIm}$:
6. Verifier samples $h \in \mathcal{H}$ with trapdoor t_h and sends a description of h to the prover.
7. Verifier receives tuple (y, d) and accepts iff $y \in h(\mathcal{X}')$. This check is efficient using t_h.
   end if

▶ **Theorem 2** (informal). *Suppose that $(\mathcal{F}, \mathcal{G}, \mathcal{H})$ is an e^{3}NTCF. Then Protocol 2 is a proof of quantumness, i.e.,*

1. ***Completeness.*** *There exists an efficient quantum prover that succeeds with probability $1 - \text{negl}(\lambda)$.*
2. ***Soundness.*** *Every efficient classical prover succeeds with probability at most $5/6 + \text{negl}(\lambda)$.*

In the theorem, λ is the security parameter. As usual, the families $(\mathcal{F}, \mathcal{G}, \mathcal{H})$ implicitly depend on the security parameter and "efficient" classical or quantum provers are those whose runtime scales polynomially in λ. For the formal statement, see [5, Theorem 4].

Proof Sketch. We have already sketched the security proof when we explained why we need to introduce the three different function families $\mathcal{F}, \mathcal{G}$, and $\mathcal{H}$. We briefly summarize the role that each of these function families and the associated challenge types $\texttt{Eq}, \texttt{sIm}$, and $\texttt{wIm}$ play, and provide a high-level explanation of how the soundness constant $5/6$ is derived.

- The *weak image test* (challenge type $\texttt{wIm}$) uses the extractable function family $\mathcal{H}$. This test ensures that for any classical prover in the protocol, there exists an extractor that extracts a preimage $x \in \mathcal{X}'$ to the output $y = h(x)$ produced by the prover. Note that as discussed above, this preimage might in principle be from the extended domain $\mathcal{X}'$, not just $\mathcal{X}$.
- The *strong image test* (challenge type $\texttt{sIm}$) uses the injective function family $\mathcal{G}$. This test, combined with the indistinguishability of the function families $\mathcal{F}, \mathcal{G}$, and $\mathcal{H}$, ensures that the prover evaluates any function f, g, or h only on inputs in the restricted domain $\mathcal{X}$. Furthermore, from this we can prove that for any $y \in \mathcal{Y}$ that has a preimage in $\mathcal{X}$ under a given *TCF function* f, the extractor will output such a preimage (rather than a different preimage in $\mathcal{X}' \setminus \mathcal{X}$).

- The *equation test* (challenge type `Eq`) uses the TCF function family $\mathcal{F}$ that has the AHCB property. The verifier checks that the prover's output (y, d) satisfies the equation $d \cdot (x_0 \oplus x_1) = 0$, with (x_0, x_1) the preimages of y. From the strong image test, we also know that the extractor for a successful classical prover will produce a preimage $x \in \mathcal{X}$ to y. Together, (x, y, d) would break the AHCB property of f, so no classical prover can win with very high probability.

The soundness factor of 5/6 arises from the fact that the adaptive hardcore bit property only gives an upper bound of 1/2 for the event that the prover fulfills the conditions of all three tests simultaneously, given a function of the family $\mathcal{F}$. Using the computational indistinguishability of the function families $\mathcal{F}, \mathcal{G}, \mathcal{H}$, and the relation

$$\Pr[A] + \Pr[B] \leq 1 + \Pr[A \wedge B]$$

we show that the overall success probability of a classical prover $\mathcal{A}$ in the prover can roughly be bounded as

$$\frac{1}{3}\Big(\Pr_{f\leftarrow\mathcal{F}}\Big[S_{\mathcal{A}}^{\mathtt{Eq}}\Big] + \Pr_{g\leftarrow\mathcal{G}}\Big[S_{\mathcal{A}}^{\mathtt{sIm}}\Big] + \Pr_{h\leftarrow\mathcal{H}}\Big[S_{\mathcal{A}}^{\mathtt{wIm}}\Big]\Big) \leq \frac{1}{3}\Big(2 + \Pr_{f\leftarrow\mathcal{F}}\Big[\text{“}S_{\mathcal{A}}^{\mathtt{wIm}} \wedge S_{\mathcal{A}}^{\mathtt{sIm}} \wedge S_{\mathcal{A}}^{\mathtt{Eq}}\text{”}\Big]\Big) \leq \frac{5}{6}$$

where $S_{\mathcal{A}}^{\mathtt{T}}$ denotes the event that $\mathcal{A}$ passes the test T, and “$S_{\mathcal{A}}^{\mathtt{wIm}} \wedge S_{\mathcal{A}}^{\mathtt{sIm}} \wedge S_{\mathcal{A}}^{\mathtt{Eq}}$” denotes the event that the prover succeeds in the equation test, and is employing a strategy that would succeed in the image tests as well. This corresponds to the event that $\mathcal{A}, \mathcal{A}^*$ produce a valid equation-image pair, which cannot occur with probability higher than 1/2 due to the AHCB property of the function family $\mathcal{F}$. ◀

A key objective in the design of our single-round proofs of quantumness was that the required circuit sizes should not be larger than for multi-round proofs of quantumness. Protocol 2 achieves this: to pass in the protocol, a quantum prover can simply prepare the state $\sum |x\rangle|p(x)\rangle$ for a given function $p \in \mathcal{F} \cup \mathcal{G} \cup \mathcal{H}$, measure the first register in the Hadamard basis to get a string d, and measure the second register in the computational basis to get an image y. These are exactly the same actions as those of an honest prover in the equation test in Protocol 1,[10] except that now the honest prover can perform the entire measurement in one step without experimentally challenging mid-circuit measurements.

2.2 Instantiating e^{3}NTCF families from DDH and LWE

We show that e^{3}NTCF can be instantiated either from DDH and t-KEA, or from LWE and LK-ϵ. Here, we only state the main results and defer a more detailed discussion of the construction to [5, Section 4] and [5, Section 6], respectively.

For the LWE-based construction, we already know that the LWE-based TCF from [13] has an AHCB property. We can combine this with suitable injective and extractable one-way functions. In fact, it turns out that for the LWE-based construction, the roles of the injective and extractable functions in Protocol 2 can be played by the same function family, i.e. we only require two distinct families $(\mathcal{F}, \mathcal{G})$. This simplifies the analysis somewhat, as we explain in [5, Section 5]. Combined with Theorem 2, we obtain the following:

[10] In our constructions of e^{3}NTCF, the functions $g \in \mathcal{G}$ and $h \in \mathcal{H}$ are essentially as costly to evaluate as $f \in \mathcal{F}$ in Protocol 1, so introducing these additional function families does not increase the demands on an honest prover.

▶ **Theorem 3** (Informal). *Assuming the classical intractability of LWE and the lattice knowledge assumption LK-ϵ, there exists a single-round proof of quantumness with completeness* $1 - \mathrm{negl}(\lambda)$ *and soundness* $3/4 + \mathrm{negl}(\lambda)$. *The circuit sizes for an honest prover in this protocol are identical to the circuit sizes in the 2-round protocol from [13].*

While a family of TCFs based on DDH was considered in [29] to construct a 3-round proof of quantumness, it had not been shown that these functions have an AHCB property. We prove this through a lossy sampling technique similar to the proof in [13], showing a reduction from the AHCB property to the *matrix d-linear assumption* [41] (which is implied by standard DDH). We then again augment this TCF family with an injective and an extractable family to get the following result.

▶ **Theorem 4** (Informal). *Assuming the classical intractability of DDH and the knowledge of exponent assumption t-KEA, there exists a single-round proof of quantumness with completeness*[11] $0.99 - \mathrm{negl}(\lambda)$ *and soundness* $5/6 + \mathrm{negl}(\lambda)$. *The circuit sizes for an honest prover in this protocol are identical to the circuit sizes in the 3-round protocol from [29].*

3 Impossibility of black-box reductions

Knowledge assumptions are non-falsifiable cryptographic assumptions [40, 20], which makes their use somewhat undesirable. A natural question is whether our main results, single-round proofs of quantumness, can also be achieved using only standard falsifiable (also called game-based) assumptions such as DDH or LWE, or even weaker assumptions like the existence of one-way functions.

As was observed in [39], the security of a single-round proof of quantumness cannot be reduced to a *quantumly hard* problem like LWE in a black-box manner. The reason for this is simple: if there existed a black-box reduction from a successful classical prover to an algorithm for breaking LWE, we could also apply that reduction to the honest quantum prover in the proof of quantumness. Since the honest quantum prover is required to succeed with high probability, this would give a quantum algorithm for LWE. This rules out the existence of such a black-box reduction.[12]

An extension of this reasoning suggests that the use of knowledge assumptions is still justified even for single-round proofs of quantumness based on computational problems that are quantumly easy: now it is of course not a contradiction to have a quantum algorithm that breaks the underlying cryptographic assumption, but we can argue that implementing an honest quantum prover in such a protocol is no easier than breaking the assumption outright: Suppose we had a single-round proof of quantumness with a black-box reduction to factoring. Then we could again use that reduction with the honest quantum prover to construct a factoring algorithm whose only quantum component is repeatedly (and independently) running the honest prover. In this sense, implementing the honest prover is as hard as breaking factoring: if we had an honest prover that was much easier to implement than Shor's algorithm, we could use that prover and the black-box reduction to construct a much more

[11] The reason completeness here is 0.99 instead of 1 is inherited from [29]. There, the quantum prover does not create a superposition over the exact range of the TCF but over a superset. However, it can be shown that the exact range contains at least a 0.99 fraction of the elements in the superset.

[12] Note that this argument does not apply to interactive protocols, ROM-based protocols, or protocols that use whitebox assumptions like ours: in those cases, one cannot simply run the reduction on the quantum prover as the reduction may perform operations that only work for classical provers, e.g. rewinding or using knowledge extractors.

practical quantum factoring algorithm. In contrast, in the DDH-based proof of quantumness from [29] and also in our single-round version thereof, implementing the honest quantum prover does not require computing discrete logarithms.

4 Related work

As mentioned in Section 1.1, cryptographic proofs of quantumness were introduced in [13]. Since then, there have been a number of follow-up works aiming to understand the types of cryptographic constructions on which these protocols can be based, as well as how to make them more efficient [30, 14, 35, 26, 4, 31, 39]. So far, only small-scale demonstrations of these protocols have been performed [49, 33], though the hope is that by further reducing the sizes of the quantum circuits and the amount of interaction between the verifier and the prover, these protocols can be performed with NISQ devices.

The only existing constructions of single-round proofs of quantumness (apart from trivial ones like asking the prover to factor a large number) use the random oracle model [14, 45]. In both of these prior works, the quantum circuits required to succeed in these protocols do not have to perform mid-circuit measurements. However, instantiating the random oracle with plausible cryptographic hash functions, like SHA-2 or SHA-3, incurs a substantial overhead. The most efficient known quantum implementations of SHA-2 and SHA-3 [28] need a number of qubits on the order of 10^4 and have a quantum gate count on the order of 10^6.

On the other hand, the ROM-based single-round proof of quantumness in [14] only requires a TCF, without the need for the AHCB property. General TCFs have been constructed from a wider variety of cryptographic assumptions, achieving lower asymptotic complexities than known NTCF constructions. Thus, despite the fact that the use of a random oracles introduces a significant overhead, a resource comparison between our LWE-based single-round proof of quantumness and the ROM-based protocol of [14] is not straightforward. A more conclusive answer on which single-round protocol admits the smallest quantum circuit for a demonstration of quantum advantage requires a detailed finite-size analysis, which we leave for future work.

Since our construction of e^3NTCFs makes use of extractable one-way functions (EOWFs), it is natural to ask whether we could have used existing results concerning these functions [16, 8, 10]. In particular, in [8], Bitansky et al. prove the existence of a class of EOWFs from the subexponential hardness of LWE against adversaries with bounded auxilary input, without having to rely on a knowledge assumption. There are at least two obstacles towards applying those results to our setting. First, the extractable one-way functions we require have to be computationally indistinguishable from TCFs. It is unclear whether the EOWFs of [8] can be suitably adapted to satisfy this requirement. Second, since one of the motivations for our work is to devise more efficient single-round proofs of quantumness, we would like to ensure that the honest quantum prover's circuits are at most as large as in the multi-round protocols. However, constructing a family of e^3NTCFs with the EOWFs in [8] would likely require larger circuits.

Knowledge assumptions in the quantum setting have also been considered in [34] to derive *quantum money* and *quantum lightning* schemes. There, the assumptions are required to be sound against quantum adversaries. This introduces some challenges in formalizing the appropriate notion of a quantum knowledge assumption. The subsequent work of [46] also discusses this point. Interestingly, this latter work points out how certain knowledge assumptions can be generically broken by a quantum adversary. In some sense, this is exactly what we exploit to arrive at our single-round proofs of quantumness.

5 Discussion and open problems

We have shown how existing knowledge assumptions, together with standard cryptographic assumptions, lead to efficient single-round proofs of quantumness. Our work opens up several avenues for future research.

One such avenue is the possibility of a *white-box proof* for a single-round proof of quantumness based only on the classical intractability of, say, LWE. This would circumvent the impossibility discussed in Section 3. As mentioned in the previous section, one possible approach would be to use the extractable one-way functions based on subexponential LWE from [8], with the caveat that this would provide soundness against classical provers with bounded auxiliary input. We leave this as an interesting but challenging open problem.

Currently, our construction necessitates the use of a TCF which satisfies the AHCB property. This is a fairly strong requirement which so far has only been achieved from LWE [13], isogeny-based group actions [3], and, in this work, the DDH assumption. It would be desirable to use TCFs that are not known to have an AHCB property, such as those based on Ring-LWE or Rabin's function (x^2 mod N), since those require smaller circuits than the TCFs based on LWE or DDH, as outlined in [29, 30]. However, it is unclear if our construction can be modified so as to not require the AHCB property; in the equation test, the prover is allowed to output *any* valid equation, hence the need for an *adaptive* hardcore bit. The protocol in [29] is able to circumvent this and use TCFs without an AHCB by introducing an additional round of interaction between the verifier and the prover, leading to a 3-round protocol. Unfortunately, there does not seem to be an obvious way of employing knowledge assumptions to reduce the round complexity of the protocol from [29]. Thus, a fundamentally different approach would be needed to achieve a single-round protocol without relying on the AHCB property. Of course, for the purpose of having more practical protocols, proving an AHCB statement for the TCFs based on Ring-LWE or Rabin's function (even relying on knowledge assumptions) would be equally useful.

We remark that the LWE-based approach is expected to be more efficient than the DDH one. This is because, as is also discussed in [29], the DDH approach requires performing a large number of group exponentiations coherently. It would therefore seem that the DDH approach is less efficient than performing Shor's algorithm to solve the discrete logarithm problem. However, as [29] points out, the proof of quantumness protocol can benefit from certain optimizations that are not known to be possible for Shor's algorithm. As an example, the group exponentiation circuits for the DDH-based proof of quantumness need not be reversible, thereby halving the depth and number of gates compared to Shor's algorithm (see section III.D in [29] for more details).

From existing knowledge assumptions one is only able to prove soundness against classical adversaries, i.e. one is able to bound the success probability of a classical prover, but one cannot make a statement about the internal operations of a successful quantum prover. This is sufficient for a proof of quantumness, but other protocols, such as certifiable randomness generation [13], remote state preparation [21], or verification of quantum computations [38], require soundness against quantum adversaries, i.e. one needs to have at least a partial characterization of any quantum adversary in the protocol. As mentioned, one can derive single-round proofs of quantumness in the random oracle model, and these can be extended to single-round versions of quantum-sound protocols by proving security in the quantum random oracle model [11, 14, 2, 47]. However, with knowledge assumptions, it is unclear what the right quantum-sound analogue would be to derive these more advanced functionalities. As mentioned in the previous section, quantum knowledge assumptions have been considered

in [34, 46] to construct quantum money and quantum lightning schemes. These could serve as a useful starting point for constructing single-round quantum protocols for functionalities like single-device randomness expansion. We leave formalizing this for future work.

The Local Hamiltonian Problem for Quasi-Quantum States: A Toy Model for the Quantum PCP Conjecture

Itai Arad

Miklos Santha
Centre for Quantum Technologies, Singapore

Abstract

In this work we define a new classical constraint satisfaction problem that shares many of the properties of the quantum local Hamiltonian problem, distinguishing it from the usual classical k-SAT problem. The problem consists of minimizing the number of violated local constraints over a restricted set of *distributions of assignments*. We show that these distributions can be 1-to-1 mapped to a superset of the quantum states, which we call *k-local quasi-quantum states*. Nevertheless, we claim that our optimization problem is essentially classical, by proving that it is an NP-complete problem. Interestingly, the optimal distribution shares many of the properties of quantum states. In particular, it is not determined straightforwardly by its local marginals, and consequently, it can be used as a classical toy model to study several aspects of Hamiltonian complexity that are different from their classical counter parts. These include the complexity of 1D systems (which is in P for classical CSPs, but is QMA-hard for quantum systems), and the lack of an easy search-to-decision reduction. Finally, we believe that our model can be used to gain insights into the quantum PCP conjecture. Indeed, while we have shown that approximating the minimal number of unsatisfiable constraints to within an $\Theta(1)$ is NP-hard, it is not clear if the problem remains hard if we want to approximate the minimal *fraction* of unsatisfiable constraints to within an $\Theta(1)$; as in the quantum PCP conjecture, naive quantization of the classical proofs does not seem to work.

2012 ACM Subject Classification Theory of computation → Complexity classes; Theory of computation → Problems, reductions and completeness; Theory of computation → Proof complexity; Theory of computation → Complexity theory and logic; Theory of computation → Quantum complexity theory

Abstract

There has been substantial recent concern that automated pricing algorithms might learn to "collude." Supra-competitive prices can emerge as a Nash equilibrium of repeated pricing games, in which sellers play strategies which threaten to punish their competitors if they ever "defect" from a set of supra-competitive prices, and these strategies can be automatically learned. But threats are anti-competitive on their face. In fact, a standard economic intuition is that supra-competitive prices emerge from *either* the use of threats, *or* a failure of one party to correctly optimize their payoff. Is this intuition correct? Would explicitly preventing threats in algorithmic decision-making prevent supra-competitive prices when sellers are optimizing for their own revenue?

No. We show that supra-competitive prices can robustly emerge even when both players are using algorithms which do not explicitly encode threats, and which optimize for their own revenue. Since deploying an algorithm is a form of commitment, we study sequential Bertrand pricing games (and a continuous variant) in which a first mover deploys an algorithm and then a second mover optimizes within the resulting environment. We show that if the first mover deploys *any* algorithm with a no-regret guarantee, and then the second mover even approximately optimizes within this now static environment, monopoly-like prices arise. The result holds for any no-regret learning algorithm deployed by the first mover and for *any* pricing policy of the second mover that obtains them profit at least as high as a random pricing would – and hence the result applies even when the second mover is optimizing only within a space of non-responsive pricing distributions which are incapable of encoding threats. In fact, there exists a set of strategies, neither of which explicitly encode threats that form a Nash equilibrium of the simultaneous pricing game in algorithm space, and lead to near monopoly prices. This suggests that the definition of "algorithmic collusion" may need to be expanded, to include strategies without explicitly encoded threats.

Finally, we would like to thank the ITCS reviewers for their helpful comments and feedback.

1 Introduction

Consider a market in which there are two sellers of some commodity. We hope and expect that competition should drive the price of the good in the market down to its production cost – for if seller A was consistently selling above cost, then there would be an opportunity for seller B to slightly undercut seller A, capturing the whole market and increasing their profit. In fact, this is the Nash (and correlated) equilibrium outcome in several classical formalizations of such competition including the Bertrand Duopoly model. We refer to pricings that are at (or near) the Nash equilibrium prices as *competitive prices*.

As the name suggests, competition is essential to maintaining competitive prices: a monopolist could freely set the price of a good as high as the market could support (which, for goods with inelastic demand, could be quite high indeed) without fear of being undercut by a competitor. So, if in a market with multiple participants, we see prices that are closer to the monopoly price than the competitive price, we might suspect "anti-competitive" behavior on the part of the sellers.

Yet, defining anti-competitive behavior turns out to be a difficult exercise. The Sherman act has been interpreted to require express agreement to coordinate on prices in the form of overt communication as a pre-requisite for liability. However, a recent line of work has focused on the ability of *pricing algorithms* to arrive at supra-competitive prices without explicit communication – concerns rooted in real world observations [4] and a growing academic literature [2, 20, 15]. The mechanism underlying most results in this literature ultimately are rooted in "folk-theorem" style equilibria of repeated pricing games [6, 22]. Broadly speaking, folk theorems establish that all pairs of prices that guarantee the sellers at least the profit they obtain with competitive pricing can be realized as equilibria of the repeated game. Crucially, the strategies which are shown to lead to these anti-competitive equilibria have explicitly encoded threats aimed at punishing the other seller if they deviate from a proscribed pricing path. Further, reinforcement learning algorithms can automatically discover these strategies; recent work [8, 18] has shown both empirically and analytically that these algorithms can converge to supra-competitive prices, and they do so by the emergence of punishments and threats, even without being explicitly programmed to learn such strategies. Using such algorithms may not violate current anti-trust law as they do not involve explicit communication, but one can imagine future legislation and case law that forbids the use of algorithms that make use of threats (appropriately defined). An algorithm is after all an explicit commitment to action as a function of its observations, and committing to an algorithm might be interpreted as communicating the content of the threat encoded within the algorithm.

To formally rule out "anti-competitive" behavior, an approach one might take is to define algorithms that do not encode threats. In fact, the standard economic stance [16, 8] has been that threats are an *explicit* requirement for collusion, distinguished from other situations in which supra-competitive prices can arise due to a "failure to optimize:"

> "To us economists, collusion is not simply a synonym of high prices but crucially involves "a reward-punishment scheme designed to provide the incentives for firms to consistently price above the competitive level" (Harrington 2018, p. 336). The reward-punishment scheme ensures that the supra-competitive outcomes may be obtained in equilibrium and do not result from a failure to optimize." [8]

A first attempt might be to say that (at least if there are other optimizers in the market) "non-responsive" algorithms which set prices completely independently of competitor prices (and consequences of competitor prices) should be permitted – indeed, if they cannot react to their competitors, then they cannot threaten them. But this is far too limiting as it does not allow for algorithms that react to market conditions. Recent work by [17] and [10] set out a principled definition of what constitutes non-collusive behavior of a pricing algorithm by defining algorithms that satisfy some internal consistency properties (calibrated regret, also known as "swap regret") and then shows that if all algorithms in the market satisfy these conditions then the outcome will be competitive prices. Can this condition be relaxed? What if the first entrant to a market deploys (and hence commits to) an algorithm that satisfies these internal consistency conditions, and then the second entrant plays a simple policy that does not satisfy the swap regret condition, but also does not encode threats (e.g. because it is entirely non responsive)? Might we still see competitive prices? Would we, in accordance with the intuition of [16, 8] see competitive prices if the follower not only did not deploy threats, but also succeeded in "optimizing"?

In this paper we show that the answer is robustly "no" by showing how a broad class of "reasonable" behavior on the part of all parties must lead to supra-competitive (near monopoly) prices. In particular, with the view that deploying an algorithm is inherently a "commitment" (at least in the short term), we study two seller pricing games in a leader-follower model, in which the leader first deploys an algorithm, and then the follower deploys an algorithm which may optimize within the market environment that is implicitly defined by the leader's pricing algorithm. If both sellers viewed this scenario as a Stackelberg game, and optimized over the set of all pricing algorithms, it would hardly be surprising if anti-competitive behavior emerged. Indeed, the Stackelberg equilibria in algorithm space (See [11]) in a repeated pricing game would involve the leader committing to an algorithm that prescribes monopoly prices and commits to punish the follower if she deviates from this prescription.

However, we instead study the behavior that emerges if sellers attempt to play reasonable algorithms. In particular, we assume the leader (following the principle set out by [17, 10]) commits to setting prices using an arbitrary *no-regret* algorithm. No-Regret algorithms are widely understood to be a "natural" class of algorithms for use in competitive environments [24], and our results will hold for any algorithm in this class, which includes the no-swap regret algorithms studied by [17, 10].

Once the leader deploys a no-regret learning algorithm, the other seller (whom we call the follower, or the optimizer) deploys an algorithm to optimize their own revenue in the environment defined by the leader's no-regret learning algorithm. Once again, we do not assume that the follower is best responding in algorithm space: they may, e.g., use a heuristic reinforcement learning algorithm to optimize over a limited set of policies – even *non-responsive* policies that are explicitly independent of the leader's prices, and hence cannot encode threats. We show that however they choose to optimize their own revenue, if they are even marginally successful (choosing any policy that guarantees them at least the revenue that a random pricing strategy would), then in combination, the two algorithms will inevitably lead to supra-competitive prices in a variety of settings. When this happens, it is not just the follower who enjoys the revenue of the high prices, but as we prove, also the leader (if the leader deployed a no-regret learning algorithm). Thus the leader will have no strong incentive to deviate from their deployed algorithm, even if they deployed it without initially being aware of the competitive environment. In fact, within the class of "reasonable" strategies we study for the leader and follower (a no-swap-regret algorithm for the leader

and a non-responsive algorithm for the follower), there exists a Nash equilibrium of the simultaneous pricing game in algorithm space, which gives *no party* any incentive to deviate, supports near-monopoly prices, and does not involve threats. This suggests that it may be worth revisiting the standard economic viewpoint [8, 16] that *threats* are a necessary precondition for collusion.

Summary of Results

We study two types of models: a simple Bertrand duopoly model, where the firm with the lowest price captures the entire demand, and a smoother multinomial-logit-based model where firms with higher prices can still capture some of the demand. Our multinomial logit model includes a temperature parameter τ that controls how sensitive the demand for each firm is to prices, and converges to a Bertrand competition when the parameter τ grows large. Within these models, we prove the following results:

1. The second entrant into the market (whom we call the optimizer) can extract a constant fraction of the monopoly price revenue against any no-regret algorithm by playing a non-responsive strategy (i.e. a fixed distribution of prices across all rounds, that does not depend on or respond to the history of play). As a result, if they approximately optimize their pricing policy (in any set of policies that includes natural fixed price distributions), they will be guaranteed a constant fraction of the monopoly revenue. Observe that this holds even if the class they optimize over *only* includes non-responsive pricing strategies, which are incapable of encoding threats.
2. Simultaneously, by deploying any no-regret algorithm, the first entrant (whom we call the learner) extracts a constant fraction of the revenue obtained by any optimizer strategy that obtains a constant fraction of the monopoly price revenue. Taken in conjunction with the previous result, this implies that if the first entrant into the market deploys (and hence commits to) a no-regret learning algorithm, and the optimizer deploys any strategy that approximately optimizes over any class of policies that includes fixed price distributions, *both* parties will extract a constant fraction of the monopoly price revenue. This has important implications: not only do supra-competitive prices emerge, but the benefits are shared across both sellers, giving neither a substantial incentive to deviate. In other words, the optimizer is not "exploiting" the no-regret learner, but rather implicitly cooperating with them, despite the absence of threats.
3. In fact, we show that if the first entrant into the market deploys a no-swap regret algorithm, then there is a non-responsive (i.e. fixed) price distribution for the optimizer that forms a *Nash* equilibrium of the simultaneous pricing game in algorithm space: i.e. *neither* player has any incentive to deviate from their selected algorithm. This demonstrates the existence of a Nash equilibrium of the game that supports supra-competitive prices and yet does not involve threats, contra to the economic intuition [8, 16] that supra-competitive prices result from *either* threats or a failure to optimize.

When we refer to supra-competitive prices in the above theoretical results, we mean prices that are within a constant factor of the monopoly price. The constants in our theorems are small, but we provide numerical evidence that the constant is in fact no smaller than $2/e \approx 0.74$.

We also prove an additional result about the Bertrand duopoly model:

- Our results apply to *any* no regret learning algorithm deployed by the first entrant into the market. This is a super-set of the no-swap regret learning algorithms proposed to be definitionally "competitive" by [17, 10]. Should no regret algorithms beyond no-swap

regret algorithms also be considered competitive? This is not the case for all no-regret dynamics – [23] show the existence of coarse correlated equilibria supported on supra-competitive prices in Bertrand pricing games, implying the existence of no-regret dynamics that result in such prices. However, we show that when both sellers use Mean-based No-Regret (MBNR) algorithms (a class which includes common no-regret learning algorithms such as multiplicative weights and follow the perturbed leader) to set prices, the empirical distribution of play always converges to the competitive price. This suggests that at least in the Bertrand Duopoly model, mean based no-regret learning algorithms might also be considered reasonable/competitive pricing strategies, in addition to the no-swap regret learners proposed by [17, 10]. We note that this result does not necessarily carry over to the more complex pricing models studied by [17].

Due to space constraints, we defer some proofs to the full version of the paper [3].

1.1 Related Work

The seminal work by [8] experimentally shows that Q-learning algorithms, a simple and central type of reinforcement learning algorithm, can learn to collude with each other via threats in a repeated, simultaneous-action pricing game. These algorithms learn to deviate to lower prices in response to another algorithm doing so, and slowly rise back to higher prices. [18] attain similar results in the sequential repeated pricing game. The authors in these works are specifically concerned with the ability of the algorithms to learn clear threats, as opposed to simply reaching supra-competitive prices. This is because, from the perspective of many economists, such threats are a requirement for collusion. The prevailing view, as espoused by [16] and [8], is that any algorithms which reach supra-competitive prices without threats must be suboptimal, and thus uninteresting as candidate pricing algorithms.

This perspective is supported by [1] (experimentally) and [2] (theoretically). These works consider a different class of reinforcement learning algorithms and show that, while they do not converge to supra-competitive prices when they have full computational capacity, they can reach supra-competitive prices if these algorithms are limited in their ability to explore. These supra-competitive prices arise even though these algorithms do not retain enough state information to encode threats. Therefore, while these works do show supra-competitive prices without threats, they are only shown arising from algorithms which are specifically designed to be suboptimal.

Another line of research has explored the emergence of supra-competitive prices as a byproduct of algorithmic symmetry. [15] show that, if two identical, deterministic algorithms are played against each other, their "exploration" will be symmetric, and hence they will be unable to ever observe the benefits of undercutting their competitors (an inherently asymmetric outcome).

[5] study algorithms that attempt to estimate the payoff of actions through stochastic experiments. They show that in certain settings in which players update the reward for the action they play, but not other actions, then the experiments can correlate the actions of the players, leading to supra-competitive prices. In contrast, the algorithms we study operate in the full information setting (because agents can observe the price played by the other agent, they can estimate the profit they would have made had they played a different price at a given time period), and are designed for adversarial settings, which are well specified in competitive environments: they are designed with the understanding that there are no reward distributions to estimate because profits depend on the evolving actions of an opponent.

In contrast to these previous works, which argue variously that the property of algorithms which leads to supra-competitive pricing are threats and sub-optimality, we argue that the core is in the fact that deploying an algorithm is a form of commitment. This is most in line

with the perspective of [20]. This work treats algorithms as a form of commitment which contributes to collusion. However, the algorithms explored in that work are constrained to simple, two-state automata, which severely limits the strategy space. By contrast, we consider the space of all possible algorithms mapping histories to future prices, and show results for broad families of "reasonable" algorithms – not just equilibrium strategies.

There is also a recent line of work on regulating pricing algorithms. Both [10] and [17] suggest that observed *swap regret* might be taken as a proxy for collusive behavior. They show, in a related but more general model than our own, that if both sellers in a duopoly have vanishing swap regret, the time-average price must converge to the competitive price. Our work highlights the importance of *both* sellers having no-swap regret; as we show, if the first entrant into a market deploys a no swap regret algorithm, then many natural behaviors for the second entrant lead to supra-competitive prices.

Finally, there is a recent line of experimental work demonstrating anti-competitive behavior in large language models, including market division in the Cournot competition model [21] and, more similarly to this work, price fixing in the Bertrand competition model [14]. These works provide evidence for the emergence of algorithmic collusion in the increasingly ubiquitous realm of LLMs, underscoring the importance of understanding the foundations of algorithmic collusion.

The emergence of anti-competitive behavior in no-regret dynamics is also explored in [19], though in a somewhat different setting – this work considers agents deploying no-regret algorithms to bid for them in an auction, and shows that agents misreporting their true item value to the algorithms can lead to collusive outcomes.

2 Model

2.1 The Single-Stage Pricing Game

We will first formally define the payoff model of the stage game, in which both sellers select a price only once and specify the payoff they obtain.

We work in a duopoly model, where two sellers are competing to sell to a single buyer. Both sellers pick from a discrete set of prices $\mathcal{P} = \{\frac{1}{k}, \frac{2}{k}, \cdots 1\}$. Here, k is a discretization parameter, and we assume that $k \geq 20$.

Game definition

We consider two sellers, who we will refer to as the Sellers 1 and 2. The action space of each seller is the set of possible prices in $(0, 1]$, up to some discretization parameter $1/k$. Both sellers can choose to distributions of prices from the set $\mathcal{P}$, and we denote the set of all distributions by $\Delta^{\mathcal{P}}$.

To define our game, we first need to define the concept of an allocation rule. An *allocation rule* is a (potentially randomized) rule that divides demand across the two sellers as a function of their chosen prices:

▶ **Definition 1** (Allocation Rule $C_i(p_1, p_2)$)**.** *An* allocation rule $C_i : \mathcal{P} \times \mathcal{P} \mapsto [0, 1]$ *is a mapping from a price pair* (p_1, p_2) *from the two sellers, respectively, to a fraction of the demand that will be allocated to seller* $i \in \{1, 2\}$*.*

Given an allocation rule that defines and controls market outcomes as a function of prices, we can now define the payoff of a seller in our single-stage game as a function of said allocation rule C.

▶ **Definition 2** (Seller Payoff in the Stage Game). *Given an allocation rule $C(.,.)$, the payoff of seller i is given by*

$$u_i(p_1, p_2) = p_i \cdot C_i(p_1, p_2). \tag{1}$$

When the sellers play distributions, the payoff of the seller is understood to be the expected payoff.

We define the buyer price as the price charged by the seller that is the output of the allocation rule.

▶ **Definition 3** (Average Buyer Price in the Stage Game). *For an allocation rule C and (mixed) strategies p_1, p_2, the average price paid by the buyer is $\mathbb{E}[p_1 C_1(p_1, p_2) + p_2 C_2(p_1, p_2)]$. Note that this means that the average buyer price is equal to the (expected) sum of payoffs of the two sellers.*

Throughout this paper we assume that the *total* demand (added across both sellers) for the item being sold is fixed and independent of the prices. Without loss of generality, this total demand is set to be normalized to 1. As a result, the "monopoly price" in these models is always 1. Within this fixed-demand model, we consider two allocation rules: a Bertrand model and a multinomial-logit-based model, both formalized in Section 2.1.1. Both allocation rules are *symmetric* and therefore the resulting games are *symmetric* as well.

We can now formally define the one-stage game studied in this paper, often informally referred to simply as the "stage game":

▶ **Definition 4** (Pricing Stage Game). *A two-player pricing stage game $G(k, C)$ is defined as a combination of:*

1. *Two sellers, respectively named 1, 2;*
2. *An action space $A = \mathcal{P} = \{\frac{1}{k}, \frac{2}{k}, \ldots, 1\}$ corresponding to possible prices that can be played by 1 and 2. We denote by p_1 the action of Seller 1 and p_2 the action of seller 2. These actions may be picked from the set of distributions over $\mathcal{P}$, which we call $\Delta^{\mathcal{P}}$.*
3. *Payoff functions $u_i(p_1, p_2)$ for $i \in \{1, 2\}$, defined as a function of the competitive allocation rule C as in Definition 2.*

A particular pricing game is defined by the allocation rule C and the discretization parameter k. We will work with symmetric allocation rules (the allocation does not depend on the labels of the sellers), which will naturally induce a symmetric finite game between the two sellers.

The one-stage game described is this section is the starting point of our study, one that helps us define competitive prices as the Nash equilibria outcome of the game. However, the primary object of our study is *repeated* interactions between sellers, described in Section 2.2.

Equilibria of the Stage Game

We will refer to two kinds of equilibria of the stage game which differ in their assumed timing. The *Nash* equilibria characterize outcomes in simultaneous play, whereas *Stackelberg* equilibria characterize outcomes of optimal play when one player may first commit to a strategy, and the other player then responds.

▶ **Definition 5** (Nash Equilibrium of the Stage Game). *A pair of (independent) distributions (p_1, p_2) for the two sellers is said to be an ε-Nash equilibrium if $u_1(p_1, p_2) \geq \max_{p \in \mathcal{P}} u_l(p, p_2) - \varepsilon$ and $u_2(p_1, p_2) \geq \max_{p \in \mathcal{P}} u_2(p_1, p) - \varepsilon$. When $\varepsilon = 0$, this pair is a Nash equilibrium.*

▶ **Definition 6** (Stackelberg Equilibrium of the Stage Game). *A pair of (independent) distributions p_1, p_2 for the two sellers is said to be an ε-Stackelberg equilibrium of the stage game with seller 1 as the leader if*

$$u_2(p_1, p_2) \geq \max_{p \in \mathcal{P}} u_2(p_1, p),$$

and

$$u_1(p_1, p_2) \geq \max_{(q_1, q_2) \in \Delta^{\mathcal{P}}} u_1(q_1, q_2) - \varepsilon$$
$$s.t. \quad u_2(q_1, q_2) \geq \max_{q \in \mathcal{P}} u_2(q_1, q).$$

When $\varepsilon = 0$, this pair is a Stackelberg equilibrium.

2.1.1 Competition Models

Now that we have defined the pricing stage game in full generality, we will instantiate it with two different specific competition rules, which result in two well-known economic pricing models.

2.1.1.1 Bertrand Competition

In the Bertrand Competition model, the seller picking the lower price captures all of the demand. The seller picking the higher price earns nothing. For cases in which sellers chose the same price p_L, they split the market equally.

▶ **Definition 7** (Bertrand Competitive Allocation Rule C_i^B). *C_i^B is a competition rule such that, given player $j \neq i$,*

$$C_i^B(p_1, p_2) = \begin{cases} 1 & p_i < p_j, \\ \frac{1}{2} & p_i = p_j, \\ 0 & p_i > p_j \end{cases} \tag{2}$$

▶ **Definition 8** (Bertrand Pricing Stage Game $G^B(k)$). *The* Bertrand Pricing Game *is a pricing game instantiated with the competition rule C^B and with a pricing discretization of $\frac{1}{k}$.*

The Bertrand model is discontinuous in that the seller who selects the lower price captures the entire market. We also study a generalization of Bertrand competition in which the fraction of the market captured by a seller is a smooth function (a logit function) of the difference in prices set by the two sellers. This model has a temperature parameter τ, and as τ tends to infinity, it recovers the Bertrand competition model as a special case.

2.1.1.2 Multinomial-logit-based Price Competition

This competition model is parameterized by a temperature parameter $\tau \geq 0$

▶ **Definition 9** (Logit Competitive Allocation Rule $C_i^{L,\tau}$). *$C_i^{L,\tau}$ is a competition rule such that for $j \neq i$:*

$$C_i^{L,\tau}(p_1, p_2) = \frac{e^{\tau p_j}}{e^{\tau p_i} + e^{\tau p_j}} \tag{3}$$

▶ **Definition 10** (Multinomial-logit-based Pricing Stage Game $G^B(k, \tau)$)**.** *The* Multinomial-logit-based Pricing Game *is a pricing game instantiated with the competition rule* $C^{L,\tau}$ *and with a pricing discretization of* $\frac{1}{k}$*.*

We prove similar results as in the Bertrand model in this logit model, assuming that the temperature parameter is sufficiently large, i.e., the allocation rule is sufficiently sensitive to differences in price. As $\tau \to \infty$, we recover the Bertrand model in the limit, since the lower price seller wins the demand with probability 1. Likewise, when $\tau = 0$, the sellers each win with probability $1/2$ regardless of their price, so it is to be expected that we need τ to be reasonably large to prove any meaningful results.

This model is a special case of the logit model of [8] and is obtained by setting all "product indices" in their model to be equal, and by removing the outside good from consideration (by setting its product index a_0 to $-\infty$), the latter action fixing the total demand.

For simplicity, in the main body of the paper we prove our results in the Bertrand game (Section 4). We show that they generalize to the Multinomial-Logit-Based pricing game in the full version of the paper.

2.2 The Repeated Pricing Game

We now move from the stage game to the repeated pricing interaction that will be our main setting of interest. The pricing game is played repeatedly over T rounds. During each round t, the two sellers simultaneously pick mixed strategies $p_{1,t},\ p_{2,t}$ over the set of prices $\mathcal{P}$ (these are independent distributions over $\mathcal{P}$). The sellers receive the corresponding utilities equal to the expected payoff of pricing $p_{1,t}$ against $p_{2,t}$ in the stage game. Both sellers observe the full mixed strategy of their opponent. Here, the pricing behavior of each player will be defined by algorithms which map history to the pricing distribution at the next round, and we study this larger interaction as a game in which the strategy space for each player is the algorithm that they will deploy. We formalize this setting below by defining the strategy space and the utility functions.

Algorithms as Strategies

The sellers' strategy space is the space of all algorithms, mapping histories to price distributions at the following round in arbitrary ways.

▶ **Definition 11.** *An algorithm* $\mathcal{A}$ *for the* T *round repeated game is a mapping from the history of play (without loss of generality of only the other seller) to the next round's action, denoted by a collection of* T *functions* $A_1, A_2 \cdots A_T$*, each of which deterministically map the transcript of play (up to the corresponding round) to a mixed strategy to be used in the next round, i.e.,* $A_{1,t}(p_{2,1}, p_{2,2}, \cdots, p_{2,t-1}) = p_{1,t}$ *for the algorithm* $\mathcal{A}_1$ *used by seller 1.*

We define a restricted subclass of algorithms below – algorithms that do not use nor respond to the history of play. Such algorithms, in particular, cannot make use of or respond to threats as they are oblivious to the behavior of their opponent.

▶ **Definition 12.** *If* A_t *is independent of its input for all* t*, we call it* non-responsive*. If in addition* $\mathcal{A}_t$ *outputs the* same *distribution for all* t *we call it static.*

If the two sellers pick algorithms $\mathcal{A}_1$ and $\mathcal{A}_2$ respectively, this induces a transcript of T price distribution pairs $((p_{1,1}, p_{2,1}), \cdots (p_{1,t}, p_{2,t}) \cdots (p_{1,T}, p_{2,T}))$ where $A_{1,t}(p_{2,1}, p_{2,2}, \cdots, p_{2,t-1}) = p_{1,t}$ and, similarly, $A_{2,t}(p_{1,1}, p_{1,2}, \cdots, p_{1,t-1}) = p_{2,t}$ for each round t.

Game definition

We again consider two sellers, who we will now refer to as the *learner* and the *optimizer*. The action space of each seller is now the set of possible *algorithms* mapping the history of play to a pricing distribution at the current round.

▶ **Definition 13** (Seller Payoff in the Repeated Game). *Let $p_l^{1:T}$ and $p_o^{1:T}$ represent the sequence of T distributions over prices by the learner and the optimizer, respectively, given $\mathcal{A}_l$ and $\mathcal{A}_o$. Then, the payoff of seller $i \in \{l, o\}$ is*

$$U_i(\mathcal{A}_l, \mathcal{A}_o) = \sum_{t=1}^{T} u_i(p_l^t, p_o^t) \tag{4}$$

We can now formally define the central game studied in this paper:

▶ **Definition 14** (Repeated Pricing Game). *A two-player repeated pricing game $G(k, C, T)$ is defined as a combination of:*

1. *Two players, named the "learner" and the "optimizer";*
2. *A time horizon T specifying the length of the repeated game;*
3. *An action space $A = \mathcal{A}^T$ corresponding to possible sequential pricing algorithms for games of length T;*
4. *Payoff functions $U_l(\mathcal{A}_l, \mathcal{A}_o)$ for the learner and $U_o(\mathcal{A}_l, \mathcal{A}_o)$ for the optimizer, defined as in Definition 13.*

A particular repeated pricing game is defined by the allocation rule C and the discretization parameter k.

Equilibrium Notions in Algorithm Space

Once again, we can study two kinds of equilibria of the repeated game in "algorithm space", depending on the timing of the game: Nash equilibria if play is simultaneous, and Stackelberg equilibria if the learner has commitment power and moves first.

▶ **Definition 15** (Nash Equilibrium in Algorithm Space). *A pair $(\mathcal{A}_l, \mathcal{A}_o)$ of algorithms for the two sellers is said to be an ε-Nash equilibrium in "algorithm space" if $U_l(\mathcal{A}_l, \mathcal{A}_o) \geq \max_{\mathcal{A} \in \mathcal{A}^T} U_l(\mathcal{A}, \mathcal{A}_o) - \varepsilon$ and $U_o(\mathcal{A}_l, \mathcal{A}_o) \geq \max_{\mathcal{A} \in \mathcal{A}^T} U_o(\mathcal{A}_l, \mathcal{A}) - \varepsilon$. When $\varepsilon = 0$, we call this pair a Nash equilibrium in algorithm space.*

▶ **Definition 16** (Stackelberg Equilibria in Algorithm Space). *A pair $(\mathcal{A}_l, \mathcal{A}_o)$ of algorithms for the two sellers is said to be an ε-approximate Stackelberg equilibrium in "algorithm space" if*

$$U_o(\mathcal{A}_l, \mathcal{A}_o) \geq \max_{\mathcal{A} \in \mathcal{A}^T} U_o(\mathcal{A}_l, \mathcal{A}),$$

and

$$U_l(\mathcal{A}_l, \mathcal{A}_o) \geq \max_{(\mathcal{B}_l, \mathcal{B}_o) \in \mathcal{A}^T} U_l(\mathcal{B}_l, \mathcal{B}_o) - \varepsilon$$
$$s.t. \;\; U_o(\mathcal{B}_l, \mathcal{B}_o) \geq \max_{\mathcal{B} \in \mathcal{A}^T} U_o(\mathcal{B}_l, \mathcal{B})$$

When $\varepsilon = 0$, we call this pair a Stackelberg equilibrium in algorithm space.

We investigate a setup in which one seller, who we call the Learner, commits to an algorithm $\mathcal{A}_L$, and then the other seller, who we call the Optimizer, responds with their own algorithm $\mathcal{A}_O$ [1]. This is reminiscent of a Stackelberg game in algorithm space; however, in contrast to standard Stackelberg games, we do not necessarily assume that the Optimizer exactly best-responds to the Learner's algorithm, or that the Learner necessarily deploys the algorithm representing the optimal commitment strategy. Instead, we examine which pricing outcomes arise under various Optimizers of different capacities, and show that, when the Optimizer is responding to a no-regret algorithm (defined in Section 3), a robust set of responses, including exactly optimal but also including approximately optimal non-responsive strategies, lead to supra-competitive prices.

Competitive vs supra-competitive prices

In the economics literature, competitive prices are defined as prices that can emerge from the static Nash equilibria of the pricing game (i.e. Nash equilibria of the stage game, where prices, rather than algorithms, form the strategy space). We formalize this below:

▶ **Definition 17** (Competitive and Supra-competitive prices). *For some pricing model G, let p be the highest price that is in the support of any Nash equilibrium of the stage pricing game. Then, p' is a competitive price if $p' \leq p$. Furthermore, p' is a supra-competitive price if $p' = \Omega_k(1)$* [2].

Supra-competitive prices are sometimes defined as any prices that are strictly above the competitive price. In this work, we use and guarantee a stronger definition, and require supra-competitive prices to be a constant fraction of the maximum possible price (1), even when the competitive price tends to 0 as $k \to \infty$. Thus our definition of supra-competitive prices really refers to "near monopoly" prices.

Throughout the paper we will regularly use high seller payoff as proof of supra-competitive prices. We make that connection explicit here, showing that in both the Bertrand and Logit models, the average price over time is exactly equal to the sum of the average utilities of the two sellers:

▶ **Definition 18** (Average Buyer Price in the Repeated pricing Game). *For an allocation rule C and seller algorithms $\mathcal{A}_l$, $\mathcal{A}_o$, the average buyer price over the rounds is simply the time average of the buyer prices over each round induced by the seller's prices and the allocation rule in the resulting transcript of play (see Definition 3).*

We make a simple observation connecting the average payoffs of the sellers with the average prices over the rounds.

▶ **Observation 19.** *The average buyer price in a repeated pricing game exactly equals the sum of the average payoffs of the sellers.*

[1] We follow the convention in prior work in renaming the leader and follower as the learner and optimizer where one of the key cases considered is the leader playing a no-(swap-)regret algorithm. This is helpful in clarifying the roles of the players, as we will use the fact that the optimizer, playing against a no-swap-regret algorithm, can get their Stackelberg *leader* value in the stage game

[2] The $\Omega_k(1)$ notation means that this quantity remains a constant between 0 and 1 regardless of the growth of k, in contrast to an expression such as $\frac{1}{k}$.

3 Online Learning Preliminaries

Classes of Algorithms

We are interested in three specific classes of algorithms that the learner might commit to: *no-regret algorithms*, *no-swap-regret algorithms*, and *mean-based algorithms*. The learner and optimizer repeatedly play a single-stage game G for T rounds. We refer to the learner's payoff function (in the stage game) as u_L and the actions chosen by the learner and optimizer in round t as $x_t \in \Delta^n$ and $y_t \in \Delta^m$ respectively (the action spaces are distributions over finite sets of actions).While we describe these algorithms from the perspective of the learner, they are also valid algorithms for the optimizer and afford them the same properties against algorithms picked by the learner.

No-regret definitions

We consider a setting in which a learner faces an adversary, here called an "optimizer" that can choose an arbitrary sequence of actions, with knowledge of the learner's algorithm. The learner obtains a payoff $u_L(x_t, y_t)$ as a function of his own action x_t and the optimizer's action y_t. A desirable property is that in hindsight, after the sequence of learner and optimizer actions have been realized, the learner does not *regret* not having played a simple strategy (like consistently playing whichever turned out to be the best fixed action in hindsight). We say that an algorithm $\mathcal{A}$ has *regret* $r(T)$ on some sequence of length T if, regardless of the sequence of optimizer actions, the learner is guaranteed that in hindsight, they obtained payoff at least as high as they could have with the best fixed action, minus $r(T)$.

▶ **Definition 20** ($r(T)$-Regret Algorithm)**.** *An algorithm has worst-case regret $r(T)$ if, for any sequence of actions $(y_1, y_2, \ldots, y_T)$ taken by the optimizer, the total payoff of the learner can be lower bounded by*

$$\sum_{t=1}^{T} u_L(x_t, y_t) \geq \left(\max_{x^* \in [n]} \sum_{t=1}^{T} u_L(x^*, y_t) \right) - r(T).$$

An algorithm is a ***no-regret algorithm*** *if it is an $r(T)$-regret algorithm with $r(T) = o(T)$.*

We also consider a strict subset of the class of no-regret algorithms, the class of *no-swap regret* algorithms. An algorithm $\mathcal{A}$ is a no-swap-regret algorithm if it has the no regret property not just marginally, but *conditionally* on each action it played. This can be formalized by requiring that the learner's cumulative payoff is at least as high as it would have been had they, retrospectively, been able to apply some *swap function* $\pi : [n] \to [n]$ to their sequence of actions in hindsight.

▶ **Definition 21** ($r(T)$-Swap Regret Algorithm)**.** *An algorithm has worst-case swap regret $r(T)$ if, for any sequence of actions $(y_1, y_2, \ldots, y_T)$ taken by the optimizer, the total payoff of the learner can be lower bounded by*

$$\sum_{t=1}^{T} u_L(x_t, y_t) \geq \max_{\pi:[n]\to[n]} \sum_{t=1}^{T} u_L(\pi(x_t), y_t) - r(T).$$

where $\pi(x_t)$ refers to the linear extension of π acting on the support of x_t.

An algorithm is a ***no-swap regret algorithm*** *if it is an $r(T)$-swap regret algorithm with $r(T) = o(T)$.*

Here the maximum is over all swap functions $\pi : [n] \to [n]$ (extended linearly to act on elements y_t of Δ_n). It is a fundamental result in the theory of online learning that both no-swap-regret algorithms and no-regret algorithms exist (see [9]).

Some no-regret algorithms have the property that at each round, they approximately best-respond to the historical sequence of losses interpreted as a mixed strategy. Following [7] and [13], we call such algorithms *mean-based algorithms*. Formally, we define mean-based algorithms as follows.

▶ **Definition 22** (Mean-Based Algorithm). *An algorithm $\mathcal{A}$ is* $\gamma(t)$-mean-based *if whenever $j, j' \in [m]$ satisfy*

$$\frac{1}{t}\sum_{s=1}^{t} u_L(j', y_s) - \frac{1}{t}\sum_{s=1}^{t} u_L(j, x_s) \geq \gamma(t),$$

then $x_{t,j} \leq \gamma(t)$ (i.e., if j is at least $\gamma(t)$ worse than some other action j' against the historical average action of the opponent, then the total probability weight on j must be at most $\gamma(t)$). A learning algorithm is mean-based *if it is $\gamma(t)$-mean-based for some $\gamma(t) = o(1)$.*

Many standard no-regret learning algorithms are mean-based, including Multiplicative Weights, Hedge, Online Gradient Descent, and others (see [7]).

Up to low order terms, best responses to no-swap regret algorithms in algorithm space are well understood: the optimizer can do no better than to play a static non-responsive strategy which at every round plays an identical action distribution that is very close (in any reasonable norm) to their optimal Stackelberg leader strategy in the stage game:

▶ **Lemma 23** ([13]). *If the learner plays a no-swap-regret algorithm, then there exists $\varepsilon = o_T(1)$ and a $o(T)$-additive best-response of the optimizer that involves playing a distribution D' in each round such that $||D - D'||_\infty \leq \varepsilon$ where D is the optimizer's leader Stackelberg strategy of the underlying stage game.*

4 Results in the Bertrand Model

4.1 Equilibria of the Stage Game

In this section, we focus on Nash and Stackleberg Equilibria of the stage game. We remind the reader that the Nash Equilibria of the stage game define which prices are competitive. In turn, this section identifies what the baseline competitive prices are in the Bertrand model (the equivalent result for the logit model can be found in the full version).

We begin by showing that in any Nash equilibrium of the Bertrand stage game, the resulting competitive prices must be at most $\frac{2}{k}$, implying in particular that competitive prices yield in total a vanishing fraction of the monopoly revenue. To prove this, we need to show that pricing high relative to the other seller's price distribution is a dominated strategy, in a robust sense. Intuitively, it is clear that the best-response to a deterministic price is to undercut your opponent. We show that the same idea works against distributions in the following Lemma that we use throughout this section. The proof is deferred to the full version.

▶ **Lemma 24.** *Consider one seller (say seller 2) in the Bertrand stage game playing a distribution d where the total weight placed on prices above x (where $x \geq \frac{3}{k}$) is equal to b, for $b \leq \frac{1}{24k}$. Then, for the other seller (seller 1), there is some price $x' < x$ such that $u_1(x', d) \geq u_1(x, d) + \frac{1}{24k^2}$.*

The above lemma has a simple corollary which will also be useful:

▶ **Corollary 25.** *In a Bertrand stage game in which one seller's distribution is d, pricing at* $p \geq max(supp(d))$ *is a strictly dominated strategy when* $\max(supp(d)) \geq \frac{3}{k}$.

We are now ready to show what constitutes competitive prices in the Bertrand game.

▶ **Lemma 26.** *All Nash Equilibria of the Bertrand stage game are supported on prices that are at most* $\frac{2}{k}$.

Proof. We will show this by induction:
Base Case: No Nash Equilibrium (NE) of this game have support on price 1. To see this, note that by Corollary 25, the price 1 is dominated for both sellers, and thus cannot be in the support of any NE.
Induction Hypothesis: If no NE has support on price $\frac{m}{k}$ or higher and m is an integer s.t. $m \geq 4$, then no NE can have support on price $\frac{m-1}{k}$. To see this, consider any NE, (d_1, d_2) such that neither distribution is supported on prices $\frac{m}{k}$ or higher. Since $max(supp(d_1)) \leq \frac{m-1}{k}$, where $\frac{m-1}{k} \geq \frac{3}{k}$, the best-response to it cannot be $\frac{m-1}{k}$ (the proof of this is deferred to the full version). Therefore d_2 cannot have support on price $\frac{m-1}{k}$. A similar argument holds for d_1, extending the induction hypothesis.
Therefore, no Nash Equilibria of the game have support on any prices above $\frac{2}{k}$. ◀

We observe a gap between the equilibrium prices of the stage game between the Nash and the Stackelberg equilibrium. The following lemma relies upon results we will show in Section 4.2.1, but we state it here for ease of organization.

▶ **Lemma 27.** *The Stackelberg Equilibria of the stage game leads to supra-competitive prices*

Proof. By Lemma 30, the optimizer can achieve utility $\Omega_k(T)$ against a no-swap regret learner (by playing a static strategy). [13] establish that the maximum possible average payoff achievable against a no-swap regret learner is upper bounded by the stage game Stackelberg leader value. Therefore, the stage game Stackelberg leader value is $\geq \Omega_k(1)$, and thus the resulting price is $\geq \Omega_k(1)$ (see Observation 19 which lower bounds the average price by the average payoff of either seller). ◀

4.2 Results for the Repeated Bertrand Game

We begin by considering the Stackelberg equilibria of the repeated Bertrand game. As we observed earlier, allowing unrestricted commitment to any possible algorithm opens the door for explicit usage of threats to maintain collusive prices. The following lemma shows that supra-competitive prices emerge out of such commitments, and is unsurprising.

▶ **Lemma 28.** *The Stackelberg Equilibrium of the repeated Bertrand game induces supra-competitive prices.*

The proof, which is based on the algorithm of [11] to find optimal algorithmic Stackelberg strategies in repeated games, is deferred to the full version. It is known that the resulting leader algorithm is "obviously" anti-competitive, in that it encodes an explicit threat for the follower. However, we show that supra-competitive prices arise from a vast array of algorithms which are not facially anti-competitive. In particular, we consider the class of mean-based no-regret algorithms and the class of no-swap regret algorithms, which are well-behaved in the following sense: for both classes of algorithms, when both sellers use any algorithm in the class, the prices converge to competitive prices.

4.2.1 Committing to No-Regret Algorithms Induces Supra-Competitive Prices

In this section, we will prove two key results pertaining to the repeated version of the game:

1. While playing against any no-regret learner, the optimizer can always guarantee themselves at least $\Omega_k(T)$ net payoff, even when restricted to static non-responsive strategies (recall: strategies which are oblivious to their opponent's behavior and simply play the same pricing distribution every day). In fact, they attain $\Omega_k(T)$ net payoff even by playing a uniform distribution over prices each day.
2. If an optimizer attains $\Omega_k(T)$ net payoff against a no-regret Learner, that no-regret Learner also obtains $\Omega_k(T)$ net payoff.

Taken together, these two results imply that, if the optimizer, optimizing in the environment defined by the learner's no-regret algorithm, does at least as they could do using a simple static and non-responsive strategy, the induced prices are supra-competitive. Furthermore, *both* the learner and the optimizer benefit from these high prices. Finally, we will show that, when the learner is playing a no-swap regret algorithm and the optimizer plays a static non-responsive best response, this is in fact an approximate *Nash* Equilibrium in algorithm space (where the approximation is a sublinear additive factor). We emphasize that despite the fact that the optimizer happens to be playing a static, non-responsive algorithm, this is a best response for them in all of (unrestricted) algorithm space. This result in fact holds true in all games not just pricing games – but in the context of pricing games, it gives an example of a Nash equilibrium with supra-competitive prices between two algorithms which do not explicitly encode threats.

To achieve these results, we must reason about an optimizer's payoff when playing against a no-regret learner. Consider a no-regret algorithm playing against a seller who plays the same distribution in each round. This fixes the expected cumulative payoff of each fixed action for the no-regret learner; and thus, by the no-regret guarantee, the learner must play a best-response for all but a diminishing fraction of rounds. This, in turn, has implications for the follower's aggregate payoff. We capture this relationship in the following lemma. Note that this lemma applies to all bimatrix repeated games, not just pricing games.

▶ **Lemma 29.** *Consider any T-round repeated game defined by a stage game G with non-negative payoffs. Against any learning algorithm with the no regret property, if the optimizer plays a static strategy s each round, the optimizer's expected payoff is at least $u_o(BR^*_\ell(s), s) \cdot T - o(T)$, where u_o is the optimizer's value in G and $BR^*_\ell(s)$ is the element of the learner's best response to s in G that minimizes $u_o(BR^*_\ell(s), s)$.*

Proof. Let the total regret of the learning algorithm be $r(T)$, and let $BR_\ell(s)$ be the set of all best responses to s from the learner. Furthermore, let $g = u_\ell(BR^*_{\ell(s)}, s) - \max_{y \in [m] \setminus BR_{\ell(s)}} u_\ell(y, s)$.

Let p^* be the average probability distribution played by the learning algorithm against s. Since there is no correlation between the two seller's randomness, the learner's average payoff is

$$u_\ell(p^*, s) \leq \mathbb{P}[p^* = x \in BR_\ell(s)] \cdot u_\ell(BR_\ell(s), s) + \mathbb{P}[p^* = x \notin BR_\ell(s)] \cdot (u_\ell(BR_\ell(s), s) - g)$$

As the learner's algorithm has average regret $\frac{r(T)}{T}$, we have that

$$\mathbb{P}[p^* = x \in BR_l(s)] \cdot u_\ell(BR_\ell(s), s) + \mathbb{P}[p^* = x \notin BR_\ell(s)] \cdot [u_\ell(BR_\ell(s), s) - g] \geq u_\ell(BR_\ell(s), s) - \frac{r(T)}{T}.$$

Therefore, $\mathbb{P}[p^* = x \notin BR_\ell(s)] \cdot g \leq \frac{r(T)}{T}$, which implies $\mathbb{P}[p^* = x \notin BR_\ell(s)] \leq \frac{r(T)}{Tg}$, and finally $\mathbb{P}[p^* = x \in BR_\ell(s)] \geq 1 - \frac{r(T)}{Tg}$.

This allows us to lower bound the payoff of the optimizer (where the first inequality implicitly uses the fact that the both sellers always get non-negative payoff) –

$$\begin{aligned}
u_o(p^*, s) &\geq \mathbb{P}[p^* = x \in BR_\ell(s)] \cdot u_o(BR_\ell^*(s), s) \\
&\geq \left(1 - \frac{r(T)}{Tc}\right) u_o(BR_\ell^*(s), s) \\
&= u_o(BR_\ell^*(s), s) - \frac{r(T)}{T} \cdot \frac{u_o(BR_\ell^*(s), s)}{g} \\
&= u_o(BR_\ell^*(s), s) - \frac{o(T)}{T} \cdot \frac{u_o(BR_\ell^*(s), s)}{g} \\
&= u_o(BR_\ell^*(s), s) - \frac{o(T)}{T}.
\end{aligned}$$

◀

We are now ready to show that if an optimizer's only goal is maximizing their own payoff, and they do even a passable job, they will get high payoff against a no-regret learner. In fact, they can do this even by performing the extremely simple static strategy of pricing uniformly randomly every day. Recall that by Observation 19, the average payoff of the optimizer lower bounds the average price. Therefore, as long as the optimizer is optimizing in the environment defined by the learner's no regret algorithm, there is a wide range of optimizer behaviors which induce supra-competitive prices. This includes all optimizers that perform better than static random pricing, ranging from approximate optimization over static responses to exact optimal dynamic responses.

▶ **Lemma 30.** *The optimizer can get payoff at least $\Omega_k(T)$ against any no-regret learner in the Bertrand model by playing a static strategy of uniformly random pricing. Formally, for any no-regret algorithm $\mathcal{A}^{noreg}$ and the static uniformly random algorithm $\mathcal{A}^r$, $U_o(\mathcal{A}_l^{noreg}, \mathcal{A}_o^r) \geq \Omega_k(T)$.*

Proof. Let r be the uniformly random distribution over prices. By Lemma 29, the optimizer's expected payoff is at least $u_2(BR_\ell^*(r), r) \cdot T - o(T)$.

First, we will prove that any best-response of the learner $BR_\ell(r) \geq \frac{1}{5}$. To see this, note that by pricing at $\frac{1}{2}$ against r, the learner's payoff would be at least

$$\begin{aligned}
\mathbb{P}\left[r > \frac{1}{2}\right] \cdot \frac{1}{2} = \mathbb{P}\left[r \geq \lfloor \frac{1}{2} + \frac{1}{k} \rfloor\right] \cdot \frac{1}{2} \\
&= \frac{1 - \lfloor \frac{1}{2} + \frac{1}{k} \rfloor}{1 - \frac{1}{k}} \cdot \frac{1}{2} \\
&\geq \left(1 - (\frac{1}{2} + \frac{1}{k})\right) \cdot \frac{1}{2} \\
&\geq \frac{\frac{1}{2} - \frac{1}{k}}{2} \\
&\geq \frac{1}{4} - \frac{1}{2k} \\
&\geq \frac{1}{4} - \frac{1}{20} = \frac{1}{5}
\end{aligned}$$

As the learner can get payoff at least $\frac{1}{5}$, their best response price will always be at least $\frac{1}{5}$, as otherwise they would always get payoff strictly less than $\frac{1}{5}$.

We now invoke Lemma 29 to lower bound the payoff of the optimizer. The worst learner best-response to the uniform distribution, from the perspective of the optimizer, must be bounded below by $\frac{1}{5}$ i.e. the optimizer must select a price that is at least $p^* := \frac{\lfloor \frac{k}{5} \rfloor}{k}$ [3]. Additionally, the optimizer's payoff is monotone increasing in the learner's price. Thus the optimizer gets total payoff at least $T \cdot u_o(r, p^*) - o(T)$. Analyzing this gives us the desired result –

$$\begin{aligned} u_o(r, p^*) \cdot T - o(T) &\geq \mathbb{E}[r | r < p^*] \cdot \mathbb{P}[r < p^*] \cdot T - o(T) \\ &\geq \mathbb{E}\left[r | r \leq p^* - \frac{1}{k}\right] \cdot \mathbb{P}\left[r \leq p^* - \frac{1}{k}\right] \cdot T - o(T) \end{aligned}$$

$\mathbb{E}[r | r <= p^* - \frac{1}{k}]$ is exactly $\frac{p^*}{2}$ (the average of $\frac{1}{k}$ and $p^* - \frac{1}{k}$). Substituting p^* results in $\frac{p^*}{2} = \frac{\lfloor \frac{k}{5} \rfloor}{10}$, this is lower bounded by $\frac{2}{25}$ (assuming $k > 20$). On the other hand, we can rewrite $\mathbb{P}\left[r \leq p^* - \frac{1}{k}\right]$ (by substituting p^*) as $\frac{\lfloor \frac{k}{5} \rfloor - 1}{k}$. This term is monotone increasing in k and lower bounded by $\frac{3}{25}$ (assuming $k > 20$). Thus, the optimizer payoff is lower bounded by $\frac{6T}{625} - o(T)$, completing the proof. ◀

Since by Observation 19 the average payoff of the optimizer lower bounds the average price, we have already shown that any no-regret algorithm induces supra-competitive prices against any optimizer who performs better than random pricing. We will now go on to show that the learner deploying the no-regret algorithm benefits from these supra-competitive prices as well.

▶ **Theorem 31.** *For any no-regret learner algorithm $\mathcal{A}_l^{noreg}$, and for any optimizer algorithm $\mathcal{A}_o$, if*

$$U_o(\mathcal{A}_l^{noreg}, \mathcal{A}_o) \geq \Omega_k(T)$$

then

$$U_l(\mathcal{A}_l^{noreg}, \mathcal{A}_o) \geq \Omega_k(T)$$

Proof. Let $U_o(\mathcal{A}_l^{noreg}, \mathcal{A}_o) \geq c \cdot T$ for some constant c between 0 and 1, independent of k.

Note that, in order to achieve c payoff on average, the optimizer must have priced at or above $\frac{c}{2}$ with average probability (over the rounds) at least $\frac{c}{2}$. Assume for contradiction that the optimizer does not do this. Then, we can upper bound their utility by assuming they capture demand in all rounds:

$$\begin{aligned} U_o(\mathcal{A}_l^{noreg}, \mathcal{A}_o) &\leq \mathbb{P}\left[p_o \geq \frac{c}{2}\right] \cdot 1 + \left(1 - \mathbb{P}\left[p_o \geq \frac{c}{2}\right]\right) \cdot \left(\frac{c}{2}\right) \\ &< \frac{c}{2} + \left(1 - \frac{c}{2}\right) \cdot \frac{c}{2} \\ &= c - \frac{c^2}{4} \end{aligned}$$

This is strictly less than c, and thus by contradiction, the optimizer must have priced at or above $\frac{c}{2}$ with frequency at least $\frac{c}{2}$.

[3] By construction, p^* is in the set of prices available to the seller

Given this, one fixed action that the learner could have taken is to price at $\frac{c}{2}$. Then,

$$U_l(\mathcal{A}_l^{noreg}, \mathcal{A}_o) \geq \frac{1}{2}\mathbb{P}\left[p_o \geq \frac{c}{2}\right] \cdot \left(\frac{c}{2}\right)$$
$$\geq \frac{1}{2} \cdot \frac{c}{2} \cdot \left(\frac{c}{2}\right) = \frac{c^2}{8}$$

By the no-regret guarantee of the learner, therefore, we have that $U_l(\mathcal{A}_l^{noreg}, \mathcal{A}_o) \geq \frac{c^2 T}{8} - o(T) = \Omega_k(T)$. ◀

We can now combine these results, to show that, if the learner deploys any no-regret algorithm in the Bertrand model and the optimizer responds via any strategy which gets them payoff at least that of static random pricing, then prices are supra-competitive and both the learner and the optimizer get a constant fraction of the profits.

▶ **Theorem 32.** *In a Bertrand repeated game, for any no-regret learner algorithm $\mathcal{A}_l^{noreg}$ and any optimizer algorithm $\mathcal{A}_o$ such that*

$$U_o(\mathcal{A}_l^{noreg}, \mathcal{A}_o) \geq U_o(\mathcal{A}_l^{noreg}, \mathcal{A}_o^r), \tag{5}$$

where $\mathcal{A}_o^r$ is the static uniformly random algorithm, we have

$$U_o(\mathcal{A}_l^{noreg}, \mathcal{A}_o) = \Omega_k(T) \tag{6}$$

$$U_l(\mathcal{A}_l^{noreg}, \mathcal{A}_o) = \Omega_k(T) \tag{7}$$

Further, the average price is $\Omega_k(1)$.

Proof. By Lemma 30, the optimizer gets payoff at least $\Omega_k(1) \cdot T$ against any no-regret algorithm by playing static random pricing. Therefore, the optimizer's payoff utilizing any strategy which is better than static random pricing also gives them a payoff of at least $\Omega_k(1) \cdot T$. Furthermore, by Theorem 31, this implies that the learner also gets a payoff of at least $\Omega_k(1) \cdot T$. Finally, by Observation 19, this implies that the average price is $\Omega_k(1)$. ◀

We show an equivalent result for the more general Multinomial-logit model in the full version of the paper. Note that despite our treatment of the problem in a sequential play setting, neither sequential play nor commitment power is necessary for our results. In fact, in the game where leader and optimizer pick their algorithm simultaneously, if one player plays any no-swap regret algorithm and their opponent plays a static strategy corresponding to the Stackelberg leader distribution of the stage game, then this forms a Nash equilibrium in algorithm space:

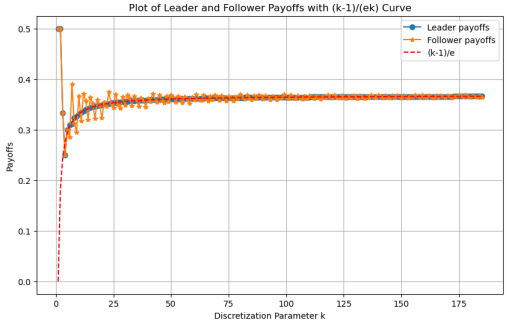
▶ **Theorem 33.** *There exists an $o(T)$-approximate Nash Equilibrium in algorithm space in any repeated game consisting of a no-swap regret algorithm for the leader and a static, non-responsive algorithm for the follower.*

Proof. In particular, such an equilibrium exists between any algorithm with total swap regret $r(T) = o(T)$ and the static algorithm which plays (something very close to) the Stackelberg leader strategy of the stage game each round. To show that this is true, we will show that each is an $\frac{o(T)}{T}$-approximate best response to the other.

First, we will show that a particular distribution (which is ε-close to the Stackelberg leader strategy of the stage game) is near-optimal against any No-Swap Regret algorithm (NSR) when played on every round. By Lemma 23, there exists a distribution D' such that $||D - D'||_\infty \leq \varepsilon$, where D is the static Stackelberg leader strategy and D' is a $o(T)$-best response to any algorithm with sublinear swap regret $r(T)$.

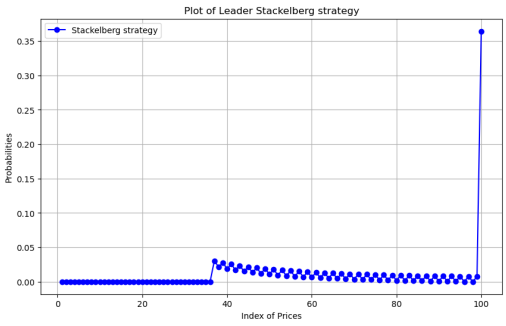
It remains to show that NSR is optimal against this distribution. However, NSR is optimal against any static distribution played on every round. The best response against any algorithm playing a static distribution is to play (one of) the best-response action(s) each day. Therefore, the gap between the average payoff of the optimal response and the average payoff attained by the NSR algorithm is bounded by the average external regret of the NSR algorithm, which is at most $r(T) = o(T)$. ◀

Here, notably, both players are "succeeding in optimizing" since they are playing best responses in algorithm space against one another, neither is using an algorithm which encodes threats, and yet the outcome is near monopoly prices.



5 Numerical Investigation of Constants

We showed in Lemma 30 that the optimizer can get a payoff of $\Omega_k(T)$ against any no-regret learner, just by playing the uniform distribution over their prices. An implication is that they would do at least as well with their optimal static strategy, which was enough for our results which are stated in asymptotic notation. While we did not get attractive constants via this simple approach, we numerically verified that the optimal static optimizer distribution against a no-regret algorithm, which is the Stackelberg leader strategy for a number of values of k, results in average prices of more than $\frac{2}{3}$ (in fact approximately $\frac{2(k-1)}{ek}$). [12] give an efficient algorithm for computing the Stackelberg equilibrium of a two player game, which we use to numerically compute the Stackelberg leader strategy as well as the payoff of the Stackelberg leader, which will approximately (up to subconstant in T additive error) be the average payoff of the optimizer repeatedly playing the Stackelberg leader strategy (using Lemma 29). Our numerical results show that the Stackelberg value of the leader (as well as the follower) is approximately $\frac{k-1}{ek}$ for a range of values of k in Figure 1a. By Observation 19, if the follower optimizes over the space of static strategies, the average price for the buyer will be $\frac{2(k-1)}{ek} \geq \frac{2}{3}$. We note that while our experiments show these prices are achievable by non-responsive optimizers for all values of k from 1 to 200, it remains interesting future work to prove that this holds for all k. Finding a closed form analytical expression for the Stackelberg leader strategy of the stage game is an open problem and would likely help in proving the conjecture for all k.



We also show the Stackelberg strategy for $k = 100$ in Figure 1b. Our numeric results also indicate that every price between 36/100 to 98/100 is (tied for being) a best response for the follower given the optimal leader commitment[4].

The code for these experiments can be found at Code Repository.

[4] In the Stackelberg Equilibrium problem, the follower typically tie-breaks in favor of the leader, in our application the optimizer adds some infinitesimal extra probability mass on price 99/100 to ensure that no-regret learner learns a unique best-response of 98/100 (which is the best outcome for the optimizer).

(a) Stackelberg Leader/Follower Payoffs for varying k.

(b) Stackelberg Leader Strategy for $k = 100$.

6 Discussion and Conclusion

Defining anti-competitive behavior is delicate. Monopoly like prices can arise in a number of scenarios: a *failure to optimize* (if e.g. players are simply not best responding to one another) as well as through *collusion* (which has been interpreted as requiring explicit *threats* when speaking of algorithmic collusion [8, 16]). Past work [17, 10] have proposed no-swap-regret algorithms as reasonable competitive algorithms in pricing scenarios, on the basis that they converge to competitive prices when both parties use them, and they seem both to successfully optimize and not to encode threats.

Our results complicate this picture. We show that if the first entrant into a market deploys a pricing algorithm with the no-swap-regret guarantee, then this very strongly incentivizes the next entrant to deploy an algorithm that will lead to supra-competitive prices. In fact, *anything the second entrant does* that obtains them profit at least that of a random pricing strategy will inevitably lead to supra-competitive prices. Moreover, this will not be at the expense of the first entrant – the no(-swap) regret learner will *also* enjoy supra-competitive revenue. And the algorithm of the second entrant can be entirely static and non-responsive, and therefore unable to encode threats. In fact, this phenomenon does not hinge on the sequential nature of play that we focus on and does not hinge on either player having commitment power. As we show, there is a Nash equilibrium of the game – in algorithm space – maintaining supra-competitive prices, which involves one player playing a no swap regret algorithm and the other playing a static pricing distribution. Both players are best responding to one another in the space of all pricing algorithms (without any restriction) and so neither player is failing to optimize – but neither are either of the players deploying threats. We suggest that this might require a reconsideration of what constitutes algorithmic collusion.

Rank Lower Bounds on Non-Local Quantum Computation

Abstract

A non-local quantum computation (NLQC) replaces an interaction between two quantum systems with a single simultaneous round of communication and shared entanglement. We study two classes of NLQC, f-routing and f-BB84, which are of relevance to classical information theoretic cryptography and quantum position-verification. We give the first non-trivial lower bounds on entanglement in both settings, but are restricted to lower bounding protocols with perfect correctness. Within this setting, we give a lower bound on the Schmidt rank of any entangled state that completes these tasks for a given function $f(x, y)$ in terms of the rank of a matrix $g(x, y)$ whose entries are zero when $f(x, y) = 0$, and strictly positive otherwise. This also leads to a lower bound on the Schmidt rank in terms of the non-deterministic quantum communication complexity of $f(x, y)$. Because of a relationship between f-routing and the conditional disclosure of secrets (CDS) primitive studied in information theoretic cryptography, we obtain a new technique for lower bounding the randomness complexity of CDS.

1 Introduction

A non-local quantum computation (NLQC) replaces a local interaction with entanglement and a single simultaneous round of communication. See Figure 1. NLQC has applications in a number of areas, including quantum position-verification [19, 18, 20], Hamiltonian simulation [3], the AdS/CFT correspondence [21, 24, 22, 23], and information theoretic cryptography [2]. In all of these settings, we are interested in understanding the resources necessary to implement a given computation in the non-local form. Lower bounds on the entanglement necessary to complete a non-local computation are so far poorly understood but are central to these applications.

(a) **(b)**

Figure 1 Local and non-local computations. a) A channel $\mathcal{T}_{AB\to AB}$ is implemented by directly interacting the input systems. b) A non-local quantum computation. The goal is for the action of this circuit on the AB systems to approximate the channel $\mathcal{T}_{AB\to AB}$.

Two important classes of non-local computations are f-routing and f-BB84, both initially studied in the context of quantum position-verification [18, 10]. These computations involve classical inputs of size n and $O(1)$ size quantum inputs. The local implementation of these computations involves computing a classical function f from the classical inputs, then doing $O(1)$ quantum operations conditioned on the outcome. A longstanding goal has been to prove that the non-local implementation of the same computation requires growing quantum resources, and in particular growing entanglement. Recently, a bound on the quantum system size was proven in [10], but this assumes a purified view that absorbs classical processing into the quantum part of the computation.[1] Another approach appears in [6], which bounds the number of quantum gates required in the non-local implementation. Here, we achieve the goal of lower bounding entanglement, at least as quantified by the Schmidt rank of the shared system, but at the cost of only considering protocols that complete f-routing or f-BB84 with perfect fidelity.[2]

It is a striking feature of non-local quantum computation that these mostly classical local computations require large quantum entanglement to implement non-locally. Beyond this, establishing this quantum-classical separation is relevant for quantum position-verification and for information theoretic cryptography. In a QPV scheme, we want to find operations that are as easy as possible for the honest player (who acts locally) to implement, but as hard as possible for the dishonest player (who implements an NLQC). Proving entanglement lower bounds for f-routing or f-BB84 gives a verification scheme where the honest player implements a nearly classical computation, while the dishonest player needs large quantum resources. This establishes the security of such QPV schemes under a bounded entanglement assumption. Our bound is only in the perfect setting and hence not immediately relevant to practical schemes, but represents a step towards proving entanglement lower bounds in the robust setting.[3]

[1] See [6] for more discussion of this point.

[2] Actually, we will see that in the case of f-routing we only need zero error on either $(x, y) \in f^{-1}(0)$ with bounded error for $(x, y) \in f^{-1}(1)$, or vice versa.

[3] Many entanglement lower bounds apply in the robust setting, see e.g. [25, 16, 23, 9], but none grow with the classical input size. We achieve growth with classical input size at the expense of robustness.

Also relevant to our work is the connection between NLQC and information theoretic cryptography. In information theoretic cryptography, we wish to understand the communication and randomness cost to establish information theoretic privacy in various cryptographic settings. A primitive known as conditional disclosure of secrets (CDS) has been identified as one of the simplest settings where one can hope to understand the cost of privacy. CDS was initially studied in the context of private information retrieval [17], has applications in secret sharing [4], and shares a number of connections to communication complexity and interactive proofs [5]. In [2], f-routing was shown to be closely related to CDS: lower bounds on entanglement cost in f-routing give lower bounds on randomness in CDS. This opens a new avenue for quantum information techniques to make contributions to classical information theoretic cryptography.

1.1 Summary of our results

An f-routing task is defined by a choice of Boolean function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$. In the task, Alice, on the left, receives a quantum system Q of $O(1)$ size and a classical string $x \in \{0,1\}^n$. Bob, on the right, receives $y \in \{0,1\}^n$. Their goal is to bring Q to Alice if $f(x,y) = 0$, and to Bob if $f(x,y) = 1$. In the setting of non-local computation, Alice and Bob may only use shared entanglement and a single round of communication to accomplish this. A difficulty in accomplishing this task arises since quantum mechanics prevents the system in register Q from being copied, and hence apparently Alice is forced to decide alone whether to keep or send Q. Furthermore, she doesn't know where Q is needed until learning y, at which point the single round of communication has already passed.

Despite the difficulty, the f-routing task can be completed for arbitrary functions f, with the most efficient known protocols using $2^{\Theta(\sqrt{n \log n})}$ entanglement and communication for arbitrary functions [2], and efficient protocols known for some low complexity classes of functions [13, 12]. So far, only an $O(1)$ lower bound is known on entanglement in f-routing, as we review in Section A. Here, we prove a new lower bound on f-routing with one-sided perfection. We define a (ϵ_0, ϵ_1)-correct f-routing scheme as one which brings Q to the left with fidelity at least $1 - \epsilon_0$ when $(x,y) \in f^{-1}(0)$ and brings Q to the right with fidelity at least $1 - \epsilon_1$ when $(x,y) \in f^{-1}(1)$. Define $FR_0(f)$ as the log of the minimal Schmidt rank of any entangled state that suffices to complete f-routing with $\epsilon_0 = 0$, $\epsilon_1 > 0$ for the function f, and $FR_1(f)$ as the analogous quantity with $\epsilon_0 > 0, \epsilon_1 = 0$. We prove the bounds

$$\begin{aligned} \mathrm{FR}_0(f) &\geq \frac{1}{4} \log \operatorname{rank}(g|_f) \ , \\ \mathrm{FR}_1(f) &\geq \frac{1}{4} \log \operatorname{rank}(g|_{\neg f}) \ , \end{aligned} \tag{1}$$

where $g|_f(x,y)$ is a real-valued function that satisfies $f(x,y) = 0 \leftrightarrow g(x,y) = 0$. For some natural functions, this provides explicit strong lower bounds. For instance, taking $f = EQ$ to be the equality function, we are assured $g(x,y)$ is diagonal with non-zero entries on the diagonal and hence is of full rank, therefore $FR_0(EQ) \geq n/4$. Similarly, we obtain linear lower bounds on $FR_1(NEQ)$ where NEQ is the non-equality function.

As mentioned above, f-routing is related closely to the conditional disclosure of secrets (CDS) primitive. A CDS instance is defined by a choice of Boolean function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$. In CDS, Alice and Bob receive inputs $x \in \{0,1\}^n$ and $y \in \{0,1\}^n$ respectively, while Alice additionally holds a secret string $s \in \{0,1\}^k$. Alice and Bob share randomness, and send messages to a referee. Their goal is for the referee to be able to determine s if and only if $f(x,y) = 1$.

In [2], it was shown that the randomness cost of CDS for a function f upper bounds the entanglement cost of an f-routing scheme for the same function. Because of this, our lower bounds on entanglement in f-routing imply the same lower bounds on randomness in CDS. Because we only need one sided perfection for our bounds to apply, it is possible to bound CDS with imperfect correctness and perfect privacy (ppCDS), or perfect correctness but imperfect privacy (pcCDS)

$$\begin{aligned} \text{ppCDS}(f) &\geq \Omega(\log \operatorname{rank}(g|_f)) \ , \\ \text{pcCDS}(f) &\geq \Omega(\log \operatorname{rank}(g|_{\neg f})) \ . \end{aligned}$$

The expressions on the left hand side denote randomness costs. This provides a new technique for bounding randomness in CDS, which is proven using the quantum information perspective but can be phrased purely in terms of classical quantities.

We also prove lower bounds against the f-BB84 class of non-local quantum computations. An f-BB84 task is defined by a choice of Boolean function $f(x, y)$ with $x \in \{0,1\}^n$ given to Alice and $y \in \{0,1\}^n$ given to Bob. The system Q is in one of the BB84 states $\{H^{f(x,y)} |b\rangle\}$, with $b \in \{0,1\}$ and $f(x, y) \in \{0,1\}$. Alice and Bob should both output b.

The f-BB84 task can be completed for arbitrary functions f, with the most efficient known protocols using $2^{\Theta(n)}$ entanglement and communication for arbitrary functions [12].[4] We prove lower bounds on the log of the Schmidt rank of any resource state that suffices to complete f-BB84 with probability 1. In particular, the same bound as in the f-routing case applies,

$$\text{FBB84}(f) \geq \frac{1}{4} \log \operatorname{rank}(g|_f) \ ,$$

where again g is a function with zeros exactly at the zeros of f. In a practical setting, f-BB84 is of particular interest because it can be made loss-tolerant [1]. Unfortunately, our bound does not carry over to the noisy setting, so is not of immediate practical value. Nonetheless, our bound is the first non-trivial entanglement bound on f-BB84. For f-BB84, the bound above leads to linear lower bounds for the equality, non-equality, set-disjointness, and greater-than functions.

We can better understand our lower bounds by relating them to communication complexity. In a quantum communication complexity protocol, Alice holds $x \in \{0,1\}^n$, Bob holds $y \in \{0,1\}^n$, and Alice and Bob communicate qubits to determine $f(x, y)$. The number of qubits of communication needed for Alice and Bob to output 1 with non-zero probability when $f(x, y) = 1$, and never output 1 when $f(x, y) = 0$ is known as the quantum non-deterministic communication complexity, $QNP^{cc}(f)$. Using the characterization of QNP^{cc} in terms of the non-deterministic rank [14, 15], we obtain

$$\begin{aligned} \log \operatorname{rank} g|_f &\geq (\text{QNP}^{\text{cc}}(f) - 1) \ , \\ \log \operatorname{rank} g|_{\neg f} &\geq (\text{coQNP}^{\text{cc}}(f) - 1) \ . \end{aligned}$$

This relates our lower bounds on CDS, f-routing, and f-BB84 to communication complexity.

[4] Note that [12] deals with the f-routing task, but their protocol is easily adapted to f-BB84.

2 Preliminaries

We let Ψ^+_{AB} denote the maximally entangled state on AB, so that

$$\left|\Psi^+\right\rangle_{AB} = \frac{1}{\sqrt{d}} \sum_{i=1}^{d} |i\rangle_A |i\rangle_B \ ,$$

and $\Psi^+_{AB} = |\Psi^+\rangle\langle\Psi^+|_{AB}$.

Given two density matrices ρ, σ, we define the fidelity by

$$F(\rho,\sigma) = \operatorname{tr}\sqrt{\sqrt{\sigma}\rho\sqrt{\sigma}} \ .$$

The fidelity is related to the one-norm distance by the Fuchs–van de Graff inequalities,

$$1 - F(\rho,\sigma) \leq \frac{1}{2}||\rho - \sigma||_1 \leq \sqrt{1-(F(\rho,\sigma))^2} \ .$$

The von Neumann entropy is defined by

$$S(A) = -\operatorname{tr}(\rho \log \rho) \ .$$

The quantum mutual information is defined by

$$I(A:B)_\rho = S(A)_\rho + S(B)_\rho - S(AB)_\rho \ ,$$

and the conditional mutual information is defined by

$$S(A|B)_\rho = S(AB)_\rho - S(B)_\rho \ .$$

We will also make use of the following statement of continuity of the conditional entropy [26],

▶ **Theorem 1** ([26]). *Suppose that*

$$\frac{1}{2}||\rho_{AB} - \sigma_{AB}||_1 \leq \epsilon \ ,$$

and let $h(x) = -x\log x - (1-x)\log(1-x)$ *be the binary entropy function. Then*

$$|S(A|B)_\rho - S(A|B)_\sigma| \leq 2\epsilon \log d_A + (1+\epsilon) h\left(\frac{\epsilon}{1+\epsilon}\right) \ .$$

We will also make use of the following observation.

▶ **Observation 2.** *Let* ρ_{AB} *be a density matrix on the* AB *system,* d *be the dimension of subsystem* A*, and* ρ_B *be the marginal of* ρ_{AB} *on the subsystem* B*. Then we have*

$$\begin{aligned}
\operatorname{tr}\left(\rho_{AB} - \frac{\mathcal{I}_A}{d}\otimes\rho_B\right)^2 &= \operatorname{tr}\left(\rho_{AB}^2 + \frac{\mathcal{I}_A}{d^2}\otimes\rho_B^2 - 2\rho_{AB}(\frac{\mathcal{I}_A}{d}\otimes\rho_B)\right) \\
&= \operatorname{tr}\left(\rho_{AB}^2\right) + \frac{1}{d^2}\operatorname{tr}(\mathcal{I}_A)\operatorname{tr}\left(\rho_B^2\right) - \frac{2}{d}\operatorname{tr}_B(\rho_B^2) \\
&= \operatorname{tr}\left(\rho_{AB}^2\right) - \frac{1}{d}\operatorname{tr}\left(\rho_B^2\right) \\
&= \operatorname{tr}\left(\rho_{AB}^2\right) - \operatorname{tr}\left(\frac{\mathcal{I}_A}{d^2}\otimes\rho_B^2\right) \ .
\end{aligned}$$

2.1 Communication complexity

We need some definitions and results from communication complexity. Consider two parties, Alice and Bob, with Alice given input $x \in \{0,1\}^n$ and Bob given input $y \in \{0,1\}^n$. Alice and Bob exchange messages and Alice outputs a bit z. The *non-deterministic quantum communication complexity* $\mathrm{QNP}^{cc}(f)$, introduced in [14], is the minimal number of qubits Alice and Bob need to exchange to both output 1 with probability larger than zero when $f(x,y) = 1$ and both output 0 with probability 1 when $f(x,y) = 0$.

A matrix M is called a non-deterministic communication complexity matrix for f exactly when $M(x,y) \neq 0$ when $f(x,y) = 1$. The non-zero entries are allowed to be any complex numbers. The minimal rank of any non-deterministic communication complexity matrix for f is denoted by $nrank(f)$ and called the non-deterministic rank. We have the following result from [15].

▶ **Theorem 3** ([15]). *The non-deterministic rank and the non-deterministic quantum communication complexity are related by*

$$\mathrm{QNP}^{\mathrm{cc}}(f) = \lceil \log(\mathrm{nrank}(f)) \rceil + 1 \ .$$

3 Lower bounds from function rank

In this section, we first start by defining and analyzing the f-routing task, and then prove our result in this setting. Next, we will show similar lower bounds for f-BB84.

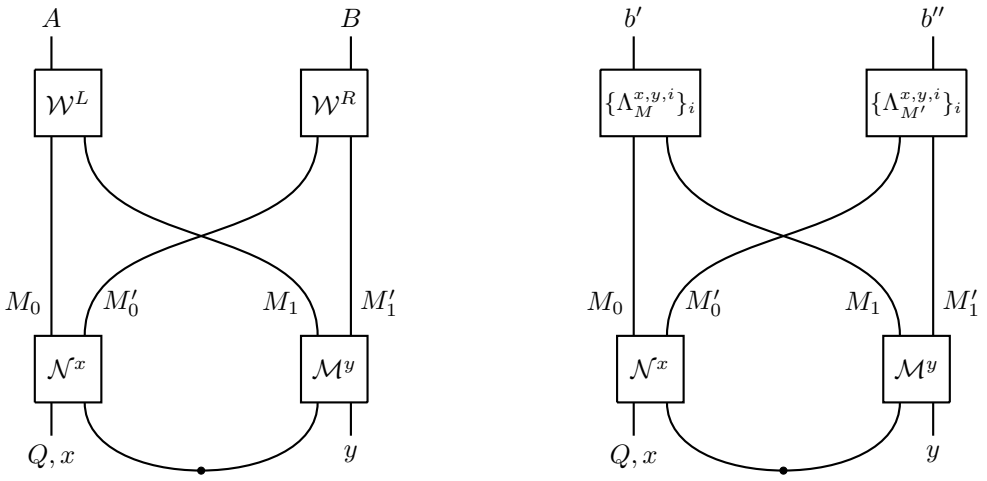
3.1 f-routing bounds from function rank

We begin with a definition of an f-routing task.

▶ **Definition 4.** *A **qubit f-routing** task is defined by a choice of Boolean function $f : \{0,1\}^{2n} \to \{0,1\}$, and a 2 dimensional Hilbert space $\mathcal{H}_Q$. Inputs $x \in \{0,1\}^n$ and system Q are given to Alice, and input $y \in \{0,1\}^n$ is given to Bob. Alice and Bob exchange one round of communication, with the combined systems received or kept by Bob labelled M' and the systems received or kept by Alice labelled M. Label the combined actions of Alice and Bob in the first round as $\mathcal{N}^{x,y}_{Q\to MM'}$. The qubit f-routing task is completed (ϵ_0, ϵ_1)-correctly on an input (x,y) if there exists a channel $\mathcal{D}^{x,y}_{M\to Q}$ such that,*

$$\text{when } f(x,y) = 0, \ \ F(\mathcal{D}^{x,y}_{M\to Q} \circ \mathrm{tr}_{M'} \circ \mathcal{N}^{x,y}_{Q\to MM'}(\Psi^+_{\bar{Q}Q}), \Psi^+_{\bar{Q}Q}) \geq 1 - \epsilon_0 \ ,$$

and there exists a channel $\mathcal{D}^{x,y}_{M'\to Q}$ such that



$$\text{when } f(x,y) = 1, \ \ F(\mathcal{D}^{x,y}_{M'\to Q} \circ \mathrm{tr}_{M} \circ \mathcal{N}^{x,y}_{Q\to MM'}(\Psi^+_{\bar{Q}Q}), \Psi^+_{\bar{Q}Q}) \geq 1 - \epsilon_1 \ .$$

In words, Alice can recover Q if $f(x,y) = 0$ and Bob can recover Q if $f(x,y) = 1$.

See the system labels shown in Figure 2a. Note that we label $M_0M_1 = M$, $M'_0M'_1 = M'$.

We will focus on f-routing with $\epsilon_0 = 0$, $\epsilon_1 \geq 0$ so that the protocol is perfectly correct on zero instances of $f(x,y)$, or with $\epsilon_0 > 0$ and $\epsilon_1 = 0$ so that the protocol is perfectly correct on 1 instances. We define the entanglement cost of an f-routing protocol to be the log of the minimal Schmidt rank of any resource system that can be used to perform the f-routing task. In notation, we define $\mathrm{FR}_0(f)$ to be entanglement cost for f-routing with $\epsilon_0 = 0$, $\epsilon_1 = 0.05$, $\mathrm{FR}_1(f)$ to be the entanglement cost when $\epsilon_0 = 0.05$, $\epsilon_1 = 0$.

Towards a lower bound in this setting, we first observe that $\rho_{\bar{Q}M'} = \rho_{\bar{Q}} \otimes \rho_{M'}$ iff $f(x,y) = 0$. We show this in the following lemma.

(a) **(b)**

Figure 2 a) General NLQC implementing a f-routing position-verification scheme. The first round operations are quantum channels that depend on the inputs $x \in \{0,1\}^n$ and $y \in \{0,1\}^n$. In the second round, Alice and Bob apply channels mapping to qubit systems A, B. If $f(x,y) = 0$ A should be maximally entangled with the reference $\bar{Q}$. If $f(x,y) = 1$ then B should be maximally entangled with R. b) Non-local quantum computation implementing a f-BB84 position-verification scheme. The first round operations are quantum channels that depend on the inputs $x \in \{0,1\}^n$ and $y \in \{0,1\}^n$. They communicate in one simultaneous exchange, and then apply measurements to their local systems. They succeed if $b = b' = b''$, with b determined by measuring a reference maximally entangled with Q.

▶ **Lemma 5.** *Suppose an f-routing protocol is perfectly correct on zero instances, and $\epsilon_1 < \epsilon_1^*$ correct on 1 instances, where ϵ_1^* depends on d_Q but is lower bounded by a constant. Then the mid-protocol state it produces, $\rho_{\bar{Q}M'}$, satisfies $\rho_{\bar{Q}M'} = \rho_{\bar{Q}} \otimes \rho_{M'}$ if and only if $f(x,y) = 0$.*

Proof. By correctness on 0 instances, we have that

$$\text{when } f(x,y) = 0, \quad F(\mathcal{D}^{x,y}_{M\to Q} \circ \mathrm{tr}_{M'} \circ \mathcal{N}^{x,y}_{Q\to MM'}(\Psi^+_{\bar{Q}Q}), \Psi^+_{\bar{Q}Q}) = 1 \ ,$$

hence $f(x,y) = 0$ implies Alice can produce a Bell state $|\Psi^+\rangle_{\bar{Q}Q}$. By data processing we have

$$2n = I(\bar{Q} : Q)_{\Psi^+_{\bar{Q}Q}} \leq I(\bar{Q} : M)_{\rho_{\bar{Q}M}} \ ,$$

but we also have the inequality

$$I(\bar{Q} : M)_\rho + I(\bar{Q} : M')_\rho \leq 2S(\bar{Q}) \ ,$$

so that $I(\bar{Q} : M') = 0$, which implies

$$\rho_{\bar{Q}M'} = \rho_{\bar{Q}} \otimes \rho_{M'} \ ,$$

as needed. Conversely, if $f(x,y) = 1$ we cannot have $\rho_{\bar{Q}M'} = \rho_{\bar{Q}} \otimes \rho_{M'}$. To see why, first recall that f-routing which is ϵ_1-correct on 1 instances has that there exists a family of channels $\{D^{x,y}_{M'\to Q}\}_{x,y}$ such that

$$\text{when } f(x,y) = 1, \quad F(\mathcal{D}^{x,y}_{M'\to Q} \circ \mathrm{tr}_{M} \circ \mathcal{N}^{x,y}_{Q\to MM'}(\Psi^+_{\bar{Q}Q}), \Psi^+_{\bar{Q}Q}) \geq 1 - \epsilon_1 \ .$$

Define

$$\sigma_{\bar{Q}Q} = \mathcal{D}^{x,y}_{M'\to Q}(\rho_{\bar{Q}M'}) \ ,$$

and use that by data processing,

$$I(\bar{Q}:M')_{\rho_{\bar{Q}M}} \geq I(\bar{Q}:Q)_{\sigma_{\bar{Q}Q}} \ .$$

But then by the Fuchs–van de Graff inequalities $\sigma_{\bar{Q}Q}$ is close in trace distance to $\Psi^+_{\bar{Q}Q}$,

$$\frac{1}{2}||\Psi^+_{\bar{Q}Q} - \sigma_{\bar{Q}Q}||_1 \leq \sqrt{2\epsilon_1 - \epsilon_1^2} \equiv \mu \ ,$$

and by continuity of the conditional entropy,

$$\begin{aligned} I(\bar{Q}:Q)_{\Psi^+} - I(\bar{Q}:Q)_{\sigma_{\bar{Q}Q}} &= S(\bar{Q}|Q)_{\Psi^+} - S(\bar{Q}|Q)_\sigma \\ &\leq 2\mu \log d_{\bar{Q}} + (1+\mu)h\left(\frac{\mu}{1+\mu}\right) \ , \end{aligned}$$

so that

$$2\log d_{\bar{Q}} - 2\mu \log d_{\bar{Q}} + (1+\mu)h\left(\frac{\mu}{1+\mu}\right) \leq I(\bar{Q}:Q)_\sigma \ .$$

We have that σ is not a tensor product whenever the left hand side of the equation above is strictly positive. For $d_Q = 2$, this occurs for $\epsilon_1 > \epsilon_1^* \approx 0.08$, and ϵ_1^* approaches 1 as $d_Q \to \infty$. ◀

Next, we define what we call a *structure function* for a protocol. The structure function is computed from the mid-protocol density matrix $\rho_{\bar{Q}MM'}$, and (as we will see) captures the zeros in $f(x,y)$.

▶ **Definition 6.** *Given an f-routing protocol with mid-protocol density matrix $\rho_{\bar{Q}MM'}$, define the **structure function** $g(x,y)$ according to*

$$g(x,y) = \mathrm{tr}\left(\rho_{\bar{Q}M'} - \frac{\mathcal{I}}{d_{\bar{Q}}} \otimes \rho_{M'}\right)^2 \ .$$

We claim that $g(x,y)$ captures some aspect of the structure in the function f which must be present in a correct f-routing protocol. More concretely we have the following.

▶ **Lemma 7.** *In a perfectly correct f-routing protocol, the structure function $g(x,y)$ is zero if and only if $f(x,y) = 0$.*

Proof. This follows because $g(x,y) = 0$ is zero if and only if $\rho_{\bar{Q}M'} = \frac{\mathcal{I}}{d_{\bar{Q}}} \otimes \rho_{M'}$, and Lemma 5 shows we have this tensor product form if and only if $f(x,y) = 0$. ◀

Our next job is to relate the function $g(x,y)$ to the entanglement available to Alice and Bob. We prove the following lemma.

▶ **Lemma 8.** *An f-routing protocol that uses a resource system with Schmidt rank d_E has a structure function of the form*

$$g(x,y) = \sum_{I=1}^{d_E^4} f_I(x) f'_I(y) \ .$$

Proof. From the general form of a non-local quantum computation protocol, the density matrix $\rho_{\bar{Q}M_0'M_1'}(x,y)$ can be expressed as

$$\rho_{\bar{Q}M_0'M_1'} = \mathcal{N}^x_{QL\to M_0'} \otimes \mathcal{M}^y_{\bar{Q}\to M_1'}(\Psi^+_{\bar{Q}Q} \otimes |\Psi\rangle\langle\Psi|_{LR}) \ .$$

We will write $|\Psi\rangle_{LR}$ in the Schmidt basis,

$$|\Psi\rangle_{LR} = \sum_{i=1}^{d_E} |i\rangle_L |i\rangle_R \ ,$$

with un-normalized vectors $|i\rangle_L, |i\rangle_R$. Then we get

$$\begin{aligned}\rho_{\bar{Q}M_0'M_1'} &= \sum_{i,j=1}^{d_E} \mathcal{N}^x_{QL\to M_0'}(\Psi^+_{Q\bar{Q}} \otimes |i\rangle\langle j|_L) \otimes \mathcal{M}^y_{R\to M_1'}(|i\rangle\langle j|_R) \\ &= \sum_{i,j=1}^{d_E} A^{x,i,j}_{\bar{Q}M_0'} \otimes B^{y,i,j}_{M_1'} \ .\end{aligned}$$

We can also compute the trace over $\bar{Q}$ where we define A and B in the second line of the previous equation and get

$$\rho_{M_0'M_1'} = \sum_{i,j=1}^{d_E} A^{x,i,j}_{M_0'} \otimes B^{y,i,j}_{M_1'} \ .$$

Next, we compute $g(x,y)$. It is convenient to make use of Observation 2 to write

$$g(x,y) = \mathrm{tr}\left(\rho^2_{\bar{Q}M'} - \frac{\mathcal{I}}{d^2_{\bar{Q}}} \otimes \rho^2_{M'}\right) \ .$$

Inserting the forms of $\rho_{\bar{Q}M'}$ and $\rho_{M'}$ into this, we obtain

$$\begin{aligned}g(x,y) &= \sum_{i,j,i',j'=1}^{d_E} \mathrm{tr}\left(\left(A^{x,i,j}_{QM_0'}A^{x,i',j'}_{QM_0'} - \frac{\mathcal{I}}{d^2_Q} \otimes A^{x,i,j}_{M_0'}A^{x,i',j'}_{M_0'}\right) \otimes B^{y,i,j}_{M_1'}B^{y,i',j'}_{M_1'}\right) \\ &= \sum_{I=1}^{d_E^4} f_I(x) f_I'(y) \ ,\end{aligned}$$

as needed. ◀

We can view $g(x,y)$ as a matrix, and $f_I(x)$, $f_I'(y)$ as vectors so that the minimal number of terms appearing in this sum is the rank of the matrix $g(x,y)$. Thus we obtain the lower bound

$$\boxed{\mathrm{FR}_0(f) \geq \frac{1}{4}\log \mathrm{rank}\, g|_f \ .} \tag{2}$$

We know that g is zero and non-zero for the same inputs as f, for which we have given the $g|_f$ notation as a reminder. In some cases, this is enough to let us lower bound the rank of g, as we discuss below.

We can also notice that we can reverse the role of M and M', and assume perfect correctness on 1 instances, leading to a similar bound,

$$\boxed{\mathrm{FR}_1(f) \geq \frac{1}{4}\log \mathrm{rank}\, g|_{\neg f} \ ,} \tag{3}$$

where $\neg f$ is the negation of f.

We can also rephrase the above bounds in terms of the non-deterministic quantum communication complexity. Observe that

$$\operatorname{rank} g|_f \geq \operatorname{nrank}(f) \ . \tag{4}$$

Because the non-deterministic rank considers matrices with arbitrary complex values where $f(x,y) = 1$, while $g|_f$ has the further constraint that it has positive real values when $f(x,y) = 1$, it is possible there are functions for which $\operatorname{rank} g|_f > \operatorname{nrank}(f)$. We have not looked for such examples.

Using Equation (4) and Theorem 3, we obtain

$$\mathrm{FR}_0(f) \geq \frac{1}{4}(\mathrm{QNP}^{\mathrm{cc}}(f) - 1) \ ,$$
$$\mathrm{FR}_1(f) \geq \frac{1}{4}(\mathrm{coQNP}^{\mathrm{cc}}(f) - 1) \ .$$

Further, for f-routing which has two sided perfection, we have

$$\mathrm{pFR}(f) \geq \frac{1}{4}\max\{\mathrm{QNP}^{\mathrm{cc}}(f), \mathrm{coQNP}^{\mathrm{cc}}(f)\} - 1 \ .$$

Or, labelling the set of function families which can be f-routed on with polylogarithmic entanglement by pFR, we have

$$\mathrm{pFR} \subseteq \mathrm{QNP}^{\mathrm{cc}} \cap \mathrm{coQNP}^{\mathrm{cc}} \ .$$

In the classical setting, $\mathrm{NP}^{\mathrm{cc}} \cap \mathrm{coNP}^{\mathrm{cc}} = \mathrm{P}^{\mathrm{cc}}$ [8], but (to our knowledge) it is not known if the quantum analogue holds.

3.2 f-BB84 bounds

▶ **Definition 9.** *A **qubit f-BB84** task is defined by a choice of Boolean function $f : \{0,1\}^{2n} \to \{0,1\}$, and a 2 dimensional Hilbert space $\mathcal{H}_Q$. Inputs $x \in \{0,1\}^n$ and system Q are given to Alice, and input $y \in \{0,1\}^n$ is given to Bob. The Q system is in the maximally entangled state with a reference $\bar{Q}$. Alice and Bob exchange one round of communication, with the combined systems received or kept by Bob labelled M and the systems received or kept by Alice labelled M'. Define projectors*

$$\Pi^{q,b} = H^q \left|b\right\rangle\!\left\langle b\right| H^q \ .$$

The qubit f-BB84 task is completed ϵ-correctly on input (x,y) if there exist POVM's $\{\Lambda_M^{x,y,0}, \Lambda_M^{x,y,1}\}$, $\{\Lambda_{M'}^{x,y,0}, \Lambda_{M'}^{x,y,1}\}$ such that,

$$\operatorname{tr}\left(\Pi_{\bar{Q}}^{f(x,y),b} \otimes \Lambda_M^{x,y,b} \otimes \Lambda_M^{x,y,b} \rho_{\bar{Q}MM'}\right) \geq 1 - \epsilon \ .$$

That is, Alice and Bob succeed when they both obtain the same outcome as the referee.

We will focus here on perfectly correct f-BB84, where $\epsilon = 0$.

As in the analysis of f-routing, we look for a function of the density matrix prepared by the protocol which captures the structure of the function $f(x,y)$. We define this next.

▶ **Definition 10.** *Given a f-BB84 protocol with mid-protocol density matrix $\rho_{\bar{Q}MM'}$, define the structure function by first defining the density matrices*

$$\rho_M^0 = \left\langle 0\right|_{\bar{Q}} \rho_{\bar{Q}M} \left|0\right\rangle_{\bar{Q}} \ ,$$
$$\rho_M^1 = \left\langle 1\right|_{\bar{Q}} \rho_{\bar{Q}M} \left|1\right\rangle_{\bar{Q}} \ .$$

These are the post measurement states on M when the referee measures R in the computational basis, and finds outcome $b = 0, 1$. We similarly define $\rho^0_{M'}$ and $\rho^1_{M'}$. Then define

$$g(x,y) = \mathrm{tr}\left(\rho^0_M \rho^1_M\right) + \mathrm{tr}\left(\rho^0_{M'} \rho^1_{M'}\right) \ .$$

We show this has the same zeros as $f(x,y)$ next.

▶ **Lemma 11.** *In a perfectly correct f-BB84 protocol, the structure function $g(x,y)$ is zero if and only if $f(x,y)$ is zero.*

Proof. We first establish the following fact: $g(x,y) = 0$ if and only if both ρ^0_M and ρ^1_M have non-overlapping support and $\rho^0_{M'}$ and $\rho^1_{M'}$ have non-overlapping support. To see this, first assume $g(x,y) = 0$. Then diagonalize ρ^0_M and ρ^1_M so that

$$\rho^0_M = \sum_i \lambda_i \left|\psi_i\right\rangle\!\left\langle\psi_i\right| \ ,$$
$$\rho^1_M = \sum_j \mu_j \left|\phi_j\right\rangle\!\left\langle\phi_j\right| \ ,$$

with $\lambda_i, \mu_j > 0$ and we have from $g(x,y) = 0$ that $\mathrm{tr}\left(\rho^0_M \rho^1_M\right) = 0$, so that

$$0 = \mathrm{tr}\left(\rho^0_M \rho^1_M\right) = \sum_{i,j} \lambda_i \mu_j \left|\left\langle\phi_j|\psi_i\right\rangle\right|^2 \ .$$

But this occurs if and only if

$$\forall i, j, \quad \left\langle\phi_j|\psi_i\right\rangle = 0 \ ,$$

so that ρ^0_M and ρ^1_M have non-overlapping support, as needed. We can similarly conclude $\rho^0_{M'}$ and $\rho^1_{M'}$ have non-overlapping support. For the converse, a direct calculation shows both $\mathrm{tr}\left(\rho^0_M \rho^1_M\right)$ and $\mathrm{tr}\left(\rho^0_{M'} \rho^1_{M'}\right)$ are 0.

Now we use this fact to relate $g(x,y) = 0$ and $f(x,y) = 0$. First, suppose that $f(x,y) = 0$. Then, the referee measures in the computational basis and so after the referee's measurement, Alice holds either ρ^0_M or ρ^1_M depending on the referee's measurement outcome. By assumption she can determine the measurement outcome perfectly, so she must be able to distinguish ρ^0_M and ρ^1_M perfectly. Thus ρ^0_M and ρ^1_M have orthogonal support. Considering the same line of reasoning but now considering Bob, whose post-measurement state is $\rho^0_{M'}$ or $\rho^1_{M'}$, these density matrices too must have orthogonal support. But then from the fact above we have $g(x,y) = 0$.

Next suppose that $f(x,y) = 1$. Then the referee measures in the Hadamard basis, so Alice's post-measurement state is one of

$$\rho^{\pm}_M = \left\langle\pm\right|_{\bar{Q}} \rho_{\bar{Q}M} \left|\pm\right\rangle_{\bar{Q}} \ .$$

For Alice to be able to determine the referee's measurement outcome, ρ^+_M and ρ^-_M must have orthogonal support, so that

$$0 = \mathrm{tr}\left(\rho^+_M \rho^-_M\right) \ . \tag{5}$$

We claim that this implies $\mathrm{tr}\left(\rho^0_M \rho^1_M\right) > 0$. To see why, note

$$\rho^{\pm}_M = \frac{1}{2}\left(\rho^0_M + \rho^1_M \pm \left\langle 0\right|_{\bar{Q}} \rho_{\bar{Q}M} \left|1\right\rangle_{\bar{Q}} \pm \left\langle 1\right|_{\bar{Q}} \rho_{\bar{Q}M} \left|0\right\rangle_{\bar{Q}}\right) \ .$$

Inserting this into Equation 5, we find that

$$\mathrm{tr}\big(\rho^0_M \rho^1_M\big) = \frac{1}{2}\left(\mathrm{tr}\big((\rho^0_M)^2\big) + \mathrm{tr}\big((\rho^1_M)^2\big)\right) > 0 \ .$$

Again, repeating the argument considering Bob's post-measurement state and his ability to determine the referee's measurement outcome, we also find that

$$\mathrm{tr}\big(\rho^0_{M'} \rho^1_{M'}\big) > 0 \ .$$

Thus, $g(x,y) > 0$ as needed. ◀

▶ **Lemma 12.** *An f-BB84 protocol that uses a resource system with Schmidt rank d_E has a structure function of the form*

$$g(x,y) = \sum_{I=1}^{2d_E^4} f_I(x) f'_I(y) \ .$$

Proof. From the general form of a non-local quantum computation protocol, the density matrix $\rho_{\bar{Q}M'_0M'_1}(x,y)$ can be expressed as

$$\rho_{\bar{Q}M'_0M'_1} = \mathcal{N}^x_{QL\to M'_0} \otimes \mathcal{M}^y_{R\to M'_1}(\Psi_{\bar{Q}Q} \otimes |\Psi\rangle\langle\Psi|_{LR}) \ .$$

We will write $|\Psi\rangle_{LR}$ in the Schmidt basis,

$$|\Psi\rangle_{LR} = \sum_{i=1}^{d_E} |i\rangle_L |i\rangle_R \ ,$$

with un-normalized vectors $|i\rangle_L, |i\rangle_R$. Then we get

$$\begin{aligned}\rho_{\bar{Q}M'_0M'_1} &= \sum_{i,j=1}^{d_E} \mathcal{N}^x_{QL\to M'_0}(\Psi^+_{\bar{Q}Q} \otimes |i\rangle\langle j|_L) \otimes \mathcal{M}^y_{R\to M'_1}(|i\rangle\langle j|_R) \\ &= \sum_{i,j=1}^{d_E} A^{x,i,j}_{\bar{Q}M'_0} \otimes B^{y,i,j}_{M'_1} \ .\end{aligned}$$

We can also project $\bar{Q}$ into $|b\rangle_{\bar{Q}}$, $b \in \{0,1\}$ to get $\rho^i_{M'}$,

$$\rho^b_{M'_0M'_1} = \sum_{i,j=1}^{d_E} A^{b,x,i,j}_{M'_0} \otimes B^{y,i,j}_{M'_1} \ .$$

A similar calculation gives ρ^b_M. Inserting these expressions into $g(x,y)$, we obtain an expression of the form

$$g(x,y) = \sum_{I=1}^{2d_E^4} f_I(x) f'_I(y) \ .$$

where the d_E^4 appears because each of the two trace terms in $g(x,y)$ comes with a product of two density matrices, each of which involves two sums running from 1 to d_E. We collect all of these sums into the index i appearing here, which now runs 1 to $2d_E^4$. ◀

Similarly to the case of f-routing, the above lemma implies that

$$\boxed{\mathrm{FBB84}(f) \geq \frac{1}{4}(\log \operatorname{rank} g|_f - 1)\ .} \tag{6}$$

where the notation $g|_f$ indicates as before that g is zero and non-zero on the same inputs as $f(x, y)$.

Also similarly to the case of f-routing, we can use Equation (4) and Theorem 3, we obtain

$$\mathrm{FBB84}(f) \geq \frac{1}{4}(\mathrm{QNP}^{\mathrm{cc}}(f) - 2)\ .$$

4 A new lower bound technique for CDS

It was recently understood [2] that f-routing is closely related to a classical information theoretic primitive known as conditional disclosure of secrets. As a consequence, our new lower bounds on f-routing imply lower bounds on CDS. In this work, we will informally describe these lower bounds, but see [7] for a more complete treatment.

The *conditional disclosure of secrets* primitive involves three parties, Alice, Bob, and the referee. Alice receives input $x \in \{0,1\}^n$, and Bob receives $y \in \{0,1\}^n$. Alice additionally holds a secret string z, and Alice and Bob share a random string r. Alice and Bob do not communicate, but each sends a message to the referee. The goal is for the referee to be able to learn z if and only if a function $f(x, y) = 1$, where the choice of the function f is known to all parties, and the referee knows both inputs x and y.

The quantum generalization of CDS, *conditional disclosure of quantum secrets* or CDQS, was recently defined [2]. In the quantum setting, Alice and Bob share a quantum state (rather than a random string) and can send quantum messages to the referee. The secret can now also be taken to be a quantum system Q rather than a classical string. The security and privacy conditions are similar to the classical case: correctness means that the referee can invert the map on Q applied by Alice and Bob when $f(x, y) = 1$, and security means the map applied by Alice and Bob is close to completely depolarizing when $f(x, y) = 0$. In general, we allow small correctness and privacy errors. See [2] for a formal definition.

We define the minimal number of qubits in Alice and Bob's shared resource system in a CDQS scheme for function f by $\mathrm{CDQS}(f)$. If we require the protocol to be perfectly correct we write $\mathrm{pcCDQS}(f)$, and when perfectly private we write $\mathrm{ppCDQS}(f)$. Similarly, for classical CDS, we use $\mathrm{CDS}(f)$ to denote the randomness cost of classical CDS. Again we modify this to $\mathrm{pcCDS}(f)$, $\mathrm{ppCDS}(f)$ for perfectly correct and perfectly private CDS randomness cost.[5]

In [2], it was shown that a good classical CDS protocol for a function f implies a good quantum CDS protocol for the same function. This leads to[6]

$$\mathrm{CDS}(f) = \Omega(\mathrm{CDQS}(f))\ ,$$

and the same relationships hold for the perfectly correct and perfectly private variants. Also in [2], it was shown that a good CDQS leads to a good f-routing protocol, and vice versa.

[5] The reader should be warned that the same notation is used to denote the *communication* cost in other papers on CDS.

[6] In fact, to obtain this we also need an amplification result which appears in [7]. These bounds are proved formally there.

This leads to

$$\mathrm{CDQS}(f) = \Theta(\mathrm{FR}(f)) \ ,$$

Also, the perfectly private and perfectly correct variants are related to f-routing with one-sided errors,

$$\mathrm{ppCDQS}(f) = \Theta(\mathrm{FR}_0(f)) \ ,$$
$$\mathrm{pcCDQS}(f) = \Theta(\mathrm{FR}_1(f)) \ .$$

This implies our lower bounds from Equation (2) and Equation (3) apply to CDS,

$$\mathrm{ppCDQS}(f) = \Omega(\log \operatorname{rank} g|_f) \ ,$$
$$\mathrm{pcCDQS}(f) = \Omega(\log \operatorname{rank} g|_{\neg f}) \ .$$

This also gives lower bounds in terms of $\mathrm{QNP}^{\mathrm{cc}}(f)$ and $\mathrm{coQNP}^{\mathrm{cc}}(f)$, and the upper bound can be written in terms of classical CDS. In this way, we can obtain the lower bound

$$\boxed{\mathrm{pcCDS}(f) \geq \Omega(\mathrm{coQNP}^{\mathrm{cc}}(f)) \ .}$$

This is similar to a lower bound obtained in [5],

$$\mathrm{pcCDS}(f) \geq \frac{1}{2}\mathrm{coNP}^{\mathrm{cc}}(f) \ .$$

The lower bound on perfectly private CDS randomness cost seems to be new,

$$\boxed{\mathrm{ppCDS}(f) \geq \Omega(\mathrm{QNP}^{\mathrm{cc}}(f)) \ .}$$

For perfect CDS, we can bound the randomness cost by the maximum of the $\mathrm{QNP}^{\mathrm{cc}}$ and $\mathrm{coNP}^{\mathrm{cc}}$ cost. If we let pCDS denote the set of families of functions for which CDS can be implemented with perfect correctness and perfect privacy using polylogarithmic randomness. Then we obtain

$$\mathrm{pCDS} \subseteq \mathrm{QNP}^{\mathrm{cc}} \cap \mathrm{coNP}^{\mathrm{cc}} \ .$$

5 Application to concrete functions

We detail lower bounds for equality, non-equality, greater than and less than, set-disjointness, and set-intersection below. We were not able to use our technique to lower bound inner product.

Our results are summarized succinctly in Figure 3.

Equality and non-equality

Choose $f(x, y)$ to be the equality function,

$$EQ(x, y) = \begin{cases} 0, & x \neq y \\ 1, & x = y \end{cases} \ .$$

Then $g(x, y)$ is zero except on the diagonal, which forces it to have full rank, so from Equation (2) and Equation (6)

$$\mathrm{FR}_0(EQ) \geq \frac{n}{4}, \qquad \mathrm{pFBB84}(EQ) \geq \frac{1}{4}(n-1) \ .$$

For the not-equals function, we can use bound from Equation (3) to obtain

$$\mathrm{FR}_1(NEQ) \geq \frac{n}{4} \ .$$

Function	pFR	FR_1	FR_0	FR
Equality	$\Theta(n)$	$\Theta(1)$	$\Theta(n)$	$\Theta(1)$
Non-Equality	$\Theta(n)$	$\Theta(n)$	$\Theta(1)$	$\Theta(1)$
Inner-Product	$O(n)$, $\Omega(1)$	$O(n)$, $\Omega(1)$	$O(n)$, $\Omega(1)$	$O(n)$, $\Omega(1)$
Greater-Than	$\Theta(n)$	$\Theta(n)$	$\Theta(n)$	$O(n)$, $\Omega(1)$
Set-Intersection	$\Theta(n)$	$\Theta(n)$	$O(n)$,$\Omega(1)$	$O(n)$, $\Omega(1)$
Set-Disjointness	$\Theta(n)$	$O(n)$,$\Omega(1)$	$\Theta(n)$	$O(n)$, $\Omega(1)$

Figure 3 Known upper and lower bounds on entanglement cost (quantified by the log Schmidt rank) in f-routing for natural functions. No non-trivial lower bounds on entanglement were known prior to this work. Linear upper bounds on all of these functions follow from [12, 13]. The $\Omega(1)$ lower bounds follow from Section A.

Greater and less than

Similarly, the "greater than" function,

$$GT(x,y) = \begin{cases} 0, & x < y \\ 1, & x \geq y \end{cases} .$$

is upper triangular with non-zero elements on the diagonal, so it also has full rank, and we obtain a linear lower bound.

$$\mathrm{FR}_0(GT) \geq \frac{n}{4}, \qquad \mathrm{pFBB84}(GT) \geq \frac{1}{4}(n-1) \ .$$

Further, because the negation of Greater-Than is also full rank, we can also bound fR_1,

$$\mathrm{FR}_1(GT) \geq \frac{n}{4} \ .$$

The same bounds hold for the "less than" function.

Set-Intersection and set-disjointness

Set disjointness is upper left triangular.[7] This implies it is full rank, therefore

$$\mathrm{FR}_0(DISJ) \geq \frac{n}{4}, \qquad \mathrm{pFBB84}(DISJ) \geq \frac{1}{4}(n-1) \ .$$

Since the negation of set intersection is set disjointness and hence of full rank, we also obtain

$$\mathrm{FR}_1(INT) \geq \frac{n}{4} \ .$$

6 Discussion

In this article, we have given the first non-trivial lower bounds on entanglement in the f-routing and f-BB84 tasks. For some natural functions, including equality, greater than, and set-disjointness, our lower bounds are linear in the classical input size. This realizes

[7] To see why, consider that on the diagonal of the truth table running top right to bottom left, we have that $x+y = 11...11$, the all 1's string. This means x and y must have non-zero values in non-overlapping locations, e.g. for two bits this diagonal consists of $(x = 00, y = 11)$, $(x = 01, y = 10)$, $(x = 10, y = 01)$ and $(x = 11, y = 00)$. Moving downward from any entry on that diagonal y becomes larger, so must now have an overlapping entry with the x string.

a long standing aspiration for f-routing and f-BB84 based position-verification schemes: that an honest party can compute a simple, classical function and perform $O(1)$ quantum operations, while a dishonest party must use entanglement that grows with the size of the classical input strings. However, this result comes at the unfortunate cost of requiring perfect correctness for the lower bounds to apply. Nonetheless, even proving bounds in this perfect case has so far been elusive, and we hope that our progress may open future avenues toward robust linear lower bounds.

An interesting observation is that our bounds lead to relations among operational quantities, e.g.

$$\mathrm{FR}_0(f) \geq \mathrm{QNP}^{cc}(f)$$

but are derived by separately relating FR_0 and QNP^{cc} to the non-deterministic rank. Given this result, it would be natural to expect a reduction at an operational level from f-routing to quantum non-deterministic communication complexity, but we know of no such reduction.

As a consequence of our lower bounds, we also obtain a new lower bound technique for randomness complexity in CDS with either perfect privacy or perfect correctness. We highlight the bound

$$\boxed{\mathrm{ppCDS}(f) \geq \Omega(\mathrm{QNP}^{\mathrm{cc}}(f)) \ .}$$

which appears to be new and incomparable to earlier bounds on ppCDS. It would be interesting to construct explicit functions for which this lower bound is tighter than earlier ones, for instance, bounds from the $\mathrm{PP}^{\mathrm{cc}}$ cost of f [4].

A $\Omega(1)$ lower bounds on entanglement in f-routing

It is straightforward to establish an $\Omega(1)$ lower bound on entanglement for f-routing, though to our knowledge this lower bound is not recorded elsewhere in the literature, so we give it here. Note that for f-BB84 a $\Omega(1)$ lower bound follows from theorem 6.1 in [11].

To show the lower bound in the f-routing setting, we will first notice that in a f-routing task we can always replace a mixed resource state Ψ_{LR} with a pure state $|\Psi\rangle_{LR}$. Our lower bound will apply whenever $f(x, y)$ has an input $x = x_0$ such that $f(x_0, y) = F(y)$ is non-constant. We will assume perfect correctness of the f-routing protocol in our arguments but the generalization to the robust setting is immediate.

Considering the perfect protocol, we allow Alice and Bob to complete the easier task of performing f-routing when they know $x = x_0$. Alice, on the left, applies a quantum channel $\mathcal{N}_{QL\to AB}$, she keeps system A and sends B to Bob. Without decreasing their success probability we can take the isometric extension of this channel and have Alice keep the purifying system so that the state on ABR is pure. Bob, who knows y, knows where system Q should be brought so can, without decreasing their success probability, always simply forward the R system to whichever party should receive Q. Correctness of the protocol then requires that both AR and BR can recover Q.

Let Q be in the maximally entangled state $\Psi^{+}_{\bar{Q}Q}$ with reference system $\bar{Q}$. Then correctness of the protocol implies that

$$\begin{aligned} I(\bar{Q} : AR) &= 2 \log d_R \ , \\ I(\bar{Q} : BR) &= 2 \log d_R \ . \end{aligned} \tag{7}$$

We claim this implies that $S(R) \geq \log d_R$. First notice that purity of $\bar{Q}ABR$ and the second line above implies $I(\bar{Q} : A) = 0$. Then we apply the inequality,

$$I(\bar{Q} : AR) \leq I(\bar{Q} : A) + 2S(R) \ ,$$

which can be proven from strong subadditivity, and using the first line of Equation (7) we are done. In the robust setting, we can prove a similar bound by applying the above argument along with the continuity of the von Neumann entropy.

Stable Matching with Interviews

Abstract

In several two-sided markets, including labor and dating, agents typically have limited information about their preferences prior to mutual interactions. This issue can result in matching frictions, as arising in the labor market for medical residencies, where high application rates are followed by a large number of interviews. Yet, the extensive literature on two-sided matching primarily focuses on models where agents know their preferences, leaving the interactions necessary for preference discovery largely overlooked. This paper studies this problem using an algorithmic approach, extending Gale-Shapley's deferred acceptance to this context.

Two algorithms are proposed. The first is an adaptive algorithm that expands upon Gale-Shapley's deferred acceptance by incorporating interviews between applicants and positions. Similar to deferred acceptance, one side sequentially proposes to the other. However, the order of proposals is carefully chosen to ensure an interim stable matching is found. Furthermore, with high probability, the number of interviews conducted by each applicant or position is limited to $O(\log^2 n)$.

In many seasonal markets, interactions occur more simultaneously, consisting of an initial interview phase followed by a clearing stage. We present a non-adaptive algorithm for generating a single stage set of in tiered random markets. The algorithm finds an interim stable matching in such markets while assigning no more than $O(\log^3 n)$ interviews to each applicant or position.

1 Introduction

In many two-sided matching markets used for dating or allocating labor, agents often interact prior to forming matches in order to gain information about their potential partners. These interactions, meant for learning preferences, can generate congestion, resulting in market inefficiencies. For example, in the market for fellowships in sports medicine, on average more than 23 applicants interview for each slot [33]. Similarly, in dating markets, such as the popular platform Tinder, only a small fraction of online conversations culminate in an in-person meeting [20, 15].

This paper considers the problem of how to alleviate interview congestion and improve welfare in two-sided matching markets. We take an algorithmic approach to form interviews and find stable matches while minimizing congestion.

We study this question in the classic two-sided marriage problem by [14]. In the model, there are n applicants and n positions. Each applicant a_i and position p_j has a publicly known value of u_i and v_j, respectively. The subjective interest of a_i for matching with p_j,

denoted by ε^A_{ij} is unknown unless the parties meet each other. The observed utility of a_i in p_j is $v_j + \varepsilon^A_{ij}$ if a_i and p_j have met, and equal to v_j otherwise. The distributions of ε^A_{ij}s are known, they are all independent, and their expected value is zero. The subjective interest ε^P_{ji} and the observed utility of positions in the applicants are defined similarly.

A matching is interim-stable if (i) all the matched pairs have interviewed each other and (ii) there are no blocking pairs with respect to the observed utilities. One simple approach for finding an interim stable matching is to ask all pairs to interview each other and then find a stable matching with respect to the observed utilities. That involves n interviews per agent. On the other hand, even in the special case in which all the u_is and v_js are equal to each other, finding an interim-stable matching requires at least $\Omega(\log n)$ interviews per agent.

The main result of the paper is to show that the number of interviews needed to find an interim-stable matching is much closer to the above lower-bound than the upper bound. In fact, it is possible to find an interim stable matching by assigning only a polylogarithmic number of interviews to each applicant or position. This is shown for both adaptive and non-adaptive models.

1.1 Approach

Adaptive algorithm. We present an adaptive algorithm that finds an interim stable matching while requiring that each applicant and position engage in at most $O(\log^2 n)$ interviews. The algorithm is applicable to a general setting, where the publicly known values assigned to applicants and positions can vary arbitrarily, and the subjective interests are independent and identically distributed.

▶ **Theorem** (See Theorem 1). *There exists an **adaptive** algorithm that finds an interim stable matching between n positions and n applicants such that with high probability every applicant and position participates in at most $O(\log^2 n)$ interviews.*

The proposed algorithm expands upon deferred acceptance [14] by dividing the process into distinct interview and proposal stages. Specifically, in the applicant-optimal version, each applicant submits a proposal to the position offering the highest observed utility. The position will accept the "highest" proposal or assign an interview if the proposing applicant has the potential to create a blocking pair, taking into account potential changes in the observed value following the interview.

The main technical ingredient of the analysis is to show the probability that an applicant gets rejected by more than $O(\log^2 n)$ consecutive positions is very small. More precisely, with probability at least $1 - n^{-3}$, each applicant a_i is matched to position p_j for $j \leq i + O(\log^2 n)$.

Non-adaptive algorithm. In the adaptive model, the algorithm is allowed to determine the sequence of interviews based on the results of previous ones. However, in practice, many markets favor a non-adaptive approach in which the interview lists are predetermined beforehand to allow the parties to streamline scheduling and the rest of the logistics.

We present a non-adaptive algorithm for interim stable matching with a poly-logarithmic number of interviews per agent. The algorithm works in tiered markets in which applicants and positions are partitioned into multiple tiers. Two applicants a_i and $a_{i'}$ in the same tier have the same publicly known value, i.e., $u_i = u_{i'}$. On the other hand, if an applicant a_i is in a higher tier than $a_{i'}$, then it is always preferred independent of the interview outcomes, i.e., for all position p_j, $\Pr[u_i + \varepsilon^P_{ji} > u_{i'} + \varepsilon^P_{ji'}] = 1$.

▶ **Theorem** (See Theorem 19). *There exists a* ***non-adaptive*** *algorithm that, with high probability, finds an interim stable matching for* ***tiered markets*** *with no more than* $O(\log^3 n)$ *interviews for each applicant or position.*

The design of the non-adaptive algorithm incorporates two key technical components. First, we observe that in markets where all applicants and positions are in a single tier, requiring each applicant to interview a set of $O(\log^2 n)$ positions chosen uniformly at random combined with an applicant-optimal Gale-Shapley algorithm results in an interim stable matching.

On the other hand, when all positions are in the same tier while applicants are in individual tiers, random interviews prove to be ineffective. This is primarily due to positions exhibiting a preference for applicants in the corresponding higher tiers. Consequently, these higher-tier applicants are given higher priority in the matching process. The challenge arises for the lowest-tier applicant who, despite undergoing a poly-logarithmic number of random interviews, struggles to find the sole available position among the interviewed positions. To address this, a different approach is taken. By fixing the order of positions, interviews are assigned to each applicant with consecutive positions whose indices closely match the tier number of the applicant. This strategy ensures that applicants with similar tier numbers have a substantial overlap of interviews. Consequently, positions that are interviewed by higher-tier applicants will be matched to them and will not be available options for lower-tier applicants.

The non-adaptive algorithm combines the above two technical ingredients with a few other ideas. Specifically, it creates a sequence of bipartite graphs $G_i(A_i, P_i, E_i)$, where each G_i may be a random graph like the first special case we considered, a sequential graph like the second special case, or a small complete bipartite graph when we have two small tiers. We refer the reader to Section 3.3 for the details of the algorithm and its analysis.

Further, in Section 3.4, we demonstrate that if applicants and positions have individual preferences within the tiers prior to the interviews, the exact same ideas and proofs presented in Section 3.3 carry over, with some mild assumptions about the distribution of individual preferences before the interviews and subjective interest arising from the interview.

The extensive literature on two-sided matching has led to a rich theory and successful designs in practice. However, most of the existing work focuses on models in which agents know their own preferences. Little is known about the interaction period in which agents learn about their preferences by interacting with each other. This paper attempts to address this gap by looking at this problem with an algorithmic lens, focusing on extending Gale-Shapley's deferred acceptance to this setting.

1.2 Related literature

Congestion and frictions in the early stages of two-sided markets stem from the lack of complete information and competition. Several approaches have been proposed to improve the screening process, including signaling, limiting the number of applications, and even coordinating interviews.

Signaling allows applicants to send programs "interest" signals [19, 10, 16], which intend to improve efficiency by helping in screening applications and interviewing applicants that are typically beyond reach. The literature has investigated how a limited number of signals indicating special interest can enhance efficiency. [16] demonstrate the impact of different signal quantities on the matching outcome. Signaling is used in the Economics job mar-

ket [9] and experimented in residency and fellowship markets [28, 30]. Instead of signaling mechanisms, this paper proposes interview mechanisms that address interview congestion by eliminating interviews that are unlikely to form a match.

Another approach considered is to limit the number of applications applicants can send. [1, 6, 32] demonstrate the benefit of limiting the number of applications when agents have complete information about their own preferences. We note that [6] and [32] further assume that agents are ex-ante symmetric.[1]

Several papers analyzed games induced by inviting agents for interviews [11, 17], demonstrating various frictions. Other CS papers study how to make interview decisions in the worst-case towards reaching a stable matching [12, 29].

A related approach for how to coordinate interviews is also studied. Specifically, [23] and [2] find that the match rate is high when agents have a similar number of interviews. [18] propose the idea of incorporating overlaps between positions. Our preference model allows for a more heterogeneous tiered market structure, which results in the non-adaptive algorithm assigning agents possibly an unequal number of interviews.

Our paper is inspired by [25, 24] who propose to conduct an interview match that will limit the number of interviews. Similar to our paper, [2] study non-adaptive interview mechanisms that generate many-to-many matching in large random markets with interim stability in the limit. In their model different applicants (positions) have heterogeneous pre-interview utilities of being matched to some position (applicant). Their heterogeneous utilities are a summation of common scores (generated from a continuous distribution) and idiosyncratic scores (and in particular the market is not tiered). Instead, we consider arbitrary homogeneous pre-interview utilities (i.e., just common scores) and propose an adaptive algorithm generating an interim stable matching for any finite market size. [2] further points to the challenge of handling tiered markets.[2] Instead our non-adaptive algorithm generates an interim-stable matching in every homogeneous tiered market.

This paper relies on the existing literature on random two-sided matching markets. Our non-adaptive algorithm incorporates the findings of [5] and [7] as a fundamental component. These prior studies specifically examine the average ranking of the matched positions for individual applicants in the applicant-proposing Gale-Shapley algorithm when preference lists are randomized. We further extend the tiered market model in [4] to allow for noisy preferences. [4] focuses on minimizing communication to reach an exact stable matching with high probability in a random market when agents know their own preferences. Instead, agents in our model know the public values and have perfect information only over public values and we seek to minimize the number of interviews required to learn about post-interview preferences in order to reach interim stability.

The concurrent work [3] extends our framework in two notable ways. First, it examines markets with *heterogeneous* pre-interview utilities, addressing scenarios where agents have differing pre-interview preferences. Second, it explores simple decentralized signaling mechanisms to determine which pairs should interview each other.

The authors demonstrate that in a single-tiered random market with sparse signals ($d = \omega(1)$), almost interim stability can be achieved. Specifically, the matching becomes perfectly interim stable after removing a vanishingly small fraction of agents. Furthermore, in the case of dense signals ($d = \Omega(\log^2 n/p)$), perfect interim stability can be attained in

[1] Limiting applications has also been proposed in for medical markets [31, 8, 26].

[2] They offer a heuristic for two-tiered markets; this heuristic adds to higher tier agents, safety interviews with lower tier agents.

imbalanced markets through short-side signaling. Additionally, they extend their results to multi-tiered markets and identify conditions under which signaling mechanisms are incentive compatible.

Finally, there is a growing literature in Economics that studies the structure stable matchings when agents have partial knowledge of their own preferences Liu et al. [22], Liu [21]. This literature does not consider the matching dynamics that arise prior to being matched. An exception is [13], which contributes to our understanding of the stages that occur prior to a match.

1.3 Our Model

Let $A = \{a_1, a_2, \ldots, a_n\}$ and $P = \{p_1, p_2, \ldots, p_n\}$ denote the set of applicants and positions respectively. The utility of applicant a_i for position p_j, v_{ij} can be written as $v_j + \varepsilon^A_{ij}$. The quantity v_j reflects the characteristics of the position, like working hours, salary, or prestige, and is public knowledge. Applicant a_i's subjective interest in position p_j is captured by ε^A_{ij}, which will only be revealed to the applicant after the interview. We assume ε^A_{ij}'s are independently sampled from a known symmetric distribution with mean zero. Define the utility of position j in applicant i, $u_{ij} = u_i + \varepsilon^P_{ji}$ similarly. Note that ε^A_{ij}'s and ε^P_{ji}'s are also independent from each other.

We define interim stable matchings. Let the *observed utility* of a_i in p_j, v^o_{ij} be $v_j + \varepsilon^A_{ij}$ if a_i and p_j have interviewed, and equal to v_j otherwise. Define u^o_{ji}'s or the observed utility of positions in the applicants similarly. A matching μ is interim stable if all the matched pairs have interviewed with each other and there are no blocking pairs with respect to observed utilities. In other words, $\{a_i, p_j\} \in \mu$ and $\{a_k, p_l\} \in \mu$ imply either $v^o_{ij} \geq v^o_{il}$ or $u^o_{ji} \geq u^o_{jk}$. Throughout the paper, we assume the applicants and positions prefer being matched to someone to remaining unmatched.

For ease of notation, we use $\mu(a_i)$ and $\mu(p_j)$ to refer to the position or the applicant they are matched to, respectively. Define $\mu(a_i) = \emptyset$ if a_i is not matched. We also use $\succ_a$ and $\succ_p$ to denote the preferences of applicants and positions, e.g., $p_j \succ_{a_i} p_{j'}$ if and only if $v^o_{ij} > v^o_{ij'}$.

We will study *adaptive* and *non-adaptive* algorithms for finding interim stable matching. Adaptive algorithms use the outcome of previous interviews to propose the next one. In contrast, non-adaptive algorithms determine the interviews that should be conducted between all the applicants and agents in one shot.

2 An Adaptive Algorithm

In this section, we present an adaptive algorithm for finding an interim stable matching. Our algorithm extends Gale-Shapley's deferred acceptance to incorporate interviews between the applicants and positions. Just like in deferred acceptance, one side makes proposals to the other sequentially, but the order of proposals is chosen carefully so that with high probability, the number of interviews needed to obtain interim stability is no more than $O(n \log^2 n)$.

▶ **Theorem 1.** *Algorithm 1 finds an interim stable matching between n positions and n applicants. Moreover, with high probability, the number of interviews done by each applicant or position is at most $O(\log^2 n)$.*

Let us start with an informal overview of the algorithm. Consider the applicant-proposing deferred acceptance mechanism. In the beginning, p_1 has the largest expected utility and is, therefore, the first choice for all applicants. Similarly, since a_1 is the applicant with the largest expected utility, it is p_1's first choice. The algorithm asks p_1 and a_1 to interview each

other. The interview may change a_1 and p_1's preferences. If they are still at the top of each other's preference list, we can match them and reject all other applicants for p_1; otherwise, we update the preference list of p_1 and a_1 and continue the process.

For an unmatched applicant a, let $\beta(a)$ be the most preferred position from which the applicant is not yet rejected. At any time, $\beta(a)$ is the position to which applicant a is going to propose next. At each step, we consider the position p_j with the smallest j such that there exists an applicant a_i where $\beta(a_i) = p_j$.

Suppose that among all proposals that p_j is receiving, a_i is the one that has the largest observed utility, i.e. $i = \arg\max_i u^o_{ij}$. If p_j and a_i have already interviewed each other, then the process is similar to deferred acceptance: if $\mu(p_j) \succ_{p_j} a_i$, position p_j rejects applicant a_i; otherwise, p_j rejects $\mu(p_j)$ and matches to a_i.

Now consider the case where p_j has not interviewed a_i. If $\mu(p_j) \succ_{p_j} a_i$ and $j < i$, p_j rejects a_i without an interview. Otherwise, p_j and a_i interview each other and update their observed utility and preference list. The algorithm ends when all agents are matched. See a formal description below.

Algorithm 1 Adaptive Algorithm for Interim Stable Matching.

Initialize $\mu(a) = \emptyset$ for $a \in A \cup P$, and $\forall i, j, v^o_{ij} = v_j, u^o_{ji} = u_i$.
while $\exists$ *an unmatched applicant* **do**
  Let j^* be the smallest index where $\beta(a_i) = p_{j^*}$, for some unmatched applicant a_i.
  Let a_{i^*} be position p_{j^*}'s favorite applicant from the set $\{a_i | \beta(a_i) = p_{j^*}, \mu(a_i) = \emptyset\}$.
  if (a_{i^*}, p_{j^*}) *have not interviewed and* $(i^* \le j^* \quad or \quad a_{i^*} \succ_{p_{j^*}} \mu(p_{j^*}))$ **then**
    Position p_{j^*} interviews applicant a_{i^*}; update $u^o_{i^*j^*}, v^o_{j^*i^*}$.
  else
    if $\mu(p_{j^*}) \succ_{p_{j^*}} a_{i^*}$ **then** p_{j^*} rejects applicant a_{i^*}.
    else
      p_{j^*} rejects applicant $\mu(p_{j^*})$ if it is not $\emptyset$.
      $\mu(a_{i^*}) \leftarrow p_{j^*}$ and $\mu(p_{j^*}) \leftarrow a_{i^*}$.
return matching μ.

2.1 Analysis of Algorithm 1

We will prove Theorem 1 in the rest of this section. We will show that in the course of the algorithm, all positions interview candidates that have a fairly similar global ranking. More specifically, with high probability, every position p_j only interviews applicants a_i where $j - O(\log^2 n) \le i \le j + O(\log n)$.

We start with a few simple observations about the algorithm. First, note that similar to the Gale-Shapley algorithm, when a position p_j gets matched to an applicant a_i, it remains matched until the end of the algorithm. Further, p_j may only reject a_i to match with a more preferable applicant.

▷ Claim 2. Suppose that unmatched position p_j and applicant a_i interview each other at some point during the algorithm and both observe non-negative ε^A_{ij} and ε^P_{ji}. Then, the algorithm (tentatively) matches them to each other. Subsequently, p_j may only interview applicants $a_{i'}$ for which $i' < \max(i, j+1)$.

Proof. If $\varepsilon_{ij}^A \geq 0$ and $\varepsilon_{ji}^P \geq 0$, the interview does not change $\beta(a_i)$ and applicant a_i remains the most preferable applicant proposing to p_j. Hence, the algorithm matches applicant a_i to position p_j in the next iteration.

Now, observe that, based on Algorithm 1 of Algorithm 1, p_j is going to interview an applicant $a_{i'}$ if either $i' \leq j$ or if $u_{i'} > u_i + \varepsilon_{ji}^P > u_i$, which implies $i' < i$. ◁

▶ **Observation 3.** *If position p_j interviews applicant a_i and $i < j$, then a_i is interviewed by all $p_{j'}$ where $i \leq j' < j$.*

Proof. Before proposing to p_j, a_i proposes to all positions $p_{j'}$ with $j' < j$. Also, based on Algorithm 1 of the algorithm, when $i \leq j'$, $p_{j'}$ does not reject a_i without an interview. ◀

The next lemma establishes that positions do not interview any applicant with a significantly higher index. Moreover, we show that with the possible exception of $8 \log n$ positions with the highest index (and lowest expected utility for the applicants), the positions get matched sequentially in the increasing order of their index.

▶ **Lemma 4.** *With probability of at least $1 - n^{-2}$, if p_j and a_i interview each other, then $i \leq j + 8 \log n$. Also, at the time an applicant a_i proposes to p_j,*

- *If $j < n - 8 \log n$, then $\mu(p_{j'}) \neq \emptyset$ for $j' < j$,*
- *If $j \geq n - 8 \log n$, then $\mu(p_{j'}) \neq \emptyset$ for $j' < n - 8 \log n$.*

Proof. The first part of the lemma holds trivially when $j \geq n - 8 \log n$. So suppose $j < n - 8 \log n$ and let S be the set of agents a_i with $i < j + 8 \log n$. At most $j - 1$ agents from S can be matched to position $p_{j'}$ for $j' < j$ at any time. Further, applicants propose to positions in the increasing order of their index. Hence, in order for p_j to get matched to an applicant $a_{i'}$ with $i' > j + 8 \log n$, it should reject at least $8 \log n$ applicants from set S. We will show that such an event is extremely unlikely.

Let $\mathcal{I}$ be the set of the indices of the first $8 \log n$ applicants interviewed by p_j. By the above argument, $\mathcal{I} \subseteq S$. By Claim 2, if p_j interviews some applicant a_i and observes that both ε_{ij}^A and ε_{ji}^P are non-negative, then p_j and a_i get matched. Since ε_{ij}^A and ε_{ji}^P are drawn independently at random from a symmetric distribution with mean zero, $\Pr[\varepsilon_{ij}^A \geq 0 \text{ and } \varepsilon_{ji}^P \geq 0] \geq 1/4$. Therefore,

$$\Pr[\nexists i \in \mathcal{I} \quad \varepsilon_{ij}^A \geq 0 \text{ and } \varepsilon_{ji}^P \geq 0] = \prod_{i \in \mathcal{I}} \Pr[\varepsilon_{ij}^A < 0 \text{ or } \varepsilon_{ji}^P < 0] \leq \left(\frac{3}{4}\right)^{8 \log n} \leq n^{-3}.$$

A union bound over the above events implies the probability that there exists an i such that a_i and p_j interview each other and $i > j + 8 \log n$ is at most n^{-2}.

The second part of the lemma follows by observing that as long as each position p_j with $j < n - 8 \log n$ gets matched to one of its first $8 \log n$ proposals, p_{j+1} does not receive any proposals before p_j is matched. ◀

For the rest of the section, we condition on the high probability events stated in Lemma 4. For $k \in [n]$, let $A_k = \{a_k, a_{k+1}, \ldots, a_n\}$ and $P_k = \{p_k, p_{k+1}, \ldots, p_n\}$. Also, let $\bar{A}_k = A \setminus A_k$ and $\bar{P}_k = P \setminus P_k$.

▷ Claim 5. For any $k \in [n]$,

$$\left|\{(a_i, p_j) \in \mu | i \geq k, j < k\}\right| \leq 8 \log n.$$

Proof. Since we condition on Lemma 4, $\{(a_i, p_j) \in \mu | i \geq k, j < k - 8\log n\} = \emptyset$. Therefore,

$$\left|\{(a_i, p_j) \in \mu | i \geq k, j < k\}\right| = \left|\{(a_i, p_j) \in \mu | i \geq k, k - 8\log n \leq j < k\}\right| \leq 8\log n. \quad \blacktriangleleft$$

▷ Claim 6. Suppose that the algorithm is considering the proposal between applicant a_{i^*} and position p_{j^*}. Then, for any $k \leq j^*$,

$$\left|\{(a_i, p_j) \in \mu | i < k, j \geq k\}\right| \leq 8\log n.$$

Proof. We need to prove the statement for $k < n - 8\log n$. By Lemma 4, when the algorithm is considering pair (a_{i^*}, p_{j^*}), we have $\mu(p_{j'}) \neq \emptyset$ for $j' < k$. By Claim 5,

$$\left|\{(a_i, p_j) \in \mu | i \geq k, j < k\}\right| \leq 8\log n$$

which implies,

$$\left|\{(a_i, p_j) \in \mu | i < k, j < k\}\right| \geq (k-1) - 8\log n. \tag{1}$$

On the other hand,

$$\begin{aligned}\left|\{(a_i, p_j) | i < k, j \geq k\}\right| &\leq (k-1) - \left|\{(a_i, p_j) | i < k, j < k\}\right| \\ &\leq 8\log n \qquad \text{(By } \textit{Equation } (1)\text{)}\end{aligned} \quad \triangleleft$$

▶ **Lemma 7.** *With a probability of at least $1 - 1/n$, if position p_j interviews applicant a_i then $j \leq i + 2000\log^2 n$.*

Proof. Let $\delta = 8\log n$ and $\gamma = 1999\log^2 n$. The statement holds for $i \geq n - \gamma - \delta$ since $n - i \leq \gamma + \delta < 2000\log^2 n$. Suppose for some $i < n - \gamma - \delta$, applicant a_i and position $p_{i+\gamma+1}$ interview each other at some point during the algorithm. At that time, by Lemma 4, all positions with index smaller than $i + \gamma + 1$ are matched to an applicant. Also, by Observation 3, all positions in $\{p_i, p_{i+1}, \ldots, p_{i+\gamma}\}$ have already interviewed a_i, but none of them is matched to a_i. We will show that the probability of such an event is at most n^{-4}.

Consider all positions p_l for $i \leq l \leq i + \gamma$ and define

$$S_l = \{a_i, a_{i+1}, \ldots, a_{l+\delta}\} \setminus \{\mu(p_{j'}) | i \leq j' < l\}.$$

By Claim 6, there are at most δ positions in the set of $\{p_{j'} | i \leq j' < l\}$ which are matched to an applicant with an index smaller than i. The rest are matched to an applicant in $\{a_i, a_{i+1}, \ldots, a_{l+\delta}\}$. Therefore, $|S_l| \leq 2\delta$.

Define Y_l to be indicating whether p_l's utility for matching to a_i is higher than being matched to all elements in S_l and X_l to be $Y_l = 1$, $\varepsilon^P_{li} \geq 0$, and $\varepsilon^A_{li} \geq 0$. By Claim 2, $X_l = 1$ implies that p_l can not be matched to an applicant with an index more than i. Further, by Claim 6 at most δ positions in $\{p_i, p_{i+1}, \ldots, p_{i+\gamma}\}$ may be matched to an applicant with index less than i, so it is sufficient to bound the probability that $X = \sum_{j=i}^{i+\gamma} X_j \leq \delta$.

Observe that $\Pr[Y_l = 1] \geq 1/(2\delta)$ for all l. Also, note that because of the independence of the subjective component of utilities, Y_l's are independent. Further, $E[X_l] = 1/4E[Y_l] \geq 1/(8\delta)$. Using Chernoff bound,

$$\Pr[X \leq \delta] \leq \Pr[|X - \mathbf{E}[X]| \geq \frac{\gamma}{16\delta}] \leq 2\exp\left(-\frac{\gamma^2/(16\delta)^2}{3\gamma/(8\delta)}\right) \leq 2\exp\left(-\frac{\gamma}{96\delta}\right) \leq n^{-2}.$$

The first inequality is due to $\mathbf{E}[X] - \frac{\gamma}{16\delta} \geq \frac{\gamma+1}{8\delta} - \frac{\gamma}{16\delta} > \frac{\gamma}{16\delta} \geq \delta$, assuming n is sufficiently large. Applying union bound over all applicants completes the proof. ◀

Proof of Theorem 1. The statements of Lemma 4 and Lemma 7 hold with high probability, for all applicants a_i. Therefore, every a_i is interviewed only by positions p_j where $j \in [\max(1, i - 8\log n), i + \min(n, 2000\log^2 n)]$. Similarly, for every position p_j in Algorithm 1, the position only interviews a_i's for which $i \in [\max(1, j - 2000\log^2 n), \min(n, j + 8\log n)]$. Therefore, the number of interviews done by each applicant or position is at most $O(\log^2 n)$.

The proof of stability is fairly similar to the analysis of deferred acceptance. Suppose there exists a blocking pair (a_i, p_j). This implies that $a_i \succ_{p_j} \mu(p_j)$ and $p_j \succ_{a_i} \mu(a_i)$. Therefore, a_i must have been rejected by p_j during one of the iterations of Algorithm 1. This implies that position p_j is matched with an applicant who has a higher observed utility, and the current match of p_j should not be worse than a_i, i.e., $\mu(p_j) \succ_{p_j} a_i$. That is a contradiction, as we initially assumed that (a_i, p_j) is a blocking pair. ◀

3 A Non-Adaptive Algorithm for Tiered Markets

The algorithm in the previous section forms the sequence of interviews adaptively, suggesting each interview based on the outcome of the earlier ones. However, many markets operate in a more simultaneous manner, where there is a stage of interviews followed by a clearing phase. Therefore, it may be more efficient if the interview lists are decided either in advance or independently for each position.

In this section, we present a non-adaptive algorithm for the problem in markets in which applicants and positions are partitioned into tiers, extending the model in [4] to allow for post interaction noise. Applicants have the same ex-ante utility for two positions in the same tier but prefer a position in a higher tier to a lower-tier position with probability 1. The same is true for positions.

More formally, let $0 = \tau_0 < \tau_1 < \ldots < \tau_M = m$ denote the tiers of positions. Remember the utility of an agent a_i for position p_j, $v_{ij} = v_j + \varepsilon^A_{ij}$. We will assume that $v_j = v_k$ if and only if p_j and p_k are in the same tier, i.e., $j, k \in [\tau_l + 1, \tau_{l+1}]$ for some l, and $v_j >> v_k$ if p_j is in a higher tier than p_k, i.e. $j \leq \tau_l < k$ for some l. Further, ε^A_{ij}'s are all independent and identically distributed, and their distributions are bounded and symmetric around 0. Therefore, $\Pr[v_{ij} \geq v_{ik}] = 1/2$ if p_j and p_k belong to the same tier and equal to 1 otherwise. We use *relative index* of a position to show the index of the position within the tier it belongs to. Formally, for position p_j where $\tau_{l-1} < j \leq \tau_l$, the relative index is equal to $j - \tau_{l-1}$. Define the tiers $0 = \gamma_0 < \gamma_1 < \ldots < \gamma_N = n$ for applicants similarly. We assume that the number of applicants and positions are equal in the general tiered markets, i.e. $n = m$, and every applicant and position will be matched. However, to develop the algorithm for the general tiered market, we use two subroutines that might need to solve a subproblem with $n \neq m$ case (see Section 3.1 and Section 3.2).

Our non-adaptive algorithm works in two phases. In the first phase, the algorithm proposes a set of interviews between the two sides. We represent this by a bipartite graph $G(A, P, E)$, where each edge $e \in E$ denotes an interview between its endpoints. In the second phase, after the interviews are conducted and the corresponding $\varepsilon^A_{ij}, \varepsilon^P_{ji}$ for $(a_i, p_j) \in E$ are revealed, the algorithm finds an interim stable matching between two sides. The main result of this section is that the proposed interviews in the first phase are such that (i) no agent or position has more than $O(\log^3 n)$ interviews, and (ii) after the interviews are done, the algorithm can find an interim stable matching supported by $G(A, P, E)$ with high probability.

In order to explain the main ideas of the algorithm, it will be instructive to look at two special cases in the following subsections.

3.1 Example 1: Single Tier Structure

In the first example, the applicants and positions are each in their own single tier, i.e. $N = M = 1$. The number of applicants and positions can be different[3] but assume that n and m are sufficiently large, and without loss of generality, $n \leq m$. In this case, first form G by connecting each applicant to δ positions chosen uniformly at random from the $P' = \{p_1, p_2, \ldots, p_n\}$.

Each applicant a_i interviews with δ positions and the distribution of ε_{ij}^A's are symmetrically distributed around 0. So, for every i, $\delta/2$ of the ε_{ij}^A's are going to be non-negative in expectation. In fact, a simple Chernoff bound shows that with high probability, for every applicant a_i, at least $\delta/3$ of positions p_j interviewing the applicant have a non-negative ε_{ij}^A.

▷ Claim 8. Among δ positions p_j that applicant a_i is interviewing, at least $\delta/3$ of them have $\varepsilon_{ij}^A \geq 0$ with probability $1 - \exp(-\delta/36)$.

Let π_i^A be the preference list of applicant a_i in the decreasing value of ε_{ij}^A (break ties randomly). It is not hard to see that each π_i^A is a random permutation chosen over the ordering of positions. Following the same argument, we can form π_j^P to be the random permutations representing the preference list of position p_j according to the decreasing values of ε_{ji}^P. The above observation allows us to take advantage of the following lemma.

▶ **Lemma 9** ([27], Theorem 6.1)**.** *Suppose that we run the applicant-proposing Gale-Shapley algorithm for the above random permutations. With probability $1 - O(m^{-c_t})$, each applicant a_i gets matched to a position with a rank less than $(2+t)\log^2 m$ in permutation π_i^A, where $c_t = 2t[3 + (4t+9)^{1/2}]^{-1}$.*

The above lemma combined with Claim 8 implies that every applicant a_i is matched with a position p_j where $\varepsilon_{ij}^A > 0$.

▶ **Lemma 10.** *For any t and δ such that $\delta \geq 3(2+t)\log^2 m$, with probability $1 - \exp(-\delta/36) - O(m^{-c_t})$, each applicant a_i gets matched to a position p_j that has interviewed a_i and $\varepsilon_{ij}^A > 0$, where $c_t = 2t[3 + (4t+9)^{1/2}]^{-1}$.*

3.2 Example 2: One Large Tier vs Multiple Singleton Tiers

In this example, all positions belong to the same tier, but each applicant is in a tier of its own. In other words, the applicants are ex-ante indifferent among positions, but all positions prefer applicant a_i to a_j when $i < j$.

Before presenting our solution, it may be worthwhile to understand why forming the interview graph randomly in the same fashion as our previous example is not suitable for this variation of the problem. First, note that since agent a_1 is the first choice for all the positions, a_1 should be matched to its most preferred position in every interim stable matching. Removing applicant a_1 and that position, the same argument applies to applicant a_2, and so on.

Now suppose that each applicant interviews δ random positions similar to the algorithm in Section 3.1. Since we choose δ random positions for applicant a_1 to interview and then applicant a_1 chooses the most preferred position after the interviews, all positions have

[3] Note that in the setting of the general tiered market, we assume $n = m$, however, the single tier structure serves as a subroutine of the algorithm for the general tiered market and might need to solve a subproblem with $n \neq m$.

the same probability of being the most preferred position for applicant a_1 in this process. Therefore, the process is equivalent to the case that we choose a random position for applicant a_1 and remove both, then we choose a random position for a_2 and remove both, and so on. Suppose the algorithm successfully matches the first $n-1$ applicants to their positions. When only the last applicant a_n remains, it is crucial to show that the only remaining position should be one of the positions that a_n interviewed. Otherwise, the resulting matching is not interim stable. Since we are removing positions randomly, the probability that the last remaining position is among the δ position that a_n interviewed is δ/m. Therefore, we cannot find an interim stable matching supported within G if we want $\delta = poly(\log m)$.

Instead, for this example, our algorithm forms G by connecting every agent a_i to positions p_j such that $j \in [\max(1, i-\theta), \min(n, i+\delta)]$, where $\theta = \Theta(\log^3 m)$ and $\delta = \Theta(\log^2 m)$. Note that the degree of applicants with an index close to 1 or n may be smaller than the rest of the applicants.

In this construction, applicants whose tiers are close to each other interview for sets of positions that are similar. Therefore, there is a high correlation between the positions to which they get matched. As a result, with high probability, for every i, the set of positions that have interviewed a_i and are not matched to one of the higher-tier applicants is non-empty. Further, a_i can find a stable match in this set. We will prove this statement in more generality in the next section when analyzing the algorithm for the general case.

3.3 An Algorithm for General Tiered Markets

We are now ready to present our algorithm and its analysis for tiered markets in their full generality. As we said before, the algorithm works in two phases. In phase 1, Algorithm 2 constructs a bipartite interview graph $G(A, P, E)$ between applicants and positions. This is done possibly in several iterations. In each iteration, i, the algorithm adds an edge set E_i between two subsets $A_i \subseteq A$ and $P_i \subseteq P$ to E. Further, it identifies whether the applicants or positions are going to be the proposing side in this part of the graph. Note that an applicant or a position can be in multiple A_is or P_is.

In the second phase, Algorithm 3 conducts the interviews between all the pairs in E and updates the preferences of the two sides. Then, in each iteration i, it removes vertices that are matched in earlier iterations and implements either a position or applicant-proposing deferred acceptance algorithm between A_i and P_i. We discuss the details of this algorithm later in the section.

In practice, one should first implement Algorithm 2 to construct the interview graph and then Algorithm 3 to implement the interviews and find the stable matching. But it will be useful for the analysis to couple the two algorithms and consider them together after each iteration i.

Algorithm 2 considers applicants and positions starting from the top. Let X and Y be the set of top-tier applicants and positions. Label the sets X and Y in such a way that $|X| \leq |Y|$. We will consider three different cases: (1) If both $|X|$ and $|Y|$ are relatively small, i.e. $|X| \leq \delta$ and $|Y| \leq \delta$ for $\delta = \Theta(\log^2 n)$, we can afford to set up an interview for each pair between X and Y. (2) If $|X| \leq \delta$ and $|Y| > \delta$, we choose a set S of size δ comprised of vertices of Y with the lowest index and set up an interview between each pair in S and X. (3) If both $|X|$ and $|Y|$ are large than δ, we use the same approach as Section 3.1. Specifically, for each vertex in X, we choose δ random vertices from the first $|X|$ positions in Y to interview.

When both $|X|$ and $|Y|$ are larger than δ, we can remove both X and the first $|X|$ vertices of Y from A and P and move to the next iteration of the algorithm. The situation is more subtle when for a short tier X, we choose a set $S \in Y$ which has a size larger than $|X|$. In this case, in the same iteration of Algorithm 3, some of the vertices of S will remain unmatched.

A priori, and without knowing the outcome of the interviews between these two sets, we do not know which vertices of S are going to remain unmatched. Therefore, we will not remove any vertex from Y immediately. Because of this subtlety, we will have to keep track of the "effective cardinality" $e(X)$ and $e(Y)$. They are updated to be equal to the number of unmatched vertices in X and Y, respectively, at the same iteration in Algorithm 3.

The algorithm continues in the same fashion. At every step, the top non-empty tiers X and Y from each side are selected and named so that $e(X) \leq e(Y)$. We call X the *short side* and Y the *long side*.

Algorithm 2 The Algorithm for Constructing the Interview Graph.

Let $\delta = 36 \log^2 n$ and $\theta = 72 \log^3 n$.
Initialize $e(X) = |X|$ for all tiers X as the number of unmatched vertices in the tier.
Initialize $G(A, P, E)$ to be an empty graph, $D \leftarrow []$, and $k \leftarrow 1$.
while $A \neq \emptyset$ *and* $P \neq \emptyset$ **do**
    Consider the top non-empty tiers of A and P and label them X and Y s.t. $e(X) \leq e(Y)$.
    if $e(Y) \leq \delta$ **then**
        Let E_k be the set of all edges between X and Y. ▷ Case 1
        $e(Y) \leftarrow e(Y) - e(X)$.
    else if $e(X) \leq \delta$ **then**
        Let S be the set of $\delta + |Y| - e(Y)$ vertices in Y with the lowest index. ▷ Case 2
        Let E_k be the set of all edges between X and S.
        $e(Y) \leftarrow e(Y) - e(X)$.
    else
        Let S be the set of $e(X) + |Y| - e(Y)$ vertices in Y with the lowest index. ▷ Case 3
        Form E_k by connecting each $x \in X$ to $\delta + |Y| - e(Y)$ random vertices of S.
        Remove all vertices of S from Y and then $e(Y) \leftarrow e(Y) - e(X) = |Y|$.
    if X *is in applicant side* **then** $D(k) \leftarrow$ 'applicant proposing';
    else $D(k) \leftarrow$ 'position proposing';
    Remove all vertices of X and $e(X) \leftarrow 0$.
    if $e(Y) = 0$ **then** remove all vertices of Y;
    if $|Y| - e(Y) \geq \theta$ **then** remove the $|Y| - e(Y) - \theta$ vertices of Y with lowest indices;
    $k \leftarrow k + 1$.
return $G(A, P, E = \bigcup_{i<k} E_i), D, k$.

In the rest of this section, we prove the correctness of the algorithm and give an upper bound on the number of interviews done by every applicant or position. First, we show that at any time during the algorithm $e(X)$ is close to $|X|$.

▶ **Invariant 11.** *For a tier X, after every iteration during the course of Algorithm 2, $e(X) \leq |X| < e(X) + \theta$.*

Proof. We prove this by induction on the number of iterations. Initially, $|X| = e(X)$. Now assume that $e(X) \leq |X| < e(X) + \theta$ before the ith iteration. If X is the short side in iteration i, then all vertices of X will be removed after this iteration, and thus $|X| = e(X) = 0$. Also, if X is the long side and the algorithm is in case 3, then $|X| = e(X)$ by Algorithm 2 of Algorithm 2.

In all other cases, $e(X)$ decreases after the iteration. Further, by Algorithm 2, if $|X| - e(X) \geq \theta$, we remove vertices of X for which $|X| < e(X) + \theta$. ◀

Also, it is not hard to see that all applications and positions will be removed by the end of Algorithm 2.

▶ **Observation 12.** *After the last iteration of Algorithm 2, all applicants and positions are removed.*

Proof. Let $X_1, \ldots, X_{\tau_M}$ be all tiers of positions and $Y_1, \ldots, Y_{\tau_N}$ be all tiers of applicants. Note that $\sum_{i=1}^{\tau_M} e(X_i) = \sum_{i=1}^{\tau_N} e(Y_i)$ at all times during the execution of Algorithm 2 since in all three cases, the effective cardinality of the short side tier is subtracted from both $\sum_{i=1}^{\tau_M} e(X_i)$ and $\sum_{i=1}^{\tau_N} e(Y_i)$. Since the algorithm does not terminate until either or both $\sum_{i=1}^{\tau_M} e(X_i) = 0$ or $\sum_{i=1}^{\tau_N} e(Y_i) = 0$, then all vertices are removed when the algorithm terminates. ◀

Algorithm 3 Algorithm for Finding a Stable Matching after the Interviews.

```
Let G(A, P, E), D, and k be the output of Algorithm 2.
Interview all edges of G.
for i = 1 to k − 1 do
    if D_i = 'applicant proposing' then
        Run applicant proposing Gale-Shapley on the unmatched endpoints of E_i.
    else
        Run position proposing Gale-Shapley on the unmatched endpoints of E_i.
return the matching.
```

We let A_i be the set of applicants that are endpoints of E_i. We define P_i similarly. Moreover, let $A'_i \subseteq A_i$ and $P'_i \subseteq P_i$ be the set of applicants and positions that are endpoints of E_i, and are unmatched when we run Gale-Shapley in Algorithm 3 between A_i and P_i. Therefore, if A_i and P_i belongs to tiers X and Y, then $|A'_i| = e(X)$ and $|P'_i| = e(Y)$ at the time of iteration i. As we mentioned before, a vertex may appear in multiple A_is or P_is. We will show that such sets are consecutive. To do so, we first give a helpful property of the algorithm.

▷ Claim 13. For a tier X that has interview with tiers $Y_1, Y_2, \ldots, Y_r$ where $e(Y_i) \leq \delta$ for all i, define X^{j-1} be tier X before interviewing with Y_j in Algorithm 2 for $j \in [1, r]$. Suppose $e(X^{j-1}) > \delta$ for $j \in [1, r]$, then all vertices in X^{j-1} with relative indices at most $S(X) + \delta - e(X^{j-1})$ will be selected for interview with Y_j, and $e(X^j) = e(X^{j-1}) - e(Y_j)$, where $S(X)$ is the initial size of tier X before the execution of Algorithm 2.

Proof. The algorithm always chooses vertices with the lowest index from the long side to interview. Consider the interview with Y_j, those are the vertices with a relative index of $S(X) - |X^{j-1}| + 1$ to $(S(X) - |X^{j-1}|) + (\delta + |X^{j-1}| - e(X^{j-1})) = S(Z) + \delta - e(X^{j-1})$. And by definition of Algorithm 2, $e(X^j) = e(X^{j-1}) - e(Y_j)$. ◁

▷ Claim 14. For each vertex v, there exist L and R such that v is in A_i or P_i iff $L \leq i \leq R$.

Proof. Let Z be the tier containing v and $S(Z)$ be the initial size of tier Z at the start of Algorithm 2. Also, let L be the first iteration considering v and $e(Z)$ be the effective size of tier Z at that point. It is not hard to see that if Z is the short side in this iteration, or if the short side Z' has size $e(Z') > \delta$, all the vertices of Z that have an interview in this iteration will be removed, and we are done. When Z is the long side and $e(Z) \leq \delta$, every vertex in Z will be interviewed.

The only remaining case to consider is where Z is on the long side, $e(Z) > \delta$, and the tiers considered alongside v are $Y_1, Y_2, \dots Y_r$, where $e(Y_i) \leq \delta$ for all i. From Claim 13 and the fact that $e(Z)$ decreases monotonically, as long as v is not removed from the graph, it will be selected for interview, which means it will be the endpoint of at least one edge in E_i. That implies v is in A_i or P_i by definition. ◁

▶ **Lemma 15.** *Suppose $a_r \in A'_i$, $|A'_i| \leq |P'_i|$, and $|P'_i| \geq \delta$. Then, with probability $1-O(1/n^2)$, a_r gets matched in iteration i of Algorithm 3 to some position $p_j \in P'_j$ such that $\varepsilon^A_{rj} > 0$.*

Proof. Let X and Y be two tiers that vertices of A_i and P_i belong to, respectively. Also, by the definition of A'_i, we have $|A'_i| = e(X)$ at the time of ith iteration. If $e(X) \leq \delta$, since $|P'_i| \geq \delta$, we choose a subset S of Y with size $\delta + |Y| - e(Y)$ and interview all edges. This set contains δ vertices that are not matched at ith iteration. By Lemma 10, if we choose $t = 10 \log^2 n / \log^2 e(Y)$, then $c_t > 2 \log n / \log e(Y)$ and with probability

$$1 - \exp(-\delta/36) - O\left(e(Y)^{-2 \log n / \log e(Y)}\right) \geq 1 - O\left(\frac{1}{n^2}\right),$$

a_r will match to a position $p_j \in P'_i$ such that $\varepsilon^A_{rj} > 0$.

Similarly, if $e(X) > \delta$, we choose a subset S of Y that contains $e(X)$ unmatched vertices. For each vertex of A'_i we interview δ random positions in P'_j. Hence, if we choose $t = 10 \log^2 n / \log^2 e(X)$ in Lemma 10, then $c_t > 2 \log n / \log e(X)$, and with probability

$$1 - \exp(-\delta/36) - O\left(e(X)^{-2 \log n / \log e(X)}\right) \geq 1 - O\left(\frac{1}{n^2}\right),$$

a_r will match to a position $p_j \in P'_i$ such that $\varepsilon^A_{rj} > 0$. ◀

▶ **Lemma 16.** *With probability $1-O(1/n^2)$, if a vertex is removed in iteration i of Algorithm 2, it will get matched via an edge in $\cup_{j \leq i} E_j$.*

Proof. Without loss of generality, assume that the removed vertex in iteration i is applicant a_r in tier X. Let Y be the tier of the other side that the algorithm considers in iteration i. First, assume that X is the short side, $e(X) \leq \delta$, and $e(Y) \leq \delta$ at iteration i. According to Case 1 of Algorithm 2, all vertices of X interview all vertices of Y, hence, the statement hold with probability 1. Now suppose that X is the short side and $e(Y) > \delta$ at iteration i. Hence, by definition, we have $|A'_i| \leq |P'_i|$ and $|P'_i| > \delta$. Therefore, by Lemma 15, a_r is matched to a position p_j such that $\varepsilon^A_{ij} > 0$ with probability $1 - O(1/n^2)$, which implies that $(a_r, p_j) \in E_i$. Furthermore, if $e(X) > \delta$, $e(Y) > \delta$, and X is the long side, $|A'_i| = |P'_i|$. Since for this case we run a position-proposing Gale-Shapley in Algorithm 3, by Lemma 15, all positions in P'_i get matched to applicants in A'_i with edges E_i. Thus, all vertices of A'_i are matched to positions in P'_i using edges E_i since we have $|A'_i| = |P'_i|$.

The only case that remains to be investigated is when X is the long side in several iterations until a_r is removed at iteration i, i.e. $a_r \in A_j$, $|A'_j| \geq |P'_j|$ for $j \in [l, i]$ and $|P'_j| \leq \delta$. Also, let $Y_l, Y_{l+1}, \dots, Y_i$ be the tiers of the other side in each iteration. Let $C_r = \sum_{l \leq j \leq i} e(Y_j)$. First, we prove that $C_r \geq \theta$.

Let X^{j-1} be tier X before the jth iteration of Algorithm 2 for $j \in [l, i+1]$. Also, let ψ be the relative position of a_r in tier X before any iteration. During iteration $j \in [l, i]$, since $|e(Y_j)| \leq \delta$, Claim 13 shows that (1) every vertex in X^j with index at most $S(X) + \delta - e(X^{j-1})$ is in A_j; (2) $e(X^j) = e(X^{j-1}) - e(Y_j)$. For X^{l-1}, the first case is that $e(X^{l-1}) = |X^{l-1}|$ and $S(X) - e(X^{l-1}) + 1 \leq \psi$ when there is no iteration on X before or when $|Y_{l-1}| > \delta$, and the second case is that $\psi > S(X) + \delta - e(X^{l-2}) \geq S(X) + e(Y_{l-1}) - e(X^{l-2}) \geq S(X) - e(X^{l-1})$

when $|Y_{l-1}| \leq \delta$. In both cases, we have $\psi \geq S(X) - e(X^{l-1}) + 1$. Since a_r is removed in iteration i, we have $S(X) - (e(X^i) + \theta) + 1 \geq \psi$, thus $C_r = \sum_{l \leq j \leq i} e(Y_j) = e(X^{l-1}) - e(X^i) \geq \theta$.

Now consider iteration j and suppose that a_r is not matched yet. Then, with a probability of at least $|P'_j|/\delta$, applicant a_r will be matched in iteration j because all applicants of A'_j are in the same tier, and subjective interests are i.i.d. Moreover, $|P'_j| = e(Y_j)$ by definition. Therefore, the probability that a_r remains unmatched after iteration i is at most

$$\prod_{j=l}^{i} \left(1 - \frac{|P'_j|}{\delta}\right) = \prod_{j=l}^{i} \left(1 - \frac{e(Y_j)}{\delta}\right) \leq \exp\left(-\frac{C_r}{\delta}\right) \leq \exp\left(-\frac{\theta}{\delta}\right),$$

which completes the proof because of our choice of δ and θ. ◀

Using a similar argument as Lemma 16, the next lemma gives a bound on the degree of every node in G.

▶ **Lemma 17.** *The number of interviews assigned to every position or applicant is at most* $O(\log^3 n)$

Proof. We will show the above for every applicant a_r. The proof for positions is the same. Let X be the tier that a_r belongs to. If X is the tier of the short side at iteration i, then a_r has at most $O(\theta)$ incident edges in E_i by definition of Algorithm 2 and Invariant 11. Also, if both $|A'_i| > \delta$ and $|P'_i| > \delta$, by Case 3 of the Algorithm 2 and Invariant 11, each vertex in A_i or P_i has at most $O(\theta)$ interviews in iteration i. Note that each vertex is in one of the above scenarios at most in one iteration since after that it gets removed. Therefore, similar to the proof of the previous lemma, it only remains to show that the number of interviews is bounded when X is the long side in several iterations until a_r is removed at iteration i, i.e. $a_r \in A_j$, $|A'_j| \geq |P'_j|$ for $j \in [l, i]$, and $|P'_j| \leq \delta$. Let $Y_l, Y_{l+1}, \ldots, Y_i$ be the tiers of the other side in each iteration.

Define C_r, ψ, and X^j for $j \in [l-1, i]$ as before. With a similar argument, we have $\psi \leq S(X) + \delta - e(X^{l-1})$, and

$$\begin{aligned}
\psi \geq S(X) - |X^{i-1}| + 1 &\geq S(X) - e(X^{i-1}) - (|X^{i-1}| - e(X^{i-1})) + 1 \\
&\geq S(X) - e(X^{i-1}) - \theta \\
&\geq S(X) - e(X^i) - (e(X^i) - e(X^{i-1})) - \theta \\
&\geq S(X) - e(X^i) - (\theta + \delta)
\end{aligned}$$

Thus, $C_r \leq e(X^{l-1}) - e(X^i) \leq \theta + 2\delta$. Note that the number of interviews for a_r is equal to $\sum_{i \leq j \leq i} |Y_j|$. For all tiers except Y_l, we have $e(Y_j) = |Y_j|$ at the time of the iteration j. Also, by Invariant 11, we have $|Y_l| \leq e(Y_l) + \theta$. Therefore,

$$\sum_{i \leq j \leq i} |Y_j| \leq e(Y_l) + \theta + \sum_{l < j \leq i} e(Y_j) = C_r + \theta \leq 2(\theta + \delta),$$

which implies the total number of interviews for vertex a_r is at most $O(\theta) = O(\log^3 n)$ before it gets removed which concludes the proof. ◀

▶ **Lemma 18.** *The matching produced by the algorithm is an interim stable matching with probability* $1 - O(1/n)$.

Proof. By Observation 12, all applicants and positions are removed from the graph after Algorithm 3 finishes. Using union bound for all vertices in Lemma 16, with probability $1 - O(1/n)$, all vertices are matched using an edge in E. Consider tiers X and X' from applicants and tiers Y and Y' from positions and suppose that X is a higher tier than X' and Y is higher than Y'. Let $H_1 = X \times Y'$ and $H_2 = X' \times Y$. We claim that at most one of the following holds: $H_1 \cap E \neq \emptyset$ or $H_2 \cap E \neq \emptyset$. Without loss of generality, suppose that $H_1 \cap E \neq \emptyset$. This implies that at some iteration i of the Algorithm 2, the algorithm considers tiers X and Y' in Algorithm 2. Hence, all vertices of Y should be already removed, which implies $H_2 \cap E = \emptyset$.

Now, consider applicant a_i and position p_j that are not matched to each other. We prove that (a_i, p_j) is not a blocking pair. Let $\mu(a_i)$ and $\mu(p_j)$ be the matches of a_i and p_j, respectively. Also, let X and Y be the tiers that include a_i and p_j, respectively. We use $X \succ X'$ to show tier X is preferable to tier X'. If $\mu(a_i) \in Y'$ such that $Y' \succ Y$, then this pair is not a blocking pair since $\mu(a_i) \succ_{a_i} p_j$. A similar argument works for $\mu(p_j)$. By the above argument, $\mu(a_i)$ and $\mu(p_j)$ does not belong to tiers Y' and X' such that $X \succ X'$ and $Y \succ Y'$. Hence, either or both $\mu(a_i) \in Y$ and $\mu(p_i) \in X$. Thus, X and Y are once considered at the same time in one iteration in Algorithm 2 of Algorithm 2.

Without loss of generality, suppose that at iteration r, the algorithm considers X and Y in Algorithm 2 and X is the short side. By definition, we have $a_i \in A'_r$. If $p_j \notin P'_r$, then $|P'_r| \geq \delta$, which implies that $\varepsilon^A_{i\mu(a_i)} > 0$. Thus, (a_i, p_j) is not a blocking pair. If $p_j \in P'_r$, since the algorithm finds a stable matching between A'_r and P'_r, then (a_i, p_j) is not a blocking pair, which finishes the proof. ◀

▶ **Theorem 19.** *There exists a non-adaptive algorithm that finds an interim stable matching for tiered ranking agents with high probability such that the number of interviews done by each applicant or position is at most* $O(\log^3 n)$.

Proof. By Lemma 18, the matching returned by the algorithm is interim stable. Furthermore, by Lemma 16, each applicant or position has at most $O(\log^3 n)$ interviews. ◀

3.4 Extension

In the aforementioned tiered market scenario, we presume the absence of ex-ante preferences within a tier. However, agents may have distinct individual preferences within tiers. For example, in the medical context preferences can be shaped by various factors, including geographical location, the availability of extracurricular activities, specific research laboratories they aspire to join, etc. To capture this characteristic of the market, we introduce the following model. Applicant a_i's utility v_{ij} for position p_j is now defined to be $v_{ij} = v_j + \eta^A_{ij} + \varepsilon^A_{ij}$, where $v_j = v_k$ if and only if p_j and p_k are in the same tier, and $v_j >> v_k$ if p_j is in a higher tier; η^A_{ij} is a small random perturbation of the ex-ante preference which is known before the interview; For now, we assume that η^A_{ij}s and ε^A_{ij}s are all drawn from the uniform distribution over [-1,1] independently. The same applies to positions.

We first briefly argue that our algorithm works for the extended tiered markets. Consider the first subproblem, Single Tier Structure.

- Using the same Chernoff bound arguments, we can prove that for each applicant, there is a constant c such that δ/c of the interviewed position has $\eta^A_{ij} + \varepsilon^A_{ij} > 1$.
- In the extended model, the preference lists are still random permutations over the randomness of both η and ε, thus each applicant will be matched to a position with a high rank.

Combine the above facts, we can give a similar argument as Lemma 10 that each applicant gets matched to an interviewed position with $\eta_{ij}^A + \varepsilon_{ij}^A > 1$. In this way, when we use it as a subroutine, it still satisfies the property that the applicant would never want to switch to positions that are not interviewed in the same tier since $\eta_{ik}^A < 1$.

Consider the second subproblem, One Large Tier v.s. Multiple Singleton Tiers. Using a similar Chernoff argument as above, it is guaranteed that a higher-tier applicant is matched to the most preferred available position that is interviewed with $\eta_{ij}^A + \varepsilon_{ij}^A > 1$. Thus they have no incentive to switch.

The proof for the extended general case is a combination of the two extended subproblems, and can be modified from the current one by changing the arguments in Lemma 15 from $\varepsilon_{ij}^A > 0$ to $\eta_{ij}^A + \varepsilon_{ij}^A > 1$.

▶ Remark. Although the boundedness of uniform distribution plays an important role in the analysis, more general distributions work, as long as with constant probability $\eta_{ij}^A + \varepsilon_{ij}^A$ is larger than the maximum of n i.i.d. η_{ik}^As.

4 Conclusion

The extensive body of work on two-sided matching has given rise to a comprehensive theory and efficient implementations in real-world scenarios. The majority of these studies assume that agents are fully aware of their preferences. This leaves a critical aspect – the interaction period where agents learn about their preferences via mutual interaction – largely under-explored. The current paper ventures into this area, using an algorithmic lens to extend Gale-Shapley's deferred acceptance to this setting.

We present an algorithmic approach that extends Gale-Shapley's deferred acceptance to include situations where agents form preferences during the interaction period. We propose two algorithms. The first, an adaptive algorithm, integrates interviews between applicants and positions into Gale-Shapley's deferred acceptance. Like deferred acceptance, one side sequentially proposes to the other. However, the order of proposals is arranged to increase the chances of achieving an interim stable match. Further, our analysis shows that the number of interviews conducted by each applicant or position is, with high probability, limited to $O(\log^2 n)$.

We also propose a non-adaptive algorithm for markets where the dynamics consist of an initial interview phase followed by a clearing stage. In these situations, having prearranged interview lists for each position may be necessary. Our non-adaptive algorithm creates these lists simultaneously. It aims to find a stable match in markets where applicants and positions are divided into tiers, and it limits the number of interviews for each applicant or position to no more than $O(\log^3 n)$.

We point out that the algorithms in this work do not account for the incentives of applicants or positions, i.e., mechanisms induced by the algorithm don't carry the dominant strategy incentive compatible (DSIC) property as the Gale-Shapley's algorithm.

A Deferred Proofs

▷ Claim 8. Among δ positions p_j that applicant a_i is interviewing, at least $\delta/3$ of them have $\varepsilon_{ij}^A \geq 0$ with probability $1 - \exp(-\delta/36)$.

Proof. Denote X_{ij} as the indicator random variable of whether $\varepsilon_{ij}^A \geq 0$, set P_i as the set of positions that applicant a_i is interviewing, and $X_i = \sum_{p_j \in P_i} X_{ij}$ as the total number of interviewed positions with $\varepsilon_{ij}^A \geq 0$. By definition, we know that X_{ij}'s are i.i.d. Bernoulli random variables with mean $1/2$. By Chernoff bound, we have

$$\Pr\left[X_i \leq \frac{\delta}{3}\right] \leq \Pr\left[X_i \leq \left(1 - \frac{1}{3}\right)\frac{\delta}{2}\right] \leq \exp\left(-\frac{\delta}{36}\right),$$

which finishes the proof. ◁

Low Sensitivity Hopsets

Abstract

Given a weighted graph $G = (V, E, w)$, a (β, ε)-hopset H is an edge set such that for any $s, t \in V$, where s can reach t in G, there is a path from s to t in $G \cup H$ which uses at most β hops whose length is in the range $[\mathsf{dist}_G(s,t), (1+\varepsilon)\mathsf{dist}_G(s,t)]$. We break away from the traditional question that asks for a hopset H that achieves small $|H|$ and small diameter β and instead study the *sensitivity* of H, a new quality measure. The sensitivity of a vertex (or edge) given a hopset H is, informally, the number of times a single hop in $G \cup H$ bypasses it; a bit more formally, assuming shortest paths in G are unique, it is the number of hopset edges $(s,t) \in H$ such that the vertex (or edge) is contained in the unique st-path in G having length exactly $\mathsf{dist}_G(s,t)$. The sensitivity associated with H is then the maximum sensitivity over all vertices (or edges). The highlights of our results are:

- A construction for $(\widetilde{O}(\sqrt{n}), 0)$-hopsets on undirected graphs with $O(\log n)$ sensitivity, complemented with a lower bound showing that $\widetilde{O}(\sqrt{n})$ is tight up to polylogarithmic factors for any construction with polylogarithmic sensitivity.
- A construction for $(n^{o(1)}, \varepsilon)$-hopsets on undirected graphs with $n^{o(1)}$ sensitivity for any $\varepsilon > 0$ that is at least inverse polylogarithmic, complemented with a lower bound on the tradeoff between β, ε, and the sensitivity.
- We define a notion of sensitivity for β-shortcut sets (which are the reachability analogues of hopsets) and give a construction for $\widetilde{O}(\sqrt{n})$-shortcut sets on *directed* graphs with $O(\log n)$ sensitivity, complemented with a lower bound showing that $\beta = \widetilde{\Omega}(n^{1/3})$ for any construction with polylogarithmic sensitivity.

We believe hopset sensitivity is a natural measure in and of itself, and could potentially find use in a diverse range of contexts. More concretely, the notion of hopset sensitivity is also directly motivated by the Differentially Private All Sets Range Queries problem [Deng et al. WADS 23]. Our result for $O(\log n)$ sensitivity $(\widetilde{O}(\sqrt{n}), 0)$-hopsets on undirected graphs immediately improves the current best-known upper bound on utility from $\widetilde{O}(n^{1/3})$ to $\widetilde{O}(n^{1/4})$ in the pure-DP setting, which is tight up to polylogarithmic factors.

1 Introduction

Many fundamental graph-theoretic problems involve the computation of reachability and shortest path distances. In a variety of computation models (e.g. parallel, distributed, streaming, dynamic), the computation of shortest paths of most state-of-the-art algorithms scales with the *hop-diameter* [7, 12, 13, 24–26, 28, 29, 33–35]. The hop-diameter of a graph refers to the maximum hop-length over reachable pairs of vertices, where the hop-length from vertex s to vertex t is the minimum number of edges in a shortest st-path. Motivated by the goal of reducing hop-diameter, Thorup introduced the notion of a *shortcut set* [44], which is a set of edges H added to a given graph G such that: $G \cup H$ has the same reachability structure as G (i.e. for all vertices s and t, s can reach t in $G \cup H$ if and only if s can reach t in G) and $G \cup H$ has small hop-diameter. The shortcut set was later generalized to the *hopset* by Cohen [16] (also informally by [35, 41]) which preserves (weighted) shortest distances in addition to reachability. Formal definitions are given below.

▶ **Definition 1** (Shortcut Set). *Given a graph $G = (V, E)$, a* β-shortcut set *of G is a set of edges $H \subseteq V \times V$ such that: (1) Every edge $(s, t) \in H$ is in the transitive closure of G. (2) For every vertex pair (s, t) in the transitive closure of G, there is an st-path in $G \cup H$ with at most β edges.*

▶ **Definition 2** (Hopset). Given a weighted graph $G = (V, E, w)$, a (β, ε)-*hopset* of G is a set of weighted edges $H \subseteq V \times V$ such that: (1) Every edge $(s, t) \in H$ has a weight of $\mathsf{dist}_G(s, t)$, where $\mathsf{dist}_G(s, t)$ stands for the shortest distance between s, t in graph G. (2) For every vertex pair (s, t) in the transitive closure of G, there is an st-path P_{st} in $G \cup H$ with at most β edges, and the weight of P_{st} is at most $(1 + \varepsilon)\mathsf{dist}_G(s, t)$.

A $(\beta, 0)$-hopset is sometimes called an exact hopset, while (β, ε)-hopsets for $\varepsilon > 0$ are called approximate hopsets. For both shortcut sets and hopsets, a natural measure of their *cost* is their size (i.e. the number of edges added). There has been a rich literature studying the tradeoff between the size of a shortcut/hopset and the hop-diameter for both directed and undirected graphs [2, 6, 8, 11, 20, 21, 30, 31, 36–40, 46, 47].

A New Problem: Low-Sensitivity Hopsets

In some settings, measuring the cost of a hopset by its total number of edges provides information that is too coarse and not descriptive enough to capture the problem. In this work, we instead consider a notion of cost that is more local to individual vertices and edges. Specifically, we define the notion of the *sensitivity* of a hopset[1].

Informally, given a graph $G = (V, E)$ and a hopset H, the sensitivity of a vertex v is the number of hopset edges that bypass v. We say a hopset edge $(s, t) \in H$ bypasses v if v is on the unique[2] st-path in G having length exactly $\mathsf{dist}_G(s, t)$. The vertex sensitivity associated

[1] To avoid redundancy, we use hopset as a general term for shortcut/approximate/hopset unless specified otherwise.

[2] We assume shortest paths are unique now. Later we formally define the conditions for non-unique shortest paths.

with H is then the maximum sensitivity over all vertices. The edge sensitivity is defined in a similar way. We denote the hopset vertex/edge sensitivity by $\|\widehat{\mathsf{v}}\|_\infty$ and $\|\widehat{\mathsf{e}}\|_\infty$[3], and defer the formal definitions to Section 3.1.

We say a hopset H has low sensitivity if it has a vertex/edge sensitivity of polylog(n). We also define an analogous notion of a *low-sensitivity shortcut set*. Since shortcut sets pertain to reachability instead of shortest paths, and there could be many paths between a vertex pair s, t, it is not clear a priori which path should absorb the sensitivity of a shortcut edge from s to t. We allow the algorithm to specify the paths; that is, the input is a graph, and the output is a path between each pair of vertices as well as a shortcut set that has low sensitivity with respect to the chosen paths.

A closely related concept is the *support size* of a hopset, first studied in [22] to get recently improved path-reporting distance oracles (PRDOs); see [14] for the latest on PRDOs. The support size of a hopset H is, loosely speaking, the number of edges in G that are bypassed by edges from H. This can be seen as the ℓ_0 norm of a certain vector whereas, in contrast, hopset sensitivity is the ℓ_∞ norm of the same vector (as the notation $\|\widehat{\mathsf{e}}\|_\infty$ suggests[4]).

At any rate, we investigate tradeoffs between hopset sensitivity and hop-diameter in this work. We believe hopset sensitivity is a natural measure in and of itself, and could potentially find use in a diverse range of contexts. In fact, low-sensitivity hopsets have already been implicitly studied in several prior works [15, 18, 23]. These prior works come from the area of differential privacy where sensitivity is a crucial concept since it captures the effect of the perturbation of individual data points on the output of an algorithm. Our new low-sensitivity hopset constructions directly improve the bounds from [18] for the problem of *Differentially Private Range Queries*. More details on this concrete application, as well as other applications of a more speculative nature, can be found in Section 1.2.

1.1 Our Results

We study upper and lower bounds for low-sensitivity shortcut sets, exact hopsets, and approximate hopsets, on both undirected and directed graphs.

To give context to our results, we draw parallels to the different regimes for traditional hopsets. For hopsets with $O(n)$ edges, there are essentially three diameter regimes: (1) directed shortcut/hopsets as well as undirected exact hopsets all provably require polynomial hop-diameter, (2) *approximate* hopsets for undirected graphs require only $n^{o(1)}$ hop-diameter, and (3) undirected shortcut sets trivially achieve diameter 2. Roughly speaking, these diameter regimes also hold for the low-sensitivity counterparts.

Our results focus on low-sensitivity undirected exact hopsets and directed shortcut sets from regime 1, as well as low-sensitivity approximate undirected hopsets from regime 2. For all of these, we prove both upper and lower bounds.

An overview of upper and lower bound results of all settings is shown in Table 1. Observe that the edge sensitivity of a hopset is always no more than the vertex sensitivity (formally proved in Section 3.2). Thus, it is always more desirable to have upper bounds for vertex sensitivity and lower bounds for edge sensitivity. All of our results are of this form.

[3] The arc is meant to be evocative of bypassing hopset edges. When they bypass vertices, we draw the arc over the symbol v and when they bypass edges, we draw the arc over the symbol e.

[4] In fact, we also look at the ℓ_1 norm in the proofs of our lower bounds in Section 5.

Table 1 Our Results for sensitivity and hop-diameter for shortcut sets, exact hopsets, and $(1+\varepsilon)$ hopsets. Regarding the undirected approximate hopset, the upper bound has $\varepsilon > 0$ at least inverse polylogarithmic and, in the lower bound, k is any positive integer and Δ is any small positive constant.

		Shortcut Set	Hopset	$(1+\varepsilon)$ Hopset
Undirected	U. B.	$\beta = O(\log^2 n)$ $\|\widehat{\mathsf{v}}\|_\infty = O(\log n)$ ([23])	$\beta = O(\sqrt{n}\log n)$ $\|\widehat{\mathsf{v}}\|_\infty = O(\log n)$ (Details in full version [4])	$\beta = n^{o(1)}$ $\|\widehat{\mathsf{v}}\|_\infty = n^{o(1)}$ (Details in full version [4])
	L. B.	–	$\|\widehat{\mathsf{e}}\|_\infty \cdot \beta^2 = \Omega(n)$ (Section 5.1)	$\beta = O_k((1/\varepsilon)^k)$ $\Rightarrow \|\widehat{\mathsf{e}}\|_\infty = \Omega(n^{\frac{1}{2^k-1}-\Delta})$ (Details in full version [4])
Directed	U. B.	$\beta = O(\sqrt{n}\log^3 n)$ $\|\widehat{\mathsf{v}}\|_\infty = O(\log n)$ (Details in full version [4])	$\beta = O(\sqrt{n}\log n)$ $\|\widehat{\mathsf{v}}\|_\infty = O(\sqrt{n}\log n)$ ([15, 18])	$\beta = O(\sqrt{n}\log n)$ $\|\widehat{\mathsf{v}}\|_\infty = O(\sqrt{n}\log n)$ (Implied by directed exact hopset)
	L. B.	$\|\widehat{\mathsf{e}}\|_\infty \cdot \beta = \Omega(n^{1/3})$ (Section 5.1)	$\|\widehat{\mathsf{e}}\|_\infty \cdot \beta^2 = \Omega(n)$ (Implied by undirected hopset)	$\|\widehat{\mathsf{e}}\|_\infty \cdot \beta = \Omega(n^{1/3})$ (Implied by directed shortcut set)

Undirected Exact Hopsets

Our first result is for low-sensitivity exact hopsets on undirected graphs. We show it is possible to achieve hop-diameter $\widetilde{O}(\sqrt{n})$ and $O(\log n)$ vertex sensitivity.

▶ **Theorem 3** (Undirected Exact Hopset Upper Bound). *There exists an algorithm producing an $(O(\sqrt{n}\log n), 0)$-hopset with $\|\widehat{\mathsf{v}}\|_\infty = O(\log n)$ over undirected and directed acyclic graphs.*

We complement our upper bound with a lower bound showing that a hop-diameter of $\widetilde{O}(\sqrt{n})$ is *tight* up to polylogarithmic factors, for any hopset with polylogarithmic (vertex- or edge-) sensitivity.

▶ **Theorem 4** (Undirected Exact Hopset Lower Bound). *Any construction of $(\beta, 0)$-hopsets H must have $\|\widehat{\mathsf{e}}\|_\infty \cdot \beta^2 = \Omega(n)$ for a graph G on n vertices.*

Our lower bound exhibits a smooth trade-off between hop-diameter and sensitivity. One could ask whether such a trade-off exists for upper bounds as well. As we show (see Remark 34), such a trade-off would imply the non-existence of certain *perfect path* systems, which is a big open problem in network design. The existence of such perfect path systems would imply, for example, better lower bounds for distance preservers [17].

Directed Shortcut Sets

For directed shortcut sets, we prove an upper bound with similar guarantees to our upper bound for undirected exact hopsets.

▶ **Theorem 5** (Directed Shortcut Set Upper Bound). *There exists an algorithm producing an $O(\sqrt{n}\log^3 n)$-shortcut set with $\|\widehat{\mathsf{v}}\|_\infty = O(\log n)$ for directed graphs.*

We complement our upper bound with a lower bound.

▶ **Theorem 6** (Directed Shortcut Set Lower Bound). *Any construction of β-shortcut sets H must have $\|\widehat{\mathsf{e}}\|_\infty \cdot \beta = \Omega(n^{1/3})$ for a directed graph G on n vertices.*

Unlike our bounds for exact undirected hopsets, our results for directed shortcut sets are not tight. In particular, for polylogarithmic vertex-sensitivity, there is a gap between hop-diameter $\widetilde{O}(n^{1/3})$ and $\widetilde{O}(\sqrt{n})$, which we leave as an open problem.

Undirected Approximate Hopsets

For undirected approximate hopsets, we prove that one can achieve much better hop-diameter than the polynomial bounds for the previously mentioned problems. In particular, we prove bounds of $n^{o(1)}$ for both sensitivity and hop-diameter when $\varepsilon > 0$ is at least inverse polylogarithmic.

▶ **Theorem 7.** *There exists an algorithm which produces a $\left(O\left((k/\varepsilon)^k \log^2 n\right), \varepsilon\right)$-hopset H with $\|\widehat{\mathsf{v}}\|_\infty = O(kn^{1/k} \log^2 n)$ for undirected graphs. For any $\varepsilon > 0$ that is at least inverse polylogarithmic, setting $k = \Theta(\sqrt{\log n})$ gives a $(n^{o(1)}, \varepsilon)$-hopset with $\|\widehat{\mathsf{v}}\|_\infty = n^{o(1)}$.*

We complement our upper bound with a lower bound.

▶ **Theorem 8.** *Fix a positive integer k and parameter $\varepsilon > 1/n^{o(1)}$. Any construction of (β, ε)-hopsets H with $\beta = O\left(\left(\frac{1}{2^{k-2}(2k-1)\varepsilon}\right)^k\right)$ has $\|\widehat{\mathsf{e}}\|_\infty \geq n^{\frac{1}{2^k-1}-\Delta}$, $\Delta > 0$.*

This lower bound is an exact analogue of the best known lower bound on the size of approximate hopsets in [2] (we just divide their size bound by n to get our sensitivity bound). For $\varepsilon > 0$ exactly inverse polylogarithmic, this lower bound says that it is not possible to have sensitivity and hop-diameter be polylogarithmic simultaneously, so we can only hope to improve either the sensitivity or diameter under this regime. We leave open whether we can get sensitivity and diameter simultaneously polylogarithmic when ε is larger than polylogarithmic (for example, constant ε).

To briefly address the problems that we do not focus on (recall that we focus on undirected exact hopsets, directed shortcut sets, and approximate undirected hopsets): Low-sensitivity undirected shortcut sets are simple (but not quite as trivial as in the traditional setting) as noted by prior work and in Observation 22. For directed hopsets, the upper bounds implicit in prior work [15, 18] remain the best-known, and from the lower bounds side, our results for undirected exact hopsets and directed shortcut sets immediately carry over to exact and approximate directed hopsets, respectively.

1.2 Applications

Our motivation for studying low-sensitivity hopsets is two-fold. The more concrete motivation is that they are already implicitly used in the problem of differentially private range queries, and our new upper bound for low-sensitivity hopsets (Theorem 3) immediately implies improved results for this problem (details below).

More generally, we believe that sensitivity is a natural measure for evaluating hopsets, as it is one way of modeling the "robustness" of a hopset: low sensitivity means that changing a vertex/edge in the underlying graph G only affects a small number of shortcuts in H. This corresponds, for example, to the following real-world scenario. In computer networking the notion of an overlay network [43] considers logical links layered on top of a physical network. The logical links support functionality in the overlay protocol but they are actually implemented along a physical path in the underlying network. Overlay networks have been

widely adopted in practice (e.g. VPN, VoIP, content delivery, P2P services) due to benefits such as encapsulation, ease of deployment, and quality of service requirements. The design of an overlay network could benefit from the resilience of low sensitivity hopsets – changes in one vertex or one edge in the underlying network only affect relatively few overlay links.

1.2.1 Differentially Private Range Query

Low-sensitivity hopsets have (implicitly) found applications in differential privacy (DP) [19]; this is the problem setting with which we are primarily motivated by. On a high level, differential privacy protects sensitive information by introducing perturbation, such that the output stays immune to the presence or absence of any individual's data. More formally,

▶ **Definition 9** (Differential Privacy)**.** For databases Y and Y' that differ on one data entry and $\epsilon > 0, \delta \geq 0$, a randomized algorithm $\mathcal{M}$ is (ϵ, δ)-*differentially private*, if for any measurable set A in the range of possible outputs, it holds that: $\Pr[\mathcal{M}(Y) \in A] \leq e^{\epsilon} \Pr[\mathcal{M}(Y') \in A] + \delta$.

The algorithm $\mathcal{M}$ is called pure-DP if $\delta = 0$ and approximate-DP otherwise[5].

Low-sensitivity hopsets have a direct application to the *All Sets Range Queries (ASRQ)* problem in differential privacy [18]. The input to ASRQ is an undirected graph G with public topology and shortest paths, and each edge is associated with a private attribute (which can be distinct from its weight). The output of ASRQ is an $n \times n$ matrix M, where entry (u, v) contains the summation of edge attributes along a shortest path between the vertex pair u, v. The DP-ASRQ problem asks for a private mechanism to output a matrix M' with the DP guarantee, while minimizing the utility or additive error, i.e. ℓ_∞ of $M - M'$. The best-known upper bound of the additive error from prior work is $\widetilde{O}(n^{1/3})$ for the pure-DP setting and $\widetilde{O}(n^{1/4})$ for the approximate-DP setting. The latter is tight up to polylogarithmic factors [10]. As we outline next, our low-sensitivity exact hopsets imply an improvement of the $\widetilde{O}(n^{1/3})$ bound for the pure-DP setting, down to the tight bound of $\widetilde{O}(n^{1/4})$, matching the approximate-DP setting.

We are able to show the connection between low-sensitivity hopsets and the DP-ASRQ problem by the following theorem, which is shown implicitly in [18].

▶ **Theorem 10.** *If there exists a $(\beta, 0)$-hopset H with edge-sensitivity $\|\widehat{\mathsf{e}}\|_\infty$ for any given undirected graph, then for any $\epsilon > 0$, there exists an ϵ-DP algorithm for the ASRQ problem such that the additive error is at most $\widetilde{O}(\frac{1}{\epsilon} \cdot \sqrt{\|\widehat{\mathsf{e}}\|_\infty \cdot \beta})$ with high probability.*

Plugging into Theorem 10 our $(\sqrt{n} \log n, 0)$-hopset with $\|\widehat{\mathsf{v}}\|_\infty = O(\log n)$ (and thus $\|\widehat{\mathsf{e}}\|_\infty = O(\log n)$) from Theorem 3, we obtain the following result:

▶ **Theorem 11** (ϵ-DP upper bound)**.** *There exists an ϵ-DP algorithm for the ASRQ problem such that the additive error is at most $\widetilde{O}(\frac{n^{1/4}}{\epsilon})$ with high probability.*

We show the proof of Theorem 11 in the full version [4] of the paper. We remark that low-sensitivity hopsets are also implicitly used in another problem studied in differential privacy: All Pairs Shortest Distances. However a direct relation like Theorem 10 is not available. We further discuss this problem in the full version [4] of the paper.

[5] Note that we are using "epsilon" in two different ways in this paper, but we disambiguate the symbols: ϵ for the differential privacy parameter, and ε for the approximation parameter of hopsets.

1.3 Organization

We first provide, in Section 2, a high-level overview of the technical challenges and ideas in our results. Formal preliminaries are then given in Section 3. Next, we show an upper bound for undirected exact hopsets in Section 4, leaving the upper bound for directed exact hopsets to the full version [4] of the paper. Our upper bounds for undirected approximate hopsets can also be found in the full version [4] of the paper. In Section 5, we show lower bounds on the sensitivity-diameter tradeoff for shortcut sets and hopsets, leaving bounds in the approximate setting to the full version [4] of the paper. We finish by listing several open problems in Section 6.

2 Technical Overview

In this section we outline the key technical ideas in our constructions. A natural starting point for proving upper and lower bounds for low-sensitivity hopsets is to simply look at bounds for traditional hopsets. As it turns out, these ideas can sometimes be massaged into the low-sensitivity setting, but they do not always give the best sensitivity bounds, which necessitates the development of new techniques.

We begin by discussing a technique from prior work on low-sensitivity hopsets that illuminates a key difference between the traditional and low-sensitivity settings.

Techniques from Prior Work: Heavy-Light Decomposition

We will start with a simple example: shortcut sets for undirected graphs. For traditional shortcut sets, this is a trivial problem. Simply add a star centered at an arbitrary vertex v to get a shortcut set with $n-1$ edges and diameter only 2. If we consider the sensitivity of this construction, we quickly realize that v has sensitivity $n-1$. Thus, this trivial solution does not work in the low-sensitivity setting. However, as noted implicitly in prior work [23], there is quite a simple construction that does work.

The solution is to use a *heavy-light decomposition* of the tree of routing paths rooted at v. A heavy-light decomposition partitions the edges of a tree into "light" edges and "heavy" paths, where any root-to-leaf path has $O(\log n)$ light edges. This is useful because we can independently shortcut each of the (vertex-disjoint) heavy paths down to diameter and sensitivity $O(\log n)$ using standard methods (see e.g. Figure 1). This results in a shortcut set with vertex-sensitivity $O(\log n)$ and diameter $O(\log^2 n)$. See Section 3.3.2 for more details.

This solution suggests a more general technique for constructing low-sensitivity hopsets: whenever a traditional hopset contains a star, simply replace it by the above heavy-light decomposition shortcutting scheme. This technique works, for instance, to translate the folklore exact hopset into the low-sensitivity setting. The folklore hopset with $\widetilde{O}(n)$ edges and $\widetilde{O}(\sqrt{n})$ hop-diameter is the following: randomly sample a set S of $\widetilde{O}(\sqrt{n})$ vertices and add a hopset edge between all pairs of reachable vertices in S (where the edge weight is the distance between its endpoints). Viewing each vertex in S as the center of a star, we can apply the heavy-light decomposition transformation to achieve both vertex-sensitivity and hop-diameter $\widetilde{O}(\sqrt{n})$ [15, 18]. This remains the best-known result for exact and approximate low-sensitivity directed hopsets.

We remark that it would also be natural to try to adapt Kogan and Parter's recent $\widetilde{O}(n^{1/3})$-diameter directed shortcut set [38] on $\widetilde{O}(n)$ edges, to the low-sensitivity setting. In short, it is not clear how to do this. The first step of their construction picks $\widetilde{O}(n^{2/3})$ chains on $\widetilde{O}(n^{1/3})$ vertices each, and shortcuts each of them. Shortcutting a single chain could add sensitivity to $\Omega(n)$ vertices and edges (since it is a chain, not a path). So, shortcutting $\widetilde{O}(n^{2/3})$ chains could already incur vertex and edge sensitivity $\widetilde{O}(n^{2/3})$.

Our Main Technical Contribution

Although the known constructions for low-sensitivity hopsets use the strategy of starting with traditional hopsets and applying the above heavy-light decomposition transformation, it is not clear that this is the optimal strategy. In particular, the low-sensitivity setting permits us freedom not allowed in the traditional setting: we can add as many edges as we'd like, as long as the sensitivity of each individual vertex is bounded. Thus, we would like to take advantage of our ability to add many edges, while ensuring that not too many of our added edges have overlapping underlying routing paths. In light of this new goal, we examine low-sensitivity hopsets from scratch, developing a new technique that is conceptually very different from any known techniques for the traditional setting.

Our main new technique allows us to improve above exact undirected hopset of prior work [15, 18] from vertex sensitivity $\widetilde{O}(\sqrt{n})$ all the way down to $O(\log n)$. Our resulting hopset with $O(\log n)$ vertex-sensitivity and $\widetilde{O}(\sqrt{n})$ hop-diameter is tight up to polylogarithmic factors in both parameters.

This technique heavily relies on the assumption that the routing paths are chosen to be *consistent*; that is, each pair of overlapping paths overlaps at one single contiguous subpath. This assumption holds for shortest paths in undirected graphs and DAGs (with a consistent tie-breaking scheme), but not for shortest paths in general directed graphs. This is why our technique does not apply to exact or approximate directed hopsets. But it does apply to directed shortcut sets when we use the technique on the DAG of SCCs, in combination with other ingredients such as carefully choosing routing paths.

Now, we outline the technique. It is a greedy algorithm for processing routing paths in a carefully chosen order. Each time we process a routing path, we shortcut the path using a simple and standard method (see Figure 1) which incurs $O(\log n)$ sensitivity. We need to be careful because if we shortcut a path that overlaps with a previously shortcutted path, the vertices in the overlap incur double the sensitivity. For this reason, when we process a path we only shortcut the segments of a path that have not been previously shortcutted. We think of it this way: every time a path is shortcutted, it cast "shadows" on other overlapping paths, and we only shortcut the non-shadowed segments of each path.

Using this method, it is immediate from the standard method for shortcutting a path, that the vertex-sensitivity is only $O(\log n)$. However, the hop-diameter is in question. The hop-diameter can be determined by roughly the number of shadows cast onto a path, since each shadow chops the path into more segments, and so the goal is to bound the number of shadows cast onto each path. Since the routing paths are consistent, we know that when we process a path it only casts at most one new shadowed segment (which may be further segmented by already existing shadows) onto every other path. This helps, but we still need to choose the order to process the paths carefully. Even with the consistency property, processing the paths in the wrong order could lead to $\Omega(n)$ vertex-sensitivity.

To choose the processing order, we carefully define a potential function and choose the path with maximum potential. The potential of a path P is rather simple to define and fast to implement: the number of vertices on P that are not on any previously chosen path. In our analysis, we show that this potential function yields an algorithm with the desired hop-diameter of $\tilde{O}(\sqrt{n})$.

Techniques for Lower Bounds

For our lower bounds, we use modifications of constructions that have previously been applied to traditional hopsets as well as spanners, emulators, distance preservers, reachability preservers, and related problems. These graph constructions are layered graphs defined by

a collection of *perfect paths*, which are unique paths (or unique shortest paths, depending on the setting) that go from the first to last layer and are pairwise edge-disjoint. These graphs are useful for traditional hopsets because their properties imply that the addition of a single edge can only decrease the hop-length of one perfect path. This condition is useful for low-sensitivity hopsets too, but the situation is more nuanced. When we add a single edge to a traditional hopset it simply counts 1 towards our budget of edges, whereas in the low-sensitivity setting the total amount of sensitivity added depends on the "length" of the added edge. Thus, we need to take into account all possible edge lengths, and consider their contributions to both sensitivity and diameter.

As a separate issue, we are interested in edge sensitivity for lower bounds. For this reason we modify known perfect path constructions by replacing each vertex by an edge, which requires a slightly more careful analysis.

Our final construction begins with a known perfect path construction and optimizes the parameters for the low-sensitivity hopset setting (which results in different graph parameters than constructions for traditional hopsets). We obtain a lower bound showing that to achieve polylogarithmic vertex or edge-sensitivity for exact undirected hopsets, the hop-diameter must be $\widetilde{\Omega}(\sqrt{n})$, which is tight with our aforementioned upper bound. We also obtain lower bounds for low-sensitivity directed shortcut sets and low-sensitivity approximate undirected hopsets, both by again appealing to known constructions of layered graphs.

▶ Remark 12. Bodwin and Hoppenworth [11] are able to prove stronger lower bounds on the number of edges in a hopset by relaxing the requirement that perfect paths are disjoint. Unfortunately, their relaxation does not immediately seem to be useful for lower bounding the *sensitivity* of a hopset; see the full version [4] of the paper for more details.

Techniques for Approximate Undirected Hopsets

For traditional hopsets with $O(n)$ size, as noted in Section 1, there are essentially 3 diameter regimes: (1) directed shortcut/hopsets as well as undirected exact hopsets all require polynomial hop-diameter, (2) *approximate* hopsets for undirected graphs require only $n^{o(1)}$ hop-diameter, and (3) undirected shortcut sets trivially achieve diameter 2. In the low-sensitivity setting, we have mainly discussed the polynomial diameter regime so far, but it also makes sense to consider the $n^{o(1)}$-hop-diameter regime for low-sensitivity approximate undirected hopsets. To this end, we extend known results for traditional approximate undirected hopsets to the low-sensitivity setting, achieving both vertex-sensitivity and hop-diameter $n^{o(1)}$ for any $\varepsilon > 0$ that is at least inverse polylogarithmic.

In the traditional setting, Huang-Pettie and Elkin-Neiman [20, 31] showed that Thorup-Zwick emulators [45] are optimal hopsets. Examining this construction, it is not clear if it has low vertex and edge sensitivity. Instead, we begin with the similar construction of Thorup-Zwick spanners (also in [45]). Recall that emulators and spanners are both sparse graphs that approximately preserve distances in graphs, but a spanner is a subgraph while an emulator can have added edges. Thus, it makes sense to consider an emulator as a hopset, but not a spanner (since it has no added edges). However, we can use the heavy-light tree decomposition shortcutting on top of the Thorup-Zwick spanner to obtain a construction that is similar to the Thorup-Zwick emulator, but now it has low sensitivity. Then, we can leverage the hopset analysis tools of Huang-Pettie to show that our $n^{o(1)}$ vertex sensitivity hopset also has hop-diameter $n^{o(1)}$ for any $\varepsilon > 0$ that is at least inverse polylogarithmic.

3 Preliminaries

3.1 Notations and Definitions

With the aim of formally defining vertex and edge sensitivity, we first introduce a couple of notions.

▶ **Definition 13** (Routing Paths)**.** Given a graph $G = (V, E)$ we call $\mathcal{P}$ a set of *routing paths* for G if for all $s, t \in V$ such that s can reach t, there is exactly one path $P \in \mathcal{P}$ such that P is a path in G with starting point s and ending point t. If G is weighted, we stipulate that the paths in $\mathcal{P}$ must be shortest paths in G.

Routing paths are meant to model paths that are deemed critical. In the context of hopsets, the routing paths must thus be shortest paths, whereas in the context of shortcut sets, any path may be chosen as a routing path.

▶ **Definition 14** (Span)**.** Given a graph $G = (V, E)$ and a tuple of a set of routing paths and a shortcut/hopset $\mathcal{A}(G) = (\mathcal{P}, H)$, we define the *span* of an edge $e = (s, t) \in H$ to be the unique path in $\mathcal{P}$ with starting point s and ending point t; we denote this with $\mathsf{span}_{\mathcal{A}(G)}(e)$. When the context is clear, we omit the subscript and write $\mathsf{span}(e)$.

We are now ready to define vertex and edge sensitivity. These are properties of (the inputs) graphs, together with (the outputs) a set of routing paths and a shortcut/hopset.

▶ **Definition 15** (Vertex Sensitivity)**.** Given a graph $G = (V, E)$ and a tuple of a set of routing paths and a shortcut/hopset $\mathcal{A}(G) = (\mathcal{P}, H)$, the *vertex sensitivity* vector, indexed by V, is denoted with $\widehat{\mathsf{v}}_{G,\mathcal{A}(G)}$. When the context is clear, we omit any subset of the subscripts: $\widehat{\mathsf{v}}$.

The value of $\widehat{\mathsf{v}}$ at index v is

$$\widehat{\mathsf{v}}(v) = |\{f \in H : v \in V(\mathsf{span}(f))\}|.$$

The worst case *vertex sensitivity* (given $G, \mathcal{A}(G)$) is

$$\|\widehat{\mathsf{v}}\|_\infty = \max_{v \in V} \widehat{\mathsf{v}}(v).$$

▶ **Definition 16** (Edge Sensitivity)**.** Given a graph $G = (V, E)$ and a tuple of a set of routing paths and a shortcut/hopset $\mathcal{A}(G) = (\mathcal{P}, H)$, the *edge sensitivity* vector, indexed by E, is denoted with $\widehat{\mathsf{e}}_{G,\mathcal{A}(G)}$. When the context is clear, we omit any subset of the subscripts: $\widehat{\mathsf{e}}$.

The value of $\widehat{\mathsf{e}}$ at index e is

$$\widehat{\mathsf{e}}(e) = |\{f \in H : e \in E(\mathsf{span}(f))\}|.$$

The worst case *edge sensitivity* (given $G, \mathcal{A}(G)$) is

$$\|\widehat{\mathsf{e}}\|_\infty = \max_{e \in E} \widehat{\mathsf{e}}(e).$$

A reason behind our choice of using vector notation to describe sensitivity is as follows: We sometimes consider the total sensitivity $\|\widehat{\mathsf{e}}\|_1 = \sum_e \widehat{\mathsf{e}}(e)$ and even the sum of sensitivities over a set $T \subseteq E$ which we write with $\mathbb{1}_T \cdot \widehat{\mathsf{e}}$ where $\mathbb{1}_T$ is the indicator vector of T and "$\cdot$" denotes the usual inner product over vectors.

Next, we define the notion of *consistency*, which will prove to be a very useful property of carefully chosen routing paths in our upper bound constructions.

▶ **Definition 17** (Consistency (Modification from [17])). A pair of paths P, P' are said to be *consistent* if their intersection contains at most one connected component. A set of paths $\mathcal{P}$ is said to be *consistent* if every pair of paths $P, P' \in \mathcal{P}$ are consistent.

A shortest path tiebreaking function chooses for each pair of vertices $s, t \in V$, where s can reach t, exactly one shortest path from s to t. We say a shortest path tiebreaking function is *consistent* if its image is consistent.

Our lower bounds go through via constructions of graphs inspired by [2, 9]; in fact we directly use Theorems 5 and 6 from the first paper and Theorem 4.6 from the second paper for our constructions, but our proofs and the way we invoke the theorems differ. A common object that appears in both papers, and that we use, are layered graphs.

▶ **Definition 18** (Layered Graphs). A graph $G = (V, E)$ is *layered* if the vertex set can be partitioned into $V = V_1 \sqcup V_2 \sqcup \ldots \sqcup V_\ell$ such that every edge goes between two consecutive parts V_i and V_{i+1}. If G is directed, then edges are oriented towards the parts with larger indices.

3.2 Relationship Between Vertex and Edge Sensitivity

We discuss how different notions of sensitivity relate to each other. First, observe that for a fixed shorctut/hopset H, its $\|\widehat{\mathsf{v}}\|_\infty$ and $\|\widehat{\mathsf{e}}\|_\infty$ could differ drastically. For example, consider an $n/2$-tipped star with tips of length 2; any H comprising of all edges from the center c to the ends of all the tips would have $\widehat{\mathsf{v}}(c) = n/2$ but $\widehat{\mathsf{e}}(e) = 1$ for all edges e. More generally, the shortcut/hopset edges with endpoint v contribute one each to $\widehat{\mathsf{v}}(v)$ whereas their contribution to the edge sensitivity can be dispersed over the routing paths incident to v. At any rate, observe that the edge sensitivity being no more than the vertex sensitivity generalizes to any graph.

▶ **Observation 19.** $\|\widehat{\mathsf{e}}_{G,\mathcal{A}(G)}\|_\infty \leq \|\widehat{\mathsf{v}}_{G,\mathcal{A}(G)}\|_\infty$.

Proof. Consider the edge $e = (u, v)$ where $\widehat{\mathsf{e}}(e) = \|\widehat{\mathsf{e}}\|_\infty$. Observe in particular that $\widehat{\mathsf{e}}(e) \leq \widehat{\mathsf{v}}(u)$ since every edge in $\mathcal{A}(G)$ contributing to $\widehat{\mathsf{e}}(e)$ also contributes to $\widehat{\mathsf{v}}(u)$. We therefore conclude that $\|\widehat{\mathsf{e}}_{G,\mathcal{A}(G)}\|_\infty \leq \|\widehat{\mathsf{v}}_{G,\mathcal{A}(G)}\|_\infty$. ◀

It follows from Observation 19 that proving upper bounds for $\|\widehat{\mathsf{v}}\|_\infty$ gets us the same bound for $\|\widehat{\mathsf{e}}\|_\infty$ and, in the contrapositive, proving lower bounds for $\|\widehat{\mathsf{e}}\|_\infty$ gets us the same bound for $\|\widehat{\mathsf{v}}\|_\infty$. We thus strive to prove upper bounds on $\|\widehat{\mathsf{v}}\|_\infty$ and lower bounds on $\|\widehat{\mathsf{e}}\|_\infty$ throughout the paper; all results presented here are of this form.

It is also useful to note that $|H| \leq n\|\widehat{\mathsf{v}}\|_\infty$ which says that small sensitivity implies hopset sizes which are not much larger than linear (i.e. none of our results produce prohibitively large hopsets). This follows, informally, since every vertex "sees" at most $\|\widehat{\mathsf{v}}\|_\infty$ hopset edges (the ones contributing to its sensitivity) and each hopset edge is "seen" at least once. Similar arguments will be described more formally in our lower bound proofs.

3.3 Algorithmic Building Blocks

In this section we describe primitive subroutines used in our constructions of shortcut/hopsets. The first tool addresses how to "shorten" paths; the second, which can be viewed as a generalization of the first, addresses how to shorten trees.

3.3.1 Path Shortcutting

PATH-HOPSET is a well-known primitive which, when given a path, reduces hop-lengths of shortest paths to $O(\log n)$ while adding no more than $O(\log n)$ sensitivity to any vertex. Intuitively, PATH-HOPSET adds an edge between the two endpoints of the path, then partitions the path into two equally sized subpaths and recurses into each of them. An example of the output of PATH-HOPSET is depicted in Figure 1.

Path-Hopset
Input: A path P from v_0 to v_ℓ
1. If $\ell < 2$ then return $\{\}$
2. Return $\{(v_0, v_\ell)\} \cup$ PATH-HOPSET$(P[v_0..v_{\lfloor \ell/2 \rfloor}]) \cup$ PATH-HOPSET$(P[v_{\lfloor \ell/2 \rfloor}..v_\ell])$

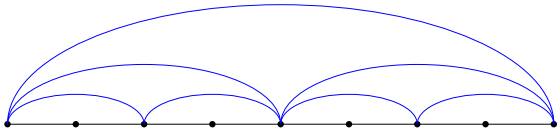

Figure 1 An example of PATH-HOPSET on a path of length 8 with vertices $v_0, \ldots, v_8$. The collection of blue edges is the shortcut/hopset output.

▶ **Observation 20.** *Given a path $P = v_0, v_1, \ldots, v_n$ (possibly oriented in the (v_i, v_{i+1}) direction), PATH-HOPSET outputs a $O(\log n)$-shortcut/hopset with $\|\hat{\mathrm{v}}\|_\infty = O(\log n)$.*

For completeness, we provide a proof in the full version [4] of the paper.

3.3.2 Tree Shortcutting via the Heavy-light Decomposition

TREE-HOPSET, described in [23], reduces the problem of shortcutting trees to that of shortcutting paths, where the instances passed to PATH-HOPSET are found via a heavy-light decomposition of the tree. A heavy-light decomposition [27] (also termed heavy path decomposition) of a rooted tree is a partitioning of its edges into "heavy" paths and "light" edges such that any root-to-leaf path passes through at most $O(\log n)$ light edges, which is captured by Proposition 21.

▶ **Proposition 21** ([27]). *Given a tree T of size n, there is a heavy-light decomposition such that*

- *any root-to-leaf path has at most $O(\log n)$ light edges;*
- *all heavy paths are vertex disjoint.*

Using the above proposition, TREE-HOPSET is specified as follows.

Tree-Hopset
Input: A tree T rooted at v
1. Return PATH-HOPSET(P) for all heavy paths P in a heavy-light decomposition of T

▶ **Observation 22.** *Given a tree T rooted at v (with possibly all edges oriented away from the root or all edges oriented towards the root),* Tree-Hopset *outputs an $O(\log^2 n)$-shortcut/hopset with $\|\widehat{\mathrm{v}}\|_\infty = O(\log n)$.*

This result is implicitly shown in the analysis of [23], but we provide a proof (in a differential-privacy-free language) in the full version [4] of the paper for completeness. Elementary use of Tree-Hopset yields the following quick results. A $O(\log^2 n)$-shortcut set construction with $\|\widehat{\mathrm{v}}\|_\infty = O(\log n)$ on undirected graphs. A directed $(O(\sqrt{n}\log n), 0)$-hopset construction with $\|\widehat{\mathrm{v}}\|_\infty = O(\sqrt{n}\log n)$. See the full version [4] of the paper for details.

4 Upper Bounds via a New Greedy Approach

This section describes a new way to construct low-sensitivity shortcut/hopsets when we are able to choose consistent routing paths; this is always possible, for example, in undirected graphs and DAGs. Using this approach, we can quite immediately get Theorem 3. With some slight care, we apply this approach to shortcut sets on directed graphs and obtain Theorem 5.

4.1 The Greedy Construction

At a schematic-level, the construction is very simple to describe: for each routing path P, processed in *some order*, apply Path-Hopset to the *uncovered pieces* of P. The details are filled in as follows.

Finding an Order to Process Paths

The order for which we process the shortest paths is described via a potential function Φ on routing paths P, which counts the number of vertices in P that have not yet been contained in a path that has thus far been processed.

▶ **Definition 23.** Let $\mathcal{P}$ be the set of all routing paths, and let $\mathcal{P}' \subseteq \mathcal{P}$ be a subset of the set of all routing paths. We define, for all $P \in \mathcal{P}$, the potential

$$\Phi_{\mathcal{P}'}(P) = |\{v \in V(P) : v \notin V(P') \text{ for all paths } P' \in \mathcal{P}'\}|.$$

If it is clear from the context, we omit the subscript and write $\Phi(P)$.

The i^{th} routing path in the order is then the one which maximizes $\Phi_{\mathcal{P}^{(i-1)}}$, where $\mathcal{P}^{(i-1)}$ is the set of the first $i-1$ routing paths in the order (that is, the ones that have already been processed).

The following is an observation that we will make use of later; it says that the potential of a path P is weakly decreasing throughout the construction process, which can be seen by noting that if P is processed then it has 0 potential and, otherwise, its vertices that are not contained in already processed paths can only drop as more and more paths are processed.

▶ **Observation 24.** *$\Phi_{\mathcal{P}^{(i)}}$ is weakly decreasing in i.*

Processing a Path

The uncovered pieces of an unprocessed path P depend on the the history of the algorithm up to the point where P is processed. These are the maximal subpaths of P for which no vertex is part of an already processed path.

▶ **Definition 25** (Uncovered pieces of a shortest path)**.** Let $\mathcal{P}'$ be the set of paths processed over so far. The *uncovered pieces* of P, given $\mathcal{P}'$, are then the maximal connected components of $\{v \in V(P) : v \notin V(P') \text{ for all paths } P' \in \mathcal{P}'\}$.

A path P is processed by running Path-Hopset on each of its uncovered pieces.

Putting Things Together

The algorithm producing an $\widetilde{O}(\sqrt{n}, 0)$-hopset with $\|\widehat{\mathrm{v}}\|_\infty = O(\log n)$ is then described by Greedy-Hopset which selects the path that maximizes the potential Φ and processes it as above, repeating until every path is processed.

Greedy-Hopset
Input: A graph $G = (V, E, w)$ with a consistent set of routing paths $\mathcal{P}$.
1. $\mathcal{P}' \leftarrow \emptyset, H \leftarrow \emptyset$
2. While $|\mathcal{P}'| < \binom{n}{2}$
   a. Select the next routing path $P^* \leftarrow \arg\max_{P \in \mathcal{P} \setminus \mathcal{P}'} \Phi_{\mathcal{P}'}(P)$, breaking ties arbitrarily
   b. $H \leftarrow H \cup$ Path-Hopset(p) for all uncovered pieces p of P^*
   c. $\mathcal{P}' \leftarrow \mathcal{P}' \cup \{P^*\}$
3. Return H

One can quickly observe that Greedy-Hopset produces a low-sensitivity shortcut/hopset.

▶ **Observation 26.** *The hopset produced by Greedy-Hopset has* $\|\widehat{\mathrm{v}}\|_\infty = O(\log n)$.

Proof. Let v be an arbitrary vertex. Its sensitivity is only ever increased in one iteration of Greedy-Hopset, namely the first time a path P is chosen such that $v \in V(P)$. We know from Observation 20 that the contribution to $\widehat{\mathrm{v}}(v)$ in one iteration is bounded by $O(\log n)$, completing the proof. ◀

Before we turn to the remaining claim that Greedy-Hopset is an $\widetilde{O}(\sqrt{n}, 0)$-hopset, we need a couple of definitions. Henceforth, let the paths be processed in the order $P_1, P_2, \ldots, P_{O(n^2)}$. First we define the *shadows* and *penumbras* cast onto P_i. Shadows are, loosely speaking, complementary to the uncovered pieces of P_i when it is processed; they serve two main purposes: (i) to bound the number of uncovered pieces when P_i is processed, and (ii) as shortcuts that can be used to traverse the covered pieces of P_i.

▶ **Definition 27** (Shadows, Penumbras)**.** For any $j < i$, the *shadows* cast by P_j onto P_i are the segments of P_j that coincide with P_i after removing all shadows cast before P_j onto P_i. Formally, they are the maximal subpaths of

$$P_i^{(j)} = \{v \in P_i \mid v \in P_j \text{ and } v \notin P_k \text{ for } k < j\},$$

defined for all $j < i$.

Let S be a shadow cast onto P_i. We call the edges in $E(S, P_i \setminus S)$ the *penumbras* of S cast onto P_i, where $E(S, P_i \setminus S)$ denotes the edges with one endpoint in S and the other in $P_i \setminus S$.

Observe that a single path P_j may cast $\Omega(j)$ shadows onto P_i. Nevertheless, if P_i has many shadows cast onto it, there must be almost as many paths which cast shadows onto P_i.

▶ **Observation 28.** *Suppose after iterating P_1 through to P_t, there are k shadows cast onto P_i for $i > t$. Then, at least $(k-1)/2$ distinct paths among P_1 through to P_t cast at least one shadow onto P_i.*

Proof. First, note that since there are k shadows cast onto P_i, there are at least $k-1$ edges in P_i which are penumbras. While the path P_j may cast many penumbras onto P_i for $j < i$, by the consistency of routing paths P_j casts at most 2 penumbra onto P_i that have not already been cast before P_j; these edges are namely the ones incident to boundary of the intersection between P_j and P_i (see Figure 2). We conclude that there are at least $(k-1)/2$ distinct paths among P_1 through to P_t that cast at least one shadow onto P_i. ◀

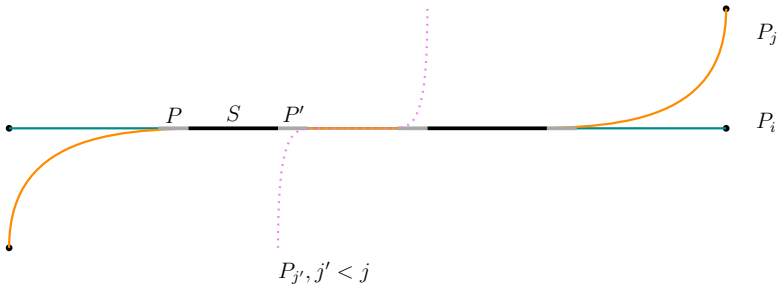

Figure 2 The penumbra P of S (a shadow cast by P_j onto P_i) is new, but the penumbra P' of S is also the penumbra of a shadow cast by $P_{j'}$ and is thus not new.

Suppose a routing path P from s to t has no more than k shadows cast onto it. Then the $G \cup \textsc{Greedy-Hopset}(G)$ hop-length from s to t is at most $\widetilde{O}(k)$; each shadow has shortcut-distance at most $O(\log n)$ by an application of Observation 20 to the time the shadow was first cast, and the remaining parts of P, of which there are $O(k)$ of them, each have shortcut-distance at most $O(\log n)$ by another application of Observation 20 at the time P is processed. Motivated by this, we now show that every routing path has at most $O(\sqrt{n})$ shadows cast onto it and every shadow on P has hop-length $O(\log n)$.

▶ **Lemma 29.** *P_i has $O(\sqrt{n})$ shadows cast onto it, for all i.*

Proof. Suppose, for a contradiction, that there is a routing path P_i which has at least $4\sqrt{n}$ shadows cast onto it. We aim to show that there are many "highly disjoint" paths that cast at least one shadow onto P_i, which will lead to a contradiction since too many such paths imply G has more than n vertices.

Towards this, let P_t for $t < i$ be the first path processed after which $\Phi(P_i) < \sqrt{n}$. Such a t must exist since, otherwise, we can invoke the monotonicity of Φ, which is weakly decreasing (see Observation 24), and Observation 28, which says that there must be at least $(4\sqrt{n}-1)/2$ distinct paths casting shadows onto P_i, to show that G has $\sqrt{n} \cdot (4\sqrt{n}-1)/2 > n$ vertices which is a contradiction.

After P_t is processed, there can be at most $\sqrt{n}$ more shadows cast onto P_i since $\Phi(P_i) < \sqrt{n}$ and each shadow cast onto P_i reduces $\Phi(P_i)$ by at least 1. There are therefore at least $3\sqrt{n}$ shadows cast onto P_i by paths processed before P_t (inclusive). Then, we can repeat the same argument as before: by Observation 24 and Observation 28 G has $\sqrt{n} \cdot (3\sqrt{n}-1)/2 > n$ vertices, leading to a contradiction. ◀

▶ **Observation 30.** *Let P be a routing path, and let S be any shadow with endpoints s, t cast onto P. Then the $G \cup$ Greedy-Hopset(G) hop-length from s to t (using edges contained in S or whose span is contained in S)[6] is bounded by $O(\log n)$.*

Proof. Let Q be the routing path casting S onto P. The claim goes through since at the time Q is processed, S is contained in an uncovered piece of Q; Greedy-Hopset makes a call to Path-Hopset on the uncovered piece of Q containing S when Q is being processed, finishing things up by Observation 20. ◀

4.2 An Upper Bound for Undirected Exact Hopsets

We are able to get upper bounds for exact hopsets on undirected graphs and DAGs immediately using Greedy-Hopset.

▶ **Theorem 3** (Undirected Exact Hopset Upper Bound)**.** *There exists an algorithm producing an $(O(\sqrt{n}\log n), 0)$-hopset with $\|\widehat{\mathbf{v}}\|_\infty = O(\log n)$ over undirected and directed acyclic graphs.*

Proof. We show the theorem for Greedy-Hopset. This follows from combining Lemma 29 and Observation 20, and also Observation 30. To spell things out, let G be an undirected or directed acyclic graph. Any routing path in G has $O(\sqrt{n})$ shadows, each shadow can be crossed within $O(\log n)$ hops (in the correct direction since G is undirected or a DAG), and the uncovered pieces of P at the time it is being processed (of which there are $O(\sqrt{n})$ many) can be crossed within $O(\log n)$ hops since Greedy-Hopset makes a call to Path-Hopset on each of these pieces.

The sensitivity claim follows directly from Observation 26. ◀

We leave our upper bound for directed exact hopsets, proving Theorem 5, to the full version [4] of the paper.

5 Lower Bounds: Sensitivity-Diameter Tradeoffs

In this section we show unconditional lower bounds for how low both the sensitivity and diameter of a construction can simultaneously be. Namely, we show Theorems 4 and 6 in Section 5.1 and leave the proof of Theorem 8 to the full version [4] of the paper.

5.1 Tradeoffs via Perfect Paths

Our lower bounds for exact hopsets and shortcut sets go through layered graphs endowed with a set of so-called perfect paths.

▶ **Definition 31** (Perfect Paths, Definition 8 in [9])**.** *Let $G = (V_1 \sqcup V_2 \sqcup \ldots \sqcup V_\ell, E)$ be a layered graph. A set of paths Π is* perfect *if each $\pi \in \Pi$ is the unique shortest path between its endpoints, each π starts in V_1 and ends in V_ℓ with exactly one node in each layer, and each $e \in E$ is in exactly one $\pi \in \Pi$.*

Layered graphs with perfect paths have been used to prove lower bounds for traditional shortcut/hopsets [17,30,32,37], and here we repurpose these constructions, with some changes, for our lower bounds. The "engine" of this section is Theorem 32 below, for which we first give some context before proving.

[6] This is an important constraint, since we wish for this claim to apply to $(\beta, 0)$-hopsets

▶ **Theorem 32.** *If there exists an ℓ-layered graph G with n nodes in each layer, and a set of perfect paths Π, then there exists a 2ℓ-layered graph G' with n nodes in each layer such that any ℓ-shortcut set or $(\ell, 0)$-hopset H on G' must have $\|\widehat{\mathsf{e}}\|_\infty \geq \frac{|\Pi|}{2n}$.*

Simplifying Assumptions

First, observe that if G is unweighted and we are concerned with directed ℓ-shortcut sets, then for any s that reaches t, the length of any st-path is completely determined by the layers they belong to; any shortcut set on G is thus also a hopset on G (where all edges of G are given weight 1). It is therefore sufficient to show the theorem for $(\ell, 0)$-hopsets.

Definition of the graph G'

We can show a lower bound for vertex sensitivity using G from the hypothesis of Theorem 32 directly (in fact, the proof is simpler). However, to get a lower bound for *edge* sensitivity, a little more care needs to be taken: we add a 0 weight edge in the "middle" of each vertex of G, which gives us G'. We now describe G' more formally.

G' is a standard transformation of G comprising of (i) vertices v^{in}, v^{out} for all $v \in V(G)$; (ii) 0 weight edges (v^{in}, v^{out}) for all $v \in V(G)$; (iii) edges (u^{out}, v^{in}) for all $(u, v) \in E(G)$, with the same weight. The proof will only look at the set of paths Π' in G' which are "lifted" from Π (dually, which project down back to Π), formally defined as follows:

$$\Pi' = \left\{(v_1^{in}, v_1^{out}, v_2^{in}, v_2^{out}, \ldots, v_\ell^{in}, v_\ell^{out}) : (v_1, v_2, \ldots, v_\ell) \in \Pi\right\}.$$

Observe that every path $\pi' \in \Pi'$ is the unique shortest path between its endpoints (which starts in the first layer and ends in layer 2ℓ), a property inherited from Π being a set of perfect paths. From this, notice that there is no choice in selecting the routing path from s to t for any $s, t \in \pi'$ for all $\pi' \in \Pi'$; any such routing path must be the subpath of π' from s to t since π' is the unique shortest path between its endpoints, and so the span of hopset edges (s, t) are fixed. Moreover, each edge of the form (u_{out}, v_{in}) is in exactly one $\pi' \in \Pi'$ since Π is perfect. Finally, note that $|\Pi'| = |\Pi|$. We are now ready to state the proof.

Proof of Theorem 32. Let G' and Π' be defined as above, and let H be any $(\ell, 0)$-hopset for G'. Let $H' \subseteq H$ be a minimal set of edges which ensures that there are ℓ hop-length shortest paths in $G' \cup H'$ between the endpoints of π' for all $\pi' \in \Pi'$. Observe that $\|\widehat{\mathsf{e}}_{G',H}\|_\infty \geq \|\widehat{\mathsf{e}}_{G',H'}\|_\infty$ since $H' \subseteq H$ and so it suffices to lower bound the latter which we now write without subscripts.

Let T be the set of all edges of the form (v_{in}, v_{out}) and $\mathbb{1}_T$ be its indicator vector; note for later that $|T| = \|\mathbb{1}_T\|_1 = n\ell$. We will lower bound the total sensitivity of edges in T and use an averaging argument to get a bound on $\|\widehat{\mathsf{e}}\|_\infty$. More specifically, we will show

$$\|\widehat{\mathsf{e}}\|_\infty \geq \mathbb{1}_T \cdot \widehat{\mathsf{e}} / \|\mathbb{1}_T\|_1 \geq x/2$$

where $\|\widehat{\mathsf{e}}\|_\infty \geq \widehat{\mathsf{e}} \cdot \mathbb{1}_T / \|\mathbb{1}_T\|_1$ comes from a simple averaging argument[7]. To this end, consider the process where we add the edges of $H' = \{e_1, e_2, \ldots, e_{|H'|}\}$ to G' one by one so that $H'_0 = \{\}$ and $H'_i = H'_{i-1} \cup \{e_i\}$, and define the potential

$$\Phi_i = \sum_{\pi' \in \Pi'} \left| E(P_{G' \cup H'_i}(\pi')) \right|$$

where $P_{G' \cup H'_i}(\pi')$ denotes a shortest path in $G' \cup H'_i$ with the smallest hop-length between the endpoints of π'. Φ_i is then the sum of said hop-lengths running over $\pi' \in \Pi'$ at stage i.

[7] To be overly indulgent, from an application of Hölder's inequality.

Observe that the initial value Φ_0 is $2|\Pi|\ell$ (since there are $|\Pi| = |\Pi'|$ paths in Π', each with hop-length exactly 2ℓ), and the final value $\Phi_{|H'|}$ is at most $|\Pi|\ell$ (since H' is an $(\ell, 0)$-hopset). Moreover, at most one summand of Φ_i differs from the corresponding summand of Φ_{i-1} for the following reason: $\mathsf{span}(e_i)$ is contained entirely and only in one $\pi' \in \Pi'$ by the minimality of H' and uniqueness of π'. For the same reason, $\mathsf{span}(e_i)$ alternates between edges not in T and edges in T and so twice the contribution of e_i to $\mathbb{1}_T \cdot \widehat{\mathsf{e}}$ is at least the decrease in potential $\Phi_{i-1} - \Phi_i$. That is,

$$\Phi_i + 2\mathbb{1}_T \cdot \widehat{\mathsf{e}}_{G',H'_i} > \Phi_{i-1} + 2\mathbb{1}_T \cdot \widehat{\mathsf{e}}_{G',H'_{i-1}}.$$

Using our observation about the initial and final values of Φ, we conclude that

$$\begin{aligned} & |\Pi|\ell + 2\mathbb{1}_T \cdot \widehat{\mathsf{e}} \geq \Phi_{|H'|} + 2\mathbb{1}_T \cdot \widehat{\mathsf{e}} > \Phi_0 + 2\mathbb{1}_T \cdot \widehat{\mathsf{e}}_{G',H'_0} = 2|\Pi|\ell \\ \implies & \mathbb{1}_T \cdot \widehat{\mathsf{e}} \geq \frac{|\Pi|\ell}{2} \\ \implies & \frac{\mathbb{1}_T \cdot \widehat{\mathsf{e}}}{\|\mathbb{1}_T\|_1} \geq \frac{|\Pi|}{2n}. && (\|\mathbb{1}_T\|_1 = n\ell) \end{aligned}$$

We conclude from the last line that $\|\widehat{\mathsf{e}}\|_\infty \geq \frac{|\Pi|}{2n}$. ◀

Finally, we can invoke Theorem 32 with known constructions to get unconditional lower bounds on the sensitivity-diameter tradeoff.

▶ **Proposition 33** (Theorem 5 of [9], earlier versions of which appear in [17, 42])**.** *For any integers $n, \ell \leq n$, and $x \leq n/\ell$, there is an ℓ-layered weighted graph G with n nodes in each layer and a set of perfect paths Π such that each node is in exactly x paths in Π.*

▶ **Theorem 4** (Undirected Exact Hopset Lower Bound)**.** *Any construction of $(\beta, 0)$-hopsets H must have $\|\widehat{\mathsf{e}}\|_\infty \cdot \beta^2 = \Omega(n)$ for a graph G on n vertices.*

Proof. For large enough N, we invoke Proposition 33, setting

- $n \leftarrow \frac{N}{2\beta}$
- $\ell \leftarrow 2\beta$
- $x \leftarrow \frac{N}{4\beta^2}$;

call this graph G_N. Note that $|\Pi|/(2n) = x/2$. We then pass each G_N into Theorem 32 to get

$$\|\widehat{\mathsf{e}}\|_\infty \geq \frac{x}{2} = \frac{N}{8\beta^2} \implies \|\widehat{\mathsf{e}}\|_\infty \cdot \beta^2 \geq \frac{N}{8},$$

which completes the proof. ◀

Observe that Theorem 4 shows that Theorem 3 is tight up to polylogarithmic factors, but it remains open whether we can explicitly trade between the sensitivity and diameter. For example, can we find a $(\widetilde{O}(n^{1/2-c}), 0)$-hopset with $\|\hat{\mathsf{v}}\|_\infty = \widetilde{O}(n^{2c})$ for any c? We close the discussion on exact hopsets with a remark on a connection between the problem of packing perfect paths in layered graphs and a possible threshold effect in the upper bounds for sensitivity-diameter tradeoffs.

▶ Remark 34. Observe that Theorem 32 connects the existence of layered graphs with many perfect paths to sensitivity-diameter tradeoffs, and this concretely manifests as a $\|\widehat{\mathsf{e}}\|_\infty \beta^2 = \Omega(N)$ bound by using the construction of Proposition 33. What are the ramifications of being able to pack even more perfect paths into an ℓ-layered graph? Let us explore one

particular hypothetical scenario. Suppose it is possible to pack N perfect paths into $\sqrt{N}$-layered graphs. Then, we are able to show (in exactly the same way as Theorem 4, but with different parameters) an $\|\hat{\mathsf{e}}\|_\infty \beta = \Omega(N)$ bound for $\beta \leq \sqrt{N}/2$. It is conceivable that such a construction may exist[8]. If such a packing does indeed exist for infinitely many values of N, this would rule out the possibility of achieving a smooth sensitivity-diameter tradeoff on the upper bound side. By Theorem 3, Greedy-Hopset produces a $(\widetilde{O}(\sqrt{n}), 0)$-hopset with $O(\log n)$ sensitivity, and any polynomial improvement to β would raise the sensitivity very abruptly from $O(\log n)$ to $\Omega(\sqrt{n})$. That is to say, a $(\widetilde{O}(n^{1/2-c}), 0)$-hopset construction could hope for no better than $\|\hat{\mathsf{v}}\|_\infty = \widetilde{\Omega}(n^{1/2+c})$ if we can pack N perfect paths into $\sqrt{N}$-layered graphs. On the flip side, this means that achieving a tradeoff like a $(\widetilde{O}(n^{1/2-c}), 0)$-hopset construction with $\|\hat{\mathsf{v}}\|_\infty$ less than $\widetilde{O}(n^{1/2+c})$ by a polynomial factor, for some constant $c > 0$, would rule out the existence of $\sqrt{N}$-layered graphs packed with N perfect paths. A similar line of reasoning also shows that any polynomial improvement to β (keeping $\|\hat{\mathsf{v}}\|_\infty = \widetilde{O}(\sqrt{n})$) over Folklore-Hopset will rule out the existence of $\sqrt{N}$-layered graphs packed with N perfect paths. The existence of layered graphs packed with as many perfect paths as possible is an open problem related to many lower bounds in the hopset/distance preservers/etc literature [11, 17]; particularly, we would get more streamlined lower bounds for hopsets matching the result of [11].

We next show a lower bound for reachability in directed graphs.

▶ **Proposition 35** (Theorem 6 of [9], earlier versions of which appear in [1, 3, 5, 17, 32]). *For any integers $n, d \geq 2, \ell \leq n^{1/d}$, and*

$$x = O\left(n^{\frac{d-1}{d+1}} \ell^{-d\frac{d-1}{d+1}}\right),$$

there is an ℓ-layered unweighted graph G with n nodes in each layer and a set of perfect paths Π such that each node is in exactly x paths in Π.

▶ **Theorem 6** (Directed Shortcut Set Lower Bound). *Any construction of β-shortcut sets H must have $\|\hat{\mathsf{e}}\|_\infty \cdot \beta = \Omega(n^{1/3})$ for a directed graph G on n vertices.*

Proof. For large enough N, we invoke Proposition 35, setting

- $n \leftarrow \frac{N}{2\beta}$
- $d \leftarrow 2$
- $\ell \leftarrow 2\beta$
- $x \leftarrow \Theta(\frac{N^{1/3}}{\beta})$;

call this graph G_N. Note that $|\Pi|/(2n) = x/2$. We then pass G_N into Theorem 32 to get

$$\|\hat{\mathsf{e}}\|_\infty \geq \frac{x}{2} = \Theta(\frac{N^{1/3}}{\beta}) \implies \|\hat{\mathsf{e}}\|_\infty \cdot \beta \geq \Omega(N^{1/3}),$$

which completes the proof. ◀

Curiously, none of our upper bounds and lower bounds for directed shortcut/hopsets match each other. New ideas are probably needed to better understand sensitivity-diameter tradeoffs (for both shortcut sets and hopsets) in the directed setting.

To see our lower bounds for approximate hopsets, proving Theorem 8, see the full version [4] of the paper.

[8] And such a construction does not contradict Theorem 3 since, there, $\beta \geq \sqrt{N} \log n > \sqrt{N}/2$.

6 Open Problems

In this section we collect a list of problems left open by our results. First and foremost, the picture pertaining to *directed* graphs is least clear.

- The bounds for shortcut sets (see Theorem 5 and Theorem 6) on directed graphs are not tight. Can we provide tight results for any specific value of sensitivity (say $O(\log n)$) if not for all values?
- The best known upper bound for directed exact hopsets is based on the folklore algorithm for traditional hopsets. It had been a long standing open problem whether this was the best we could do, and it is only within the last year that the folklore algorithm has been shown to be optimal [11]. Can similarly fresh ideas close the gap between the folklore algorithm and lower bounds here?
- We know essentially nothing insightful about the situation for directed approximate hopsets, besides the fact that our shortcut set lower bound in Theorem 6 applies (since a directed approximate hopset is a directed shortcut set). Find a non-trivial upper bound.

While more is known for undirected graphs, there are certainly gaps left to fill.

- The upper bound given by Greedy-Hopset only works for a specific sensitivity regime (i.e. it completes the picture for only one point on the tradeoff curve). Find a non-trivial algorithm, that outputs hopsets close to the curve of Theorem 4, where the sensitivity is tunable to values larger than polylogarithmic. See Remark 34 for more context surrounding this problem.
- Our lower bounds for undirected approximate hopsets in Theorem 8 are not tight; they do not address the regime when ε is a constant well. For a constant $\varepsilon > 0$, do there exist (β, ε)-hopsets with β and $\|\widehat{\mathrm{v}}\|_\infty$ simultaneously polylogarithmic, or must one of the quantities necessarily be superpolylogarithmic?

Finally, we believe that hopset sensitivity is a natural notion which should have concrete algorithmic applications beyond differential privacy. Where else can low-sensitivity hopsets can be used as a primitive?

Abstract

We show a number of connections between two types of search problems: (1) the problem of finding an L-wise *multicollision* in the output of a function; and (2) the problem of finding two codewords in a code (or two vectors in a lattice) that are within distance d of each other. Specifically, we study these problems in the *total* regime, in which L and d are chosen so that such a solution is guaranteed to exist, though it might be hard to find.

In more detail, we study the total search problem in which the input is a function $\mathcal{C} : [A] \to [B]$ (represented as a circuit) and the goal is to find $L \leq \lceil A/B \rceil$ *distinct* elements $x_1, \ldots, x_L \in A$ such that $\mathcal{C}(x_1) = \cdots = \mathcal{C}(x_L)$. The associated complexity classes Polynomial Multi-Pigeonhole Principle ((A, B)-PMPP^L) consist of all problems that reduce to this problem.

We show close connections between (A, B)-PMPP^L and many celebrated upper bounds on the minimum distance of a code or lattice (and on the list-decoding radius). In particular, we show that the associated computational problems (i.e., the problem of finding two distinct codewords or lattice points that are close to each other) are in (A, B)-PMPP^L, with a more-or-less smooth tradeoff between the distance d and the parameters A, B, and L. These connections are particularly rich in the case of codes, in which case we show that multiple incomparable bounds on the minimum distance lie in seemingly incomparable complexity classes.

Surprisingly, we also show that the computational problems associated with some bounds on the minimum distance of codes are actually *hard* for these classes (for codes represented by arbitrary circuits). In fact, we show that finding two vectors within a certain distance d is actually hard for the important (and well-studied) class $\mathsf{PWPP} = (B^2, B)$-PMPP^2 in essentially all parameter regimes for which an efficient algorithm is not known, so that our hardness results are essentially tight. In fact, for some d (depending on the block length, message length, and alphabet size), we obtain both hardness and containment. We therefore completely settle the complexity of this problem for such parameters and add coding problems to the short list of problems known to be complete for PWPP.

We also study (A, B)-PMPP^L as an interesting family of complexity classes in its own right, and we uncover a rich structure. Specifically, we use recent techniques from the cryptographic literature on multicollision-resistant hash functions to (1) show inclusions of the form (A, B)-$\mathsf{PMPP}^L \subseteq (A', B')$-$\mathsf{PMPP}^{L'}$ for certain non-trivial parameters; (2) black-box separations between such classes in different parameter regimes; and (3) a non-black-box proof that (A, B)-$\mathsf{PMPP}^L \in \mathsf{FP}$ if (A', B')-$\mathsf{PMPP}^{L'} \in \mathsf{FP}$ for yet another parameter regime. We also show that (A, B)-PMPP^L lies in the recently introduced complexity class Polynomial Long Choice for some parameters.

1 Introduction

We study *the complexity of total coding problems*, as well as total lattice problems. (We focus on coding problems in the introduction.)

Recall that a q-ary code with messages of length k, block length n, and distance d is a function $\mathcal{C} : \mathbb{F}_q^k \to \mathbb{F}_q^n$ such that

$$d = \min_{\boldsymbol{x}_1 \neq \boldsymbol{x}_2} \Delta(\mathcal{C}(\boldsymbol{x}_1), \mathcal{C}(\boldsymbol{x}_2)) \ ,$$

where Δ is the Hamming distance, i.e., the number of entries in which two elements in $\mathbb{F}_q^n$ differ. For our purposes, we think of $\mathcal{C}$ as an arbitrary circuit with size $\mathrm{poly}(n, k, \log q)$. (Much of the literature is concerned with the special case when $\mathcal{C}$ is a non-singular *linear* function, in which case the code is called a *linear* code. We discuss our choice of definition more in Section 1.5.)

The most fundamental question in coding theory is to find bounds on d for fixed n, k, and q. In other words, one wishes to argue that any set of q^k points in $\mathbb{F}_q^n$ must contain two points that are within Hamming distance d for the smallest value of d possible. Many beautiful upper bounds on the distance d are known in terms of n, k, and q.

We therefore define the natural family of computational search problem associated with this question. Specifically, we define the $(n, k, d)_q$-Short Distance Problem ($(n, k, d)_q$-SDP) as the computational search problem in which the input is a circuit $\mathcal{C} : \mathbb{F}_q^k \to \mathbb{F}_q^n$ and the goal is to find $\boldsymbol{x}_1 \neq \boldsymbol{x}_2$ such that $\Delta(\mathcal{C}(\boldsymbol{x}_1), \mathcal{C}(\boldsymbol{x}_2)) \leq d$.[1] Notice that $(n, k, d)_q$-SDP is total if and only if all q-ary codes with message length k and block length n have distance at most d.

So, upper bounds on the minimum distance of a code correspond to proofs of *totality* of SDP for some choice of $d = d(n, k, q)$. In other words, such bounds can be viewed as proofs that for such a choice of d, SDP is in the complexity class TFNP, which consists of *total* search problems with efficiently verifiable solutions. Starting with the seminal work of

[1] The problem of finding $\boldsymbol{x}_1 \neq \boldsymbol{x}_2$ that minimizes $\Delta(\mathcal{C}(\boldsymbol{x}_1), \mathcal{C}(\boldsymbol{x}_2))$ for the given input $\mathcal{C}$ is called the Minimum Distance Problem (MDP), and it is known to be NP-hard, even to approximate, and even for linear codes [14]. In contrast, SDP only asks for two codewords within some fixed distance, independent of the minimum distance of the code. Furthermore, one is often interested only in the important special case in which $\mathcal{C}$ computes a linear function over $\mathbb{F}_q$, but we stick to this more general setting because our upper bounds for this problem apply even to arbitrary codes (making them stronger), and unfortunately our lower bounds seem to require us to work with arbitrary codes specified by circuits.

Papadimitriou [34], the study of TFNP has focused largely on placing important total search problems in subclasses of TFNP, where it is often convenient to think of each subclass as capturing problems whose totality can be attributed to a particular fundamental principle. E.g., PPP (which we will discuss much more shortly) can be thought of as the subclass of TFNP corresponding to problems whose totality can be proven via a particular version of the pigeonhole principle.

It is therefore natural to ask what more we can say about the complexity of $(n, k, d)_q$-SDP when $d = d(n, k, q)$ is equal to one of the many celebrated upper bounds on the minimum distance of a q-ary code with block length n and message length k. Indeed, there are now many important upper bounds known on the minimum distance of codes (in terms of n, k, and q), such as the Singleton bound [39], the Hamming bound [19], the Plotkin bound [36], the Elias-Bassalygo bound [3], and the MRRW bound(s) [29]. These bounds are ubiquitous in the computer science literature and beyond. (See, e.g., [18].)

However, in spite of the importance of these bounds, there has been surprisingly little work addressing the complexity of the associated (total) search problems of actually finding a pair of distinct codewords within one of these bounds. Indeed, to our knowledge, the only prior work directly addressing such a question is the beautiful (and recent) work of Debris-Alazard, Ducas, and van Woerden [11], which showed (among other things) that the problem of solving SDP on linear codes within the Griesmer bound [16] can be solved efficiently.

1.1 The problem of finding multicollisions

In this work, we will show connections between the complexity of such total coding (and lattice) problems and a natural family of total search problems.

Specifically, for integers $A > B$ and $L \geq 2$, we consider the computational problem in which the input is a circuit $\mathcal{C} : [A] \to [B]$,[2] and the goal is to find L distinct input values $x_1, x_2, \ldots, x_L$ such that $\mathcal{C}(x_1) = \mathcal{C}(x_2) = \cdots = \mathcal{C}(x_L)$. Notice that, by the (generalized) pigeonhole principle, this problem is total if (and only if) the size A of the domain of $\mathcal{C}$ and the size B of its range satisfy $L \leq \lceil A/B \rceil$. We will focus on the regime in which the problem is total.

In the special case when $L = 2$ and $A = B + 1$, this is the canonical complete problem for the Polynomial Pigeonhole Principle complexity class (PPP).[3] This class was introduced by Papadimitriou in his work studying problems in TFNP (i.e., total search problems in FNP) [34]. Since then, the class PPP has been of great interest because it is known to contain many important computational problems, such as the problem of breaking a cryptographic collision-resistant hash function, the problem of breaking a one-way permutation, factoring (under randomized reductions) [22], and many more problems of interest [41, 8]. Most relevantly to our work, the problem of finding a non-zero vector in a lattice within Minkowski's bound (in the ℓ_∞ norm, though see below) was shown to be in PPP in [2].

Because of its relationship with the pigeonhole principle, we call the computational problem of finding such a collision Pigeon. (Papadimitriou originally used this name for the special case when $L = 2$ [34].) In fact, we get a family of problems (A, B)-Pigeon^L,

[2] See the full version [4] for discussion of what we mean by a circuit with input size A and output size B when A and B are not necessarily powers of 2.

[3] When $L = 2$ and $A/B \geq 1 + 1/\operatorname{poly}(\log B)$, one obtains the canonical complete problem for Polynomial Weak Pigeonhole Principle complexity class (PWPP). We will say much more about this distinction later, but for now we largely ignore this.

parameterized by the circuit input size A, the circuit output size B, and the number of colliding inputs $L \leq \lceil A/B \rceil$ that we must find. Accordingly, we define the complexity class (A, B)-PMPP^L as the set of all search problems that have a polynomial-time (Karp) reduction to (A, B)-Pigeon^L.[4]

In the complexity-theoretic literature, there is very little work on Pigeon for $L > 2$ (although we note Sotiraki's thesis [40, Section 4.5] as foundational work in this direction; and see also Section 1.3 for discussion of recent independent work by [21]). On the other hand, there is an exciting line of work in the cryptographic literature studying *multicollision-resistant hash functions* [23, 33, 43, 5, 28, 6, 25, 40, 13, 37, 20]. From our perspective, one can think of such cryptographic works as studying the *average-case* complexity of the Pigeon problem (under efficiently sampleable distributions of circuits $\mathcal{C}$). However, even these works have not fully explored this space, primarily focusing on the case where L is constant and $\log A \gtrsim 2 \log B$.

1.2 Our results

In this work, we show many connections between coding and lattice problems and PMPP. We also further study the classes (A, B)-PMPP^L.

1.2.1 Connections between coding problems and PMPP

Our first set of results shows a number of connections between PMPP and computational search problems related to error-correcting codes. (See Figure 1 for a summary of some of our results for binary codes.)

1.2.1.1 Upper bounds on the Shortest Distance Problem

We show that many of the celebrated bounds on the minimum distance of a code yield versions of SDP that are in different versions of PMPP, including the Singleton bound [39], the Hamming bound [19], the Plotkin bound [36], and the Elias-Bassalygo bound [3]. The following theorem shows some of these results.

▶ **Theorem 1** (Informal, see full version [4]). *The following hold for any n, k, and prime power q and any constant $\varepsilon > 0$.*

1. (n, k, d_S)-SDP$_q$ *is in* PWPP *for* $d_S(n, k, q) := n - k + 1$ *equal to the Singleton bound.*
2. (n, k, d_H)-SDP$_q$ *is in* PPP *and* $(n, k, (1 + \varepsilon)d_H)$-SDP$_q$ *is in* PWPP *for* $d_H = d_H(n, k, q)$ *equal to the Hamming bound.*
3. (n, k, d_P)-SDP$_q$ *is in* PMPP *for* $d_P(n, k, q) = (1 - 1/q + \varepsilon)(n - k)$ *slightly larger than the Plotkin bound.*
4. (n, k, d_E)-SDP$_q$ *is in* PMPP *for* $d_E(n, k, q)$ *equal to the Elias-Bassalygo bound.*

In fact, these results are special cases of more general results that we prove. Specifically, we show that one can obtain smaller values of d by increasing L *or* decreasing A (while holding B fixed and maintaining totality).

Our smooth tradeoff in particular is perhaps a bit surprising. Indeed, it is a-priori not clear why it would be useful to take $L > 2$ in such a reduction, since, after all, the goal in SDP is to find *two* codewords. (Of course, this is because our reductions mimic the proofs of

[4] To define PMPP formally, A and B should be functions of some asymptotic parameter n, and L might also be a function of n. But, we mostly ignore this issue in the introduction for simplicity.

the Plotkin and Elias-Bassalygo bounds. Both proofs work by first finding $L > 2$ codewords that lie in a relatively small Hamming ball and then showing that two of these codewords must be quite close to each other.)

1.2.1.2 Tight hardness for SDP and completeness when $L = 2$

We next show tight hardness results for SDP. In particular, we consider both the case when a code is represented by an arbitrary circuit $\mathcal{C}$ *and* the case when a code is represented in systematic form (i.e., the case when the first k symbols in a codeword consist of the message; see Section 1.5). We call this restricted problem sysSDP.

▶ **Theorem 2** (Informal, see full version [4]). *For any n, k, and prime power q and any constant $\varepsilon > 0$, (n, k, d)-SDP$_q$ is* PWPP*-hard for $d(n, k, q) = (1 - 1/q - \varepsilon)n$. Furthermore, (n, k, d_P)-sysSDP$_q$ is* PWPP*-hard for distance $d_P(n, k, q) = (1-1/q-\varepsilon)(n-k)$ slightly below the Plotkin bound.*

Theorem 2 is essentially tight. In particular, for $d \geq (1 - 1/q)n$, it is easy to see that SDP can be solved efficiently. And, we show that there is also a simple efficient algorithm for sysSDP for $d \gtrsim (1-1/q)(n-k)$ (see full version [4]). So, Theorem 2 essentially characterizes when there is a polynomial-time algorithm for SDP and sysSDP (assuming that FP $\neq$ PWPP).

Furthermore, there is a large overlap between the parameter regime for which we show containment in PWPP and the regime for which we show PWPP-hardness (both for arbitrary codes and codes in systematic form), so that for a large range of parameters we show that SDP is actually *complete* for PWPP. This essentially settles the complexity of SDP in these regimes and adds SDP to the relatively short list of problems known to be complete for this class. For example, we show that in many settings, the Hamming bound is PWPP-complete. (Since the Hamming bound can be viewed as a coding-theoretic analogue of Minkowski's bound for lattices, one might view this result as resolving a coding-theoretic analogue of the conjecture that Minkowski's bound is PPP-complete [2]. However, perhaps a better coding-theoretic analogue would be PPP-hardness of this problem over *linear* codes, which we do not prove. See Section 1.6.)

We summarize these results for binary codes in Figure 1. The picture for q-ary codes is quite similar (with the various bounds replaced by their q-ary versions). See full version [4] for the details.

1.2.1.3 Finding *many* close codewords and PMPP

We also show analogous results for the problem of finding *many* codewords that all lie in a small ball. This problem corresponds to bounds on the *list decoding* radius of a code (just as the problem of finding close pairs of codewords corresponds to bounds on the *unique decoding* radius).

We first show that list-decoding generalizations of the Singleton bound and the Hamming bound lie in PMPP for appropriate parameters. (See full version [4]) We then show that the problem of finding many codewords that all lie in a small ball is also *hard* for PMPP for some choices of parameters.

Our results for this problem are significantly more subtle than the $L = 2$ case, since for $L > 2$, the complexity of (A, B)-Pigeon^L seems to vary quite a bit with the parameters, whereas for $L = 2$, the parameters A and B matter much less. In particular, for $L > 2$ we do not find a complete problem for PMPP^L. See full version [4] for the details.

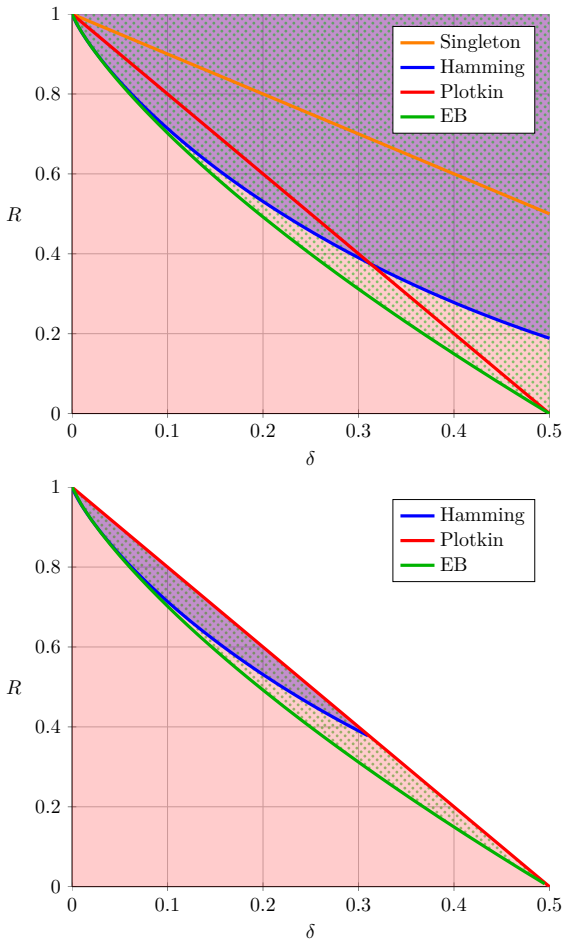

Figure 1 Two plots showing the complexity of the problem of finding two codewords within relative distance $\delta := d/n$ in a code with rate $R := k/n$ for binary codes (represented by circuits). The shaded red region represents PWPP-hardness. (The entirety of both figures are shaded red.) Regions not shown ($\delta > 1/2$ for the left figure and $\delta > 1 - 2R$ for the right figure) are known to be in FP. The shaded blue region represents containment in PWPP. The region of overlap between red and blue therefore represents regimes where the problem is PWPP-complete. The area covered with green dots represents problems in PMPP^L for some $L \geq 2$. The left figure is for arbitrary (binary) codes represented by arbitrary circuits, while the right figure is for (binary) codes in systematic form. (See Section 1.5 for discussion of systematic form and how we define codes in this context.)

1.2.2 Lattice problems in PMPP

We next show similar results for computational lattice problems. Recall that a lattice is the set of all integer linear combinations of n linearly independent basis vectors $\mathbf{B} = (\boldsymbol{b}_1, \ldots, \boldsymbol{b}_n) \in \mathbb{Z}^n$, i.e.,

$$\mathcal{L} = \mathcal{L}(\mathbf{B}) = \{z_1\boldsymbol{b}_1 + \cdots + z_n\boldsymbol{b}_n \ : \ z_i \in \mathbb{Z}\} \ .$$

A fundamental question about lattices asks when there must exist a non-zero lattice point $\boldsymbol{y} \in \mathcal{L}_{\neq \mathbf{0}}$ such that $\|\boldsymbol{y}\|_K \leq r$, where $\|\cdot\|_K$ is some norm of interest and r is some bound.

Minkowski's celebrated theorem [32] tells us that such a $\boldsymbol{y}$ is guaranteed to exist for some

$$r \leq 2\det(\mathcal{L})^{1/n}/\operatorname{vol}(K)^{1/n} ,$$

where $\det(\mathcal{L}) := |\det(\mathbf{B})|$ is the lattice determinant and K is the unit ball of the norm $\|\cdot\|_K$. The corresponding computational problem Minkowski_K is the search problem in which the input is a basis $\mathbf{B}$ for a lattice, and the goal is to output a non-zero vector $\boldsymbol{y} \in \mathcal{L}_{\neq \mathbf{0}}$ such that

$$\|\boldsymbol{y}\|_K \leq 2\det(\mathcal{L})^{1/n}/\operatorname{vol}(K)^{1/n} .$$

This problem is quite important in cryptography, particularly in the ℓ_2 norm. In the special case of the ℓ_∞ norm, it is known that $\text{Minkowski}_\infty \in \mathsf{PPP}$, and Ban, Jain, Papadimitriou, Psomas, and Rubinstein [2] conjectured that Minkowski_∞ is actually PPP-complete. (This conjecture remains open.)

We study the more general problem of finding $\boldsymbol{y} \in \mathcal{L}_{\neq \mathbf{0}}$ with

$$\|\boldsymbol{y}\|_p \leq \gamma \det(\mathcal{L})^{1/n} ,$$

where

$$\|\boldsymbol{y}\|_p := (|y_1|^p + \cdots + |y_n|^p)^{1/p}$$

is the ℓ_p norm. This problem is known as the γ-Hermite Shortest Vector Problem (γ-HSVP_p). Since this problem is relevant to cryptography, it is very well studied for a wide range of parameters γ [27, 38, 15, 31, 1], particularly for $p = 2$.

The case $\gamma = 2/\operatorname{vol}(\mathcal{B}_p^n)^{1/n}$ corresponds to Minkowski_p, where $\mathcal{B}_p^n$ is the unit ℓ_p ball. However, Minkowski's bound is not tight (except in the case when K tiles space, such as when K is the hypercube). For example, Blichfeldt improved on Minkowski's celebrated theorem in the ℓ_2 norm, proving that γ-HSVP_2 is still total when $\gamma \approx \sqrt{2}/\operatorname{vol}(\mathcal{B}_2^n)^{1/n}$ [7].[5]

Perhaps surprisingly, we show that γ-$\text{HSVP}_2 \in (A, B)$-PMPP^L for $\gamma \approx \sqrt{2}/\operatorname{vol}(\mathcal{B}_2^n)^{1/n}$ and appropriate choices of A, B, and L. In fact, we show a smooth tradeoff between the Hermite factor γ and the parameters A, B, and L, showing that one can obtain shorter vectors by either increasing L or decreasing the ratio between A and B (while maintaining totality). A similar story holds for ℓ_p norms more generally.

▶ **Theorem 3** (Informal; see full version [4]). *For any constant integer $p \geq 1$ and any $A, B, L \in \mathbb{Z}^+$ satisfying $2^{s(n)} = B < A \leq 2^{\text{poly}(n)}$ and $L \leq \lceil A/B \rceil$ for a sufficiently large polynomial $s(n)$, it holds that γ-$\text{HSVP}_p \in (A, B)$-PMPP^L for*

$$\gamma \approx d_p(L, n) \cdot (A/B)^{1/n} \cdot \operatorname{vol}(\mathcal{B}_p^n)^{-1/n} ,$$

where n is the rank of the lattice in the γ-HSVP instance and $1 \leq d_p(L, n) \leq 2$ is a particular function that is decreasing in the parameter L.

[5] We note that Blichfeldt proved two distinct relevant theorems in this context, which might easily confuse the reader. So, we endeavor to clarify here. The theorem commonly referred to as "Blichfeldt's theorem" says that any measurable set $S \subset \mathbb{R}^n$ with $\operatorname{vol}(S) > \det(\mathcal{L})$ is guaranteed to contain two points $\boldsymbol{x}_1, \boldsymbol{x}_2 \in S$ with $\boldsymbol{x}_1 \neq \boldsymbol{x}_2$ such that $\boldsymbol{x}_1 - \boldsymbol{x}_2 \in \mathcal{L}$. This theorem is often discussed in the context of total lattice problems because it can be used to prove Minkowski's theorem. In fact, Sotiraki, Zampetakis, and Zirdelis introduced a related computational problem that they called BLICHFELDT (in which the set S is represented implicitly by a circuit), and they showed that BLICHFELDT is actually PPP-complete. It is not clear how BLICHFELDT is related to γ-HSVP for $\gamma \approx \sqrt{2}/\operatorname{vol}(\mathcal{B}_2^n)^{1/n}$ (except that they are two computational lattice problems whose totality was proven by Blichfeldt).

1.2.3 Containments between different classes

The above results bring new attention to the classes PMPP. So, we next study containments between these PMPP classes with different parameters A, B, and L, and other classes of interest in TFNP.

Recall that the celebrated Merkle-Damgård construction [30, 10] shows that the ratio of the input size A to the output size B of a circuit essentially does not matter in the special case when $L = 2$, since one can efficiently reduce from the problem of finding a single collision (i.e., $L = 2$) in a barely compressing circuit $\mathcal{C} : A \to B$ with $A = B + B/\operatorname{poly}(\log B)$ to the (seemingly much easier) problem of finding a single collision in a much more compressing circuit $\mathcal{C}' : A' \to B$ with $\log A' = \log(B)^C$ for any constant $C > 1$. In our terminology,

$$(B + B/\operatorname{poly}(\log B), B)\text{-PMPP}^2 = (2^{\log^C B}, B)\text{-PMPP}^2 .$$

This surprising collapse of complexity classes is known as *domain extension*, and it has innumerable applications in cryptography and complexity theory.[6]

Already in 2004, Joux noticed that Merkle and Damgård's elegant domain extension technique does not seem to work for $L > 2$ [23]. So, it appears that for $L > 2$, the relationship between A and B (i.e., how "compressing" the circuit $\mathcal{C}$ is) might matter quite a bit. This suggests a surprising fundamental difference between the case $L = 2$ and the case when $L > 2$.

However, we show two (rather weak) notions of domain extension that still work in the setting of multicollisions. The first such result follows by analyzing the Merkle-Damgård construction in this setting and showing that it does achieve *something*, albeit with a large loss in parameters. The second result shows a more sophisticated reduction (using Merkle trees together with list-recoverable codes) that is better than the Merkle-Damgård-based reduction in the regime where A is very large compared to B. The latter result can be thought of as a translation into our setting of a beautiful result due to Bitanski, Kalai, and Paneth [6] in the setting of multicollision-resistant hash functions. (In fact, the proof is substantially simpler in our setting than in that of [6], since we do not have to worry about the many additional issues that arise in the average-case setting.)

Together, these results show that it is possible to reduce the problem of finding multicollisions in a less compressing function to the problem of finding multicollisions in a more compressing function, but at the expense of a large loss in the number of collisions found.

▶ **Theorem 4** (Informal; see full version [4]). *For $m > a > b$,*

$$(2^a, 2^b)\text{-PMPP}^{L'} \subseteq (2^m, 2^b)\text{-PMPP}^L$$

for $L' \approx L^{(a-b)/(m-b)}$.

For any $r \geq 2$, any $k \geq 1$, and any L,

$$(2^{vr}, 2^v)\text{-PMPP}^{M'} \subseteq (2^{vrk}, 2^v)\text{-PMPP}^M$$

under randomized reductions, for

$$M' \approx M^{\log r/(2\log r + \log k + \log(M)/2)} .$$

[6] Admittedly, we are deliberately conflating the distinction between the problem of breaking a cryptographic hash function (which is what Merkle and Damgård actually studied) and the problem of finding a collision in an arbitrary worst-case circuit. All of the above statements hold in both cases.

We also show that the class PMPP is contained in the recently introduced ([35]) complexity class Polynomial Long Choice (PLC), for appropriate choices of the parameters A, B, and L. In fact, we show a reduction to the Unary Long Choice problem. (This result was recently independently discovered in [21]. See Section 1.3.) This strengthens a result of Pasarkar, Papadimitriou, and Yannakakis [35], who showed that PWPP $\subseteq$ PLC.

▶ **Theorem 5** (Informal; see full version [4]). *For any $L < n$,*

$(2^n, 2^{n-L})$-PMPP$^L \subseteq$ PLC

1.2.4 Black-box separations (and a non-black-box non-separation)

Our final set of results concerns black-box separations between (A, B)-PMPP^L for different values of A, B, and L, which suggest that it might be hard to prove stronger containments than what we show above. However, we note that recent independent work of Jain, Li, Robere, and Xun [21] also showed exciting black-box separations of this form. While our results are formally incomparable to theirs, we believe that the results of [21] are more interesting than our own. (See Section 1.3.)

The starting point for our results is a beautiful idea due to Komargodski, Naor, and Yogev [25] for separating $(2^n, 2^{n/2})$-PMPP^L from $(2^n, 2^{n/2})$-PMPP$^{L'}$ for any constants $L \neq L'$ (particularly in the average-case setting relevant to cryptography). Unfortunately, however, the proof in [25] had a subtle bug that does not seem easy to fix [26].

We use similar ideas to show two different black-box separations, which can be seen as partial evidence that domain extension and range compression are not possible when $L > 2$. However, we note that our black-box separations are rather weak, since they only rule out rather fine-grained black-box reductions between the classes.

Finally, we show that a very clever non-black-box proof due to Rothblum and Vasudevan [37] extends to our setting. In particular, Rothblum and Vasudevan show, using non-black-box techniques, that the existence of a certain sufficiently strong multicollision-resistant hash function implies the existence of a collision-resistant hash function. We prove an analogue of their result in our (worst-case) setting, showing that suitable hardness of PMPP for large L implies hardness of PMPP for smaller L. (After a preliminary version of this work appeared, Buzek and Tessaro [9] improved upon the main result in [37]. We do not know whether the stronger result in [9] extends to our setting.)

As these results are rather technical, we refer the reader to the full version [4] for the details.

1.3 Comparison with Jain, Li, Robere, and Xun

Recent exciting work by Jain, Li, Robere, and Xun [21] also defines and studies the computational problem (A, B)-Pigeon^L and the associated complexity class (A, B)-PMPP^L (with slightly different notation). (They also define additional classes that correspond to the union of (A, B)-PMPP^L over different parameters A, B, and L.) [21] is concurrent with and independent of this work (and appeared as a preprint shortly before we released a preprint of the present work). Here, we provide a brief comparison of their work with ours.

Both the present work and [21] define multi-collision classes and study relationships between them. At a high level, [21] has morally stronger (although formally incomparable) results on the structural complexity of these classes, whereas the present work focuses on showing containment and hardness of coding and lattice problems with respect to these classes (which [21] does not study at all).

In terms of structural complexity, [21] contains exciting black-box separation results, which, although formally incomparable to our black-box separations, we think of as stronger. In particular, [21] are essentially able to black-box separate (A, B)-PMPP^L from (A', B')-PMPP$^{L'}$ for *any* constants $L \neq L'$ and *any* (reasonable) A, B, A', and B'. They also show black-box separations between PMPP and other interesting complexity classes in TFNP, and in particular show a black-box separation between the Ramsey problem and PMPP. We refer the reader to [21] for the technical details.

[21] also studies the relationship between PLC and PMPP. Indeed, they prove a result that is essentially identical to our Theorem 5, which shows that PMPP $\subseteq$ PLC for certain parameters. (Formally, our technical result in the full version [4] is more general than the analogous result in [21], but it is clear that the proof in [21] yields the more general result as well.) In addition, they show a containment in the other direction, that PLC $\subseteq$ PMPP, albeit for different parameters. Finally, [21] shows that an interesting problem in TFBQP is in PMPP. The latter two results have no analogue in the present work.

In this work, we focus on the relationship of PMPP with coding and lattice problems (see the full version [4]). We also show Merkle-Damgård-style reductions between PMPP with different parameters (see full version [4]) and a non-block-box non-separation in the style of [37] (see full version [4]). These topics are not studied in [21].

1.4 Other related work

Our work lies at the intersection of a number of different areas, and there is therefore much related work to discuss in addition to [21]. Here, we focus on how this prior work relates to our work.

The complexity of total lattice problems

The complexity of Minkowski's bound and HSVP more generally is quite well studied, particularly in the ℓ_∞ norm and the ℓ_2 norm. In particular, algorithms for HSVP_2 play a very important role in lattice-based cryptography, and algorithms for HSVP_2 with different approximation factors are a very active area of research [27, 38, 15, 31, 1]. Some of these algorithms can be viewed as constructive proofs of classical results about the minimum distance of a lattice relative to the determinant. (For example, the celebrated LLL algorithm gives a constructive proof of Hermite's bound [27], and the slide reduction algorithm gives a constructive proof of Mordell's inequality [15].)

Finding a vector within Minkowski's bound in the ℓ_∞ norm is considered one of the most important problems in the complexity class PPP. In particular, Ban, Jain, Papadimitriou, Psomas, and Rubinstein showed that other important problems in PPP can be reduced to this problem, and they conjectured that this problem is actually PPP-complete [2]. Sotiraki, Zampetakis, and Zirdelis further investigated the relationship between lattice problems, PPP, and PWPP, showing two problems related to lattices that are PPP-complete and PWPP-complete respectively [41].

The complexity of total coding problems

To our knowledge, much less is known about the complexity of total problems that arise in coding theory. Instead, much work has focused on the *γ-approximate Minimum Distance Problem* (γ-MDP), in which the input is a linear code and the goal is to output a pair of distinct codewords $\boldsymbol{c}_1, \boldsymbol{c}_2$ such that the distance between them is within a factor γ of the minimum distance of the input code (or, since the code is linear, one can equivalently output a non-zero codeword with nearly minimal Hamming weight). This problem is known to be

NP-hard [42], even to approximate [14]. In contrast, we are interested in the problem of finding distinct codewords $\boldsymbol{c}_1, \boldsymbol{c}_2$ that are within distance d, where d depends only on the message length k and block size n of the code (and *not* on the minimum distance). We are particularly interested in the total regime, where such problems are very unlikely to be NP-hard.

To our knowledge, the only direct work in this area is a beautiful paper by Debris-Alazard, Ducas, and van Woerden [11], which showed an LLL-like algorithm for linear codes that efficiently finds codewords within the Griesmer bound [16]. (Note that this algorithm only works for linear codes, and indeed the Griesmer bound itself only applies to linear codes.)

Literature on multicollisions

There is quite a bit of prior work in the cryptography literature on *multicollision-resistant hash functions*. In our terminology, a multicollision-resistant hash function is some efficiently sampleable distribution of instances of (A, B)-Pigeon^L (i.e., circuits $\mathcal{C} : [A] \to [B]$) that are actually hard (i.e., that cannot be solved by polynomial-time algorithms with non-negligible probability). A survey of this literature is beyond the scope of this work. Broadly speaking, work in this area has been concerned with (1) understanding the relationship between collision resistance and multicollision resistance (i.e., the relationship between the case when $L = 2$ and the case when $L > 2$); (2) finding applications of multicollision-resistant hash functions; and (3) building multicollision-resistant hash functions from various cryptographic hardness assumptions.

Many of the techniques that we use to understand the relationship between (A, B)-Pigeon^L in different parameter regimes are directly inspired by this cryptographic literature. In particular, our inclusion based on Merkle trees and list-recoverable codes is a direct adaption of Bitanski, Kalai, and Paneth's construction from the cryptographic setting to our setting [6]; our black-box separations are inspired by [25]; and our non-black-box non-separation is a direct adaptation of Rothblum and Vasudevan's proof from the cryptographic setting to our setting [37]. (See also the very recent work of [9].)

In contrast, there is very little prior work in the worst-case setting. To our knowledge, the only works that consider the worst-case complexity of finding multicollisions are Komargodski, Naor, and Yogev [25] and Sotiraki [40] (though see Section 1.3). In both of these works, the worst-case complexity of (A, B)-Pigeon^L is not the primary focus, but both do define the special cases of the complexity class (A, B)-PMPP^L, when $A = B^2$ (specifically, $A = 2^{2n}$ and $B = 2^n$) and L is a constant. This is a natural setting of parameters, but we show interesting results in other parameter regimes as well.

Sotiraki in particular shows a complete problem for PMPP that is similar to the PPP-complete and PWPP-complete problems from [41]. In particular, Sotiraki's PMPP-complete problem bears some resemblance to certain lattice and coding problems, though the relationship is unclear. We refer the reader to [41, 40] for more.

Komargodski, Naor, and Yogev claimed a black-box separation between $(2^{2n}, 2^n)$-PMPP^L and $(2^{2n}, 2^n)$-PMPP$^{L'}$ for any constants $L' < L$, but their elegant proof contained a subtle bug that has not been fixed [26]. Our black-box separations use similar ideas but are weaker than what they originally claimed.

Literature on PPP and PWPP

In contrast, there is much literature studying the complexity classes PPP and PWPP, which correspond to the special case of PMPP when $L = 2$ (in different parameter regimes). PPP was introduced by Papadimitriou in his seminal work [34]. (PWPP appeared in many works

but seems to have been first named PWPP in [22].) Since then, many problems of interest have been shown to be contained in either PWPP or PPP [22, 2, 41, 8]. Until recently, only a small handful of problems were known to be complete for PPP or PWPP [34, 41, 2]. However, Bourneuf, Folwarczný, Hubáček, Rosen, and Schwartzbach recently showed a number of problems arising from extremal combinatorics that are complete for either PPP or PWPP [8].

There has also been some literature concerned with generalizing PPP and PWPP to classes other than PMPP. In particular, Pasarkar, Papadimitriou, and Yannakakis [35] recently introduced the class Polynomial Long Choice (PLC), which can be thought of as corresponding to the generalization of the pigeonhole principle obtained by iterating the pigeonhole principle many times.

1.5 A note on "codes" represented by circuits, injectivity, and systematic form

The coding theory results in this paper are concerned with the problem of finding close codewords (or many codewords that lie in a relatively small ball) in a "code" *represented by an arbitrary circuit* $\mathcal{C} : \mathbb{F}_q^k \to \mathbb{F}_q^n$ with size $\text{poly}(n, k, \log q)$. It is far more common in the literature to consider *linear* codes represented by a generator matrix (or, equivalently, an invertible circuit with linear gates). (Sometimes when arbitrary codes are considered in the literature, the code is simply represented by listing all q^k points, while we represent our codes succinctly.)

Whether one should really think of a generic circuit $\mathcal{C} : \mathbb{F}_q^k \to \mathbb{F}_q^n$ as representing a "code" is not so clear. In particular, such a circuit might not be *injective*, i.e., there might be distinct "messages" $\boldsymbol{x}_1, \boldsymbol{x}_2 \in \mathbb{F}_q^k$ that map to the same "codeword" $\mathcal{C}(\boldsymbol{x}_1) = \mathcal{C}(\boldsymbol{x}_2)$. (And, there is likely no way to efficiently determine whether such a circuit is injective. Indeed, determining this is coNP-complete.) But, we find the coding-theoretic perspective to be quite useful. In particular, the notion of the distance of a code still makes sense with this slightly more general definition, and the bounds on the distance that we discuss in this paper still apply. Indeed, much of coding theory still makes sense if we treat such degenerate, non-injective codes simply as "codes with distance 0," and standard bounds in coding theory, such as the Singleton and Hamming bounds, still apply.

Of course, it is not an issue, and actually a strength that our upper bounds apply to such general "codes." Indeed, any upper bound that applies in the more general case when "codes" are represented by arbitrary circuits certainly applies to the special case of injective circuits or the even more special (and quite important) case of linear codes.

For our lower bounds, however, this can be viewed as a major flaw in our model. To partially mitigate this, we prove our hardness results in two different settings.

In the first "generic" setting, we show hardness for "codes" represented by arbitrary circuits $\mathcal{C} : [q]^k \to [q]^n$, with no presumed structure. In particular, the circuit is not necessarily injective. Indeed, one may argue that our reductions are rather artificial, in that the reductions often produce "codes" $\mathcal{C}$ such that $\Delta(\mathcal{C}(\boldsymbol{x}_i), \mathcal{C}(\boldsymbol{x}_j))$ is either zero or strictly larger than d, where d is the bound on the distance needed to solve the associated coding problem. So, these reductions rely quite heavily on this rather strange definition of a code in which multiple messages can map to the same codeword.

In the "systematic" setting, our codes $\mathcal{C} : [q]^k \to [q]^n$ are in *systematic* form, which means that the first k characters of $\mathcal{C}(\boldsymbol{x})$ are simply $\boldsymbol{x}$ itself. (Formally, we actually work with a smaller circuit $\mathcal{C}' : [q]^k \to [q]^{n-k}$, and we simply interpret $(\boldsymbol{x}, \mathcal{C}'(\boldsymbol{x}))$ as the codeword associated with $\boldsymbol{x}$.) Such circuits are clearly injective, and therefore this setting is much less artificial. (Codes in systematic form are also quite fundamental objects that arise naturally in coding theory.) In this setting, our formal results are a bit different, and we even show

that there are efficient algorithms for this setting in regimes where the problem is provably hard for codes represented by arbitrary circuits. However, the high-level picture is the same. In particular, we still show completeness in this setting. (See Figure 1.)

1.6 Open problems

We leave a number of interesting open problems. Here, we mention some of them.

Complexity of coding and lattice problems

We place the computational problems associated with a number of fundamental bounds on the minimum distance of a code in PMPP. However, we were unable to say anything non-trivial about the complexity of Delsarte's linear programming bound [12] and the closely related MRRW bound(s) [29], which are the best known bounds in an important range of parameters. The associated computational problems are, by definition, in TFNP, but we do not know any natural subclass of TFNP that contains these problems.

Similarly, the best known bound on the minimum distance in the ℓ_2 norm of a lattice relative to the determinant is the celebrated bound due to Kabatjanskiĭ and Levenšteĭn [24] (which is better than Blichfeldt's [7] by a factor of roughly $2^{1/10}$). The problem of finding a vector within the Kabatjanskiĭ and Levenšteĭn bound is again, by definition, in TFNP, but we do not know any natural subclass of TFNP that contains this problem.

In a different direction, we show hardness of various total coding problems (and even completeness in some regimes), but only for codes represented by circuits. It would be very exciting to show hardness results of total problems on *linear* codes (represented, e.g., by generator matrices), since these are the more standard problems. (The analogous question for lattices was already asked in [2] and also remains open.)

Better understanding of PMPP across different regimes

The first question that comes to mind about the complexity classes (A, B)-PMPP^L is, of course, "how do these classes relate to each other across different parameter regimes?" In the case when $L = 2$, it has long been known that the relationship between A and B does not matter much. For example,

$$((1 + 1/\operatorname{poly}(n)) \cdot 2^n, 2^n)\text{-PMPP}^2 = ((2^{n+\operatorname{poly}(n)}, 2^n)\text{-PMPP}^2 = \text{PWPP} .$$

For $L > 2$, it seems unlikely that a similar result holds. We instead describe a rich and rather complicated set of inclusions (and non-black-box relationships) among these classes, as well as black-box separations.

However, we have no evidence that these results are tight. One would ideally like to show black-box separations and inclusions that are tight with one another. (Or, alternatively, one might hope to prove non-trivial equalities (A, B)-PMPP$^L = (A', B')$-PMPP$^{L'}$ like what we know in the case of $L = L' = 2$.) The analogous average-case question has been the topic of much research in the cryptography literature [23, 33, 43, 5, 6, 25, 28, 13, 40, 37, 20], but to the authors' knowledge the worst-case setting was barely explored before this work and the recent exciting (concurrent and independent) work of Jain, Li, Robere, and Xun [21].

2 Upper bounds for coding problems

In this section, we prove that SDP and DenseBall are contained in PMPP in many parameter regimes of interest. In particular, for SDP, we show such results when the distance $d(n, k, q)$ corresponds to a number of celebrated bounds on the minimum distance of a code, including

the Singleton bound (Corollary 7), the Plotkin bound (Corollary 8), the Hamming bound (Corollary 13), and the Elias-Bassalygo bound (Corollary 15). For DenseBall, we show analogous results for the list Singleton bound (Corollary 11) and list Hamming bound (Corollary 13).

In fact, all of these results are corollaries of four technical results: Theorem 6, which reduces SDP to Pigeon via a simple truncation technique; Theorem 10, which does something similar for DenseBall; Theorem 12, which reduces DenseBall to Pigeon by "finding many overlapping Hamming balls centered on codewords"; and Theorem 14, which shows a generic reduction from SDP to DenseBall.

We also show in Section 2.1.1 an efficient algorithm for SDP within the Plotkin bound for codes in systematic form.

2.1 Upper bounds for the Singleton and Plotkin bounds

We start by giving a fairly general reduction from SDP (the problem of finding a pair of close codewords) to Pigeon^L. On input an instance $\mathcal{C}$ of SDP, the reduction works by defining a compressing circuit $\mathcal{C}'$ that truncates the output of $\mathcal{C}$. It then finds $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_L$ such that $\mathcal{C}'(\boldsymbol{x}_1) = \cdots = \mathcal{C}'(\boldsymbol{x}_L)$ using its Pigeon^L oracle, and finally outputs a pair $\boldsymbol{x}_i \neq \boldsymbol{x}_j$ that minimizes $\Delta(\mathcal{C}(\boldsymbol{x}_i), \mathcal{C}(\boldsymbol{x}_j))$. We then observe that special cases of this general result place (n, k, d)-SDP$_q$ in PWPP for d corresponding to the Singleton bound (Corollary 7) and PMPP for d corresponding to the Plotkin bound (Corollary 8).

▶ **Theorem 6.** *Let $k, m, n, q, L \in \mathbb{Z}^+$ be such that $m \leq k \leq n$ and $2 \leq L \leq q^{k-m}$ with $L \leq \mathrm{poly}(n, \log q)$. Then there is a Karp reduction from (n, k, d)-SDP$_q$ to (q^k, q^m)-Pigeon^L where $d := d_q^*(n - m, L)$.*

Proof. See full version [4]. ◀

We get useful corollaries from Theorem 6 that show how to compute vectors achieving the Singleton bound (the $L = 2$ case) and the Plotkin bound (for larger L) using a Pigeon^L oracle.

We now show that the problem of finding a pair of codewords whose distance is at most the Singleton bound is in PWPP.

▶ **Corollary 7** (Singleton bound in PWPP)**.** *Let $k, n, q \in \mathbb{Z}^+$ with $k \leq n$. Then there is a Karp reduction from $(n, k, n - k + 1)$-SDP$_q$ to (q^k, q^{k-1})-Pigeon^2. In particular, $(n, k, n - k + 1)$-SDP$_q$ is in PWPP.*

Proof. The claim follows from Theorem 6 by setting $m := k - 1$ and noting that, trivially, $d_q^*(n - m, L) = d_q^*(n - k + 1, L) \leq n - k + 1$ for any $L \geq 2$. ◀

We now show that the problem of computing a pair of codewords whose distance satisfies the high-rate Plotkin bound is in PMPP.

▶ **Corollary 8** (Plotkin bound in PMPP)**.** *Let $k, n, d, m, q, L \in \mathbb{Z}^+$ be such that $k \leq n$, $L \leq \mathrm{poly}(n)$, $L \leq q^{k-m}$, and*

$$d > \frac{L}{L-1}\left(1 - \frac{1}{q}\right)(n - m)\ , \tag{1}$$

then there is a Karp reduction from $(n, k, d-1)$-SDP$_q$ to (q^k, q^m)-Pigeon^L which runs in time $\mathrm{poly}(n, \log(q))$.

Proof. See full version [4]. ◀

2.1.1 Efficiently solving sysSDP up to the Plotkin bound

We now note that there is an efficient algorithm for finding codewords within the Plotkin bound *when the code is in systematic form.* In other words, we show that (n, k, d)-sysSDP$_q$ can be solved efficiently for d below the Plotkin bound, where we recall that sysSDP is the special case of SDP in which the code is in systematic form.

▶ **Theorem 9.** *Let $k, n, q \in \mathbb{Z}^+$ with $k < n$ and $q \geq 2$. There is a* poly(n, q)*-time algorithm for* (n, k, d)-sysSDP$_q$ *where*

$$d := (1 - 1/q)(n - k + \lceil \log_q(4qn) \rceil) \ .$$

Proof. See full version [4]. ◀

2.2 An upper bound for the list Singleton bound

Next, we give a reduction from DenseBall to Pigeon similar to the reduction from SDP to Pigeon in Theorem 6. We then show that this reduction places the *list* Singleton bound (i.e., a variant of the Singleton bound that corresponds to list decoding rather than unique decoding) in PMPP (up to a small error).

▶ **Theorem 10.** *Let $k, n, m, q, L \in \mathbb{Z}^+$ be such that $m < n$ and $2 \leq L \leq q^{k-m}$. Then there is a Karp reduction from* $(n, k, n - m - \lfloor (n - m)/L \rfloor)$-DenseBall$_q^L$ *to* (q^k, q^m)-Pigeon^L.

Proof. See full version [4]. ◀

Finally, we show that the problem of computing a set of codewords lying in a ball whose radius *almost* satisfies the list Singleton bound is in PMPP.

▶ **Corollary 11** (List Singleton bound in PMPP)**.** *Let $n, k, q, L \in \mathbb{Z}^+$ with $k > \lfloor \log_q(L) \rfloor$, let $m := k - \lfloor \log_q L \rfloor$, and let*

$$t := n - m + \lfloor (n - m)/L \rfloor = n - k + \lfloor \log_q L \rfloor - \lfloor (n - k + \lfloor \log_q L \rfloor)/L \rfloor \ . \tag{2}$$

Then (n, k, t)-DenseBall$_q^L$ *is in* (q^k, q^m)-PMPP^L.

Proof. See full version [4]. ◀

We remark that the radius t in Equation (2) is almost as small the smallest t satisfying the list Singleton bound. Indeed, one can check that any t satisfying the list Singleton bound must be such that

$$t > (1 - 1/L) \cdot (n - k + \log_q(L - 1)) \ ,$$

and that the radius t in Equation (2) satisfies

$$t \leq (1 - 1/L) \cdot (n - k + \lfloor \log_q(L) \rfloor) + 1 \ .$$

2.3 Upper bounds for the (list) Hamming and Elias-Bassalygo bounds

We now show containment of (n, k, d)-SDP$_q$ in PMPP, where d corresponds to the Hamming bound and Elias-Bassalygo bound. In particular, when d is equal to the value given by the Hamming bound, we show that SDP is contained in PPP (see Item 1 of Corollary 13) and for d slightly above the Hamming bound, SDP is contained in PWPP (see Item 2 of Corollary 13). In fact, we show a more general result that applies to the generalization (n, k, d)-DenseBall$_q^L$

of SDP and shows that for d within the *list* Hamming bound, this problem is in PMPP (see Item 3 of Corollary 13). We then show that (n, k, d)-SDP$_q$ is in PMPP whenever d above the Elias-Bassalygo, via a generic reduction from SDP to DenseBall (see Corollary 15). In fact, we obtain a smooth tradeoff between the distance d obtained by the reduction and the parameters A, B, and L in the reduction to (A, B)-Pigeon^L.

2.3.1 The (list) Hamming bound

We now give a reduction from DenseBall to Pigeon^L, the key to which is the circuit $\mathcal{C}_H^{n,V,q}$ giving an injection from $[V]$ into a Hamming ball for sufficiently large V defined in the full version [4]. (In fact, we will use such circuits $\mathcal{C}_H^{n,V,q}$ that are *bijective*.)

▶ **Theorem 12.** *Let $n, k, t, L \in \mathbb{Z}^+$, and let q be a prime power satisfying*

$$L \leq \left\lceil \frac{q^k \cdot V_q^n(t)}{q^n} \right\rceil .$$

Then there is a Karp reduction from (n, k, t)-DenseBall$_q^L$ to $(q^k \cdot V_q^n(t), q^n)$-Pigeon^L.

Proof. See full version [4]. ◀

We now use Theorem 12 to show that SDP and DenseBall with parameters corresponding to the (list) Hamming bound are in (one or more of) PPP, PWPP, and PMPP.

▶ **Corollary 13** ((List) Hamming bound in PPP, PWPP, and PMPP)**.** *Let $n, k, t, q, L \in \mathbb{Z}^+$ with $2 \leq q \leq \mathrm{poly}(n)$ and $L \leq \mathrm{poly}(n)$. Let*

$$\widetilde{L} := \frac{q^k \cdot V_q^n(t)}{q^n} .$$

Then:
1. *If $\widetilde{L} > 1$, then $(n, k, 2t)$-SDP$_q$ is in PPP.*
2. *If $\widetilde{L} \geq 1 + 1/\mathrm{poly}(n)$, then $(n, k, 2t)$-SDP$_q$ is in PWPP.*
3. *If $\widetilde{L} \geq L$, then (n, k, t)-DenseBall$_q^L$ is in $(q^k \cdot V_q^n(t), q^n)$-PMPP^L.*

Proof. See full version [4]. ◀

2.3.2 E pluribus duo – from many codewords to two

We now give a simple reduction from SDP to DenseBall^L for $L \geq 2$. The idea is that a ball of small radius t containing $L \geq 2$ codewords $\mathcal{C}(\boldsymbol{x}_1), \ldots, \mathcal{C}(\boldsymbol{x}_L)$ must contain a pair of codewords at small distance d. Clearly such a pair must exist at distance at most $2t$, but in fact when L is larger it is possible to get a better upper bound. So, the reduction simply computes the distance $\Delta(\mathcal{C}(\boldsymbol{x}_i), \mathcal{C}(\boldsymbol{x}_j))$ between each pair of codewords $\mathcal{C}(\boldsymbol{x}_i), \mathcal{C}(\boldsymbol{x}_j)$ for $i \neq j$, and outputs a pair $\boldsymbol{x}_i, \boldsymbol{x}_j$ that minimizes $\Delta(\mathcal{C}(\boldsymbol{x}_i), \mathcal{C}(\boldsymbol{x}_j))$.

▶ **Theorem 14.** *Let $n, k, t, q, L \in \mathbb{Z}^+$ be such that*

$$L \leq \left\lceil \frac{q^k \cdot V_q^n(t)}{q^n} \right\rceil .$$

Then there is a $\mathrm{poly}(n, L, \log q)$-time Karp reduction from (n, k, d)-SDP$_q$ to (n, k, t)-DenseBall$_q^L$, where $d := d_{[q]^n, \Delta}(t, L)$.

Proof. See full version [4]. ◀

2.3.3 The Elias-Bassalygo bound

We are now ready to show that the problem of computing a pair of codewords satisfying the Elias-Bassalygo bound is in PMPP.

▶ **Corollary 15** (Elias-Bassalygo bound in PMPP). *Let $n, k, d, t, q \in \mathbb{Z}^+$ with $t < J_q(d/n) \cdot n$, let $L := qnd + 1$, and suppose that*

$$L \leq \left\lceil \frac{q^k \cdot V_q^n(t)}{q^n} \right\rceil .$$

Then there is a poly(n, q)*-time Karp reduction from $(n, k, d-1)$-SDP$_q$ to $(q^k \cdot V_q^n(t), q^n)$-*Pigeon^L*. In particular, $(n, k, d-1)$-SDP$_q$ is in $(q^k \cdot V_q^n(t), q^n)$-*PMPP^L*.*

Proof. See full version [4]. ◀

3 Hardness of coding problems

We now turn to proving *hardness results* for SDP and DenseBall. In each of our hardness reductions we first assume that a gadget code, specified by a circuit $\mathcal{C}_A$, is given to the reduction as auxiliary input. We then instantiate the gadget code $\mathcal{C}_A$ with an explicit efficiently computable code $\mathcal{C}_A$ to obtain a true Karp reduction.

3.1 PWPP-hardness of SDP

We first show a generic reduction, with auxiliary from Pigeon^2 to SDP.

▶ **Theorem 16.** *Let $k, m, n, d, d' \in \mathbb{Z}^+$ be such that $m < k$ and $d < d'$. Let q be a prime power. Then there is a Karp reduction from (q^k, q^m)-*Pigeon^2 *to (n, k, d)-SDP$_q$ that takes a circuit $\mathcal{C}_A : \mathbb{F}_q^m \to \mathbb{F}_q^n$ defining an $(n, m, d')_q$ code as auxiliary input.*

Proof. See full version [4]. ◀

We will instantiate the reduction in Theorem 16 with codes $\mathcal{C}_A$ meeting the Zyablov bound, which can be computed in polynomial time (see [18, Theorem 10.2.1]). In fact, what we state is the special case of the (effective) Zyablov bound with sub-constant rate.[7]

▶ **Theorem 17** (Zyablov bound [44]). *For any (efficiently computable) $k = k(n) = o(n)$, constant prime power q, and constant $\varepsilon > 0$, there is a* poly(n)*-time algorithm that takes as input n and computes (a circuit representing) a code $\mathcal{C}_q^{\mathsf{Zyb}} : \mathbb{F}_q^k \to \mathbb{F}_q^n$ with relative distance $\delta \geq 1 - 1/q - \varepsilon$ for sufficiently large n.*

We now show that SDP is PWPP-hard on q-ary codes of relative distance $\delta := d/n$ less than $1 - 1/q$ and any constant rate. This hardness corresponds to the red shaded region in the top plot in Figure 1. We remark that $(n, k, \delta n)$-SDP$_q$ is easy for $\delta \geq 1 - 1/q$. In particular, for such any such δ, this problem can be solved by choosing any collection of polynomially many codewords and outputting the closest pair among them. So, Corollary 18 shows essentially tight hardness of SDP in terms of δ.

[7] We note that the premise of [18, Theorem 10.2.1] is stated with the requirement $\delta < 1/2$. While $\delta < 1/2$ is necessary for the $q = 2$ case, for general constant q, the result holds for $\delta < 1 - 1/q$, as in Theorem 17. It is also evident from the proof of the Zyablov bound that the result extends to superconstant q as well – i.e., that for any prime power q that is an unbounded function of n and any $k = o(n)$, there is an efficiently computable family of codes $\mathcal{C} : \mathbb{F}_q^k \to \mathbb{F}_q^n$ with relative distance $1 - \varepsilon$.

▶ **Corollary 18** (PWPP-hardness of SDP). *Let q be a fixed prime power and let $\varepsilon, \varepsilon' > 0$ be constants. Then for all sufficiently large $n, k, d \in \mathbb{Z}^+$ with $k \le n \le \mathrm{poly}(k)$ and $d \le (1 - 1/q - \varepsilon')n$, there is a Karp reduction from $(q^k, q^{k^{1-\varepsilon}})$-Pigeon^2 to (n, k, d)-SDP$_q$.*

In particular, $(n, Rn, \delta n)$-SDP$_q$ is PWPP*-hard for any constant rate for any constant rate $R \in (0, 1]$ and constant relative distance $\delta \in (0, 1 - 1/q)$.*

Proof. See full version [4]. ◀

▶ Remark 19. We remark that the assumption $k \le n$ (equivalently, $R \le 1$) in Corollary 18 is not necessary, except to ensure that the instance $\mathcal{C}'$ of SDP output by the reduction meets the definition of a code used there. In fact, modifying Corollary 18 slightly shows PWPP-hardness of "(n, k, d)-SDP$_q$" for any $n \ge \Omega(k^\varepsilon)$ for constant $\varepsilon > 0$ (and any constant relative distance less than). This is because the hard instances $\mathcal{C}'$ of SDP constructed in Corollary 18 are such that either $\mathcal{C}'(\boldsymbol{x}) = \mathcal{C}'(\boldsymbol{y})$ or $\Delta(\mathcal{C}'(\boldsymbol{x}), \mathcal{C}'(\boldsymbol{y}))$ is large for $\boldsymbol{x} \neq \boldsymbol{y}$.

We also extend Corollary 18 to codes in systematic form (and in particular to codes with distance $d \ge 1$, which are represented by injective circuits; see Section 1.5). This hardness corresponds to the red shaded region in the bottom plot in Figure 1.

▶ **Corollary 20** (PWPP-hardness of sysSDP). *Let q be a fixed prime power and let $\varepsilon, \varepsilon' > 0$ be constants. Then for all sufficiently large $n, k, d \in \mathbb{Z}^+$ with $k \le n - k \le \mathrm{poly}(k)$ and $d \le (1 - 1/q - \varepsilon')(n - k)$, there is a Karp reduction from $(q^k, q^{(n-k)^{1-\varepsilon}})$-Pigeon^2 to (n, k, d)-sysSDP$_q$.*

In particular, $(n, Rn, \delta n)$-sysSDP$_q$ is PWPP*-hard for any constant rate $R \in (0, 1)$ and constant relative distance $\delta \in (0, (1 - 1/q) \cdot (1 - R))$.*

Proof. See full version [4]. ◀

3.2 PMPP-hardness of DenseBall

We next show a reduction from Pigeon^L for $L \ge 2$ to DenseBall analogous to Theorem 16.

▶ **Theorem 21.** *Let $k, m, n, t, L, L_A, L' \in \mathbb{Z}^+$ and let q be a prime power. Suppose that $L' \le \min\{\mathrm{poly}(n), q^{n-k}\}$ and $L \le \min\{\lceil L'/L_A \rceil, q^{k-m}\}$. Then there is a Karp reduction from (q^k, q^m)-Pigeon^L to (n, k, t)-DenseBall$_q^{L'}$ that takes a circuit $\mathcal{C}_A : \mathbb{F}_q^m \to \mathbb{F}_q^n$ defining a (t, L_A)-list decodable-code with minimum distance at least 1 (i.e., $\mathcal{C}_A$ is injective) as auxiliary input.*

Proof. See full version [4]. ◀

We now state a result on explicit codes that nearly achieve list-decoding capacity [17] (see also [18, Theorem 17.3.8]). We note in passing that these codes are folded Reed-Solomon codes, but we will only use them in a black-box way as our gadget codes $\mathcal{C}_A$ in Theorem 21.

▶ **Theorem 22** ([17], [18, Theorem 17.3.8]). *For any constant rate $R^* \in (0, 1)$, any sufficiently small constant $\varepsilon > 0$, and all sufficiently large $n \in \mathbb{Z}^+$, there exist linear q-ary $((1 - R^* - \varepsilon)n, L_A)$-list-decodable codes $\mathcal{C}_q^{\mathsf{FRS}}$ of dimension $R^* \cdot n$ and sufficiently large block length n, for some*

$$L_A \le \left(\frac{n}{\varepsilon}\right)^{O(1/\varepsilon)}, \quad q \le \left(\frac{n}{\varepsilon}\right)^{O(1/\varepsilon^2)}.$$

Furthermore, there is a $\mathrm{poly}(n)$-time algorithm for computing (a circuit representing) such codes $\mathcal{C}_q^{\mathsf{FRS}}$.

Finally, we use Theorem 22 to prove PMPP-hardness of DenseBall.

▶ **Corollary 23** (PMPP-hardness of DenseBall)**.** *For any constants $R, \rho \in (0,1)$ and positive integers $m := m(n) < o(n)$ and $L := L(n) \leq \text{poly}(n)$, there exists a prime power $q := q(n) \leq \text{poly}(n)$ and a list size $L' := L'(n) \leq \text{poly}(n)$ such that there is a Karp reduction from (q^k, q^m)-Pigeon^L to $(n, k, \rho n)$-DenseBall$_q^{L'}$, where $k := k(n) = \lfloor Rn \rfloor$.*

In particular, for these parameters, $(n, k, \rho n)$-DenseBall$_q^{L'}$ is (q^k, q^m)-PMPP^L-hard.

Proof. See full version [4]. ◀

As with SDP, we also show hardness of DenseBall for codes in systematic form. (See Section 1.5.)

▶ **Corollary 24** (PMPP-hardness of sysDenseBall)**.** *For any constants $R \in (0,1)$ and $0 < \rho < 1 - R$ and positive integers $m := m(n) < o(n)$ and $L := L(n) \leq \text{poly}(n)$, there exists a prime power $q = q(n) \leq \text{poly}(n)$ and a list size $L' = L'(n) \leq \text{poly}(n)$ such that there is a Karp reduction from (q^k, q^m)-Pigeon^L to $(n, k, \rho n)$-sysDenseBall$_q^{L'}$, where $k := k(n) = \lfloor Rn \rfloor$.*

In particular, for these parameters, $(n, k, \rho n)$-sysDenseBall$_q^{L'}$ is (q^k, q^m)-PMPP^L-hard

Proof. See full version [4]. ◀

4 Finding short lattice vectors is in PMPP

In this section, we show that the problem of finding suitably short non-zero lattice vectors (in ℓ_p norms) can be placed in (A, B)-PMPP^L, with a smooth tradeoff between the length of the vector obtained and L and B. In particular, when $L = 2$ and $A \approx B$, we find vectors whose length is at most the bound given by Minkowski's celebrated theorem [32] (up to a factor of $1 + 1/n^C$ for an arbitrarily large constant $C > 0$), and when $L = \text{poly}(n)$ and $A \approx LB$, we find shorter vectors, corresponding to a stronger bound due to Blichfeldt [7]. (Blichfeldt proved his bound in the ℓ_2 norm, but we generalize it. Again, we match Blichfeldt's bound up to a factor of $1 + 1/n^C$ for an arbitrarily large constant $C > 0$.)

To that end, we first prove the following technical proposition. We then derive the above results as corollaries.

▶ **Proposition 25.** *There is an algorithm that takes as input $p \geq 1$, a radius $r \geq 1$, an integer $q \geq 1$, integers $A > B \geq 1$, an integer $L \geq 1$, and a basis $\mathbf{B} \in \mathbb{Z}^{n \times n}$ for a lattice $\mathcal{L} = \mathcal{L}(\mathbf{B})$, makes a single query to an (A, B)-Pigeon^L oracle, and outputs a lattice vector $\boldsymbol{y} \in \mathcal{L}(\mathbf{B})$ with the following behavior. If $L \leq \lceil A/B \rceil$, $q \geq 100pn/r$ and*

$$q^n \det(\mathcal{L}) \leq B < A \leq \left(1 - \frac{20n}{rq}\right) \cdot q^n \cdot \text{vol}(\mathcal{B}_p^n(r)) \,,$$

then $0 < \|\boldsymbol{y}\|_p \leq d_{\ell_p^n}(r, L)$. Furthermore, the algorithm runs in time $\text{poly}(n, L, \log A, \log r, \log \|\mathbf{B}\|)$.

Proof. See full version [4] ◀

Recall that we are interested in γ-HSVP$_p$ for $\gamma \approx \text{vol}(\mathcal{B}_p^n(1))^{-1/n}$.

▶ **Corollary 26.** *Let $p \geq 1$ be a constant integer, and let $A = A(n), B = B(n), L = L(n) \in \mathbb{Z}^+$ be such that $2^{s(n)} = B < A \leq 2^{\text{poly}(n)}$ and $L \leq \lceil A/B \rceil$ for a sufficiently large polynomial $s(n)$. Then γ-HSVP$_p \in (A, B)$-Pigeon^L for*

$$\gamma := (1 + o(1)) \cdot \text{vol}(\mathcal{B}_p^n(1))^{-1/n} \cdot (A/B)^{1/n} \cdot d_{\ell_p^n}(1, L) \,,$$

where n is the rank of the lattice $\mathcal{L}$ in the γ-HSVP$_p$ instance.

In particular, $\gamma_M := 2 \cdot \mathrm{vol}(\mathcal{B}_p^n(1))^{-1/n}$ *corresponds to Minkowski's theorem , and* $((1 + o(1))\gamma_M)$-$\mathrm{HSVP}_p \in \mathsf{PWPP}$. *Furthermore, for the case of* $p = 2$, $\gamma_B := \sqrt{2} \cdot \mathrm{vol}(\mathcal{B}_2^n(1))^{-1/n}$ *corresponds to Blichfeldt's theorem , and* $((1 + o(1))\gamma_B)$-$\mathrm{HSVP}_2 \in (2LB, B)$-$\mathsf{PMPP}^L$ *for any* $L = \mathrm{poly}(\log B)$.

Abstract

In this paper, we begin the exploration of vertex-ordering problems through the lens of exponential-time approximation algorithms. In particular, we ask the following question: Can we simultaneously beat the running times of the fastest known (exponential-time) exact algorithms and the best known approximation factors that can be achieved in polynomial time? Following the recent research initiated by Esmer et al. (ESA 2022, IPEC 2023, SODA 2024) on vertex-subset problems, and by Inamdar et al. (ITCS 2024) on graph-partitioning problems, we focus on vertex-ordering problems. In particular, we give positive results for Feedback Arc Set, Optimal Linear Arrangement, Cutwidth, and Pathwidth. Most of our algorithms build upon a novel "balanced-cut" approach – which is our main conceptual contribution. This allows us to solve various problems in very general settings allowing for directed and arc-weighted input graphs. Our main technical contribution is a $(1+\varepsilon)$-approximation for any $\varepsilon > 0$ for (weighted) Feedback Arc Set in $O^*((2-\delta_\varepsilon)^n)$ time, where $\delta_\varepsilon > 0$ is a constant only depending on ε.

1 Introduction

Many NP-hard problems admit algorithms running in time $O^*(2^n)$[1]. Moreover, for fundamental problems like Satisfiability or Set Cover, there are plausible conjectures, namely Strong Exponential Time Hypothesis (SETH) or the Set Cover Conjecture, respectively,

[1] Throughout the introduction, n will have the "natural" meaning, e.g., number of variables/vertices/elements, and the O^*-notation hides polynomial factors. See Section 2 for more details about the latter.

which state that these problems do not admit algorithms running in time $O^*((2-\varepsilon)^n)$ for any $\varepsilon > 0$. Although these conjectures have been used as a source of analogous running-time lower bound for other problems, many graph problems are not covered by such results. Indeed, quite a few long-standing exponential-time barriers have finally been overcome in recent years [33, 37, 34], giving new life to the field of *moderately exponential-time algorithms* [22].

Improving upon the trivial $O^*(2^n)$-time algorithm for "vertex-subset problems" on graphs, Fomin et al. [21] designed a general framework called *monotone local search* (MLS). This framework enables the creation of state-of-the-art exact exponential algorithms for a wide range of such problems by leveraging the corresponding parameterized algorithms as black-box components. On the other hand, for graph partitioning and vertex-ordering problems, even the $O^*(2^n)$-time algorithm does not follow from a trivial brute force of the search space. Nevertheless, many such problems do admit $O^*(2^n)$-time algorithms via advanced techniques such as Held-Karp-style dynamic programming [23, 6] or speeding up the natural dynamic program via fast subset convolution [26]. For these latter two classes of problems, beating the $O^*(2^n)$ barrier has proven to be challenging, with the notable exception of k-Cut for which Lokshtanov et al. [31] designed an $O^*((2-\varepsilon)^n)$-time algorithm for some fixed $\varepsilon > 0$. Due to the lack of any progress for many of these intensively studied vertex-ordering problems, we think it is the right time to relax the question just slightly in the following way.

> Can we show or exclude $(1+\varepsilon)$-approximations for vertex-ordering problems that run in $O((2-\delta)^n)$ time?

We show that this question can be answered affirmatively for Feedback Arc Set, but we were not able to achieve the same for any other problem. However, the methods we develop for Feedback Arc Set allow us to answer another natural (weaker) relaxation:

> Can we simultaneously beat the running times of the fastest known (exponential-time) exact algorithms and the best known approximation factors that can be achieved in polynomial-time for vertex-ordering problems?

Given the difficulty in surmounting the current-best exact exponential-time algorithms, there has been a growing research interest in answering the latter relaxation. This is also justified given the fact that most of the problems are known to be APX-hard – they do not admit arbitrarily good approximations. In some cases, problems do not even admit constant-factor approximations in polynomial time assuming $P \neq NP$. To the best of our knowledge, the first exponential-time approximation algorithms were given by Williams [36] who showed how to generalize $O^*(2^{\omega n/3})$-time algorithms for (unweighted) Max Cut and Max 2-SAT to $(1+\varepsilon)$-approximations for the weighted variants using "rounding tricks"; here ω denotes the fast matrix multiplication constant. Quite recently, Alman et al. [1] showed that Max Sat can also be approximated faster than $O^*(2^n)$, that is, they showed that for each $\varepsilon > 0$, there is a $(1+\varepsilon)$-approximation in $O^*((2-\delta_\varepsilon)^n)$ time where $\delta_\varepsilon > 0$ is a constant only depending on ε. Moreover, the monotone local search framework of Fomin et al. [21] was extended to give exponential-time approximation schemes for vertex-subset problems in the works of Esmer et al. [15, 16, 17]. Even more recently, Inamdar et al. [26] gave a framework for designing exponential-time approximation schemes for graph partitioning (i.e., cut) problems and a few more examples for specific problems are known [8, 9, 4]. However, none of these techniques seem applicable to vertex-ordering problems, where the objective is to find an ordering of vertices that satisfies some polynomial-time satisfiable predicate, such as Feedback Arc Set, Optimal Linear Arrangement, Cutwidth, and Pathwidth. For all of the above except Pathwidth, the $O^*(2^n)$-time dynamic programming remains the

Table 1 An overview of our results for unweighted input graphs. For each problem in the left column, we show an algorithm with approximation factor in the middle column and the running time is shown in the right column. The value $\omega < 2.373$ is the fast matrix multiplication exponent and $\delta > 0$ is a constant that depends on ε.

problem	approximation factor	running time
Feedback Arc Set	$1+\varepsilon$	$O^*((2-\delta)^n)$

Optimal Linear Arrangement	$1.5+\varepsilon$	$O^*((2-\delta)^n)$
Directed Optimal Linear Arrangement	$2+\varepsilon$	$O^*((2-\delta)^n)$
Directed Pathwidth	2	$O^*(1.66^n)$

best known algorithm–even including constant-factor approximations. Moreover, the question whether e.g., Feedback Arc Set or Cutwidth can be solved faster than $O^*(2^n)$ have been explicit open problems for a long time [22, 24, 25, 12]. This reinforces our belief that it is time to study exponential-time approximation algorithms for vertex-ordering problems. The only example of such a study is in the case of (directed or undirected) bandwidth [13, 28]. Our results are summarized in Table 1. We believe that working on these vertex-ordering problems from a new angle will further enhance our understanding of them and we hope that there might be some interesting connections to find that use ideas from the vast knowledge acquired on these problems both from the world of polynomial-time approximations and from the world of exact exponential-time algorithms.

In the rest of this section, we survey a few different vertex-ordering problems and previous work related to them. Afterwards, we give an overview of our results and a high-level intuition of our main conceptual contribution.

Problem Definitions and Related Work

We now introduce the different problems used in this paper and briefly state relevant related work for each of them.

We start with a directed version of Minimum Cut with an additional size constraint.

Directed Minimum $(k, n-k)$-Cut

Input: A directed graph G and an integer k.

Task: Find a set L of exactly k vertices such that the number of arcs from $V \setminus L$ to L is minimized.

The undirected version of this problem was introduced by Bonnet et al. [7], who showed fixed-parameter tractability of the problem when parameterized by $k + \mathrm{OPT}$, where OPT is the minimum number of arcs from $V \setminus L$ to L for any set L of size k. We are not aware of any mentioning of the directed problem anywhere. We also study a weighted generalization where we are given an additional non-negative arc-weight function w and instead of minimizing the number of arcs from $V \setminus L$ to L, we instead minimize the weight of the arc set from $V \setminus L$ to L. Directed Minimum $(k, n-k)$-Cut will be at the heart of most of our algorithms.

We continue with Feedback Arc Set. It can be defined both in terms of a subset of arcs of an input graph and as a vertex-ordering problem. The former definition asks for a given directed graph $G = (V, A)$ to find a minimum-size set of arcs whose removal turns G into a directed acyclic graph (DAG). We give the definition as a vertex-ordering problem as this will turn out to be more useful for us later.

Feedback Arc Set
Input: A directed graph $G = (V, A)$.
Task: Find an ordering π of V minimizing the number of backward arcs with respect to π.

Feedback Arc Set can be solved in $O(2^n n^2)$ time by the Held-Karp algorithm [23]. The weighted version of this problem asks for an ordering such that the sum of weights of all backward arcs is minimized. The best known polynomial-time approximaiton algorithm (for both the weighted and unweighted variants) achieves an approximation factor of $O(\log(n) \log\log(n))$ [18] and any approximation better than 1.36 in polynomial time would refute $P \neq NP$ [29, 14]. As stated above, we achieve a $(1+\varepsilon)$-approximation for Feedback Arc Set faster than $O(2^n)$ for any $\varepsilon > 0$. We mention that some of the methods used for this result can also be applied to other vertex-ordering problems (to obtain constant-factor approximations). We list a few such problems in the following.

In Optimal Linear Arrangement (also known as Minimum Linear Arrangement), one is asked for an ordering of a graph that minimizes the sum of stretches of all (backward) arcs. Equivalently, the problem asks for an ordering minimizing the sum of cut sizes over all positions. In the following, we denote by cut^i_π for an ordering π of the vertices and an integer i, the set of all edges (or arcs) from a vertex after position i to a vertex at position at most i.

Optimal Linear Arrangement
Input: An directed or undirected graph G with vertex set V.
Task: Find an ordering π of V minimizing $\sum_{i=1}^{n-1} |\,\mathrm{cut}^i_\pi\,|$.

In the weighted setting, we want to minimize $\sum_{i=1}^{n-1} \sum_{e \in \mathrm{cut}^i_\pi} w(e)$. Optimal Linear Arrangement can be solved in $O^*(2^n)$ time [6] and the best known polynomial-time algorithm achieves an approximation factor in $O(\sqrt{\log(n)} \log\log(n))$ [20, 10]. It remains NP-hard even when restricted to interval graphs but there it can be 2-approximated in polynomial time [11].

In the problem Directed Cutwidth[2], we are looking for an ordering that minimizes the maximum size of any cut^i_π. Formally, it is defined as follows.

Directed Cutwidth
Input: A directed graph $G = (V, A)$.
Task: Find an ordering π of V minimizing $\max_{i \in [n-1]} |\,\mathrm{cut}^i_\pi\,|$.

In the weighted setting, we want to minimize the weight $\max_{i \in [n-1]} \sum_{e \in \mathrm{cut}^i_\pi} w(e)$ instead of the cardinality. Directed Cutwidth can be solved in $O(2^n n^2)$ time and the weighted version can be solved in $O(2^n n^2 \log(w_{\max}))$ time by the Held-Karp algorithm [23]. The best known approximation factor achieved by a polynomial-time algorithm is $O(\log^{1.5}(n))$ [3]. A quantum algorithm running in $O(1.817^n)$ time is also known [2] and if the input graph is undirected, then the problem admits a $\log^{1+o(1)}(n)$-approximation [5].

Finally, we study Directed Pathwidth. It is a directed generalization of Pathwidth which itself is variation of treewidth where the tree decomposition is restricted to being a path. It is known that Pathwidth has an equivalent definition in terms of vertex orderings

[2] We mention in passing that there is some inconsistency in the existing literature regarding the name Directed Cutwidth. An alternative definition takes a directed acyclic graph as input and searches for a topological ordering of the vertices minimizing the (undirected) cutwidth.

and this remains true also for the directed variant [30]. For a position i, consider the number of vertices v that appear before position i that have in-neighbors that appear after position i. The equivalent definition of Directed Pathwidth asks for an ordering that minimizes the maximum quantity over all positions. The formal definition in terms of vertex orderings is as follows.

Directed Pathwidth
Input: A directed graph $G = (V, A)$.
Task: Find an ordering π of V minimizing

$$\max_{i \in [n-1]} |\{v \in V \mid \pi(v) \leq i \wedge (\exists u \in V.\ \pi(u) > i \wedge (u, v) \in A)\}|.$$

The fastest exact algorithm for Directed Pathwidth runs in $O(1.89^n)$ time [30] and the best known approximation factor of a polynomial-time algorithm is $O(\log^{1.5}(n))$ [19]. The undirected pathwidth can be $\log^{1+o(1)}(n)$-approximated in polynomial time [5].

Overview

In this work, we initiate the study of exponential-time approximation algorithms for vertex-ordering problems. A recurring theme in our algorithms is a "balanced-cut" strategy, which results in a running time that is strictly faster than $O^*(2^n)$ and which we consider our main conceptual contribution. We briefly describe the main idea here. We first show how to find a partition of the set of vertices in a graph into two sets L and R of given sizes such that the number of arcs from R to L is (approximately) minimized, that is, we solve Directed Minimum $(k, n-k)$-Cut.[3] Depending on the specific problem at hand, we then either solve the two instances induced by these sets of vertices exactly or approximately. Finally, we show how to combine the two partial solutions with the computed cut between R and L. For Feedback Arc Set, we design an additional "self-improving" $(1+\varepsilon)$-approximation algorithm by combining the above approach with a novel bootstrapping strategy.

The rest of this work is structured as follows. In Section 2, we introduce notation and concepts used in this work. We show our results for unweighted problems in Section 3 and for weighted problems in Section 4. We conclude with Section 5.

2 Preliminaries

For a positive integer $n \in \mathbb{N}$, we denote by $[n]$ the set $\{1, 2, \ldots, n\}$. We use standard graph-theoretic notation. In particular, for a given graph $G = (V, E)$ and a set $V' \subseteq V$ of vertices, we use $G[V']$ to denote the subgraph of G induced by V'. To avoid confusion, we will use the term *edges* for undirected graphs and the term *arcs* for directed graphs. Moreover, we will refer to the edge set of an undirected input graph by E and the arc set of a directed input graph by A. All graphs in this work are simple, that is, they do not contain self-loops or parallel edges/arcs (but we allow in the directed case both the arc (u, v) and the arc (v, u) to be present at the same time for a pair of vertices $u \neq v$). We always denote the number of vertices in the input graph by n and the number of edges/arcs by m. We say that a graph is edge-weighted (respectively arc-weighted) if we are given an additional weight function $w \colon E \to \mathbb{N}$ ($w \colon A \to \mathbb{N}$). The weight of an edge $e \in E$ is then $w(e)$ and the weight of a set $E' \subseteq E$ of edges is the sum of edge weights of edges in E.

[3] We mention that we do not always just consider a single partition. Sometimes, we iterate over many such partitions and return the best solution over all considered partitions.

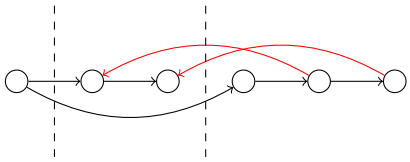

Figure 1 An example for cut_π in the directed setting. The vertices are ordered by some ordering π from left to right. The cuts cut_π^1 and cut_π^3 are depicted by dashed lines. The cut cut_π^1 is empty and the cut cut_π^3 consists of all the red arcs. The stretch of both red arcs is 3.

A *ordering* π of the vertices of a graph G with vertex set V is a bijection between V and $|V|$. For a directed graph $G = (V, A)$ and an ordering π of V, we say that an arc (u, v) is forward with respect to π if $\pi(u) < \pi(v)$ and the arc is backward with respect to π otherwise. The stretch of an edge $\{u, v\}$ (or an arc (u, v)) is $|\pi(u) - \pi(v)|$. For an integer $i \in [n]$, we say the cut at position i with respect to π is $\mathrm{cut}_\pi^i = \{\{u, v\} \in E \mid \pi(u) > i \wedge \pi(v) \leq i\}$. In the directed case, we use the definition $\mathrm{cut}_\pi^i = \{(u, v) \in A \mid \pi(u) > i \wedge \pi(v) \leq i\}$. See Figure 1 for an example.

We assume familiarity with the Bachmann–Landau notation (also known as big-O notation) and we use O^* to hide polynomial factors in the input size. We note, that this on the one hand hides polynomial factors in $\log(w_{\max})$, where $w_{\max}$ is the largest weight in the input graph. On the other hand, $O^*(\alpha^n) \subseteq O((\alpha + \varepsilon)^n)$ for any $\alpha \geq 1$ and any $\varepsilon > 0$.

3 Unweighted Problems

In this section, we present our algorithms for unweighted input graphs. We present all algorithms for the directed case but mention that it is straight-forward to adapt all of these algorithms to the undirected case. Most of our results are based on the following faster algorithm for Directed Minimum $(k, n-k)$-Cut which is a generalization of a similar algorithm for Maximum Cut by Williams [36]. Here and in the following, $\omega < 2.373$ is the matrix-multiplication exponent.

▶ **Proposition 1.** *Directed Minimum $(k, n-k)$-Cut can be solved in $O^*(\min(2^{\frac{\omega n}{3}}, n^{\omega k}))$ time.*

Proof. Let $(G = (V, A), k)$ be an input instance of Directed Minimum $(k, n-k)$-Cut. We partition V arbitrarily into three sets V_1, V_2, and V_3 of (roughly) equal size. Next, we guess in $O(n^2)$ time how many vertices of V_1, V_2, and V_3 belong to an optimal solution L. Let these numbers be k_1, k_2 and $k_3 = k - k_1 - k_2$. Next, we build a graph H as follows. For each $i \in [3]$, we introduce a vertex v_j^i for each subset $V_j^i \subseteq V_i$ with $|V_j^i| = k_i$. Let $\delta(v_j^i) = |\{(u, w) \in A \mid u \in V_i \setminus V_j^i \wedge w \in V_j^i\}|$ be the number of arcs from $V_i \setminus V_j^i$ to V_j^i. Note that H contains $O(\min(2^{n/3}, \binom{n/3}{k}))$ vertices. For each pair of vertices $v_j^i, v_{j'}^{i'}$ with $i \neq i'$, we add an edge between them. We set the weight of this edge to

$$|\{(u, w) \in A \mid u \in V_i \setminus V_j^i \wedge w \in V_{j'}^{i'}\}|$$
$$+ |\{(u, w) \in A \mid u \in V_{i'} \setminus V_{j'}^{i'} \wedge w \in V_j^i\}| + \frac{\delta(v_j^i) + \delta(v_{j'}^{i'})}{2}.$$

Note that each edge weight is at most n^2. Next, for each pair $i \neq i'$, we guess the weight of the edge $\{v_j^i, v_{j'}^{i'}\}$ in a minimum-weight triangle in H (without guessing the indices j and j'). Note that there are n^6 possible guesses. For each guess, we compute in time linear in the size of H

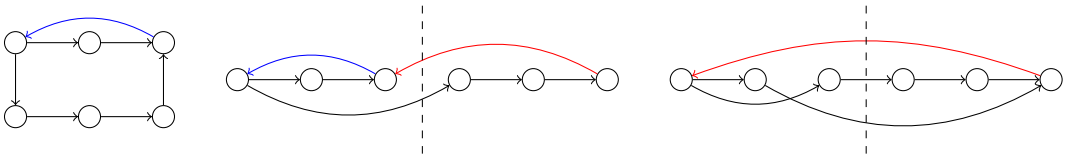

Figure 2 An example of Feedback Arc Set. The input graph is given on the left and the middle/right show two optimal solutions for Directed Minimum $(k, n-k)$-Cut with $k = 3$ (red arcs). The optimal solution to Feedback Arc Set is shown in blue (and coincides with the red arc on the right). If we use the cut in the middle picture, then we can only find a 2-approximation while the cut on the right leads to an optimal solution.

a subgraph which only contains the edges corresponding to the current guess. We then check whether this subgraph contains a triangle in $O^*((\min(2^{\frac{n}{3}}, \binom{n/3}{k}))^\omega) = O^*(\min(2^{\frac{\omega n}{3}}, n^{\omega k}))$ time [27]. The algorithm also finds a triangle if one exists. After going through all possible guesses, we report the triangle of minimum weight. Note that this weight corresponds by construction to a minimum directed $(k, n-k)$-cut such that $|L \cap V_i| = k_i$ for all $i \in [3]$. Since we iterate over all possible choices of k_i, we always find a minimum-weight directed $(k, n-k)$-cut. The total running time is in $O^*(\min(2^{\frac{\omega n}{3}}, n^{\omega k}))$. ◀

3.1 Feedback Arc Set

We next show how to use Proposition 1 to design a $(1+\varepsilon)$-approximation for Feedback Arc Set for any $\varepsilon > 0$ that is faster than the $O^*(2^n)$-time Held-Karp algorithm. We first show how to find a 2-approximation in $O^*(2^{\frac{\omega n}{3}})$ time and then show how to use a $(1+\frac{1}{k})$-approximation to find a $(1+\frac{1}{k+1})$-approximation.

▶ **Lemma 2.** *Feedback Arc Set can be 2-approximated in $O^*(2^{\frac{\omega n}{3}})$ time.*

Proof. Let $G = (V, A)$ be an input graph for Feedback Arc Set. We first compute an optimal solution $L \subseteq V$ of the instance $(G, \lfloor \frac{n}{2} \rfloor)$ of Directed Minimum $(k, n-k)$-Cut in $O^*(2^{\frac{\omega n}{3}})$ time using Proposition 1. Observe that $|L| = \lfloor \frac{n}{2} \rfloor$, and that the number of arcs from $V \setminus L$ to L is a lower bound for the size of a minimum feedback arc set in G. Let this set of arcs be A' and let the set of arcs from L to $V \setminus L$ be A''. Next, we solve the two instances $G[L]$ and $G[V \setminus L]$ of Feedback Arc Set optimally in $O^*(2^{\frac{n}{2}})$ time [23]. See Figure 2 for an example. Since a feedback arc set in a graph is also a feedback arc set in any subgraph, it holds that the optimal solutions in $G[L]$ and $G[V \setminus L]$ are combined a lower bound for the size of a feedback arc set in G. Hence, placing the vertices of L in the computed order before the vertices of $V \setminus L$ in the computed order yields a 2-approximation as each arc in A' contributes one and the arcs in A'' do not contribute anything. The running time is in $O^*(2^{\frac{\omega n}{3}} + 2^{\frac{n}{2}}) = O^*(2^{\frac{\omega n}{3}})$. ◀

We next show how to use any constant-factor approximation for Feedback Arc Set that is faster than $O^*(2^n)$ to compute a better constant factor approximation that is also faster than $O^*(2^n)$. This "boosting technique" results in the following approximation scheme.

▶ **Theorem 3.** *For each constant $\varepsilon > 0$, there is a $\delta_\varepsilon > 0$ such that Feedback Arc Set can be $(1+\varepsilon)$-approximated in $O((2-\delta_\varepsilon)^n)$ time.*

Proof. We prove this statement by showing via induction that for each $k \geq 1$, there is a $\delta_k > 0$ such that Feedback Arc Set can be $(1+\frac{1}{k})$-approximated in $O((2-\delta_k)^n)$ time. Since any constant $\varepsilon > 0$ is larger than $\frac{1}{k}$ for some constant value of k, this will prove the

theorem. Note that the base case $k = 1$ is proven by Lemma 2. It remains to show the induction step, that is, assuming that the statement is true for some value of k, we need to show that the statement is also true for $k + 1$. To this end, let k be arbitrary but fixed and assume that Feedback Arc Set can be $(1 + \frac{1}{k})$-approximated in $(2 - \delta_k)^n$ time for some $\delta_k > 0$. Let γ be the solution to the equation

$$\frac{\gamma \log(\gamma) - (\gamma - 1)\log(\gamma - 1)}{\gamma - 1} = 1 - \log(2 - \delta_k),$$

where all logarithms use base 2, and let $\alpha = \frac{1}{\gamma}$.[4] Note that $\gamma \geq 2$ exists for each $0 < \delta_k < 1$ as the right side of the equations is some value between zero and one and the left side evaluates to 2 for $\gamma = 2$ and tends towards 0 for increasing values of γ as shown next. Note that the left side of the previous equation is equivalent to $(\log(\gamma) - \log(\gamma - 1)) + \frac{\log(\gamma)}{\gamma - 1}$. The first summand describes the derivative of the logarithm (which is $\frac{1}{\ln(2)\gamma}$) and therefore tends towards 0 for increasing values of γ. The second summand also clearly tends towards zero as the logarithm grows sublinearly.

We next describe the $(1 + \frac{1}{k+1})$-approximation for Feedback Arc Set. Let $G = (V, A)$ be the input graph and let n be the number of vertices in V. For the sake of simplicity, we will assume that αn is an integer to avoid dealing with rounding issues (which will vanish in the Bachmann-Landau notation anyway). Bodlaender et al. [6] showed how to solve Feedback Arc Set exactly in $O^*(2^n)$ time. Importantly, their algorithm iterates over all induced subgraphs (in order of increasing size), and computes the optimal solution for each induced subgraph in polynomial time for each subgraph. We use their algorithm for all induced subgraphs with at most αn vertices. Let $\mathcal{V}$ be the set of all sets of vertices of size exactly αn. Using the algorithm by Bodlaender et al. [6] to compute the optimal solution for all graphs induced by sets in $\mathcal{V}$ takes $O^*(\binom{n}{\alpha n})$ time. In the same time, we can also compute for each $V' \in \mathcal{V}$ the number of arcs in $\{(u, v) \mid u \in V \setminus V' \wedge v \in V'\}$. Let $a(V')$ denote this number and let $V^* \in \mathcal{V}$ be a set minimizing $a(V^*)$. We then use the algorithm by Bodlaender et al. [6] to solve the instance $G[V \setminus V^*]$ optimally in $O^*(2^{(1-\alpha)n})$ time and for all other $V' \in \mathcal{V}$, we use the $(1 + \frac{1}{k})$-approximation for $G[V \setminus V']$ that runs in $O((2 - \delta_k)^{(1-\alpha)n})$ time. Finally for each $V' \in \mathcal{V}$, we compute the sum of the optimal value for $G[V']$ plus $a(V')$ plus the size of the computed solution for $G[V \setminus V']$. We return the smallest number found (or the set associated to the smallest number if we want to return the feedback arc set).

It remains to show that our algorithm always produces a $(1 + \frac{1}{k+1})$-approximation and to analyze the running time. For the approximation factor, let F be a feedback arc set of G of minimum size and let $\mathrm{OPT} = |F|$. We distinguish between the following two cases. Either $a(V^*) \leq \frac{1}{k+1}\,\mathrm{OPT}$ or $a(V^*) > \frac{1}{k+1}\,\mathrm{OPT}$. In the first case, note that the solution we computed for V^* consists of optimal solutions for $G[V^*]$ and $G[V \setminus V^*]$ plus $a(V^*)$. Since the first two summands are combined at most OPT and $a(V^*) \leq \frac{1}{k+1}\,\mathrm{OPT}$, we indeed return a feedback arc set of size at most $(1 + \frac{1}{k+1})\,\mathrm{OPT}$. If $a(V^*) > \frac{1}{k+1}\,\mathrm{OPT}$, then note that for each $V' \in \mathcal{V}$ it holds that $a(V') > \frac{1}{k+1}\,\mathrm{OPT}$. Moreover, since the graph $G' = (V, A \setminus F)$ is acyclic, it has a topological ordering. Let V'' be the set of the first αn vertices in that topological ordering. Let d be the size of a minimum feedback arc set in $G[V \setminus V'']$ and let $c = \frac{d}{\mathrm{OPT}}$. Note that $c \leq \frac{k}{k+1}$. Finally, the solution we compute for V'' has size

[4] We note that γ is roughly $-\frac{W(-\frac{(2-\delta_k)(1-\log(2-\delta_k))}{2})}{1-\log(2-\delta_k)}$, where W is the Lambert W function (also known as the product logarithm). It is known that this function cannot be expressed in terms of elementary functions.

$$(1-c)\,\mathrm{OPT}+(1+\frac{1}{k})c\,\mathrm{OPT} \leq \mathrm{OPT}-c\,\mathrm{OPT}+c\,\mathrm{OPT}+\frac{1}{k}\frac{k}{k+1}\,\mathrm{OPT} = (1+\frac{1}{k+1})\,\mathrm{OPT}\,.$$

Thus, we also return a $(1+\frac{1}{k+1})$-approximation in this case.

Let us now analyze the running time. Recall that $\gamma = \frac{1}{\alpha}$. Computing $\mathcal{V}$, $a(V')$, and the optimal solution for $G[V']$ for each $V' \in \mathcal{V}$ take $O^*(\binom{n}{\alpha n})$ time. Solving the instance $G[V \setminus V^*]$ optimally takes $O^*(2^{(1-\alpha)n})$ time. Computing the approximate solutions for all sets in $\mathcal{V}$ takes overall $O^*(\binom{n}{\alpha n} \cdot (2-\delta_k)^{(1-\alpha)n})$ time. By standard arguments, $\binom{n}{\alpha n} \in O((\frac{\gamma^\gamma}{(\gamma-1)^{\gamma-1}})^{\alpha n})$ [35]. Hence

$$\begin{aligned}
O(\binom{n}{\alpha n} \cdot (2-\delta_k)^{(1-\alpha)n}) &= O(2^{\log(\frac{\gamma^\gamma}{(\gamma-1)^{\gamma-1}})^{\alpha n})} \cdot 2^{\log((2-\delta_k)^{(1-\alpha)n})}) \\
&\subseteq O(2^{\alpha n(\log(\gamma^\gamma)-\log((\gamma-1)^{\gamma-1}))+(1-\alpha)n\log(2-\delta_k)}) \\
&\subseteq O(2^{(1-\alpha)n\left(\frac{\alpha}{1-\alpha}(\gamma\log(\gamma)-(\gamma-1)\log(\gamma-1))+\log(2-\delta_k)\right)}) \\
&\subseteq O(2^{(1-\alpha)n\left(\frac{\gamma\log(\gamma)-(\gamma-1)\log(\gamma-1)}{\gamma-1}+\log(2-\delta_k)\right)}) \\
&\subseteq O(2^{(1-\alpha)n}),
\end{aligned}$$

where again all logarithms use base 2. The last equality is due to the definition of γ. Thus, the total running time of our algorithm is $O^*(2^{(1-\alpha)n})$. This is in $O((2-\delta_{k+1})^n)$ time for any $0 < \delta_{k+1} < 2-2^{1-\alpha}$. This completes the induction step and concludes the proof. ◀

3.2 Cutwidth

We continue with Directed Cutwidth. We again show how to use Proposition 1 to compute a 2-approximaiton.

▶ **Proposition 4.** *Directed Cutwidth can be 2-approximated in $O^*(2^{\frac{\omega n}{3}})$ time.*

Proof. Let $G = (V, A)$ be an input to Directed Cutwidth. We first find an optimal solution L to the instance $(G, \lfloor \frac{n}{2} \rfloor)$ of Directed Minimum $(k, n-k)$-Cut in $O^*(2^{\frac{\omega n}{3}})$ time using Proposition 1. Let $R = V \setminus L$ and let A^* be the set of arcs (u, v) with $u \in R$ and $v \in L$. Note that the size of A^* is by definition a lower bound for the directed cutwidth of G. Next, we can solve $G[L]$ and $G[R]$ optimally in $O^*(2^{\frac{n}{2}})$ time [23]. Since adding a vertex and/or arc to a graph cannot decrease its directed cutwidth, we have that the cutwidth of $G[L]$ and $G[R]$ are both at most the cutwidth of G. Hence, placing all vertices in L according to the computed solution for $G[L]$ and then all vertices in R according to the solution for $G[R]$ gives an ordering for the graph $G' = (V, A \setminus A^*)$ that shows that the cutwidth of G' is at most the cutwidth of G. See Figure 3 for an example. Adding the set A^* to G' can increase the cutwidth by at most $|A^*|$ and adding arcs (u, v) with $u \in L$ and $v \in R$ does not increase the directed cutwidth. Thus, the computed ordering is a 2-approximation as the size of A^* is at most the cutwidth of G as shown above. Note that the running time is in $O^*(2^{\frac{\omega n}{3}} + 2^{\frac{n}{2}}) = O^*(2^{\frac{\omega n}{3}})$. This concludes the proof. ◀

Unfortunately, due to the inherent maxima nature of Directed Cutwidth, we do not know how to apply a boosting technique similar to Theorem 3 to get an approximation factor smaller than 2.

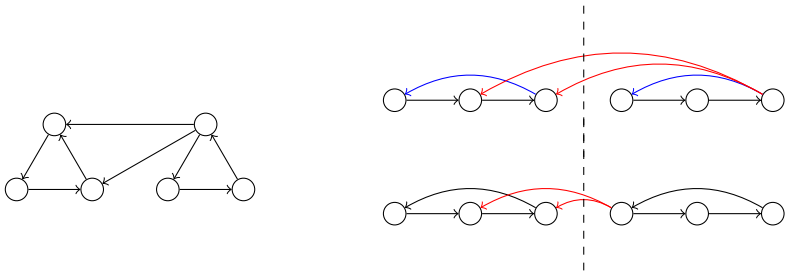

Figure 3 An example of Directed Cutwidth. The input instance is depicted on the left with the exception that all vertices in the left triangle have arcs towards all vertices in the right triangle unless the respective reverse arc is present. We decided to not show these arcs for the sake of readibility. On the right, two optimal solutions to Directed Minimum $(k, n-k)$-Cut with $k = 3$ are shown (red arcs) with optimal orderings for the two respective subproblems of Directed Cutwidth are depicted. The ordering shown on the top has a directed cutwidth of 3 (e.g. at positions 4 and 5) and the ordering on the bottom has a directed cutwidth of 2.

3.3 Optimal Linear Arrangement

In this section, we study Optimal Linear Arrangement. We show how to compute a $(2+\varepsilon)$-approximation for Directed Optimal Linear Arrangement for each $\varepsilon > 0$ in $O((2-\delta_\varepsilon)^n)$ time for some $\delta_\varepsilon > 0$ only depending on ε. We then show how to improve the algorithm in the undirected setting to achieve a $(\frac{3}{2}+\varepsilon)$-approximation in the same time.

▶ **Proposition 5.** *For every $0 < \alpha < 1$, there is a $(1 + \frac{1}{(1-\alpha)})$-approximation for Directed Optimal Linear Arrangement that runs in $O^*(2^{\frac{\omega n}{3}} + 2^{(1-\frac{\alpha}{2})n})$ time, where ω is the matrix-multiplication exponent.*

Proof. Let $G = (V, A)$ be an input to Directed Optimal Linear Arrangement. We use Proposition 1 to solve Directed Minimum $(k, n-k)$-Cut for each $\frac{\alpha n}{2} \leq k \leq n - \frac{\alpha n}{2}$. This takes $O^*(2^{\frac{\omega n}{3}})$ time. Let k' be a value where the number of arcs from $V \setminus L$ to L are minimum for some set L of size k'. Let L' be a set of vertices of size k' minimizing the number of arcs from $R' = V \setminus L'$ to L' and let A' be the set of arcs from R' to L'. By the pigeonhole principle, the size of A' is at most $\frac{\mathrm{OPT}}{(1-\alpha)n}$ where OPT is the optimal directed-optimal-linear-arrangement value for G (the value we want to minimize in Directed Optimal Linear Arrangement). Note that $|L'|, |R'| \leq (1 - \frac{\alpha}{2})n$. Next, we solve the instances $G[L]$ and $G[R]$ optimally in $O^*(2^{(1-\frac{\alpha}{2})n})$ time using the algorithm by Bodlaender et al. [6]. To get an approximation for the whole graph G, we first order all vertices in L according to the computed solution for $G[L]$ and then all vertices in R according to the computed solution for R. Note that this is an optimal solution for the graph $G' = (V, A \setminus A')$. It remains to add the arcs between L and R. Note that each edge in A' can contribute at most n and therefore the edges in A' can contribute at most $\frac{\mathrm{OPT}}{1-\alpha}$ in total. Arcs from L to R do not contribute as they are forward arcs in the computed ordering. Added to the cost for G' (which is at most OPT), this yields the claimed approximation factor. The running time is in $O^*(2^{\frac{\omega n}{3}} + 2^{(1-\frac{\alpha}{2})n})$. ◀

We mention that the above result yields a 2.72-approximation in $O^*(2^{\frac{\omega n}{3}})$ time, assuming the currently known value of $\omega < 2.372$. We next show how to improve the approximation factor to $(\frac{3}{2}+\varepsilon)$ in the undirected setting. The general strategy is the same but in the end, we use the fact that an ordering and its reverse have the same value in terms of Optimal Linear Arrangement and leverage this fact to argue that contribution of each edge between the two parts is at most $\frac{n}{2}$ on average.

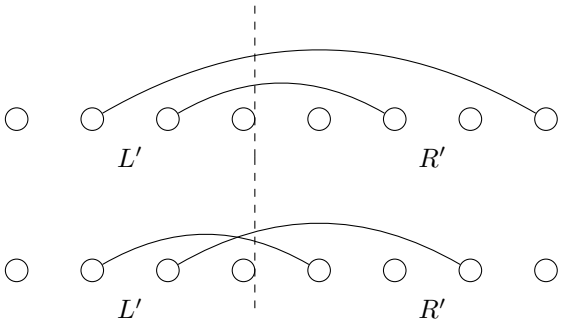

Figure 4 An example of Optimal Linear Arrangement where the vertices are divided into two parts L' and R' with two edges between the two parts and some ordering within the two parts is fixed. For the sake of simplicity, we do not show edges within the two parts. The two orderings only differ in that we reverse the ordering of the vertices in R'. The average length within L' of the two edges between L' and R' is 1.5 in both orderings. The average length within R' is 3 in the above ordering and $2'$ in the below ordering.

▶ **Proposition 6.** *For each constant $0 < \alpha < 1$, there is a $(1 + \frac{1}{2(1-\alpha)})$-approximation for Optimal Linear Arrangement that runs in $O^*(2^{\frac{\omega n}{3}} + 2^{(1-\frac{\alpha}{2})n})$ time, where ω is the matrix-multiplication exponent.*

Proof. Let $G = (V, E)$ be an input graph for Optimal Linear Arrangement. We start the same as in Proposition 5, that is, we solve Minimum $(k, n-k)$-Cut for each $\frac{\alpha n}{2} \leq k \leq \frac{n}{2}$, define sets L', R', and E' and value OPT, and solve $G[L']$ and $G[R']$ optimally in $O^*(2^{\frac{\omega n}{3}} + 2^{(1-\frac{\alpha}{2})n})$ time overall. Let $i = |L'|$. We next test for both L' and R' whether the average length of edges in E' is smaller if we order the vertices according to the computed solution or in the reverse order. To this end, we pretend that the endpoint outside the respective part is fixed at position i. See Figure 4 for an example. We pick for each of the two the ordering which results in shorter average lengths and observe that the average length of an edge in E' is now at most $\frac{n}{2}$ as the average length "in L'" is at most $\frac{|L'|-1}{2}$, the average length "in R'" is at most $\frac{|R'|+1}{2}$, and $|L'| + |R'| = n$. The combined cost for all edges in E' is therefore at most $\frac{\text{OPT}}{(1-\alpha)n} \cdot \frac{n}{2} = \frac{\text{OPT}}{2(1-\alpha)}$ and added to the cost for G' (which is at most OPT), this yields the claimed approximation factor. The running time is in $O^*(2^{\frac{\omega n}{3}} + 2^{(1-\frac{\alpha}{2})n})$. ◀

The above results yields a 1.86-approximation in $O^*(2^{\frac{\omega n}{3}})$ time using the currently known value of $\omega \approx 2.372$.

3.4 Pathwidth

We conclude this section with a 2-approximation for Directed Pathwidth in $O(1.66^n)$ time. We point out that this result stands out from the previous in two ways: Directed Pathwidth can be solved in $O(1.89^n)$ time and our algorithm is not based on Proposition 1.

▶ **Theorem 7.** *Directed Pathwidth can be 2-approximated in $O(1.66^n)$ time.*

Proof. Let $G = (V, A)$ be the input graph for which we want to approximate the pathwidth, let $\alpha \approx 0.204$ be the solution to the equation $1.89^{1-\alpha} = (\frac{1}{\alpha})^{\alpha}(\frac{1}{1-\alpha})^{1-\alpha}$, and let OPT be the (unknown) directed pathwidth of G. We first use the algorithm by Bodlaender et al. [6] to find a set V' of αn vertices (and an ordering of these vertices) such that independent of the ordering of the remaining $(1-\alpha)n$ vertices, it holds for each position i that at most OPT

vertices before position $\min(i, \alpha n)$ have in-neighbors after position i. This can be done in time $O^*((\frac{1}{\alpha})^{\alpha n}(\frac{1}{1-\alpha})^{(1-\alpha)n}) = O^*(1.89^{(1-\alpha)n})$. Next, we solve the instance $G[V \setminus V']$ of Directed Pathwidth optimally in $O^*(1.89^{(1-\alpha)n})$ time [30]. We return the ordering that places the vertices in V' first (in the order that was computed before) and then all vertices in $V \setminus V'$ in the order corresponding to the solution for $G[V \setminus V']$. Note that it holds for each position $i > \alpha n$ that at most OPT vertices before position αn have in-neighbors after position i and at most OPT vertices between position $\alpha n + 1$ and i have in-neighbors after position i, that is, the computed ordering is a 2-approximation. The running time is in $O^*(1.89^{(1-\alpha)n}) \approx O^*(1.89^{(0.796)n}) \subseteq O(1.66^n)$. This concludes the proof. ◀

4 Weighted Problems

In this section, we consider weighted generalizations of the problems studied in the last section. We denote the largest weight in the input by $w_{\max}$. We mention that if $w_{\max}$ is polynomially upper-bounded in n, then all of our previous results generalize in a straight-forward way. Hence, we mainly focus on cases where $w_{\max}$ is large compared to n. An assumption that is often made when dealing with weighted problems is that all numbers can be added and subtracted in constant time. However, in the realm of very large weights, this assumption is highly unrealistic as even reading the weight from input takes $O(\log(w_{\max}))$ time (which we sometimes hide in the O^*-notation). We decided to not make the above assumption which basically adds an additional $O(\log(w_{\max}))$ factor to all running times.

We mention that we do not study a weighted version of Directed Pathwidth. To the best of our knowledge, this problem has only been studied once [32] and our algorithm behind Theorem 7 computes a 2-approximation even in the weighted setting if we have an exact (slower) algorithm. We suspect that the $O(1.89^n)$-time algorithm by Kitsunai et al. [30] generalizes to the weighted setting but this was never proven and proving it here would go beyond the scope of this paper.

We start with an arc-weighted generalization of Directed Minimum $(k, n-k)$-Cut. We mention that if this generalization can be solved in $O^*(2^{\frac{\omega n}{3}})$ time, then our previous algorithms for Feedback Arc Set, Directed Optimal Linear Arrangement, and Directed Cutwidth can all easily be generalized to the weighted setting. Unfortunately, even for (undirected) Weighted Max Cut, no such algorithm is known. However, Williams [36] showed how to compute a $(1+\varepsilon)$-approximation for Weighted Max Cut in $O^*(2^{\frac{\omega n}{3}}(\frac{1}{\varepsilon})^3)$ time. We will generalize this result to Weighted Directed Minimum $(k, n-k)$-Cut and show how to use this approximation for the other problems.

▶ **Proposition 8.** *For any $\varepsilon > 0$, Weighted Directed Minimum $(k, n-k)$-Cut can be $(1+\varepsilon)$-approximated in $O(2^{\frac{\omega n}{3}} \cdot \log(w_{\max}) \cdot (\frac{1}{\varepsilon})^2 \cdot k^2)$ time.*

Proof. Let $(G = (V, A), k)$ be an input instance and let $\varepsilon > 0$ be an arbitrary but fixed value. We partition V arbitrarily into three sets V_1, V_2, and V_3 of (roughly) equal size. Next, we guess in $O(k^2)$ time how many vertices of V_1, V_2, and V_3 belong to an optimal solution A. Let these numbers be k_1, k_2 and $k_3 = k - k_1 - k_2$. Next, we build an undirected graph H with edge weights as follows. For each $i \in [3]$, we introduce a vertex v_j^i for each subset $V_j^i \subseteq V_i$ with $|V_j^i| = k_i$. Note that the number of vertices in H is in $O(2^{n/3})$. For each vertex v_j^i, let $d(v_j^i)$ denote the sum of weights of all arcs from vertices in V_j^i to vertices in $V_i \setminus V_j^i$ in G. For each pair of vertices $v_j^i, v_{j'}^{i'}$ with $i \neq i'$, we add an edge between them of weight

$$\frac{d(v_j^i) + d(v_{j'}^{i'})}{2} + \sum_{\{(u,w) \in A \mid u \in V_j^i \wedge w \in V_{i'} \setminus V_{j'}^{i'}\} \cup \{(u,w) \in A \mid u \in V_{j'}^{i'} \wedge w \in V_i \setminus V_j^i\}} w((u,w)).$$

Using an algorithm by Zwick [38] (see also Williams [36]), we find a $(1+\varepsilon)$-approximation for the minimum-weight triangle in H in $O(2^{\frac{\omega n}{3}} \frac{1}{\varepsilon} \log(\frac{n^2 w_{\max}}{\varepsilon})) \subseteq O(2^{\frac{\omega n}{3}} (\frac{1}{\varepsilon})^2 \log(w_{\max}))$ time. Note that $\log(n^2 w_{\max}) \leq \log({w_{\max}}^3) \leq 3\log(w_{\max})$ as we assume $w_{\max} > n$. Moreover, each triangle in H corresponds to a directed $(k, n-k)$-cut in H of the same weight and each directed $(k, n-k)$-cut with k_i vertices in V_i for each $i \in [3]$ corresponds to a triangle of the same weight in H. Hence, we compute a $(1+\varepsilon)$-approximation for Weighted Directed Minimum $(k, n-k)$-Cut. The total running time is in $O(2^{\frac{\omega n}{3}} \log(w_{\max})(\frac{1}{\varepsilon})^2 k^2)$ and this concludes the proof. ◀

4.1 Feedback Arc Set

We next show how to use Proposition 8 to get faster approximation algorithms for the weighted variants of the other vertex-ordering problems we consider. We start with Weighted Feedback Arc Set. Similar to the unweighted case, we first show a constant factor approximation and then show a boosting technique to achieve any $(1+\varepsilon)$-approximation.

▶ **Proposition 9.** *Weighted Feedback Arc Set admits a 3-approximation that can be computed in $O(2^{\frac{\omega n}{3}} \log(w_{\max})k^2)$ time.*

Proof. Let $G = (V, A)$ be an input graph for Weighted Feedback Arc Set. We first compute a 2-approximation L for the instance $(G, \lfloor \frac{n}{2} \rfloor)$ of Weighted Directed Minimum $(k, n-k)$-Cut in $O(2^{\frac{\omega n}{3}} \log(w_{\max})k^2)$ time using Proposition 8 with $\varepsilon = 1$. Note that half the sum of weights of arcs from $R = V \setminus L$ to L is a lower bound for the size of a minimum feedback arc set. We refer to Figure 2 for an illustration and mention that this time the weight of all red arcs is a 2-approximation for an optimal cut. Next, we solve the two instances $G[L]$ and $G[R]$ of Weighted Feedback Arc Set optimally in $O(2^{\frac{n}{2}} n^2 \log(w_{\max}))$ time [23]. Placing the vertices of L in the computed order before the vertices of R in the computed order yields a 3-approximation as the weights of the feedback arcs within both instances are combined also a lower bound for the weight of a minimum-weight feedback arc set in G. The running time is in $O(2^{\frac{\omega n}{3}} \log(w_{\max})k^2)$ as $\frac{\omega}{3} > \frac{1}{2}$. ◀

We next present the boosting technique in the weighted setting. It is very similar to the unweighted setting with two minor adjustments: the formulas change slightly due to the fact that we start with a 3-approximation rather than a 2-approximation and an additional factor of $O(\log(w_{\max}))$ is used when using the algorithm by Bodlaender et al. [6]. We present the entire proof for the sake of completeness.

▶ **Theorem 10.** *For each $\varepsilon > 0$, there is a $\delta > 0$ such that Weighted Feedback Arc Set can be $(1+\varepsilon)$-approximated in $O((2-\delta)^n \cdot \log(w_{\max}))$ time.*

Proof. We prove this statement by showing via induction that for each $k \geq 1$, there is a $\delta > 0$ such that Weighted Feedback Arc Set can be $(1 + \frac{2}{k})$-approximated in $O((2-\delta)^n \log(w_{\max}))$ time. Since any $\varepsilon > 0$ is larger than $\frac{2}{k}$ for some value of k, this will prove the theorem. Note that the base case $k = 1$ is proven by Proposition 9. It remains to show the induction step, that is, assuming that the statement is true for some value of k, we need to show that the statement is also true for $k+1$. To this end, let k be arbitrary but fixed and assume that Weighted Feedback Arc Set can be $(1 + \frac{2}{k})$-approximated in $(2-\delta_k)^n$ time for some $\delta_k > 0$. Let γ be the solution to the equation

$$\frac{\gamma \log(\gamma) - (\gamma - 1)\log(\gamma - 1)}{\gamma - 1} = 1 - \log(2 - \delta_k),$$

where all logarithms use base 2, and let $\alpha = \frac{1}{\gamma}$.

We next describe how to get the $(1+\frac{2}{k+1})$-approximation for Weighted Feedback Arc Set. Let $G=(V,A)$ be the input graph and let n be the number of vertices in V. For the sake of simplicity, we will again assume that αn is an integer. Let $\mathcal{V}$ be the set of all vertices with exactly αn vertices. Using the algorithm by Bodlaender et al. [6], we compute the optimal solution for all graphs induced by sets in $\mathcal{V}$. This takes $O(\binom{n}{\alpha n}\operatorname{poly}(n)\log(w_{\max}))$ time. In the same time, we can also compute for each $V'\in\mathcal{V}$ the sum of weights of arcs in $\{(u,v)\mid u\in V\setminus V'\wedge v\in V'\}$. Let $a(V')$ denote this number and let $V^*\in\mathcal{V}$ be a set minimizing $a(V^*)$. We then use the algorithm by Bodlaender et al. [6] to solve the instance $G[V\setminus V^*]$ optimally in $O(2^{(1-\alpha)n}\operatorname{poly}(n)\log(w_{\max}))$ time and for all other $V'\in\mathcal{V}$, we use the $(1+\frac{2}{k})$-approximation for $G[V\setminus V']$ that runs in $O((2-\delta_k)^{(1-\alpha)n})$ time. Finally, we for each $V'\in\mathcal{V}$, we compute the sum of the optimal value for $G[V']$ plus $a(V')$ plus the size of the computed solution for $G[V\setminus V']$. We return the smallest number found.

It remains to show that our algorithm always produces a $(1+\frac{2}{k+1})$-approximation and to analyze the running time. For the approximation factor, let F be a feedback arc set of G of minimum weight OPT. We distinguish between the following two cases. Either $a(V^*)\leq\frac{2}{k+1}\operatorname{OPT}$ or $a(V^*)>\frac{2}{k+1}\operatorname{OPT}$. In the first case, note that the solution we computed for V^* consists of optimal solutions for $G[V^*]$ and $G[V\setminus V^*]$ plus $a(V^*)$. Since the first two summands are combined at most OPT and $a(V^*)\leq\frac{2}{k+1}\operatorname{OPT}$, we indeed return a feedback arc set of size at most $(1+\frac{2}{k+1})\operatorname{OPT}$. If $a(V^*)>\frac{2}{k+1}\operatorname{OPT}$, then note that for each $V'\in\mathcal{V}$ it holds that $a(V')>\frac{2}{k+1}\operatorname{OPT}$. Moreover, since the graph $G'=(V,A\setminus F)$ is acyclic, it has a topological ordering. Let V'' be the set of the first αn vertices in that topological ordering. Let d be the weight of a feedback arc set of minimum weight in $G[V\setminus V'']$. Note that $d\leq\frac{k-1}{k+1}\operatorname{OPT}$. The solution we compute for V'' has size $(\operatorname{OPT}-d)+(1+\frac{2}{k})d\leq(1+\frac{2(k-1)}{k(k+1)})\operatorname{OPT}<(1+\frac{2}{k+1})\operatorname{OPT}$. Thus also in this case, we return a $(1+\frac{2}{k+1})$-approximation.

We conclude with analyzing the running time. Recall that $\gamma=\frac{1}{\alpha}$. Computing $\mathcal{V}$, $a(V')$, and the optimal solution for $G[V']$ for each $V'\in\mathcal{V}$ takes $O(\binom{n}{\alpha n}\operatorname{poly}(n)\log(w_{\max}))$ time. Solving the instance $G[V\setminus V^*]$ optimally takes $O(2^{(1-\alpha)n}\operatorname{poly}(n)\log(w_{\max}))$ time. Approximating the solutions for all sets in $\mathcal{V}$ takes $O(\binom{n}{\alpha n}\cdot(2-\delta_k)^{(1-\alpha)n}\cdot\log(w_{\max}))$ time in total. As shown in the proof for Theorem 3, it holds that $O(\binom{n}{\alpha n}\cdot(2-\delta_k)^{(1-\alpha)n})\subseteq O(2^{(1-\alpha)n})$. Thus, the total running time of our algorithm is in $O^*(2^{(1-\alpha)n})$ and in $O((2-\delta)^n\log(w_{\max}))$ for any $0<\delta<2-2^{1-\alpha}$. This concludes the proof. ◀

4.2 Cutwidth and Optimal Linear Arrangement

In this final part, we generalize our algorithms for Directed Cutwidth and Directed Optimal Linear Arrangement to the weighted setting. Since all generalizations follow the same simple structure, we only show the result for Directed Cutwidth.

▶ **Proposition 11.** *Weighted Directed Cutwidth admits a $(2+\varepsilon)$-approximation in time $O(2^{\frac{\omega n}{3}}\log(w_{\max})(\frac{1}{\varepsilon})^2k^2)$.*

Proof. The proof is similar to the proof of Proposition 4. Let $(G=(V,A),w)$ be the input instance to Weighted Directed Cutwidth. We find a $(1+\varepsilon)$-approximation for the instance $(G,w,\lfloor\frac{n}{2}\rfloor)$ of Weighted Directed Minimum $(k,n-k)$-Cut using Proposition 8. This takes $O(2^{\frac{\omega n}{3}}\log(w_{\max})(\frac{1}{\varepsilon})^2k^2)$ time. Let L be the set of vertices returned by Proposition 1, let $R=V\setminus L$, and let $A'\subseteq A$ be the set of arcs from R to L. Note that $\frac{w(A')}{1+\varepsilon}$ is by definition a lower bound for the weighted directed cutwidth of G. Next, we can solve $G[L]$ and $G[R]$ optimally in $O^*(2^{\frac{n}{2}}\log(w_{\max}))$ time [23]. Since adding a vertex

and/or arc to a graph cannot decrease its cutwidth, we have that the weighted directed cutwidth of $G[L]$ and $G[R]$ are both at most the weighted directed cutwidth of G. Adding the edges from L to R also does not increase the cutwidth. Hence, placing all vertices in L according to the computing solution for $G[L]$ and then all vertices in R according to the solution for $G[R]$ gives an ordering for the graph $G' = (V, A \setminus A')$ that shows that the weighted directed cutwidth of G' is at most the weighted directed cutwidth of G. Adding the set A' to G' can increase the cutwidth by at most $w(A')$ and hence the computed ordering is a $(2+\varepsilon)$-approximation. The running time is in $O(2^{\frac{\omega n}{3}} \log(w_{\max})(\frac{1}{\varepsilon})^2 k^2)$ as $\frac{\omega}{3} > \frac{1}{2}$ and this concludes the proof. ◀

The generalizations for Optimal Linear Arrangement and Directed Optimal Linear Arrangement are basically the same and are hence omitted. We just mention that the slightly weaker running time $(1 - \frac{\alpha}{4})$ instead of $(1 - \frac{\alpha}{2})$ in the exponent comes from the fact that we only have a $(1+\varepsilon)$-approximation for Weighted Directed Minimum $(k, n-k)$-Cut (where we set $\varepsilon = \frac{\alpha}{2}$ and then compute the approximation for all $\frac{\alpha}{4}n \leq k \leq (1 - \frac{\alpha}{4})n$ in order to compensate. The correctness then follows from the fact that $\frac{1+\frac{\alpha}{2}}{1-\frac{\alpha}{2}} \leq \frac{1}{1-\alpha}$ for all $\alpha > 0$.

▶ **Proposition 12.** *For each constant $0 < \alpha < 1$, there is a $(1 + \frac{1}{1-\alpha})$-approximation for Directed Optimal Linear Arrangement that runs in $O^*(2^{\frac{\omega n}{3}} + 2^{(1-\frac{\alpha}{4})n})$ time.*

▶ **Proposition 13.** *For each constant $0 < \alpha < 1$, there is a $(1 + \frac{1}{2(1-\alpha)})$-approximation for Optimal Linear Arrangement that runs in $O^*(2^{\frac{\omega n}{3}} + 2^{(1-\frac{\alpha}{4})n})$ time.*

5 Conclusion

In this work, we initiated the study of faster exponential-time approximation algorithms for vertex-ordering problems. For Feedback Arc Set we designed an approximation scheme using a novel self-improving technique. For other problems, we showed how to compute a constant-factor approximation. We mention that the best known polynomial-time algorithms do not achieve a factor better than $O(\sqrt{\log(n)})$.

We conclude with a few open problems. One obvious direction is to design a faster exponential-time algorithm for Directed Minimum $(k, n-k)$-Cut– exact or approximate – which would immediately yield faster approximation algorithms for almost all of the problems considered in this paper. Next, there are a lot more (vertex-ordering) problems that are also interesting to study. Examples include Treewidth, Subset Feedback Vertex/Arc Set (here also the restriction to tournament graphs is often studied), Travelling Sales Person, Bandwidth, or Minimum Fill-In. Second, can our constant-factor approximations be improved to $(1+\varepsilon)$ as in the case of Feedback Arc Set? On a related note, we are not aware of any tool to show lower bounds for exponential-time approximations and most known hypotheses like SETH seem to weak to base such lower bounds on. In particular, a reasonably sounding candidate one could call Gap-SETH (a combination of SETH and Gap-ETH) is not true as shown by Alman et al. [1]. Hence, we ask the following question:

> What would be a sensible hypothesis to exclude $(1+\varepsilon)$-approximations in $O((2-\delta_\varepsilon)^n)$ time for some $\delta_\varepsilon > 0$ depending only on ε for different problems?

Finally, all our algorithms use exponential space (here, the bottleneck is our exact algorithm for Directed Minimum $(k, n-k)$-Cut, which first builds an exponential-size graph). Can this be reduced to polynomial space while still beating the fastest known exact algorithms?

On Fault Tolerant Single-Shot Logical State Preparation and Robust Long-Range Entanglement

Abstract

Preparing encoded logical states is the first step in a fault-tolerant quantum computation. Standard approaches based on concatenation or repeated measurement incur a significant time overhead. The Raussendorf-Bravyi-Harrington cluster state [23] offers an alternative: a single-shot preparation of encoded states of the surface code, by means of a constant depth quantum circuit, followed by a single round of measurement and classical feedforward [7]. In this work we generalize this approach and prove that single-shot logical state preparation can be achieved for arbitrary quantum LDPC codes. Our proof relies on a minimum-weight decoder and is based on a generalization of Gottesman's clustering-of-errors argument [12]. As an application, we also prove single-shot preparation of the encoded GHZ state in arbitrary quantum LDPC codes. This shows that adaptive noisy constant depth quantum circuits are capable of generating generic robust long-range entanglement.

1 Introduction

Single-shot logical state preparation is a procedure in which a code state (such as the logical $|0\rangle$ or $|+\rangle$ state) of a quantum error correcting code is prepared by a constant depth quantum circuit, followed by one round of single qubit measurements, and an adaptive Pauli correction using classical feedforward. In this paper, we prove that every CSS quantum LDPC code admits a single-shot state preparation procedure with logarithmic space overhead that is fault tolerant against local stochastic noise, generalizing prior work by [7] for the surface code.

The fact that single-shot logical state preparation is feasible is non-trivial: after all, logical states of quantum LDPC codes have circuit lower bounds and cannot be prepared by a constant depth quantum circuit [6, 14, 1]. This issue is circumvented via the additional measurement and classical feedforward. Due to the simplicity of the quantum circuit, there has been a recent theoretical and experimental interest in preparing physically interesting

(a) The Alternating Tanner Graph state $|\mathrm{ATG}\rangle$. **(b)** $|\mathrm{ATG}\rangle$ of the surface code.

Figure 1 (a) The ATG is a graph state, defined on a vertex set comprised of layers of copies of the code block and the Z (resp. X) Tanner graph (in blue, resp. red) of the qLDPC code. (b) The RBH cluster state [23], which prepares code states of the surface code in a 3D cubic lattice arrangement, is a special case of this construction.

quantum states using these adaptive shallow circuits [22, 20, 21, 8, 25, 10, 28, 16, 24]. Fault tolerance is a key aspect of a faithful experimental preparation of these states, where one must argue that the state is still interesting even though the shallow circuit is noisy. Our result provides a general recipe for fault tolerant state preparation, which can be used for state initialization in fault tolerant quantum computation, as well as a candidate for an experimental demonstration of long-range entangled states using adaptive shallow circuits that is robust to noise.

The intuition behind our result is to realize *repeated measurement* via *measurement-based quantum computation*. The standard approach to initialize a quantum LDPC code in the logical $|+\rangle$ state is as follows: first initialize all physical qubits in a code block in the $|+\rangle$ state, then perform repeated Z and X syndrome measurements, and finally perform a Pauli error correction using classical feedforward based on the syndrome measurement outcomes. A key observation here is that the repeated measurements are non-adaptive, thus we can attempt to simulate this process using a cluster state, achieving a space-time trade-off.

This naturally leads to a construction which we refer to as the Alternating Tanner Graph state $|\mathrm{ATG}\rangle$ (Figure 1, also known as a foliated quantum code [3]): there are $2T+1$ copies of the code block. A copy of the Z Tanner graph is placed on each odd layer (simulating Z syndrome measurements), and a copy of the X Tanner graph is placed on each even layer (simulating X syndrome measurements). Vertical connections are added between code qubits of neighboring layers, which is used to propagate quantum computation in the time direction. To prepare this cluster state in constant depth, we initialize all qubits in the $|+\rangle$ state and apply a CZ gate on each edge. When applied to the surface code, the $|\mathrm{ATG}\rangle$ is equivalent to the Raussendorf-Bravyi-Harrington (RBH) cluster state [23].

1.1 Results

We start with an informal description of single-shot logical state preparation. Consider a set of noisy qubits divided into two subsystems A and B. Single-shot logical state preparation is performed via the following procedure:

1. Initialize all qubits in the (noisy) $|+\rangle$ state.
2. Perform a (noisy) constant depth quantum circuit W.
3. Measure all qubits in A in the Hadamard $(|+\rangle, |-\rangle)$ basis, obtaining a bitstring $s \in \{0,1\}^{|A|}$. In the absence of noise, the unnormalized post-measurement state equals $|\pm_s\rangle\langle\pm_s|_A \cdot W |+\rangle_{AB}$.
4. Use a classical computer to calculate a Pauli operator $P(s)$ (supported on B) based on s, and apply $P(s)$ to the post-measurement state.[1]

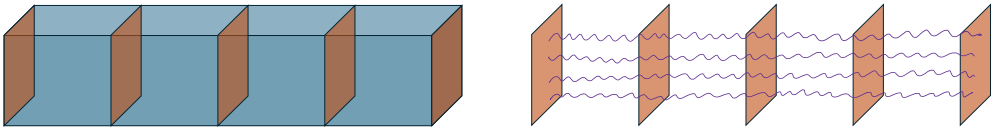
In the absence of noise, the final (unnormalized) state is given by

$$\left(|\pm_s\rangle\langle\pm_s|_A \otimes P(s)_B\right) \cdot W |+\rangle_{AB} . \tag{1}$$

Let us begin by understanding what this procedure can achieve in the absence of noise. With a suitable choice of W, one can imagine that step 3 is measuring the stabilizers/parity checks of a quantum LDPC code (where B contains code qubits and A contains ancilla qubits for syndrome measurement), which collapses the state into a random syndrome subspace s (some eigenspace of the code Hamiltonian). Step 4 then performs syndrome decoding and corrects the Pauli error, thus preparing an encoded code state.[2]

The key question is what can the above procedure achieve in the noisy setting, where every initial qubit, gate and measurement is subject to some small constant amount of noise (throughout this section, we assume the noise rate is below some constant threshold). Ideally, we would like to achieve *fault-tolerant* single-shot logical state preparation, which means that the final state in the presence of noise is the desired encoded logical state, up to some residual stochastic noise. This residual noise is benign in the sense that it is correctable with the LDPC code; and the final state (with residual noise) can be used as the initial state of a fault tolerant quantum computation.

The conceptual challenge to achieve fault tolerance here is that the noisy quantum circuit only has constant depth, therefore we cannot hope to correct errors during the state preparation procedure using standard means. The RBH cluster state and its generalization, the ATG [23, 3, 15], is a carefully designed construction where after the bulk of the state is measured, the remaining boundaries/surfaces encode a logical state in the quantum error correcting code up to a Pauli correction. The intuition that this scheme might be fault tolerant lies in the redundancy embedded into the bulk ancilla qubits. Here, we give a general fault-tolerance proof that works for arbitrary quantum LDPC codes.



▶ **Theorem 1.** *Fix an integer T. There exists a fault tolerant, single shot logical state preparation procedure for the encoded $|\overline{0}\rangle, |\overline{+}\rangle$ states[3] of an arbitrary $[[n,k,d]]$ CSS LDPC code, using $O(n \cdot T)$ ancilla qubits, with success probability at least $1 - nT \cdot 2^{-\Omega(\min(d,T))}$.*

As discussed earlier, the Alternating Tanner Graph (ATG) state (Figure 1) naturally gives rise to redundancies akin to those in a repeated syndrome measurements protocol. Our proof of fault-tolerance leverages an information-theoretic minimum-weight decoder, and is based on the clustering-of-errors argument by [12, 18] for decoding LDPC codes from repeated measurements (see below for a more detailed overview).

[1] Classical computation is assumed to be performed instantly, such that there is no additional noise on the quantum state during this step of the computation.

[2] What code state are we preparing? For example, assume there is only one logical qubit. Notice that the logical X operator of the CSS LDPC code is stabilized by the initial state and commutes with the measurement. Therefore we are able to prepare the encoded $|+\rangle$ state. The encoded $|0\rangle$ state can be prepared similarly by initializing all qubits in $|0\rangle$.

[3] Note that there are k logical qubits, and we can prepare either $\left|\overline{0}^{\otimes k}\right\rangle$ or $\left|\overline{+}^{\otimes k}\right\rangle$.

(a) Measurement pattern of $|\mathrm{ATG}\rangle$. **(b)** Encoded GHZ state.

Figure 2 (a) We prepare $|\mathrm{ATG}\rangle$ of an arbitrary LDPC code using a noisy shallow circuit and measure the bulk (blue), leaving m surfaces (orange) unmeasured. (b) After decoding and feedforward, the state becomes the encoded GHZ state across the m surfaces, up to residual stochastic noise.

Efficient decoding. In our single-shot logical state preparation result discussed above, the classical decoding procedure (computing $P(s)$ from s) relies on an information-theoretic minimum weight decoder, and is not necessarily computationally efficient.[4] A natural question is whether an efficient decoder that runs in $\mathsf{poly}(n)$ time exists for single-shot logical state preparation, especially if the code is known to have an efficient decoder for quantum error correction.[5] Here, we complement our results by showing a simple reduction to the efficient decoding of logical state preparation based on repeated syndrome measurements.

▶ **Theorem 2.** *If a family of $[[n, k, d]]$ CSS LDPC codes admits an efficient decoder for fault-tolerant logical state preparation based on T rounds of repeated syndrome measurements, then it further admits an efficient decoder for a fault-tolerant single shot logical state preparation procedure using $O(n \cdot T)$ ancilla qubits.*

In other words, one can tradeoff time for space in logical state preparation. As discussed earlier, this reduction stems from mapping the repeated measurements circuit to a constant depth circuit via measurement based quantum computation, and as we illustrate naturally gives rise to the alternating tanner graph state $|\mathrm{ATG}\rangle$.

Robust long-range entanglement. Next we show that the ATG provides a powerful framework that goes beyond the preparation of encoded $|\overline{0}\rangle$ and $|\overline{+}\rangle$ as in logical state preparation based on repeated measurements, due to the flexibility in *choosing different measurement patterns* in the ATG. As an example, we show fault tolerant single-shot preparation of the encoded GHZ state

$$|\mathrm{GHZ}_m\rangle = \frac{1}{\sqrt{2}}\left(|0\rangle^{\otimes m} + |1\rangle^{\otimes m}\right) \tag{2}$$

for any $m \geq 2$ in an arbitrary quantum LDPC code. Here we summarize the algorithm for GHZ state preparation, and then discuss this result from the perspective of robust long-range entanglement and noisy shallow circuits.

To prepare the GHZ state, we measure the ATG in the following pattern, depicted (horizontally) in Figure 2a: we measure all the check qubits of all code blocks (blue and red in Figure 1), as well as all code qubits in the bulk (blue in Figure 2a), with the exception of a careful choice of m layers of n code qubits (in orange). We prove that the resulting state, after minimum-weight decoding and feedforward, is in fact the encoded GHZ state across the m blocks (Figure 2b) up to residual stochastic noise.

[4] By dynamic programming, the decoding algorithm can be made to run in $\leq T \cdot \exp(n)$ time.
[5] We emphasize the distinction between a decoder for error-correction, and a decoder for state preparation.

▶ **Theorem 3.** *Fix integers m, T. There exists a fault tolerant, single shot logical state preparation procedure for the encoded $\left|\overline{\mathrm{GHZ}_m^{\otimes k}}\right\rangle$ state of an arbitrary $[[n, k, d]]$ CSS LDPC code, using $O(n \cdot T)$ ancilla qubits, with success probability at least $1 - nT \cdot 2^{-\Omega(\min(d, T/m))}$.*

This generalizes the RBH construction [23] for the surface code with $m = 2$ and $k = 1$, that is, the encoded Bell state $\frac{1}{\sqrt{2}}\left(\left|\overline{00}\right\rangle + \left|\overline{11}\right\rangle\right)$ in the surface code. Let us review the features of the entanglement in the resulting GHZ state:

- **Noise robust.** The preparation procedure uses a noisy constant depth circuit (with noise rate below a constant threshold). Yet, the resulting GHZ state is encoded in a LDPC code and is subject to residual local stochastic noise that is correctable with the code.
- **Generic.** The construction works for arbitrary quantum LDPC codes.
- **Macroscopic.** The final state encodes $m \cdot k$ logical qubits into $m \cdot n$ physical qubits, which can achieve a constant encoding rate using high-rate codes such as hypergraph product codes [26, 17].
- **Long range.** There are two aspects of long range entanglement: the first is the entanglement among physical qubits in each code block (which can exhibit topological order), the second is the logical GHZ entanglement that spans m code blocks.

Finally, we discuss this result from the perspective of noisy shallow quantum circuits. The first step of this state preparation algorithm is to apply a constant depth circuit on a volume of qubits. At this point, there is no long-range entanglement at all. However, after the bulk (blue in Figure 2a) is measured, long-range entanglement is created across the orange blocks (Figure 2b): the subsequent decoding and feedforward operations are only used to correct the state into the desired GHZ state, but cannot create entanglement. Therefore, the GHZ-type entanglement is created by the teleportation effect of measurement. Interestingly, this teleportation effect is robust to noise.

We remark that Theorem 3 implies Theorem 1 as a special case. An interesting future direction is to explore whether there exists other families of interesting states that can be prepared using the ATG framework.

Proof of fault tolerance. The fault-tolerance of our single-shot logical state preparation scheme has two main components. First, we identify the stabilizer structure of $|\mathrm{ATG}\rangle$. As remarked earlier, the fault tolerance arises from redundancies in the ancilla qubits. Concretely, that manifests in the redundancies of the stabilizers of $|\mathrm{ATG}\rangle$, which contains certain "meta-checks". Second, we adapt the clustering arguments by [18, 12] for decoding quantum LDPC codes from random errors to our setting, and develop analogous techniques to argue that the meta-checks contain enough redundancy to be robust against random errors.

The meta-check information. Following [7], inside the $|\mathrm{ATG}\rangle$ (which is a stabilizer state), one can define stabilizers which cleanly factorize into a product of X Pauli's on the bulk of the graph state. We refer to these stabilizers as "meta-checks", since

1. After measuring the bulk in the X basis, they remain stabilizers of the post-measurement state,

2. They inbuild redundancies ("syndrome of syndromes") into the measured string s.

These redundancies will later allow us to use s to infer errors that occur on the bulk, and in turn, correctly decode the error $P(s)$ for the qubits on the boundary. Here we give an example and defer a rigorous exposition to [2, Section 3.2]. Recall that on every even layer t

of the ATG, there is a copy of the Z-Tanner graph lying on the layers $t-1$ and $t+1$ adjacent to it. Now, consider a Z-check of the code denoted as c, and let $\mathsf{Supp}(c) \subseteq [n]$ be the set of qubits it acts on. We show that the following operator

$$X_{(c,t-1)} \otimes X_{(c,t+1)} \bigotimes_{i \in \mathsf{Supp}(c)} X_{(i,t)}, \tag{3}$$

which applies a Pauli-X on the copies of the check qubit c in layers $t-1$ and $t+1$, as well as the qubits supported in the check in layer t, is a stabilizer of $|\mathrm{ATG}\rangle$.

While perhaps a bit abstract at first, this operator captures the change in the Z syndrome after a layer of data-errors on the code and measurement errors on the checks: akin to the redundancy between adjacent syndrome measurements that appear in a repeated syndrome measurement protocol. The fact that these stabilizers factorize cleanly into products of X Paulis is non-trivial and depends carefully on the structure of $|\mathrm{ATG}\rangle$, which we discuss further in [2, Section 3.2].

The clustering argument. [18, 12] showed that any quantum LDPC code can correct random Pauli errors (below a constant threshold noise rate), even in the presence of syndrome measurement errors, by repeating the syndrome measurements T times and running an information-theoretic minimum weight decoder. Their proof reasoned that the data-errors and syndrome-errors could be arranged in a low degree graph known as the *syndrome adjacency graph*, wherein the locations of mismatch errors (where the output of the decoder does not match the true error) clusters into connected components. By a percolation argument on this low-degree graph, one can argue these clusters are unlikely to "contrive" into configurations that induce logical errors on the code. Roughly speaking, the probability of a logical error is upper bounded by

$$\begin{aligned} &\sum_{s \geq d} \underbrace{\left(\#\text{ of Connected Components } |K| = s\right)}_{\text{A union bound over clusters of size } s} \times \underbrace{\left(p^{\Omega(s)}\right)}_{\text{Odds of such a cluster}} \\ &\approx \sum_{s \geq d} (p \cdot z)^{\Omega(s)} \approx (pz)^d, \end{aligned} \tag{4}$$

where only clusters of size larger than the code distance d can incur logical errors, and z is the degree of the graph.[6]

Here, we broadly follow this strategy and construct an analogous low-degree syndrome adjacency graph which captures where our min-weight decoder incorrectly guesses a data or check error. Unfortunately, making this argument rigorous is easier said than done. Arguably the main challenge lies in relating the size of clusters of mismatch errors, to the number of true physical errors which lie within the cluster, to properly claim the decay rate $p^{\Omega(s)}$ with the cluster size. As we discuss in [2, Section 5] and [2, Appendix C], this calculation is highly dependent on the boundary conditions of the syndrome adjacency graph, tailored for Bell states and to GHZ states.

1.2 Discussion and other related works

Fault tolerant shallow circuits. As a direct corollary, our single-shot logical state preparation can be used as the basis of a fault tolerant implementation of a shallow quantum circuit.

[6] A function only of the locality of the LDPC code. We assumed the noise rate is bounded by a threshold $p < z^{-1}$ for the geometric series to converge.

▶ **Corollary 4.** *Fix an arbitrary quantum LDPC code Q. Let C be a constant depth quantum circuit which uses $|0\rangle$ or $|+\rangle$ or GHZ initial states, gates which are transversal in Q, and measurements in the standard or Hadamard basis. Then there is a constant depth fault tolerant implementation of C which uses a single round of mid-circuit measurement and feedforward.*

Here we simply run our single-shot logical state preparation scheme to prepare encoded initial states, and then directly apply transversal gates. Since the logical circuit is constant depth, the residual local stochastic noise still remains local stochastic, and the logical Z or X measurements at the end can be decoded using the code.

A natural question is whether we can remove the mid-circuit measurement and feedforward, and implement an ideal shallow quantum circuit purely via a noisy shallow quantum circuit. Ref. [7] gives such an example: starting from RBH, they directly apply a logical Clifford circuit *without* correcting the Pauli error $P(s)$. However, since the logical circuit is Clifford, the Pauli error $P(s)$ is propagated through the circuit and corrected at the end. Our result similarly implies a more general version:

▶ **Corollary 5.** *Fix an arbitrary quantum LDPC code Q. Let C be a constant depth quantum circuit which uses $|0\rangle$ or $|+\rangle$ or GHZ initial states, and gates which are Clifford and transversal in Q, and measurements in the standard or Hadamard basis. Then there is a constant depth fault tolerant implementation of C using a noisy circuit (without mid-circuit measurements and feedforward).*

Note that we do not address the issue of decoding efficiency. In particular, although Corollary 5 does not need mid-circuit decoding, the decoding at the end of the circuit may still be inefficient. An interesting direction is to explore if Corollary 5 can be the basis of other quantum advantage experiments with noisy shallow quantum circuits against shallow classical circuits, as in [7].

Single-shot preparation of general stabilizer states. Beyond GHZ state preparation, we show that single-shot logical state preparation can also be achieved for more general stabilizer states, using a combination of the ATG and Steane's logical measurement. Let $|\psi\rangle$ be a m-qubit stabilizer state with the following structure: there exists a set of m stabilizer generators that can be divided into two sets $S_X \subseteq \{I, X\}^{\otimes m}$ and $S_Z \subseteq \{I, Z\}^{\otimes m}$, such that either S_X or S_Z has constant weight and degree. The m-qubit GHZ state is such an example, where $S_X = \{X^{\otimes m}\}$ and $S_Z = \{Z_1Z_2, Z_2Z_3, \ldots, Z_{m-1}Z_m\}$. We prove fault tolerant single-shot preparation for any such state $|\psi\rangle$ encoded across m copies of an arbitrary quantum LDPC code. See [2, Appendix D] for more details.

Single-shot quantum error correction. A closely related concept to our work is single-shot quantum error correction [5]: consider an encoded code block subject to random errors, it is shown that for certain codes a single round of syndrome measurement suffices to correct the error (instead of performing repeated syndrome measurements), even in the presence of syndrome measurement errors. Examples include high-dimensional color codes [4, 5] and toric codes [19], hypergraph product codes [11], quantum Tanner codes [13] and hyperbolic codes [9].

As the ATG is closely related to repeated syndrome measurements, it is natural to ask whether single-shot logical state preparation with *constant* space overhead exists for those codes, or more generally, for any code with single-shot error correction. While this is proven for 3D gauge color codes [4, 5], it is unclear whether a general reduction from single-shot

logical state preparation to single-shot error correction exists. The key issue is that single-shot error correction is defined in the context of correcting errors on an existing encoded code block, while single-shot logical state preparation is about preparing an encoded code state *from scratch*. We leave further exploration of this issue for future work; it is an interesting question in the context of reducing the spacetime overhead of quantum fault tolerance (also see [27]).

Random Restrictions of Bounded Low Degree Polynomials Are Juntas

Sreejata Kishor Bhattacharya
School of Technology and Computer Science, Tata Institute of Fundamental Research, Mumbai, India

Abstract

We study the effects of random restrictions on low degree functions that are *bounded* on every point of the Boolean cube. Our main result shows that, with high probability, the restricted function can be approximated by a junta of arity that is just polynomial in the original degree. More precisely, let $f : \{\pm 1\}^n \to [0, 1]$ be a degree d polynomial ($d \geq 2$) and let ρ denote a random restriction with survival probability $O(\log(d)/d)$. Then, with probability at least $1 - d^{-\Omega(1)}$, there exists a function $g : \{\pm 1\}^n \to [0, 1]$ depending on at most $d^{O(1)}$ coordinates such that $||f_\rho - g||_2^2 \leq d^{-1-\Omega(1)}$.

Our result has the following consequence for the well known, outstanding conjecture of Aaronson and Ambainis. The Aaronson-Ambainis conjecture was formulated to show that the acceptance probability of a quantum query algorithm can be well approximated almost everywhere by a classical query algorithm with a polynomial blow-up: it speculates that a polynomal $f : \{\pm 1\}^n \to [0, 1]$ with degree d has a coordinate with influence $\geq \text{poly}(1/d, \mathsf{Var}[f])$. Our result shows that this is true for a non-negligible fraction of random restrictions of f assuming $\mathsf{Var}[f]$ is not too low.

Our work combines the ideas of Dinur, Friedgut, Kindler and O'Donnell [7] with an approximation theoretic result, first reported in the recent work of Filmus, Hatami, Keller and Lifshitz [8].

1 Introduction

The analysis of Boolean functions is a vibrant field with connections and applications to diverse areas. While several outstanding results have been established for Boolean functions, the closely related class of *bounded* functions, i.e. those which take value in the real interval $[0, 1]$ at every point of the Boolean cube, remains far less understood. Indeed, such bounded functions are of great significance. As mentioned in Dinur, Friedgut, Kindler and O'Donnell [7], "such bounded functions often arise naturally, particularly as weighted averages of boolean functions; e.g., as Fourier transforms of boolean functions, as noise-convolutions of boolean functions, in the context of random walks on the discrete cube, and in hardness-of approximation theory in computational complexity", and it is often important to understand when such functions depend essentially only on a few number of coordinates.

In this work, we study the effects of random restrictions on such bounded functions of low degree. The study of random restrictions of Boolean functions has been invaluable for establishing circuit lower bounds (see for example, [9, 10, 21]), proof complexity (see for example, [5, 11]), de-randomization (see for example, [12]), and several other areas. Our main result shows a remarkable similarity in the behavior of bounded functions with their Boolean cousins, when hit with random restrictions.

By now, it is worth recalling that a classical result of Dinur, Friedgut, Kindler and O'Donnell [7] showed that bounded functions whose Fourier tail above degree k is $\leq \exp(-O(k^2))$ are approximable by juntas with arity $\exp(O(k))$. They also showed that this result is tight in general. We are interested in the case when the function has small degree d. What additional structure follows from this stronger condition? To take cue on what to expect, let's recall the case of Boolean functions. If $f : \{\pm 1\}^n \to \{0,1\}$ is a degree d Boolean function, a seminal result of Beals, Buhrman, Cleve, Mosca, and de Wolf [4] shows that f can be represented by a DNF of width $d^{O(1)}$. By the celebrated Hastad's switching lemma, this implies that if f is hit with a random restriction with survival probability $1/d^{O(1)}$, with high probability f becomes constant. We show something similar is true for bounded functions as well: if $f : \{\pm 1\}^n \to [0,1]$ is a degree d, *bounded* function and f is hit with a random restriction with survival probability $O(\log(d)/d)$, with high probability it can be well-approximated by a junta depending only on $\text{poly}(d)$ coordinates. This is despite the fact that the expected number of variables that remain alive is $O\left(n \cdot \frac{\log d}{d}\right)$.

▶ **Theorem 1 (Main Theorem).** *For any constants $C_1, C_2 > 0$, there exist constants $C_3, C_4, C_5 > 0$ such that the following holds:*
Let $f : \{\pm 1\}^n \to [0,1]$ be a degree d polynomial and let ρ be a random restriction with survival probability $\frac{\log(d)}{C_3 d}$. With probability at least $1 - d^{-C_2}$, f_ρ is a $(d^{-C_1}\mathsf{Var}[f], \mathsf{Var}[f]^{-2}d^{C_4})$ junta. Moreover, if J denotes the set of coordinates on which the junta depends, for each $j \in J$ we have $\mathsf{Inf}_j[f] \geq \mathsf{Var}[f]^2 d^{-C_5}$.

This result has interesting consequences for the Aaronson-Ambainis conjecture, which we explain next.

One of the central open problems in the field of quantum query complexity is determining if there exists a partial function which is defined on a large fraction of the Boolean hypercube (say, constant) but whose quantum query complexity and classical query complexity are super-polynomially separated. The result of Beals et. al. [4] shows that no such separation is possible when the function is defined on the entire hypercube. On the other hand, functions for which we know such a separation (e.g. - Forrelation [1] , Bernstein-Vazirani [6]) are defined on an exponentially small fraction of the hypercube. A possible explanation as to why all known functions exhibiting large gaps between quantum and classical query complexity have very small support size would be the following folklore conjecture:

▶ **Conjecture 2.** *Let Q be a quantum query algorithm with Boolean output on n qubits making q queries. Let $P : \{\pm 1\}^n \to [0,1]$ be given by $P(x) = Pr[Q \text{ outputs 1 on } x]$. For any $\epsilon > 0$, there exists a classical query algorithm A such that $\mathsf{E}[(A(x) - Q(x))^2] \leq \epsilon$ and A makes at most $\mathsf{poly}\left(q, \frac{1}{\epsilon}\right)$ queries.*

It is known that if Q makes at most q queries, then P is given by a polynomial of degree at most $2q$. Although P has more structure than any arbitrary low degree bounded polynomial, it is further conjectured that such structure is not necessary. In other words, we forget the fact that P arises from a quantum query algorithm and instead try to construct a classical query algorithm for *any* bounded low-degree polynomial. This led to the following conjecture (also folklore).

▶ **Conjecture 3.** *Let $P : \{\pm 1\}^n \to [0,1]$ be a degree d polynomial. For any $\epsilon > 0$, there exists a classical decision tree T of depth at most $\mathsf{poly}(d, 1/\epsilon)$ such that $\mathsf{E}[(P(x) - T(x))^2] \leq \epsilon$.*

Aaronson and Ambainis [2] proposed the following query algorithm to estimate P: suppose the variance of the function is sufficiently small. Then we terminate the query algorithm and output the average over the unqueried coordinates. If not, we query the coordinate with the highest *influence* and restrict the function according to the response received. We keep doing this until we have made too many queries or the variance has become sufficiently low. In order to show that this algorithm gives an accurate estimate, [2] observed that it is sufficient to prove the following conjecture.

▶ **Conjecture 4** (Aaronson-Ambainis conjecture). *Let $f : \{\pm 1\}^n \to [0,1]$ be a degree d polynomial. Then, there exists a coordinate j such that $\mathsf{Inf}_j[f] \geq \mathsf{poly}(1/d, \mathsf{Var}[f])$.*

As a side remark, we mention that O'Donnell et al. [18] had shown previously that functions which can be approximated by decision trees have a coordinate with high influence. So conjectures 3 and 4 are equivalent.

The Aaronson-Ambainis Conjecture has received significant attention in the past few years. In 2006, a result of Dinur, Friedgut, Kindler and O'Donnell [7] showed that the conjecture is true if $\mathsf{poly}(d)$ is replaced by $\exp(d)$. In 2012, Montanaro [16] proved the conjecture in the special case of block-multilinear forms where all coefficients have the same magnitude. In 2016, O'Donnell and Zhao [19] showed that it suffices to prove the conjecture for a special class of polynomials known as *one-block decoupled polynomials*. In 2020, Keller and Klein [13] claimed to have found a proof for the conjecture but their paper had a subtle flaw and turned out to be wrong. More recently, Lovett and Zhang [15] initiated a new line of attack using the notions of *fractional block sensitivity* and *fractional certificate complexity*. In 2022, Bansal, Sinha and de Wolf [3] proved that this conjecture is true for *completely bounded block multilinear forms* – a class of polynomials that captures a special kind of quantum query algorithms.

In this work, we show that Aaronson-Ambainis conjecture is true for a large fraction of random restrictions of f assuming $\mathsf{Var}[f]$ is not too low. More precisely, we have:

▶ **Theorem 5.** *There exist constants $C_1, C_2 > 0$ such that the following holds: let $f : \{\pm 1\}^n \to [0,1]$ be a degree d polynomial ($d \geq 2$) with $\mathsf{Var}[f] \geq 1/d$. Let ρ denote a random restriction with survival probability $\dfrac{\log(d)}{C_1 d}$. Then,*

$$\mathsf{Pr}\left[f_\rho \text{ has a coordinate with influence } \geq \frac{\mathsf{Var}[f]^2}{d^{C_2}}\right] \geq \frac{\mathsf{Var}[f]\log(d)}{50 C_1 d}.$$

We view this result as evidence that the Aaronson-Ambainis Conjecture is true, and hope it gives new insights into the conjecture.

We also observe that our result implies one of the two main unconditional results proven in a recent paper of Lovett and Zhang [15] about the existence of small sensitive blocks albeit with a slightly different set of parameters.

Let $f : \{\pm 1\}^n \to [0,1]$. An input $x \in \{\pm 1\}^n$ is said to be (r, ϵ) sensitive if there exists a y such that $d(x,y) \leq r$ and $|f(x) - f(y)| \geq \epsilon$. [15] proves the following:

▶ **Theorem 6** (Lovett and Zhang [15]). *If $f : \{\pm 1\}^n \to [0,1]$ has degree d, then at least $\Omega(\mathsf{Var}[f])$ fraction of the inputs are (r, ϵ) sensitive where $\epsilon = poly(\mathsf{Var}[f]/d), r = poly(d, 1/\epsilon, \log(n))$*

An immediate consequence of our result is that at least $\Omega((\mathsf{Var}[f]/d)^{O(1)})$ fraction of inputs are $(1, \epsilon)$ sensitive where $\epsilon = \mathrm{poly}(\mathsf{Var}[f]/d)$. Thus, while we lose a bit in the fraction of sensitive inputs, we gain by letting our block size be exactly 1 instead of $\mathrm{poly}(d, 1/\epsilon, \log(n))$.

It is interesting to remark that our techniques and those of Lovett and Zhang seem quite different. We further remark that [15] shows that if one can show *every* input has a small sensitive block, Aaronson-Ambainis conjecture will follow.

We believe that Theorem 5 opens up some possible lines of attack to the Aaronson-Ambainis conjecture:

- Assuming a supposed counterexample $f : \{\pm 1\}^n \to [0,1]$, modify it appropriately (e.g., by composing it with some appropriate gadget or applying a low noise operator) to get a function $\tilde{f} : \{\pm 1\}^{\tilde{n}} \to [0,1]$ such that most of its random restrictions remain a counterexample. Combined with our result, this will prove Aaronson-Ambainis conjecture. This approach is discussed in a bit more detail in the conclusion.
- If we can construct a decision tree that queries y (the input to the fixed part) in a few coordinates and outputs an influential coordinate of f_y (the restricted function) with high probability, Aaronson-Ambainis conjecture will follow from the work of Keller and Klein. Again, this approach is discussed in a bit more detail in the conclusion.

2 Organization

We introduce notations and necessary preliminaries in section 3. We give a high level overview of our proof in section 4. In section 5 we compile some lemmas that will be needed in our main proof. Our main results are proven in section 6. Our main result is proven in section 6.2. It says that most random restrictions of a bounded low-degree function can be approximated by a small junta. In section 6.3 we prove that Aaronson-Ambainis conjecture is true for a non-negligible fraction of random restrictions.

3 Notations and preliminaries

Query algorithms

1. A classical query algorithm A (or equivalently, a decision tree) for computing a function $f : \{\pm 1\}^n \to \mathbb{R}$ can access the input $x \in \{\pm 1\}^n$ by adaptively issuing queries to its bits. We assume internal computations have no cost. The depth of the query algorithm/decision tree is the maximum number of bit queries issued on an input. We say A ϵ-approximates f if $||f - A||_2^2 = \mathsf{E}_{x \in \{\pm 1\}^n}\left[(f(x) - A(x))^2\right] \leq \epsilon$.
   For a partial function $f : S(\subseteq \{\pm 1\}^n) \to \{0,1\}$, its classical query complexity $D(f)$ is the smallest d for which there exists a decision tree T of depth d such that $T(x) = f(x)$ for all $x \in S$.
2. A quantum query algorithm can access the input $x \in \{\pm 1\}^n$ via an oracle O_x. The register has n qubits and some ancilla qubits. The oracle O_x applies the following unitary operation on the first n qubits:

   $$O_x|s_1 s_2 \cdots s_n\rangle = (-1)^{\langle x,s\rangle}|s_1 s_2 \cdots s_n\rangle.$$

   The quantum query algorithm applies a sequence of unitary operators, where each operator is either O_x or an input-independent unitary operator U. In the end, it measures the first qubit and outputs the measurement result. The number of queries issued is the number of times O_x is applied.
   Notice that a quantum query algorithm Q naturally defines a function $P : \{\pm 1\}^n \to [0,1]$:

   $$P(x) = \Pr[Q \text{ outputs 1 on input } x].$$

   It is well-known that if Q makes q queries, then P is a degree $2q$ polynomial.

For a function $f : S(\subseteq \{\pm 1\}^n) \to \{0,1\}$, we define its quantum query complexity $Q(f)$ to be the smallest q for which there exists a quantum query algorithm Q making q queries such that for all $x \in S$,

$$\Pr[Q \text{ outputs 1 on input } x] \begin{cases} \geq 2/3 & \text{if } f(x) = 1 \\ \leq 1/3 & \text{if } f(x) = 0. \end{cases}$$

Analysis of boolean functions

In this section we recall some results from analysis of boolean functions. A good reference is O' Donnell's textbook [17].

1. Any function $f : \{\pm 1\}^n \to \mathbb{R}$ has a unique representation as $f(x) = \sum_{S \subseteq [n]} \hat{f}(S)\chi_S(x)$ where $\chi_S(x) = \prod_{i \in S} x_i$. The coefficients $\hat{f}(S)$ are the Fourier coefficients of f. The degree of f is $\max\{|S||\hat{f}(S) \neq 0\}$.
2. The variance of f is
$$\mathsf{Var}_{x \in \{\pm 1\}^n}[f(x)] = \sum_{S \neq \phi} \hat{f}(S)^2.$$
3. For a cooordinate i, the influence of the i'th coordinate is defined as
$$\begin{aligned} \mathsf{Inf}_i[f] &= \mathsf{E}_{x \in \{\pm 1\}^n}\left[\left(\frac{f(x) - f(x^{(i)})}{2}\right)^2\right] \\ &= \sum_{i \in S} \hat{f}(S)^2. \end{aligned}$$
The total influence of f is
$$\mathsf{Inf}[f] = \sum_{i \in [n]} \mathsf{Inf}_i[f] = \sum_S |S|\hat{f}(S)^2.$$
From the Fourier expansion it is clear that if $\deg(f) \leq d, \mathsf{Inf}[f] \leq d\mathsf{Var}[f]$.
4. Given two functions $f, g\{\pm 1\}^n \to \mathbb{R}$, we say g $\epsilon-$approximates f if $||f - g||_2^2 = \mathsf{E}_x\left[(f(x) - g(x))^2\right] \leq \epsilon$.
5. For a point $x \in \{\pm 1\}^n$ and a subset $S \subseteq [n]$ and $-1 \leq \rho \leq 1$, we define a distribution $N_{\rho,S}(x)$ on $\{\pm 1\}^n$ as follows:
   - The bits $y_1, y_2, \cdots, y_n$ are independent, and
$$\mathsf{Pr}[y_i = x_i] = \begin{cases} 1 & \text{if } i \notin S \\ (1+\rho)/2 & \text{if } i \in S. \end{cases}$$
When $S = [n]$, we abbreviate $N_{\rho,S}(x)$ by $N_\rho(x)$.
6. For $f : \{\pm 1\}^n \to \mathbb{R}$ and $-1 \leq \rho \leq 1$ define $T_\rho f : \{\pm 1\}^n \to \mathbb{R}$ by
$$T_\rho f(x) = \mathsf{E}_{z \leftarrow N_\rho(x)}[f(z)].$$
It is easy to see that the Fourier expansion of $T_\rho f$ is given by
$$T_\rho f(x) = \sum_{S \subseteq [n]} \rho^{|S|}\hat{f}(S)\chi_S(x).$$

7. A function $f : \{\pm 1\}^n \to \mathbb{R}$ is a *junta of arity l* or *l-junta* if there exists a subset $S \subseteq [n], |S| \leq l$ such that f only depends on the coordinates in S. We say f is a (ϵ, l) junta if it can be ϵ-approximated by a l-junta, i.e., there exists a l-junta g such that $||f - g||_2^2 \leq \epsilon$.
8. A restriction $\rho = (S, y)$ of $f : \{\pm 1\}^n \to \mathbb{R}$ is specified by a subset $S \subseteq [n]$ and an assignment $y \in \{\pm 1\}^{[n]\setminus S}$. Such a restriction naturally induces a function $f_\rho : \{\pm 1\}^S \to \mathbb{R}$. Sometimes we shall write f_y instead of f_ρ (note that S is determined by y since $y \in \{\pm 1\}^{[n]\setminus S}$).
   By a random restriction with survival probability p, we mean sampling $\rho = (S, y \in \{\pm 1\}^{[n]\setminus S})$ where each coordinate $i \in [n]$ is included in S with probability p independently, and each bit of y is independently set to a uniformly random bit.

▶ Remark 7. Throughout the paper, all growing parameters (e.g., the degree d) will be assumed to be larger than some sufficiently big constant. This is to make the expressions look neat, as we will be replacing terms like $(C_1)^k \text{poly}(k)$ by $(C_2)^k$ where $C_2 > C_1$.

4 Proof Overview

The main result in this paper is a structural result for bounded low-degree functions similar in spirit to Hastad's switching lemma [10]. Roughly speaking, we show that for come constant $C > 0$, the following holds: let $f : \{\pm 1\}^n \to [0, 1]$ be a polynomial of degree d, and let ρ denote a random restriction with survival probability $\frac{\log(d)}{Cd}$. Then,

$$\Pr\left[f_\rho \text{ is a } (O(d^{-C}), O(d^C)) \text{ junta}\right] \geq 1 - \frac{1}{d^{\Omega(1)}}.$$

Once this is established, we can prove Aaronson-Ambainis conjecture for random restrictions as follows: it is easy to see that

$$\mathsf{Pr}\left[\mathsf{Var}[f_\rho] \geq \frac{\mathsf{Var}[f]\log(d)}{2Cd}\right] \geq \frac{\mathsf{Var}[f]\log(d)}{2Cd}.$$

This probability will be significantly more than the failure probability of the main result $\left(\frac{1}{d^{\Omega(1)}}\right)$ (this is the only place where we need the lower bound on $\mathsf{Var}[f]$). So for a $\Omega(\mathsf{Var}[f]\log(d)/d)$ fraction of random restrictions, the variance of f_ρ is high *and* f_ρ can be well approximated by a junta with arity $\mathsf{poly}(d)$. This means one of the coordinates of the junta must have high influence. This concludes the proof.

Now we give a brief overview of how we prove the main result (Theorem 1). The starting point is the work by Dinur, Friedgut et al. [7] which states the following:

▶ **Theorem 8** (Dinur et al. [7]). *For any $f : \{\pm 1\}^n \to [0, 1]$, if*

$$\sum_{|S|>k} \hat{f}(S)^2 \leq \exp(-O(k^2 \log(k)/\epsilon)),$$

then f is a $(\epsilon, 2^{O(k)}/\epsilon^2)$ junta.

In other words, if the Fourier tail above a certain level k is bounded, then f can be well approximated by juntas of arity roughly $2^{O(k)}$.

We start with the observation that random restrictions have bounded Fourier tails (Lemma 15): if the function has degree d and we make a random restriction with survival probability $\frac{\log(d)}{Cd}$ where $C > 1$ is a large constant, using Chernoff bound we can show that with very high probability the Fourier weight above level $\log(d)$ will be low; around the order of $\exp(-\Omega(C\log(d)))$. If we can manage to bring the Fourier weight above $\log(d)$ small enough so that Theorem 8 applies, then we will get that f_ρ can be well approximated by a $\mathsf{poly}(d)$ junta. Unfortunately, if we try this, it turns out that we have to set the survival probability so low that on expectation the variance of f_ρ goes down significantly as well. In other words, while it is true that f_ρ can be well-approximated by juntas, it is for a trivial reason that its variance itself is very low. (And moreover, this is also true for functions $f : \{\pm 1\}^n \to \mathbb{R}$ that are merely L^2 bounded i.e, $\mathsf{E}[f^2] \leq 1$, so we would not be using any additional structure that arises from the fact that f is *pointwise* bounded.)

In order to make this approach work, we need to improve the tail bound $\exp(-O(k^2\log(k))/\epsilon)$ in Theorem 8. The problematic term is the quadratic $\exp(-O(k^2))$ in the exponential. If the dominant term were to the order of $\exp(-O(k))$ instead, the calculations would go through. Can we hope to increase the tail bound to $\exp(-O(k))$ while paying a cost by increasing the junta arity? Unfortunately, again, this is not possible: [7] constructs a function which shows that the tail bound is essentially tight upto the $\log(k)$ factor - their function has $||f^{>k}||_2^2 \approx \exp(-\Theta(k^2))$ but approximating it to even $1/3$ accuracy requires reading $\Omega(n)$ coordinates. Our key observation is that the function constructed by [7] has full degree whereas we are working with random restrictions of a low degree function, so in addition to the fact that the Fourier tail of f_ρ above level $\log(d)$ is very small, we also know that f_ρ has degree d. Can we hope to improve the tail bound in Theorem 8 if we have the additional restriction that the function is of degree d? Indeed, this turns out to be true. We prove the following result in section 6 (Theorem 28):

▶ **Theorem 9.** *There exists a constant C such that the following is true:*
If $f : \{\pm 1\}^n \to [0,1]$ has degree d and $\sum_{|S|>k} \hat{f}(S)^2 \leq \frac{\epsilon}{C^k d^C}$, f is a $(\epsilon, \epsilon^{-2}d^C C^k)$ junta.

Below we briefly discuss how we are able to improve the tail bound under the additional degree assumption. Dinur et al [7] prove their tail bound (Theorem 8) by showing the following result (we are omitting the exact quantitative parameters here for reading convenience).

▶ **Theorem 10.** *Let $h : \{\pm 1\}^n \to \mathbb{R}$ be a degree k function with $\mathsf{E}[h^2] \leq 1$ (but not necessarily pointwise bounded) which cannot be approximated by $2^{O(k)}$ juntas to accuracy μ. Then, for any function $g : \{\pm 1\}^n \to [0,1]$, $E[(h-g)^2] \geq \varepsilon$.*

Let's sketch how [7] proves Theorem 8 using Theorem 10. They assume f is not approximable by $2^{O(k)}$ juntas - their goal is then to show that the Fourier tail above level k, $||f^{\geq k}||_2^2$, is large. To do so, they use Theorem 10: they take h to be the truncated function $h = f^{\leq k}$ and g to be the original function $g = f$. This then lower bounds $\mathsf{E}[(f - f^{\leq k})^2]$ which is precisely the Fourier tail above weight k. Thus, the distance lower bound ε in Theorem 10 governs the Fourier tail lower bound in Theorem 8. Since in Theorem 28 we have the additional information that f is of degree d, for our purposes it will suffice to lower bound the distance of h from bounded degree d functions, not necessarily *all* bounded functions. In section 6.2 we prove a result of the following form (again, we are omitting the exact parameters for reading convenience; for the exact statement see Theorem 26).

▶ **Theorem 11** (Informal version of Theorem 26). *Let $h : \{\pm 1\}^n \to \mathbb{R}$ be a degree k function with $\mathsf{E}[h^2] \leq 1$ (but not necessarily pointwise bounded) which cannot be approximated by $2^{O(k)}$ juntas to accuracy μ. Then, for any degree d function $g : \{\pm 1\}^n \to [0,1]$, $E[(h-g)^2] \geq \tilde{\varepsilon}$.*

The parameter $\tilde{\varepsilon}$ in Theorem 11 is bigger than the corresponding ε parameter in Theorem 10 because we are only lower bounding the distance of h from bounded *low-degree* functions whereas Theorem 10 lower bounds the distance of h from *arbitrary* bounded functions. It turns out that the improvement in this parameter is sufficiently good for the calculations to go through.

In order to prove Theorem 11 we shall use the main idea of the proof of [7] along with a structural restriction for bounded low-degree functions proved first in Filmus et al. [8], and later used by Keller-Klein [13] and Lovett-Zhang [15]. Given any function $f : \{\pm 1\}^n \to \mathbb{R}$ and $x \in \{\pm 1\}^n$ define the *block sensitivity* of f at x to be

$$\mathrm{bs}(f,x) = \sup \left[\sum_{j \in [k]} \left| f(x) - f(x^{(B_j)}) \right| \right]$$

where the supremum ranges over all partitions $(B_1, B_2, \cdots, B_k)$ of the variables ($x^{(B_j)}$ denotes x with the coordinates in B_j flipped). Define the block sensitivity of f to be $\mathrm{bs}(f) = \sup_x \mathrm{bs}(f,x)$. We shall use the following fact about bounded low-degree functions:

▶ **Theorem 12.** *If $f : \{\pm 1\}^n \to [0,1]$ has degree d, $bs(f) \leq 6d^2$.*

We give a high-level overview of how we are able to improve upon the bound of ε using the fact that the block sensitivity of a bounded low degree function is small. At one point in their proof, [7] lower bounds the probability of a linear form of Rademacher random variables $l(x_1, x_2, \cdots, x_t) = a_1 x_1 + \cdots + a_t x_t$ exceeding a certain threshold times its standard deviation, i.e.,

$$\mathsf{Pr}\left[a_1 x_1 + \cdots + a_t x_t \geq \alpha \sqrt{a_1^2 + \cdots + a_t^2} \right].$$

(In the proof, $l(x_1, \cdots, x_t)$ is the linear part of a restriction of f: $\sum_{j \in U} \hat{f}_j(U) x_j$ for some $U \subseteq [n]$.)

For each such point x where this linear form is high, [7] shows that *many related points* x' must have $f(x') > 2$. (To be precise, these related points are obtained by applying an appropriate noise operator to x.) Using this they conclude that f must deviate from the interval $[0,1]$ too often and therefore cannot be approximated by any bounded function.

We follow the proof of [7] up until this point. Instead of directly lower bounding the probability that $a_1 x_1 + \cdots + a_t x_t$ is high, we partition the set of variables $[t]$ into L blocks $B_1, \cdots, B_L$ (L is an appropriately chosen parameter) such that each block gets roughly same total weight: for all $j \in [L]$,

$$\sum_{i \in B_j} a_i^2 \geq \frac{a_1^2 + \cdots + a_t^2}{2L}.$$

It will turn out that the a_i's are sufficiently small for such a partition to exist. For each block we lower bound the probability that the linear form restricted to this block is high:

$$\mathsf{Pr}\left[\sum_{j \in B_i} a_j x_j \geq \tilde{\alpha} \sqrt{\sum_{j \in B_i} a_j^2} \right].$$

Now, on a random assignment z, the linear form restricted to many of these blocks will be high. Take such a block B_i: $\sum_{j \in B_i} a_j z_j \geq \tilde{\alpha} \sqrt{\sum_{j \in B_i} a_j^2}$. For each such block we will be able to find a large number of related points z_i such that $|f(z) - f(z_i)|$ is large. (In our case, these related points are obtained by applying an appropriate noise operator restricted to B_i.) Crucially, these related points will differ from z only at B_i. Thus, we will find many points which differ from z at disjoint sets and whose f differ from z significantly. This will show that f cannot be too close to a bounded low degree function, because those functions have low block sensitivity.

Our advantage is that we need to set α' so that we can conclude $|f(z) - f(z')|$ is only somewhat larger than $\Omega(d^2/L)$ (as opposed to $\Omega(1)$ in [7]) - by setting L large enough this allows us to set a much smaller α and get rid of the quadratic exponential dependence.

5 Tools

In this section we compile some lemmas that we shall use in our proof.

A reverse Markov inequality

We will use the following simple inequality throughout the proof.

▶ **Lemma 13.** *Let X be a random variable such that $X \leq M$ with probability 1. Let $\mathsf{E}[X] = \mu > 0$. Then, $\mathsf{Pr}[X \geq \mu/2] \geq \frac{\mu}{2M}$.*

Proof. Assume $\mathsf{Pr}[X \geq \mu/2] < \frac{\mu}{2M}$. Then,

$$\mathsf{E}[X] \leq \mathsf{Pr}[X \geq \mu/2]M + \mathsf{Pr}[X \leq \mu/2]\frac{\mu}{2} < \mu,$$

contradiction. ◀

An anticoncentration inequality for linear forms of Rademacher random variables

▶ **Lemma 14.** *There exists a universal constant K such that the following holds: let $x_1, \cdots, x_n$ be independent Rademacher random variables and let $l(x_1, \cdots, x_n) = a_1 x_1 + \cdots + a_n x_n$. Let $\sigma = \sqrt{a_1^2 + \cdots + a_n^2}$. Suppose $|a_i| \leq \frac{\sigma}{Kt}$. Then,*

$$\Pr[l(x_1, \cdots, x_n) \geq t\sigma] \geq \exp(-Kt^2).$$

Proof. Equation 4.2 in [14]. ◀

Random restrictions have small tail

▶ **Lemma 15.** *Let $f : \{\pm 1\}^n \to \mathbb{R}$ have degree d, $C > 1$ be a sufficiently large constant, and let $\rho = (S, y \in \{\pm 1\}^{[n]\setminus S})$ be a random restriction with survival probability $\frac{\log(d)}{Cd}$. Let $k = \log(d)$. Then,*

$$\mathsf{E}\left[\sum_{|T|>k} \hat{f}_y(T)^2\right] \leq \exp(-C\log(d)/8)\mathsf{Var}[f].$$

Proof. First suppose $(S, y \in \{\pm 1\}^{[n]\setminus S})$ is a fixed restriction. Note that for $z \in \{\pm 1\}^S$,

$$f_y(z) = \sum_{U \subseteq [n]} \hat{f}(U)\chi_U(y, z)$$

so for $T \subseteq [S]$, $\hat{f}_y(T) = \sum_{U \subseteq S} \hat{f}(U \cup T)\chi_U(y)$. By Parseval's theorem, for a fixed S,

$$\mathsf{E}_y\left[\hat{f}_y(T)^2\right] = \sum_{U \subseteq [n]\setminus S} \hat{f}(U \cup T)^2.$$

Therefore, for a fixed S,

$$\mathsf{E}_y\left[\sum_{|T|>k} \hat{f}_y(T)^2\right] = \sum_{V \subseteq [n], |V \cap S|>k} \hat{f}(V)^2.$$

Randomizing over S again,

$$\mathsf{E}_{S,y}\left[\sum_{|T|>k} \hat{f}_y(T)^2\right] = \sum_{V \subseteq [n]} \Pr[|V \cap S| > k]\hat{f}(V)^2.$$

Since f has degree d, we only need to worry about the terms where $|V| \leq d$. Also, for $|V| \leq k$ the relevant probability is 0. Since each element is included in S with probability $\frac{\log(d)}{Cd}$, by Chernoff bound, for each V with $|V| \leq d$,

$$\Pr\left[|V \cap S| > k\right] \leq \exp((C-1)^2 k/4C) \leq \exp(-C\log(d)/8).$$

Thus we get that

$$\mathsf{E}_{S,y}\left[\sum_{|T|>k} \hat{f}_y(T)^2\right] \leq \exp(-C\log(d)/8) \sum_{T \neq \phi} \hat{f}(T)^2 = \exp(-C\log(d)/8)\mathsf{Var}[f]. \quad \blacktriangleleft$$

Random restrictions don't have low variance

▶ **Lemma 16.** *Let $f : \{\pm 1\}^n \to \mathbb{R}$ be any function and let $\rho = (S, y \in \{\pm 1\}^{[n]\setminus S})$ be a random restriction with survival probability p. Then,* $\mathsf{E}[\mathsf{Var}[f_\rho]] \geq p\mathsf{Var}[f]$.

Proof. Fix a restriction $(S, y \in \{\pm 1\}^{[n]\setminus S})$. For each $T \subseteq S$, $\hat{f}_y(T) = \sum_{U \subseteq [n]\setminus S} \hat{f}(T \cup U)\chi_U(y)$.

Thus, by Parseval's theorem, for a fixed S,

$$\mathsf{E}_y[\mathsf{Var}[f_y]] = \sum_{T : T \cap S \neq \phi} \hat{f}(T)^2.$$

Randomizing over S again,

$$\begin{aligned}
\mathsf{E}_{S,y}[\mathsf{Var}[f_y]] &= \sum_{T \neq \phi} \Pr[T \cap S \neq \phi]\hat{f}(T)^2 \\
&= \sum_{T \neq \phi} \left(1 - (1-p)^{|T|}\right)\hat{f}(T)^2 \\
&\geq \sum_{T \neq \phi} p\hat{f}(T)^2 \\
&= p\mathsf{Var}[f].
\end{aligned}$$

$\blacktriangleleft$

Random restrictions with appropriate survival probability put large Fourier mass on the linear level

▶ **Lemma 17** (implicit in [7]). *Let $f : \{\pm 1\}^n \to \mathbb{R}$, $J \subseteq [n]$ and k be such that*

$$\sum_{2^k \leq |T \cap J^c| < 2^{k+1}} \hat{f}(T)^2 \geq \mu.$$

Consider a random restriction $\rho = (S, y \in \{\pm 1\}^{[n]\setminus S})$ where each $j \in J$ is fixed and given a uniformly random assignment, and each $i \in J^c$ is kept alive with probability $p = 2^{-k}$. Then,

$$\mathsf{E}\left[\sum_{i \in S} \hat{f}_y(\{i\})^2\right] \geq \frac{\mu}{20}.$$

Proof. For a fixed $(S, y \in \{\pm 1\}^{[n]\setminus S})$ (note that $J \cap S = \phi$) and $j \in S$ we have

$$\hat{f}_y(\{j\}) = \sum_{T \subseteq [n], T \cap S = \{j\}} \hat{f}(T)\chi_{T\setminus\{j\}}(y).$$

By Parseval's theorem, for a fixed S,

$$\mathsf{E}_y\left[\hat{f}_y(\{j\})^2\right] = \sum_{T \subseteq [n], T \cap S = \{j\}} \hat{f}(T)^2.$$

Randomizing over S,

$$\begin{aligned}\mathsf{E}\left[\sum_{j \in S} \hat{f}_y(\{j\})^2\right] &= \sum_{T \subseteq [n]} \left[\sum_{j \in [n]} \Pr[T \cap S = \{j\}]\right] \hat{f}(T)^2 \\ &\geq \sum_{2^k \leq |T \cap J^c| < 2^{k+1}} |T| p (1-p)^{|T|-1} \hat{f}(T)^2.\end{aligned}$$

By standard inequalities, for $n \in [1/p, 2/p)$, $np(1-p)^{n-1} \geq 1/20$. It follows that

$$\mathsf{E}_y\left[\hat{f}_y(\{j\})^2\right] \geq \frac{\mu}{20}.$$ ◀

Some hypercontractive inequalities for low degree functions

These lemmas and their proofs can be found in [7].

▶ **Lemma 18** (Corollary 2.4 in [7]). *There exists a universal constant $W > 0$ such that the following holds:*

Let $f : \{\pm 1\}^n \to \mathbb{R}$ be a degree k function. Let $\mathsf{E}[f^2] = \sigma^2$. Then,

$$\mathsf{E}\left[f(z)^2 1_{f(z)^2 \leq W^k \sigma^2}\right] \geq \frac{1}{2}\mathsf{E}[f(z)^2].$$

▶ **Lemma 19** (Lemma 2.5 in [7]). *There exists a universal constant $B > 0$ such that the following holds:*

Let $f : \{\pm 1\}^n \to \mathbb{R}$ be a degree k function. Let $\rho \in [-1/2, 1/2]$ be a noise parameter, and $x_0 \in \{\pm 1\}^n$. Suppose $\mathsf{E}_{z \leftarrow N_\rho(x_0)}[f(z) - f(x_0)] = \mu \geq 0$. Then,

$$\Pr_{z \leftarrow N_\rho(x_0)}[f(z) - f(x_0) \geq \mu] \geq \frac{1}{B^k}.$$

The noise lemma

This is the main result of [7]. We use a slight variant. First we recall some known results from approximation theory.

▶ **Lemma 20.** *For any k, there exist constants $\rho_1, \rho_2, \cdots, \rho_{k+1} \in [-1/2, 1/2]$ with the following property: for any polynomial of degree k, $p(x) = a_0 + a_1 x + \cdots + a_k x^k$, there exists a $j \in [k+1]$ such that $p(\rho_j) \geq \frac{a_1}{2(k+1)}$.*

Proof. Page 112 in [20]. ◀

Now we state the lemma.

▶ **Lemma 21.** *There exists a universal constant $B > 0$ such that the following holds: Consider a degree k polynomial $f : \{\pm 1\}^n \to \mathbb{R}$. Let $S \subseteq [n]$ and $\ell(x) = \sum_{i \in S} \hat{f}(\{i\}) x_i$.*

Consider an input $x_0 \in \{\pm 1\}^n$ such that $\ell(x_0) \geq \gamma$. Sample a $z \leftarrow \{\pm 1\}^n$ by the following procedure:

1. *Sample $\rho \leftarrow \{\rho_1, \cdots, \rho_{k+1}\}$ uniformly at random.*
2. *Sample $z \leftarrow N_{\rho,S}(x_0)$.*

Then,

$$\Pr\left[f(z) - f(x_0) \geq \frac{\gamma}{2(k+1)}\right] \geq \frac{1}{(k+1)B^k}.$$

▶ Remark 22. Observe that z differs from x only in the coordinates of S. This will be crucial later on.

Proof. Take B to be the same universal constant as in Lemma 19. By replacing f with an appropriate restriction if necessary, we can assume $S = [n]$. Consider the polynomial $p(\rho) = T_\rho f(x_0) - f(x_0)$. From the Fourier expansion of noise operator, we see that

$$p(\rho) = \sum_{S \neq \phi} \rho^{|S|} \hat{f}(S).$$

This is a degree k polynomial in ρ with linear coefficient $l(x_0)$. By Lemma 20, there exists a $h \in [k+1]$ such that $p(\rho_h) \geq \gamma/(2k+2)$. By Lemma 19,

$$\Pr_{z \leftarrow N_\rho(x_0)}\left[f(z) - f(x_0) \geq \frac{\gamma}{2(k+1)} | \rho = \rho_h\right] \geq \frac{1}{B^k}.$$

We choose $\rho = \rho_h$ in step (1) with probability $1/(k+1)$, so

$$\Pr_{z \leftarrow N_\rho(x_0)}\left[f(z) - f(x_0) \geq \frac{\gamma}{2(k+1)}\right] \geq \frac{1}{(k+1)B^k}.$$ ◀

Partitioning a set of numbers in a balanced manner

We need an easy lemma about partitioning a set of weights none of which is too large into disjoint buckets where each bucket gets roughly the same total weight. We will later use this lemma on the set of small linear Fourier coefficients of a function.

▶ **Lemma 23.** *Let $a_1, a_2, \cdots, a_n$ be a set of non-negative real numbers and $1 \leq L \leq n$. Suppose $a_i \leq \frac{a_1 + a_2 + \cdots + a_n}{2L}$ for all $1 \leq i \leq n$. Then, there exists a partition $(B_1, B_2, \cdots, B_L)$ of $[n]$ such that for all $1 \leq j \leq L$,*

$$\sum_{i \in B_j} a_i \geq \frac{a_1 + \cdots + a_n}{2L}.$$

Proof. Start with an arbitrary partition $(B_1, B_2, \cdots, B_L)$. Then, refine it iteratively according to the following algorithm.

Refinement algorithm:

1. Locate a j such that the condition is violated for j, i.e.,

   $$\sum_{i \in B_j} a_i < \frac{a_1 + \cdots + a_n}{2L}.$$

   If no such j exists, terminate.
2. Locate a k such that

   $$\sum_{i \in B_k} a_i \geq \frac{a_1 + \cdots + a_n}{L}.$$

3. Take an arbitrary $l \in B_k$ such that $a_l \neq 0$ and place it in B_j;

   $$B_k \leftarrow B_k \setminus \{l\}$$

   $$B_j \leftarrow B_j \cup \{l\}$$

An appropriate k always exists in step (2) by an averaging argument. Since $a_l \leq \frac{a_1 + \cdots + a_n}{2L}$, the size of B_k does not go below $\frac{a_1 + \cdots + a_n}{2L}$ after step (3). It is easy to see this procedure must terminate. Formally, notice that the quantity

$$\sum_{j \in [L]} \min\left(\frac{a_1 + \cdots + a_n}{2L} - \sum_{i \in B_j} a_i, 0\right)$$

reduces by $\frac{1}{2L} \min\{a_i | a_i \neq 0\}$ at each step, so at some point of time it must be 0 at which point the algorithm terminates and returns a valid partition. ◀

Bounded low-degree functions have low block sensitivity

▶ **Lemma 24.** *Let $f : \{\pm 1\}^n \to [0, 1]$ be a polynomial of degree d. Then, $bs(f) \leq 6d^2$.*

Proof. Let $B_1, B_2, \cdots, B_k$ be any partition of $[n]$. Our goal is to show that for all $x \in \{\pm 1\}^n$,

$$\sum_{i=1}^{k} |f(x) - f(x^{(B_i)})| \leq 6d^2.$$

Let $g : \{\pm 1\}^k \to [0, 1]$ be the function obtained from f obtained by identifying the variables of B_i with a single variable y_i for $1 \leq i \leq k$. By Proposition 3.7 in [8], we have, for every

$y \in \{\pm 1\}^k$,

$$\sum_{i=1}^{k} |g(y) - g(y^{(i)})| \leq 6d^2.$$

This implies

$$\sum_{i=1}^{k} |f(x) - f(x^{(B_i)})| \leq 6d^2,$$

as desired. ◀

6 Main results

6.1 Improved tail bound for low degree functions

This section is the core technical part of our work. In Theorem 26 we show that if we have a function $f : \{\pm 1\}^n \to \mathbb{R}$ *(not necessarily bounded)* with $\mathsf{E}[f^2] \leq 1$ which cannot be approximated by juntas, then f cannot be well-approximated by bounded low-degree functions. In Theorem 28 we use Theorem 26 on the truncated function $f^{\leq k}$ to conclude that the tail bound appearing in [7] (Theorem 8) can be improved under the additional assumption that f has degree d.

▶ Remark 25. For a subset $J \subseteq [n]$, consider the junta $u : \{\pm 1\}^n \to \mathbb{R}$ which reads the coordinates of J and outputs the average over the unqueried coordinates. It is easy to see that $u(x) = \sum_{S \subseteq J} \hat{f}(S)\chi_S(x)$, so $||u - f||_2^2 = \sum_{S \not\subseteq J} \hat{f}(S)^2$. Thus, u approximates f if and only if $\sum_{S \not\subseteq J} \hat{f}(S)^2$ is small.

In fact, it is easy to see that there exists a function u depending only on coordinates of J such that $||f - u||_2^2 \leq \epsilon$ if and only if $\sum_{S \not\subseteq J} \hat{f}(S)^2 \leq \epsilon$. This immediately follows from the Fourier expansion of $f - u$.

▶ **Theorem 26.** *There exists a constant C such that the following holds:*
Let $f : \{\pm 1\}^n \to \mathbb{R}$ be a degree k function (not necessarily bounded) with $\mathsf{E}[f^2] \leq 1$. Let $J = \{j | \mathsf{Inf}_j[f] \geq \theta\}$ where $\theta = \frac{\mu^2}{C^k d^C}$. If $\sum_{S \not\subseteq J} \hat{f}(S)^2 \geq \mu$, then for any degree d function $g : \{\pm 1\}^n \to [0, 1]$, $\mathsf{E}[(f(x) - g(x))^2] \geq \delta = \frac{\mu}{C^k d^C}$.

▶ Remark 27. Notice here that although f is not pointwise bounded, g is.

Proof. Let W, B, K be the universal constants from Lemma 18, Lemma 21 and Lemma 14 respectively. We take C to be a constant sufficiently larger than B, K, W.

There exists a t such that

$$\sum_{2^t \leq |S \cap J^c| < 2^{t+1}} \hat{f}(S)^2 \geq \frac{\mu}{\log(k)}.$$

Let $\rho = (U, y \in \{\pm 1\}^{[n] \setminus U})$ $(U \subseteq J^c)$ be a random restriction where each $j \in J$ is fixed to a uniformly random assignment, and survival probability for each $j \notin J$ is 2^{-t}. By Lemma 17,

$$\mathsf{E}\left[\sum_{j \in U} \hat{f}_y(\{j\})^2\right] \geq \frac{\mu}{20 \log(k)}.$$

Fix a U such that

$$\mathsf{E}_{y\in\{\pm1\}^{[n]\setminus U}}\left[\sum_{j\in U}\hat{f}_y(\{j\})^2\right]\geq\frac{\mu}{20\log(k)}.$$

By Parseval's theorem we have for all $j\in U$,

$$\mathsf{E}\left[\hat{f}_y(\{j\})^2\right]=\sum_{S\cap U=\{j\}}\hat{f}(S)^2\leq\mathsf{Inf}_j[f].$$

For each $y\in\{\pm1\}^{[n]\setminus U}$ define $\mathsf{SMALL}_y=\{j|\hat{f}_y(\{j\})^2\leq W^k\mathsf{Inf}_j[f]\}$. Observe that for all y,

$$\sum_{j\in\mathsf{SMALL}_y}\hat{f}_y(\{j\})^2\leq W^k\mathsf{Inf}[f]\leq k\cdot W^k\leq(2W)^k.$$

For each $j\in U$ we have from Lemma 18

$$\mathsf{E}\left[\hat{f}_y(\{j\})^2\mathsf{1}_{\hat{f}_y(\{j\})^2\leq W^k\mathsf{Inf}_j[j]}\right]\geq\frac{1}{2}\mathsf{E}\left[\hat{f}_y(\{j\})^2\right].$$

Thus,

$$\mathsf{E}_{y\in\{\pm1\}^{[n]\setminus U}}\left[\sum_{j\in\mathsf{SMALL}_y}\hat{f}_y(\{j\})^2\right]\geq\frac{\mu}{40\log(k)},$$

so applying Lemma 13 [2]

$$\mathsf{Pr}_{y\in\{\pm1\}^{[n]\setminus U}}\left[\sum_{j\in\mathsf{SMALL}_y}\hat{f}_y(\{j\})^2\geq\frac{\mu}{80\log(k)}\right]\geq\frac{\mu}{80\log(k)(2W)^k}\geq\frac{\mu}{(3W)^k}.$$

Call $y\in\{\pm1\}^{[n]\setminus U}$ for which $\sum_{j\in\mathsf{SMALL}_y}\hat{f}_y(\{j\})^2\geq\frac{\mu}{80\log(k)}$ to be *good*. Let $\mathrm{GOOD}=\{y\in\{\pm1\}^{[n]\setminus U}|y\text{ is good}\}$. Let $L=\left\lceil\frac{(2B)^kd^8}{\mathsf{Var}[f]}\right\rceil$. For each good y, choose a partition $\mathsf{DIVIDE}(y)=(B_1,B_2,\cdots,B_L)$ of SMALL_y such that for all $1\leq i\leq L$,

$$\sum_{j\in B_i}\hat{f}_y(\{j\})^2\geq\frac{\mu}{160L\log(k)}.$$

(If there are multiple such partitions, choose any one of them and call it $\mathsf{DIVIDE}(y)$.)

Our choice of parameters ensures that for all $j\in\mathsf{SMALL}_y$, $\hat{f}_y(\{j\})^2\leq\frac{\mu}{160L\log(k)}$, so such a partition exists by Lemma 23. Let $\rho_1,\rho_2,\cdots,\rho_{k+1}$ be the constants from Lemma 20.

Suppose, for the sake of contradiction, there exists a degree d polynomial $g:\{\pm1\}^n\to[0,1]$ such that $\mathsf{E}[(f(x)-g(x))^2]\leq\delta$. Throughout the rest of the proof, for a string $s_1\in\{\pm1\}^{[n]\setminus U}$ and a string $s_2\in\{\pm1\}^U$, the pair (s_1,s_2) denotes the string $s\in\{\pm1\}^n$ which agrees with s_1 on $[n]\setminus U$ and with s_2 on U. Consider the following randomized procedure which returns a real number.

[2] See remark 7.

Procedure 1:
1. Sample a $y \in \mathsf{GOOD}$ uniformly at random.
2. Sample $\rho \leftarrow \{\rho_1, \rho_2, \cdots, \rho_{k+1}\}$ uniformly at random.
3. Sample $z \leftarrow \{\pm 1\}^U$ uniformly at random.
4. Let $\mathsf{DIVIDE}(y) = (B_1, B_2, \cdots, B_L)$. Sample $\tilde{z}^{(i)} \leftarrow N_{B_i,\rho}(z)$ for $1 \le i \le L$.
5. Return $\sum_{i=1}^{L} |f(y,z) - f(y,\tilde{z}^{(i)})|$.

We estimate the probability that procedure 1 returns a number $> 15d^2$ in two different ways. First, we obtain a lower bound from the defintion of GOOD. Then, we obtain an upper bound using the assumption that $\mathsf{E}[(f(x) - g(x))^2] \le \delta$ and the fact that $\mathsf{Pr}[y \text{ is good}]$ is somewhat large. These two bounds will contradict each other - and that will prove the theorem.

Lower bound. Fix a $y \in \mathsf{GOOD}$. Let $\mathsf{DIVIDE}(y) = (B_1, B_2, \cdots, B_L)$.

Let $w = \sqrt{\dfrac{\mu}{160L\log(k)}}$. For each $i \in [L]$ we have

$$\sqrt{\sum_{j \in B_i} \hat{f}_y(\{j\})^2} \ge w.$$

Choose α such that $\alpha w = \dfrac{100d^4(2B)^k}{L}$. Our choice of L ensures that $\alpha \le 1$. Moreover, our choice for influence threshold θ ensures that $|\hat{f}_y(\{j\})| \le \dfrac{w}{K\alpha}$ for all $j \in B_i$ where K is the universal constant from the Lemma 14.

Therefore, we can apply Lemma 14 to obtain that

$$\mathsf{Pr}_{z \in \{\pm 1\}^{B_i}} \left[\sum_{j \in B_i} z_j \hat{f}_y(\{j\}) \ge \frac{100d^4(2B)^k}{L} \right] \ge \exp(-K\alpha^2) \ge \frac{1}{K_1}.$$

Here $K_1 = \exp(K)$ is an absolute constant.

By Lemma 21 applied on the restriction $f_y : \{\pm 1\}^U \to \mathbb{R}$, as we sample $z \leftarrow \{\pm 1\}^U$ u.a.r, $\rho \leftarrow \{\rho_1, \cdots, \rho_{k+1}\}$ u.a.r, $\tilde{z}^{(i)} \leftarrow N_{\rho,B_i}(z)$, we have that

$$\mathsf{Pr}\left[|f(y,z) - f(y,\tilde{z}^{(i)})| \ge \frac{30d^3(2B)^k}{L} \right] \ge \frac{1}{K_1(k+1)B^k} \ge \frac{1}{(2B)^k}.$$

By linearity of expectation,

$$\mathsf{E}\left[\left| \left\{ i \in [L] \middle| |f(y,z) - f(y,\tilde{z}^{(i)})| \ge \frac{30d^3(2B)^k}{L} \right\} \right| \right] \ge \frac{L}{(2B)^k}.$$

Using Lemma 13,

$$\mathsf{Pr}\left[\left| \left\{ i \in [L] \middle| |f(y,z) - f(y,\tilde{z}^{(i)})| \ge \frac{30d^3(2B)^k}{L} \right\} \right| \ge \frac{L}{2 \times (2B)^k} \right] \ge \frac{1}{2 \times (2B)^k}.$$

Observe that

$$\left| \left\{ i \in [L] \middle| |f(y,z) - f(y,\tilde{z}^{(i)})| \ge \frac{30d^3(2B)^k}{L} \right\} \right| \ge \frac{L}{2 \times (2B)^k} \implies \sum_{i \in [L]} |f(y,z) - f(y,\tilde{z}^{(i)})| \ge 15d^3.$$

We conclude that for all $y \in \mathsf{GOOD}$, as $z, \tilde{z}^{(1)}, \cdots, \tilde{z}^{(L)}$ are sampled as in Procedure 1,

$$\mathsf{Pr}\left[\sum_{i\in[L]} |f(y,z) - f(y,\tilde{z}^{(i)})| \geq 15d^3\right] \geq \frac{1}{2\times(2B)^k}.$$

Thus, with probability at least $\frac{1}{2\times(2B)^k}$, procedure 1 returns a number greater than $15d^2$(as $15d^3 > 15d^2$).

Upper bound. Since $\mathsf{E}[(f(x)-g(x))^2] \leq \delta$ and $\mathsf{Pr}_{y\in\{\pm1\}^{[n]\setminus U}}[y \text{ is good}] \geq \mu/(3W)^k$, we have that

$$\mathsf{E}[(f(x)-g(x))^2 | x_{[n]\setminus U} \text{ is good}] \leq \frac{\delta}{\mu}(3W)^k.$$

Now consider a uniformly sampled $y \in \mathsf{GOOD}$. Observe that as we sample $z \leftarrow \{\pm1\}^U$ u.a.r, $\rho \leftarrow \{\rho_1, \cdots, \rho_{k+1}\}$ u.a.r and $\tilde{z}^{(i)} \leftarrow N_{\rho,B_i}(z)$, the marginal distribution of $\tilde{z}^{(i)}$ is uniform on $\{\pm1\}^U$. By Markov's inequality, we have

$$\mathsf{Pr}\left[(f(y,z)-g(y,z))^2 \geq \frac{1}{L^2}\right] \leq \frac{L^2\delta}{\mu}(3W)^k$$

and for all $i \in [L]$,

$$\mathsf{Pr}\left[(f(y,\tilde{z}^{(i)})-g(y,\tilde{z}^{(i)}))^2 \geq \frac{1}{L^2}\right] \leq \frac{L^2\delta}{\mu}(3W)^k.$$

By union bound, the probability that $(f(y,z)-g(y,z))^2 \geq \frac{1}{L^2}$ or for some i, $(f(y,\tilde{z}^{(i)}) - g(y,\tilde{z}^{(i)}))^2 \geq \frac{1}{L^2}$ is at most $(L+1)\frac{L^2\delta}{\mu}(3W)^k \leq \frac{2L^3\delta}{\mu}(3W)^k$. Our choice of δ ensures that this quantity is less than $< \frac{1}{2\times(2B)^k}$. Observe that if none of these bad events holds, since the block sensitivity of g is bounded above by $6d^2$ (Theorem 24), we have that

$$\sum_{i\in[L]} |g(y,z)-g(y,\tilde{z}^{(i)})| \leq 6d^2 \implies \sum_{i\in[L]} |f(y,z)-f(y,\tilde{z}^{(i)})| \leq 6d^2+1 < 15d^2.$$

Thus, we conclude

$$\mathsf{Pr}\left[\sum_{i\in[L]} |f(y,z)-f(y,\tilde{z}^{(i)})| > 15d^2\right] < \frac{2L^3\delta}{\mu}(3W)^k < \frac{1}{2\times(2B)^k}.$$

As promised, we get conflicting lower and upper bounds for the probability that procedure 1 returns a number $> 15d^2$. This is our desired contradiction. ◀

Now we show that we can improve the tail bound of Theorem 8 under the additional assumption that f has low degree. This follows straightforwardly from Theorem 26.

▶ **Theorem 28.** *There exists a universal constant $C > 0$ such that the following is true: Let $f : \{\pm1\}^n \to [0,1]$ be a degree d function. Let $\theta = \frac{\mathsf{Var}[f]^2}{d^C C^k}$ and $J = \{j | \mathsf{Inf}_j[f] \geq \theta\}$. If $\sum_{S\not\subseteq J} \hat{f}(S)^2 \geq \mu$, then $\sum_{|S|>k} \hat{f}(S)^2 \geq \frac{\mu}{d^C C^k}$.*

Proof. Assume $\sum_{|S|>k} \hat{f}(S)^2 < \mu/2$ (otherwise we are done). Let $\tilde{C}$ be the universal constant from Theorem 26.

The idea is to apply Theorem 26 to the truncated function

$$f^{\leq k}(x) = \sum_{|S|\leq k} \hat{f}(S)\chi_S(x).$$

Note that while $f^{\leq k}$ is not pointwise bounded, it satisfies $\mathsf{E}[(f^{\leq k})^2] \leq 1$ and $\mathsf{Inf}_j[f^{\leq k}] \leq \mathsf{Inf}_j[f]$ for all j (this is clear from the Fourier expressions). Let $H = \{j|\mathsf{Inf}_j[f^{\leq k}] \geq \theta\}$. We have $H \subseteq J$, so

$$\sum_{S \not\subseteq H} \hat{f^{\leq k}}(S)^2 \geq \sum_{S \not\subseteq J} \hat{f}(S)^2 - \frac{\mu}{2} \geq \frac{\mu}{2}.$$

Applying Theorem 26, we get that for any bounded degree d $g : \{\pm 1\}^n \to [0,1]$, $\mathsf{E}[(f(x) - g(x))^2] \geq \frac{\mu}{2d^{\tilde{C}}\tilde{C}^k}$. Taking g to be our original function f, we get the desired tail lower bound:

$$\mathsf{E}[(f - f^{\leq k})^2] \geq \frac{\mu}{2d^{\tilde{C}}\tilde{C}^k} \implies \sum_{|S|>k} \hat{f}(S)^2 > \frac{\mu}{2d^{\tilde{C}}\tilde{C}^k}.$$

Taking C to be a slightly larger constant than $\tilde{C}$, we get that

$$\sum_{|S|>k} \hat{f}(S)^2 \geq \frac{\mu}{d^C C^k}.$$ ◀

6.2 Random restrictions can be approximated by juntas

In this section we use the fact that random restrictions have bounded tails to show that they can be approximated by juntas. This is our main result.

▶ **Theorem 29 (Restatement of Theorem 1).** *For any constants $\tilde{C}_1, \tilde{C}_2 > 0$, there exist constants $\tilde{C}_3, \tilde{C}_4, \tilde{C}_5 > 0$ such that the following holds:*
Let $f : \{\pm 1\}^n \to [0,1]$ be a degree d polynomial and let ρ be a random restriction with survival probability $\frac{\log(d)}{\tilde{C}_3 d}$. With probability at least $1 - d^{-\tilde{C}_2}$, f_ρ is a $(d^{-\tilde{C}_1}\mathsf{Var}[f], \mathsf{Var}[f]^{-2}d^{\tilde{C}_4})$ junta. Moreover, if J denotes the set of coordinates on which the junta depends, for each $j \in J$ we have $\mathsf{Inf}_j[f] \geq \mathsf{Var}[f]^2 d^{-\tilde{C}_5}$.

Proof. We consider a random restriction with survival probability $\frac{\log(d)}{\tilde{C}_3 d}$.

By Lemma 15, the expected Fourier tail of f_ρ above level $\log(d)$ is at most $\exp(-\tilde{C}_3 \log(d)/8)\mathsf{Var}[f] = \frac{\mathsf{Var}[f]}{d^{\tilde{C}_3/8}}$. By Markov's inequality, with probability at least $1 - d^{\tilde{C}_3/16}$, the Fourier tail above $\log(d)$ is $\leq \frac{\mathsf{Var}[f]}{d^{\tilde{C}_3/16}}$. Let C be the constant from Theorem 28. Let $\mu = \frac{\mathsf{Var}[f]}{d^{\tilde{C}_3/16}} d^C C^{\log(d)} = \frac{\mathsf{Var}[f]}{d^{\tilde{C}_3/16}} d^{2C}$, $\theta = \frac{\mu^2}{d^C C^{\log(d)}} = \frac{\mu^2}{d^{2C}}$ and $J = \{j|\mathsf{Inf}_j[f_\rho] \geq \theta\}$. Let $u_\rho : \{\pm 1\}^n \to [0,1]$ be the function which reads the coordinates in J and outputs the average of f_ρ over the coordinates in J^c. Choose $\tilde{C}_3$ large enough so that $\mu \leq d^{-\tilde{C}_1}\mathsf{Var}[f]$. Applying Theorem 28, we see that u_ρ approximates f_ρ to accuracy $d^{-\tilde{C}_1}\mathsf{Var}[f]$. Using the fact that total influence is bounded by d, we see that u_ρ has arity $\leq \mathsf{Var}[f]^{-2}d^{C'\tilde{C}_3}$ for a universal constant C'. Taking $(\tilde{C}_4, \tilde{C}_5) = (C'\tilde{C}_3, \tilde{C}_3/32 - 2C)$, we are done. ◀

6.3 Aaronson-Ambainis Conjecture is true for random restrictions

▶ **Theorem 30 (Restatement of Theorem 5).** *There exist constants $C_1, C_2 > 0$ such that the following holds: let $f : \{\pm 1\}^n \to [0,1]$ be a degree d polynomial ($d \geq 2$) with $\mathsf{Var}[f] \geq 1/d$. Let ρ denote a random restriction with alive probability $\frac{\log(d)}{C_1 d}$. Then,*

$$\mathsf{Pr}\left[f_\rho \text{ has a coordinate with influence } \geq \frac{\mathsf{Var}[f]^2}{d^{C_2}}\right] \geq \frac{\mathsf{Var}[f]\log(d)}{50 C_1 d}.$$

Proof. Let M be a large constant. Apply Theorem 29 with $(\tilde{C}_1, \tilde{C}_2) = (M, M)$ to get constants $\tilde{C}_3, \tilde{C}_4, \tilde{C}_5$. Let ρ be a random restriction with survival probability $\frac{\log(d)}{\tilde{C}_3 d}$. By Lemma 16,

$$\mathsf{E}[\mathsf{Var}[f_\rho]] \geq \frac{\mathsf{Var}[f]\log(d)}{\tilde{C}_3 d}$$

so by Lemma 13,

$$\mathsf{Pr}\left[\mathsf{Var}[f_\rho] \geq \frac{\mathsf{Var}[f]\log(d)}{2\tilde{C}_3 d}\right] \geq \frac{\mathsf{Var}[f]\log(d)}{2\tilde{C}_3 d}.$$

Since $\mathsf{Var}[f] \geq 1/d$, $d^{-M} \leq \frac{\mathsf{Var}[f]\log(d)}{10\tilde{C}_3 d}$. By Theorem 29 and Remark 25, with probability at least $1 - d^{-M}$, there exists a $J_\rho \subseteq [n]$ such that every coordinate in J_ρ has influence $\geq \mathsf{Var}[f_\rho]^2 d^{-\tilde{C}_5}$ and

$$\sum_{S \not\subseteq J_\rho} \hat{f}_\rho(S)^2 \leq d^{-M}\mathsf{Var}[f].$$

So with probability at least $\frac{\mathsf{Var}[f]\log(d)}{2\tilde{C}_3 d} - d^{-M} \geq \frac{\mathsf{Var}[f]\log(d)}{4\tilde{C}_3 d}$, both these events (high variance of f_ρ and existence of J_ρ) hold and we have that

$$\sum_{S \subseteq J_\rho} \hat{f}_\rho(S)^2 \geq \mathsf{Var}[f_\rho] - d^{-M}\mathsf{Var}[f] \geq \frac{\mathsf{Var}[f]\log(d)}{4\tilde{C}_3 d}.$$

In particular, we have that $J_\rho \neq \phi$. Since for each $j \in J_\rho$ we have $\mathsf{Inf}_j[f_\rho] \geq \mathsf{Var}[f_\rho]^2 d^{-\tilde{C}_5}$, we are done by taking $(C_1, C_2) = (\tilde{C}_3, 2 + \tilde{C}_5)$. ◀

7 Conclusions and further directions

In this paper, we showed that if $f : \{\pm 1\}^n \to [0,1]$ is a degree d polynomial, a large fraction of its random restrictions have an influential coordinate.

It would be interesting to see if we can extend this to the full Aaronson-Ambainis conjecture. We describe a few potential approaches here.

- Given a degree d polynomial $f : \{\pm 1\}^n \to [0,1]$, we can lift it with a Boolean function $g : \{\pm 1\}^m \to \{\pm 1\}^n$ each of whose coordinates g_i is unbiased and given by a low degree function. Then, the lifted polynomial $f \odot g : \{\pm 1\}^m \to [0,1]$ will be a low degree polynomial. As long as the g_i's are pairwise independent, the variance of f will be preserved as well. Our result shows that a large fraction of random restrictions of

$f \odot g$ have an influential coordinate. Can we construct $g_1, g_2, \cdots, g_n$ appropriately such that this allows us to conclude f must have an influential coordinate as well? The g_i's should introduce correlations between the different input bits of f so that most random restrictions of $f \odot g^m$ *look the same* in some appropriate sense.

- Our result shows that for a non-negligible fraction of $y \in \{\pm 1\}^{[n]\setminus U}$, there exists a j such that $\mathsf{Inf}_j[f_y] \geq \mathrm{Var}[f]^2/d^{O(1)}$. Can we construct a decision tree of height $\mathrm{poly}(d)$ which, on input y, outputs one of the influential coordinates of f_y with high probability? If this is possible, this will imply Aaronson-Aambainis via the approach of Keller and Klein. We may additionally assume that for all j, $\mathrm{Inf}_j[f] = \mathrm{E}_y[\mathrm{Inf}_j[f_y]] \leq \mathrm{Var}[f]^2/d^{10000}$ (otherwise the result holds for f anyway). So basically the situation looks like this: for a non-negligible fraction of y, for some j, $\mathrm{Inf}_j[f_y]$ is significantly higher than its expectation ($\mathrm{Inf}_j[f]$) – and we want to probe y in a few bits to locate such a j.

Abstract

The Cohn–Umans (FOCS '03) group-theoretic framework for matrix multiplication produces fast matrix multiplication algorithms from three subsets of a finite group G satisfying a simple combinatorial condition (the Triple Product Property). The complexity of such an algorithm then depends on the representation theory of G. In this paper we extend the group-theoretic framework to the setting of *infinite* groups. In particular, this allows us to obtain constructions in Lie groups, with favorable parameters, that are provably impossible in finite groups of Lie type (Blasiak, Cohn, Grochow, Pratt, and Umans, ITCS '23). Previously the Lie group setting was investigated purely as an analogue of the finite group case; a key contribution in this paper is a fully developed framework for obtaining bona fide matrix multiplication algorithms directly from Lie group constructions.

As part of this framework, we introduce "separating functions" as a necessary new design component, and show that when the underlying group is $G = \mathrm{GL}_n$, these functions are polynomials with their degree being the key parameter. In particular, we show that a construction with "half-dimensional" subgroups and optimal degree would imply $\omega = 2$. We then build up machinery that reduces the problem of constructing optimal-degree separating polynomials to the problem of constructing a *single* polynomial (and a corresponding set of group elements) in a ring of invariant polynomials determined by two out of the three subgroups that satisfy the Triple Product Property. This machinery combines border rank with the Lie algebras associated with the Lie subgroups in a critical way.

We give several constructions illustrating the main components of the new framework, culminating in a construction in a special unitary group that achieves separating polynomials of optimal degree, meeting one of the key challenges. The subgroups in this construction have dimension *approaching* half the ambient dimension, but (just barely) too slowly. We argue that features of the classical Lie groups make it unlikely that constructions in these particular groups could produce nontrivial bounds on ω unless they prove $\omega = 2$. One way to get $\omega = 2$ via our new framework would be to lift our existing construction from the special unitary group to GL_n, and improve the dimension of the subgroups from $\frac{\dim G}{2} - \Theta(n)$ to $\frac{\dim G}{2} - o(n)$.

1 Introduction

Matrix multiplication is a fundamental algebraic operation with myriad algorithmic applications, and as such, determining its complexity is a central question in computational complexity. Since Strassen's 1969 discovery [26] that one could beat the straightforward $O(n^3)$ method with one that used only $O(n^{\log_2 7}) = O(n^{2.81\cdots})$ arithmetic operations, there has been a long line of work improving upper bounds on the complexity of matrix multiplication. It is standard to define the exponent ω of matrix multiplication as the smallest number such that $n \times n$ matrices can be multiplied using $n^{\omega+o(1)}$ arithmetic operations, and a somewhat surprising folklore conjecture is that $\omega = 2$, which would mean matrices can be multiplied asymptotically almost as quickly as they can be added. The current best bound is that $\omega \leq 2.371339$ [29], and proving or disproving that $\omega = 2$ remains a longstanding open question.

In [14], an approach towards this problem was proposed based on embedding matrix multiplication into the multiplication operation in the group algebra of a finite group. Group algebra multiplication then reduces to the multiplication of block-diagonal matrices, where the sizes of these blocks are determined by the (typically well-understood) representation theory of the group. Ultimately, one hopes to reduce a single matrix multiplication to the multiplication of (many) smaller matrices. Within this very general framework, certain families of groups have subsequently been shown to have structural properties that prevent a reduction that would yield $\omega = 2$ using this framework [7, 8, 9]. Other groups remain potentially viable, and the overall approach remains one of the two main lines of research towards improving upper bounds on ω, the other being the traditional "direct" tensor methods (e. g., [24, 27, 15, 28, 16, 21, 2, 18]), which also seem to be running up against several barrier results [3, 12, 1, 11].

In more detail, the reduction to group algebra multiplication is possible when one identifies a finite group G and sets $X, Y, Z \subseteq G$ satisfying the *triple product property* (TPP): for any $x, x' \in X$, $y, y' \in Y$, and $z, z' \in Z$,

$$xx'^{-1}yy'^{-1}zz'^{-1} = 1_G \iff x = x', y = y', z = z'.$$

If $X, Y, Z \subseteq G$ satisfy the TPP, then we can multiply two complex matrices A and B, of sizes $|X| \times |Y|$ and $|Y| \times |Z|$, resp., as follows. Index A with $X \times Y$, with $A[x, y]$ denoting the x, y entry of A, and index B with $Y \times Z$. Then we define the elements

$$\overline{A} = \sum_{x,y} A[x, y](xy^{-1}) \quad \text{and} \quad \overline{B} = \sum_{y,z} B[y, z](yz^{-1})$$

of the group ring $\mathbb{C}[G]$ and observe that the TPP implies that

$$\overline{A} \cdot \overline{B} = \sum_{x,z} (AB)[x, z](xz^{-1}) + E, \tag{1.1}$$

where $E \in \mathbb{C}[G]$ is supported on $XY^{-1}YZ^{-1} \setminus XZ^{-1}$. It is a standard fact of representation theory that, as algebras, $\mathbb{C}[G] \cong \bigoplus_i M_{d_i}(\mathbb{C})$, where M_{d_i} denotes the ring of $d_i \times d_i$ matrices, the sum is over the irreducible representations of G, and the d_i are the dimensions of those representations. This leads to the inequality:

▶ **Theorem 1.1** ([14, Theorem 4.1]). *If X, Y, Z satisfy the TPP in a finite group G, then*

$$(|X||Y||Z|)^{\omega/3} \leq \sum_i d_i^\omega,$$

where d_i are the dimensions of the irreducible representations of G.

The upper bound on ω from Theorem 1.1 depends on a trade-off between the size of the matrix multiplication that can be embedded into $\mathbb{C}[G]$ (reflected in $|X|, |Y|, |Z|$) and the dimensions of the irreducible representations of G. In abelian groups, the latter are optimal: all d_i are 1. However, already in [14] it was observed that abelian groups cannot do better than the trivial construction $X = G$ and $Y = Z = \{1\}$, and thus cannot yield any bound better than the trivial bound $\omega \leq 3$. It was shown in [13] that non-abelian groups can achieve highly nontrivial bounds on ω (including many of the state-of-the-art bounds over the last decade), but obtaining such bounds requires a careful interplay between the size of the construction and the representation dimensions. Several families of groups have been shown not to admit constructions for which Theorem 1.1 would give $\omega = 2$, although many families of groups remain possibilities.

Because of the difficulty of finding such constructions, it is useful to look for other potential sources of examples of groups and group-like objects that could yield such constructions. Cohn and Umans [14] gave a construction of a TPP triple in the infinite group $\mathrm{GL}_n(\mathbb{R})$, despite having, at the time, no way of getting a (finite) matrix multiplication algorithm from such a construction.

One natural approach (that ends up not working) is to take a construction in a Lie group and try to transfer it to a finite group of Lie type, such as taking a construction in $\mathrm{GL}_n(\mathbb{R})$ and attempting an analogous construction in $\mathrm{GL}_n(\mathbb{F}_q)$. Indeed, a construction in $\mathrm{GL}_n(\mathbb{R})$ was given in [14] using the lower unitriangular, orthogonal, and upper unitriangular subgroups; this inspired a nontrivial TPP in the finite group $\mathrm{SL}_2(\mathbb{F}_q)$, where the orthogonal group is replaced by matrices of the form $\begin{pmatrix} 1+a & a \\ -a & 1-a \end{pmatrix}$. However, in that example, we have $|X| = |Y| = |Z| = q$, but $\mathrm{SL}_2(\mathbb{F}_q)$ has irreducible representations of dimension $q+1$, and reducing a $q \times q$ matrix multiplication to a $(q+1) \times (q+1)$ matrix multiplication doesn't give any bound on ω. More generally, in [9] it was shown that one cannot achieve $\omega = 2$ via Theorem 1.1 in any finite groups of Lie type, ruling out any such construction in $\mathrm{GL}_n(\mathbb{F}_q)$ or similar groups (though possibilities remain open to use related groups such as direct products of finite groups of Lie type). Thus, the Lie-type constructions remained only an analogy.

1.1 First main contribution: algorithms from infinite groups

In this paper, one of our main innovations is to extend the group-theoretic framework [14] to allow finite matrix multiplication algorithms from constructions in arbitrary – even infinite – groups. To achieve this, rather than using the entire group algebra $\mathbb{C}[G]$, which is infinite-dimensional when G is infinite, we focus only on sets of functions $G \to \mathbb{C}$ that (1) are linearly computable from a finite set of finite-dimensional representations of G (even when G is infinite) and (2) "separate" the elements in the group algebra that are in the linear span of $XY^{-1}YZ^{-1}$ (the support of (1.1)), in a sense made precise below (Definition 2.1). Our first main theorem in this generalized framework is then:

▶ **Theorem A** (Theorem 2.2). *Let G be a group (not necessarily finite), with finite subsets X, Y, Z satisfying the TPP. If R_{sep} is a set of finite-dimensional complex representations of G whose matrix entries separate $XY^{-1}YZ^{-1}$ (see Definition 2.1), then*

$$(|X|\,|Y|\,|Z|)^{\omega/3} \leq \sum_{\rho \in R_{\text{sep}}} (\dim \rho)^{\omega}.$$

It is even conceivable that this result could be used to improve the bounds from known constructions of TPPs in finite groups, by using only a subset of the group's irreducible representations rather than all of them.

But perhaps the main payoff of Theorem A is that it allows, for the first time, the derivation of matrix multiplication algorithms from infinite groups. This opens a huge variety of potential constructions to explore, even beyond those in Lie groups that will be the focus of the rest of the paper.

1.2 Second main contribution: quantitative targets for proving $\omega = 2$ in classical Lie groups

Another main contribution in this paper is to develop a series of tools and techniques, and to identify key targets to aim for, for getting good constructions using Theorem A in Lie groups such as $\mathrm{GL}_n(\mathbb{R})$, $\mathrm{GL}_n(\mathbb{C})$, or the unitary group U_n. Lie groups are defined as groups that are also smooth manifolds, and where the group multiplication and inverse are continuous in terms of the manifold topology. In fact, all of our constructions in this paper will be in one of these three groups, though much of the machinery we develop works for general matrix Lie groups, and it would be interesting to explore constructions in other Lie groups such as symplectic groups, orthogonal groups, exceptional simple Lie groups, or nilpotent or solvable Lie groups.

Before coming to the constructions, we highlight how the framework of Theorem A allows us to take the analogy from [14, 9], and turn it into a formal implication whose conclusion is a bound on ω. To briefly recall the analogy: elementary arguments show that any TPP triple in a finite group must satisfy $|X|\,|Y|\,|Z| \leq |G|^{3/2}$, called the *packing bound* because of the nature of the proof. Because $\sum d_i^2 = |G|$ in finite groups, it follows that any sequence of constructions that achieves $\omega = 2$ via Theorem 1.1 (not our new Theorem A) must asymptotically *meet the packing bound*, in the sense that $|X|\,|Y|\,|Z| \geq |G|^{3/2-o(1)}$. The analogy studied in [14, 9] is to think of Lie subgroups of dimension d as "roughly corresponding" to finite subsets of size q^d. Under this analogy, if X_n, Y_n, Z_n are families of Lie subgroups of Lie groups G_n that satisfy the TPP, then meeting the packing bound is analogous to the condition

$$\dim X_n + \dim Y_n + \dim Z_n \geq (3/2 - o_n(1)) \dim G_n. \tag{1.2}$$

A simple construction in the original Cohn–Umans paper [14, Theorem 6.1] shows this is indeed possible (with additional such constructions developed in [9]), and this construction forms the basis for a running example we will use throughout this paper to illustrate the development of our new framework.

Running example in $\mathbf{GL}_n(\mathbb{R})$

▶ **Theorem 1.2** ([14, Theorem 6.1]). *Let $G = \mathrm{GL}_n(\mathbb{R})$ and let X be the subgroup of lower unitriangular matrices, $Y = \mathrm{O}_n(\mathbb{R})$ (the orthogonal matrices), and Z be the subgroup of upper unitriangular matrices. Then the triple X, Y, Z satisfies the TPP.*

The dimension of G is n^2, and the dimension of each of the three subgroups is $n^2/2 - n/2$, so this construction meets the packing bound in the sense of (1.2) [9].

But there still remains the issue of how to use such a construction, even in concert with Theorem A, to get upper bounds on ω. And for this we require a deeper dive into representation theory, which will lead us to the key quantitative goals for these constructions.

In the case of the groups $\mathrm{GL}_n(\mathbb{R})$, $\mathrm{GL}_n(\mathbb{C})$, and U_n, rather than focusing on choosing arbitrary collections of representations to play the role of R_{sep} in Theorem A, we can exploit a relationship between the representations of these groups and the set of all degree-d polynomials. Namely, the irreducible representations of these groups are indexed by integer partitions into at most n parts, and the matrix entries of the representations corresponding to partitions of d, taken all together, span precisely the set of all degree-d polynomial functions on the group. Careful quantitative estimates then lead us to key targets for the degree of functions that separate out the elements of $XY^{-1}YZ^{-1}$ compared to the size of the finite TPP construction:

▶ **Theorem B** (Corollary 2.8, summarized). *If $X_{q,n}, Y_{q,n}, Z_{q,n} \subseteq \mathrm{GL}_n(\mathbb{C})$ (or U_n) satisfy the TPP and have sizes at least $q^{n^2/2-o_n(n)}$, and there are separating polynomials for $(X_{q,n}, Y_{q,n}, Z_{q,n})$ of degree at most $q^{1+o_q(1)}$, then Theorem A implies $\omega = 2$.*

Note how our new framework (Theorem A) has allowed us to take the analogy above whereby d-dimensional subgroups correspond to finite sets of size q^d, and turn it into a theorem that actually implies a bound on ω out of any such construction, rather than merely being an analogy. However, in this setup, as $\dim G = n^2$, we see that the bound we need on the size of the TPP triple is not $|X||Y||Z| \geq q^{(3/2-o_n(1))\dim G}$ as suggested in the previous Lie analogy of the packing bound [14, 9], but is slightly tighter, of the form $q^{(3/2-o_n(1/n))\dim G}$, and the example in Theorem 1.2 above falls short of this latter bound.

Our challenge is thus to find TPP constructions in GL_n or U_n that meet the bounds of Theorem B: three subsets in GL_n or U_n satisfying the TPP, of size at least $q^{n^2/2-o_n(n)}$, and admitting separating polynomials of degree at most $q^{1+o_q(1)}$.

1.3 Third main contribution: optimal degree using border rank, Lie algebras, and invariant theory

Our third main contribution is to show how to very nearly meet the conditions of Theorem B, using border rank, Lie algebras, and invariant theory. We also believe these techniques will have further uses. Our main theorem coming out of these constructions is:

▶ **Theorem C** (Summary of Theorem 3.1). *For any n and q, there are three subsets $X_q, Y_q, Z_q \subseteq \mathrm{U}_n$, all of size at least $q^{n^2/4-n/4}$, which satisfy the TPP and admit border-separating polynomials of degree $O(q)$.*

Note that this falls short of the conditions needed for Theorem B in only two ways: we get a construction of size $q^{(1/2)\dim G-\Theta(n)}$ where $G = \mathrm{U}_n$, whereas Theorem B would require both that the construction be in GL_n, and that it approach half the dimension just slightly faster, with sets of size $q^{(1/2)\dim \mathrm{GL}_n - o_n(n)}$, rather than our current $q^{(1/2)\dim \mathrm{U}_n-\Theta(n)}$. In addition to the sizes being very nearly right, the degree bound *does* satisfy the degree bound required by Theorem B (even slightly better than is needed: we get $O(q)$ whereas Theorem B only needs degree at most $q^{1+o_q(q)}$).

While in principle all one needs here is a sequence of finite sets X_q, Y_q, Z_q for infinitely many q, an appealing way to get such a sequence is to find Lie subgroups or submanifolds $X, Y, Z \subseteq \mathrm{GL}_n(\mathbb{C})$ – as in Theorem 1.2 – and then let X_q be some nicely constructed finite subset of X, etc. For example, when X is the subgroup of lower unitriangular matrices, we can take X_q to be the the lower unitriangular matrices with entries in $[0, q] \cap \mathbb{Z}$. And indeed, this is how the construction of Theorem C proceeds.

To get our constructions, we will combine three additional ingredients on top of Theorems A and B: Lie algebras, border rank, and invariant theory. Here we give a brief overview of these ingredients and how they mix together.

Lie algebras. In Sophus Lie's original development of Lie groups in the late 1800s, he realized that many questions about these continuous groups can be reduced to simpler questions of linear algebra, by focusing on the corresponding Lie algebras, which are, in particular, vector spaces, rather than more complicated manifolds. The Lie algebra $\mathrm{Lie}(G)$ associated to a Lie group G is "just" the tangent space to G (remember G is also a manifold) at the identity element. The Lie algebra is then a vector space. While the group structure of G induces an algebraic structure on $\mathrm{Lie}(G)$, in this paper we will have no need of its algebraic structure. We will only need a few basic facts (see, e. g., [22, 4, 19]):

- The Lie algebra of $\mathrm{GL}_n(\mathbb{C})$ is $M_n(\mathbb{C})$, the space of all $n \times n$ complex matrices.
- The Lie algebra of the orthogonal group $O_n(\mathbb{R})$ consists precisely of all skew-symmetric real matrices.
- The Lie algebra of the unitary group consists of the skew-Hermitian matrices.
- If G is a matrix Lie group – a Lie group that is a subgroup and submanifold of $\mathrm{GL}_n(\mathbb{C})$ – then its Lie algebra $\mathrm{Lie}(G)$ is a linear subspace of matrices. And if $A \in \mathrm{Lie}(G)$, then for all sufficiently small $\varepsilon > 0$, $\exp(\varepsilon A)$ (using the ordinary power series for the matrix exponential) is in G.

As with many problems on Lie groups, we would like to take advantage of the simpler, linear-algebraic nature of Lie algebras in our constructions.

Border rank. It turns out that the key tool for using Lie algebras in our setting is the concept of *border rank*. Although known to Terracini 100 years ago, border rank was rediscovered in the context of matrix multiplication by Bini *et al.* [5, 6]. Bini had developed computer code to search for algebraic algorithms for matrix multiplication, and some of the coefficients in his numerical calculations kept going off to infinity. At first he thought this was an error in his code, but in fact it reflects the fundamental phenomenon of border rank: for each fixed size n_0, it is possible that there is a sequence of algorithms, none of which correctly multiply $n_0 \times n_0$ matrices, but which, *in the limit*, in fact do so. If the algorithms in the sequence use only r non-constant multiplications, we say that matrix multiplication has border rank at most r. The border rank is always at most the ordinary rank, and it turns out that the exponent of matrix multiplication is the same whether measured with ordinary rank or border rank. Border rank has played an important role in essentially all newly developed matrix multiplication algorithm since then.

A bit more formally, a "border algorithm" for matrix multiplication can be viewed as a single bilinear algorithm that has coefficients that are Laurent series in ε – that is, power series that allow finitely many negative powers of ε as well – and such that it computes matrix multiplication in the limit as $\varepsilon \to 0$, that is, it computes a function of the form $(A, B) \mapsto AB + O(\varepsilon)$. (Note that, despite the algorithm itself being allowed to contain $1/\varepsilon$ in its intermediate operations, corresponding to Bini's coefficients that were going off to infinity, the function computed at the end should have such negative powers of ε cancel.)

Combining Lie algebras and border rank. It turns out that combining border rank with Lie algebras is very natural; here we exhibit just two advantages to doing so. If $X, Y, Z \subseteq \mathrm{GL}_n(\mathbb{C})$ are Lie subgroups that satisfy the TPP (as in Theorem 1.2), then we can take advantage of the simple linear-algebraic nature of their Lie algebras to help construct finite subsets of

X, Y, Z. An example we will return to is that if $Y = O_n(\mathbb{R})$ is the orthogonal group, it is a bit tricky to choose $q^{\dim O_n}$ many elements of Y in a principled way directly. But since $\mathrm{Lie}(Y)$ consists of all the skew-symmetric matrices, we can get a finite subset of Y by simply considering

$$Y'_\varepsilon = \{\exp(\varepsilon A) : A \text{ skew-symmetric with all } A_{ij} \in [0, q] \cap \mathbb{Z}\}$$

for $\varepsilon > 0$ sufficiently small.

A second advantage can be gotten by not choosing ε as above to be a fixed but small value, but rather allowing to the ε used in the expression $\exp(\varepsilon A)$ to be the same as the parameter ε used in the definition of border rank. In this setting, instead of finding a set of functions that exactly separates $XY^{-1}YZ^{-1}$ according to Definition 2.1, we can find functions that do so only up to $O(\varepsilon)$ (Definition 2.5). This both gives us more freedom in the construction, and combines very naturally with the Lie algebraic construction suggested above. Namely, when all the elements of X', Y', Z' are of the form $\exp(\varepsilon A)$ for various A in their Lie algebras, we see that an expression of the form $xy^{-1}y'z^{-1}$ becomes

$$\exp(\varepsilon A)\exp(-\varepsilon B)\exp(\varepsilon B')\exp(-\varepsilon C) = I + \varepsilon(A - B + B' - C) + O(\varepsilon^2).$$

Our border-separating polynomials can then directly access $A - B + B' - C$ by subtracting off I and dividing by ε; this leaves additional $O(\varepsilon)$ terms, but in the border setting that is still allowed. Thus combining Lie algebras and border rank lets us shift the problem from finding separating polynomials in the entries of a product of matrices and their inverses to finding (border-)separating polynomials in the entries of the simpler linear combination $A - B + B' - C$.

However, the linear combination $A - B + B' - C$ still "mixes" entries from the three subalgebras, and this causes some difficulty in the the task of designing (border-)separating polynomials. Our final ingredient is to use invariant theory to simplify this task even further.

1.4 Fourth main contribution: leveraging invariant polynomials

If we restrict our attention to polynomials $p(M)$ that are invariant under left multiplication by X and right multiplication by Z^{-1}, that is, $p(xMz^{-1}) = p(M)$ for all $x \in X, z \in Z$, we can get direct access to the $B' - B$ term above. Namely, if p is such an invariant polynomial, then

$$\begin{aligned} p(\exp(\varepsilon A)\exp(-\varepsilon B)\exp(\varepsilon B')\exp(-\varepsilon C)) &= p(\exp(-\varepsilon B)\exp(\varepsilon B')) \\ &= p(I + \varepsilon(-B + B') + O(\varepsilon^2)), \end{aligned}$$

where the first equality occurs because $\exp(\varepsilon A)$ is in X and $\exp(\varepsilon C)$ is in Z, and p is invariant under the action of X and Z. We codify this idea into the following key lemma, which is used in the proof of Theorem C. We state it in a simplified form, which is not correct as stated but captures the spirit of a special case. See Lemma 2.11 for the full and correct statement.

▶ **Lemma D** (Oversimplified version of Lemma 2.11). *Suppose X, Y, Z are three Lie subgroups of $\mathrm{GL}_n(\mathbb{C})$ that satisfy the TPP. If Y'_ε is a finite set of ε-parametrized families in Y, and there is a polynomial $p_\varepsilon(g)$ that is invariant under left multiplication by X and right multiplication by Z, such that*

$$p_\varepsilon(g) = \begin{cases} 1 + O(\varepsilon) & \text{if } g = I \\ 0 + O(\varepsilon) & \text{if } g \in (Y'_\varepsilon)^{-1}Y'_\varepsilon \setminus \{I\} \end{cases}$$

then there are finite subsets $X'_\varepsilon, Y'_\varepsilon$ of ε-parametrized elements of X and Z, of sizes $q^{\dim X}$ (resp., $q^{\dim Z}$) and border-separating polynomials for $(X'_\varepsilon, Y'_\varepsilon, Z'_\varepsilon)$ of degree $\deg p + O(q)$.

Thus, once we have a TPP construction of the "right" dimension (e. g., according to Theorem B), Lemma D implies that instead of finding appropriate finite subsets of X, Y, Z and a *set* of separating polynomials, to get $\omega = 2$ all we have to do is find an appropriate finite subset of Y and a *single* polynomial p as in the lemma, whose degree is $O(q)$.

When X and Z are well-studied subgroups, the ring of their invariant polynomials is often well understood, and this represents a significant simplification of the construction problem. The full detail of Lemma 2.11 is more complicated, but the additional complications in the statement of the lemma give us even further simplifications of the construction problem, which we take advantage of in our constructions in the running example and in Section 3. We also expect the techniques of this lemma to have further uses for additional constructions in the future.

1.5 Paper outline

In Section 2.1 we give the necessary definitions and proof of Theorem A, and in Section 2.2 we give its border rank version. In Section 2.3 we discuss the needed background on the representation theory of $\mathrm{GL}_n(\mathbb{C})$ – much of which we can use in a black-box fashion – and prove Theorem B. In Section 2.4 we show how to combine invariant theory, border rank, and Lie algebras to simplify the construction task; the key here is Lemma 2.11. In Section 3 we use the preceding ideas to give the construction that proves Theorem C. Finally, in Section 4 we conclude with our outlook and several open problems suggested by our framework.

Throughout the development of the framework in Section 2, we continue the example from Theorem 1.2 as a running example, and we show how each piece of the framework can be realized in that case.

The full version of the paper contains complete proofs of all claims [10].

2 A group-theoretic framework for infinite groups

In this section we describe the group-theoretic framework for obtaining matrix multiplication algorithms in infinite groups. The basic framework is in the next subsection, followed by a border-rank version for the important case of Lie groups. Subsection 2.3 proves some key bounds on the dimensions of irreducible representations of GL_n and U_n, which are the containing groups for our constructions in this paper. Finally subsection 2.4 describes machinery that reduces the main design task to finding a single separating polynomial in an invariant ring. These components come together in Section 3, where we give a construction achieving optimal degree separating polynomials.

2.1 Algorithms from the TPP in infinite groups

Let G be a group – not necessarily finite – with finite subsets X, Y, Z satisfying the TPP. Then we can embed matrix multiplication into the group algebra $\mathbb{C}[G]$ as in the case of finite groups. Note that $\mathbb{C}[G]$, where G may be infinite, consists of formal sums $\sum_{g\in G} \alpha_g g$, but now where each such sum has at most finitely many nonzero terms. Multiplication is as in the finite case.

To multiply a complex matrix A of size $|X| \times |Y|$ by a complex matrix B of size $|Y| \times |Z|$, we follow the approach described in the introduction. Indexing A by $X \times Y$ and B by $Y \times Z$, we define elements

$$\overline{A} = \sum_{x\in X, y\in Y} A[x,y](xy^{-1}) \quad \text{and} \quad \overline{B} = \sum_{y\in Y, z\in Z} B[y,z](yz^{-1})$$

of $\mathbb{C}[G]$ and observe that, as in the finite group case, the TPP implies that

$$\overline{A} \cdot \overline{B} = \sum_{x \in X, z \in Z} (AB)[x,z](xz^{-1}) + E, \tag{2.1}$$

where $E \in \mathbb{C}[G]$ is supported on $XY^{-1}YZ^{-1} \setminus XZ^{-1}$.

However, as the group algebra is no longer finite-dimensional when G is infinite, it is not immediately clear that the multiplication in the group algebra expressed in (2.1) can be carried out by a finite algorithm, even despite the fact that all the sums involved are themselves finite. One of our key new innovations is to introduce a new viewpoint on such a construction that will enable us to get a finite bilinear algorithm out of the above construction.

▶ **Definition 2.1.** *Given subsets $X, Y, Z \subseteq G$ of a group G, a* set of separating functions for (X, Y, Z) *is a collection of functions $\{f_{x,z} \colon G \to \mathbb{C} \mid x \in X, z \in Z\}$ such that*

$$f_{x,z}(g) = \begin{cases} 1 & \text{if } g = xz^{-1}, \text{ and} \\ 0 & \text{if } g \in XY^{-1}YZ^{-1} \setminus \{xz^{-1}\}. \end{cases}$$

Such functions always exist, but for them to be useful in matrix multiplication algorithms we need them to be in some sense "simple." To formulate the relevant notion – in which "simple" will ultimately imply "computable by smaller matrix multiplications" – we recall a standard definition from representation theory. Given a finite-dimensional representation $\rho \colon G \to \mathrm{GL}_n(\mathbb{C})$, a *representative function* of G associated to ρ (see, e. g., Procesi's book [23, §8.2][1]) is any function $G \to \mathbb{C}$ that is in the linear span of the functions $\{(g \mapsto \rho(g)_{i,j}) \mid i, j \in [n]\}$. Note that if ρ, ρ' are equivalent representations, they have the same set of representative functions. If $\mathcal{I}$ is a set of representations, we write $\mathrm{RepFun}(\mathcal{I})$ for the $\mathbb{C}$-linear span of all the representative functions of the representations in $\mathcal{I}$.

▶ **Theorem 2.2.** *Let G be a group (not necessarily finite), with finite subsets X, Y, Z satisfying the TPP. If R_{sep} is a finite set of finite-dimensional complex representations of G such that $\mathrm{RepFun}(R_{\mathrm{sep}})$ contains a set of separating functions for (X, Y, Z), then*

$$(|X||Y||Z|)^{\omega/3} \leq \sum_{\rho \in R_{\mathrm{sep}}} (\dim \rho)^{\omega}.$$

In particular, for $D = \sum_{\rho \in R_{\mathrm{sep}}} (\dim \rho)^2$ and $d_{max} = \max\{\dim \rho : \rho \in R_{\mathrm{sep}}\}$,

$$(|X||Y||Z|)^{\omega/3} \leq D \cdot d_{max}^{\omega-2}.$$

If G is a finite group, we may take $R_{\mathrm{sep}} = \mathrm{Irr}(G)$, the set of all irreducible representations of G, as $\mathrm{RepFun}(\mathrm{Irr}(G))$ is the collection of *all* functions $G \to \mathbb{C}$ when G is finite. In that case, we also have $D = |G|$, recovering the original theorem for finite groups [14, Theorem 4.1] as a special case of Theorem 2.2.

[1] The notion of representative function we use here is fairly standard; if one consults Procesi's book, one will see that his book works in the setting where G is a topological group, and requires the representations involved to be continuous, but the definition we use here works just as well. When G is a Lie group, as in our constructions later in the paper, the representations we use will in fact be continuous in the natural manifold topology on G rather than the discrete topology.

▶ Remark 2.3. In families of groups $\{G_i\}$ with "rapidly growing" irreducible representation dimensions, this theorem exhibits an "all-or-nothing" phenomenon, which we explain here. For the constructions in this paper and other natural constructions in classical Lie groups, $d_{max} \geq D^{1/2-g(i)}$ for some $g \in o(1)$ (and this is what we mean by "rapidly growing irreducible representation dimensions"). If we let $V = (|X||Y||Z|)^{1/3}$, it is clear that we must have $V > d_{max}$ for the inequality to imply *any* upper bound on ω. Together with the observation that d_{max} approaches $D^{1/2}$, this means that to prove any upper bound on ω we must have $V \geq D^{1/2-f(i)}$ for some $f \in o(1)$. The inequality from the theorem then becomes

$$D^{(1/2-f(i))\omega} \leq V^\omega \leq D \cdot d_{max}^{\omega-2} \leq D \cdot D^{(1/2-g(i))(\omega-2)}.$$

Taking the base-D logarithm of both sides, we get

$$\omega/2 - f(i)\omega \leq \omega/2 - g(i)\omega + 2g(i),$$

which implies $\omega \leq 2\left(\frac{g(i)}{g(i)-f(i)}\right)$. In constructions the natural thing to do is to ensure $f(i)$ goes to zero more rapidly than $g(i)$, in which case $\omega = 2$. While it is *possible* that $f(i)$ could approach $cg(i)$ for some $c > 0$ and yield an upper bound on ω strictly between 2 and 3, this would require detailed knowledge of the lower order terms of d_{max} and/or very fine control of the lower order terms of V, which we do not typically have.

Proof. Let X, Y, Z, R_{sep} be as in the statement, and let $\{f_{x,z} \mid x \in X, z \in Z\}$ be the claimed set of separating functions contained in $\text{RepFun}(R_{\text{sep}})$. For $f\colon G \to \mathbb{C}$, let $\overline{f}\colon \mathbb{C}[G] \to \mathbb{C}$ denote its unique linear extension to the group ring $\overline{f}(\sum \alpha_g g) := \sum \alpha_g f(g)$; as these sums have only finitely many nonzero terms by definition of the group ring (even when G is infinite), there is no issue of convergence. Applying $\overline{f_{x,z}}$ to (2.1) gives

$$\overline{f_{x,z}}(\overline{A} \cdot \overline{B}) = \sum_{x' \in X, z' \in Z} (AB)[x', z'] f_{x,z}(x'(z')^{-1}) + \overline{f_{x,z}}(E) = (AB)[x, z] + 0, \tag{2.2}$$

for $f_{x,z}$ is zero on all group elements of $X(Y)^{-1}Y(Z)^{-1}$ other than xz^{-1}, and (2.1) is entirely supported on $X(Y)^{-1}Y(Z)^{-1}$. To turn this into a finite algorithm, we will show that we can essentially do exactly the application of $\overline{f_{x,z}}$ in (2.2), but working only in the representations in R_{sep} rather than working in the full group ring.

For a representation $\rho \in R_{\text{sep}}$, let $\overline{\rho}$ denote the unique linear extension of ρ to $\mathbb{C}[G]$: $\overline{\rho}(\sum \alpha_g g) = \sum \alpha_g \rho(g)$, and let $\rho_{i,j}(g)$ be the (i,j) entry of the matrix $\rho(g)$, which we think of as a function $\rho_{i,j}\colon G \to \mathbb{C}$. Since $f_{x,z}$ is in $\text{RepFun}(R_{\text{sep}})$ by assumption, we can write $f_{x,z}$ as a $\mathbb{C}$-linear combination of the functions $\{\rho_{i,j} \mid \rho \in R_{\text{sep}},\ i,j \in [\dim \rho]\}$, say $f_{x,z} = \sum_{\rho \in R_{\text{sep}}} \sum_{i,j \in [\dim \rho]} M_{x,z,i,j} \rho_{i,j}$. Then we define $\widehat{f_{x,z}}(\rho)$ to be the matrix $M_{x,z,*,*}$, i.e.,

$$f_{x,z}(g) = \sum_{\rho \in R_{\text{sep}}} \sum_{i,j \in [\dim \rho]} \widehat{f_{x,z}}(\rho)_{i,j} \rho_{i,j}(g)$$

for all $x \in X, z \in Z, g \in G$. Finally, extending linearly and applying $\overline{f_{x,z}}$ to $\overline{A} \cdot \overline{B}$ as in (2.2), we get

$$\begin{aligned}
(AB)[x,z] &= \overline{f_{x,z}}(\overline{A} \cdot \overline{B}) \\
&= \sum_{\rho \in R_{\text{sep}}} \sum_{i,j \in [\dim \rho]} \widehat{f_{x,z}}(\rho)_{i,j} \overline{\rho_{i,j}}(\overline{A} \cdot \overline{B}) \\
&= \sum_{\rho \in R_{\text{sep}}} \langle \widehat{f_{x,z}}(\rho), \overline{\rho}(\overline{A} \cdot \overline{B}) \rangle \\
&= \sum_{\rho \in R_{\text{sep}}} \langle \widehat{f_{x,z}}(\rho), \overline{\rho}(\overline{A}) \cdot \overline{\rho}(\overline{B}) \rangle
\end{aligned}$$

The summation and inner product are linear functions whose coefficients are independent of the input matrices A, B, so they are "free" in a bilinear algorithm.

The product $\overline{\rho}(\overline{A}) \cdot \overline{\rho}(\overline{B})$ is a product of $d_\rho \times d_\rho$ matrices, where $d_\rho = \dim \rho$. Hence, the bilinear (i.e., tensor) rank of the preceding expression gives the following bound. Using rk to denote the tensor rank, and $\langle n, m, p \rangle$ to denote the tensor corresponding to matrix multiplication of an $n \times m$ matrix times and $m \times p$ matrix, we get

$$\mathrm{rk}\,\langle |X|, |Y|, |Z| \rangle \leq \sum_{\rho \in R_{\mathrm{sep}}} \mathrm{rk}\,\langle d_\rho, d_\rho, d_\rho \rangle.$$

Exactly as in the finite group case [14], by symmetrizing we effectively get a square matrix multiplication of size $(|X|\,|Y|\,|Z|)^{1/3}$ on the left side, and by the tensor power trick the right side here can be replaced by $\sum_{\rho \in R_{\mathrm{sep}}} (\dim \rho)^\omega$. For the last sentence of the theorem statement, we have $\sum_{\rho \in R_{\mathrm{sep}}} d_\rho^\omega \leq \sum d_\rho^2 d_{max}^{\omega-2} = d_{max}^{\omega-2} \cdot D$. ◀

▶ Remark 2.4. The image $\overline{\rho}(\mathbb{C}[G])$ is the full $d_\rho \times d_\rho$ matrix ring if and only if ρ is an irreducible representation. In particular, although we will not take advantage of this in the present paper, we note that when ρ is not irreducible, we can replace $\mathrm{rk}\,\langle d_\rho, d_\rho, d_\rho \rangle$ (or d_ρ^ω) with the tensor rank of multiplying matrices in the image of $\overline{\rho}$, which may only be a subspace of all matrices. (This was true in the case of finite groups as well, but over $\mathbb{C}$ for finite groups we can use irreducible representations without loss of generality. For finite groups and representations in characteristic dividing $|G|$ this no longer holds, and for infinite groups even in characteristic zero it need not hold.)

2.2 Border rank version in Lie groups

For this section, let G be a (real or complex) Lie group. This includes familiar groups such as $\mathrm{GL}_n(\mathbb{R})$, $\mathrm{GL}_n(\mathbb{C})$, the orthogonal group O_n, and the unitary group U_n. Indeed, these examples will be the primary groups we use in our constructions later in the paper, although the framework laid out in this section is by no means limited to these particular examples.

For the purposes of this section, by a *1-parameter family* of elements of G we mean an analytic function $x\colon (0, \alpha) \to G$ for some $\alpha > 0$. If $X = \{x_1, \ldots, x_k\}$ is a collection of 1-parameter families x_i and ε is in their domain of definition, then we write $X(\varepsilon) = \{x_1(\varepsilon), \ldots, x_k(\varepsilon)\}$, which is just a finite subset of G.

▶ **Definition 2.5** (Border-separating functions). *Given sets X, Y, Z of 1-parameter families of elements of G with domain of definition $(0, \alpha)$, a* set of border-separating functions for (X, Y, Z) *is a collection of analytic functions $\{f_{x,z}\colon G \times (0, \alpha) \to \mathbb{C} \mid x \in X, z \in Z\}$ such that, for $0 < \varepsilon < \alpha$,*

$$f_{x,z}(g, \varepsilon) = \begin{cases} 1 + O(\varepsilon) & \text{if } g = x(\varepsilon) z(\varepsilon)^{-1}, \text{ and} \\ 0 + O(\varepsilon) & \text{if } g \in X(\varepsilon) Y(\varepsilon)^{-1} Y(\varepsilon) Z(\varepsilon)^{-1} \setminus \{x(\varepsilon) z(\varepsilon)^{-1}\}. \end{cases}$$

Here, as is standard for analytic functions of a small variable ε, the big-Oh notation means asymptotically as $\varepsilon \to 0$.

Now, we take our representative functions to come from *analytic* representations of our Lie group, and, as in most things related to border rank, allow ourselves 1-parameter families of representative functions. Let $\mathbb{C}^{(0,\alpha)}$ denote the set of analytic functions $(0, \alpha) \to \mathbb{C}$. Given a set $\mathcal{I}$ of analytic representations of G, we write $\mathrm{RepFun}_{\mathrm{fam}}(\mathcal{I})$ for the $\mathbb{C}^{(0,\alpha)}$-linear span of all the representative functions associated to any $\rho \in \mathcal{I}$.

Given three sets X, Y, Z of 1-parameter families of elements of G, we say they satisfy the TPP if $X(\varepsilon), Y(\varepsilon), Z(\varepsilon)$ satisfy the TPP for all ε in their domain of definition. Given such X, Y, Z, we may encode ε-approximate matrix multiplication (à la border rank) into the group ring $\mathbb{C}[G]$ in a similar manner as before, but now parameterized by $\varepsilon \in (0, \alpha)$. For an $|X| \times |Y|$ matrix A and $|Y| \times |Z|$ matrix B, we define the following functions $(0, \alpha) \to \mathbb{C}[G]$:

$$\overline{A}(\varepsilon) = \sum_{i\in[n], j\in[m]} A[i,j](x_i(\varepsilon)y_j(\varepsilon)^{-1}) \quad \text{and} \quad \overline{B}(\varepsilon) = \sum_{j\in[m], k\in[\ell]} B[j,k](y_j(\varepsilon)z_k(\varepsilon)^{-1}).$$

Then

$$\overline{A}(\varepsilon) \cdot \overline{B}(\varepsilon) = \sum_{i\in[n], k\in[\ell]} (AB)[i,k](x(\varepsilon)z(\varepsilon)^{-1}) + E(\varepsilon), \tag{2.3}$$

where $E(\varepsilon) \in \mathbb{C}[G]$ is supported on $X(\varepsilon)Y(\varepsilon)^{-1}Y(\varepsilon)Z(\varepsilon)^{-1} \setminus X(\varepsilon)Z(\varepsilon)^{-1}$.

▶ **Theorem 2.6.** *Let G be a* ***Lie***[2] *group, with finite sets X, Y, Z of* ***1-parameter families*** *satisfying the TPP. If R_{sep} is a finite set of finite-dimensional* ***analytic*** *representations of G such that $\text{RepFun}_{\boldsymbol{fam}}(R_{\text{sep}})$ contains a set of* ***border-****separating functions for (X, Y, Z), then*

$$(|X|\,|Y|\,|Z|)^{\omega/3} \leq \sum_{\rho\in R_{\text{sep}}} (\dim \rho)^{\omega}.$$

In particular, for $D = \sum_{\rho\in R_{\text{sep}}} (\dim \rho)^2$, and $d_{max} = \max\{\dim \rho : \rho \in R_{\text{sep}}\}$,

$$(|X|\,|Y|\,|Z|)^{\omega/3} \leq D \cdot d_{max}^{\omega-2}.$$

The proof is very similar to Theorem 2.2, but using border rank instead of rank, so we postpone it to the full version of the paper [10].

An appealing way to use the freedom of border rank is to first find a TPP construction of Lie subgroups X, Y, Z, and then to define finite subsets of those three using their Lie algebras, viz.:

$$X' = \{\exp(\varepsilon a) : a \in A, \text{ some finite subset of the Lie algebra of } X\},$$

where $\varepsilon \to 0$ is the parameter we use for border rank. We will in fact show how to do this in a fairly generic way in Lemma 2.11 below, using some additional machinery that we develop first.

2.3 From representations to degree bounds in GL_n and U_n

In this paper, our constructions will all take place in GL_n or (slight variants of) the unitary group U_n, although the framework of Theorems 2.2 and 2.6 is much more general. These groups have some useful properties that will motivate some of the machinery we develop below – even though that machinery will also end up being more general – so we take a brief interlude to highlight the relevant properties of GL_n, before returning to the general abstract framework in the next section.

For both GL_n and U_n, there is a natural correspondence between representations and polynomials of a given degree. By focusing on separating polynomials (instead of more general separating functions), this correspondence will allow our constructions to focus only

[2] We have put in **bold** the parts of the statement of Theorem 2.6 that differ from Theorem 2.2.

on the *degree* of the separating polynomials. The upshot is that instead of thinking directly about what representations will comprise R_{sep}, we can focus solely on the degree of our separating polynomials when working in these groups.

In the rest of this section we review the relevant aspects of the representation theory of GL_n and U_n, and extract from those the relevant target bounds on degree to get bounds on ω. A standard reference for the representation theory of these groups is [19]. It is a standard fact in representation theory that the finite-dimensional representation theory of these two groups are essentially the same, and everything we say in this section will apply to both groups.

The irreducible polynomial representations ρ of $\mathrm{GL}_n(\mathbb{C})$ and U_n – where the entries of the matrix $\rho(g)$ are polynomials in the entries of the matrix g – are indexed by integer partitions $\lambda = (\lambda_1, \ldots, \lambda_n)$ with at most n parts, where $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n \geq 0$. The matrix coefficients of the irreducible representations indexed by partitions of s span the functions from G to $\mathbb{C}$ that are expressible as degree s polynomials in the entries of GL_n. We write $\mathrm{Irr}_s(G)$ to denote the set of (pairwise non-isomorphic) irreducible representations of G indexed by partitions of the integer s.

The following bound will determine the target degree of the separating polynomials in our constructions, as in Corollary 2.8 below.

▶ **Lemma 2.7.** *Let $n \geq 3$ and $s \geq 2$. For $\rho \in \mathrm{Irr}_s(\mathrm{GL}_n)$ (resp., $\mathrm{Irr}_s(\mathrm{U}_n)$), $\dim(\rho) \leq s^{\binom{n}{2}}$.*

Although the result follows from some simple asymptotic analysis of standard results about the representation theory of GL_n, we could not find it in the literature, so we provide a full proof in [10].

Here and below it is helpful to think of n as large but fixed, and s growing independently of n.

▶ **Corollary 2.8.** *Suppose $X, Y, Z \subseteq \mathrm{GL}_n(\mathbb{C})$ (or U_n) satisfy the TPP, and there is a set of separating polynomials for (X, Y, Z) of degree at most s. Then ω satisfies*

$$(|X|\,|Y|\,|Z|)^{\omega/3} \leq s^{\binom{n}{2}(\omega-2)} \cdot \binom{s+n^2}{n^2}.$$

In particular, if $|X|, |Y|, |Z| \geq s^{(1-o_s(1))(n^2/2-o_n(n))}$, then $\omega = 2$.

The same holds if X, Y, Z are 1-parameter families that satisfy the TPP and we replace separating polynomials with border-separating polynomials.

Equivalently, if $|X|, |Y|, |Z| \geq q^{n^2/2-o_n(n)}$ and there are (border-)separating polynomials of degree at most $q^{1+o_q(1)}$, then $\omega = 2$. See the full version of the paper for a proof [10].

Next we show that the Lie TPP construction of [14] (Theorem 1.2 above) in fact admits separating polynomials of degree $O(q^2)$. In Section 2.4, we will show how to use a border-rank version of our framework to construct *finite* sets X, Y, Z, whose size we can then compare to the degree of the separating polynomials as in Corollary 2.8.

Separating polynomials for the running example in $\mathbf{GL}_n(\mathbb{R})$

We begin by describing a finite subset Y_q of the orthogonal group O_n, with the property that the diagonal entries of matrices in the quotient set $Q(Y_q)$ have a limited number of possible values, in the sense formalized in the following lemma. Here we treat n as fixed, so the implicit constant in $O(q^2)$ can depend on n.

▶ **Lemma 2.9.** *For each positive integer q, there exists a subset $Y_q \subseteq \mathrm{O}_n$ of cardinality at least $q^{n^2/2-(5/2)n}$, with the following property: for all $y, y' \in Y_q$, if y and y' agree in their first i columns, then*

$$(y^T y')[i+1, i+1] \in W_q,$$

where $W_q \subseteq \mathbb{R}$ is a fixed finite set of cardinality $O(q^2)$.

For a proof, see the full version of the paper [10].

We remark that one might hope to improve the cardinality of W_q to $O(q^{2-\varepsilon})$ by replacing V_i with a more cleverly chosen set of unit vectors with fewer distinct pairwise inner products. This would lead to an improved bound on the degree of the separating polynomials described in the following theorem, and if one could take $\varepsilon = 1$ this would yield separating polynomials of optimal degree. Unfortunately, this is impossible by the solution to the high-dimensional version of the Erdős distinct distances problem [25].

▶ **Theorem 2.10.** *Let G, X, Y, Z be as in Theorem 1.2, let $X_q \subseteq X$ be those lower unitriangular matrices whose below-diagonal entries are integers in $\{1, 2, \ldots, q\}$, let $Z_q \subseteq Z$ be those upper unitriangular matrices whose above-diagonal entries are integers in $\{1, 2, \ldots, q\}$, and let $Y_q \subseteq Y$ be the set of orthogonal matrices guaranteed by Lemma 2.9. Then there are separating polynomials for X_q, Y_q, Z_q of degree $O(q^2)$.*

For a proof, see the full version of the paper [10].

Note that here we have $\dim X = \dim Y = \dim Z = (n^2 - n)/2$, but for Corollary 2.8 we would need them to have dimension $n^2/2 - o_n(n)$, and the separating polynomial we get has degree $O_q(q^2)$, but Corollary 2.8 needs degree at most $q^{1+o_q(1)}$. In Section 3 we give a construction of the same relative dimension (namely, $\frac{\dim G}{2} - \Theta(n)$) but with separating polynomials of degree $O(q)$, meeting the degree bound of Corollary 2.8.

2.4 Separating polynomials from a single invariant polynomial

In this section, we return to the case of a general matrix Lie group $G \subseteq \mathrm{GL}_n(\mathbb{C})$ or $\mathrm{GL}_n(\mathbb{R})$, and we show how to leverage invariant theory to construct separating polynomials whose degree is not too large, and that thus have a hope of meeting the degree bound of Corollary 2.8 in the case of $G = \mathrm{GL}_n(\mathbb{C})$ or $G = \mathrm{U}_n$.

The key result in this section, Lemma 2.11, combines border rank and Lie algebras, as suggested at the end of Section 2.2, with a new ingredient from invariant theory. The lemma lets us "split" the construction of sets satisfying the TPP and (border-)separating polynomials into two parts: the first part only involves the first and third sets X and Z (essentially, a separating polynomial version of the "double product property" (DPP), which is that $x^{-1}x'z^{-1}z' = 1$ iff $x = x'$ and $z = z'$)), and the second part involves only the middle set Y and the ring of XZ-invariant polynomials. From one view, this lets us start with a Y, and "work backwards," shifting the design task onto X, Z, and their invariant polynomials.

More specifically, Lemma 2.11 instantiates the following idea. Roughly, we would like to construct the separating polynomial $f_{x,z}$ as a product of three factors: one that is the indicator function of x among the set X (1 on x, zero on all other elements of X), one that is the indicator function of z^{-1} among Z^{-1}, and one on that is the indicator function p_0 of I among $Y^{-1}Y$. However, the issue here is that $f_{x,z}$, and hence these factors, does not really have separate access to these three parts: it only gets as input the product $xy^{-1}y'z^{-1}$. Our initial motivation to use invariant polynomials was that if p_0 has the property that $p_0(xy^{-1}y'z^{-1}) = p_0(y^{-1}y')$ for all $x \in X, z \in Z$, then it in fact *does* get direct access to only the Y-part of the input. Lemma 2.11 then gives generic machinery that, from such an XZ-invariant p_0, constructs a full set of (border-)separating polynomials, which have the correct degree if p_0 has the correct degree.

One advantage of this approach, in addition to separating out the design task associated with Y more from the specification of X and Z, is that it only necessitates the construction of at most three polynomials p_0, p_X, p_Z, rather than a whole set $\{f_{x,z}\}$ of $|X|\,|Z|$-many polynomials, and the p_X, p_Z polynomials are usually easy to construct if X and Z satisfy the DPP.

We now proceed with the technical details. By a *polynomial* on a matrix Lie group $G \subseteq \mathrm{GL}_n(\mathbb{C})$ or $G \subseteq \mathrm{GL}_n(\mathbb{R})$, we mean a function $G \to \mathbb{C}$ that can be expressed as a polynomial in the n^2 matrix entries x_{ij} of elements of G, with complex coefficients,[3] and similarly for a polynomial on the Lie algebra $\mathrm{Lie}(G) \subseteq M_n(\mathbb{C})$. By a 1-parameter family of polynomials we mean a polynomial in the n^2 matrix entries x_{ij} of elements of G, with coefficients in $\mathbb{C}^{(0,\alpha)}$ for some $\alpha > 0$.

Because we will use it frequently, we introduce the notation

$$\mathrm{Inv}_{X,Z} = \{p \in \mathbb{C}[M_{ij} : i,j \in [n]] \mid p(xMz) = p(M) \text{ for all } x \in X, z \in Z\}.$$

It is readily observed that $\mathrm{Inv}_{X,Z}$ is closed under multiplication and addition, and hence is a subring of the polynomial ring. In favorable (and many well-studied) cases, this subring is finitely generated over $\mathbb{C}$ (see, e. g., [20, 17]), and when a finite generating set of $\mathrm{Inv}_{X,Z}$ is known, we can focus on designing a polynomial that is composed with those generating invariants – which is then automatically invariant itself – in order to obtain p_0. We will see an example of this below.

In a Lie group G, for convenience let us say a subset $X \subseteq G$ is a *Lie submanifold* if X is a submanifold containing the identity of G, and such that for every v in the tangent space of X at the identity, for all sufficiently small $\varepsilon > 0$, the exponential $\exp(\varepsilon t)$ is in X. If X is a Lie submanifold, we use $\mathrm{Lie}(X)$ to denote the tangent space to X at the identity, even though this need not be a Lie algebra.

▶ **Lemma 2.11** (Splitting separating functions into invariant functions and double-product property)**.** *Let G be a matrix Lie subgroup of $\mathrm{GL}_n(\mathbb{F})$ for $\mathbb{F} \in \{\mathbb{R}, \mathbb{C}\}$, with Lie submanifolds X, Z and a finite set Y of 1-parameter families. Let q be a positive integer.*

[3] Warning: for readers familiar with algebraic geometry, if G is an algebraic group our definition here is *not* quite the same thing as an element of the coordinate ring of G. For example, when $G = \mathrm{U}_n$, we view G as a subset of $\mathrm{GL}_n(\mathbb{C})$ and want to consider polynomials only in the n^2 matrix entries of these complex matrices, but as an algebraic group G is a *real* algebraic group, with twice as many (real) coordinates, and this difference of a factor of 2 can actually be important. We believe there is a modification of our framework that works in the setting of algebraic groups, but leave that for future work.

If there exist

- *continuous functions* $f_X\colon \mathbb{F}^{d_X} \to \mathrm{Lie}(X)$ *and* $f_Z\colon \mathbb{F}^{d_Z} \to \mathrm{Lie}(Z)$*, and polynomials* $p_X\colon \mathrm{Lie}(G) \to \mathbb{F}^{d_X}$ *and* $p_Z\colon \mathrm{Lie}(G) \to \mathbb{F}^{d_Z}$ *such that*

$$p_X(f_X(v) - f_Z(v')) = v \qquad \text{and} \qquad p_Z(f_X(v) - f_Z(v')) = v',$$

for all $v \in \mathbb{F}^{d_X}, v' \in \mathbb{F}^{d_Z}$,[4]

and

- *a 1-parameter family of polynomials* $p_0(g,\varepsilon) \in \mathrm{Inv}_{X,Z}$ *such that*

$$p_0(g,\varepsilon) = \begin{cases} 1 + O(\varepsilon) & \text{if } g = I \\ 0 + O(\varepsilon) & \text{if } g \in Y(\varepsilon)^{-1}Y(\varepsilon) \setminus \{I\}, \end{cases}$$

then there exist

- *a reparametrization* Y' *of* Y *and finite sets* X', Z' *of 1-parameter families in* X*,* Z *(resp.) such that* $X'(\varepsilon), Y'(\varepsilon), Z'(\varepsilon)$ *satisfy the TPP for all* ε *in some non-empty range* $(0, \alpha')$*,* $|X'| \geq q^{d_X}$*, and* $|Z'| \geq q^{d_Z}$*, and*
- *a set of border-separating polynomials for* (X', Y', Z') *of degree*[5] *at most* $\deg p_0 + O((d_X + d_Z)q)$*.*

As the first condition of Lemma 2.11 may be a little intimidating, before the proof we give an example to help allay such fears:

▶ **Lemma 2.12.** *If* $X, Z \leq G \leq \mathrm{GL}_n(\mathbb{R})$ *are Lie subgroups that intersect trivially, then there exist* f_X, f_Z, p_X, p_Z *satisfying the first condition of Lemma 2.11, with* $d_X = \dim X$ *and* $d_Z = \dim Z$*.*

Note that if we drop the requirement that p_0 be in $\mathrm{Inv}_{X,Z}$, then the hypotheses of Lemma 2.11 would be almost trivially satisfied whenever X and Z have trivial intersection. In applying Lemma 2.11, it is only the use of invariants that adds any real difficulty; however, the use of invariants is also a lynchpin to reach the conclusion.

For the proofs of Lemmas 2.11 and 2.12. see the full version of the paper [10].

Continuing our running example, we now show how to satisfy the hypothesis of Lemma 2.11, and thus get a TPP construction using border rank, invariant polynomials, and Lie algebras.

Example of a separating polynomial in the invariant ring

We return to the example in $\mathrm{GL}_n(\mathbb{R})$ described in Theorem 1.2. The following lemma is straightforward to check. Let lpm_i denote the polynomial that is the i-th leading principal minor of an $n \times n$ matrix; that is, lpm_i is the determinant of the upper-left $i \times i$ submatrix of an $n \times n$ matrix.

▶ **Lemma 2.13.** *Let* $X, Z \subseteq \mathrm{GL}_n(\mathbb{R})$ *be the sets of lower unitriangular matrices and the upper unitriangular matrices, respectively. Then* $\mathrm{Inv}_{X,Z}$ *contains the leading principal minors.*

---

[4] Notice that, since p_X, p_Z essentially invert f_X, f_Z on the sum of their images, this condition implies that $\mathrm{Span}_{\mathbb{F}}(\mathrm{Image}(f_X)) \cap \mathrm{Span}_{\mathbb{F}}(\mathrm{Image}(f_Z)) = 0$, a DPP-like condition.

[5] Degree as measured only as a function of the matrix entries – ε is still considered a separate parameter. Equivalently, degree as polynomials with coefficients in $\mathbb{C}^{(0,\alpha)}$.

In fact, in this case $\mathrm{Inv}_{X,Z}$ is generated by the leading principal minors, but we will not need this stronger fact for our constructions.

▶ **Theorem 2.14.** *Let G, X, Y, Z be as in Theorem 1.2. For any $q > 0$, there is a set $\widetilde{Y}$ of 1-parameter families taking values in Y, of size $q^{\dim Y}$, as well as functions f_X, f_Z, polynomials p_X, p_Z, and a 1-parameter family of polynomials p_0 of degree $O(q^2)$ satisfying the hypotheses of Lemma 2.11 with $d_X = \dim X$, $d_Z = \dim Z$, and $\widetilde{Y}$ replacing Y.*

Consequently, there is a TPP construction with sizes $q^{\dim X}, q^{\dim Y}, q^{\dim Z}$, resp., admitting border-separating polynomials of degree $O(q^2)$.

For a proof, see the full version of the paper [10].

3 Separating polynomials of degree $O(q)$

In this section we give a construction, now in a non-compact special unitary group, in which the Lie subgroups X, Y, Z satisfy the TPP and have dimension approaching half the ambient dimension. We show the existence of finite sets $X_q \subseteq X$, $Y_q \subseteq Y$, and $Z_q \subseteq Z$ satisfying $|X_q| = q^{\dim X}$, $|Y_q| = q^{\dim Y}$, $|Z_q| = q^{\dim Z}$ and with separating polynomials of degree $O(q)$. As shown in Corollary 2.8, this degree bound is the quantitative requirement on the degree for achieving exponent 2; where the construction falls short is that it approaches half the dimension "just barely" too slowly, at a rate of $\Theta_n(n)$ rather than $o_n(n)$, and second, it is in a unitary group, so it approaches half the dimension of the unitary group, rather than half the dimension of $\mathrm{GL}_n(\mathbb{C})$.

3.1 The construction

We assume n is even and define the containing group

$$G = \mathrm{SU}_{n/2,n/2} = \{M \in \mathrm{GL}_n(\mathbb{C}) \mid M^* Q M = Q \text{ and } \det(M) = 1\},$$
$$\text{with } Q = \left(\begin{array}{c|c} I & \\ \hline & -I \end{array}\right).$$

Further, let J be the matrix with ones on the antidiagonal (in positions $(n+1-i, i)$),

$$U = \frac{1}{\sqrt{2}} \cdot \left(\begin{array}{c|c} I & J \\ \hline J & -I \end{array}\right),$$
$$D_0 = \mathrm{diag}(n, n-1, n-2, \ldots, n/2+1, (n/2+1)^{-1}, (n/2+2)^{-1}, \ldots, n^{-1}),$$

and

$$D = U D_0 U^*. \tag{3.1}$$

The only properties we will need from these matrices are that D_0 is diagonal, $D_0^* D_0$ has distinct, positive, real diagonal entries, and U is unitary such that $U D_0 U^*$ is in G, but we use these particular matrices for concreteness. In Lemma 3.6 we will show that D as in (3.1) is indeed in G.

The group $\mathrm{SU}_{n/2,n/2}$ is not compact, and it may be less familiar than the compact group SU_n, but it is equally useful for our purposes. Both $\mathrm{SU}_{n/2,n/2}$ and SU_n are subgroups of $\mathrm{SL}_n(\mathbb{C})$, and their irreducible representations are exactly the restrictions of those of $\mathrm{SL}_n(\mathbb{C})$. See the appendix of the full version [10] for a brief review of this topic.

The subgroup $\mathrm{U}_n \cap G$ is the block diagonal subgroup $U_{n/2} \times U_{n/2}$, and we need the following subspace, which is close to $\mathrm{Lie}(U_n \cap G)$ but is just a bit smaller:

$$S = \left\{ \left(\begin{array}{c|c} A_0 & 0 \\ \hline 0 & A_1 \end{array} \right) \mid A_0, A_1 \text{ are skew-Hermitian with zeros on the diagonal} \right\}.$$

▶ **Theorem 3.1.** *Let G, D, and S be as above. Let $\mathcal{I}_q \subset \mathbb{C}$ be the set of $a + ib$ with $a, b \in [-\lceil\sqrt{q}/2\rceil, \lceil\sqrt{q}/2\rceil]$. Define the following ε-parametrized subsets of G:*

$$X = \{D^{-1} \exp(\varepsilon A) D \mid A \in S\},$$
$$Z = \{D \exp(\varepsilon A) D^{-1} \mid A \in S\},$$
$$Y_q = \left\{ \exp(\varepsilon A) \mid A \in S, \text{ entries of } A \text{ lie in } \mathcal{I}_q \right\}.$$

Then there exist f_X, f_Z, p_X, p_Z, and p_0 of degree $O(q)$ satisfying the hypothesis of Lemma 2.11. Hence by Lemma 2.11, there exist three ε-parametrized subsets $X_q, Y_q, Z_q \subseteq G$, all of size at least $q^{n^2/4 - n/2}$, which satisfy the TPP and admit border-separating polynomials of degree $O(q)$.

3.2 A precursor construction in $\mathbf{GL}_n(\mathbb{C})$

In preparation for the proof of Theorem 3.1, we first establish a precursor in the containing group $\mathrm{GL}_n(\mathbb{C})$. Recall that the unitary group U_n is the set of matrices M for which $M^*M = I$, and it has half the dimension of the containing group.[6] We will shortly show that three conjugates of U_n in $\mathrm{GL}_n(\mathbb{C})$ almost satisfy the TPP (Theorem 3.3). The proof will make use of the following lemma:

▶ **Lemma 3.2.** *If $M \in \mathrm{U}_n$ and $D = UD_0U^*$ as defined above, then*

$$\mathrm{tr}(D^*M^*D^*DMD) \leq \mathrm{tr}((D^*D)^2)$$

with equality if and only if U^*MU is diagonal.

For a proof, see the full version of the paper [10].

This lemma gives a convenient way to prove that the three subgroups defined in the following theorem satisfy the TPP up to a "failure at the diagonal":

▶ **Theorem 3.3.** *Let $D = UD_0U^*$ be as defined as above. Then the three subgroups $X = D^{-1}\mathrm{U}_nD$, $Y = \mathrm{U}_n$, and $Z = D\mathrm{U}_nD^{-1}$ of $\mathrm{GL}_n(\mathbb{C})$ satisfy the following property. For all*

$$x = D^{-1}M_1D \in X, \quad y = M_2 \in Y, \quad z = DM_3D^{-1} \in Z,$$

if $xyz = I$, then U^*M_1U, U^*M_2U, and U^*M_3U are diagonal matrices.

For a proof, see the full version of the paper [10].

In the variant presented in the next section, we will form our TPP sets as exponentials of Lie algebra elements, and for this, we need a version of Lemma 3.2 that describes the deviation of $\mathrm{tr}(D^*M^*D^*DMD)$ below $\mathrm{tr}((D^*D)^2)$ explicitly as a function of the infinitesimal. Recall that the Lie algebra of U_n is the set of skew-Hermitian matrices.

[6] The unitary group is a real algebraic group, so we need to count real dimensions. The containing group has $2n^2$ real dimensions and the unitary group has n^2 real dimensions.

▶ **Lemma 3.4.** *Let $D = UD_0U^*$ be as defined above, with $d_1, d_2, \ldots, d_n$ being the diagonal entries of D_0. Let A, B be skew-Hermitian matrices and let $M = \exp(\varepsilon A)(\exp(\varepsilon B))^{-1}$. Then*

$$\operatorname{tr}(D^*M^*D^*DMD) = \operatorname{tr}((D^*D)^2) - \varepsilon^2 \sum_{i<j} (|d_i|^2 - |d_j|^2)^2 |C[i,j]|^2 + O(\varepsilon^3),$$

where $C = U^*(A - B)U$. In particular, this quantity is $\operatorname{tr}((D^*D)^2) + O(\varepsilon^3)$ if and only if C is diagonal.

For a proof, see the full version of the paper [10].

In preparation for the next subsection, we now describe some invariant polynomials in $\mathrm{Inv}_{X,Z}$ that we'll use below, where $X = D^{-1}\mathrm{U}_n D$ and $Z = D\mathrm{U}_n D^{-1}$. For an $n \times n$ matrix M and subsets $S, T \subseteq [n]$, we use $M_{S,T}$ to denote the $|S| \times |T|$ sub-matrix of M whose rows are indexed by the elements of S and whose columns are indexed by the elements of T.

▶ **Lemma 3.5.** *For each k, the function $p_k(M)$ defined as*

$$\sum_{\substack{S,T \subseteq [n] \\ |S|=|T|=k}} |\det((DMD)_{S,T})|^2$$

lies in $\mathrm{Inv}_{X,Z}$, where $X = D^{-1}\mathrm{U}_n D$ and $Z = D\mathrm{U}_n D^{-1}$.

We have been implicitly using this fact for p_1, which happens to be the complex Frobenius norm-squared function. In particular, $\operatorname{tr}(D^*M^*D^*DMD) = p_1(M)$. For a proof of Lemma 3.5, see the full version of the paper [10].

Note that because of the complex norm, these functions are not polynomials in the complex matrix entries (but they are polynomials in the entries of the natural real embedding into twice the dimension). In the next section we restrict the containing group to a special unitary group, which has the crucial side effect of making these functions polynomials in the *complex* matrix entries, because the complex conjugate of a given entry can be found as low-degree polynomial of the entries of the inverse matrix.

3.3 Proof of Theorem 3.1

Recall that the containing group of our construction in Theorem 3.1 is the following unitary group:

$$G = \mathrm{SU}_{n/2,n/2} = \{M \in \mathrm{GL}_n(\mathbb{C}) \mid M^*QM = Q \text{ and } \det(M) = 1\},$$
$$\text{with } Q = \left(\begin{array}{c|c} I & \\ \hline & -I \end{array}\right).$$

Our TPP triple in G stated in Theorem 3.1 is obtained by taking the "almost TPP" triple of Theorem 3.3 (recall that the construction almost satisfies the TPP except for a "failure at the diagonal") and intersecting it with G. In this section, we will fix the failure at the diagonal using Lemma 2.11, to get a genuine TPP construction and border-separating polynomials of the optimal degree.

Recall that our construction in G is given by

$$X = \{D^{-1}\exp(\varepsilon A)D \mid A \in S\},$$
$$Z = \{D\exp(\varepsilon A)D^{-1} \mid A \in S\},$$
$$Y_q = \{\exp(\varepsilon A) \mid A \in S, \text{ entries of } A \text{ lie in } \mathcal{I}_q\},$$

where $\mathcal{I}_q \subset \mathbb{C}$ is the set of $a + ib$ with $a, b \in [-\lceil\sqrt{q}/2\rceil, \lceil\sqrt{q}/2\rceil]$ and

$$S = \left\{ \left(\begin{array}{c|c} A_0 & 0 \\ \hline 0 & A_1 \end{array}\right) \mid A_0, A_1 \text{ are skew-Hermitian with zeros on the diagonal} \right\}.$$

We will prove Theorem 3.1 in three steps.

Step 1 summary: We show that the sets X and Z in the theorem statement are subsets of $D^{-1}\mathrm{U}_n D \cap G$ and $D\mathrm{U}_n D^{-1} \cap G$ and hence the ring of invariant polynomials contains the polynomials specified in Lemma 3.5. To do this we'll describe the Lie algebra of $U_n \cap G$, and show that D is in G.

Step 2 summary: Next, we describe the separating polynomial for Y_q in this invariant ring, and show that it has degree $O(q)$ as promised.

Step 3 summary: Finally we describe the functions f_X, f_Z, p_X, and p_Z and apply Lemma 2.11. For this we prove a version of the double product property for X and Z.

Step 1: Our TPP triple is defined relative to D, and we now show that the D defined in Section 3.1 is indeed in G as claimed. Recall that we use J for the matrix with ones on the antidiagonal $(n + 1 - i, i)$ and zeroes elsewhere (not the all-ones matrix).

▶ **Lemma 3.6.** *The matrix $D = UD_0U^*$ is an element of G, where*

$$U = \frac{1}{\sqrt{2}} \cdot \left(\begin{array}{c|c} I & J \\ \hline J & -I \end{array}\right),$$

and $D_0 = \mathrm{diag}(n, n-1, n-2, \ldots, n/2+1, (n/2+1)^{-1}, (n/2+2)^{-1}, \ldots, n^{-1})$.

See the full version for the proof [10].

Given that we will define our TPP triple by intersecting the three subgroups from the previous subsection with G, we start by describing the intersection of $Y = \mathrm{U}_n$ with G:

▶ **Lemma 3.7.**

$$\mathrm{U}_n \cap G = \left\{ \left(\begin{array}{c|c} M_{1,1} & 0 \\ \hline 0 & M_{2,2} \end{array}\right) : M_{1,1}, M_{2,2} \in \mathrm{U}_{n/2} \text{ and } \det(M_{1,1}M_{2,2}) = 1 \right\}.$$

See the full version for the proof [10].

A simple corollary, using the fact that the Lie algebra of the unitary group is the algebra of skew-Hermitian matrices, is the following.

▶ **Corollary 3.8.** *The Lie algebra of $\mathrm{U}_n \cap G$ is*

$$\mathrm{Lie}(\mathrm{U}_n \cap G) = \left\{ \left(\begin{array}{c|c} A_0 & 0 \\ \hline 0 & A_1 \end{array}\right) \mid A_0^* = -A_0,\ A_1^* = -A_1,\ \mathrm{tr}(A_0) + \mathrm{tr}(A_1) = 0 \right\}.$$

In particular, for any such matrix A and for all sufficiently small $\varepsilon > 0$, the exponential $\exp(\varepsilon A)$ is in $\mathrm{U}_n \cap G$.

Now our subsets X and Z are contained in subgroups $D^{-1}\mathrm{U}_n D$ and $D\mathrm{U}_n D^{-1}$, respectively, so the invariant polynomials of Lemma 3.5 are invariant under left multiplication by X and right multiplication by Z as before.

Step 2: A key property of G as the containing group, given that the invariant functions of Lemma 3.5 depend on the complex conjugate of matrix entries in addition to the matrix entries themselves, is described in the following straightforward lemma:

▶ **Lemma 3.9.** *For any $M \in G$,*

$$\overline{M[i,j]} = (-1)^{i+j} \det((QMQ)_{-i,-j})$$

where $(QMQ)_{-i,-j}$ denotes the submatrix obtained by deleting the i-th row and j-th column.

▶ **Theorem 3.10.** *Let D be as in Lemma 3.6 and Y_q as above. For $A, B \in Y_q$, if we set $M = \exp(\varepsilon A)\exp(\varepsilon B)^{-1}$, then*

$$\frac{\operatorname{tr}((D^*D)^2) - \operatorname{tr}(D^*M^*D^*DMD)}{\varepsilon^2} = c + O(\varepsilon),$$

where $2(n!)^2 c$ is a nonnegative integer satisfying $c = O(q)$ and for which $c = 0$ iff $A = B$.

For a proof, see the full version of the paper [10].

We note that $|Y_q| \geq q^{n^2/4 - n/2}$ and so if we define the polynomial $r(z)$ to be 1 on 0 and 0 on any other positive integer multiple of $1/(2(n!)^2)$ up to $O(q)$, then the function

$$p_0(M) = r((\operatorname{tr}((D^*D)^2) - \operatorname{tr}(D^*M^*D^*DMD))/\varepsilon^2)$$

is a separating function in the ring of invariant functions, of the desired degree $O(q)$. The fact that this is a *polynomial* follows from Lemma 3.9. Because $\operatorname{tr}(D^*M^*D^*DMD)$ is the polynomial $p_1(M)$ of Lemma 3.5, it is invariant under the left/right action of $D^{-1}U_nD$ and DU_nD^{-1}. From step 1 we know that $X \subseteq D^{-1}U_nD$ and $Z \subseteq DU_nD^{-1}$, and hence $p_0 \in \operatorname{Inv}_{X,Z}$.

Step 3: We now turn to describing the functions f_X, f_Z, p_X, and p_Z, beginning with showing that X and Z satisfy a version of the double product property.

▶ **Lemma 3.11.** *For $x \in D^{-1}SD$ and $y \in DSD^{-1}$, $x + y = 0$ iff $x = y = 0$.*

For a proof, see the full version of the paper [10].

▶ **Lemma 3.12.** *For X, Z as above, there exist functions f_X, f_Z and polynomials p_X, p_Z over $\mathbb{C}$ satisfying the first condition of Lemma 2.11 with $d_X = d_Z = n^2/4 - n/2$.*

For a proof, see the full version of the paper [10].

This completes the proof of Theorem 3.1.

4 Conclusions and open problems

In this paper we gave an extension of the group–theoretic framework of [14] to infinite groups (Theorem 2.2). Within this framework we explored constructions in Lie groups, raising the key question: do there exist three subsets in GL_n satisfying the TPP, of size at least $q^{n^2/2 - o_n(n)}$, and admitting separating polynomials of degree at most $q^{1+o_q(1)}$? If the answer is yes, then $\omega = 2$ (Corollary 2.8).

Towards obtaining such a construction, we developed tools using invariant theory and Lie algebras to simplify the task of designing separating polynomials (Subsection 2.4). We then put these tools to use in Section 3 to obtain a construction in U_n satisfying the target degree bound, with sets of size q^m with m approaching half the ambient dimension.

This raises several directions for future research:

- Can one obtain a construction with sets of size q^m for m approaching half the ambient dimension and separating polynomials of degree at most $q^{1+o_q(q)}$, but in GL_n rather than U_n?

- Can one obtain a construction with separating polynomials of degree at most $q^{1+o_q(q)}$ in $G_n = \mathrm{GL}_n$ or $G_n = \mathrm{U}_n$ with sets of size $q^{\dim G_n/2-o(n)}$, rather than $q^{\dim G_n/2-\Theta(n)}$?
- Our general framework opens up the possibility of using other infinite groups (not necessarily Lie groups), which remains to be explored.
- Another type of construction that is now possible is one in a single, fixed infinite group (say, GL_3), with growing families of sets (X_q, Y_q, Z_q). In contrast, our current constructions require us to take n growing as well, or more generally, a growing family of containing groups.

Abstract

Differential privacy and sublinear algorithms are both rapidly emerging algorithmic themes in times of big data analysis. Although recent works have shown the existence of differentially private sublinear algorithms for many problems including graph parameter estimation and clustering, little is known regarding hardness results on these algorithms. In this paper, we initiate the study of lower bounds for problems that aim for both differentially-private and sublinear-time algorithms. Our main result is the incompatibility of both the desiderata in the general case. In particular, we prove that a simple problem based on one-way marginals yields both a differentially-private algorithm, as well as a sublinear-time algorithm, but does not admit a "strictly" sublinear-time algorithm that is also differentially private.

1 Introduction

While individuals have long demanded privacy-preserving analysis and processing of their data, their adoption and enforcement by governmental and private standards, policies, and jurisdictions are now accelerating. This urgency stems, in part, from the dramatic growth in the amount of data collected, aggregated, and analyzed per individual in recent years. The sheer volume of data also poses a computational challenge as resource demands scale with data size. Thus, it is expedient to develop privacy preserving algorithms for data-analysis whose resource requirements scale sub-linearly in the size of the input dataset. Two algorithmic

concepts that formalize these two objectives are *differential privacy* (DP) and *sublinear algorithms*. A randomized algorithm is differentially private if its output distribution does not change significantly when we slightly modify the input dataset to add/remove an individuals data i.e., a row in the dataset. Sublinear algorithms comprise classes of algorithms that have time or space complexity that is sublinear in their input size. Previous work in the intersection of both fields has promoted several classical sublinear algorithms to differentially private sublinear time algorithms for the same problems, e.g., sublinear-time clustering [3], graph parameter estimation [4] or sublinear-space heavy hitters in streaming [27, 6].

Intuitively, one might expect that privacy and sublinear time necessarily have a symbiotic relationship, i.e., if only a fraction of the data is processed, a significant amount of sensitive information may remain unread. Recent work [5] demonstrated that if a function $f\colon D \to \mathbb{R}$ has low global sensitivity (i.e., f is amenable to DP) and there exists a *sufficiently accurate* sublinear-time approximation algorithm for f, then there exists an accurate sublinear time DP approximation for f. This lead [5] to ask whether or not a similar transformation might apply for functions $f\colon D \to \mathbb{R}^d$ with multi-dimensional output. In this paper, we provide an example of a function $f\colon D \to \mathbb{R}^d$ with the following properties (1) there is an efficient sublinear time approximation algorithm for f, (2) there is a differentially private approximation algorithm for f running in time $O(|D|)$, and (3) any accurate differentially private approximation algorithm must run in time $\tilde{\Omega}(|D|)$. Thus, the intuition that privacy and sublinear time algorithms necessarily have a symbiotic relationship is incorrect.

Existing Model for DP Lower Bounds. Consider a database $D \in \{0,1\}^{n\times d}$ with n rows where each row corresponds to an individual's record with d binary attributes. The model in this case is that the database D consists of a sample (according to a uniform or possibly adversarial distribution) from a larger population (or universe), and we are interested in answering queries on the sample (e.g., what fraction of individual records in D satisfy some property q?). One of the interesting questions in DP lower bounds is the following: Suppose we fix a family of queries $\mathcal{Q}$ and the dimensionality of database records d, then what is the sample complexity required to achieve DP and statistical accuracy for $\mathcal{Q}$? Here the *sample complexity* is defined as the minimum number of records n such that there exists a (possibly computationally unbounded) algorithm that achieves both DP and accuracy.

A key problem that has been at the center of addressing this question is the *one-way marginal problem*. The one-way marginal problem takes a database $D \in \{0,1\}^{n\times d}$ and releases the average values of all d columns. The best known private algorithm which has running time polynomial in the universe size is based on the multiplicative weights mechanism, and it achieves $(O(1), o(1/n))$-DP for $n \in O(\sqrt{d}\log|\mathcal{Q}|)$ [17]. Any pure DP algorithm for this problem requires $n \geq \Omega(d)$ samples [18], while [8] showed that $n \geq \tilde{\Omega}(\sqrt{d})$ samples are necessary to solve this problem with approximate DP and within an additive error of $1/3$.

Existing Models for Sublinear-Time Algorithms. The works on sublinear-time algorithms utilize different input models, many of them tailored to the representation of the input, e.g., whether it is a function or a graph. These models typically define query oracles, i.e., mechanisms to access the input in a structured way. For example, the dense graph model [16] defines an adjacency query oracle that, given a pair of indices (i, j), returns the entry $A(i, j)$ of the adjacency matrix A of the input graph. Query oracles enable an analysis of what parts, and more generally how much of the input was accessed by an algorithm. Since the fraction of input read is a lower bound for the time complexity of an algorithm, query access models are crucial to prove both sublinear-time upper and lower bounds.

Our Model. A challenge of proving lower bounds for sublinear time, differentially private algorithms lies in devising and applying a technique for analysis that combines the properties of both models. Lower bounds for differential privacy state a lower bound on the sample complexity that is required to guarantee privacy and non-trivial accuracy. These bounds do not state how much of the input an algorithm needs to *read* to guarantee privacy and accuracy, but only what input size *is required* to (potentially) enable such an algorithm. On the other hand, lower bounds for sublinear time algorithms state a bound on the time complexity as a function of the input size m. Note that time complexity is at least query complexity, and a lower bound on the latter immediately implies a lower bound on time complexity as well.

In our setting, we fix the number of records n, as well as the dimensionality d of the database, i.e., our problem size is $m = n \cdot d$. We define queries in our model to be *attribute queries*, i.e., querying the j-th attribute of a row i in the database D is denoted as $D(i, j)$. We emphasize that our use of the term *query* in our model is as in the sublinear-time algorithms model, and it is different from its use in conventional DP literature. Specifically, queries in DP literature refer to types of questions that the data analyst can make to the database to infer something about the population, whereas queries in the sublinear algorithms model refer to how the algorithm can access the input dataset D. In our work, we fix a problem of interest $\mathcal{P}$ on database D (e.g., the one-way marginal problem), and we consider an algorithm that solves the problem $\mathcal{P}$ on input D. Then we are interested in understanding the minimum number of (attribute) queries that an algorithm can make to solve the problem $\mathcal{P}$ and satisfy both DP and accuracy, which we call the *query complexity*.

Result of [8] does not apply in our model. For the problem of one-way marginals, we know that $n \in \tilde{\Omega}(\sqrt{d})$ [8] records are required for any algorithm to achieve both DP and accuracy. For $m = \tilde{\Omega}(d^{3/2})$, there exists a DP algorithm that can solve this problem with $\tilde{O}(m)$ queries, i.e., the algorithm can query the entire dataset and add Gaussian noise. Using Hoeffding bounds one can analyze a simple non-private algorithm with accuracy $1/3$ that has query complexity $O(d \log d)$, which is sublinear in the problem size m. However, it is not clear whether $O(m)$ queries are necessary to achieve both DP and accuracy in our model. One might be tempted to directly apply the result of [8] to say that $\tilde{\Omega}(m)$ queries are necessary, but this does not work as the results of [8] focus on sample complexity. In particular, in our model it would be possible to distribute attribute queries across all rows (making $o(d)$ attribute queries in each row) so that every row is (partially) examined but the total number of queries is still $o(m)$. In particular, a sublinear time algorithm can substantially reduce ℓ_1 and ℓ_2 sensitivity by ensuring that the maximum number of queries in each row is $o(d)$. [1]

The sample complexity lower bound of [8] uses fingerprinting codes to show that the output of an algorithm that is both DP and reasonably accurate for the one-way marginal problem can be used to reidentify an individual record, which contradicts the DP property. Intuitively, fingerprinting codes provide the guarantee that if an algorithm obtains an accurate answer after examining *at most* c rows in the database then it is possible to reidentify at

[1] Suppose for example, that $m = d^2$ so that there are d attribute columns and d rows and consider two sublinear time algorithms: Algorithm 1 examines the first $\sqrt{d}$ rows and outputs the marginals for these samples. By contrast, Algorithm 2 uses rows $i\sqrt{d}+1$ to $(i+1)\sqrt{d}$ to compute the marginals columns $i\sqrt{d}+1$ to $(i+1)\sqrt{d}$ for each $i < \sqrt{d}$. Both algorithms examine the same number of cells in the database $d\sqrt{d}$, but the ℓ_1 (resp. ℓ_2) sensitivity of the algorithms are quite different. Algorithm 1 has ℓ_1 (resp. ℓ_2) sensitivity $\sqrt{d}$ (resp. 1) while Algorithm 2 has ℓ_1 (resp. ℓ_2) sensitivity 1 (resp. $d^{-0.25}$).

least one of the corresponding users. However, if the attacker examines more than c rows, then *we cannot prove that privacy is violated as fingerprinting codes no longer provide the guarantee that we can reidentify one of the corresponding users.* In our model, an algorithm is allowed to make arbitrary attribute queries and is not restricted to querying all attributes corresponding to a fixed row, thus it is more difficult to prove a lower bound of this nature in our model. In particular, instead of sampling c rows an attacker could distribute the attribute queries across all rows (making $c = o(d)$ attribute queries in each row). The total number of cells examined is still cd, but the overall coalition has size $d \geq c$. Fingerprinting codes provide no guarantee of being able to trace a colluder since the overall coalition (number of rows in which some query was made) is larger than c. Thus, we cannot prove that privacy is violated.

Crucially, their construction relies on the algorithm being able to query the entire row (aka record) of the database and the fact that for a fixed coalition size c a fingerprinting code can trace an individual in any coalition of size $\leq c$ with high probability, as long as the individual *actively* colluded.

Our Contribution. We give the first separation between the query complexity of a non-private, sublinear-time algorithm and a DP sublinear-time algorithm (up to a log factor). We remind the reader that a lower bound on query complexity naturally implies a lower bound on time complexity as the time taken by an algorithm must be at least the number of queries made. Thus our theorem on query complexity also gives a lower bound for sublinear-time DP algorithms.

▶ **Theorem 1** (Informal Theorem). *There exists a problem $\mathcal{P}$ of size m such that*

1. *$\mathcal{P}$ can be solved privately with $O(m)$ query and time complexity.*
2. *$\mathcal{P}$ can be solved non-privately with $O(m^{2/3}\log(m)) \in o(m)$ query and time complexity.*
3. *Any algorithm that solves $\mathcal{P}$ with $(1/3, 1/3)$-accuracy and $(O(1), o(1/m))$-DP must have $\Omega(m/\log(m)) = \tilde{\Omega}(m)$ query and time complexity.*

We note that [8] implies that any accurate, DP algorithm for $\mathcal{P}$ requires $n \in \Omega(\sqrt{d})$, and we can in fact invoke the theorem for the *hardest* case and choose m so that $n = \Theta(\sqrt{d})$.[2] For full details on the definition of the problem and the formal version of the theorem, see Definition 21 and Theorem 26. Summarized in words, $\mathcal{P}$ is solvable under differential privacy, and there exists a non-private sublinear-time algorithm to solve $\mathcal{P}$, but any DP algorithm must read (almost) the entire dataset, and thus have at least (nearly) linear running time. Our techniques build upon a rich literature of using fingerprinting codes in DP lower bounds. We note that the $\log(m)$ factor in our main result (Item 3) of Theorem 1 arises from the nearly-optimal Tardos fingerprinting code used in our lower bound construction. Thus it seems unlikely that this result can be improved unless one bypasses using fingerprinting codes entirely in the DP lower bound construction.

1.1 Technical Overview

Fingerprinting code (FPC) and DP. We start the construction of our lower bound with the privacy lower bounds based on fingerprinting codes [8]. For a set of n users and a parameter $c \leq n$, an (n, d, c)-FPC consists of two algorithms $(Gen, Trace)$. The algorithm Gen on input n outputs a codebook $C \in \{0,1\}^{n\times d}$ where each row is a codeword of user $i \in [n]$ with code

[2] We call $n = \Theta(\sqrt{d})$ the hardest case because, when n becomes larger as a function of d, [1] show that subsampling can improve the privacy/accuracy trade-off of existing DP algorithms.

length $d = d(n, c)$. It guarantees that if at most c users collude to combine their codewords into a new codeword c' and the new code satisfies some (mild) *marking condition* – namely that if every colluder has the same bit b in the j-th bit of their codeword, then the j-th bit of c' must also be b – then the $Trace$ algorithm of the fingerprinting code can identify at least one colluder with high probability.[3] Bun et al. [8] used fingerprinting codes to show that the output of any accurate algorithm for the one-way marginal problem must satisfy the marking condition for sufficiently large d, and therefore, at least one row (i.e., individual) from the database is identifiable – making this algorithm not private. In more detail, given a fingerprinting code $(Gen, Trace)$, suppose a coalition of n users builds dataset $D \in \{0,1\}^{n \times d}$ where each row corresponds to a codeword of length d from the codebook Gen. For $j \in [d]$, if every user has bit b in the j-th bit of their codeword then the one-way marginal answer for that column will be b. It is shown that any algorithm that has non-trivial accuracy for answering the one-way marginals on D can be used to obtain a codeword that satisfies the marking condition. Therefore, using $Trace$ on such a codeword leads to identifying an individual in dataset D. Since an adversary is able to identify a user in D based on the answer given by the algorithm, this clearly violates DP.

Techniques of [8] do not directly apply. In our model, an algorithm only sees a subset of the entries in the entire database via attribute queries. Suppose a coalition of $c \leq n$ users belongs to a dataset $D \in \{0,1\}^{n \times d}$ where each row corresponds to a codeword of length d. As a warm-up, let us first assume that an algorithm that solves the one-way marginal problem on input $D \in \{0,1\}^{n \times d}$ always queries for entire rows and that an adversary can simulate a query oracle to the algorithm's queries, i.e., respond with rows that exactly correspond to the set of c colluders (for more details see Section 5.1). To apply a fingerprinting code argument to such an algorithm, an adversary must identify a row from this subset of c rows by examining the output of the algorithm. However, since the accuracy guarantee of the algorithm applies (only) to the *whole* dataset, we cannot make the same argument as above to conclude that the marking condition holds for the *subsample* of rows. In other words, we need to ensure that the output of an accurate algorithm that only sees a subsample of rows can also satisfy the marking condition. The techniques of [8] do not ensure such a property.

Permute Rows and Pad and Permute Columns Fingerprinting codes (PR-PPC FPC). In order to achieve the property described above, we need to ensure that any attempt of the algorithm to spoil the marking condition would contradict its accuracy guarantees. We achieve this property by padding $O(d)$ additional columns to the codebook C to obtain $C' \in \{0,1\}^{n \times d'}$, where $d' = O(d)$, so that (codebook) columns whose output could be modified to violate the marking condition and (padded) columns whose modification would violate the accuracy guarantee are indistinguishable in the subsample with good probability. Padded columns have been used to define a variant of a fingerprinting code in previous work to achieve smooth DP lower bounds [22]. In our work, we not only need a variant of FPC with padded columns, but we also need to permute the rows of the codebook (see Section 4 for the construction). This is because we need to define a sampling procedure with certain properties for the adversary to obtain a dataset on c rows from a distribution over databases of n rows, and one way to do so is permuting the rows of the codebook and outputting the first c rows (e.g., see Theorem 15 and Theorem 27).

[3] The idea of fingerprinting codes becomes colorful when imagining a publisher who distributes advance copies to press and wants to add watermarks that are robust, e.g., against pirated copies that result from averaging the copies of multiple colluders. To see that the marking assumption is a mild condition, consider that the codeword is hidden in the much larger content.

▶ Remark 2. We note that [8] used a similar padding technique to argue about obtaining error-robust codes from "weakly-robust" codes (see Lemma 6.4 in [8]). In particular, we could argue that the property that we need for our purpose is achieved by an error robust code. However, we choose to start with a weaker construction, as we do not inherently need the error robustness property.

Secret Sharing Encoding. Finally, we overcome the assumption that the algorithm queries for entire rows by applying a secret sharing scheme to the padded codebook (see Section 5.2). In particular, an adversary can encode each row $x_i \in \{0,1\}^{d'}$ with respect to a random polynomial of degree $2d' - 1$ as a share of size $2d$. The shares are defined by the d codebook values and d random values from the field. For each query of the algorithm, the adversary answers with a share from the second half. Information theory implies that the algorithm can only recover the d codebook values after querying for all d random value shares. Thus, we obtain a derivate of the one-way marginal problem that requires the algorithm to query an entire row to reveal the padded code book row. While there exist a DP algorithm (Theorem 24) and a sublinear-time algorithm (Theorem 25) for this derived problem as well, we show that there exists no sublinear-time DP algorithm (up to a log factor) that can query for arbitrary entries in the database.

2 Related Work

Fingerprinting codes were first introduced in the context of DP lower bounds by [8]. Prior to their work, traitor-tracing schemes (which can be thought of as a cryptographic analogue of information-theoretic fingerprinting codes) were used by [12, 26] to obtain computational hardness results for DP. Subsequent works have refined and generalized the connection between DP and fingerprinting codes in many ways [23, 24, 14, 7, 21, 20, 9]. The fingerprinting code techniques of proving DP lower bounds have been used in many settings including principal component analysis [15], empirical risk minimization [2], mean estimation [8, 20], regression [9], gaussian covariance estimation [21]. Recently [22] use fingerprinting codes to give smooth lower bounds for many problems including the 1-cluster problem and k-means clustering.

In the streaming model, [10] give a separation between the space complexity of differentially private algorithms and non-private algorithms – under cryptographic assumptions they show that there exists a problem that requires exponentially more space to be solved efficiently by a DP algorithm vs a non-private algorithm. By contrast, our focus is on lower bounding the running time (query complexity) of a differentially private algorithm. Our bounds do not require any cryptographic assumptions. [19] give a lower bound in the continual release model, in particular they show that there exists a problem for which any DP continual release algorithm has error $\tilde{\Omega}(T^{1/3})$ times larger than the error of a DP algorithm in the static setting where T is the length of the stream.

3 Preliminaries

We define a database $D \in \mathcal{X}^n$ to be an ordered tuple of n rows $(x_1, \ldots, x_n) \in \mathcal{X}$, where $\mathcal{X}$ is the data universe. For our purposes, we typically take $\mathcal{X} = \{0,1\}^d$. Databases D and D' are neighboring if they differ by a single row and we denote this by $D \sim D'$. In more detail, we can replace the i-th row of a database D with some fixed element of $\mathcal{X}$ to obtain dataset $D_{-i} \sim D$. Importantly both D and D_{-i} are databases of the same size.

▶ **Definition 3** (Differential Privacy [11]). *Randomized algorithm $\mathcal{A} : \mathcal{X}^n \to \mathcal{R}$ is (ε, δ)-differentially private if for every two neighboring databases $D \sim D'$ and every subset $S \subseteq \mathcal{R}$,*

$$\Pr[\mathcal{A}(D) \in S] \leq e^{\varepsilon} \Pr[\mathcal{A}(D') \in S] + \delta$$

▶ **Definition 4** (Accuracy). *Randomized algorithm $\mathcal{A} : \mathcal{X}^n \to \mathbb{R}^d$ is (α, p)-accurate for problem $\mathcal{P}$ if for every $D \in \mathcal{X}^n$, with probability at least $1 - p$, the output of $\mathcal{A}$ is a vector $a \in \{0,1\}^d$ that satisfies $|a_{\mathcal{P}}(D) - a| \leq \alpha$ where $a_{\mathcal{P}}(D)$ denotes the exact solution of the problem $\mathcal{P}$ on input D.*

The following definition of fingerprinting codes is "fully-collusion-resilient". For any coalition of users S who collectively produce a string $y \in \{0,1\}^d$ as output, as long as y satisfies the *marking condition* – for all positions $1 \leq j \leq d$, if the values x_{ij} for all users i in coalition S agree with some letter $s \in \{0,1\}$, then $y_j = s$ – then the combined codeword y can be traced back to a user in the coalition. Formally, for a codebook $C \in \{0,1\}^{n \times d}$, and a coalition $S \subseteq [n]$, we define the set of feasible codewords for C_S to be

$$F(C_S) = \{c' \in \{0,1\}^d \mid \forall j \in [d], \exists i \in S, c'_j = c_{ij}\}$$

▶ **Definition 5** (Fingerprinting Codes [8]). *For any $n, d \in \mathbb{N}, \xi \in (0,1]$, a pair of algorithms $(Gen, Trace)$ is an (n, d, c)-fingerprinting code with security ξ against a coalition of size c if Gen outputs a codebook $C \in \{0,1\}^{n \times d}$ and secret state st and for every (possibly randomized) adversary $\mathcal{A}_{FP}$, and every coalition $S \subseteq [n]$ such that $|S| \leq c$, if we set $c' \leftarrow_R \mathcal{A}_{FP}(C_S)$ then*

1. $\Pr[c' \in F(C_S) \wedge Trace(c') = \perp] \leq \xi$
2. $\Pr[Trace(c') \in [n] \setminus S] \leq \xi$

where C_S contains the rows of C given by S, and the probability is taken over the coins of C, $Trace$, and $\mathcal{A}_{FP}$. The algorithms Gen and $Trace$ may share a common state denoted as st.

▶ Remark 6. Although the adversary $\mathcal{A}_{FP}$ is defined as taking the coalition of users' rows as input, we may abuse this notation and consider the entire codebook or a different input (related to the codebook) altogether. This does not change the security guarantees of the FPC against adversary $\mathcal{A}_{FP}$ because the security guarantee holds as long as the output of $\mathcal{A}_{FP}$ is a result of the users in the coalition S actively colluding.

▶ **Theorem 7** (Tardos Fingerprinting Code [25]). *For every $n \in \mathbb{N}$ and $4 \leq c \leq n$, there exists an (n, d, c)-fingerprinting code of length $d = O(c^2 \log(n/\xi))$ with security $\xi \in [0,1]$ against coalitions of size c.*

▶ **Theorem 8** (Gaussian Mechanism, [13]). *Let $\varepsilon, \delta \in (0,1)$ and $f : \mathbb{N}^d \to \mathbb{R}^d$. For $c > \sqrt{2\ln(1.25/\delta)}/\varepsilon$, the Gaussian Mechanism with standard deviation parameter $\sigma \geq c\Delta_2 f$ is (ε, δ)-DP, where Δ_2 is the ℓ_2-norm sensitivity of f.*

▶ **Lemma 9.** *For $n \geq \sqrt{200d\ln(20d)\ln(1.25/\delta)}/\varepsilon \in \tilde{\Omega}(\sqrt{d})$, given a dataset $D \in \{0,1\}^{n \times d}$, there exists a $(1/10, 1/10)$-accurate (ε, δ)-DP algorithm that solves the one-way marginals problem with $O(m)$ attribute queries, where $m = n \cdot d$.*

Proof. We note that the ℓ_2-sensitivity of the one-way marginals problem on a database $\{0,1\}^{n \times d}$ is $\sqrt{d}/n$. For $n \geq \sqrt{200d\ln(20d)\ln(1.25/\delta)}/\varepsilon \in \tilde{\Omega}(\sqrt{d})$, the Gaussian Mechanism is $(1/10, 1/10)$-accurate with

$$\sigma = \frac{\sqrt{2\ln(1.25/\delta)}}{\varepsilon} \cdot \frac{\varepsilon\sqrt{200d}}{\sqrt{2\ln(1.25/\delta) \cdot d\ln(10d)}} = \frac{1}{\sqrt{200\ln(10d)}},$$

$$\text{as } \Pr_{X \sim \mathcal{N}(0,\sigma^2)}\left[X \geq \frac{1}{10}\right] \leq 2e^{-\frac{1}{200\sigma^2}} \leq \frac{1}{20d}$$

by the Cramer-Chernoff inequality and a union bound over all d columns of the dataset. ◀

4 Permute Rows and Pad and Permute Columns Fingerprinting Codes (PR-PPC FPC)

In this section, we first introduce our pad and permute variant of the original fingerprinting codes where we Permute Rows and Pad and Permute Columns (PR-PPC (n, d, c, ℓ)-FPC). Given $(Gen, Trace)$ of an (n, d, c)-FPC, we construct Gen' and $Trace'$ in Algorithm 1 and Algorithm 2 to produce a PR-PPC (n, d, c, ℓ)-FPC. In more detail, Gen' samples codebook C and secret state st from Gen where $C \in \{0,1\}^{n \times d}$. It then permutes the rows via a random permutation π_R, after which it pads 2ℓ columns and performs another random permutation π on the columns. Then, it releases the resulting codebook $C' \in \{0,1\}^{n \times d'}$, where $d' = d + 2\ell$ and ℓ is the parameter which controls the number of columns padded to C. Note that the row permutation π_R is public while the column permutation π is part of the new secret state st'. The algorithm $Trace'$ receives an answer vector of dimension d' and uses its secret state $st' = (st, \pi)$ to feed the vector entries that correspond to the original first d columns via π^{-1} to $Trace$ and releases the output of $Trace$. We obtain the following result directly from the definition of Gen' and $Trace'$.

▶ **Corollary 10.** *Given an (n, d, c)-FPC, $\ell \geq 0$, and the corresponding PR-PPC (n, d, c, ℓ)-FPC, the properties of $Trace$ as stated by Definition 5 translate directly to $Trace'$.*

Algorithm 1 Gen'.

Require: Number of users $n \in \mathbb{N}$, number of padded 0/1 columns ℓ

1: Sample codebook $(C, st) \leftarrow Gen(n)$ such that $C \in \{0,1\}^{n \times d}$.
2: Sample random permutation $\pi : [d'] \to [d']$ where $d' := d + 2\ell$. For an $n \times d'$ matrix A, define $n \times d'$ matrix $\pi(A)$ such that $\pi(j)$-th column of $\pi(A)$ equals to the j-th column of A for every $j \in [d']$.
3: Sample random permutation $\pi_R : [n] \to [n]$. For an n-row matrix A, define $\pi_R(A)$ such that $\pi_R(i)$-th row of $\pi_R(A)$ equals to the i-th row of A for every $i \in [n]$.
4: $C^{\pi_R} \leftarrow$ Permute rows of C via random permutation π_R.
5: $C_{pad} \leftarrow$ Pad ℓ columns of all 1's and ℓ columns of all 0's to matrix C^{π_R}.
6: $C' \leftarrow$Permute the columns of C_{pad} according to random permutation π.
7: Output C' along with the new secret state $st' := (st, \pi)$ and permutation π_R.

Algorithm 2 $Trace'$.

Require: Answer vector $\mathbf{a} = (a^1, \ldots, a^{d'}) \in \{0,1\}^{d'}$, secret state $st' = (\pi, st)$

1: Output $Trace(\mathbf{a}_{og}, st)$ where $\mathbf{a}_{og} = (a^{\pi(1)}, \ldots, a^{\pi(d)}) \in \{0,1\}^d$.

We define the *feasible sample property* of an FPC below. Informally, it states that if we have an algorithm that takes a sample of rows from a codebook as input, and the algorithm's output is a feasible codeword for the entire codebook, then the same output should be a feasible codeword for the sample.

▶ **Definition 11** (Feasible Sample Property)**.** *Let $C \in \{0,1\}^{n \times d}$ be a codebook of an (n, d, c)-FPC, $S \subseteq [n]$ be a coalition and $C_S \subseteq C$ be the matrix consisting of the corresponding rows indexed by S. Given an algorithm $\mathcal{A}$ that takes as input C_S and outputs a vector $\mathbf{o} \in \{0,1\}^d$, the feasible sample property states that if $\mathbf{o} \in F(C)$, then $\mathbf{o} \in F(C_S)$.*

▶ **Lemma 12.** *PR-PPC (n, d, c, ℓ)-FPC satisfies the feasible sample property with probability at least $1 - \frac{d}{\ell}$.*

Proof. Given $(Gen', Trace')$ of PR-PPC (n, d, c, ℓ)-FPC which produces codebook $C' \in \{0,1\}^{n \times d'}$ and sampling algorithm $\mathcal{A}$ which takes as input $C'_S \subseteq C'$ and outputs a vector $\mathbf{o} \in \{0,1\}^{d'}$ where $d' = d + 2\ell$, we define the event BAD_S as $\mathbf{o} \in F(C')$ but $\mathbf{o} \notin F(C'_S)$.

We denote the indices of columns of C' in which all the bits are 1 as $C'_{|1}$ and the indices of columns in which all the bits are 0 as $C'_{|0}$. Similarly, we define $C'_{S|1}$ and $C'_{S|0}$ for the columns that are all 1 and all 0 in C'_S, respectively. Note that $C'_{|1} \subseteq C'_{S|1}$ and $C'_{|0} \subseteq C'_{S|0}$. Since by definition, algorithm $\mathcal{A}$ only has access to the set of rows in C'_S, in order for the output $\mathbf{o}$ to satisfy $\mathbf{o} \in F(C')$ but $\mathbf{o} \notin F(C'_S)$, an adversary that aims for BAD_S must flip a bit of the resulting codeword that originates from $\{C'_{S|1} \cup C'_{S|0}\} \setminus \{C'_{|1} \cup C'_{|0}\}$. In other words, the event BAD_S occurs only if the adversary identifies a column from C' that contains at least one 0 and one 1, but reduces to an all-1 or all-0 column in C'_S.

More formally, the adversary can pick the bit $b \in \{0,1\}$ resulting in a column from $C'_{S|b}$ to flip. The probability that the adversary correctly identifies a column from $C'_{S|b} \setminus C'_{|b}$ is at most $\frac{|C'_{S|b} \setminus C'_{|b}|}{|C'_{S|b}|}$. Observe that $|C'_{S|b}| \geq |C'_{|b}| \geq \ell$ due to the ℓ padded all-b columns, and therefore $|C'_{S|b} \setminus C'_{|b}| \leq |C'_{S|b}| - |C'_{|b}| \leq (d + \ell) - \ell = d$. Thus, the probability that event BAD_S occurs is at most $\max_{b \in \{0,1\}} \frac{|C'_{S|b} \setminus C'_{|b}|}{|C'_{S|b}|} \leq \frac{d}{\ell}$. ◀

5 Lower Bound

We present our lower bound for sublinear-time DP algorithms in this section. In Section 5.1 we discuss a warm-up problem, where the algorithm can only make row queries to release the one-way marginals of the dataset. We present our main result and the lower bound construction for algorithms that can make arbitrary attribute queries in Section 5.2. In the sequel, our problem space has size $m = n \cdot d = \Omega(d\sqrt{d})$ and our results will be in terms of dimension d.

5.1 Warm Up: Using a Random Oracle

In this section, we first present a warm-up problem which we call the Random Oracle Problem ($\mathcal{P}_{RO}$). This is an extension of the one-way marginals problem in the following manner – for an input dataset $D = (x_1, \ldots, x_n)$, and access to a random oracle H, the $\mathcal{P}_{RO}$ problem takes as input an encoded dataset $D_H = (z_1, \ldots, z_n)$ in which $z_i = H(i) \oplus x_i$, and outputs the one-way marginals of the underlying dataset D (see Definition 13 for a formal definition). The main intuition for introducing such a problem is that we want to force an algorithm that solves this problem to query an entire row. Recall that in our (final) model an algorithm is allowed to make arbitrary attribute queries – however, given D_H, in order to approximate or exactly compute the one-way marginals of D, an algorithm needs to query $H(i)$ for $i \in [n]$, as otherwise, by the properties of the random oracle and one-time pad (OTP), the value of x_i is information-theoretically hidden.

▶ **Definition 13** (Random Oracle Problem $\mathcal{P}_{RO}$)**.** *Given a random oracle $H : [n] \to \{0,1\}^d$, and a dataset $D = (x_1, \ldots, x_n)$ where $x_i \in \{0,1\}^d$, define dataset $D_H := (z_1, \ldots, z_n)$ where $z_i = H(i) \oplus x_i$. For simplicity of notation, we refer to the operation for obtaining D_H from D as $H(D)$. The problem $\mathcal{P}_{RO}$ on input D_H releases the one-way marginals of D.*

We use $\mathcal{P}_{RO}(D)$ to denote that $\mathcal{P}_{RO}$ releases the one-way marginals of the underlying dataset D.

Query Model. On input $D_H \in (\{0,1\}^d)^n$, an algorithm can query the random oracle H through *row queries*, i.e., given a row index $i \in [n]$ of D_H, the answer given is $H(i) \in \{0,1\}^d$. We note that our final result in this subsection will still be presented in the form of attribute queries as 1 row query translates to d attribute queries.

Observe that there exists an (ε, δ)-DP algorithm for $\mathcal{P}_{RO}(D)$ that on input D_H, queries the entire dataset via row queries to the random oracle H, i.e., it makes $dn = O(d\sqrt{d})$ queries. After obtaining the rows to the underlying dataset D it releases the one-way marginals using the Gaussian Mechanism (see Lemma 9). We also note that there exists a sublinear non-DP algorithm for $\mathcal{P}_{RO}(D)$ which makes $O(d \log d)$ queries, which is a simple corollary of Hoeffding bounds. Our goal in this section is to prove the lower bound below. Recall that $n \in \Omega(\sqrt{d})$, so the problem size is $\Omega(d\sqrt{d})$.

▶ **Theorem 14** (Lower Bound for $\mathcal{P}_{RO}$)**.** *Any algorithm that solves the problem $\mathcal{P}_{RO}$ with s attribute query complexity, $(1/3, 1/3)$-accuracy and $(O(1), o(1/s))$-DP must have $s = \Omega(d\sqrt{d/\log(d)})$.*

We present a high level overview of the proof of Theorem 14 here. We first show that given an (n, d, c)-FPC, there exists a distribution on c rows from which an adversary $\mathcal{B}$ can sample and create an n-row input instance for an algorithm $\mathcal{A}$ that accurately solves $\mathcal{P}_{RO}$ (see Theorem 15). Next we argue that the rounded output of $\mathcal{A}$, denoted as $\mathbf{a}$, is a feasible codeword for the sample of c rows as long as $\mathcal{A}$ is accurate in a non-trivial manner and $\mathbf{a}$ is feasible for the entire dataset (see Lemma 17). The adversary $\mathcal{B}$ can then use the output from $\mathcal{A}$ to (potentially) reidentify an individual from the coalition of size c. Next we relate these claims back to DP through Lemma 18, which states that if there exists a distribution $\mathcal{C}$ on $c \leq n$ row databases according to Theorem 15, then there is no (ε, δ)-DP algorithm $\mathcal{A}$ that is $(1/3, 1/3)$-accurate for $\mathcal{P}_{RO}$ with $\varepsilon = O(1)$ and $\delta = o(1/c)$. Finally, invoking the Tardos construction for fingerprinting codes in Theorem 7 gives us our lower bound.

▶ **Theorem 15.** *For every $n, d \in \mathbb{N}$, $\xi \in [0,1]$ and $c \leq n$, if there exists an (n, d, c)-fingerprinting code with security ξ, then there exists a distribution on c-row databases $\mathcal{C}_{\mathcal{S}}$, a row permutation $\pi_R : [n] \to [n]$, and an adversary $\mathcal{B}$ for every randomized algorithm $\mathcal{A}$ with row query complexity c and $(1/3, 1/3)$-accuracy for $\mathcal{P}_{RO}$ such that*

1. $\Pr_{C'_S \leftarrow \mathcal{C}_{\mathcal{S}}}[\mathcal{B}^{\mathcal{A}}(C'_S) = \perp] \leq \xi$
2. *For every $i \in [c]$, $\Pr_{C'_S \leftarrow \mathcal{C}_{\mathcal{S}}}[\mathcal{B}^{\mathcal{A}}(C'_{S_{-i}}) = \pi_R^{-1}(i)] \leq \xi$.*

The probabilities are taken over the random coins of $\mathcal{B}$ and the choice of C'_S.

Let $(Gen, Trace)$ be the promised (n, d, c)-fingerprinting code in the theorem statement. We first construct a PR-PPC (n, d, c, ℓ)-FPC with $\ell := 100d$ (see Section 4 for details).

The distribution $\mathcal{C}_{\mathcal{S}}$ on c-row databases is implicitly defined through the sampling process below

1. Let $C' \leftarrow Gen'(n, 100d)$ (see Algorithm 1) where $C' \in \{0,1\}^{n \times d'}$ and $d' = d + 100d = 101d$. Note that Gen' also outputs π_R which is a public permutation on rows.
2. Let $C'_S = (x_1, \ldots, x_c) \in \{0,1\}^{c \times d'}$ be the first c rows of $C' \in \{0,1\}^{n \times d'}$
3. Output C'_S

Next we define the privacy adversary $\mathcal{B}$.

Adversary $\mathcal{B}$ Algorithm. Adversary $\mathcal{B}$ receives C'_S as input and does the following:

1. Create a database $D = (r_1, \ldots, r_n) \in \{0,1\}^{n \times d'}$ where each row $r_i \in \{0,1\}^{d'}$ consists of 0/1 entries sampled independently and uniformly at random.

2. Given oracle access to randomized algorithm $\mathcal{A}$ which solves $\mathcal{P}_{RO}$ on input D, $\mathcal{B}$ simulates the answer to the distinct i_j-th row query (where $j \in [c]$) made by $\mathcal{A}$ to random oracle H as follows:
   a. Return $H(i_j) := r_{i_j} \oplus x_j$.
3. Let $\mathbf{a}$ be the output of $\mathcal{A}(D)$ where $\mathbf{a} \in [0,1]^{d'}$. Round each entry of $\mathbf{a}$ to $\{0,1\}$, call this new vector $\bar{\mathbf{a}} \in \{0,1\}^{d'}$.
4. Output $Trace'(\bar{\mathbf{a}})$

Analysis. We focus on proving that Property 1 and Property 2 of the theorem statement are indeed satisfied by adversary $\mathcal{B}$.

Recall the notation in Definition 13 where $\mathcal{P}_{RO}(C')$ means that $\mathcal{P}_{RO}$ releases the one-way marginals of the underlying dataset C'. We first show that $\mathcal{A}$ solving $\mathcal{P}_{RO}(H(D))$ is perfectly indistinguishable from $\mathcal{A}$ solving $\mathcal{P}_{RO}(C')$ in Lemma 16. This is necessary as $Trace'$ can only identify an individual in the coalition of size c with respect to the codebook C' produced by Gen'.

▶ **Lemma 16.** *$\mathcal{A}$ solving $\mathcal{P}_{RO}(H(D))$ is perfectly indistinguishable from $\mathcal{A}$ solving $\mathcal{P}_{RO}(C')$.*

Proof. We define the following experiments.

Real World.
1. Given $C' = (x_1, \ldots, x_n)$ where $(C', st') \leftarrow Gen'(\ell)$ with $\ell = 100d$, let $C'_S = (x_1, \ldots, x_c)$.
2. Create a database $D = (r_1, \ldots, r_n)$ where $r_i \in \{0,1\}^{d'}$ are random entries.
3. Let $\mathbf{a}$ be the output of $\mathcal{A}(D)$ where $\mathbf{a} \in [0,1]^{d'}$. Simulate H as follows:
   a. Let $i_1, \ldots, i_c$ be distinct queries made to H. For $j \in [c]$, fix $H(i_j) := r_{i_j} \oplus x_j$

Ideal World.
1. Given codebook $C' = (x_1, \ldots, x_n)$ where $(C', st') \leftarrow Gen'(\ell)$ with $\ell = 100d$, let $H(C') = (z_1, \ldots, z_n)$ (see Definition 13 for $H(\cdot)$ notation).
2. Let $\mathbf{a} \leftarrow \mathcal{A}(H(C'))$ where $\mathbf{a} \in [0,1]^{d'}$.
   a. Let $i_1, \ldots, i_c$ be distinct arbitrary queries made to H. For $j \in [c]$, H returns the following answer $H(i_j) := z_{i_j} \oplus x_j$

In the **Real World**, $\mathcal{A}$ is provided $D = (r_1, \ldots, r_n)$ as input (where D is generated in the same manner as by adversary $\mathcal{B}$), while the **Ideal World** is one in which $\mathcal{A}$ takes $H(C')$ as input. We show that $\mathcal{A}$ learns the same information in the **Real World** and the **Ideal World**, i.e., these views are perfectly indistinguishable. Observe that the only difference from the viewpoint of $\mathcal{A}$ between the **Real World** and the **Ideal World** is that H is simulated in the former via indices fixed by C'_S whereas H is queried on arbitrary indices in the latter. Since the rows of C' have already been permuted (recall Algorithm 1), by nature of the random oracle H, these two instances are perfectly indistinguishable. ◀

Recall that the security condition of the fingerprinting code (see Definition 5) only holds if $\bar{\mathbf{a}}$ is a feasible codeword for the coalition of rows, i.e., C'_S in our case. The following lemma states that if $\mathcal{A}$ is accurate for $\mathcal{P}_{RO}(C')$, then the rounded output of $\mathcal{A}$ is indeed a feasible codeword for both C' and C'_S.

▶ **Lemma 17.** *Suppose $\mathcal{A}$ is $(1/3, 1/3)$-accurate for $\mathcal{P}_{RO}(C')$. Then the rounded output $\bar{\mathbf{a}}$ from algorithm $\mathcal{A}$ is a feasible codeword for both C' and C'_S with probability at least $1 - \frac{1}{3} - \frac{1}{100}$.*

In other words, with probability at least $1 - \frac{1}{3} - \frac{1}{100}$, $\bar{\mathbf{a}} \in F(C')$ and $\bar{\mathbf{a}} \in F(C'_S)$.

Proof. Assuming that $\mathcal{A}$ is $(1/3, 1/3)$-accurate for $\mathcal{P}_{RO}(C')$, we first show that $\bar{\mathbf{a}}$ is a feasible codeword for C' with probability at least $2/3$. By the accuracy guarantee of $\mathcal{A}$, we know that for any column i_j $|\mathbf{a}_{i_j} - a_{i_j}| \leq 1/3$ where a_{i_j} is the actual 1-way marginal for column i_j with probability at least $2/3$. Thus for any column i_j of all 1's in C', $\mathbf{a}_{i_j} \geq 2/3$ which means $\bar{\mathbf{a}}_{i_j} = 1$, thus satisfying the marking condition. A similar argument holds for the case when a column is all 0's.

Next, using the fact that we use a PR-PPC $(n, d, c, 100d)$-FPC and that $\bar{\mathbf{a}} \in F(C')$ with probability at least $2/3$, we can invoke Lemma 12 which states that the feasible sample property is satisfied by our PR-PPC FPC construction. Note that in our case, the sampling algorithm described in Definition 11 is $\mathcal{A}$ together with the postprocessing step of rounding the output of $\mathcal{A}$. Also, even though $\mathcal{A}$ takes the entire dataset as input, it effectively only has access to the rows of the underlying sample via queries to $\mathcal{B}$ and thus satisfies the properties required in Definition 11. Lemma 12 states that with probability $\leq \frac{1}{100}$, $\bar{\mathbf{a}}$ is not a feasible codeword for C'_S. By a union bound we have that $1 - \frac{1}{3} - \frac{1}{100}$, $\bar{\mathbf{a}}$ must be a feasible codeword for C'_S. ◀

Proof of Theorem 15. From the above Lemma 17, we have that $\mathcal{A}$ is $(1/3, 1/3)$-accurate for $\mathcal{P}_{RO}(C')$ implies that $\bar{\mathbf{a}}$ is a feasible codeword for C'_S. By the security of the fingerprinting code, Corollary 10 and Lemma 16, we have that $\Pr[\bar{\mathbf{a}} \in F(C'_S) \wedge Trace'(\bar{\mathbf{a}}) = \perp] \leq \xi$. Since $\mathcal{B}$ releases the output of $Trace'(\bar{\mathbf{a}})$, the event $\mathcal{B}^{\mathcal{A}}(C'_S) = \perp$ is identical to $Trace'(\bar{\mathbf{a}}) = \perp$. Thus Property 1 of the theorem statement which states that the probability that $\mathcal{B}$ outputs $\perp$ is bounded by ξ follows. Property 2 follows directly from the soundness property of the fingerprinting code. ◀

▶ **Lemma 18.** *Suppose there exists a distribution on $c \leq n$ row databases $\mathcal{C}_{\mathcal{S}}$ according to Theorem 15. Then there is no (ε, δ)-DP algorithm $\mathcal{A}$ with query complexity c that is $(1/3, 1/3)$-accurate for $\mathcal{P}_{RO}$ with $\varepsilon = O(1)$ and $\delta = o(1/c)$.*

Proof. Suppose C'_S is sampled from the distribution on c-row databases $\mathcal{C}_{\mathcal{S}}$ and $\mathcal{B}$ is the adversary from Theorem 15. From the lemma statement we know that $\mathcal{A}$ is $(1/3, 1/3)$-accurate, thus using Lemma 17 and Theorem 15, we have that $\Pr[\pi_R(\mathcal{B}^{\mathcal{A}}(C'_S)) \in [c]] \geq 1 - \frac{1}{3} - \frac{1}{100} - \xi \geq \Omega(1)$. By an averaging argument, this means that there exists some $i^* \in [c]$ for which $\Pr[\pi_R(\mathcal{B}^{\mathcal{A}}(C'_S)) = i^*] \geq \Omega(1/c)$. However, if $\xi = o(1/c)$ by Property 2 in Theorem 15 we have that $\Pr[\pi_R(\mathcal{B}^{\mathcal{A}}(C'_{S_{-i^*}})) = i^*] \leq \xi = o(1/c)$.

In other words, the probability of $\mathcal{B}^{\mathcal{A}}$ outputting a fixed output i^* on neighboring input databases C'_S and $C'_{S_{-i^*}}$ is different, which violates (ε, δ)-DP for any $\varepsilon = O(1)$ and $\delta = o(1/c)$. We note here that since $\mathcal{A}$ can make at most c row queries, the DP guarantee for $\mathcal{A}$ must hold for any neighboring sample of c rows. Since $\mathcal{B}$ does some postprocessing of the output from $\mathcal{A}$, and we have shown that $\mathcal{B}$ cannot be (ε, δ)-DP, this implies that $\mathcal{A}$ cannot be (ε, δ)-DP for any $\varepsilon = O(1)$ and $\delta = o(1/c)$. ◀

5.2 Using a Secret Sharing Encoding

In this section, we remove the requirement of an algorithm querying an entire row that we enforced in the previous section. We first define the security requirement of a general encoding scheme that is sufficient to construct our DP lower bound in Definition 19. We then show that the Shamir encoding as defined in Definition 20 satisfies the security requirement (see Theorem 23). We define a problem based on this secret sharing encoding called $\mathcal{P}_{SS}$ (see Definition 21) that uses the encoding to release the one-way marginals of an underlying dataset. Finally, we show that this problem cannot have a sublinear time DP algorithm with reasonable accuracy (see Theorem 26).

▶ **Definition 19** (Security Game). *Let* $\mathtt{Exp}(\mathsf{Enc}_d, \mathcal{A}, q, d, x)$ *denote the following experiment: (1) the challenger computes* $y_0 \leftarrow \mathsf{Enc}_d(x)$ *and* $y_1 \leftarrow \mathsf{Enc}_d(0^d)$*, picks a random bit* b *and outputs* $y = y_b$*. (2)* $\mathcal{A}^y(d, q, x)$ *is given oracle access to* y *and may make up to* q *queries to the string* y*. (3) The game ends when the attacker* $\mathcal{A}$ *outputs a guess* b'*. (4) The output of the experiment is* $\mathtt{Exp}(\mathsf{Enc}_d, \mathcal{A}, q, d, x) = 1$ *if* $b' = b$ *and the attacker made at most* q *queries to* y*; otherwise the output of the experiment is* $\mathtt{Exp}(\mathcal{A}, q, d, x) = 0$*. We say that the scheme* Enc_d *is* $(q(d), d, \gamma(q, d))$*-secure if for all* $x \in \{0,1\}^d$ *and all attackers* $\mathcal{A}$ *making at most* q *queries we have*

$$\Pr[\mathtt{Exp}(\mathsf{Enc}_d, \mathcal{A}, q, d, x) = 1] \leq \frac{1}{2} + \gamma(q, d)$$

▶ **Definition 20** (Shamir Encoding). *Given a row* $x_i \in \{0,1\}^d$ *where* $i \in [n]$ *and a field* $\mathbb{F}$ *s.t.* $|\mathbb{F}| > 4d$ *let* $SS_d(x_i)$ *be the following encoding (1) pick random field elements* $\alpha_1^{(i)}, \ldots, \alpha_d^{(i)}, \alpha_{d+1}^{(i)}, \ldots, \alpha_{3d}^{(i)}$ *(distinct) and* $z_{d+1}^{(i)}, \ldots, z_{2d}^{(i)}$ *and define the polynomial* $p_i(\cdot)$ *of degree* $2d-1$ *s.t.* $p_i(\alpha_j^{(i)}) = x_j$ *and* $p_i(\alpha_{d+j}^{(i)}) = z_{d+j}^{(i)}$ *for* $j \leq d$*. (2) publish* $SS_d(x_i) = \left(\alpha_1^{(i)}, \ldots, \alpha_d^{(i)}, \{(\alpha_j^{(i)}, p_i(\alpha_j^{(i)}))\}_{j=d+1}^{3d}\right)$ *as share of* x_i*.*

▶ **Definition 21** (Secret Sharing Problem $\mathcal{P}_{SS}$). *Let dataset* $D := (x_1, \ldots, x_n) \in \{0,1\}^{n \times d}$*. Given* $D_S := (SS_d(x_1), \ldots, SS_d(x_n))$*, the goal of the secret-sharing problem* $\mathcal{P}_{SS}$ *is to release all the one-way marginals of dataset* D*.*

We use $\mathcal{P}_{SS,d}(D)$ *to denote that* $\mathcal{P}_{SS}$ *releases the one-way marginals of the underlying dataset* D *with dimension* d*.*

Query Model. On input D_S, an algorithm solving the $\mathcal{P}_{SS}$ problem can make attribute queries to obtain the underlying dataset D and release its one-way marginals. For a row $i \in [n]$, the i_j-th attribute query returns the pair of field elements $(\alpha_{j+d}^{(i)}, p(\alpha_{j+d}^{(i)}))$ of share $SS_d(x_i)$ for $1 \leq j \leq 2d$. We note that the prefix of $SS_d(x_i)$ given by $\alpha_1^{(i)}, \ldots, \alpha_d^{(i)}$ is published separately after an attribute query for the row i has been queried. In other words, the prefix does not count towards the query complexity of the algorithm.

▶ Remark 22. We remark that one can also define a different query model in which the prefix is released to the adversary whenever the i-th row is queried and our results still hold.

For completeness, we first show that the Shamir encoding SS_d defined in Definition 20 is $(q(d), d, 0)$-secure (as defined in Definition 19) where $q(d) = d$.

▶ **Theorem 23.** *The scheme* SS_d *is* $(d, d, 0)$*-secure.*

Proof. Let $x \in \{0,1\}^d$ and field $\mathbb{F}$ s.t. $|\mathbb{F}| > 4d$. Recall the secret sharing scheme $SS_d(x) = (\alpha_1, \ldots, \alpha_d, \{(\alpha_j, p(\alpha_j))\}_{j=d+1}^{3d})$ defined in Definition 20. We describe two experiments below where the Real World experiment simulates the view of the adversary and the Ideal World experiment just randomly outputs field elements. We will show that these two experiments are perfectly indistinguishable, and the security claim follows.

Real World(x).

1. Query $SS_d(x)$ for the first $q(d) = d$ pairs of coordinates and let the answers be the prefix $\alpha_1, \ldots \alpha_d$ and $\{(\alpha_{j+d}, z_{j+d})\}_{j \in [d]}$.
2. Output $\alpha_1, \ldots \alpha_d$ and $\{(\alpha_{j+d}, z_{j+d})\}_{j \in [d]}$

Ideal World(x).
1. Uniformly sample $\alpha'_1, \ldots, \alpha'_d, \alpha'_{d+1}, \ldots, \alpha'_{2d}, r_{d+1}, \ldots, r_{2d}$ from $\mathbb{F}$.
2. Output $\alpha'_1, \ldots \alpha'_d$ and $\{(\alpha'_{j+d}, r_{j+d})\}_{j\in[d]}$

Since by construction, the first d pairs of coordinates returned by SS_d and the prefix of size d correspond to $3d$ random field elements, the view of the **Real World** is therefore just the uniform distribution on $3d$ field elements and thus is identical to that of the view of the **Ideal World**. ◀

We present our main lower bound result in Theorem 26. Before we proceed, we first demonstrate the existence of a DP linear-time algorithm and non-DP sublinear-time algorithm for $\mathcal{P}_{SS}$ below.

▶ **Theorem 24.** *There exists a (ε, δ)-DP algorithm that solves the problem $\mathcal{P}_{SS}$ with $O(d\sqrt{d})$ attribute query complexity and $(1/10, 1/10)$-accuracy.*

Proof. On input D_S, the algorithm queries the entire dataset via attribute queries, i.e., it makes $dn = O(d\sqrt{d})$ queries. Given $SS(x_i) = (\alpha_1^{(i)}, \ldots, \alpha_d^{(i)}, \{(\alpha_j^{(i)}, p_i(\alpha_j^{(i)}))\}_{j=d+1}^{3d})$ for a row $i \in [n]$, the algorithm first recovers the polynomial p_i of degree $2d-1$ by doing Lagrange Interpolation over the $2d$ points given by $\{(\alpha_j^{(i)}, p_i(\alpha_j^{(i)}))\}_{j=d+1}^{3d}$. Then the original row x_i is obtained by evaluating $(p_i(\alpha_1^{(i)}), \ldots, p_i(\alpha_d^{(i)}))$. Once the original rows $x_i, \ldots, x_n$ are recovered in this manner, the algorithm can release the one-way marginals by adding Gaussian noise as detailed in Lemma 9. ◀

▶ **Theorem 25.** *There exists a sublinear-time algorithm that solves the problem $\mathcal{P}_{SS}$ with s attribute query complexity $O(d \log d)$ and $(1/10, 1/10)$-accuracy.*

Proof. The algorithm makes $O(d \log d)$ attribute queries and performs the same decoding procedure as outlined in the proof of Theorem 24 to obtain the underlying $\log(d)$ rows and computes the one-way marginals on this subset of rows. The accuracy of this algorithm is a simple corollary of Hoeffding bounds. Recall that $n \in \Omega(\sqrt{d})$, so the problem size is $\Omega(d\sqrt{d})$. ◀

▶ **Theorem 26** (Main Theorem). *Any algorithm that solves the problem $\mathcal{P}_{SS}$ with s attribute query complexity, $(1/3, 1/3)$-accuracy and $(O(1), o(1/n))$-DP must have $s = \Omega(d\sqrt{d/\log(d)})$.*

In order to prove Theorem 26, we follow a similar strategy as presented in the warm-up Section 5.1. Given an (n, d, c)-FPC, we first show how to construct a c-row distribution and an adversary $\mathcal{B}$ that can identify a user in the coalition of size c in Theorem 27.

▶ **Theorem 27.** *For every $n, d \in \mathbb{N}$, $\xi \in [0, 1]$ and $c \leq n$, if there exists an (n, d, c)-fingerprinting code with security ξ, then there exists a distribution on c-row databases $\mathcal{C}_\mathcal{S}$, a row permutation $\pi_R : [n] \to [n]$ and an adversary $\mathcal{B}$ for every randomized algorithm $\mathcal{A}$ with attribute query complexity cd' and $(1/3, 1/3)$-accuracy for $\mathcal{P}_{SS}$ such that*
1. $\Pr_{C'_S \leftarrow \mathcal{C}_\mathcal{S}}[\mathcal{B}^\mathcal{A}(C'_S) = \perp] \leq \xi$
2. *For every $i \in [c]$, $\Pr_{C'_S \leftarrow \mathcal{C}_\mathcal{S}}[\mathcal{B}^\mathcal{A}(C'_{S_{-i}}) = \pi_R^{-1}(i)] \leq \xi$.*

where $d' = 101d$ and the probability is over the random coins of $\mathcal{B}$ and the choice of C'_S.

Let $(Gen, Trace)$ be the promised (n, d, c)-fingerprinting code in the theorem statement. We first construct a PR-PPC (n, d, c, ℓ)-FPC with $\ell := 100d$ (see Section 4 for details).

The distribution $\mathcal{C}_\mathcal{S}$ on c-row databases is implicitly defined through the sampling process below:

1. Let $C' \leftarrow Gen'(n, d')$ (see Algorithm 1) where $C' \in \{0,1\}^{n \times d'}$ and $d' = 101d$.
2. Let $C'_S = (x_1, \ldots, x_c) \in \{0,1\}^{c \times d'}$ be the first c rows of $C' \in \{0,1\}^{n \times d'}$
3. Output C'_S

Next we define the privacy adversary $\mathcal{B}$.

Adversary $\mathcal{B}$ Algorithm. Let $\mathbb{F}$ be a finite field of order q' where $q' > 4d'$. Adversary $\mathcal{B}$ receives $C'_S = (x_1, \ldots, x_c)$ as input and feeds the algorithm $\mathcal{A}$ an input instance $C'_{\mathcal{B}}$ of $\mathcal{P}_{SS,d'}(C')$ by simulating answers to attribute queries made by $\mathcal{A}$ as described in Step 2a below. $\mathcal{B}$ then uses the rounded answer returned by $\mathcal{A}$ (Step 2b) to obtain an individual in the coalition by invoking $Trace'$ in Step 2c.

1. Initialize $q_i = 0$ for each row $i \in [n]$ and initialize a counter $t = 0$.
2. Simulate the oracle algorithm $\mathcal{A}$ with query access to an $(n \times 2d')$ database $C'_{\mathcal{B}}$:
   a. When $\mathcal{A}$ makes a fresh query (i, j), update $q_i = q_i + 1$ and
      - If $q_i \leq d'$, then set $b = q_i + d'$. Respond with a random pair of field elements $(\alpha_b^{(i)}, z_b^i)$. Record this tuple.
      - If $q_i = d' + 1$, then
        i. Increment t by one.
        ii. Define the entire polynomial p_i randomly, subject to the constraints that it is consistent with row x_t and the previous responses sent for row i: $p_i(\alpha_j^{(i)}) = x_{t,j}$ for $j \leq d'$ and $p_i(\alpha_b^{(i)}) = z_b^i$ for $j > d'$.
        iii. Send $\mathcal{A}$ the response $(\alpha_{j+d'}^{(i)}, p_i(\alpha_{j+d'}^{(i)}))$.
      - If $q_i > d' + 1$, then the polynomial p_i is already defined. Send the response $(\alpha_{j+d'}^{(i)}, p_i(\alpha_{j+d'}^{(i)}))$.
   b. When $\mathcal{A}$ outputs a vector $\mathbf{a} \in [0,1]^{d'}$, round its entries to $0, 1$ and call it $\bar{\mathbf{a}} \in \{0,1\}^{d'}$.
   c. Return $Trace'(\bar{\mathbf{a}})$.

We emphasize that although algorithm $\mathcal{A}$ can make attribute queries to more than c rows, the adversary $\mathcal{B}$ never defines a secret sharing polynomial for more than $t \leq c$ rows of the input C'_S.

▶ **Lemma 28.** *Suppose $\mathcal{A}$ is $(1/3, 1/3)$-accurate for $\mathcal{P}_{SS,d'}(C')$. Then the rounded output $\bar{\mathbf{a}}$ from algorithm $\mathcal{A}$ is a feasible codeword for both C' and C'_S with probability at least $1 - \frac{1}{3} - \frac{1}{100}$.*

In other words, with probability at least $1 - \frac{1}{3} - \frac{1}{100}$, $\bar{\mathbf{a}} \in F(C')$ and $\bar{\mathbf{a}} \in F(C'_S)$.

Proof. Assuming that $\mathcal{A}$ is $(1/3, 1/3)$-accurate for $\mathcal{P}_{SS,d'}(C')$, we first show that $\bar{\mathbf{a}}$ is a feasible codeword for C' with probability at least $2/3$. By the accuracy guarantee of $\mathcal{A}$, we know that for any column i_j with probability at least $2/3$, $|\mathbf{a}_{i_j} - a_{i_j}| \leq 1/3$ where a_{i_j} is the actual one-way marginal for column i_j. Thus for any column i_j of all 1's in C', $\mathbf{a}_{i_j} \geq 2/3$ which means $\bar{\mathbf{a}}_{i_j} = 1$, thus satisfying the marking condition. A similar argument holds for the case when a column is all 0's.

Next, using the fact that we use a PR-PPC $(n, d, c, 100d)$-FPC and that $\bar{\mathbf{a}} \in F(C')$ with probability at least $2/3$, we can invoke Lemma 12 which states that the feasible sample property is satisfied by our PR-PPC FPC construction. Note that in our case, the sampling algorithm described in Definition 11 is $\mathcal{A}$ together with the postprocessing step of rounding the output of $\mathcal{A}$. Also, even though $\mathcal{A}$ takes the entire dataset as input, it effectively only has access to the rows of the underlying sample via queries to $\mathcal{B}$ and thus satisfies the properties required in Definition 11. In particular, recall that the adversary maintains the invariant $t \leq c$. Lemma 12 states that with probability $\leq \frac{1}{100}$, $\bar{\mathbf{a}}$ is not a feasible codeword for C'_S. By a union bound we have that $1 - \frac{1}{3} - \frac{1}{100}$, $\bar{\mathbf{a}}$ must be a feasible codeword for C'_S. ◀

Proof of Theorem 27. From the above Lemma 28, we have that $\mathcal{A}$ is $(1/3, 1/3)$-accurate for $\mathcal{P}_{SS,d'}(C')$ implies that $\bar{\mathbf{a}}$ is a feasible codeword for C'_S. By the security of the underlying (n, d, c)-fingerprinting code and the corresponding security guarantee of the PR-PPC $(n, d, c, 100d)$-FPC given by Corollary 10, we have that $\Pr[\bar{\mathbf{a}} \in F(C'_S) \wedge Trace'(\bar{\mathbf{a}}) = \perp] \leq \xi$. Since $\mathcal{B}$ releases the output of $Trace'(\bar{\mathbf{a}})$, the event $\mathcal{B}^{\mathcal{A}}(C'_S) = \perp$ is identical to $Trace'(\bar{\mathbf{a}}) = \perp$. Thus Property 1 of the theorem statement which states that the probability that $\mathcal{B}$ outputs $\perp$ is bounded by ξ follows. Property 2 follows directly from the soundness property of the fingerprinting code. ◀

▶ **Corollary 29.** *$\mathcal{A}$ must make at least $c \cdot d'$ attribute queries to $C_{\mathcal{B}}$ to obtain c rows of C'_S where $d' = 101d$.*

Proof. Recall that Theorem 23 states that $SS_{d'}$ is $(d', d', 0)$-secure where $d' = 101d$. Thus, in order to obtain each row of C'_S, $\mathcal{A}$ must make at least d' cell queries. The statement follows from the fact that $\mathcal{A}$ queries for c rows in total. ◀

▶ **Lemma 30.** *Suppose there exists a distribution on $c \leq n$ row databases according to Theorem 27. Then there is no (ε, δ)-DP algorithm $\mathcal{A}$ with row query complexity c that is $(1/3, 1/3)$-accurate for $\mathcal{P}_{SS}$ with $\varepsilon = O(1)$ and $\delta = o(1/c)$.*

Proof. Suppose C'_S is sampled from the distribution on c-row databases $\mathcal{C}_{\mathcal{S}}$ and $\mathcal{B}$ is the adversary from Theorem 27. From the lemma statement we know that $\mathcal{A}$ is $(1/3, 1/3)$-accurate, thus using Lemma 28 and Theorem 27, we have that $\Pr[\pi_R(\mathcal{B}^{\mathcal{A}}(C'_S)) \in [c]] \geq 1 - \frac{1}{3} - \frac{1}{100} - \xi \geq \Omega(1)$. By an averaging argument, this means that there exists some $i^* \in [c]$ for which $\Pr[\pi_R(\mathcal{B}^{\mathcal{A}}(C'_S)) = i^*] \geq \Omega(1/c)$. However, if $\xi = o(1/c)$ by Property 2 in Theorem 27 we have that $\Pr[\pi_R(\mathcal{B}^{\mathcal{A}}(C'_{S_{-i^*}})) = i^*] \leq \xi = o(1/c)$.

In other words, the probability of $\mathcal{B}^{\mathcal{A}}$ outputting a fixed output i^* on neighboring input databases C'_S and $C'_{S_{-i^*}}$ is different which violates (ε, δ)-DP for any $\varepsilon = O(1)$ and $\delta = o(1/c)$. We note here that since $\mathcal{A}$ can make at most c row queries, the DP guarantee for $\mathcal{A}$ must hold for any neighboring sample of c rows. Since $\mathcal{B}$ does some postprocessing of the output from $\mathcal{A}$, and we have shown that $\mathcal{B}$ cannot be (ε, δ)-DP, this implies that $\mathcal{A}$ cannot be (ε, δ)-DP for any $\varepsilon = O(1)$ and $\delta = o(1/c)$. ◀

Proof of Theorem 26 . Recall that Lemma 30 states that if there exists a distribution $\mathcal{C}_{\mathcal{S}}$ on $c \leq n$ row databases, then there is no (ε, δ)-DP algorithm $\mathcal{A}$ that is $(1/3, 1/3)$-accurate for $\mathcal{P}_{SS}$ with $\varepsilon = O(1)$ and $\delta = o(1/c)$. From Theorem 27, such a distribution can be constructed from an (n, d, c)-fingerprinting code. Finally, invoking the Tardos construction for fingerprinting codes in Theorem 7, we get that the row query complexity must be $c = \Omega(\sqrt{d/\log(d)})$. Using Corollary 29, we know that the cell query complexity must be at least $c \cdot d' \geq \Omega(d\sqrt{d/\log(d)})$ where $d' = 101d$. ◀

Estimating Euclidean Distance to Linearity

Andrej Bogdanov
University of Ottawa, Canada

Lorenzo Taschin
EPFL, Lausanne, Switzerland

Abstract

Given oracle access to a real-valued function on the n-dimensional Boolean cube, how many queries does it take to estimate the squared Euclidean distance to its closest linear function within ϵ? Our main result is that $O(\log^3(1/\epsilon) \cdot 1/\epsilon^2)$ queries suffice. Not only is the query complexity independent of n but it is optimal up to the polylogarithmic factor.

Our estimator evaluates f on pairs correlated by noise rates chosen to cancel out the low-degree contributions to f while leaving the linear part intact. The query complexity is optimized when the noise rates are multiples of Chebyshev nodes.

In contrast, we show that the dependence on n is unavoidable in two closely related settings. For estimation from random samples, $\Theta(\sqrt{n}/\epsilon + 1/\epsilon^2)$ samples are necessary and sufficient. For agnostically learning a linear approximation with ϵ mean-square regret under the uniform distribution, $\Omega(n/\sqrt{\epsilon})$ nonadaptively chosen queries are necessary, while $O(n/\epsilon)$ random samples are known to be sufficient (Linial, Mansour, and Nisan).

Our upper bounds apply to functions with bounded 4-norm. Our lower bounds apply even to ± 1-valued functions.

1 Introduction

Finding linear approximations is perhaps the most important problem in statistics and data science. *Linear regression* [11, Section 9.2] seeks to learn the "best" linear predictor ℓ for f from labeled data $(x, f(x))$. Owing to its wide applicability and computational advantages, approximation error is often measured as the minimum squared loss $\mathbf{E}[(f(x) - \ell(x))^2]$ under some distribution on examples.

Our main question of interest is whether *estimating* the minimum squared loss can be performed more efficiently than learning the predictor. A highly efficient estimator can be potentially used to decide whether learning a linear model is sensible at all.

We aim to highlight the conceptual distinctions between estimation and learning. We demonstrate that a complexity gap between the two problems is already exhibited by arguably the simplest distribution on examples: The uniform distribution over the Boolean cube $\{\pm 1\}^n$.

Under the uniform distribution, the minimum squared loss is the distance between the function of interest viewed as a vector in 2^n-dimensional Euclidean space and the n-dimensional subspace spanned by the linear functions. In this setting estimating the squared distance is essentially equivalent to estimating the squared length of the projection.

The power of linear regression in machine learning applications is derived to a great extent from the distribution-free nature of the training algorithms. In contrast our results concern linear regression for a known distribution. We believe that distribution-specific regression is interesting for several reasons.

First, restrictive assumptions on the data distribution may improve performance. For example, distributions in which some features linearly approximate other features can be problematic for popular algorithms like gradient descent. The uniform distribution, as a model of pairwise independence, avoids such obstacles.

Second, distribution-specific algorithms sometimes serve as a stepping stone to distribution-free ones. In the context of property testing this strategy was successful in obtaining distribution-free algorithms for combinatorial properties like monotonicity [6] as well as algebraic ones like linearity and low-degree representability [6, 5].

Third, negative results about learning and estimation are stronger in the distribution-specific model. Distribution-free learning must succeed for all concepts in the given class *and* all distributions on examples. To understand the limitations it is natural to decouple the complexities of the concept class and of the distribution. Do learning and estimation remain hard even when the distribution is simple?

In this work we focus on information-theoretic measures of complexity. Our principal measure of performance is the *query complexity* m. The time complexity of all our algorithms is linear in mn, namely in the size of the labeled dataset. We study both algorithms that choose their queries and ones that are provided with uniformly random examples.

Our results

Our results are summarized in Table 1. Our main contribution is Theorem 1: The squared linear projection of f

$$\mathbf{W}^1[f] = \mathbf{E}[f^2] - \min_{\text{linear } \ell} \mathbf{E}[(f(x) - \ell(x))^2] \tag{1}$$

can be estimated within ϵ with $\tilde{O}(1/\epsilon^2)$ chosen queries.[1] In contrast, learning the requisite approximation and obtaining the same estimate from random samples both entail queries that grow at least as fast as some root of n.

Table 1 Query complexity of ϵ-estimating $\mathbf{W}^1[f]$ and ϵ-learning the linear part of f. All positive results assume $\|f\|_4 \leq 1$. All negative results hold even for ± 1-valued f.

	chosen queries	random samples
estimation	$O(\log^3(1/\epsilon) \cdot 1/\epsilon^2)$ (Theorem 1) $\Omega(1/\epsilon^2)$ (Theorem 8)	$O(\sqrt{n}/\epsilon + 1/\epsilon^2)$ (Theorem 18) $\Omega(\sqrt{n}/\epsilon + 1/\epsilon^2)$ (Theorem 19 + 8)
learning	$O(n/\epsilon)$ [8] $\Omega(n/\sqrt{\epsilon})$ non-adaptive (Theorem 11)	$O(n/\epsilon)$ [8] $\Omega(n/\sqrt{\epsilon})$ (Theorem 11)

[1] The query complexities of the squared projection and the squared distance to linearity are the same up to constant factor since $\mathbf{E}[f^2]$ can be estimated from $O(1/\epsilon^2)$ samples assuming $\|f\|_4$ is bounded. For similar reasons so are the squared projection and distance to the space of affine functions.

We found this result surprising from a Fourier-analytic perspective. Our quantity of interest is the sum of squares of all n first-level Fourier coefficients of f. Up to the polylogarithmic factor, estimating the sum has the same query complexity as estimating any of its individual terms, or estimating the squared mean of f.

In the decision version of estimation also known as *tolerant testing* [10], the objective is to distinguish functions that are θ-close to linear from those that are $\theta + \epsilon$-far. In particular, the algorithm of Theorem 1 is a tolerant tester for any value of θ. In the intolerant limit $\theta = 0$, algorithms with $O(1/\epsilon)$ query complexity are known [1, 3]. For functions over $\mathbb{R}^n$ the query complexity is also $O(1/\epsilon)$ under Gaussian measure [7], and $O(\log(1/\epsilon) \cdot 1/\epsilon)$ under arbitrary measure [5]. With the exception of [7], these testers appear not to be robust against small perturbations as their soundness is analyzed with respect to the Hamming distance. The tester of Khot and Moshkovitz [7] can be viewed as an estimator, albeit one with large constant bias.

Our positive results apply to functions with bounded 4-norm. Boundedness of the 2-norm is clearly insufficient: The point function $f(x) = 2^n \mathbb{1}(x = a)$ for a random point a has unit 2-norm and unit squared distance to linearity, yet is indistinguishable from the all-zero function with $o(2^n)$ queries. We did not investigate whether p-norm boundedness for $2 < p < 4$ is sufficient.

In contrast, in Theorem 11 we show that proper learning of a linear hypothesis for f that is within ϵ squared distance of optimal has non-adaptive query complexity linear in n, specifically $\Omega(n/\sqrt{\epsilon})$. Our technique also yields a $\Omega(\log n/\sqrt{\epsilon})$ general (adaptive) lower bound. On the positive side, it is known that $O(n/\epsilon)$ random samples are sufficient for learning via empirical risk mininization [8]. The $\sqrt{\epsilon}$ gap between the lower and upper bounds is reminiscent of analogous gaps in distribution-free agnostic learning of deterministic concept classes [2].

In Theorems 18 and 19 we show that the sample complexity of estimating $\mathbf{W}^1[f]$ is $\sqrt{n}/\epsilon + 1/\epsilon^2$ up to constant factor. As a consequence of Theorems 18 and 11, estimation requires fewer random samples than learning in the regime $\epsilon = \omega(n^{-2/3})$.

Techniques

Estimation from chosen queries

Algorithm 1 estimates the linear projection of f by a suitably scaled product $f(x)f(y)$ evaluated on a pair (x, y) of correlated inputs. The query complexity can be decoupled from the input length n already when the pairs (x_i, y_i) are independent, marginally uniform, and of sufficiently low correlation $\rho = \mathbf{E}\, x_i y_i$. For simplicity assume f is unbiased and ± 1-valued. By orthogonal decomposition (see (2)),

$$\mathbf{E}\, f(x)f(y) = \rho\|f^{=1}\|^2 + \rho^2\|f^{=2}\|^2 + \cdots + \rho^n\|f^{=n}\|^2,$$

where $f^{=d}$ is the degree-d part of f (see precise definition in Section 2). By Parseval's identity, $\rho^{-1}f(x)f(y)$ estimates $\mathbf{W}^1[f] = \|f^{=1}\|^2$ with bias at most $\sum_{k>1}|\rho|^{k-1}\|f^{=k}\|^2 \le |\rho|$. By choosing the bias-variance tradeoff $\rho \approx \epsilon/2$, empirically averaging this estimator yields an ϵ-approximation of $\mathbf{W}^1[f]$ with $O(1/\epsilon^4)$ queries.

To improve the query complexity we work with a more general class of distributions on pairs (x, y). Barring additional information on f, it is sensible that the distribution should place equal probability on all pairs (x, y) whose difference has fixed Hamming weight. A special class of such distibutions is mixtures of ρ-correlated pairs over some distribution $d(\rho)$ on noise rates.

The uniform mixture of ρ and $-\rho$-correlated pairs already improves the query complexity to $O(1/\epsilon^3)$. The reason is that the related Fourier decomposition

$$\mathbf{E}\ (\text{sign of correlation}) f(x)f(y) = \rho\|f^{=1}\|^2 + \rho^3\|f^{=3}\|^2 + \rho^5\|f^{=5}\|^2 + \cdots$$

cancels out all even levels, thus reducing the bias of the estimator from ρ to ρ^2.

To achieve our query complexity of $O(\log^3(1/\epsilon)1/\epsilon^2)$ we construct a mixture of noise rates $\alpha_1\rho, \ldots, \alpha_\ell\rho$ that annihilates levels 2 up to $\ell - 1$ while minimizing the contribution of levels ℓ and higher. A close to optimal error is achieved using Chebyshev interpolation. We give evidence that a $\Omega(\log^2(1/\epsilon)1/\epsilon^2)$ lower bound is inherent in this approach (Claim 6), but we do not know if it can be bypassed in general.

In Remark 7 we explain why the low complexity of Algorithm 1 owes not only to the choice of interpolation scheme, but to some serendipity in the constraints (6) on the noise rates.

The proof of Theorem 8 is based on a reduction from the problem of estimating the bias of a coin.

Learning lower bound

Theorem 11 is proved in two steps. Proposition 12 addresses the regime of constant error ϵ. It is proved by exhibiting a family of $2^{\Omega(n)}$ functions whose linear projections are $\Omega(1)$-far apart. The existence of this family is established using the probabilistic method in Lemma 13. An algorithm of sublinear query complexity is unlikely to disambiguate among members of the family and cannot be accurate.

In Proposition 15 we give a self-reduction for learning linear approximations from query complexity q and constant error to query complexity $O(q/\sqrt{\epsilon})$ and error ϵ. The reduction applies to any query model.

Estimation from samples

The random variable $f(x)f(y)\langle x, y\rangle$ with random x, y is an unbiased estimator of $\mathbf{W}^1[f]$. To improve its variance at optimal query cost we average it over all $\binom{m}{2}$ pairs of examples (Algorithm 2 and Theorem 18). For constant ϵ, the lower bound in Theorem 19 is exhibited by a sign-rounded linear function ℓ with independent Gaussian coefficients. Such a function is weakly pseudorandom against $o(\sqrt{n})$ examples yet has constant correlation with ℓ. We achieve optimal dependence on ϵ by adding Gaussian noise to ℓ.

Extensions and future work

We believe that a result analogous to Theorem 1 can be obtained for functions over $\mathbb{R}^n$ under standard Gaussian measure using related techniques. It would be interesting to investigate the general setting of product distributions under Efron-Stein decomposition. The biased Boolean cube could be a good test case.

Theorem 1 can be extended to approximate the degree-d part of f with $\log^{O(d)}(1/\epsilon) \cdot 1/\epsilon^2$ queries. Both extensions might be sensible in the context of regression, where a mix of categorical (Boolean) and numerical (Gaussian) data and higher-degree models (capturing e.g. decision trees) are more realistic.

An interesting open question is whether the polylogarithmic factor can be eliminated. We speculate that this may be possible under the stronger assumption that f is bounded in infinity-norm.

Organization

Section 2 has a brief background on Fourier analysis of Boolean functions. In Sections 3, 4, and 5 we present our results on estimation from chosen queries, learning, and estimation from samples, respectively.

2 Fourier analysis over the Boolean cube

We use standard notation from Boolean function analysis [9]. All functions are real-valued over the Boolean cube $\{\pm 1\}^n$ under uniform measure. Such functions live in Hilbert space under inner product $\mathbf{E} fg$. The p-norm of a function is $\|f\|_p = \mathbf{E}[|f|^p]^{1/p}$, with $p = 2$ usually omitted. The monomials $\{\prod_{i\in S} x_i : S \subseteq [n]\}$ form an orthonormal basis. f admits orthogonal decompositions

$$f = f^{=0} + f^{=1} + \cdots + f^{=n} = \mathbf{E} f + f^{=1} + f^{\geq 2}$$

with $f^{=j}$ (resp., $f^{\geq j}$) being the projection onto the subspace spanned by monomials of degree exactly (resp., at least) j. Our main object of interest is the linear part $f^{=1}$, especially its weight

$$\mathbf{W}^1[f] = \|f^{=1}\|^2 = \mathbf{E} f f^{=1}.$$

The orthogonal decomposition can be further refined into the complete Fourier decomposition

$$f(x) = \sum\nolimits_{S\subseteq[n]} \hat{f}(S) \prod\nolimits_{i\in S} x_i, \qquad \text{where} \qquad \hat{f}(S) = \mathbf{E} f(x) \prod\nolimits_{i\in S} x_i.$$

By orthogonality, $\mathbf{E} fg = \sum \mathbf{E} f^{=i} g^{=i} = \sum \hat{f}(S)\hat{g}(S)$ (Plancherel's formula). In particular, when $f = g$

$$\|f\|^2 = \sum \|f^{=j}\|^2 = \sum \hat{f}(S)^2. \qquad \text{(Parseval's identity)}$$

By orthogonality, the distance to linearity $\mathbf{E}[(f(x) - \ell(x))^2]$ is minimized when $\ell = f^{=1}$. The minimizer equals

$$\min_{\text{linear } \ell} \mathbf{E}[(f(x) - \ell(x))^2] = \|f\|^2 - \|f^{=1}\|^2 = \mathbf{E}[f^2] - \mathbf{W}^1[f]$$

as in (1).

A ρ-biased string in $\{\pm 1\}^n$ is one in which the coordinates are independent and ρ-biased. We use $x \cdot y$ for the pointwise product of strings x and y in $\{\pm 1\}^n$. Multiplying by a ρ-biased string and averaging the outcome has the effect of dampening the higher-degree terms:

$$\mathbf{E}_{\rho\text{-biased } e}[f(x \cdot e)] = f^{=0}(x) + \rho f^{=1}(x) + \rho^2 f^{=2}(x) + \cdots \tag{2}$$

3 Estimation from chosen queries

▶ **Theorem 1.** *There is an algorithm that makes $O(\log(\|f\|_4^2/\epsilon)^3 \cdot \|f\|_4^4/\epsilon^2)$ queries to f and outputs a value within ϵ of $\mathbf{W}^1[f]$ with probability at least $2/3$.*

The algorithm takes the empirical average of m instantiations of Algorithm 1 with parameters $m = 96\ell^3/\epsilon'^2$, $\ell = \log 1/\epsilon' + 1$, $\rho = \epsilon'^{(\ell-1)^{-1}}/6$, and $\epsilon' = \epsilon/\|f\|_4^2$. (We may assume ϵ' is an inverse power of two as this doesn't change the asymptotics.)

Algorithm 1 Estimator $\tilde{W}^1[f]$ from chosen queries.

Parameters: $0 < \rho < 1$ and $\ell \in \mathbb{N}$
Setup: Set $\alpha_1, \ldots, \alpha_\ell \in [-1, 1]$ as in (5). Calculate $d_1, \ldots, d_\ell$ as in (6).
Sample i from $\{1, \ldots, \ell\}$ with probability $|d_i|/\|d\|_1$.
Sample random x and $\alpha_i\rho$-biased e_i.
Output $\tilde{W}^1[f] = \rho^{-1}\|d\|_1 \cdot \operatorname{sign} d_i \cdot f(x)f(x \cdot e_i)$

The conditional bias of this estimator given x is $f(x)g(x)$, where

$$g = \rho^{-1} \sum d_i N_{\alpha_i \rho} f(x).$$

Here N_ρ is the noise operator $N_\rho f(x) = \mathbf{E}[f(x \cdot e)]$ for a ρ-biased e. The constants d_i, α_i are chosen so that the first Fourier level of f survives but all other levels among the first $\ell - 1$ are annihilated:

$$g^{=j} = \begin{cases} 0, & \text{if } j = 0 \text{ or } 2 \le j < \ell \\ f^{=j}, & \text{if } j = 1 \end{cases} \tag{3}$$

The theorem is proved by balancing the bias and the variance of the estimator $\tilde{W}^1$. The next two claims bound the bias and the variance respectively. Their proofs are in Section 3.1.

▷ Claim 2. $|\mathbf{E}\,\tilde{W}^1[f] - \mathbf{W}^1[f]| \le \|d\|_1 \cdot \rho^{\ell-1}\|f^{\ge \ell}\|^2$.

▷ Claim 3. $\tilde{W}^1[f]$ has variance at most $\rho^{-2} \cdot \|d\|_1^2 \cdot \|f\|_4^4$.

The quantity $\|d\|_1$ governs both. We analyze it next. Expanding g in the Fourier basis and applying (2), the constraints (3) translate to

$$\rho^{-1} \sum_{i=1}^{\ell} d_i (\alpha_i \rho)^j = \begin{cases} 0, & \text{if } j = 0 \text{ or } 2 \le j < \ell \\ 1, & \text{if } j = 1. \end{cases}$$

We seek a short solution to the linear system

$$\sum_i d_i \alpha_i^j = \begin{cases} 0, & \text{if } j = 0 \text{ or } 2 \le j < \ell \\ 1, & \text{if } j = 1. \end{cases} \tag{4}$$

in unknowns $d_1, \ldots, d_\ell$. The existence of a short solution strongly depends on the choice of evaluation points $\alpha_1, \cdots, \alpha_\ell$. The Chebyshev nodes

$$\alpha_i = \cos\Big(\pi \frac{2i - 1}{2\ell}\Big) \tag{5}$$

are close to best possible for this purpose, as will be argued in Corollary 5 and Claim 6.

▷ Claim 4. $d_i = d(\alpha_i)$, where

$$d(t) = \frac{2}{\ell} \sum_{\text{odd } j\,=\,1}^{\ell-1} (-1)^{(j-1)/2} \cdot j T_j(t), \tag{6}$$

and T_j is the j-th Chebyshev polynomial of the first kind.

Proof. The first ℓ Chebyshev polynomials $T_0, \ldots, T_{\ell-1}$ are orthogonal with respect to inner product over the Chebyshev nodes:

$$\sum_i T_j(\alpha_i)T_{j'}(\alpha_i) = \begin{cases} 0, & \text{if } j \neq j', \\ \ell/2, & \text{if } j = j' \neq 0, \\ \ell, & \text{if } j = j' = 0. \end{cases}.$$

Using the facts $T_0(t) = 1, T_1(t) = t$, and that $T_j'(0)$ is zero for even j and $(-1)^{(j-1)/2}j$ for odd j we derive the unique Chebyshev expansion

$$d(t) = \sum \hat{d}(j)T_j(t). \tag{7}$$

By orthogonality, $\hat{d}(j)$ equals $(2/\ell)\sum d(\alpha_i)T_j(\alpha_i)$, when $j \neq 0$ and half that when $j = 0$. In the latter case, the first equation in (4) says that

$$\hat{d}(0) = \frac{1}{\ell}\sum_i d(\alpha_i)T_0(\alpha_i) = \frac{1}{\ell}\sum d_i = 0.$$

Otherwise, the polynomial $T_j(t) - T_j'(0)t$ has no linear term, so

$$\sum_i d(\alpha_i)(T_j(\alpha_i) - T_j'(0)\alpha_i)$$

expands as a linear combination of $\sum_i d_i\alpha_i^k$ for $k \leq j, k \neq 1$. By (4) such linear combinations vanish. Therefore if $j \neq 1$,

$$\hat{d}(j) = \frac{2}{\ell}\sum_i d_i T_j'(0)\alpha_i = \frac{2}{\ell}T_j'(0) = \begin{cases} (2/\ell)(-1)^{(j-1)/2} \cdot j, & \text{if } j \text{ is odd} \\ 0, & \text{if } j \text{ is even.} \end{cases}$$

Plugging into (7) produces the desired formula (6). ◁

▶ **Corollary 5.** $\|d\| \leq \ell$.

Proof. By orthogonality we have the explicit formula

$$\|d\|^2 = \ell\hat{d}(0)^2 + \frac{\ell}{2}\hat{d}(1)^2 + \cdots + \frac{\ell}{2}\hat{d}(\ell-1)^2 = \frac{2}{\ell}\sum_{\text{odd } j\,=\,1}^{\ell-1} j^2,$$

which is at most twice the sum of odd integers between 1 and ℓ. Those can be matched into $\ell/2$ pairs that add up to ℓ giving the ℓ^2 upper bound. ◀

Therefore $\|d\|_1 \leq \ell^{3/2}$. This bound is within a $\sqrt{\ell}$ factor of optimal for any choice of roots:

▷ Claim 6. For any choice of $-1 \leq \alpha_1, \ldots, \alpha_\ell \leq 1$, any d that solves (4) has length $\|d\|_1 \geq \ell - 1$.

Matching this bound (up to constant factor) would result in a $\log\|f\|_4^2/\epsilon$ factor improvement in query complexity. We do not know if d as in (6) achieves it already.

Proof. Set j equal to ℓ or $\ell - 1$, whichever is odd. Take a linear combination of equations (4) weighted by the coefficients t of T_j. As T_j is bounded on $[-1, 1]$,

$$\|d\|_1 \geq \left|\sum_i d_i T_j(\alpha_i)\right| = \left|\sum_{i,k} d_i\alpha_i^k t_k\right| = |t_1| = j.$$ ◀

▶ Remark 7. By the same argument, had the right-hand side of (6) been replaced by $\mathbb{1}(j = \ell)$, there would have been no solution d of 1-norm less than $2^{\ell-1}$. Thus the low complexity of Algorithm 1 owes not only to the choice of noise parameters α_i but to the fortunate form of the right-hand side in the linear system (6).

3.1 Proof of Theorem 1

Proof of Theorem 1. By Chebyshev's inequality, the empirical average of m samples of an estimator with variance v is within $2\sqrt{v/m}$ of its mean except with probability 1/4. By Claim 2 and Claim 3, with probability at least 3/4,

$$|\tilde{W}^1[f] - \mathbf{W}^1[f]| \le \|d\|_1 \rho^{\ell-1} \|f^{\ge \ell}\|^2 + \sqrt{\frac{2\rho^{-2}\|d\|_1^2}{m}} \cdot \|f\|_4^2.$$

As $\|f^{\ge\ell}\| \le \|f\|_4$, it is sufficient that the choices of ρ, ℓ, m satisfy

$$\|d\|_1 \rho^{\ell-1} \le \frac{\epsilon'}{2} \quad \text{and} \quad \frac{2\rho^{-2}\|d\|_1^2}{m} \le \frac{\epsilon'^2}{4},$$

for $\epsilon' = \epsilon/\|f\|_4^2$. By Claim 5, $\|d\|_1 \le \sqrt{\ell} \cdot \|d\|_2 \le \ell^{3/2}$. The choice $\rho = \epsilon'^{(\ell-1)^{-1}}/6$ ensures that for $\ell \ge 2$,

$$\|d\|_1 \rho^{\ell-1} \le \frac{\ell^{3/2}}{6^{\ell-1}} \cdot \epsilon' \le \frac{1}{2}\epsilon'.$$

As $\ell = \log 1/\epsilon' + 1$,

$$\frac{2\rho^{-2}\|d\|_1^2}{m} \le \frac{24\ell^3}{m},$$

which is at most $\epsilon'^2/4$ by our choice $m = 96\ell^3/\epsilon'^2$. ◀

Proof of Claim 2. The bias of the estimator is $\mathbf{E}[fg] - \mathbf{W}^1[f] = \mathbf{E}[fg] - \|f^{=1}\|^2$. The first ℓ levels of g are given by (3), so $\mathbf{E}[f^{<\ell} g^{<\ell}] = \|f^{=1}\|^2$. As for $j \ge \ell$, by (2),

$$g^{=j} = \rho^{-1} \sum d_i (N_{\alpha_i \rho} f)^{=j} = \sum d_i (\alpha_i \rho)^j f^{=j}$$

from where

$$\begin{aligned}
|\mathbf{E}\,\tilde{W}^1[f] - \mathbf{W}^1[f]| &= |\mathbf{E}[f^{\ge\ell} g^{\ge\ell}]| \\
&\le \sum_{j\ge\ell} \rho^{j-1} \sum_i |d_i \alpha_i^j| \cdot \|f^{=j}\|^2 && \text{(by triangle inequality)} \\
&\le \rho^{\ell-1}\|d\|_1 \sum_{j\ge\ell} \|f^{=j}\|^2 && (|\alpha_i| \le 1) \\
&= \rho^{\ell-1}\|d\|_1 \|f^{\ge\ell}\|^2. && \blacktriangleleft
\end{aligned}$$

Proof of Claim 3. Operator N_ρ is contractive: $\|N_\rho g\| \le \|g\|$ for all ρ and g.

$$\begin{aligned}
\mathbf{Var}\,\tilde{W}^1[f] &\le \mathbf{E}[\tilde{W}^1[f]^2] \\
&= \rho^{-2}\|d\|_1^2\, \mathbf{E}\,\mathbf{E}[f^2 \cdot N_{\alpha_i\rho}(f^2)|i] \\
&\le \rho^{-2}\|d\|_1^2\, \mathbf{E}\sqrt{\mathbf{E}[f^4|i] \cdot \mathbf{E}[N_{\alpha_i\rho}(f^2)^2|i]} && \text{by Cauchy-Schwarz} \\
&\le \rho^{-2}\|d\|_1^2 \cdot \|f^2\| \cdot \|f^2\| && \text{by contractivity} \\
&= \rho^{-2}\|d\|_1^2 \|f\|_4^4. && \blacktriangleleft
\end{aligned}$$

3.2 Lower bound

▶ **Theorem 8.** *For every $o(1/\epsilon^2)$-query algorithm A there exists a Boolean-valued f such that $|A(f) - \mathbf{W}^1[f]| > \epsilon$ with probability at least $1/4$, as long as $\epsilon = \Omega(n^{3/2}2^{-n/2})$.*

The advantage of a distinguisher D with respect to random variable f and g is the absolute difference in the probabilities that D accepts f and g. The maximum possible distinguishing advantage is known to equal the minimum possible probability of the event $f \neq g$ under all couplings of f and g, i.e., joint distributions over (f, g) that are consistent with their marginals.

▶ **Fact 9.** *Assuming $0 \leq \beta < \alpha < 0.9$, distinguishing between independent α and β-biased coin flips with advantage at least $1/4$ requires $\Omega(1/(\alpha - \beta)^2)$ samples.*

Proof. There are several proofs for the case $\beta = 0$, see for example [13]. The general case reduces to this special case. Consider the reduction that takes the outcome of a coin flip, outputs it with probability $1 - \beta$, and outputs 1 otherwise. This reduction maps unbiased coins into β-biased ones and $(\alpha - \beta)/(1 - \beta)$-biased coins into α-biased ones. Distinguishing the latter with advantage $1/4$ therefore requires $\Omega((1 - \beta)^2/(\alpha - \beta)^2)$ samples. ◀

Proof of Theorem 8. Choose any $0.5 < \beta < \alpha < 0.9$ with $\alpha - \beta = 5\epsilon$. Let f (resp., g) be a probabilistic Boolean function in which the values $f(x)$ are independent αx_1-biased, (resp., βx_1-biased). By Claim 10 $\mathbf{W}^1[f]$ is at least $\alpha^2 - \epsilon$, and $\mathbf{W}^1[g]$ is at most $\beta^2 + \epsilon$ except with probability at most $1/4$. Therefore

$$\mathbf{W}^1[f] - \mathbf{W}^1[g] \geq \alpha^2 - \beta^2 - 2\epsilon = (\alpha - \beta)(\alpha + \beta) - 2\epsilon \geq 3\epsilon$$

by our choice of α and β. Had A been ϵ-accurate with probability $3/4$, by a union bound,

$$\begin{aligned}\Pr[|A(f) - A(g)| \leq \epsilon] \leq &\Pr[|A(f) - \mathbf{W}^1[f]| \geq \epsilon] + \Pr[|A(g) - \mathbf{W}^1[g]| \geq \epsilon] \\ &+ \Pr[|\mathbf{W}^1[f] - \mathbf{W}^1[g]| \leq 3\epsilon] \\ \leq &3/4\end{aligned}$$

so $\Pr[f \neq g] \geq \Pr[|A(f) - A(g)| > \epsilon] > 1/4$. As this holds for an arbitrary coupling of f and g, the two can be $1/4$-distinguished.

We now show this is impossible, namely f and g cannot be $1/4$-distinguished with $q = o(1/\epsilon^2)$ queries. For if they could be by some algorithm A, then the following algorithm can distinguish α and β-biased coin flips with q queries, contradicting Fact 9: Whenever A makes a new query x, flip a coin, multiply the outcome by x_1 and provide this answer. The view of A when the reduction provides α and β-biased coins is identical to interactions with f and g, respectively. ◀

▷ Claim 10. Let h be a random Boolean function whose values are independent ± 1 bits. Then $|\mathbf{W}^1[h] - \mathbf{W}^1[\mathbf{E}\, h]| \leq \epsilon$ except with probability at most $O(n^3 2^{-n}/\epsilon^2)$.

Proof. By independence, $\mathbf{Var}[\hat{h}(i)] \leq 2^{-n}$ for every i so by Chebyshev's inequality, $|\hat{h}(i) - \mathbf{E}\,\hat{h}(i)| \leq \epsilon/2n$ except with probability $O(n^2 2^{-n}/\epsilon^2)$. Therefore $|\hat{h}(i)^2 - \mathbf{E}[\hat{h}(i)]^2| = |\hat{h}(i) + \mathbf{E}\,\hat{h}(i)| \cdot |\hat{h}(i) - \mathbf{E}\,\hat{h}(i)| \leq \epsilon/n$. The claim follows from a union bound and the triangle inequality. ◁

For this argument to result in a $\Omega(1/\epsilon^2)$ lower bound it is essential that α and β be bounded away both from 0 and from 1: Had they been too close to 1 the coins would have been distinguishable from $O(1/\epsilon)$ samples. Had they been too close to 0, the typical distance between $W^1[f]$ and $W^1[g]$ would have been $O(\epsilon^2)$.

4 Learning

In the setting of *distribution-free* (agnostic) learning of a linear approximation from independent random samples, $\Omega(n/\epsilon)$ samples are necessary for properly learning a bounded n-dimensional function with respect to expected square loss error [12]. This bound can be matched by an improper learning algorithm but not by empirical risk minimization [14].

Shamir [12] points out that in general, loss minimization (output a linear hypothesis ℓ such that $\mathbf{E}[(f(x) - \ell(x))^2]$ is ϵ-close to best possible) and model approximation (find ℓ such that $\mathbf{E}[(\ell(x) - \ell^\star(x))^2] \leq \epsilon$ for the $\ell^\star$ that minimizes $\mathbf{E}[(f(x) - \ell^\star(x))^2]$) are not equivalent problems.

In the context of learning under the uniform distribution, however, the two problems are equivalent to approximating the projection $f^{\leq 1}$ onto the space of linear functions. Linial, Mansour, and Nisan [8] showed that the approximation can be calculated from $O(n/\epsilon)$ samples via empirical risk minimization.

We show a query complexity lower bound of $\Omega(n/\sqrt{\epsilon})$ for proper agnostic learning, even when the learner is given non-adaptive query access to f.

▶ **Theorem 11.** *For every non-adaptive algorithm A that makes $o(n/\sqrt{\epsilon})$ queries and outputs an affine hypothesis, there is an $f\colon \{\pm 1\}^n \to \{\pm 1\}$ such that $\|f - A(f)\|^2 \leq \|f - f^{\leq 1}\|^2 + \epsilon$ only with probability $2^{-\Omega(n)}$ assuming $\epsilon \geq 2^{-(1-o(1))n/2}$.*

Our proof technique also gives a $\Omega(\log n/\sqrt{\epsilon})$ query complexity lower bound for adaptive A.

Theorem 11 is proved in two steps. In Proposition 12 we establish it for sufficiently small but constant ϵ. In Proposition 15 we give a reduction from agnostically learning linear approximations with constant mean-square error and q queries to the same problem with mean-square error ϵ and $O(q/\sqrt{\epsilon})$ queries. The reduction is flexible with respect to the learning model, and even to the task. It can also be applied to estimation but gives a worse dependence on ϵ than what we have in Theorems 8 and 19.

4.1 Lower bound for constant error

▶ **Proposition 12.** *For every $\kappa < 1$ there exist ϵ, η such that for n sufficiently large and for every non-adaptive algorithm A that makes at most κn queries and outputs an affine hypothesis, there exists $f\colon \{\pm 1\}^n \to \{\pm 1\}$ such that $\|f - A(f)\|^2 \leq \|f - f^{\leq 1}\|^2 + \epsilon$ with probability at most $2^{-\eta n}$.*

A $\log n - O(1)$ adaptive query complexity lower bound follows from the same assumptions as adaptive algorithms that make q Boolean-valued queries can be simulated with 2^q non-adaptive queries.

The proof relies on the following lemma, which states that there is a large set of Boolean functions whose close-to-best linear approximations are mutually far apart. Any candidate learning algorithm with too few queries does not have enough information to disambiguate between these functions and is unlikely to output an approximately correct hypothesis.

▶ **Lemma 13.** *For every $\rho < 1$ there exists $\epsilon > 0$ such that for sufficiently large n, there is a set $\mathcal{P}$ of $2^{\rho n}$ pairs of functions (f, ℓ) over domain $\{-1, 1\}^n$, where f is boolean-valued, ℓ is linear and real-valued, and*

1. *For every $(f, \ell) \in \mathcal{P}$, $\|\ell - f^{\leq 1}\| \leq \sqrt{\epsilon}$.*
2. *For all distinct $(f, \ell), (f', \ell') \in \mathcal{P}$, $\|\ell - \ell'\| \geq 4\sqrt{\epsilon}$.*

By the triangle inequality:

▶ **Corollary 14.** *For every $\rho < 1$ there exists $\epsilon > 0$ and a set $\mathcal{F}$ of $2^{\rho n}$ Boolean functions such that for every $f \neq g \in \mathcal{F}$, $f^{\leq 1}$ and $g^{\leq 1}$ are at least $2\sqrt{\epsilon}$ far apart.*

By Yao's Minimax principle, to prove Proposition 12 it suffices (and is necessary) to give a probability distribution over the possible inputs f and show that any non-adaptive algorithm that makes too few queries is likely to fail on this distribution. Our distribution is uniform over the collection from Corollary 14: As $\log|\mathcal{F}|$ is larger than the query complexity, the algorithm does not have enough information to disambiguate between candidate inputs in $\mathcal{F}$ and is therefore unlikely to be correct.

Proof of Proposition 12. Choose f at random from the set of functions $\mathcal{F}$ in Corollary 14 instantiated with ρ satisfying $1 - \rho = (1 - \kappa)/2$. Let f_Q denote the restriction of f on the query set Q. Conditioned on the choice of Q, by the law of total expectation

$$\begin{aligned}
\mathbf{E}\,\frac{1}{|\{g \in \mathcal{F}\colon g_Q = f_Q\}|} &= \sum_{a \in \mathrm{Supp} f_Q} \frac{1}{|\{g \in \mathcal{F}\colon g_Q = a\}|} \cdot \Pr_{f \sim \mathcal{F}}[f_Q = a] \\
&= \sum_{a \in \mathrm{Supp} f_Q} \frac{1}{|\mathcal{F}| \Pr_{g \sim \mathcal{F}}[g_Q = a]} \cdot \Pr_{f \sim \mathcal{F}}[f_Q = a] \\
&= \frac{|\mathrm{Supp} f_Q|}{|\mathcal{F}|} \\
&\leq \frac{2^q}{|\mathcal{F}|},
\end{aligned}$$

where q is the query complexity. By our choice of parameters this is at most $2^{-(1-\kappa)n/2}$.

The left-hand side upper bounds the probability that the algorithm succeeds. For conditioned on the view of A and the choice of f, its input is equally likely to have been any function in the set $S_f = \{g \in \mathcal{F}\colon g_Q = f_Q\}$. However, the output h of $A(f)$ could be accurate for at most one function in this set: If

$$\begin{aligned}
&\|g - h\|^2 \leq \|g^{\leq 1} - g\|^2 + \epsilon \quad \text{and} \\
&\|g' - h\|^2 \leq \|g'^{\leq 1} - g'\|^2 + \epsilon
\end{aligned}$$

by Pythagoras' theorem $\|g^{\leq 1} - h\|^2, \|g'^{\leq 1} - h\|^2 \leq \epsilon$. By the triangle inequality $g^{\leq 1}$ and $g'^{\leq 1}$ are $2\sqrt{\epsilon}$-close, so it must be that $g = g'$. Therefore $A(f)$ succeeds with probability at most $1/|S_f|$. ◀

4.2 Trading accuracy for queries

We describe a reduction R that, given access to a high-accuracy learner A that requires access to many queries, learns with low accuracy but fewer queries.

When A makes a query, the reduction flips a coin with success probability $\delta = 2\sqrt{\epsilon/\epsilon_0}$. If the coin flip succeeds, the reduction forwards the query and returns the answer to A. If it fails, the reduction answers the query randomly. When A outputs its answer h, the reduction returns h/δ.

The reduction can be implemented in any query model (random samples, non-adaptive, adaptive). We show that it is effective in the context of approximately learning linear approximations.

We show correctness for Boolean-valued functions as it matches our application, but the proposition should hold more generally under any p-norm bound.

▶ **Proposition 15.** *If A makes q queries and outputs h such that $\|h - f^{\leq 1}\|^2 \leq \epsilon$ given Boolean-valued f as input, then $R^A(f)$ makes at most $q' = 4\sqrt{\epsilon/\epsilon_0}q$ queries except with probability $2^{-\Omega(q')}$, and outputs h' such that $\|h' - f^{\leq 1}\|^2 \leq \epsilon_0$ except with probability $O(n/\epsilon 2^n)$.*

Proof.

Query complexity. The number of queries is a Binomial(q, δ) random variable. By a Chernoff bound it exceeds $2\delta q$ with probability at most $2^{-\Omega(\delta q)}$.

Correctness. The input to A provided by R is indistinguishable from a function f' obtained by corrupting f by noise of rate δ, namely $f'(x) = N(x)f(x)$, where $N(x)$ are independent δ-biased bits. By the triangle inequality,

$$\|h/\delta - f^{\leq 1}\| \leq \frac{1}{\delta}\|h - f'^{\leq 1}\| + \frac{1}{\delta}\|f'^{\leq 1} - \delta f^{\leq 1}\|.$$

By our choice of δ, the first term on the right is at most $\sqrt{\epsilon_0}/2$, so it suffices to upper bound the second one by that much. In expectation, using Parseval's identity,

$$\mathbf{E}\|f'^{\leq 1} - \delta f^{\leq 1}\|^2 = \frac{(1-\delta^2)(n+1)}{2^n}, \tag{8}$$

By Markov's inequality, $\delta^{-1}\|f'^{\leq 1} - \delta f^{\leq 1}\| \leq \sqrt{\epsilon_0}/2$ except with probability $O(n/\epsilon 2^n)$. ◀

As an aside, R can be implemented in a "complexity-preserving" manner in the sense that if A is only guaranteed to work on "low-complexity" inputs f (e.g. those of small circuit complexity) then R^A works on all inputs of slightly lower complexity. The reason is that Proposition 15 (specifically (8)) only relies on the *pairwise* independence of the noise.

Proof of Theorem 11. Fix $\kappa = 1/2$ and let ϵ_0 be the corresponding ϵ from Proposition 12. Suppose A succeeds with higher probability. By Proposition 15 R^A makes $o(n) < n/2$ queries, succeeds with probability $2^{-o(n)}$, and outputs an ϵ_0-approximation, violating Proposition 12. ◀

A $\Omega(\log n/\sqrt{\epsilon})$ adaptive query lower bound follows from the same argument.

4.3 Proof of Lemma 13

▷ Claim 16. For every ϵ there exists a Boolean function $f\colon \{-1,1\}^n \to \{-1,1\}$ such that $\|f^{\leq 1} - \ell\|^2 \leq \epsilon$ for sufficiently large n, where $\ell(x) = (\gamma/\sqrt{n})(x_1 + \cdots + x_n)$, assuming $4\sqrt{6}\gamma^2 \exp(-1/4\gamma^2) \leq \epsilon$.

The proof uses the following special case of Khintchine's inequality:

▶ **Fact 17** (Khintchine's inequality). *For every linear function $\ell : \{-1,1\}^n \to \mathbb{R}$, $\|\ell\|_4^4 \leq 3\|\ell\|_2^4$.*

Proof of Claim 16. We show that a random f from a suitable distribution satisfies the desired property with nonzero probability. For each x, $f(x)$ is a random $\{-1,1\}$ outcome with bias

$$\ell(x)\mathbb{1}(|\ell(x)| \leq 1) = \begin{cases} \ell(x), & \text{if } |\ell(x)| \leq 1 \\ 0, & \text{if not.} \end{cases}$$

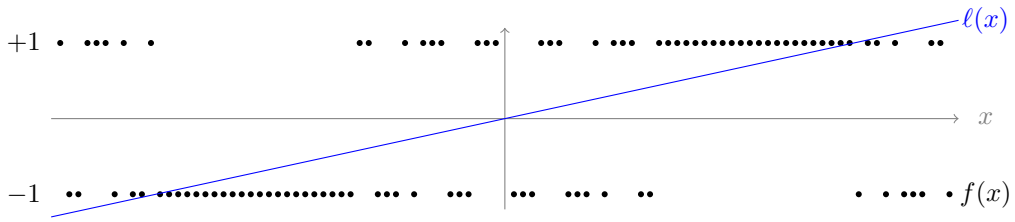

Figure 1 Illustration of f. When $|\ell(x)| \leq 1$, $f(x)$ is $\ell(x)$-biased. Otherwise, it is unbiased.

The values of f are chosen independently conditioned on $f(-x) = -f(x)$ for every x. (This folding simplifies the proof a little bit.) The construction is illustrated in Figure 1. By construction, f is balanced. By Parseval's identity,

$$\|f^{\leq 1} - \ell\|^2 = \sum_{i=1}^{n} (\hat{f}(i) - \gamma/\sqrt{n})^2. \tag{9}$$

We analyze the concentration of $\hat{f}(i)$. In expectation, and by linearity of expectation,

$$\begin{aligned}
\mathbf{E}\,\hat{f}(i) &= \mathbf{E}[x_i f(x)] \\
&= \mathbf{E}\,\mathbf{E}[x_i f(x)|x] \\
&= \mathbf{E}[x_i \ell(x) \mathbb{1}(|\ell(x)| \leq 1)] \\
&= \mathbf{E}[x_i \ell(x)] - \mathbf{E}[x_i \ell(x) \mathbb{1}(|\ell(x)| > 1)] \\
&= \frac{\gamma}{\sqrt{n}} - \hat{g}(i),
\end{aligned}$$

where g is the function $g(x) = \ell(x)\mathbb{1}(|\ell(x)| > 1)$. As g is a symmetric function, its first-level Fourier coefficients are equal and must therefore have absolute value

$$\begin{aligned}
|\hat{g}(i)| &= \sqrt{\frac{\hat{g}(1)^2 + \cdots + \hat{g}(n)^2}{n}} \\
&\leq \sqrt{\frac{\mathbf{E}[g(x)^2]}{n}} && \text{by Parseval's identity} \\
&= \frac{1}{\sqrt{n}} \sqrt{\mathbf{E}[\ell(x)^2 \mathbb{1}(|\ell(x)| > 1)]} \\
&\leq \frac{1}{\sqrt{n}} \sqrt[4]{\mathbf{E}[\ell(x)^4] \Pr[|\ell(x)| > 1]} && \text{by Cauchy-Schwarz} \\
&\leq \frac{1}{\sqrt{n}} \sqrt[4]{3\|\ell\|^4 \Pr[|\ell(x)| > 1]} && \text{by Fact 17} \\
&\leq \frac{\sqrt[4]{6}\gamma}{\sqrt{n}} \exp\left(-\frac{1}{8\gamma^2}\right) && \text{by Hoeffding's bound} \\
&\leq \sqrt{\epsilon/4n} && \text{by the assumption on } \gamma.
\end{aligned}$$

As $\hat{f}(i)$ is the average of $2^n/2$ independent outcomes, by Hoeffding's bound

$$\Pr\left[|\hat{f}(i) - \mathbf{E}\,\hat{f}(i)| > \sqrt{\epsilon/4n}\right] \leq 2\exp(-2^n\epsilon/8n).$$

Assuming n is sufficiently large so that $2\exp(-2^n\epsilon/8n)$ is less than $1/n$, by the triangle inequality and a union bound, $|\hat{f}(i) - \gamma/\sqrt{n}| \leq \sqrt{\epsilon/n}$ for all i with positive probability. By (9) there must exist a choice of f for which $\|f^{\leq 1} - \ell\|^2 \leq \epsilon$. ◀

Proof of Lemma 13. Let γ satisfy $4\sqrt{6}\gamma^2\exp(-1/4\gamma^2)=\epsilon$, $\mathcal{C}$ be a code over $\{-1,1\}^n$ of rate ρ and mininum relative Hamming distance $4\epsilon/\gamma^2$. Such codes exist for sufficiently large n by the Gilbert-Varshamov bound. Let (f,ℓ) be the pair of functions from Claim 16. The collection $\mathcal{P}$ consists of the pairs $(f_\sigma,\ell_\sigma)\colon \sigma\in\mathcal{C}$, where $g_\sigma(x)$ is the function $g(\sigma_1x_1,\dots,\sigma_nx_n)$.

As g_σ is a permutation of g, $\|f^{\le1}_\sigma-\ell^{\le1}_\sigma\|^2=\|f-\ell\|^2\le\epsilon$ proving property 1. As for property 2, by Parseval's identity, for $\sigma\neq\sigma'\in\mathcal{C}$,

$$\|\ell_\sigma-\ell_{\sigma'}\|^2=\sum\frac{\gamma^2}{n}(\sigma_i-\sigma'_i)^2=\frac{4\gamma^2}{n}\sum\mathbb{1}(\sigma_i\neq\sigma'_i)\ge16\epsilon$$

by our choice of parameters. ◀

5 Estimation from uniform samples

The queries in Algorithm 1 come in pairwise correlated pairs $(x,x\cdot e_i)$. They can be emulated from independent pairs (x,y) after reweighting by the likelihood ratio thereby preserving the bias of the estimator. However, the variance of the likelihood ratio grows exponentially in $\Theta(n\rho^2)$, leading to a comparable blowup in the estimator variance (which becomes $\approx 2^{\Omega(n\rho^2)}/\rho^2$). Such an algorithm is not query efficient as the seemingly optimal choice of $\rho\approx1/\sqrt{n}$ still fails to attain sublinear complexity.

5.1 The algorithm

Instead of adapting Algorithm 1, our pair-based sample mean estimator directly calculates the empirical mean of the unbiased estimator $A(x,y)=f(x)f(y)\langle x,y\rangle$ averaged over all pairs of samples. The reuse of samples creates correlations, but their covariances are dominated by their individual variances.

Algorithm 2 pair-based sample mean estimator.

given samples $x^1,\dots x^m\overset{i.i.d}{\sim}\{-1,1\}^n$
return $\tilde{W}^1[f]=\binom{m}{2}^{-1}\sum_{i<j}^m A(x^i,x^j)$, where $A(x,y)=f(x)f(y)\langle x,y\rangle$

The algorithm can be implemented in complexity linear in mn (the bit complexity of the samples) by evaluating the equivalent formula

$$\tilde{W}^1[f]=\binom{m}{2}^{-1}\cdot\left(\sum_i\Big(\sum\nolimits_j f(x^j)x^j_i\Big)^2-n\sum_j f(x^j)^2\right).$$

▶ **Theorem 18.** *For $m=O(\sqrt{n}\|f\|_4^2/\epsilon+\|f\|_4^4/\epsilon^2)$ independent and uniform samples, $|\tilde{W}^1[f]-\mathbf{W}^1[f]|\le\epsilon$ with probability at least $2/3$.*

Proof. When x and y are random, A and therefore $\tilde{W}^1[f]$ is an unbiased estimator of $\mathbf{W}^1[f]$:

$$\begin{aligned}\mathbf{E}\left[A(x,y)\right]&=\mathbf{E}\left[f(x)f(y)\langle x,y\rangle\right]\\&=\sum_{i=1}^n\mathbf{E}\left[f(x)x_if(y)y_i\right]\\&=\sum_{i=1}^n\mathbf{E}\left[f(x)x_i\right]^2\\&=\sum_{i=1}^n\hat{f}(i)^2=\mathbf{W}^1[f]\end{aligned}$$

The variance of $\tilde{W}^1[f]$ is the sum of the (co)variances of pairs $A(x^i, x^j)$ and $A(x^{i'}, x^{j'})$ indexed by $i < j$ and $i' < j'$ scaled by $\binom{m}{2}^{-2}$. Only intersecting pairs have nonzero contribution. There are $\binom{m}{2}$ and $2(m-2)\binom{m}{2}$ pairs of intersection size 2 and 1, respectively, resulting in

$$\mathbf{Var}\,\tilde{W}^1[f] = \frac{2}{m(m-1)}v + \frac{4(m-2)}{m(m-1)}c$$

where for independent x, y, z,

$$\begin{aligned}
v &= \mathbf{Var}\,A(x,y) \\
&\le \mathbf{E}\,A(x,y)^2 \\
&= \mathbf{E}\,f(x)^2 f(y)^2 \langle x,y\rangle^2 \\
&\le \sqrt{\mathbf{E}\,f(x)^4 f(y)^4}\sqrt{\mathbf{E}\langle x,y\rangle^4} && \text{by Cauchy-Schwarz} \\
&= \|f\|_4^4 \cdot \sqrt{3}n && \text{by Fact 17}
\end{aligned}$$

and

$$\begin{aligned}
c &= \mathbf{Cov}[A(x,y), A(x,z)] \\
&\le \mathbf{E}\,A(x,y)A(x,z) \\
&= \mathbf{E}\,\mathbf{E}[A(x,y) \mid x]^2 \\
&= \mathbf{E}\left[f(x)^2\,\mathbf{E}\left[f(y)\langle x,y\rangle \mid x\right]^2\right] \\
&\le \sqrt{\|f\|_4^4\,\mathbf{E}\,\mathbf{E}\left[f(y)\langle x,y\rangle \mid x\right]^4} && \text{by Cauchy-Schwarz} \\
&= \|f\|_4^2 \cdot \|f^{=1}\|_4^2 && \text{by Plancherel's formula} \\
&= \|f\|_4^2 \cdot \sqrt{3}\|f^{=1}\|_2^2 && \text{by Fact 17} \\
&\le \sqrt{3}\|f\|_4^4.
\end{aligned}$$

Summing up, $\mathbf{Var}\,\tilde{W}^1[f] = O(n/m^2 + 1/m) \cdot \|f\|_4^4$. The conclusion follows by applying Chebyshev's inequality to $\tilde{W}^1[f]$. ◀

5.2 Lower bound

We show that for sample-based algorithms (unlike query-based) for this problem the dependence on the dimension is inherent. More precisely, the following theorem say that Algorithm 2 is optimal in the sample model.

▶ **Theorem 19.** *For every (possibly randomized) A there exists $f\colon \{\pm1\}^n \to \{\pm1\}$ so that when given m independent examples $(x, f(x))$ with uniform x, A outputs a value within ϵ of $\mathbf{W}^1[f]$ with probability at most $1/2 + O(m\epsilon/\sqrt{n}) + O((n/\epsilon)2^{-n})$.*

The proof in fact shows that the query complexity bound in Theorem 18 is tight in all parameters, even if $\|f\|_4$ is weakened to $\|f\|_\infty$ in the statement.

To prove Theorem 19, we construct a function f that is weakly pseudorandom given $o(\sqrt{n}/\epsilon)$ examples but for which $\mathbf{W}^1[f]$ is likely to be $\Omega(\epsilon)$. In contrast, $\mathbf{W}^1[f]$ for a random function is concentrated around 2^{-n}.

The function f is the sign of

$$g_{Z,N}(x) = \sqrt{\epsilon/n} \cdot \langle x, Z\rangle + \sqrt{1-\epsilon} \cdot N(x),$$

where Z is an n-dimensional standard normal and N is a standard normal function over $\{-1,1\}^n$ (the 2^n values $N(x)$ are independent standard normals as x ranges over $\{-1,1\}^n$.)

▷ Claim 20. The statistical distance between $(x^1, O(x^1)), \ldots, (x^m, O(x^m))$ when $O = f$ and O is a random function is at most $O(m\epsilon/\sqrt{n})$.

Proof. It is sufficient to show the claim for the real-valued functions $g = g_{Z,N}$ and N, as f and a random Boolean function are obtained by taking signs of g and N, respectively, and postprocessing cannot increase statistical distance.

We will assume without loss of generality that $x^1, \ldots, x^m$ are all distinct as repetitions can only decrease statistical distance. Fixing $x^1, \ldots, x^m$, $g(x^1), \ldots, g(x^m)$ are jointly centered Gaussian with covariance matrix

$$\Sigma_{ij} = \begin{cases} (\epsilon/n)\langle x^i, x^j\rangle & \text{if } i \neq j, \\ 1, & \text{if } i = j \end{cases}$$

The covariance matrix of $N(x^1), \ldots, N(x^m)$ is the identity Id. The conditional statistical distance given $x^1, \ldots, x^m$ is at most [4]

$$O(\|\Sigma - Id\|_F) = O\left(\frac{\epsilon}{n}\sqrt{\sum\nolimits_{i\neq j}\langle x^i, x^j\rangle^2}\right).$$

By Cauchy-Schwarz, the average, unconditional statistical distance is at most

$$O\left(\frac{\epsilon}{n}\sqrt{\sum\nolimits_{i\neq j}\mathbf{E}\langle x^i, x^j\rangle^2}\right) = O\left(\frac{\epsilon}{n}\sqrt{m^2\cdot n}\right) = O(m\epsilon/\sqrt{n}). \qquad \blacktriangleleft$$

▷ Claim 21. For every z such that $n/64 \leq \|z\|^2 \leq 4n$, $\mathbf{E}[\langle X, z\rangle \operatorname{sign} g_{z,N}(X)|N] = \Omega(\sqrt{\epsilon n})$ except with probability $O(\epsilon \cdot 2^{-n})$.

Proof. The expression inside the expectation is (up to a $\sqrt{n}$ factor) of the form $t\operatorname{sign}(\sqrt{\epsilon}t + \sqrt{1-\epsilon}N)$ for $t = \langle X, z\rangle/\sqrt{n}$. For fixed t and standard normal N

$$\mathbf{E}[t\operatorname{sign}(\sqrt{\epsilon}t + \sqrt{1-\epsilon}N)] = 2|t|\Pr(|N| < \sqrt{\epsilon/(1-\epsilon)}|t|) \geq 2|t|\Pr(|N| < \sqrt{\epsilon}|t|). \tag{10}$$

As the right-hand side is always nonnegative,

$$\begin{aligned}
&\mathbf{E}[\langle X, z\rangle \operatorname{sign} g_{z,N}(X)] \\
&\geq \mathbf{E}[\langle X, z\rangle \operatorname{sign} g_{z,N}(X) | |\langle X, z\rangle| \geq \|z\|/3] \cdot \Pr(|\langle X, z\rangle| \geq \|z\|/3) \\
&\geq 2(\|z\|/3)\Pr(|N| < \sqrt{\epsilon}/24) \cdot \Pr(|\langle X, z\rangle| \geq \|z\|/3) && \text{by (10)} \\
&= \Omega(\sqrt{n} \cdot \Pr(|N| < \sqrt{\epsilon}/24 \cdot 3)) && \text{by Khinchine's inequality} \\
&= \Omega(\sqrt{\epsilon n}).
\end{aligned}$$

By independence of the values $\operatorname{sign} g_{z,N}(x)$ across x,

$$\begin{aligned}
\mathbf{Var}\,\mathbf{E}[\langle X, z\rangle \operatorname{sign} g_{z,N}(X)|N] &= \mathbf{Var}\,\frac{1}{2^n}\sum_x \langle x, z\rangle \operatorname{sign} g_{z,N}(x) \\
&= \frac{1}{2^{2n}}\sum_x \langle x, z\rangle^2\,\mathbf{Var}\operatorname{sign} g_{z,N}(x) \\
&\leq \frac{1}{2^{2n}}\sum_x \langle x, z\rangle^2 \\
&= \frac{\|z\|^2}{2^n}.
\end{aligned}$$

The claim follows from Chebyshev's inequality. $\triangleleft$

▷ Claim 22. $\mathbf{W}^1[f] \geq \Omega(\epsilon)$ except with probability $\Omega(2^{-n})$.

Proof. By the Cauchy-Schwarz inequality, for any linear function ℓ,

$$\langle f, \ell \rangle^2 = \langle f^{\leq 1}, \ell \rangle^2 \leq \|f^{\leq 1}\|^2 \cdot \|\ell\|^2 = \mathbf{W}^1[f] \cdot \|\ell\|^2.$$

The function $\ell(x) = \langle x, Z \rangle$ has squared 2-norm $\sum Z_i^2$, which is between $n/64$ and $4n$ except with probability 2^{-n}. Applying Claim 21,

$$\mathbf{W}^1[f] \geq \frac{\langle f, \ell \rangle^2}{\|\ell\|^2} = \frac{\mathbf{E}[\langle X, Z \rangle \operatorname{sign} g_{Z,N}(X) | N, Z]^2}{\mathbf{E}[\langle X, Z \rangle^2 | Z]} = \Omega(\epsilon). \quad \blacktriangleleft$$

▷ Claim 23. For a random Boolean function r, $\mathbf{W}^1[r] \leq \epsilon$ except with probability $(n/\epsilon)2^{-n}$.

Proof. By symmetry the expectation is $n2^{-n}$. The bound follows from Markov's inequality. ◁

Proof of Theorem 19. Applying Claims 22 with ϵ in the definition of f scaled up by a suitable constant factor, $\mathbf{W}^1[f] > 3\epsilon$ except with probability $O(2^{-n})$. By Claim 23, $\mathbf{W}^1[r] \leq \epsilon$ except with probability $(n/\epsilon)2^{-n}$.

Let D be the distinguisher that accepts if A's output is greater than 2ϵ and rejects if not. If A is correct with probability at least $(1 + \delta)/2$ on every input, then D accepts f with probability at least $1/2 + \delta/2 - O(2^{-n})$ while D accepts r with probability at most $1/2 - \delta/2 + (n/\epsilon)2^{-n}$. As D's distinguishing advantage cannot exceed A's, the statistical distance between A's views on inputs f and r is at least $\delta - O((n/\epsilon)2^{-n})$. By Claim 20 it is at most $O(m\epsilon/\sqrt{n})$, from where $\delta \leq O(m\epsilon/\sqrt{n}) + O((n/\epsilon)2^{-n})$. ◀

Abstract

A graph class admits an implicit representation if, for every positive integer n, its n-vertex graphs have a $O(\log n)$-bit (adjacency) labeling scheme, i.e., their vertices can be labeled by binary strings of length $O(\log n)$ such that the presence of an edge between any pair of vertices can be deduced solely from their labels. The famous Implicit Graph Conjecture posited that every hereditary (i.e., closed under taking induced subgraphs) factorial (i.e., containing $2^{O(n \log n)}$ n-vertex graphs) class admits an implicit representation. The conjecture was recently refuted [Hatami and Hatami, FOCS '22], and does not even hold among monotone (i.e., closed under taking subgraphs) factorial classes [Bonnet et al., ICALP '24]. However, monotone small (i.e., containing at most $n!c^n$ many n-vertex graphs for some constant c) classes do admit implicit representations.

This motivates the Small Implicit Graph Conjecture: Every hereditary small class admits an $O(\log n)$-bit labeling scheme. We provide evidence supporting the Small Implicit Graph Conjecture. First, we show that every small weakly sparse (i.e., excluding some fixed bipartite complete graph as a subgraph) class has an implicit representation. This is a consequence of the following fact of independent interest proved in the paper: Every weakly sparse small class has bounded expansion (hence, in particular, bounded degeneracy). Second, we show that every hereditary small class admits an $O(\log^3 n)$-bit labeling scheme, which provides a substantial improvement of the best-known polynomial upper bound of $n^{1-\varepsilon}$ on the size of adjacency labeling schemes for such classes. This is a consequence of another fact of independent interest proved in the paper: Every small class has neighborhood complexity $O(n \log n)$.

1 Introduction

A *class* of graphs is a set of graphs which is closed under isomorphism. For a class of graphs $\mathcal{X}$ we denote by $\mathcal{X}_n$ the set of graphs in $\mathcal{X}$ with vertex set $[n]$. Let $\mathcal{X}$ be a class of graphs and $b : \mathbb{N} \to \mathbb{N}$ be a function. A $b(n)$-*bit adjacency labeling scheme* (or simply $b(n)$-*bit labeling scheme*) for $\mathcal{X}$ is a pair (encoder, decoder) of algorithms where for any n-vertex graph $G \in \mathcal{X}_n$ the encoder assigns binary strings, called *labels*, of length $b(n)$ to the vertices of G such that the adjacency between any pair of vertices can be inferred by the decoder only from their labels. We note that the decoder depends on the class $\mathcal{X}$, but not on the graph G. The function $b(\cdot)$ is the *size* of the labeling scheme. Adjacency labeling schemes were introduced by Kannan, Naor, and Rudich [35, 36], and independently by Muller [41] in the late 1980s and have been actively studied since then.

The binary word, obtained by concatenating labels of the vertices of a graph $G \in \mathcal{X}_n$ assigned by an adjacency labeling scheme, uniquely determines graph G. Thus, a $b(n)$-bit labeling scheme cannot represent more than $2^{nb(n)}$ graphs on n vertices, and therefore, if $\mathcal{X}$ admits a $b(n)$-bit labeling scheme, then $|\mathcal{X}_n| \leqslant 2^{nb(n)}$. This implies a lower bound of $\frac{\log |\mathcal{X}_n|}{n}$ on the size $b(n)$ of any adjacency labeling scheme for $\mathcal{X}$. We say that a graph class $\mathcal{X}$ admits an *implicit representation*, if it admits an information-theoretic *order optimal* adjacency labeling scheme, i.e., if $\mathcal{X}$ has a $b(n)$-bit labeling scheme, where $b(n) = O(\log |\mathcal{X}_n|/n)$. A natural and important question is: which classes admit an adjacency labeling scheme of a size that matches this information-theoretic lower bound?

Of particular interest is the case of adjacency labeling schemes of size $O(\log n)$. This is because, under the natural assumption that vertices get assigned pairwise distinct labels, $\lceil \log n \rceil$ is a lower bound on the size of any labeling scheme. Thus, understanding the expressive power of the labeling schemes of size of order $\log n$ is a natural question.

By the above discussion adjacency labeling schemes of size $O(\log n)$ can only exist for (at most) *factorial* graph classes, i.e., classes $\mathcal{X}$ in which the number $|\mathcal{X}_n|$ of n-vertex graphs grows not faster than $2^{\Theta(n \log n)}$. It is known that the latter condition alone is not enough to guarantee adjacency labels of size $O(\log n)$ [41]. Kannan, Naor, and Rudich [35] asked if the extra restriction on $\mathcal{X}$ of being *hereditary*, i.e., closed under taking induced subgraphs, would be enough for the existence of $O(\log n)$-bit adjacency labeling scheme. This question was later stated by Spinrad [46] in the form of a conjecture, reiterated by Scheinerman [29, Chapter 6], that became known as the *Implicit Graph Conjecture*.

(*IGC*): Any hereditary factorial graph class admits an $O(\log n)$-bit labeling scheme.

The conjecture remained open for three decades until it was recently refuted in a strong form by Hatami and Hatami, who showed that for any δ there exists a hereditary factorial class that does not admit an $(n^{1/2-\delta})$-bit labeling scheme [33]. This refutation leaves wide open the question of characterizing hereditary graph classes that admit $O(\log n)$-bit labeling schemes and no plausible conjectural dichotomy is currently available.

It was recently shown that IGC does not hold even in the family of *monotone* graph classes, the hereditary classes which are closed under taking (not necessarily induced) subgraphs [11]. On the positive side, it was shown in the same work that IGC holds for every monotone *small* class, i.e., a monotone class $\mathcal{X}$ with $|\mathcal{X}_n| \leqslant n! \cdot c^n$ for some constant $c > 0$.

The hereditary small classes form a subfamily of hereditary factorial classes that contains many classes of practical or theoretical importance. For instance, forests [44], planar graphs [47], classes of bounded treewidth [8], proper minor-closes classes [43], unit interval graphs [32], classes of bounded clique-width [3], and more generally, classes of bounded

twin-width [13] are all small. All of these classes are known to admit order-optimal, and, sometimes, even asymptotically optimal adjacency labeling schemes. For example, forests admit a $(\log n + O(1))$-bit labeling scheme [5], planar graphs admit a $(1 + o(1)) \log n$-bit labeling scheme [19], classes of bounded treewidth admit a $(1+o(1)) \log n$-bit labeling scheme [28], proper minor-closed classes admit a $(2 + o(1)) \log n$-bit labeling scheme [28], graphs of clique-width at most k admit a $O(k \log k \cdot \log n)$-bit labeling scheme [46, 7], and graphs of twin-width at most k admit a $2^{2^{O(k)}} \cdot \log n$-bit labeling scheme [13]. It is known that not every hereditary (and even monotone) small class admits an asymptotically optimal labeling scheme of size $(1 + o(1)) \log n$ [10]. However, this does not rule out the existence of order optimal labeling schemes of size $O(\log n)$ for all hereditary small classes. Alon [4] recently showed that every hereditary class $\mathcal{X}$ with $|\mathcal{X}_n| = 2^{o(n^2)}$ (which include all hereditary small classes) admits an adjacency labeling scheme of size $n^{1-\varepsilon}$ for some $\varepsilon > 0$ depending on the class. To our knowledge, no better upper bound was established for hereditary small classes.

The importance of hereditary small classes and the existence of $O(\log n)$-bit labeling schemes for all monotone small classes motivated the formulation of the *Small Implicit Graph Conjecture*.

(*Small IGC*) [11]: Any hereditary small graph class admits an $O(\log n)$-bit labeling scheme.

1.1 Our contribution

In this paper we provide evidence toward the Small Implicit Graph Conjecture in two independent directions. First, we show that the Small IGC holds in the important special case of weakly sparse graph classes. Secondly, we obtain an adjacency labeling scheme of polylogarithmic size for any hereditary small class substantially improving upon the best-known polynomial-size upper bound on adjacency labeling schemes for such classes.

Our first result is a consequence of a structural property of small classes of graphs. To state this property, we need to introduce some terms. A hereditary class $\mathcal{X}$ is said to be *weakly sparse* if there exists an integer t such that the complete bipartite graph $K_{t,t}$ is not a subgraph of any graph of $\mathcal{X}$. The *degeneracy* of a graph G is the minimum number k such that every induced subgraph of G contains a vertex of degree at most k. We defer a formal definition of *bounded expansion* until Section 2 as it is somewhat technical. Instead, we note that *bounded expansion* generalizes *bounded degeneracy*, thus Theorem 1 a fortiori holds when the former is replaced by the latter.

▶ **Theorem 1.** *Every weakly sparse small class has bounded expansion.*

This structural insight into small graph classes is of independent interest due to the significance of weakly sparse graph classes. The notion of weakly sparseness is the broadest form of sparsity. It generalizes the properties of bounded degree, bounded degeneracy, and nowhere denseness [42]. By the celebrated Kővári–Sós–Turán theorem [37], among hereditary classes, weakly sparse classes are precisely the classes of graphs with a truly subquadratic number of edges. It is often observed that the extra restriction of being weakly sparse significantly simplifies the structure of graphs possessing a particular property. For example, weakly sparse graph classes of bounded clique-width have bounded treewidth [31]; weakly sparse graph classes of bounded twin-width have bounded expansion, and thus bounded degeneracy [13] (a fact that Theorem 1 generalizes, as it was proven in the same paper that every class of bounded twin-width is small); weakly sparse string graphs have bounded degeneracy [26], and even polynomial expansion [23]; weakly sparse graph classes that are well-quasi-ordered by the induced-subgraph relation have bounded pathwidth [6], etc.

A conjecture from 2016 [1], driving an ongoing program in algorithmic graph theory, suggests that, under some widely-believed complexity-theoretic assumption, a hereditary graph class admits a fixed-parameter tractable (FPT) first-order (FO) model-checking algorithm if and only if it is monadically dependent.[1] It was recently proven that every hereditary small class is monadically dependent [17] (and, in the same paper, the *only if* part of the conjecture was established). Thus, if the conjecture holds, it should in particular be true that every hereditary small class admits an FPT FO model-checking algorithm. Theorem 1 confirms that this is indeed the case within weakly sparse classes, as such an algorithm is known to exist for classes of bounded expansion [22].

Dvořák and Norine proved that if the expansion of a class is upper bounded by a sufficiently slowly-growing subexponential function, then the class is small [24]. From the definition of *expansion* given in the next section, it should be clear that the converse cannot hold since the small classes consisting of all complete graphs or of all bipartite complete graphs have unbounded expansion. A minimum requirement to establish a partial converse is thus that the class is weakly sparse. Theorem 1 confirms that under this condition the expansion of any small class is indeed bounded (albeit not necessarily by a subexponential nor a single-exponential function).

We apply Theorem 1 to obtain our first main result that the Small IGC holds for weakly sparse graph classes. This follows from a classical labeling scheme for classes of bounded degeneracy [35] (see also [11, Lemma 3.5]).

▶ **Theorem 2.** *Every weakly sparse small class admits an $O(\log n)$-bit adjacency labeling scheme.*

Our second main result holds more generally for any hereditary small class and goes some way toward the full strength of the Small IGC.

▶ **Theorem 3.** *Every hereditary small class admits an $O(\log^3 n)$-bit adjacency labeling scheme.*

This result is based on our second structural result of independent interest that hereditary small graph classes have low neighborhood complexity.

▶ **Theorem 4.** *The neighborhood complexity of any hereditary small graph class is $O(n \log n)$.*

The neighborhood complexity is a measure of structural complexity of graphs. Informally (a formal definition is given in Section 2), it reflects the diversity of the set system of the vertex neighborhoods in the graph. Low neighborhood complexity of graph classes implies nice structural and algorithmic properties. For example, in the universe of monotone graph classes, linear neighborhood complexity characterizes classes of bounded expansion [45], and almost linear neighborhood complexity characterizes nowhere dense classes [25]. Low neighborhood complexity is also used to obtain FPT algorithms for various graph problems (see for instance [25, 14]), and was recently used as a central ingredient of an FPT algorithm for the FO model-checking problem on monadically stable graph classes [16]. It is known that every hereditary graph class of bounded twin-width has linear neighborhood complexity [14] (see also [12] for improved bounds). We omit formal definitions and result statements, and refer the reader to the respective work.

[1] As with the other side remarks, we do not define the technical terms in this sentence since they will not reappear.

We obtain our Theorem 3 by combining Theorem 4 with some known result from the theory of sets systems about paths with low crossing number. In a standard form the latter result is not suitable for our need, and therefore we reformulate it and provide a self-contained proof. We believe that the result stated in this form can be of use for other needs.

1.2 Organization

The paper is organized as follows. In Section 3, we prove that weakly sparse small classes have bounded expansion (and thus bounded degeneracy); from this, we derive an $O(\log n)$-bit adjacency labeling scheme for such classes. In Section 4.1, we show that every hereditary small class has neighborhood complexity $O(n \log n)$. In Section 4.2, we use this result together with a classical result from the theory of set systems stated in a suitable form, to obtain $O(\log^3 n)$-bit labeling schemes for all hereditary small classes. In Section A, we provide a self-contained proof of the required form of the result from the theory of set systems. In the next section, we introduced necessary notation and state auxiliary facts.

2 Preliminaries

Graphs

We denote by $V(G)$ and $E(G)$ the vertex set and edge set of a graph G, respectively. When we refer to an n-vertex graph G as *labeled*, we mean that the vertex set of G is $[n]$, and we distinguish two different labeled graphs even if they are isomorphic. For a set of graphs X, we denote by $\mathrm{Lab}(X)$ the set of all labeled graphs isomorphic to a graph in X. A graph H is an *induced subgraph* of G (resp. *subgraph* of G), if it can be obtained by removing vertices of G (resp. by removing vertices and edges of G). A subgraph H of G is *spanning* if $V(H) = V(G)$. We denote by $G[S]$ the subgraph of G induced by S, i.e., obtained by removing every vertex of $V(G) \setminus S$.

The *degree* of a vertex v in G, denoted by $\deg(v)$, is the number of vertices in G adjacent to v. The *minimum* (respectively, *maximum*) *degree of* G is the minimum (respectively, maximum) degree of a vertex in G. The *average degree of* G is the ratio $\sum_{v \in V(G)} \deg(v)/|V(G)|$. Recall that the degeneracy of G is the minimum number k such that every induced subgraph of G contains a vertex of degree at most k. The following are immediate consequences of these definitions: (1) if the minimum degree of G is at least d, then the average degree of G and the degeneracy of G is at least d; (2) if the degeneracy of G is at least d, then G contains an induced subgraph of minimum degree at least d. One more relation between these three parameters is the following folklore result, which is not hard to derive by iteratively removing vertices of degree less than $d/2$.

▶ **Observation 5.** *If the average degree of a graph G is at least d, then G contains an induced subgraph of minimum degree, and thus average degree, at least $\lceil d/2 \rceil$.*

We use $G - S$ as a shorthand for $G[V(G) \setminus S]$, and $G - v$, for $G - \{v\}$. We denote by $\mathrm{Aut}(G)$ the automorphism group of a graph G, and we set $\mathrm{aut}(G) := |\mathrm{Aut}(G)|$. If X is a set of pairwise non-isomorphic n-vertex graphs, then the number of labeled graphs isomorphic to a graph in X is exactly

$$|\mathrm{Lab}(X)| = \sum_{G \in X} \frac{n!}{\mathrm{aut}(G)}. \tag{1}$$

For any non-negative integer r, the *r-subdivision* of a graph G, denoted by $r\text{-}\mathrm{subd}(G)$, is the graph obtained from G by adding one path P_{uv} on r vertices for each edge $uv \in E(G)$, and

by replacing each edge $uv \in E(G)$ by a $(r+1)$-edge path $uP_{uv}v$. In the special case were $r = 0$, r-subd(G) is the graph G. We will refer to a vertex from one of the paths P_{uv} as a *subdivision vertex* and to other vertices as *branching vertices*.

For completeness, we include a definition[2] of classes of *bounded expansion*. A class $\mathcal{C}$ has *bounded expansion* if there is a function $f : \mathbb{N} \to \mathbb{R}$ such that for every integer $r \geqslant 0$, no r-subdivision of a graph of average degree larger than $f(r)$ is a subgraph of a graph in $\mathcal{C}$. We will only apply existing results on classes of bounded expansion, and we will do so in a black-box fashion. Thus the reader should only observe that these classes are weakly sparse and of bounded average degree (by virtue of satisfying the given property for $r = 0$).

Graph Classes

A class of graphs is *hereditary* if it is closed under taking induced subgraphs, and it is *monotone* if it closed under taking subgraphs. A hereditary graph class is *small* if there exists a constant c such that the number of n-vertex *labeled* graphs in the class is at most $n! \cdot c^n$ for every $n \in \mathbb{N}$.

Graph contiguity

The *contiguity* of a graph G, denoted $\mathrm{ctg}(G)$, is the minimum integer k such that there exists a linear order of its vertices in which the neighborhood of each vertex of G can be partitioned into at most k disjoint intervals. For a function $k : \mathbb{N} \to \mathbb{N}$ and a class of graphs $\mathcal{C}$, we say that $\mathcal{C}$ has contiguity at most k, if for every n-vertex graph $G \in \mathcal{C}$ the contiguity of G is at most $k(n)$.

The idea of contiguity was introduced in the context of range searching under the name of *crossing number of spanning paths* [48] (see also Section A). Independently, it was introduced in the context of DNA reconstruction under the name of *k-consecutive ones property* [30], which generalizes the notion of *consecutive ones property* for matrices [15, 27]. More recently, the concept was utilized as part of an FPT algorithm for the FO model-checking problem on monadically stable graph classes [16], and has appeared in the context of implicit graph representations [4, 2, 9]. In particular, Alon used it to show that every hereditary graph class $\mathcal{X}$ with $|\mathcal{X}_n| = 2^{o(n^2)}$ admits a $n^{1-\varepsilon}$-bit labeling scheme for some $\varepsilon = \varepsilon(\mathcal{X}) > 0$ [4]. This was done via the following simple connection between contiguity and adjacency labeling schemes.

▶ **Proposition 6.** *Let $k : \mathbb{N} \to \mathbb{N}$ be a function, and $\mathcal{C}$ be a class of graphs of contiguity at most k. Then $\mathcal{C}$ admits an adjacency labeling scheme of size at most $(2k(n) + 1) \log n$.*

Proof. Let G be a n-vertex graph in $\mathcal{C}$. To construct adjacency labels for G of the target size, we fix a linear ordering σ of the vertices of G witnessing contiguity at most $k(n)$. The label of a vertex v of G then consists of its position in σ, followed by the positions of the endpoints of the at most $k(n)$ intervals describing the neighborhood of v. The decoder infers adjacency between two vertices u and v by testing if the position of u in σ belongs to one of the intervals describing the neighborhood of v. ◀

Set systems, shatter functions, and neighborhood complexity

A pair $(X, \mathcal{S})$, where X is a finite set and $\mathcal{S}$ is a family of subsets of X is called a set system. The *incidence matrix* M of the set system $(X, \mathcal{S})$ is the matrix with $|X|$ columns and $|\mathcal{S}|$ rows indexed by the elements of X and $\mathcal{S}$, respectively, where M_{ij} is 1 if the i-th set of $\mathcal{S}$ contains the j-th element of X, and 0 otherwise.

[2] Actually, we rather give an established characterization [20] as it is more compact.

The *primal shatter function* of a set system $(X, \mathcal{S})$ is the function $\pi_{\mathcal{S}}$ given by

$$\pi_{\mathcal{S}}(m) = \max_{A \subseteq X,\, |A|=m} |\{Y \cap A \ : \ Y \in \mathcal{S}\}|.$$

The set system $(X^*, \mathcal{S}^*)$, where $X^* = \mathcal{S}$, $\mathcal{S}^* = \{S_x \ : \ x \in X\}$, and $S_x = \{S \in \mathcal{S} \ : \ x \in X\}$, is called the dual set system of $(X, \mathcal{S})$. The shatter function of $(X^*, \mathcal{S}^*)$ is called the *dual shatter function* of $(X, \mathcal{S})$. Note that if M is the incidence matrix of (X, S), then the transpose of M is the incidence matrix of $(X^*, \mathcal{S}^*)$. A subset $A \subseteq X$ is *shattered* by $\mathcal{S}$ if every subset B of A can be obtained as the intersection $B = A \cap Y$ for some $Y \in \mathcal{S}$, i.e., $\{Y \cap A \mid Y \in \mathcal{S}\} = 2^A$. The *Vapnik–Chervonenkis dimension* (or *VC dimension* for short) of $\mathcal{S}$ is the maximum of the sizes of all shattered subsets of X.

Given a vertex v of a graph G, we use standard notation $N_G(v)$ to denote the set $\{u : vu \in E(G)\}$ of neighbors of v in G. The *neighborhood set system* of G is the set system $(V(G), \mathcal{N}_G)$ where

$$\mathcal{N}_G = \{N_G(v) : v \in V(G)\}.$$

Observe that the adjacency matrix of G is the incidence matrix of $(V(G), \mathcal{N}_G)$. Thus, since the adjacency matrix of an undirected graph is symmetric, the primal and the dual shatter functions of a neighborhood set system coincide.

▶ **Observation 7.** *For neighborhood set systems, the primal and dual shatter functions coincide. That is, for any n-vertex graph G,*

$$\pi_{\mathcal{N}_G}(m) = \pi^*_{\mathcal{N}_G}(m) \qquad \text{for all } m \in [n].$$

We define the *neighborhood complexity* of a graph G, denoted by ν_G, as the primal (equivalently, dual) shatter function of its neighborhood set system, i.e., $\nu_G(m) = \pi_{\mathcal{N}_G}(m) = \pi^*_{\mathcal{N}_G}(m)$ for all $m \in [|V(G)|]$.

Given a graph class $\mathcal{C}$, the *neighborhood complexity* of $\mathcal{C}$ is the function $\nu_{\mathcal{C}} : \mathbb{N} \to \mathbb{N}$ defined by

$$\nu_{\mathcal{C}}(n) := \sup_{G \in \mathcal{C},\, A \subseteq V(G),\, |A|=n} |\{N(v) \cap A \ : \ v \in V(G)\}| = \sup_{G \in \mathcal{C}} \pi_{\mathcal{N}(G)}(n) = \sup_{G \in \mathcal{C}} \nu_G(n).$$

3 Implicit representation for weakly sparse small classes

In this section we prove Theorem 1, which states that any weakly sparse small class has bounded expansion, and hence, in particular, bounded degeneracy. Together with the known labeling scheme for bounded degeneracy graphs (see e.g. [11, Lemma 3.5]), this immediately implies that any weakly sparse small class admits an $O(\log n)$-bit adjacency labeling scheme (Theorem 2).

The proof of Theorem 1 relies on the fact (Corollary 10) that for any weakly sparse class $\mathcal{X}$ of unbounded expansion there exists an integer $r \geqslant 1$ such that $\mathcal{X}$ contains r-subdivisions of graphs of arbitrarily large average degree. This is a consequence of the forward direction of a characterization of classes of (un)bounded expansion by Dvořák [21] and a classical result due to Kühn and Osthus [39], both stated below.

▶ **Theorem 8** ([21, Theorem 5, $(a) \Leftrightarrow (c)$])**.** *A hereditary graph class $\mathcal{X}$ has unbounded expansion if and only if there is an integer $r \geqslant 0$ such that for any integer d, $\mathcal{X}$ contains the r-subdivision of a graph of average degree at least d.*

▶ **Theorem 9** ([39, Theorem 2]). *For all $d, t \in \mathbb{N}$, there exists an integer $D := D(d,t)$ such that every $K_{t,t}$-free graph G of average degree at least D contains $1\text{-subd}(F)$ as an induced subgraph for some graph F of average degree at least d.*

We now extract the announced fact, of which we will only need the *only if* direction.

▶ **Corollary 10.** *A weakly sparse graph class $\mathcal{X}$ is of unbounded expansion if and only if there is an integer $r \geqslant 1$ such that for any integer d, $\mathcal{X}$ contains the r-subdivision of a graph of average degree at least d.*

Proof. The *if* part follows directly from Theorem 8. For the *only if* part, we first apply the corresponding implication in Theorem 8. If $r \geqslant 1$, we are done. If instead $r = 0$, then $\mathcal{X}$ contains graphs of arbitrarily large average degree. Therefore, Theorem 9 implies that $\mathcal{X}$ contains 1-subdivisions of graphs of arbitrarily large average degree, i.e., the sought statement holds for $r = 1$. ◀

Equipped with this tool, the proof of Theorem 1 shows the contrapositive as follows. Assuming a weakly sparse class $\mathcal{X}$ has unbounded expansion, we fix a positive integer r such that $\mathcal{X}$ contains r-subdivisions of graphs of arbitrarily large average degree, which exists by Corollary 10. Let F be a graph with large average degree such that the r-subdivision of F is in $\mathcal{X}$. First, we extract from F a subgraph H with large minimum degree that contains a bounded-degree spanning tree. This is possible due to Observation 5 and the following lemma.

▶ **Lemma 11** ([11, Lemma 3.3]). *Let F be a graph of minimum degree d. Then F has an induced subgraph H of minimum degree at least d with a spanning tree of* maximum degree *at most d.*

Next, we use the properties of H to show that it contains many (not necessarily induced) subgraphs each with a small number of automorphisms, which are translated to many *induced* subgraphs with a small number of automorphisms in the r-subdivision of H and thus in the r-subdivision of the original graph F. This allows us to lower bound the number of labeled graphs on the same number of vertices in $\mathcal{X}$ by counting subgraphs of H, and finally conclude that $\mathcal{X}$ is not small. The quantitative connection is made possible by the following observations.

▶ **Observation 12.** *For any integer $r \geqslant 0$, two graphs G and H are isomorphic if and only if $r\text{-subd}(G)$ and $r\text{-subd}(H)$ are isomorphic.*

▶ **Observation 13.** *Let F be a graph. For any integer $r > 0$, for every subgraph H of F, the graph $r\text{-subd}(H)$ is isomorphic to an induced subgraph of $r\text{-subd}(F)$.*

▶ **Observation 14.** *Let G be a connected graph containing a vertex of degree at least 3, then*

$$\mathrm{aut}(r\text{-subd}(G)) = \mathrm{aut}(G).$$

Proof. We start by showing that any automorphism φ of $r\text{-subd}(G)$ maps branching vertices to branching vertices and subdivision vertices to subdivision vertices. First, note that as G has a vertex of degree at least 3, the graph $r\text{-subd}(G)$ also has a vertex of degree at least 3 (hence a branching vertex) say u, which must be mapped by φ to a vertex of degree at least 3 (hence, to a branching vertex), say v. Now, since G is connected, the branching vertices are exactly the ones that are at distances 0 (mod $r+1$) from u, and they are mapped to

vertices that are at distances 0 (mod $r+1$) from v, and thus, to branching vertices. Hence, the restriction $\tilde{\varphi}$ of φ to the branching vertices of r-subd(G) is a permutation of the vertices of G. We claim that $\tilde{\varphi}$ is an automorphism of G. Indeed, two vertices a and b are adjacent in G if and only if a and b are at distance $r+1$ in r-subd(G) if and only if $\varphi(a)$ and $\varphi(b)$ are at distance $r+1$ in r-subd(G) if and only if $\tilde{\varphi}(a) = \varphi(a)$ and $\tilde{\varphi}(b) = \varphi(b)$ are adjacent in G.

From this, we deduce that $\varphi \mapsto \tilde{\varphi}$ is a bijection between the automorphisms of r-subd(G) and the automorphisms of G: it is injective since an automorphism of r-subd(G) is uniquely determined by the images of the branching vertices, and surjective since there are at least as many automorphisms of r-subd(G) as there are of G. Hence, $\mathrm{aut}(r\text{-subd}(G)) = \mathrm{aut}(G)$. ◀

Before proceeding to our main result, we provide some basic facts about automorphisms, which we will rely on. Given two graphs F and G, we denote by $\#\mathrm{Sub}(F \to G)$ the number of subgraphs of G isomorphic to F, and by $\#\mathrm{Emb}(F \to G)$ the number of embeddings of F into G, i.e., the number of injective homomorphisms from F to G. Thus

$$\#\mathrm{Emb}(F \to G) = \#\mathrm{Sub}(F \to G) \cdot \mathrm{aut}(F).$$

For instance, if G is the cycle on an even number n of vertices, and F is the disjoint union of $n/2$ edges, then $\#\mathrm{Sub}(F \to G) = 2$ and $\mathrm{aut}(F) = (n/2)! \cdot 2^{\frac{n}{2}}$, so $\#\mathrm{Emb}(F \to G) = (n/2)! \cdot 2^{\frac{n}{2}+1}$.

We will use the following two well known facts (see [38]).

▶ **Lemma 15.** *Let F be a spanning subgraph of a graph G. Then*

$$\mathrm{aut}(G) \leqslant \#\mathrm{Emb}(F \to G) = \#\mathrm{Sub}(F \to G) \cdot \mathrm{aut}(F).$$

▶ **Lemma 16.** *Let G be a connected graph of maximum degree Δ. Then*

$$\mathrm{aut}(G) \leqslant n \cdot \Delta! \cdot (\Delta - 1)^{n-\Delta-1} \leqslant n\Delta^n.$$

We apply the above two facts to upper bound the number of automorphisms of a graph containing a bounded-degree spanning tree in terms its average degree.

▶ **Lemma 17.** *Let $d \geqslant 1$ and G be a connected n-vertex graph with at most dn edges, which has a spanning tree T of maximum degree τ. Then* $\mathrm{aut}(G) \leqslant (6\tau d)^n$.

Proof. By Lemma 16, $\mathrm{aut}(T) \leqslant n\tau^n \leqslant (2\tau)^n$. Moreover, $\#\mathrm{Sub}(T \to G)$ is at most the number of ways of choosing $n-1$ edges among $E(G)$. Hence

$$\#\mathrm{Sub}(T \to G) \leqslant \binom{dn}{n-1} \leqslant \left(\frac{edn}{n-1}\right)^{n-1} = \left(1 + \frac{1}{n-1}\right)^{n-1} \cdot (ed)^{n-1} \leqslant e(ed)^{n-1} \leqslant (ed)^n,$$

where in the penultimate inequality we used the fact that $1 + x \leqslant e^x$ for any real x. Hence, by Lemma 15, we have $\mathrm{aut}(G) \leqslant \#\mathrm{Sub}(T \to G) \cdot \mathrm{aut}(T) \leqslant (ed)^n \cdot (2\tau)^n \leqslant (6\tau d)^n$. ◀

We are now ready to prove the main result of this section.

▶ **Theorem 1.** *Every weakly sparse small class has bounded expansion.*

Proof. For the sake of contradiction, suppose that a weakly sparse graph class $\mathcal{X}$ has unbounded expansion, but there exists a constant c such that for every $n \in \mathbb{N}$ the number of labeled n-vertex graphs in $\mathcal{X}$ is at most $n! \cdot c^n$. Let $r \geqslant 1$ be an integer such that $\mathcal{X}$ contains r-subdivisions of graphs of arbitrary large average degree, which exists by Corollary 10.

Let $\delta := 24$, $d := \lceil \max(\delta^2, \delta c^{2r}) \rceil$. Let F be a graph of average degree at least $4d$, such that r-subd(F) is in $\mathcal{X}$, and let F' be a subgraph of F of minimum degree at least $2d$, which exists by Observation 5. By Lemma 11, F' contains a subgraph H' of minimum degree at

least $2d$ with a spanning tree T of maximum degree $2d$. If H' has more than $d|V(H')|$ edges, we remove all but $d|V(H')| - (|V(H')| - 1)$ of them from the set $E(H') \setminus E(T)$ to obtain a spanning subgraph with exactly $d|V(H')|$ edges that still contains T as a spanning tree. We denote this subgraph by H and let $k := |V(H)|$, and thus $|E(H)| = dk$.

Let $\mathcal{H}$ be the set of spanning subgraphs of H that contain T as a subgraph and have exactly δk edges. Then, since $\delta \leqslant d$, we have

$$|\mathcal{H}| = \binom{dk-(k-1)}{\delta k-(k-1)} \geqslant \binom{dk-k}{\delta k-k} \geqslant \left(\frac{d-1}{\delta-1}\right)^{(\delta-1)k} \geqslant \left(\frac{d}{\delta}\right)^{(\delta-1)k}.$$

Since every graph in $\mathcal{H}$ has $\delta k \leqslant dk$ edges and contains a spanning tree of maximum degree $2d$, from Lemma 17,

$$\max_{A\in\mathcal{H}} \operatorname{aut}(A) \leqslant (6 \cdot 2d \cdot d)^k \leqslant (4d)^{2k}. \tag{2}$$

Thus, denoting by $\mathcal{U}$ the set of pairwise non-isomorphic graphs in $\mathcal{H}$, we obtain

$$|\mathcal{U}| \geqslant \frac{|\mathcal{H}|}{\max_{A\in\mathcal{H}} \operatorname{aut}(A)} \geqslant \left(\frac{d}{\delta}\right)^{(\delta-1)k} \cdot \frac{1}{(4d)^{2k}} = \left(\frac{d}{\delta}\right)^{(\delta+1)k} \cdot \frac{\delta^{2k}}{4^{2k} \cdot d^{4k}} = \left(\frac{d}{\delta}\right)^{(\delta+1)k} \cdot \frac{6^{2k}}{d^{4k}} \tag{3}$$

Let $r\text{-}\operatorname{subd}(\mathcal{U})$ be the set of r-subdivisions of graphs in $\mathcal{U}$, and observe that every graph in $r\text{-}\operatorname{subd}(\mathcal{U})$ has exactly $N := (r\delta+1)k$ vertices. Since every graph in $\mathcal{U}$ is a subgraph of F, and $r\text{-}\operatorname{subd}(F)$ is in $\mathcal{X}$, Observation 13 implies that every graph in $r\text{-}\operatorname{subd}(\mathcal{U})$ is in $\mathcal{X}$. Thus, to contradict the assumption that, for every $n \in \mathbb{N}$, class $\mathcal{X}$ has at most $n! \cdot c^n$ labeled n-vertex graphs, it is enough to show that $|\operatorname{Lab}(r\text{-}\operatorname{subd}(\mathcal{U}))| > c^N \cdot N!$. This is what we do in the remainder of the proof.

It follows from Observation 12 that $r\text{-}\operatorname{subd}(\mathcal{U})$ is a set of pairwise non-isomorphic graphs and $|r\text{-}\operatorname{subd}(\mathcal{U})| = |\mathcal{U}|$. Furthermore, since every graph A in $\mathcal{H}$ is connected and has k vertices and $\delta k \geqslant k+1$ edges, it contains a vertex of degree at least 3 and thus, by Observation 14, $\operatorname{aut}(r\text{-}\operatorname{subd}(A)) = \operatorname{aut}(A)$. Therefore, from Equation (1), we have

$$|\operatorname{Lab}(r\text{-}\operatorname{subd}(\mathcal{U}))| \geqslant |r\text{-}\operatorname{subd}(\mathcal{U})| \cdot \frac{N!}{\max_{A\in\mathcal{H}} \operatorname{aut}(r\text{-}\operatorname{subd}(A))} = |\mathcal{U}| \cdot \frac{N!}{\max_{A\in\mathcal{H}} \operatorname{aut}(A)},$$

and thus, from (2) and (3), and the fact that $N/r = (\delta + 1/r)k \leqslant (\delta+1)k$, we obtain

$$|\operatorname{Lab}(r\text{-}\operatorname{subd}(\mathcal{U}))| \geqslant \left(\frac{d}{\delta}\right)^{N/r} \cdot \frac{6^{2k}}{d^{4k}} \cdot \frac{N!}{(4d)^{2k}} > \left(\frac{d}{\delta}\right)^{N/r} \cdot \frac{N!}{d^{6k}},$$

Finally, since $\frac{N}{4r} = \frac{(r\delta+1)k}{4r} > \frac{\delta k}{4} = 6k$, and d satisfies both $\sqrt{d} \geqslant \delta$ and $(d/\delta)^{1/r} \geqslant c^2$, we have

$$|\operatorname{Lab}(r\text{-}\operatorname{subd}(\mathcal{U}))| > \left(\frac{d}{\delta}\right)^{\frac{N}{2r}} \cdot \left(\frac{d}{\delta}\right)^{\frac{N}{2r}} \cdot \frac{N!}{d^{6k}} \geqslant \left(\frac{d}{\delta}\right)^{\frac{N}{2r}} \cdot d^{\frac{N}{4r}} \cdot \frac{N!}{d^{6k}} > \left(\left(\frac{d}{\delta}\right)^{1/r}\right)^{\frac{N}{2}} \cdot N! \geqslant c^N \cdot N!,$$

which completes the proof. ◀

4 Short adjacency labels for small classes

In this section we prove:

▶ **Theorem 3.** *Every hereditary small class admits an $O(\log^3 n)$-bit adjacency labeling scheme.*

To do so, we first show a result of independent interest (in Section 4.1), that the neighborhood complexity of any small class is at most $O(n \log n)$. Then, we prove in Section 4.2 that such neighborhood complexity implies $O(\log^2 n)$ contiguity. The latter together with Proposition 6 implies Theorem 3. The core part of this proof strategy is to show how the bound on the neighborhood complexity can be translated to the bound on contiguity. This is done via a classical result from the theory of set systems of bounded Vapnik-Chervonenkis dimension on so-called *paths with low crossing number* (Theorem 18) applied to neighborhood set systems. While the result about paths with low crossing number is a known fact, we need it in somewhat unusual form that we could not find elsewhere in the literature. Therefore, in Section A we present a self-contained proof of this result in a suitable form.

4.1 Neighborhood complexity of small classes

In this section we show that small classes have low neighborhood complexity.

▶ **Theorem 4.** *The neighborhood complexity of any hereditary small graph class is $O(n \log n)$.*

Proof. Let $\mathcal{C}$ be a hereditary small class of graphs and $c \geqslant 1$ be a constant such that $|\mathcal{C}_n| \leqslant n! \cdot c^n$ holds for every $n \in \mathbb{N}$. To prove the claim, we will show that for every graph H in $\mathcal{C}$ it holds that

$$\nu_H(m) < 9c^2 m \log(m+1) \qquad \text{for all } m \in [|V(H)|].$$

Suppose this is not the case. Then, by definition, there exists a graph $H \in \mathcal{C}$ and an n-element set $A \subseteq V(H)$ such that $|\{N_H(v) \cap A \ : \ v \in V(H)\}| \geqslant 9c^2 n \log(n+1)$. Note that the latter inequality implies $n \geqslant 4$. Let $B' \subseteq V(H)$ be any maximum-size set of vertices whose neighborhoods have pairwise distinct intersections with A in the graph H, and let $B := B' \setminus A$. Denote by G the subgraph of H induced by $A \cup B$. By the assumption, we have

1. $|A| = n$,
2. $|B| \geqslant |B'| - |A| \geqslant 9c^2 n \log(n+1) - n > 8c^2 n \log n$,
3. $A \cap B = \emptyset$, and
4. all vertices in B have pairwise distinct neighborhoods in A in graph G.

Let $n_1 := n\lfloor \log n \rfloor$ and $N := n_1 + n$. We will show that the hereditary closure of G contains more than $N! c^N$ labeled graphs on N vertices, i.e., that $|\mathrm{Lab}(\mathrm{IndSub}_N(G))| > N! c^N$, where $\mathrm{IndSub}_N(G)$ is the set of N-vertex induced subgraphs of G. This would contradict our assumption on the number of graphs in $\mathcal{C}$. To do this, let us first fix a labeling of A using the integers from 1 to n. We claim that any two distinct labeled subsets $X_1, X_2 \subseteq B$ of size n_1, labeled with the integers from $n+1$ to N, induce two distinct labeled graphs $G_1 = G[A \cup X_1]$ and $G_2 = G[A \cup X_2]$ contained in $\mathcal{C}$. Indeed, since all vertices in B have pairwise distinct neighborhoods in A, G_1 and G_2 contain a vertex with the same label in $[n+1, N]$ but different neighborhoods in A (i.e. different neighborhoods among vertices with labels from $[n]$).

Hence, the number of N-vertex labeled graphs in $\mathcal{C}$ that are induced subgraphs of G is lower bounded by the number of ways to choose a labeled subset of size n_1 from B, which is

$$n_1! \cdot \binom{|B|}{n_1} \geqslant n_1! \cdot \left(\frac{|B|}{n_1}\right)^{n_1} > n_1! \cdot (8c^2)^{n_1}. \tag{4}$$

We want to show that this is more than the total number of N-vertex labeled graphs in $\mathcal{C}$, which, by assumption, does not exceed

$$N! \cdot c^N = (n_1+n)! \cdot c^{n_1+n} \leqslant n_1! \cdot (n_1+n)^n \cdot c^{2n_1}. \tag{5}$$

From Equation (4) and Equation (5), we should then show that

$$n_1! \cdot (8c^2)^{n_1} \geqslant n_1! \cdot (n_1 + n)^n \cdot c^{2n_1},$$

which is equivalent to establishing that

$$8^{n_1} = 2^{3n_1} \geqslant (n_1 + n)^n = 2^{n \log(n_1+n)}.$$

The latter indeed holds since

$$\begin{aligned} n \log(n_1 + n) &\leqslant n \log(2n\lfloor \log n \rfloor) \\ &\leqslant n \log 2 + n \log n + n \log\lfloor \log n \rfloor \\ &\leqslant n(1 + \log 2) + n\lfloor \log n \rfloor + n \log\lfloor \log n \rfloor \\ &\leqslant n\lfloor \log n \rfloor + n\lfloor \log n \rfloor + n \log\lfloor \log n \rfloor \\ &\leqslant n_1 + n_1 + n_1 = 3n_1, \end{aligned}$$

where the penultimate inequality holds because $n \geqslant 4$. ◀

4.2 From neighborhood complexity to contiguity

In this section, we first show how to translate a bound on neighborhood complexity to a bound on contiguity (Theorem 20), and then apply it to obtain bounds on contiguity for hereditary small classes (Theorem 21). A crucial technical tool that we use to establish this translation is a suitable form of a known result about paths with low crossing number (Theorem 18). To state this result we must first introduce the required notions.

Let $(X, \mathcal{S})$ be a set system. A set $S \in \mathcal{S}$ *crosses* a 2-element set $\{x, y\} \subset X$ if exactly one of x and y belongs to S. Let $\mathcal{F}$ be a multiset of 2-element subsets in X. The *crossing number of $\mathcal{F}$ with respect to a set $S \in \mathcal{S}$* is the number of elements in $\mathcal{F}$ that are crossed by S. The *crossing number of $\mathcal{F}$ with respect to $\mathcal{S}$* is the maximum crossing number of $\mathcal{F}$ with respect to a set $S \in \mathcal{S}$. If $(X, \mathcal{F})$, considered as a graph, is a path spanning all elements of X, then we say that $(X, \mathcal{F})$ is a path on X. In this case, the crossing number of $\mathcal{F}$ is referred to as the crossing number of the corresponding path. We are now ready to state the main technical tool whose self-contained proof can be found in Section A.

▶ **Theorem 18.** *Let X be an n-element set, $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a strictly increasing function, and d be a natural number. Let $(X, \mathcal{S})$ be a set system of VC dimension d that satisfies $\pi^*_{\mathcal{S}}(m) \leqslant f(m)$ for all $m \in [n]$. Then there exists a path on X with crossing number at most*

$$2 \log |\mathcal{S}| + 10d \cdot \sum_{j=1}^{n} \frac{1}{f^{-1}(j/2)}.$$

We will apply Theorem 18 to neighborhood set systems. Its importance in our context is due to (a) the fact that the dual shatter function of the neighborhood set system of a graph coincides with its primal dual function (Observation 7), i.e., the neighborhood complexity of the graph; and (b) the following observation about close relationship between the crossing number of a path for the neighborhood set system and the contiguity of the graph.

▶ **Observation 19.** *Let G be an n-vertex graph. If there exists a path on $V(G)$ that has crossing number with respect to $\mathcal{N}_G$ at most k, then the contiguity of G is at most $k/2 + 1$.*

Proof. Let $\{\{v_1, v_2\}, \{v_2, v_3\}, \ldots, \{v_{n-1}, v_n\}\}$ be a path on $V(G)$ with crossing number with respect to $\mathcal{N}_G$ at most k. We claim that the linear ordering $\sigma = v_1, v_2, \ldots, v_n$ of $V(G)$ witnesses the target bound on the contiguity of G.

Let v be an arbitrary vertex in G and let N be its neighborhood. For convenience, mark a vertex of G by 1 if it belongs to N and 0 otherwise. This marking together with the ordering σ correspond to the binary word $w = w_1 w_2 \ldots w_n$, where w_i is the mark of v_i for every $i \in [n]$. A relation between pairs crossed and neighborhoods partitioned now follows from two observations:

1. in the word w, the maximal intervals of consecutive 1s correspond to intervals of consecutive vertices in σ that partition the neighborhood N of v;
2. each pair of consecutive letters $w_i w_{i+1}$ in w with $w_i \neq w_{i+1}$ corresponds to a crossing of $\{v_i, v_{i+1}\}$ by N.

To conclude, each interval in the partition of N corresponds to two crossings apart from the at most two intervals at each end of the ordering which each corresponds to one crossing. Thus the number of intervals is at most $2 + \lfloor \frac{k-2}{2} \rfloor \leqslant k/2 + 1$, as claimed. ◀

The next theorem translates a bound on neighborhood complexity to a bound on contiguity. It follows directly from Theorem 18, Observation 19, Observation 7, and the definition of neighborhood complexity.

▶ **Theorem 20.** *Let G be an n-vertex graph, $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a strictly increasing function, and d be a natural number. If $(V, \mathcal{N}_G)$ has VC dimension d and $\nu_G(m) \leqslant f(m)$ for all $m \in [n]$, then*

$$\mathrm{ctg}(G) \leqslant 1 + \log n + 5d \cdot \sum_{j=1}^{n} \frac{1}{f^{-1}(j/2)}.$$

We now apply Theorem 20 to hereditary small classes, which have $O(n \log n)$ neighborhood complexity by Theorem 4, to obtain a bound on their contiguity in closed form.

▶ **Theorem 21.** *Let $\mathcal{X}$ be a hereditary small class, then the contiguity of $\mathcal{X}$ is $O(\log^2 n)$.*

Proof. Since $\mathcal{X}$ is a small class, by Theorem 4 there exists some constant C such that $\nu_{\mathcal{X}} \leqslant f(n)$ where $f(n) := Cn \log n$. Consequently, for every $n \in \mathbb{N}$ and every n-vertex graph $G \in \mathcal{X}$, we have $\pi_{\mathcal{N}_G}(m) \leqslant f(m)$ for all $m \in [n]$. Thus, by definition, the VC dimension d of $(V(G), \mathcal{N}_G)$ satisfies $2^d \leqslant Cd \log d$, which implies

$$d \leqslant \log C + \log d + \log\log d \leqslant \log C + 4d/5,$$

and therefore $d \leqslant 4 \log C$.

Now, by Theorem 20, we have

$$\mathrm{ctg}(G) \leqslant 1 + \log n + 20 \cdot \log C \cdot \sum_{j=1}^{n} \frac{1}{f^{-1}(j)}. \tag{6}$$

Since f is increasing on $[1, \infty)$ with image $[0, \infty)$, its inverse f^{-1} exists on $[0, \infty)$, and is also increasing. The exact inverse f^{-1} is somewhat complicated, in particular $f^{-1}(1) = e^{W(\ln(2)/C)}$, where $W(\cdot)$ is the Lambert function. We consider $f^{-1}(1) > 0$ just as a constant depending on C, and show that

$$f^{-1}(x) \geqslant \frac{x}{C \log x} \qquad \text{for all } x \geqslant 2. \tag{7}$$

To show (7), since $\log x \geqslant 1$ for all $x \geqslant 2$ and we can assume $C \geqslant 1$, we have

$$f\left(\frac{x}{C\log x}\right) = C \cdot \frac{x}{C\log x} \cdot \log\left(\frac{x}{C\log x}\right) \leqslant x. \tag{8}$$

Thus, applying f^{-1} to both sides of (8) gives $f^{-1}(x) \geqslant \frac{x}{C\log x}$, establishing (7).

Then, by (6),

$$\begin{aligned}\mathrm{ctg}(G) &\leqslant 1 + \log n + 20 \cdot \log C \cdot \sum_{j=1}^{n} \frac{1}{f^{-1}(j)} \\ &\leqslant 1 + \log n + 20 \cdot \log C \cdot e^{-W(\ln(2)/C)} + 20 \cdot \log C \cdot \sum_{j=2}^{n} \frac{C\log j}{j} \\ &= \Theta(\log^2 n),\end{aligned}$$

as claimed. ◀

The main Theorem 3 of this section is a consequence of Theorems 4 and 21 and Proposition 6.

5 Conclusion

In this paper we obtained strong evidence in support of the Small Implicit Graph Conjecture that posits that every hereditary small class admits an $O(\log n)$-bit adjacency labeling scheme. Specifically, we showed that (1) every weakly sparse small class admits such a labeling scheme; (2) every hereditary small class admits an $O(\log^3 n)$-bit adjacency labeling scheme. To obtain these results we established two structural properties of hereditary small classes that are of independent interest. The first property is that every weakly sparse small class has bounded degeneracy, and even, bounded expansion. The second property is that every hereditary small class has neighborhood complexity $O(n \log n)$.

The latter property leaves a tantalizing open question of whether the bound on the neighborhood complexity can be further improved. All hereditary small classes known to us have linear neighborhood complexity (e.g., classes of bounded twin-width [14, 12]), which motivates the following:

▶ **Conjecture 22.** *Every hereditary small class of graphs has neighborhood complexity $O(n)$.*

If this conjecture is true, our approach would imply $O(\log^2 n)$-bit labeling schemes for all hereditary small classes.

A Paths with low crossing number

The main goal of this section is to provide a self-contained proof of Theorem 18. To state the theorem, we recall definitions of some crucial notions. Given a set system $(X, \mathcal{S})$, we say that a set $S \in \mathcal{S}$ *crosses* a 2-element set $\{x, y\} \subset X$ if exactly one of x and y belongs to S. Let $\mathcal{F}$ be a multiset of 2-element subsets in X. The crossing number of $\mathcal{F}$ with respect to a set $S \in \mathcal{S}$ is the number of elements in $\mathcal{F}$ that are crossed by S. The crossing number of $\mathcal{F}$ with respect to $\mathcal{S}$ is the maximum crossing number of $\mathcal{F}$ with respect to a set $S \in \mathcal{S}$. If $(X, \mathcal{F})$, considered as a graph, is a tree or a path spanning all elements of X, then we say that $(X, \mathcal{F})$ is a tree or a path on X, respectively. In this case, the crossing number of $\mathcal{F}$ is referred to as the crossing number of the corresponding tree or path, respectively.

▶ **Theorem 18.** *Let X be an n-element set, $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a strictly increasing function, and d be a natural number. Let $(X, \mathcal{S})$ be a set system of VC dimension d that satisfies $\pi^*_{\mathcal{S}}(m) \leqslant f(m)$ for all $m \in [n]$. Then there exists a path on X with crossing number at most*

$$2 \log |\mathcal{S}| + 10d \cdot \sum_{j=1}^{n} \frac{1}{f^{-1}(j/2)}.$$

This theorem is a known result stated in an unusual form, but one that is useful for us. The main feature of the above formulation is that the bound on the dual shatter function is given in a general form (expressed as a function f) rather than polynomial; in turn, the bound on the crossing number is expressed via the inverse of f. More specifically, the above formulation has two main differences compared to the standard one (for instance [40, 48]). First, in a standard formulation, the bound on the dual shatter function is $\pi^*_{\mathcal{S}}(m) \leqslant m^r$ for some constant $r > 1$. Second, the resulting bound on the crossing number of a path on X is in the form of $O(n^{1-1/r})$. Note that if we take $f(m)$ to be m^r in Theorem 18, then $f^{-1}(m) = m^{1/r}$ and

$$2 \log |\mathcal{S}| + 10d \cdot \sum_{j=1}^{n} \frac{1}{(j/2)^{1/r}}$$

can be upper bounded by $O(n^{1-1/r})$, which recovers the result in a standard form.

The benefit of the present formulation is that one can apply Theorem 18 when a preferable upper bound on $\pi^*_{\mathcal{S}}(m)$ is non-polynomial. For example, if $f(m) = m \cdot g(m)$ for some non-decreasing function $g(m)$, then Theorem 18 gives a bound of $O(g(n) \cdot \log n)$ on the crossing number. In particular, this becomes useful when $g(m) = m^{o(1)}$; e.g., if $g(m) = \log(m)$, the bound on the crossing number becomes $O(\log^2 n)$.

To provide a self-contained proof of Theorem 18, we need to state a number of auxiliary known results in a suitable (non-standard) form and repeat their proofs with some adjustments. Before each statement we explain how its formulation and proof differs from standard ones. We hope this exposition might be of use in some other work.

Packing lemma

We begin with Haussler's Packing Lemma [34] (Lemma 23), which is an improvement over a quantitatively weaker Packing Lemma obtained by Dudley [18] and re-discovered by Welzl [48]. The proof below is a simplification by Chazelle of Haussler's proof [34], which is taken from Matoušek's book [40].

A set system $(X, \mathcal{S})$ is *δ-separated* if for any two distinct sets $S_1, S_2 \in \mathcal{S}$ their symmetric difference contains at least δ elements, i.e., $|(S_1 \setminus S_2) \cup (S_2 \setminus S_1)| \geqslant \delta$. In a standard formulation, the lemma assumes that the shatter function $\pi_{\mathcal{S}}(m)$ is bounded by $O(m^r)$ for some r, and the bound on the cardinality of a δ-separated set $\mathcal{P}$ is $O((n/\delta)^r)$. For our purposes, in Lemma 23, we state the bound on $|\mathcal{P}|$ directly in terms of the shatter function. Note that the standard form of the lemma follows from ours if one uses the bound $\pi_{\mathcal{S}}(m) = O(m^r)$. The difference of the proof below from the one in [40] is that in Equation (13) we bound t in terms of the shatter function directly, rather than in terms of the bound on the shatter function.

▶ **Lemma 23** (Packing Lemma, see [40, Lemma 5.14]). *Let $(X, \mathcal{S})$ be a set system on an n-element set of VC dimension d. Let $\delta \in [n]$ be an integer, and let $\mathcal{P} \subseteq \mathcal{S}$ be δ-separated. Then,*

$$|\mathcal{P}| \leqslant 2 \cdot \pi_{\mathcal{S}}\left(\left\lceil \frac{4dn}{\delta} \right\rceil\right).$$

Before we prove this lemma we must introduce an auxiliary graph construction. For a set system $(X, \mathcal{S})$, we define the *unit distance graph* $\mathrm{UD}(\mathcal{S})$ to be the graph with

$$V(\mathrm{UD}(\mathcal{S})) = \mathcal{S} \qquad \text{and} \qquad E(\mathrm{UD}(\mathcal{S})) = \{\{S, S'\} : |S \Delta S'| = 1\}.$$

We will also need the following bound on the number of its edges.

▶ **Lemma 24** ([40, Lemma 5.15]). *If $(X, \mathcal{S})$ is a set system of VC dimension d on a finite set X then the unit distance graph $\mathrm{UD}(\mathcal{S})$ has at most $d|\mathcal{S}|$ edges.*

With this, we are now ready to prove the Packing Lemma.

Proof of Lemma 23. Choose a random s-element subset $A \subseteq X$, where s is given by

$$s := \left\lceil \frac{4dn}{\delta} \right\rceil. \tag{9}$$

Set $\mathcal{Q} := \{S \cap A \ : \ S \in \mathcal{P}\}$, and for each set $Q \in \mathcal{Q}$ define its weight $w(Q)$ as the number of sets $S \in \mathcal{P}$ with $S \cap A = Q$. Note that

$$\sum_{Q \in \mathcal{Q}} w(Q) = |\mathcal{P}|.$$

Let $E := E(\mathrm{UD}(\mathcal{Q}))$ be the edge set of the unit distance graph $\mathrm{UD}(\mathcal{Q})$, and define an edge weighting of $\mathrm{UD}(\mathcal{Q})$ by giving each edge $e = \{Q, Q'\} \in E$ weight $w(e) := \min(w(Q), w(Q'))$. Let

$$W = \sum_{e \in E} w(e),$$

where we note that this random variable depends on the random choice of A. The desired bound on $|\mathcal{P}|$ in the Packing Lemma is obtained by estimating the expectation of W in two different ways.

First, we claim that for any set $A \subseteq X$, we have the following (deterministic) bound on W

$$W \leqslant 2d \cdot \sum_{Q \in \mathcal{Q}} w(Q) = 2d \cdot |\mathcal{P}|. \tag{10}$$

To see this, note first that the VC dimension of $\mathcal{P}$ is at most d, and thus, by Lemma 24, the unit distance graph $\mathrm{UD}(\mathcal{Q})$ has some vertex Q_0 of degree at most $2d$. By removing Q_0, the total edge weight drops by at most $2d \cdot w(Q_0)$, and we are left with a unit distance graph on $(X, \mathcal{Q}')$, where $\mathcal{Q}' = \mathcal{Q} \setminus Q_0$ and $\mathcal{Q}'$ has VC dimension at most d. We can thus repeat this process until no vertices are left, and we see that the sum of edge weights removed is at most $2d$ times the sum of vertex weights, as claimed.

Next, we bound the expectation $\mathbb{E}[W]$ from below by considering the following random experiment. First, we choose a random $(s-1)$-element set $A \subseteq X$, and then we choose a random element $a \in X \setminus A'$. The set $A = A' \cup \{a\}$ is a uniform random s-element subset of X, we consider $\mathrm{UD}(\mathcal{Q})$ with the same edge weighting as above. Each edge of $\mathrm{UD}(\mathcal{Q})$ is a pair of sets of $\mathcal{Q}$ differing in exactly one element of A. We let $E_1 \subseteq E$ be the edges for which the difference element is a, and let W_1 be the sum of their weights. By symmetry, we have

$$\mathbb{E}[W] = s \cdot \mathbb{E}[W_1]. \tag{11}$$

We are going to bound $\mathbb{E}[W_1]$ from below. Let $A' \subset X$ be an arbitrary but fixed $(s-1)$-element set. We estimate the conditional expectation $\mathbb{E}[W_1 \mid A']$; that is, the expected value of W_1 when conditioned on a fixed set A', and $a \in X \setminus A'$ is selected uniformly at random. Divide the sets of $\mathcal{P}$ into equivalence classes $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_t$ according to their intersection with the set A'. By the definition of $\pi_{\mathcal{S}}(x)$ and since it is non-decreasing, we have

$$t \leqslant \pi_{\mathcal{S}}(s-1) \leqslant \pi_{\mathcal{S}}(s). \tag{12}$$

Let $\mathcal{P}_i$ be one of the equivalence classes, and $b := |\mathcal{P}_i|$. Suppose that an element $a \in X \setminus A'$ has been chosen. If b_1 sets of $\mathcal{P}_i$ contain a and $b_2 = b - b_1$ sets do not contain a, then the class $\mathcal{P}_i$ gives rise to an edge of E_1 of weight $\min(b_1, b_2)$. Note that b_1 and b_2 depend on the choice of a while b does not.

For any non-negative real numbers b_1, b_2 with $b_1 + b_2 = b$, we have $\min(b_1, b_2) \geqslant b_1 b_2 / b$. The value $b_1 b_2$ is the number of ordered pairs of sets (S_1, S_2) with S_1, S_2 being two sets from the class $\mathcal{P}_i$ where one contains a and the other one does not. Now, since $\mathcal{P}$ is δ-separated by hypothesis, if $S_1, S_2 \in \mathcal{P}_i$ are two distinct sets, then they differ in at least δ elements. Therefore, the probability that S_1 and S_2 differ in a random element $a \in X \setminus A'$ is at least $\frac{\delta}{n-s+1} \geqslant \delta/n$. Hence the expected contribution of each pair (S_1, S_2) of distinct sets of $\mathcal{P}_i$ to the quantity $b_1 b_2$ is at least δ/n, thus

$$\mathbb{E}[b_1 b_2 \mid A'] \geqslant b(b-1) \cdot \frac{\delta}{n}.$$

Consequently, the expected contribution $\mathbb{E}[\min(b_1, b_2) \mid A']$ of the equivalence class $\mathcal{P}_i$ to the sum of edge weights W_1 is at least $\mathbb{E}[b_1 b_2/b \mid A'] \geqslant (b-1)\delta/n$. Summing up over all equivalence classes, and using the bound on t from (12),

$$\mathbb{E}[W_1] \geqslant \mathbb{E}[W_1 \mid A'] \geqslant \frac{\delta}{n} \sum_{i=1}^{t} (|\mathcal{P}_i| - 1) \geqslant \frac{\delta}{n} (|\mathcal{P}| - t) \geqslant \frac{\delta}{n} (|\mathcal{P}| - \pi_{\mathcal{S}}(s)). \tag{13}$$

Combining this with the estimate (10), the equality (11), and the definition (9) of s, leads to

$$2d \cdot |\mathcal{P}| \geqslant s \cdot \frac{\delta}{n} \cdot (|\mathcal{P}| - \pi_{\mathcal{S}}(s)) \geqslant 4d \cdot (|\mathcal{P}| - \pi_{\mathcal{S}}(s)).$$

Rearranging gives $|\mathcal{P}| \leqslant 2 \cdot \pi_{\mathcal{S}}(s)$, so the statement follows from (9). ◀

Short Edge Lemma

A standard form of the Short Edge Lemma assumes a polynomial bound on the dual shatter function, i.e., $\pi^*_{\mathcal{S}}(m) = O(m^r)$ for some constant $r > 1$, and the resulting bound is expressed via the bound $O(m^{1/r})$ on the inverse of $\pi^*_{\mathcal{S}}(m)$. In our presentation of the Short Edge Lemma (Lemma 25) below we use a bound on the dual shatter function in a general from expressed as a function f, and the resulting bound is stated in terms of f^{-1}, the inverse of f. As before, by plugging in the bound $\pi^*_{\mathcal{S}}(m) = O(m^r)$ in Lemma 25 one would recover the standard form of the lemma. The proof is taken from [40] with suitable adjustments.

▶ **Lemma 25** (Short Edge Lemma, see [40, Lemma 5.18])**.** *Let X be an n-element set, $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a strictly increasing function, and d be a natural number. Let $(X, \mathcal{S})$ be a set system of VC dimension d with $\pi^*_{\mathcal{S}}(m) \leqslant f(m)$ for all $m \in [n]$. Then, for any multiset $\mathcal{Q}$ with elements from $\mathcal{S}$, there exist elements $x, y \in X$ such that the edge $\{x, y\}$ is crossed by at most*

$$5d \cdot \frac{|\mathcal{Q}|}{f^{-1}(n/2)}$$

sets of $\mathcal{Q}$.

Proof. We form a set system $\mathcal{D}$ which is dual to $\mathcal{Q}$. That is, we consider the multiset $\mathcal{Q}$ as the ground set (if some set appears in $\mathcal{Q}$ several times, then it is considered with the appropriate multiplicity). For each $x \in X$, we let D_x be the set of all sets of $\mathcal{Q}$ containing x, and we set

$$\mathcal{D} = \{D_x : x \in X\}.$$

The symmetric difference $D_x \Delta D_y$ of two sets from $\mathcal{D}$ consists of the sets in $\mathcal{Q}$ crossing the pair $\{x, y\}$. We thus want to show that $D_x \Delta D_y$ is small for some $x \neq y$. We may assume $D_x \neq D_y$ for $x \neq y$, as otherwise we are done, and hence $|\mathcal{D}| = |X| = n$.

The primal shatter function $\pi_{\mathcal{D}}$ is certainly no larger than the dual shatter function $\pi^*_{\mathcal{S}}$, and hence $\pi_{\mathcal{D}}(m) \leqslant f(m)$ by the assumption on $\pi^*_{\mathcal{S}}$. Suppose that any two sets $D_x, D_y \in \mathcal{D}$ have symmetric difference at least δ, then the packing lemma (Lemma 23) implies

$$n = |\mathcal{D}| \leqslant 2 \cdot \pi^*_{\mathcal{S}} \left(\left\lceil \frac{4d|\mathcal{Q}|}{\delta} \right\rceil \right) \leqslant 2f \left(\left\lceil \frac{4d|\mathcal{Q}|}{\delta} \right\rceil \right).$$

Since f is strictly increasing, f^{-1} is also strictly increasing. Therefore, we have

$$f^{-1}(n/2) \leqslant \left\lceil \frac{4d|\mathcal{Q}|}{\delta} \right\rceil \leqslant \frac{5d|\mathcal{Q}|}{\delta},$$

and therefore

$$\delta \leqslant 5d \cdot \frac{|\mathcal{Q}|}{f^{-1}(n/2)},$$

as claimed. ◀

Trees with low crossing number

As with the Short Edge Lemma, the following result (Theorem 26) is stated with a general bound f on the dual shatter function and the resulting bound on the crossing number of a tree is expressed in terms of f^{-1}, the inverse of f. The proof is taken from [40], which is very similar to Welzl's original proof [48]. The statement in [40] is for crossing number of matchings, and therefore it is slightly modified to work for trees as in [48].

▶ **Theorem 26** (see [40, Lemma 5.17]). *Let X be an n-element set, $f : \mathbb{R}_{\geqslant 0} \to \mathbb{R}_{\geqslant 0}$ be a strictly increasing function, and d be a natural number. Let $(X, \mathcal{S})$ be a set system of VC dimension d with $\pi^*_{\mathcal{S}}(m) \leqslant f(m)$ for all $m \in [n]$. Then there exists a tree T on X with crossing number at most*

$$\log|\mathcal{S}| + 5d \cdot \sum_{j=1}^{n} \frac{1}{f^{-1}(j/2)}.$$

Proof. We build T by selecting edges one by one according to the following strategy.

1. Suppose $\{u_1, v_1\}, \ldots, \{u_i, v_i\}$ have already been selected.
2. Define the weight $w_i(S)$ of a set $S \in \mathcal{S}$ as $2^{k_i(S)}$, where $k_i(S)$ is the number of edges among $\{u_1, v_1\}, \ldots, \{u_i, v_i\}$ crossed by S. In particular, $w_0(S) = 1$ for all $S \in \mathcal{S}$.
3. We select the next edge $\{u_{i+1}, v_{i+1}\}$ from $X_i = X \setminus \{u_1, u_2, \ldots, u_i\}$ as a pair of points with the total weight of sets crossing $\{u_{i+1}, v_{i+1}\}$ being the smallest possible.
4. We continue in this manner until $n - 1$ edges have been selected.

Let $E := \{\{u_1, v_1\}, \{u_2, v_2\} \ldots, \{u_{n-1}, v_{n-1}\}\}$. Then $T = (X, E)$ is a tree. Next, we will bound the crossing number k of the resulting tree T. To this end, we estimate the final total weight of all sets of $\mathcal{S}$, i.e.,

$$w_{n-1}(\mathcal{S}) = \sum_{S \in \mathcal{S}} w_{n-1}(S).$$

By definition of w_{n-1} we have $k \leqslant \log w_{n-1}(\mathcal{S})$.

Let us investigate how $w_{i+1}(\mathcal{S})$ increases compared to $w_i(\mathcal{S})$. Let $\mathcal{S}_{i+1}$ denote the collection of the sets of $\mathcal{S}$ crossing $\{u_{i+1}, v_{i+1}\}$. For each set in $\mathcal{S}_{i+1}$ the weight increases by a multiplicative factor of two, and for the other sets it remains unchanged. From this we get

$$w_{i+1}(\mathcal{S}) = w_i(\mathcal{S}) - w_i(\mathcal{S}_{i+1}) + 2w_i(\mathcal{S}_{i+1}) = w_i(\mathcal{S}) \left[1 + \frac{w_i(\mathcal{S}_{i+1})}{w_i(\mathcal{S})}\right].$$

We now estimate $\frac{w_i(\mathcal{S}_{i+1})}{w_i(\mathcal{S})}$ using the Short Edge Lemma (Lemma 25). To begin we define a multiset $\mathcal{Q}_i$ of sets by adding $S \cap X_i$ to $\mathcal{Q}_i$ with multiplicity $w_i(S)$ for every $S \in \mathcal{S}$. Thus

$$|\mathcal{Q}_i| = \sum_{S \in \mathcal{S}} w_i(S) = w_i(\mathcal{S}).$$

Note that, by the construction of $\mathcal{Q}_i$, the number of sets in $\mathcal{Q}_i$ that cross $\{u_{i+1}, v_{i+1}\}$ is $w_i(\mathcal{S}_{i+1})$. Furthermore, by our choice of edge in (2) and (3), the edge $\{u_{i+1}, v_{i+1}\}$ is crossed

by the minimum number of sets in $\mathcal{Q}_i$. Thus, by applying the Short Edge Lemma on the set system $(X_i, \{S \cap X_i \ : \ S \in \mathcal{S}\})$ to the multiset $\mathcal{Q}_i$, and defining $n_i := |X_i| = n - i$, we obtain:

$$w_i(\mathcal{S}_{i+1}) \leqslant 5d \cdot \frac{w_i(\mathcal{S})}{f^{-1}(n_i/2)}.$$

Hence, we have

$$w_{i+1}(\mathcal{S}) \leqslant w_i(\mathcal{S}) \left[1 + \frac{5d}{f^{-1}((n-i)/2)}\right].$$

Therefore

$$w_{n-1} \leqslant w_0(\mathcal{S}) \cdot \prod_{i=0}^{n-1} \left[1 + \frac{5d}{f^{-1}((n-i)/2)}\right] = |\mathcal{S}| \cdot \prod_{j=1}^{n} \left[1 + \frac{5d}{f^{-1}(j/2)}\right].$$

Taking logarithms of both sides and using the inequality $\ln(1+x) \leqslant x$ we obtain

$$k \leqslant \log w_{n-1}(\mathcal{S}) \leqslant \log |\mathcal{S}| + 5d \cdot \sum_{j=1}^{n} \frac{1}{f^{-1}(j/2)},$$

as claimed. ◀

From a tree to a path

Finally, Theorem 18 is obtained from Theorem 26 by using the following Lemma 27 to "convert" a tree with crossing number k to a path with crossing number at most $2k$. The argument is taken from [48] and we provided it here for completeness.

▶ **Lemma 27** ([48, Lemma 3.3])**.** *Let $(X, \mathcal{S})$ be a set system, and T be a tree on X with crossing number at most k with respect to $\mathcal{S}$. Then, there exists a path on X with crossing number at most $2k$ with respect to $\mathcal{S}$.*

Proof. We begin with the following claim.

▷ Claim 28. Given any family $\mathcal{F}$ of two element sets on X, replacing any pair $\{x, y\}, \{y, z\} \in \mathcal{F}$ by the set $\{x, z\}$ will not increase the crossing number with respect to $\mathcal{S}$.

Proof of Claim. If any $S \in \mathcal{S}$ crosses $\{x, z\}$, then exactly one of x or y is not contained in S. Thus, S must cross one of $\{x, y\}$ or $\{y, z\}$. ◁

Let $\mathcal{D} = \{\{u_1, u_2\}, \{u_2, u_3\}, \ldots, \{u_{\ell-1}, u_\ell\}\}$ be a multiset consisting of edges from T in the order they are traversed in a depth-first search (DFS) tour[3] of T starting from an arbitrary vertex. Additionally, let $x_1, \ldots, x_n$ be a labeling of X in the order they are discovered by the DFS tour $\mathcal{D}$.

Note that each edge of T appears exactly twice in $\mathcal{D}$, thus the crossing number of $\mathcal{D}$ is at most $2k$. We can now apply Claim 28 iteratively to reduce $\mathcal{D}$ to $\{\{x_1, x_2\}, \{x_2, x_3\}, \ldots, \{x_{n-1}, x_n\}\}$ without increasing the crossing number with respect to $\mathcal{S}$. ◀

[3] A DFS tour visits all vertices of the tree starting from a given vertex and going as far as possible down a given branch, then backtracking until it finds an unexplored path.

Round-Vs-Resilience Tradeoffs for Binary Feedback Channels

Abstract

In a celebrated result from the 60's, Berlekamp showed that feedback can be used to increase the maximum fraction of adversarial noise that can be tolerated by binary error correcting codes from $\frac{1}{4}$ to $\frac{1}{3}$. However, his result relies on the assumption that feedback is "continuous", i.e., after every utilization of the channel, the sender gets the symbol received by the receiver. While this assumption is natural in some settings, in other settings it may be unreasonable or too costly to maintain.

In this work, we initiate the study of *round-restricted feedback channels*, where the number r of feedback rounds is possibly much smaller than the number of utilizations of the channel. *Error correcting codes* for such channels are *protocols* where the sender can ask for feedback at most r times, and, upon a feedback request, it obtains all the symbols received since its last feedback request. We design such error correcting protocols for both the adversarial binary *erasure* channel and for the adversarial binary *corruption* (bit flip) channel. For the erasure channel, we give an exact characterization of the round-vs-resilience tradeoff by designing a (constant rate) protocol with r feedback rounds, for every r, and proving that its noise resilience is optimal.

Designing such error correcting protocols for the *corruption* channel is substantially more involved. We show that obtaining the optimal resilience, even with one feedback round ($r = 1$), requires settling (proving or disproving) a new, seemingly unrelated, "clean" *combinatorial conjecture*, about the maximum cut in weighted graphs versus the "imbalance" of an average cut. Specifically, we prove an upper bound on the optimal resilience (impossibility result), and show that the existence of a matching lower bound (a protocol) is *equivalent* to the correctness of our conjecture.

1 Introduction

Cybernetics. Consider the following two scenarios. Scenario one: a steersperson wishes to steer a longship to shore. She maintains a steady course in a changing environment (wind, waves, storms, currents, tides, etc.) by adjusting her steering in continual response to the effect it is observed as having. Scenario two: a teacher has a semester-worth of topics he wishes to teach to his class. He schedules exams throughout the semester to help him adapt his pace and determine what material should be repeated.

The above two scenarios are examples of *cybernetics*, a field that studies *self-regulating* processes. A core concept in cybernetics is *circular causality*, which is typically implemented using *feedback* mechanisms, where the observed outcomes of actions are taken as inputs for further actions. This is the case for, e.g., spacecraft navigators, artificial limbs, and our bodies' regulation of hormone and blood sugar levels. The term Cybernetics[1] was coined in 1948 by the mathematician and philosopher Norbert Wiener for "the science of control and communication in the animal and the machine" [37], following exchanges between numerous fields during the 1940s, including anthropology, mathematics, neuroscience, psychology, and engineering.

Feedback in information theory. Cybernetics grew alongside and built on Claude Shannon's information theory, that was developed to improve the transmission of information and introduced the notion of *error correcting codes*. Shannon was interested in knowing whether the existence of a "feedback link" in the channel, where after every utilization of the channel, the (possibly incorrect) symbol obtained by the receiver is also given to the sender, allows for better codes. A discouraging early result by Shannon showed that feedback does not improve the capacity of memoryless channels [31]. It would be another decade or so before Berlekamp proves that feedback can, in fact, increase the maximum fraction of *adversarial* errors that can be tolerated. Specifically, Berlekamp showed that the *maximum noise resilience* of the (adversarial) binary channel increases from $\frac{1}{4}$ to $\frac{1}{3}$ given feedback [4, 5] (also see [39, 35, 1]).

A key property of the feedback channel exploited by Berlekamp's result, as well as by follow up work, is that it supports "*continuous*" feedback – after *every* communication round, the sender gets the symbol received by the receiver. This assumption is natural in some settings, e.g., in scenario one, the steersperson continuously watches the ship's motion as she steers. However, this assumption may be unreasonable or too costly to maintain in other settings, e.g., in scenario two, the teacher may not want to continuously quiz his students.

This work: round-restricted feedback. Motivated by such examples, in this work, we initiate the study of *round-restricted feedback channels*, where the number of feedback rounds is possibly much smaller than the number of communication rounds. Specifically, we wish to design protocols with optimal noise resilience that allow the sender (Alice) to transmit a message to the receiver (Bob), where during the execution of the protocol, the sender can ask for feedback at most r times. Upon such a request, the sender obtains all the bits received by the receiver from the last time feedback was solicited.

One can consider two models for scheduling the feedback rounds: the *adaptive* and the *non-adaptive* models. In the non-adaptive model, the sender decides ahead of time (before the protocol is run and before the input is known) when to schedule the r feedback rounds, while in the adaptive model, the timing of each feedback request may depend on the previously received feedback. In the second scenario, for example, the non-adaptive setting

[1] Interestingly, Cybernetics comes from the Greek word "Kubernetes", which means steersperson.

corresponds to scheduling all exams at the beginning of the semester, while the adaptive setting corresponds to scheduling the next exam after the previous one was given. While our techniques hold for both the adaptive and non-adaptive settings, we choose to present our results for the non-adaptive setting. See Section 1.3 and Section 2.1 for a discussion of the implication of our techniques for the adaptive setting.

We consider such message transmission protocols with r feedback rounds over both the (adversarial) binary *erasure channel*, that erases some of the sent bits (those bits are received as "$\perp$"), and over the (adversarial) binary *corruption channel*, that flips some of the sent bits. As was mentioned before, classical results in information theory show that with no feedback the maximum noise resilience of the binary corruption channel is $\frac{1}{4}$ [25], while with continuous feedback, the maximum resilience improves to $\frac{1}{3}$ [4, 5]. For the binary erasure channel, it is known that with no feedback the maximum resilience is $\frac{1}{2}$, and it is easy to see that with continuous feedback it approaches 1: the sender re-transmits each symbol until the receiver receives it.

We mention that rounds (or passes) are often considered to be a scarce resource and that round-restricted algorithms are extensively studied in other communication settings, e.g., communication complexity, distributed computing, streaming algorithms, and cryptographic protocols, and that we draw inspiration from these settings.

1.1 Our Results and Conjecture

Due to page limit, sections containing formal discussion on the corruption case and all proofs are deferred to the full version [8]. Here, we focus on the erasure case and only provide high level ideas for the corruption case.

1.1.1 The (Adversarial) Binary Erasure Channel

As discussed above, the maximum resilience of the erasure channel is known for the extreme cases of no feedback and of continuous feedback. Our first result is an optimal *round-vs-resilience tradeoff* for the erasure channel with any number of non-adaptive feedback rounds.

▶ **Theorem 1.** *The maximum noise resilience of the (adversarial) binary erasure channel with r rounds of feedback is $\frac{5}{7}$ if $r = 1$ and $1 - \frac{7}{12(r+1)}$ if $r > 1$. Furthermore, the maximum noise resilience can be obtained by a* deterministic, constant-rate *protocol.*

Theorem 1 can be viewed as a "hierarchy theorem", showing that more feedback rounds allow for strictly better resilience. On the other hand, Theorem 1 also shows that a constant number $O_\epsilon(1)$ of feedback rounds already suffices to get a noise resilience of $1 - \epsilon$ for the erasure channel.

Techniques. The main ingredient in our proof of Theorem 1 is the construction of a *list decodable* code for the binary erasure channel with m codewords, for *all* (not necessarily asymptotic) values of m. Our code is optimal in the sense that it achieves the maximum error resilience for every list size simultaneously. We emphasize that for our protocols, we need such a code for all possible m, which corresponds to all possible "block sizes". We call codes with small m's "*small codes*". Given these codes, the protocols we use to prove Theorem 1 are rather simple – after every feedback round, Alice and Bob agree on a (smaller, unless there was a lot of noise) set Γ of candidate inputs x and Alice encodes x with our optimal list decodable code with $m = |\Gamma|$ codewords. On the analysis front, we are able to

argue that, unless the adversary erases many of the sent bits, the size of the candidate set Γ shrinks substantially between feedback rounds, and measure this shrinkage exactly. See Section 2.1 for a detailed overview.

1.1.2 The (Adversarial) Binary Corruption Channel

Theorem 1 gives a complete characterization of the noise resilience of the erasure feedback channel as a function of the number of feedback rounds. However, as will be explained next, the case of corruptions is much more involved, and we will focus on protocols with one round of feedback. We mention that since the adaptive and non-adaptive models are the same for protocols with one feedback round, the results in this section hold for both the adaptive and non-adaptive settings. Our next theorem gives an upper bound on the noise resilience of such one-round protocols.

▶ **Theorem 2.** *The maximum noise resilience of the (adversarial) binary corruption channel with one round of feedback is at most* $\frac{7}{23}$.

We conjecture that the upper bound of $\frac{7}{23}$ on the noise resilience in Theorem 2 is tight, and that it can be achieved by a constant-rate protocol. Perhaps surprisingly, proving this is *equivalent* to showing the following combinatorial conjecture about the existence of large cuts in graphs.

▶ **Conjecture 3.** *Let G be a graph with n vertices and non-negative edge weights summing up to 1. Let $\mathsf{wt}(S)$ be the sum of weights of all the edges with both endpoints in the subset of vertices S, and let $\mathsf{Max\text{-}Cut}(G)$ be the maximum total weight of all the edges across any cut in G. Then,*[2]

$$\mathsf{Max\text{-}Cut}(G) \geq \tfrac{2}{3} - \tfrac{16}{15} \cdot \mathop{\mathbb{E}}_{S\subseteq[n]}\left[\min\left(\mathsf{wt}(S), \mathsf{wt}(\overline{S})\right)\right]. \tag{1}$$

We prove Conjecture 3 for (large enough) graphs where all edges have equal weight, i.e., "unweighted" graphs. However, the case for general weighted graphs seems much harder, and, despite our best effort, we were unable to prove (or disprove) it. We also mention that Conjecture 3 is tight for some graphs (e.g., cliques of size 3 and 5 with edges of equal weight), and related bounds on $\mathsf{Max\text{-}Cut}$ were studied in other contexts, e.g., [26, 2, 22].

The next theorem gives the equivalence between Conjecture 3 and the tightness of Theorem 2.

▶ **Theorem 4.** *Theorem 2 is tight if and only if Conjecture 3 holds. Furthermore, Conjecture 3 implies a* constant rate *protocol achieving the maximum noise resilience.*

In essence, Theorem 4 connects the problem of designing optimal error correcting protocols with one round of feedback to a combinatorial question about graphs. As we discuss later in Section 2.2, our techniques can also be used to connect the problem of designing optimal error correcting protocols with multiple rounds of feedback to similar questions about graphs.

---

[2] As the expectations of $\mathsf{wt}(S)$ and $\mathsf{wt}(\overline{S})$, for a uniformly random S, are $\frac{1}{4}$, Equation (1) can be equivalently written as $\mathsf{Max\text{-}Cut}(G) \geq \frac{6}{15} + \frac{8}{15} \cdot \mathbb{E}_{S\subseteq[n]}\left[\left|\mathsf{wt}(S) - \mathsf{wt}(\overline{S})\right|\right]$, where the term inside the expectation is the "imbalance" of a random cut.

Techniques. The proof of Theorem 4 is technically involved and a detailed overview can be found in Section 2.2. At a high level, the main ingredient in designing our protocol is the construction of a special type of "weighted" codes, called dc-*codes*. A dc-code C is parameterized by a "distance contribution function" dc that assigns a value in $[0,1]$ to each possible message $x \in \{0,1\}^k$. We require that for all $x \neq x' \in \{0,1\}^k$, the codewords $C(x)$ and $C(x')$ are at least (relative) Hamming distance $\mathsf{dc}(x) + \mathsf{dc}(x')$ apart. Equivalently, we ask that the balls of radii $\mathsf{dc}(x)$ around $C(x)$ are all disjoint.[3] We note that unlike traditional error correcting codes that have only one distance guarantee for all pairs of codewords (i.e., the minimum distance), the distance guarantees for different pairs of codewords in a dc-code are different. In fact, traditional codes can be viewed as dc-codes for a constant dc function.

dc-codes for non-constant dc functions are useful for our protocol as if the adversary already used up many of its corruptions before the feedback round, Alice knows she can afford to send her message x encoded with an error correcting code that does not guarantee a large distance between $C(x)$ and the other codewords. Geometrically, designing a dc-code is a sphere packing problem where we need to pack spheres of different radii $\mathsf{dc}(x)$. As for some x's a small radius $\mathsf{dc}(x)$ suffices, some of the spheres are small, which allows the other spheres being packed to be larger.

The proof of Theorem 4 shows that Conjecture 3 implies the existence of dc-codes that are needed for our protocol to work. We assume that Alice uses a uniformly random code to encode her message before the feedback. The codeword sent by Alice can be corrupted by the channel in many ways, and each such way would imply a function dc such that Alice would like to use a dc-code to encode her message after the feedback. We denote by Q the set of dc functions for which the corresponding dc-codes are needed by our protocol. We also denote by P the set of dc functions for which dc-codes exist. We wish to show $Q \subseteq P$. To this end, we show that both P and Q are closed and convex, and that in every direction z, the extremal point of P in direction z is "farther" than the extremal point of Q in direction z. We then recast this geometric problem as a combinatorial problem by interpreting the direction vector z as a weighted graph G, and show that the extremal point of P in direction z corresponds to a Max-Cut in G (as in the left hand side of Conjecture 3), while the extremal point of Q in direction z corresponds to the right hand side of Conjecture 3.

For the converse direction of Theorem 4, we show that the arguments in the above paragraph are actually equivalences, except for the assumption that Alice uses a randomly sampled code to encode her message before the feedback. At a high level, we use *Ramsey theory* to show that the assumption that this code is a random code is, at least in some sense, without loss of generality (see Section 2.2.2 for a more precise statement).

1.2 Related Work

Feedback channels were studied since the early days of information theory and are still actively studied [31, 24, 14, 5, 9, 27, 32, 13, 33, 34, to cite a few]. While feedback does not increase the capacity of discrete memoryless channels with vanishing error, there are settings where feedback is known to allow improvement, like in the 0-error capacity case [31], and under variable decision time [9].

Partial feedback. Haeupler, Kamath, and Velingker [23] considered the setting where the feedback is partial, and showed that even if Alice receives feedback bits from Bob for an arbitrarily small constant fraction of her transmissions, resilience close to (the optimal

[3] We mention that dc-codes are an example of non-equally spaced codes defined in [11].

resilience of) $\frac{1}{3}$ is possible using a randomized protocol. However, the number of feedback rounds their protocol needs grows linearly with n, the length of Alice's input. See [36] for a subsequent result.

Independently and concurrently to our work, [15] improved [23] and showed a deterministic protocol that uses $\mathcal{O}(\log n)$ feedback bits over $\mathcal{O}(1)$ feedback rounds to get resilience approaching $\frac{1}{3}$, along with a similar result for the erasure channel showing that the resilience approaches 1 for this channel. The main difference between [15] and the current work is that we focus on finding the optimal resilience for any given number r of feedback rounds whereas [15] focuses on showing that the resilience approaches the optimal value as the constant r increases. Additionally, their work measures both the number of feedback rounds and the number of feedback bits, while we only focus on the number of rounds.

Two-way codes and interactive codes. As discussed above, feedback is also known to increase the noise resilience of the adversarial binary corruption channel [4, 5], and this result played a big role in recent work in *interactive coding* [10, 18, 17] and *two-way coding* [16, 19, 11]. In interactive coding [28, 29, 30], we wish to simulate a communication protocol Π that was designed to work over the noiseless channel, by a protocol Π' that works over a noisy channel. In the setting of two-way codes, like in the setting of traditional error correcting codes, Alice wishes to transmit a message x to Bob over a noisy channel. However, unlike the case of traditional codes, where Alice is the only party that can transmit messages, in two-way codes Bob can also use the (noisy) channel to transmit messages back to Alice.

Observe that since Bob has no input, any two-way code can be run over the feedback channel and thus two-way error correcting codes can be viewed as protocols over a *noisy feedback* channel. In particular, since the noise tolerance of the binary corruption channel is only $\frac{1}{3}$, the noise resilience of binary two-way codes over the binary corruption channel is at most $\frac{1}{3}$. In the same way, results for the bounded round feedback channel give upper bounds on the noise resilience of the corresponding two-way channels.

Gupta, Kalai, and Zhang [16, 19] studied two-way error correcting codes over the binary *erasure channel*. Their main result is a code that is resilient to a $\frac{3}{5}$ fraction of adversarial errors, improving on the noise tolerance of the one-way binary erasure channel that is known to be $\frac{1}{2}$. We mention that the two-way coding schemes of [16, 19] exchange (almost) linear number of messages. The work of [16] also gives an upper bound of $\frac{2}{3}$ on the maximum tolerance of the two-way binary erasure channel, and an upper bound of $\frac{2}{7}$ on the maximum tolerance of the two-way binary corruption channel. Given those upper bounds, a corollary of our results is that even a single round of noiseless feedback allows for a better error tolerance than any number of noisy feedback rounds over both the erasure and corruption channels[4].

The recent work of Efremenko, Kol, Saxena, and Zhang [11] shows that the maximum noise resilience of two-way error correcting codes for the binary corruption channel is strictly better than the noise resilience of traditional error correcting codes for this channel, which is

[4] To see why, observe that if Bob's messages are noiseless, we can assume without loss of generality that Bob's messages are much shorter, say at most an ϵ fraction, of Alice's messages. Indeed, if not, consider a modified protocol where all messages from Alice are repeated k times, for some large k. For the erasure channel, either all the repetitions of a bit from Alice are erased or Bob knows the bit exactly. Thus, his communication does not grow with k. For the corruption channel, it suffices for Bob to say how many of the repetitions were received as 1, which can be done using $\log k \ll k$ bits.
Moreover, we mention that for this claim, we do not need to rely on Conjecture 3, as a lower bound slightly smaller than $\frac{7}{23}$ (but greater than $\frac{2}{7}$) on the maximum error resilience of protocols with one feedback round over the binary corruption channel can be obtained unconditionally using our techniques (but is not included in the current work).

known to be $\frac{1}{4}$ [25]. At a very high level, those results for two-way codes are obtained by implementing a (weak) feedback mechanism over channels with no built-in feedback. Related ideas were used in [10, 18, 17] to give interactive binary error correcting codes with high noise resilience.

List decodable codes. List decodable codes were introduced in the 50's [12, 38] and have been studied over numerous papers and found many applications since then. We next list the works most related to ours. Most of the work on list decoding was done in the asymptotic regime, where the number of codewords goes to infinity. In this work, we are interested in the optimal list decodable codes for any (potentially small) number of codewords. However, as an ingredient in our proof, we use the asymptotic results of [3] (see also [6, 21, 7]) for optimal list decoding of the corruption channel (see Lemma 11). The list decoding question was also considered for other channels, for example, over the corruption channel with feedback [32] and the erasure channel [20].

1.3 Open Problems

Our work suggests the study of feedback channels through a new lens, namely, their feedback round complexity. We next list some suggestions for future work in this direction.

Graph-theoretic conjectures. The most immediate question we leave open is proving Conjecture 3 for all weighted graphs. We also propose the following potentially related conjecture, which is tight for all odd cliques with edges of equal weight.

▶ **Conjecture 5.** *Let G be a graph with n vertices and non-negative edge weights summing up to 1. Let $\mathsf{wt}(i)$ be the sum of weights of all edges incident on vertex i. Then,*

$$\mathsf{Max\text{-}Cut}(G) \geq \frac{1}{2} + \frac{1}{8} \cdot \sum_{i \in [n]} \mathsf{wt}(i)^2.$$

Round-vs-resilience tradeoff for other channels. Proving Conjecture 3 would imply that our protocol in Theorem 4 has optimal noise resilience among protocols with one round of feedback over the corruption channel. Obtaining a general round-vs-resilience tradeoff for any number of feedback rounds r for the corruption channel and for other well-studied channels (e.g., the binary insertion-deletion channel[5], the binary deletion-only channel, and non-binary channels), would be interesting.

Adaptive corruptions over the erasure channel. Theorem 1 considers the case of *non-adaptive* feedback rounds, where Alice decides ahead of time when to ask for feedback. It can be shown that the case of *adaptive* feedback rounds, where Alice chooses when to ask for another round of feedback after seeing the previous feedback, allows for (strictly) better round-vs-resilience tradeoffs. Our techniques can be used to write a recursive formula for the noise resilience in the adaptive case, and finding a "clean", closed-form formula for this setting (if one exists) is left open (see Section 2.1).

[5] We note that this first requires a suitable definition for the insertion-deletion channel with constant number of rounds.

2 Proof Overview

In this section, we overview the proofs of Theorems 1 and 4, starting with the relatively easier Theorem 1.

2.1 Result for the Erasure Channel – Theorem 1

The defining feature of the erasure channel is that the receiver (Bob) either receives the bit sent by Alice or receives a special erasure symbol $\perp$. This means that in any round where Bob receives $\perp$, he is certain that this is due to the erasures in the channel, while if he receives a symbol different from $\perp$, he is certain that the symbol must be what Alice sent in that round. In turn, this means that Bob knows exactly the amount of erasures introduced by the channel and also means that Bob can (recall that he is trying to determine Alice's input) remove from consideration any candidate input that is "inconsistent" and would make Alice send a different symbol in any such round.

The general format of a protocol. The above observation implies that protocols for the erasure channel with r rounds of feedback (and therefore $r+1$ messages from Alice) have the following format: Alice starts with an input $x \in \Gamma_0 = \{0,1\}^n$. For her first message, she takes a code[6] $C_0 : \Gamma_0 \to \{0,1\}^*$ and sends $C_0(x)$ to Bob. Some of the bits of $C_0(x)$ are received correctly by Bob, while the remaining bits are erased and replaced with $\perp$. Using the bits he received correctly, Bob can calculate the number of erasures N_1 introduced by the channel in this round and can identify a subset $\Gamma_1 \subseteq \Gamma_0$ of inputs for Alice that are consistent with the message he received. Note that Alice's input x must be in Γ_1.

Then, a feedback round takes place, and as Alice learns all the received symbols, she can also compute N_1 and Γ_1. As both parties now know these values, they can now "forget" this round and "reduce"[7] to a smaller problem where Alice wants to transmit an element $x \in \Gamma_1$ to Bob using a protocol with $r-1$ rounds of feedback and the maximum number of erasures the channel can insert is N_1 lower than what it was before. Continuing this way, the goal of the parties is to reduce to a problem with 0 rounds of feedback, and set of inputs Γ_r such that there exists a (standard) error correcting code for elements in Γ_r resilient to the number of erasures that the channel can insert in the last round.

List-decodable small codes. It is readily seen that the protocol format described above does not care about the exact strings in the sets $\Gamma_0, \ldots, \Gamma_r$, as long as their sizes stay the same. Thus, the question of whether or not the above protocol format can be instantiated to get a protocol that is resilient to θ fraction of adversarial erasures, for some $\theta \in [0,1]$, reduces to determining when to schedule the feedback rounds, and given two feedback rounds, determining the codes C_i to be used by Alice between these rounds. The codes C_i should be such that, given an initial set size $m = |\Gamma_i|$ and a target set size[8] $k = |\Gamma_{i+1}|$, the number

[6] At this point, it may be helpful to view this as a function instead of a code. We explain why we are calling it a code later. Also, a more precise way to state this would be to say that there exists an $L > 0$ such that $C_0 : \Gamma_0 \to \{0,1\}^L$, as all codewords need to be of the same length to avoid the parties from signaling through the length of the codeword. Nonetheless, we stick with statements like $C_0 : \Gamma_0 \to \{0,1\}^*$ throughout this sketch for simplicity.

[7] We elaborate what this means exactly in the paragraph on adaptive feedback rounds below.

[8] Note that k is not known to the parties in advance, and thus it will be ideal if the code used is optimal for all k simultaneously.

of erasures required to reduce the set size from m to k is the highest. Using such codes, Alice ensures that unless the adversary invests many erasures, the set of candidates shrinks substantially between feedback rounds. We first focus on designing such codes.

Codes like the above are known as list decodable codes, and have been well studied in the asymptotic regime, where m tends to infinity, and exact answers are known (see, e.g., [12, 38, 6, 20, 7, 3, 32] and Lemma 11). However, for our purposes, we need the exact answer for smaller values of m as well. Codes with small m, i.e., "small codes" or codes with few codewords, have recently received a lot of attention and have proven to be useful in designing binary protocols with high error resilience in several contexts [10, 11, 16, 18, 19]. In the current paper, we provide a complete analysis of the list-decodability of these codes for the erasure channel, giving a function $\mathsf{d}(m,k)$ that characterizes exactly the minimum amount of erasure noise needed such that for *any* code $C : [m] \to \{0,1\}^*$, one can erase $\mathsf{d}(m,k)$ fraction of the bits and ensure that Bob gets a list of candidates of length strictly smaller than k.

The formula for $\mathsf{d}(m,k)$ is given in Equation (7). Proving that this formula is correct requires showing both a construction (of codes with resilience approaching $\mathsf{d}(m,k)$) and an impossibility result. Our construction has the nice property that the same code is tight simultaneously for all values of k. Roughly speaking, our code achieves this optimal erasure noise resilience by ensuring that every coordinate is as differentiating as possible, i.e., we ensure that for all coordinates j, exactly $\lfloor \frac{m}{2} \rfloor$ (uniformly chosen) codewords have 0 in that coordinate, while the remaining $\lceil \frac{m}{2} \rceil$ codewords have 1 (see Lemmas 9 and 10). This is as opposed to randomly sampled codes where, e.g., a $\frac{1}{2^m}$ fraction (which is large for small m) of the coordinates are expected to be 0 for all the codewords, and therefore not differentiate between any pair of codewords.

Scheduling the feedback rounds. Even with an exact formula for $\mathsf{d}(m,k)$ in hand, it still remains to schedule the feedback round correctly in order to maximize the overall noise resilience of the obtained protocol. The fact that our constructed code is tight simultaneously for all values of k is of great help for this part, as the actual value of k is determined by the erasures inserted by the channel and not in our control. This means that in order to schedule the feedback rounds optimally, one needs to go over all possible values of k (across all rounds) that may happen over the channel and maximize the corresponding error resilience. This requires a careful analysis of the obtained formula for $\mathsf{d}(m,k)$.

Adaptive feedback rounds. We finish this section by briefly discussing the extension of our result to adaptive feedback rounds, as hinted in Section 1.3. Recall our reduction above from r to $r-1$ feedback rounds, and note that this reduction is not perfect in the following sense: the erasures inserted by the adversary in Alice's first message in the r-round protocol dictate the set Γ_1 of candidates and the budget of the $(r-1)$-round protocol. Observe that the $(r-1)$-round protocol with maximal noise resilience for transmitting a message depends on the size of the set of candidates and on the erasure budget. Now, since our r-round protocol is non-adaptive, meaning that the timing of all feedback rounds is fixed in advance and cannot be recalculated given the erasures in the first round, our r-round protocol may reduce to a sub-optimal $(r-1)$-round protocol. Therefore, when scheduling the feedback rounds for our r-round protocol, one needs to consider the values of k that are possible across all rounds in order to get the optimal schedule.

On the other hand, if the feedback rounds can be scheduled adaptively, the reduction is indeed perfect. In this case, one just needs to schedule the first feedback round beforehand based on the possible values of $k = |\Gamma_1|$ for this round alone, and then, upon seeing the N_1

and Γ_1 values, one can take the $(r-1)$-feedback round protocol with the maximum error resilience (when Alice's input is from Γ_1 and the number of erasures is N_1 lower) and schedule the remaining feedback rounds according to this protocol. Thus, our techniques also lead to a tight recursive formula for the maximum error resilience in the case of adaptive feedback rounds, but converting it to a "clean" closed form formula (if at all possible) is left open.

2.2 Result for the Corruption Channel – Theorem 4

Compared to the erasure channel, where Bob knows exactly the amount of noise inserted and can safely eliminate many candidate inputs for Alice, the corruption channel is much harder. Here, upon receiving a message from Alice, all Bob can compute is, given a candidate input y for Alice, what is the number $\mathsf{N}(y)$ of corruptions the channel inserted assuming Alice's input was indeed y. Crucially, this value of $\mathsf{N}(y)$ may be very different for different y, and unless it exceeds the maximum possible number of corruptions in the channel (which can only happen when the protocol is quite far advanced), it can never have Bob eliminate y from consideration entirely.

Consider now a protocol over the corruption channel with one round of feedback (and therefore, two messages from Alice). Suppose that Alice's input x comes from the set $\{0,1\}^n$. As explained above, after receiving the first message from Alice, Bob knows $\mathsf{N}(y)$ for all $y \in \{0,1\}^n$. By subtracting $\mathsf{N}(y)$ from the maximum possible number of corruptions, Bob can compute, for all $y \in \{0,1\}^n$, a number $\mathsf{dc}(y)$ which is the leftover corruptions, or, equivalently, the degree to which the second message of Alice can be corrupted, assuming her input is y. As Alice receives feedback from Bob, she can also compute the values $\mathsf{dc}(y)$ for all $y \in \{0,1\}^n$. In the remainder of this sketch, we normalize $\mathsf{dc}(y)$ by dividing it by the length of Alice's second message. This will result in a value in $[0,1]$.

dc-codes. Using this feedback, Alice's goal in her second message is to allow Bob to uniquely identify her input. If $C : \{0,1\}^n \to \{0,1\}^*$ is the code used by Alice in her second message, the only way Bob can uniquely decode Alice's input is if for all $y \neq y' \in \{0,1\}^n$, the codewords $C(y)$ and $C(y')$ are at least (relative) Hamming distance $\mathsf{dc}(y) + \mathsf{dc}(y')$ apart. The reason is that if y is Alice's input, then the adversary has fractional budget $\mathsf{dc}(y)$ that it can use to corrupt $C(y)$, and thus the codeword received by Bob can be any string of (relative) Hamming distance at most $\mathsf{dc}(y)$ from $C(y)$. Similarly, if y' is Alice's input, then the codeword received by Bob can be any string of Hamming distance at most $\mathsf{dc}(y')$ from $C(y')$. Note that the adversary cannot arrange for the received encodings to be the same if and only if $C(y)$ and $C(y')$ are at least (relative) Hamming distance $\mathsf{dc}(y) + \mathsf{dc}(y')$ apart. We call a code that satisfies this (relative) Hamming distance property a dc-code and mention that the values $\mathsf{dc}(y)$ can equivalently be seen as the "distance contributed" by y in such a code.

We note that unlike traditional error correcting codes that have only one distance guarantee for all pairs of codewords (i.e., the minimum distance), for dc-codes, the distance between a pair of codewords may be different depending on the "compatibility" of the messages they encode. Specifically, we think of each codeword as having a different "radius" and the code needs to "pack" all the induced balls of different radii. We point out that dc-codes are an example of non-equally spaced codes defined in [11].

We also observe that the small code used in our protocol for erasures can be viewed as a dc-code where $\mathsf{dc}(y) = 0$ for all inputs y that Bob has ruled out (and therefore, do not need any distance guarantees), and $\mathsf{dc}(y) = c$ for all inputs y that he has not ruled out, where c is

the best possible constant (c is determined by the $\mathsf{d}(m,k)$ function). We mention that for the erasure channel, our protocol also needed list-decoding guarantees that are not needed here as we are only attempting to get a one feedback round protocol.

The discussion so far shows that the existence of a protocol with a given error resilience amounts to determining whether or not it holds that for all functions $\mathsf{dc}(\cdot)$ that can be induced by the corruptions inserted in Alice's first message, there exists a dc-code that Alice can use to compute her second message. Curiously, we show in the next subsection that this question is equivalent to our seemingly unrelated combinatorial conjecture (Conjecture 3) about the existence of large cuts in graphs.

Towards multiple rounds of feedback. The above approach of designing dc-codes (that have no rounds of feedback) to construct protocols with one round of feedback can be generalized. One can similarly argue that, for any $r \geq 0$, dc-codes with r rounds of feedback can be used to construct protocols with $r+1$ rounds of feedback. Analogously to the above, the "extra" round is the first round, and dictates which dc-code is used in the rest of the protocol. Moreover, questions about constructing dc-codes with r rounds of feedback can be translated to questions about graphs. The $r = 0$ case is explained next, but similar ideas may be used for general r, with appropriate changes in the definitions of the set P and Q (see below).

2.2.1 Conjecture 3 Implies a Tight Protocol

We first show why Conjecture 3 implies the existence of a tight protocol. In fact, we shall show the existence of a protocol where Alice's message in the first round is simply the encoding of her input x using a randomly sampled code. Let $m = 2^n$. A distance function is a function $\mathsf{dist} : \binom{[m]}{2} \to \mathbb{R}$, where $\binom{[m]}{2}$ is the set of all subsets of $[m]$ of size 2. For a code $C : [m] \to \{0,1\}^*$, we denote by dist_C the distance function induced by C, i.e., $\mathsf{dist}_C(i,i')$ is the (relative) Hamming distance between $C(i)$ and $C(i')$. For a distance contribution function dc, we denote by $\mathsf{dist}_{\mathsf{dc}}$ the distance function induced by dc, i.e., $\mathsf{dist}_{\mathsf{dc}}(i,i') = \mathsf{dc}(i) + \mathsf{dc}(i')$. For simplicity, throughout this overview we assume that $\mathsf{dc}(y) = 1 - \mathsf{N}(y)$ (recall that $\mathsf{dc}(y)$ is actually the normalized leftover corruption count, but in this sketch we will ignore the exact multiplicative and additive constants in this function).

Recasting as a geometric problem. We denote by P the set of all distance functions dist_C that are induced by codes $C : [m] \to \{0,1\}^*$. We denote by Q the set of all distance functions $\mathsf{dist}_{\mathsf{dc}}$ induced by dc functions that can be obtained by the corruptions inserted in Alice's first message (recall that dc depends on N, which is a function of the corruptions inserted in Alice's first message). In other words, P is the set of distance functions that can be realized and Q is the set of distance functions required by our protocol. We wish to prove $Q \subseteq P$.

We view distance functions dist as $\binom{m}{2}$-dimensional vectors. We observe that both P and Q are closed and convex and that the set P is "downwards-closed", meaning that if $\mathsf{dist} \in P$ then any dist' that is coordinate wise at most dist is also in P. This means that showing $Q \subseteq P$ is equivalent to showing that for all $\binom{m}{2}$-dimensional non-negative hyperplanes z, it holds that:

$$\max_{\mathsf{dist} \in P} \langle z, \mathsf{dist} \rangle \geq \max_{\mathsf{dist} \in Q} \langle z, \mathsf{dist} \rangle, \tag{2}$$

Recasting as a combinatorial problem. By scaling, we can assume that the entries of z sum to 1 and view them as the weights on the edges of an m-vertex graph G_z as in Conjecture 3. As both P and Q are closed and convex, both the maximums are attained at one of their vertices.

To reason about Equation (2), it will be useful to represent a code $C : [m] \to \{0,1\}^L$ as a sequence of L one-bit functions $b : [m] \to \{0,1\}$ (the first one-bit function corresponds to the first coordinate of $C(i)$, etc.). Observe that for the code $b : [m] \to \{0,1\}$ (i.e., $L = 1$), it holds that dist_b is a boolean function with $\mathsf{dist}_b(i,i') = 1$ if and only if $b(i) \neq b(i')$.

The LHS of Equation (2). Since a general code C is a sequence of one-bit functions, it can be shown that the function dist_C is a convex combination of the functions dist_b that are induced by one-bit functions b. In particular, this means that the vertices of P are distance functions induced by one-bit functions. Using the expression above for dist_b for one-bit function $b : [m] \to \{0,1\}$, the value of $\langle z, \mathsf{dist}_b \rangle$ is the value of the cut in the graph G_z indicated by b:

$$\langle z, \mathsf{dist}_b \rangle = \sum_{(i,i')} z_{i,i'} \cdot \mathsf{dist}_b(i,i') = \sum_{(i,i'):\, b(i) \neq b(i')} z_{i,i'}. \tag{3}$$

Thus, the left hand side of Equation (2) is the maximum cut in G_z, as in Conjecture 3.

The RHS of Equation (2). We view the code used by Alice in her first message as a sequence of one-bit functions. Since in our protocol this code is randomly sampled, each of the 2^m one-bit functions is expected to appear equally often in Alice's message[9]. As the channel can corrupt each of these one-bit functions independently of all the others, we get that a distance function dist can be induced by the corruptions inserted in Alice's first message (i.e., $\mathsf{dist} \in Q$) if and only if it is the expectation (under the uniform distribution over one-bit functions) of the distance functions that can be induced by corrupting one-bit functions.

Now, if Alice is sending a one-bit function $b : [m] \to \{0,1\}$, there are only two possibilities for Bob: either he receives a 0 or he receives a 1. Let dc_b be the distance contribution function dictated by Bob's received bit. We next show that in the former case, where Bob receives 0, the value of $\langle z, \mathsf{dist}_{\mathsf{dc}_b} \rangle$ is the value of the cut in G_z indicated by b plus twice the weight of all edges such that $b(\cdot) = 0$ on both its endpoints. To see that, recall that $\mathsf{dist}_{\mathsf{dc}_b}(i,i') = \mathsf{dc}_b(i) + \mathsf{dc}_b(i')$ and that we assume $\mathsf{dc}_b(y) = 1 - \mathsf{N}(y)$. In our case, $\mathsf{dc}_b(i) = 1 - 0 = 1$ if $b(i) = 0$ (Alice's bit was not corrupted) and $\mathsf{dc}_b(i) = 0$ if $b(i) = 1$ (Alice's bit was corrupted). This implies that $\mathsf{dist}_{\mathsf{dc}_b}(i,i') = 0$ if $b(i) = b(i') = 1$, and that $\mathsf{dist}_{\mathsf{dc}_b}(i,i') = 1$ if $b(i) \neq b(i')$, and that $\mathsf{dist}_{\mathsf{dc}_b}(i,i') = 2$ if $b(i) = b(i') = 0$. Therefore,

$$\max_{\mathsf{dist} \in Q} \langle z, \mathsf{dist}_{\mathsf{dc}_b} \rangle = \sum_{(i,i')} z_{i,i'} \cdot \mathsf{dist}_{\mathsf{dc}_b}(i,i') = \sum_{(i,i'):\, b(i) \neq b(i')} z_{i,i'} + \sum_{(i,i'):\, b(i) = b(i') = 0} 2 \cdot z_{i,i'}. \tag{4}$$

Similarly, it can be shown that in the latter case, where Bob gets 1, the value of $\langle z, \mathsf{dist}_{\mathsf{dc}_b} \rangle$ is the value of the cut in G_z indicated by b plus twice the weight of all edges such that $b(\cdot) = 1$ on both its endpoints.

[9] We mention that this is only in expectation and the length of Alice's message need not depend exponentially on m.

Recall that the bit function b is a uniformly random bit-function. Taking an expectation over one bit functions b, the value of the cut in G_z indicated by b is exactly the constant $\frac{1}{2}$ and the other terms on the right hand side of Equation (3) and Equation (4) are exactly as on the right hand side of Conjecture 3, where the maximum becomes minimum because of the constants involved. Equation (2) now directly follows from Conjecture 3.

2.2.2 A Tight Protocol Implies Conjecture 3

We now finish this sketch by arguing why a tight protocol implies Conjecture 3. For this, we note that all the arguments in Section 2.2.1 were actually equivalences, except two, one of which was explicitly stated and one was not. The explicit one was our assumption that Alice's first message is simply the encoding of her input using a randomly sampled code. The second one was that Alice gets feedback from Bob at round $\frac{8T}{23}$, where T is the total number of rounds of the protocol. The constant $\frac{8}{23}$ may seem arbitrary, but it is the constant one gets when one tries to match the constants obtained in the analysis in Section 2.2.1 with the constants in Conjecture 3.

Both these assumptions are actually without loss of generality. We start by arguing this for the second one, again ignoring the actual constants and only stating the high level idea. Roughly speaking, the second assumption is without loss of generality as Conjecture 3 is tight for cliques of size 3 and 5, and if the constant is anything other than $\frac{8}{23}$, Equation (2) will fail to hold for z corresponding to one of these cliques.

It remains to show why the first assumption is without loss of generality. For this, our approach is to take an arbitrary code $C : [m] \to \{0,1\}^*$ that Alice may use for her first message, and in several steps, convert it to a code that looks more and more like a random code, at the cost of a smaller m. In each step k, we convert C to a code that is k-random, in the sense that any set of k codewords of the new code looks like k codewords from a randomly sampled code.

For $k = 1$, this means that we have to show that each codeword has an equal number of 0s and 1s, and this can be easily achieved by concatenating all codewords with their negations (which preserves the distance properties). We now show how to get a 2-random code from a 1-random code, noting that similar (but technically more involved) ideas allow us to get a $(k+1)$-random code from a k-random code, for any $k \geq 1$. To show that a code is 2-random, we need to show that it is 1-random and that the fractional distance between any pair of codewords is (roughly) $\frac{1}{2}$.

For this, let $\epsilon > 0$ be an error parameter and construct a complete graph with the m codewords as the vertices, and color the edge between codewords i and i' as (1) red, if the fractional distance between them is smaller than $\frac{1}{2} - \epsilon$, (2) blue, if the fractional distance between them is between $\frac{1}{2} - \epsilon$ and $\frac{1}{2} + \epsilon$, (3) green, if the fractional distance between them is larger than $\frac{1}{2} + \epsilon$. As m gets larger and larger, Ramsey theory tells us that there must exist a large (going to infinity with m) monochromatic clique in this graph. This clique cannot be red, as we show that a large number of pairwise close codewords can be used to break the protocol. It also cannot be green, as that would violate known distance bounds for error correcting codes. Thus, it must be blue, implying that restricting attention to this clique gives us our desired 2-random code.

3 Model and Preliminaries

3.1 Notation and Preliminaries

For $x \in \mathbb{R}$, let $\overrightarrow{x}$ be the vector (of appropriate dimension inferred from context) with all its coordinates being x. Throughtout, all inequalities between vectors are coordinate-wise. For $k \geq 0$, $\Delta^k = \{(x_0, \ldots, x_k) \in \mathbb{R}^{k+1} \mid \sum_{i=0}^{k} x_i = 1 \text{ and } x_i \geq 0 \text{ for all } i \in [0,k]\}$ denotes the k-dimensional standard simplex. For $x \in \mathbb{R}$ and $k \geq 0$, we write $x^{\underline{k}}$ as a shorthand for falling factorial $\prod_{i=0}^{k-1}(x-i)$.[10] For a set S and $k \geq 0$, let $\binom{S}{k}$ be the collection of all subsets of S of size k. For a function $f : X \to Y$ and subset $X' \subseteq X$, $f|_{X'}$ denotes the restriction of f onto X'. For $x, y \geq 1$, $\mathsf{R}(x,y)$ is the (two-color) Ramsey number for x, y, which is well-known to be finite. For $k \geq 1$ and two bit strings $x, y \in \{0,1\}^k$, their Hamming distance is $\Delta(x,y) = \sum_{i=1}^{k} \mathbb{1}[x_i \neq y_i]$.

3.2 Our Model: Round-Restricted Binary Feedback Channels

We now define (deterministic, binary) *protocols* with (non-adaptive) round-restricted feedback for the message transfer task, where Alice has an input and Bob's goal is to learn this input. Such a protocol is defined by a tuple:

$$\Pi = \Big(n, r, \{L_i\}_{i\in[r+1]}, \{f_i\}_{i\in[r+1]}, \mathsf{out}\Big), \tag{5}$$

where (1) $\{0,1\}^n$ is the set of all possible inputs for Alice; (2) r is the number of feedback rounds. Equivalently, we can say that Alice speaks in $r+1$ rounds; (3) For all $i \in [r+1]$, L_i is the length of Alice's message in the i-th round. Throughout, we use $L = \sum_{i=1}^{r+1} L_i$; (4) For all $i \in [r+1]$, $f_i : \{0,1\}^n \times \{0,1,\perp\}^{L_1} \times \cdots \times \{0,1,\perp\}^{L_{i-1}} \to \{0,1\}^{L_i}$ is the message function Alice uses in the i-th round; (5) $\mathsf{out} : \{0,1,\perp\}^{L_1} \times \cdots \times \{0,1,\perp\}^{L_{r+1}} \to \{0,1\}^n$ is the function Bob uses to compute the output.

Execution of a protocol. Let Π be a protocol as above. An adversary for Π is defined by a function $\mathsf{Adv} : \{0,1\}^n \to \{0,1,\perp\}^{L_1} \times \cdots \times \{0,1,\perp\}^{L_{r+1}}$. For $i \in [r+1]$, we will use $\mathsf{Adv}_i(\cdot)$ to denote the function that outputs the i-th coordinate of $\mathsf{Adv}(\cdot)$. We next define an execution of Π in the presence of an adversary Adv for Π: At the beginning of the execution, Alice starts with an input $x \in \{0,1\}^n$. The execution consists of $r+1$ rounds and before the i-th round, for $i \in [r+1]$, Alice and Bob have the (same) transcript $\tau_{<i} \in \{0,1,\perp\}^{L_1} \times \cdots \times \{0,1,\perp\}^{L_{i-1}}$. In round i, Alice computes the message $f_i(x, \tau_{<i}) \in \{0,1,\perp\}^{L_i}$ and sends it to Bob bit by bit, while Bob receives the string $\tau_i = \mathsf{Adv}_i(x)$. As we assume a feedback channel, if $i \leq r$, Alice also receives the string τ_i and both the parties add τ_i to $\tau_{<i}$ and continue executing the protocol.

If $i = r+1$, the execution of the protocol terminates and Bob outputs $\mathsf{out}(\tau_{\leq r+1})$. Observe that this execution is completely determined by x, Π, and Adv. We denote the output of Π on input x in the presence of adversary Adv by $\mathsf{out}_{\Pi,\mathsf{Adv}}(x)$.

Counting the noise. Let Π be a protocol as above and Adv be an adversary for Π. For $x \in \{0,1\}^n$, the amount of noise added by Adv in Π on input x is the number of times Bobs' received bit is different from the bit Alice sent. Formally, we have:

$$\mathsf{noise}_{\Pi,\mathsf{Adv}}(x) = \sum_{i=1}^{r+1} \Delta(\mathsf{Adv}_i(x), f_i(x, \mathsf{Adv}_{<i}(x))). \tag{6}$$

[10] See also Falling factorials (Wikipedia) for the notation.

For $\theta \in [0,1]$, we say that an adversary Adv has budget θ if we have

$$\max_{x \in \{0,1\}^n} \mathsf{noise}_{\Pi,\mathsf{Adv}}(x) \leq \theta L.$$

Types of Adversaries. Let Π be a protocol as above and Adv be an adversary for Π. We say that Adv is a *corruption adversary* if it never outputs the symbol $\perp$, i.e., for all $x \in \{0,1\}^n$ and all $i \in [r+1]$, we have $\mathsf{Adv}_i(x) \in \{0,1\}^{L_i}$. We say that Adv is an *erasure adversary* if it only "erases" the symbols sent by Alice. More precisely, we say that Adv is an erasure adversary if for all $x \in \{0,1\}^n$, all $i \in [r+1]$, and all $j \in [L_i]$, if $(\mathsf{Adv}_i(x))_j \neq \perp$, then we have $(\mathsf{Adv}_i(x))_j = (f_i(x, \mathsf{Adv}_{<i}(x)))_j$.

Resilience of a protocol. Let Π be a protocol as above and $\theta \in [0,1]$. We say that Π *has resilience* θ over the binary erasure channel if for all erasure adversaries with budget θ and all $x \in \{0,1\}^n$, it holds that $\mathsf{out}_{\Pi,\mathsf{Adv}}(x) = x$. Resilience over the binary corruption channel is defined analogously.

4 Optimal List-Decodable Small Codes

In this section, we construct the codes used by our protocol.

4.1 Definitions of List Decodability

Codes for erasures. We start by defining list decodability for erasures.

▶ **Definition 6.** *Let $m, k, L \geq 1$ and $d \in [0,1]$. We say that a code $C : [m] \to \{0,1\}^L$ is less-than-k-list decodable for erasures up to radius d if for all subsets $\Gamma \in \binom{[m]}{k}$, we have $\mathsf{ns}_C(\Gamma) > d$, where:*

$$\mathsf{ns}_C(\Gamma) = 1 - \frac{1}{L} \cdot \sum_{j=1}^{L} \mathbb{1}[\exists b \in \{0,1\} \ \forall i \in \Gamma : C_j(i) = b].$$

To get the intuition behind the definition of ns, observe that $\mathsf{ns}_C(\Gamma)$ is the minimum fraction e of erasures for which there exists $\tau \in \{0,1,\perp\}^L$ such that for all $i \in \Gamma$, it is possible to erase $e \cdot L$ symbols from $C(i)$ and get τ. Observe that this is equal to the fraction of coordinates where the encodings $\{C(i)\}_{i \in \Gamma}$ are *not* all the same (ns = not same).

For $m, k \geq 1$, we define $\mathsf{d}_{\mathsf{erase}}(m,k)$ to be the supremum of all values $d \in [0,1]$ for which there exists $L \geq 1$ and a code $C : [m] \to \{0,1\}^L$ that is less-than-k-list decodable for erasures up to radius d.

Codes for corruptions. Next, we define list decodability for corruptions:

▶ **Definition 7.** *Let $m, k, L \geq 1$ and $d \in [0,1]$. We say that a code $C : [m] \to \{0,1\}^L$ is less-than-k-list decodable for corruptions up to radius d if for all $\tilde{x} \in \{0,1\}^L$, we have*

$$|\{i \in [m] : \Delta(C(i), \tilde{x}) < dL\}| < k.$$

Analogous to $\mathsf{d}_{\mathsf{erase}}$, for $m, k \geq 1$, we define $\mathsf{d}_{\mathsf{corr}}(m,k)$ to be the supremum of all values $d \in [0,1]$ for which there exists $L \geq 1$ and a code $C : [m] \to \{0,1\}^L$ that is less-than-k-list decodable for corruptions up to radius d.

4.2 Lemmas about $\mathsf{d}_{\mathsf{erase}}$ and $\mathsf{d}_{\mathsf{corr}}$

In this section, we show the results we need about $\mathsf{d}_{\mathsf{erase}}$ and $\mathsf{d}_{\mathsf{corr}}$. First, we define a helper function $\mathsf{d}(\cdot,\cdot)$:

$$\mathsf{d}(m,k) = 1 - \frac{\binom{\lfloor m/2 \rfloor}{k} + \binom{\lceil m/2 \rceil}{k}}{\binom{m}{k}}. \tag{7}$$

We now show some useful properties of the function d defined in Equation (7).

▷ Claim 8. The following hold:

1. For all $m \geq k \geq 1$, it holds that
$$\mathsf{d}(m,k) = 1 - \frac{(\lceil m/2 \rceil - 1)^{\underline{k-1}}}{(2\lceil m/2 \rceil - 1)^{\underline{k-1}}}.$$
2. For all $m_2 \geq m_1 \geq k \geq 1$, it holds that $\mathsf{d}(m_2,k) \leq \mathsf{d}(m_1,k)$, and moreover,
$$\lim_{m\to\infty} \mathsf{d}(m,k) = 1 - \frac{1}{2^{k-1}}.$$
It follows that $\mathsf{d}(m,k) \geq 1 - \frac{1}{2^{k-1}}$ for all $m \geq k \geq 1$.
3. For all $m \geq k_2 \geq k_1 \geq 1$, it holds that $\mathsf{d}(m,k_2) \geq \mathsf{d}(m,k_1)$.

4.2.1 Lemmas about $\mathsf{d}_{\mathsf{erase}}$

We now show that the functions $\mathsf{d}_{\mathsf{erase}}$ and d are the exact same. Owing to this lemma, we omit writing erase in the subscript in the rest of this text.

▶ **Lemma 9.** *For all $m,k \geq 1$, we have:*

$$\mathsf{d}_{\mathsf{erase}}(m,k) = \mathsf{d}(m,k).$$

▶ **Lemma 10.** *For all $\epsilon > 0$, there exists a constant K such that for all $K' \geq K$ and for all $m \geq 1$, there exists a code $C : [m] \to \{0,1\}^{K' \log m}$ such that for all $k \in [m]$, the code C is less-than-k-list decodable up to radius $\mathsf{d}(m,k) - \epsilon$.*

4.2.2 Lemmas about $\mathsf{d}_{\mathsf{corr}}$

Using the results of Section 4.2.1, we show the following lemma:

▶ **Lemma 11.** *For all $m,k \geq 2$, we have:*

$$\mathsf{d}_{\mathsf{corr}}(m,2) = \frac{\mathsf{d}(m,2)}{2} \qquad \text{and} \qquad \lim_{m\to\infty} \mathsf{d}_{\mathsf{corr}}(m,k) = \frac{1}{2} - \frac{\binom{k-1}{\lceil k/2 \rceil - 1}}{2^k}.$$

5 Protocols Against Erasures

In this section, we show one direction of Theorem 1, as formalized below. Later, in Section 6, we prove the other direction.

▶ **Theorem 12.** *For all $\epsilon > 0$ and $r,n \in \mathbb{N}$, there exists a constant-rate (polynomial in ϵ) protocol for message transfer with r rounds of feedback, input length n, and the following resilience over the binary erasure channel:*

$$\begin{cases} \frac{5}{7} - \epsilon, & \text{if } r = 1 \\ 1 - \frac{7}{12(r+1)} - \epsilon, & \text{if } r > 1 \end{cases}.$$

We prove Theorem 12 in the rest of this section. Throughout, we fix $\epsilon > 0$ and $r, n \in \mathbb{N}$. We assume $r < \frac{10}{\epsilon}$. This is without loss of generality as a protocol for large r follows from a protocol for smaller r.

5.1 Our Protocol

Let K be the constant from Lemma 10 for ϵ. For all $K' \geq K$ and all $m \geq 1$, let $C_{m,K'} : [m] \to \{0,1\}^{K' \log m}$ be as promised by Lemma 10. We will omit K' when it is clear from context. For a set Γ of size m, we will also view C_m as a code $C_\Gamma : \Gamma \to \{0,1\}^{K' \log m}$. Our protocol is given in Algorithm 1, where the lengths of the rounds are given as follows:

$$L_i = \begin{cases} \frac{4}{3} \cdot Kn, & \text{if } i = r = 1 \\ Kn, & \text{otherwise} \end{cases}. \tag{8}$$

Algorithm 1 Message transfer protocol over the erasure channel with $r \geq 1$ feedback rounds.

Input: Alice has input $x \in \Gamma_0 = \{0,1\}^n$.
Output: Bob outputs $y \in \{0,1\}^n$.

1: **for** $i = 1, \ldots, r+1$ **do**
2: Alice sends $C_{\Gamma_{i-1}}(x) \in \{0,1\}^{L_i}$ bit by bit.
3: Bob receives $\tau_i \in \{0,1,\perp\}^{L_i}$ and sends τ_i via the noiseless feedback channel.
4: Bob computes

$$\Gamma_i = \{x' \in \Gamma_{i-1} \mid \forall j \in [L_i] : \tau_{i,j} \in \{C_{\Gamma_{i-1},j}(x'), \perp\}\}.$$

5: If $i \leq r$, Alice receives τ_i as feedback and also computes Γ_i as above.
6: **end for**
7: Bob outputs the lexicographically first element in Γ_{r+1}, aborting if $\Gamma_{r+1} = \emptyset$.

5.2 Analysis

We now analyze Algorithm 1 and finish proving Theorem 12. That the protocol is constant rate is clear from Algorithm 1. It remains to show that it has the claimed noise resilience. For this, we fix an input x for Alice and an erasure adversary Adv for the protocol with desired budget as in Theorem 12. Observe that fixing x and Adv fixes the value of all the variables in the execution of Algorithm 1. For the analysis, we first show that:

▶ **Lemma 13.** *For all $i \in [0, r+1]$, we have $x \in \Gamma_i$.*

▶ **Lemma 14.** *For all $m \geq k' \geq k \geq 2$ such that $(k', k) \neq (3, 2)$, it holds that*

$$\mathsf{d}(m, k') + \mathsf{d}(k', k) \geq 1 + \mathsf{d}(m, k).$$

At a high level, Lemma 14 will be applied as follows: Consider an adversary that shrinks the set Γ from size m to size k' in a given round and from size k' to size k in the next round. Lemma 14 shows that, if the two rounds are of equal length (recall from Equation (8) that the round lengths are always the same except when $i = r = 1$), then it is always better for the adversary to erase one of the rounds completely and shrink from size m to size k directly in the other round.

We now divide the proof into two cases based on whether or not $r = 1$.

5.2.1 Proof of Theorem 12 When $r = 1$

Let $k_i = |\Gamma_i|$ for $i \in [0, 2]$. We prove the theorem by showing that $k_2 \leq 1$. Together with Lemma 13 and Algorithm 1, this shows the correctness of Algorithm 1.

Observe that at the beginning of the i-th round, Alice and Bob agree on Γ_{i-1}, the subset of all remaining possibilities for x from the perspective of Bob, that are still consistent with the partial transcript $\tau_1, \ldots, \tau_{i-1}$ so far. In order to keep Bob confused among Γ_i, the adversary has to erase at least a $\mathsf{d}(k_{i-1}, k_i) - \epsilon$ fraction of Alice's i-th message, due to Lemma 10. As this holds for all rounds, the overall fraction of erasures is lower bounded by

$$\frac{4}{7}(\mathsf{d}(k_0, k_1) - \epsilon) + \frac{3}{7}(\mathsf{d}(k_1, k_2) - \epsilon) = \frac{4\mathsf{d}(k_0, k_1) + 3\mathsf{d}(k_1, k_2)}{7} - \epsilon.$$

Now suppose $k_2 \geq 2$. It is sufficient to show $4\mathsf{d}(k_0, k_1) + 3\mathsf{d}(k_1, k_2) \geq 5$ for a contradiction. Without loss of generality, we assume $k_2 = 2$ since $\mathsf{d}(k_1, k_2)$ only decrease as k_2 becomes smaller by Item 3 of Claim 8. If $k_1 = 3$, we have

$$4\mathsf{d}(k_0, k_1) + 3\mathsf{d}(k_1, k_2) = 4\mathsf{d}(k_0, 3) + 3\mathsf{d}(3, 2) \geq 4 \cdot \frac{3}{4} + 3 \cdot \frac{2}{3} = 5$$

by Item 2 of Claim 8. Otherwise, by Lemma 14, we also get

$$\begin{aligned}
4\mathsf{d}(k_0, k_1) + 3\mathsf{d}(k_1, k_2) &= 4(\mathsf{d}(k_0, k_1) + \mathsf{d}(k_1, 2)) - \mathsf{d}(k_1, 2) \\
&\geq 4(1 + \mathsf{d}(k_0, 2)) - \mathsf{d}(k_1, 2) \\
&\geq 3 + 4\mathsf{d}(k_0, 2) && \text{(as } \mathsf{d}(\cdot, \cdot) \text{ is always upper bounded by 1)} \\
&\geq 3 + 4 \cdot \frac{1}{2} && \text{(by Item 2 of Claim 8)} \\
&= 5.
\end{aligned}$$

5.2.2 Proof of Theorem 12 When $r > 1$

Let $k_i = |\Gamma_i|$ for $i \in [0, r+1]$. Similarly to the proof in Section 5.2.1, we show that $k_{r+1} \leq 1$. This ensures Bob outputs the correct $y = x$ because of Lemma 13 and Algorithm 1. Using a similar argument to Section 5.2.1, we have that the overall fraction of erasures is lower bounded by

$$\frac{1}{r+1} \cdot \sum_{i=1}^{r+1} \mathsf{d}(k_{i-1}, k_i) - \epsilon.$$

Now for the purpose of contradiction, suppose that $k_{r+1} \geq 2$. It is sufficient to show

$$\frac{1}{r+1} \cdot \sum_{i=1}^{r+1} \mathsf{d}(k_{i-1}, k_i) \geq 1 - \frac{7}{12(r+1)}.$$

In the following, we again assume without loss of generality that $k_{r+1} = 2$ since $\mathsf{d}(k_r, k_{r+1})$ decreases as k_{r+1} becomes smaller by Item 3 of Claim 8. Let $j = \min\{t \in [r+1] \mid k_t \leq 3\}$. By repeatedly applying Lemma 14, we have

$$\begin{aligned}
&\frac{1}{r+1}\cdot\sum_{i=1}^{r+1}\mathsf{d}(k_{i-1},k_i)\\
&\qquad\geq\frac{1}{r+1}\cdot\left(1+\mathsf{d}(k_0,k_2)+\sum_{i=3}^{r+1}\mathsf{d}(k_{i-1},k_i)\right)\\
&\qquad\quad\vdots\\
&\qquad\geq\frac{1}{r+1}\cdot\left(j-1+\mathsf{d}(k_0,k_j)+\sum_{i=j+1}^{r+1}\mathsf{d}(k_{i-1},k_i)\right).
\end{aligned}$$

Since $k_0\geq\cdots\geq k_{r+1}=2$ by definition of Γ_i, either $k_j=2$ or $k_j=3$.

In the former case where $k_j=2$, we also have $k_{j+1}=\cdots=k_{r+1}=2$ and thus

$$\begin{aligned}
&\frac{1}{r+1}\cdot\sum_{i=1}^{r+1}\mathsf{d}(k_{i-1},k_i)\\
&\qquad\geq\frac{1}{r+1}\cdot\left(j-1+\mathsf{d}(k_0,k_j)+\sum_{i=j+1}^{r+1}\mathsf{d}(k_{i-1},k_i)\right)\\
&\qquad=\frac{1}{r+1}\cdot\left(j-1+\mathsf{d}(k_0,2)+(r+1-j)\cdot\mathsf{d}(2,2)\right)\\
&\qquad\geq\frac{1}{r+1}\cdot\left(j-1+\frac{1}{2}+r+1-j\right)\qquad\text{(by Item 2 of Claim 8)}\\
&\qquad=1-\frac{1}{2(r+1)}\\
&\qquad\geq1-\frac{7}{12(r+1)}.
\end{aligned}$$

In the latter case where $k_j=3$, let $j'=\min\{t\in[r+1]\mid k_t=2\}$. Then we have

$$\begin{aligned}
&\frac{1}{r+1}\cdot\sum_{i=1}^{r+1}\mathsf{d}(k_{i-1},k_i)\\
&\qquad\geq\frac{1}{r+1}\cdot\left(j-1+\mathsf{d}(k_0,k_j)+\sum_{i=j+1}^{r+1}\mathsf{d}(k_{i-1},k_i)\right)\\
&\qquad=\frac{1}{r+1}\cdot\left(j-1+\mathsf{d}(k_0,3)+(j'-1-j)\cdot\mathsf{d}(3,3)+\mathsf{d}(3,2)+(r+1-j')\cdot\mathsf{d}(2,2)\right)\\
&\qquad\geq\frac{1}{r+1}\cdot\left(j-1+\frac{3}{4}+j'-1-j+\frac{2}{3}+r+1-j'\right)\qquad\text{(by Item 2 of Claim 8)}\\
&\qquad=1-\frac{7}{12(r+1)}.
\end{aligned}$$

This concludes the proof.

6 Impossibility Result for Erasures

In this section, we show the other direction of Theorem 1, as formalized below.

▶ **Theorem 15.** *For all $r \in \mathbb{N}$, there exists an $n \in \mathbb{N}$ such that the resilience of any protocol for message transfer with r rounds of feedback and input length n over the binary erasure channel is at most:*

$$\begin{cases} \frac{5}{7}, & \text{if } r = 1 \\ 1 - \frac{7}{12(r+1)}, & \text{if } r > 1 \end{cases}.$$

We prove Theorem 15 in the rest of this section. Throughout, we work with a fixed $r \in \mathbb{N}$ and define n to be large enough for asymptotic inequalities to hold. We now divide the proof into two cases based on whether or not $r = 1$.

6.1 Proof of Theorem 15 When $r = 1$

Fix a protocol Π with input length n and one round of feedback. Recall Equation (5) and let L_1, L_2 be the lengths of Alice's messages sent in the two rounds, and $f_1 : \{0,1\}^n \to \{0,1\}^{L_1}$, $f_2 : \{0,1\}^n \times \{0,1,\perp\}^{L_1} \to \{0,1\}^{L_2}$ be the two message functions Alice uses in the two rounds.

First suppose that $L_1 \geq \frac{4}{7}(L_1 + L_2)$. By Lemma 9, there exists a subset $\Gamma = \{x_1, x_2\} \in \binom{\{0,1\}^n}{2}$ such that $\mathsf{ns}_{f_1}(\Gamma) \leq \mathsf{d}(2^n, 2)$. This implies the adversary is able to erase a $\mathsf{d}(2^n, 2)$ fraction of Alice's first message so that Bob's view when Alice's input is x_1 is identical to Bob's view when Alice's input is x_2, and therefore Bob is forced to send the same feedback $\tau_1 \in \{0,1,\perp\}^{L_1}$ in both cases. Now the adversary simply erases Alice's second message entirely implying that Bob can never output the correct answer. By Item 2 of Claim 8, the overall fraction of erasures is upper bounded as

$$\mathsf{d}(2^n, 2) \cdot \frac{L_1}{L_1 + L_2} + 1 \cdot \frac{L_2}{L_1 + L_2} \leq \frac{4 \cdot \mathsf{d}(2^n, 2) + 3}{7} \xrightarrow{n \to \infty} \frac{5}{7}.$$

Now consider the other case where $L_1 \leq \frac{4}{7}(L_1 + L_2)$. Again by Lemma 9, there exists a subset $\Gamma = \{x_1, x_2, x_3\} \in \binom{\{0,1\}^n}{3}$ such that $\mathsf{ns}_{f_1}(\Gamma) \leq \mathsf{d}(2^n, 3)$. In this case, the adversary erases a $\mathsf{d}(2^n, 3)$ fraction of Alice's first message so that Bob's view is the same when Alice's input is any of x_1, x_2, x_3. Bob must send the same feedback $\tau_1 \in \{0,1\}^{L_1}$ in all three cases. Note that $f_2(\cdot, \tau_1)$ can also be viewed as a valid code and thus Lemma 9 still applies. In particular, it is always possible to erase a $\mathsf{d}(3, 2) = \frac{2}{3}$ fraction of Alice's second message so that for at least two of x_1, x_2, x_3, Bob's view remains the same at the end of the protocol. This concludes the proof as the overall fraction of erasures is at most

$$\mathsf{d}(2^n, 3) \cdot \frac{L_1}{L_1 + L_2} + \frac{2}{3} \cdot \frac{L_2}{L_1 + L_2} \leq \frac{4 \cdot \mathsf{d}(2^n, 3) + 3 \cdot \frac{2}{3}}{7} \xrightarrow{n \to \infty} \frac{5}{7}.$$

6.2 Proof of Theorem 15 When $r > 1$

Fix a protocol Π with input length n and r rounds of feedback. Recall Equation (5) and for $t \in [r+1]$, let L_t be the length of Alice's message sent in the t-th round. Let $L = \sum_{t=1}^{r+1} L_t$.

We prove the theorem using an approach similar to Section 6.2, i.e., the adversary is always able to erase Alice's messages in such a way that Bob has the same view at the end of the protocol for at least two different inputs. In particular, the adversary erases the entire messages of all rounds except for $i = \arg\max_{t \in [r+1]} L_t$, the longest round, and $j = \arg\max_{t \in [r+1] \setminus \{i\}} L_t$, the second longest round. Then we have

$$L_i \geq \frac{L}{r+1}, \tag{9}$$

$$L_j \geq \frac{L - L_i}{r}. \tag{10}$$

First consider the case where $i < j$. Since the first $i-1$ rounds are completely erased, Bob obviously has the same view for all possible inputs at the beginning of the i-th round. By Lemma 9, the adversary can erase a $\mathsf{d}(2^n, 3)$ fraction of Alice's i-th message so that Bob's view is the same when Alice's input is any of some subset $\Gamma = \{x_1, x_2, x_3\} \subseteq \{0,1\}^n$. This remains true at the beginning of the j-th round as all intermediate rounds are completely erased. Now again by Lemma 9, the adversary is able to erase a $\mathsf{d}(3,2) = \frac{2}{3}$ fraction of Alice's j-th message so that Bob still has the same view at the end of the j-th round, for at least two of x_1, x_2, x_3. As all remaining rounds are also completely erased, Bob can never output the correct answer at the end of the protocol. By Item 2 of Claim 8, the overall fraction of erasures is upper bounded as

$$\begin{aligned}
&\mathsf{d}(2^n,3)\cdot\frac{L_i}{L} + \frac{2}{3}\cdot\frac{L_j}{L} + 1\cdot\frac{L - L_i - L_j}{L} \\
&\quad= 1 - \big(1 - \mathsf{d}(2^n,3)\big)\cdot\frac{L_i}{L} - \frac{1}{3}\cdot\frac{L_j}{L} \\
&\quad\leq 1 - \big(1 - \mathsf{d}(2^n,3)\big)\cdot\frac{L_i}{L} - \frac{1}{3r}\cdot\frac{L - L_i}{L} && \text{(by Equation (10))} \\
&\quad= 1 - \frac{1}{3r} - \left(1 - \mathsf{d}(2^n,3) - \frac{1}{3r}\right)\cdot\frac{L_i}{L} \\
&\quad\leq 1 - \frac{1}{3r} - \left(1 - \mathsf{d}(2^n,3) - \frac{1}{3r}\right)\cdot\frac{1}{r+1} \\
&\qquad\qquad \text{(as } 1 - \mathsf{d}(2^n,3) \xrightarrow{n\to\infty} \tfrac{1}{4} > \tfrac{1}{3r} \text{ for } r \geq 2\text{, and by Equation (9))} \\
&\quad\xrightarrow{n\to\infty} 1 - \frac{7}{12(r+1)}.
\end{aligned}$$

Now suppose that $i > j$. In this case, a similar argument shows the adversary must be able to confuse Bob by erasing a $\mathsf{d}(2^n,3)$ fraction of Alice's j-th message as well as a $\mathsf{d}(3,2) = \frac{2}{3}$ fraction of Alice's i-th message (in addition to completely erasing all other rounds of messages). Observe that $L_i \geq L_j$ by definition and that $\mathsf{d}(2^n,3) \xrightarrow{n\to\infty} \frac{3}{4} \geq \frac{2}{3}$. So the overall fraction of erasures is at most

$$\mathsf{d}(2^n,3)\cdot\frac{L_j}{L} + \frac{2}{3}\cdot\frac{L_i}{L} + 1\cdot\frac{L - L_i - L_j}{L} \leq \mathsf{d}(2^n,3)\cdot\frac{L_i}{L} + \frac{2}{3}\cdot\frac{L_j}{L} + \frac{L - L_i - L_j}{L},$$

which has the desired upper bound as already shown above.

Abstract

Accumulation schemes are a simple yet powerful primitive that enable highly efficient constructions of incrementally verifiable computation (IVC). Unfortunately, all prior accumulation schemes rely on homomorphic vector commitments whose security is based on public-key assumptions. It is an interesting open question to construct efficient accumulation schemes that avoid the need for such assumptions.

In this paper, we answer this question affirmatively by constructing an accumulation scheme from *non-homomorphic* vector commitments which can be realized from solely symmetric-key assumptions (e.g., Merkle trees). We overcome the need for homomorphisms by instead performing spot-checks over error-correcting encodings of the committed vectors.

Unlike prior accumulation schemes, our scheme only supports a bounded number of accumulation steps. We show that such *bounded-depth* accumulation still suffices to construct proof-carrying data (a generalization of IVC). We also demonstrate several optimizations to our PCD construction which greatly improve concrete efficiency.

1 Introduction

Proof-carrying data (PCD) [27] is a powerful cryptographic primitive that enables mutually distrustful parties to perform distributed computations that run indefinitely, while ensuring that the correctness of every intermediate step can be verified efficiently. PCD is a generalization of the prior notion of *incrementally verifiable computation* (IVC) [52].[1]

[1] IVC is the special case of PCD where the distributed computation graph is a line.

© Benedikt Bünz, Pratyush Mishra, Wilson Nguyen, and William Wang;

PCD has found numerous applications in both theory and practice, including enforcing language semantics [29], complexity-preserving succinct arguments [10, 9], verifiable MapReduce computations [28], image provenance [42], and consensus protocols and blockchains [44, 38, 14, 24, 19]. It is thus a key question to understand security assumptions that PCD constructions require, as well as the efficiency that they can attain under these assumptions.

Let us review how existing PCD constructions fare along both dimensions. For simplicity, we focus on the special case of IVC in the following discussion.

PCD from succinctly verifiable arguments

The standard construction of PCD is via recursive composition of succinct non-interactive arguments of knowledge (SNARKs) [10, 8, 9, 26]. Informally, to prove a t-step computation, the PCD prover proves that the t-th step is correct, and there exists a valid proof for the first $t-1$ steps. The state-of-the-art works in this line follow the template of Fractal [26] by relying on SNARKs in the random oracle model.[2] This means that we can achieve PCD (heuristically) from only symmetric-key cryptography, but at the cost of relying on the existence of SNARKs, which are complex to construct and incur (asymptotically and concretely) high costs for the PCD prover.

PCD from accumulation

A recent popular approach to avoid this reliance on SNARKs is to construct PCD via *accumulation schemes* [22, 21, 41]. Roughly speaking, instead of recursively checking proofs as above, the PCD prover "accumulates" the proof for each step into a running accumulator, and then the PCD verifier performs a single expensive check on the final accumulator. This line of work has led to simple and efficient PCD schemes that incur low costs for the PCD prover, and so has seen much interest in new constructions and deployments [21, 41, 20, 34, 39, 40]. Unfortunately, all known accumulation schemes rely on homomorphic vector commitments that are only known to exist under public-key assumptions. Additionally, because most existing homomorphic vector commitments are not known to achieve post-quantum security, the resulting accumulation schemes are also quantum-insecure.

Our question

We are thus left in an unsatisfactory state of affairs: on the one hand we have PCD from ROM-based SNARKs that (heuristically) relies on the minimal symmetric-key assumptions, but incurs high PCD prover costs due to this reliance on SNARKs, while on the other hand we have PCD from accumulation that relies on public-key assumptions, but achieves comparatively lower PCD prover costs by avoiding SNARKs. This motivates the questions we tackle in this paper: can we design PCD that achieves low prover costs by avoiding SNARKs, while simultaneously minimizing assumptions?

1.1 Our contributions

We answer this question positively by constructing accumulation schemes *solely* in the random-oracle model. Our constructions satisfy a weaker notion of accumulation than that considered in prior work, but we show that this weaker notion still suffices to construct PCD (again, heuristically after instantiating the random oracle). We provide details below.

[2] The concrete PCD construction makes non-black-box use of the SNARK verifier, which requires us to heuristically instantiate the random oracle.

(1) Bounded-depth accumulation

We introduce a new notion of *bounded-depth* accumulation schemes that can only provide (knowledge) soundness guarantees for a limited number of consecutive accumulation steps. In contrast, prior accumulation schemes support an unbounded number of accumulation steps.

(2) PCD from bounded-depth accumulation

We show that this weaker notion of accumulation still suffices to construct (a variant of) proof-carrying data. In particular, we show that bounded-depth accumulation suffices to construct PCD for computation graphs of a-priori bounded depth $O(1)$, which is already sufficient for many applications, including the primary application of constructing polynomial-length IVC [10].

We note that, like our construction, all prior PCD constructions only provably support computation graphs of bounded depth [10]. However, unlike these prior works, our construction is vulnerable to attacks when the depth of the computation graph exceeds an *a priori* fixed constant. See Remarks 2 and 3 for details.

(3) Efficient constructions of bounded-depth accumulation

We construct efficient bounded-depth accumulation schemes from any (non-homomorphic) vector commitment scheme (e.g., random-oracle based Merkle trees) and *any* linear code.

Compared to the prior state-of-the-art accumulation schemes, our construction has several advantages beyond just avoiding public-key assumptions, such as true linear time for the accumulation prover,[3] and plausible post-quantum security.[4] (We note that both our construction and prior accumulation schemes rely on the random oracle model; it is an open question to construct an accumulation scheme in the standard model.)

(4) Efficiency of and optimizations for instantiated PCD

Instantiating our generic PCD construction with our accumulation scheme leads to PCD schemes with numerous prover efficiency benefits compared to prior work. We also provide several optimizations for this scheme, including support for "batch" accumulation, a new low-overhead compiler from low-depth PCD to IVC, and a new *hybrid* PCD scheme that combines our low-depth PCD with any SNARK-based PCD scheme to achieve the best of both worlds. We detail the impact of these optimizations in Table 1.

Our scheme also has prover efficiency benefits beyond those captured by Table 1. To elaborate on these, we briefly detail the key factors that contribute to PCD prover cost. In all practical PCD constructions, to produce a proof for the next step of the distributed computation, the PCD prover invokes an underlying cryptographic proof system to prove satisfaction of a circuit C_{PCD} that contains a circuit representation C_Φ of the computation step (or *PCD predicate* Φ), and also performs other checks required by the PCD construction. Thus, PCD prover efficiency is determined by the prover efficiency of this proof system, and by the cost $|C_{\mathsf{PCD}}| - |C_\Phi|$ of the additional checks. We call the former the *proof-system overhead*, and the latter the PCD *circuit overhead*.

[3] To accumulate proofs for circuits of size n, prior accumulation schemes require performing an n-sized multi-scalar multiplication over elliptic-curve groups. As explained in prior work [37], this operation requires $\omega(n)$ group operations, and is hence not truly linear time.

[4] We only claim plausible post-quantum security, as we prove our construction in the random oracle model, instead of the quantum random oracle model [12]. We believe that our results can be extended to the latter model by applying techniques from prior work [25], but leave this to future work.

Table 1 Comparison of IVC schemes constructed from PCD over a tree of depth d and arity m. All costs omit constant factors. The circuit overhead measures $|C_{\mathsf{PCD}}| - |C_{\Phi}|$. The table displays the cost per invocation of Φ. Above n is the size of the recursive circuit, $n^{\star} = O(d^{\star}mn)$ is the circuit size of the accumulation decider for the recursive circuit, $|C_{\mathsf{MT}}|$ is the circuit size of checking a membership proof in a Merkle Tree with n leaves. T_{MT} is the time it takes to verify a Merkle Tree opening. Note that Fractal supports IVC computations of unbounded length, whereas all but the hybrid construction presented in this paper have a length bound of m^d.

scheme	circuit overhead per step	IVC verifier
Fractal [26]	$\lambda \log n \cdot \lvert C_{\mathsf{MT}}\rvert$	$\lambda \log n \cdot T_{\mathsf{MT}}$
+ STIR [2] (concurrent)	$(\log n + \lambda \log\log n) \cdot \lvert C_{\mathsf{MT}}\rvert$	$(\log n + \lambda \log\log n) \cdot T_{\mathsf{MT}}$
this paper	$d \cdot \lambda \cdot \lvert C_{\mathsf{MT}}\rvert$	$d \cdot n$
+ batch comm. (Sec 2.5)	$\frac{d\cdot\lambda}{m} \cdot \lvert C_{\mathsf{MT}}\rvert$	$d \cdot m \cdot n$
+ low-overhead IVC (Sec 2.6)	$\frac{d\cdot\lambda}{m^2} \cdot \lvert C_{\mathsf{MT}}\rvert$	$d \cdot m \cdot n$
+ hybrid (Sec 2.7)	$(\frac{d^{\star}\cdot\lambda}{m^2} + \frac{\lambda \log n^{\star}}{m^{d^{\star}}}) \cdot \lvert C_{\mathsf{MT}}\rvert$	$\lambda \log n^{\star} \cdot T_{\mathsf{MT}}$

PCD constructions based on ROM-based SNARKs have been able to achieve best-in-class proof-system overhead via extensive asymptotic and concrete optimizations (e.g., by achieving truly linear-time provers [15, 16, 17, 37], or relying on small fields [31]), but suffer from high PCD circuit overhead as the SNARK verifier subcircuit must perform numerous expensive random oracle calls.

Accumulation-based PCD constructions, on the other hand, have the smallest PCD circuit overhead (e.g., just ten thousand gates for Nova [41] vs. over one million gates for Fractal [26]). They also try to lower proof-system overhead by avoiding some cryptographic work (e.g., by requiring commitments only to the witness [20]), and via efficient arithmetizations of predicates (e.g., via cheap custom gates[5]). However, the remaining cryptographic work is quite expensive as it requires public-key operations, and hence the proof-system overhead of these constructions is relatively high.

Our construction of bounded-depth accumulation achieves the best of both worlds: it enjoys the low PCD circuit overhead of accumulation-based PCD constructions while taking advantage of the proof-system optimizations enjoyed by both approaches. In fact, the combination opens up new efficiency improvements that are not possible in either of the two paradigms alone. For example, all known ROM-SNARK-based PCD constructions thus far have relied on Reed–Solomon codes, and incur quasilinear prover costs from the quasilinear encoding time of these codes. Our construction, on the other hand, allows the use of any linear code, including linear-time-encodable codes [50, 33, 37], thus reducing prover costs.

1.2 Related work

PCD from symmetric-key assumptions

As noted in Section 1, the only end-to-end construction of PCD from symmetric-key assumptions is that of Chiesa, Ojha, and Spooner [26]. We provide a quantitative comparison in Table 1, and focus here on a qualitative comparison. Their construction is based on the Fractal SNARK, which they prove secure in the random oracle model.[6]

[5] Custom gates enforce checks beyond simple addition and multiplication. Examples include high-degree polynomial gates [35] and lookup gates [15, 36]. See [23, 30, 3] for empirical evidence of the benefits of such gates.

[6] Like us, their PCD construction must instantiate the random oracle with a concrete hash function, and can hence only achieve heuristic security.

Boneh, Drake, Fisch, and Gabizon [13] propose an optimization of the foregoing approach that batches the most expensive component, the low-degree test, across multiple proofs. While this concretely reduces prover cost, it does not lead to an asymptotic improvement in the prover overhead.

Like Fractal and similar SNARKs, our construction is able to take advantage of recent advances in the design of efficient code-based Interactive Oracle Proofs (IOPs) [7, 48]. For example, like recent work [51, 46, 31], we can greatly improve efficiency by relying on extension fields of small characteristic. Furthermore, unlike existing works, our fields do not need to have any special algebraic structure (e.g., large multiplicative subgroups).

PCD from public-key assumptions

Except the foregoing, all existing concretely-efficient IVC/PCD constructions [9, 18, 22, 21, 13, 41, 39, 20, 34, 40] rely on public-key assumptions, and in particular rely on the hardness of computing discrete logarithms over elliptic curve groups, which forces the usage of cryptographically large fields. Furthermore, efficient implementations require *cycles of elliptic curves*, which have proved unwieldy to implement correctly in practice [43]. In comparison, our construction avoids the need for public-key assumptions and this additional algebraic structure, and is able to use non-cryptographic field sizes.

Concurrent work

The concurrent work LatticeFold [11] takes a complementary approach to constructing plausibly post-quantum accumulation-based PCD: it constructs an accumulation/folding scheme from lattice-based assumptions. Unlike our construction, their accumulation scheme directly supports unbounded depth, allowing it to serve as a drop-in replacement in many existing constructions of accumulation-based PCD. However, this comes at a cost: at each accumulation step, the prover must demonstrate that the accumulation result has a small norm, which incurs a non-trivial computational cost. Furthermore, the dependence on lattice-based assumptions means that their scheme still relies on public-key assumptions.

An interesting direction for future work would be to combine the two approaches to reduce the need for small-norm checks. For example, one could construct a more efficient PCD scheme by first designing a bounded-depth accumulation scheme that relies on the bounded homomorphism supported by lattice commitments. One could then use the transformation of Section 2.7 to combine the resulting (bounded-depth) PCD scheme with the (unbounded-depth) LatticeFold PCD scheme to achieve a more efficient construction than either scheme alone.

Another concurrent work, STIR [2], provides a new proximity test that can be used as a drop-in replacement for the proximity test [5] used in Fractal [26]. As noted in Table 1, our schemes still have lower recursion overhead than this optimized baseline. Furthermore, this new STIR + Fractal-based PCD should also be compatible with our hybrid construction from Section 2.7.

▶ Remark 1 (security of bounded-depth PCD). All PCD schemes (including ours) only provably support computation graphs of depth $O(1)$. However, while there are no known attacks that break the security of prior schemes when the depth is $\omega(1)$, the same is not true for our scheme. As we explain in Section 2.1, our scheme is vulnerable to a relatively straightforward attack that obviates any security guarantees when the depth of the computation graph exceeds an *a priori* fixed constant. We emphasize that even such bounded-depth PCD is already powerful enough to support many interesting applications, including the primary application of constructing polynomial-length IVC [10]. See Remarks 2 and 3 for a more detailed discussion.

2 Techniques

We begin by reviewing the definition of an accumulation scheme [22, 21].[7] At a high level, it is used to perform *batch verification* of a predicate which, for us, will be a non-interactive argument's verifier $\mathcal{V}$. In other words, an accumulation scheme is used to check that $\mathcal{V}(\mathbb{x}_1, \pi_1), \ldots, \mathcal{V}(\mathbb{x}_n, \pi_n)$ all accept, more efficiently than the naive approach of individually verifying each instance $\mathbb{x}_i$ and proof π_i.

The workflow of an accumulation scheme is as follows. There are three main algorithms: a prover P, verifier V, and decider D. The prover is initialized with an empty accumulator acc_0, which is used to accumulate an input $(\mathbb{x}_1, \pi_1)$ into a new accumulator acc_1. The prover additionally outputs a proof; we write this as $(\mathsf{acc}_1, \mathsf{pf}_1) \leftarrow \mathrm{P}(\mathbb{x}_1, \pi_1, \mathsf{acc}_0)$. Later, acc_1 can be used to accumulate a second input, i.e., $(\mathsf{acc}_2, \mathsf{pf}_2) \leftarrow \mathrm{P}(\mathbb{x}_2, \pi_2, \mathsf{acc}_1)$, and so on. The correctness of a sequence of accumulations can then be established by checking that: (a) each accumulation step is valid, i.e., $\mathrm{V}(\mathbb{x}_i, \pi_i, \mathsf{acc}_{i-1}, \mathsf{acc}_i, \mathsf{pf}_i) = 1$; and (b) the final accumulator is valid, i.e., $\mathrm{D}(\mathsf{acc}_n) = 1$.

Notice that the decider only acts on the final accumulator, whereas the verifier acts on each accumulation step. Therefore, the crux of an accumulation scheme is making verification as cheap as possible. Towards this, we require that an accumulator acc can be split into a short instance part $\mathsf{acc}.\mathbb{x}$ and a (possibly) long witness part $\mathsf{acc}.\mathbb{w}$; we use $\mathsf{acc} = (\mathsf{acc}.\mathbb{x}, \mathsf{acc}.\mathbb{w})$ as shorthand. Similarly, we require that an argument proof can be split into instance and witness parts $\pi = (\pi.\mathbb{x}, \pi.\mathbb{w})$. The point is that the verifier can only look at the instance parts; we write this as $\mathrm{V}(\mathbb{x}_i, \pi_i.\mathbb{x}, \mathsf{acc}_{i-1}.\mathbb{x}, \mathsf{acc}_i.\mathbb{x}, \mathsf{pf}_i)$.

Definition

An accumulation scheme must satisfy the following properties.

- *Completeness:* The honest accumulation $(\mathsf{acc}', \mathsf{pf}) \leftarrow \mathrm{P}(\mathbb{x}, \pi, \mathsf{acc})$ of *any* valid input and accumulator should pass both the verifier's and decider's checks. That is, if $\mathcal{V}(\mathbb{x}, \pi) = 1$ and $\mathrm{D}(\mathsf{acc}) = 1$, then $\mathrm{V}(\mathbb{x}, \pi.\mathbb{x}, \mathsf{acc}.\mathbb{x}, \mathsf{acc}'.\mathbb{x}, \mathsf{pf}) = 1$ and $\mathrm{D}(\mathsf{acc}') = 1$.
- *Knowledge soundness:* If a new accumulator acc' passes the verifier's and decider's checks, then an efficient extractor can find a valid input and old accumulator that explains acc'. That is, if $\mathrm{D}(\mathsf{acc}') = 1$ and $\mathrm{V}(\mathbb{x}, \pi.\mathbb{x}, \mathsf{acc}.\mathbb{x}, \mathsf{acc}'.\mathbb{x}, \mathsf{pf}) = 1$, then an efficient extractor can find the witness part of the proof, $\pi.\mathbb{w}$, and the witness part of the old accumulator, $\mathsf{acc}.\mathbb{w}$, such that $\mathcal{V}(\mathbb{x}, \pi) = 1$ and $\mathrm{D}(\mathsf{acc}) = 1$.
- *Efficiency:* The cost of running the accumulation verifier n times plus the cost of running the accumulation decider once should be lower than the cost of running the argument verifier n times.

Accumulation schemes can be generalized to handle multiple inputs and accumulators in each step. For example, the prover's syntax would be $\mathrm{P}([\mathbb{x}_i, \pi_i]_{i=1}^{m_1}, [\mathsf{acc}_i]_{i=1}^{m_2})$, where m_1 and m_2 are the arities; see Section 3 for a comprehensive definition.

Prior constructions

All prior accumulation schemes [22, 21, 41, 20, 34, 39, 40] crucially use *additively homomorphic vector commitment schemes*. Informally, a vector commitment scheme allows one to construct a succinct commitment cm to a vector $\mathbf{v} \in \mathbb{F}^n$. The scheme is additively homomorphic if,

[7] We restrict our presentation to *split* accumulation schemes, as defined in [21].

given $\mathsf{cm}_1 = \mathsf{Commit}(\mathbf{v}_1)$ and $\mathsf{cm}_2 = \mathsf{Commit}(\mathbf{v}_2)$, $\mathsf{cm}_3 = \alpha \cdot \mathsf{cm}_1 + \beta \cdot \mathsf{cm}_2$ is a commitment to $\alpha\mathbf{v}_1 + \beta\mathbf{v}_2$. We remark that all known additively homomorphic vector commitment schemes, e.g., Pedersen commitments [45], rely on public-key assumptions.

The general blueprint for an accumulation scheme is as follows. An accumulator witness $\mathsf{acc}.\mathbb{w} \in \mathbb{F}^n$ is a vector, and the corresponding instance $\mathsf{acc}.\mathbb{x}$ is a commitment to $\mathsf{acc}.\mathbb{w}$. For simplicity, suppose the prover claims that acc_1 and acc_2 accumulate into acc_3. Roughly speaking, we want to guarantee that the output accumulator is a random linear combination of the input accumulators. The verifier checks this by computing the linear combination of the input commitments $\mathsf{acc}_1.\mathbb{x}$ and $\mathsf{acc}_2.\mathbb{x}$, and checking that the result equals the output commitment $\mathsf{acc}_3.\mathbb{x}$ [41, 20]. Later, the decider will check that $\mathsf{acc}_3.\mathbb{w}$ is a "good" vector, and that $\mathsf{acc}_3.\mathbb{x}$ commits to $\mathsf{acc}_3.\mathbb{w}$. Since commitments are binding, acc_3 must be the correct linear combination of acc_1 and acc_2.

We have omitted many details, most notably how to accumulate argument proofs. However, from this description alone we can observe two key properties of the vector commitment scheme. First, it has succinct commitments; this allows the verifier to be efficient. Second, it is additively homomorphic; this allows the verifier to perform meaningful checks. As noted earlier, this combination of properties unfortunately seems to require public-key assumptions.

2.1 Checking linearity

To overcome the foregoing limitation, we make a key observation: to verify that the output accumulator is a linear combination of the input accumulators, it is not necessary to directly compute a linear combination of the input commitments. Instead, it suffices to *check* that the output accumulator commits to a vector that is a linear combination of the vectors committed by the input accumulators. This idea is a natural one, and has appeared before under the name of "linear combination schemes" [13].

Recall that we want to check that $\mathsf{acc}_3.\mathbb{w} = \alpha \cdot \mathsf{acc}_1.\mathbb{w} + \beta \cdot \mathsf{acc}_2.\mathbb{w}$, where $\alpha, \beta \in \mathbb{F}$ are previously chosen scalars. More precisely, we want to check that $\mathbf{v}_3 = \alpha\mathbf{v}_1 + \beta\mathbf{v}_2$, where $\mathbf{v}_1$, $\mathbf{v}_2$, and $\mathbf{v}_3$ are the underlying committed vectors of $\mathsf{acc}_1.\mathbb{x}$, $\mathsf{acc}_2.\mathbb{x}$, and $\mathsf{acc}_3.\mathbb{x}$ (and since commitments are binding, these vectors correspond with the accumulator witnesses). A *linearity check* is a protocol between the prover and the verifier that convinces the verifier of this claim. Assuming the verifier is public-coin, this can be made non-interactive using random oracles.

Our goal is to construct a linearity check which does not require homomorphic vector commitments. Instead, we require vector commitments with *local openings*. Informally, these allow the prover to generate a succinct proof that the underlying committed vector's i-th element is some claimed value. For example, Merkle tree commitments support local openings with proof size $O(\lambda \log n)$.

Distance spot checks

The key tool that we will be relying on is a protocol for convincing the verifier that two committed vectors are at most a constant distance apart. Concretely, let cm_1 and cm_2 be commitments to vectors $\mathbf{v}_1$ and $\mathbf{v}_2$ respectively. We say that $\mathbf{v}_1$ and $\mathbf{v}_2$ are δ-far apart if they differ in at most δn locations. To show that $\mathbf{v}_1$ and $\mathbf{v}_2$ are at most δ-far apart, the prover and verifier engage in the following protocol:

1. The verifier uniformly samples an index $i \in [n]$ and sends it to the prover.
2. The prover responds with the purported i-th elements of $\mathbf{v}_1$ and $\mathbf{v}_2$, along with opening proofs.

3. The verifier accepts if these opening proofs are valid and the claimed elements are equal. Clearly, if $\mathbf{v}_1$ and $\mathbf{v}_2$ are δ-far apart, then the verifier will reject with probability δ. For any constant $\delta > 0$, this soundness error can be made negligible with $\Theta(\lambda)$ parallel repetitions.

Linearity spot checks

This protocol easily generalizes to testing any kind of element-wise property, and in particular we can use it to check that $\mathbf{v}_3$ is δ-close to the "virtual vector" $\alpha\mathbf{v}_1 + \beta\mathbf{v}_2$. Unfortunately, we need to ensure that the two vectors are equal at all locations. Suppose a cheating prover commits to a vector that only differs from $\alpha\mathbf{v}_1 + \beta\mathbf{v}_2$ at a *single* location j. Detecting this would require $\Theta(\lambda n)$ repetitions (essentially opening the entire commitment), which violates the accumulation verifier's efficiency requirement.

2.1.1 Error-resilient linearity checks from codes

It seems that we are at an impasse: our spot check can only guarantee that two vectors are δ-close, but the accumulation scheme requires exact agreement. To overcome this issue, we need to make our accumulation scheme resilient to a constant δ-fraction of corruptions. We do so by relying on linear codes, and in particular those which enjoy good distance properties, such as the Reed–Solomon code [47].

At a high level, we make the following changes to the accumulation scheme blueprint. Let C be a linear code, and let δ be a constant which is smaller than the unique decoding radius of C. The accumulator witness is a codeword $C(\mathbf{w})$, and the corresponding instance $\mathsf{acc}.\mathbb{x}$ is a commitment to $\mathsf{acc}.\mathbb{w}$. The accumulation verifier checks that the output accumulator is δ-close to a random linear combination of the input accumulators by running the linearity spot check. Later, the decider will check that $\mathsf{acc}_3.\mathbb{w}$ is the encoding of a good vector, and that $\mathsf{acc}_3.\mathbb{x}$ commits to $\mathsf{acc}_3.\mathbb{w}$.

Knowledge soundness

We would like our linearity spot check to satisfy the following knowledge soundness property. Suppose a (possibly malicious) prover outputs commitments cm_1, cm_2, and cm_3 which pass the check. Furthermore, suppose that cm_3 commits to a vector $\mathbf{v}_3$. Then an efficient extractor can find vectors $\mathbf{v}_1$ and $\mathbf{v}_2$ such that (a) $\alpha\mathbf{v}_1 + \beta\mathbf{v}_2$ is δ-close to $\mathbf{v}_3$; and (b) cm_1 and cm_2 commit to $\mathbf{v}_1$ and $\mathbf{v}_2$. Notice that if we can extract vectors that satisfy 2.1.1, then our previous analysis of the spot check implies 2.1.1. Extraction turns out to be fairly straightforward: if we use Merkle commitments with a random oracle as the hash function, then we can find $\mathbf{v}_1$ and $\mathbf{v}_2$ by observing the prover's random oracle queries [52].[8]

Returning to accumulation, suppose that a (possibly malicious) prover outputs $\mathsf{acc}_1.\mathbb{x}$, $\mathsf{acc}_2.\mathbb{x}$, and acc_3 which pass the verifier's and decider's checks. Since the verifier runs the spot check, we can extract accumulator witnesses $\mathsf{acc}_1.\mathbb{w}$ and $\mathsf{acc}_2.\mathbb{w}$ such that $\alpha \cdot \mathsf{acc}_1.\mathbb{w} + \beta \cdot \mathsf{acc}_2.\mathbb{w}$ is δ-close to $\mathsf{acc}_3.\mathbb{w}$. Since the decider accepts $\mathsf{acc}_3.\mathbb{w}$, we know that $\mathsf{acc}_3.\mathbb{w}$ is a codeword $C(\mathbf{w}_3)$. Similarly, we need $\mathsf{acc}_1.\mathbb{w}$ and $\mathsf{acc}_2.\mathbb{w}$ to be codewords in order for the decider to accept $\mathsf{acc}_1.\mathbb{w}$ and $\mathsf{acc}_2.\mathbb{w}$. Unfortunately, this is simply not the case. For example, a cheating prover can always choose $\mathsf{acc}_1.\mathbb{w}$ which agrees with a codeword at all but one location, and this will almost certainly go undetected.

[8] To be precise, we must also consider a malicious prover that does not commit to a full vector; see the full version of the paper.

Can we still say something meaningful about the extracted witnesses? We argue that intuitively, since α and β are (possibly correlated) random scalars, with high probability $\mathsf{acc}_1.\mathbb{w}$ and $\mathsf{acc}_2.\mathbb{w}$ are themselves δ-close to codewords. Moreover, $\mathsf{acc}_1.\mathbb{w}$ and $\mathsf{acc}_2.\mathbb{w}$ decode to $\mathbf{w}_1$ and $\mathbf{w}_2$ such that $\alpha \cdot \mathbf{w}_1 + \beta \cdot \mathbf{w}_2 = \mathbf{w}_3$. This intuition can be formally proven using a suitable "proximity gap" result [6], which exists for a variety of parameter regimes.

The upshot is that we extract accumulators acc_1 and acc_2 which are only accepted by a *relaxed* decider. Namely, given an accumulator acc, this decider checks that $\mathsf{acc}.\mathbb{x}$ commits to $\mathsf{acc}.\mathbb{w}$, and moreover that $\mathsf{acc}.\mathbb{w}$ is δ-close to the code.

Recursive extraction

The foregoing analysis suffices for a single step of accumulation. However, in order to construct PCD, we will have to recursively extract from old accumulators. It is straightforward to see that a recursively extracted accumulator is only guaranteed to be 2δ-close to the code, since we are extracting from an accumulator that may already be δ-far from the code. More generally, k steps of recursion will only guarantee accumulators that are $k\delta$-close to the code. We will see that once $k\delta$ is larger than the unique decoding radius, extraction is no longer meaningful. In particular, this leads to the following concrete attack: a cheating prover can start with a bad codeword (rejected by the decider) and, over the k accumulation steps, incrementally move it to a good codeword (accepted by the decider). This motivates our notion of "bounded-depth" accumulation, which is not captured by existing definitions [21].

2.2 Defining bounded-depth accumulation

To describe our construction which only supports accumulation up to a certain (constant) depth, we introduce a new, relaxed knowledge soundness property; the key differences are highlighted in blue. We say that an accumulation scheme has *bounded-depth knowledge soundness* (with maximum depth d) if there exists a *family of deciders* $\{\mathrm{D}_s\}_{s=0}^{d}$, where D is equivalent to D_0, such that the following holds. If $\mathrm{D}_{s-1}(\mathsf{acc}') = 1$ and $\mathrm{V}(\mathbb{x}, \pi.\mathbb{x}, \mathsf{acc}.\mathbb{x}, \mathsf{acc}'.\mathbb{x}) = 1$, then an efficient extractor can find $\pi.\mathbb{w}$ and $\mathsf{acc}.\mathbb{w}$ such that $\mathcal{V}(\mathbb{x}, \pi) = 1$ and $\mathrm{D}_s(\mathsf{acc}) = 1$.

This is a meaningful definition. In addition to generalizing standard knowledge soundness, which can be recovered by setting $d = \infty$ and using a single decider D, it captures our construction based on error-resilient linearity checks: D_s is the decider that only accepts if the accumulator is at most $s\delta$-far from the code, and in particular D_0 only accepts codewords. The depth bound d is the maximum number of recursive extractions that we can perform before $d\delta$ exceeds the unique decoding radius of the code.

2.3 Bounded-depth PCD from bounded-depth accumulation

Existing theorems that build PCD from accumulation [21, 13, 41] do not immediately translate to the bounded-depth setting. To see why, let us recall a simplified version of the construction from [21]. Suppose we have an accumulation scheme for a *non-interactive argument of knowledge* (NARK). Informally, a PCD proof for z_i, which consists of a NARK proof π_i and accumulator acc_i, certifies that $z_i = F^i(z_0)$, where z_0 is some initial value. We maintain the invariant that if π_i and acc_i are valid, then the computation is correct up to the i-th step.

- The PCD prover receives a proof (π_i, acc_i) for z_i, and wants to output a proof for z_{i+1}. First, it accumulates π_i and acc_i into a new accumulator acc_{i+1}, generating an accumulation proof pf_{i+1}. Next, it generates a NARK proof π_{i+1} for the following claim, expressed as a circuit R (see Figure 1): "$z_{i+1} = F(z_i)$, and there exists a NARK proof π_i, old accumulator acc_i, and accumulation proof pf_{i+1} which correctly accumulate into acc_{i+1}." The proof for z_{i+1} is $(\pi_{i+1}, \mathsf{acc}_{i+1})$.

$R(\mathbb{x} = (z_{i+1}, \mathsf{acc}_{i+1}.\mathbb{x}), \mathbb{w} = (z_i, \pi_i.\mathbb{x}, \mathsf{acc}_i.\mathbb{x}, \mathsf{pf}_{i+1})) :$
1. Check that $z_{i+1} = F(z_i)$.
2. Set $\mathbb{x}_i = (z_i, \mathsf{acc}_i.\mathbb{x})$.
3. Check that $\mathrm{V}(\mathbb{x}_i, \pi_i, \mathsf{acc}_i.\mathbb{x}, \mathsf{acc}_{i+1}.\mathbb{x}, \mathsf{pf}_{i+1}) = 1$.

Figure 1 Recursion circuit for PCD.

- The PCD verifier checks a proof (π_i, acc_i) for z_i by running the NARK verifier on π_i and the decider on acc_i.

Now suppose we replace the accumulation scheme with one that only has bounded-depth knowledge soundness. The construction remains the same, but we must provide a new soundness analysis.

PCD knowledge soundness

We need to construct an extractor which, given an accepting proof (π_T, acc_T) for z_T, extracts a sequence of values $z_0, \ldots, z_T$ such that $z_{i+1} = F(z_i)$ for all i. [21] gives the following strategy, which *interleaves* the NARK extractor and accumulation extractor. Suppose we have z_{i+1}, π_{i+1}, and acc_{i+1}. First, we invoke the NARK extractor to obtain $(z_i, \pi_i.\mathbb{x}, \mathsf{acc}_i.\mathbb{x}, \mathsf{pf}_{i+1})$. Second, we invoke the accumulation extractor to obtain $(\pi_i.\mathbb{w}, \mathsf{acc}_i.\mathbb{w})$. This gives us π_i and acc_i, and the process continues. We maintain the invariant that in the i-th step, π_i and acc_i are valid.

With bounded-depth accumulation, we need to maintain a slightly weaker invariant: in the i-th step, instead of requiring that acc_i is accepted by the *strict* decider D, we only require that it is accepted by the i-th *relaxed* decider D_i. This discussion only provides a high-level overview of the proof strategy, and only describes an *IVC* construction; we describe the full PCD construction that supports arbitrary (bounded-depth) computation graphs, along with a full soundness analysis, in the full version of the paper.

▶ Remark 2 (bounded-depth PCD suffices). As presented, our PCD scheme supports up to d steps of computation, where d is the maximum depth of the accumulation scheme. We call this *bounded-depth PCD*. Since d will realistically be a small constant, this seems to be of limited use: most computations require more than a constant number of steps! Fortunately, even such a limited PCD scheme can be used to construct IVC for *any* polynomial-length computation [10]. The idea is for the PCD prover to receive multiple proofs in each step, yielding a *computation tree*. In particular, if we can accumulate m inputs and m accumulators in a single step, then our PCD scheme can support computation trees of size m^d. Setting $m = \lambda$ and $d = O(1)$ allows us to support polynomial-size computations.

▶ Remark 3 (bounded-depth vs. constant-depth PCD). Perhaps surprisingly, even with standard (unbounded) accumulation, [21] is only able to construct *constant-depth PCD*.[9] This is because the size of the PCD extractor grows exponentially in the computation's depth, regardless of the accumulation scheme's knowledge soundness property. We remark that this limitation is largely theoretical: there is no known attack which exploits unbounded recursive proof composition. In contrast, the depth bound in bounded-depth PCD is not merely an artifact of the analysis: there exists a concrete attack that can be mounted against our construction when the depth exceeds d. This means that the tree-based strategy described in Remark 2 is *necessary* for real-world implementations, unlike in prior work.

[9] This is slightly different from bounded-depth PCD, where the maximum depth must be fixed in advance.

2.4 Constructing bounded-depth accumulation

Our starting point is the ProtoStar and ProtoGalaxy accumulation schemes [20, 34]. They support a general class of non-interactive arguments where consists of the NP witness along with a short vector commitment to the witness, and whose verifier performs three steps: (a) computing Fiat–Shamir challenges; (b) checking vector commitment openings; and (c) evaluating a polynomial over the instance, challenges, and openings. The key insight of ProtoStar and ProtoGalaxy is that the accumulation verifier can cheaply perform the first step, while batching the remaining steps and deferring it to the decider.

Let us recall ProtoGalaxy's strategy [34], focusing on the case where we are trying to accumulate claims about satisfaction of R1CS, a popular NP language in the succinct argument literature. Recall that an R1CS instance consists of constraint matrices $A, B, C \in \mathbb{F}^{N \times (\ell+n)}$, and is said to be satisfied by a public input $x \in \mathbb{F}^\ell$ and witness $w \in \mathbb{F}^n$ if $A \cdot (x||w) \circ B \cdot (x||w) - C \cdot (x||w) = 0^N$. In ProtoGalaxy, a NARK proof for an R1CS instance with public input x would consist of the proof witness, which is just the R1CS witness w, and the proof instance, which is just a vector commitment to w. The polynomial p evaluated by the verifier is of the form $p(x, w) = A \cdot (x||w) \circ B \cdot (x||w) - C \cdot (x||w)$. Then, to accumulate R1CS claims, ProtoGalaxy's accumulator witness $\mathsf{acc.w}$ is *also* a vector $w \in \mathbb{F}^n$, and its accumulator instance $\mathsf{acc.x}$ consists of a vector $\vec{x} \in \mathbb{F}^\ell$, a (homomorphic) vector commitment to w, and an error term $e \in \mathbb{F}$. Thus, a NARK proof verification claim can be seen as a special case of the accumulator verification case where the error term is zero.

To accumulate m such (accumulation or NARK) verification claims for accumulators $\mathsf{acc}_1, \ldots, \mathsf{acc}_m$, ProtoGalaxy relies on the following univariate polynomial identity:

$$p\left(\sum_{i=1}^{m} L_i(X) \cdot x_i, \sum_{i=1}^{m} L_i(X) \cdot w_i\right) = \sum_{i=1}^{m} L_i(X) \cdot e_i \mod v_H(X),$$

where L_i is the i-th Lagrange polynomial of some m-sized set $H \subset \mathbb{F}$, and $v_H(X)$ is the vanishing polynomial on H. For some quotient polynomial q, this claim can be rewritten as

$$p\left(\sum_{i=1}^{m} L_i(X) \cdot x_i, \sum_{i=1}^{m} L_i(X) \cdot w_i\right) = \sum_{i=1}^{m} L_i(X) \cdot e_i + q(X) \cdot v_H(X),$$

and this formulation allows the verifier to check the identity at a random point $\alpha \in \mathbb{F}$ if the prover sends q.

This allows us to accumulate the m input claims as follows. The prover constructs a new accumulator acc whose new instance is $x := \sum_i L_i(\alpha) \cdot x_i$, new witness vector is $w := \sum_i L_i(\alpha) \cdot w_i$, and the new error is $e := v(\alpha) \cdot q(\alpha) + \sum_i L_i(\alpha) \cdot e_i$. The verifier checks that acc was computed correctly by homomorphically computing the new vector commitment, and directly computing the new instance and new error term. Finally, the accumulation decider completes the checks by asserting that that $p(x, w) = e$.[10]

Our construction

We follow the same strategy, except we replace homomorphic computations with error-resilient linearity checks. Concretely, we make the following changes. An accumulator witness is a codeword $f \in C$, and an accumulator instance consists of a vector commitment to f and an

[10] Technically speaking, this check, as stated, is ill-formed, as the output of p is an N-sized vector, while e is a single field element. However, this can be fixed by taking a random linear combinations of the output vector. ProtoStar and ProtoGalaxy show how to represent the latter task *also* as a low-degree polynomial evaluation.

error term $e \in \mathbb{F}$. The decider accepts an accumulator if f is the encoding of a vector $w \in \mathbb{F}^n$ such that $p(x, w) = e$. Finally, as discussed in Section 2.1, the verifier uses a linearity check to ensure that the new accumulator acc is sufficiently consistent with the old accumulators $\mathsf{acc}_1, \ldots, \mathsf{acc}_m$.

Overall, our construction inherits many desirable properties from ProtoStar [20] and ProtoGalaxy [34], including support for arbitrary arity $m = \text{poly}(\lambda)$, which is crucial for constructing PCD (see Remark 2), and efficient support for custom gates.

Extension to arbitrary linear codes

A key parameter in our construction is the linear code. We use Reed–Solomon codes because they display a proximity gap when the coefficients are Lagrange evaluations $L_1(\alpha), \ldots, L_m(\alpha)$. However, a modified version of our construction extends to arbitrary linear codes. This is advantageous as these codes can have asymptotically faster encoding time compared to Reed–Solomon codes [37]. The construction can work with any proximity gap (e.g., uniformly random coefficients). The key idea is to commit to two codes within the accumulator, one for proximity checking and the other for the algebraic check using $p(X)$. See Section 4.3 for details.

Efficiency

The cost of the accumulation verifier is dominated by that of the linearity checker. Recall that to achieve negligible knowledge soundness error at depth d, the latter checks that two code words are $d \cdot \delta$ close via $k = O(d \cdot \lambda)$ spot checks, where δ is such that $d \cdot \delta$ is less than the unique decoding radius of the code. Overall, when instantiated with the Merkle tree-based vector commitment, the accumulation verifier checks $O(d \cdot \lambda)$ Merkle tree paths. When applying this construction to the PCD scheme in Section 2.3, the latter cost becomes the *recursive overhead* of the PCD prover. As noted in Table 1, this cost is asymptotically better than the $O(\log n \cdot \lambda)$ cost of prior SNARK-based PCD schemes [26].

A keen reader may notice that a disadvantage of our construction is that recursive overhead scales with the depth of the PCD computation graph. We now present several optimizations that reduce the depth of the PCD tree and significantly improve the efficiency of the resulting PCD scheme in practice.

2.5 Optimization: batch commitments

Recall from Remarks 2 and 3 that for our PCD construction, reducing the depth of the computation graph is essential for achieving provable security guarantees, and the standard depth-reduction technique for the case of IVC [10] works by constructing a *PCD tree* whose leaves comprise the actual computation being performed. To achieve constant computation depth, Bitansky et al. [10] set the arity m of this tree to be super-constant (i.e., $m = \lambda$). The per-node recursive overhead of our PCD construction in this setting is the cost of performing linearity checks on m codewords of size n, which costs $O(m \cdot \lambda \cdot \log n)$ hashes when using Merkle trees. We now describe how to reduce this to just $O(\lambda(\log n + m))$ hashes.

Recall that the linearity checker opens all m codewords at the same locations. This means that for each spot-check, each of the m Merkle trees is opened at the same leaf. We take advantage of this repetitive structure by committing to all m codewords using a *single* Merkle tree whose i-th leaf is the concatenation of the i-th symbols of the codewords. Each spot-check now requires opening only a single Merkle tree path (and checking the leaf hash), leading to a cost of $O(\lambda(\log n + m))$ hashes for $O(\lambda)$ spot checks, as required.

However, this modification comes at a cost: it requires us to commit to all codewords together at the same time. While this is straightforward at the leaf layer, it gets more complex at higher layers. For example, even committing to a new accumulator now requires waiting for the batch of "sibling" new accumulators, which in turn means that we must wait for m accumulations (each of size m) to complete before we can compute the commitments to the m new accumulators. Overall, across the entire tree, this requires the PCD prover to maintain a state of $O(m^2)$ "pending" accumulators. We provide more details in the full version of the paper.

2.6 Optimization: low-overhead IVC from accumulation

We give a generic optimization which improves on the PCD-to-IVC compiler of Bitansky et al. [52, 10]. They construct a (polynomial-length) IVC scheme for a function F by using a (constant-depth) PCD scheme for a related function F'. In particular, F' computes F (at leaf nodes) and performs consistency checks (at internal nodes). This is wasteful: even though we do not need to prove anything about F at internal nodes, the PCD prover still generates a proof for F' (which is dominated by F).

We improve this compiler by constructing an IVC scheme with minimal overhead. The core idea is that we first construct a tree of accumulators for F, i.e., a tree the leaf nodes are proofs for F, and each parent accumulates its children. Then, we construct a PCD tree which proves that the accumulation tree was constructed correctly. When the PCD scheme is instantiated with our accumulation-based construction, the PCD circuit now checks *two* accumulation verifiers: one that checks the correctness of the accumulation tree, and one that helps check the correctness of the PCD tree.

Accumulating separately means that we no longer have to generate NARK proofs for F at internal nodes. Additionally, because we only need to show that internal nodes of the accumulation tree were constructed correctly, our PCD tree has one fewer layer than before. This further reduces cost, in particular for higher arities (as m grows, the leaf layer of a tree contains a higher fraction of nodes). We provide more details in the full version of this paper.

2.7 Optimization: PCD composition

The recursive overhead of our PCD scheme grows linearly with the maximum supported depth. This is contrast with SNARK-based PCD schemes like Fractal [26], which do not suffer from such an efficiency loss. However, these schemes pay a higher per-step cost anyway, and are thus asymptotically less efficient than our PCD scheme for low recursion depths.

We provide a generic optimization to combine SNARK-based PCD schemes with our PCD scheme to achieve a scheme that achieves better efficiency than either scheme alone. The core idea is to first use our accumulation-based PCD up to some depth d_1, and then prove the PCD verifier for the latter with a SNARK-based PCD scheme on top. When invoked with tree PCD, this means that the SNARK-based PCD scheme is invoked only every m^{d_1} steps. By choosing d_1 appropriately, the resulting scheme achieves better efficiency than either scheme alone. Furthermore, the resulting scheme supports *arbitrary* constant depth, as opposed to our accumulation-based scheme, which only supports an *a priori* fixed depth. We provide more details in the full version of this paper.

3 Bounded-depth accumulation

Let $\mathsf{ARG} = (\mathcal{G}, \mathcal{P}, \mathcal{V})$ be a non-interactive argument where knowledge soundness (but not necessarily completeness) additionally holds for a "relaxed" verifier $\tilde{\mathcal{V}}$. Suppose proofs can be split into two parts, i.e., $\pi = (\pi.\mathbb{x}, \pi.\mathbb{w})$. Let qx denote $(\mathbb{x}, \pi.\mathbb{x})$, where $\mathbb{x}$ is an instance of the relation; call this the *verifier input instance*. Let qw denote $\pi.\mathbb{w}$; call this the *verifier input witness*. We write $\mathcal{V}(\mathsf{pp}, \mathbb{i}, \mathsf{qx}_i, \mathsf{qw}_i)$ as shorthand for the verifier running on $\mathbb{x}$ and π. We write acc as shorthand for the tuple $(\mathsf{acc}.\mathbb{x}, \mathsf{acc}.\mathbb{w})$. An *accumulation scheme* in the random oracle model for ARG is a tuple of algorithms $\mathsf{AS} = (\mathrm{G}, \mathrm{I}, \mathrm{P}, \mathrm{V}, \mathrm{D})$ with the following syntax and properties.

- $\mathrm{G}(1^\lambda) \to \mathsf{pp}_{\mathsf{AS}}$: On input a security parameter λ, the generator G samples and outputs accumulation parameters $\mathsf{pp}_{\mathsf{AS}}$.
- $\mathrm{I}(\mathsf{pp}_{\mathsf{AS}}, \mathsf{pp}, \mathbb{i}) \to (\mathsf{apk}, \mathsf{avk}, \mathsf{dk})$: On input accumulation parameters $\mathsf{pp}_{\mathsf{AS}}$ and argument parameters pp, the indexer I deterministically computes and outputs a proving key apk, verification key avk, and decision key dk.
- $\mathrm{P}(\mathsf{apk}, [\mathsf{qx}_i, \mathsf{qw}_i]_{i=1}^{m_1}, [\mathsf{acc}_i]_{i=1}^{m_2}) \to (\mathsf{acc}, \mathsf{pf})$: On input the proving key apk, verifier inputs $[\mathsf{qx}_i, \mathsf{qw}_i]_{i=1}^{m_1}$, and accumulators $[\mathsf{acc}_i]_{i=1}^{m_2}$, the accumulation prover P outputs a new accumulator acc and proof pf. Here, m_1 and m_2 are fixed arities which may be functions of λ.
- $\mathrm{V}(\mathsf{avk}, [\mathsf{qx}_i]_{i=1}^{m_1}, [\mathsf{acc}.\mathbb{x}_i]_{i=1}^{m_2}, \mathsf{acc}.\mathbb{x}, \mathsf{pf}) \to \{0,1\}$: On input the verifying key avk, verifier input instances $[\mathsf{qx}_i]_{i=1}^{m_1}$, accumulator instances $[\mathsf{acc}.\mathbb{x}_i]_{i=1}^{m_2}$, new accumulator instance $\mathsf{acc}.\mathbb{x}$, and proof pf, the accumulation verifier V outputs a bit indicating whether $\mathsf{acc}.\mathbb{x}$ correctly accumulates the other instances.
- $\mathrm{D}(\mathsf{dk}, \mathsf{acc}) \to \{0,1\}$: On input the decision key dk and accumulator acc, the decider outputs a bit indicating whether acc is a valid accumulator.

Completeness

For every (unbounded) adversary $\mathcal{A}$,

$$\Pr\left[\begin{array}{c} \forall i \in [m_1], \mathcal{V}(\mathsf{pp}, \mathbb{i}, \mathsf{qx}_i, \mathsf{qw}_i) = 1 \\ \forall i \in [m_2], \mathrm{D}(\mathsf{dk}, \mathsf{acc}_i) = 1 \\ \Downarrow \\ \mathrm{V}(\mathsf{avk}, [\mathsf{qx}_i]_{i=1}^{m_1}, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m_2}, \mathsf{acc}.\mathbb{x}, \mathsf{pf}) = 1 \\ \mathrm{D}(\mathsf{dk}, \mathsf{acc}) = 1 \end{array} \middle| \begin{array}{r} \rho \leftarrow \mathcal{U}(\lambda) \\ \mathsf{pp}_{\mathsf{AS}} \leftarrow \mathrm{G}(1^\lambda) \\ \mathsf{pp} \leftarrow \mathcal{G}(1^\lambda) \\ (\mathbb{i}, [\mathsf{qx}_i, \mathsf{qw}_i]_{i=1}^{m_1}, [\mathsf{acc}_i]_{i=1}^{m_2}) \leftarrow \mathcal{A}(\mathsf{pp}_{\mathsf{AS}}, \mathsf{pp}) \\ (\mathsf{apk}, \mathsf{avk}, \mathsf{dk}) \leftarrow \mathrm{I}(\mathsf{pp}_{\mathsf{AS}}, \mathsf{pp}, \mathbb{i}) \\ (\mathsf{acc}, \mathsf{pf}) \leftarrow \mathrm{P}(\mathsf{apk}, [\mathsf{qx}_i, \mathsf{qw}_i]_{i=1}^{m_1}, [\mathsf{acc}_i]_{i=1}^{m_2}) \end{array}\right] = 1.$$

To bootstrap accumulation, we also assume the prover can efficiently construct a dummy accumulator and proof, denoted $\mathsf{acc} = \mathrm{P}(\mathsf{apk}, \bot)$, which the decider accepts.

Knowledge soundness

We say that AS has bounded-depth knowledge soundness (with maximum depth d_s) if there exists a *family of deciders* $\{\mathrm{D}_s\}_{s=0}^{d_s}$, where D is equivalent to D_0, such that the following holds. There exists an expected polynomial time extractor E such that for every depth parameter $s \in [d_s]$, expected polynomial time adversary $\tilde{\mathrm{P}}$, and auxiliary input distribution $\mathcal{D}$, the following probability is negligibly close to 1:

$$\Pr\left[\begin{array}{c} \mathrm{V}^\rho(\mathsf{avk}, [\mathsf{qx}_i]_{i=1}^{m_1}, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m_2}, \mathsf{acc}.\mathbb{x}, \mathsf{pf}) = 1 \\ \mathrm{D}_{s-1}(\mathsf{dk}, \mathsf{acc}) = 1 \\ \Downarrow \\ \forall i \in [m_1], \tilde{\mathcal{V}}(\mathsf{pp}, \mathbb{i}, \mathsf{qx}_i, \mathsf{qw}_i) = 1 \\ \forall i \in [m_2], \mathrm{D}_s(\mathsf{dk}, \mathsf{acc}_i) = 1 \end{array} \middle| \begin{array}{r} \rho \leftarrow \mathcal{U}(\lambda) \\ \mathsf{pp}_{\mathsf{AS}} \leftarrow \mathrm{G}(1^\lambda) \\ \mathsf{pp} \leftarrow \mathcal{G}(1^\lambda) \\ \mathsf{ai} \leftarrow \mathcal{D}(1^\lambda) \\ (\mathbb{i}, [\mathsf{qx}_i]_{i=1}^{m_1}, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m_2}, \mathsf{acc}, \mathsf{pf}; r) \leftarrow \tilde{\mathrm{P}}(\mathsf{pp}_{\mathsf{AS}}, \mathsf{pp}, \mathsf{ai}) \\ ([\mathsf{qw}_i]_{i=1}^{m_1}, [\mathsf{acc}_i.\mathbb{w}]_{i=1}^{m_2}) \leftarrow \mathrm{E}^{\tilde{\mathrm{P}}}(\mathsf{pp}_{\mathsf{AS}}, \mathsf{pp}, \mathsf{ai}, r) \\ (\mathsf{apk}, \mathsf{avk}, \mathsf{dk}) \leftarrow \mathrm{I}(\mathsf{pp}_{\mathsf{AS}}, \mathsf{pp}, \mathbb{i}) \end{array}\right]$$

The extractor implicitly receives s as input.

▶ Remark 4. We can also define a bounded-depth version of completeness with a separate family of deciders. In the completeness definition, valid accumulators for the i-th decider accumulate to a valid accumulator for the $(i+1)$-th decider. This is important in settings where even an honest prover can only perform a bounded number of accumulations.

4 Constructing bounded-depth accumulation

We construct a bounded-depth accumulation scheme, which supports (possibly distinct) arities $m_1 = \text{poly}(\lambda)$ and $m_2 = \text{poly}(\lambda)$, for a general class of non-interactive arguments. Across all of our constructions, we fix the following global constants: depth bound d_s, code rate $R \in (0,1)$, and distance $\delta \leq (1-R)/(2d_s)$; this guarantees that $d_s\delta$ is smaller than the unique decoding radius of a Reed–Solomon code with rate R. Additionally, we use domain separation on the random oracle ρ to model three disjoint oracles: ρ_H for Merkle trees and hashing, ρ_{ARG} for the argument verifier's randomness, and ρ_{AS} for the accumulation verifier's randomness. When querying ρ_{ARG} and ρ_{AS}, we assume the random oracle's output is used to sample from the verifier's challenge set. All security proofs are deferred to the full version of the paper.

Notation

If x, y, z are vectors, we will often interpret tuples like $(x,(y,z))$ as a vector consisting of x, y, z concatenated together. Given a codeword $f \in C$, let $\hat{f}$ denote the corresponding message which encodes to f. We write $\mathbf{f}$ as shorthand for the tuple $(f^{(1)}, \ldots, f^{(\mu)})$ and $\mathbf{C}$ as shorthand for the Cartesian product $C^{(1)} \times \cdots \times C^{(\mu)}$. Similarly, let $\hat{\mathbf{f}} = (\hat{f}^{(1)}, \ldots, \hat{f}^{(\mu)})$ and $\Delta(\mathbf{f}, \mathbf{g}) = \max_{j \in [\mu]} \Delta(f^{(j)}, g^{(j)})$. When querying locations in a codeword, let $\mathbf{Q} = (\mathcal{Q}^{(1)}, \ldots, \mathcal{Q}^{(\mu)})$ and $\mathbf{f}[\mathbf{Q}] = (f^{(1)}[\mathcal{Q}^{(1)}], \ldots, f^{(\mu)}[\mathcal{Q}^{(\mu)}])$. We use arrow notation as shorthand for tuples of commitment data, e.g., $\vec{\mathsf{cm}} = (\mathsf{cm}^{(1)}, \ldots, \mathsf{cm}^{(\mu)})$. Vector commitment functions map over tuples, e.g., $(\vec{\mathsf{cm}}, \vec{\mathsf{aux}}) \leftarrow \mathsf{VC.Commit}(\mathsf{vp}, \mathbf{f})$ should be interpreted as saying "for each $j \in [\mu]$, let $(\vec{\mathsf{cm}}^{(j)}, \vec{\mathsf{aux}}^{(j)}) \leftarrow \mathsf{VC.Commit}(\mathsf{vp}, f^{(j)})$."

4.1 Non-interactive argument

Our starting point is any special-sound interactive proof with an algebraic verifier. By this, we mean that the verifier's check can be expressed as a sequence of degree d polynomials (derived from the index) which take the transcript as input. The verifier accepts if all of the polynomials evaluate to zero.

In more detail, we require an interactive proof for some indexed relation $\mathcal{R}(\mathbb{F})$. Let μ be the number of rounds in the protocol; this may be a function of the index. For simplicity, we assume that the instance $\mathbb{x}$, the prover's messages $m^{(1)}, \ldots, m^{(\mu)}$, and the verifier's challenges $r^{(1)}, \ldots, r^{(\mu)}$ are all vectors over $\mathbb{F}$; their lengths may be a function of the index. From the index, the verifier derives degree d polynomials $p_1, \ldots, p_\ell$ over $\mathbb{F}$. It accepts if, for all i, $p_i(\mathbb{x}, \mathbf{r}, \mathbf{m}) = 0$.

Compressing the verifier

Without loss of generality, we can assume that the algebraic verifier consists of a single polynomial. This is because multiple polynomial checks can be compressed into a single check, e.g., by using the following technique due to [34, 20].

Let Π be an interactive proof where the verifier's check consists of ℓ polynomials $p_0, \ldots, p_{\ell-1}$, each of degree d. We transform this into an interactive proof $\mathsf{CV}[\Pi]$ for the same relation, where the verifier's check is a single polynomial

$$p(\vec{X}, \vec{Y}) = \sum_{i=0}^{\ell-1} \mathsf{pow}_i(\vec{Y}) \cdot p_i(\vec{X}).$$

Here, pow_i is the unique degree $\log \ell$ polynomial satisfying $\mathsf{pow}_i(1, \beta, \beta^2, \beta^4, \ldots, \beta^{\ell/2}) = \beta^i$ for all $\beta \in \mathbb{F}$. It follows that p is of degree $d + \log \ell$. The interactive protocol is the same as before, except that the verifier additionally samples a challenge $y = (1, \beta, \beta^2, \beta^4, \ldots, \beta^{\ell/2})$ where $\beta \leftarrow \mathbb{F}$. The verifier accepts if $p(x, y) = 0$, where x is the transcript from the original proof.

If Π is $(k_1, \ldots, k_\mu)$-special-sound, then $\mathsf{CV}[\Pi]$ is $(k_1, \ldots, k_\mu, \ell)$-special-sound. To see why, suppose we have a tree T of accepting transcripts for $\mathsf{CV}[\Pi]$. Consider an arbitrary node in the penultimate layer of the tree. Its children correspond with transcripts of the form $(x, y_1), \ldots, (x, y_\ell)$, each y_i distinct. Since the transcripts are accepting, the degree $\ell - 1$ univariate polynomial $\sum_{i=0}^{\ell-1} Z^i \cdot p_i(x)$ is zero at ℓ points. It follows that f is the zero polynomial and, for all i, $p_i(x) = 0$. Let T' denote T with its bottom layer removed. We have shown that T' is a tree of accepting transcripts for Π. Hence, we construct an extractor for $\mathsf{CV}[\Pi]$ by running the extractor for Π on T'.

Committing to messages

In order to achieve efficient accumulation, we will instead have the prover send commitments to messages. Only in the final move of the protocol does the prover send openings to all of the commitments. Strictly speaking, this is only special-sound for an "augmented relation"; namely, there exists an extractor which, given a tree of accepting transcripts, outputs either a witness or a break of the commitment scheme. Nonetheless, assuming the scheme is computationally binding, applying the Fiat-Shamir transformation yields a non-interactive argument of knowledge for the original relation. We refer to [20] for a more detailed analysis.

Removing interaction

Given a special-sound interactive proof (P, V), we apply the Fiat–Shamir transformation (with commitments) to get a non-interactive argument of knowledge [4]. In order to achieve efficient accumulation, we use a standard variant of the transformation where the index is first hashed to a succinct value τ. The Fiat–Shamir transform outputs a non-interactive argument $\mathsf{ARG} = (\mathcal{G}, \mathcal{P}, \mathcal{V})$, shown in Figure 2, for the indexed relation family $\{\mathcal{R}_{\mathsf{pp}} = \mathcal{R}(\mathbb{F})\}$. We also define an indexer $\mathcal{I}$ as a helper algorithm.

Attema et al. [4] prove that multi-round public-coin protocols can be compiled into non-interactive arguments. However, their definition of knowledge-soundness is slightly different from ours: they require that the extractor succeeds with non-negligible probability if the adversary succeeds with non-negligible probability. Our definition, on the other hand, requires that the extractor succeeds with all but negligible probability whenever the adversary succeeds. However, these definitions are equivalent as one can boost the extractor's success probability by running it until it succeeds. This works as the extractor is only required to run in *expected* polynomial time.

$\mathcal{G}(1^\lambda)$:

1. Choose a suitable field $\mathbb{F}, \log|\mathbb{F}| = \Omega(\lambda)$.
2. Let $\mathsf{vp} \leftarrow \mathsf{VC.Setup}(1^\lambda, \mathbb{F})$.
3. Output $\mathsf{pp} = (\mathbb{F}, \mathsf{vp})$.

$\mathcal{I}^\rho(\mathsf{pp} = (\mathbb{F}, \mathsf{vp}), \mathbb{i})$:

1. Query $\tau \leftarrow \rho_H(\mathbb{i})$.
2. From $\mathbb{F}$ and $\mathbb{i}$, derive the following parameters, collected into $\mathbb{p}$:
   - The number of rounds, denoted μ.
   - The length of the instance.
   - For each $j \in [\mu]$, the length, denoted $\ell^{(j)}$, of the prover's j-th message.
   - For each $j \in [\mu]$, the format of the verifier's j-th challenge.
3. From $\mathbb{F}$ and $\mathbb{i}$, derive the verifier's check p.
4. For each $j \in [\mu]$, let $C^{(j)}$ be a Reed–Solomon code over $\mathbb{F}$ with dimension $\ell^{(j)}$, rate R, and evaluation domain $L^{(j)}$.
5. Output $\mathsf{ipk} = (\mathbb{F}, \mathsf{vp}, \mathbb{i}, \tau, \mathbb{p}, \mathbf{C})$ and $\mathsf{ivk} = (\mathbb{F}, \mathsf{vp}, \tau, \mathbb{p}, p, \mathbf{C})$.

$\mathcal{P}^\rho(\mathsf{pp}, \mathbb{i}, \mathbb{x}, \mathbb{w})$:

1. Compute the proving key $\mathsf{ipk} = (\mathbb{F}, \mathsf{vp}, \mathbb{i}, \tau, \mathbb{p}, \mathbf{C})$ according to $\mathcal{I}^\rho(\mathsf{pp}, \mathbb{i})$.
2. For $j \in [\mu]$:
   - Compute the prover's j-th message $m^{(j)} \leftarrow P(\mathbb{F}, \mathbb{i}, \mathbb{x}, \mathbb{w}, [m^{(i)}, r^{(i)}]_{i=1}^{j-1})$.
   - Encode $m^{(j)}$ to $f^{(j)} \in C^{(j)}$.
   - Let $(\mathsf{cm}^{(j)}, \mathsf{aux}^{(j)}) \leftarrow \mathsf{VC.Commit}^{\rho_H}(\mathsf{vp}, f^{(j)})$.
   - Query $r^{(j)} \leftarrow \rho_{\mathsf{ARG}}(\tau, \mathbb{x}, \mathsf{cm}^{(1)}, \ldots, \mathsf{cm}^{(j)})$.
3. Output $\pi = (\vec{\mathsf{cm}}, \vec{\mathsf{aux}})$.

$\mathcal{V}^\rho(\mathsf{pp}, \mathbb{i}, \mathbb{x}, \pi = (\vec{\mathsf{cm}}, \vec{\mathsf{aux}}))$:

1. Compute the verification key $\mathsf{ivk} = (\mathbb{F}, \mathsf{vp}, \tau, \mathbb{p}, p, \mathbf{C})$ according to $\mathcal{I}^\rho(\mathsf{pp}, \mathbb{i})$.
2. For each $j \in [\mu]$, query $r^{(j)} \leftarrow \rho_{\mathsf{ARG}}(\tau, \mathbb{x}, \mathsf{cm}^{(1)}, \ldots, \mathsf{cm}^{(j)})$.
3. Let $\mathbf{f} \leftarrow \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}, \vec{\mathsf{aux}})$.
4. Verify that $\mathbf{f} \in \mathbf{C}$.
5. Accept if $p(\mathbb{x}, \mathbf{r}, \hat{\mathbf{f}}) = 0$.

$\tilde{\mathcal{V}}^\rho(\mathsf{pp}, \mathbb{i}, \mathbb{x}, \pi = (\vec{\mathsf{cm}}, \vec{\mathsf{aux}}))$:

1. Compute the verification key $\mathsf{ivk} = (\mathbb{F}, \mathsf{vp}, \tau, \mathbb{p}, p, \mathbf{C})$ according to $\mathcal{I}^\rho(\mathsf{pp}, \mathbb{i})$.
2. For each $j \in [\mu]$, query $r^{(j)} \leftarrow \rho_{\mathsf{ARG}}(\tau, \mathbb{x}, \mathsf{cm}^{(1)}, \ldots, \mathsf{cm}^{(j)})$.
3. Let $\mathbf{f} \leftarrow \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}, \vec{\mathsf{aux}})$.
4. Find $\mathbf{g} \in \mathbf{C}$ by uniquely decoding $\mathbf{f}$. If no such codeword exists, reject.
5. Accept if $p(\mathbb{x}, \mathbf{r}, \hat{\mathbf{g}}) = 0$.

Figure 2 Non-interactive argument algorithms.

Relaxed verifier

We use a specific commitment scheme to support accumulation: the prover sends a vector commitment to a codeword of the message, along with the full auxiliary data. We relax the verifier in two different ways to get $\tilde{\mathcal{V}}$ (also shown in Figure 2). First, we allow it to decode noisy codewords. Second, we allow it to accept partial openings to the vector commitment where the missing positions are interpreted as erasure errors. Because the verifier only accepts when the partial opening is decodable, the prover is still bound to a unique (decoded) vector; hence, knowledge soundness is not affected.

4.2 Accumulation scheme

Fix a subset $H \subset \mathbb{F}$ of size $m = m_1 + m_2$; this may be a function of λ. We construct an accumulation scheme $\mathsf{AS} = (\mathrm{G}, \mathrm{I}, \mathrm{P}, \mathrm{V}, \mathrm{D})$ for ARG. The argument verifier inputs are split into $\mathsf{qx} = (\mathbb{x}, \vec{\mathsf{cm}})$ and $\mathsf{qw} = \mathsf{a}\vec{\mathsf{u}}\mathsf{x}$. Accumulators have a nearly identical structure; in fact, any verifier input $(\mathsf{qx}, \mathsf{qw})$ can be converted into an accumulator acc by setting $\mathsf{acc}.\mathbb{w} = \mathsf{qw}$ and $\mathsf{acc}.\mathbb{x} = \textsc{CastInput}^{\rho}(\tau, \mathsf{qx})$, which is defined below.

$\textsc{CastInput}^{\rho}(\tau, \mathsf{qx} = (\mathbb{x}, \vec{\mathsf{cm}}))$:
1. For each $j \in [\mu]$, query $r^{(j)} \leftarrow \rho_{\mathsf{ARG}}(\tau, \mathbb{x}, \mathsf{cm}^{(1)}, \ldots, \mathsf{cm}^{(j)})$.
2. Collect $\mathbb{x}$ and $\mathbf{r}$ into a vector x.
3. Output $\mathsf{acc}.\mathbb{x} = (0, x, \vec{\mathsf{cm}})$.

We also define a helper function which casts $[\mathsf{qx}_i]_{i=1}^{m_1}$ and $[\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m_2}$ into a single list of $m = m_1 + m_2$ accumulator instances.

$\textsc{Cast}^{\rho}(\tau, [\mathsf{qx}_i]_{i=1}^{m_1}, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m_2})$:
1. Output $[\textsc{CastInput}(\tau, \mathsf{qx}_1), \ldots, \textsc{CastInput}(\tau, \mathsf{qx}_{m_1}), \mathsf{acc}_1.\mathbb{x}, \ldots, \mathsf{acc}_{m_2}.\mathbb{x}]$.

Finally, we define helper functions which perform the bulk of proving and verification.

$\textsc{Prove}^{\rho}(\mathsf{apk}, [e_i, x_i, \vec{\mathsf{cm}}_i, \mathsf{a}\vec{\mathsf{u}}\mathsf{x}_i]_{i=1}^{m})$:
1. For each $i \in [m]$, let $\mathbf{f}_i \leftarrow \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}_i, \mathsf{a}\vec{\mathsf{u}}\mathsf{x}_i)$.
2. Compute the univariate polynomial $q \in \mathbb{F}[X]$ of degree at most $d(m-1) - m$ such that
$$p\left(\sum_{i=1}^{m} L_{i,H}(X) \cdot (x_i, \hat{\mathbf{f}}_i)\right) = v_H(X) \cdot q(X) + \sum_{i=1}^{m} L_{i,H}(X) \cdot e_i.$$
3. Query $\alpha \leftarrow \rho_{\mathsf{AS}}(\tau, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m}, q)$, where $\alpha \in \mathbb{F}$ is a uniformly sampled field element.
4. Compute $e = v(\alpha) \cdot q(\alpha) + \sum_i L_i(\alpha) \cdot e_i$.
5. Compute $(x, \hat{\mathbf{f}}) = \sum_i L_i(\alpha) \cdot (x_i, \hat{\mathbf{f}}_i)$.
6. Let $(\vec{\mathsf{cm}}, \mathsf{a}\vec{\mathsf{u}}\mathsf{x}) \leftarrow \mathsf{VC.Commit}^{\rho_H}(\mathsf{vp}, \mathbf{f})$.
7. Set $\mathsf{acc}.\mathbb{x} = (e, x, \vec{\mathsf{cm}})$ and $\mathsf{acc}.\mathbb{w} = \mathsf{a}\vec{\mathsf{u}}\mathsf{x}$.
8. Query $\mathbf{Q} \leftarrow \rho_{\mathsf{AS}}(\tau, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m}, q, \mathsf{acc}.\mathbb{x})$, where $\mathcal{Q}^{(j)}$ is a uniformly sampled t-sized subset of $L^{(j)}$.
9. For each $i \in [m]$, let $\vec{\mathsf{op}}_i \leftarrow \mathsf{VC.Open}^{\rho_H}(\mathsf{vp}, \mathsf{a}\vec{\mathsf{u}}\mathsf{x}_i, \mathbf{Q})$.
10. Let $\vec{\mathsf{op}} \leftarrow \mathsf{VC.Open}^{\rho_H}(\mathsf{vp}, \mathsf{a}\vec{\mathsf{u}}\mathsf{x}, \mathbf{Q})$.
11. Output acc and $\mathsf{pf} = (q, [\vec{\mathsf{op}}_i]_{i=1}^{m}, \vec{\mathsf{op}})$.

$\textsc{Verify}^{\rho}(\mathsf{avk}, [e_i, x_i, \vec{\mathsf{cm}}_i]_{i=1}^m, (e, x, \vec{\mathsf{cm}}), (q, [\vec{\mathsf{op}}_i]_{i=1}^m, \vec{\mathsf{op}}))$:

1. Query $\alpha \leftarrow \rho_{\mathsf{AS}}(\tau, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^m, q)$.
2. Query $\mathbf{Q} \leftarrow \rho_{\mathsf{AS}}(\tau, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^m, q, \mathsf{acc}.\mathbb{x})$.
3. For each $i \in [m]$, let $\mathbf{v}_i = \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}_i, \vec{\mathsf{op}}_i)$. If $\mathbf{v}_i[\mathbf{Q}]$ contains $\perp$, reject.
4. Let $\mathbf{v} = \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}, \vec{\mathsf{op}}, \mathbf{Q})$. If $\mathbf{v}[\mathbf{Q}]$ contains $\perp$, reject.
5. Verify that $e = v_H(\alpha) \cdot q(\alpha) + \sum_{i=1}^m L_{i,H}(\alpha) \cdot e_i$.
6. Verify that $(x, \mathbf{v}) = \sum_{i=1}^m L_{i,H}(\alpha) \cdot (x_i, \mathbf{v}_i)$.

See Figure 3 for a full description of AS, along with the family of deciders.

$\mathrm{G}(1^\lambda)$:

1. Choose a suitable spot check parameter $t = \Omega(\lambda)$.
2. Output $\mathsf{pp}_{\mathsf{AS}} = t$.

$\mathrm{I}^{\rho}(\mathsf{pp}_{\mathsf{AS}} = t, \mathsf{pp} = (\mathbb{F}, \mathsf{vp}), \mathbb{i})$:

1. Obtain $\tau, \mathbb{p}, p, \mathbf{C}$ from $\mathcal{I}^{\rho}(\mathsf{pp}, \mathbb{i})$.
2. Output $\mathsf{apk} = (\mathbb{F}, \mathsf{vp}, t, \tau, \mathbb{p}, p, \mathbf{C})$, $\mathsf{avk} = (\mathbb{F}, \mathsf{vp}, t, \tau, \mathbb{p}, \mathbf{C})$, and $\mathsf{dk} = (\mathbb{F}, \mathsf{vp}, \mathbb{p}, p, \mathbf{C})$.

$\mathrm{P}^{\rho}(\mathsf{apk}, [\mathsf{qx}_i, \mathsf{qw}_i]_{i=1}^{m_1}, [\mathsf{acc}]_{i=1}^{m_2})$:

1. Let $[e_i, x_i, \vec{\mathsf{cm}}_i]_{i=1}^m \leftarrow \textsc{Cast}(\tau, [\mathsf{qx}_i]_{i=1}^{m_1}, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m_2})$.
2. Parse $[\vec{\mathsf{aux}}_i]_{i=1}^m = [\mathsf{qw}_1, \ldots, \mathsf{qw}_{m_1}, \mathsf{acc}_1.\mathbb{w}, \ldots, \mathsf{acc}_{m_2}.\mathbb{w}]$.
3. Output $\textsc{Prove}^{\rho}(\mathsf{apk}, [e_i, x_i, \vec{\mathsf{cm}}_i, \vec{\mathsf{aux}}_i]_{i=1}^m)$.

$\mathrm{V}^{\rho}(\mathsf{avk}, [\mathsf{qx}_i]_{i=1}^{m_1}, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m_2}, \mathsf{acc}.\mathbb{x}, \mathsf{pf})$:

1. Let $[e_i, x_i, \vec{\mathsf{cm}}_i]_{i=1}^m \leftarrow \textsc{Cast}(\tau, [\mathsf{qx}_i]_{i=1}^{m_1}, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^{m_2})$.
2. Accept if $\textsc{Verify}(\mathsf{avk}, [e_i, x_i, \vec{\mathsf{cm}}_i]_{i=1}^m, \mathsf{acc}.\mathbb{x}, \mathsf{pf})$ accepts.

$\mathrm{D}_s^{\rho}(\mathsf{dk}, \mathsf{acc}.\mathbb{x} = (e, x, \vec{\mathsf{cm}}), \mathsf{acc}.\mathbb{w} = \vec{\mathsf{aux}})$:

1. Let $\mathbf{f} \leftarrow \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}, \vec{\mathsf{aux}})$.
2. Find $\mathbf{g} \in \mathbf{C}, \Delta(\mathbf{f}, \mathbf{g}) \leq s\delta$ by decoding $\mathbf{f}$. If no such codeword exists, reject.
3. Accept if $p(x, \hat{\mathbf{g}}) = e$.

Figure 3 Accumulation scheme algorithms.

4.3 Using arbitrary linear codes

At first glance, our accumulation scheme does not use any special properties of the Reed–Solomon code. Because other codes might have desirable properties, e.g., linear-time encoding, this motivates the following question: can we instantiate it with an arbitrary linear code, so long as it has good distance? Recall that the accumulator's vectors are a random linear combination of the input vectors. In particular, the coefficients are Lagrange evaluations of a random field element; this is necessary for compressing the polynomial evaluation claims. Unfortunately, existing proximity gaps for arbitrary linear codes [49, 1, 32] do not support this specific distribution of coefficients.

Separating the proximity claim

In some sense, our construction accumulates two distinct claims for the same vector: a polynomial evaluation claim, and a proximity claim. To overcome the foregoing issue, we modify our accumulation scheme to separate these claims. Specifically, each accumulator now

holds *two* codewords: the first is a linear combination using Lagrange coefficients, and the second is a linear combination using proximity gap coefficients. Accordingly, the accumulation verifier uses the first codeword to compress evaluation claims, and the second codeword to maintain proximity. This will be roughly twice as expensive as before.

▶ **Definition 5** (Proximity gaps for linear codes)**.** *Let C be a linear code with relative distance d and blocklength n. We will treat elements of C as functions $v : [n] \to \mathbb{F}$. Let* Gen *be a function that takes in randomness* rnd *and outputs coefficients $r_1, \ldots, r_m \in \mathbb{F}$. We say that C has a proximity gap with respect to distribution* Gen*, error* err*, and proximity bound* B *if the following holds.*

For any $\delta \leq \mathsf{B}$ and arbitrary functions $u_1, \ldots, u_m \in \mathbb{F}^n : [n] \to \mathbb{F}$, if

$$\Pr_{\mathsf{rnd}}\left[\Delta\left(\sum_{i=1}^m r_i \cdot u_i, C\right) \leq \delta \;:\; (r_1, \ldots, r_m) \leftarrow \mathsf{Gen}(\mathsf{rnd})\right] > \mathsf{err}(m),$$

then for all $(r_1, \ldots, r_m)$ in the support of the distribution $\mathsf{Gen}(\mathsf{rnd})$*, we have*

$$\Delta\left(\sum_{i=1}^m r_i \cdot u_i, C\right) \leq \delta.$$

Furthermore, there exists $v_1, \ldots, v_m \in C$ such that for all $(r_1, \ldots, r_m)$ in the support,

$$\Delta\left(\sum_{i=1}^m r_i \cdot u_i, \sum_{i=1}^m r_i \cdot v_i\right) \leq \delta,$$

and in fact $|\{x \in [n] : (u_1(x), \ldots, u_m(x)) \neq (v_1(x), \ldots, v_m(x))\}| \leq \delta n$.

▶ **Lemma 6.** *Let C be a linear code with relative distance d, blocklength n, and proximity gap with respect to distribution* Gen*, error* err*, and proximity bound* B*. For $\delta \leq \mathsf{B}$ and vectors $f_1, \ldots, f_m \in \mathbb{F}^n$, suppose the following holds:*

$$\Pr_{\mathsf{rnd}}\left[\Delta\left(\sum_{i=1}^m r_i \cdot f_i, C\right) \leq \delta \;:\; (r_1, \ldots, r_m) \leftarrow \mathsf{Gen}(\mathsf{rnd})\right] > \mathsf{err}(m)$$

Then there exists a subdomain $L' \subseteq [n]$ and codewords $g_1, \ldots, g_m \in C$ such that the following holds. First, $|L'|/[n] \geq 1 - \delta$. Second, for all $i \in [m]$, f_i and g_i agree on L'.

Construction

We use linear codes with efficient unique decoding up to $\mathsf{B} = O(1)$, the error bound of the proximity gap. Fix $\delta \leq \mathsf{B}/d_s$; this guarantees that $d_s\delta \leq \mathsf{B}$ which is smaller than the unique decoding radius. The modified construction is shown below; all changes are highlighted in blue. We omit the description of unchanged algorithms from Figure 3.

$\textsc{CastInput}^{\rho}(\tau, \mathsf{qx} = (\mathbb{x}, \vec{\mathsf{cm}}))$:

1. For each $j \in [\mu]$, query $r^{(j)} \leftarrow \rho_{\mathsf{ARG}}(\tau, \mathbb{x}, \mathsf{cm}^{(1)}, \ldots, \mathsf{cm}^{(j)})$.
2. Collect $\mathbb{x}$ and $\mathbf{r}$ into a vector x.
3. Output $\mathsf{acc}.\mathbb{x} = (0, x, \vec{\mathsf{cm}}, \vec{\mathsf{cm}}')$, where $\vec{\mathsf{cm}}'$ are commitments to zero vectors.

$\textsc{Prove}^{\rho}(\mathsf{apk}, [e_i, x_i, \vec{\mathsf{cm}}_i, \vec{\mathsf{aux}}_i, \vec{\mathsf{cm}}'_i, \vec{\mathsf{aux}}'_i]_{i=1}^m)$:

1. For each $i \in [m]$, let $\mathbf{f}_i \leftarrow \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}_i, \vec{\mathsf{aux}}_i)$, and $\mathbf{f}'_i \leftarrow \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}'_i, \vec{\mathsf{aux}}'_i)$.
2. Compute the univariate polynomial $q \in \mathbb{F}[X]$ of degree at most $d(m-1) - m$ such that

$$p\left(\sum_{i=1}^{m} L_{i,H}(X) \cdot (x_i, \hat{\mathbf{f}}_i)\right) = v_H(X) \cdot q(X) + \sum_{i=1}^{n} L_{i,H}(X) \cdot e_i.$$

3. Query $\alpha, \mathsf{rnd} \leftarrow \rho_{\mathsf{AS}}(\tau, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^m, q)$, where $\alpha \in \mathbb{F}$ and rnd are sampled uniformly.
4. Compute $e = v(\alpha) \cdot q(\alpha) + \sum_i L_i(\alpha) \cdot e_i$.
5. Compute $(x, \hat{\mathbf{f}}) = \sum_i L_i(\alpha) \cdot (x_i, \hat{\mathbf{f}}_i)$.
6. Let $(r_1, \ldots, r_m, r'_1, \ldots, r'_m) \leftarrow \mathsf{Gen}(\mathsf{rnd})$. Compute $\mathbf{f}' = \sum_{i=1}^m r_i \cdot \mathbf{f}_i + r'_i \cdot \mathbf{f}'_i$.
7. Let $(\vec{\mathsf{cm}}, \vec{\mathsf{aux}}) \leftarrow \mathsf{VC.Commit}^{\rho_H}(\mathsf{vp}, \mathbf{f})$, and $(\vec{\mathsf{cm}}', \vec{\mathsf{aux}}') \leftarrow \mathsf{VC.Commit}^{\rho_H}(\mathsf{vp}, \mathbf{f}')$.
8. Set $\mathsf{acc}.\mathbb{x} = (e, x, \vec{\mathsf{cm}}, \vec{\mathsf{cm}}')$ and $\mathsf{acc}.\mathbb{w} = (\vec{\mathsf{aux}}, \vec{\mathsf{aux}}')$.
9. Query $\mathbf{Q} \leftarrow \rho_{\mathsf{AS}}(\tau, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^m, q, \mathsf{acc}.\mathbb{x})$, where $\mathcal{Q}^{(j)}$ is a uniformly sampled t-sized subset of $[n]$.
10. For each $i \in [m]$, let $\vec{\mathsf{op}}_i \leftarrow \mathsf{VC.Open}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{aux}}_i, \mathbf{Q})$, and $\vec{\mathsf{op}}'_i \leftarrow \mathsf{VC.Open}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{aux}}'_i, \mathbf{Q})$.
11. Let $\vec{\mathsf{op}} \leftarrow \mathsf{VC.Open}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{aux}}, \mathbf{Q})$, and $\vec{\mathsf{op}}' \leftarrow \mathsf{VC.Open}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{aux}}', \mathbf{Q})$.
12. Output acc and $\mathsf{pf} = (q, [\vec{\mathsf{op}}_i, \vec{\mathsf{op}}'_i]_{i=1}^m, \vec{\mathsf{op}}, \vec{\mathsf{op}}')$.

$\textsc{Verify}^{\rho}(\mathsf{avk}, [e_i, x_i, \vec{\mathsf{cm}}_i, \vec{\mathsf{cm}}'_i]_{i=1}^m, (e, x, \vec{\mathsf{cm}}, \vec{\mathsf{cm}}'), (q, [\vec{\mathsf{op}}_i, \vec{\mathsf{op}}'_i]_{i=1}^m, \vec{\mathsf{op}}, \vec{\mathsf{op}}'))$:

1. Query $\alpha, \mathsf{rnd} \leftarrow \rho_{\mathsf{AS}}(\tau, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^m, q)$.
2. Query $\mathbf{Q} \leftarrow \rho_{\mathsf{AS}}(\tau, [\mathsf{acc}_i.\mathbb{x}]_{i=1}^m, q, \mathsf{acc}.\mathbb{x})$.
3. For each $i \in [m]$, let $\mathbf{v}_i = \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}_i, \vec{\mathsf{op}}_i)$. If $\mathbf{v}_i[\mathbf{Q}]$ contains $\perp$, reject.
4. Let $\mathbf{v} = \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}, \vec{\mathsf{op}}, \mathbf{Q})$. If $\mathbf{v}[\mathbf{Q}]$ contains $\perp$, reject.
5. For each $i \in [m]$, let $\mathbf{v}'_i = \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}'_i, \vec{\mathsf{op}}'_i)$. If $\mathbf{v}'_i[\mathbf{Q}]$ contains $\perp$, reject.
6. Let $\mathbf{v}' = \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}', \vec{\mathsf{op}}', \mathbf{Q})$. If $\mathbf{v}'[\mathbf{Q}]$ contains $\perp$, reject.
7. Verify that $e = v_H(\alpha) \cdot q(\alpha) + \sum_{i=1}^n L_{i,H}(\alpha) \cdot e_i$.
8. Verify that $(x, \mathbf{v}) = \sum_{i=1}^m L_{i,H}(\alpha) \cdot (x_i, \mathbf{v}_i)$.
9. Let $(r_1, \ldots, r_m, r'_1, \ldots, r'_m) \leftarrow \mathsf{Gen}(\mathsf{rnd})$. Verify that $\mathbf{v}' = \sum_{i=1}^m r_i \cdot v_i + r'_i \cdot v'_i$.

$\mathrm{D}_s^{\rho}(\mathsf{dk}, \mathsf{acc}.\mathbb{x} = (e, x, \vec{\mathsf{cm}}, \vec{\mathsf{cm}}'), \mathsf{acc}.\mathbb{w} = (\vec{\mathsf{aux}}, \vec{\mathsf{aux}}'))$:

1. Let $\mathbf{f} \leftarrow \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}, \vec{\mathsf{aux}})$.
2. Let $\mathbf{f}' \leftarrow \mathsf{VC.Answer}^{\rho_H}(\mathsf{vp}, \vec{\mathsf{cm}}', \vec{\mathsf{aux}}')$.
3. Find $\mathbf{g}, \mathbf{g}' \in \mathbf{C}$ such that $\Delta(\mathbf{f}, \mathbf{g}), \Delta(\mathbf{f}', \mathbf{g}') \leq (s-1)\delta$ by decoding $\mathbf{f}$ and $\mathbf{f}'$. If no such codewords exists, reject.
4. Accept if $p(x, \hat{\mathbf{g}}) = e$.

Abstract

We initiate the study of approximately counting the number of list packings of a graph. The analogous problem for usual vertex coloring and list coloring has attracted substantial attention. For list packing the setup is similar, but we seek a full decomposition of the lists of colors into pairwise-disjoint proper list colorings. The existence of a list packing implies the existence of a list coloring, but the converse is false. Recent works on list packing have focused on existence or extremal results of on the number of list packings, but here we turn to the algorithmic aspects of counting and sampling.

In graphs of maximum degree Δ and when the number of colors is at least $\Omega(\Delta^2)$, we give a fully polynomial-time randomized approximation scheme (FPRAS) based on rapid mixing of a natural Markov chain (the Glauber dynamics) which we analyze with the path coupling technique. Some motivation for our work is the investigation of an atypical spin system, one where the number of spins for each vertex is much larger than the graph degree.

1 Introduction

The classic graph coloring problem is to determine, for a graph $G = (V, E)$ and number of colors q, whether there is a coloring $f : V \to [q]$ such that f is proper in the sense that $f(u) \neq f(v)$ for every edge $uv \in E$. List coloring emerged in the late 20th century as an adversarial version of this problem [27, 13]. To define list coloring, we take a list size $q \in \mathbb{N}$ and assign to each $u \in V$ a list of allowed colors $L(u)$ of size q. One can think of the list assignment L as supplied by an adversary who might try to prevent the existence of a coloring respecting the lists. If, under any choices of such an assignment of lists, the graph G admits a proper coloring f such that $f(u) \in L(u)$ for every vertex u, then we say that G is q-list

colorable (also known as q-choosable in some works). In some ways list coloring and classical graph coloring are similar, e.g., the complete graph on n vertices requires $q \geq n$ for both problems. But all bipartite graphs can be colored with two colors, while $K_{n,n}$ requires lists of length $\Omega(\log n)$ in the list coloring setting [13].

List coloring also arises naturally in various other ways. Notably, if we take a classic graph coloring problem and pre-color some vertices then we can express the problem of completing the coloring through list coloring. We set $L(u)$ to be the subset of the colors not used by any pre-colored vertex in the neighborhood of u (though these lists may not have equal sizes). The idea of list coloring has been extended in several interesting directions, and in this work we study a very recent and structured variant known as list packing [6]. The setup is the same as for list coloring with a fixed list size q, but instead of seeking just one proper coloring where each vertex is colored from its list, we seek q pairwise-disjoint proper colorings from the lists. We consider two colorings f and f' of a graph disjoint if, for all vertices u we have $f(u) \neq f'(u)$. We call this collection of q pairwise-disjoint proper list colorings a *list packing*. Given a graph G and list size q, if a list packing can be found for any lists of size q chosen by an adversary then we say that G is q-list packable.

One motivation for list packing in [6] is to challenge the state-of-the-art in list coloring. For example, a folklore result states that a bipartite graph of maximum degree Δ is q-list colorable for $q \geq (1 + o(1))\Delta/\log \Delta$ (see also [1] and a recent improvement of the leading constant due to Bradshaw [4]). Amongst other foundational results on list packing, the folklore result was matched for the significantly more structured notion of list packing in [6]. A notable difference between known results for list packing and list coloring is that a general graph of maximum degree Δ is q-list packable for $q \geq 2\Delta$ (improved to $q \geq 2\Delta - 2$ for $\Delta \geq 4$ in [8]); whilst such G are q-list colorable for $q \geq \Delta + 1$ (and even $q = \Delta$ if $\Delta \geq 3$ and G does not contain a clique on $\Delta + 1$ vertices [13]). Despite the gap in known results, there is scant evidence that more than $\Delta + 1$ colors are ever required for list packing [8, 6].

Early work on list packing has focused on the problem of existence, though many arguments for existence also provide efficient constructions of list packings. An extremal perspective on counting list packings was recently investigated by Kaul and Mudrock [21], and related problems where one seeks many list colorings or "flexible" list colorings are studied in [20, 7]. In this work we turn to the study of approximately counting the number of L-packings of a graph G with a fixed q-list assignment L. This is a natural question by analogy with the same questions for graph coloring and list coloring: is there an efficient procedure that, given a graph G and a number of colors q, approximates the number of proper q-colorings of G (e.g., to within a factor 2)? This question is well-studied in the field of approximate counting and sampling, and is an important test-bed for algorithmic techniques. A longstanding open question is the existence of such an approximate counting algorithm that works for all $q \geq \Delta + 1$ on graphs of maximum degree Δ. An influential collection of results using various techniques requires conditions such as $q \geq e\Delta + 1$ [2], $q \geq 2\Delta$ [17, 22], $q \geq 11\Delta/6$ [26], and even $q \geq (11/6 - \epsilon)\Delta$ for some small $\epsilon > 0$ [10, 9]. Another branch of research on the algorithmic aspects of counting graph colorings seeks to sample perfectly uniformly from the set of proper q-colorings of a graph. The pioneering result is due to Huber [15], with improvements and new techniques supplied in a number of later works [23, 22, 3, 16]. Interestingly, one application of such perfect samplers is to design approximate counting algorithms that can be faster than analogous approaches which use approximate samplers.

Motivated by simple and powerful ideas such as the Markov chain Monte Carlo approach to counting colorings due to Jerrum [17] (see also [25]), we seek similar results for list packing. The list packing problem, however, presents novel difficulties. Observe that finding a list

coloring gets strictly easier as the list size q grows. Supposing that one has a technique that works with lists of size q_0, then given larger lists one can take arbitrary subsets of the lists of size q_0 and apply the technique in a black-box fashion. In contrast, for list packing with larger q we are required to find ever more list colorings which must also be pairwise-disjoint. Given lists of size $q > q_0$, it is not at all clear how to extend an arbitrary collection of q_0 pairwise-disjoint list colorings to a full list packing. The methods of [8, 6] provide evidence that showing the *existence* of a list packing does get easier with larger q, albeit for less straightforward and general reasons. Whether *counting* list packings should get easier as q grows is another matter, but we confirm this principle in the setting of approximate counting by giving an algorithm that approximately counts list packings which works for all q large enough in terms of the maximum degree.

Approximate counting of combinatorial objects such as list colorings, independent sets, and matchings corresponds to approximating the so-called partition function of a spin system from statistical physics. We are interested in the study of counting and sampling list packings as it presents an unusual type of spin system. Typically, the number of spins available for each vertex in a spin system is small. In the Ising model of magnetism vertices take a spin from $\{+, -\}$, and in the (antiferromagnetic) Potts model associated with proper q-colorings, the spins are the q colors. Parameter ranges frequently studied for this model on graphs of maximum degree Δ include the case when q is close to $\Delta + 1$. The natural spin system associated with q-list packings, however, has $q!$ spins for each vertex. Since a vertex u has a list of q colors which we must decompose into q choices, one for each list coloring in the packing, the spins for u naturally correspond to permutations of the list $L(u)$. One of our contributions is to study a somewhat natural combinatorial problem which involves a spin system on bounded degree graphs with many more spins than commonly-studied examples. We hope that further insights into algorithmic techniques for approximate counting can be gained by studying an unusual spin system.

2 Results

Our main result is the existence of an approximate counting algorithm for list packings. We define an ϵ-approximation of a real number x as a real number y satisfying $e^{-\epsilon} \leq x/y \leq e^{\epsilon}$. We use the standard notion of a *fully polynomial-time randomized approximation scheme* (FPRAS) for a counting problem. This is a randomized algorithm that, given $\epsilon > 0$, yields an ϵ-approximation of the true answer in time polynomial in the input size and $1/\epsilon$.

Before we state the result, we need some more notation for list packings focusing on a specific list assignment L. Given a graph G we call an assignment $L : V(G) \to 2^{\mathbb{N}}$ of lists of colors to the vertices of G such that $|L(u)| = q$ for all vertices u a q-list assignment of G. A proper coloring f of G such that $f(u) \in L(u)$ for all vertices u is called an L-coloring, or a list coloring if the lists L are understood from context. Given a graph G and a q-list assignment L, we call a collection of q pairwise-disjoint L-colorings of G an L-packing. Note that an L-packing corresponds to permutation of the lists $L(v)$ for each vertex v.

▶ **Theorem 1.** *There is an absolute constant C such that the following holds. For any $\Delta \geq 1$ and $q \geq C\Delta^2$, let G be a graph of maximum degree Δ. Then for any q-list assignment L of G, there is an FPRAS for the number of L-packings of G.*

We prove this result by analyzing the so-called "heat-bath Glauber dynamics" for list packing. Briefly, the state space is the set of list packings of the graph and transitions involve resampling a uniform random valid permutation of the list of a uniform random choice of

vertex. We define "valid" carefully and analyze this Markov chain later, noting here that we prove Theorem 1 by establishing rapid mixing of this chain and hence an approximate sampling algorithm for a uniform L-packing under the same conditions.

A natural combinatorial problem on matchings in balanced bipartite graphs of large minimum degree emerges during the proof of Theorem 1, leading to a probabilistic result stated below that may be of independent interest. This is because the valid permutations of the list $L(v)$ correspond precisely to the perfect matchings in an auxiliary bipartite graph that we construct from the list packing on the neighbors of v. Throughout, we assume that Δ and q are fixed constants and do not analyze the case where they are allowed to depend on the number n of vertices of G as then algorithmic issues related to (perfectly) sampling perfect matchings in $2q$-vertex bipartite graphs become trivial[2]. We do not attempt to optimize the dependence of the running time on q or Δ.

Given a set A, we write $\mathcal{U}_A$ for the uniform distribution on A. When a fixed q is clear from context, let d_{C} be the Cayley metric on the symmetric group S_q. That is, $d_{\mathrm{C}}(\rho, \rho')$ is the minimum number of transpositions which one must compose with ρ to turn it into ρ'. This is merely graph distance on the Cayley graph of S_q generated by the transpositions. We associate perfect matchings in a balanced bipartite graph $H = ([q] \sqcup [q], E)$ with permutations $\rho \in S_q$ where $(i, \rho(i)) \in E$ for each i.

Given two random variables X, Y defined on the discrete probability spaces (Ω_X, p_X) and (Ω_Y, p_Y), a coupling of X, Y is a random variable $\gamma = (X', Y')$ defined on a probability space $(\Omega_X \times \Omega_Y, p_\gamma)$ such that X and X' have identical distributions and Y and Y' have identical distributions.

Given a Markov chain Z_t with state space Ω and transition matrix P, a coupling of Z_t is a Markov chain (X_t, Y_t) with state space $\Omega \times \Omega$ and transition matrix $\widehat{P}$ satisfying

$$\sum_{y' \in \Omega} \widehat{P}((x, y), (x', y')) = P(x, x'),$$
$$\sum_{x' \in \Omega} \widehat{P}((x, y), (x', y')) = P(y, y').$$

That is, each coordinate of the coupling is a faithful copy of Z_t, though the transitions of the coordinates are not necessarily independent.

▶ **Lemma 2.** *There are constants C_1, C_2 such that the following hold. Suppose that $q \geq C_1\Delta$, and let $H = (V, E)$ be a bipartite graph in which $|V| = 2q$ and the bipartition is balanced. Suppose that H has minimum degree at least $q - \Delta$. Let $e \in E$ be an edge of H, let $\mathcal{L}$ be the set of perfect matchings of H containing e, and let $\mathcal{R}$ the set of perfect matchings of H not containing e. Then there is a coupling γ of $\mathcal{U}_{\mathcal{R}}$ and $\mathcal{U}_{\mathcal{L} \cup \mathcal{R}}$ such that*

$$\mathbb{E}_{(\rho, \rho') \sim \gamma}[d_{\mathrm{C}}(\rho, \rho')] \leq \frac{C_2\Delta}{q}.$$

This lemma is the main bottleneck for improving the dependence of q on Δ in our main theorem. In particular, removing the factor of Δ would also improve Theorem 1 by a factor of Δ.

[2] Given a bipartite graph of constant order which contains a perfect matching, sampling a perfect matching uniformly at random can be done in constant time, e.g. by exhaustively enumerating the perfect matchings and selecting one at random.

3 Technical overview

We prove Theorem 1 by the standard Markov chain Monte Carlo approach and the path coupling technique of Bubley and Dyer [5]. We study an ergodic Markov chain – the heat-bath Glauber dynamics – whose stationary distribution is uniform on the list packings of a graph, and use path coupling to show rapid mixing. Then a well-known and generic reduction from counting to sampling yields Theorem 1. Path coupling reduces the potentially challenging task of proving rapid mixing of a Markov chain to designing a coupling on adjacent states according to some graph Γ on the state space Ω. We largely follow the notation of [12] and consider

$$\mathcal{M} := \{P^t p_0\}_{t=0}^{\infty},$$

an ergodic Markov chain on state space Ω with initial distribution p_0 and transition operator P. We denote the (unique) stationary distribution by π, and denote by $p_t := P^t p_0$ the distribution of the state of the chain $\mathcal{M}$ after t steps. We use the standard notion of mixing time of Markov chains given by

$$t_{\text{mix}}(\epsilon) := \max_{p_0} \min \{t \geq 0 : d_{\text{TV}}(p_t, \pi) \leq \epsilon\},$$

where d_{TV} is total variation distance.

Typically, we write ω and ω' for states of the chain before a transition and $\sigma := P\omega$, $\sigma' := P\omega'$ for the (random) states after one step of the chain from ω and ω' respectively.

▶ **Theorem 3** (Bubley and Dyer [5], see also [12]). *Let Ω be the state space of a Markov chain $\mathcal{M}$ and let Γ be a weighted, directed graph on vertex set Ω with edge weights in $\mathbb{N}$. Let δ be the quasi-metric[3] on Ω given by taking shortest paths in Γ, and suppose that $\delta(\omega, \omega') \leq D < \infty$ for all $\omega, \omega' \in \Omega$.*

For each $(\omega, \omega') \in E(\Gamma)$, suppose that we have a coupling γ, of the random variables σ (with distribution $P\omega$) and σ' (with distribution $P\omega'$) for which $\mathbb{E}_{(\sigma,\sigma')\sim\gamma}[\delta(\sigma, \sigma')] \leq \beta\delta(\omega, \omega')$. Then if $\beta < 1$, we have $t_{\text{mix}}(\epsilon) \leq \log(D/\epsilon)/(1-\beta)$.

The theorem may seem rather abstract, so we briefly discuss a well-known application to list coloring as a warm-up to the main argument for list packing. Let G be a graph of maximum degree Δ and let L be a q-list assignment of G. Let Ω be the set of L-colorings of G, and let $\mathcal{M}$ be the heat-bath Glauber dynamics on Ω, defined as follows. Note that states $\omega \in \Omega$ are colorings and hence functions $V(G) \to \mathbb{N}$. A transition of $\mathcal{M}$ from a state ω is performed by choosing a vertex $u \in V(G)$ uniformly at random, sampling a color c in $L(u) \setminus \omega(N(u))$, and moving to the state σ with $\sigma(u) = c$ and $\sigma(v) = \omega(v)$ for all $v \neq u$. That is, the transition operator P is defined via

1. sampling a vertex $u \sim \mathcal{U}_{V(G)}$,
2. sampling a color $c \sim \mathcal{U}_{L(u)\setminus\omega(N(u))}$,
3. defining σ by $\sigma(v) := \begin{cases} c & v = u \\ \omega(v) & v \neq u \end{cases}$, and moving to the state σ.

Note that $L(u) \setminus \omega(N(u))$ is the set of available colors for u. These colors are in the list $L(u)$ but are not used by the coloring ω on the neighbors of u so setting $\omega(u)$ to one of them yields a valid list coloring. This chain is reversible, and when $q \geq \Delta + 2$ it is ergodic [18, Exercises 4.1] with stationary distribution uniform on Ω.

[3] that is, a function which satisfies the conditions of a metric except symmetry

For the purpose of constructing the couplings required by Theorem 3, let Γ be the weighted, directed graph on Ω where (ω, ω') is an edge if and only if the colorings ω, ω' differ at exactly one vertex and let all edge weights be 1. From the proof of ergodicity [18] it follows that we can take $D = (\Delta + 1)n$ in Theorem 3 and define couplings as follows. Let $(\omega, \omega') \in E(\Gamma)$ and suppose that the colorings ω and ω' differ at the vertex v^*. Sample $u \in V(G)$ uniformly at random and update the color of u in both chains (intuitively, this decision helps the chains coalesce). That is, the distribution γ of (σ, σ') is defined by the Markov transition $(\omega, \omega') \overset{P_\gamma}{\mapsto} (\sigma, \sigma')$ itself defined by

1. sampling a vertex $u \sim \mathcal{U}_{V(G)}$,
2. sampling a pair of available colors (a, b) from a distribution γ_c such that

$$\gamma_c := \underset{\substack{\gamma' \text{ is a coupling of} \\ \mathcal{U}_{L(u)\setminus\omega(N(u))} \text{ and } \mathcal{U}_{L(u)\setminus\omega'(N(u))}}}{\arg\max} \Pr_{(a,b)\sim\gamma'}(a = b) \tag{1}$$

3. defining σ and σ' by updating the color of u in each to a and b respectively:

$$\sigma(v) := \begin{cases} a & v = u \\ \omega(v) & v \neq u \end{cases}, \qquad \sigma'(v) := \begin{cases} b & v = u \\ \omega(v) & v \neq u \end{cases},$$

and moving to the state (σ, σ').

Observe that γ_c is defined as the coupling on the uniform distributions of available colors, $\mathcal{U}_{L(u)\setminus\omega(N(u))}$ and $\mathcal{U}_{L(u)\setminus\omega'(N(u))}$, which maximizes the probability the colors are the same. The important property of this definition in terms of applying Theorem 3 is that this coupling minimizes the expectation of the discrete metric on the sample.

If $u \in N(v^*)$ the sets of available colors for u can be different making γ_c nontrivial. In this case, let $C = \omega(N(u) \setminus \{v^*\})$ and note that the two sets of available colors are $A = (L(u) \setminus C) \setminus \{\omega(v^*)\}$ and $B = (L(u) \setminus C) \setminus \{\omega'(v^*)\}$. We wish to couple $\mathcal{U}_A$ and $\mathcal{U}_B$ such that the probability of choosing the same color is maximized, and the best general coupling is not too hard to find.

▶ **Lemma 4** (See e.g., [18, Lemma 4.10]). *Let U be a finite set and $A, B \subset U$. Then there is a coupling γ_c of $\mathcal{U}_A$ and $\mathcal{U}_B$ such that*

$$\Pr_{(a,b)\sim\gamma_c}(a = b) = \frac{|A \cap B|}{\max\{|A|, |B|\}},$$

where (a, b) is a random element of $A \times B$ chosen according to the coupling γ_c.

Let $m = \max\{|A|, |B|\}$. We have $A \cap B = (L(u) \setminus C) \setminus \{\omega(v^*), \omega'(v^*)\}$. Checking the four cases according to whether each of $\omega(v^*)$ and $\omega'(v^*)$ are in $L(u) \setminus C$, we observe that $|A \cap B| \geq m - 1$. By Lemma 4, we can ensure that the two chains choose the same color with probability at least $1 - 1/m$. Considering the definitions of A and B, we also have $m \geq q - \Delta$. Returning to the analysis of the coupling γ described above, we have

$$\mathbb{E}_{(\sigma,\sigma')\sim\gamma}[\delta(\sigma, \sigma')] \leq 1 + \frac{1}{n}\left(-1 + \frac{\Delta}{q - \Delta}\right).$$

This comes from the facts that $\delta(\omega, \omega') = 1$ by assumption, the probability $1/n$ that we successfully reduce the distance by 1 in an update to v^*, and the probability of at most Δ/n that we choose to update a neighbor of v^*, and in this case fail to choose the same color in the coupling of the color choice in each chain given by Lemma 4 (which occurs with probability at most $1/(q - \Delta)$ given that we update a neighbor of v^*). Set β to the right-hand side above and solve for $\beta < 1$ to obtain $q > 2\Delta$.

Well-known works that first studied this technique [17, 5, 18] give a similar proof, though Jerrum [17] manually constructed a coupling of the Markov chain and did not appeal to path coupling. With path coupling, it is slightly easier to study a variant of the Markov chain known as the "Metropolis Glauber dynamics" where the transition is defined slightly differently, though the same lower bound on q is required in the argument for this chain.

Our argument for list packing follows the same outline as above using the heat-bath dynamics for list packings, but it is much harder to construct the coupling. In particular, we need an analogue of Lemma 4 for the much more intricate combinatorial setting of list packings. We describe this in the next subsection.

3.1 Coupling perfect matchings

In the list packing setting, each spin is a permutation of a list. The central problem one faces when adapting the above sketch to list packing is the issue of coupling the choice of available permutations in the case that we are updating the spin of u in two copies of the Glauber dynamics which differ at a neighbor $v \in N(u)$. It turns out (see e.g. [6] and earlier works such as [24]) that there is an auxiliary bipartite graph in which available permutations for u correspond to perfect matchings.

Given a graph G with q-list assignment L, let Ω be the set of L-packings of G, and let $\omega \in \Omega$. Let $f_1, \dots, f_q$ be the L-colorings represented by ω. To be explicit, suppose that for each vertex v of G we write $L(v)$ in ascending order as $c_{1,v}, \dots, c_{q,v}$. Then we identify $V(G)$ with $[n]$ and consider Ω as a subset of S_q^n such that with $v \in [n]$ we define $f_1, \dots, f_q : V(G) \to \mathbb{N}$ by $f_i(v) = c_{\omega_v(i),v}$, where we interpret ω_v as a permutation of $L(v)$ so that $\omega_v(i)$ is the color assigned to v in the ith coloring in the packing. This notation has the advantage that many of the dependencies are explicit, but to avoid a proliferation of subscripts we omit them where it is possible to fix some context in advance.

For a vertex $u \in V(G)$, we construct the *availability graph* $H_u = H_u(G, L, \omega)$ as follows. We consider the vertex set of H_u as $[q] \sqcup [q]$, the disjoint union of two copies of the set $[q]$. The left copy consists of "packing indices" and the right copy consists of "list indices". For clarity, the edges of H_u are considered oriented from left to right so that (i, j) joins packing index i to list index j. Suppose that $L(u) = \{c_1, \dots, c_q\}$ is supplied in some fixed order. Then in H_u we include each edge $(i, j) \in [q]^2$ such that c_j is an available color for u in the coloring f_i. That is, (i, j) is an edge of H_u if and only if $c_j \notin f_i(N(u))$. One can check the defintions and observe that perfect matchings in H_u correspond to the available permutations $\rho \in S_q$ for u in the sense that setting ω_u to an available ρ yields a valid list packing. The heat-bath Glauber dynamics for L-packings thus works in much the same way as for L-colorings. The transition from a state ω is defined by choosing a vertex $u \in V(G)$ uniformly at random, and then a perfect matching in $H_u(G, L, \omega)$ uniformly at random. It is straightforward to check that the chain is reversible and has uniform stationary distribution; we prove that it is ergodic (for large enough q) in Lemma 7.

An important consideration when G has maximum degree Δ is that H_u has minimum degree $q - \Delta$. This follows from the properties of a list packing: at packing index i any color that is not available must be used by f_i on a neighbor of u and there are at most Δ such neighbors. Similarly, for a color c_j with color index j, any packing index i in which c_j is not available is explained by c_j being used by f_i on $N(u)$. Since the colorings in a packing are pairwise-disjoint, each such index must be due to distinct neighbors of u, of which there are at most Δ. It is useful to observe that for any $\omega \in S_q^n$, even one that may not be a proper list packing in the sense that the q list colorings it represents may not be proper, the definition of availability graph still makes sense and the observation on the minimum

degree still applies. That is, the key property of q-list packings on graphs of maximum degree Δ that yields the minimum degree bound $q - \Delta$ is that the list colorings represented are pairwise-disjoint. This fact is convenient in the proof of Lemma 5.

To construct the coupling we consider the weighted, directed graph Γ on Ω where (ω, ω') is an edge if and only if the list packings ω and ω' differ at exactly one vertex. For the edge $(\omega, \omega') \in E(\Gamma)$, let v be the unique vertex at which the two packings differ, and assign weight $d_{\mathrm{C}}(\omega_v, \omega'_v)$ to the edge. As with list coloring, the key computation is how much the expected distance changes for one step of the coupling in the case that we start at (ω, ω') and update a neighbor u of the unique vertex v at which ω and ω' differ. We prove the following result which plays the role of Lemma 4 in our proof.

▶ **Lemma 5.** *There is a universal constant C such that if $q > C\Delta^2$ the following holds.*

Let $(\omega, \omega') \in E(\Gamma)$ be an edge of weight ψ in Γ and let v be the unique vertex at which ω and ω' differ. Let $u \in N(v)$ and consider the availability graphs H and H' for u in the packings ω and ω' respectively.

Then there exists a coupling γ of the uniform distributions on perfect matchings on H and H' which satisfies

$$\mathbb{E}_{(\rho,\rho')\sim\gamma}[d_{\mathrm{C}}(\rho, \rho')] \leq \frac{\psi}{2\Delta}.$$

Note that in the conclusion any bound strictly better than ψ/Δ suffices for an application of Theorem 3, and one might expect to obtain results in the case of exactly ψ/Δ as well [17, 5, 12]. We do not attempt to optimize the constant C in our argument and hence $\psi/(2\Delta)$ is sufficient. Lemma 5 is a simple corollary of Lemma 2, and with these results in hand the rest of the argument for Theorem 1 is standard.

3.2 Organization

In Section 4 we define a Markov chain on list packings, prove ergodicity and establish rapid mixing given our results on coupling perfect matchings. In Section 5 we prove Lemmas 2 and 5. We conclude with some remarks in Section 6.

4 Glauber dynamics for list packing

In this section we fix an n-vertex graph G of maximum degree Δ, a q-list assignment L of G, and let Ω be the set of L-packings of G.

We consider heat-bath Glauber dynamics $\mathcal{M} = \mathcal{M}(G, L)$ for list packing. Given a state $\omega \in \Omega$ and a vertex $u \in V(G)$, we say that a permutation ρ in S_q is *available* for u in ω if setting ω_u to ρ yields a valid list packing. Transitions of $\mathcal{M}$ are defined as follows. From state $\omega \in \Omega$, choose vertex $u \in V(G)$ uniformly at random, choose an available permutation $\rho \in S_q$ uniformly at random, and let the new state be σ given by $\sigma_u = \rho$ and $\sigma_v = \omega_v$ for $v \neq u$. It is straightforward to check that this is a reversible Markov chain on Ω with uniform stationary distribution. The question of ergodicity is less straightforward, though the standard argument for list coloring adapts easily. We require a simple corollary of Hall's classic result on perfect matchings in bipartite graphs.

▶ **Lemma 6** (Corollary of Hall's theorem [14])**.** *Let H be a bipartite graph with q vertices on each side and minimum degree $d \geq q/2$. Then H contains a perfect matching.*

Sketch proof. Let the bipartition be $A \sqcup B$ and consider a subset $X \subset A$. If $1 \leq |X| \leq d$ then $|N(X)| \geq d \geq |X|$. If instead $d+1 \leq |X| \leq q$ then $N(X)$ must be all of B since for each neighborhood of a vertex in B must intersect X. The result follows from Hall's theorem. ◀

▶ **Lemma 7.** *For $q \geq 2\Delta + 2$ the Markov chain $\mathcal{M}$ is ergodic.*

Proof. Because there are self-transitions at every state, it suffices to show that the (finite) state space is connected.

Every state $\omega \in \Omega$ can be connected to an arbitrary $\omega' \in \Omega$ as follows. Label the vertices of G with the integers $1, \ldots, n$ arbitrarily, and for $i = 1, \ldots, n$, sequentially turn ω_i into ω'_i as follows. If setting ω_i equal to ω'_i is not possible (i.e. ω'_i is not available for i in ω) then it's because some neighbor j of i with $j > i$ uses a color at a particular packing index which conflicts with ω_i. To solution is to repack each such neighbor j in ω, i.e. change ω_j to a new permutation of $L(j)$, in turn such that the repacking is proper *and* avoids any such conflicts. These repacking steps are steps of the chain.

To perform the repacking, we find a perfect matching in a suitable modification of the availability graph $H'_j = H_j(G, L, \omega')$. Recall that perfect matchings in H'_j correspond to the available permutations ρ for u in ω'. We have an additional condition on the permutation ρ that we seek, namely that ρ does not correspond to a color choice for j that is incompatible with turning ω_i into ω'_i. We can encode this in the availability graph by deleting an edge (a, b) such that the b-th color in $L(j)$ is used at packing index a in color choices represented by ω'_i. After this modification, the availability graph has minimum degree $q - \Delta - 1$, so the condition $q \geq 2\Delta + 2$ allows for an application of Lemma 6. This shows that the necessary repackings exist, and thus that Ω is connected by transitions of the chain that occur with positive probability. ◀

▶ **Theorem 8.** *The mixing time $t_{\text{mix}}(\epsilon)$ of $\mathcal{M}$ is at most $O(n \log(n/\epsilon))$.*

Proof. We apply Theorem 3 with the following coupling defined on edges of the weighted graph Γ on Ω such that (ω, ω') is an edge of weight $d_{\text{C}}(\omega_v, \omega'_v)$ whenever ω and ω' differ at a single vertex v. Lemma 7 shows that Γ is connected, and we note that the diameter D is at most $(\Delta + 1)(q - 1)n = O(n)$. This is because the sequence of steps constructed in Lemma 7 consists of edges of Γ, the total number of steps is at most $(\Delta + 1)n$ because we repack each vertex v at most once for each neighbor of v to avoid conflict and at most once more to agree with ω'. As the Cayley distance on S_q takes values in $\{0, 1, \ldots, q - 1\}$, the diameter bound follows.

Let (ω, ω') be an edge of Γ of weight ψ. We define the coupling as follows. We choose $u \in V(G)$ uniformly at random and update u in both packings. If $u \notin N(v)$ then the sets of available permutations of $L(u)$ in both packings are identical and we choose one uniformly at random to use in both chains. If $u = v$ this results in a distance of zero, else the distance is unchanged. If $u \in N(v)$ then we use the coupling of Lemma 5 to choose the permutations of $L(u)$ in the packings. Let (σ, σ') be the random state after one step of the coupling started from (ω, ω'). Then

$$\mathbb{E}[\delta(\sigma, \sigma')] \leq \psi + \frac{1}{n}\left(-\psi + \Delta\frac{\psi}{2\Delta}\right) = \psi\left(1 - \frac{1}{2n}\right).$$

Theorem 3 now gives mixing time $t_{\text{mix}}(\epsilon) = O(n \log(n/\epsilon))$. ◀

The proof of Theorem 1 using Theorem 8 is now entirely standard. We sketch the argument here. Counting list packings is a *self-reducible* problem in the sense of [19] and so having an almost-uniform sampler, which follows from running the Markov chain for

polynomially many steps, is equivalent to having an FPRAS. Concretely, construct a sequence $G = G_m \supset \cdots \supset G_1 \supset G_0 = (V(G), \emptyset)$ of graphs by starting from G and removing an arbitrary edge to form the next member of the sequence. For a fixed q-list assignment L of G we can let Ω_i be the set of L-packings of G_i and write

$$|\Omega_m| = |\Omega_0| \prod_{i=1}^{m} \frac{|\Omega_i|}{|\Omega_{i-1}|}.$$

We have $|\Omega_0| = (q!)^n$ and can estimate each ratio in the product as it's the probability that when we choose a unformly random $\omega \in \Omega_{i-1}$ we have $\omega \in \Omega_i$. We also note that $\frac{1}{1+q!} \leq \frac{|\Omega_i|}{|\Omega_{i-1}|} \leq 1$ because $\Omega_i \subset \Omega_{i-1}$ and we can construct the following bipartite graph B on $(\Omega_{i-1} \setminus \Omega_i) \sqcup \Omega_i$. Let uv be the edge removed from G_i to form G_{i-1}, and include the edge (ω, ω') in B if ω' can be obtained from Ω by permuting the list of u. Then any $\omega \in \Omega_{i-1} \setminus \Omega_i$ is connected to at least one element in Ω_i by Lemma 6, and there are at most $q!$ ways to permute $L(u)$ so from the other side the degrees are at most $q!$. We do not attempt to optimize this argument; more intricate arguments yield stronger lower bounds, but we are merely interested in a bound independent of n. This observation lets us repeat the analysis of Jerrum [17] for the case of colorings in the setting of list packings. Briefly, we use multiple copies of the almost uniform sampler offered by the Markov chain to estimate each ratio. To make this work, one has to bound the variance of the estimator for each ratio and manage the overall error with Chebyshev's inequality, but this is standard. See e.g., [17].

5 Coupling matchings

In this section we prove Lemmas 2 and 5. We first collect some results on auxiliary bipartite graphs.

▶ **Lemma 9.** *Let $G = (V, E)$ be a bipartite graph with bipartition $V = L \cup R$. Let μ_L and μ_R be probability distributions over L and R. Let*

$$p = \min_{A \subseteq L} [1 - \mu_L(A) + \mu_R(N(A))].$$

There exists a coupling γ of μ_L and μ_R such that when $(v, w) \sim \gamma$, with probability p, vw is an edge of G.

Proof. This follows from the max-flow min-cut theorem after introducing a source vertex s, a sink vertex t, and introducing the following edges:

1. for $v \in L$, the edge sv with capacity $\mu_L(v)$,
2. for $v \in R$, the edge vt with capacity $\mu_R(v)$,
3. for each edge $e \in G$, an edge with capacity ∞.

A max flow corresponds to a coupling γ of the type we require with maximum probability that vw is an edge. The value of the max flow is the same as the value of the min cut. If S, T is a finite cut with $s \in S$, $t \in T$, letting $A = S \cap L$, $B = S \cap R$, we must have $N(A) \subseteq B$, and the value is $\mu_L(A^c) + \mu_R(B) \geq \mu_L(A^c) + \mu_R(N(A))$. Equality is achieved for $B = N(A)$. Taking the minimum over A then gives the lemma. ◀

▶ **Corollary 10.** *Let $G = (V, E)$ be a bipartite graph with bipartition $V = L \cup R$. Suppose that each vertex in L has degree contained in $[m_L, M_L]$ and each vertex in R has degree contained in $[m_R, M_R]$. Then there exists a coupling γ of the uniform distributions $\mathcal{U}_L$ and $\mathcal{U}_R$ on L and R respectively such that when $(v, w) \sim \gamma$, with probability at least $\frac{m_L m_R}{M_L M_R}$, vw is an edge of G.*

Proof. For each subset $A \subseteq L$, we can bound the number of edges between A and $N(A)$:

$$m_L|A| \leq |E(A, N(A))| \leq M_R|N(A)|.$$

We also have

$$m_R|R| \leq |E| \leq M_L|L|.$$

Then for any set $A \subseteq L$,

$$\frac{|N(A)|/|R|}{|A|/|L|} = \frac{|N(A)|}{|A|} \cdot \frac{|L|}{|R|} \geq \frac{m_L m_R}{M_L M_R}.$$

Then for any such A,

$$1 - \mathcal{U}_L(A) + \mathcal{U}_R(N(A)) \geq 1 - \mathcal{U}_L(A) + \frac{m_L m_R}{M_L M_R} \cdot \mathcal{U}_L(A) \geq \frac{m_L m_R}{M_L M_R}.$$

The conclusion follows from Lemma 9. ◀

We are now ready to prove Lemma 2, which we restate for convenience.

▶ **Lemma 2.** *There are constants C_1, C_2 such that the following hold. Suppose that $q \geq C_1\Delta$, and let $H = (V, E)$ be a bipartite graph in which $|V| = 2q$ and the bipartition is balanced. Suppose that H has minimum degree at least $q - \Delta$. Let $e \in E$ be an edge of H, let $\mathcal{L}$ be the set of perfect matchings of H containing e, and let $\mathcal{R}$ the set of perfect matchings of H not containing e. Then there is a coupling γ of $\mathcal{U}_{\mathcal{R}}$ and $\mathcal{U}_{\mathcal{L}\cup\mathcal{R}}$ such that*

$$\mathbb{E}_{(\rho,\rho')\sim\gamma}[d_{\mathrm{C}}(\rho, \rho')] \leq \frac{C_2\Delta}{q}.$$

Proof. Label the bipartitions by $[q]$. Without loss of generality the edge e is $(1, 1)$. We define an auxiliary bipartite graph on $\mathcal{L} \cup \mathcal{R}$ as follows. For $\rho \in \mathcal{L}$ and $\rho' \in \mathcal{R}$, connect ρ and ρ' by an edge if $\rho(1\,i\,j) = \rho'$ for some $i, j \in [q] \setminus \{1\}$ with $i \neq j$, i.e., they differ by a 3-cycle containing 1. Note that here we use standard group-theoretic notation for permutations in S_q so that e.g. $\rho(1\,i\,j)$ is the product of the permutation ρ and the permutation $(1\,i\,j)$ (in standard cycle notation).

We bound the degrees of arbitrary matchings $\rho \in \mathcal{L}$ and $\rho' \in \mathcal{R}$. Given ρ, we count the number of i, j for which $\rho(1\,i\,j) \in \mathcal{R}$. Let $N(i) = \{j : (i, j) \in E\}$ and $N'(j) = \{i : (i, j) \in E\}$. Given $\rho \in L$, we know that $\rho(1) = 1$. We choose $j \in N'(1) \setminus \{1\}$; there are at least $q - \Delta - 1$ choices. Any possible value of i must be in the set $S_- \setminus \{j\}$, where $S_- := \{\rho^{-1}(k) : k \in N(1) \setminus \{1\}\}$; $S_- \setminus \{j\}$ has size at least $q - \Delta - 2$. A valid pair (i, j) is exactly one where $j \in N'(1) \setminus \{1\}$, $i \in S_- \setminus \{j\}$, and $(i, \rho(j)) \in E$. Since at most $\Delta + 1$ of edges $(i, \rho(j))$, $j \in N'(1) \setminus \{1\}$ can land outside E, at least $q - 2\Delta - 3$ of these edges are valid, i.e., there are at least $(q - \Delta - 1)(q - 2\Delta - 3)$ valid choices of (i, j). There are at most $(q - 1)(q - 2)$ choices.

Next, given $\rho' \in \mathcal{R}$, we count the number of $i, j \in [q] \setminus \{1\}$, $i \neq j$ for which $\rho' = \rho(1\,i\,j)$ where $\rho \in \mathcal{L}$. First, note we must have $\rho'(j) = 1$. The requirement on i is that $i \in N'(\rho'(1))$ and $\rho'(i) \in N(j)$. There are at least $q - \Delta - 2$ indices besides 1 and j satisfying each condition, so at least $q - 2\Delta - 4$ possible indices. There are at most $q - 2$ choices. By Corollary 10, there is a coupling γ of $\mathcal{U}_{\mathcal{L}}$ and $\mathcal{U}_{\mathcal{R}}$ such that with probability at least

$$p := \frac{(q - \Delta - 1)(q - 2\Delta - 3)}{(q - 1)(q - 2)} \cdot \frac{q - 2\Delta - 4}{q - 2},$$

$(\rho, \rho') \in E$ are connected by an edge and hence have Cayley distance at most two. For appropriate choices of $C_1, K > 0$, $1 - p \leq K\Delta/q$ for $q \geq C_1\Delta$. For this coupling γ, we hence have

$$\mathbb{E}_{(\rho,\rho')\sim\gamma}[d_{\mathrm{C}}(\rho, \rho')] \leq \frac{K\Delta}{q} \cdot q + \left(1 - \frac{K\Delta}{q}\right) \cdot 2 \leq K'\Delta$$

for an appropriate constant $K' > 0$.

Next, note that we can define a coupling between $\mathcal{U}_{\mathcal{L}\cup\mathcal{R}}$ and $\mathcal{U}_{\mathcal{R}}$ as a mixture of the identity coupling between $\mathcal{U}_{\mathcal{R}}$ and $\mathcal{U}_{\mathcal{R}}$ (with probability $\frac{|\mathcal{R}|}{|\mathcal{L}|+|\mathcal{R}|}$) and the above coupling (with probability $\frac{|\mathcal{L}|}{|\mathcal{L}|+|\mathcal{R}|}$). The expected distance for this coupling is then

$$\frac{|\mathcal{L}|}{|\mathcal{L}| + |\mathcal{R}|} \cdot K'\Delta \leq \frac{q-2}{(q-2) + (q-\Delta-1)(q-2\Delta-3)} \cdot K'\Delta \leq \frac{C_2\Delta}{q}$$

for appropriate $C_2 > 0$, as needed. ◀

▶ **Lemma 5.** *There is a universal constant C such that if $q > C\Delta^2$ the following holds.*

Let $(\omega, \omega') \in E(\Gamma)$ be an edge of weight ψ in Γ and let v be the unique vertex at which ω and ω' differ. Let $u \in N(v)$ and consider the availability graphs H and H' for u in the packings ω and ω' respectively.

Then there exists a coupling γ of the uniform distributions on perfect matchings on H and H' which satisfies

$$\mathbb{E}_{(\rho,\rho')\sim\gamma}[d_{\mathrm{C}}(\rho, \rho')] \leq \frac{\psi}{2\Delta}.$$

Proof. Formally, we proceed by induction on ψ, though we need a more general statement for the induction hypothesis. It is convenient to relax the requirement that ω and ω' are valid list packings. For the application, it is important that the pair (ω, ω') are valid list packings which agree on every vertex except u, but we construct the coupling of perfect matchings in H and H' using a sequence of *near-valid* list packings $\omega'' \in S_q^n$ in the sense that ω'' agrees with ω and ω' on all vertices except u, but we allow the (pairwise-disjoint) colorings it represents to have monochromatic edges incident to v. We can still construct availability graphs for u in these near-valid packings and consider their sets of perfect matchings for the purposes of constructing an eventual coupling of the perfect matchings in H and H'. With these definitions in place, the generalization that we prove by induction is the statement obtained by replacing the assumption that ω and ω' are valid packings with the assumption that they are near-valid.

The base case is $\psi = 0$ in which the trivial coupling suffices as H and H', and hence their sets of perfect matchings, are identical.

The induction step follows from Lemma 2. The fact that $d_{\mathrm{C}}(\omega_v, \omega'_v) = \psi$ means that there is a sequence of transpositions $\tau_1, \ldots, \tau_\psi$ such that $\omega_v = \tau_\psi \cdots \tau_1 \omega'_v$. Let H'' be the availability graph of the vertex u in the near-valid packing ω'' such that $\omega''_v = \tau_\psi \omega_v$ and ω'' agrees with ω on all other vertices. By induction, there is a coupling γ' of the uniform distributions on perfect matchings in H'' and H' such that

$$\mathbb{E}_{(\rho'',\rho')\sim\gamma'}[d_{\mathrm{C}}(\rho'', \rho')] \leq \frac{\psi - 1}{2\Delta}.$$

Without loss of generality, suppose that ω_v is the identity. Let $\tau_\psi = (i\, j)$, and note that this gives

$$E(H) \setminus E(H'') \subset \{(i,j),(j,i)\} \qquad \text{and} \qquad E(H'') \setminus E(H) \subset \{(i,i),(j,j)\}.$$

This is because any difference between the edges of H and H' is explained by applying τ to ω_v. When τ is a transposition, we swap the packing index of the coloring at which two colors in the list of v are used, which can swap two edges of the complement of the availability graph. It can be the case that the swapped color indices refer to different colors in $L(u)$ which is why we do not have equality.

We start with the case that

$$E(H) \setminus E(H'') = \{(i,j),(j,i)\} \qquad \text{and} \qquad E(H'') \setminus E(H) = \{(i,i),(j,j)\},$$

the other cases are similar. Let X be the set of perfect matchings in H and let X'' be the set of perfect matchings in H''. We seek a coupling of $\mathcal{U}_X$ and $\mathcal{U}_{X''}$ which we will combine with the coupling γ' to obtain the desired result.

We apply Lemma 2 to H and $H-(i,j)$, yielding a coupling γ_1 of $\mathcal{U}_X$ and $\mathcal{U}_Y$, where Y is the set of perfect matchings in $H-(i,j)$. We can apply Lemma 2 again to $H-(i,j)$ and $H-(i,j)-(j,i)$, yielding a coupling γ_2 of $\mathcal{U}_Y$ and $\mathcal{U}_Z$, where Z is the set of perfect matchings in $H-(i,j)-(j,i)$. There is a slight technicality here as the minimum degree of $H-(i,j)$ is $q-\Delta-1$, but this can be handled by setting Δ to $\Delta+1$ and adjusting the constants slightly. Analogously, starting from H'', we construct a coupling γ_1'' of $\mathcal{U}_{X''}$ and $\mathcal{U}_{Y''}$ and a coupling γ_2'' of $\mathcal{U}_{Y''}$ and $\mathcal{U}_Z$, where Y'' is the set of perfect matchings in $H''-(i,i)$. A careful composition of these couplings gives the result. The composition of these couplings yields a distribution on $X \times Y \times Z \times Y'' \times X''$ which is uniform on each individual set in the Cartesian product, and such that the expected distance between permutations from adjacent sets in the Cartesian product is at most $C_2\Delta/q$. Taking the first and last coordinate yields a coupling γ'' of $\mathcal{U}_X$ and $\mathcal{U}_{X''}$ such that

$$\mathbb{E}_{(\pi,\pi'')\sim\gamma''}[d_{\mathrm{C}}(\pi,\pi'')] < \frac{4C_2\Delta}{q}.$$

This can be combined with γ' obtained by induction in the same way. Simple composition yields a distribution on $X \times X'' \times X'$ which is uniform on each individual set in the Cartesian product. Taking the first and last coordinates we have a coupling γ of $\mathcal{U}_X$ and $\mathcal{U}_{X'}$ such that

$$\mathbb{E}_{(\pi,\pi')\sim\gamma}[d_{\mathrm{C}}(\pi,\pi')] < \frac{\psi-1}{2\Delta} + \frac{4C_2\Delta}{q}.$$

Since we assume $q \geq C\Delta^2$, for a large enough C this is at most $\psi/(2\Delta)$ as required. The other cases proceed similarly, but require fewer applications of Lemma 2 and yield a stronger upper bound. ◀

6 Concluding remarks

Many natural questions remain unanswered. We have chosen to extend some of the most fundamental techniques for counting list colorings to list packings, but there are many more recent improvements to consider. Dyer and Greenhill [11] study a Markov chain on (list) colorings whose transitions are defined by properly recoloring both endpoints of a uniform random edge and show that its mixing time is less than that of Glauber dynamics studied in [17, 25]. The flip dynamics employed by Vigoda [26] for counting colorings is an important technique that gets significantly below the number of colors required by Jerrum's approach. Extending Vigoda's approach to list *coloring* was first done by Chen et al. [10], roughly 20 years after Vigoda's breakthrough. Though they also surpassed a significant barrier at $11\Delta/6$ colors related to 1-step contractions in Hamming distance of two colorings that differ at a

vertex. The history of this problem suggests that further generalizations, e.g. to list packing may not be straightforward. While one can consider analogous dynamics for list packings and hope to reduce the bound on q in Theorem 1, we do not have results showing the existence of list packings in graphs of maximum degree Δ for fewer than $2\Delta - 2$ colors. In another direction, the use of more advanced Markov chain techniques to give perfect sampling of list packings could be interesting.

We finish with a natural conjecture on approximately counting list packings.

▶ **Conjecture 11.** *For each Δ and $q \geq 2\Delta$ there is an FPRAS for counting the number of q-list packings of graphs of maximum degree Δ.*

At the time of writing, we know of no reason that the lower bound on q cannot be reduced to, say, $\Delta + 1$. The value 2Δ represents a significant barrier in the sense that the existence of a list packing when $q \geq 2\Delta$ is an elementary consequence of Hall's theorem (though arguably not entirely trivial).

Locally Private Histograms in All Privacy Regimes

Abstract

Frequency estimation, a.k.a. histograms, is a workhorse of data analysis, and as such has been thoroughly studied under differentially privacy. In particular, computing histograms in the *local* model of privacy has been the focus of a fruitful recent line of work, and various algorithms have been proposed, achieving the order-optimal ℓ_∞ error in the high-privacy (small ε) regime while balancing other considerations such as time- and communication-efficiency. However, to the best of our knowledge, the picture is much less clear when it comes to the medium- or low-privacy regime (large ε), despite its increased relevance in practice. In this paper, we investigate locally private histograms, and the very related distribution learning task, in this medium-to-low privacy regime, and establish near-tight (and somewhat unexpected) bounds on the ℓ_∞ error achievable. As a direct corollary of our results, we obtain a protocol for histograms in the *shuffle* model of differential privacy, with accuracy matching previous algorithms but significantly better message and communication complexity.

Our theoretical findings emerge from a novel analysis, which appears to improve bounds across the board for the locally private histogram problem. We back our theoretical findings by an empirical comparison of existing algorithms in all privacy regimes, to assess their typical performance and behaviour beyond the worst-case setting.

1 Introduction

Frequency estimation is a fundamental problem of statistics: besides its use for basic surveying, it is also used as a building block in distribution learning, identifying heavy hitters in sparse domains, and regression, correlation or covariance analysis. As such, frequency estimation (and the closely related problem of heavy hitters) have been thoroughly studied in a variety of settings, ranging from streaming to privacy-preserving analytics. We here focus on the latter, and specifically on the *local* model of differential privacy (LDP), where the data is distributed across a large number of users, and each datum is subject to stringent differential privacy requirements. This question has, over the past decade, received a lot of attention, starting with [8, 28]; as we elaborate in Section 1.1, much is known about locally private frequency

estimation, to the point that it may seem the question has been, already fully resolved – both in theory and practice. However, most recent large-scale implementations of local privacy (see, e.g., [5, 18]) must balance many efficiency objectives, including the bandwidth and computational requirements (as, among others, a proxy for energy consumption), and, above all, the estimation accuracy. Keeping this accuracy in check has, in turn, led to the common use of relatively large values of the "privacy parameter" ε, far from the original rule of thumb of $\varepsilon \ll 1$.[1]

In view of the relevance of frequency estimation to privacy-preserving algorithms and deployments, it is crucial that theory be informed by, and applicable to practice; and that constant factors, bounds on achievability, and the behaviour of estimation error in all parameter regimes are well understood. Yet, to the best of our knowledge, most if not all of the previous theoretical work on locally private frequency estimation focuses on the high-privacy $\varepsilon \ll 1$ regime, leaving the low-privacy regime by and large uncharted. Addressing this gap in our theoretical understanding is the focus of our work.

The question and setting

We will focus on examining the standard worst-case estimation error, or the ℓ_∞-error as it is most relevant to the problem, with special importance for controlling error rates in heavy hitters. Specifically, when estimating the empirical frequencies $q = (q_1, \ldots, q_k)$ over a universe $\mathcal{X}$ of size k from n users, the (expected) error is given by

$$\mathbb{E}[\|\hat{q} - q\|_\infty] = \mathbb{E}\left[\max_{1 \le i \le k} |\hat{q}_i - q_i|\right] \tag{1}$$

where the expectation is taken over the (possibly randomised) algorithm given as input the users' data, and $\hat{q}$ is the vector of estimated frequencies. We are interested in the worst-case error over all possible datasets, that is, the supremum of the above quantity over all inputs $X := (X_1, \ldots, X_n) \in \mathcal{X}^n$ (equivalently, all q). We will seek algorithms ("protocols") to minimize this worst-case error under the constraint of (pure) local privacy (see Section 2), parameterized by the privacy parameter $\varepsilon > 0$. As in most distributed settings, one can consider several variants depending on whether a common random seed is available to the users (public-coin protocols) or not (private-coin protocols). It is known that for locally private frequency estimation allowing public-coin protocols can provably reduce the communication requirements [3];[2] similarly, one can allow some back and forth between users and the central server (interactive protocols). However, the public-coin or interactive settings come at an increased deployment costs, and are often less easy (or even impossible) to implement as they require either broadcasting from the center or sustained two-way communication between the parties. As our focus is chiefly on analyzing the most versatile setting, we hereafter restrict ourselves for our algorithms to the private-coin (non-interactive) setting; however, we mention that our lower bounds apply to the public-coin setting as well.

A closely related question is that of *distribution learning* under ℓ_∞ loss, which differs from frequency estimation in that the dataset X is not arbitrary, but instead assumed to be drawn i.i.d. from an unknown probability distribution q over $\mathcal{X}$: in this sense, distribution learning

[1] See, for instance, the list of real-case use of differential privacy maintained here, which includes use cases of LDP along with the correspond stated values of ε: `https://desfontain.es/blog/real-world-differential-privacy.html`.

[2] Specifically, the cited paper establishes a separation between public- and private- coin protocols, showing that the former can achieve vanishing error even with constant-length communication per user, a setting where the latter must incur $\Omega(1)$ error. To complement this, it is known that using public randomness one can always reduce the per-player communication to $\lceil \varepsilon \rceil$ bits [8].

is an "easier" problem than frequency estimation, and an algorithm for the latter implies one for the former.[3] Formal definitions, as well as the relation between these two questions, can be found in Section 2. In this paper, we therefore focus on frequency estimation, and will point out the implications for distribution learning as corollaries.

Connection to shuffle privacy

To conclude this subsection, we mention that besides the use of large values of ε in practical deployments of locally private algorithms, which calls for a better understanding of the tasks in this parameter regime, another motivation for studying the "low-privacy regime" comes from the emergence of another model of differential privacy, *shuffle privacy* [15, 21], and its increasingly widespread adoption. Indeed, it is known that one generic way to obtain shuffle private algorithms is via the so-called "amplification-by-shuffling" technique (see, e.g., [23]), whereby a locally private algorithm with high ε (low privacy) yields a shuffle private protocol with small ε (high privacy), and the same number of messages and communication cost. This makes characterizing the low-privacy regime of locally private algorithms a very consequential question, especially for fundamental tasks such as frequency estimation and the related distribution learning.

1.1 Prior work

Many innovative algorithms have been proposed in recent years for locally private histograms and distribution estimation [22, 3, 14, 34, 33, 25, 24], with a subset focusing on ℓ_∞-error.[4] A lower bound of $\ell_\infty = \Omega(\sqrt{\log k/\varepsilon^2 n})$ for frequency estimation under local differential privacy was established by [8] for most regimes of k, n, and small privacy parameter ε; and various LDP protocols asymptotically achieving this bound have been proposed (see Table 1).

Most recently, upper bounds on ℓ_∞ for frequency estimation were derived in [14], and evaluated empirically in [24]. For large ε, i.e., the "low-privacy regime," to the best of our knowledge the best current results are (1) a bound of $O(\sqrt{\log k/\varepsilon n})$ on the ℓ_∞ error rate established in [14], and, (2) an upper bound of $O(\sqrt{\log k/(e^{\varepsilon/2} n)} + (\log k)/n)$ from [29] (Theorem 2), based on CountSketch: note that this error does not vanish as ε grows.

In [25], it was stated that under most commonly used metrics $(\ell_\infty, \ell_2^2, \ell_1)$, the error is primary driven by the variance of an algorithm. We show that at least for ℓ_∞ a close look at sub-Gaussian, and sub-gamma behaviour can better capture the error in low-privacy regimes. Additionally, [14] raise the question of whether the upper bound of $O(\sqrt{\log k/\varepsilon n})$, is tight in the low privacy regime. We show in Theorem 14 that, quite surprisingly, it is not. Histograms have also seen detailed analysis in the shuffle model as both a practical question [26, 27, 15, 16, 9] and as a benchmark for reasoning about the power of the shuffle model [6]. As two points of comparison we highlight [26] which introduced a multiple–message protocol for shuffled histograms achieving expected ℓ_∞-error $O(\sqrt{\log k \log(1/\delta)}/(\varepsilon n))$ with $O(k^{1/100})$ rounds of communication, and [6] which demonstrated expected maximum error of $O(\log(1/\delta)/(\varepsilon^2 n))$ with $k+1$ rounds. While our results do not achieve the latter bound, we show surprisingly that the former can be achieved in some fairly permissive parameter regimes with only a single message.

[3] There are some subtleties here, but it is worth noting, as a baseline, that absent privacy constraints it is well-known that the error of learning to ℓ_∞ scales as $1/\sqrt{n}$ with no dependence on the alphabet size k; while frequency estimation can be done with zero error, as each user can simply send their data.

[4] For distribution estimation, a common error measure in the literature is ℓ_1, corresponding to total variation distance.

Table 1 Selection of best known upper bounds for communication, ℓ_∞ and ℓ_2^2-error, where the shaded cells are our results († *indicates results not established in the corresponding paper, but that we derive for completeness.*) As discussed above, "private-coin" refers to the fact that the users do not require access to a common random seed (typically easier to implement than "public-coin" protocols, where they do). We note that all public-coin protocols mentioned here can be made private-coin at the cost of an $O(\log k)$ blowup factor in the communication cost.

Protocol	Private-coin	Communication	ℓ_∞ error	ℓ_2^2 error
RAPPOR	✓	k	$\sqrt{\frac{\log k}{n\min(1,\varepsilon^2)}}$ $\sqrt{\frac{\log k}{n\min(\varepsilon,\varepsilon^2)}}$ $\sqrt{\frac{\log k}{ne^{\varepsilon/2}}} + \frac{\log k}{n\varepsilon}\cdot\log n$	$\frac{ke^{\varepsilon/2}}{n\left(e^{\varepsilon/2}-1\right)^2}$

1.2 Overview of results

We here summarise our main results, and briefly discuss the underlying techniques. While we focus on two protocols in particular, the techniques themselves are broadly applicable. Our first set of results concerns the ℓ_∞ error rate achievable by LDP protocols for frequency estimation. We first recall, as a baseline, a general transformation which converts any LDP protocol with optimal error in the high-privacy regime into another LDP protocol with *reasonable error* in the low-privacy regime, at the cost of a blowup in communication:

▶ **Proposition 1** (Informal; see Proposition 9)**.** *Let A be any locally private protocol for frequency estimation with expected ℓ_∞ error $O\left(\sqrt{\log k/(n\varepsilon^2)}\right)$ for $\varepsilon \le 1$, using ℓ bits of communication per user. Then there is a locally private protocol A' achieving error*

$$O\left(\sqrt{\frac{\log k}{n\min(\varepsilon,\varepsilon^2)}}\right)$$

for all $\varepsilon > 0$, using $\ell\lceil\varepsilon\rceil$ bits of of communication per user.

We emphasise that this transformation is not new, and mimics an argument found in, e.g., [14]. This general transformation is quite appealing, as it provides (in theory) good performance in the low-privacy regime "for free" given any good enough LDP protocol for the high-privacy one. However, this comes at a price: first, the communication blowup, which could be impractical; second, a loss in constant factors, which while relatively small might still be prohibitive; and, perhaps more importantly, *this requires changing the existing algorithm* (and as a result the data analysis pipeline), which is often a significant hurdle. Our

second result, focusing on one of the earliest, versatile, and (at least in its "vanilla" version) conceptually simple LDP protocols for frequency estimation, RAPPOR [22], shows that this transformation is not actually necessary, and that RAPPOR actually achieves this improved bound *without* modification:

▶ **Theorem 2** (Informal; see Theorem 13). *The (simple version of) RAPPOR achieves expected ℓ_∞ error*

$$O\left(\sqrt{\frac{\log k}{n \min(\varepsilon, \varepsilon^2)}}\right)$$

for all $\varepsilon > 0$, using k bits of of communication per user.

In comparison, using the generic transformation above on RAPPOR would require $\lceil \varepsilon \rceil$ k-bit messages per user, and, in terms of worst-case theoretical bounds, an expected error worse by a factor $\simeq 2.04$. As such, our first result can be summarized as saying that *analyzing (again) an existing algorithm can be better than modifying it* – and, quite importantly, that it may not be necessary to change an existing algorithmic pipeline to inherit better guarantees.

The proof of the above result relies on a careful analysis of the expected maximum of sums of Bernoulli random variables, and specifically on a fine-grained analysis of their subgaussian behaviour in the "highly biased" regime. While RAPPOR is particularly amenable to this analysis, we believe that this technique is highly general and applicable to a broad range of LDP protocols, for example those following the general "scheme template" of [4].

Yet, trying to establish optimality of this $\min(\varepsilon, \varepsilon^2)$ scaling turned out to be very challenging. And indeed, *this is for a good reason:* as we show, it is actually possible to achieve significantly better error rate in the low-privacy regime – and, surprisingly, this much better error is again attained by RAPPOR, out-of-the-box:

▶ **Theorem 3** (Informal; see Theorem 14). *The (simple version of) RAPPOR achieves expected ℓ_∞ error*

$$\tilde{O}\left(\max\left(\sqrt{\frac{\log k}{n e^{\varepsilon/2}}}, \frac{\log k}{n\varepsilon}\right)\right)$$

for all $\varepsilon \geq 1$, using k bits of of communication per user.

The $\tilde{O}$ notation here only hides a single $\log n$ factor in the second term. As the ℓ_∞ error is always at most 1, up to this $\log n$ factor this is always better than Theorem 2.

The proof of this result requires going beyond the sub-gaussian concentration behaviour alluded to before, and instead analyse the maximum of these sums of Bernoulli random variables as *sub-gamma* random variables. More precisely, we draw upon very recent work by [17] (see also [10]) on "local Glivenko–Cantelli" results, which provide refined concentration bounds for mean estimation of high-dimensional product distributions – in our case, the distributions over $\{0,1\}^k$ arising from the use of RAPPOR.

The above result is appealing, in that it not only yields better error rate than previously known (or, in many cases, believed to be possible) in the $\varepsilon \gg 1$ regime; but also in that it is achieved "for free" by an existing and widely used algorithm. However, it does have one negative aspect: namely, that RAPPOR is, in its standard version, very inefficient from a communication point of view, as it require one k-bit message from each user – far from the ideal $O(\log k)$ bits one could hope for. Luckily, as mentioned above, the analysis underlying Theorem 3 is quite general, and applies to a broad range of locally private

estimation algorithms. While it does not lead to the improved bound for *all* such protocols, we show that it applies, for instance, to the recently proposed Projective Geometry Response protocol of Feldman, Nelson, Nguyen, and Talwar [24], whose performance was originally only analyzed for ℓ_2 error:

▶ **Theorem 4** (Informal; see Theorem 18)**.** *Projective Geometry Response (PGR) achieves expected ℓ_∞ error*

$$\tilde{O}\left(\max\left(\sqrt{\frac{\log k}{ne^\varepsilon}}, \frac{\log k}{n\varepsilon}\right)\right)$$

for all $\varepsilon \geq 1$, using $O(\log k)$ bits of of communication per user.

Note that again this is achieved "out-of-the-box" by an existing algorithm, without any modification! As a result, this inherits all of the features of PGR its authors originally established: crucially, its computational efficiency. We also point out that the stated guarantee is even slightly better than that of RAPPOR, as the first term now features an $e^{-\varepsilon}$ dependence (instead of the $e^{-\varepsilon/2}$ of Theorem 3).

We then turn to prove optimally of this error rate, and show that this is, up to a logarithmic factor, optimal for any LDP protocol:

▶ **Theorem 5** (Informal; see Theorem 24)**.** *Any LDP protocol for frequency estimation must have, in the worst case, expected ℓ_∞ error*

$$\Omega\left(\sqrt{\frac{\log k}{n\varepsilon^2}}\right)$$

for $\varepsilon \in (0, 1]$, and

$$\Omega\left(\max\left(\sqrt{\frac{\log k}{ne^\varepsilon}}, \frac{\log k}{n\varepsilon}\right)\right)$$

for $\varepsilon \geq 1$.

We remark that this lower bound also applies to the "easier" question of distribution learning, as we will state momentarily. The first part of this lower bound, as mentioned before, was already known; the second part is new, and, while not necessarily difficult to show in hindsight, does require significant care in combining inequalities between various information-theoretic quantities to avoid ending up with a vacuous bound. In this sense, our main contribution for the lower bound is to establish it in a self-contained, streamlined fashion, by drawing on the "chi-square contraction" framework of [2]; and – importantly – that it matches the upper bound obtained earlier in *both* the high- and low-privacy regimes. Another interesting aspect of this lower bound is that all three terms are derived separately, but from the same family of hard instances: a dataset where almost all users hold the same element.

Implications for shuffle privacy

By combining our new results on LDP protocols for histograms in the low-privacy regime with known "amplification-by-shuffling" results, we are able to obtain a simple, robust shuffle (approximate) DP protocol using only *one* message per user of logarithmic length, while achieving state-of-the-art:

▶ **Theorem 6** (Informal; see Theorem 27). *Shuffling the Projective Geometry Response protocol achieves expected ℓ_∞ error*

$$O\left(\frac{\sqrt{\log(k)\log(1/\delta)}}{n\varepsilon}\right)$$

for all $\varepsilon \in [\Omega(1/\sqrt{n}), 1]$, with $O(\log k)$ bits of communication and a single message per user.

This matches that of the best known shuffle DP protocols, but with a much lower message and communication complexity. It was, to the best of our knowledge, still open whether achieving these "best of three worlds" guarantees was possible.

We conclude by providing the corollary of our results for distribution learning, using the known connection to frequency estimation (along with the standard lower bound of $\Omega(1/\sqrt{n})$ on the error rate for the question, absent privacy constraints):

▶ **Corollary 7.** *For distribution learning under local privacy constraints, the minmax ℓ_∞ error achievable is at most*

$$\tilde{O}\left(\max\left(\sqrt{\frac{\log k}{ne^\varepsilon}}, \frac{\log k}{n\varepsilon}, \frac{1}{\sqrt{n}}\right)\right)$$

for all $\varepsilon \geq 1$, and

$$O\left(\sqrt{\frac{\log k}{n\varepsilon^2}}\right)$$

for $\varepsilon \in (0, 1]$; and this is tight, up to a logarithmic factor (in n). Moreover, the upper bound is attained by PGR, using $O(\log k)$ bits of of communication per user.

Organisation

After providing some background and setting notation, we establish our theoretical results (upper bounds on the error rate) in Section 3, followed by information-theoretic lower bounds in Section 4 and applications to shuffle privacy in Section 5. Finally, we discuss our results and potential future work in Section 6. Several proofs and a discussion of empirical analyses – omitted for clarity of exposition – can be found in the full version.

2 Preliminaries and notation

(Local) differential privacy

We first recall the definition of local differential privacy (LDP):

▶ **Definition 8** (Locally private randomiser). *An algorithm $Q\colon \mathcal{X} \to \mathcal{Y}$ satisfies ε-differential privacy if for all pairs of inputs $x, x' \in \mathcal{X}$, all sets of outputs $S \subseteq \mathcal{Y}$ are ε-close,*

$$\Pr[\,Q(x) \in S\,] \leq e^\varepsilon \Pr[\,Q(x') \in S\,].$$

A *locally private protocol* is typically a pair of algorithms $Q\colon \mathcal{X} \to \mathcal{Y}$, executed by the user on their data, and $A\colon \mathcal{Y}^n \to \mathcal{X}^k$, executed by the server to transform the randomised outputs into an unbiased estimator for the true quantity. It is well known (see, e.g., [19]) that all LDP Frequency Estimation algorithms have a stochastic matrix representation which maps every element in the input alphabet to a probability distribution over the output

alphabet. Furthermore, [30] demonstrated that all optimal mechanisms obey a "binary" property, in that their stochastic matrix only contains probabilities weighted by either e^{ε} or 1 (appropriately normalised). Recently another "family of LDP protocols" was introduced by [4] and used in [24], where each input is associated with a set of high probability outputs determined by some useful set system.

Frequency Estimation

Under frequency estimation, the aim is to estimate the empirical frequency of the observations. We denote the dataset of n observations as $X^n \coloneqq \{x_1, \ldots, x_n\}$ and their empirical frequencies as the probability vector $q \coloneqq q(X^n)$, where $q_i \coloneqq \frac{1}{n}\sum_{j=1}^{n} \mathbb{1}_{\{x_j=i\}}$. That is, q is an element of the probability simplex,

$$\Delta_k \coloneqq \left\{ p \in \mathbb{R}^k_{\geq 0} : \sum_{i=1}^{k} p_i = 1 \right\}$$

A *frequency estimator* over an alphabet $[k]$ is a (possibly randomized) function $\mathcal{A}\colon [k]^n \to \Delta_k$, which approximates the true frequencies sufficiently well. The quality of the resulting approximation, denoted $\hat{q}$, is measured through a suitably chosen loss function. Typical choices of distance are the ℓ_r norms, for $r \in [1, \infty]$; in this paper, we will be mostly concerned with the ℓ_∞ distance, where $d(q, \hat{q}) = \|q - \hat{q}\|_\infty = \max_{1\leq i\leq k} |q_i - \hat{q}_i|$, and consider the *expected loss* $\mathbb{E}[\|q - \hat{q}\|_\infty]$ (where the expectation is over the randomness of the frequency estimator).

Distribution learning (estimation)

Given independent and identically distributed (i.i.d.) samples from an unknown probability distribution p, the goal of distribution learning (density estimation) is to find a distribution $\hat{p}$ that approximates p sufficiently well. As before, the quality of the approximation is typically measured through a suitably chosen loss function, quantifying the distance between the true distribution p and its approximation $\hat{p}$. From the above, one can see that the key difference between frequency and distribution (under the same loss function) is that in the former, observations are arbitrary, while in the latter they are assumed i.i.d. from some common underlying probability distribution. As such, the expected loss also takes into account the randomness of the samples themselves.

Frequency Estimation implies Distribution Estimation

For any given distance measure d we denote the expected sampling error (under loss d) between the empirical histogram $\hat{p}_n$ from n i.i.d. samples and the true underlying distribution p as $\Phi(d, k, n)$:

$$\Phi(d, k, n) = \sup_{p\in\Delta_k} \mathbb{E}[d(p, \hat{p}_n)]$$

Further, denote the optimal worst-case (over p) expected error under loss d from n i.i.d. samples under ε-LDP constraints as $\Phi^{\text{priv}} \coloneqq \Phi^{\text{priv}}(d, \varepsilon, k, n)$. The "optimal" here refers to quantifying over all locally private distribution estimators. We can analogously express the optimal expected loss when learning the empirical frequencies as $\varphi^{\text{priv}} \coloneqq \varphi^{\text{priv}}(d, \varepsilon, k, n)$.

▶ **Fact 1.** *Accurate* frequency *estimation implies accurate* distribution *estimation: namely,* $\Phi^{\text{priv}}(d, \varepsilon, k, n) \leq \Phi(d, k, n) + \varphi^{\text{priv}}(d, \varepsilon, k, n)$.

For specific norms this allows us to derive (1) a lower bound on φ^{priv} (locally private frequency estimation) from a lower bound on Φ^{priv} (locally private distribution estimation), and (2) an upper bound on Φ^{priv} from an upper bound on φ^{priv}, recalling that (see, for instance, [31, 13])

$$\Phi(d,k,n) = \begin{cases} \Theta\left(\sqrt{\frac{k}{n}}\right) & \text{when } d = \ell_1 \\ \Theta\left(\frac{1}{\sqrt{n}}\right) & \text{when } d = \ell_2, \ell_\infty \end{cases}$$

3 Better algorithms in the low-privacy regime

Although the order-optimal ℓ_∞ error rates for LDP frequency estimation and distribution learning are well-understood by now in the high-privacy regime, with many distinct algorithms achieving the tight

$$O\left(\sqrt{\frac{\log k}{n\varepsilon^2}}\right)$$

expected error bound, much less is understood about the best achievable error for large, or even medium, values of ε. In this section, we first revisit (and slightly generalize) an idea from [14], which shows how to convert any protocol "optimal in the high-privacy regime" to a related protocol "good enough in the low-privacy regime as well", at the price of a blowup in communication (Section 3.1). We then focus on the specific example of RAPPOR, showing that – perhaps surprisingly – this simple protocol does already achieve the same bound by *without any modification* nor communication blowup (Section 3.2). We finally show that for distribution learning, this very same RAPPOR in fact achieves an *even better* error rate than this, leveraging very recent results on concentration of the empirical mean for high-dimensional distributions, due to [17, 10] (Section 3.3).

3.1 A generic transformation, and a baseline

Here we prove the following generic statement:

▶ **Proposition 9.** *Suppose there exists a symmetric*[5] *LDP protocol A for frequency estimation achieving expected ℓ_∞ error*

$$\mathcal{E}(n,k,\varepsilon) = O\left(\sqrt{\frac{\log k}{n\min(1,\varepsilon^2)}}\right)$$

for $\varepsilon \le 1$, with m messages and ℓ bits of communication per user. Then, for every integer $L \ge 1$, there exists an LDP protocol A' for frequency estimation achieving expected ℓ_∞ error

$$\mathcal{E}\left(n\cdot\min(\lceil\varepsilon\rceil, L), k, \frac{\varepsilon}{\min(\lceil\varepsilon\rceil, L)}\right) = O\left(\sqrt{\frac{\log k}{n\min(L,\varepsilon,\varepsilon^2)}}\right)$$

for all $\varepsilon > 0$, with $m\min(\lceil\varepsilon\rceil, L)$ messages and $\ell\min(\lceil\varepsilon\rceil, L)$ bits of communication per user. Further, if A is a public-coin (resp. private-coin) protocol, then so is A'.

[5] i.e., where all users use the same randomiser.

The idea behind this result is not new, and is used (in a slightly less general form) in [14, Appendix E.4]. We restate and prove it in this paper in a self-contained form, as we believe it to be of broader interest.

As a direct corollary (setting $L = \lceil \varepsilon \rceil$), applying the above to Hadamard Response and RAPPOR, for instance, we obtain the following bounds:

▶ **Corollary 10.** *For every $\varepsilon > 0$, there exists a private-coin ε-LDP protocol (namely, a modification of Hadamard Response) for frequency estimation with expected ℓ_∞ error*

$$O\left(\sqrt{\frac{\log k}{n \min(\varepsilon, \varepsilon^2)}}\right)$$

using $\lceil \varepsilon \rceil$ messages per user, and $\log k + O(1)$ bits per message.

▶ **Corollary 11.** *For every $\varepsilon > 0$, there exists a private-coin ε-LDP protocol (namely, a modification of RAPPOR) for frequency estimation with expected ℓ_∞ error*

$$O\left(\sqrt{\frac{\log k}{n \min(\varepsilon, \varepsilon^2)}}\right)$$

using $\lceil \varepsilon \rceil$ messages per user, and k bits per message.

3.2 Tighter analysis for RAPPOR

To do so, we first recall some facts and notation about RAPPOR, which will help with the analysis of its performance. A common simplification of the RAPPOR protocol [4, 3] is to parameterise it by ε as follows.

1. Given input $x_i \in [k]$, one-hot encode it onto a k-bit vector e_x s.t. only the x'th bit is 1.
2. Flip each bit independently with probability $\frac{1}{e^{\varepsilon/2}+1}$ and send the resulting noisy bit-vector Y_i to the server.[6]
3. The server then receives n noisy bit vectors, computes $\bar{Y} \leftarrow \frac{1}{n}\sum_{i=1}^{n} Y_i$, and estimates

$$\hat{q} = \frac{e^{\varepsilon/2}+1}{e^{\varepsilon/2}-1}\bar{Y} - \frac{1}{e^{\varepsilon/2}-1}\mathbf{1}_k \tag{2}$$

where $\mathbf{1}$ is the 1-vector of size k.

A standard fact, which we recall here for completeness, is that $\hat{q}$ defined above is an unbiased estimator for the true vector of frequencies q:

▶ **Lemma 12** (Expectation of $\hat{q}$)**.** *We have $\mathbb{E}[\hat{q}] = q$.*

We then have $\mathbb{E}[\|\hat{q} - q\|_\infty] = \frac{e^{\varepsilon/2}+1}{e^{\varepsilon/2}-1}\mathbb{E}\left[\|\bar{Y} - \mathbb{E}\left[\bar{Y}\right]\|_\infty\right]$, and so to bound the expected ℓ_∞ error is suffices to bound that of the expected maximum deviation of the $\bar{Y}_j$'s from their mean. Now, each $\bar{Y}_j$ is the (normalised) sum of n independent Bernoulli random variables: the standard way to analyse this maximum is to recall that a sum of n independent Bernoullis is a sub-gaussian random variable with parameter[7] at most $\frac{n}{4}$. Standard results (see, for example [32, Chapter 2]) on the maximum of k (not necessarily independent) sub-Gaussian random variables then give

$$\mathbb{E}[\|\hat{q} - q\|_\infty] \leq \frac{e^{\varepsilon/2}+1}{e^{\varepsilon/2}-1}\sqrt{\frac{\log k}{2n}}$$

[6] This is just the "Permanent Randomised Response" step of RAPPOR parameterised by ε.

[7] Importantly, note that this may not coincide with the variance of X, although it does in some important cases (e.g., for a Gaussian r.v.).

which indeed behaves as $O(\sqrt{\log k/(n\varepsilon^2)})$ for small ε. However, the bound quickly degrades for large ε, and only yields $O(\sqrt{\log k/n})$ (no dependence on the privacy parameter at all!) as ε grows.

To remedy this, we will need a tighter analysis of the subgaussian parameter of Bernoulli random variables in the "very biased" regime (which is the one we have to handle for large ε, as then $\frac{1}{e^{\varepsilon/2}+1} \approx 0$). Specifically, we will rely on the following characterisation of the sub-gaussian norm $\sigma^2(p)$ of a (centered) Bern(p) random variable, known as the Kearns–Saul inequality, and which can be found in, e.g., [12]:

$$\sigma^2(p) = \begin{cases} 0, & p \in \{0,1\} \\ \frac{1}{4}, & p = \frac{1}{2} \\ \frac{2p-1}{2\log\frac{p}{1-p}} \end{cases} \tag{3}$$

Importantly, this expression is symmetric: $\sigma^2(p) = \sigma^2(1-p)$ for all $p \in [0,1]$. In our setting, each Y_j is the sum of n independent Bernoulli random variables with one of two symmetric parameters, $p := \frac{1}{e^{\varepsilon/2}+1}$ or $1-p = \frac{e^{\varepsilon/2}}{e^{\varepsilon/2}+1}$. The sub-Gaussian norm at play is then $\sigma^2(p) = \frac{e^{\varepsilon/2}-1}{(e^{\varepsilon/2}+1)\varepsilon}$. Using sub-additivity of the sub-gaussian parameter for independent random variables, we can bound the sub-Gaussian norm of Y_j as

$$\sigma^2(Y_j) \leq \frac{(e^{\varepsilon/2}-1)}{(e^{\varepsilon/2}+1)n\varepsilon} \tag{4}$$

We can use this to bound the maximum error of the estimator.

▶ **Theorem 13** (Expected maximum error of RAPPOR). *The expected maximum of $\hat{q}$ is given by*

$$\mathbb{E}[\|\hat{q}-q\|_\infty] \leq \sqrt{\frac{2\left(e^{\varepsilon/2}+1\right)\log k}{n\left(e^{\varepsilon/2}-1\right)\varepsilon}} \in O\left(\sqrt{\frac{\log k}{n\min(\varepsilon,\varepsilon^2)}}\right) \tag{5}$$

proving the main result of this subsection.

3.3 Optimal analysis for RAPPOR

It is natural to wonder whether this $\min(\varepsilon,\varepsilon^2)$ dependence on the privacy parameter is order-optimal; especially as it appears in other locally private estimation tasks, such as mean estimation for high-dimensional Gaussians or product distributions [20, 1]. Quite surprisingly, we will show that for frequency estimation the ℓ_∞ error rate given in Equation (5) is *not* optimal for large values of ε, and that even the simple RAPPOR algorithm can achieve significantly better.

▶ **Theorem 14.** *For $\varepsilon \geq 1$, the expected ℓ_∞ error of RAPPOR for frequency estimation satisfies*

$$\mathbb{E}[\|\hat{q}-q\|_\infty] = O\left(\sqrt{\frac{\log k}{ne^{\varepsilon/2}}} + \frac{\log k}{n\varepsilon}\cdot\log n\right).$$

Importantly, this is better than the bound in Equation (5) whenever $n = \tilde{\Omega}(\log k/\varepsilon)$, which is the regime of interest (small constant, or vanishing, error). To see why this better bound may hold for large ε, recall that the bound given in Equation (5) relies on analyzing the

expected maximum of k (centered) Binomials random variables using their *sub-gaussian* behavior. This is good when the parameters of the Binomials are not too skewed; however, in the low privacy regimes, the parameters of the Bernoulli summands become very close to 0 (or 1): in that case, to analyze the expected maximum of the Binomials it is tighter to see them as having a *sub-gamma* behavior. Details follow.

Proof of Theorem 14. As alluded to above, we want to analyze the expected behavior of the maximum of Binomial random variables *beyond* the sub-gaussian regime. Invoking generic bounds for sub-gamma random variables such as [11, Corollary 2.6], unfortunately, does not lend itself to the order-optimal bounds either. Instead, we rely on the "local Glivenko–Cantelli" bounds recently obtained by [17, 10], which provide a more refined upper bound: to introduce the result we will invoke, we first need some notation.

▶ **Definition 15.** *Given $\mu \in [0,1]^{\mathbb{N}}$, denote by $\tilde{\mu} \in [0,1/2]^{\mathbb{N}}$ the sequence defined by $\tilde{\mu}_i = \min(\mu, 1-\mu)$ for all $i \geq 1$, and by $\tilde{\mu}^{\downarrow}$ its non-increasing rearrangement. Finally, let p_μ denote the product distribution over $\{0,1\}^{\mathbb{N}}$ with mean vector μ.*

With this in hand, the main result of [17] can be restated as follows:

▶ **Theorem 16** ([17, Theorem 3])**.** *Let $n \geq 21$, and suppose that $\mu \in [0,1]^{\mathbb{N}}$ is such that $\lim_{i\to\infty} \tilde{\mu}_i^{\downarrow} = 0$. Let $\hat{\mu}_n = \frac{1}{n}\sum_{j=1}^{n} X_j \in [0,1]^{\mathbb{N}}$ denote the empirical estimator for μ given n i.i.d. samples $X_1, \dots, X_n$ from p_μ. Then the following holds:*

$$\mathbb{E}[\|\hat{\mu}_n - \mu\|_\infty] \lesssim \sup_{i\geq 1} \sqrt{\frac{\tilde{\mu}_i^{\downarrow} \log(i+1)}{n}} + \frac{\log n}{n} \sup_{i\geq 1} \frac{\log(i+1)}{\log \frac{1}{\tilde{\mu}_i^{\downarrow}}}$$

(Note that [10] recently improved on this results by up to a $\log n$ factor in the second term. For simplicity, we use the slightly weaker result of [17], as it is easier to manipulate.)

We want to apply this result to bounding $\mathbb{E}\big[\|\bar{Y} - \mathbb{E}\big[\bar{Y}\big]\|_\infty\big]$. However, we face one obstacle in doing so, as we do not have a product distribution over $\{0,1\}^k$: while $\bar{Y}_1, \dots, \bar{Y}_k$ are indeed independent, and each of the form

$$\bar{Y}_i = \frac{1}{n}\sum_{j=1}^{n} Y_{i,j}$$

where $Y_{i,1}, \dots, Y_{i,n}$ are independent Bernoulli random variables, these Bernoullis are not identically distributed: exactly $n_i = nq_i$ of them have parameter $1-p = \frac{e^{\varepsilon/2}}{e^{\varepsilon/2}+1}$, and the remaining $n - n_i$ have parameter $p = \frac{1}{e^{\varepsilon/2}+1}$. Of course, we do not know the n_i's, as this is what we are trying to estimate; all we have is that

$$\sum_{i=1}^{k} n_i = n\,.$$

To circumvent this issue, let us write, for each $1 \leq i \leq k$,

$$\bar{Y}_i = \bar{Y}_i^{+} + \bar{Y}_i^{-}$$

where $n\bar{Y}_i^{+} \sim \mathrm{Bin}(n_i, 1-p)$, $n\bar{Y}_i^{-} \sim \mathrm{Bin}(n-n_i, p)$ are independent. We can then express

$$\begin{aligned}\mathbb{E}\left[\|\bar{Y}-\mathbb{E}\left[\bar{Y}\right]\|_\infty\right] &= \mathbb{E}\left[\max_{1\le i\le k}\left|\bar{Y}_i-\mathbb{E}\left[\bar{Y}_i\right]\right|\right]\\ &= \mathbb{E}\left[\max_{1\le i\le k}\left(\left|\bar{Y}_i^+-\mathbb{E}\left[\bar{Y}_i^+\right]\right|+\left|\bar{Y}_i^--\mathbb{E}\left[\bar{Y}_i^-\right]\right|\right)\right]\\ &\le \mathbb{E}\left[\max_{1\le i\le k}\left|\bar{Y}_i^+-\mathbb{E}\left[\bar{Y}_i^+\right]\right|\right]+\mathbb{E}\left[\max_{1\le i\le k}\left|\bar{Y}_i^--\mathbb{E}\left[\bar{Y}_i^-\right]\right|\right] \qquad (6)\end{aligned}$$

Now, instead of taking the maximum of k sums of Bernoullis with different parameters but same number of summands (n summands), we take the maximum of k sums of Bernoullis with the same parameter (i.e., Binomials) but different number of summands (at most n). This does not necessarily seem like an improvement, and still does not let us apply Theorem 16 to either of the two expectations. However, *if* we could argue that "adding summands to each Binomial" cannot decrease the expected maximum, then we would be in good shape: that is, we want to upper bound

$$\mathbb{E}\left[\max_{1\le i\le k}\left|\bar{Y}_i^+-\mathbb{E}\left[\bar{Y}_i^+\right]\right|\right]$$

by

$$\mathbb{E}\left[\max_{1\le i\le k}\left|Z_i^+-\mathbb{E}\left[Z_i^+\right]\right|\right]$$

where $nZ_i^+ \sim \mathrm{Bin}(n, 1-p)$ (instead of $\mathrm{Bin}(n_i, 1-p)$). Intuitively, this seems reasonable, as adding independent summands should make the Binomial more likely to deviate from its expectation. The next lemma makes this intuition rigorous:

▶ **Lemma 17.** *Fix $n_1,\dots,n_k,m_1,\dots,m_k \in \mathbb{N}$ and $p_1,\dots,p_k \in [0,1]$, with $n_i \le m_i$ for all i. Let $N_1,\dots,N_k$ and $M_1,\dots,M_k$ be (not necessarily independent) random variables with $N_i \sim \mathrm{Bin}(n_i,p_i)$ and $M_i \sim \mathrm{Bin}(m_i,p_i)$. Then*

$$\mathbb{E}\left[\max_{1\le i\le k}|N_i-\mathbb{E}[N_i]|\right] \le \mathbb{E}\left[\max_{1\le i\le k}|M_i-\mathbb{E}[M_i]|\right].$$

Proof. Set $\tilde{N}_i \coloneqq N_i-\mathbb{E}[N_i]$ and $\tilde{M}_i \coloneqq M_i-\mathbb{E}[M_i]$ for all $1\le i\le k$. We give a coupling of $\tilde{N}_i, \tilde{M}_i$ such that

$$\mathbb{E}\left[\,\tilde{M}_i \;\middle|\; \tilde{N}_i\,\right] = \tilde{N}_i\,.$$

Such a coupling can be obtained by setting $\tilde{M}_i = \tilde{N}_i+\Delta_i-\mathbb{E}[\Delta_i]$, where $\Delta_i \sim \mathrm{Bin}(m_i-n_i,p_i)$ is independent of $\tilde{N}_i$. Then it is easy to check that $\tilde{M}_i$ has the right distribution, since $N_i+\Delta_i \sim \mathrm{Bin}(m_i,p_i)$; and the the conditional expectation is indeed as claimed. Using this coupling, we obtain

$$\begin{aligned}\mathbb{E}\left[\max_{1\le i\le k}|\tilde{N}_i|\right] &= \mathbb{E}\left[\max_{1\le i\le k}\left|\mathbb{E}\left[\,\tilde{M}_i \;\middle|\; \tilde{N}_i\,\right]\right|\right]\\ &\le \mathbb{E}\left[\mathbb{E}\left[\max_{1\le i\le k}|\tilde{M}_i| \;\middle|\; \tilde{N}_i\right]\right] && \text{(Jensen's inequality)}\\ &= \mathbb{E}\left[\max_{1\le i\le k}|\tilde{M}_i|\right]\end{aligned}$$

establishing the lemma.[8] ◀

[8] More generally, via the existence of this coupling the argument shows that $(\tilde{N}_1,\dots,\tilde{N}_k) \preceq_{\mathrm{cx}} (\tilde{M}_1,\dots,\tilde{M}_k)$ (domination in the convex order), which in turn is equivalent to having $\mathbb{E}\left[\phi(\tilde{N}_1,\dots,\tilde{N}_k)\right] \le \mathbb{E}\left[\phi(\tilde{M}_1,\dots,\tilde{M}_k)\right]$ for every convex function ϕ.

Let $Z_1^+, \ldots, Z_k^+$ (resp. $Z_1^-, \ldots, Z_k^-$) be i.i.d. with $nZ_i^+ \sim \mathrm{Bin}(n, 1-p)$ random variables (resp. $nZ_i^- \sim \mathrm{Bin}(n,p)$). Invoking Lemma 17 with $m_1 = \cdots = m_k = n$ separately on the two expectations of Equation (6), we get

$$\mathbb{E}\left[\|\bar{Y} - \mathbb{E}\left[\bar{Y}\right]\|_\infty\right] \leq \mathbb{E}\left[\max_{1\leq i\leq k} \left|Z_i^+ - \mathbb{E}\left[Z_i^+\right]\right|\right] + \mathbb{E}\left[\max_{1\leq i\leq k} \left|Z_i^- - \mathbb{E}\left[Z_i^-\right]\right|\right]$$

Both of the terms in the RHS now fit the setting of Theorem 16. Moreover, since their parameters are p (for the first expectation) and $1-p$ (for the second), in both case the corresponding $\tilde{mu}_i = \min(p, 1-p) = p = \frac{1}{e^{\varepsilon/2}+1}$ is the same, and applying the theorem will give the same upper bound for both expectations. Thus, Theorem 16 yields

$$\mathbb{E}\left[\|\bar{Y} - \mathbb{E}\left[\bar{Y}\right]\|_\infty\right] \lesssim \sqrt{\frac{p\log(k+1)}{n}} + \frac{\log n}{n} \cdot \frac{\log(k+1)}{\log\frac{1}{p}}$$

Recalling the setting of p, along with the fact that $\mathbb{E}[\|\hat{q} - q\|_\infty] = \frac{e^{\varepsilon/2}+1}{e^{\varepsilon/2}-1}\mathbb{E}\left[\|\bar{Y} - \mathbb{E}\left[\bar{Y}\right]\|_\infty\right]$, finally gives

$$\mathbb{E}\left[\|\bar{Y} - \mathbb{E}\left[\bar{Y}\right]\|_\infty\right] \lesssim \sqrt{\frac{\log(k+1)}{n} \cdot \frac{e^{\varepsilon/2}+1}{(e^{\varepsilon/2}-1)^2}} + \frac{\log n}{n} \cdot \frac{e^{\varepsilon/2}+1}{e^{\varepsilon/2}-1} \cdot \frac{\log(k+1)}{\log(e^{\varepsilon/2}+1)} \tag{7}$$

To conclude, observe that the right hand side is $O\left(\sqrt{\frac{\log k}{n\varepsilon^2}} + \frac{\log k}{n\varepsilon} \cdot \log n\right)$ for $\varepsilon \leq 1$, and $O\left(\sqrt{\frac{\log k}{ne^{\varepsilon/2}}} + \frac{\log k}{n\varepsilon} \cdot \log n\right)$ for $\varepsilon \geq 1$. ◀

3.4 Upper bound for Projective Geometry Response

Projective geometry response (PGR), introduced by [24] achieves optimal rates for ℓ_2^2 error, communication, and near-optimal processing time. The protocol is based on the general template established in [4]: specifically, PGR relies on a set structure defined by *projective planes*, as detailed next. For a prime power d and $k = \frac{d^t-1}{d-1}$, the authors define a t-dimensional vector space $\mathbb{F}_d^t$, where each element $x \in [k]$ is represented by one of the canonical basis vectors. These basis vectors in turn each uniquely determine a projective plane $S(x)$, such that there are $s = |S(x)| = \frac{d^{t-1}-1}{d-1}$ "high probability" elements. Every one of these sets in turn has an intersection with every other set of size $c = |S(x) \cap S(x')| = \frac{d^{t-2}-1}{d-1}$. By choosing a prime power $d \approx e^\varepsilon + 1$, optimal error is achieved.

▶ **Theorem 18.** *Projective geometry response (PGR) [24] achieves the optimal rate for ℓ_∞ error. More specifically, the expected ℓ_∞ error of Projective Geometry Response for frequency estimation satisfies*

$$\begin{aligned}\mathbb{E}[\|\hat{q} - q\|_\infty] &\leq \sqrt{\frac{16(2e^\varepsilon+1)^2\log(k+1)}{e^\varepsilon(e^\varepsilon-1)^2 n}} + \frac{4(2e^\varepsilon+1)\log(k+1)}{(e^\varepsilon-1)\varepsilon n}\log n \\ &\in O\left(\sqrt{\frac{\log k}{ne^\varepsilon}} + \frac{\log k}{n\varepsilon}\log n\right)\end{aligned}$$

We will make use of the size of each subset s and the size of each intersection c as described above, as well as the probability of returning any element y from the output alphabet, given x as an input:

$$Q(Y = y \mid X = x) = \begin{cases} \frac{e^\varepsilon}{se^\varepsilon + k - s} & \text{if } y \in S(x) \\ \frac{s-c}{se^\varepsilon + k - s} & \text{otherwise.} \end{cases} \tag{8}$$

The estimate $\hat{q}$ of the frequency vector is then given by

$$\hat{q}_x \coloneqq \alpha \cdot \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}_{Y_i \in S(x)} + \beta, \qquad x \in [k] \tag{9}$$

where

$$\alpha = \frac{(e^\varepsilon - 1)s + k}{(e^\varepsilon - 1)(s - c)}, \qquad \beta = -\frac{(e^\varepsilon - 1)c + s}{(e^\varepsilon - 1)(s - c)} \tag{10}$$

so that $\hat{q}$ is an unbiased estimator of the true frequency vector q. Since a prime power can be found within a factor 2 of any number, we can choose d such that

$$e^\varepsilon + 1 \leq d \leq 2(e^\varepsilon + 1) \tag{11}$$

(While we could instead choose $d < e^\varepsilon + 1$ and set the inequality to be an undershoot by a factor two, an investigation in that direction led to worse constants and trickier analysis.) Recall that, for every integer ℓ,

$$d^\ell - 1 = (d-1)(1 + d + \ldots + d^{\ell-1}), \tag{12}$$

an identity we will rely on extensively in the rest of the section.

▶ Remark 19. Note that, as introduced above, we must have $k = \frac{d^t - 1}{d-1}$ for a prime power d satisfying (11). Other values of k must be rounded up, losing up to a factor $O(e^\varepsilon)$ in the domain size (i.e., working instead with a domain size $k' = O(e^\varepsilon k)$). We hereafter ignore this detail, which does not affect the final bound of Theorem 18 unless $\varepsilon \gg \log k$; and assume that k is of the form stated above. For the same reason, we additionally can assume $t \geq 3$.

Proof of Theorem 18. We start with two lemmas which will be useful in proving the optimal error rate.

▶ **Lemma 20.** *The common size s of every subset $S(x)$, $x \in [k]$, satisfies $s \geq e^\varepsilon + 2$.*

Proof. We can rewrite s as

$$s = \frac{d^{t-1} - 1}{d - 1} = \sum_{i=0}^{t-2} d^i$$

As $t \geq 3$, we have, by applying Equations (11) and (12)

$$s = \frac{d^{t-1} - 1}{d - 1} = \sum_{i=0}^{t-2} d^i \geq 1 + d \geq e^\varepsilon + 2. \qquad \blacktriangleleft$$

Now remembering that whatever expected error we compute will be multiplied by the normalising constant α, we would like to bound that in terms of ε.

▶ **Lemma 21.** *The value α defined in* (10) *satisfies $\alpha \leq 2 + \frac{2+d}{e^\varepsilon - 1} \leq 2 + \frac{4 + 2e^\varepsilon}{e^\varepsilon - 1}$.*

Proof. First note that

$$\alpha = \frac{(e^\varepsilon - 1)s + k}{(e^\varepsilon - 1)(s - c)} = \frac{s}{(s - c)} + \frac{k}{(e^\varepsilon - 1)(s - c)}$$

and note that by simple application of Equation (12) we get $s - c = d^{t-2}$. Applying the identity again we get:

$$\frac{s}{d^{t-2}} = \sum_{i=0}^{t-2} \frac{1}{d^{i-t+2}} = \frac{1}{d^{t-2}} + \frac{1}{d^{t-1}} + \ldots + 1 \leq 2 \tag{13}$$

where the final inequality comes from the fact that with $d \geq 2$ this is bounded by the geometric series. For k we have the same series, with the addition of a single d term.

$$\frac{k}{d^{t-2}} = \sum_{i=0}^{t-1} \frac{1}{d^{i-t+2}} = \frac{1}{d^{t-2}} + \frac{1}{d^{t-1}} + \ldots + 1 + d$$

The result is then at most $2 + d \leq 2 + 2(e^\varepsilon + 1)$, by applying Equation (11). ◀

We are now ready to apply Theorem 16. As we did for RAPPOR, we will break the expected maximum into the sum of error over two vectors of binomials $Z^+ = \mathrm{Bin}(n, p^+)$ and $Z^- = \mathrm{Bin}(n, p^-)$ where, recalling (8),

$$p^+ = \frac{e^\varepsilon}{se^\varepsilon + k - s}, \qquad p^- = \frac{s - c}{se^\varepsilon + k - s} \tag{14}$$

In this case we do not have that $p^+ = 1 - p^-$ so we will need to bound the following

$$\mathbb{E}\left[\|\hat{q} - q\|_\infty\right] \leq \alpha \left(\sqrt{\frac{\log(k+1)}{n}} \left(\sqrt{p^+} + \sqrt{p^-} \right) + \frac{\log(k+1)}{n} \log(n) \left(\frac{1}{\log(1/p^+)} + \frac{1}{\log(1/p^-)} \right) \right).$$

We briefly note that while RAPPOR has clear independence between coordinates, the result of Theorem 16 due to [17] does not require independence; therefore it applies to PGR, and is likely suitable for the analysis of other subset-based protocols.

First we will upper bound $\sqrt{p^+} + \sqrt{p^-}$:

▶ **Lemma 22.** *For p^+, p^- defined in (14), we have $p^+ + p^- \leq 2/e^\varepsilon$, and so $\sqrt{p^+} + \sqrt{p^-} \leq \sqrt{4/e^\varepsilon}$.*

Proof. First, p^+ is clearly less than $\frac{1}{s}$ when we remove $k - s$ from the denominator, and so is at most $1/(e^\varepsilon + 2) \leq 1/e^\varepsilon$ by Lemma 20. For the other term, notice that by Equation (13) we have $s/(s - c) \geq 1$, from which,

$$p^- \leq \frac{s - c}{se^\varepsilon} \leq \frac{1}{e^\varepsilon}$$

Overall, we get that $p^+ + p^- \leq 2/e^\varepsilon$. The conclusion follows from the AM-GM inequality, as $\sqrt{p^+} + \sqrt{p^-} \leq \sqrt{2(p^+ + p^-)}$. ◀

Next we bound $\log^{-1}(1/p^+) + \log^{-1}(1/p^-)$:

▶ **Lemma 23.** *We have $\frac{1}{\log(1/p^+)} + \frac{1}{\log(1/p^-)} \leq \frac{2}{\varepsilon}$.*

Proof. We will proceed in both cases by lower-bounding the denominators. First,

$$\log(1/p^-) = \log\left(\frac{se^\varepsilon + k - s}{s - c}\right) \geq \log\left(\frac{se^\varepsilon}{s - c}\right) \geq \log(e^\varepsilon) = \varepsilon.$$

Next,

$$\begin{aligned}\log(1/p^+) = \log\left(\frac{se^\varepsilon + k - s}{e^\varepsilon}\right) &\geq \log(s) \\ &\geq \log(e^\varepsilon + 2) && \text{(Lemma 20)} \\ &\geq \varepsilon\end{aligned}$$

As such adding the reciprocals of both terms give a bound of $2/\varepsilon$. ◀

The only step left to bound the ℓ_∞ error of PGR is to take the product of these bounds. Proceeding to do so, we arrive at:

$$\mathbb{E}[\|\hat{q} - q\|_\infty] \leq \sqrt{\frac{16(2e^\varepsilon + 1)^2 \log(k+1)}{e^\varepsilon(e^\varepsilon - 1)^2 n}} + \frac{4(2e^\varepsilon + 1)\log(k+1)}{(e^\varepsilon - 1)\varepsilon n}\log n$$

which in the low privacy regime gives:

$$\mathbb{E}[\|\hat{q} - q\|_\infty] \in O\left(\sqrt{\frac{\log k}{ne^\varepsilon}} + \frac{\log k}{n\varepsilon}\log n\right)$$

as claimed. ◀

4 Worst-case, information-theoretic lower bounds

We will follow the "chi-squared lower bound" framework of [2] to obtain our information-theoretic lower bounds against non-interactive locally private protocols:

▶ **Theorem 24.** *Fix any $\varepsilon > 0$. Any non-interactive (public- or private-coin) protocol Π for distribution estimation from n users must have minmax expected ℓ_∞ error*

$$\Omega\left(\max\left(\sqrt{\frac{\log k}{n(e^\varepsilon - 1)^2}}, \sqrt{\frac{\log k}{ne^\varepsilon}}, \frac{\log k}{n\varepsilon}\right)\right)$$

Proof. Suppose there exists a (non-interactive, public- or private-coin) ε-LDP protocol Π for n users which learns any $\mathbf{p}$ to expected ℓ_∞ error α when each user gets an independent sample from $\mathbf{p}$ as input:

$$\mathbb{E}[\|\mathbf{p} - \hat{\mathbf{p}}\|_\infty] \leq \alpha \tag{15}$$

where $\hat{\mathbf{p}}$ is the output of Π when run on $X_1, \ldots, X_n \sim \mathbf{p}$.

Now, consider the family $\mathcal{P}_\alpha = \{\mathbf{p}_z\}_{z\in[k]}$ of probability distributions over $[k]$, where, for $z \in [k]$, $\mathbf{p}_z$ is defined by

$$\mathbf{p}_z(x) = \frac{1 - 4\alpha}{k} + 4\alpha\mathbb{1}_{\{z=x\}}, \qquad x \in [k] \tag{16}$$

(that is, $\mathbf{p}_z$ is a mixture of the uniform distribution $\mathbf{u}_k$ and a point mass on z, with mixture coefficients $1 - 4\alpha$ and 4α). Consider the following process: first, we select Z from $[k]$ uniformly at random, then generate n i.i.d. samples $X_1, \ldots, X_n$ from $\mathbf{p}_Z$ and run Π on these samples, obtaining a hypothesis $\hat{\mathbf{p}}$. We finally set $\hat{Z}$ to be the element of the domain with the largest probability under $\hat{\mathbf{p}}$, i.e.,

$$\hat{Z} = \operatorname*{argmax}_{i\in[k]} \hat{\mathbf{p}}(i)$$

(breaking ties arbitrarily). The first claim is that doing so allows one to guess the correct value of Z with high probability: indeed, since the gap between the highest and second highest element of $\mathbf{p}_Z$ is 4α, we have

$$\Pr\Big[\,\hat{Z} = Z\,\Big] \geq \Pr[\,\|\mathbf{p} - \hat{\mathbf{p}}\|_\infty < 2\alpha\,] \geq 1 - \frac{\mathbb{E}[\|\mathbf{p}_Z - \hat{\mathbf{p}}\|_\infty]}{2\alpha} \geq \frac{1}{2} \tag{17}$$

the second-to-last inequality being Markov's. However, by Fano's inequality applied to the Markov chain $Z - \mathbf{p}_Z - X^n - (Y^n, R) - \hat{\mathbf{p}} - \hat{Z}$ (where X^n is the tuple of i.i.d. samples, and (Y^n, R) denotes the tuple of n messages, along with the public randomness, resulting from the protocol Π), we get, recalling that Z is chosen uniformly in $[k]$, that

$$\Pr\Big[\,\hat{Z} = Z\,\Big] \leq \frac{I(Z \wedge (Y^n, R)) + \log 2}{\log k} \tag{18}$$

and so, putting Equations (17) and (18) together, we get

$$I(Z \wedge (Y^n, R)) \geq \frac{1}{2}\log\frac{k}{4} = \Omega(\log k)\,. \tag{19}$$

This gives us the first ingredient: a lower bound on $I(Z \wedge (Y^n, R))$. For the second, we need to obtain an upper bound on this same mutual information as a function of ε, n, k, and α. To do so, observe first that, by the chain rule

$$I(Z \wedge (Y^n, R)) = I(Z \wedge Y^n \mid R) + I(Z \wedge R) = I(Z \wedge Y^n \mid R)$$

the second equality follows from the independence of the public randomness R from Z. This is convenient, as the messages $Y^n = (Y_1, \ldots, Y_n)$ are independent conditioned on R, and so we get

$$I(Z \wedge (Y^n, R)) \leq \sum_{j=1}^{n} I(Z \wedge Y_j \mid R) \leq n \cdot \max_{1 \leq j \leq n} I(Z \wedge Y_j \mid R) \tag{20}$$

Consider any user j, using locally private randomizer $Q = Q_{j,R} \colon [k] \to \mathcal{Y}$ (for notational simplicity, we drop afterwards the dependence on j and R). Let $\bar{\mathbf{p}} = \mathbb{E}_Z[\mathbf{p}_Z]$ denote the average input distribution (over Z), i.e., the uniform mixture of all $\mathbf{p}_z$'s. Then we can rewrite the mutual information as

$$I(Z \wedge Y_j \mid R) = \mathbb{E}_Z\big[\mathrm{KL}\big(Q^{\mathbf{p}_Z} \,||\, Q^{\bar{\mathbf{p}}}\big)\big] \tag{21}$$

where, for a given input distribution $\mathbf{p}$, $Q^{\mathbf{p}}(\cdot) = \mathbb{E}_{X \sim \mathbf{p}}[Q(\cdot \mid X)]$ denotes the output distribution (over $\mathcal{Y}$) induced by the randomizer Q on input $X \sim \mathbf{p}$.

First lower bound (good for small ε). We then proceed by upperbounding the KL divergence by the χ^2 one and unrolling the latter's definition, getting

$$\begin{aligned} I(Z \wedge Y_j \mid R) \leq \mathbb{E}_Z\big[\chi^2\big(Q^{\mathbf{p}_Z} \,||\, Q^{\bar{\mathbf{p}}}\big)\big] &= \mathbb{E}_Z\left[\sum_{y \in \mathcal{Y}} \frac{(\mathbb{E}_{X \sim \mathbf{p}_Z}[Q(y \mid X)] - \mathbb{E}_{X \sim \bar{\mathbf{p}}}[Q(y \mid X)])^2}{\mathbb{E}_{X \sim \bar{\mathbf{p}}}[Q(y \mid X)]}\right] \\ &= \mathbb{E}_Z\left[\sum_{y \in \mathcal{Y}} \frac{\Big(\sum_{x \in [k]} Q(y \mid x)(\mathbf{p}_Z(x) - \bar{\mathbf{p}}(x))\Big)^2}{\sum_{x \in [k]} Q(y \mid x)\bar{\mathbf{p}}(x)}\right] \end{aligned}$$

Note, observing that, for our choice of $\mathcal{P}_\alpha$, $\bar{\mathbf{p}}$ is simply the uniform distribution over $[k]$, and that for all $x \in [k]$ we then have $\mathbf{p}_Z(x) - \bar{\mathbf{p}}(x) = 4\alpha\big(\mathbb{1}_{\{Z=x\}} - \frac{1}{k}\big)$. Then, letting $\Phi(x) = e_x - \frac{1}{k}\mathbf{1}_k \in \mathbb{R}^k$ for $x \in [k]$, we get

$$\begin{aligned} I(Z \wedge Y_j \mid R) &\le 16\alpha^2 k^2 \cdot \mathbb{E}_Z\left[\sum_{y\in\mathcal{Y}} \frac{\big(\mathbb{E}_{X\sim\mathbf{u}}\big[Q(y \mid X)\big(\mathbb{1}_{\{Z=X\}} - \frac{1}{k}\big)\big]\big)^2}{\mathbb{E}_{X\sim\mathbf{u}}[Q(y \mid X)]}\right] \\ &= 16\alpha^2 k^2 \cdot \sum_{y\in\mathcal{Y}} \frac{\mathbb{E}_Z\Big[\big(\mathbb{E}_{X\sim\mathbf{u}}\big[Q(y \mid X)\big(\mathbb{1}_{\{Z=X\}} - \frac{1}{k}\big)\big]\big)^2\Big]}{\mathbb{E}_{X\sim\mathbf{u}}[Q(y \mid X)]} \\ &= 16\alpha^2 k \cdot \sum_{y\in\mathcal{Y}} \frac{\sum_{i=1}^k \big(\mathbb{E}_{X\sim\mathbf{u}}\big[Q(y \mid X)\big(\mathbb{1}_{\{i=X\}} - \frac{1}{k}\big)\big]\big)^2}{\mathbb{E}_{X\sim\mathbf{u}}[Q(y \mid X)]} \\ &= 16\alpha^2 k \cdot \sum_{y\in\mathcal{Y}} \frac{\sum_{i=1}^k \mathbb{E}_{X\sim\mathbf{u}}[Q(y \mid X)\Phi(X)_i]^2}{\mathbb{E}_{X\sim\mathbf{u}}[Q(y \mid X)]} \end{aligned} \tag{22}$$

Note that, for any fixed $1 \le i < j \le k$, we have

$$\mathbb{E}_{X\sim\mathbf{u}}[\Phi_i(X)] = 0, \quad \mathbb{E}_{X\sim\mathbf{u}}\big[\Phi_i(X)^2\big] = \frac{1}{k}\left(1 - \frac{1}{k}\right), \quad \mathbb{E}_{X\sim\mathbf{u}}[|\Phi_i(X)|] = \frac{2}{k}\left(1 - \frac{1}{k}\right),$$

For simplicity, we write $\mathbb{E}_X[\cdot]$ for $\mathbb{E}_{X\sim\mathbf{u}}[\cdot]$. We will use the fact that, Q being ε-LDP, we have

$$|Q(y \mid x) - \mathbb{E}_X[Q(y \mid X)]| \le (e^\varepsilon - 1)\mathbb{E}_X[Q(y \mid X)] \tag{23}$$

for every $x \in [k]$ and $y \in \mathcal{Y}$. With this in hand, starting from (22), we can write

$$I(Z \wedge Y_j \mid R) \le 16\alpha^2 k \sum_{y\in\mathcal{Y}} \frac{\sum_{i=1}^k \mathbb{E}_X[Q(y \mid X)\Phi(X)_i]^2}{\mathbb{E}_X[Q(y \mid X)]} \le 64\alpha^2(e^\varepsilon - 1)^2\,.$$

where the derivation relies on the fact that $\mathbb{E}_X[\Phi_i(X)] = 0$, (23), and $\mathbb{E}_{X\sim\mathbf{u}}[|\Phi_i(X)|] \le \frac{2}{k}$ (details can be found in the full version). Using this last bound along with Equations (19) and (20), we get that

$$\frac{1}{2}\log\frac{k}{4} \le I(Z \wedge (Y^n, R)) \le 64\alpha^2 n(e^\varepsilon - 1)^2\,, \tag{24}$$

i.e.,

$$\alpha \ge \frac{1}{8\sqrt{2}}\sqrt{\frac{\log\frac{k}{4}}{n(e^\varepsilon - 1)^2}}, \tag{25}$$

showing the $\Omega\left(\sqrt{\frac{\log k}{n\varepsilon^2}}\right)$ lower bound for small ε.

The second and third lower bounds can be established in an analogous fashion: the details can be found in the full version. ◀

5 Amplification by shuffling

As mentioned in the Introduction, one of the key motivations for studying locally private histogram estimation in the low privacy (high-ε) regime is the implication for histogram estimation in the *shuffle* model of privacy (see, e.g., [27, 26, 7, 16]), in light of the "plug-and-play" amplification-by-shuffling results allowing to "translate" the former into the latter. Specifically, we will use the following result of Feldman, McMillan, and Talwar:

▶ **Theorem 25** ([23, Theorem 3.1]). *For any domain $\mathcal{X}$, let $R\colon \mathcal{X} \to \mathcal{Y}$ be an ε_L-DP local randomiser; and let S be the algorithm that given a tuple of n messages $\vec{y} \in \mathcal{Y}^n$, samples a uniform random permutation π over $[n]$ and outputs $(\vec{y}_{\pi(1)}, \ldots, \vec{y}_{\pi(n)})$. Then for any $\delta \in (0,1]$ such that $\varepsilon_L \leq \log \frac{n}{16\log(2/\delta)}$, $S \circ R^n$ is (ε,δ)-DP, where*

$$\varepsilon \leq \log\left(1 + 8\frac{e^{\varepsilon_L}-1}{e^{\varepsilon_L}+1}\left(\sqrt{\frac{e^{\varepsilon_L}\log(4/\delta)}{n}} + \frac{e^{\varepsilon_L}}{n}\right)\right).$$

In particular, if $\varepsilon_L \geq 1$ then $\varepsilon = O\Big(\sqrt{e^{\varepsilon_L}\log(1/\delta)/n}\Big)$, and if $\varepsilon_L < 1$ then $\varepsilon = O\Big(\varepsilon_L\sqrt{\log(1/\delta)/n}\Big)$.

This implies the following:

▶ **Lemma 26** (Amplification by shuffling). *Fix any $\delta \in (0,1]$, $\varepsilon \in (0,1]$, and n such that $\varepsilon > 16\sqrt{\log(4/\delta)/n}$. Then, for*

$$\varepsilon_L \coloneqq \log\frac{\varepsilon^2 n}{256\log(4/\delta)} = \Theta\left(\log\frac{\varepsilon^2 n}{\log(1/\delta)}\right),$$

shuffling the messages of n users using the same ε_L-LDP randomizer satisfies (robust) (ε,δ)-shuffle differential privacy.

Proof. Note that for ε, δ as in the statement and ε_L as defined, we have $0 < \varepsilon_L \leq \log\frac{n}{16\log(2/\delta)}$. Applying Theorem 25, we get (ε', δ) privacy for

$$\varepsilon' = \log\Big(1 + 8\underbrace{\frac{e^{\varepsilon_L}-1}{e^{\varepsilon_L}+1}}_{\leq 1}\Big(\frac{\varepsilon}{16} + \underbrace{\frac{\varepsilon^2}{256\log(4/\delta)}}_{\leq \varepsilon/16}\Big)\Big) \leq \varepsilon$$

which proves the statement. ◀

▶ **Theorem 27.** *For $n = \Omega\Big(\frac{\log(1/\delta)}{\varepsilon^2}\Big)$ and $\varepsilon \in (0,1]$, Shuffled Projective Geometry Response achieves maximum error $O\left(\frac{\sqrt{\log(k)\log(1/\delta)}}{n\varepsilon}\right)$, with $O(\log k)$ bits of communication (and one single message) per user.*

Proof. For $n \geq \frac{500}{\varepsilon^2}\log\frac{4}{\delta}$, the restriction on ε from Lemma 26 holds, and, setting ε_L as in the lemma, we also have $\varepsilon_L = \Omega(1)$. We then invoke the bound of Theorem 18, focusing on first part of the bound, which dominates when $\frac{\log k}{n} \cdot \log^2 n \leq \frac{\varepsilon_L^2}{e^{\varepsilon_L}}$. This leads to an upper bound on the error of the order

$$\sqrt{\frac{\log k}{ne^{\varepsilon_L}}} = \sqrt{\frac{\log(k)}{n\varepsilon^2\frac{n}{\log(1/\delta)}}} = \frac{\sqrt{\log(k)\log(1/\delta)}}{n\varepsilon}$$

as desired. It only remains to argue that the first term of the bound did, indeed, dominate the error. As mentioned above, this is the case whenever

$$\frac{e^{\varepsilon_L}}{\varepsilon_L^2} \cdot \log k \ll \frac{n}{\log^2 n}$$

for which a weaker, sufficient condition is $\frac{e^{\varepsilon_L}}{\varepsilon_L^2} \ll \frac{n}{\log^2 n}$, that is, $n \gg e^{\varepsilon_L}$. But this follows from our setting of ε_L, such that $e^{\varepsilon_L} = \underbrace{\frac{\varepsilon^2}{256\log(4/\delta)}}_{\ll 1} \cdot n$. ◀

Comparing this result with the summary of local, shuffle, and central histogram error bounds available in [16, Table 1] shows that with shuffled PGR achieves the best error of any protocol which sends a constant number of messages.

More specifically, focusing on 3 representative known protocols: the only known one-message-per-user protocol, due to [16], achieves much worse error,[9] and requires k bits of communication per user; while the protocol of [26], which achieves the same error as Theorem 27, uses $k^{\Omega(1)}$ $(\log k)$-bit messages per user. Finally, a protocol of [6] does achieve better error, but at the cost of performing $k+1$ rounds, each with $\log k$ communication per user. Thus, our bounds demonstrates that shuffled PGR achieve state-of-the-art ℓ_∞–error with only *one* message of $\log k$ bits.

6 Discussion and future work

The logarithmic factor in the upper bound. We prove our upper bounds using the result of [17], which is where the $\log n$ term appears. The authors conjectured that this term could be removed in general, but follow–up work [10] demonstrated by counter–example that this is not the case. They do, however, show that there is a distribution–dependent interpolation between the term being $T(n)/n$ and $T(n)\log n/n$. This logarithmic factor has implications for understanding which error regime is dominating, given the parameters of the algorithm (ε, k, n). While it is possible to imagine that a careful application of the tools in [10] could resolve this matter in general or for a specific use–case, in the meantime we emphasise that empirical analysis is still crucial.

Tighter analysis of other protocols. While we analyse RAPPOR which admits a simple analysis due to the independence of coordinates, and Projective Geometry Response which represents the state of the art in low-communication LDP protocols, we believe the tools introduced in this paper are applicable in a very general way to most LDP protocols. Of particular interest would be Subset Selection, which has optimal mutual information between inputs and outputs of the local randomiser, and the two Hadamard Response protocols that we include in our empirical analysis.

Histograms in the shuffle model. While our shuffle DP result (Theorem 27) yields better error, communication, and number of messages, it does have a limitation on the parameter range, namely $n = \Omega(\log(1/\delta)/\varepsilon^2)$. It would be interesting to weaken this requirement to match the central DP one (where the dependence on ε is only linear). Moreover, one could hope to further improve the resulting error to the central DP bound (i.e., a $\min(\log k, \log(1/\delta))$ dependence instead of $\sqrt{\log k \log(1/\delta)}$), or, alternatively, prove a matching lower bound separating the two models.

Broader applicability of lower bound techniques. While we prove lower bounds for the specific case of ℓ_∞ frequency estimation, the tools used are extremely general and we imagine that their application could provide new lower bounds for a variety of problems in the LDP setting, especially with the low–privacy regime in mind.

[9] And has the same restriction $n = \Omega(\log(1/\delta)/\varepsilon^2)$ on the parameters.

Abstract

In this work, we study the problem of testing *m-grainedness* of probability distributions over an n-element universe $\mathcal{U}$, or, equivalently, of whether a probability distribution is induced by a multiset $S \subseteq \mathcal{U}$ of size $|S| = m$. Recently, Goldreich and Ron (Computational Complexity, 2023) proved that $\Omega(n^c)$ samples are necessary for testing this property, for any $c < 1$ and $m = \Theta(n)$. They also conjectured that $\Omega(\frac{m}{\log m})$ samples are necessary for testing this property when $m = \Theta(n)$. In this work, we positively settle this conjecture.

Using a known connection to the Distribution over Huge objects (DoHo) model introduced by Goldreich and Ron (TheoretiCS, 2023), we leverage our results to provide improved bounds for uniformity testing in the DoHo model.

1 Introduction

The field of distribution testing [7, 6] is concerned with providing statistically accurate information about large datasets or their underlying probability distributions, given very scarce data (sample size). Drawing insights from property testing [20, 27], distribution testing lies at the intersection of theoretical computer science, statistics, and learning theory; and has received significant attention over the past two decades, with many algorithms, insights, and new theoretical access models to the data being proposed and analyzed. We refer the reader to recent surveys [8, 4, 9] and textbook [19, Chapter 11] for more on distribution testing and property testing.

In the most standard access model, the algorithm accesses the underlying unknown probability distribution D (usually assumed to be over a known discrete domain of size n) by obtaining independent, identically distributed (i.i.d.) samples from it. The goal of the algorithm is then, given a fixed property $\Pi \subseteq \Delta_n$ (a subset of the n-dimensional probability simplex Δ_n) and a distance parameter $\varepsilon \in (0, 1]$, as follows:

- If $D \in \Pi$, the algorithm must output accept with probability at least $2/3$;
- If $\mathsf{d_{TV}}(D, Q) > \varepsilon$ for all $Q \in \Pi$, the algorithm must output reject with probability at least $2/3$;

where $\mathsf{d_{TV}}$ denotes the *total variation distance* between distributions, and the probability is taken over the choice of the samples and the internal randomness of the algorithm. This is defined as the *ε-testing* of the property Π. The minimum number of samples $s = s(n, \varepsilon)$ necessary to achieve this task in the worst case (over all possible distributions D) is the *sample complexity* of testing Π. That is, the testing task requires the algorithm, given as few samples as possible, to distinguish with high probability between distributions which have the property, and those which are "far" from having it.

Many other access models have been introduced, providing additional types of queries to the algorithm, or changing the distance metric, or both (see [8] for an overview): among them is the Distribution over Huge Objects (DoHO) model, recently introduced by Goldreich and Ron [23] to capture settings where full access to the data sampled is itself costly or impractical, due to the size of these objects. In the simplest version of this model, the distribution D is defined over the n-dimensional hypercube $\{0, 1\}^n$, where n is assumed to be very large; given a sample $x \sim D$, the algorithm must then choose which bits of x to observe, paying a unit cost for every such query made. The distance metric to quantify "farness" between distributions also differs from that of the standard formulation, and instead is taken to be the Earthmover distance (EMD) between probability distributions, with underlying metric chosen to be the (relative) Hamming distance between n-bit strings. (For the formal definition of this model, and the relation to the standard sampling model, see Section 1.3.)

Many different properties of distributions have been studied, some of them quite extensively: among those, *uniformity* ($\Pi = \{U_\Omega\}$, consisting of the single uniform distribution over the whole domain Ω), *generalized uniformity* [5] ($\Pi_U = \{U_S : S \subseteq \Omega\}$, consisting of all distributions uniform over *some* subset of the domain), and *parameterized uniformity* ($\Pi_m = \{U_S : S \subseteq \Omega, |S| = m\}$, consisting of all distributions uniform over *some* size-m subset of the domain) [23], and m-grainedness (denoted Π°_m, which we will define shortly) [18, 22] are the most relevant to this work.

In this paper, we will focus on two distribution testing tasks, intimately related:

- Testing m-grainedness of distributions in the standard sampling model (property Π°_m); and
- Testing parameterized uniformity in the DoHO model.

Grainedness of distributions

A probability distribution $D \in \Delta_n$ over a discrete set Ω of n elements is said to be *m-grained*, for a given parameter m, if all its probabilities are integer multiples of $1/m$. That is,

$$mD(x) \in \mathbb{N}^{\geq 0}, \qquad x \in \Omega\,.$$

Such distributions naturally arise due to quantization (e.g., binning of continuous or discrete distributions), or when sampling from datasets: that is, if $S \subseteq \Omega$ is a multiset of size m, uniformly sampling from S with replacement yields an m-grained distribution D_S over Ω.

Throughout this work, we will assume $\varepsilon \in (0,1)$ is a constant. Thus, $m < n/\varepsilon = O(n)$. Previous works fixed $m = \Theta(n)$ but these results can also be extended for $m = O(n)$, and therefore our results are stated in terms of m, instead of n.

Recent work of Goldreich and Ron [22] showed that $\Omega(m^c)$ samples are necessary for testing this property, for any fixed $c < 1$. A sample complexity upper bound of $O(\frac{m}{\log m})$ also follows from previous work of Valiant and Valiant [29], which led [22] to conjecture a lower bound of $\Omega(\frac{m}{\log m})$ samples. Our main contribution is to resolve this conjecture, showing that, indeed, $\Theta(\frac{m}{\log m})$ samples are necessary and sufficient for m-grainedness testing:

▶ **Theorem 1.1.** *Let n be a sufficiently large integer, $m = O(n)$, and let $\varepsilon \in (0,1)$ be a sufficiently small constant. Then, ε-testing m-grainedness of distributions over $[n]$ requires $\Omega(\frac{m}{\log m})$ samples.*

We note that the restriction $m = O(n)$ is necessary, as if $m = n/\alpha$ for some $\alpha < 1$, *every* distribution is α-close to being m-grained. Recall that we assume ε is a small constant. Moreover, the problem of testing m-grainedness becomes trivial when $m \geq n/\varepsilon$ as in that case every distribution is ε-close to being m-grained. Along the way, we also present as a warmup a new proof of the lower bound of $\Omega(n^c)$ samples for m-grainedness testing:

▶ **Theorem 1.2.** *Let n be a sufficiently large integer, $m = O(n)$, and let $\varepsilon \in (0,1)$ be a sufficiently small constant. Then, for any fixed constant $c \in (0,1)$, ε-testing m-grainedness of distributions over $[n]$ requires $\Omega(m^c)$ samples.*

While this is a strictly weaker result than our main lower bound, our proof strategy differs significantly from that of [22], and may be of independent interest.

Parameterized uniformity testing in the DoHO model

In a separate work [23], Goldreich and Ron studied the problem of parameterized uniformity testing in the Huge Object model. Among other results, they established a connection between m-grainedness testing in the *standard* model and testing Π_m in the DoHO model:

▶ **Theorem 1.3** ([23, Theorem 2.13])**.** *Assume that, for constant $\varepsilon \in (0,1)$, ε-testing m-grainedness in the standard model has sample complexity $\Omega(\frac{m}{\log m})$. Then, for every $1 \leq m \leq n$ and constant $\varepsilon' \in (0, \frac{\varepsilon}{2})$, ε'-testing Π_m for distribution over $\{0,1\}^n$ in the DoHO model has* query *complexity $\Omega(\frac{m}{\log m})$.*

Our lower bound for m-grainedness immediately implies that this result holds unconditionally. In the same paper, the authors provided an algorithm for testing Π_m using $\widetilde{O}(m)$ samples and queries (for constant $\varepsilon = \Omega(1)$), which together with the above – now unconditional – lower bound settles the complexity of testing Π_m in the DoHO model, up to logarithmic factors, *for $m \leq n$*. One may be tempted to assume the same query complexity lower bound holds in all parameter regimes: perhaps surprisingly, our next result is a new and simple algorithm for testing Π_m in the DoHO model which takes $O(m^{2/3})$ samples and performs $O(m^{2/3}n)$ queries:

▶ **Theorem 1.4.** *There is an algorithm which, given an integer $m \in \mathbb{N}$ and constant $\varepsilon \in (0,1)$, ε-tests the property Π_m of distributions over $\{0,1\}^n$ in the DoHO model, taking $\mathcal{O}(m^{2/3})$ samples and performing $\mathcal{O}(m^{2/3} \cdot n)$ queries. Moreover, any ε-tester for Π_m in the DoHO model must take $\Omega(m^{2/3})$ samples.*

Notably, this improves the upper bound of Goldreich and Ron whenever $n^3 \leq m \leq 2^n$, and rules out any $\tilde{\Omega}(m)$ query complexity lower bound for the whole range of m.

1.1 Overview of our techniques

Lower bound for m-grainedness testing

Our lower bound approach follows Le Cam's two-point method: we will design two distributions of distributions D_{yes} and D_{no} such that the distributions in D_{yes} are m-grained and the distributions in D_{no} are "far" from being m-grained in variation distance. The name of the game is then to prove that it is information-theoretically impossible to distinguish between D_{yes} and D_{no}.

To achieve this, we will rely on the *moment-matching* technique, particularly suited to properties like m-grained (which are symmetric, i.e., invariant to relabelling of the domain elements). Broadly, if two probability distributions D_{yes} and D_{no} have sufficiently similar moments $\|D_{\mathsf{yes}}\|_t^t \approx \|D_{\mathsf{no}}\|_t^t$, for say $1 \leq t \leq K$, then it is hard to distinguish (a permutation of) D_{yes} from (a permutation of) D_{no} by using $o(n^{1-1/K}/K)$ samples. That is, the more moments one can match, the more samples one needs to tell two distributions apart. Note that setting $K = \Theta(\log n)$ would then lead to an $\Omega(\frac{n}{\log n})$ lower bound (and that, as remarked later, in our case we can assume without loss of generality, for the sake of the lower bound argument, that $m = \Theta(n)$.) This approach has been used in the literature extensively [26, 29, 28, 30, 31, 32, 10], and has proven to be very successful in obtaining tight lower bounds for a range of symmetric properties. We will rely on the formulation of the technique described by [32], which maps the problem of matching moments of two full probability distributions (an n-dimensional object) to that of matching moments of two single-dimensional random variables U and V: these two random variables will then be used to generate the probability distributions: intuitively (and as described below), "n independent draws from U will give $D_{\mathsf{yes}}(1), \ldots, D_{\mathsf{yes}}(n)$" (and similarly for D_{no} and V).

Thus, a crucial ingredient in our lower bound is the construction of a pair of discrete random variables U and V whose first logarithmically many moments are identical. Using n independent copies of U (resp. V), we will then define a random measure over $[n]$, which corresponds to a "yes"-instance D_{yes} (resp., a "no"-instance D_{no}). Thus, another requirement on our construction of U and V is that the first one should yield an m-grained distribution, while the second should correspond to a distribution far from being m-grained. We will formalize this in Lemma 2.2.

To build these two random variables U and V, we will, as previously done in the literature, rely on the properties of the Chebyshev polynomial T_d of degree $d = O(\log n)$, defining U and V to be supported on disjoint subsets of the roots of a suitable polynomial $P(x)$, where the probability mass assigned to a given root r is proportional to $1/|P'(r)|$. The idea is that some of the roots of P, those corresponding to U, will be multiples of $1/m$ (leading to m-grained probabilities) while the others, corresponding to V, will be odd multiples of $1/(2m)$ (leading to "far-from-m-grained" probabilities): for instance, we would take

$$P(x) = x\left(x - \frac{1}{2m}\right)\left(1 - \frac{1}{m}\right)T_d(c \cdot x)$$

for some scaling constant $c > 0$. The remaining roots will be that of the Chebyshev polynomial T_d, which are there to ensure that we can match sufficiently many moments of U and V.

However, this approach, which underlies most of previous work, cannot be directly used here: indeed, while the resulting two random variables U, V *could* be made to have many matching moments, and as such be hard to distinguish, doing so will put a lot of probability mass on the roots of the Chebyshev polynomial T_d both for U and V; and these roots are not multiples of $1/m$. This would have the undesirable effect of making *both* our distributions far from being m-grained. Trying to fix this the obvious requires to ensure very little mass is

put by U (and so V) on the roots of T_d, which in turns limits the number of moments that can be matched. (Note that fixing this by choosing not to use the Chebyshev polynomial T_d at all but instead choosing $P(x)$ of the form $P(x) = x\left(x - \frac{1}{2m}\right) \cdot \left(x - \frac{1}{m}\right) \cdots \left(x - \frac{L}{m}\right)$, for some large constant integer L, does get part of the way there and provides a non-trivial result, leading to our (weaker) $\Omega(m^c)$ lower bound for every $c < 1$).

To remedy this, we take a different route, using an idea we believe to be of independent interest and applicable to other lower bounds: instead of using Chebyshev polynomials directly, we will be using a *modified* version of Chebyshev polynomials, $\tilde{T}_d$, defined from T_d by first rounding its roots to multiples of $1/m$. By carefully analyzing the resulting polynomial, we can show that it behaves, for our lower bound construction purposes, similarly to the Chebyshev polynomial, and so we can use it to define both U and V. This allows us to match more moments, leading to our final $\Omega(m/\log m)$ lower bound.

Upper bound for parameterized uniformity testing

In contrast, the idea underlying our upper bound for testing Π_m in the DoHO model is relatively straightforward: namely, by making n queries per sample, we can simulate any testing algorithm in the *standard* sampling model, as we now have observed the full samples. This, along with the relation between TV distance and EMD distance, allows us to lift any s-sample tester for Π_m in the standard sampling model to an s-sample, $s \cdot n$-query tester for Π_m in the DoHO model.

The only issue with this plan is that *there is no known (nontrivial) tester for* Π_m *in the standard sampling model.* There is, however, a known testing algorithm for the related property of generalized uniformity, Π_U. Our key contribution here is then to use this known tester A to derive a tester B for Π_m in the standard sampling model. Notably, this is not as immediate as it seems, and our algorithm needs to use A in a whitebox way, and combine this with an additional test to estimate the ℓ_2 norm of the unknown distribution D. The subtlety here (and the reason for which we cannot use *any* A in a blackbox fashion, but need to use a specific algorithm due to [5]) is that being close to *some* uniform distribution over *some* subset does not immediately allow to conclude about being close to *some* uniform distribution over some m*-size* subset – even if we are guaranteed the ℓ_2 norm of D is close to $1/m$.

1.2 Related work

The field of distribution testing has its roots in theoretical computer science with the work of Goldreich and Ron [21], who designed a uniformity testing algorithm as a tool to check whether a graph is an expander; and formally defined and introduced in [7]. [6] studied the problem of identity testing, which generalizes the problem of uniformity testing. Over the last two decades, this field has seen significant growth, and a host of new tools and techniques have emerged, see [25, 1, 18, 16, 14, 15, 11] to name a few. See the surveys [8, 4, 9] and the book of [19, Chapter 11] for more details.

The study of grained distributions was done implicitly in the work of [26], and later [18] studied it in more detail.

As mentioned earlier, the Huge Object model was introduced by [23]. Since then, there have been several works focusing on this model. [13] defined the notion of *index-invariant properties*, a set of properties that are invariant under the permutation of the indices (these properties are different than label-invariant properties). They showed that index-invariant properties whose VC dimension of the support set is bounded can be learned using a constant

number of queries, depending only on the VC dimension. They also gave tight separation between adaptive and non-adaptive testers for index and non-index-invariant properties. Later, [2] studied various different notions of adaptivity, and showed several separation results. Very recently, [3] studied the problem of support size testing in this model.

1.3 Preliminaries

For a positive integer n, let $[n]$ denote the set $\{1, \ldots, n\}$. We will use the standard asymptotic notation $\mathcal{O}(\cdot), \Omega(\cdot), \Theta(\cdot)$, and, in some cases, the (somewhat less) standard notation $\widetilde{O}(\cdot)$, which omits poly-logarithmic dependencies in the parameters for readability.

We will use several notions of distance between two distributions.

▶ **Definition 1.5.** *Let D_1 and D_2 be two probability distributions over a domain Ω. The ℓ_1* distance *between D_1 and D_2 is defined as*

$$\|D_1 - D_2\|_1 = \sum_{x \in \Omega} |D_1(x) - D_2(x)|.$$

The total variation distance *between D_1 and D_2 is defined as:*

$$\mathsf{d}_{\mathsf{TV}}(D_1, D_2) = \frac{1}{2} \cdot \|D_1 - D_2\|_1 = \sup_{S \subseteq \Omega} (D_1(S) - D_2(S)).$$

▶ **Definition 1.6** (EMD with respect to Hamming distance)**.** *Let D_1, D_2 be two distributions defined over the n-dimensional Hamming cube $\{0,1\}^n$ and d_H be the (relative) Hamming distance over $\{0,1\}^n$. Then the* Earth Mover distance *(EMD) between D_1 and D_2 is defined as follows:*

$$\mathsf{d}_{\mathsf{EM}}(D_1, D_2) := \inf_{T \in \mathcal{T}(D_1, D_2)} \mathbb{E}_{(x,y) \sim T} \left[d_H(x, y) \right]$$

where $\mathcal{T}(D_1, D_2)$ denotes the set of all couplings between μ and τ.

Since we are working with the (relative) Hamming distance, $d_H(x, y) \leq 1$. Then directly from the definitions of $\mathsf{d}_{\mathsf{EM}}(D_1, D_2)$ and $d_H(x, y)$, we get the following simple yet useful observation connecting total variation and EMD distances between two distributions.

▶ **Observation 1.7** (Relation between EMD and TV distances)**.** *Let D_1 and D_2 be two distributions over the n-dimensional Hamming cube $\{0,1\}^n$. Then,*

$$\mathsf{d}_{\mathsf{EM}}(D_1, D_2) \leq \mathsf{d}_{\mathsf{TV}}(D_1, D_2).$$

▶ **Definition 1.8** (Huge Object Model)**.** *Consider a discrete distribution D supported over the n-dimensional Hamming cube $\{0,1\}^n$. D is accessed by obtaining iid samples, where each sample obtained is an n-bit Boolean string. In addition to the sampling oracle, there is also a query oracle associated with D, where the tester can query any index $i \in [n]$ for any samples (say j-th sample s_j) obtained, and the query oracle will return the i-th bit of s_j. The goal is then to minimize both the total sample and query complexities required to decide a property.*

Note that this Huge Object model is particularly suited for studying high-dimensional distributions, where the dimension of the underlying domain is so large that even reading a single sample in its entirety might not be feasible.

Finally, we state here some technical result which will be used in our lower bounds proofs:

▶ **Lemma 1.9** ([31, Lemma 4])**.** *Let W_1, W_2 be discrete random variables taking values in $[0, \Lambda]$. If $\mathbb{E}[W_1^t] = \mathbb{E}[W_2^t]$ for $1 \leq t \leq T$, then*

$$\mathsf{d}_{\mathsf{TV}}\Big(\mathbb{E}_{W_1}[\mathsf{Poi}(W_1)], \mathbb{E}_{W_2}[\mathsf{Poi}(W_2)]\Big) \leq \left(\frac{e\Lambda}{2T}\right)^T.$$

▶ **Fact 1.10** ([10, Fact 7], [24]). *Let p be a degree-d polynomial with distinct roots $r_1, \ldots, r_d$. Then, for every $0 \le k \le d-2$, we have that $\sum_{i=1}^{d} \frac{r_i^k}{p'(r_i)} = 0$.*

We will be using the following two well-known trigonometric inequalities.

▶ **Fact 1.11.**

(i) *For $x \in [0, \pi]$, the following holds:*

$$\sin x \ge \frac{2}{\pi} \min(x, \pi - x) \tag{1}$$

(ii) *For $x \in [-\pi/2, \pi/2]$, the following holds:*

$$|\frac{4}{\pi} \cdot x| \ge |\sin x| \ge |\frac{2}{\pi} \cdot x|, \tag{2}$$

Organization

The rest of the paper is organized as follows. In Section 2, we present a new proof of the lower bound of $\Omega(m^c)$ samples. Then in Section 3, we present the $\Omega(m/\log m)$ lower bound for testing m-grainedness. In Section 4, we present our result of uniformity testing in the Huge Object Model. We conclude in Section 5 with some open questions. Due to the shortage of space, the formal proofs of some claims are deferred to the full version of the paper [12].

2 An $\Omega(m^c)$ lower bound for testing m-grainedness

In this section, we prove Theorem 1.2, thereby presenting a new proof of the lower bound of [22].

▶ **Theorem 1.2.** *Let n be a sufficiently large integer, $m = O(n)$, and let $\varepsilon \in (0,1)$ be a sufficiently small constant. Then, for any fixed constant $c \in (0,1)$, ε-testing m-grainedness of distributions over $[n]$ requires $\Omega(m^c)$ samples.*

Note that it suffices to consider the case $m = \Theta(n)$, as if $m \ll n$ one can then embed the hard instances in a larger domain, lifting the lower bound. As a result, we hereafter assume without loss of generality that $m = \Theta(n)$. We start by stating a relatively standard theorem which will be crucial in the proof of our sample complexity lower bound, and whose proof is deferred to the full version [12].

▶ **Theorem 2.1.** *Fix positive integers m, n, s, where $n > 4.3 \times 10^8$ and $m \le C_0(n-1)$ for some absolute constant $C_0 \in \mathbb{R}$. Suppose there exist random variables U and V, where U is supported on $\{0, \frac{1}{m}, \ldots, \frac{m}{m}\}$; $\Pr\left[V \in \{\frac{1}{2m}, \frac{3}{2m}, \ldots, \frac{2m-1}{2m}\}\right] \ge \frac{2}{3}$; and they satisfy the following three conditions,*

$$\max(U, V) \le \frac{20 \log^2(n-1)}{(n-1)}, \tag{3}$$

$$\mathbb{E}[U] = \mathbb{E}[V] \le \frac{1}{2(n-1)}. \tag{4}$$

$$\mathsf{d}_{\mathsf{TV}}\left(\mathbb{E}[\mathrm{Poi}(sU)], \mathbb{E}[\mathrm{Poi}(sV)]\right) \le \frac{1}{20(n-1)}, \tag{5}$$

Then any tester taking less than $s/2$ number of samples from unknown distribution p cannot distinguish between the cases that p is m-grained and p is at least $\frac{1}{8C_0}$-far from any m-grained distributions in TV distance with probability $3/5$.

In order to prove Theorem 1.2, we will be using the following lemma.

▶ **Lemma 2.2.** *There exist constants L, K, such that for any n and $m = L(n-1)$, there exist two discrete random variables U and V such that the following Equations* (6), (7), (8) *and* (9) *hold.*

$$\mathsf{Support}(U) \subseteq \frac{\mathbb{Z}}{m} \text{ and } \mathsf{Support}(V) \subseteq \frac{2\mathbb{Z}+1}{2m} \tag{6}$$

$$U, V \leq \frac{L}{m} \tag{7}$$

$$\mathbb{E}[U] = \mathbb{E}[V] \leq \frac{1}{2(n-1)}. \tag{8}$$

$$\mathbb{E}[U^t] = \mathbb{E}[V^t] \quad \text{for} \quad t \in [K]. \tag{9}$$

In order to prove the above lemma, we will use the following polynomial to construct our U and V (fix any positive integer L):

$$P(x) = x\left(x - \frac{1}{2m}\right)\left(x - \frac{2}{2m}\right)\left(x - \frac{3}{2m}\right)\cdots\left(x - \frac{2L}{2m}\right) \tag{10}$$

In the context of Lemma 2.2, the random variable U will be supported on the roots $0, \frac{1}{m}, \frac{2}{m}, \ldots, \frac{L}{m}$. Similarly, the random variable V will be supported on the roots $\frac{1}{2m}, \frac{3}{2m}, \ldots, \ldots, \frac{2L-1}{2m}$.

Proof of Lemma 2.2. We will first describe the construction of random variables U and V, associated with the polynomial P. Namely, let $\Pr[U = r] \propto \frac{1}{|P'(r)|}$ for r in the support of U (every derivative is positive when r is in the support of U, i.e., $r \in \{0, \frac{1}{m}, \frac{2}{m}, \ldots, \frac{L}{m}\}$). Similarly, we have $\Pr[V = r] \propto \frac{1}{|P'(r)|}$ for r in the support of V (likewise, all derivative will be negative). The normalization term is simply

$$Z_P := \sum_{i=0}^{L} \frac{1}{|P'(\frac{i}{m})|} = \sum_{i=1}^{L} \frac{1}{|P'(\frac{2i-1}{2m})|}.$$

And we can show that

$$Z_P = \sum_{k=0}^{L} \frac{\binom{2L}{2k}(2m)^{2L}}{(2L)!} = \frac{(2m)^{2L}}{(2L)!}\sum_{k=0}^{L}\binom{2L}{2k} = \frac{(2m)^{2L}}{(2L)!}\cdot 2^{2L-1}.$$

Applying Fact 1.10 with $k = 0$, we can notice that the two summations are equal (U has all positive roots and V all negative).

Proof of Equation (7). The largest value of U and V is the largest root of the polynomial P: $\max\{U, V\} \leq L/m$.

Proof of Equation (8). Let us compute the derivative of the polynomial P in Equation (10). For any $k \in [2L] \cup \{0\}$, we have the following:

$$\begin{aligned} P'\left(\frac{k}{2m}\right) &= \prod_{\ell=0}^{k-1}\frac{k-\ell}{2m}\prod_{\ell=k+1}^{2L}\frac{\ell-k}{2m}(-1)^{2\ell-k} \\ &= \frac{(-1)^k}{(2m)^{2L}}k!(2L-k)! \\ &= (-1)^k\frac{(2L)!}{\binom{2L}{k}(2m)^{2L}} \end{aligned}$$

Now let us compute $\mathbb{E}[U]$ as follows:

$$\begin{aligned}\mathbb{E}[U] &= \Pr[U=0]\cdot 0 + \sum_{\ell:\ \ell \text{ even},\ \ell\in[2m]} \Pr\left[U=\frac{\ell}{m}\right]\cdot\frac{\ell}{m}\\ &= \frac{1}{Z_P}\sum_{k=0}^{L}\frac{2k}{2m}\frac{\binom{2L}{2k}(2m)^{2L}}{(2L)!}\\ &= \frac{1}{m}\frac{\sum_{k=0}^{L}k\binom{2L}{2k}}{2^{2L-1}}\\ &= \frac{L}{2m}\end{aligned}$$

We finally upper bound the expectation:

$$\frac{1}{2(n-1)} \geq \frac{L}{2m} = \mathbb{E}[U] \Rightarrow m \geq L(n-1). \tag{11}$$

Proof of Equation (9). Their first $K = 2L-1$ moments are matched by recalling Fact 1.10 (applied for $k = t$) and how U and V are constructed. ◀

Proof of Theorem 1.2. Using Lemma 1.9 on random variables constructed in Lemma 2.2, by setting $m = 2L(n-1) = \Theta(n)$, we know $\Lambda = s\cdot\frac{L}{m}$, we get that

$$\mathsf{d}_{\mathsf{TV}}(\mathbb{E}[\mathrm{Poi}(sU),\mathrm{Poi}(sV)]) \leq \left(\frac{es\cdot\frac{L}{m}}{2K}\right)^{K} \leq \frac{1}{2(n-1)},$$

which gives,

$$s \leq 2(n-1)\left(\frac{2K}{e}\right)\cdot\left(\frac{1}{2(n-1)}\right)^{1/K}.$$

Further simplification yields,

$$s \leq \left(\frac{4L-2}{e}\right)(2(n-1))^{1-\frac{1}{2L-1}}.$$

Applying Theorem 2.1, gives the lower bound $s = \Omega\left(n^{1-\frac{1}{2L-1}}\right)$. For any constant $c < 1$, one can choose L large enough such that $c \leq 1-\frac{1}{2L-1}$, and thus concludes our proof. ◀

3 $\Omega(\frac{m}{\log m})$ lower bound for m-grainedness (Proof of Theorem 1.1)

In this section, we will be proving the following theorem:

▶ **Theorem 1.1.** *Let n be a sufficiently large integer, $m = O(n)$, and let $\varepsilon \in (0,1)$ be a sufficiently small constant. Then, ε-testing m-grainedness of distributions over $[n]$ requires $\Omega(\frac{m}{\log m})$ samples.*

Similar to the proof of Theorem 1.2, we will make use of Theorem 2.1 to prove our $\Omega(\frac{m}{\log m})$ lower bound. Namely, we will construct two random variables U and V such that they can be used to construct approximate probability vector for m-grained and mostly $2m$-grained and their first $\log(m)$ moments match. In particular, we will prove the following lemma:

▶ **Lemma 3.1.** *For $m = 70(n-1)$ and $n > 20$, there exist discrete random variables U and V such that the following hold:*

$$\Pr[V = \frac{1}{2m}] \geq 2/3. \tag{12}$$

$$\mathsf{Support}(U) \subseteq \frac{\mathbb{Z}}{m} \tag{13}$$

$$0 \leq U, V \leq \frac{20\log^2(n-1)}{n-1}. \tag{14}$$

$$\mathbb{E}[U] = \mathbb{E}[V] \leq \frac{1}{20(n-1)}. \tag{15}$$

$$\mathbb{E}[U^t] = \mathbb{E}[V^t] \text{ for } \ t \in [3 \cdot \log(n-1)] \tag{16}$$

3.1 Construction of U and V

The main focus of this subsection is to establish Lemma 3.1.

Fact 1.10 allows us to define two random variables U and V with matching moments up to the degree of some polynomial – similar to the analysis in Section 2, by simply defining U and V through its roots and partitioning them by the signs of the derivatives at those roots. However, the challenge here is, we need to match even higher degree (in Section 2, we can match them up to a constant degree C_1, here we need to match them up to $\Theta(\log m) = \Theta(\log n)$ degree), all while keeping every other conditions unchanged: U is m-grained and V on the most part is $(2m)$-grained; maximum value of the support size does not blow up; and more importantly, the expectation could be bounded by $O(1/n)$. Notably, if we try to match higher degree: say instead of constant, we make $L = O(\log n)$ in Equation (11), with $m = \Theta(n)$, using the construction in Section 2. It will fail miserably – the expectation $\mathbb{E}[U]$ will exceed $O(1/n)$, and so when we take n copies of U or V, it would not be a distribution in an approximate sense.

To work around this and match degree (by implication, moments) as high as possible, we take the (shifted) Chebyshev polynomial of degree d and we will later use properties of this polynomial to construct our prior variables U and V. Recall that the shifted Chebyshev polynomial of the first kind is defined as follows:

$$p_{T_d}(x) = T_d(1 - \Delta x) = 2^{d-1}\Delta^d \cdot \prod_{i=1}^{d}(x - t_i), \tag{17}$$

where $T_d(\theta) = \cos(d \cdot \arccos\theta)$, for $\theta \in [-1, 1]$; t_i denotes the roots of the degree-d (shifted) Chebyshev polynomial for every $i \in [d]$; $\Delta \in \mathbb{R}$, a parameter to be chosen in the analysis later.

However, as mentioned in the introduction, instead of using the shifted Chebyshev polynomial directly, we will be using a variant of it for our proof. For this purpose, we will define the polynomial $\tilde{p}_{T_d}$, a slightly modified Chebyshev polynomial of degree d, by "rounding up to the nearest multiple of $1/m$" its d roots:

$$\tilde{p}_{T_d}(x) = \tilde{T}_d(1 - \Delta \cdot x) = 2^{d-1}\Delta^d \cdot \prod_{i=1}^{d}(x - \tilde{t}_i) \tag{18}$$

where $\frac{1}{m} + t_i \geq \tilde{t}_i = \frac{1}{m}\lceil mt_i \rceil \geq t_i$.

Putting these ideas together, we will focus on two polynomials based on the Chebyshev polynomial and modified Chebyshev polynomial respectively (obtained by appending Chebyshev polynomial to $x(x-\frac{1}{2m})(x-\frac{1}{m})$):

$$p(x) = x\left(x-\frac{1}{2m}\right)\left(x-\frac{1}{m}\right)\cdot p_{T_d}(x) \tag{19}$$

$$\tilde{p}(x) = x\left(x-\frac{1}{2m}\right)\left(x-\frac{1}{m}\right)\cdot \tilde{p}_{T_d}(x) \tag{20}$$

Through polynomial $\tilde{p}$ in Equation (20), we can construct two random variables U and V identified by their probability mass function. Namely, we define U as follows:

$$\Pr[U=r] \propto \frac{1}{|\tilde{p}'(r)|} \quad \text{if } \tilde{p}'(r)>0 \text{ and } r \text{ is a root of } \tilde{p} \tag{21}$$

Similarly, we define the random variable V as follows:

$$\Pr[V=r] \propto \frac{1}{|\tilde{p}'(r)|} \quad \text{if } \tilde{p}'(r)<0 \text{ and } r \text{ is a root of } \tilde{p} \tag{22}$$

For both U and V, we assign probability 0 to the roots not specified. Thus, by setting $k=0$ in Fact 1.10 and noting that the negative and positive terms sum to 0, the normalization factor are equal for both U and V, and can be expressed as follows:

▶ **Observation 3.2.**

$$Z_{\tilde{p}} = Z(\Delta,m,d) = \frac{1}{\tilde{p}'(0)} + \frac{1}{\tilde{p}'(\frac{1}{m})} + \sum_{j=1}^{d}\frac{\mathbb{1}_{\{\tilde{p}'(\tilde{t}_j)>0\}}}{\tilde{p}'(\tilde{t}_j)} = \frac{1}{|\tilde{p}'(\frac{1}{2m})|} + \sum_{j=1}^{d}\frac{\mathbb{1}_{\{\tilde{p}'(\tilde{t}_j)<0\}}}{|\tilde{p}'(\tilde{t}_j)|}. \tag{23}$$

The reasons we are taking the shifted Chebyshev polynomial and "round the roots up" are two-fold: first, this kind of construction (before rounding) was used to prove lower bounds with $\Omega(n/\log n)$ complexity before, by constructing a polynomial of degree $\Theta(\log n)$ with certain constraints [10]. Second, we need to make sure that the distributions derived from U are m-grained with very high probability. Yet, using the shifted Chebyshev directly, some of the roots of U (the positive roots) resulting from T_d will not be m-grained with non-trivial probability. Intuitively, we want to leverage the known properties of the shifted Chebyshev p_{T_d} and argue that rounding up and creating $\tilde{p}_{T_d}$ will only "mildly" change those properties.

Since we are deciding the support of U, V based on the evaluation of derivative at each root of $\tilde{p}_{T_d}$ and argue that it is somewhat close to p_{T_d}, we need to first make sure that the signs of derivative at the main three roots remain the same as p_{T_d}'s (the rest of the roots' derivative's signs, the ones induced by $\tilde{p}_{T_d}$, will not affect the argument). Note that the sign of the polynomial $\tilde{p}_{T_d}$ when evaluated at $0, 1/2m, 1/m$ is not changed (same as p_{T_d}), as $(0-t_j)$ and $(0-\tilde{t}_j)$ have the same sign; we also have $1/2m, 1/m \le t_j \le \tilde{t}_j$, via a constraint on setting Δ and therefore we can conclude that

$$p_{T_d}(0)\cdot\tilde{p}_{T_d}(0)>0; \quad p_{T_d}(1/2m)\cdot\tilde{p}_{T_d}(1/2m)>0; \quad p_{T_d}(1/m)\cdot\tilde{p}_{T_d}(1/m)>0.$$

Next, we compute their corresponding derivatives of the two polynomials evaluated at the roots t_ℓ and $\tilde{t}_\ell$.

$$p'(t_\ell) = t_\ell\left(t_\ell-\frac{1}{2m}\right)\left(t_\ell-\frac{1}{m}\right)2^{d-1}\Delta^d\prod_{j\neq\ell}(t_j-t_\ell) \tag{24}$$

Table 1 Properties of the polynomial p and its distinct $d+3$ roots. $|p'(r_1)|, |p'(r_2)|, |p'(r_3)|$'s upper and lower bounds are proven in Claim A.7 of the full version [12].

roots	value of $p'(r_\ell)$	bound on $\lvert p'(r_\ell)\rvert$
$r_1 = 0$	$\frac{1}{2m^2} \cdot T_d(1)$	$\Theta\left(\frac{1}{m^2}\right)$
$r_2 = \frac{1}{2m}$	$-\frac{1}{4m^2} \cdot T_d\left(1 - \frac{\Delta}{2m}\right)$	$\Theta\left(\frac{1}{m^2}\right)$
$r_3 = \frac{1}{m}$	$\frac{1}{2m^2} \cdot T_d\left(1 - \frac{\Delta}{m}\right)$	$\Theta\left(\frac{1}{m^2}\right)$
$r_{\ell+3} = t_\ell = \frac{2}{\Delta}\sin^2\left(\frac{\pi}{2}\left(\frac{2\ell-1}{2d}\right)\right)$	$p'(t_\ell) = t_\ell \cdot \left(t_\ell - \frac{1}{2m}\right) \cdot \left(t_\ell - \frac{1}{m}\right) \cdot T'_d(t_\ell)$	$\Theta\left(\frac{\ell^5}{\Delta^2 d^4}\right)$

$$\tilde{p}'(\tilde{t}_\ell) = \tilde{t}_\ell \left(\tilde{t}_\ell - \frac{1}{2m}\right)\left(\tilde{t}_\ell - \frac{1}{m}\right) 2^{d-1}\Delta^d \prod_{j\neq\ell}(\tilde{t}_j - \tilde{t}_\ell) \tag{25}$$

Here, note that by construction, all the roots of $\tilde{p}_{T_d}$ will be m-grained (see Equation (18)). Moreover, 0 and $\frac{1}{m}$ are m-grained roots of $\widetilde{p}(x)$ (see Equation (20)). On the other hand, the root $\frac{1}{2m}$ of the polynomial $\widetilde{p}(x)$ is not m-grained by definition.

In the context of Lemma 3.1, the random variable U will be supported on the roots 0, $\frac{1}{m}$, and a subset of the roots $\widetilde{t}_\ell$ of the modified Chebyshev polynomial $\widetilde{p}_{T_d}$ from Equation (18), for $\ell \in [d]$. On the other hand, the random variable V will be supported over $\frac{1}{2m}$ and a disjoint (from support of U constructed by modified Chebeshev roots of $\tilde{p}_{T_d}$) subset of the modified Chebyshev polynomial roots. U and V's support form a partition for all roots of $\tilde{p}_{T_d}$.

To prove Lemma 3.1, we need a few claims, that we state below and whose proof can be found in the full version [12].

▷ Claim 3.3 (Relation between roots at $\tilde{p}'$ and p').

$$\frac{|\tilde{p}'(\tilde{t}_\ell)|}{|p'(t_\ell)|} \geq \exp\left(-\frac{12\Delta}{m/d^2}\right) \text{ for every } \ell \in [d]. \tag{26}$$

$$1 \leq \frac{|\tilde{p}'(0)|}{|p'(0)|}, \quad 1 \leq \frac{|\tilde{p}'(1/m)|}{|p'(1/m)|} \leq 6, \quad 1 \leq \frac{|\widetilde{p}'(1/2m)|}{|p'(1/2m)|} \leq 6. \tag{27}$$

The proofs of Equation (26) and Equation (27) can be found in Appendix A.1 of the full version (Claims A.2 to A.5). From now onwards, we will assume that Claim 3.3 holds.

For the lower bound, we will be choosing $\Delta = \frac{m}{20d^2}$ and $d = \sqrt{10}\log(n-1)$.

▶ **Observation 3.4.** *Let t_j and $\tilde{t}_j$ be the roots of the Cheybyshev and modified Chebyshev polynomials, for any $j \in [d]$. When $\Delta \leq \frac{m}{2d^2}$, we have that*

$$\tilde{t}_j \geq t_j \geq \frac{1}{m}.$$

Proof. Using Equation (2), we can lower bound t_j for any j,

$$t_j = \frac{1}{\Delta}\left(1 - \cos\left(\frac{2j-1}{2d}\pi\right)\right) = \frac{2}{\Delta}\sin^2\left(\frac{\pi}{2}\left(\frac{2j-1}{2d}\right)\right) \geq \frac{2}{\Delta}\left(\frac{2j-1}{2d}\right)^2 \geq \frac{1}{m}, \tag{28}$$

where the last inequality follows from $2j-1 \geq 1$ (which holds for all $j \geq 1$), and our assumption on Δ. Moreover, we also have:

$$\tilde{t}_j = \frac{1}{m}\lceil mt_j \rceil \geq t_j \geq \frac{1}{m}$$

where the last inequality follows from Equation (28). This completes the proof. ◀

We need the following two claims (Claim 3.5 and Claim 3.6) whose proofs are deferred to Appendix A.2 of the full version [12], to show that $\Pr[V = \frac{1}{2m}] \geq \Omega(1)$ in Claim 3.7 as required by Equation (12).

▷ Claim 3.5. Suppose $1 \leq \frac{|\widetilde{p'}(\frac{1}{2m})|}{|p'(\frac{1}{2m})|} \leq 6$ holds and $\Delta \leq \frac{2m}{9d^2}$. Then we have,

$$\Pr\left[V = \frac{1}{2m}\right] \propto \frac{1}{|\tilde{p}'(\frac{1}{2m})|} \geq \frac{2}{3}m^2.$$

▷ Claim 3.6. Suppose that $\Delta \leq \frac{2m}{9d^2}$. For any $j \in [d]$, let $\tilde{t}_j$ denote the j-th root of the modified Chebyshev polynomial $\widetilde{p}$. Then we have:

$$\Pr\left[V \neq \frac{1}{2m}\right] \propto \sum_{j=1}^{d} \frac{\mathbb{1}_{\{\tilde{p}'(\tilde{t}_j)<0\}}}{|\tilde{p}'(\tilde{t}_j)|} \leq \exp\left(\frac{12\Delta}{m/d^2}\right) \cdot \frac{66}{\pi} \cdot \Delta^2 d^4.$$

▷ Claim 3.7. If $\Delta \leq \frac{m}{20d^2}$, then

$$\Pr\left[V = \frac{1}{2m}\right] = \frac{1}{|\tilde{p}'(\frac{1}{2m})| \cdot Z} \geq \frac{5}{6},$$

where Z is the normalizing constant defined in Equation (23).

Proof. Following the definition of the random variable V (Equation (22)) and the normalization term $Z_{\tilde{p}}$ (Equation (23)), we can say that:

$$\Pr\left[V = \frac{1}{2m}\right] = \frac{1}{|\tilde{p}'(\frac{1}{2m})| \cdot Z} = \frac{1}{1 + \left(\sum_{j=1}^{d} \frac{\mathbb{1}_{\{\tilde{p}'(\tilde{t}_j)<0\}}}{|\tilde{p}'(\tilde{t}_j)|}\right) \cdot |\tilde{p}'(\frac{1}{2m})|}.$$

Combining Claim 3.5 and Claim 3.6, we see that

$$\begin{aligned}
\left(\sum_{j=1}^{d} \frac{\mathbb{1}_{\{\tilde{p}'(\tilde{t}_j)<0\}}}{|\tilde{p}'(\tilde{t}_j)|}\right) \cdot |\tilde{p}'(\frac{1}{2m})| &\leq \frac{3\exp\left(\frac{12\Delta}{m/d^2}\right)}{2m^2} \cdot \frac{66}{\pi} \cdot \Delta^2 d^4 \\
&= \frac{99}{\pi}\exp\left(\frac{12\Delta}{m/d^2}\right) \cdot \frac{\Delta^2 d^4}{m^2} \\
&\leq \frac{99}{\pi}\exp\left(\frac{12\frac{m}{20d^2}}{m/d^2}\right) \cdot \frac{\left(\frac{m}{20d^2}\right)^2 d^4}{m^2} \quad [\because \Delta \leq \frac{m}{20d^2}] \\
&\leq \frac{99}{\pi}\exp(\frac{12}{20}) \cdot \frac{1}{400} \leq \frac{1}{5}.
\end{aligned}$$

Thus, we can say that

$$\Pr\left[V = \frac{1}{2m}\right] = \frac{1}{1 + \left(\sum_{j=1}^{d} \frac{\mathbb{1}_{\{\tilde{p}'(\tilde{t}_j)<0\}}}{|\tilde{p}'(\tilde{t}_j)|}\right) \cdot |\tilde{p}'(\frac{1}{2m})|} \geq \frac{5}{6}.$$

This completes the proof. ◁

Now we are ready to prove Lemma 3.1.

Proof of Lemma 3.1. We now prove that the random variables U and V defined in Section 3.1 satisfies Equation (12)-Equation (16). We begin by setting $\Delta = \frac{m}{20d^2}$.

Proof of Equation (12). Using Claim 3.7, we know that

$$\Pr\left[V = \frac{1}{2m}\right] \geq 5/6.$$

Proof of Equation (14). The largest value of U and V are the largest root of the modified Chebyshev polynomial. Now let us first upper bound the largest value of the roots of the Chebyshev polynomial. The largest value of the roots of Chebyshev polynomial is:

$$\max_{\ell\in[d]} t_\ell = \max_{\ell\in[d]} \frac{1}{\Delta}\left(1 - \cos\left(\frac{2\ell-1}{2d}\pi\right)\right) = \frac{2}{\Delta}\sin^2\left(\frac{\pi}{2}\left(\frac{2d-1}{2d}\right)\right) \leq \frac{2}{\Delta},$$

where the last inequality is obtained via Equation (2). So, the largest value of the roots of the modified Chebyshev polynomial is:

$$\max_{\ell\in[d]} \tilde{t}_\ell = \frac{1}{m}\lceil mt_j\rceil \leq \frac{2}{\Delta} + \frac{1}{m} = \frac{40d^2+1}{m},$$

The last equality follows from the fact that $\Delta = \frac{m}{20d^2}$. Plugging the values of $m = 70(n-1)$ and $d = \sqrt{10}\log(n-1)$, we have the result.

Proof of Equation (15). Recall that the random variable U is supported on the roots 0, $1/m$ and a subset of the roots of the modified Chebyshev polynomial (Equation (18)). Let us start by computing an upper bound on $\mathbb{E}[U]$.

$$\begin{aligned}
\mathbb{E}[U] &\leq \Pr[U=0]\cdot 0 + \Pr[U=\frac{1}{m}]\cdot\frac{1}{m} + \sum_{j=1}^{d}\Pr[U=\tilde{t}_j]\cdot\tilde{t}_j \\
&= \Pr[U=\frac{1}{m}]\cdot\frac{1}{m} + \frac{1}{Z_{\tilde{p}}}\left(\sum_{j=1}^{d}\tilde{t}_j\cdot\frac{1}{|\tilde{p}'(\tilde{t}_j)|}\right) \quad [Z_{\tilde{p}} \text{ is the normalization term, see Equation (23)}] \\
&\leq \frac{1}{m} + \frac{1}{Z_{\tilde{p}}}\left(\sum_{j=1}^{d}\left(t_j+\frac{1}{m}\right)\cdot\frac{\exp\left(\frac{12\Delta}{m/d^2}\right)}{|p'(t_j)|}\right) \qquad \left[\because \tilde{t}_j = \frac{1}{m}\lceil mt_j\rceil \text{ and Equation (26)}\right] \\
&\leq \frac{1}{m} + \frac{1}{Z_{\tilde{p}}}\left(\sum_{j=1}^{d}\left(1+\frac{1}{2}\right)t_j\cdot\frac{\exp\left(\frac{12\Delta}{m/d^2}\right)}{\frac{\Delta}{4}\cdot t_j^3\cdot\frac{d}{\sin\frac{2j-1}{2d}}}\right) \\
&\qquad [\because \text{using the proof of Claim 3.6 (Appendix A.2, full version [12])}] \\
&= \frac{1}{m} + \frac{1}{Z_{\tilde{p}}}\left(\sum_{j=1}^{d}\frac{6\cdot\exp\left(\frac{12\Delta}{m/d^2}\right)}{\Delta\cdot\left(\frac{4}{\Delta^2}\sin^4\left(\frac{\pi}{2}\cdot\frac{2j-1}{2d}\right)\right)\cdot\frac{d}{\sin\frac{2j-1}{2d}}}\right) \qquad [\because t_j = \tfrac{2}{\Delta}\sin^2\left(\tfrac{\pi}{2}\left(\tfrac{2j-1}{2d}\right)\right)] \\
&\leq \frac{1}{m} + \frac{1}{Z_{\tilde{p}}}\left(\sum_{j=1}^{d}\frac{6\cdot\exp\left(\frac{12\Delta}{m/d^2}\right)}{\left(\frac{4}{\Delta}\cdot\left(\frac{2j-1}{2d}\right)^4\right)\cdot\frac{d}{\frac{4}{\pi}\cdot\frac{(2j-1)}{2d}}}\right) \qquad [\because \text{Via Equation (2)}] \\

&\leq \frac{1}{m} + 17\cdot\frac{\exp\left(\frac{12\Delta}{m/d^2}\right)\cdot\Delta d^2}{Z_{\tilde{p}}} \qquad \left[\because \sum_{i=1}^{\infty}\frac{6}{\pi\cdot(i-1/2)^3} \leq 17\right]
\end{aligned}$$

$$= \frac{1}{m} + \frac{17\times 3}{2}\cdot\frac{\exp\left(\frac{12\Delta}{m/d^2}\right)\cdot\Delta d^2}{m^2} \qquad \left[\because Z_{\tilde{p}} \geq \frac{1}{|\tilde{p}'(\frac{1}{2m})|} \geq \frac{2}{3}m^2 \text{ via Equation (23) \& Claim 3.5}\right]$$

$$\leq \frac{7}{2m} = \frac{1}{20(n-1)} \qquad \left[\because \Delta \leq \frac{m}{20d^2} \;\&\; m = 70(n-1)\right]$$

Since Equation (16) holds, as we will prove below, we know that $\mathbb{E}[U] = \mathbb{E}[V]$. This implies that $\mathbb{E}[V] \leq \frac{1}{20(n-1)}$ holds as well.

Proof of Equation (16). We have $\mathbb{E}[U^t] = \mathbb{E}[V^t]$ for $1 \leq t \leq d+1$ from Fact 1.10 and Observation 3.2. ◀

3.2 Putting it together: proof of the $\Omega(m/\log m)$ lower bound

We are now ready to prove the lower bound of m-grainedness testing (Theorem 1.1): we will combine the results from Lemma 3.1, Lemma 1.9 and Theorem 2.1 to show our main $\Omega(m/\log m)$ lower bound in Theorem 1.1.

Proof of Theorem 1.1. Let us fix $n > 20, m = 70(n-1)$, and $s \geq 1$ be a parameter (we will later on set it to $s = \Theta(n/\log n)$). From Lemma 3.1, we know that there exist two discrete random variables U and V with the matching moments properties. Now we will use Lemma 1.9 for sU, sV. Following Lemma 3.1 and Lemma 1.9, we have $\Lambda \leq s \cdot \frac{20\log^2(n-1)}{n-1}$ and $T = 3\cdot\log(n-1)$

$$\mathsf{d}_{\mathsf{TV}}\left(\mathbb{E}[\mathrm{Poi}(sU), \mathbb{E}[\mathrm{Poi}(sV)]]\right) \leq \left(\frac{e\cdot s\cdot\frac{20\log^2(n-1)}{n-1}}{3\cdot\log(n-1)}\right)^{3\cdot\log(n-1)}.$$

And we want to satisfy Equation (5), as all others have been matched to use Theorem 2.1.

$$\left(\frac{e\cdot s\cdot\frac{20\log^2(n-1)}{n-1}}{3\cdot\log(n-1)}\right)^{3\cdot\log(n-1)} \leq \frac{1}{20(n-1)} \Leftrightarrow \frac{e\cdot s\cdot 20\log(n-1)}{3(n-1)} \leq \left(\frac{1}{20(n-1)}\right)^{\frac{1}{3\cdot\log(n-1)}}$$

For $n \geq 21$, we have

$$\frac{e\cdot s\cdot 20\log(n-1)}{3(n-1)} \leq \frac{1}{4} \leq \left(\frac{1}{20(n-1)}\right)^{\frac{1}{3\cdot\log(n-1)}},$$

and thus for $s = \frac{3(n-1)}{80e\log(n-1)}$, we can invoke, and get a sample complexity lower bound in Theorem 1.1, noting that $m = 70(n-1) = \Theta(n)$. Thus

$$\frac{s}{2} = \frac{3(n-1)}{160e\log(n-1)} = \Omega\left(\frac{m}{\log m}\right).$$

This concludes our proof. ◀

4 Uniformity Testing in the DoHo Model

In this section, we prove the following result on parameterized uniformity testing in the DoHO model, improving on the known $\tilde{O}(m)$-query upper bound in the regime $m \geq n^3$.

▶ **Theorem 4.1.** *For any m and constant $\varepsilon > 0$, the property Π_m of distributions over $\{0,1\}^n$ defined as*

$$\Pi_m = \{U_S : S \subseteq \{0,1\}^n, |S| = m\}$$

can be ε-tested in the DoHO model using $s = \mathcal{O}(m^{2/3}/\varepsilon^6)$ samples and $s\cdot n$ queries. Moreover, $\Omega(m^{2/3})$ samples are necessary.

Proof. The algorithm itself is quite simple, and follows from combining existing algorithms for *generalized uniformity* testing in the standard sampling model [5, 17] with an additional "check" of the ℓ_2 norm of the distribution: the tester is described in Algorithm 1. The query complexity follows trivially from the stated sample complexity, as n queries suffice to read the full sample.

Specifically, the algorithm is as follows:

Algorithm 1 Algorithm to test Π_m.

1: Set $\delta \leftarrow 1/6$, and $\alpha = \Theta(\varepsilon)$.
2: Run the adaptive ℓ_2 norm estimator of [5, Lemma 3.1] to obtain an $(1 \pm \varepsilon/10)$ estimate $\hat{\rho}$ of $\|D\|_2^2$ (with error probability δ) using $O(\sqrt{m}/\varepsilon^2)$ samples. If the algorithm does not terminate with this number of samples, or if the estimate is not in $(1 \pm \varepsilon/10)/m$, output reject.
3: Run the generalized uniformity tester of [5] on s (fully queried) samples from D with (TV) distance parameter α and error probability δ. If it rejects, output reject.
4: Output accept.

We now argue correctness. By a union bound, both subroutines behave as they should with overall probability 2/3: we hereafter assume their output is correct.

- *Completeness:* Assume $D \in \Pi_m$. Then $\|D\|_2^2 = \frac{1}{m}$, so $\hat{\rho} \in [\frac{1-\varepsilon/10}{m}, \frac{1+\varepsilon/10}{m}]$ and the first step does not reject. Similarly, $D \in \Pi_U = \bigcup_{k=1}^{\infty} \Pi_k$, so the generalized uniformity tester (which is by definition a tester for Π_U) accepts. Overall, Algorithm 1 returns accept.
- *Soundness:* By contrapositive, suppose Algorithm 1 returns accept. Since the second subroutine did not reject, it must be the case that D is $\frac{\varepsilon}{2}$-close (in total variation distance) to a distribution U_T, uniform on some subset T of a given size k. Moreover, the algorithm of [5] provides the extra guarantee that $(1 - O(\varepsilon))\|D\|_2^2 \leq \frac{1}{k} \leq (1 + O(\varepsilon))\|D\|_2^2$ (see [5, Lemma 3.4]).[1]

  Now, let $U_S \in \Pi_m$ be a closest distribution to D, over all subsets S of size m:

$$\mathsf{d}_{\mathsf{TV}}(D, U_S) \leq \mathsf{d}_{\mathsf{TV}}(D, U_T) + \mathsf{d}_{\mathsf{TV}}(U_T, U_S) \leq \frac{\varepsilon}{2} + 1 - \frac{\min(m,k)}{\max(m,k)}$$

  where the second inequality follows the minimum TV distance between two uniform distributions on supports k and m, which occurs when the supports of the distributions overlap as much as possible, and is equal to $1 - \frac{\min(m,k)}{\max(m,k)}$. In particular, we have $1 - \frac{\min(m,k)}{\max(m,k)} \leq \frac{\varepsilon}{2}$ if

$$\frac{1}{1 - \frac{\varepsilon}{2}} \cdot m \leq k \leq (1 - \tfrac{\varepsilon}{2}) \cdot m$$

  Now, to see why this holds, observe that by our first check, $\|D\|_2^2$ is within a $(1 \pm \frac{\varepsilon}{10})$ factor of $\frac{1}{m}$, and, by the additional guarantee of the [5] tester (adjusting the constant in the setting of α), within a $(1 \pm \frac{\varepsilon}{10})$ factor of $\frac{1}{k}$. This implies that m and k are within a $1 \pm \frac{\varepsilon}{4}$ factor of each other, and thus that $1 - \frac{\min(m,k)}{\max(m,k)} \leq \frac{\varepsilon}{2}$. Overall, this establishes that $\mathsf{d}_{\mathsf{TV}}(D, U_S) \leq \varepsilon$.

Finally, the claimed lower bound follows directly from the lower bound on generalized uniformity testing of [17], which holds even when the target size of the support is given. ◀

[1] This is why we chose to use this specific algorithm, instead of that of [17], which has better sample complexity (with respect to ε) but does not provide this extra guarantee.

5 Conclusion and open problems

In this work, we studied the problem of testing m-grainedness of distributions. We established a new lower bound of $\Omega(m/\log m)$ samples, improving on the previous lower bound of $\Omega(m^c)$ due to [22], thereby settling a conjecture by [22]. Along the way, we also obtained an alternative, simpler proof of the $\Omega(m^c)$ lower bound. By leveraging a reduction between the testing models due to [23], our result implies an optimal lower bound for uniformity testing in the DoHO (Distributions over Huge Objects) model, settling another conjecture of [23]. Finally, we provided a simple tester for uniformity testing in this DoHO model, with improved sample complexity for a large range of the parameters.

Our work leaves open several new avenues of research in this context; we list two of them below:

- **(i)** Our lower bound for m-grainedness testing establishes the optimal dependence on the parameter m, for constant proximity parameter $\varepsilon = \Omega(1)$. It would be interesting to fully characterize the complexity of the question, including the dependence on ε.
- **(ii)** From [23], it is known that testing uniformity over an m-element subset of $\{0,1\}^n$ requires $\Omega(m/\log m)$ queries, for $m \leq n$; and that $\tilde{O}(m)$ queries are sufficient for all m. Our own tester (Theorem 4.1) shows an upper bound of $O(m^{2/3}n)$ queries, better in the regime $m \geq n^3$. This leaves understanding the landscape of parameterized uniformity testing, especially in the intermediate regime $n \ll m \ll n^3$, as an open and intriguing question.

The Randomness Complexity of Differential Privacy

Clément L. Canonne

Abstract

We initiate the study of the *randomness complexity* of differential privacy, i.e., how many random bits an algorithm needs in order to generate accurate differentially private releases. As a test case, we focus on the task of releasing the results of d counting queries, or equivalently all one-way marginals on a d-dimensional dataset with boolean attributes. While standard differentially private mechanisms for this task have randomness complexity that grows linearly with d, we show that, surprisingly, only $\log_2 d + O(1)$ random bits (in expectation) suffice to achieve an error that depends polynomially on d (and is independent of the size n of the dataset), and furthermore this is possible with pure, unbounded differential privacy and privacy-loss parameter $\varepsilon = 1/\operatorname{poly}(d)$. Conversely, we show that at least $\log_2 d - O(1)$ random bits are also necessary for nontrivial accuracy, even with approximate, bounded DP, provided the privacy-loss parameters satisfy $\varepsilon, \delta \leq 1/\operatorname{poly}(d)$. We obtain our results by establishing a close connection between the randomness complexity of differentially private mechanisms and the geometric notion of "deterministic rounding schemes" recently introduced and studied by Vander Woude et al. (2022, 2023).

1 Introduction

Differential privacy [5] is a widely accepted theoretical framework for protecting the privacy of individuals in a database while analysts query the database for statistical information. Differentially private (DP) mechanisms provide quantitative guarantees and tradeoffs on the level of privacy afforded to individuals and the accuracy of answers to queries. In order to provide these guarantees, DP mechanisms rely on the use of carefully calibrated "random noise" to protect privacy. Thus, large-scale deployments of differential privacy can require a

© Clément L. Canonne, Francis E. Su, and Salil P. Vadhan;
licensed under Creative Commons License CC-BY 4.0

massive amount of high-quality random (or cryptographically pseudorandom) bits.[1] Indeed, Garfinkel and LeClerc [7] estimate that the U.S. Census Bureau's differentially private TopDown Algorithm as used for the 2020 Decennial Census required at least 90 terabytes of random bits, and described major engineering challenges in generating those bits with sufficient efficiency and security. As they write in their conclusion,

> *"The need to generate a large number of high-quality random numbers is a largely unrecognized requirement of a production differential privacy system."*

Motivated by these challenges, and following the long line of inquiry in theoretical computer science on the role and necessity of randomness in computation, we initiate the study of the *randomness complexity of differential privacy*:

> What is the minimum amount of randomness required by differentially private mechanisms to achieve a specific level of accuracy?

We will quantify this "minimal amount of randomness" using either the maximum or expected *number of random bits* used by a differentially private algorithm, as a function of the dataset dimensions, privacy-loss parameters, and accuracy. For the sake of concreteness, we focus in this work on a specific task, *summation* (or *one-way marginal*) queries, which asks to provide an estimate of the sum of d-dimensional (binary) vectors, each corresponding to a different individual in the dataset.

In more detail, the task of summation is as follows: the dataset x consists of data from n individuals, each contributing a d-dimensional binary vector x_i. We can think of x as a $n \times d$ matrix with rows $x_1, ..., x_n$. The mechanism $M(x)$ must output an estimate $\hat{x} \in \mathbb{R}^d$ of $\text{sum}(x) := \sum_{i=1}^{n} x_i$, such that $\|\hat{x} - \text{sum}(x)\|_\infty \leq \alpha$ with probability at least $1 - \beta$. We call such a mechanism (α, β)-*accurate*. (See Definition 2.3 for a formal definition.)

We require that the mechanism M also satisfies (ε, δ)-*differential privacy* ((ε, δ)-*DP*) for some parameters $\varepsilon \geq 0, \delta \in [0, 1]$, which means that for every pair of datasets x, x' that differ on one row, we have

$$\forall S \qquad \Pr[M(x) \in S] \leq e^{\varepsilon} \cdot \Pr[M(x') \in S] + \delta.$$

When $\delta = 0$, this is called *pure* differential privacy, and we say that M is ε-*DP*. Our algorithm will work in the so-called *unbounded DP* setting, where the size n of the dataset is private information and thus needs to be protected by differential privacy like any other statistic. In contrast, our lower bound applies to the (easier) bounded DP setting, where n is public and fixed. (See Definitions 2.2 and 2.3 for formal definitions.)

We define the *maximum randomness complexity* $R_0(M)$ of a mechanism $M \colon (\{0,1\}^d)^n \to \mathbb{R}^d$ as the maximum over databases $x \in (\{0,1\}^d)^n$ of the maximum number of random bits used by M on input x. We define the *expected randomness complexity* $R(M)$ of a mechanism $M \colon (\{0,1\}^d)^n \to \mathbb{R}^d$ as the maximum over databases $x \in (\{0,1\}^d)^n$ of the expected number of random bits used by M on input x.

Differentially private summation is a well-studied question, for which many approximately optimal (in terms of accuracy) DP mechanisms have been proposed and analyzed. One of the simplest is the Laplace mechanism, which consists in adding d-dimensional Laplace noise

[1] In this work, we focus on using truly random bits to achieve the standard definition of DP with information-theoretic security. Later in the introduction, we discuss how this relates to the use of pseudorandom bits to implement DP with computational security, as typically done in practice.

with scale parameter d/ε to the true value $\mathrm{sum}(x)$. This can be shown to have ℓ_∞ error $\tilde{O}(d)/\varepsilon$ with high probability, which is optimal up to log factors. (Here $\tilde{O}(f)$ is shorthand for a function that is $O(f \cdot \log^c f)$ for an unspecified constant $c > 0$.) However, this comes at a significant cost, as adding continuous Laplace noise would technically require an infinite number of random bits. Instead, one can choose to add (independent) geometric noise to each coordinate of the true count, using a symmetrized Geometric random variable. This similarly will achieve nearly optimal ℓ_∞ error, but now with a finite expected randomness complexity. Unfortunately, the expected number of random bits required, $\tilde{O}_\varepsilon(d)$, still scales at least linearly with the dimension. (Here the $\tilde{O}_\varepsilon$ means that ε is treated as a constant, on which the hidden constants in the $\tilde{O}$ can depend.)

At first, this linear scaling seems inherent: For $d = 1$, to achieve non-trivial accuracy every DP mechanism must have entropy $\Omega(1)$:

▶ **Lemma 1.1.** *For every $\alpha < n/2$ and $\beta < 1/2$ and every (α, β)-accurate ε-DP mechanism $M\colon \{0,1\}^n \to \mathbb{R}$ for binary counts, there is some database $x \in \{0,1\}^n$ such that $H(M(x)) \geq 1 - \frac{\varepsilon}{2 \ln 2}$.*

Here $H(M(x))$ denotes the Shannon entropy of the output distribution $M(x)$, which is a lower bound on the expected number of random bits used by M. (We provide a simple proof of Lemma 1.1 in the full version.) Given that, in the d-dimensional summation task, the d dimensions are totally independent, one might expect the entropy required to be additive across dimensions, leading to an $\Omega(d)$ lower bound on expected randomness complexity.

Our results

Surprisingly, the above intuition turns out to be false: by leveraging recent work on *deterministic rounding schemes*, we show that the expected randomness complexity can be made as low as $\log_2 d + O(1)$, while still achieving good accuracy (i.e., an error that is polynomial in the dimension d, independent of the size n of the database):

▶ **Theorem 1.2** (Informal; see Corollary 3.2)**.** *For every $\ell > 0$ and $\varepsilon > 0$, there is an ε-DP mechanism $M\colon (\{0,1\}^d)^* \to \mathbb{R}^d$ (in the unbounded DP setting) such that the expected randomness complexity of M satisfies*

$$R(M) \leq \left\lceil \frac{d}{\ell} \right\rceil \cdot \log_2(\ell + 1) + O(1)$$

and for every $\beta \geq 1/\operatorname{poly}(d)$, M is (α, β)-accurate for summation with

$$\alpha = \frac{\tilde{O}(d) \cdot \ell}{\varepsilon}.$$

Taking $\ell = d$ gives expected randomness complexity $\log_2 d + O(1)$ as claimed. Furthermore, with this setting of ℓ and $\varepsilon \geq 1/\operatorname{poly}(d)$, the accuracy is $\alpha = \operatorname{poly}(d)$, independent of n. If we instead take $\ell = 1$, we get near-optimal accuracy $\alpha = \tilde{O}(d)/\varepsilon$, but then the expected randomness complexity becomes $d + O(1)$. Choosing $1 < \ell < d$ provides a tradeoff between these two extremes.

For bounding the *maximum* randomness complexity, we necessarily[2] relax to approximate DP:

[2] If M uses at most r random bits, then for every database x, the support of the distribution $M(x)$ is of size at most 2^r. However, a pure DP algorithm must have the same support on every input database. A summation mechanism with nontrivial accuracy on datasets of size n should at least distinguish the 2^d datasets where all n rows are the same, and thus must have $r \geq d$.

▶ **Theorem 1.3** (Informal; see Corollary 3.4). *For every $\ell > 0$, $\varepsilon > 0$, $\delta \in (0, 1/d)$, there is an (ε, δ)-DP mechanism $M : (\{0,1\}^d)^* \to \mathbb{R}^d$ (in the unbounded DP setting) such that the maximum randomness complexity of M satisfies*

$$R_0(M) \leq \left\lceil \frac{d}{\ell} \right\rceil \cdot \log_2(\ell + 1) + \log_2(1/\delta) + O(1)$$

and for every $\beta \geq 1/\operatorname{poly}(d)$, M is (α, β)-accurate for summation with

$$\alpha = O\left(\frac{\sqrt{d} \cdot \ell \cdot \log(1/\delta)}{\varepsilon} \right).$$

Again, the randomness complexity is minimized at $\ell = d$, which gives $R_0(M) \leq \log_2 d + \log_2(1/\delta) + O(1)$ and $\alpha = O(d^{3/2}) \cdot \log(1/\delta)/\varepsilon$, and the latter is again a factor of $\Theta(d \cdot \sqrt{\log(1/\delta)})$ larger than the error achievable with unlimited randomness. Typically, δ is taken to be cryptographically negligible, so $\delta \leq d^{-\omega(1)}$ and our bound on the maximum randomness complexity becomes $R_0(M) \leq (1 + o(1)) \cdot \log_2(1/\delta)$.

Next, we prove lower bounds showing that the randomness complexity we achieve is nearly optimal (in certain parameter regimes):

▶ **Theorem 1.4** (Informal; see Corollary 4.2). *Suppose that $M : (\{0,1\}^d)^n \to \mathbb{R}^d$ is an (ε, δ)-DP mechanism (in the bounded DP setting) that is (α, β)-accurate for summation, where $\alpha \leq n/2 - 1$. Then the maximum randomness complexity of M satisfies*

$$R_0(M) \geq \min\{d, \log_2(1/\delta)\}.$$

If in addition, $\beta \leq 1/d$, $\varepsilon \leq 1/d$, and $\delta \leq 1/O(d^2)$. Then both the maximum and expected randomness complexities of M satisfy:

$$R_0(M) \geq R(M) \geq \log_2 d - O(1).$$

Let's examine the constraint on the parameters. The constraint on α essentially just requires that M has nontrivial accuracy. Indeed, accuracy $n/2$ on datasets of size n can trivially be achieved by the deterministic mechanism that always outputs $(n/2, n/2, \ldots, n/2) \in \mathbb{R}^d$; this mechanism is $(n/2, 0)$-accurate, 0-DP, and has randomness complexity 0. The constraint on δ is quite mild, since δ is intended to be cryptographically small, and in particular subpolynomial in input size parameters like d and n. The constraints on β and ε are more nontrivial. They match our upper bound, in the sense that Theorem 1.2 achieves expected randomness complexity $\log_2 d + O(1)$ even when $\beta, \varepsilon = 1/d$. However, it would be interesting to know whether even smaller randomness complexity is possible when ε and β are constants.

Connection to geometry

The key ingredient in our results is a two-way connection to the notion of *deterministic rounding schemes* recently introduced and studied by Vander Woude, Dixon, Pavan, Radcliffe, and Vinodchandran [11, 12]. Deterministic rounding schemes provide methods for rounding data in $\mathbb{R}^d$ to nearby points so that any ball of small enough radius rounds to only a small number of points. As discussed in [11, 12], such rounding schemes are equivalent to the geometric notion of a *secluded partition*, which is a partition of $\mathbb{R}^d$ into sets of bounded radius such that balls of a sufficiently small radius do not intersect too many sets of the partition. We tie these ideas to the randomness complexity of accurate DP algorithms. In particular, our $\log_2 d \pm \Theta(1) = \log_2(d + 1) \pm \Theta(1)$ upper and lower bounds on randomness complexity

are intimately tied to the fact that in d dimensions, bounded-radius sets that cover $\mathbb{R}^d$ must contain intersections of at least size $d+1$ at certain points, and it is possible to find covers where no more than $d+1$ sets ever jointly intersect. In the theory of set intersections, these ideas are closely related to KKM covers of bounded polyhedra and the Polytopal Sperner lemma [3], and in fact our initial proofs of our results (not included here) came through these connections.

Related work on replicability

Recent work [4] has studied the randomness complexity of *replicable algorithms* using similar geometric tools. There are bidirectional conversions between replicable algorithms and approximate differentially private algorithms [8, 1] for problems about "population statistics," where the dataset consists of iid samples from an unknown distribution and the goal is to estimate statistics abut the distribution. In contrast, our focus is on "empirical statistics," where there is no iid assumption on the dataset and the goal is to estimate statistics of the dataset itself (as in the motivating use case of the 2020 U.S. Census). One can convert differentially private algorithms for population statistics into ones for empirical statistics (see, e.g., [2]), but this conversion incurs a high cost in randomness complexity (running the DP algorithm for population statistics on a dataset formed by sampling n rows from the input dataset independently with replacement). In the reverse direction, differentially private algorithms for empirical statistics are also automatically differentially private algorithms for population statistics (provided the dataset size n is large enough so that the empirical statistics approximate the population statistics with high probability), but converting a DP algorithm for population statistics into a replicable algorithm also appears to incur a large cost in randomness complexity. Thus neither our upper bound nor our lower bound appear to follow as a black box from the existing results on replicability, but it will be interesting to explore whether the techniques in either setting can be used to improve or extend any of the results in the other.

On using pseudorandom bits

In practice, implementations of differential privacy (including for the 2020 Decennial U.S. Census [7]) do not use truly random bits, but use pseudorandom bits generated by a cryptographically strong pseudorandom generator from a short seed, which is assumed to be truly random (or at least have sufficiently high entropy). If the differentially private algorithms satisfy the standard information-theoretic definition of DP (Definition 2.2) when run with truly random bits, then when executed using cryptographically strong pseudorandom bits, they satisfy a natural and convincing relaxation of differential privacy to computationally bounded adversaries [9]. Although the use of a pseudorandom generator reduces the number of truly random bits needed to equal the seed length of the generator, there is still a substantial cost if the differentially private algorithm is designed to use a huge number of random bits, since we must run the pseudorandom generator enough times to produce all of those bits. This is the cost referred to by Garfinkel and LeClerc [7], and it motivates our focus on the number of truly random bits needed to achieve information-theoretic DP. Furthermore, our Theorem 1.2 shows that we can reduce the expected number of truly random bits to be even smaller than the seed length of a cryptographic pseudorandom generator. Specifically, a cryptographic pseudorandom generator requires seed length at least $\log_2(1/\delta)$, where δ is a bound on the probability with which any computationally bounded adversary can distinguish the pseudorandom bits from uniform. This δ plays an analogous role in computational

differential privacy to the δ in information-theoretic (ε, δ)-DP. Typically, δ is taken to be cryptographically negligible, so $\delta = d^{-\omega(1)}$ and the randomness complexity $\log_2(d+1)+O(1)$ of Theorem 1.2 is asymptotically smaller than $\log_2(1/\delta)$.

Overview of the proofs

The high-level idea of our upper bound (algorithmic result) starts with the following observation: if we could post-process the output of a DP mechanism M to only allow a small number of outcomes on every database without hurting its accuracy too much, then we would be in good shape: for every database x, having $|\mathrm{supp}(M(x))| \leq k$ implies that $H(M(x))$ is at most $\log_2 k$, and so we obtain a new mechanism M' with low entropy but similar accuracy. Now, M' could still have very high randomness complexity $R(M')$ (since M itself could have been using a lot of random bits), but it is a standard fact in information theory (based on Huffman coding) that any discrete random variable Y can be generated using at most $H(Y)+O(1)$ random bits on average. Thus, there is yet another mechanism M'' with randomness complexity at most $\log_2 k + O(1)$.

Unfortunately, if we want to achieve pure DP as in Theorem 1.2, it is too much to hope for bounding the randomness complexity via support size. (See Footnote 2.) Instead, we will ensure that there is a set S_x of size at most k such that $M(x) \in S_x$ with probability at least $1-\gamma$, for a small $\gamma > 0$; we'll take $\gamma = 1/d$. If we can also ensure that the entropy of $M(x)$ conditioned on $M(x) \notin S_x$ is bounded by $O(1/\gamma)$, then this suffices to achieve an overall entropy of at most $\log_2 k + O(1)$.

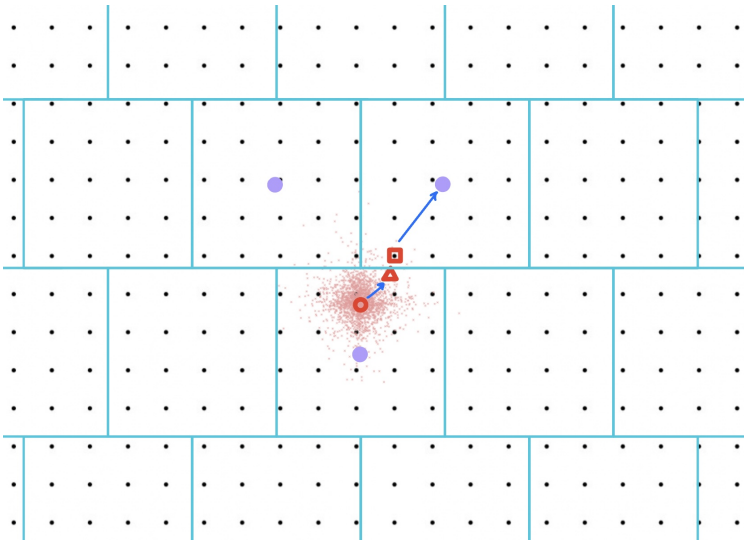

Figure 1 Using a deterministic rounding scheme (the square cells round to their center points) to construct a DP mechanism M for $\mathrm{sum}(x)$ with low randomness complexity. Given a dataset x with $\mathrm{sum}(x)$ at the annular dot, we add Laplace noise (depicted here by the diamond cloud of points). With high probability this lands somewhere nearby (the triangular dot). Next, we round that to the nearest point in a suitably chosen grid (the square dot) – the limited grid options help keep the resulting entropy low. We then use the given deterministic rounding scheme to jump to the center of the cell containing the square dot. This defines a DP mechanism with low entropy, because there are only a small number k (here, $k = 3$) of cell centers that could be in the high probability support of this mechanism applied to x.

To implement the above plan, we start with any accurate ε-DP mechanism M, say one based on the Laplace mechanism. The crucial step is then how to achieve the post-processing step. This we do with a deterministic rounding scheme f. Such a scheme will take the output $M(x)$ and round it to a nearby point $f(M(x))$, say at ℓ_∞ distance at most r from $M(x)$. We choose r to be large enough so that the noise in $M(x)$ will be of magnitude (in ℓ_∞ norm) at most $r \cdot \tau$ with high probability, for a sufficiently small τ. f is called a (k, τ) deterministic rounding scheme of radius r if on every ℓ_∞ ball of radius $r \cdot \tau$, f takes on at most k distinct values. With such a scheme, we get that $f(M(x))$ lies in a set of size k with high probability.

So then the question becomes what parameters (k, τ) are possible, and this is exactly what is addressed in the work of Vander Woude et al. [12]. In particular, they construct a scheme with $k = (d+1)^\ell$ and $\tau = 1/(2\ell)$, which is what we use in Theorem 1.2. As noted above, completing the proof of the theorem requires controlling the entropy of $M(x)$ also conditioned on the event that the noise is large. This we achieve by an additional coarsening of the output of $M(x)$, via a standard rounding of every coordinate to a multiple of $r \cdot \tau/2$, before applying the deterministic rounding scheme f.

For our upper bound on maximum randomness complexity (Theorem 1.3), we apply the same strategy as above to the Gaussian mechanism for differential privacy. In this case, we replace our use of Huffman coding with the fact that if we have a random variable Y that lies in a set S of size at most k with probability at least $1 - \gamma$, then for every $\eta > 0$, using at most $\log_2 k + \log_2(1/\eta) + O(1)$ random bits, we can generate a random variable Y' that is at total variation distance at most $\eta + \gamma$ from Y.

To prove our lower bound of $\log_2 d - O(1)$ (second part of Theorem 1.4) on expected randomness complexity, we show how randomness-efficient DP mechanisms for summation with good accuracy imply the existence of deterministic rounding schemes with good parameters: where the parameters k, τ of the rounding schemes are directly related to the randomness complexity of the DP mechanism M. This allows us to invoke impossibility results from [11, 12] on the existence of "too-good-to-be-true" deterministic rounding schemes to rule out DP mechanisms which are simultaneously accurate and randomness-efficient. In more detail, the main steps of the lower bound are as follows: given a purported ε-DP mechanism M for summation with low randomness complexity, (1) we embed the hypergrid $[n]^d$ into the space of d-dimensional datasets of size n, $(\{0,1\}^d)^n$, such that ℓ_1 distance in the former maps to Hamming distance in the latter and computing summation on a given dataset $x = x^{(v)}$ allows one to retrieve the original hypergrid vector $v \in [n]^d$. (2) We use the randomness guarantees of M to extract, from its output distribution on a given database $x^{(v)}$, the highest-probability representative output $y^{(v)}$, which defines a deterministic rounding scheme f:

$$\underbrace{v \in [n]^d \rightsquigarrow x^{(v)} \overset{M}{\rightsquigarrow} y^{(v)} \in \mathbb{R}^d}_{f}$$

(3) we leverage the accuracy guarantees of M to argue that this rounding y is indeed close to v; and, finally, (4) we invoke the (group) privacy guarantee of M to show that the image of any given ℓ_∞ ball by our newly-defined rounding scheme cannot contain too many "representatives" $y^{(v)}$. There is one last step required, as the rounding scheme f outline above is only defined on $[n]^d$: to conclude, we need to "lift" this rounding scheme to the whole of $\mathbb{R}^d$ while preserving its properties, which we do by a careful tiling of the space $\mathbb{R}^d$ with translations and reflections of the hypergrid.

The lower bound of $\min\{d, \log_2(1/\delta)\}$ on maximum randomness complexity follows from observing that any (ε, δ)-DP mechanism that uses less than $\log_2(1/\delta)$ random bits is ε'-DP for some finite ε', and then we can apply the argument of Footnote 2 to deduce $R_0(M) \geq d$.

Directions for Future Work

We conclude this introduction by mentioning some open questions, and directions for future work.

The first question is whether one can close the gap between our upper and lower bounds. Our upper bounds show that randomness complexity $\log_2 d + O(1)$ can be achieved with accuracy $\alpha = \text{poly}(d)/\varepsilon$, but to achieve near-optimal accuracy $\alpha = \tilde{O}(d)/\varepsilon$, we only achieve randomness complexity $d + O(1)$. Can our algorithm be improved to achieve logarithmic randomness complexity with near-optimal accuracy? Or can our lower bound be improved to show that linear randomness complexity is necessary for near-optimal accuracy? As discussed earlier, another question is to remove some of the constraints on parameters, like ε and β, in our lower bound, or else show that sub-logarithmic randomness complexity is possible when these parameters are constant.

A second question whether one can obtain *efficient* low-randomness DP mechanisms, e.g., running in time $\text{poly}(n, d)$. Recall that our mechanisms from Theorem 1.2 and Theorem 1.3 rely on computationally inefficient procedures (e.g., Huffman coding) to convert a mechanism with low output entropy into one with low randomness complexity. For this reason, as well as the aforementioned accuracy loss, we would not recommend using our mechanisms in practice (even though our work was inspired by the practical concerns raised in [7]). Still, it raises the hope for practical DP mechanisms that are much more randomness-efficient than ones currently used.

As a test case we focused in this paper on the task of differentially private summation: extending our study of the randomness requirement of DP mechanisms to other statistical releases, or attempting to provide a general treatment of the randomness complexity of differential privacy, would be an interesting direction.

Finally, as mentioned earlier, exploring connections to recent work on replicable algorithms may also prove to be fruitful.

2 Preliminaries

2.1 Differential Privacy

Consider a database x consisting of n entries chosen from some domain $\mathcal{X}$: that is, x is an element of $\mathcal{X}^n$. If each entry of the database consists of d numerical attributes, then $\mathcal{X}$ might be $\mathbb{R}^d$ or $\mathbb{N}^d$ (for discrete data) or $\{0,1\}^d$ (for binary data). It is convenient to think of x as an $n \times d$ matrix, with each row of the matrix being the vector $x_i = (x_{ij})_{1 \le j \le d}$. In general, when the size of the database n is unknown, or allowed to grow, we will denote it by $|x|$, and accordingly consider databases in $\mathcal{X}^* = \cup_{n=0}^{\infty} \mathcal{X}^n$.

▶ **Definition 2.1** (Database metrics and adjacency). *For two databases $x, x' \in \mathcal{X}^*$, their* insert-delete distance *(aka LCS distance) $D_{\text{ID}}(x, x')$ is the number of insertions and deletions of elements of $\mathcal{X}$ to transform x into x'. For two databases $x, x' \in \mathcal{X}^*$ such that $|x| = |x'|$, their* Hamming distance *$D_{\text{Ham}}(x, x')$ is the number of rows i such that $x_i \neq x'_i$. If $|x| \neq |x'|$, we define $D_{\text{Ham}}(x, x') = \infty$. For a database metric D, we say that x and x' are* adjacent *with respect to D, denoted $x \sim_D x'$ if $D(x, x') \le 1$.*

We use D_{ID} to capture *unbounded differential privacy*, where the size n of the dataset is unknown and considered private information that needs to be protected. D_{Ham} captures *bounded differential privacy*, where the size n is public information, known to a potential adversary. Since $D_{\text{ID}}(x, x') \le 2 \cdot D_{\text{Ham}}(x, x')$ for databases x, x' of the same size, unbounded-DP algorithms are also bounded DP, up to a factor of 2 in the privacy-loss parameters. We state our positive result in the unbounded-DP setting and our negative result in the bounded-DP setting, making both results stronger.

▶ **Definition 2.2** (Differential privacy). *Fix $\varepsilon > 0$ and $\delta \in [0,1]$. A randomized algorithm $M\colon \mathcal{X}^* \to \mathcal{Y}$ is* (ε,δ)-differentially private *(or (ε,δ)-DP) with respect to database metric D if for every pair of adjacent databases $x \sim_D x'$ in $\mathcal{X}^*$ and every measurable $S \subseteq \mathcal{Y}$, we have*

$$\Pr[M(x) \in S] \leq e^{\varepsilon} \cdot \Pr[M(x') \in S] + \delta.$$

If $\delta = 0$, we simply say M is ε-DP.

We restrict our attention in this article to databases where each record has d binary attributes, so $\mathcal{X} = \{0,1\}^d$, and to mechanisms that output an estimate of the sum of the attributes. This motivates the following definition:

▶ **Definition 2.3** (Accuracy). *Given $\alpha \geq 0$ and $\beta \in [0,1]$, a randomized algorithm $M\colon (\{0,1\}^d)^n \to \mathbb{R}^d$ is said to be* (α,β)-accurate for summation *if for every $x \in (\{0,1\}^d)^*$, we have*

$$\Pr[\|M(x) - \mathrm{sum}(x)\|_\infty > \alpha] \leq \beta,$$

where

$$\mathrm{sum}(x) = \sum_{i=1}^{|x|} x_i \in \mathbb{R}^d.$$

Note that we used $(\{0,1\}^d)^n$ rather than $(\{0,1\}^d)^*$ as the domain of M. This allows for the possibility that, even in the unbounded DP setting, the accuracy of the mechanism depends on the size n of the dataset, as well as the dimension d and the privacy parameters ε and δ.

Two key features of differential privacy are its *immunity to post-processing* and its *group privacy* property:

▶ **Lemma 2.4** (Postprocessing). *Let $M\colon \mathcal{X} \to \mathcal{Y}$ be an (ε,δ)-DP mechanism, and $f\colon \mathcal{Y} \to \mathcal{Z}$ be any (possibly randomized) function. Then $f \circ M$ is (ε,δ)-DP.*

▶ **Lemma 2.5** (Group privacy). *Let $M\colon \mathcal{X} \to \mathcal{Y}$ be an (ε,δ)-DP mechanism with respect to database metric D, and $x, x' \in \mathcal{X}^*$ be two databases at distance $D(x,x') \leq k$. Then, for every measurable $S \subseteq \mathcal{Y}$, we have*

$$\Pr[M(x) \in S] \leq e^{k\varepsilon} \cdot \Pr[M(x') \in S] + k e^{(k-1)\varepsilon}\delta.$$

We refer the reader to, e.g., [6, 10] for more background on differential privacy and the proof of these properties. We also briefly recall the definition and guarantees of two of the standard noise mechanisms used in differential privacy, the Laplace and Gaussian mechanisms:

▶ **Lemma 2.6** (Laplace mechanism; see e.g., [6, Theorems 3.6 and 3.8]). *Suppose $f\colon \mathcal{X}^* \to \mathbb{R}^d$ has ℓ_1 sensitivity $\Delta_1(f)$, that is, $\Delta_1(f) = \max_{x \sim_D x'} \|f(x) - f(x')\|_1$. Then, for every $\varepsilon > 0$, the mechanism $M\colon \mathcal{X}^* \to \mathbb{R}^d$ defined by*

$$M(x) = f(x) + \mathrm{Lap}(\Delta_1(f)/\varepsilon)^d$$

is ε-DP, where $\mathrm{Lap}(b)^d$ denotes the product distribution over $\mathbb{R}^d$ with iid marginals distributed as a Laplace with scale parameter $b > 0$ (i.e., probability density function $f(x) = \frac{1}{2b}e^{-|x|/b}$). Moreover, its accuracy satisfies the following: for every $\beta \in (0,1]$,

$$\Pr\left[\|M(x) - f(x)\|_\infty \geq \frac{\Delta_1(f)}{\varepsilon} \ln \frac{d}{\beta}\right] \leq \beta\,.$$

▶ **Lemma 2.7** (Gaussian mechanism; see e.g., [6, Theorems 3.22 and A.1]). *Suppose $f\colon \mathcal{X}^* \to \mathbb{R}^d$ has ℓ_2 sensitivity $\Delta_2(f)$, that is, $\Delta_2(f) = \max_{x \sim_D x'} \|f(x) - f(x')\|_2$. Then, for every $\varepsilon \in (0,1]$ and $\delta \in (0,1]$, the mechanism $M\colon \mathcal{X}^* \to \mathbb{R}^d$ defined by*

$$M(x) = f(x) + \mathcal{N}\left(0, \left(\frac{\Delta_2(f)}{\varepsilon} \cdot \sqrt{2 \ln \frac{1.25}{\delta}}\right)^2\right)^d$$

is (ε, δ)-DP, where $\mathcal{N}(0, \sigma^2)^d$ denotes the product distribution over $\mathbb{R}^d$ with iid marginals distributed as a Normal distribution with mean 0 and variance σ^2. Moreover, its accuracy satisfies the following: for every $\beta \in (0,1]$,

$$\Pr\left[\|M(x) - f(x)\|_\infty \geq \frac{\Delta_2(f)}{\varepsilon} \cdot 2\sqrt{\ln \frac{1.25}{\delta} \cdot \ln \frac{2d}{\beta}}\right] \leq \beta\,.$$

2.2 Randomness Complexity

We work with a model of randomized algorithms where the algorithm has access to a coin-tossing oracle that returns an independent, unbiased random bit on each invocation. The *number of random bits* used by M on a particular execution is defined to be the number of the calls to the coin-tossing oracle (which is a random variable, as the algorithm could adaptively decide whether to call the oracle again or not depending on the results of prior coin tosses). We require that on all inputs, the algorithm halts with probability 1 over the coin tosses received.

We define below two natural measures of randomness complexity. Like with accuracy, we will use $\mathcal{X}^n$ as the domain rather than $\mathcal{X}^*$ to allow the possibility that the randomness complexity depends on the size n of the dataset.

▶ **Definition 2.8** (randomness complexity). *For a randomized algorithm $M\colon \mathcal{X}^n \to \mathcal{Y}$ and $\gamma \in [0,1]$, we define:*

- *$R(M)$ = the maximum over $x \in \mathcal{X}^n$ of the expected number of random bits used by M on input x, where the expectation is taken over the coin tosses of M.*
- *$R_0(M)$: the maximum over x of the maximum number of random bits used by M on input x.*

Rather than work directly with randomness complexity, it is more convenient for us to work with measures of *output entropy*:

▶ **Definition 2.9.** *For a randomized algorithm $M\colon \mathcal{X}^n \to \mathcal{Y}$, we define*

- *$H(M) = \max_x H(M(x))$, where $H(Y)$ denotes the Shannon entropy of random variable Y (in bits), defined as $\mathbb{E}_{y \leftarrow Y}[\log_2(1/\Pr[Y=y])]$.*
- *$H_\infty(M) = \max_x H_\infty(M(x))$, where $H_\infty(Y)$ denotes the min-entropy of random variable Y, defined as $\log_2[1/(\max_y \Pr[Y=y])]$.*
- *$H_0(M) = \max_x H_0(M(x))$, where $H_0(Y)$ denotes the max-entropy of random variable Y, defined as $\log_2 |\mathrm{supp}(Y)|$.*
- *$H_0^\gamma(M) = \max_x H_0^\gamma(M(x))$, where $H_0^\gamma(Y)$ denotes the γ-smoothed max-entropy of random variable Y, which is defined to be the minimum of $H_0(Y \mid E)$ over (probabilistic) events $E = E(Y)$ of probability at least $1-\gamma$.*

Some basic relations between the randomness complexity measures and the output entropy measures are as follows:

▶ **Lemma 2.10.** *For any randomized algorithm $M\colon \mathcal{X}^n \to \mathcal{Y}$, the following hold:*

1. $H_\infty(M) \le H(M) \le H_0(M)$, $H_0^\gamma(M) \le H_0(M)$, $R(M) \le R_0(M)$.
2. $H(M) \le R(M)$ *and* $H_0(M) \le R_0(M)$.
3. *For every M, there is an M' such that $R(M') \le H(M) + O(1)$ and on every input x, $M'(x)$ is identically distributed to x'.*
4. *For every M and $\gamma, \eta > 0$, there is an M' such that $R_0(M') \le \lceil H_0^\gamma(M) + \log_2(1/\eta)\rceil$ and for every x, $M'(x)$ is at total variation distance at most $\gamma + \eta$ from $M(x)$.*

In particular, Item 2 says that a lower bound on output entropy is also a lower bound on randomness complexity. Items 3 and 4 say that we can go in the other direction as well, by modifying the mechanism.

2.3 Deterministic Rounding Schemes and Secluded Partitions

A crucial building block for our results is the notion of *deterministic rounding scheme*, recently introduced by Vander Woude, Dixon, Pavan, Radcliffe, and Vinodchandran [12]. Although they defined such a scheme as a function $f : \mathbb{R}^d \to \mathbb{R}^d$, we generalize their definition slightly to include functions $f : S \to \mathbb{R}^d$ on an arbitrary domain S and a radius parameter ρ that becomes necessary when S is not all of $\mathbb{R}^d$:

▶ **Definition 2.11.** *For $k \in \mathbb{N}$, $\rho, \tau \in \mathbb{R}^{\ge 0}$, and $S \subseteq \mathbb{R}^d$, a function $f : S \to \mathbb{R}^d$ is said to be a (k, τ)*-deterministic rounding scheme of radius ρ on S *if the following two conditions hold:*

1. *for all $z \in S$, $\|f(z) - z\|_\infty \le \rho$;*
2. *for all $z \in \mathbb{R}^d$, $|\{\, f(y) : y \in B_\infty(z, 2\tau \cdot \rho) \cap S \,\}| \le k$.*

where $B_\infty(z, r)$ denotes the closed ℓ_∞ ball of radius r centered at z. That is, each f "rounds" inputs to nearby points (within ρ), and inputs that are close (in a $2\tau \cdot \rho$-ball) can only be rounded to a small number k of representatives.

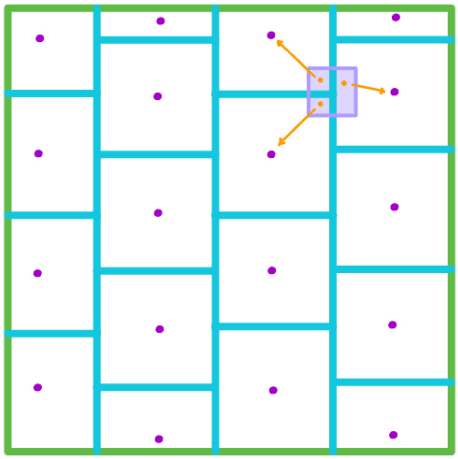

Figure 2 A (k, τ)-deterministic rounding scheme of radius $\rho \approx 0.14$ on $S = [0, 1]^2$, where $k = 3$ and $\tau = \frac{1}{4}$. Points in each cell round to one point inside that cell, never moving more than ρ in ℓ_∞-distance. The shaded box is a ℓ_∞ ball of radius $2\tau \cdot \rho$, and all balls of this size will round to at most $k = 3$ points.

When $S = \mathbb{R}^d$, the parameter ρ is not important; if f is a (k, τ) deterministic rounding scheme of radius ρ, then for every $c > 0$, we see that $f'(x) = cf(x/c)$ is a (k, τ) deterministic rounding scheme of radius $c\rho$. When ρ is not specified, its default value is $\rho = 1/2$, matching

the radius of "round-to-the-nearest-integer." However, we will also consider deterministic rounding schemes on $S = [0,1]^d$; then the choice of ρ is more important. Indeed, $[0,1]^d$ has a trivial $(1,\infty)$-deterministic rounding scheme of radius $1/2$, where all points get rounded to the center of $[0,1]^d$, but it has no $(1,\infty)$-deterministic rounding scheme of radius $1/4$.

As pointed out by Vander Woude et al. [12, Observation 1.3], deterministic rounding schemes have a nice geometric interpretation as (k,τ)-*secluded partitions*: partitions of S by sets of ℓ_∞ radius at most ρ such that every ℓ_∞ ball of radius $2\tau \cdot \rho$ intersects at most k sets in the partition. Using this geometric perspective, Vander Woude et al. prove the following upper and lower bounds:

▶ **Theorem 2.12** ([11, 12]). *For every $d \in \mathbb{N}$, there exists a $(d+1, \frac{1}{2d})$-deterministic rounding scheme $f : \mathbb{R}^d \to \mathbb{R}^d$. More generally, for every $\ell \in \mathbb{N}$, there exists a $((\ell+1)^{\lceil d/\ell \rceil}, \frac{1}{2\ell})$-deterministic rounding scheme $f : \mathbb{R}^d \to \mathbb{R}^d$.*

▶ **Theorem 2.13** ([11, 12]). *If $f : \mathbb{R}^d \to \mathbb{R}^d$ is a (k,τ)-deterministic rounding scheme and $\tau > 0$, then*

$$k \geq \max\{d+1, (1+2\tau)^d\}.$$

3 Upper bounds for summation

In this section, we establish our upper bound results, which state that good deterministic rounding schemes imply differentially private mechanisms for summation with low randomness complexity (Theorem 3.1).

We begin with our upper bound on expected randomness complexity.

▶ **Theorem 3.1.** *Suppose there exists a (k,τ)-deterministic rounding scheme $f : \mathbb{R}^d \to \mathbb{R}^d$. Then for every $\varepsilon > 0$, there is a mechanism $M : (\{0,1\}^d)^* \to \mathbb{R}^d$ that is ε-DP with respect to D_{ID} satisfying*

$$\begin{aligned} H_0^{1/d}(M) &\leq \log_2 k \qquad \text{and} \\ H(M) &\leq \log_2 k + O(1), \end{aligned}$$

such that, for every $\beta \in (0,1]$, M is (α,β)-accurate for summation for

$$\alpha = O\left(\frac{d \cdot \log(d/\beta)}{\varepsilon} + \frac{d \cdot \log d}{\tau\varepsilon}\right).$$

Combining this with Theorem 2.12 and the conversion from output entropy to randomness complexity (Lemma 2.10, Item 3), we get:

▶ **Corollary 3.2.** *For every $d, \ell, \varepsilon > 0$, there is a mechanism $M : (\{0,1\}^d)^* \to \mathbb{R}^d$ that is ε-DP with respect to D_{ID} satisfying*

$$R(M) \leq \left\lceil \frac{d}{\ell} \right\rceil \cdot \log_2(\ell+1) + O(1),$$

such that, for every $\beta \in (0,1]$, M is (α,β)-accurate for summation for

$$\alpha = O\left(\frac{d \cdot \log(d/\beta)}{\varepsilon} + \frac{\ell \cdot d \cdot \log d}{\varepsilon}\right).$$

In particular, taking $\ell = d$, we obtain $H(M) \leq \log_2 d + O(1)$ and

$$\alpha = O\left(\frac{d \cdot \log(d/\beta)}{\varepsilon} + \frac{d^2 \cdot \log d}{\varepsilon}\right).$$

Proof of Theorem 3.1. Let $f\colon \mathbb{R}^d \to \mathbb{R}^d$ be a (k,τ)-deterministic rounding scheme. Without loss of generality, by scaling, we can assume that f has radius $r/2$, for a parameter $r > 0$ to be determined later in the proof. Then we have that for every $z \in \mathbb{R}^d$,

1. $\|f(z) - z\|_\infty \le r/2$, and
2. $|\{\ f(y) :\ y \in B_\infty(z, r\cdot\tau)\ \}| \le k$.

Now define this mechanism M on a database x:

Mechanism $M(x)$.

1. Draw $\eta \sim \mathrm{Lap}(d/\varepsilon)^d$, and let $y = \mathrm{round}_{r\cdot\tau}(\mathrm{sum}(x) + \eta)$,[3]
2. Output $f(y)$.

By the post-processing property of differential privacy and the ε-DP guarantees of the Laplace mechanism, M is itself ε-DP: it remains to argue about its accuracy and randomness complexity. By the accuracy of the Laplace mechanism (Lemma 2.6), we have that, with probability at least $1-\beta$, the noise infusion introduces an error of at most

$$\|\eta\|_\infty \le \frac{\ln(d/\beta)\cdot d}{\varepsilon}.$$

Rounding the coordinates of $\mathrm{sum}(x) + \eta$ to the nearest multiple of $r\cdot\tau$ and replacing y with $f(y)$ increase the ℓ_∞ error by at most $r\cdot\tau/2 + r/2$, so we have (α,β)-accuracy for

$$\alpha = (1+\tau)\cdot\frac{r}{2} + \frac{\ln(d/\beta)\cdot d}{\varepsilon}.$$

For the randomness complexity, by the same analysis as in the accuracy above (but replacing β with $1/d$), we have that with probability at least $1 - 1/d$, the following event E holds:

$$\text{event } E : \|\eta\|_\infty \le r_0 \text{ for } r_0 := \frac{2d\ln d}{\varepsilon}.$$

Conditioned on E, the point y lies in an ℓ_∞ ball of radius $r_0 + r\cdot\tau/2$ around $\mathrm{sum}(x)$. By setting $r = 2r_0/\tau$, y lies in a ball of radius $2r_0 = r\cdot\tau$, and the fact that f is a (k,τ) deterministic rounding scheme of radius r tell us that, conditioned on E, the support size of $M(x)$ is at most k, and in particular has entropy at most $\log_2 k$. Thus, we have $H_0^{1/d}(M(x)) \le \log_2 k$.

To bound $H(M(x))$ overall, we also need to bound the entropy of $M(x)$ conditioned on $\neg E$, which is upper bounded by the entropy of $y = \mathrm{round}_{r\cdot\tau}(\mathrm{sum}(x) + \eta)$ conditioned on $\neg E$. $\neg E$ is the event that at least one coordinate of η has magnitude larger than r_0; the remainder may or may not have magnitude larger than r_0. Conditional on $\neg E$, coordinate i of y is distributed as $\mathrm{round}_{r\cdot\tau}(\mathrm{sum}(x)_i + \eta_i)$, where η_i is a mixture of $\mathrm{Lap}(d/\varepsilon)$ conditioned on having magnitude at most r_0 and $\mathrm{Lap}(d/\varepsilon)$ conditioned on having magnitude greater than r_0. Provided that $r\cdot\tau/2 = \Omega(d/\varepsilon)$, such a distribution has entropy $O(1)$, similarly to how a geometric distribution with parameter $p = \Omega(1)$ has entropy $H(p)/p = O(1)$.[4] By

[3] Note that the distribution of y is *not* the same as applying the Geometric Mechanism (i.e. Discrete Laplace Mechanism) supported on integer multiples of $r\cdot\tau$. To apply the Geometric Mechanism, we would need to first round $\mathrm{sum}(x)$ to a multiple of $r\cdot\tau$, which would substantially increase the sensitivity and increase the amount of noise we need to add. We could apply the Geometric Mechanism to $\mathrm{sum}(x)$ instead of the Laplace Mechanism prior to the rounding step, but it does not simplify anything in the analysis below.

[4] For a bit more detail: observe that, before conditioning, the distribution of $\mathrm{round}_{r\cdot\tau}(\mathrm{sum}(x)_i + \eta_i)$ is a mixture of a point mass and two geometric distributions: a point mass on $m = \mathrm{round}_{r\cdot\tau}(\mathrm{sum}(x)_i)$, a geometric distribution on the multiples of $r\cdot\tau/2$ smaller than m (assuming wlog that $m < \mathrm{sum}(x)_i$), and a geometric distribution supported on the multiples of $r\cdot\tau/2$ greater than or equal to $\mathrm{sum}(x)_i$.

our setting of r above, $r \cdot \tau/2$ is larger than d/ε by a factor of $2\ln(d) = \Omega(1)$. With $O(1)$ entropy contributed from each coordinate, we get $O(d)$ entropy overall conditioned on $\neg E$. (The coordinates of y are not independent conditioned on $\neg E$, but entropy is subadditive even for dependent random variables.)

Thus, letting I be the indicator random variable for event E, we have

$$\begin{aligned} H(M(x)) &\leq H(M(x), I) \\ &= H(M(x) \mid I) + H(I) \\ &\leq \Pr[E] \cdot H(M(x) \mid E) + \Pr[\neg E] \cdot H(M(x) \mid \neg E) + H\left(\frac{1}{d}\right) \\ &\leq 1 \cdot \log_2 k + \frac{1}{d} \cdot O(d) + 1 \\ &= \log_2 k + O(1). \end{aligned}$$

The accuracy bound follows by plugging our setting for r_0 and $r = 2r_0/\tau$ into the expression for α above. ◀

Now we turn to our upper bound on maximum randomness complexity.

▶ **Theorem 3.3.** *Suppose there exists a (k, τ)-deterministic rounding scheme $f\colon \mathbb{R}^d \to \mathbb{R}^d$. Then for every $\varepsilon > 0$, there is a mechanism $M\colon (\{0,1\}^d)^* \to \mathbb{R}^d$ that is (ε, δ)-DP with respect to D_{ID} satisfying $H_0^\gamma(M) \leq \log_2 k$ and such that, for every $\beta \in (0, 1]$, M is (α, β)-accurate for summation for*

$$\alpha = O\left(\frac{\sqrt{d \cdot \log(1/\delta) \cdot \log(d/\beta)}}{\varepsilon} + \frac{\sqrt{d \cdot \log(1/\delta) \cdot \log(d/\gamma)}}{\tau\varepsilon}\right).$$

Combining this with Theorem 2.12 and the conversion from output entropy to randomness complexity (Lemma 2.10, Item 4), we get:

▶ **Corollary 3.4.** *For every $d, \ell \in \mathbb{N}$, $\varepsilon > 0$ and $\delta \in (0, 1/d)$, there is a mechanism $M\colon (\{0,1\}^d)^* \to \mathbb{R}^d$ that is (ε, δ)-DP with respect to D_{ID} satisfying*

$$R_0(M) \leq \left\lceil \frac{d}{\ell} \right\rceil \cdot \log_2(\ell + 1) + \log_2\left(\frac{1}{\delta}\right) + O(1),$$

such that, for every $\beta \in (0, 1]$, M is (α, β)-accurate for summation for

$$\alpha = O\left(\frac{\sqrt{d \cdot \log(1/\delta) \cdot \log(d/\beta)}}{\varepsilon} + \frac{\ell \cdot \sqrt{d} \cdot \log(1/\delta)}{\varepsilon}\right).$$

In particular, taking $\ell = d$, we obtain $R_0(M) \leq \log_2 d + \log_2(1/\delta) + O(1)$ and

$$\alpha = O\left(\frac{\sqrt{d \cdot \log(1/\delta) \cdot \log(d/\beta)}}{\varepsilon} + \frac{d^{3/2} \cdot \log(1/\delta)}{\varepsilon}\right).$$

Proof Sketch of Theorem 3.3. Follow the proof of Theorem 3.1 but replace the use of the Laplace mechanism (Lemma 2.6) with the Gaussian mechanism (Lemma 2.7), and define the event E using the accuracy bound r_0 that holds with probability at least $1 - \gamma$ (rather than $1 - 1/d$). In this proof, there is no need to analyze $H(M(x)|\neg E)$. ◀

Under the assumption that $r \cdot \tau = \Omega(d/\varepsilon)$, the parameter p of these geometric distributions is bounded away from 1, i.e., the probability mass of each point in the support is a constant factor smaller than the point in the support closer to m. This latter property is preserved under conditioning on $|\eta_i| \leq r_0$ or conditioning on $|\eta_i| > r_0$, and suffices to ensure entropy $O(1)$.

4 Lower bound for summation

We now turn to establishing a lower bound on the randomness complexity of any accurate DP mechanism for summation. To strengthen the result, we will consider the bounded DP setting and allow approximate DP mechanisms; and our conclusion will yield a lower bound on the min-entropy $H_\infty(M)$ of any such DP mechanism.

▶ **Theorem 4.1.** *Suppose that $M\colon (\{0,1\}^d)^n \to \mathbb{R}^d$ is a mechanism that is a (ε,δ)-DP mechanism with respect to D_{Ham} with $H_\infty(M) \le \log_2 K$ that is (α,β)-accurate for summation for $\beta < 1/K$ and $\alpha \le n/2-1$. Then, for every $\tau > 0$, there exists a (k,τ)-deterministic rounding scheme with*

$$k \le \frac{K \cdot e^{\varepsilon h}}{1 - hKe^{\varepsilon h}\delta}$$

where

$$h = \min\left(d \cdot \left(8(\alpha+1)\cdot\frac{\tau}{1-2\tau}+1\right), n\right).$$

Observe that when we take $\tau \to 0$, we have $h \to \min\{d,n\} \le d$, so, at least when $\delta = 0$ our upper bound on k becomes $k \le K \cdot e^{\varepsilon d}$. By the lower bound on deterministic rounding schemes (Theorem 2.13), we know that $k \ge d+1$, so we obtain an entropy lower bound of $H_\infty(M) = \log_2 K \ge \log_2(d+1) - O(\varepsilon d)$. When $\varepsilon = O(1/d)$, this matches our best upper bound on randomness complexity up to an additive constant (the case $\ell = d$ in Corollary 3.2). For positive δ, we only lose an additive constant in the lower bound provided that $\delta \le 1/(2dKe^{\varepsilon d})$. Using the fact that $H_\infty(M) \le H(M) \le R(M)$, we obtain:

▶ **Corollary 4.2.** *Suppose that $M\colon (\{0,1\}^d)^n \to \mathbb{R}^d$ is a mechanism that is (ε,δ)-DP mechanism with respect to D_{Ham} with $\alpha \le n/2-1$, $\varepsilon \le 1/d$, $\beta < 1/d$, and $\delta \le 1/(6d^2)$. Then*

$$R(M) \ge \log_2 d - O(1).$$

(The conditions involving K in Theorem 4.1 disappear by doing a case analysis. If $H_\infty(M) > \log_2 d$, then we are done. Otherwise, we can set $K = d$ in Theorem 4.1.)

We will prove Theorem 4.1 by first constructing a deterministic rounding scheme for the cube $[0,1]^d$ and then lifting it to a deterministic rounding scheme for all of $\mathbb{R}^d$ by the following lemma (whose proof we defer to later).

▶ **Lemma 4.3.** *Suppose there exists a (k,τ)-deterministic rounding scheme $f\colon [0,1]^d \to \mathbb{R}^d$ of radius $\rho < 1/2$, where $\tau \in (0,1)$. Then there exists a (k,ζ)-deterministic rounding scheme $\tilde{f}\colon \mathbb{R}^d \to \mathbb{R}^d$, for $\zeta = \max\{\frac{\tau}{4-2\tau}, \frac{\tau}{2+4\rho}\}$.*

Proof of Theorem 4.1. By Lemma 4.3, it suffices to to construct a (k,τ')-deterministic rounding scheme $f\colon [0,1]^d \to \mathbb{R}^d$ of radius $\rho < 1/2$ with $\tau' = 4\tau/(1+2\tau)$ or $\tau' = \tau(2+4\rho)$.

Let $G = \{0,1,2,\dots,n\}^d$ be the d-dimensional hypergrid: we identify each point $v \in G$ of the grid with a dataset $x^{(v)} \in (\{0,1\}^d)^n$ in the following fashion. For row $i \in [n]$ and column $j \in [d]$, we have

$$x^{(v)}_{ij} = \mathbb{1}_{\{v_j \ge i\}},$$

where $\mathbb{1}$ denotes the indicator function. That is, if $v = (v_1,\dots,v_d)$, then $x^{(v)}$ is an $n \times d$ matrix where in each column j, the first v_j entries are ones and any remaining entries are zeroes. It follows that $\mathrm{sum}(x^{(v)}) = v$, and if u, v are at ℓ_1 distance at most a, then $x^{(u)}$ and $x^{(v)}$ are at distance at most a from each other as datasets: $D_{\mathrm{Ham}}(x^{(u)}, x^{(v)}) \le \|u - v\|_1$.

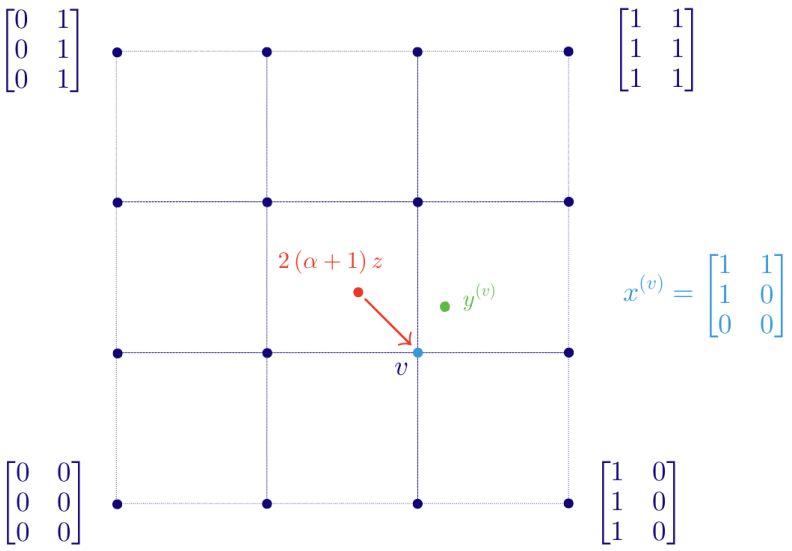

Figure 3 The hypergrid G for $d = 2$ and $n = 3$. Each integer point $v \in G = \{0, 1, 2, 3\}^2$ corresponds to a dataset $x^{(v)}$ (a 3×2 matrix) with the property that $\text{sum}(x^{(v)}) = v$ (the column sums of the matrix at v is just v). The figure shows how a point $z \in [0, 1]^2$, scaled by $2(\alpha + 1)$, is rounded to the nearest v, here $(2, 1)$. The given summation mechanism M takes $x^{(v)}$ to a nearby point $y^{(v)}$. Not shown: this grid is then scaled back down to yield the desired deterministic rounding scheme on $[0, 1]^2$.

Since $H_\infty(M) \le \log_2 K$, for every $v \in G$, there is some output $y^{(v)} \in \mathbb{R}^d$ such that $\Pr[M(x^{(v)}) = y^{(v)}] \ge 1/K$. (If there are several such outputs, choose the lexicographically largest.)

Now we construct our function $f\colon [0, 1]^d \to \mathbb{R}^d$ as follows. For every $z \in [0, 1]^d$, let $v = v(z)$ be a point in G obtained by rounding all coordinates of $2(\alpha + 1) \cdot z$ to the nearest integer (and rounding up if halfway between integers). The resulting v is in G because $2(\alpha + 1) \le n$, and by construction v is at ℓ_∞ distance at most $1/2$ from $2(\alpha + 1) \cdot z$. Then $y^{(v)}$ exists as noted above. See Figure 3. Set

$$f(z) = y^{(v)}/(2\alpha + 2).$$

To show that f is a deterministic rounding scheme, we analyze the two properties separately.

- To show that $\|f(z) - z\|_\infty \le \rho < 1/2$, we use the accuracy of the mechanism. Fix any $z \in [0, 1]^d$: by construction, $2(\alpha + 1) \cdot z$ and $v = v(z)$ are at ℓ_∞ distance at most $1/2$. Recall that we have

  $$\Pr[\|M(x^{(v)}) - \text{sum}(x^{(v)})\|_\infty > \alpha] \le \beta,$$

  and

  $$\Pr[M(x^{(v)}) = y^{(v)}] \ge \frac{1}{K}.$$

  Since $\beta < 1/K$, the outcome of $M(x^{(v)})$ has probability at most $1/K$ of being farther than α from $\text{sum}(x^{(v)})$. Since the particular outcome $y^{(v)}$ has probability greater than $1/K$, then $y^{(v)}$ must be at ℓ_∞ distance at most α from $\text{sum}(x^{(v)}) = v$, and hence at ℓ_∞ distance at most $\alpha + 1/2$ from $2(\alpha + 1) \cdot z$. Hence, $f(z) = y^{(v)}/(2\alpha + 2)$ is at ℓ_∞ distance at most $\rho = \frac{1}{2\alpha+2} \cdot \frac{2\alpha+1}{2} < \frac{1}{2}$ from z.

- For the second, we use the privacy guarantee of the mechanism: consider a closed ℓ_∞ ball $B(w, \tau')$ and points $z_1, \ldots, z_k \in B(w, \tau')$ such that there are k distinct outputs $f(z_1), \ldots, f(z_k)$. Let $v_1, \ldots, v_k$ be the corresponding gridpoints, i.e., $v_i = v(z_i)$. Recall that $f(z_i) = y^{(v_i)}/(2\alpha + 2)$, so the $y^{(v_i)}$'s are all distinct.
  Since $z_1, \ldots, z_k$ are all in $B(w, \tau')$, the gridpoints $v_1, \ldots, v_k$ are all at ℓ_∞ distance at most $2(\alpha+1)\tau' + 1/2$ from $2(\alpha+1)w$, which is itself at ℓ_∞ distance at most $1/2$ from some gridpoint v_0. In particular, each v_i is at ℓ_1 distance at most $d \cdot (2(\alpha+1)\tau' + 1)$ from v_0, so the dataset $x^{(v_i)}$ is at distance at most h from $x^{(v_0)}$ in Hamming distance, for

  $$h = \min(d \cdot (2(\alpha+1)\tau' + 1), n).$$

  By (group) differential privacy, for each $1 \le i \le k$, we have

  $$\Pr[M(x^{(v_0)}) = y^{(v_i)}] \ge e^{-\varepsilon \cdot h} \cdot \Pr[M(x^{(v_i)}) = y^{(v_i)}] - he^{(h-1)\varepsilon}\delta \ge e^{-\varepsilon \cdot h} \cdot \frac{1}{K} - he^{-\varepsilon}\delta.$$

  Summing over $1 \le i \le k$, we get

  $$1 \ge \sum_{i=1}^{k} \Pr[M(x^{(v_0)}) = y^{(v_i)}] \ge e^{-\varepsilon \cdot h} \cdot \frac{k}{K} - khe^{-\varepsilon}\delta.$$

  Reorganizing and upper bounding $e^{-\varepsilon} \le 1$, we have

  $$k \le \frac{K \cdot e^{\varepsilon h}}{1 - hKe^{h\varepsilon}\delta}$$

  as desired.

As mentioned earlier, all that remains is to invoke Lemma 4.3 to lift our deterministic rounding scheme from $[0,1]^d$ to the whole of $\mathbb{R}^d$. ◀

It only remains to establish Lemma 4.3.

Proof of Lemma 4.3. Fix a (k, τ)-deterministic rounding scheme $f\colon [0,1]^d \to \mathbb{R}^d$ of radius $\rho < 1/2$, with $\tau < 1$. Although the image of f might extend to points outside $[0,1]^d$ by ℓ_∞-distance $\rho < 1/2$, we may assume without loss of generality that the image of f is contained in $[0,1]^d$ because projecting the outputs of f to the nearest point in $[0,1]^d$ preserves both properties of a deterministic rounding scheme.

We first modify f so that it behaves nicely near the faces of the cube to get a rounding scheme f', then we show how to extend that to all of $\mathbb{R}^d$ to get the desired rounding scheme f''.

We define $f'\colon [0,1]^d \to [0,1]^d$ by the following process, which is also illustrated in Figure 4.

1. Given $x \in [0,1]^d$, for each $i \in [d]$, set

   $$x'_i = \begin{cases} 0 & \text{if } x_i \le \tau/2 \\ 1 & \text{if } x_i \ge 1 - \tau/2 \\ x_i & \text{otherwise.} \end{cases}$$

   That is, if x is in a "moat" of width $\tau/2$, then it is $\tau/2$-close to one (or possibly several) face(s) of the cube and x' is the projection of x onto (the intersection of) the face(s). Otherwise, set $x' = x$. Note that x' is well-defined by our assumption that $\tau < 1$.

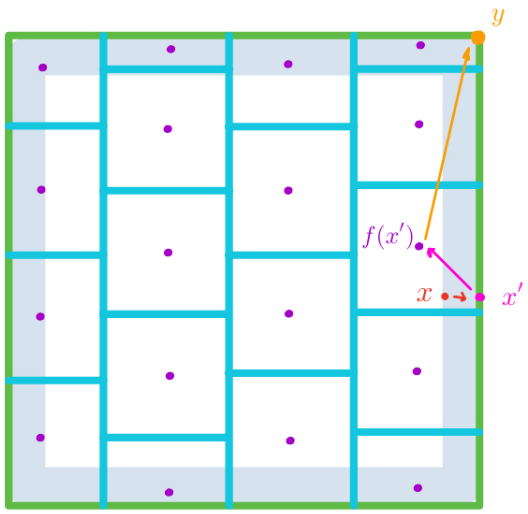

Figure 4 The trajectory of a point in $[0,1]^2$ as it moves from x to x' to $f(x')$ to y. This composition defines the rounding scheme f' on $[0,1]^2$, given any rounding scheme f on $[0,1]^2$. In the case shown, f rounds points in each cell to a point inside. The shaded area is a "moat" of thickness $\tau/2$ where points get projected onto the boundary (and are otherwise not moved) before applying f. The final step is rounding to a corner of $[0,1]^2$.

2. For each $i \in [d]$, set

$$y_i = \begin{cases} 0 & \text{if } 0 \le f(x')_i < \frac{1}{2} \\ 1 & \text{if } \frac{1}{2} \le f(x')_i \le 1. \end{cases}$$

   (Recall that we can assume without loss of generality that the image of f is in $[0,1]^d$.) That is, we round $f(x')$ to the nearest corner of the cube.
3. Set $f'(x) := (y_1, \ldots, y_d) \in \mathbb{R}^d$.

To understand the radius of f', consider Figure 4. The first step from x to x' is bounded (in ℓ_∞ distance) by $\tau/2$ (and is zero if x is not in the moat). The second step from x' to $f(x')$ is bounded by ρ (the radius of f). The third step from $f(x')$ to y is bounded by $1/2$ (since it is rounding to a cube corner). The triangle inequality shows the total distance from x to y is bounded by $1/2 + \rho + \tau/2$, but Figure 4 suggests we can improve this bound: some cancellation is occurring in axes directions where x is close to the boundary. To make this intuition precise, we do casework.

- If $x_i \le \tau/2$ or $x_i \ge 1 - \tau/2$, then since $|f(x')_i - x'_i| \le \rho < 1/2$, we see from y_i's definition that $y_i = x'_i$ so that

$$|y_i - x_i| = |x'_i - x_i| \le \frac{\tau}{2}.$$

- If $\tau/2 < x_i < 1 - \tau/2$, then since $y_i \in \{0,1\}$, we have

$$|y_i - x_i| < 1 - \frac{\tau}{2}.$$

  But when $\tau/2 < x_i < 1 - \tau/2$ we also have $x'_i = x_i$, which implies that

$$|y_i - x_i| \le |(y_i - f(x')_i)| + |f(x')_i - x'_i| \le \frac{1}{2} + \rho.$$

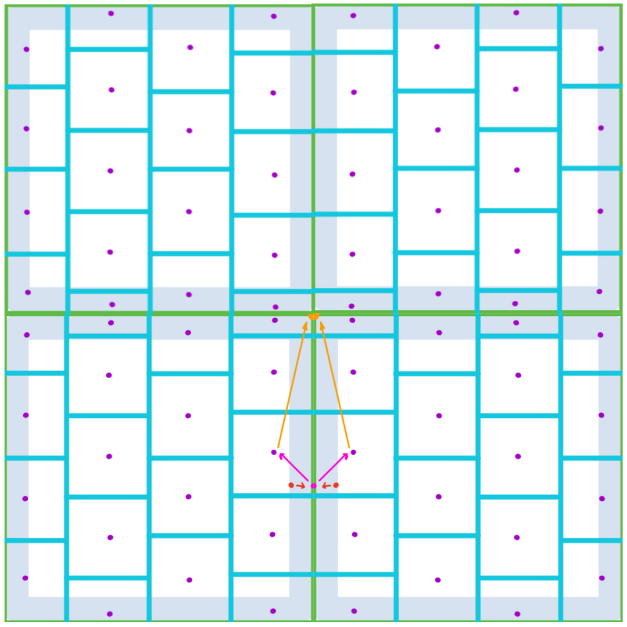

Figure 5 The construction of a rounding scheme f'' on $\mathbb{R}^2$ from a rounding scheme f' on the box $[0,1]^2$ that was illustrated in Figure 4. The definition of f' is reflected across the sides of the box to fill out $\mathbb{R}^2$. Nearby points in the moats of each box have similar fates as their reflections.

Since $\tau < 1$, the bound $\tau/2$ never exceeds either $1 - \frac{\tau}{2}$ or $\frac{1}{2} + \rho$. So, for all x,

$$\|f'(x) - x\|_\infty \leq \min\left\{1 - \frac{\tau}{2}, \frac{1}{2} + \rho\right\},$$

establishing the bound on the radius.

Observe that for every ℓ_∞ ball $B_\infty(z, \tau/2)$ of radius $\tau/2$, we have

$$|f'(B_\infty(z,\tau/2) \cap [0,1]^d)| \leq |f(B_\infty(z,\tau) \cap [0,1]^d)| \leq k.$$

This is because if $\|x - z\|_\infty \leq \tau/2$, then $\|x' - z\|_\infty \leq \tau$, and we obtain $f'(x)$ by applying f to x' and then projecting.

From f', we construct a deterministic rounding scheme $f'' \colon \mathbb{R}^d \to \mathbb{R}^d$ by using f' in each unit cube, but reflected so that points on either side of a unit cube boundary behave similarly. See Figure 5. We define f'' as follows:

Given $x \in \mathbb{R}^d$.

1. For each $i \in [d]$, write $x_i = r_i + s_i e_i$, where $r_i \in 2\mathbb{Z}$, $s_i \in \{\pm 1\}$, and $e_i \in [0,1]$. Note that this is not unique when $x_i \in \mathbb{Z}$, as two decompositions are then possible with either $s_i = 1$ and one with $s_i = -1$ (but both with the same value of $e_i \in \{0,1\}$).[5] We will show that the output $f''(x)$ is independent of the choice we make.
2. Let $e = (e_1, \ldots, e_d) \in [0,1]^d$.
3. For each $i \in [d]$, set $y_i = r_i + s_i f'(e)_i$.
4. Set $f''(x) = (y_1, \ldots, y_d)$.

[5] Specifically: if x_i is an even integer, then (r_i, s_i, e_i) could be either $(x_i, 1, 0)$ or $(x_i, -1, 0)$. If x_i is an odd integer, then the two options are $(x_i - 1, 1, 1)$ and $(x_i + 1, -1, 1)$.

The fact that $f''(x)$ is well-defined, regardless of the non-unique decompositions when x_i is boolean follows from the facts that (a) the vector e is independent of how those choices are made (already noted above), and (b) when $e_i \in \{0,1\}$, we have $e'_i = e_i$ and $f'(e)_i = e'_i$ (shown earlier for points x where x_i close to 0 or 1), so that $y_i = r_i + s_i f'(e)_i = r_i + s_i e_i = x_i$, regardless of whether we chose to use $s_i = 1$ or $s_i = -1$.

We can now analyze the guarantees this f'' provides. For every $x \in \mathbb{R}^d$, since $|s_i| = 1$ for all i we get

$$\|f''(x) - x\|_\infty = \|f'(e) - e\|_\infty \leq \min\left\{\frac{2-\tau}{2}, \frac{1+2\rho}{2}\right\}$$

recalling the radius of f' established earlier. Next, consider any ℓ_∞ ball B of radius at most $\tau/2$. We claim that $|f''(B)| = |f''(B')|$ for an ℓ_∞ ball $B' \subseteq B$ that is entirely contained within a single unit hypercube whose corners are in $\mathbb{Z}^d$, and thus $|f''(B')| \leq k$ by the guarantees of f'. The reason is that if $x \in \mathbb{R}^d$ is within ℓ_∞ distance $\tau/2$ from a face F of a unit hypercube, $f''(x) = f''(x')$, where x' is the projection of x to F. Thus we can remove portions of B that are on the opposite side of a face from its center without changing $f(B)$. (More formally, if we write $B = [a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_d, b_d]$, then for any dimension i where there is an integer c_i strictly between a_i and b_i, we can replace the interval $[a_i, b_i]$ with the shorter of $[a_i, c_i]$ and $[c_i, b_i]$ without changing $f(B)$.)

Therefore, f'' is a (k, ζ)-deterministic rounding scheme of radius $r = \min\left\{\frac{2-\tau}{2}, \frac{1+2\rho}{2}\right\}$

$$\zeta = \frac{\tau/2}{2r} = \max\left\{\frac{\tau}{2(2-\tau)}, \frac{\tau}{2(1+2\rho)}\right\}. \qquad \blacktriangleleft$$

Abstract

We explore the applicability of coresets – a small subset of the input dataset that approximates a predefined set of queries – to the 1-center problem in ℓ_1 spaces. This approach could potentially extend to solving the 1-center problem in related metric spaces, and has implications for streaming and dynamic algorithms.

We show that in ℓ_1, unlike in Euclidean space, even weak coresets exhibit exponential dependency on the underlying dimension. Moreover, while inputs with a unique optimal center admit better bounds, they are not dimension independent. We then relax the guarantee of the coreset further, to merely approximate the value (optimal cost of 1-center), and obtain a dimension-independent coreset for every desired accuracy $\epsilon > 0$. Finally, we discuss the broader implications of our findings to related metric spaces, and show explicit implications to Jaccard and Kendall's tau distances.

1 Introduction

Clustering is a fundamental task in unsupervised learning and data analysis in general, with wide-ranging applications. Typically, the input is a dataset of n points in $\mathbb{R}^d$ or some other feature space of dimension d, and the objective is to partition the dataset into clusters, each characterized by a high degree of similarity. In the current era of big data, both the number of points and their dimension are often excessive, making the computational demands significant. In center-based clustering, the goal is to further assign to each cluster a representative "center" point. The number of centers (and ergo clusters) is often specified in advance, and denoted by k, giving rise to the fundamental k-center, k-median and k-mean problems, which are famous for their simplicity and broad applicability. The case $k = 1$ is particularly important as the most basic setting, and focuses not on partitioning the points but rather on aggregating them, by identifying a representative that best captures the entire dataset.

We study the 1-center problem in ℓ_1 metrics (i.e., Manhattan distance). The motivation for ℓ_1 metrics is twofold. First, ℓ_1 metrics arise in many practical settings, especially when the dimension is large. Second, common discrete metric spaces, such as the Hamming, Kendall's tau, and Jaccard metrics, are closely related to ℓ_1, as they can be embedded into $\mathbb{R}^d$ endowed with the ℓ_1 metric with all distances preserved isometrically (i.e., with no distortion).

The 1-center problem has been investigated extensively in many metric spaces. In the context of strings, 1-center under the Hamming distance and Edit Distance is a classical problem known as the Closest String Problem [26, 27, 29]. In the context of permutations (a common model for rankings), 1-center under Kendall's tau distance is known as the maximum rank aggregation problem [5, 32]. The 1-center problem has also been studied in other discrete metrics, such as the Ulam distance between permutations and the Jaccard distance between sets [9, 13]. Additionally, recent work studied the 1-center problem under various metrics, including ℓ_p, edit distance, and Ulam, specifically to examine how the time complexity depends on the dimension d [1]. In fact, the 1-center problem is known to be NP-hard in many metric spaces, and it seems that each one requires distinct algorithmic techniques. For some metrics, a PTAS is known, while for others, the existence of a PTAS or even a non-trivial approximation algorithm remains an open question and an active area of research.

A coreset is a data-summarization concept, where the input dataset is replaced by a small subset that approximates its clustering properties. It can lead to significant reductions in computational resources, particularly storage and communication, and plays a pivotal role in modern algorithmic settings, such as streaming, distributed, and dynamic. It is thus crucial to understand the tradeoff between the size of a coreset and its accuracy (approximation factor). Coresets have been studied intensely since their introduction by [2], see the surveys [3, 21, 28, 31], and they have been successfully applied in a broad range of settings, for example different clustering objectives and metric spaces. Surprisingly, little is known about coresets in ℓ_1, particularly in high dimension, leaving significant gaps in our understanding. Small coresets in ℓ_1, if they exist and can be computed efficiently, could potentially pave the way for a unified approach for 1-center also in related metrics, like Kendall's tau and Ulam. Moreover, studying coresets for these metrics may provide insights into the geometric structure of these metric spaces.

1.1 Problem setup

In the 1-*center problem*, also known as *Minimum Enclosing Ball (MEB)*, the input is a set P of points in a metric space (X, dist), and the goal is to find a center point $c \in X$ that minimizes the objective function $\mathrm{cost}(c, P) := \max_{p \in P} \mathrm{dist}(p, c)$. Denote the optimal value by $\mathrm{opt}(P) := \min_{c \in X} \mathrm{cost}(c, P)$, and observe that it is monotone, i.e., $Q \subseteq P$ implies $\mathrm{opt}(Q) \leqslant \mathrm{opt}(P)$. While we mostly consider the space $(\mathbb{R}^d, \ell_1)$, these definitions capture also other metrics, like Kendall's tau distance where X is the set of permutations over $[d]$.

There are different (and sometimes inconsistent) definitions for coresets, which were usually developed when the desirable guarantees were deemed impossible or difficult to prove, leading to more relaxed guarantees. We face this same issue (especially for high dimension), and thus consider a sequence of definitions. For brevity, we present only the definitions most relevant to our work, and do not discuss possible generalizations (e.g., to k-center) or variants that appear in the literature. A common and very useful type of coreset is a *strong coreset*, which approximates the cost of every center, as follows.

▶ **Definition 1.1** (Strong Coreset). *A subset $Q \subseteq P$ is a* strong ϵ-coreset *for a 1-center instance $P \subseteq X$ if*

$$\forall c \in X, \qquad \mathrm{cost}(c, P) \leqslant (1+\epsilon)\,\mathrm{cost}(c, Q). \tag{1}$$

The guarantee in (1) is extremely effective in reducing (the task of solving) P to Q, with a small loss in the objective value. In Euclidean spaces, strong coresets for 1-center are known, however their size is exponential in the dimension, namely, $|Q| \leqslant (1/\epsilon)^{O(d)}$ [3], and unfortunately this upper bound is existentially tight.[1] The upper bound actually extends to every metric space with doubling dimension d [4, 10, 20], and therefore applies to $\mathbb{R}^d$ endowed with the ℓ_1 norm (or every other norm).

It is thus natural to ask: Can the coreset size be improved specifically for ℓ_1 norm? If not, can weaker notions lead to polynomial (in d) or even dimension-independent size?

1.2 Our results

Weak coresets. We point our attention to a more relaxed notion, called *weak coreset*, which only approximates the cost of certain centers, namely, centers that may be found by solving the coreset instance. Trivially, every strong ϵ-coreset is also a weak ϵ-coreset.

▶ **Definition 1.2** (Weak Coreset). *A subset $Q \subseteq P$ is a* weak ϵ-coreset *for a 1-center instance $P \subseteq X$ if*

$$\forall c^Q \in \operatorname*{argmin}_{c \in X} \mathrm{cost}(c, Q), \qquad \mathrm{cost}(c^Q, P) \leqslant (1+\epsilon)\,\mathrm{cost}(c^Q, Q). \tag{2}$$

Weak coresets were introduced in [8] specifically for 1-center in Euclidean space. It is well-known that in Euclidean space, there is a unique optimal solution,[2] which is why previous work often refers to c^Q as *the* optimal center. The challenge then becomes how to extend this definition to other metric spaces, like ℓ_1 norm, that might have multiple optimal solutions. The typical use of a coreset Q is to apply an algorithm on Q and take the resulting center c^Q as an approximated solution for the original instance P. Since a generic algorithm might pick any of the multiple optimal centers for Q, it is essential to have a guarantee that applies to every possible optimal solution c^Q for Q, hence the universal quantifier ("for all") in (2).

Remarkably, in Euclidean space, every instance P admits a weak ϵ-coreset of size $\lceil 1/\epsilon \rceil$, which is independent of the input size $n = |P|$ and of the Euclidean dimension d, and is in fact tight [7]. This result improved an earlier $O(1/\epsilon^2)$ bound from [8], which was also dimension independent. Can similar bounds be proved for ℓ_1 metrics?

We demonstrate that, in sharp contrast to the ℓ_2 setting, weak coresets in ℓ_1 are dimension dependent and moreover grow exponentially with d, even for a fixed $\epsilon > 0$. At the same time, we show how to construct a strong 0-coreset of size 2^d, which again contrasts with the ℓ_2 setting (and doubling metric spaces), where coresets grow with $1/\epsilon$ and are thus not applicable for $\epsilon = 0$. It is well-known that a strong coreset is *composable*, i.e., the union of coresets is itself a coreset for the union of the original datasets, which is very useful for designing algorithms in the streaming and dynamic settings. Thus, our coreset construction can be used in these settings, particularly in low dimension.

[1] There is a folklore lower bound, which follows by considering an instance P formed by an ϵ-net of the unit sphere S^{d-1}; every strong coreset must contain all of P and thus have size $(1/\epsilon)^{\Omega(d)}$.

[2] The uniqueness follows from the fact that ℓ_2 is strictly convex, whereas ℓ_1 is convex but not strictly convex.

▶ **Theorem 1.3.** *Consider the* 1*-center problem in* $\mathbb{R}^d$ *under* ℓ_1 *norm.*
(a) *Every instance* $P \subset \mathbb{R}^d$ *admits a strong* 0*-coreset of size* 2^d*.*
(b) *There exists* $P \subset \mathbb{R}^d$*, such that every weak* ϵ*-coreset for* $\epsilon < \frac{1}{3}$ *must have size* $2^{\Omega(d)}$*.*

We prove this theorem in Section 2. The upper bound leverages the unique geometry of ℓ_1, where only 2^d directions are in effect important. The lower bound builds a hard instance and employs classical techniques from coding theory, particularly the Hamming bound. We remark that an unpublished result from [30, Theorem 5], for a related problem about a convex shape in ℓ_2 metric, seems to imply a weak ϵ-coreset of size $\text{poly}(d/\epsilon)$ for our problem of 1-center in ℓ_1 metrics. This would contradict our lower bound in Theorem 1.3, indicating that its statement is inaccurate or its proof is flawed; see also a similar discussion in [6].

Due to the exponential dependency on d in the general case, it is important to identify cases with a smaller coreset size, say $\text{poly}(d)$ or even dimension independent. Additionally, one may suspect that the huge disparity between ℓ_1 and Euclidean space, which does admit a dimension-independent weak coreset [7, 8], is the fact that in ℓ_1 the optimal center need not be unique. We thus study the special case of ℓ_1 where the optimal center is unique, which may occur naturally in certain contexts, or be "enforced" by adding at most two points to the input dataset. We provide bounds that are exponentially smaller than in the general case, but still depend on d, which establishes that ℓ_1 is inherently more complex than ℓ_2.

▶ **Theorem 1.4.** *Consider the* 1*-center problem in* $\mathbb{R}^d$ *under* ℓ_1 *norm, on instances that have a unique optimal center.*
(a) *Every instance* $P \subset \mathbb{R}^d$ *with unique optimum admits a weak* 0*-coreset of size* $2d$*.*
(b) *There exists* $P \subset \mathbb{R}^d$ *with unique optimum, such that every weak* ϵ*-coreset for fixed* $\epsilon < 1$ *must have size* $\Omega(\log d)$*.*

We prove this theorem in Section 3. We further conjecture that the lower bound can be improved to $\Omega(d)$, and prove it in the special case $\epsilon = 0$ using Hadamard code. The upper bound in our theorem employs tools from convex geometry, specifically the Steinitz Theorem, which is relatively obscure, to prove the existence non-constructively (i.e., without an efficient algorithm). For the lower bound, we consider the instance $P = \{\pm 1\}^d$, which has a unique optimal center at the origin, and show that a coreset Q that is too small, must have an optimal center c^Q in which most coordinates are ± 1, and this center is clearly a poor solution for P.

Value-preserving coreset. To further reduce the coreset size, we consider an even less restrictive variant that preserves solely the objective function $\text{opt}(P)$, without imposing any conditions on the optimal centers of the coreset. This concept, which we shall refer to as a *value-preserving coreset*, has been studied previously under the general term "coreset" [6, 14, 33], and it is most useful in applications that focus on measuring the similarity among points in the cluster, rather than identifying a center. It is easy to verify that every weak coreset is also a value-preserving coreset.

▶ **Definition 1.5** (Value-Preserving Coreset)**.** *A subset* $Q \subseteq P$ *is a* value-preserving ϵ-coreset *for a* 1*-center instance* $P \subseteq X$ *if*

$$\text{opt}(P) \leqslant (1+\epsilon)\,\text{opt}(Q). \tag{3}$$

We show that there exist value-preserving ϵ-coresets of size $\tilde{O}(1/\epsilon^2)$, which is dimension independent, in contrast with Theorems 1.3 and 1.4. We thus establish a sharp separation between preserving an optimal solution (center point) or only preserving its value. This result

is stated in the next theorem and proved in Section 4. It also answers a question posed in [6], which studies a generalization of 1-center, called the Minimum Enclosing Polytope problem, and asks for polytopes that admit a dimension-independent value-preserving coreset.[3]

▶ **Theorem 1.6.** *Consider the* 1*-center problem in* $\mathbb{R}^d$ *under* ℓ_1 *norm. Every instance* $P \subset \mathbb{R}^d$ *admits a value-preserving* ϵ*-coreset of size* $O(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon})$.

We prove this theorem in Section 4. Our algorithm is based on random sampling, a technique that was rarely used (if at all) for 1-center coresets, but widely used for k-median and k-means coresets [15, 18, 22]. This is very natural because sampling is an excellent fit for objectives like k-median that that are formed by summation, but not for objectives like k-center that are formed by maximization, which are sensitive to missing even one term. It is thus not surprising that our sampling is conducted not on the 1-center problem but rather on its dual. More precisely, we formulate 1-center as a linear programming (LP) problem and write its dual problem, then solve this dual problem to obtain sampling probabilities for the input points. Crucially, the dual objective is formed by summation, and is thus conducive to sampling. Compared with the primal-dual framework, our algorithm is dual-only and it solves the dual LP explicitly, which is then related in the analysis to the primal via strong duality. Our sampling is similar to the randomized rounding commonly used in approximation algorithms, however its purpose here is to generate a coreset instead of a solution, and also the analysis is somewhat different.

Related metrics and applications. We demonstrate that our results for weak coresets in ℓ_1 (in Sections 2 and 3) apply also to other discrete metric spaces. Specifically, we provide in Section 5 examples that use Kendall's tau and Jaccard metrics, drawing inspiration from the results obtained in the ℓ_1 setting.

1.3 Related work

Another closely related aggregation problem is 1-median. This problem, unlike 1-center, can be solved in ℓ_1 metrics easily, by simply taking in each coordinate the median value of the input points. Utilizing this structure, 1-median in ℓ_1 metrics has a weak ϵ-coreset of size $O(\epsilon^{-2} \log(1/\epsilon))$, which is independent of the dimension [19], in sharp contrast to 1-center. The 1-median problem also admits a PTAS (approximation arbitrarily close to 1 in polynomial time) in many other metrics, including Kendall's tau distance [25], Jaccard distance [16], and a near-linear time PTAS in ℓ_2 [17]. However, it is unclear if a PTAS exists for edit distance, or even for a special case called Ulam distance, and the best upper bound is $(2 - \rho)$-approximation for some fixed $\rho > 0$ [11, 12].

2 Weak ϵ-coresets in ℓ_1

2.1 Construction of strong 0-coreset of size 2^d

In this section we will prove the following theorem:

▶ **Theorem 2.1.** *Every instance* $P \subset \mathbb{R}^d$ *admits a strong* 0*-coreset of size* 2^d.

[3] Prior to our result showing that the ℓ_1 ball (also known as the cross-polytope) admits dimension-independent value-preserving coreset, the only known example was the parallelotope, which trivially has a value-preserving 0-coreset with only 2 points.

Proof. Let $\Sigma = \{-1, 1\}^d$ denote the set of all sign vectors in $\mathbb{R}^d$. For each sign vector $\sigma \in \Sigma$, let p_σ be a point in P such that the inner product $p_\sigma \cdot \sigma$ is maximized. Define $Q_\Sigma = \{p_\sigma : \sigma \in \Sigma\}$, clearly $|Q_\Sigma| \leqslant |\Sigma| = 2^d$.

Let $c \in \mathbb{R}^d$. Since Q_Σ is a subset of P, we have that $\text{cost}(c, Q_\Sigma) \leqslant \text{cost}(c, P)$. Let p be some point in P, then there exists a sign vector $\sigma \in \Sigma$ for which we can write the distance between p and c as:

$$\|p - c\|_1 = \sigma \cdot (p - c) = \sigma \cdot p - \sigma \cdot c$$

By definition of Q_Σ, there exists a point $p_\sigma \in Q_\Sigma$ satisfying $\sigma \cdot p \leqslant \sigma \cdot p_\sigma$. Thus,

$$\|p - c\|_1 = \sigma \cdot p - \sigma \cdot c \leqslant \sigma \cdot p_\sigma - \sigma \cdot c \leqslant \sigma \cdot (p_\sigma - c) \leqslant |\sigma \cdot (p_\sigma - c)| \leqslant \|p_\sigma - c\|_1 \leqslant \text{cost}(c, Q_\Sigma).$$

That is,

$$\text{cost}(c, P) = \max_{p \in P} \|p - c\|_1 \leqslant \text{cost}(c, Q_\Sigma)$$ ◀

2.2 Lower bound of $2^{\Omega(d)}$ for weak ϵ-coresets

In this section, we present a set $P \subseteq \mathbb{R}^d$ of size $2^{d(1-o(1))}$ that has only a trivial 0-coreset, namely, only itself. Furthermore, weak ϵ-coresets of P, for $\epsilon \in (0, \frac{1}{3})$, must have size $2^{\Omega(d)}$.

▶ **Theorem 2.2.** *There exists a set $P \subseteq \mathbb{R}^d$ of size $2^{d(1-o(1))}$, such that*

- *if $Q \subseteq P$ is a weak 0-coreset of P, then $Q = P$; and*
- *for all $\epsilon \in [0, \frac{1}{3})$, if $Q \subseteq P$ is a weak ϵ-coreset of P, then $|Q| \geqslant 2^{\Omega(d)}$.*

Proof. We may assume without loss of generality that d is even, as otherwise we can take the construction for $d - 1$ and append 0 to all the points (vectors).

Denote by $\vec{1}$ the vector $(1, 1, \ldots, 1)$, and let $B \subseteq \{\pm 1\}^d$ be the set of points that are balanced, in the sense that they have an equal number of 1 and -1 coordinates, i.e., $B = \{b \in \{\pm 1\}^d : \sum_{i=1}^d b_i = 0\}$. Fix $0 < \delta \leqslant \frac{1}{3}$, and let $P = \{-\vec{1}, \vec{1}\} \bigcup (1-\delta)B$, where $(1-\delta)B$ denotes the set of points in B scaled by factor $1 - \delta$. Thus, $|P| = 2 + \binom{d}{d/2} = \Theta(2^d/\sqrt{d})$. One can verify that the origin $\vec{0} \in \mathbb{R}^d$ is an optimal center, with value d. However it is not unique; to see this, observe that the antipodal pair $\{-\vec{1}, \vec{1}\}$ establishes the optimal value $\text{opt}(P) = d$, thus an optimal center must have the same distance d to each of them, which holds for points $x \in [-1, 1]^d$ that lie on the hyperplane $\sum_{i=1}^d x_i = 0$. The set $(1 - \delta)B$ restricts the optimal solutions (inside that hyperplane) in a delicate manner, as we shall see.

We first show that P is the only weak 0-coreset of P. Let $Q \subseteq P$ be a weak 0-coreset, and notice that $\text{opt}(Q) = \text{opt}(P) = d$, implying that Q must contain the antipodal pair $-\vec{1}$ and $\vec{1}$. Assume towards contradiction that Q is a proper subset of P. Then there exists $(1 - \delta)\tilde{b} \in P \backslash Q$ for some $\tilde{b} \in B$. Let $\eta = \frac{1}{d}$ and consider $c^* = -(1 + \eta)\delta\tilde{b}$; it cannot be an optimal center of P, because

$$\left\|-(1 + \eta)\delta\tilde{b} - (1 - \delta)\tilde{b}\right\|_1 = \left\|(-1 - \eta\delta)\tilde{b}\right\|_1 = (1 + \eta\delta)\left\|\tilde{b}\right\|_1 > d.$$

We next show that this point $c^* = -(1+\eta)\delta\tilde{b}$ is an optimal center of Q. Indeed, observe that $\delta \leqslant \frac{1}{3}$ implies $(1 + \eta)\delta \leqslant 1 - \delta$, and thus the sign of $1 - \delta$ will not change if we add/subtract to it $(1 + \eta)\delta$. Let $\text{sgn}(x) \in \{-1, 0, 1\}$ denote the sign function. Now consider $a \in Q$; its distance to $-(1 + \eta)\delta\tilde{b}$ is:

$$\left\|a+(1+\eta)\delta\tilde{b}\right\|_1 = \sum_{i=1}^{d}\left|a_i+(1+\eta)\delta\tilde{b}_i\right| = \sum_{i=1}^{d}\operatorname{sgn}(a_i)\left(a_i+(1+\eta)\delta\tilde{b}_i\right)$$
$$= \|a\|_1 + (1+\eta)\delta\sum_{i=1}^{d}\operatorname{sgn}(a_i)\tilde{b}_i. \tag{4}$$

In the case $a \in \{-\vec{1},\vec{1}\}$, the above equals d. In the remaining case $a \in Q\backslash\{-\vec{1},\vec{1}\}$, the choice of $\tilde{b}$ implies that $\sum_{i=1}^{d}\operatorname{sgn}(a_i)\tilde{b}_i \leqslant d-2$, and thus

$$\left\|a+(1+\eta)\delta\tilde{b}\right\|_1 \leqslant \|a\|_1 + (1+\eta)\delta(d-2) \leqslant (1-\delta)d + (1+\eta)\delta(d-2) < d.$$

We have thus confirmed that $-(1+\eta)\delta\tilde{b}$ is an optimal center of Q, but not for P. This contradicts our assumption that Q is a weak 0-coreset, and completes the proof of the first item.

To prove the second item, let $P \subset \mathbb{R}^d$ be as before but now for $\delta = \frac{1}{3}$, and consider a weak ϵ-coreset Q of P, for some $0 < \epsilon < \delta = \frac{1}{3}$. Notice that Q must contain both $-\vec{1}$ and $\vec{1}$, as otherwise, if $-\vec{1},\vec{1} \notin Q$, consider the origin $\vec{0} \in \mathbb{R}^d$ as a center. If Q contains just one of $\{-\vec{1},\vec{1}\}$ say $\vec{1}$, consider $\delta\vec{1}$ as a center. In both cases, we obtain that $\operatorname{opt}(Q) \leqslant (1-\delta)d < (1-\epsilon)d < \frac{1}{1+\epsilon}\operatorname{opt}(P)$, in contradiction to the weak ϵ-coreset.

Denote by $\psi(Q)$ the minimum Hamming distance between any point in B and its furthest point in Q, that is, $\psi(Q) = \min_{b\in B}\max_{a\in Q}\operatorname{Hamm}(a,b)$. The next proposition follows by a standard counting-bound.

▶ **Proposition 2.3.** *If* $|Q| \leqslant \frac{1}{\sqrt{2d}}2^{0.18d}$, *then* $\psi(Q) < \frac{3}{4}d$.

Proof. Denote by $C_{\frac{3d}{4}}(a)$ the set of all points in $\{\pm1\}^d$ whose Hamming distance from $a \in \{\pm1\}^d$ is at least $\frac{3d}{4}$. Then

$$\left|C_{\frac{3d}{4}}(a)\right| \leqslant \sum_{0\leqslant j\leqslant\frac{d}{4}}\binom{d}{j} \leqslant 2^{dH(\frac{1}{4})},$$

where the last inequality is the known entropy bound for binomial coefficients and $H(p) = -p\log p - (1-p)\log(1-p)$, hence $H(\frac{1}{4}) \approx 0.811$. Taking a union over all $a \in Q$,

$$\left|\bigcup_{a\in Q}C_{\frac{3d}{4}}(a)\right| \leqslant \sum_{a\in Q}\left|C_{\frac{3d}{4}}(a)\right| \leqslant 2^{dH(\frac{1}{4})}|Q| < \binom{d}{d/2} = |B|,$$

where in the last inequality we used the known bound $\frac{1}{\sqrt{2d}}2^d \leqslant \binom{d}{d/2}$. Hence, there exists some point in B for which the maximum Hamming distance to points in Q is smaller than $\frac{3d}{4}$. ◀

Assume towards contradiction that $|Q| \leqslant \frac{1}{\sqrt{2d}}2^{0.18d}$. Then by Proposition 2.3, there is a point $\tilde{b} \in B$ for which the maximum Hamming distance to points in Q is smaller than $\frac{3d}{4}$. We next show that the point $2\delta\tilde{b}$ is an optimal center for Q. Similarly to Equation (4), since $2\delta \leqslant 1-\delta$, for every $a \in Q$ we can write:

$$\left\|a-2\delta\tilde{b}\right\|_1 = \sum_{i=1}^{d}\left|a_i-2\delta\tilde{b}_i\right| = \|a\|_1 - 2\delta\sum_{i=1}^{d}\operatorname{sgn}(a_i)\tilde{b}_i,$$

where:

$$\sum_{i=1}^{d} \operatorname{sgn}(a_i)\tilde{b}_i = \sum_{i:\operatorname{sgn}(a_i)=\operatorname{sgn}(\tilde{b}_i)} 1 - \sum_{i:\operatorname{sgn}(a_i)\neq\operatorname{sgn}(\tilde{b}_i)} 1 = d - 2\operatorname{Hamm}(a,\tilde{b}),$$

and thus:

$$\left\|a - 2\delta\tilde{b}\right\|_1 = \|a\|_1 - 2\delta d + 4\delta \operatorname{Hamm}(a,\tilde{b}).$$

In the case $a \in \{-\vec{1},\vec{1}\}$, since $\tilde{b} \in B$ then we have $\left\|a - 2\delta\tilde{b}\right\|_1 = \|a\|_1 = d$. Otherwise $a \in (1-\delta)B$, and $\left\|a - 2\delta\tilde{b}\right\|_1 < \|a\|_1 - 2\delta d + 4\delta \cdot \frac{3}{4}d \leqslant (1-\delta)d + \delta d = d$. In both cases, the distance from $a \in Q$ to $2\delta\tilde{b}$ is at most $d = \operatorname{opt}(Q)$, with equality for some $a \in Q$. Thus, $2\delta\tilde{b}$ is an optimal center for Q. However, $\operatorname{cost}(2\delta\tilde{b}, P) \geqslant \left\|2\delta\tilde{b} + (1-\delta)\tilde{b}\right\|_1 = (1+\delta)d > (1+\epsilon)\operatorname{opt}(P)$. This contradicts that Q is a weak ϵ-coreset of P, and completes the proof of Theorem 2.2. ◀

3 Weak ϵ-coresets in ℓ_1 for inputs with a unique solution

In this section we consider the special case, where the input P has a unique optimal center. We show that even in this special case, the size of the coreset depends on the dimension and provide a lower bound of $\Omega(\log d)$ on the size of every ϵ-coreset for any fixed $\epsilon < 1$. This restriction over ϵ is necessary, as for larger values of ϵ, a naive coreset construction (based on Gonzalez algorithm for k-center [23]) with only 2 points achieves a 3-approximation.[4] We also prove that there always exists a weak 0-coreset of size at most $2d$. This is in stark contrast to Section 2, where we show that in the general case of multiple solutions, 0-coresets might require size exponential in d. Lastly, we present a set such that every weak 0-coreset of this set is of size $2d$, hence the upper bound of $2d$ is tight for the case $\epsilon = 0$.

3.1 Lower bound of $\Omega(\log d)$ for weak ϵ-coresets

▶ **Theorem 3.1.** *Fix $\epsilon < 1$ and consider the set of points $P = \{\pm 1\}^d \subset \mathbb{R}^d$. Then P has a unique optimal center and every weak ϵ-coreset of P must have $\Omega(\log d)$ points.*

Proof. It is easy to note that the origin $\vec{0} \in \mathbb{R}^d$ is a unique optimal center with value d as the input contains a point from every face of the ℓ_1 ball centered at $\vec{0}$. Consider a weak ϵ-coreset $Q \subset P$ of size $|Q| \leqslant \frac{1}{2}\log d$. Every point $p \in Q$ induces a partition Π_p of $[d]$ into at most two parts, by splitting the coordinates of p into the positive and negative ones. Let Π be the common refinement of all these partitions (i.e. placing $i, j \in [d]$ in the same part of Π if and only if for every $p \in P$ they are in the same part of Π_p). Since each Π_p has at most two parts, Π has at most $2^{|Q|} \leqslant \sqrt{d}$ parts. Observe that for every point $p \in Q$, coordinates in the same part of Π have the same sign.

Consider an optimal center c^* for Q. The idea is to modify it iteratively, without increasing its cost for Q, so as to have more coordinates take values in $\{-1, 1\}$. Each iteration takes two indices i, j in the same part of Π, whose coordinates in c^* are *both* not in $\{-1, 1\}$, say, $-1 < c^*_i \leqslant c^*_j < 1$. The iterations stop when no such indices exist. Now add δ to c^*_i and $-\delta$ to c^*_j, where $\delta > 0$ is as large as possible while keeping both new values in the range

[4] Pick arbitrary $p \in P$, then a point $p' \in P$ that is furthest from p, and take $Q = \{p, p'\}$ as the coreset. Note that $\operatorname{opt}(Q) = \frac{1}{2}\left\|p - p'\right\|_1$, and $\frac{1}{2}(p + p')$ is a possible optimal center. For every optimal center c^* for Q, we can write $\operatorname{cost}(c^*, P) \leqslant \left\|c^* - p\right\|_1 + \operatorname{cost}(p, P) \leqslant 1.5\left\|p - p'\right\|_1 = 3\operatorname{opt}(Q) \leqslant 3\operatorname{opt}(P)$.

$[-1,1]$, that is, $\delta = \min\{1 - c_j^*, c_i^* - 1\}$. It is easy to see that after this modification, at least one of c_i^* and c_j^* will be in $\{\pm 1\}$, and at the same time the distance to every $p \in Q$ does not change. The iteration stop at a center $\bar{c}^*$, where in each part of Π at most one coordinate is not in $\{\pm 1\}$, and in total at most $|\Pi| \leqslant 2^{|Q|} \leqslant \sqrt{d}$ coordinates are not in $\{\pm 1\}$.

Finally, we show that $\bar{c}^*$, which is an optimal center for Q, has a too large cost for P. Consider the point in P that is closest to $-\bar{c}^*$, i.e., where each coordinate of $-\bar{c}^*$ is rounded to the nearest value among $\{\pm 1\}$. This point disagrees with $-\bar{c}^*$ (i.e., rounding was "needed") on at most $|\Pi|$ coordinates, hence its distance from $\bar{c}^*$ is at least $2d - |\Pi|$, hence $\operatorname{cost}(\bar{c}^*, P) \geqslant 2d - |\Pi| \geqslant 2d - \sqrt{d} > (1+\epsilon)\operatorname{opt}(P)$. ◀

We remark that the proof works also for the discrete space $\{-1, 0, +1\}^d$ (endowed with ℓ_1 norm), which has more limited choices for the center point, e.g., for c^* above. Moreover, note that the distance of the modified optimal center $\bar{c}^*$ from $\vec{0}$ is at least $d - 2^{|Q|}$.

3.2 Upper bound of $2d$ for weak 0-coresets

We will show that if P has a unique solution, then P has a weak 0-coreset of size at most $2d$.

Two standard notations from the domain of convex geometry are the convex-hull and the interior. The convex hull of P, denoted $\operatorname{conv}(P)$, consists of all convex combinations of points in P, that is every point in $\operatorname{conv}(P)$ can be expressed as a weighted sum of points from P with non-negative weights summing to 1. The interior of P, denoted $\operatorname{int}(P)$, refers to the set of points that lie strictly inside the convex hull. In other words, it consists of points that can be surrounded by a small ball completely contained within $\operatorname{conv}(P)$.

An important tool we use is Steinitz's theorem [24].

▶ **Theorem 3.2** (Steinitz's theorem). *Let $\vec{0} \in \operatorname{int}(\operatorname{conv}(S))$ for some $S \subseteq \mathbb{R}^d$. Then there exists $R \subseteq S$ of size at most $2d$, such that $\vec{0} \in \operatorname{int}(\operatorname{conv}(Q))$.*

Next we introduce the notion of complete set, we will then provide an alternative formulation of Steinitz's theorem that will be useful in our application.

▶ **Definition 3.3.** *A set $S \subseteq \mathbb{R}^d$ is complete if for every $v \in \mathbb{R}^d \backslash \{\vec{0}\}$ there exists $s \in S$ with $v \cdot s > 0$.*

▶ **Lemma 3.4.** *$\vec{0} \in \operatorname{int}(\operatorname{conv}(S))$ if and only if S is complete.*

Proof. ($\Rightarrow$) : Write $\vec{0}$ as a convex combination, $\vec{0} = \sum_i \lambda_i s_i$ where $\lambda_i \geqslant 0$ and $\sum_i \lambda_i = 1$. Then,

$$0 = v \cdot \vec{0} = v \cdot (\sum_i \lambda_i s_i) = \sum_i \lambda_i (v \cdot s_i)$$

If for all s_i, $v \cdot s_i \leqslant 0$, then it must hold that for all s_i, $v \cdot s_i = 0$, but then $\vec{0}$ is not in the interior of $\operatorname{conv}(S)$.

($\Leftarrow$) : If $\vec{0} \notin \operatorname{int}(\operatorname{conv}(S))$ then there exists a hyperplane $\mathcal{H}$ containing $\vec{0}$ such that $S \subseteq \mathcal{H}^+$. Since $\vec{0}$ is a point in the hyperplane we can write the hyperplane equation as $vx = 0$ for some $v \in \mathbb{R}^d \backslash \{\vec{0}\}$. It follows that $v \cdot s \leqslant 0$ for every $s \in S$, hence S is not complete. ◀

This leads to the following alternative statement of Steinitz's theorem.

▶ **Corollary 3.5.** *If $S \subseteq \mathbb{R}^d$ is complete, then there exists $R \subseteq S$ of size at most $2d$, such that R is complete.*

W.l.o.g., assume that $\vec{0}$ is the unique solution of P and let $\text{opt}(P) = \text{cost}(\vec{0}, P) = r$. Since $\vec{0}$ is unique, we can further assume that $\left\|\vec{0} - p\right\|_1 = r$ for every $p \in P$; otherwise, any points that do not satisfy this can be removed without affecting the optimal solution or its cost. Given a pair $a = (\sigma, p) \in \{-1, 1\}^d \times P$, we denote by $\mathcal{H}_a$ the hyperplane $\sigma \cdot (x - p) = r$ and by $\mathcal{H}_a^+$ the halfspace $\sigma \cdot (x - p) \leqslant r$. In general, $x \in \mathbb{R}^d$ is a feasible 1-center of P if for every $p \in P$, $\|x - p\|_1 \leqslant r$. Assuming r is known, we can write the LP formulation of the 1-center problem with d variables $x = (x_1, ..., x_d)$ and the $2^d|P|$ constraints $\sigma \cdot (x - p) \leqslant r$ for every $\sigma \in \{-1, 1\}^d$ and $p \in P$. That is, every constraint defines a hyperplane $\mathcal{H}_{(\sigma,p)}$. We further remove from the set of constraints $\{-1, 1\}^d \times P$, pairs (σ, p) for which $\vec{0} \notin \mathcal{H}_{(\sigma,p)}$ and denote the updated set of constraint by $A = S \times P$. Note that no points from P are removed in this process, as each has distance r from $\vec{0}$. Since $\vec{0}$ is the unique optimal solution of P, this also does not change the set of feasible solutions, and $\vec{0}$ is the unique intersection point of all hyperplanes in A.

▶ **Proposition 3.6.** *Let $A = S \times P$ be non-empty set such that $\vec{0} \in \mathcal{H}_a$ for every $a \in A$. Then, $\bigcap_{a \in A} \mathcal{H}_a^+ = \{\vec{0}\}$ if and only if S is complete.*

Proof. ($\Rightarrow$) : Let $v \in \mathbb{R}^d \backslash \{\vec{0}\}$, then there exists $a \in A$ such that $v \notin \mathcal{H}_a^+$. That is, $\sigma \cdot (v - p) > r$ and since $\vec{0} \in \mathcal{H}_a$, $\sigma \cdot (\vec{0} - p) = r$, and it follows $\sigma \cdot v > 0$.

($\Leftarrow$) : A is non-empty so clearly $\vec{0} \in \bigcap_{a \in A} \mathcal{H}_a^+$. Let $v \neq \vec{0}$, then there exists $(\sigma, p) \in A$ such that $\sigma \cdot v > 0$. Since $\vec{0} \in \mathcal{H}_a$ we have $\sigma(\vec{0} - p) = r$, it follows that $\sigma(v - p) > r$, that is, $v \notin \mathcal{H}_a^+$. ◀

We are now ready to prove our main Theorem:

▶ **Theorem 3.7.** *Every instance $P \subset \mathbb{R}^d$ with unique optimum admits a weak 0-coreset of size $2d$.*

Proof. By Proposition 3.6 the set S is complete and by Corollary 3.5 there exists $R \subseteq S$ such that R is complete and of size at most $2d$. For each $\sigma \in R$ we select a single point $p \in P$ such that the pair (σ, p) is a constraint in A. That is we obtain a set of at most $2d$ different points from P we denote by Q and denote by A' this refined set of constraints. Since R is complete, using the second direction of Proposition 3.6 we have that $\bigcap_{a \in A'} \mathcal{H}_a^+ = \{\vec{0}\}$, meaning that Q is a weak 0-coreset of size at most $2d$. ◀

We conclude this section by providing an example of a set P of size $2d$, where P is the sole weak 0-coreset of itself, demonstrating that the upper bound of $2d$ cannot be further improved. The set P is composed of the row vectors of the Hadamard matrix and their negations. The proof is provided in Appendix A.1.

4 Value-preserving coresets

In this section we provide an algorithm for constructing a dimension-independent value-preserving ϵ-coreset for 1-center. In addition, we provide a complete characterization for the special case $\epsilon = 0$, by showing a 0-coreset of size $d + 1$, and moreover that this bound is tight, see in Section 4.2.

▶ **Theorem 4.1.** *For every instance $P \subset \mathbb{R}^d$ and $0 < \epsilon < 1$, there exists a subset $S \subseteq P$ of $O(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon})$ points such that*

$$\text{opt}(S) \geqslant (1 - \varepsilon)\,\text{opt}(P).$$

Our proof of Theorem 4.1 is based on the following LP formulation of 1-center and its dual. Unlike many primal-dual algorithms, our algorithm needs to explicitly solve and use this optimal dual solution to guide the coreset construction.

LP formulation of 1-center. Observe that 1-center on input $P \subset \mathbb{R}^d$ is equivalent to the following mathematical program with variables r and $x = (x_1, \ldots, x_d)$.

$$\begin{aligned} \text{minimize} \quad & r \\ \text{subject to} \quad & \sum_{i\in[d]} |p_i - x_i| \leqslant r && \forall p \in P. \end{aligned}$$

This is formally not an LP due to the absolute values in the constraints, but each such constraint can obviously be expanded into 2^d linear constraints, which leads to the following equivalent LP formulation.

$$\begin{aligned} \text{minimize} \quad & r \\ \text{subject to} \quad & \sum_{i\in[d]} \sigma_i(p_i - x_i) \leqslant r && \forall \sigma \in \{\pm 1\}^d, p \in P \\ & r \in \mathbb{R}, x \in \mathbb{R}^d. \end{aligned}$$

We derive the dual of this LP, with $2^d n$ variables $\{u_{\sigma,p}\}_{\sigma,p}$, as follows. One can think of each pair (σ, p) as generating a "new" point $(\sigma_1 p_i, \ldots, \sigma_d p_d) \in \mathbb{R}^d$, that is obtained from $p \in P$ by flipping signs.

$$\begin{aligned} \text{maximize} \quad & \sum_{\sigma\in\{\pm1\}^d} \sum_{p\in P} \sum_{i\in[d]} \sigma_i p_i u_{\sigma,p} && && \text{(DLP)} \\ \text{subject to} \quad & \sum_{\sigma\in\{\pm1\}^d} \sum_{p\in P} \sigma_i u_{\sigma,p} = 0 && \forall i \in [d] \\ & \sum_{\sigma\in\{\pm1\}^d} \sum_{p\in P} u_{\sigma,p} = 1 \\ & u_{\sigma,p} \geqslant 0 && \forall \sigma \in \{\pm 1\}^d, p \in P. \end{aligned}$$

Coreset Algorithm. Our coreset construction, presented in Algorithm 1, builds the coreset by sampling, where the probabilities come from an optimal solution to (DLP). Technically, our sampling step is similar to randomized rounding that is often used in approximation algorithms, however we use it here to find a coreset rather than an approximate solution. The analysis of this algorithm appears in Section 4.1. We slightly abuse terminology and refer to $\widehat{W}$ as a multiset, but formally it is always a sequence of m pairs, namely, $\widehat{W} := ((\hat{\sigma}^1, p^1), \ldots, (\hat{\sigma}^m, p^m))$, hence, summing over all $(\hat{\sigma}, p) \in \widehat{W}$ actually means summation over $j \in [m]$.

Algorithm 1 Value-preserving ϵ-coreset.

1 shift P such that $\sum_{p\in P} p = \vec{0}$ and solve (DLP) on P to obtain an optimal solution u^*
2 let $\widehat{W}$ be a multiset of $m := O(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon})$ i.i.d. samples from the distribution u^*
    // m is an even number, u^* viewed as distribution over $\{\pm1\}^d \times P$
3 return $S := \{p : (\sigma, p) \in \widehat{W}\}$

▶ Remark 4.2. Algorithm 1 can be implemented in poly(nd)-time. The most expensive step is clearly to solve the dual LP. Since it has only $d+1$ constraints, one can solve it while using only poly(d) non-zero variables. Alternatively, one can first solve the primal LP using an ellipsoid algorithm, to find a subset of poly(n) constraints that has the same optimal value, and then solve the dual of this smaller primal LP. Moreover, inspecting the analysis, particularly (6), one can verify that it suffices to $(1+\varepsilon)$-approximate the dual LP.

4.1 Proof of Theorem 4.1: Analysis of Algorithm 1

We shall prove that the algorithm's output S satisfies $\Pr[\mathrm{opt}(S) \geqslant (1-\epsilon)\,\mathrm{opt}(P)] \geqslant 0.8$. The plan is to build a dual solution for $S \subset \mathbb{R}^d$, and show that with high probability, this dual solution is feasible for (DLP) and its objective is at least $(1-\epsilon)$ times the optimal value (of the same dual LP) for P. This would imply that $\mathrm{DLP}(S) \geqslant (1-\epsilon)\cdot\mathrm{DLP}(P)$, where $\mathrm{DLP}(P)$ denotes the optimal value of (DLP) on input P, and by strong LP duality this is equivalent to $\mathrm{opt}(S) \geqslant (1-\epsilon)\cdot\mathrm{opt}(P)$, proving the theorem.

A lower bound on opt(P). Recall that Algorithm 1 shifts P so that $\sum_{p\in P} p = \vec{0}$. This does not change the optimal value, hence our analysis simply assumes that the input P already satisfies $\sum_{p\in P} p = \vec{0}$, avoiding cumbersome notations for before and after the shift. This property of P yields the following immediate lower bound on $\mathrm{opt}(P)$.

▶ **Lemma 4.3.** *If $P \subset \mathbb{R}^d$ satisfies $\sum_{p\in P} p = \vec{0}$, then $\mathrm{opt}(P) \geqslant \max\{\|p\|_1/2 :\ p \in P\}$.*

Proof. For every point $p \in P$,

$$\|p\|_1 = \left\| \tfrac{1}{|P|} \sum_{q\in P} (p-q) \right\|_1 \leqslant \tfrac{1}{|P|} \sum_{q\in P} \|p-q\|_1 \leqslant 2\,\mathrm{opt}(P). \qquad \blacktriangleleft$$

Dual solution induced by $\widehat{W}$. We now wish to use $\widehat{W}$ from Algorithm 1 to construct a solution for the dual LP. Informally, the idea is to construct a solution $u^{\widehat{W}}$ (can also think of it as a vector with $2^d n$ coordinates), that is the average of m sparse solutions, namely, each has a single non-zero variable, whose value is 1 and it is drawn at random from the probability distribution defined by u^* (think of u^* as a vector with $2^d n$ coordinates that sum to 1), using precisely the random draws made in Algorithm 1. Next, we formalize this construction in a slightly more general form.

Given a multiset $Z \subseteq \{\pm 1\}^d \times P$ of size m, such as $\widehat{W}$, we define the *dual solution induced* by Z, denoted u^Z, as follows. Take each pair $(\sigma, p) \in Z$ and build a dual solution u, where the variable corresponding to this pair is set as $u_{\sigma,p} = 1$, and the other $2^d n - 1$ variables are set to zero, and then we average all these m solutions. Formally, u^Z is given by

$$u^Z_{\sigma',p'} := \tfrac{1}{m} \sum_{(\sigma,p)\in Z} \mathbb{1}_{\{\sigma'=\sigma, p'=p\}}.$$

The following fact rewrites certain linear forms over u^Z, that appear in (DLP), in terms of pairs $(\sigma, p) \in Z$.

▶ **Fact 4.4.** *Let u^Z be induced by some $Z \subseteq \{\pm 1\}^d \times P$ as above. Then for every $i \in [d]$,*

$$\sum_{\sigma\in\{\pm1\}^d} \sum_{p\in P} \sigma_i u^Z_{\sigma,p} = \tfrac{1}{m} \sum_{(\sigma,p)\in Z} \sigma_i,$$
$$\sum_{\sigma\in\{\pm1\}^d} \sum_{p\in P} \sigma_i p_i u^Z_{\sigma,p} = \tfrac{1}{m} \sum_{(\sigma,p)\in Z} \sigma_i p_i.$$

Initial dual solution. Before building a *feasible* dual solution for (DLP) on S, we first consider an initial dual solution $\widehat{u} := u^{\widehat{W}}$, which is just the solution induced by $\widehat{W}$ from Algorithm 1. We shall see below that $\widehat{u}$ is feasible in an expected sense, and that turning the expectation into a high-probability guarantee introduces an additive error in the constraints (and in the objective). Nonetheless, this is still useful as we will later "fix" this solution into one that does satisfy the constraints (without additive error).

Let us examine this initial random solution $\widehat{u}$. It always satisfies the second constraint of (DLP) by construction (recall that $\widehat{u}$ is the average of m sparse solutions), i.e.,

$$\sum_{\sigma\in\{\pm1\}^d}\sum_{p\in S}\widehat{u}_{\sigma,p} = m\cdot\tfrac{1}{m} = 1.$$

By linearity of expectation, $\widehat{u}$ satisfies the first constraint in expectation (the middle term uses Theorem 4.4 to provide an alternate formulation),

$$\forall i\in[d],\quad \mathbb{E}\Big[\sum_{\sigma\in\{\pm1\}^d}\sum_{p\in P}\sigma_i\widehat{u}_{\sigma,p}\Big] = \mathbb{E}\Big[\tfrac{1}{m}\sum_{(\sigma,p)\in\widehat{W}}\sigma_i\Big] = \tfrac{1}{m}\cdot m\cdot\sum_{\sigma\in\{\pm1\}^d}\sum_{p\in P}\sigma_i u^*_{\sigma,p} = 0. \quad (5)$$

And again by linearity of expectation, the expected objective of $\widehat{u}$ is the same as the optimal solution u^*, because:

$$\mathbb{E}\Big[\sum_{\sigma\in\{\pm1\}^d}\sum_{p\in P}\sum_{i\in[d]}\sigma_i p_i\widehat{u}_{\sigma,p}\Big] = \mathbb{E}\Big[\frac{1}{m}\sum_{i\in[d]}\sum_{(\sigma,p)\in\widehat{W}}\sigma_i p_i\Big] = \mathrm{opt}(P). \quad (6)$$

Almost feasibility. We bound the deviation of $\widehat{u}$ from satisfying the first constraint, as follows. Consider $i\in[d]$ and let $\mathcal{F}_i$ be the event that $|\sum_{\sigma\in\{\pm1\}^d}\sum_{p\in S}\sigma_i\widehat{u}_{\sigma,p}| > \epsilon$, which by Theorem 4.4 can be also written as $|\frac{1}{m}\sum_{(\sigma,p)\in\widehat{W}}\sigma_i| > \epsilon$. Informally, we want to bound the probability of this event, because when it does not occur, the constraint is "almost satisfied". By applying Hoeffding's inequality, where we use (5) for the expectation and the fact that $|\sigma_i|\leqslant 1$, we get (by our choice of m),

$$\Pr[\mathcal{F}_i] = \Pr\Big[\Big|\tfrac{1}{m}\sum_{(\sigma,p)\in\widehat{W}}\sigma_i\Big| > \epsilon\Big] \leqslant 2e^{-\Omega(\epsilon^2 m)} \leqslant \epsilon. \quad (7)$$

A feasible solution u. We next use $\widehat{W}$ to construct a new multiset W whose induced dual u^W is feasible, and in particular satisfies the first constraint. We will then take our final dual solution to be $u := u^W$, and it will remain to bound its objective value. At a high level, W is obtained by "flipping" some of the signs appearing in $\widehat{W}$. More precisely, given $\widehat{W} = ((\widehat{\sigma}^1,p^1),\ldots,(\widehat{\sigma}^m,p^m))$, we shall define new sign vectors $\sigma^1,\ldots,\sigma^m$ but keep the exact same points $p^1,\ldots,p^m\in P$, and construct $W = ((\sigma^1,p^1),\ldots,(\sigma^m,p^m))$. It will be convenient to arrange the sign vectors $\widehat{\sigma}^1,\ldots,\widehat{\sigma}^m$ as the rows of a matrix $\widehat{M}\in\{\pm1\}^{m\times d}$, and use this $\widehat{M}$ to define a new matrix M, whose rows define the new sign vectors $\sigma^1,\ldots,\sigma^m$.

We construct M (from $\widehat{M}$) using the following procedure, which operates separately on each column $i\in[d]$. First copy column i of $\widehat{M}$ to be also column i of M, and let n_i^+ and n_i^- be the number of positive and negative entries in this column, respectively. If $n_i^+ = n_i^-$, leave this column of M as is, noticing that it sums to zero. Otherwise, flip $\frac{|n_i^+ - n_i^-|}{2}$ signs chosen carefully from among the majority sign in column i, and this will ensure that column i of M sums to zero. (This is possible because m is even.) The careful choice (which signs to flip) will favor row indices $j\in[m]$ with small value $|p_i^j|$. Formally, let $R_i\subseteq[m]$ be the

set of rows j with the majority sign in column i of $\widehat{M}$, then sort the indices $j \in R_i$ by their value $|p_i^j|$, pick the $|n_i^+ - n_i^-|/2$ indices with smallest value (breaking ties arbitrarily), and flip their entries. As explained above, the rows of the resulting matrix M define sign vectors $\sigma^1, \ldots, \sigma^m$, which in turn define $W = ((\sigma^1, p^1), \ldots, (\sigma^m, p^m))$, and our final dual solution is $u = u^W$.

▶ **Lemma 4.5.** *The solution $u = u^W$ is feasible for* (DLP) *on S.*

Proof. The first constraint is satisfied because the signs in every column of M sum to zero. The second constraint is satisfied because flipping a sign σ_i^j "moves" some amount (say $1/m$) from variable $u_{\sigma,p}$ to $u_{\sigma',p}$, where σ, σ' differ in coordinate j, but the total remains the same. Finally, it uses only variables $u_{\sigma,p}$ for $p \in S$, i.e., all other variables are 0, and thus it is feasible not only for (DLP) on P but also on S. ◀

The next lemma bounds the decrease in objective when constructing w from $\widehat{W}$, i.e., comparing that of u with that of $\widehat{u}$. Its proof is based on an averaging argument.

▶ **Lemma 4.6.** *For all $i \in [d]$,*

$$\Big| \sum_{(\sigma,p)\in\widehat{W}} \sigma_i p_i - \sum_{(\sigma,p)\in W} \sigma_i p_i \Big| \leqslant \frac{2|n_i^+ - n_i^-|}{m} \sum_{(\sigma,p)\in\widehat{W}} |p_i|.$$

Proof. We consider only the case $n_i^+ \geqslant n_i^-$, as the other case is symmetric. Since $n_i^+ + n_i^- = m$, we have $n_i^+ \geqslant m/2$. Recall that the construction of M flips in column i exactly $\frac{n_i^+ - n_i^-}{2}$ signs, picking the indices $j \in R_i$ with smallest value $|p_i^j|$. Every such flip changes the objective by $2|p_i^j|$, and the number of choices $|R_i| = n_i^+ \geqslant m/2$, hence by an averaging argument,

$$\Big| \sum_{(\sigma,p)\in\widehat{W}} \sigma_i p_i - \sum_{(\sigma,p)\in W} \sigma_i p_i \Big| \leqslant \frac{(n_i^+ - n_i^-)/2}{|R_i|} \sum_{j\in R_i} 2|p_i^j| \leqslant \frac{n_i^+ - n_i^-}{m/2} \sum_{j\in[m]} |p_i^j|. \qquad ◀$$

The objective value of u. Using Theorem 4.4, we can write the objective value of u as

$$L := \sum_{i\in[d]} \sum_{\sigma\in\{\pm1\}^d} \sum_{p\in S} \sigma_i p_i u_{\sigma,p} = \tfrac{1}{m} \sum_{i\in[d]} \sum_{(\sigma,p)\in W} \sigma_i p_i. \tag{8}$$

and that of $\widehat{u}$ as

$$\widehat{L} := \sum_{i\in[d]} \sum_{\sigma\in\{\pm1\}^d} \sum_{p\in S} \sigma_i p_i \widehat{u}_{\sigma,p} = \tfrac{1}{m} \sum_{i\in[d]} \sum_{(\sigma,p)\in\widehat{W}} \sigma_i p_i, \tag{9}$$

Our plan is to bound L (with high probability) by relating it to $\widehat{L}$, and then bound the latter using Chebyshev's inequality. These steps rely on the next two lemmas, and before proving them, we show how they imply Theorem 4.1.

▶ **Lemma 4.7.** $\mathbb{E}[|L - \widehat{L}|] \leqslant O(\epsilon)\operatorname{opt}(P)$.

▶ **Lemma 4.8.** $\operatorname{Var}(\widehat{L}) \leqslant \frac{4}{m}(\operatorname{opt}(P))^2$.

Proof of Theorem 4.1. We already established in Theorem 4.5 that u is a feasible solution for (DLP) on S, hence $\operatorname{opt}(S) \geqslant L$. It thus suffices to show that $\Pr[L \geqslant (1 - O(\epsilon))\operatorname{opt}(P)] \geqslant 0.8$. By Theorem 4.7 and Markov's inequality, $\Pr[|L - \widehat{L}| \leqslant O(\epsilon)\operatorname{opt}(P)] \geqslant 0.9$. Next, we apply Chebyshev's inequality to $\widehat{L}$, using the variance bound Theorem 4.8 and our choice of m, to obtain $\Pr[|\widehat{L} - \mathbb{E}[\widehat{L}]| \geqslant \epsilon \operatorname{opt}(P)] \leqslant \frac{4/m}{\epsilon^2} \leqslant 0.1$. Recall also from (6) that $\mathbb{E}[\widehat{L}] = \operatorname{opt}(P)$. It follows by a union bound that with probability at least 0.8,

$$L \geqslant \widehat{L} - O(\epsilon)\operatorname{opt}(P) \geqslant (1 - O(\epsilon))\operatorname{opt}(P). \qquad ◀$$

Proof of Theorem 4.7. Observe that $\mathcal{F}_i$ is the event that $|n_i^+ - n_i^-| > \epsilon m$, in which case we can still bound $|n_i^+ - n_i^-| \leqslant m$ (which holds always). Thus, $|n_i^+ - n_i^-| \leqslant \epsilon m + \mathbb{1}_{\mathcal{F}_i} \cdot m$. Now applying Theorem 4.6 for every $i \in [d]$ and taking a sum, we get (after dividing by m)

$$\begin{aligned}\tfrac{1}{m}\Big|\sum_{i\in[d]}\sum_{(\sigma,p)\in\widehat{W}}\sigma_i p_i - \sum_{i\in[d]}\sum_{(\sigma,p)\in W}\sigma_i p_i\Big| &\leqslant \tfrac{1}{m}\sum_{i\in[d]}\frac{2|n_i^+ - n_i^-|}{m}\sum_{(\sigma,p)\in\widehat{W}}|p_i| \\ &\leqslant \tfrac{2}{m}\sum_{i\in[d]}\Big[(\epsilon + \mathbb{1}_{\mathcal{F}_i})\sum_{(\sigma,p)\in\widehat{W}}|p_i|\Big]. \qquad (10)\end{aligned}$$

To bound (10) further, we expand its final expression into two parts. We then bound one part in (11) using Theorem 4.3, and the other part in Theorem 4.9.

$$\mathbb{E}\Big[\tfrac{1}{m}\sum_{i\in[d]}\epsilon\sum_{(\sigma,p)\in\widehat{W}}|p_i|\Big] = \epsilon\cdot\mathbb{E}\Big[\tfrac{1}{m}\sum_{(\sigma,p)\in\widehat{W}}\|p_i\|_1\Big] \leqslant 2\epsilon\cdot\mathrm{opt}(P). \qquad (11)$$

▷ Claim 4.9. $\mathbb{E}\Big[\tfrac{1}{m}\sum_{i\in[d]}\mathbb{1}_{\mathcal{F}_i}\sum_{(\sigma,p)\in\widehat{W}}|p_i|\Big] \leqslant 2\epsilon\cdot\mathrm{opt}(P).$

Proof. The main obstacle here is that we have a product of two random variables, $\mathbb{1}_{\mathcal{F}_i}$ and $|p_i|$, that are not independent. Intuitively, their dependence should be relatively small, and our actual proof bounds their product with another product, of two independent random variables. Recall that $\widehat{W} = \{(\hat{\sigma}^1, p^1), \ldots, (\hat{\sigma}^m, p^m)\}$ consists of m i.i.d. samples, hence we can focus on analyzing (say) the last one, formally

$$\mathbb{E}\Big[\tfrac{1}{m}\sum_{i\in[d]}\mathbb{1}_{\mathcal{F}_i}\cdot\sum_{(\sigma,p)\in\widehat{W}}|p_i|\Big] = \mathbb{E}\Big[\sum_{i\in[d]}\mathbb{1}_{\mathcal{F}_i}\cdot|p_i^m|\Big].$$

Consider $i \in [d]$, and define $\mathcal{F}_i'$ to be the event that $|\frac{1}{m}\sum_{j=1}^{m-1}\hat{\sigma}_i^j| > \epsilon - \frac{1}{m}$. Observe that $\mathbb{1}_{\mathcal{F}_i} \leqslant \mathbb{1}_{\mathcal{F}_i'}$ because if $\mathcal{F}_i$ occurs then also $\mathcal{F}_i'$ must occur. The crux is that $\mathcal{F}_i'$ is independent of $(\hat{\sigma}^m, p^m)$, and thus $\mathbb{E}[\mathbb{1}_{\mathcal{F}_i'}\cdot|p_i^m|] = \mathbb{E}[\mathbb{1}_{\mathcal{F}_i'}]\cdot\mathbb{E}[|p_i^m|]$. We can still bound $\mathbb{E}[\mathbb{1}_{\mathcal{F}_i'}] = \Pr[\mathcal{F}_i'] \leqslant \epsilon$ by the argument we had for $\mathcal{F}_i$ in (7), except that we use $m-1$ instead of m. Altogether,

$$\mathbb{E}\Big[\sum_{i\in[d]}\mathbb{1}_{\mathcal{F}_i}\cdot|p_i^m|\Big] \leqslant \mathbb{E}\Big[\sum_{i\in[d]}\mathbb{1}_{\mathcal{F}_i'}\cdot|p_i^m|\Big] = \sum_{i\in[d]}\mathbb{E}[\mathbb{1}_{\mathcal{F}_i'}]\cdot\mathbb{E}[|p_i^m|] \leqslant \epsilon\cdot\mathbb{E}[\|p^m\|_1],$$

and the claim follows by using Theorem 4.3 to bound $\|p^m\|_1 \leqslant 2\,\mathrm{opt}(P)$. ◁

We now proceed with the proof of Theorem 4.7. Plugging the bounds from (11) and Theorem 4.9 into (10), we obtain

$$\mathbb{E}\Big[\tfrac{1}{m}\Big|\sum_{i\in[d]}\sum_{(\sigma,p)\in W}\sigma_i p_i - \sum_{i\in[d]}\sum_{(\sigma,p)\in\widehat{W}}\sigma_i p_i\Big|\Big] \leqslant O(\epsilon)\,\mathrm{opt}(P).$$

which completes the proof of Theorem 4.7. ◀

Proof of Theorem 4.8. For $\sigma \in \{\pm 1\}^d$ and $p \in P$, define $X_{\sigma,p} := \sum_{i\in[d]}\sigma_i p_i$. Then we can write

$$\widehat{L} = \tfrac{1}{m}\sum_{i\in[d]}\sum_{(\sigma,p)\in\widehat{W}}\sigma_i p_i = \tfrac{1}{m}\sum_{(\sigma,p)\in\widehat{W}}X_{\sigma,p}.$$

Observe that for every (σ, p) we have $|X_{\sigma,p}| \leqslant \sum_{i\in[d]} |p_i| \leqslant 2\operatorname{opt}(P)$ by Theorem 4.3. Now since the m samples in $\widehat{W}$ are independent, the variance of their sum is the sum of their variances, and we obtain

$$\operatorname{Var}(\widehat{L}) = \tfrac{1}{m^2} \cdot \operatorname{Var}\Big(\sum_{(\sigma,p)\in\widehat{W}} X_{\sigma,p}\Big) \leqslant \tfrac{1}{m^2} \cdot m \cdot (2\operatorname{opt}(P))^2 = \tfrac{4}{m}(\operatorname{opt}(P))^2. \tag{12}$$

This completes the proof of Theorem 4.8. ◀

4.2 Lower bound for value-preserving 0-coreset

The Helly number of a body S, denoted $\mathcal{H}(S)$, is the smallest positive integer h, such that if every subset of size h from a family of translations of S has a non-empty intersection, then the entire family also has a non-empty intersection. The Helly theorem shows that the Helly number of every convex body is smaller than or equal to $d + 1$.

The Helly number is equivalent to a worst-case result of value-preserving 0-coreset (cf. [6]). In the next proposition we show that the $d + 1$ upper bound is tight, that is, the Helly number of the ℓ_1 ball is $d + 1$.

▶ **Proposition 4.10.** *Assume $d > 2$. There exists $P \subset \mathbb{R}^d$, such that every value-preserving 0-coreset must have size $d + 1$.*

Proof. Consider the set of $d + 1$ points $P = \{p_0, \ldots, p_d\}$, where $p_0 = (-1, -1, \ldots, -1)$ and p_i is the vector with all entries equal to 1 except for a -1 in the i-th position. We will show that:

- The point $\vec{0} = (0, 0, \ldots, 0)$ is the only center of P with a cost of d.
- Each subset of P containing d points has a cost strictly less than d.

To prove the first claim, let c be an optimal center of P, clearly $c \in [-1, 1]^d$. We know that for every i:

$$\operatorname{cost}(c, P) \geqslant \frac{1}{2}(\|c - p_0\|_1 + \|c - p_i\|_1) = \frac{1}{2}(2(d-1) + 2|c_i + 1|) = d - 1 + |c_i + 1|$$

On the other hand, $\operatorname{cost}(c, P) \leqslant d$, since the zero vector $\vec{0}$ has a cost d, consequently $1 \geqslant |c_i + 1|$ for all i. This implies $c_i \leqslant 0$ for all i, leading to:

$$\operatorname{cost}(c, P) \geqslant \|c - p_i\|_1 \geqslant (d-1) + (1 + c_i) - \sum_{j\neq i} c_j = d + c_i - \sum_{j\neq i} c_j$$

Since $d \geqslant \operatorname{cost}(c, P)$, it follows that $\sum_{j\neq i} c_j \geqslant c_i$ for all i. Given that $d > 2$, this implies $c = \vec{0}$.

For the second claim, consider any subset Q of d points. If $p_0 \notin Q$, then clearly $\operatorname{opt}(Q) < d$. Assuming $p_0 \in Q$ and, without loss of generality, $p_d \notin Q$, we set $c_i = -\frac{1}{d-2}$ for $i < d$, and $c_d = 1$. The cost for this choice of c is:

$$\begin{aligned}\operatorname{cost}(c, P) &= \max\Big\{2 + (d-1)|-1-c_i|, (d-2)|1-c_i| + |-1-c_i|\Big\} \\ &= \max\Big\{2 + (d-1)(1+c_i), (d-2)(1-c_i) + (1+c_i)\Big\} < d\end{aligned}$$ ◀

5 Generalization to discrete metric spaces

In this section we show how to extend our lower bounds results to other discrete metric spaces by providing two examples for Jaccard and Kendall's tau metric spaces.

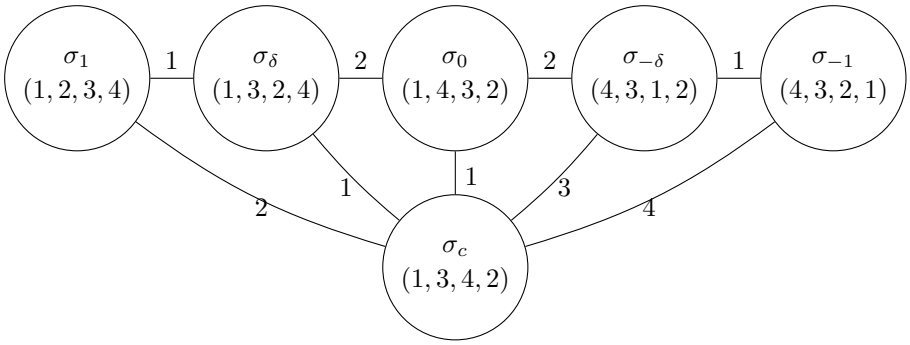

Figure 1 The figure shows the distances between the different base permutations used in the construction of the set P in Proposition 5.1. The distances between $\sigma_1, \sigma_\delta, \sigma_0, \sigma_{-\delta}, \sigma_{-1}$ are additive over the straight lines. The curved lines indicate the distances from $(1,3,4,2)$ to the others.

5.1 Theorem 2.2 in Kendall's tau metric space

Denote by $\mathcal{S}_d$ the set of permutations over the set of elements $[d]$. For two permutations $\sigma_1, \sigma_2 \in \mathcal{S}_d$, the Kendall's tau distance is the number of pairs (i,j) such that the order of i and j is reversed between σ_1 and σ_2. Formally,

$$\tau(\sigma_1,\sigma_2) = \left|\left\{\{i,j\} : (\sigma_1(i)-\sigma_1(j))(\sigma_2(i)-\sigma_2(j)) < 0\right\}\right|$$

Following a similar approach as in Section 2 we will prove a lower bound of size $2^{\Omega(d)}$ on the size of weak coreset.

▶ **Proposition 5.1.** *There exists a set $P \subseteq \mathcal{S}_{4d}$, such that for all $\epsilon \in [0, \frac{1}{3})$, if $Q \subseteq P$ is a weak ϵ-coreset of P, then $|Q| \geqslant 2^{\Omega(d)}$.*

Proof. We will design a gadget that will allow us to replicate the structure of P that is given in the proof of Theorem 2.2. We denote $\sigma_1 = (1,2,3,4)$, $\sigma_\delta = (1,3,2,4)$, $\sigma_0 = (1,4,3,2)$, $\sigma_{-\delta} = (4,3,1,2)$, $\sigma_{-1} = (4,3,2,1)$ and $\sigma_c = (1,3,4,2)$. The distances between these base permutations are detailed in Figure 1.

We will now introduce some notations that will allow us to describe permutations in $\mathcal{S}_{4d}$ using the base permutations. For $\sigma = (\pi_1, \ldots, \pi_k)$, with a slight abuse of notation, we denote by $i + \sigma$ the permutation $(i + \pi_1, \ldots, i + \pi_k)$ and also introduce an operator $\odot$ to denote the product $A \odot B = \{\sigma \cdot \hat{\sigma} : \sigma \in A, \hat{\sigma} \in B\}$ where the product of two permutations is their composition. We will extend a base permutation over 4 elements to a permutation over $4d$ elements using the notation $\sigma_{\vec{x}} = (0 + \sigma_x) \cdot (4 + \sigma_x) \cdot \ldots \cdot (4(d-1) + \sigma_x)$, for $x \in \{-1, -\delta, 0, \delta, 1, c\}$. Now we are ready to describe P. Let $B = \odot_{i=0}^{d-1}\{4i + \sigma_\delta, 4i + \sigma_{-\delta}\}$, then $P = B \cup \{\sigma_{\vec{1}}, \sigma_{-\vec{1}}\}$. The permutation $\sigma_{\vec{0}}$, has cost $3d$ (see also Figure 1) and this cost is optimal the base permutations composing $\sigma_{\vec{1}}, \sigma_{-\vec{1}}$ are antipodal (for every $i \leqslant d-1$, every pair that agrees with $(4i + \sigma_1)$ disagrees with $(4i + \sigma_{-1})$, and vice versa).

Let Q be a weak ϵ-coreset of P. Notice that Q must contain both $\sigma_{-\vec{1}}$ and $\sigma_{\vec{1}}$, as otherwise, if $\sigma_{-\vec{1}}, \sigma_{\vec{1}} \notin Q$, consider $\sigma_{\vec{0}}$ as a center, and if Q contains just one of $\{\sigma_{-\vec{1}}, \sigma_{\vec{1}}\}$ say $\sigma_{\vec{1}}$, consider the permutation $\sigma_{\vec{c}}$ as a center. In both cases, we obtain that $2d = \mathrm{opt}(Q) < \frac{1}{1+\epsilon}\,\mathrm{opt}(P) = \frac{1}{1+\epsilon}3d$, in contradiction that Q is a weak ϵ-coreset.

Similarly to Proposition 2.3 it follows that if $|Q| \leqslant \frac{1}{\sqrt{2d}}2^{0.18d}$, then there exists $b \in B$ such that the Kendall tau distance $\tau(b,q) \leqslant 3d$ for every $q \in Q$. That is, b is an optimal center of Q. However, $\mathrm{cost}(b,P) = 4d$, by considering the opposite permutation of b in P, thus $|Q| \geqslant 2^{\Omega(d)}$. ◀

5.2 Theorem 3.1 in the Jaccard metric space

For two sets A and B, the Jaccard distance is defined as: $J(A,B) = 1 - \frac{|A\cap B|}{|A\cup B|}$. We will use the symbol $\circledast$ to denote the product $A \circledast B = \{a \cup b : a \in A, b \in B\}$.

Following a similar approach as in Section 3.1 we will prove a lower bound of size $\Omega(\log d)$ on the size of weak coreset.

▶ **Proposition 5.2.** *Let $P = \circledast_{i=0}^{d-1} \{\{3i\}, \{3i, 3i+1, 3i+2\}\}$ be a collection of sets, i.e. points in the Jaccard metric space. For every $\epsilon < \frac{1}{3}$, a weak ϵ-coreset has $\Omega(\log d)$ points.*

Proof. Let $\mathcal{U} = \{0, 1, \ldots, 3d-1\}$ denote the universe. We also denote elements in $\mathcal{U}$ as *type 0* if their remainder modulo 3 is 0 and *type 1* otherwise. Note that all type 0 elements appear in every subset of P and thus appear in every optimal center of every coreset of P. It is then easy to verify that the set of optimal centers of P is the $\circledast$ product of $\{3i+1, 3i+2\}$ for $i \in [d]$, along with all type 0 elements, and that $\mathrm{opt}(P) = \frac{1}{2}$.

Using the same arguments as in the proof of Theorem 3.1, assume $Q \subset P$ is a weak ϵ-coreset of size $t \leqslant \frac{1}{2}\log d$. We denote by $A_i = \{3i\}$ and $B_i = \{3i, 3i+1, 3i+2\}$ the two building blocks of the set P, corresponding to -1 and 1 in the proof of Theorem 3.1. Every set in $p \in Q$ induces a partition of $\mathcal{U}$ into at most two parts, depending on their assignment to A_i or B_i. Again, we use Π to denote the common refinement of all these partitions.

Let c^* be any optimal 1-center of Q, and consider a partition $A \in \Pi$. Let k denote the number of type 1 elements from A in c^*. By selecting k different type 1 elements from A, say the first k type 1 indices of A, we preserve the cost of c^* over Q, as the number of differences c^* has with each $p \in Q$ remains unchanged. We apply this modifications for all partitions in Π and denote the new center by $\bar{c}^*$. However, by the construction of $\bar{c}^*$ there exists $p \in P$ such that p intersects at most one type 1 element of $\bar{c}^*$ in every partition and the union of p and c^* is $\mathcal{U}$. Consequently, the distance between c^* and p is at least $1 - \frac{d+|\Pi|}{3d} \geqslant \frac{2}{3} - \frac{2^t}{3d} = \frac{2}{3} - \frac{\sqrt{d}}{3d} > (1+\epsilon)\,\mathrm{opt}(P)$. ◀

A Appendix

A.1 Lower bound for weak 0-coreset for inputs with a unique solution

We present an example of a set P of size $2d$, where P is the sole weak 0-coreset of itself. This demonstrates that the upper bound of $2d$ is indeed tight.

We start with a simple proposition regarding the distances from a given point within the unit hypercube to two antipodal vertices of the cube.

▶ **Proposition A.1.** *If $p \in \{-1,1\}^d$ and $x \in [-1,1]^d$ then $\|p-x\|_1 + \|(-p)-x\|_1 = 2d$.*

Proof. $\|p-x\|_1 + \|(-p)-x\|_1 = \sum_{i=1}^{d} |1-x_i| + |-1-x_i| = \sum_{i=1}^{d}((1-x_i)+(1+x_i)) = \sum_{i=1}^{d} 2 = 2d$ ◀

An immediate consequence of the above proposition is that the cost of every optimal center of P is at least d for every set $P \subseteq \{-1,1\}^d$ containing an antipodal pair. Since $\vec{0}$ has cost at most d to P we get that $\mathrm{opt}(P) = d$ and that $\vec{0}$ is an optimal center. This is summarized in the following corollary.

▶ **Corollary A.2.** *If $P \subseteq [-1,1]^d$ contains antipodal pair, then $\mathrm{opt}(P) = d$.*

Let H denote the set of row vectors of the Hadamard matrix, and let $P = H \cup -H$.

▶ **Proposition A.3.** *There exists $P \subset \mathbb{R}^d$ with unique optimum, such that every weak 0-coreset must have size $2d$.*

Proof. Following Corollary A.2, $\mathrm{opt}(P) = d$. We will further show that if $Q \subseteq P$ does not contain an antipodal pair, then $\mathrm{opt}(Q) < d$. Note that for $a, b \in P$, $a \neq \pm b$ we have $a \cdot b = 0$. Also, since $a, b \in \{-1,1\}^d$, $a \cdot b = \sum_{i:a_i=b_i} 1 - \sum_{i:a_i \neq b_i} 1 = d - 2\sum_{i:a_i \neq b_i} 1$. That is:

$$\|a-b\|_1 = 2 \sum_{i:a_i \neq b_i} 1 = d - a \cdot b = d \tag{13}$$

That is, the distance from every $a \in P$ to all points $P \backslash \{a, -a\}$ is d.

Let $c = \frac{1}{|Q|}\sum_{q \in Q} q$ be some center. Since Q does not contain an antipodal pair it follows that $|Q| \leqslant d$. Now, using Equation 13, for every $\tilde{q} \in Q$:

$$\|c-\tilde{q}\|_1 = \frac{1}{|Q|}\left\|\sum_{q \in Q} q - \tilde{q}\right\|_1 = \frac{1}{|Q|}\left\|\sum_{q \in Q, q \neq \tilde{q}} d\right\|_1 = \frac{|Q|-1}{|Q|}d < d$$

That is $\mathrm{opt}(Q) < d$. It follows that every weak 0-coreset of P contains an antipodal pair. If a weak 0-coreset Q is a proper subset of P then there exists $q \in Q$ with $-q \notin Q$. But $\mathrm{cost}(q, Q) = d = \mathrm{opt}(Q)$, whereas $\mathrm{cost}(q, P) = 2d$. Hence P is the sole weak 0-coreset of P. ◀

Extracting Dual Solutions via Primal Optimizers

Abstract

We provide a general method to convert a "primal" black-box algorithm for solving regularized convex-concave minimax optimization problems into an algorithm for solving the associated dual maximin optimization problem. Our method adds recursive regularization over a logarithmic number of rounds where each round consists of an approximate regularized primal optimization followed by the computation of a dual best response. We apply this result to obtain new state-of-the-art runtimes for solving matrix games in specific parameter regimes, obtain improved query complexity for solving the dual of the CVaR distributionally robust optimization (DRO) problem, and recover the optimal query complexity for finding a stationary point of a convex function.

1 Introduction

We consider the foundational problem of efficiently solving convex-concave games. For nonempty, closed, convex constraint sets $\mathcal{X} \subseteq \mathbb{R}^d$ and $\mathcal{Y} \subseteq \mathbb{R}^n$ and differentiable convex-concave objective function $\psi : \mathbb{R}^d \times \mathbb{R}^n \to \mathbb{R}$ (namely, $\psi(\cdot, y)$ is convex for any fixed y and $\psi(x, \cdot)$ is concave for any fixed x), we consider the following *primal*, minimax optimization problem (P) and its associated *dual*, maximin optimization problem (D):

$$\underset{x\in\mathcal{X}}{\text{minimize}}\, f(x) \text{ for } f(x) \coloneqq \max_{y\in\mathcal{Y}} \psi(x, y), \text{ and} \tag{P}$$

$$\underset{y\in\mathcal{Y}}{\text{maximize}}\, \phi(y) \text{ for } \phi(y) \coloneqq \min_{x\in\mathcal{X}} \psi(x, y). \tag{D}$$

If additionally $\mathcal{X}$ and $\mathcal{Y}$ are bounded (which we assume for simplicity in the introduction but generalize later), every pair of primal and dual optimizers $x^\star \in \operatorname{argmin}_{x\in\mathcal{X}} f(x)$ and $y^\star \in \operatorname{argmax}_{y\in\mathcal{Y}} \phi(y)$ satisfies the *minimax principle*: $f(x^\star) = \phi(y^\star) = \psi(x^\star, y^\star)$.

Convex-concave games are pervasive in algorithm design, machine learning, data analysis, and optimization. For example, the games induced by bilinear objectives, i.e., $\psi(x,y) = x^\top Ay + b^\top x + c^\top y$, where $\mathcal{X}$ and $\mathcal{Y}$ are either the simplex, $\Delta^k \coloneqq \{x \in \mathbb{R}^k_{\geq 0} : \|x\|_1 = 1\}$, or the Euclidean ball, $B^k \coloneqq \{x \in \mathbb{R}^k : \|x\|_2 \leq 1\}$, encompass zero-sum games, linear programming, hard-margin support vector machines (SVMs), and minimum enclosing/maximum inscribed ball [14, 2, 31, 10]. Additionally, the case when $\psi(x,y) = \sum_{i=1}^n y_i f_i(x)$ for some functions $f_i : \mathbb{R}^d \to \mathbb{R}$ and $\mathcal{Y}$ is a subset of the simplex encompasses a variety of distributionally robust optimization (DRO) problems [29, 5] and (for $\mathcal{Y} = \Delta^n$) the problem of minimizing the maximum loss [6, 8, 4].

In this paper, we study the following question:

> *Given only a black-box oracle which solves (regularized versions of)* (P) *to ϵ accuracy, and a black-box oracle for computing an exact dual best response $y_x \coloneqq \operatorname{argmax}_{y\in\mathcal{Y}} \psi(x,y)$ to any primal point $x \in \mathcal{X}$, can we extract an ϵ-optimal solution to* (D)*?*

We develop a general *dual-extraction framework* which answers this question in the affirmative. We show that as long as these oracles can be implemented as cheaply as obtaining an ϵ-optimal point of (P), then our framework can obtain an ϵ-optimal point of (D) at the same cost as that of obtaining an ϵ-optimal point of (P), up to logarithmic factors. We then instantiate our framework to obtain new state-of-the-art results in the settings of bilinear matrix games and DRO. Finally, as evidence of its broader applicability, we show that our framework can be used to recover the optimal complexity for computing a stationary point of a smooth convex function.

In the remainder of the introduction we describe our results in greater detail (Section 1.1), give an overview of the dual extraction framework and its analysis (Section 1.2), discuss related work (Section 1.3), and provide a roadmap for the remainder of the paper (Section 1.4).

1.1 Our results

From primal algorithms to dual optimization

We give a general framework which obtains an ϵ-optimal solution to (D) via a sequence of calls to two black-box oracles: (i) an oracle for obtaining an ϵ-optimal point of a regularized version of (P), and (ii) an oracle for obtaining a dual best response $y_x \coloneqq \operatorname{argmax}_{y\in\mathcal{Y}} \psi(x,y)$ for a given $x \in \mathcal{X}$. In particular, we show it is always possible to obtain an ϵ-optimal point to (D) with at most a logarithmic number of calls to each of these oracles, where the regularized primal optimization oracle is always called to an accuracy of ϵ over a logarithmic factor. We also provide an alternate scheme (or more specifically choice of parameters) for applications where the cost of obtaining an ϵ-optimal point of the regularized primal problem decreases sufficiently as the regularization level increases. In such cases, e.g., in our stationary point application, it is possible to avoid even logarithmic factor increases in computational complexity for approximately solving (D) relative to the complexity of approximately solving (P).

Application 1: Bilinear matrix games

In this application, $\psi(x,y) \coloneqq x^\top Ay$ for a matrix $A \in \mathbb{R}^{d\times n}$, $\mathcal{Y}$ is the simplex Δ^n, and $\mathcal{X}$ is either the simplex Δ^d or the unit Euclidean ball B^d. Recently, [8] gave a new state-of-the-art runtime in certain parameter regimes of $\widetilde{O}(nd + n(d/\epsilon)^{2/3} + d\epsilon^{-2})$ for obtaining an expected ϵ-optimal point for the primal problem (P) for this setup. However, unlike previous algorithms

for bilinear matrix games (see Section 1.3 for details), their algorithm does not return an ϵ-optimal solution for the dual (D), and their runtime is not symmetric in the dimensions n and d. As a result, it was unclear whether the same runtime is achievable for obtaining an ϵ-optimal solution of the dual (D). We resolve this question by applying our general framework to achieve an expected ϵ-optimal point of (D) with runtime $\widetilde{O}(nd + n(d/\epsilon)^{2/3} + d\epsilon^{-2})$. We then observe (see Corollary 22) that in the setting where $\mathcal{X} = \Delta^d$, our result can equivalently be viewed as a new state-of-the-art runtime of $\widetilde{O}(nd + d(n/\epsilon)^{2/3} + n\epsilon^{-2})$ for obtaining an ϵ-optimal point of the primal (P) due to the symmetry of ψ and the constraint sets.

Application 2: CVaR at level α DRO

In this application, $\psi(x, y) \coloneqq \sum_{i=1}^n y_i f_i(x)$ for convex, bounded, and Lipschitz loss functions $f_i : \mathbb{R}^d \to \mathbb{R}$, $\mathcal{X}$ is a convex, compact set, and $\mathcal{Y} \coloneqq \left\{y \in \Delta^n : \|y\|_\infty \le \frac{1}{\alpha n}\right\}$ is the CVaR at level α uncertainty set for $\alpha \in [1/n, 1]$. The primal (P) is a canonical and well-studied DRO problem, and corresponds to the average of the top α fraction of the losses. We consider this problem given access to a first-order oracle that, when queried at $x \in \mathbb{R}^d$ and $i \in [n]$, outputs $(f_i(x), \nabla f_i(x))$. Ignoring dependencies other than α, the target accuracy $\epsilon > 0$, and the number of losses n for brevity, [29] gave a matching upper and lower bound (up to logarithmic factors) of $\widetilde{O}(\alpha^{-1}\epsilon^{-2})$ queries to obtain an expected ϵ-optimal point of the primal (P). However, the best known query complexity for obtaining an expected ϵ-optimal point of the dual (D) was $\widetilde{O}(n\epsilon^{-2})$ prior to this paper (see Section 1.3 for details). Applying our general framework to this setting, we obtain an algorithm with a new state-of-the-art query complexity of $\widetilde{O}(\alpha^{-1}\epsilon^{-2} + n)$ for obtaining an expected ϵ-optimal point of the dual (D). In particular, note that this complexity is nearly linear in n when $\epsilon \ge (\alpha n)^{-2}$.

Application 3: Obtaining stationary points of convex functions

In this application, we show that our framework yields an alternative optimal approach for computing an approximate critical point of a smooth convex function given a gradient oracle. Specifically, for $\gamma > 0$ and convex and β-smooth $h : \mathbb{R}^n \to \mathbb{R}$, in Section 5, we give an algorithm which computes $x \in \mathbb{R}^n$ such that $\|\nabla h(x)\|_2 \le \gamma$ using $O\left(\sqrt{\beta\Delta}/\gamma\right)$ gradient queries, where $\Delta \coloneqq h(x_0) - \inf_{x \in \mathbb{R}^n} h(x)$ is the initial suboptimalityf. While this optimal complexity has been achieved before [24, 37, 15, 28, 27], that we achieve it is a consequence of our general framework illustrates its broad applicability.

For this application, we instantiate our framework with $\psi(x, y) \coloneqq \langle x, y\rangle - h^*(y)$, where $h^* : \mathbb{R}^n \to \mathbb{R}$ denotes the convex conjugate of h. (For reasons discussed in Section 5, we actually first substitute h for an appropriately regularized version of h, call it f, before applying the framework, but the following discussion still holds with respect to f.) This objective function ψ is known as the *Fenchel game* and has been used in the past to recover classic convex optimization algorithms (e.g., the Frank-Wolfe algorithm and Nesterov's accelerated methods) via a minimax framework [1, 43, 12, 23]. In the Fenchel game, a dual best response corresponds to a gradient evaluation:

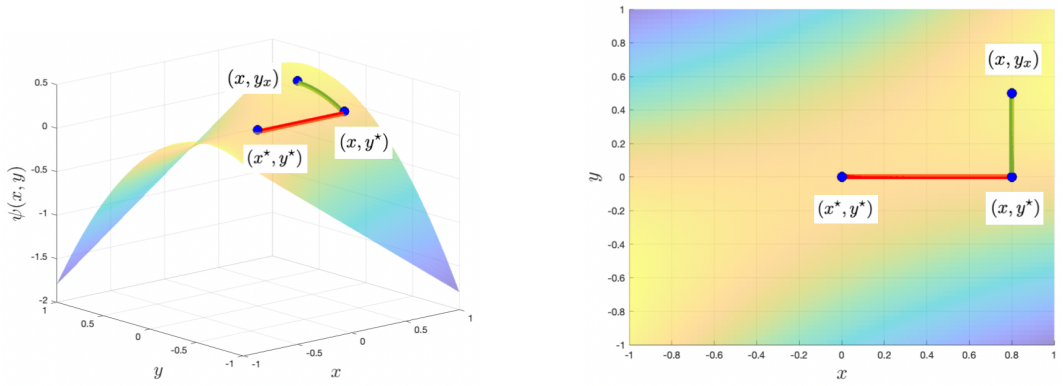
$$\operatorname*{argmax}_{y \in \mathbb{R}^n} \{\langle x, y\rangle - h^*(y)\} = \nabla h(x),$$

and we show that approximately optimal points for the dual objective (D) must have small norm. As a result, obtaining an approximately optimal dual point y as a best response to a primal point x yields a bound on the norm of $y = \nabla f(x)$. Furthermore, we note that in this setting, adding regularization to ψ with respect to an appropriate choice of

distance-generating function (namely h^*) is equivalent to rescaling and recentering the primal function f, as well as the point at which a gradient is taken in the dual best response computation (cf. Lemma 14 in the full version). Thus, the properties of the Fenchel game extend naturally to appropriately regularized versions of ψ.

1.2 Overview of the framework and analysis

We now give an overview of the dual-extraction framework. Our framework applies generally to a set of assumptions given in Section 3.1 (cf. Definition 9), but for now we specialize to the assumptions given above, namely: (i) the constraint sets $\mathcal{X}$ and $\mathcal{Y}$ are nonempty, compact, and convex; and (ii) ψ is differentiable and convex-concave. Throughout this section, let $\|\cdot\|$ denote any norm on $\mathbb{R}^n$ and assume that the dual function, ϕ, is L-Lipschitz with respect to $\|\cdot\|$.[1] Let $r : \mathbb{R}^n \to \mathbb{R}$ denote a differentiable distance-generating function (dgf) which is μ_r-strongly convex with respect to $\|\cdot\|$ for $\mu_r > 0$,[2] and let $V_u(v) \coloneqq r(v) - r(u) - \langle \nabla r(u), v - u \rangle$ denote the associated Bregman divergence. For the sake of illustration, it may be helpful to consider the choices $\|\cdot\| \coloneqq \|\cdot\|_2$, $r(u) \coloneqq \frac{1}{2}\|u\|_2^2$, $\mu_r = 1$, and $V_u(v) = \frac{1}{2}\|u - v\|_2^2$ in the following, in which case relative strong convexity with respect to r is equivalent to the standard notion of strong convexity with respect to $\|\cdot\|_2$.



How should we obtain an ϵ-optimal point for (D) using the two oracles discussed previously, namely: (i) an oracle for approximately solving a regularized primal objective, and (ii) an oracle for computing a dual best response? We call (i) a dual-regularized primal optimization (DRPO) oracle and (ii) a dual-regularized best response (DRBR) oracle; their formal definitions are given in Section 3.1. Note that to solve (D), one cannot simply solve the primal problem (P) to high accuracy and then compute a dual best response. Consider $\psi(x, y) = xy$ with $\mathcal{X} = \mathcal{Y} = [-1, 1]$; clearly $x^\star = y^\star = 0$, but for any x arbitrarily close to $x^\star$, the dual best response is either -1 or 1.

The key observation underlying our framework is that if $\psi(x, \cdot)$ is strongly concave for a given $x \in \mathcal{X}$, it is possible to upper bound the distance between the best response $y_x \coloneqq \operatorname{argmax}_{y \in \mathcal{Y}} \psi(x, y)$ and the dual optimum $y^\star$ in terms of the primal suboptimality of x. Figure 1 illustrates why this should be the case when subtracting a quadratic regularizer in y (so that $\psi(x, \cdot)$ is strongly concave) to the preceding example of $\psi(x, y) = xy$. We generalize this intuition in the following lemma (replacing strong concavity with relative strong concavity and a distance bound with a divergence bound), which is itself generalized further and proven in Section 3:

▶ **Lemma 1** (Lemma 3 from the full version specialized). *For a given $x \in \mathcal{X}$, suppose $-\psi(x, \cdot)$ is μ-strongly convex relative to the dgf r for some $\mu > 0$. Then $y_x \coloneqq \operatorname{argmax}_{y \in \mathcal{Y}} \psi(x, y)$ satisfies*

$$V_{y_x}(y^\star) \leq \frac{f(x) - f(x^\star)}{\mu}.$$

[1] This is a weak assumption since we ensure at most a logarithmic dependence on L; see Remark 5.
[2] Section 2 gives the general setup for a distance-generating function which also covers the case where $\operatorname{dom} r \neq \mathbb{R}^n$.

(a) **(b)**

Figure 1 An example to give intuition behind Lemma 1. Here, $\psi(x, y) = xy - 0.8y^2$, $(x^\star, y^\star) = (0, 0)$, $x = 0.8$, and $y_x = 0.5$. To see why it is possible to bound $|y^\star - y_x|$ in terms of the primal suboptimality $f(x) - f(x^\star)$, note that by the strong concavity of $\psi(x, \cdot)$ and the fact that y_x is the maximizer of $\psi(x, \cdot)$ over $\mathcal{Y}$, we can upper bound $|y^\star - y_x|$ in terms of $\psi(x, y_x) - \psi(x, y^\star)$ (the vertical drop over the green line) via a standard strong-concavity inequality. In turn, $\psi(x, y_x) - \psi(x, y^\star)$ can be upper bounded by $\psi(x, y_x) - \psi(x^\star, y^\star) = f(x) - f(x^\star)$ (the vertical drop over the green line plus the vertical drop over the red line) due to the fact that $\psi(x^\star, y^\star) \le \psi(x, y^\star)$ by the optimality of $x^\star$.

A first try

In particular, Lemma 1 suggests the following approach: Define "dual-regularized" versions of ψ, ϕ, f as follows for $\lambda > 0$ and $y_0 \in \mathcal{Y}$:

$$\begin{aligned} \psi_1(x, y) &\coloneqq \psi(x, y) - \lambda V_{y_0}(y), \\ f_1(x) &\coloneqq \max_{y \in \mathcal{Y}} \psi_1(x, y), \\ \phi_1(y) &\coloneqq \min_{x \in \mathcal{X}} \psi_1(x, y)\,. \end{aligned}$$

(Here, the subscript 1 denotes one level of regularization and will be extended later.) For any $x \in \mathcal{X}$, note that $-\psi_1(x, \cdot)$ is λ-strongly convex relative to r, in which case Lemma 1 applied to ψ_1 yields

$$V_{y_x}(y_1^\star) \le \frac{f_1(x) - f_1(x_1^\star)}{\lambda}, \tag{1}$$

for $y_1^\star \coloneqq \operatorname{argmax}_{y \in \mathcal{Y}} \phi_1(y)$, $x_1^\star \in \operatorname{argmin}_{x \in \mathcal{X}} f_1(x)$, and $y_x \coloneqq \operatorname{argmax}_{y \in \mathcal{Y}} \psi_1(x, y)$. Then note

$$\phi(y_1^\star) \ge \phi_1(y_1^\star) \ge \phi_1(y^\star) = \min_{x \in \mathcal{X}} \left\{\psi(x, y^\star) - \lambda V_{y_0}(y^\star)\right\} = \phi(y^\star) - \lambda V_{y_0}(y^\star)\,, \tag{2}$$

where the first inequality follows since $\phi \ge \phi_1$ pointwise. Then by the L-Lipschitzness of ϕ and μ_r-strong convexity of r, it is straightforward to bound the suboptimality of y_x as

$$\phi(y^\star) - \phi(y_x) \le \lambda V_{y_0}(y^\star) + L\sqrt{\frac{2(f_1(x) - f_1(x_1^\star))}{\mu_r \lambda}}. \tag{3}$$

Consequently, an ϵ-optimal point for (D) can be obtained via our oracles as follows: Set $\lambda \leftarrow \frac{\epsilon}{2V_{y_0}(y^\star)}$, and use the DRPO oracle on the regularized primal problem to obtain $x \in \mathcal{X}$ such that

$$f_1(x) - f_1(x_1^\star) \le \frac{\epsilon^3 \mu_r}{16L^2 \cdot V_{y_0}(y^\star)}\,. \tag{4}$$

Then the best response to x with respect to ψ_1, namely $y_x \coloneqq \operatorname{argmax}_{y \in \mathcal{Y}} \psi_1(x, y)$, is ϵ-optimal by (3). However, a typical setting in our applications is $V_{y_0}(y^\star) = \Omega(1)$, $\mu_r = 1$, and $L \geq 1$, in which case ensuring (4) requires solving the regularized primal problem to $O(\epsilon^3)$ error.

Recursive regularization and the dual-extraction framework

To lower the accuracy requirements, we apply dual regularization recursively. A key issue with the preceding argument is that it required a nontrivial bound on $V_{y_0}(y^\star)$. However, it provided us with a nontrivial bound (1) on $V_{y_x}(y_1^\star)$, the "level-one equivalent" of $V_{y_0}(y^\star)$. This suggests solving f_1 to lower accuracy while still obtaining a bound on $V_{y_x}(y_1^\star)$ due to (1), and then adding regularization centered at y_x with a larger value of λ. Indeed, our framework recursively repeats this process until the total regularization is large enough so that (a term similar to) the right-hand side of (3) can be bounded by ϵ, despite never needing to solve a regularized primal problem to high accuracy.

To more precisely describe our approach, let $\psi_0 \coloneqq \psi, f_0 \coloneqq f, \phi_0 \coloneqq \phi$. Over iterations $k = 1, 2, \ldots, K$, our framework implicitly constructs a sequence of convex-concave games $\psi_k : \mathbb{R}^d \times \mathbb{R}^n \to \mathbb{R}$, along with corresponding primal and dual functions $f_k : \mathcal{X} \to \mathbb{R}$ and $\phi_k : \mathcal{Y} \to \mathbb{R}$ respectively, as follows:

$$\begin{aligned} \psi_k(x, y) &\coloneqq \psi_{k-1}(x, y) - \lambda_{k-1} V_{y_{k-1}}(y), \\ f_k(x) &\coloneqq \max_{y \in \mathcal{Y}} \psi_k(x, y), \\ \phi_k(y) &\coloneqq \min_{x \in \mathcal{X}} \psi_k(x, y). \end{aligned} \tag{5}$$

Here, $(\lambda_k \in \mathbb{R}_{>0})_{k=0}^{K-1}$ is a dual-regularization schedule given as input to the framework, and $(y_k \in \mathcal{Y})_{i=0}^{K}$ is a sequence of dual-regularization "centers" generated by the algorithm, with y_0 given as input. For $k \in \{0\} \cup [K]$, it will be useful to let $y_k^\star$ denote a maximizer of ϕ_k over $\mathcal{Y}$ and $x_k^\star$ denote a minimizer of f_k over $\mathcal{X}$, with $y_0^\star \coloneqq y^\star$ and $x_0^\star \coloneqq x^\star$ in particular.

Over the K rounds of recursive dual regularization, we aim to balance two goals:

- On the one hand, we want λ_k to increase quickly so that $-\psi_k(x, \cdot)$ is very strongly convex relative to r, thereby allowing us to apply Lemma 1 with a larger strong convexity constant.
- On the other hand, we want to maintain the invariant that, roughly speaking, $y_k^\star$ is always $\epsilon/2$-optimal for the original dual ϕ. Indeed, we were constrained in choosing λ in (2) to be on the order of $\epsilon / V_{y_0}(y^\star)$ to ensure $y_1^\star$ is $\epsilon/2$-optimal for ϕ. A similar "constraint" on the dual-regularization schedule $(\lambda_k)_{k=0}^{K-1}$ appears when (2) is extended to additional levels of regularization. This prevents us from increasing λ_k too quickly.

In all the applications in this paper we choose $\lambda_k \approx 2\lambda_{k-1}$. λ_0 typically must remain on the order of $\epsilon / V_{y_0}(y^\star)$ due to the second point.

Pseudocode of the framework is given in Algorithm 1. Each successive dual-regularization center y_k is computed via the DRBR oracle (Line 5) as a best response to a primal point x_k obtained via the DRPO oracle (Line 4). In Section 3, we generalize Algorithm 1 (cf. Algorithm 2) in several ways: (i) we allow for stochasticity in the DRPO oracle; (ii) we allow for distance-generating functions r such that $\operatorname{dom} r \neq \mathbb{R}^n$; (iii) we give different but equivalent characterizations of x_k and y_k which facilitate the derivation of explicit expressions for the DRPO and DRBR oracles in applications.

Algorithm 1 Dual-extraction framework (Algorithm 2 specialized).

Input: Initial dual-regularization center $y_0 \in \mathcal{Y}$, iteration count $K \in \mathbb{N}$, dual-regularization schedule $(\lambda_k \in \mathbb{R}_{>0})_{k=0}^{K-1}$, primal-accuracy schedule $(\epsilon_k \in \mathbb{R}_{>0})_{k=1}^{K}$, DRPO and DRBR oracles

$\psi_0 \coloneqq \psi$, $f_0 \coloneqq f$, and $\phi_0 \coloneqq \phi$

for $k = 1, 2, \ldots, K$ **do**

  Define ψ_k, f_k, and ϕ_k as in (5)

  Let $x_k \in \mathcal{X}$ be such that $f_k(x_k) - f_k(x_k^\star) \le \epsilon_k$ // Computed via the DRPO oracle

  $y_k = \operatorname{argmax}_{y \in \mathcal{Y}} \psi_k(x_k, y)$ // Computed via the DRBR oracle

return y_K

Analysis of Algorithm 1

Theorem 2 is our main result for Algorithm 1. We then instantiate Theorem 2 with two illustrative choices of parameters in Corollaries 5 and 7, and defer the proofs of the latter to their general versions in Section 3. All of the remarks below (Remarks 3, 5, 7) are stated with reference to the specialized results in this section (Theorem 2 and Corollaries 4, 6 resp.), but extend immediately to the corresponding general versions (Theorem 15 and Corollaries 16, 17 resp.).

▶ **Theorem 2** (Theorem 15 specialized). *Algorithm 1 returns y_K satisfying*

$$V_{y_K}(u) \le \frac{\epsilon_K}{\Lambda_K} \text{ where } \Lambda_k \coloneqq \sum_{j=0}^{k-1} \lambda_j \text{ for } k \in [K] \tag{6}$$

and $u \in \mathcal{Y}$ is a point with dual suboptimality bounded as

$$\phi(y^\star) - \phi(u) \le \lambda_0 V_{y_0}(y^\star) + \sum_{k=1}^{K-1} \frac{\lambda_k}{\Lambda_k} \epsilon_k. \tag{7}$$

If we additionally assume that ϕ is L-Lipschitz with respect to $\|\cdot\|$, we can directly bound the suboptimality of y_K as

$$\phi(y^\star) - \phi(y_K) \le \lambda_0 V_{y_0}(y^\star) + \sum_{k=1}^{K-1} \frac{\lambda_k}{\Lambda_k} \epsilon_k + L\sqrt{\frac{2}{\mu_r} \frac{\epsilon_K}{\Lambda_K}}. \tag{8}$$

Proof. We claim the first half of Theorem 2 holds with $u \leftarrow y_K^\star$. To see this, note that we can bound the suboptimality of $y_K^\star$ as

$$\begin{aligned}
\phi(y_K^\star) \overset{(i)}{\ge} \phi_K(y_K^\star) \ge \phi_K(y_{K-1}^\star) &= \max_{x \in \mathcal{X}} \left\{ \psi_{K-1}(x, y_{K-1}^\star) - \lambda_{K-1} V_{y_{K-1}}\left(y_{K-1}^\star\right) \right\} \\
&= \phi_{K-1}(y_{K-1}^\star) - \lambda_{K-1} V_{y_{K-1}}\left(y_{K-1}^\star\right) \\
&\overset{(ii)}{\ge} \phi_0(y_0^\star) - \lambda_0 V_{y_0}(y_0^\star) - \sum_{k=1}^{K-1} \lambda_k V_{y_k}(y_k^\star) \\
&\overset{(iii)}{\ge} \phi(y^\star) - \lambda_0 V_{y_0}(y^\star) - \sum_{k=1}^{K-1} \frac{\lambda_k}{\Lambda_k} \epsilon_k,
\end{aligned}$$

where (i) follows since $\phi \geq \phi_K$ pointwise, (ii) follows from repeating the argument in the previous lines recursively (starting by lower bounding $\phi_{K-1}(y^\star_{K-1})$, etc.), and (iii) uses Lemma 1 applied to ψ_k, which yields by Lines 4 and 5 in Algorithm 1:

$$V_{y_k}(y^\star_k) \leq \frac{f_k(x_k) - f_k(x^\star_k)}{\Lambda_k} \leq \frac{\epsilon_k}{\Lambda_k},$$

since $\psi_k(x, \cdot) = \psi(x, \cdot) + \sum_{j=0}^{k-1} \lambda_j V_{y_j}(\cdot)$ is Λ_k-strongly concave relative to $-r$. Thus, we have proven Equation 7, and Equation 6 follows again from Lemma 1 applied to ψ_K. Equation 8 then follows since the fact that r is μ_r-strongly convex with respect to $\|\cdot\|$ and Equation 6 imply

$$\|y_K - y^\star_K\| \leq \sqrt{\frac{2}{\mu_r} V_{y_K}(y^\star_K)} \leq \sqrt{\frac{2}{\mu_r} \frac{\epsilon_K}{\Lambda_K}}. \qquad \blacktriangleleft$$

We give a remark regarding how to pick the parameters $(\lambda_k)_{k=0}^{K-1}$ and $(\epsilon_k)_{k=1}^{K}$ when applying Theorem 2:

▶ Remark 3 (Picking the parameters for Theorem 2). Equation 8 can be interpreted as follows: To ensure y_K is ϵ-optimal for ϕ, it suffices to choose the sequences $(\lambda_k)_{k=0}^{K-1}$ and $(\epsilon_k)_{k=1}^{K}$ so that the right side of (8) is at most ϵ. Then the first term, $\lambda_0 V_{y_0}(y^\star)$, constrains λ_0 to be on the order of $\epsilon / V_{y_0}(y^\star)$. Skipping ahead, the third term, $L\sqrt{\frac{2}{\mu_r}\frac{\epsilon_K}{\Lambda_K}}$, is the reason we always choose $\lambda_k \approx 2\lambda_{k-1}$ in our applications, as this ensures Λ_K is large enough to handle this term with K only needing to be logarithmic in the problem parameters. Then the second term, $\sum_{k=1}^{K-1} \frac{\lambda_k}{\Lambda_k}\epsilon_k$, effectively constrains roughly $\sum_{k=1}^{K-1} \epsilon_k \leq \epsilon$, as $\lambda_k / \Lambda_k \approx 1$.

▶ **Corollary 4** (Corollary 16 specialized). *Suppose ϕ is L-Lipschitz with respect to $\|\cdot\|$, and let $B > 0$ be such that $V_{y_0}(y^\star) \leq B$. Then for any $\epsilon > 0$, and $K \geq \max\left\{\log_2 \frac{L^2 B}{\mu_r \epsilon^2}, 1\right\} + 10$, the output of Algorithm 1 with dual-regularization and primal-accuracy schedules of*

$$\lambda_k = 2^k \frac{\epsilon}{4B} \text{ for } k \in \{0\} \cup [K-1] \text{ and } \epsilon_k = \frac{\epsilon}{4K} \text{ for } k \in [K]$$

satisfies $\phi(y^\star) - \phi(y_K) \leq \epsilon$.

▶ Remark 5. Corollary 4 achieves the stated goal of obtaining an ϵ-optimal point for (D) by running for a number of iterations which depends logarithmically on the problem parameters, and solving each dual-regularized primal subproblem to an accuracy of ϵ divided by a logarithmic factor. Note in particular the logarithmic dependence on the dual divergence bound B and dual Lipschitz constant L, meaning these are weak assumptions. Furthermore, it is clear from the proof of Theorem 2 that ϕ only need be L-Lipschitz on a set containing y_K and $y^\star_K$.

▶ **Corollary 6** (Corollary 17 specialized). *Let $B > 0$ be such that $V_{y_0}(y^\star) \leq B$. Then for any $\epsilon > 0$ and $K \in \mathbb{N}$, the output of Algorithm 1 with dual-regularization and primal-accuracy schedules of*

$$\lambda_k = 2^k \frac{\epsilon}{4B} \text{ for } k \in \{0\} \cup [K-1] \text{ and } \epsilon_k = \frac{\epsilon}{8 \cdot 1.5^k} \text{ for } k \in [K]$$

satisfies

$$\|y_K - u\| \leq \frac{1}{1.5^K} \sqrt{\frac{2B}{\mu_r}},$$

where $u \in \mathcal{Y}$ is a point whose suboptimality is at most ϵ, i.e., $\phi(y^\star) - \phi(u) \leq \epsilon$.
