List Decoding Bounds for Binary Codes with Noiseless Feedback

Meghal Gupta
University of California Berkeley, CA, USA

Rachel Yun Zhang
Massachusetts Institute of Technology, Cambridge, MA, USA

Abstract

In an error-correcting code, a sender encodes a message $x \in \{0,1\}^k$ such that it is still decodable by a receiver on the other end of a noisy channel. In the setting of *error-correcting codes with feedback*, after sending each bit, the sender learns what was received at the other end and can tailor future messages accordingly.

While the unique decoding radius of feedback codes has long been known to be $\frac{1}{3}$, the list decoding capabilities of feedback codes is not well understood. In this paper, we provide the first nontrivial bounds on the list decoding radius of feedback codes for lists of size ℓ. For $\ell = 2$, we fully determine the 2-list decoding radius to be $\frac{3}{7}$. For larger values of ℓ, we show an upper bound of $\frac{1}{2} - \frac{1}{2^{\ell+2}-2}$, and show that the same techniques for the $\ell = 2$ case cannot match this upper bound in general.

1 Introduction

Consider the problem of error-correcting codes with feedback [3]. Alice wishes to communicate a message $x \in \{0,1\}^k$ to Bob by transmitting a sequence of n bits over a noisy channel. After sending each bit, she receives *feedback* through a noiseless channel, telling her what bit Bob actually received. She can use this feedback to adaptively decide her next bit of communication, potentially allowing for improvement over classical error-correcting codes. As in the classical setting, the goal is to communicate in a way such that even if some fraction r of Alice's bits are adversarially corrupted, Bob can still correctly determine x.

For classical error-correcting codes *without* feedback, the Plotkin bound [26] states that Bob cannot uniquely decode x if more than $\frac{1}{4}$ of the communication is adversarially corrupted. In other words, the unique decoding radius for binary error-correcting codes is $\frac{1}{4}$.[1] The corresponding question for codes with feedback was first posed by Berlekamp in his 1964 thesis, "Block Coding with Noiseless Feedback": What is the maximum fraction r of errors from which a feedback-based error-correcting code can still uniquely be decoded? Remarkably, he proved that in the feedback setting, the unique decoding radius increases to $\frac{1}{3}$, surpassing the Plotkin bound.

[1] In this introduction, when we state a resilience threshold/radius r, we mean that for any $\epsilon > 0$ there exists a protocol resilient to $r - \epsilon$ errors, with rate $O_\epsilon(1)$. For sake of simplicity, we've omitted all ϵ's from this introduction.

While Berlekamp's result tells us the unique decoding radius of feedback codes, little is known about the list-decoding case. In list-decoding, first introduced by Elias [9] and Wozencraft [34], the goal is for Bob to output a small *list* of messages including Alice's. The concept of list decoding for non-feedback codes has proven to be quite illuminating for understanding the Hamming space and for various other applications (see e.g. [13] for further discussion).

In the classical setting, list decoding is useful because it can be done at a larger error radius than unique decoding. In fact, the optimal list decoding radius is known for (non-feedback) codes. For decoding into a list of size ℓ, the optimal radius is known to be $\frac{1}{2} - \binom{2s}{s} \cdot 2^{-2s-1}$ where $s := \lfloor \frac{\ell}{2} \rfloor$, which is asymptotically $\frac{1}{2} - \Theta(\ell^{-1/2})$ [5]. This is achieved by positive rate random codes.

In this paper, we investigate the analogous question for feedback codes, first posed in [30]. In a feedback code, what is the maximum fraction r of adversarial errors such that Bob can always learn a list of size ℓ containing Alice's message? We denote such a code as a (ℓ, r)-list decodable feedback code. In our work, we provide the first non-trivial unconditional lower and upper bounds for this question.

1.1 Results And Further Discussion

Our first result gives an upper bound on the error resilience (decoding radius) of an ℓ-list decodable feedback code.

▶ **Theorem 1.** *For any positive integer ℓ, there is no $\left(\ell, \frac{1}{2} - \frac{1}{2^{\ell+2}-2}\right)$-list feedback code.*

Prior to this work, the only known bound on the list decoding radius of feedback codes, aside from the trivial upper bound of $\frac{1}{2}$, was given in [30]. That result showed upper bounds for a specific subclass of feedback codes that satisfy a "generalized translation" property. It turns out this generalized translation property is not very comprehensive: we will in fact demonstrate a code that breaks the upper bound proven in [30]. In contrast, our upper bound is unconditional and applies to all feedback codes.

In the case of $\ell = 1$, Theorem 1 provides an upper bound of $\frac{1}{3}$ on the unique decoding radius, consistent with the result in [3]. The key question, however, is whether this bound is tight in general. Although we do not have an answer for arbitrary ℓ, we are able to show it is true in the specific case of $\ell = 2$. Specifically, we show that for any $\varepsilon > 0$, there exists a $\left(2, \frac{3}{7} - \varepsilon\right)$-list feedback code, matching the upper bound established by Theorem 1.

▶ **Theorem 2.** *For any $\varepsilon > 0$, there is a $\left(2, \frac{3}{7} - \varepsilon\right)$-list feedback code where $n = O_\varepsilon(k)$.*

The particular feedback code we used to achieve $\left(2, \frac{3}{7} - \epsilon\right)$-list decodability is the same code found in [31], which Spencer and Winkler showed achieves unique decoding up to radius $\frac{1}{3} - \epsilon$. The code, which we'll denote SW, is defined in Section 4. Compared to the $(\frac{1}{3} - \epsilon)$-unique decodability analysis in [31], however, our analysis is significantly more involved, requiring us to characterize the likelihood of four inputs rather than one possible input at once.

A reasonable conjecture at this point is that the SW protocol will always give a $\left(\ell, \frac{1}{2} - \frac{1}{2^{\ell+2}-2}\right)$-list decodable code. This would show that Theorem 1 is optimal.

Unfortunately, this turns out not to be true. We show that for $\ell = 3$, the error resilience of the Spencer-Winkler protocol does not match the upper bound given in Theorem 1. There is an adversarial corruption strategy on SW that requires only $\frac{31}{67} \approx 0.4627$ fraction of corruptions to confuse Bob between four different inputs, whereas the bound given by Theorem 1 is $\frac{7}{15} \approx 0.4667$.

▶ **Theorem 3.** *For any $\varepsilon > 0$, the feedback code* SW *(defined in Section 4) is not $\left(3, \frac{31}{67} + \varepsilon\right)$-list decodable for any choice of encoding length $n = n(k)$.*

Although this result states that the SW feedback code is not $\left(3, \frac{7}{15}\right)$-list decodable, it remains unknown whether a different feedback code achieves this bound or whether the upper bound can be improved.

Even the asymptotic behavior for this question remains unknown. Our upper bound suggests that the feedback list decoding radius could approach $\frac{1}{2}$ exponentially fast with respect to the list size ℓ. That is, the radius for ℓ-list decoding is given by $\frac{1}{2} - 2^{-O(\ell)}$. We conjecture that this exponential bound is in fact optimal for the feedback case and propose proving or disproving this as an interesting direction for future research.

In the case of standard ECC's (without feedback), as mentioned earlier, the optimal list decoding radius is $\frac{1}{2} - \binom{2s}{s} \cdot 2^{-2s-1}$ for $s = \left\lfloor \frac{\ell}{2} \right\rfloor$ [5]. That is, for any $\varepsilon > 0$, there exist $\left(\ell, \frac{1}{2} - \binom{2s}{s} \cdot 2^{-2s-1} - \varepsilon\right)$-list decodable codes. Asymptotically, this bound says that the list decoding radius is approximately $\frac{1}{2} - \Theta(\ell^{-1/2})$, which approaches $\frac{1}{2}$ much slower than the conjectured $\frac{1}{2} - 2^{-O(\ell)}$ radius for the feedback case. Even short of proving the exponential bound, demonstrating a separation between the asymptotics for the feedback and non-feedback cases would be an intriguing result.

1.2 Related Works

1.2.1 Error Correcting Codes with Feedback

We already mentioned the seminal work of [3] which introduced the concept of error-correcting codes with feedback. Berlekamp studied adversarial corruption strategies and proved that $\frac{1}{3}$ was the optimal error resilience for a feedback ECC in the face of adversarial errors. Feedback ECC's have also been studied for the binary symmetric channel, where every bit is flipped independently with some fixed probability [4, 35].

Particularly relevant is the work of [30], who initiated the study of list decoding feedback codes and gave some preliminary bounds on the list decoding capacities and radii of codes with noiseless feedback. Using generalizations of Berlekamp's methods, he provides upper bounds on list-decoding capacities for strategies that satisfy what he call a "generalized translation" property. By contrast, our upper bounds make no assumptions about the types of protocols allowed and are fully general.

Many other works on error-correcting codes with feedback present themselves instead under the lens of *adaptive search with lies*. The two setups are equivalent, and our results imply results in the field of adaptive search with lies. We discuss the relationship below.

1.2.1.1 Adaptive Search with Lies

An equivalent way of looking at error-correcting codes with unlimited feedback is as follows: After every message from Alice, Bob asks a yes or no question about Alice's input, and Alice's next bit is a response to that question. Then, the adversary can corrupt Alice's responses, but only up to some fraction α of the time. Bob is "searching" for Alice's input in a range $[N]$ by asking these yes/no questions, and receiving an incorrect answer up to an α fraction of the time. This game is known as the Rényi-Ulam game, independently introduced by Rényi in [27] and Ulam [33].

Two excellent surveys on the research in this area are presented in [8, 25]. There are a number of works that aspire to improve upon [3]. For example, [22] presents a strategy with optimal rate (asking the least possible number of questions) while still achieving the

best error-correction threshold. An alternative construction meeting the same optimal error resilience was given in [31]. We mention that some works focus on a fixed (constant) number of lies rather than resilience to a fraction of errors, and ask for the smallest number of questions necessary. [24] shows the optimal bound for one lie, the original Rényi-Ulam game. Followups find the optimal strategy for two and three lies as well [20, 7].

1.2.1.2 Limited Feedback/Questions

The works of [23, 1] study the minimal number of rounds, or *batches*, of questions Bob needs to ask when conducting adaptive search in the Ulam-Renyi model. The work of [25] poses the open question of how many batches of feedback are necessary before the optimal strategy becomes essentially the same as the fully adaptive setting.

In a more code-centric view, this model corresponds to a feedback code with *limited feedback*, where Alice receives feedback only a few times throughout the protocol instead of after every bit she sends. [21] studied the case where the feedback Alice receives consists of a small fraction of Alice's rounds. [12] took this direction even further, showing that a constant number of rounds of feedback consisting of only $\log(n)$ bits is enough to achieve the same unique decoding radius as for the unlimited feedback case. [29] showed that with $O(1)$ bits of feedback, one can achieve the zero-error capacity of the error channel with full noiseless feedback.

1.2.2 List Decoding

The notion of list decoding was introduced by Elias [9] and Wozencraft [34]. The goal is for Bob to output a small *list* of messages including Alice's. Although they introduced list-decoding in the setting of random error models, the main focus since then has been for adversarial error models. See [32, 16, 14] for surveys on the topic.

One main advantage is that list decoding enables correcting up to a factor two more worst-case errors compared to unique decoding. As we stated earlier, the optimal tradeoff between the list size ℓ and error tolerance (in the classical non-feedback setting) is known [5]. This work shows that there are positive rate codes achieving this maximum possible error tolerance. An analogous result for q-ary codes was shown in [28].

Another advantage of list-decoding is that it allows for better rate codes. One can ask what the optimal tradeoff between the error tolerance r and the rate R of the code is, when the list size is required to small or constant, but not necessarily achieving the optimal bounds above. In the large alphabet setting, a simple random coding argument shows that $r > 1 - R - o(1)$ is achievable. The work of [19] provides an explicit positive rate efficiently encodable/decodable code for this task using folded Reed Solomon codes. This research has since been expanded upon, including in [15, 6, 11, 2].

Works such as [18, 17] also discuss the tradeoff between all three parameters: list size, error tolerance, and rate.

2 Definitions

Before stating our results, let us formally define a list decodable feedback ECC.

▶ **Definition 4** ((ℓ, r)-List Decodable Feedback Code). *A (ℓ, r)-list feedback code is a family of protocols $\{\pi_k\}_{k\in\mathbb{N}}$ from Alice to Bob defined as follows for each $k \in \mathbb{N}$.*

- *Alice begins with an input $x \in \{0,1\}^k$ that she intends to communicate to Bob.*

- *In each of $n = n(k) = |\pi_k|$ rounds, Alice sends a single bit that may be flipped (by an adversary). At the end of the round, Alice learns whether the bit was flipped.*
- *At the end of the protocol, Bob must output a list L of size ℓ that must contain x, as long as at most rn bits were flipped throughout the protocol.*

The Coin Game Reformulation

Throughout the remainder of the paper, we'll argue our results about list decodable feedback ECC's in the language of a *coin game* played between two players Bob and Eve. To this end, we reformulate the task of communicating over a noisy channel with feedback as this aforementioned coin game. A version of this coin game reformulation was first given by [31] but is quite similar to the adaptive search with lies formulation of [33] and [27].

▶ **Definition 5** (($\ell, r; K, n$)-Coin Game). *In the* coin game *parametrized by $K, n, \ell \in \mathbb{N}$ and $r \in [0, 1]$, two players Bob and Eve are playing a game on a number line. At the beginning of the game, all K coins are at position 0. In each of n rounds, Bob partitions the coins into two sets, and Eve chooses a set for which Bob moves all the coins up by 1.*

Eve wins if, at the end of the n rounds, there are $\geqslant \ell + 1$ coins all with positions $\leqslant rn$, and Bob wins otherwise.

The connection to feedback codes is as follows. The $K = 2^k$ coins correspond to all possible values of Alice's input. For each of the n rounds of the feedback code, Bob partitions the coins into two sets based on the two possibilities 0 and 1 for Alice's next message. Based on the bit that he receives, he increments the position of all coins in the opposite set; that is, the coins for which Alice would have sent the opposite bit. In this manner, at any point in time, each coin's position is the number of corruptions that must have occurred so far if the given coin were actually Alice's input.

Let's say we want a scheme that is (ℓ, r)-list decodable. Bob wins if at the end of the n rounds, there are at most ℓ coins left with positions $< rn$ (we say all other coins have "fallen off the board"). Eve's goal, on the other hand, is to pick a set that Bob hears each round so that at the end of the game there are $> \ell$ coins left on the board. If she's able to pick *any* sequence of sets such that $> \ell$ coins are left on the board at the end of the game, then the resulting code is necessarily not (ℓ, r)-list decodable, since any of the $> \ell$ coins left on the board could've been Alice's input.

Notation

Let us define the notation that we will use for a coin game.

- For a coin x, $\mathsf{pos}_t(x)$ denotes the position of coin x after t rounds.
- $c_t(i)$ denotes the coin with the i'th smallest position at t rounds.
- For $i \in [K]$, $\mathsf{posc}_t(i) = \mathsf{pos}_t(c(i))$ denotes the position of the coin with the i'th smallest position after t rounds.

3 Upper Bound

In this section, we show an upper bound (impossibility result) that no ℓ-list feedback code can achieve an error resilience greater than $\frac{1}{2} - \frac{1}{2^{\ell+2}-2} = \frac{2^\ell - 1}{2^{\ell+1}-1}$. Let us state the main theorem of this section.

▶ **Theorem 1.** *For any positive integer ℓ, there is no $\left(\ell, \frac{1}{2} - \frac{1}{2^{\ell+2}-2}\right)$-list feedback code.*

In the formulation of the coin game, we wish to establish that in an n-round protocol with K coins, the adversary can always maintain $\ell+1$ coins below position $\frac{2^\ell-1}{2^{\ell+1}-1}\cdot n$ for any K sufficiently large compared to ℓ. From this, we formally conclude Theorem 1 in Section 3.3.

We begin by establishing the statement for $\ell = 1$; that is, the adversary can always maintain 2 coins at or below position $\frac{1}{3}\cdot n$. This statement was known as early as [3] when the concept of feedback codes was introduced, but we recreate a proof here. Our proof for general ℓ is inductive and therefore requires establishing the $\ell = 1$ case first.

3.1 Base Case: 1-List Feedback Codes

We want to show that the adversary can always maintain the second coin at or below position $\frac{1}{3}\cdot n$. However, in order to use our statement as an appropriate base case for the inductive hypothesis in Section 3.2, we actually show the following stronger statement about partially completed coin games.

Consider a partially completed coin game where m of the n rounds have been played already. Then, the adversary can limit $\mathsf{posc}_n(2)$ in terms of these variables, specifically by the expression $\max\left\{\left\lceil\frac{1}{3}\cdot(n-m+\mathsf{posc}_m(1)+\mathsf{posc}_m(2)+\mathsf{posc}_m(3))\right\rceil, \mathsf{pos}_m(2)\right\}$. In particular, the case where $m=0$ corresponds to the situation where the entire coin game is remaining, and indeed the expression says that $\mathsf{posc}_n(2)$ is at most $\frac{1}{3}\cdot n$.

▶ **Theorem 6.** *For any $\varepsilon > 0$, the following holds for sufficiently large n. Consider an n-round coin game on $K = 3$ coins in which m rounds have already been completed. Then, the adversary can ensure at the end of the n rounds that*

$$\mathsf{posc}_n(2) \leqslant \max\left\{\left\lceil\frac{1}{3}\cdot(n-m+\mathsf{posc}_m(1)+\mathsf{posc}_m(2)+\mathsf{posc}_m(3))\right\rceil, \mathsf{posc}_m(2)\right\}.$$

Before proving this, let us informally describe the strategy Eve uses to achieve this bound. This strategy is essentially identical to what has appeared in previous literature such as [10]. For most of the protocol, she simply chooses the smaller (fewer elements) of the two sets given by Bob. That way, she need only move up one coin, and so on average, a coin move up by $\frac{1}{3}$, which is what gives the $\frac{1}{3}\cdot(n-m)$ term in the stated bound. However, the issue is that the coins need not move evenly. For example, the first coin may not move at all, while the last two coins each move by $\frac{1}{2}\cdot(n-m)$. Then, the position of the second coin increases too much, but in compensation, we have some leeway with the first coin. To use this, once the first coin is sufficiently low in position that it can never surpass the second coin, Eve switches strategies to always choosing the set that *does not* contain the second coin. Now, although the average coin can move up more per round, the second coin no longer moves which is what we wanted, and we do not risk the first coin catching up to the second by doing this.

Proof. Let $\theta = \max\left\{\left\lceil\frac{1}{3}\cdot(n-m+\mathsf{posc}_m(1)+\mathsf{posc}_m(2)+\mathsf{posc}_m(3))\right\rceil, \mathsf{posc}_m(2)\right\}$. In each round t, Bob chooses the set S_t and its complement $\overline{S_t}$ (both subsets of the 3 coins in the game), and the adversary Eve needs to choose one set for which to move up the coins by 1 each. Eve uses the following strategy.

For a round t, while $\mathsf{posc}_{t-1}(2) < \theta$, Eve always chooses the smaller of S_t and $\overline{S_t}$, that is the one with fewer elements. (Note that the inequality in this condition is strict, so, for example, if $\mathsf{posc}_m(2) \geqslant \left\lceil\frac{1}{3}\cdot(n-m+\mathsf{posc}_m(1)+\mathsf{posc}_m(2)+\mathsf{posc}_m(3))\right\rceil$, it is possible to skip this step entirely.)

Once $\mathsf{posc}_t(2)$ reaches θ, then Eve instead always selects the set not containing the coin in the second position.

Let us say this transition between the two strategies occurs at round $T+1$, so Eve spends rounds $m+1$ through T inclusive doing the first strategy, and the rest of the protocol doing the second strategy. (If this round T never occurs, then at the end of the protocol, $\mathsf{posc}_n(2) < \theta$ as we desired.) Our goal will be to show that in the remaining $n-T$ rounds, the first coin will not pass the second coin, even if it is selected to increase every time. Then there will be two coins left at the end of the protocol, both with position $\leqslant \theta$.

Between rounds $m+1$ and T, in every step, the total positions of the coins are increasing by at most 1. Also, the first time the inequality is violated, we must have $\mathsf{posc}_T(2) = \theta \geqslant \left\lceil \frac{1}{3} \cdot (n - m + \mathsf{posc}_m(1) + \mathsf{posc}_m(2) + \mathsf{posc}_m(3)) \right\rceil$. Therefore, at the end of round T, it holds that

$$\begin{aligned}
&\mathsf{posc}_T(1) + \mathsf{posc}_T(2) + \mathsf{posc}_T(3) \leqslant \mathsf{posc}_m(1) + \mathsf{posc}_m(2) + \mathsf{posc}_m(3) + T - m \\
\implies &\mathsf{posc}_T(1) + 2\mathsf{posc}_T(2) \leqslant \mathsf{posc}_m(1) + \mathsf{posc}_m(2) + \mathsf{posc}_m(3) + T - m \\
\implies &\mathsf{posc}_T(1) - \mathsf{posc}_T(2) + 3 \cdot \left\lceil \frac{1}{3} \cdot (n - m + \mathsf{posc}_m(1) + \mathsf{posc}_m(2) + \mathsf{posc}_m(3)) \right\rceil \\
&\qquad \leqslant \mathsf{posc}_m(1) + \mathsf{posc}_m(2) + \mathsf{posc}_m(3) + T - m \\
\implies &\mathsf{posc}_T(1) - \mathsf{posc}_T(2) \\
&\qquad \leqslant \mathsf{posc}_m(1) - \mathsf{posc}_m(2) + \mathsf{posc}_m(3) + T - m - (n - m + \mathsf{posc}_m(1) + \mathsf{posc}_m(2) + \mathsf{posc}_m(3)) \\
&\qquad \leqslant T - n \\
\implies &\mathsf{posc}_T(2) - \mathsf{posc}_T(1) \geqslant n - T
\end{aligned}$$

In other words, in the remaining $n-T$ rounds, the first coin will not be able to switch positions with the second or third coin. As such, $\mathsf{posc}(2)$ will never increase since it is never selected, and the first coin never surpasses it.

This concludes the proof, as it means that $\mathsf{posc}_n(2)$ stays at θ (or never reached θ). ◀

3.2 Inductive Step: ℓ-List Feedback Codes

In this section, we establish the inductive step. We inductively show an analog of Theorem 6 for larger list sizes.

▶ **Theorem 7.** *For any positive integer ℓ, the following holds for sufficiently large n. Consider an n-round coin game on $K = 2^{\ell+1} - 1$ coins in which m rounds have already been completed. For round $m \in [n]$, let*

$$\theta_\ell := \left\lceil \frac{1}{2^{\ell+1} - 1} \cdot \left((2^\ell - 1) \cdot (n - m) + \mathsf{posc}_m(1) + \ldots + \mathsf{posc}_m(K) \right) \right\rceil.$$

If $\mathsf{posc}_m(1) \geqslant \theta_\ell + m - n$ then Eve can ensure at the end of the n rounds that $\mathsf{posc}_n(\ell+1) \leqslant \theta_\ell$.

Again, before proving this formally, let us describe Eve's strategy at a high level. Her strategy to achieve this bound will be recursive. At the start of the protocol, she chooses the smaller of Bob's two sets at every step, so that the average coin moves by $\frac{2^\ell - 1}{2^{\ell+1} - 1}$, giving the $\frac{2^\ell - 1}{2^{\ell+1} - 1} \cdot (n - m)$ term in the bound. As with the $\ell = 1$ case, this doesn't give the desired bound for the final position of the $(\ell+1)$'th coin because it's possible the first few coins did not move at all, while the $(\ell+1)$'th coin moved by more. However, it can be shown that in compensation, the position of the first coin must be very low in this case. Once the first coin is at a low enough position that even if it is selected in every remaining round, it can no longer exceed θ_ℓ by the end of the protocol, Eve switches strategies. Now, she needs to ensure that of the remaining coins, ℓ of them remain below position θ_ℓ (since we have already found one coin that will definitely remain below θ_ℓ). This is where her strategy becomes recursive: she simulates a new coin game on the leftmost $2^\ell - 1$ coins of the $2^{\ell+1} - 2$ remaining coins and plays on these coins according to her (recursively described) strategy for the case of $\ell - 1$.

Proof. First we check that the statement holds for the base case $\ell = 1$. This follows from Theorem 6. In this case, we have that

$$\begin{aligned}\theta_1 &:= \left\lceil \frac{1}{3} \cdot (n - m + \mathsf{posc}_m(1) + \mathsf{posc}_m(2) + \mathsf{posc}_m(3)) \right\rceil \\ &\geqslant \frac{1}{3} \cdot (n - m + \mathsf{posc}_m(1) + \mathsf{posc}_m(2) + \mathsf{posc}_m(3)) \\ &\geqslant \frac{1}{3} \cdot (\theta_1 + 2\mathsf{posc}_m(2)).\end{aligned}$$

In the last step, we used the condition in the Theorem 7 that $\mathsf{posc}_m(1) \geqslant \theta_\ell + m - n$. Rearranging, this implies that $\theta_1 \geqslant \mathsf{posc}_m(2)$. Theorem 6 states that $\mathsf{posc}_n(2) \leqslant \max\{\theta_1, \mathsf{posc}_m(2)\} = \theta_1$, since $\theta_1 \geqslant \mathsf{posc}_m(2)$, which is what we wanted to prove.

For the inductive step, let us assume the statement is true for $\ell - 1$ and prove it for ℓ. Throughout the proof, let $\Sigma_m := \mathsf{posc}_m(1) + \ldots + \mathsf{posc}_m(K)$.

In each round t, Bob's two sets are S_t and its complement $\overline{S_t}$, and the adversary Eve needs to choose one set for which to move up the coins by 1 each. Eve uses the following strategy.

For a round t, while $\mathsf{posc}_{t-1}(1) > \theta_\ell + (t-1) - n$, Eve always chooses the one of S_t and $\overline{S_t}$ with fewer elements. Note that the first time it is violated, $\mathsf{posc}_t(1) = \theta_\ell + t - n$, even if it is already violated immediately at round $t = m + 1$ by the assumption. Denote the round it is first violated as T if it is ever violated.

At this point (after round T) or at the start of the protocol if the condition began by being violated, it is impossible for the coin $c_T(1)$ to ever hit the threshold θ_ℓ, since its position can only increase by 1 for each of the remaining $n - T$ rounds. Thus Eve can ignore the first coin, and play a coin game on only the remaining $2^{\ell+1} - 1$ coins, with the goal of keeping $\mathsf{posc}_n(\ell)$ below θ_ℓ. She also opts to exclude the second half of these coins $c_T(2^\ell + 1), \ldots, c_T(2^{\ell+1} - 1)$ from her new coin game as well, and simply assumes that they will end up above the threshold. In all, the players are playing a new a coin game on $2^\ell - 1$ coins which correspond to $c_T(2), \ldots, c_T(2^\ell)$, with Eve having the goal of keeping $\mathsf{posc}_n(\ell)$ below θ_ℓ. She executes the strategy for this recursively, keeping $\mathsf{posc}_n(\ell)$ bounded by what Theorem 7 says for $\ell - 1$.

Now, let us analyze this strategy.

First, we address the case where round T never occurs. In this case, at the end of the protocol, it holds that $\mathsf{posc}_n(1) > \theta_\ell - n + n = \theta_\ell$. Since Eve is picking the smaller of S_t and $\overline{S_t}$ each time, it holds that

$$\begin{aligned}&\mathsf{posc}_n(1) + \ldots + \mathsf{posc}_n(2^{\ell+1} - 1) \leqslant (2^\ell - 1) \cdot (n - m) + \Sigma_m \\ \implies &\mathsf{posc}_n(1) \leqslant \frac{1}{2^{\ell+1} - 1} \cdot \left((2^\ell - 1) \cdot (n - m) + \Sigma_m\right) \leqslant \theta_\ell,\end{aligned}$$

which is a contradiction, where the last inequality follows because the middle term is at most θ_ℓ by definition.

Next, we address the case where round T occurs at some time $m \leqslant T \leqslant n$. After round T, it holds that $\mathsf{posc}_T(1) = \theta_\ell + T - n$ exactly, and so

$$\begin{aligned}&\mathsf{posc}_T(1) + \ldots + \mathsf{posc}_T(2^{\ell+1} - 1) \leqslant (2^\ell - 1) \cdot (T - m) + \Sigma_m \\ \implies &\mathsf{posc}_T(2) + \ldots + \mathsf{posc}_T(2^{\ell+1} - 1) \leqslant (2^\ell - 2) \cdot T - (2^\ell - 1) \cdot m - \theta_\ell + n + \Sigma_m \\ \implies &\mathsf{posc}_T(2) + \ldots + \mathsf{posc}_T(2^\ell) \leqslant (2^{\ell-1} - 1) \cdot T - \frac{2^\ell - 1}{2} \cdot m + \frac{1}{2} \cdot (n + \Sigma_m - \theta_\ell). \qquad (1)\end{aligned}$$

The coin in position 1 at time T can never fall off the board, because its position can only increment by 1 in each of the last $T-n$ rounds, and so we can disregard it. We will now apply the inductive hypothesis to a new game played on the $2^\ell - 1$ coins in positions 2 through 2^ℓ at time T, corresponding to the coins in positions 2 through 2^ℓ at time T. We will renumber the coins, so we can view this new game as being played on $2^\ell - 1$ coins numbered 1 through $2^\ell - 1$, where the position functions are given by pos' and posc'. Denote

$$\theta'_{\ell-1} := \left\lceil \frac{1}{2^\ell - 1} \cdot \left((2^{\ell-1} - 1) \cdot (n - T) + \mathsf{posc}'_T(1) + \ldots + \mathsf{posc}'_T(2^\ell - 1) \right) \right\rceil.$$

Our goal is to show that $\theta'_{\ell-1} \leqslant \theta_\ell$. This will prove the inductive step for the following reasons:

- We have that $\mathsf{posc}'_T(1) = \mathsf{posc}_T(2) \geqslant \mathsf{posc}_T(1) = \theta_\ell - T + n \geqslant \theta'_{\ell-1} - T + n$, so the condition for the inductive step of the theorem is met.
- We know that $\mathsf{posc}_n(\ell+1) \leqslant \max\{\mathsf{posc}'_n(\ell), \theta_\ell\}$, because coin $c_T(1)$ cannot surpass θ_ℓ and all of coins $c_T(2) \ldots c_T(\ell+1)$ are at most $\mathsf{posc}'_n(\ell)$. Moreover, by the inductive hypothesis, we know that $\mathsf{posc}'_n(\ell) < \theta'_{\ell-1} \leqslant \theta_\ell$, and so $\mathsf{posc}_n(\ell+1) \leqslant \theta_\ell$ as we wanted.

Now, we show the desired statement that $\theta'_{\ell-1} \leqslant \theta_\ell$. Using the bound (1) we found on $\mathsf{posc}_T(2) + \ldots + \mathsf{posc}_T(2^\ell) = \mathsf{posc}'_T(1) + \ldots + \mathsf{posc}'_T(2^\ell - 1)$, we have that

$$\begin{aligned}
\theta'_{\ell-1} &= \left\lceil \frac{1}{2^\ell - 1} \cdot \left((2^{\ell-1} - 1) \cdot (n - T) + \mathsf{posc}'_T(1) + \ldots + \mathsf{posc}'_T(2^\ell - 1) \right) \right\rceil \\
&< \left\lceil \frac{1}{2^\ell - 1} \cdot \left((2^{\ell-1} - 1) \cdot (n - T) + (2^{\ell-1} - 1) \cdot T - \frac{2^\ell - 1}{2} \cdot m + \frac{1}{2} \cdot (n + \Sigma_m - \theta_\ell) \right) \right\rceil \\
&= \left\lceil \frac{1}{2^{\ell+1} - 2} \cdot \left((2^\ell - 1) \cdot (n - m) + \Sigma_m - \theta_\ell \right) \right\rceil \\
&\leqslant \left\lceil \frac{1}{2^{\ell+1} - 2} \cdot \left(1 - \frac{1}{2^{\ell+1} - 1} \right) \left((2^\ell - 1) \cdot (n - m) + \Sigma_m \right) \right\rceil \\
&= \left\lceil \frac{1}{2^{\ell+1} - 1} \cdot \left((2^\ell - 1) \cdot (n - m) + \Sigma_m \right) \right\rceil = \theta_\ell.
\end{aligned}$$

This concludes the inductive step of Theorem 7. ◀

3.3 Conclude Theorem 1

Finally, let us conclude Theorem 1. Let the number of coins K be at least $8 \cdot (2^{\ell+1} - 1)$. For Eve's first move, have her choose the one of S_1 and $\overline{S_1}$ (Bob's two provided sets) with fewer elements, so that at least half the coins remain at position 0. For her second move, have her choose the one of S_2 and $\overline{S_2}$ that keeps the most coins at 0, which will keep at leat $\frac{1}{4}$ of the coins at 0. She will do this one more time, so that after 3 moves, there are at least $2^{\ell+1} - 1$ coins at position 0.

Even if there are more than $2^{\ell+1} - 1$ coins at position 0, from now, Eve will fix a subset of $2^{\ell+1} - 1$ coins to play a coin game on. She wants to show that in this new $n-3$ turn coin game, she can keep $\mathsf{posc}_{n-3}(\ell+1) \leqslant \frac{2^\ell - 1}{2^{\ell+1} - 1} \cdot n$. This follows by setting $m = 0$ in Theorem 7. The theorem states that Eve can always guarantee that $\ell+1$ coins stay at or below position $\left\lceil \frac{2^\ell - 1}{2^{\ell+1} - 1} \cdot (n-3) \right\rceil \leqslant \frac{2^\ell - 1}{2^{\ell+1} - 1} \cdot n$. Therefore $\left(\ell+1, \frac{2^\ell - 1}{2^{\ell+1} - 1}\right)$-list decoding is not possible.

4 Optimal 2-List Feedback Codes

In this section, we will prove that the feedback ECC from Spencer-Winkler [31] achieves $\left(2, \frac{3}{7} - \epsilon\right)$-list decodability, matching the upper bound for $\ell = 2$ given in Theorem 1.

4.1 The Spencer-Winkler Coin Game

Let us begin by defining the Spencer-Winkler strategy for the coin game.

Protocol 1 : The Spencer-Winkler (SW) Coin Game

Alice has a coin $x \in \{0,1\}^k$. Bob and Eve play the coin game with $K = 2^k$ coins. In each of n rounds, Bob partitions the coins into two sets based on the parity of their positions on the board. That is, he numbers the coins from 1 to K, where 1 is assigned to the coin with the smallest position, and K is the coin that is furthest away. The odd numbered coins are in one set, and the even numbered coins are in the other. Eve chooses a set whose coins to move up by 1.

We will also denote by SW the feedback code corresponding to this family of coin game strategies. When defining a feedback code SW, we must also specify a choice of the code length $n(k)$. It was shown in [31] that SW achieves the unique decoding bound of $\frac{1}{3} - \epsilon$ for feedback codes.

▶ **Theorem 8** ([31]). *Let $n = \frac{k}{\epsilon}$. Then in the* SW *coin game, no matter which sets Eve chooses each round, it will hold that*

$$\mathsf{posc}_n(2) > \left(\frac{1}{3} - O(\epsilon)\right) \cdot n.$$

Thus the SW *coin game gives a feedback code that is uniquely decodable up to radius $\frac{1}{3} - O(\epsilon)$.*

Our goal through the rest of this section is to prove a statement about the list decodability of SW to list size 2. This proves Theorem 2.

▶ **Theorem 9.** *In the* SW *coin game, no matter which sets Eve chooses each round, it holds that*

$$\mathsf{posc}_n(3) > \left(\frac{3}{7} - 2\epsilon\right) \cdot n.$$

That is, the SW *coin game with $n = \frac{24k}{\epsilon^3}$ gives a feedback code that is $\left(2, \frac{2}{7} - 2\epsilon\right)$-list-decodable.*

4.2 Some Useful Inequalities

Throughout this section, let $n = \frac{24k}{\epsilon^3}$. Our proof that the SW protocol achieves $(2, \frac{3}{7})$-list decoding follows from two inequalities, given in Lemmas 11 and 12. First, let us prove a statement about how the position of the i'th coin at each round can change.

▷ Claim 10. For any $t \in [n-1]$ and for any $i \in [K]$, it holds that

$$\mathsf{posc}_{t+1}(i) - \mathsf{posc}_t(i) \in \{0, 1\}.$$

Proof. The i'th coin $c_{t+1}(i)$ at time $t+1$ being at position $\mathsf{posc}_{t+1}(i)$ means that at time t there must've been $\geqslant i-1$ coins with positions $\leqslant \mathsf{posc}_{t+1}(i)$ and $\geqslant K - i$ coins with positions $\geqslant \mathsf{pos}_t(c_{t+1}(i)) \geqslant \mathsf{posc}_{t+1}(i) - 1$. This means that the i'th coin at time t must've had position in the range $[\mathsf{posc}_{t+1}(i) - 1, \mathsf{posc}_{t+1}(i)]$, from which the claim follows. ◁

Now, we are ready to state our first key lemma, that the gaps between the positions of the first two coins must always be at least the gap between the positions of the third and fourth coins at any timestep.

▶ **Lemma 11.** *At any point in the* SW *protocol, the following inequality holds:*

$$\mathsf{posc}_t(2) - \mathsf{posc}_t(1) + 1 \geqslant \mathsf{posc}_t(4) - \mathsf{posc}_t(3). \tag{2}$$

Proof. We prove this via straightforward induction. Let us assume at time t that $\mathsf{posc}_t(2) - \mathsf{posc}_t(1) + 1 \geqslant \mathsf{posc}_t(4) - \mathsf{posc}_t(3)$. This is certainly true at time $t = 0$, since all coins are at position 0.

By applying Claim 10, it follows that $\mathsf{posc}_{t+1}(2) - \mathsf{posc}_{t+1}(1) = \mathsf{posc}_t(2) - \mathsf{posc}_t(1) + \{-1, 0, 1\}$ and similarly $\mathsf{posc}_{t+1}(4) - \mathsf{posc}_{t+1}(3) = \mathsf{posc}_t(4) - \mathsf{posc}_t(3) + \{-1, 0, 1\}$. This means that $(\mathsf{posc}(4) - \mathsf{posc}(3)) - (\mathsf{posc}(2) - \mathsf{posc}(1))$ can change by at most 2 each round, and we can focus on the relevant case that

$$(\mathsf{posc}_t(4) - \mathsf{posc}_t(3)) - (\mathsf{posc}_t(2) - \mathsf{posc}_t(t)) \in \{0, 1\}. \tag{3}$$

We split the induction into two cases. The first is if Bob moves the odd set. In this case, Bob will move up coins $c_t(1)$ and $c_t(3)$. If $c_t(4) - c_t(3) > 0$, then this means that $c_t(4) - c_t(3)$ will decrease by 1, and $c_t(2) - c_t(1)$ will change by at most 1, so (2) will still hold at time $t + 1$. If $c_t(4) - c_t(3) = 0$, then $c_{t+1}(4) - c_{t+1}(3) \leqslant 1$, and also by (3) it must be true that $\mathsf{posc}_t(2) - \mathsf{posc}_t(1) = 0$, so $c_{t+1}(2) - c_{t+1}(1) \in \{0, 1\}$ as well. Therefore, $(c_{t+1}(4) - c_{t+1}(3)) - (c_{t+1}(2) - c_{t+1}(1)) \leqslant 1$ as desired.

The second case is if Bob moves the even set. In this case, Bob will move up coins $c_t(2)$ and $c_t(4)$. If $\mathsf{posc}_t(3) - \mathsf{posc}_t(2) > 0$, then $c_t(1), c_t(2)$, and $c_t(3)$ will still be the first, second, and third coins at time $t+1$. Then $\mathsf{posc}_{t+1}(2) - \mathsf{posc}_{t+1}(1) = (\mathsf{posc}_t(2) + 1) - \mathsf{posc}_t(1)$, while $\mathsf{posc}_{t+1}(4) - \mathsf{posc}_{t+1}(3) \leqslant (\mathsf{posc}_t(4) + 1) - \mathsf{posc}_t(3)$ by Claim 10, so (2) clearly follows. On the other hand, if $\mathsf{posc}_t(2) = \mathsf{posc}_t(3)$, then moving coins the second and fourth coins at time t is equivalent to moving the third and fourth coins at time t, so $\mathsf{posc}_{t+1}(2) - \mathsf{posc}_{t+1}(1) = \mathsf{posc}_t(2) - \mathsf{posc}_t(1)$. If $\mathsf{posc}_t(4) > \mathsf{posc}_t(3)$, then $\mathsf{posc}_{t+1}(3) = \mathsf{posc}_t(3) + 1$, so $\mathsf{posc}_{t+1}(4) - \mathsf{posc}_{t+1}(3) \leqslant \mathsf{posc}_t(4) - \mathsf{posc}_t(3)$, and (2) follows. Otherwise if $\mathsf{posc}_t(4) - \mathsf{posc}_t(3) = 0$, this means by (3) that $\mathsf{posc}_t(2) - \mathsf{posc}_t(1) = 0$, and since $\mathsf{posc}_{t+1}(4) = \mathsf{posc}_t(4) + \{0, 1\}$ and $\mathsf{posc}_{t+1}(3) = \mathsf{posc}_t(3) + \{0, 1\}$ by Claim 10, we have that $\mathsf{posc}_{t+1}(4) - \mathsf{posc}_{t+1}(3) \leqslant 1$, so again (2) follows. ◀

The second key lemma is about the sum of the positions of the first four coins at any timestep.

▶ **Lemma 12.** *At any round $0 \leqslant \tau \leqslant n$, the following holds:*

$$\frac{1}{2}\mathsf{posc}_\tau(1) + \mathsf{posc}_\tau(2) + \mathsf{posc}_\tau(3) + \mathsf{posc}_\tau(4) \geqslant \frac{3\tau}{2} - 5\epsilon n.$$

Proof. In order to analyze the positions of four coins collectively, we define a new derivative coin game that we call the *quadruple coin game*. The coins in this quadruple coin game are four-tuples of coins in the old game, for a total of $\binom{K}{4}$ coins in the new game. Let the set of coins in the original game be denoted S, and let the set of quadruple coins be denoted S^{q}. The position of quadruple coin $(x_1, x_2, x_3, x_4) \in S^{\mathsf{q}}$ at time t is $\frac{1}{2}\mathsf{pos}_t(x_1) + \mathsf{pos}_t(x_2) + \mathsf{pos}_t(x_3) + \mathsf{pos}_t(x_4)$, where here we assume that the four coins x_1, x_2, x_3, x_4 are ordered according to increasing position at time t.

We denote by $c_t^{\mathsf{q}}(i_1, i_2, i_3, i_4)$ the quadruple coin $(c_t(i_1), c_t(i_2), c_t(i_3), c_t(i_4))$, and by $\mathsf{posc}_t^{\mathsf{q}}(i_1, i_2, i_3, i_4) = pos_t^{\mathsf{q}}(c_t(i_1, i_2, i_3, i_4))$ its position at time t. Our goal is to show that in this quaduple coin game, coin $c_n(1, 2, 3, 4)$ will be at position $\frac{3}{2}n - 4\epsilon n$ at the end of the protocol.

To do this, we will show that on average, the quadruple coins must be moving at $\approx \frac{3}{2}$ units per round, and furthermore that no coins are left behind. What we mean by the latter is that for any quadruple coin that doesn't move enough in a given round, there is some earlier coin that is moving more than enough and compensating for the slower movement by the first coin. Precisely, we will do this via a bijection.

Let us first define $u_t(i)$ to be the amount that coin $c_t(i)$ is moved in round $t+1$. We remark that this is *not* the value $\mathsf{posc}_{t+1}(i) - \mathsf{posc}_t(i)$, since after round t, the coins may change their orders so that $c_t(i)$ is no longer the i'th coin. We will also define $u_t^{\mathfrak{q}}(i_1, i_2, i_3, i_4)$ to be the amount that quadruple coin $c_t^{\mathfrak{q}}(i_1, i_2, i_3, i_4)$ is moved in time $t+1$. In general, when we write a 4-tuple, the four numbers should be in increasing order. We can also define the poset relation on 4-tuples of indices in $[K]$ by $(i_1, i_2, i_3, i_4) < (j_1, j_2, j_3, j_4)$ if $i_\iota \leqslant j_\iota$ for all $\iota \in [4]$.

▷ Claim 13. At any time t there is a bijection of indices $\binom{[K]}{4} \ni (i_1, i_2, i_3, i_4) \leftrightarrow (j_1, j_2, j_3, j_4) \in \binom{[K]}{4}$ such that for any bijected values $(i_1, i_2, i_3, i_4) \leftrightarrow (j_1, j_2, j_3, j_4)$,

$$u_t^{\mathfrak{q}}(i_1, i_2, i_3, i_4) + u_t^{\mathfrak{q}}(j_1, j_2, j_3, j_4) \geqslant 3,$$

and furthermore if $u_t^{\mathfrak{q}}(i_1, i_2, i_3, i_4) < \frac{3}{2}$ then $(j_1, j_2, j_3, j_4) < (i_1, i_2, i_3, i_4)$.

Proof. We will define this bijection φ_t by defining φ_t on tuples (i_1, i_2, i_3, i_4) for which $u_t^{\mathfrak{q}}(i_1, i_2, i_3, i_4) < \frac{3}{2}$. For all other tuples that remain unbijected after this process, we can pair them up arbitrarily.

Consider a tuple (i_1, i_2, i_3, i_4) for which $u_t^{\mathfrak{q}}(i_1, i_2, i_3, i_4) < \frac{3}{2}$. Let's suppose that Bob is moving the even coins in round $t+1$ (we'll define the bijection for the odd case in the same way, except switching the words "even" and "odd" everywhere). The only way $u_t^{\mathfrak{q}}(i_1, i_2, i_3, i_4)$ can be less than $\frac{3}{2}$ is if there is at most one even index among the four. Let us define the map φ_t depending on which of the i_ι is even.

$$\varphi_t(i_1, i_2, i_3, i_4) = \begin{cases} (i_1, i_2 - 1, i_3 - 1, i_4 - 1) & i_1, i_2, i_3, i_4 \text{ all odd} \\ (i_1, i_2, i_3 - 1, i_4) & i_1, i_2, i_3 \text{ odd and } i_4 \text{ even} \\ (i_1, i_2 - 1, i_3, i_4) & i_1, i_2, i_4 \text{ odd and } i_3 \text{ even} \\ (i_1, i_2, i_3, i_4 - 1) & i_1, i_3, i_4 \text{ odd and } i_2 \text{ even} \\ (i_1, i_2, i_3, i_4 - 1) & i_2, i_3, i_4 \text{ odd and } i_1 \text{ even.} \end{cases}$$

It's straightforward to check that these are all well defined, and that each of the bijected tuples contains four distinct elements. (Recall we always assume $i_1 < i_2 < i_3 < i_4$.)

Next, we also need to check that $\varphi_t(i_1, i_2, i_3, i_4) \neq \varphi_t(i'_1, i'_2, i'_3, i'_4)$ for all $(i_1, i_2, i_3, i_4) \neq (i'_1, i'_2, i'_3, i'_4)$. To see this, we show how to invert each tuple in the image of the map φ_t as we've defined so far. The key observation is that the five cases give five different parity tuples for the output tuple: for instance, the first case that i_1, i_2, i_3, i_4 are all odd results in an output where the parities are (odd, even, even, even), whereas all the rest of the maps give outputs where two indices are odd and two are even, so we always know how to invert a tuple that is (odd, even, even, even).

$$\varphi_t^{-1}(j_1, j_2, j_3, j_4) = \begin{cases} (j_1, j_2 + 1, j_3 + 1, j_4 + 1) & j_1 \text{ odd and } j_2, j_3, j_4 \text{ odd} \\ (j_1, j_2, j_3 + 1, j_4) & j_1, j_2 \text{ odd and } j_3, j_4 \text{ even} \\ (j_1, j_2 + 1, j_3, j_4) & j_1, j_4 \text{ odd and } j_2, j_3 \text{ even} \\ (j_1, j_2, j_3, j_4 + 1) & j_1, j_3 \text{ odd and } j_2, j_4 \text{ even} \\ (j_1, j_2, j_3, j_4 + 1) & j_2, j_3 \text{ odd and } j_1, j_4 \text{ even.} \end{cases}$$

Finally, we check that $u_t^{\mathsf{q}}(i_1,i_2,i_3,i_4) + u_t^{\mathsf{q}}(\varphi_t(i_1,i_2,i_3,i_4)) \geqslant 3$. In the first case that i_1,i_2,i_3,i_4 are all odd and $_t^{\mathsf{q}}(i_1,i_2,i_3,i_4) = 0$, $\varphi_t(i_1,i_2,i_3,i_4)$ has three even indices, so $u_t^{\mathsf{q}}(\varphi_t(i_1,i_2,i_3,i_4)) = 3$. In all the other cases, (i_1,i_2,i_3,i_4) has one even index and $\varphi_t(i_1,i_2,i_3,i_4)$ has two even indices so $u_t^{\mathsf{q}}(i_1,i_2,i_3,i_4) + u_t^{\mathsf{q}}(\varphi_t(i_1,i_2,i_3,i_4)) = 1+2 = 3$. ◁

Now, let us define the potential function

$$\psi(t) = \sum_{(x_1,x_2,x_3,x_4)\in\binom{\{0,1\}^k}{4}} w_t(x_1,x_2,x_3,x_4),$$

where

$$w_t(x_1,x_2,x_3,x_4) = (1+\epsilon)^{\frac{1}{3}\cdot d_t(x_1,x_2,x_3,x_4)}$$

and

$$d_t(x_1,x_2,x_3,x_4) = \max\left\{0, \frac{3t}{2} - \mathsf{pos}_t^{\mathsf{q}}(x_1,x_2,x_3,x_4)\right\}.$$

Since $\mathsf{pos}_0^{\mathsf{q}}(x_1,x_2,x_3,x_4) = 0$ for all (x_1,x_2,x_3,x_4) at the start of the game, $\psi(0) = \binom{K}{4}$.

▷ Claim 14. For any time t, let us consider any bijected pair $(i_1,i_2,i_3,i_4) \leftrightarrow (j_1,j_2,j_3,j_4)$ under φ_t. Define $(x_1,x_2,x_3,x_4) = c_t^{\mathsf{q}}(i_1,i_2,i_3,i_4)$ and $(y_1,y_2,y_3,y_4) = c_t^{\mathsf{q}}(j_1,j_2,j_3,j_4)$. Then,

$$w_{t+1}(x_1,x_2,x_3,x_4) + w_{t+1}(y_1,y_2,y_3,y_4) \leqslant e^{\epsilon^2/2}\cdot(w_t(x_1,x_2,x_3,x_4) + w_t(y_1,y_2,y_3,y_4)) + \epsilon,$$

Proof. We proceed by casework on whether $u_t(x_1,x_2,x_3,x_4)$ and $u_t(y_1,y_2,y_3,y_4)$ are greater than or less than $\frac{3}{2}$.

Case 1: *Both $u_t(x_1,x_2,x_3,x_4)$ and $u_t(y_1,y_2,y_3,y_4)$ are at least $\frac{3}{2}$.*

In this case, $d_{t+1}(x_1,x_2,x_3,x_4) \leqslant d_t(x_1,x_2,x_3,x_4)$ and $d_{t+1}(y_1,y_2,y_3,y_4) \leqslant d_t(y_1,y_2,y_3,y_4)$, so

$$\begin{aligned}
&w_{t+1}(x_1,x_2,x_3,x_4) + w_{t+1}(y_1,y_2,y_3,y_4)\\
&\quad\leqslant w_t(x_1,x_2,x_3,x_4) + w_t(y_1,y_2,y_3,y_4)\\
&\quad\leqslant e^{\epsilon^2/2}\cdot(w_t(x_1,x_2,x_3,x_4) + w_t(y_1,y_2,y_3,y_4)) + \epsilon.
\end{aligned}$$

Case 2: $u_t(x_1,x_2,x_3,x_4) < \frac{3}{2}$.

We write $u_t(x_1,x_2,x_3,x_4) = \frac{3}{2} - \delta$ for some $\delta > 0$. Then $d_{t+1}(x_1,x_2,x_3,x_4) \leqslant d_t(x_1,x_2,x_3,x_4) + \delta$ and $u_t(y_1,y_2,y_3,y_4) \geqslant \frac{3}{2} - \delta$. Let us again do casework on whether $d_t(y_1,y_2,y_3,y_4)$ is larger or smaller than δ.

Subcase 2.1: $d_t(y_1,y_2,y_3,y_4) \geqslant \delta$.

In this case, $d_{t+1}(y_1,y_2,y_3,y_4) \leqslant d_t(y_1,y_2,y_3,y_4) - \delta$. Then

$$\begin{aligned}
&w_{t+1}(x_1,x_2,x_3,x_4) + w_{t+1}(y_1,y_2,y_3,y_4)\\
&\quad\leqslant (1+\epsilon)^{\frac{1}{3}\delta} w_t(x_1,x_2,x_3,x_4) + (1+\epsilon)^{-\frac{1}{3}\delta} w_t(y_1,y_2,y_3,y_4)\\
&\quad\leqslant \frac{(1+\epsilon)^{\frac{1}{3}\delta} + (1+\epsilon)^{-\frac{1}{3}\delta}}{2}\cdot(w_t(x_1,x_2,x_3,x_4) + w_t(y_1,y_2,y_3,y_4))\\
&\quad\leqslant \frac{(1+\epsilon) + (1+\epsilon)^{-1}}{2}\cdot(w_t(x_1,x_2,x_3,x_4) + w_t(y_1,y_2,y_3,y_4))\\
&\quad\leqslant e^{\epsilon^2/2}\,(w_t(x_1,x_2,x_3,x_4) + w_t(y_1,y_2,y_3,y_4))\\
&\quad\leqslant e^{\epsilon^2/2}\,(w_t(x_1,x_2,x_3,x_4) + w_t(y_1,y_2,y_3,y_4)) + \epsilon,
\end{aligned}$$

where the second inequality follows from $(j_1, j_2, j_3, j_4) < (i_1, i_2, i_3, i_4) \implies w_t(x_1, x_2, x_3, x_4) \leqslant w_t(y_1, y_2, y_3, y_4)$ and the rearrangement inequality, and the thir inequality follows from $\frac{1}{3}\delta \leqslant \frac{1}{2} < 1$.

Subcase 2.2: $d_t(y_1, y_2, y_3, y_4) < \delta$.

In this case, $d_{t+1}(y_1, y_2, y_3, y_4) = 0$, and $d_{t+1}(x_1, x_2, x_3, x_4) \leqslant d_t(x_1, x_2, x_3, x_4) + \delta \leqslant d_t(y_1, y_2, y_3, y_4) + \delta < 2\delta$. Then

$$\begin{aligned}
&w_{t+1}(x_1, x_2, x_3, x_4) + w_{t+1}(y_1, y_2, y_3, y_4) \\
&\quad\leqslant (1+\epsilon)^{\frac{2}{3}\cdot 2\delta} + (1+\epsilon)^0 \\
&\quad\leqslant 2 + \epsilon \\
&\quad\leqslant (w_t(x_1, x_2, x_3, x_4) + w_t(y_1, y_2, y_3, y_4)) + \epsilon \\
&\quad\leqslant e^{\epsilon^2/2}\,(w_t(x_1, x_2, x_3, x_4) + w_t(y_1, y_2, y_3, y_4)) + \epsilon.
\end{aligned}$$

◁

Now, using Claim 14 and summing over all bijected tuples $(i_1, i_2, i_3, i_4) \leftrightarrow (j_1, j_2, j_3, j_4)$, we get

$$\psi(t+1) \leqslant e^{\epsilon^2/2} \cdot \psi(t) + \epsilon \cdot \frac{\binom{K}{4}}{2}.$$

Solving the reccurence, we get

$$\begin{aligned}
\psi(t+1) &\leqslant e^{(t+1)\epsilon^2/2} \cdot \binom{K}{4} + \frac{e^{(t+1)\epsilon^2/2} - 1}{e^{\epsilon^2/2} - 1} \cdot \epsilon \cdot \frac{\binom{K}{4}}{2} \\
&\leqslant e^{(t+1)\epsilon^2/2} \cdot \binom{K}{4} \cdot \left(1 + \frac{1}{2(e^{\epsilon^2/2} - 1)}\right) \\
&\leqslant e^{(t+1)\epsilon^2/2} \cdot \binom{K}{4} \cdot \left(1 + \frac{1}{\epsilon}\right).
\end{aligned}$$

Finally, we get our bound on $\frac{1}{2}\mathsf{posc}_\tau(1) + \mathsf{posc}_\tau(2) + \mathsf{posc}_\tau(3) + \mathsf{posc}_\tau(4)$. Let $x_1 = c^{\mathsf{q}}_\tau(1)$, $x_2 = c^{\mathsf{q}}_\tau(2)$, $x_3 = c^{\mathsf{q}}_\tau(3)$, and $x_4 = c^{\mathsf{q}}_\tau(4)$. We have that

$$\begin{aligned}
w_\tau(x_1, x_2, x_3, x_4) = (1+\epsilon)^{\frac{1}{3}\cdot d_\tau(x_1, x_2, x_3, x_4)} &< \psi(\tau) \\
&\leqslant e^{\tau\epsilon^2/2} \cdot \binom{K}{4} \cdot \left(1 + \frac{1}{\epsilon}\right) \\
&\leqslant e^{\tau\epsilon^2/2} \cdot K^4 \cdot \left(1 + \frac{1}{\epsilon}\right),
\end{aligned}$$

which gives

$$\begin{aligned}
\frac{3\tau}{2} - \mathsf{pos}^{\mathsf{q}}_\tau(x_1, x_2, x_3, x_4) &\leqslant d_\tau(x_1, x_2, x_3, x_4) \\
&< \frac{3}{\ln(1+\epsilon)} \cdot \left(\tau\epsilon^2/2 + 4\ln K + \ln\left(1 + \frac{1}{\epsilon}\right)\right) \\
&\leqslant \frac{6}{\epsilon} \cdot \left(n\epsilon^2/2 + 4\ln K + \frac{1}{\epsilon}\right) \\
&\leqslant 3\epsilon n + \frac{6}{\epsilon} \cdot \left(4\ln K + \frac{1}{\epsilon}\right) \\
&\leqslant 5\epsilon n,
\end{aligned}$$

where we use that $\tau \leqslant n$, $\frac{\epsilon}{2} \leqslant \ln(1+\epsilon)$, and $\ln\left(1+\frac{1}{\epsilon}\right) \leqslant 1/\epsilon$, and where the last inequality follows from $n = \frac{24k}{\epsilon^3}$ so that

$$\frac{6}{\epsilon} \cdot \left(4\ln K + \frac{1}{\epsilon}\right) \leqslant \frac{6}{\epsilon}\left(4k + \frac{1}{\epsilon}\right) = \epsilon^2 n + \frac{\epsilon}{4} n < 2\epsilon n.$$

This completes the proof of Lemma 12. ◀

4.3 The $(2, \frac{3}{7} - \epsilon)$-List Decodability of SW

We now return to our main goal of this section, which is to show that SW is 2-list decodable up to radius $\frac{3}{7}$. We restate the theorem below for convenience.

▶ **Theorem 9.** *In the* SW *coin game, no matter which sets Eve chooses each round, it holds that*

$$\mathsf{posc}_n(3) > \left(\frac{3}{7} - 2\epsilon\right) \cdot n.$$

That is, the SW *coin game with* $n = \frac{24k}{\epsilon^3}$ *gives a feedback code that is* $\left(2, \frac{2}{7} - 2\epsilon\right)$*-list-decodable.*

Proof. Consider the first round $n - f$ at which $\mathsf{posc}_{n-f}(4) > \left(\frac{3}{7} - 2\epsilon\right) n$. There must be such a round because $\frac{1}{2}\mathsf{posc}_n(1) + \mathsf{posc}_n(2) + \mathsf{posc}_n(3) + \mathsf{posc}_n(4) \geqslant \frac{3}{2}n - 5\epsilon n$ by Lemma 12, so $\mathsf{posc}_n(4) \geqslant \frac{2}{7} \cdot \left(\frac{3}{2}n - 7\epsilon n\right) = \left(\frac{3}{7} - 2\epsilon\right) n$. After round $n - f$, there only remains 3 relevant coins upon the board. Our goal is to show that another falls off.

Suppose that in round $n - f$ that the first coin is at position $\left(\frac{3}{7} - 2\epsilon\right) n - p$. From Lemma 11, we know that

$$\begin{aligned}
\mathsf{posc}_{n-f}(2) + \mathsf{posc}_{n-f}(3) &\geqslant \mathsf{posc}_{n-f}(1) + \mathsf{posc}_{n-f}(4) - 1 \\
&= \frac{6}{7}n - p - 4\epsilon n - 1 \\
&\geqslant \frac{6}{7}n - p - 5\epsilon n. \qquad (4)
\end{aligned}$$

We also know from Lemma 12 that

$$\begin{aligned}
\mathsf{posc}_{n-f}(2) + \mathsf{posc}_{n-f}(3) &\geqslant \frac{3}{2}(n-f) - 5\epsilon n - \frac{1}{2}\mathsf{posc}_{n-f}(1) - \mathsf{posc}_{n-f}(4) \\
&\geqslant \frac{3}{2}(n-f) - 5\epsilon n - \frac{1}{2}\left(\left(\frac{3}{7} - 2\epsilon\right)n - p\right) - \left(\frac{3}{7} - 2\epsilon\right)n \\
&= \frac{6}{7}n - \frac{3}{2}f + \frac{1}{2}p - 2\epsilon n. \qquad (5)
\end{aligned}$$

Adding $\frac{1}{3}$ of Equation 4 and $\frac{2}{3}$ of Equation 5, we get

$$\mathsf{posc}_{n-f}(2) + \mathsf{posc}_{n-f}(3) \geqslant \frac{6}{7}n - f - 3\epsilon n. \qquad (6)$$

Now, suppose that the third coin does not reach position $\left(\frac{3}{7} - 3\epsilon\right) n$ by the end of the game. Then, at least one of the second and third coins must move in each of the last f rounds, so that $\mathsf{posc}_t(2) + \mathsf{posc}_t(3)$ increases by at least 1 each round. This means that at round n,

$$\begin{aligned}
\mathsf{posc}_n(2) + \mathsf{posc}_n(3) &\geqslant \mathsf{posc}_{n-f}(2) + \mathsf{posc}_{n-f}(3) + f \\
&\geqslant \left(\frac{6}{7} - 3\epsilon\right) n,
\end{aligned}$$

which gives that $\mathsf{posc}_n(3) \geqslant \frac{1}{2}\left(\frac{6}{7} - 3\epsilon\right) n > \left(\frac{3}{7} - 2\epsilon\right) n$, a contradiction on our assumption that the third coin never falls off the board.

Therefore, no matter which sets the adversary chooses, there will always be at most two coins left on the board at the end of the game. ◀

5 Spencer-Winkler Does Not Give $\left(3, \frac{7}{15}\right)$-List Feedback Codes

In Section 4, we showed that the Spencer-Winkler strategy for Alice and Bob achieves a $(2, \frac{3}{7})$-list feedback code. In this strategy, Bob always splits the sets into the even-numbered coins and the odd-numbered coins.

A reasonable conjecture might be that this strategy is always optimal, and, in fact, we do not know of any proof that it is not. However, in this section we will show that for $\ell = 3$, it does not match our upper bound of $\frac{7}{15}$ from Section 3. Whether this is because the protocol is suboptimal or because the upper bound is not tight remains open for further investigation.

▶ **Theorem 3.** *For any $\varepsilon > 0$, the feedback code* SW *(defined in Section 4) is not $\left(3, \frac{31}{67} + \varepsilon\right)$-list decodable for any choice of encoding length $n = n(k)$.*

As in the previous sections, we discuss the counterexample in the coin game formulation. We will show an attack for all large enough k. In this setting, Bob has $K = 2^k$ coins for some $k > 1000\varepsilon^{-1}$, and in each of n rounds (Alice and Bob choose n), he partitions the coins into 2 sets. Then, Eve chooses one of the two sets in which to move all the coins up by 1. Eve wins if, at the end of the protocol, at least 4 coins remain $\lesssim \frac{31}{67}n$.

5.1 Eve's Strategy

We begin by stating Eve's procedure for determining which set of coins to select at each step. For simplicity, we'll assume that n is a multiple of 67 and write $n = 67q$. We'll further assume q is even and εq is an integer.

Protocol 2 : Eve's Procedure

Alice has a coin $x \in \{0,1\}^k$. She and Bob simulate the coin game with $K = 2^k$ coins. For the n rounds, Eve does the following:

1. For the first $32q$ rounds, Eve selects (moves up by 1) the even coins.
2. For the next $16q$ rounds, Eve selects the odd coins.
3. For the next $8q$ rounds, Eve selects the even coins.
4. For the next $4q$ rounds, Eve selects the odd coins.
5. For the next $4q$ rounds, Eve selects the even coins.
6. For the final $3q$ rounds, Eve selects the odd coins.

5.2 Analysis of Eve's Strategy

We will establish our main sequence of claims giving an upper bound on the positions of the first few coins after each of these steps (and a step in between as well). The claims are written out below and summarized by the following table. For each upper bound, we additionally add $+\varepsilon q$, although we do not write it into the table for brevity.

Establishing the bounds in the table would show that $\mathsf{posc}_m(4) \leqslant 31q + \varepsilon q < \left(\frac{31}{67} + \varepsilon\right) \cdot n$ at the end of the n rounds, which establishes Theorem 3.

Now, we will prove the bounds listed in the table. Each argument below will establish the bounds indicated by the corresponding symbol. Each argument requires only that the bounds in the previous line of the table hold, so we can prove the bounds in a top-down order.

	$\mathsf{posc}_m(1)$	$\mathsf{posc}_m(2)$	$\mathsf{posc}_m(3)$	$\mathsf{posc}_m(4)$	$\mathsf{posc}_m(5)$
(even) $m = 32q$	0 (▲)	16q (●)	16q (●)	16q (●)	16q (●)
(odd) $m = 48q$	16q (■)	16q (♦)	24q (●)	24q (●)	24q (●)
(even) $m = 56q$	16q (▲)	24q (■)	24q (♦)	28q (●)	28q (●)
(odd) $m = 60q$	20q (■)	24q (♦)	28q (■)	28q (♦)	30q (●)
(even) $m = 62q$	20q (▲)	26q (■)	28q (♦)	30q (■)	30q (♦)
(even) $m = 64q$	20q (▲)	28q (■)	28q (♦)	31q (♣)	31q (♣)
(odd) $m = 67q$	23q (■)	28q (♦)	31q (■)	31q (♦)	33.5q (●)

Figure 3 An upper bound on the positions of the first 5 coins after m rounds. To each listed position bound, additionally add $+\varepsilon q$. Eve's selection of odd or even is also noted. Symbols in the cells are referenced in the proofs below.

To show the (▲) bounds, note that selecting the even coins never moves the coin in position 1.

Next, we establish the (●) bounds with the following claim. It shows us that for all times m, for $i \leqslant 6$ we have that $\mathsf{posc}_m(i) < \frac{1}{2} \cdot m + \varepsilon q$

▷ Claim 15. For any round m, as long as k is sufficiently large, it holds that $\mathsf{posc}_m(6) < \frac{1}{2} \cdot m + \varepsilon q$.

Proof. Since at all steps, only the odd coins or even coins move (and there are an even number of coins total), it holds that

$$\mathsf{posc}_m(1) + \ldots + \mathsf{posc}_m(K) \leqslant \frac{1}{2} \cdot Km$$

Then,

$$\frac{1}{2} \cdot Km > \mathsf{posc}_m(6) + \ldots + \mathsf{posc}_m(K) \geqslant (K-6) \cdot \mathsf{posc}_m(6)$$

which implies that

$$\mathsf{posc}_m(6) < \frac{1}{2} \cdot \frac{Km}{K-6} < \frac{1}{2} \cdot m + \varepsilon q$$

where the last line holds if $K = 2^k$ is sufficiently large, for example larger than $1000\varepsilon^{-1}$. ◁

To show the (■) bounds, note the following claim.

▷ Claim 16. For all $i \in [K]$, between rounds t and t', it holds that $\mathsf{posc}_{t'}(i) - \mathsf{posc}_t(i) \leqslant t' - t$.

Proof. All of coins $c_t(1), \ldots, c_t(i)$ must have have position at most $\mathsf{posc}_t(i)$ after round t. They can all move at most $t' - t$ by round t', so there are at least t' coins at position $\mathsf{posc}_t(i) + (t' - t)$ or earlier by the end of round t', which is what we desired. ◁

Next, we establish the (♦) bounds with the following claim.

▷ Claim 17. For all coins $i \in [K-1]$ and times t and t', if the set corresponding to parity $i+1$ is not chosen in that interval, then $\mathsf{posc}_{t'}(i+1) \leqslant \max\{\mathsf{posc}_t(i+1), \mathsf{posc}_t(i) + t' - t\}$.

Proof. Let $d := \mathsf{posc}_t(i+1) - \mathsf{posc}_t(i)$. For the first d steps then, the coins $c_t(1), \ldots, c_t(i)$ are all necessarily before the coin $c_t(i+1)$. Then, $\mathsf{posc}_t(i+1)$ does not increase for those d rounds (if $t'-t < d$, then simply stop at round t'. Then, by Claim 16, in the remaining $\max\{t'-t-d, 0\}$ rounds, $\mathsf{posc}_t(i+1)$ increases by at most 1. Therefore, in total, the final position of $c_t(i+1)$ after round t' is $\max\{t'-t-d+\mathsf{posc}_t(i+1), \mathsf{posc}_t(i+1)\}$. is This gives the desired bound because $t'-t-d+\mathsf{posc}_t(i+1) \leqslant t'-t+\mathsf{posc}_t(i)-\mathsf{posc}_t(i+1)+\mathsf{posc}_t(i+1) = t'-t+\mathsf{posc}_t(i)$ as desired. ◁

Finally, we establish the (♣) bounds specifically for $\mathsf{posc}_m(4)$ and $\mathsf{posc}_m(5)$ between rounds $62q$ and $64q$.

▷ Claim 18. After round $m+d$ where $m = 62q$ and d is even and $d \leqslant 2q$, it holds that $\mathsf{posc}_{m+d}(5) \leqslant 30q + d/2 + \varepsilon q$.

Proof. We will show this statement inductively. This holds when $d = 0$ as the base case.

Assume this is true for d, and we'll prove it for $d+2$. By Claim 16, $\mathsf{posc}(5)$ can increase by at most 2 in these 2 steps, so we only have to address the case where $\mathsf{posc}_{m+d}(5) = 30q+d/2+\varepsilon q$ exactly. Moreover, we must have $\mathsf{posc}_{m+d}(4) = 30q+d/2+\varepsilon q$ or $\mathsf{posc}_{m+d}(4) = 30q+d/2+\varepsilon q$ exactly, otherwise we would be done by Claim 17.

All the coins $c_m(1), c_m(2), c_m(3)$ are in position at most $28q+d+\varepsilon q < 30q+d/2+\varepsilon q-10$ at the end of d steps, so they cannot surpass $c_{m+d}(4)$ during these next 2 steps.

In both the cases where $\mathsf{posc}_{m+d}(4) = 30q + d/2 + \varepsilon q$ and $\mathsf{posc}_{m+d}(4) = 30q + d/2 + \varepsilon q$, both the 4th and 5th positions move up by exactly 1 if the first three coins are guaranteed to be out of the picture. ◁

Abstract

We prove a hardness of sampling result for the anti-ferromagnetic Ising model on random graphs of average degree d for large constant d, proving that when the normalized inverse temperature satisfies $\beta > 1$ (asymptotically corresponding to the condensation threshold), then w.h.p. over the random graph there is no stable sampling algorithm that can output a sample close in W_2 distance to the Gibbs measure. The results also apply to a fixed-magnetization version of the model, showing that there are no stable sampling algorithms for low but positive temperature max and min bisection distributions. These results show a gap in the tractability of search and sampling problems: while there are efficient algorithms to find near optimizers, stable sampling algorithms cannot access the Gibbs distribution concentrated on such solutions.

Our techniques involve extensions of the interpolation technique relating behavior of the mean field Sherrington-Kirkpatrick model to behavior of Ising models on random graphs of average degree d for large d. While previous interpolation arguments compared the free energies of the two models, our argument compares the average energies and average overlaps in the two models.

1 Introduction

The study of disordered systems is at the intersection of statistical physics, probability theory, and computer science. Models of disordered systems, such as the Edwards–Anderson model, Sherrington–Kirkpatrick model, random constraint satisfaction problems, and combinatorial optimization problems on random networks, have been studied from many different perspectives, including as toy models of complex physical systems and as a source of random computational problems on which to test algorithms and understand the sources of algorithmic intractability.

In the algorithmic context, disordered systems present at least two natural algorithmic challenges: the first is the *search problem*, that of finding a high quality solution to an optimization problem or finding a near ground state in the language of statistical physics; the second is the *sampling problem*, that of (approximately) sampling from a Gibbs measure that weights solutions exponentially by their objective value.

One striking phenomenon that has been discovered is a gap between the tractability of search and sampling. That is, for certain choices of parameters in some models of disordered systems, the search problem is tractable (there exist polynomial-time or even near-linear time algorithms to find high quality solutions), while no efficient sampling algorithms are known, and in fact broad classes of sampling algorithms can be proved to be ineffective. So while high quality solutions can be found efficiently, these solutions are not typical, in the sense that the distribution of solutions found by a given search algorithm is far from the equilibrium Gibbs measure.

A prime example of this phenomenon occurs in the Sherrington–Kirkpatrick (SK) model [36], an Ising model on the complete graph on n vertices in which the $\binom{n}{2}$ coupling constants are independent Gaussian random variables (see e.g [32] for a mathematical survey of the model). Here, after appropriate normalization, the key parameter is β, the inverse temperature of the model. Parisi famously predicted a formula for the limiting free energy of the SK model as a function of β [33, 34]; this formula is non-analytic at $\beta = 1$, indicating the existence of the phase transition at this point. The Parisi formula was proved rigorously by Guerra [23] and Talagrand [39], with methods that have proved very influential in mathematics, physics, and computer science in the past two decades. Along with the Parisi formula comes information about the SK Gibbs measure itself; in particular, Parisi identified the "average overlap" of two independent samples from the Gibbs measure as an order parameter for the phase transition [35] and developed the theory of a hierarchy of "replica symmetry breaking". Thus the equilibrium picture of the SK model is fairly well understood, with the phase transition identified at $\beta = 1$.

Turning to the algorithmic search problem, the task is to find a solution $\sigma \in \{\pm 1\}^n$ that (approximately) maximizes the probability mass function of the SK model; that is, the task of finding a ground state or near ground state of the model. Montanari [30], partly inspired by the work of Subag on spherical spin glasses [38], proposed an algorithm for this task based on approximate message passing, which finds an approximate optimizer under the widely believed assumption that the SK model has "no overlap gap" (sometimes also referred to as "full replica symmetry breaking") for large enough β. This approach was later extended to mixed p-spin models [3], which can be thought of as the generalization of the Ising model to hypergraphs.

For the sampling problem, however, the picture is less optimistic. It was predicted by physicists that the simple Glauber dynamics should converge fast as long as $\beta < 1$ [37], but progress on a rigorous proof of this statement has only come recently. A series of recent works [7, 22, 18, 5] showed that Glauber dynamics does indeed converge quickly if $\beta < 1/4$ (more specifically, in $O(n \log n)$ steps). A more recent work [6] has further extended the range of rapid convergence to values beyond $\beta = 1/4$. Using a different approach based on *stochastic localization*, El Alaoui, Montanari, and Sellke [4] gave a different sampling algorithm that approximately samples from the SK Gibbs measure for $\beta < 1/2$, with the approximation in terms of the Wasserstein distance instead of the total variation distance guarantees given by previous works. This result was later improved to the entire replica-symmetric phase $\beta < 1$ by Celentano [11]. On the other hand, obstacles seem to arise after the phase transition at $\beta = 1$. El Alaoui, Montanari, and Sellke showed that when $\beta > 1$, the onset of *disorder chaos* naturally obstructs *stable* sampling algorithms [4]. Similar ideas were used recently by El Alaoui and Gamarnik to rule out stable sampling algorithms for the symmetric binary perceptron problem [1].

One can ask whether this gap in tractability for the search and sampling problems is universal for certain classes of disordered systems. The SK model is an example of a *mean-field model*: all spins (variables) interact with each other. Mean-field models have the

advantage of being mathematically tractable to some degree, but the disadvantage of being unrealistic from the physics perspective as well as the perspective of large real-world networks. Seeking a trade-off between these two aspects, physicists have studied *diluted mean-field models*: that is, statistical physics models on random graphs or hypergraphs of constant average degree [29]. These models inherit some of the symmetries of mean-field models while also having some non-trivial local geometry. The study of diluted mean field models in physics led to rich and surprising predictions for the behavior of optimization problems on random graphs and random constraint satisfaction problems [27, 25, 20]. Rigorously proving these predictions is a major task in mathematics and theoretical computer science.

The specific diluted mean-field model we address here is the anti-ferromagnetic Ising model on sparse random graphs. The Hamiltonian of this model is the number of edges in the random graph cut by the given configuration, and the ground states correspond to the maximum cuts in the graph. Finding a maximum cut in a graph is one of the best-known constraint satisfaction problems, and due to this connection this model has been studied extensively in computer science as well as statistical physics. It is known that as the average degree of the random graph increases, many aspects of this model can be understood via the SK model. Dembo, Montanari, and Sen showed that the typical size of a maximum cut in both Erdős-Rényi random graphs and random regular graphs can be related to the ground state energy of SK model [21]. They proved this by interpolating the free energy between the two models (described in more detail below). El Alaoui, Montanari, and Sellke then gave an algorithm for finding a near maximum cut in a random regular graph by adapting Montanari's message-passing algorithm for the SK model [2]. Similar results have also been shown for the more general mixed p-spin models and their diluted counterparts [24, 13].

It is natural to ask if this connection between the anti-ferromagnetic Ising model and the SK model can be extended further. In particular, does the search vs. sampling phenomenon also arise in the anti-ferromagnetic Ising model on random graphs? In this paper, we give an affirmative answer to this question.

1.1 Main Results

Before stating our main results we introduce some necessary definitions and notation. We refer to an element in $\{-1,1\}^n$ as a *configuration*. Given a graph G and its adjacency matrix A_G, we define the *Ising Hamiltonian* $H_G(\sigma) = \sum_{1\le i\le j\le n}(A_G)_{ij}\sigma(i)\sigma(j)$. Note that $\frac{|E(G)|+H_G(\sigma)}{2}$ is exactly the number of edges in the graph whose endpoints are assigned the same spin by σ. In particular, a ground state (i.e., a configuration that minimizes the Hamiltonian) of H_G corresponds to a maximum cut in the graph. For any *inverse temperature parameter* $\beta \in \mathbb{R}$, H_G induces the *Gibbs distribution*

$$\mu_{\beta,G}(\sigma) = \frac{\exp(-\beta H(\sigma))}{Z_G(\beta)}.$$

where

$$Z_G(\beta) = \sum_{\sigma'\in\{-1,1\}^n} \exp(-\beta H(\sigma'))$$

is the *partition function*, the normalizing constant of the Gibbs distribution.

In this paper, as is common in prior works, the random graph model we consider will be the Poissonized random multigraph model $\mathbb{G}^{\mathrm{Po}}_{n,d}$, where we first sample the number of edges from a Poisson distribution with mean $dn/2$ (so that the expected average degree is d), and then for each edge sample both of its endpoints independently from $[n] = \{1, 2, \dots, n\}$.

Given any two measures μ_1, μ_2 over $\{-1,1\}^n$, we define their *normalized Wasserstein distance* to be

$$W_{2,n}(\mu_1,\mu_2) = \inf_{\pi\in\Gamma(\mu_1,\mu_2)} \left(\mathop{\mathbf{E}}_{(\sigma_1,\sigma_2)\sim\pi} \left[\frac{1}{n}\sum_{i=1}^{n} (\sigma_1(i)-\sigma_2(i))^2 \right] \right)^{1/2},$$

where $\Gamma(\mu_1,\mu_2)$ is the set of all couplings of μ_1 and μ_2; that is, measures over $\{-1,1\}^n \times \{-1,1\}^n$ whose marginal on the first argument is μ_1 and the second μ_2.

Our main result is a hardness of sampling theorem in terms of the $W_{2,n}$ distance for the measure $\mu_{\beta,G}$ against *stable* sampling algorithms where $G \sim \mathbb{G}^{\mathrm{Po}}_{n,d}$. Informally, a sampling algorithm is stable if its output is insensitive to small perturbations of the input. See Definition 12 for a formal definition.

▶ **Theorem 1.** *Let $\{\mathsf{ALG}_n\}_{n\geq 1}$ be a family of randomized sampling algorithms where ALG_n takes as input an n-vertex (multi-)graph G and an inverse temperature parameter β and produces an output law $\mu^{\mathsf{ALG}}_{\beta,G}$ over $\{-1,1\}^n$. For every $\beta > 1$ and d sufficiently large, if $\{\mathsf{ALG}_n\}_{n\geq 1}$ is* stable *at inverse temperature parameter $\beta/\sqrt{d}$, then*

$$\liminf_{n\to\infty} \mathop{\mathbf{E}}_{G\sim\mathbb{G}^{\mathrm{Po}}_{n,d}} \left[W_{2,n}\left(\mu^{\mathsf{ALG}}_{\beta/\sqrt{d},G}, \mu_{\beta/\sqrt{d},G}\right)\right] > 0.$$

That is, stable algorithms cannot sample from the model with vanishing error in Wasserstein distance.

It is known that the replica symmetry breaking threshold for $\mathbb{G}^{\mathrm{Po}}_{n,d}$ occurs at the Kesten-Stigum bound $\beta^\dagger(d) = \frac{1}{2}\log\frac{\sqrt{d}+1}{\sqrt{d}-1}$[1] [31, 19], so the threshold $\beta = 1$ corresponds exactly to the normalized limit $\lim_{d\to\infty}\sqrt{d}\cdot\beta^\dagger(d) = 1$. Note that $\beta = 1$ is also the replica symmetry breaking threshold of the Sherrington-Kirkpatrick model.

As it turns out, the same proof for Theorem 1 yields sampling hardness for near-maximum and near-minimum bisections as well. Let $A_n = \{\sigma\in\{-1,1\}^n : |\sum_{i=1}^n \sigma(i)| \leq 1\}$ be the set of configurations in which the numbers of $+1$s and -1s differ by at most one, which we refer to as *bisections*. The Gibbs distribution $\mu_{\beta,G}$ when restricted to A_n gives

$$\mu^{\mathsf{bis}}_{\beta,G}(\sigma) = \frac{\exp(-\beta H(\sigma))}{Z^{\mathsf{bis}}_G(\beta)}.$$

where

$$Z^{\mathsf{bis}}_G(\beta) = \sum_{\sigma'\in A_n} \exp(-\beta H(\sigma'))$$

is the bisection partition function. Note that $\mu^{\mathsf{bis}}_{\beta,G}(\sigma)$ prefers bisections that cut more edges when $\beta > 0$, and bisections with fewer edges when $\beta < 0$. This model is also known as the zero-magnetization Ising model and has been studied both in the statistical physics literature on disordered systems [28] and recently in computer science [10, 8, 26].

▶ **Theorem 2.** *Let $\{\mathsf{ALG}_n\}_{n\geq 1}$ be a family of randomized sampling algorithms where ALG_n takes as input an n-vertex (multi-)graph G and an inverse temperature parameter β and produces an output law $\mu^{\mathsf{ALG}}_{\beta,G}$ over $\{-1,1\}^n$. For every $\beta\in\mathbb{R}$ such that $|\beta| > 1$ and d sufficiently large, if $\{\mathsf{ALG}_n\}_{n\geq 1}$ is* stable *at inverse temperature parameter $\beta/\sqrt{d}$, then*

$$\liminf_{n\to\infty} \mathop{\mathbf{E}}_{G\sim\mathbb{G}^{\mathrm{Po}}_{n,d}} \left[W_{2,n}\left(\mu^{\mathsf{ALG}}_{\beta/\sqrt{d},G}, \mu^{\mathsf{bis}}_{\beta/\sqrt{d},G}\right)\right] > 0.$$

[1] Unless otherwise specified, all logarithms in this paper are natural logarithms.

Theorems 1 and 2 exhibit a gap between search and sampling for the maximum cut and max/minimum bisection problem: while we have a search algorithm known under the widely believed "No Overlap Gap" conjecture [2] [2], no stable algorithm can sample from the Gibbs distribution with arbitrary precision in the Wasserstein metric. Put another way, the algorithm of [2] finds solutions of value $(1-\epsilon)\cdot \mathrm{OPT}$ for any fixed $\epsilon > 0$; Theorems 1 and 2 rule out stable algorithms that sample solutions of these values approximately uniformly, since a standard reduction of counting to sampling (e.g [9]) reduces the task of sampling from the Gibbs distribution to sampling uniformly from solutions of a given value.

1.2 Techniques

To show that sampling from the anti-ferromagnetic Ising Gibbs distribution on random graphs is hard for stable sampling algorithms, we use the framework that was used by [4] to show that sampling from the Sherrington-Kirkpatrick Gibbs distribution is hard. The key quantity in this approach is the *overlap* between two configurations σ_1, σ_2, defined by

$$R_{1,2}(\sigma_1,\sigma_2) := \frac{1}{n}\sum_{i=1}^{n}\sigma_1(i)\sigma_2(i)\,.$$

The framework consists of the following two steps:

1. Show that w.h.p. over the disorder, the average of the squared overlap $R_{1,2}(\sigma_1,\sigma_2)^2$ with respect to two independent samples σ_1 and σ_2 from the Gibbs distribution is at least some positive constant independent of n. In particular, this is expected to hold when the Gibbs distribution exhibits replica symmetry breaking, which explains the threshold $\beta = 1$.
2. Show that the Gibbs distribution exhibits *disorder chaos*. That is, if we perturb the input (the random coupling constants in the case of the SK model or the random graph in the case of the Ising model) slightly (see Section 2 for a formal definition of this perturbation) and then take a sample σ_1 from the Gibbs distribution for the original system and a sample σ_2 from the Gibbs distribution for the perturbed system, with high probability $R_{1,2}(\sigma_1,\sigma_2)$ is very close to zero.

Combining these two steps and using a connection between $R_{1,2}$ and $W_{2,n}$ distance (see Lemma 15), we have that for arbitrarily small perturbations, the $W_{2,n}$ distance between the original Gibbs distribution and the perturbed Gibbs distribution is at least some positive constant. However, for stable sampling algorithms, if we make the perturbation sufficiently small then the $W_{2,n}$ distance between the old and new output distributions can also be arbitrarily small. This implies that the output distribution of any stable sampling algorithm will have strictly positive $W_{2,n}$ distance from the target Gibbs distribution.

In order to carry out this framework for sparse random graph models, we prove new *structural properties* of the Gibbs measures $\mu_{\beta/\sqrt{d},G}$ and $\mu^{\mathsf{bis}}_{\beta/\sqrt{d},G}$ and connect them to those of the Gibbs measures $\mu_{\beta,\mathbf{g}}$ and $\mu^{\mathsf{bis}}_{\beta,\mathbf{g}}$ of the SK model (see Section 2 for the formal definition of $\mu_{\beta,\mathbf{g}}$ and $\mu^{\mathsf{bis}}_{\beta,\mathbf{g}}$). This further extends the close connection between the behavior of the SK model and the sparse random graph model. Previously, it was shown by Dembo, Montanari, and Sen [21] that the *free energy* of the sparse model converges to that of the SK model as the average degree d increases to infinity. We first extend this to the average Hamiltonian of

[2] [2] stated the result for random regular graphs, but it can be transferred to other graph models using e.g. the argument in [13].

a sample drawn from the Gibbs distribution, showing that this quantity also converges in the same manner, regardless of the bisection restriction. This is done by using convexity of the free energy and a well-known observation that the average Hamiltonian can be obtained by taking derivative of the free energy (see (3.1) and (3.2)). The main difficulty here is establishing that the limiting free energy is the same regardless of the bisection restriction, the details of which can be found in the full version of this paper.

▶ **Proposition 3.**

(a) *For every $\beta \geq 0$, we have*

$$\lim_{d\to\infty} \limsup_{n\to\infty} \frac{1}{n} \left| \mathop{\mathbf{E}}_{\mathbf{g}} \left[\mathop{\mathbf{E}}_{\sigma\sim\mu_{\beta,\mathbf{g}}} [H_{\mathrm{SK}}(\sigma)] \right] - \frac{1}{\sqrt{d}} \mathop{\mathbf{E}}_{G} \left[\mathop{\mathbf{E}}_{\sigma\sim\mu_{\beta/\sqrt{d},G}} [H_G(\sigma)] \right] \right| = 0.$$

(b) *For every $\beta \in \mathbb{R}$, we have*

$$\lim_{d\to\infty} \limsup_{n\to\infty} \frac{1}{n} \left| \mathop{\mathbf{E}}_{\mathbf{g}} \left[\mathop{\mathbf{E}}_{\sigma\sim\mu^{\mathsf{bis}}_{\beta,\mathbf{g}}} [H_{\mathrm{SK}}(\sigma)] \right] - \frac{1}{\sqrt{d}} \mathop{\mathbf{E}}_{G} \left[\mathop{\mathbf{E}}_{\sigma\sim\mu^{\mathsf{bis}}_{\beta/\sqrt{d},G}} [H_G(\sigma)] \right] \right| = 0.$$

Our main technical contribution is the following proposition which says that as the average degree d goes to infinity, the expected average squared overlap between two independent samples from the Gibbs measure $\mu_{\beta/\sqrt{d},G}$ converges to those sampled from the Gibbs measure $\mu_{\beta,\mathbf{g}}$ of the SK model, again regardless of the bisection restriction. This gives the first ingredient in the sampling hardness framework. For the SK Hamiltonian, there is a known connection between the average Hamiltonian and the average squared overlap, which can be established using the Gaussian integration by parts trick (see e.g. [32] for more details). In this paper, we show that one can use the Stein-Chen identity for the Poisson distribution (see Lemma 24) in place of the Gaussian integration by parts trick to establish a similar connection for the sparse model in the large degree limit.

▶ **Proposition 4.**

(a) *For any $\beta \geq 0$,*

$$\lim_{d\to\infty} \limsup_{n\to\infty} \left| \mathop{\mathbf{E}}_{\mathbf{g}} \left[\mathop{\mathbf{E}}_{\sigma_1,\sigma_2\sim\mu_{\beta,\mathbf{g}}} \left[R_{1,2}(\sigma_1,\sigma_2)^2 \right] \right] - \mathop{\mathbf{E}}_{G} \left[\mathop{\mathbf{E}}_{\sigma_1,\sigma_2\sim\mu_{\beta/\sqrt{d},G}} \left[R_{1,2}(\sigma_1,\sigma_2)^2 \right] \right] \right| = 0.$$

(b) *For any $\beta \in \mathbb{R}$,*

$$\lim_{d\to\infty} \limsup_{n\to\infty} \left| \mathop{\mathbf{E}}_{\mathbf{g}} \left[\mathop{\mathbf{E}}_{\sigma_1,\sigma_2\sim\mu^{\mathsf{bis}}_{\beta,\mathbf{g}}} \left[R_{1,2}(\sigma_1,\sigma_2)^2 \right] \right] - \mathop{\mathbf{E}}_{G} \left[\mathop{\mathbf{E}}_{\sigma_1,\sigma_2\sim\mu^{\mathsf{bis}}_{\beta/\sqrt{d},G}} \left[R_{1,2}(\sigma_1,\sigma_2)^2 \right] \right] \right| = 0.$$

Finally, to obtain disorder chaos for the sparse model which is the second component in the sampling hardness framework, we use the fact that two configurations sampled from the coupled system for the SK model have nontrivial overlap with only exponentially small probability (see Theorem 29). This causes a gap in free energy between the coupled system and uncoupled system, which can then be transferred to the sparse model using the interpolation result by [17, 16]. We can then translate this gap back to a disorder chaos statement.

1.3 Organization

The paper is organized as follows. In Section 2 we set up the notation and give a detailed overview of the proof. In Section 3 and Section 4, we establish the correspondence of average energy and average overlap between the two models. Finally in Section 5, we transfer the disorder chaos property from the SK model to the sparse random graph models.

2 Overview of the proof

Gibbs distributions

For $\sigma \in \{-1,1\}^n, \mathbf{X} \in \mathbb{R}^{n\times n}$, we define the Hamiltonian

$$H(\sigma;\mathbf{X}) := \sum_{i,j=1}^{n} \mathbf{X}_{ij}\sigma(i)\sigma(j).$$

For any $\beta \in \mathbb{R}$, it induces the following Gibbs distribution on $\{-1,+1\}^n$:

$$\mu_{\beta,\mathbf{X}}(\sigma) = \frac{\exp\left(-\beta H(\sigma;\mathbf{X})\right)}{Z(\beta,\mathbf{X})},$$

where $Z(\beta,\mathbf{X}) = \sum_{\sigma\in\{-1,1\}^n} \exp\left(-\beta H(\sigma;\mathbf{X})\right)$ is the normalizing factor commonly referred to as the partition function. β is commonly referred to as the *inverse temperature* parameter in statistical physics. We also consider the restriction of the above distribution to bisections $\sigma \in A_n$, with

$$\mu^{\mathsf{bis}}_{\beta,\mathbf{X}}(\sigma) = \frac{\exp\left(-\beta H(\sigma;\mathbf{X})\right)}{Z^{\mathsf{bis}}(\beta,\mathbf{X})}, \quad Z^{\mathsf{bis}}(\beta,\mathbf{X}) = \sum_{\sigma\in A_n} \exp\left(-\beta H(\sigma;\mathbf{X})\right).$$

We refer to such restricted versions as bisection models. In statistical physics literature, this is sometimes also called the model with *zero magnetization* and the version without the bisection restriction is called the model with *non-fixed magnetization*. Here, the term magnetization refers to the quantity $m(\sigma) = \sum_{i=1}^{n} \sigma(i)/n$. We sometimes also write $\mu(\sigma;\beta,\mathbf{X})$ and $\mu^{\mathsf{bis}}(\sigma;\beta,\mathbf{X})$ instead of $\mu_{\beta,\mathbf{X}}(\sigma)$ and $\mu^{\mathsf{bis}}_{\beta,\mathbf{X}}(\sigma)$ if we wish to stress the dependence on β and $\mathbf{X}$.

$\mathbf{X}$ is a random matrix drawn from some distribution and in this paper we consider two important cases. In the first case, $\mathbf{X} = \mathbf{g}$, where $\mathbf{g}_{ij} \sim N(0,1/2n)$ independently. This is known as the Sherrington-Kirkpatrick model. In the second case we have $\mathbf{X} = \mathbf{A}$, where each entry $\mathbf{A}_{ij}$ is an independent $\mathrm{Po}(d/2n)$ random variable for some parameter $d > 0$. This case corresponds to sparse random (multi-)graphs with average degree d, where the vertex set is $[n] = \{1,2,\ldots,n\}$ and the multiplicity of the edge $\{i,j\}$ is $\mathbf{A}_{ij} + \mathbf{A}_{ji}$ if $i \neq j$ and $\mathbf{A}_{ii}$ if $i = j$ (note that here $\mathbf{A}$ is not the adjacency matrix of the graph and can be asymmetric). Any configuration σ can be thought of as the indicator vector for a cut where the vertices assigned 1 by σ is on one side and those assigned -1 is on the other side, and $H(\sigma;\mathbf{A})$ is equal to the difference between the number of edges crossing the cut and the number of edges not crossing the cut. When $\beta > 0$, the Gibbs measure prefers those configurations that cut more edges, and this corresponds to the *Maximum Cut* problem for the non-fixed magnetization model and the *Maximum Bisection* problem for the zero-magnetization model. This case is known as the anti-ferromagnetic Ising model in the statistical physic literature. When $\beta < 0$, the non-fixed magnetization model corresponds to the *Minimum Cut* problem while the zero-magnetization model corresponds to the *Minimum Bisection* problem. This case is known as the ferromagnetic Ising model in the statistical physic literature.

For notational convenience, we sometimes drop the random matrix and write $H_{\mathrm{SK}}(\sigma) := H(\sigma;\mathbf{g})$ and $H_d(\sigma) := H(\sigma;\mathbf{A})$. We sometimes refer to these two models as *dense* or *sparse* models respectively.

Gibbs average

For any function $f : \{-1,1\}^n \to \mathbb{R}$, we can define its average with respect to μ or μ^{bis}:

$$\langle f(\sigma)\rangle_{\beta,\mathbf{X}} = \sum_{\sigma\in\{-1,1\}^n} f(\sigma)\mu_{\beta,\mathbf{X}}(\sigma), \quad \langle f(\sigma)\rangle^{\mathsf{bis}}_{\beta,\mathbf{X}} = \sum_{\sigma\in A_n} f(\sigma)\mu^{\mathsf{bis}}_{\beta,\mathbf{X}}(\sigma).$$

We can extend this definition to functions $f : \{-1,1\}^{n\times k} \to \mathbb{R}$ which take multiple configurations as inputs, in which case we assume that the configurations are sampled independently from the Gibbs distribution:

$$\langle f(\sigma_1,\ldots,\sigma_k)\rangle_{\beta,\mathbf{X}} = \sum_{\sigma_1,\ldots,\sigma_k\in\{-1,1\}^n} \mu_{\beta,\mathbf{X}}(\sigma_1)\cdots\mu_{\beta,\mathbf{X}}(\sigma_k)f(\sigma_1,\ldots,\sigma_k),$$

and the average over μ^{bis} is defined similarly. We sometimes drop the subscripts if they are clear from context. One function of particular interest to us is the *overlap* between two configurations, defined as

$$R_{1,2}(\sigma_1,\sigma_2) = \frac{1}{n}\sum_{i=1}^{n}\sigma_1(i)\sigma_2(i).$$

$R_{1,2}$ gives the normalized inner product between two configurations. If $\langle|R_{1,2}(\sigma_1,\sigma_2)|\rangle_{\beta,\mathbf{X}}$ is close to zero, then two configurations independently sampled from the Gibbs distribution $\mu_{\beta,\mathbf{X}}(\sigma)$ are nearly orthogonal.

Free energy

The free energy for these models is defined as follows.

$$\Phi_{n,\mathrm{SK}}(\beta) = \frac{1}{n}\mathop{\mathbf{E}}_{\mathbf{g}}\left[\log Z(\beta,\mathbf{g})\right], \quad \Phi_{n,d}(\beta) = \frac{1}{n}\mathop{\mathbf{E}}_{\mathbf{A}}\left[\log Z(\beta,\mathbf{A})\right].$$

We can also define free energy in a similar way when restricted to bisections.

$$\Phi^{\mathsf{bis}}_{n,\mathrm{SK}}(\beta) = \frac{1}{n}\mathop{\mathbf{E}}_{\mathbf{g}}\left[\log Z^{\mathsf{bis}}(\beta,\mathbf{g})\right], \quad \Phi^{\mathsf{bis}}_{n,d}(\beta) = \frac{1}{n}\mathop{\mathbf{E}}_{\mathbf{A}}\left[\log Z^{\mathsf{bis}}(\beta,\mathbf{A})\right].$$

The following proposition is a simple consequence of Cauchy-Schwarz.

▶ **Proposition 5.** *Both* $\log Z(\beta,\mathbf{X})$ *and* $\log Z^{\mathsf{bis}}(\beta,\mathbf{X})$ *are convex in* β.

Proof. For any β_1,β_2 we have

$$\begin{aligned} Z\left(\frac{\beta_1+\beta_2}{2},\mathbf{X}\right) &= \sum_{\sigma\in\{-1,1\}^n}\exp\left(-\frac{\beta_1+\beta_2}{2}H(\sigma;\mathbf{X})\right) \\ &\le \sqrt{\left(\sum_{\sigma\in\{-1,1\}^n}\exp\left(-\beta_1 H(\sigma;\mathbf{X})\right)\right)\left(\sum_{\sigma\in\{-1,1\}^n}\exp\left(-\beta_2 H(\sigma;\mathbf{X})\right)\right)} \\ &= \sqrt{Z(\beta_1,\mathbf{X})Z(\beta_2,\mathbf{X})}. \end{aligned}$$

Taking the logarithm of both sides, we get that $\log Z(\beta,\mathbf{X})$ is convex in β. The convexity of $\log Z^{\mathsf{bis}}(\beta,\mathbf{X})$ can be shown in the same way. ◀

By taking expectation over the randomness of $\mathbf{X}$ we immediately obtain the following corollary.

▶ **Corollary 6.** $\Phi_{n,\mathrm{SK}}(\beta), \Phi^{\mathsf{bis}}_{n,\mathrm{SK}}(\beta), \Phi_{n,d}(\beta), \Phi^{\mathsf{bis}}_{n,d}(\beta)$ *are all convex in* β.

Correspondence between dense and sparse models

It is known that as the average degree d gets larger, the sparse model will "converge" to the dense model in some sense. Dembo, Montanari, and Sen proved this for the free energy of these two models using a clever interpolation argument:

▶ **Lemma 7** ([21]). *There exist constants $c_1, c_2, c_3 > 0$ independent of n, β, d such that for any $\beta \in \mathbb{R}$,*

$$\left|\Phi^{\mathsf{bis}}_{n,d}\left(\frac{\beta}{\sqrt{d}}\right) - \Phi^{\mathsf{bis}}_{n,\mathrm{SK}}(\beta)\right| \le c_1\frac{|\beta|^3}{\sqrt{d}} + c_2\frac{\beta^4}{d} + c_3|\beta|\sqrt{d}\cdot\frac{1}{n^2}.^3$$

In this paper, we further extend this correspondence to the average energy $\langle H(\sigma)\rangle$ as well as the average overlap $\langle R_{1,2}(\sigma_1,\sigma_2)^2\rangle$.

▶ **Proposition 8** (Restatement of Proposition 3).
(a) *For every $\beta \ge 0$, we have*

$$\lim_{d\to\infty}\limsup_{n\to\infty}\frac{1}{n}\left|\mathbf{E}_{\mathbf{g}}[\langle H_{\mathrm{SK}}(\sigma)\rangle_{\beta,\mathbf{g}}] - \frac{1}{\sqrt{d}}\mathbf{E}_{\mathbf{A}}[\langle H_d(\sigma)\rangle_{\beta/\sqrt{d},\mathbf{A}}]\right| = 0.$$

(b) *For every $\beta \in \mathbb{R}$, we have*

$$\lim_{d\to\infty}\limsup_{n\to\infty}\frac{1}{n}\left|\mathbf{E}_{\mathbf{g}}[\langle H_{\mathrm{SK}}(\sigma)\rangle^{\mathsf{bis}}_{\beta,\mathbf{g}}] - \frac{1}{\sqrt{d}}\mathbf{E}_{\mathbf{A}}[\langle H_d(\sigma)\rangle^{\mathsf{bis}}_{\beta/\sqrt{d},\mathbf{A}}]\right| = 0.$$

▶ **Proposition 9** (Restatement of Proposition 4).
(a) *For any $\beta \ge 0$,*

$$\lim_{d\to\infty}\limsup_{n\to\infty}\left|\mathbf{E}_{\mathbf{g}}[\langle R_{1,2}^2\rangle_{\beta,\mathbf{g}}] - \mathbf{E}_{\mathbf{A}}[\langle R_{1,2}^2\rangle_{\beta/\sqrt{d},\mathbf{A}}]\right| = 0.$$

(b) *For any $\beta \in \mathbb{R}$,*

$$\lim_{d\to\infty}\limsup_{n\to\infty}\left|\mathbf{E}_{\mathbf{g}}[\langle R_{1,2}^2\rangle^{\mathsf{bis}}_{\beta,\mathbf{g}}] - \mathbf{E}_{\mathbf{A}}[\langle R_{1,2}^2\rangle^{\mathsf{bis}}_{\beta/\sqrt{d},\mathbf{A}}]\right| = 0.$$

We prove Proposition 8 in Section 3 and Proposition 9 in Section 4.

Disorder chaos and stable algorithms

Disorder chaos is a well-studied phenomenon in spin glass theory. The term "disorder" refers to the random matrix $\mathbf{X}$, and "chaos" describes what happens to the Gibbs distribution if we slightly perturb $\mathbf{X}$. For the SK model, consider the following notion of perturbation. Let $\mathbf{g}, \mathbf{g}'$ be two independent copies of Gaussian matrices where $\mathbf{g}_{ij}, \mathbf{g}'_{ij} \sim N(0, 1/2n)$ independently for each i, j. Given any perturbation parameter $t \ge 0$, we can consider the two measures $\mu_{\beta,\mathbf{g}}(\sigma)$ and $\mu_{\beta,\mathbf{g}_t}(\sigma)$ where $\mathbf{g}_t = \sqrt{1-t}\mathbf{g} + \sqrt{t}\mathbf{g}'$. Define $\langle f(\sigma_1,\sigma_2)\rangle_{\beta,\mathbf{g},\mathbf{g}_t}$ to be the average of $f(\sigma_1,\sigma_2)$ where $\sigma_1 \sim \mu_{\beta,\mathbf{g}}$ and $\sigma_2 \sim \mu_{\beta,\mathbf{g}_t}$ sampled independently from these two distributions respectively, i.e.,

$$\langle f(\sigma_1,\sigma_2)\rangle_{\beta,\mathbf{g},\mathbf{g}_t} = \sum_{\sigma_1,\sigma_2\in\{-1,1\}^n} f(\sigma_1,\sigma_2)\mu_{\beta,\mathbf{g}}(\sigma_1)\mu_{\beta,\mathbf{g}_t}(\sigma_2).$$

It is known that two such samples σ_1, σ_2 will likely have some nontrivial overlap when $t = 0$, in which case there is no perturbation and $\langle f(\sigma_1,\sigma_2)\rangle_{\beta,\mathbf{g},\mathbf{g}_t}$ is simply $\langle f(\sigma_1,\sigma_2)\rangle_{\beta,\mathbf{g}}$.

▶ **Theorem 10** (See e.g. [4]). *If $|\beta| > 1$, then there exists $\epsilon = \epsilon(\beta) > 0$ such that*

$$\lim_{n\to\infty} \mathbf{E}_{\mathbf{g}} \left[\langle R_{1,2}(\sigma_1,\sigma_2)^2\rangle_{\beta,\mathbf{g}}\right] \geq \epsilon(\beta). \tag{2.1}$$

However, when $t > 0$, then the overlap will be zero in the $n \to \infty$ limit.

▶ **Theorem 11** ([12]). *For all $\beta \in \mathbb{R}, t \in (0,1]$, we have*

$$\lim_{n\to\infty} \mathbf{E}_{\mathbf{g},\mathbf{g}'} \left[\langle R_{1,2}(\sigma_1,\sigma_2)^2\rangle_{\beta,\mathbf{g},\mathbf{g}_t}\right] = 0. \tag{2.2}$$

If we think of the expression on the left hand side of (2.1) and (2.2) as a function of t, then (2.1) and (2.2) together suggest that this function is not right-continuous at $t = 0$ if $|\beta| > 1$. It was shown in [4] that this property very naturally obstructs a class of sampling algorithms for $\mu_{\beta,\mathbf{g}}$.

▶ **Definition 12** (Definition 2.2 in [4]). *Let $\{\mathsf{ALG}_n\}_{n\geq 1}$ be a family of sampling algorithms for the Gibbs measure $\mu_{\beta,\mathbf{g}}$, where ALG_n takes an $n \times n$ matrix $\mathbf{g}$ and $\beta \in \mathbb{R}$ as input and outputs an assignment in $\{-1,1\}^n$. Let $\mu^{\mathsf{ALG}}_{\beta,\mathbf{g}}$ be the output law of ALG_n. We say that $\{\mathsf{ALG}_n\}_{n\geq 1}$ is stable (with respect to disorder at β), if*

$$\lim_{t\to 0} \limsup_{n\to\infty} \mathbf{E}\left[W_{2,n}(\mu^{\mathsf{ALG}}_{\beta,\mathbf{g}}, \mu^{\mathsf{ALG}}_{\beta,\mathbf{g}_t})\right] = 0. \tag{2.3}$$

Intuitively, (2.3) means that stable algorithms are not able to make the leap at the discontinuity $t = 0$ implied by (2.1) and (2.2), and therefore must be producing a distribution that is bounded away from the Gibbs distribution $\mu_{\beta,\mathbf{g}}$ in terms of the $W_{2,n}$ distance. This intuition is formalized in [4] as the following theorem.

▶ **Theorem 13** (Theorem 2.6 in [4]). *Fix β such that $|\beta| > 1$. Let $\{\mathsf{ALG}_n\}_{n\geq 1}$ be a family of sampling algorithms for the Gibbs measure $\mu_{\beta,\mathbf{g}}$ that is stable with respect to disorder at β, then*

$$\liminf_{n\to\infty} \mathbf{E}_{\mathbf{g}} \left[W_{2,n}(\mu_{\beta,\mathbf{g}}, \mu^{\mathsf{ALG}}_{\beta,\mathbf{g}})\right] > 0.$$

In this paper, we obstruct stable sampling algorithms for sparse models as well. For the sparse models, we consider a slightly different notion of perturbation. Fix the average degree $d > 0$ and the perturbation parameter $t \in [0,1]$, we will take three independent random matrices $\mathbf{A}^{(1-t)}, \mathbf{A}^{(t,1)}, \mathbf{A}^{(t,2)}$ such that $\mathbf{A}^{(1-t)}_{ij} \sim \mathrm{Po}((1-t)d/(2n))$, $\mathbf{A}^{(t,1)}_{ij}, \mathbf{A}^{(t,2)}_{ij} \sim \mathrm{Po}(td/(2n))$ independently for all $i, j \in [n]$. We then define $\mathbf{A} = \mathbf{A}^{(1-t)} + \mathbf{A}^{(t,1)}$ and $\mathbf{A}_t = \mathbf{A}^{(1-t)} + \mathbf{A}^{(t,2)}$. Similarly to Definition 12, we say that a family of sampling algorithms $\{\mathsf{ALG}_n\}_{n\geq 1}$ with inputs β and $\mathbf{A}$ is stable at inverse temperature β if

$$\lim_{t\to 0} \limsup_{n\to\infty} \mathbf{E}\left[W_{2,n}(\mu^{\mathsf{ALG}}_{\beta,\mathbf{A}}, \mu^{\mathsf{ALG}}_{\beta,\mathbf{A}_t})\right] = 0. \tag{2.4}$$

As an example, it was recently shown that stable algorithms implemented by Boolean circuits with bounded depth are stable [1].

When $t = 0$, we have by Proposition 9 and Theorem 10 that for $\beta > 1$,

$$\lim_{d\to\infty} \liminf_{n\to\infty} \mathbf{E}_{\mathbf{A}}[\langle R^2_{1,2}\rangle_{\beta/\sqrt{d},\mathbf{A}}] > 0, \tag{2.5}$$

and for β with $|\beta| > 1$

$$\lim_{d\to\infty} \liminf_{n\to\infty} \mathbf{E}_{\mathbf{A}}[\langle R^2_{1,2}\rangle^{\mathsf{bis}}_{\beta/\sqrt{d},\mathbf{A}}] > 0.$$

On the other hand, if $t > 0$, we show in the following lemma that the overlap tends to zero as n goes to infinity.

▶ **Lemma 14.** *Fix $t > 0$.*

(a) *For any $\beta \geq 0$,*

$$\lim_{d\to\infty} \limsup_{n\to\infty} \mathbf{E}[\langle R_{1,2}^2 \rangle_{\beta/\sqrt{d},\mathbf{A},\mathbf{A}_t}] = 0. \tag{2.6}$$

(b) *For any $\beta \in \mathbb{R}$,*

$$\lim_{d\to\infty} \limsup_{n\to\infty} \mathbf{E}[\langle R_{1,2}^2 \rangle^{\mathsf{bis}}_{\beta/\sqrt{d},\mathbf{A},\mathbf{A}_t}] = 0.$$

The following lemma establishes the connection between the overlap and the $W_{2,n}$ distance.

▶ **Lemma 15** (Lemma 5.3 in [4]). *Fix $n \in \mathbb{N}$. Let $\mu_1, \mu_2, \nu_1, \nu_2$ be distributions over $\{-1,+1\}^n$. We have*

$$\left| \mathop{\mathbf{E}}_{(\sigma,\sigma')\sim\mu_1\otimes\nu_1} [|R_{1,2}(\sigma,\sigma')|] - \mathop{\mathbf{E}}_{(\sigma,\sigma')\sim\mu_2\otimes\nu_2} [|R_{1,2}(\sigma,\sigma')|] \right| \leq W_{2,n}(\mu_1,\mu_2) + W_{2,n}(\nu_1,\nu_2).$$

We now have the ingredients needed for proving Theorem 1. Theorem 2 can be proved in the same way and we omit the details here.

Proof of Theorem 1. We drop the inverse temperature parameter in the $\langle\cdot\rangle$ notation for brevity. For any arbitrary $t > 0$, by choosing $\mu_1 = \mu_2 = \nu_1 = \mu_{\beta/\sqrt{d},\mathbf{A}}$ and $\nu_2 = \mu_{\beta/\sqrt{d},\mathbf{A}_t}$ in Lemma 15, we get that

$$W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}}, \mu_{\beta/\sqrt{d},\mathbf{A}_t}) \geq \left| \langle |R_{1,2}(\sigma,\sigma')| \rangle_{\mathbf{A}} - \langle |R_{1,2}(\sigma,\sigma')| \rangle_{\mathbf{A},\mathbf{A}_t} \right|.$$

Taking expectation on both sides, we obtain

$$\begin{aligned} \mathop{\mathbf{E}}_{\mathbf{A},\mathbf{A}_t} \left[W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}}, \mu_{\beta/\sqrt{d},\mathbf{A}_t}) \right] &\geq \mathop{\mathbf{E}}_{\mathbf{A},\mathbf{A}_t} \left[\left| \langle |R_{1,2}(\sigma,\sigma')| \rangle_{\mathbf{A}} - \langle |R_{1,2}(\sigma,\sigma')| \rangle_{\mathbf{A},\mathbf{A}_t} \right| \right] \\ &\geq \mathop{\mathbf{E}}_{\mathbf{A},\mathbf{A}_t} \left[\langle |R_{1,2}(\sigma,\sigma')| \rangle_{\mathbf{A}} \right] - \mathop{\mathbf{E}}_{\mathbf{A},\mathbf{A}_t} \left[\langle |R_{1,2}(\sigma,\sigma')| \rangle_{\mathbf{A},\mathbf{A}_t} \right]. \end{aligned}$$

In the second inequality we used the fact that $|a-b| \geq |a| - |b|$ for any $a, b \in \mathbb{R}$. Taking lim inf on both sides, we obtain

$$\begin{aligned} &\liminf_{n\to\infty} \mathop{\mathbf{E}}_{\mathbf{A},\mathbf{A}_t} \left[W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}}, \mu_{\beta/\sqrt{d},\mathbf{A}_t}) \right] \\ \geq &\liminf_{n\to\infty} \mathop{\mathbf{E}}_{\mathbf{A},\mathbf{A}_t} \left[\langle |R_{1,2}(\sigma,\sigma')| \rangle_{\mathbf{A}} \right] - \limsup_{n\to\infty} \mathop{\mathbf{E}}_{\mathbf{A},\mathbf{A}_t} \left[\langle |R_{1,2}(\sigma,\sigma')| \rangle_{\mathbf{A},\mathbf{A}_t} \right]. \end{aligned}$$

By (2.5) and (2.6), if d is sufficiently large, for some $\epsilon = \epsilon(\beta) > 0$ independent of t,

$$\liminf_{n\to\infty} \mathop{\mathbf{E}}_{\mathbf{A},\mathbf{A}_t} \left[W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}}, \mu_{\beta/\sqrt{d},\mathbf{A}_t}) \right] \geq \epsilon.$$

By the triangle inequality, we have

$$\begin{aligned} &W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}}, \mu_{\beta/\sqrt{d},\mathbf{A}_t}) \\ \leq &W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}}, \mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}}) + W_{2,n}(\mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}}, \mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}_t}) + W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}_t}, \mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}_t}). \end{aligned}$$

Since $\mathbf{A}$ and $\mathbf{A}_t$ have the same distribution, we have

$$\mathbf{E}\left[W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}}, \mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}}) \right] = \mathbf{E}\left[W_{2,n}(\mu_{\beta/\sqrt{d},\mathbf{A}_t}, \mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}_t}) \right].$$

Since $\{\mathsf{ALG}_n\}_n$ is stable at any inverse temperature, by (2.4) and taking t sufficiently small we have

$$\limsup_{n\to\infty} \mathbf{E}\left[W_{2,n}(\mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}}, \mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}_t})\right] \le \frac{\epsilon}{2}.$$

It follows that

$$\liminf_{n\to\infty} \mathbf{E}\left[W_{2,n}(\mu^{\mathsf{ALG}}_{\beta/\sqrt{d},\mathbf{A}}, \mu_{\beta/\sqrt{d},\mathbf{A}})\right] \ge \frac{\epsilon}{4}. \qquad \blacktriangleleft$$

Free energy of coupled bisection models

In subsequent proofs, we will need the following results on the free energy for coupled bisection models. More specifically, we show that the limiting free energy does not change under the bisection constraint for both dense and sparse models (for the sparse model we require $d \to \infty$). Intuitively, in the case of SK model this holds because the symmetry of its disorder implies that there is nothing special about the all-one direction. The sparse case requires more care since it no longer has the symmetry, but we overcome this difficulty using Poisson concentration arguments. Due to the space constraint, proofs will be omitted here and we refer interested readers to the full version of this paper.

Let us define (β is omitted from the notation for simplicity)

$$Z^S_{\mathbf{g},\mathbf{g}_t} = \sum_{\substack{\sigma_1,\sigma_2\in\{-1,1\}^n \\ R_{1,2}(\sigma_1,\sigma_2)\in S}} \exp\left(-\beta(H(\sigma_1;\mathbf{g}) + H(\sigma_2;\mathbf{g}_t))\right)$$

and

$$Z^{S,\mathsf{bis}}_{\mathbf{g},\mathbf{g}_t} = \sum_{\substack{\sigma_1,\sigma_2\in A_n \\ R_{1,2}(\sigma_1,\sigma_2)\in S}} \exp\left(-\beta(H(\sigma_1;\mathbf{g}) + H(\sigma_2;\mathbf{g}_t))\right).$$

Similarly for the sparse model, let us define

$$Z^S_{\mathbf{A},\mathbf{A}_t} = \sum_{\substack{\sigma_1,\sigma_2\in\{-1,1\}^n \\ R_{1,2}(\sigma_1,\sigma_2)\in S}} \exp\left(-\frac{\beta}{\sqrt{d}}\cdot(H(\sigma_1;\mathbf{A}) + H(\sigma_2;\mathbf{A}_t))\right),$$

$$Z^{S,\mathsf{bis}}_{\mathbf{A},\mathbf{A}_t} = \sum_{\substack{\sigma_1,\sigma_2\in A_n \\ R_{1,2}(\sigma_1,\sigma_2)\in S}} \exp\left(-\frac{\beta}{\sqrt{d}}\cdot(H(\sigma_1;\mathbf{A}) + H(\sigma_2;\mathbf{A}_t))\right).$$

▶ **Theorem 16.** *Let $S \subseteq [-1,1]$. For any $\beta \in \mathbb{R}$, we have*

$$\lim_{n\to\infty} \frac{1}{n}\mathbf{E}\left[\log Z^{S,\mathsf{bis}}_{\mathbf{g},\mathbf{g}_t} - \log Z^S_{\mathbf{g},\mathbf{g}_t}\right] = 0.$$

By letting $t = 0$ and $S = [-1,1]$, we immediately obtain the following.

▶ **Corollary 17.** *We have*

$$\lim_{n\to\infty} \left(\Phi^{\mathsf{bis}}_{n,\mathrm{SK}}(\beta) - \Phi_{n,\mathrm{SK}}(\beta)\right) = 0.$$

▶ **Lemma 18.** *Fix $\beta, d > 0$ and $t \in [0,1]$. For every $\delta \in (0,1/2)$, there exists a constant $C = C(\beta,d)$ such that for all sufficiently large n*

$$\Pr\left[\left|\log Z^S_{\mathbf{A},\mathbf{A}_t} - \mathbf{E}[\log Z^S_{\mathbf{A},\mathbf{A}_t}]\right| \ge n^{1/2+\delta}\right] \le \exp\left(-C\cdot n^{2\delta}\right)$$

and

$$\Pr\left[\left|\log Z^{S,\mathsf{bis}}_{\mathbf{A},\mathbf{A}_t} - \mathbf{E}[\log Z^{S,\mathsf{bis}}_{\mathbf{A},\mathbf{A}_t}]\right| \ge n^{1/2+\delta}\right] \le \exp\left(-C\cdot n^{2\delta}\right).$$

▶ **Theorem 19.** *Let $0 \le a < b$. For every $\epsilon > 0$, if d is sufficiently large, then for every $\beta \in [a, b]$,*

$$\limsup_{n\to\infty} \frac{1}{n} \left| \mathbf{E} \log Z^{S}_{\mathbf{A},\mathbf{A}_t} - \mathbf{E} \log Z^{S,\mathsf{bis}}_{\mathbf{A},\mathbf{A}_t} \right| \le \epsilon.$$

Again, by letting $t = 0$ and $S = [-1, 1]$, we immediately obtain the following.

▶ **Theorem 20.** *Let $0 \le a < b$. For every $\epsilon > 0$, if d is sufficiently large, then for every $\beta \in [a, b]$,*

$$\limsup_{n\to\infty} \left| \Phi_{n,d}\left(\frac{\beta}{\sqrt{d}}\right) - \Phi^{\mathsf{bis}}_{n,d}\left(\frac{\beta}{\sqrt{d}}\right) \right| \le \epsilon.$$

3 Interpolating the average energy between SK and the diluted model

In this section we prove Proposition 8 and establish the interpolation of average energy between sparse and dense models. By Lemma 7, we already know that the free energy of the sparse model converges to that of the dense model as the average degree d goes to infinity. The following connection between free energy and average energy is well-known:

$$\frac{\partial}{\partial\beta} \mathbf{E}\left[\log Z(\beta, \mathbf{X})\right] = \mathbf{E}\left[\frac{\sum_{\sigma\in\{-1,1\}^n} -H(\sigma;\mathbf{X}) \exp(-\beta H(\sigma;\mathbf{X}))}{Z(\beta,\mathbf{X})}\right] = -\mathbf{E}\left[\langle H(\sigma;\mathbf{X})\rangle_{\beta,\mathbf{X}}\right]. \tag{3.1}$$

Similarly,

$$\frac{\partial}{\partial\beta} \mathbf{E}\left[\log Z^{\mathsf{bis}}(\beta, \mathbf{X})\right] = \mathbf{E}\left[\frac{\sum_{\sigma\in A_n} -H(\sigma;\mathbf{X}) \exp(-\beta H(\sigma;\mathbf{X}))}{Z^{\mathsf{bis}}(\beta,\mathbf{X})}\right] = -\mathbf{E}\left[\langle H(\sigma;\mathbf{X})\rangle^{\mathsf{bis}}_{\beta,\mathbf{X}}\right]. \tag{3.2}$$

To obtain convergence of the partial derivatives, we use the following elementary fact sometimes known as Griffith's lemma in statistical physics.

▶ **Proposition 21** (See e.g. [41])**.** *Let $(f_\alpha)_{\alpha\ge 0}$ be a family of convex and differentiable functions that converges pointwise in an open interval I to f, then $\lim_{\alpha\to\infty} f'_\alpha(x) = f'(x)$ at every $x \in I$ where $f'(x)$ exists.*

Proof of Proposition 8. Proposition 8 says that

(a) For every $\beta \ge 0$, $\lim_{d\to\infty} \limsup_{n\to\infty} \frac{1}{n} \left| \mathbf{E}_{\mathbf{g}}[\langle H_{\mathrm{SK}}(\sigma)\rangle_{\beta,\mathbf{g}}] - \frac{1}{\sqrt{d}} \mathbf{E}_{\mathbf{A}}[\langle H_d(\sigma)\rangle_{\beta/\sqrt{d},\mathbf{A}}] \right| = 0.$

(b) For every $\beta \in \mathbb{R}$, $\lim_{d\to\infty} \limsup_{n\to\infty} \frac{1}{n} \left| \mathbf{E}_{\mathbf{g}}[\langle H_{\mathrm{SK}}(\sigma)\rangle^{\mathsf{bis}}_{\beta,\mathbf{g}}] - \frac{1}{\sqrt{d}} \mathbf{E}_{\mathbf{A}}[\langle H_d(\sigma)\rangle^{\mathsf{bis}}_{\beta/\sqrt{d},\mathbf{A}}] \right| = 0.$

We first prove part (b). Assume for the sake of contradiction that for some $\beta_0 \in \mathbb{R}$

$$\limsup_{d\to\infty} \limsup_{n\to\infty} \frac{1}{n} \left| \mathbf{E}_{\mathbf{g}}[\langle H_{\mathrm{SK}}(\sigma)\rangle^{\mathsf{bis}}_{\beta_0,\mathbf{g}}] - \frac{1}{\sqrt{d}} \mathbf{E}_{\mathbf{A}}[\langle H_d(\sigma)\rangle^{\mathsf{bis}}_{\beta_0/\sqrt{d},\mathbf{A}}] \right| = \epsilon > 0.$$

It follows that we can choose a sequence of pairs $(d_i, n_i)_{i\in\mathbb{N}}$ such that

$$\lim_{i\to\infty} \frac{1}{n_i} \left| \mathbf{E}_{\mathbf{g}}[\langle H_{\mathrm{SK}}(\sigma)\rangle^{\mathsf{bis}}_{\beta_0,\mathbf{g}}] - \frac{1}{\sqrt{d_i}} \mathbf{E}_{\mathbf{A}}[\langle H_{d_i}(\sigma)\rangle^{\mathsf{bis}}_{\beta_0/\sqrt{d_i},\mathbf{A}}] \right| = \epsilon. \tag{3.3}$$

Note that for every i, n_i can be chosen to be sufficiently large so that the $o_n(1)$ term in Lemma 7 is $\leq 1/d_i$, and under this assumption we have $\left(\Phi^{\mathsf{bis}}_{n_i,d_i}\left(\frac{\beta}{\sqrt{d_i}}\right)\right)_{i\in\mathbb{N}}$ as a family of functions of β converges pointwise[4] to $\lim_{i\to\infty}\Phi^{\mathsf{bis}}_{n_i,\mathrm{SK}}(\beta)$. Here we remark that it is known that the limit $\lim_{n\to\infty}\Phi_{n,\mathrm{SK}}(\beta)$ exists and is differentiable in β [39, 40], and by Corollary 17 we have

$$\lim_{n\to\infty}\Phi_{n,\mathrm{SK}}(\beta)=\lim_{n\to\infty}\Phi^{\mathsf{bis}}_{n,\mathrm{SK}}(\beta)=\lim_{i\to\infty}\Phi^{\mathsf{bis}}_{n_i,\mathrm{SK}}(\beta).$$

By Proposition 21, we have

$$\lim_{i\to\infty}\frac{\partial}{\partial\beta}\Phi^{\mathsf{bis}}_{n_i,d_i}\left(\frac{\beta}{\sqrt{d_i}}\right)=\frac{\partial}{\partial\beta}\lim_{n\to\infty}\Phi^{\mathsf{bis}}_{n,\mathrm{SK}}(\beta)=\lim_{n\to\infty}\frac{\partial}{\partial\beta}\Phi^{\mathsf{bis}}_{n,\mathrm{SK}}(\beta)=\lim_{i\to\infty}\frac{\partial}{\partial\beta}\Phi^{\mathsf{bis}}_{n_i,\mathrm{SK}}(\beta) \quad (3.4)$$

for every $\beta\in\mathbb{R}$. By (3.2), we have

$$\frac{\partial}{\partial\beta}\Phi^{\mathsf{bis}}_{n,d}\left(\frac{\beta}{\sqrt{d}}\right)=-\frac{1}{\sqrt{d}\cdot n}\mathop{\mathbf{E}}_{\mathbf{A}}\left[\langle H_d(\sigma)\rangle^{\mathsf{bis}}_{\beta/\sqrt{d},\mathbf{A}}\right], \quad (3.5)$$

and

$$\frac{\partial}{\partial\beta}\Phi^{\mathsf{bis}}_{n,\mathrm{SK}}(\beta)=-\frac{1}{n}\mathop{\mathbf{E}}_{\mathbf{g}}[\langle H_{\mathrm{SK}}(\sigma)\rangle^{\mathsf{bis}}_{\beta,\mathbf{g}}]. \quad (3.6)$$

(3.4), (3.5), and (3.6) imply that

$$\lim_{i\to\infty}\frac{1}{n_i}\left|\mathop{\mathbf{E}}_{\mathbf{g}}[\langle H_{\mathrm{SK}}(\sigma)\rangle^{\mathsf{bis}}_{\beta_0,\mathbf{g}}]-\frac{1}{\sqrt{d_i}}\mathop{\mathbf{E}}_{\mathbf{A}}[\langle H_{d_i}(\sigma)\rangle^{\mathsf{bis}}_{\beta_0/\sqrt{d_i},\mathbf{A}}]\right|=0.$$

However, this contradicts (3.3), so we obtain part (b).

For part (a), note that by Theorem 20, for any bounded open interval $I\subset[0,+\infty)$, we can choose the sequence $(d_i,n_i)_{i\in\mathbb{N}}$ to satisfy the additional requirement that

$$\lim_{i\to\infty}\Phi^{\mathsf{bis}}_{n_i,d_i}(\beta/\sqrt{d_i})=\lim_{i\to\infty}\Phi_{n_i,d_i}(\beta/\sqrt{d_i})$$

for all $\beta\in I$. In particular, we can choose I to include any desired $\beta_0>0$ (when $\beta=0$ the Gibbs measure is uniform and part (a) trivially holds). We can then invoke Proposition 21 again and proceed with the same proof. ◀

4 Interpolating the average overlap between SK and the diluted model

In this section we prove Proposition 9. Since the proofs are mostly the same, we will only prove item (a) in Proposition 9. We first state the following well-known fact which relates the average energy to the average overlap of the Gibbs distribution in the SK model.

▶ **Lemma 22** (See e.g. [32]). *For every $\beta\in\mathbb{R}$, we have*

$$\frac{1}{n}\mathop{\mathbf{E}}_{\mathbf{g}}\left[\langle H_{\mathrm{SK}}(\sigma)\rangle\right]=\frac{\beta}{2}\mathop{\mathbf{E}}_{\mathbf{g}}[1-\langle R^2_{1,2}\rangle_{\beta,\mathbf{g}}].$$

The proof of Lemma 22 uses the following proposition.

[4] The convergence is in fact uniform in any bounded interval.

▶ **Proposition 23.** *Let $\mathbf{X} \in \mathbb{R}^{n\times n}, \beta \in \mathbb{R}$. We have*

$$\sum_{\sigma\in\{-1,1\}^n} \sum_{i,j=1}^{n} \sigma(i)\sigma(j)\frac{\partial}{\partial \mathbf{X}_{ij}}\mu(\sigma;\beta,\mathbf{X}) = -\beta n^2\left(1-\langle R_{1,2}^2\rangle_{\beta,\mathbf{X}}\right)$$

Proof. For every $\sigma \in \{-1,1\}^n$ and $i,j \in [n]$, we have

$$\begin{aligned}
&\frac{\partial}{\partial \mathbf{X}_{ij}}\mu(\sigma;\beta,\mathbf{X}) \\
=&\frac{\partial}{\partial \mathbf{X}_{ij}}\left(\frac{\exp\left(-\beta H(\sigma;\mathbf{X})\right)}{Z(\beta,\mathbf{X})}\right) \\
=&(-\beta)\left(\sigma(i)\sigma(j)\mu(\sigma;\beta,\mathbf{X}) - \sum_{\sigma'\in\{-1,1\}^n}\sigma'(i)\sigma'(j)\cdot\mu(\sigma;\beta,\mathbf{X})\mu(\sigma';\beta,\mathbf{X})\right). \qquad (4.1)
\end{aligned}$$

Summing over all σ, i, j, we obtain

$$\begin{aligned}
&\sum_{\sigma\in\{-1,1\}^n} \sum_{i,j=1}^{n} \sigma(i)\sigma(j)\frac{\partial}{\partial \mathbf{X}_{ij}}\mu(\sigma;\beta,\mathbf{X}) \\
=&\sum_{\sigma\in\{-1,1\}^n} \sum_{i,j=1}^{n} \sigma(i)\sigma(j)\cdot(-\beta)\Bigg(\sigma(i)\sigma(j)\mu(\sigma;\beta,\mathbf{X}) \\
&\qquad\qquad - \sum_{\sigma'\in\{-1,1\}^n}\sigma'(i)\sigma'(j)\cdot\mu(\sigma;\beta,\mathbf{X})\mu(\sigma';\beta,\mathbf{X})\Bigg) \\
=&-\beta n^2\left(1-\langle R_{1,2}^2\rangle_{\beta,\mathbf{X}}\right). \qquad \blacktriangleleft
\end{aligned}$$

Lemma 22 can be proved using Proposition 23 and the Gaussian integration by parts formula. We prove a statement similar to Lemma 22, but for the sparse model. We will use the following lemma, known as the Stein-Chen identity for the Poisson distribution, in place of Gaussian integration by parts.

▶ **Lemma 24** ([14])**.** *Let $X \sim \mathrm{Po}(\lambda)$. For any bounded function f, we have*

$$\mathbf{E}[X\cdot f(X)] = \lambda\,\mathbf{E}[f(X+1)].$$

▶ **Lemma 25.** *Let $\mathbf{J}_{ij}$ be the matrix with 1 in the (i,j)-th entry and 0 everywhere else. Then there exists $\xi \in [0,1]$ such that*

$$\left|\mu(\sigma;\beta/\sqrt{d},\mathbf{X}+\mathbf{J}_{ij}) - \mu(\sigma;\beta/\sqrt{d},\mathbf{X}) - \frac{\partial}{\partial \mathbf{X}_{ij}}\mu(\sigma;\beta/\sqrt{d},\mathbf{X})\right| \le \frac{3\beta^2}{d}\cdot\mu(\sigma;\beta/\sqrt{d},\mathbf{X}+\xi\mathbf{J}_{ij}). \qquad (4.2)$$

Proof. Since μ is infinitely differentiable in each entry of $\mathbf{X}$, by Taylor's Theorem, there exists $\xi \in [0,1]$ such that

$$\mu(\sigma;\beta/\sqrt{d},\mathbf{X}+\mathbf{J}_{ij}) - \mu(\sigma;\beta/\sqrt{d},\mathbf{X}) - \frac{\partial}{\partial \mathbf{X}_{ij}}\mu(\sigma;\beta/\sqrt{d},\mathbf{X}) = \frac{1}{2}\cdot\frac{\partial^2}{\partial \mathbf{X}_{ij}^2}\mu(\sigma;\beta/\sqrt{d},\mathbf{X}+\xi\mathbf{J}_{ij}). \qquad (4.3)$$

It remains to bound $\frac{\partial^2}{\partial \mathbf{X}_{ij}^2}\mu(\sigma;\beta/\sqrt{d},\mathbf{X}+\xi\mathbf{J}_{ij})$. By (4.1), we have (omitting $\beta/\sqrt{d},\mathbf{X}+\xi\mathbf{J}_{ij}$ from the notation for simplicity)

$$\begin{aligned}\frac{\partial^2}{\partial \mathbf{X}_{ij}^2}\mu(\sigma) &= \frac{\partial}{\partial \mathbf{X}_{ij}}\left(\left(-\frac{\beta}{\sqrt{d}}\right)\left(\sigma(i)\sigma(j)-\sum_{\sigma'\in\{-1,1\}^n}\sigma'(i)\sigma'(j)\mu(\sigma')\right)\mu(\sigma)\right)\\ &= \left(-\frac{\beta}{\sqrt{d}}\right)^2\left(-1+\sum_{\sigma',\sigma''\in\{-1,1\}^n}\sigma'(i)\sigma'(j)\sigma''(i)\sigma''(j)\mu(\sigma')\mu(\sigma'')\right)\mu(\sigma)\\ &\quad+\left(-\frac{\beta}{\sqrt{d}}\right)^2\left(\sigma(i)\sigma(j)-\sum_{\sigma'\in\{-1,1\}^n}\sigma'(i)\sigma'(j)\mu(\sigma')\right)^2\mu(\sigma).\end{aligned}$$

Since

$$\left|\sum_{\sigma',\sigma''\in\{-1,1\}^n}\sigma'(i)\sigma'(j)\sigma''(i)\sigma''(j)\mu(\sigma')\mu(\sigma'')\right| = |\langle\sigma'(i)\sigma'(j)\sigma''(i)\sigma''(j)\rangle| \le 1$$

and similarly

$$\left|\sum_{\sigma'\in\{-1,1\}^n}\sigma'(i)\sigma'(j)\mu(\sigma')\right| = |\langle\sigma'(i)\sigma'(j)\rangle| \le 1,$$

it follows that

$$\left|\frac{\partial^2}{\partial \mathbf{X}_{ij}^2}\mu(\sigma)\right| \le \frac{\beta^2}{d}(2+4)\mu(\sigma) = \frac{6\beta^2}{d}\mu(\sigma). \tag{4.4}$$

(4.3) and (4.4) together imply (4.2). ◀

▶ **Proposition 26.** *Let $\mathbf{J}_{ij}$ be the matrix with 1 in the (i,j)-th entry and 0 everywhere else. For any $\xi\in\mathbb{R}$, we have*

$$\mathrm{e}^{-2\beta|\xi|}\cdot\mu(\sigma;\beta,\mathbf{X}) \le \mu(\sigma;\beta,\mathbf{X}+\xi\mathbf{J}_{ij}) \le \mathrm{e}^{2\beta|\xi|}\cdot\mu(\sigma;\beta,\mathbf{X})$$

Proof. We have

$$\exp(-\beta H(\sigma;\mathbf{X}+\xi\mathbf{J}_{ij})) = \exp(-\beta H(\sigma;\mathbf{X})-\beta H(\sigma;\xi\mathbf{J}_{ij})) = \exp(-\beta H(\sigma;\mathbf{X}))\cdot\mathrm{e}^{-\beta\xi\sigma(i)\sigma(j)},$$

which implies that

$$\mathrm{e}^{-\beta|\xi|}\exp(-\beta H(\sigma;\mathbf{X})) \le \exp(-\beta H(\sigma;\mathbf{X}+\xi\mathbf{J}_{ij})) \le \mathrm{e}^{\beta|\xi|}\exp(-\beta H(\sigma;\mathbf{X})).$$

Summing over $\sigma\in\{-1,1\}^n$, we obtain

$$\mathrm{e}^{-\beta|\xi|}Z(\beta,\mathbf{X}) \le Z(\beta,\mathbf{X}+\xi\mathbf{J}_{ij}) \le \mathrm{e}^{\beta|\xi|}Z(\beta,\mathbf{X}).$$

Since these quantities are all strictly positive, we have

$$\mu(\sigma;\beta,\mathbf{X}+\xi\mathbf{J}_{ij}) = \frac{\exp(-\beta H(\sigma;\mathbf{X}+\xi\mathbf{J}_{ij}))}{Z(\beta,\mathbf{X}+\xi\mathbf{J}_{ij})} \le \frac{\mathrm{e}^{\beta|\xi|}\exp(-\beta H(\sigma;\mathbf{X}))}{\mathrm{e}^{-\beta|\xi|}Z(\beta,\mathbf{X})} = \mathrm{e}^{2\beta|\xi|}\cdot\mu(\sigma;\beta,\mathbf{X})$$

and similarly

$$\mathrm{e}^{-2\beta|\xi|}\cdot\mu(\sigma;\beta,\mathbf{X}) \le \mu(\sigma;\beta,\mathbf{X}+\xi\mathbf{J}_{ij}).$$ ◀

▶ **Lemma 27.** *For every $\beta \in \mathbb{R}$, we have*

$$\frac{1}{\sqrt{d}n}\,\mathbf{E}\left[\langle H_d(\sigma)\rangle_{\frac{\beta}{\sqrt{d}},\mathbf{A}}\right] = \frac{\sqrt{d}}{2}\cdot\mathbf{E}\left[\left\langle\left(\frac{1}{n}\sum_{i=1}^{n}\sigma(i)\right)^2\right\rangle_{\frac{\beta}{\sqrt{d}},\mathbf{A}}\right] - \frac{\beta}{2}\,\mathbf{E}\left[1-\langle R_{1,2}^2\rangle_{\frac{\beta}{\sqrt{d}},\mathbf{A}}\right] + O_d\left(\frac{1}{\sqrt{d}}\right).$$

Proof. For simplicity, we drop the subscripts from $\langle\cdot\rangle$. We have

$$\begin{aligned}\frac{1}{\sqrt{d}n}\,\mathbf{E}\left[\langle H_d(\sigma)\rangle\right] &= \frac{1}{\sqrt{d}n}\,\mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n}\sum_{i,j=1}^{n}\sigma(i)\sigma(j)\mathbf{A}_{ij}\cdot\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right)\right]\\ &= \frac{1}{\sqrt{d}n}\cdot\frac{d}{2n}\cdot\mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n}\sum_{i,j=1}^{n}\sigma(i)\sigma(j)\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}+\mathbf{J}_{ij}\right)\right]\\ &= \frac{\sqrt{d}}{2n^2}\cdot\mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n}\sum_{i,j=1}^{n}\sigma(i)\sigma(j)\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}+\mathbf{J}_{ij}\right)\right]. \qquad (4.5)\end{aligned}$$

Here in the second equality we invoked Lemma 24. By Lemma 25, for some $\xi_{\sigma,i,j}\in[0,1]$ we have

$$\begin{aligned}&\left|\mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n}\sum_{i,j=1}^{n}\sigma(i)\sigma(j)\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}+\mathbf{J}_{ij}\right)\right]\right.\\ &\qquad\left.-\,\mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n}\sum_{i,j=1}^{n}\sigma(i)\sigma(j)\left(\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right)+\frac{\partial}{\partial\mathbf{A}_{ij}}\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right)\right)\right]\right|\\ &\le\frac{3\beta^2}{d}\cdot\mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n}\sum_{i,j=1}^{n}\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}+\xi_{\sigma,i,j}\mathbf{J}_{ij}\right)\right]\\ &\le\frac{3\beta^2}{d}\cdot n^2\cdot\mathrm{e}^{2\beta/\sqrt{d}}\cdot\mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n}\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right)\right]\\ &=\frac{3\beta^2}{d}\cdot n^2\cdot\mathrm{e}^{2\beta/\sqrt{d}}, \qquad (4.6)\end{aligned}$$

where the last inequality is due to Proposition 26. We observe that

$$\sum_{\sigma\in\{-1,1\}^n}\sum_{i,j=1}^{n}\sigma(i)\sigma(j)\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right) = n^2\cdot\left\langle\left(\frac{1}{n}\sum_{i=1}^{n}\sigma(i)\right)^2\right\rangle. \qquad (4.7)$$

By Proposition 23, we also have

$$\sum_{\sigma\in\{-1,1\}^n}\sum_{i,j=1}^{n}\sigma(i)\sigma(j)\frac{\partial}{\partial\mathbf{A}_{ij}}\mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right) = -\frac{\beta}{\sqrt{d}}\cdot n^2\left(1-\langle R_{1,2}^2\rangle\right). \qquad (4.8)$$

The lemma follows by combining (4.5), (4.6), (4.7), and (4.8). ◀

The next proposition deals with the first term in the above lemma. Note that this term is trivially bounded in the bisection models for all $\beta\in\mathbb{R}$.

▶ **Proposition 28.** *For every $\beta \geq 0$, we have*

$$\lim_{d\to\infty} \sqrt{d} \cdot \limsup_{n\to\infty} \mathbf{E}\left[\left\langle \left(\frac{1}{n}\sum_{i=1}^{n}\sigma(i)\right)^2 \right\rangle_{\beta/\sqrt{d},\mathbf{A}}\right] = 0.$$

Proof. Fix an arbitrary $\epsilon > 0$ and let $S(n,\epsilon) = \{\sigma \in \{-1,1\}^n \mid -\epsilon n \leq \sum_{i=1}^n \sigma(i) \leq \epsilon n\}$. We have

$$\begin{aligned}
&\mathbf{E}\left[\left\langle \left(\frac{1}{n}\sum_{i=1}^{n}\sigma(i)\right)^2 \right\rangle_{\beta/\sqrt{d},\mathbf{A}}\right] \\
&= \mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n}\left(\frac{1}{n}\sum_{i=1}^{n}\sigma(i)\right)^2 \cdot \mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right)\right] \\
&\leq \mathbf{E}\left[\sum_{\sigma\in S(n,\epsilon/d^{1/4})}\left(\frac{\epsilon}{d^{1/4}}\right)^2 \cdot \mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right)\right] \\
&\qquad + \mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n\setminus S(n,\epsilon/d^{1/4})} 1 \cdot \mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right)\right] \\
&\leq \left(\frac{\epsilon}{d^{1/4}}\right)^2 + \mathbf{E}\left[\sum_{\sigma\in\{-1,1\}^n\setminus S(n,\epsilon/d^{1/4})} \mu\left(\sigma;\beta/\sqrt{d},\mathbf{A}\right)\right]. \qquad (4.9)
\end{aligned}$$

Recall that $A_n = \{\sigma \in \{-1,1\}^n : |\sum_{i=1}^n \sigma(i)| \leq 1\}$. Given $\sigma \in \{-1,1\}^n\setminus S(n,\epsilon/d^{1/4})$, take a $\tau \in A_n$ such that $R_{1,2}(\tau,\sigma) = \max_{\sigma'\in A_n} R_{1,2}(\sigma',\sigma)$. By Poisson concentration properties (see full version for details), we have that there exists a constant $C = C(\epsilon) > 0$ such that with probability $1 - 2\cdot\exp(-Cd^{1/4}n)$ we have $H_d(\sigma) - H_d(\tau) \geq \frac{\epsilon^2\sqrt{d}n}{4}$, and consequently

$$\mu(\sigma;\beta/\sqrt{d},\mathbf{A}) \leq \mu(\tau;\beta/\sqrt{d},\mathbf{A}) \cdot \exp\left(-\frac{\beta\epsilon^2 n}{4}\right).$$

By taking expectations, we obtain

$$\begin{aligned}
\mathbf{E}[\mu(\sigma;\beta/\sqrt{d},\mathbf{A})] &\leq \mathbf{E}[\mu(\tau;\beta/\sqrt{d},\mathbf{A})] \cdot \exp\left(-\frac{\beta\epsilon^2 n}{4}\right) + 2\cdot\exp(-Cd^{1/4}n) \\
&\leq \frac{1}{|A_n|}\cdot\exp\left(-\frac{\beta\epsilon^2 n}{4}\right) + 2\cdot\exp(-Cd^{1/4}n). \qquad (4.10)
\end{aligned}$$

Here in the last inequality we used the fact that $\mathbf{E}[\mu(\tau;\beta/\sqrt{d},\mathbf{A})]$ is the same for all $\tau \in A_n$.

Combining (4.9) and (4.10), we obtain

$$\sqrt{d}\cdot\mathbf{E}\left[\left\langle \left(\frac{1}{n}\sum_{i=1}^{n}\sigma(i)\right)^2 \right\rangle_{\beta/\sqrt{d},\mathbf{A}}\right] \leq \epsilon^2 + \sqrt{d}\cdot 2^n\left(\frac{1}{|A_n|}\cdot\exp\left(-\frac{\beta\epsilon^2 n}{4}\right) + 2\exp(-Cd^{1/4}n)\right).$$

If d is sufficiently large, the above gives

$$\sqrt{d}\cdot\limsup_{n\to\infty}\mathbf{E}\left[\left\langle \left(\frac{1}{n}\sum_{i=1}^{n}\sigma(i)\right)^2 \right\rangle_{\beta/\sqrt{d},\mathbf{A}}\right] \leq \epsilon^2.$$

The proposition follows since ϵ is chosen arbitrarily. ◀

We are now ready to prove Proposition 9.

Proof of Proposition 9. For part (a), by Lemma 22, Lemma 27, and Proposition 28, we have

$$\begin{aligned}
&\lim_{d\to\infty} \limsup_{n\to\infty} \frac{1}{n} \left| \mathop{\mathbf{E}}_{\mathbf{g}} \left[\langle H_{\mathrm{SK}}(\sigma) \rangle_{\beta,\mathbf{g}} \right] - \frac{1}{\sqrt{d}} \mathop{\mathbf{E}}_{\mathbf{A}} \left[\langle H_d(\sigma) \rangle_{\beta/\sqrt{d},\mathbf{A}} \right] \right| \\
&= \lim_{d\to\infty} \left(\frac{\beta}{2} \limsup_{n\to\infty} \left| \mathop{\mathbf{E}}_{\mathbf{g}} \left[1 - \langle R_{1,2}^2 \rangle_{\beta,\mathbf{g}} \right] - \mathop{\mathbf{E}}_{\mathbf{A}} \left[1 - \langle R_{1,2}^2 \rangle_{\frac{\beta}{\sqrt{d}},\mathbf{A}} \right] \right| \right. \\
&\qquad \left. + \frac{\sqrt{d}}{2} \mathop{\mathbf{E}} \left[\left\langle \left(\frac{1}{n} \sum_{i=1}^{n} \sigma(i) \right)^2 \right\rangle_{\frac{\beta}{\sqrt{d}},\mathbf{A}} \right] + O_d\left(\frac{1}{\sqrt{d}} \right) \right) \\
&= \frac{\beta}{2} \cdot \lim_{d\to\infty} \limsup_{n\to\infty} \left| \mathop{\mathbf{E}}_{\mathbf{g}} \left[\langle R_{1,2}^2 \rangle_{\beta,\mathbf{g}} \right] - \mathop{\mathbf{E}}_{\mathbf{A}} \left[\langle R_{1,2}^2 \rangle_{\frac{\beta}{\sqrt{d}},\mathbf{A}} \right] \right|.
\end{aligned}$$

Part (a) then follows by applying Proposition 8. Part (b) follows in a similar manner and we omit the details. ◀

5 Disorder chaos for sparse models

Let $\mathbf{g}, \mathbf{g}_t, \mathbf{A}, \mathbf{A}_t$ be random matrices as defined in Section 2 and let $S \subseteq [-1,1]$. Recall that we also defined the following short-hand notation:

$$\begin{aligned}
Z^{S}_{\mathbf{g},\mathbf{g}_t} &= \sum_{\substack{\sigma_1,\sigma_2 \in \{-1,1\}^n \\ R_{1,2}(\sigma_1,\sigma_2)\in S}} \exp\left(-\beta(H(\sigma_1;\mathbf{g}) + H(\sigma_2;\mathbf{g}_t))\right), \\
Z^{S,\mathsf{bis}}_{\mathbf{g},\mathbf{g}_t} &= \sum_{\substack{\sigma_1,\sigma_2 \in A_n \\ R_{1,2}(\sigma_1,\sigma_2)\in S}} \exp\left(-\beta(H(\sigma_1;\mathbf{g}) + H(\sigma_2;\mathbf{g}_t))\right), \\
Z^{S}_{\mathbf{A},\mathbf{A}_t} &= \sum_{\substack{\sigma_1,\sigma_2 \in \{-1,1\}^n \\ R_{1,2}(\sigma_1,\sigma_2)\in S}} \exp\left(-\frac{\beta}{\sqrt{d}} \cdot (H(\sigma_1;\mathbf{A}) + H(\sigma_2;\mathbf{A}_t))\right), \\
Z^{S,\mathsf{bis}}_{\mathbf{A},\mathbf{A}_t} &= \sum_{\substack{\sigma_1,\sigma_2 \in A_n \\ R_{1,2}(\sigma_1,\sigma_2)\in S}} \exp\left(-\frac{\beta}{\sqrt{d}} \cdot (H(\sigma_1;\mathbf{A}) + H(\sigma_2;\mathbf{A}_t))\right).
\end{aligned}$$

It is known that the SK model exhibits disorder chaos at any temperature.

▶ **Theorem 29** (Theorem 9 in [15]). *Let $\beta \in \mathbb{R}$, $t > 0$. Fix an arbitrary $\epsilon > 0$. Let $I_\epsilon = [-1,-\epsilon] \cup [\epsilon,1]$. There exists some constant $K > 0$ such that for every $n \in \mathbb{N}$,*

$$\mathbf{E}\left[\frac{Z^{I_\epsilon}_{\mathbf{g},\mathbf{g}_t}}{Z^{[-1,1]}_{\mathbf{g},\mathbf{g}_t}} \right] \le K \cdot \exp(-n/K).$$

Theorem 29 immediately implies that the overlap of two configurations sampled from the coupled system $\mu_{\mathbf{g},\mathbf{g}_t}$ is nearly zero.

▶ **Corollary 30.** *If $t > 0$, then*

$$\lim_{n\to\infty} \mathbf{E}\left[\langle R_{1,2}^2 \rangle_{\beta,\mathbf{g},\mathbf{g}_t} \right] = 0.$$

Proof. For any $\epsilon > 0$, we have

$$\begin{aligned}\mathbf{E}\left[\langle R_{1,2}^2\rangle_{\beta,\mathbf{g},\mathbf{g}_t}\right] &\le \epsilon^2 \cdot \mathbf{E}\left[\frac{Z_{\mathbf{g},\mathbf{g}_t}^{[-\epsilon,\epsilon]}}{Z_{\mathbf{g},\mathbf{g}_t}^{[-1,1]}}\right] + 1 \cdot \mathbf{E}\left[\frac{Z_{\mathbf{g},\mathbf{g}_t}^{I_\epsilon}}{Z_{\mathbf{g},\mathbf{g}_t}^{[-1,1]}}\right] \\ &\le \epsilon^2 + K \cdot \exp(-n/K).\end{aligned}$$

Here we used Theorem 29 and the fact that $Z_{\mathbf{g},\mathbf{g}_t}^{[-\epsilon,\epsilon]} \le Z_{\mathbf{g},\mathbf{g}_t}^{[-1,1]}$. It follows that

$$\limsup_{n\to\infty} \mathbf{E}\left[\langle R_{1,2}^2\rangle_{\beta,\mathbf{g},\mathbf{g}_t}\right] \le \epsilon^2$$

for any arbitrary $\epsilon > 0$, and the corollary follows. ◀

The exponentially small fraction in Theorem 29 can be translated into a constant gap between the free energy of coupled and uncoupled systems.

▶ **Proposition 31.** *For every $\epsilon > 0$, there exists some constant $K > 0$ such that*

$$\limsup_{n\to\infty}\left(\frac{1}{n}\mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{I_\epsilon}\right] - \frac{1}{n}\mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{[-1,1]}\right]\right) \le -\frac{1}{K}.$$

Proof. By Theorem 29 and Jensen's inequality

$$\begin{aligned}\frac{1}{n}\mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{I_\epsilon}\right] - \frac{1}{n}\mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{[-1,1]}\right] &= \frac{1}{n}\mathbf{E}\left[\log \frac{Z_{\mathbf{g},\mathbf{g}_t}^{I_\epsilon}}{Z_{\mathbf{g},\mathbf{g}_t}^{[-1,1]}}\right] \\ &\le \frac{1}{n}\log \mathbf{E}\left[\frac{Z_{\mathbf{g},\mathbf{g}_t}^{I_\epsilon}}{Z_{\mathbf{g},\mathbf{g}_t}^{[-1,1]}}\right] \le -\frac{1}{K} + O\left(\frac{1}{n}\right).\end{aligned}$$

The proposition follows by taking n to infinity. ◀

The following theorem, which is a generalized version of Lemma 7, allows us to transfer this free energy gap to sparse models.

▶ **Theorem 32** (See e.g. [17, 16])**.** *For any $\beta \in \mathbb{R}$,*

$$\left|\frac{1}{n}\mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{I_\epsilon,\mathsf{bis}}\right] - \frac{1}{n}\mathbf{E}\left[\log Z_{\mathbf{A},\mathbf{A}_t}^{I_\epsilon,\mathsf{bis}}\right]\right| \le O_d\left(\frac{1}{\sqrt{d}}\right) + \sqrt{d}\cdot o_n(1).$$

We are now ready to prove Lemma 14.

Proof of Lemma 14. As before, we only prove part (a). Fix some arbitrary $\epsilon > 0$. By Theorem 16, for both $S = I_\epsilon$ and $S = [-1,1]$ we have

$$\lim_{n\to\infty}\frac{1}{n}\left(\mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{S,\mathsf{bis}}\right] - \mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{S}\right]\right) = 0.$$

By Proposition 31, for some constant $K = K(\epsilon) > 0$, we have

$$\limsup_{n\to\infty}\frac{1}{n}\left(\mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{I_\epsilon,\mathsf{bis}}\right] - \mathbf{E}\left[\log Z_{\mathbf{g},\mathbf{g}_t}^{[-1,1],\mathsf{bis}}\right]\right) \le -\frac{1}{K}.$$

We can then use Theorem 32 to transfer this gap to the sparse model and obtain

$$\lim_{d\to\infty}\limsup_{n\to\infty}\frac{1}{n}\left(\mathbf{E}\left[\log Z_{\mathbf{A},\mathbf{A}_t}^{I_\epsilon,\mathsf{bis}}\right] - \mathbf{E}\left[\log Z_{\mathbf{A},\mathbf{A}_t}^{[-1,1],\mathsf{bis}}\right]\right) \le -\frac{1}{K}.$$

By Theorem 19, we then have

$$\lim_{d\to\infty} \limsup_{n\to\infty} \frac{1}{n}\left(\mathbf{E}\left[\log Z^{I_\epsilon}_{\mathbf{A},\mathbf{A}_t}\right] - \mathbf{E}\left[\log Z^{[-1,1]}_{\mathbf{A},\mathbf{A}_t}\right]\right) \leq -\frac{1}{K}.$$

This means that if d is sufficiently large, then for all sufficiently large n we have

$$\frac{1}{n}\mathbf{E}\left[\log Z^{I_\epsilon}_{\mathbf{A},\mathbf{A}_t}\right] - \frac{1}{n}\mathbf{E}\left[\log Z^{[-1,1]}_{\mathbf{A},\mathbf{A}_t}\right] \leq -\frac{1}{2K}.$$

By Lemma 18, we have that with probability at least $1 - o_n(1)$

$$\frac{1}{n}\log Z^{I_\epsilon}_{\mathbf{A},\mathbf{A}_t} - \frac{1}{n}\log Z^{[-1,1]}_{\mathbf{A},\mathbf{A}_t} \leq -\frac{1}{4K},$$

which rearranges to

$$\frac{Z^{I_\epsilon}_{\mathbf{A},\mathbf{A}_t}}{Z^{[-1,1]}_{\mathbf{A},\mathbf{A}_t}} \leq \exp\left(-\frac{n}{4K}\right).$$

It follows that

$$\mathbf{E}[\langle R^2_{1,2}\rangle_{\beta/\sqrt{d},\mathbf{A},\mathbf{A}_t}] \leq \epsilon^2 + \mathbf{E}\left[\frac{Z^{I_\epsilon}_{\mathbf{A},\mathbf{A}_t}}{Z^{[-1,1]}_{\mathbf{A},\mathbf{A}_t}}\right] \leq \epsilon^2 + \exp\left(-\frac{n}{4K}\right) + o_n(1).$$

By taking n to infinity, we have $\limsup_{n\to\infty} \mathbf{E}[\langle R^2_{1,2}\rangle_{\beta/\sqrt{d},\mathbf{A},\mathbf{A}_t}] \leq \epsilon^2$. This completes the proof. ◀

A High Dimensional Cramer's Rule Connecting Homogeneous Multilinear Equations to Hyperdeterminants

Antoine Joux
CISPA – Helmholtz Center for Information Security, Saarbrücken, Germany

Anand Kumar Narayanan
SandboxAQ, Palo Alto, CA, USA

Abstract

We present a new algorithm for solving homogeneous multilinear equations, which are high dimensional generalisations of solving homogeneous linear equations. First, we present a linear time reduction from solving generic homogeneous multilinear equations to computing hyperdeterminants, via a high dimensional Cramer's rule. Hyperdeterminants are generalisations of determinants, associated with tensors of formats generalising square matrices. Second, we devise arithmetic circuits to compute hyperdeterminants of boundary format tensors. Boundary format tensors are those that generalise square matrices in the strictest sense. Consequently, we obtain arithmetic circuits for solving generic homogeneous boundary format multilinear equations. The complexity as a function of the input dimension varies across boundary format families, ranging from quasi-polynomial to sub exponential. Curiously, the quasi-polynomial complexity arises for families of increasing dimension, including the family of multipartite quantum systems made of d qubits and one qudit. Finally, we identify potential directions to resolve the hardness the hyperdeterminants, notably modulo prime numbers through the cryptographically significant tensor isomorphism complexity class.

1 Introduction

1.1 Homogeneous multilinear systems

The familiar problem of solving homogeneous linear equations is to take a square matrix A and find a non zero vector x such that Ax is the zero vector. We devise algorithms for the natural high dimensional generalisation, which we call solving homogeneous multilinear equations. Let us rephrase what it means to solve homogeneous linear equations, to emphasise the motif that generalises. Given a square matrix A, find a pair of non zero vectors $\left(x^{(0)}, x^{(1)}\right)$ such that removing one of the vectors from the bilinear product $x^{(0)}Ax^{(1)}$ equals the zero vector. The solutions are merely pairs of non zero vectors $\left(x^{(0)}, x^{(1)}\right)$ with $x^{(0)}$ in the left kernel of A and $x^{(1)}$ in the right kernel of A. In homogeneous multilinear equations, a tensor A of dimension $r+1$ will be cast as the input in place of the square matrix. Multiplying A by the vectors $\left(x^{(0)}, x^{(1)}, \ldots, x^{(r)}\right)$ in the corresponding dimensions is a multilinear map taking this tuple of vectors to a scalar. If we remove one of the vectors from the multiplication, the result is a vector. The solution we demand is a tuple of vectors $\left(x^{(0)}, x^{(1)}, \ldots, x^{(r)}\right)$ such that removing one of the vectors from the multilinear product gives the zero vector, irrespective of

which one was removed. See definition 1 for the formal statement. We address the problem over the field of complex numbers and describe algorithms in the formalism of arithmetic circuits. Key to our approach is the hyperdeterminant.

1.2 Hyperdeterminants

The determinant of a square matrix is a homogeneous integer polynomial in the matrix entries that vanishes precisely when the matrix is singular. The hyperdeterminant is a high dimensional analogue of the determinant conceived by Cayley [3]. The hyperdeterminant is a homogeneous integer polynomial in the coordinates of the tensor that vanishes precisely when the tensor is singular. This notion of singularity is geometric and defined through projective duality. Except for a foray by Schläfli, the subject remained dormant for nearly a century and a half [22]. It was revived in the comprehensive work of Gelfand, Kapranov and Zelevinsky [11, 12], which contains most of the mathematical ingredients required in this paper.

1.2.1 Tensor formats

Just as the determinant is only defined for square matrices, the hyperdeterminant is only defined for certain formats of tensors. An $(r+1)$-dimensional tensor product of complex vector spaces of dimensions $k_0+1, k_1+1, \ldots, k_r+1$ constitutes a $(k_0+1) \times (k_1+1) \times \ldots \times (k_r+1)$ format. Say $k_0 \geq k_1 \geq \ldots \geq k_r$. The hyperdeterminant is defined for formats where the largest vector space dimension k_0 satisfies the convexity constraint $k_0 \leq k_1 + k_2 + \ldots + k_r$. Such formats generalise square matrices. Boundary formats are those satisfying the convexity constraint with equality, that is, $k_0 = k_1 + k_2 + \ldots + k_r$. The special case $r = 1$ corresponds to square matrices. Boundary formats generalise square matrices to higher dimensions in the strictest sense. To quote Gelfand, Kapranov and Zelevinsky [11], *"It is instructive to think of matrices of boundary format as proper high dimensional analogs of ordinary square matrices"*. Formats satisfying $k_0 < k_1 + k_2 + \ldots + k_r$ are called interior formats.

1.2.2 Hardness of Hyperdeterminants

We use hyperdeterminants as a means to solve homogeneous multilinear equations, but they are of intrinsic interest in complexity theory. The computational complexity of hyperdeterminants remains a mystery, either restricted to three dimensions or in general. Unlike the determinant (the two dimensional case), computing the hyperdeterminant (in three or more dimensions) is believed to be VNP-hard, yet a proof remains elusive. Testing if a given tensor is singular (has hyperdeterminant zero) is conjectured to be NP-hard [10]. Likewise, computing the hyperdeterminant is conjectured to be #P-hard in the counting model and VNP-hard in the arithmetic circuit model [10]. Several closely related three dimensional problems (such as zero testing singular values, defined for general formats in [16]) are proven to be NP, VNP or #P hard, but these instance are of formats where the hyperdeterminant is not defined. In particular, known hardness reductions to tensor problems seem to fall apart in formats satisfying the convexity constraint. Computing the combinatorial hyperdeterminant is known to be hard [10]. But the combinatorial hyperdeterminant more closely resembles the permanent and does not have the algebraic/geometric structure that underlies the hyperdeterminant. Another aspect to keep in mind is that the hyperdeterminant can have degree exponential in the size of the input, even in three dimensions. For instance, to write down a $(2n+1) \times (n+1) \times (n+1)$ boundary format tensor takes only cubic in n entries. However the degree of the hyperdeterminant is $(2n+1)!/n!^2 \approx 2^n$.

1.2.3 Hyperdeterminants and quantum information

Hyperdeterminants arise in quantum information when the amplitudes of quantum states are considered as normalised tensors in a projective space. The absolute value of the hyperdeterminant of three qubits ($r = 2, k_0 = k_1 = k_2 = 1$) is known as 3-tangle, an important entanglement measure generalising concurrence (the usual determinant) of bipartite systems [6]. In particular, the hyperdeterminant is invariant under local operations and classical communication (LOCC). Further significance of hyperdeterminants to quantum information was identified by Miyake and Wadati [18], through projective duality between separability and singularity.

1.3 Our Contribution

1.3.1 Reducing homogeneous multilinear systems to hyperdeterminants

The geometric notion of singularity of a tensor (the hyperdeterminant vanishing) is equivalent to the algebraic notion of degeneracy that ensures the existence of a solution to homogeneous multilinear equations. Therefore, we may test if there is a solution to the homogeneous multilinear equation by checking if the hyperdeterminant of the tensor is zero. This correspondence begs the question as to if the solutions of the multilinear equation can be inferred through computation of the hyperdeterminant. It is important to consider the model of computation for the hyperdeterminant. The minimal computational assumption is a black-box that computes the hyperdeterminant of a given tensor. But, it is not obvious how useful black-box access is. The exponential degree of the hyperdeterminant and the lack of obvious structure (such as sparsity) make interpolating the hyperdeterminant as a polynomial using black-box evaluations difficult. We instead consider white-box computation: an arithmetic circuit that takes tensor entries as inputs and outputs the hyperdeterminant.

In § 3, we present a reduction. Given an arithmetic circuit that computes the hyperdeterminant (for a tensor format), we build an arithmetic circuit of asymptotically the same size that solves generic multilinear equations (of the same format). The key to the reduction is a theorem of Gelfand, Kapranov and Zelevinsky relating the Segre embedding of solutions of multilinear equations with partial derivatives of the hyperdeterminant. It may be thought of as a high dimensional generalisation of Cramer's rule. We invoke the Baur-Strassen algorithm to construct arithmetic circuits for all these partial derivatives at once from the arithmetic circuit computing the hyperdeterminant, thereby completing the reduction with only linear complexity.

The qualifier "generic" in generic homogeneous multilinear equations refers to there being at most one projective solution. Geometrically, this translates to the input tensor either being non-singular or a simple singularity. That is, the tensor cannot be a zero of the hyperdeterminant of multiplicity greater than one. Weyman and Zelevinsky proved that non-generic tensors (roots of the hyperdeterminant of multiplicity greater than one) form a co-dimension one projective subvariety of singular tensors [30]. Therefore non-generic tensors fall into a Zariski closed subspace, justifying the "generic" label. It remains an open problem if the non generic case can be handled by methods similar to our reduction.

1.3.2 Computing Hyperdeterminants of boundary formats

In § 4, we devise arithmetic circuits to compute hyperdeterminants of boundary format tensors. There is one circuit for each boundary format. The tensor entries are the inputs to the arithmetic circuit. The main ingredient in the construction is a correspondence between the

hyperdeterminant of boundary format tensors and the determinant of a linear transformation connecting sections of vector bundles built from the tensor [11, Theorem 4.3] (see also, [7]). Concretely, the linear transformation is between two spaces of multihomogeneous polynomials in the coordinate ring with prescribed degrees. The square matrix of this linear transformation is of dimension equal to the degree $(k_0+1)!/(k_1!k_2!\dots k_r!)$ of the hyperdeterminant, which could range from 2^{k_0} to $(k_0+1)!$. By choosing a monomial bases for the polynomial spaces, we ensure that the matrix entries are either zero or entries from the tensor. An arithmetic circuit for computing the determinant for this square matrix yields an arithmetic circuit for computing the hyperdeterminant. The circuit complexity is the degree of the hyperdeterminant $(k_0+1)!/(k_1!k_2!\dots k_r!)$ raised to small exponent to account for determinant computation. In many cases this exponent can be taken to be the matrix multiplication exponent ω. At worst, the exponent is 4, for division-free circuits that accommodate computation over arbitrary rings, including fields of positive characteristic dividing the degree of the hyperdeterminant.

1.3.3 Complexity

The reduction and the algorithm for computing the hyperdeterminant in concert yield $O\left(\left(\frac{(k_0+1)!}{k_1!k_2!\dots k_r!}\right)^{\omega}\right)$ sized arithmetic circuits to solve generic homogeneous boundary format multilinear equations. To make sense of this complexity, consider the following two families of boundary format tensors. For the three dimensional family $(2n+1)\times(n+1)\times(n+1)$, the complexity is $O\left(((2n+1)!/n!^2)^{\omega}\right)$. This is roughly $O\left(2^{n\omega}\right)$, simply exponential in the dimension $4n+3$ of the output. This is sub-exponential in the dimension $(2n+1)(n+1)^2$ of the input. For the $d+1$ dimensional family $(d+1)\times\underbrace{2\times 2\times\ldots\times 2}_{d}$, the circuit complexity $O\left((d+1)!\right)$ is quasi polynomial in the input dimension $(d+1)2^d$. It is remarkable that a natural tensor problem without structure has a quasi polynomial time algorithm time for a family of increasing dimension. Further, this family captures $(d+1)$-partite quantum system consisting of d qubits and a qudit. The hyperdeterminant vanishing is related to the existence of a partition of the $(d+1)$-partite system across which the quantum state splits into a product [18]. For the most common d-partite setting consisting of d qubits, Schläfli's method [22] suggests an algorithm to compute hyperdeterminants that is recursive across the dimensions. A rigorous analysis of such a recursive algorithm based on Schläfli's method is left for future work.

In terms of algorithms to compare with, Gröbner basis methods can be deployed to solve homogeneous multilinear equations. But applying them naively only guarantees a solution in double exponential time (over Global fields such as $\mathbb{C}$). The performance of Gröbner basis techniques tailored to this problem warrants further investigation. For instance, determinantal structure was exploited in Gröbner basis algorithms addressing similar problems by Spaenlehauer [26, 27] and M. Safey El Din, and Ê. Schost [21]. Our results hint that there are monomial orderings for which Gröbner methods tailored to solving homogeneous multilinear equations are fast.

1.3.4 Towards proving hardness of hyperdeterminants

The mystery surrounding the hardness of computing the hyperdeterminant drew us to the problems addressed in this work. A technical difficulty in proving the hardness of the hyperdeterminants using well known techniques (such as in [16]) is the following. When one tries to embed a hard computational problem into computing hyperdeterminants of three

dimensional tensors, one of the dimensions of blows up and we land in a tensor format for which the hyperdeterminant does not exist. An important consequence of our reduction is that *if solving homogeneous multilinear equations is hard for some family boundary or interior formats, then so is computing the hyperdeterminant! Therefore, to prove the hardness of computing hyperdeterminants, it now suffices to prove the hardness of solving homogeneous multilinear equations for some family of boundary or interior formats.* To this end, an intermediate step might be to reduce solving inhomogeneous multilinear equations to solving homogeneous multilinear equations, since it seems easier to encode known NP-hard problems as the former. Further, our work suggests it may be fruitful to consider boundary formats such as $(2n+1) \times (n+1) \times (n+1)$, for they may accommodate more geometric methods.

Finally, in § 5, we investigate the possibility of proving the hardness computing hyperdeterminants modulo primes. To this end, we identify the (cryptographically significant) complexity class (**TI**) of tensor isomorphism problems as candidates to reduce from. In particular, we reduce the tensor isomorphism problem with respect to the special linear group action to computing hyperdeterminants modulo primes. But the tensor isomorphism complexity class is defined with isomorphisms under the general linear group action. It is not known if the tensor isomorphism problem with the special linear group action is **TI**-hard. If the answer turns out to be yes, then our reduction implies that computing hyperdeterminants modulo primes is cryptographically hard, in the sense that the average case **TI** instances are distinguished from random tensor pairs by the hyperdeterminant. If the hyperdeterminant were easy, those cryptosystems would be broken. Over fixed field sizes, it might be possible to prove that the tensor isomorphism problem with the special linear group action is indeed **TI**-hard, following ideas similar to [24]. We thank an anonymous referee for pointing out this possibility and leave this to future work.

2 Preliminaries: Tensor singularity and hyperdeterminants

2.1 Cayley's hyperdeterminants

Let $V_0, V_1, \ldots, V_r$ be $r+1$ vector spaces over the complex numbers $\mathbb{C}$ of respective dimensions $k_0+1, k_1+1, \ldots, k_r+1$. Fix a coordinate system $x^{(j)} = (x_0^{(j)}, x_1^{(j)}, \ldots, x_{k_j}^{(j)})$ for the j^{th}-vector space V_j, or equivalently an ordered basis for the dual V_j^*. Identify an $(r+1)$ dimensional tensor $A \in V_0^* \otimes V_1^* \otimes \ldots \otimes V_r^*$ with an $r+1$-dimensional matrix

$$A = (a_{i_0,i_1,\ldots,i_r}, 0 \leq i_0 \leq k_0, 0 \leq i_1 \leq k_1, \ldots, 0 \leq i_r \leq k_r)$$

of format $(k_0+1) \times (k_1+1) \times \ldots \times (k_r+1)$.

Square matrices are a special case ($r = 1$ and $k_0 = k_1$) and come with the familiar determinant whose vanishing characterises singularity/degeneracy. The hyperdeterminant is a multidimensional generalisation of the determinant that characterises singularity/degeneracy for tensors formats that generalise square matrices. We start with a geometric definition, equivalent analytic (singularity) and algebraic (degeneracy) formulations follow thereafter.

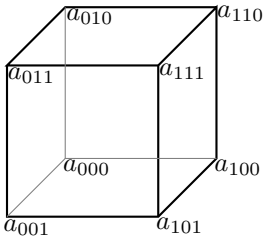
2.1.1 Geometric definition

Let $\mathbb{P}(V_j) \cong \mathbb{P}^{k_j}$ be the projectivisation of V_j. We need the Cartesian product of these projective spaces, yet desire that the product itself is projective. Let X be the image of the Cartesian product (purely separable tensors) $\mathbb{P}^{k_0} \times \mathbb{P}^{k_1} \times \ldots \times \mathbb{P}^{k_r}$ under the Segre embedding

$$\mathbb{P}(V_0) \times \mathbb{P}(V_1) \times \ldots \times \mathbb{P}(V_r) \hookrightarrow \mathbb{P}\left(V_0 \otimes V_1 \otimes \ldots \otimes V_r\right) \cong \mathbb{P}^{(k_0+1)(k_1+1)\ldots(k_r+1)-1}$$

$$\left(\left(x_0^{(0)} : x_1^{(0)} : \ldots : x_{k_0}^{(0)}\right), \ldots, \left(x_0^{(r)} : x_1^{(r)} : \ \ldots : x_{k_r}^{(r)}\right)\right) \tag{2.1}$$

$$\longmapsto \left(x_0^{(0)} x_0^{(1)} \ldots x_0^{(r)} : \ldots : x_{k_0}^{(0)} x_{k_1}^{(1)} \ldots x_{k_r}^{(r)}\right). \tag{2.2}$$



The image under the embedding is a smooth projective variety called the Segre variety, which we denote by X. Let $X^{\check{}}$ denote the projectively dual variety of X consisting of all hyperplanes in the ambient projective space $\mathbb{P}\left(V_0 \otimes V_1 \otimes \ldots \otimes V_r\right)$ tangent to X at some point. By projective duality (hyperplanes $\leftrightarrow$ points), $X^{\check{}}$ is a variety in the dual projective space $\mathbb{P}\left(V_0 \otimes V_1 \otimes \ldots \otimes V_r\right)^*$. Gelfand, Kapranov and Zelevinsky characterised precisely when $X^{\check{}}$ is a hypersurface (that is, co-dimension one). It is when the convexity condition

$$\forall\ 0 \leq j \leq r, \quad k_j \leq \sum_{\ell \neq j} k_\ell$$

holds, which we assume from here on. Being a hypersurface, the defining equation of $X^{\check{}}$ is a homogeneous polynomial in the coefficients $a_{i_1,i_2,\ldots,i_d}$, defined to be the hyperdeterminant $Det()$. It is an irreducible polynomial with integer coefficients. It can be made unique by insisting that the coefficients are co-prime and choosing a sign.

2.1.2 Example

The first example is the $r = 1$ case, of the usual 2 dimensional matrices. The convexity constraint simplifies to $k_0 = k_1$, confining to square matrices. For square matrices, the hyperdeterminant coincides with the classical determinant. The following first example in 3 dimensions goes back to Cayley [3] and the advent of hyperdeterminants. It is synonymous with the tripartite entanglement measure 3-tangle of three qubits. The hyperdeterminant of a $2 \times 2 \times 2$ format tensor A indexed by the vertices of a cube is

$$\begin{aligned} Det(A) = {} & a_{000}^2 a_{111}^2 + a_{001}^2 a_{110}^2 + a_{010}^2 a_{101}^2 + a_{011}^2 a_{100}^2 \\ & -2(a_{000}a_{001}a_{110}a_{111} + a_{000}a_{010}a_{101}a_{111} + a_{000}a_{011}a_{100}a_{111} \\ & +a_{001}a_{010}a_{101}a_{110} + a_{001}a_{011}a_{110}a_{100} + a_{010}a_{011}a_{101}a_{100}) \\ & +4(a_{000}a_{011}a_{101}a_{110} + a_{001}a_{010}a_{100}a_{111}). \end{aligned}$$

The first group of monomials correspond to the four opposing vertices across the main diagonals. The second group to the six pairs of opposing sides. The last group to the two tetrahedrons with edges on the diagonals of the faces.

2.1.3 Boundary and interior formats

Without loss of generality, assume from here on that $k_0 \geq k_1 \geq \ldots \geq k_r$. The convexity condition (which we remind, we always assume) simplifies to $k_0 \leq \sum_{\ell=1}^{r} k_\ell$. Boundary formats are those meeting the convexity constraint with equality, that is $k_0 = \sum_{\ell=1}^{r} k_\ell$. Interior formats are those satisfying the strict convexity constraint $k_0 < \sum_{\ell=1}^{r} k_\ell$.

3 Solving multilinear equations through hyperdeterminants

3.1 Hyperdeterminants, degeneracy of tensors and multilinear equations

▶ **Definition 1.** *(Solving homogeneous multilinear equations) Given a tensor A, decide if there is a $w \in X$ such that in every dimension j,*

$$\nabla_{A,j}(w) := \sum_{0 \le i_j \le k_j} \left(\sum_{\substack{0 \le i_0 \le k_0 \\ \dots \\ 0 \le i_r \le k_r}} a_{i_0,i_1,\dots,i_r} w_{i_0}^{(0)} w_{i_1}^{(1)} \dots w_{i_{j-1}}^{(j-1)} w_{i_{j+1}}^{(j+1)} \dots w_{i_r}^{(r)} \right) x_{i_j}^{(j)} = 0 \left(\in V_j^*\right).$$

The inner summation is over all dimensions except j. If such a solution w exists, find one. A tensor A is said to be degenerate if there is such a w.

Since the Segre variety X lives in the projective tensor space $\mathbb{P}(V_0 \otimes V_1 \otimes \dots \otimes V_r)$, it is expensive to write down the solution $w \in X$ as a tensor. Instead, we may output a tuple of vectors in the Cartesian space $\mathbb{P}^{k_0} \times \mathbb{P}^{k_1} \times \dots \times \mathbb{P}^{k_r}$ whose image under the Segre embedding is a solution $w \in X$.

▶ **Lemma 2** ([12, Chap 14, Prop. 1.1])**.** *A tensor A is degenerate if and only if $Det(A) = 0$.*

Proof. We sketch the proof from [12, Chap 14, Prop. 1.1] to give an impression of the connection between degeneracy and hyperdeterminants. To this end, consider the following analytic notion of singularity to complement the geometric definition of hyperdeterminants. To clarify the relation of hyperdeterminants to singularity of tensors, ask when the hyperplane $\{A = 0\}$ carved by A is in $X^\vee$. It is precisely when there is a point $x \in X$ at which the hyperplane $\{A = 0\}$ is tangent. This happens precisely when there is a point $x \in X$ such that the multilinear form (arising from the restriction of A on X)

$$f_A(x) := \sum_{\substack{0 \le i_0 \le k_0 \\ \dots \\ 0 \le i_r \le k_r}} a_{i_0,i_1,\dots,i_r} x_{i_0}^{(0)} x_{i_1}^{(1)} \dots x_{i_r}^{(r)} \text{ and all its partial derivatives } \frac{\partial f_A(x)}{\partial x_{i_j}^{(j)}}, \ \forall j, i_j$$

vanish. In particular, such an x is a singular point of the hyperplane $\{A = 0\}$. We may thus identify the hyperdeterminantal variety $X^\vee$ with singular tensors. By inspection, we see that the condition for singularity and degeneracy are the same. ◀

Therefore the decision making part of solving homogeneous multilinear equations is equivalent to testing if $Det(A) = 0$. Can hyperdeterminants be used to find solutions? We prove that they can, for the generic case of the problem, which we next define.

▶ **Definition 3** (Solving generic homogeneous multilinear equations)**.** *Given a tensor A with a promise that A is either non singular or a non singular point of $X^\vee$, solve the homogeneous multilinear equation with input A.*

We next justify why this promise version captures generic instances of the problem. As we saw before, by projective duality, there is a point $w \in X$ in the Segre variety solving the homogeneous multilinear equation corresponding to A if and only if A is in the Hyperdeterminantal variety $X^\vee$. Further, A could either be a singular point (that is, a zero of multiplicity greater than one) or a non singular point on $X^\vee$. If A is a non singular point in $X^\vee$, then there is a unique solution w, which the problem demands that we find. If A is a singular point in $X^\vee$, then we have to detect that this is the case. But, we do not have

to find a solution. Remarkably, for dimension at least three (that is, $r > 1$), excluding the interior format $2 \times 2 \times 2$, Weyman and Zelevinsky proved that the singular points of $X^\check{}$ form a co-dimension one projective sub variety [30]. Therefore, by dimension considerations, a generic singular tensor is indeed a non singular point on $X^\check{}$. The non-generic tensor inputs we abandon are in a Zariski closed subspace.

A high dimensional Cramer's rule

We reduce solving generic homogeneous multilinear equation to computing hyperdeterminants through the following characterisation of the unique solution by Gelfand, Kapranov and Zelevinsky [11, Proposition 1.2]. Let A be the input describing the homogeneous multilinear equation with the promise that A is a non singular point of $X^\check{}$. If $Det(A) \neq 0$, output that there is no solution. If $Det(A) = 0$, then the promise ensures that there is a unique solution w. Let B be a tensor of the same format as the input A, but with with entries $b_{i_0,i_1,\ldots,i_r}$ that are commuting indeterminates. The hyperdeterminant $Det(B)$ is then an integer polynomial in the indeterminates $b_{i_0,i_1,\ldots,i_r}$. Up to a normalisation factor, for all $i_0, i_1, \ldots, i_r$, the unique solution

$$w = \left(w_0^{(0)} w_0^{(1)} \ldots w_0^{(r)} : \ldots : w_{k_0}^{(0)} w_{k_1}^{(1)} \ldots w_{k_r}^{(r)}\right) \in X \subseteq \mathbb{P}\left(V_0 \otimes V_1 \otimes \ldots \otimes V_r\right)$$

in the Segre variety satisfies

$$w_{i_0}^{(0)} w_{i_1}^{(1)} \ldots w_{i_r}^{(r)} = \frac{\partial Det(B)}{\partial b_{i_0,i_1,\ldots,i_r}} \Big|_{B=A} . \tag{3.1}$$

It is too expensive to write out w as a point in the ambient tensor space $\mathbb{P}\left(V_0 \otimes V_1 \otimes \ldots \otimes V_r\right)$. Its pre-image

$$\left(\left(w_0^{(0)} : w_1^{(0)} : \ldots : w_{k_0}^{(0)}\right), \ldots, \left(w_0^{(r)} : w_1^{(r)} : \ldots : w_{k_r}^{(r)}\right)\right) \in \mathbb{P}(V_0) \times \mathbb{P}(V_1) \times \ldots \times \mathbb{P}(V_r)$$

in the Cartesian space is a succinct representation that we can explicitly write down. Returning a tuple of vectors as the solution is also in the spirit of the homogeneous linear equations that we are generalising. Since A is a non singular point of $X^\check{}$, there is at least one $(\widehat{i_0}, \widehat{i_1}, \ldots, \widehat{i_r})$ such that $\frac{\partial Det(B)}{\partial b_{\widehat{i_0},\widehat{i_1},\ldots,\widehat{i_r}}} \Big|_{B=A} \neq 0$. By equation 3.1, $w_{\widehat{i_0}}^{(0)}, w_{\widehat{i_1}}^{(1)}, \ldots, w_{\widehat{i_r}}^{(r)}$ are all non zero, which allows us to set them all to one as normalisation,

$$w_{\widehat{i_0}}^{(0)} = w_{\widehat{i_1}}^{(1)} = \ldots, w_{\widehat{i_r}}^{(r)} = 1.$$

With one non zero coordinate in each vector set to one, the i_j-th coordinate of the j-th vector is given by

$$w_{i_j}^{(j)} = \frac{\partial Det(B)}{\partial b_{\widehat{i_0},\ldots,\widehat{i_{j-1}},i_j,\widehat{i_{j+1}},\ldots,\widehat{i_r}}} \Big|_{B=A} . \tag{3.2}$$

Given an arithmetic circuit to compute the hyperdeterminant (for the format of A), the Baur-Strassen algorithm [1] constructs an arithmetic circuit that computes all $k_0 k_1 \ldots k_r$ of the partial derivatives

$$\left(\frac{\partial Det(B)}{\partial b_{i_0,i_1,\ldots,i_r}} \Big|_{B=A}, 0 \leq j \leq r, 1 \leq i_0 \leq k_0, 1 \leq i_1 \leq k_1, \ldots, 1 \leq i_r \leq k_r\right)$$

sought (in determining non zero coordinates and in equation 3.2) at once. Remarkably, the size of this arithmetic circuit is only a small constant times that of the circuit for computing the hyperdeterminant.

▶ Remark 4. For our reduction of solving multilinear equations to hyperdeterminants to hold for quantum algorithms, we need a quantum version of Baur-Strassen that converts a quantum circuit computing the hyperdeterminant into one computing all its partial deivatives demanded by equation 3.2. While there is work on quantum versions of Baur-Stassen/automatic differentiation, they are not known to work in generality. But there is an approximate algorithm of Jordan [13] for computing the gradient that suffices if we are only interested in solving the multilinear system up to first order errors.

4 Hyperdeterminants of boundary format

In this section, we devise an algorithm that given a boundary format tensor A, computes its hyperdeterminant. The algorithm can be realised as an arithmetic circuit. Recall that for boundary formats, $k_0 = k_1 + k_2 + \ldots + k_r$. Hyperdeterminants of boundary formats have a simple interpretation as resultants of a system of multilinear forms following the "Cayley trick". Slices of A in the first dimension form a collection of $k_0 + 1$ multilinear forms

$$f_A^{(i_0)}(x) := \sum_{\substack{0 \le i_1 \le k_1 \\ \ldots \\ 0 \le i_r \le k_r}} a_{i_0, i_1, \ldots, i_r} x_{i_1}^{(1)} x_{i_2}^{(2)} \ldots x_{i_r}^{(r)}, \quad 0 \le i_0 \le k_0. \tag{4.1}$$

The hyperdeterminant $Det(A)$ vanishes precisely when the resultant of $f_A^{(i_0)}(x),\ 0 \le i_0 \le k_0$ does. For positive integers $s_1, s_2, \ldots, s_r$, let

$$S(s_1, s_2, \ldots, s_r) \cong \mathrm{Sym}^{s_1}(V_1) \otimes \mathrm{Sym}^{s_2}(V_2) \otimes \ldots \otimes \mathrm{Sym}^{s_r}(V_r)$$

denote the space of polynomials that are for each $j \in 1, 2, \ldots, d$ homogeneous of degree s_j in the coordinates $x_{i_j}^{(j)}, 0 \le i_j \le k_j$. Set $m_1 := 0$ and for $j > 1$, set $m_j := k_1 + k_2 + \ldots + k_{j-1}$. The conception of our algorithms is primarily due to the following theorem relating boundary format hyperdeterminants to determinants of large matrices built with the above slices.

▶ **Theorem 5** (Gelfand-Kapranov-Zelevinsky, [11, Theorem 4.3]). *The hyperdeterminant $Det(A)$ of a boundary format $A \in V_0^* \otimes V_1^* \otimes \ldots \otimes V_r^*$ equals (up to sign) the determinant of the linear operator*

$$\delta_A : S(m_1, m_2, \ldots, m_r)^{k_0+1} \longrightarrow S(m_1 + 1, m_2 + 1, \ldots, m_r + 1)$$

$$(g_0, g_1, \ldots, g_{k_0}) \longmapsto \sum_{i_0=0}^{k_0} f_A^{(i_0)} g_{i_0}.$$

Proof. See [11][Theorem 4.3] or [7] for proofs. ◀

The matrix of δ is indeed square. We may count monomials and verify that the dimensions

$$\dim\left(S(m_1, m_2, \ldots, m_r)^{k_0+1}\right) = \frac{(k_0+1)!}{k_1! k_2! \ldots k_r!}$$

and

$$\dim\left(S(m_1 + 1, m_2 + 1, \ldots, m_r + 1)\right) = (k_1 + k_2 + \ldots + k_r + 1)\binom{k_1 + k_2 + \ldots + k_r}{k_1, k_2, \ldots, k_r}$$

of the two spaces of polynomials are the same. By theorem 5, this count is also the degree of the hyperdeterminant

$$\deg(Det(A)) = \frac{(k_0+1)!}{k_1! k_2! \ldots k_r!} = (k_1 + k_2 + \ldots + k_r + 1)\binom{k_1 + k_2 + \ldots + k_r}{k_1, k_2, \ldots, k_r}. \tag{4.2}$$

Theorem 5 gives a determinantal identity for each choice of permutation of the vector spaces $V_1, V_2, \ldots, V_r$, which is implicit in the statement. It is not clear if there is a choice of permutation better suited to computation than the others. We now have all the ingredients to describe the hyperdeterminant computation.

Computation of the hyperdeterminant

Let A be the input tensor. Fix lexicographic ordered monomial bases P and Q respectively for $S(m_1, m_2, \ldots, m_r)$ and $S(m_1+1, m_2+1, \ldots, m_r+1)$. With bases fixed, we will also denote the matrix of δ_A by δ_A. For $p \in P, q \in Q$, the (p,q)-th entry $\delta_A^{(p,q)}$ of δ_A is either 0 or an $a_{i'_0,i'_1,\ldots,i'_r}$ for some $i'_0, i'_1, \ldots, i'_r$. Since $\log(\deg(Det(A)))$ is polynomial in k_0, the encoding $(p,q) \longmapsto 0$ or $i'_0, i'_1, \ldots, i'_r$ is easy to compute in time polynomial in k_0. This encoding transforms an arithmetic circuit for computing the determinant of a $\frac{(k_0+1)!}{k_1!k_2!\ldots k_r!} \times \frac{(k_0+1)!}{k_1!k_2!\ldots k_r!}$ square matrix into an arithmetic circuit to compute the hyperdeterminant. The complexity of the circuit is $O\left(\left(\frac{(k_0+1)!}{k_1!k_2!\ldots k_r!}\right)^4\right)$, using a division-free circuit for the determinant [17]. We conclude with an illustrative example of the determinantal identity underlying the hyperdeterminant computation.

Example

Let $A = (a_{i_0,i_1,i_2})$ be a tensor of the simplest three dimensional boundary format, namely $3 \times 2 \times 2$. Through lexicographic monomial orderings, fix ordered bases $\left(x_0^{(2)}, x_1^{(2)}\right)$ of $S(0,1)$ and $\left(x_0^{(1)}x_0^{(2)}x_0^{(2)}, x_0^{(1)}x_0^{(2)}x_1^{(2)}, x_0^{(1)}x_1^{(2)}x_1^{(2)}, x_1^{(1)}x_0^{(2)}x_0^{(2)}, x_1^{(1)}x_0^{(2)}x_1^{(2)}, x_1^{(1)}x_1^{(2)}x_1^{(2)}\right)$ of $S(1,2)$. Then

$$\delta_A : S(0,1)^3 \longrightarrow S(1,2)$$

corresponds to the matrix

$$\begin{pmatrix} a_{000} & 0 & a_{100} & 0 & a_{200} & 0 \\ a_{001} & 0 & a_{101} & 0 & a_{201} & 0 \\ a_{010} & a_{000} & a_{110} & a_{100} & a_{210} & a_{200} \\ a_{011} & a_{001} & a_{111} & a_{101} & a_{211} & a_{201} \\ 0 & a_{010} & 0 & a_{110} & 0 & a_{210} \\ 0 & a_{011} & 0 & a_{111} & 0 & a_{211} \end{pmatrix}.$$

5 On the hardness of computing hyperdeterminants modulo primes

Let p denote a prime. Recall from § 2 that for valid tensor formats, $Det()$ is a polynomial with integer coefficients, that is primitive and uniquely defined by choosing a sign. We prove that given a tensor $A = (a_{i_0,i_1,i_2}, 0 \leq i_0, i_1, i_2 \leq n)$ of "cubical" format $(n+1)\times(n+1)\times(n+1)$ with integer coordinates (that is, $\forall (i_0,i_1,i_2), a_{i_0,i_1,i_2} \in \mathbb{Z}$), it is hard to compute $Det(A)$ mod p, under certain post-quantum cryptographic assumptions.

Let $\mathbb{F}_p$ denote the finite field with a prime number p element. Fix an algebraic closure $\bar{\mathbb{F}}_p$ of $\mathbb{F}_p$. The theory of hyperdeterminants is yet to be worked out rigorously over $\bar{\mathbb{F}}_p$, unlike the theory over complex numbers developed by Gelfand, Kapranov and Zelevinsky. The key issue is that the geometric theory of projective duality used in the very definition of hyperdeterminants does not in general translate to positive characteristic. Thankfully, in our particular context, the duality used to define and prove the existence of hyperdeterminants is

proven to hold true over $\bar{\mathbb{F}}_p$ for all primes p by Kaji [14]. We will work under the assumption that the basic properties of hyperdeterminants from [11] translate to $\bar{\mathbb{F}}_p$. In particular, the hyperdeterminant over $\bar{\mathbb{F}}_p$ is $Det(A)$ mod p, the hyperdeterminant over the integers modulo p. We defer rigorous proofs to later works, focusing instead on sketching the main ideas in the reduction.

We next state the computational problem of computing hyperdeterminants modulo primes. To control the length of the input, without loss of generality, we may assume that the coordinates $a_{i_0,i_1,i_2} \in \mathbb{F}_p$ instead of being integers. It is therefore convenient to think of the input as being

$$A = (a_{i_0,i_1,i_2}, 0 \leq i_0, i_1, i_2 \leq n) \in (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*$$

of "cubical" format $(n+1) \times (n+1) \times (n+1)$ over $\mathbb{F}_p$. Let $Det_{n+1,p}()$ denote the polynomial over $\mathbb{F}_p$ obtained by reducing $Det()$ modulo p. In particular,

$$Det_{n+1,p}() \in \mathbb{F}_p[a_{i_0,i_1,i_2}, 0 \leq i_0, i_1, i_2 \leq n]$$

is a non zero polynomial in the coordinate ring of A. As a convention, we will use $Det_{n+1,p}()$ to denote the polynomial and $Det_{n+1,p}(A)$ to denote its evaluation at a tensor A. The computational problem in question is then given a tensor A to compute $Det_{n+1,p}(A) \in \mathbb{F}_p$. Associated with a cubical tensor $A \in (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*$ is the trilinear form

$$f_A(x^{(0)}, x^{(1)}, x^{(2)}) := \sum_{0 \leq i_0, i_1, i_2 \leq n} a_{i_0,i_1,i_2} x^{(0)}_{i_0} x^{(1)}_{i_1} x^{(2)}_{i_2}.$$

Triples $(G_0, G_1, G_2) \in (GL_{n+1}(\mathbb{F}_p))^3$ of invertible $(n+1) \times (n+1)$ matrices act on A (or equivalently f_A) in the natural way,

$$(G_0, G_1, G_2) \circ f_A := f_A(G_0 x^{(0)}, G_1 x^{(1)}, G_2 x^{(2)}).$$

Call two tensors A and B as isomorphic if there exists a triple $(G_0, G_1, G_2) \in (GL_{n+1}(\mathbb{F}_p))^3$ such that $f_B = (G_0, G_1, G_2) \circ f_A$. This is indeed an equivalence relation. In particular, it is symmetric since $f_B = (G_0, G_1, G_2) \circ f_A$ if and only if $f_A = (G_0^{-1}, G_1^{-1}, G_2^{-1}) \circ f_B$.

The Tensor Isomorphism Problem. To decide if two cubical tensors over finite fields are isomorphic is the tensor isomorphism problem, which is believed to be hard. Grochow and Qiao built an intricate web of hard problems that reduce to tensor isomorphism, including some longstanding hard problems that lay at the foundation of multivariate cryptography. Complexity theoretically, the tensor isomorphism problem is $NP \cap co - AM$, and believed to be hard on average in theory and practice [9]. The best known run time of $p^{O(n^{11/6})}$ is through Sun's p-group isomorphism algorithm [28] (in conjunction with a reduction in [8]). The promise search version, given two isomorphic A, B to find a $(G_0, G_1, G_2) \in (GL_{n+1}(\mathbb{F}_p))^3$ such that $f_B = (G_0, G_1, G_2) \circ f_A$ is also believed hard. Spurred on by this hardness, several post-quantum digital signature schemes including MEDS [5] and ALTEQ [2, 29] have recently been proposed and submitted to NIST call for post-quantum signatures, all reliant on tensor isomorphism hardness assumptions, or hardness assumptions that reduce to tensor isomorphism.

We focus our attention on MEDS which involves the exact tensor isomorphism stated in our context. The signature scheme is built as follows. First a zero-knowledge interactive protocol is constructed based on the Goldreich-Micali-Wigderson protocol for graph isomorphisms. Except, the graph isomorphism problem is recast with tensor isomorphism

problem. Then the interaction in the zero-knowledge protocol is removed using the Fiat-Shamir transformation to yield a signature scheme. We identify the following hardness assumption underlying the soundness and zero-knowledge proofs of the interactive protocol as one that easily relates to hyperdeterminants.

▶ **Assumption 6.** *Draw a tensor* $A \in (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*$ *uniformly at random. Draw a triple* $(G_0, G_1, G_2) \in (GL_{n+1}(\mathbb{F}_p))^3$ *of invertible matrices uniformly at random and set* $f_B := (G_0, G_1, G_2) \circ f_A$. *The pair* (A, B) *is computationally indistinguishable from a uniformly random pair of tensors in* $\left((\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*\right)^2$.

An algorithm that distinguishes such an isomorphic pair (A, B) from a uniformly random pair of tensors can be used to either recover the key in a No-Message-Attack or forge the signature in a Chosen-Message-Attack.

Unfortunately, we don't quite know how to use the hyperdeterminant to build a distinguisher for assumption 6. The reason being that the hyperdeterminant is only a relative invariant of the $(GL_{n+1}(\mathbb{F}_p))^3$ action. That is, for all $A \in (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*$ and for all $(G_0, G_1, G_2) \in (GL_{n+1}(\mathbb{F}_p))^3$,

$$Det_{n+1,p}((G_0, G_1, G_2) \circ f_A) = C(G_0, G_1, G_2) Det_{n+1,p}(f_A),$$

where the "constant" $C(G_0, G_1, G_2)$ depends on the acting matrices. However, if we restrict to $(SL_{n+1}(\mathbb{F}_p))^3$ action, then the hyperdeterminant is an invariant, that is, for all $A \in (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*$ and for all $(G_0, G_1, G_2) \in (SL_{n+1}(\mathbb{F}_p))^3$,

$$Det_{n+1,p}((G_0, G_1, G_2) \circ f_A) = Det_{n+1,p}(f_A).$$

We observe that there is a natural hardness reduction from the tensor isomorphism problem restricted to the $(SL_{n+1}(\mathbb{F}_p))^3$ action to the hyperdeterminant. To this end, we next write out the hardness assumption restricted to the $(SL_{n+1}(\mathbb{F}_p))^3$ action, followed by the distinguisher with blackbox access to the hyperdeterminant that reduces the tensor isomorphism problem with the $(SL_{n+1}(\mathbb{F}_p))^3$ action to the hyperdeterminant.

▶ **Assumption 7.** *Draw a tensor* $A \in (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*$ *uniformly at random. Draw a triple* $(G_0, G_1, G_2) \in (SL_{n+1}(\mathbb{F}_p))^3$ *of determinant one matrices uniformly at random and set* $f_B := (G_0, G_1, G_2) \circ f_A$. *The pair* (A, B) *is computationally indistinguishable from a uniformly random pair of tensors in* $\left((\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*\right)^2$.

Distinguisher. Given a pair of tensors $(A, B) \in \left((\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*\right)^2$, decide that the input is a pair of isomorphic tensors if and only if $Det_{n+1,p}(A) = Det_{n+1,p}(B)$.

By invariance, if A and B are isomorphic, then indeed $Det_{n+1,p}(A) = Det_{n+1,p}(B)$, meaning the distinguisher is always correct when presented with two isomorphic tensors. Therefore, for our distinguisher to succeed, it suffices to prove that for a uniformly random tensor A, $det(A)$ is not concentrated on a particular value in $\mathbb{F}_p$. In the following lemma, for large enough field size p (growing exponentially with n), we prove for uniformly random A that $Det(A)$ is close to uniformly distributed. For such large p, our distinguisher succeeds with probability close to $1 - 1/p$. We take the lemma as strong evidence that there is no arithmetic obstruction to equidistribution, meaning equidistribution should hold for even for small p. The requirement on p being large is merely an artifact our proof methods and our distinguisher should succeed with probability close to $1 - 1/p$ for all p.

▶ **Lemma 8.** *Fix the tensor dimension n and a positive parameter $c > 1$. For every large enough prime $p \geq (n/2)^{\frac{c-1}{c}} 2^{\frac{(c-1)n}{c}\left(1+\frac{3}{2}\log_2 n\right)}$, and for every $u \in \mathbb{F}_p$,*

$$Prob_A\left(Det_{n+1,p}(A) = u\right) \leq \frac{1}{p^{1/c}} + o\left(\frac{1}{p^{\frac{1}{c}}}\right),$$

where the probability is taken over uniform $A \in (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*$. For even larger primes p with $p \geq 5(n/2)^{13/3} 2^{\frac{13n}{3}\left(1+\frac{3}{2}\log_2 n\right)}$, for every $u \in \mathbb{F}_p$,

$$Prob_A\left(Det_{n+1,p}(A) = u\right) \leq \frac{1}{p} + o\left(\frac{1}{p}\right),$$

a tighter bound showing that the Hyperdeterminant values are nearly uniformly distributed.

Proof. Since the hyperdeterminant is a primitive polynomial with integer coefficients, reduction by p gives a non zero polynomial $Det_{n+1,p}() \in \mathbb{F}_p[a_{i_0,i_1,i_2}, 0 \leq i_0, i_1, i_2 \leq n]$. By [12, Cor. 2.9], its degree is bounded by

$$\deg(Det_{n+1,p}()) \leq \sum_{0\leq j\leq k/2} \frac{(j+k_1)!}{j!^3(k-2j)!} 2^{k-2j} \leq \sum_{0\leq j\leq k/2} n^{3j} 2^{n-2j} \leq \frac{n}{2} 2^{n\left(1+\frac{3}{2}\log n\right)}.$$

Further, $Det_{n+1,p}() - u$ is a non-zero polynomial with the same degree bound. Bounding the number of roots of $Det_{n+1,p}() - u$ by Schwartz-Zippel lemma [23],

$$Prob_A\left(Det_{n+1,p}(A) = u\right) \leq \frac{\deg(Det_{n+1,p}() - u)}{p}.$$

This proves the first bound in the lemma, for every choice of $c > 1$. If one desires a tighter bound towards the uniformity of the hyperdeterminant values, we can resort to the more sophisticated Lang-Weil bound [15]. The fewer the number of components of the variety generated by $Det_{n+1,p}() - u$, the better the Lang-Weil bound. Over the complex numbers, the hyperdeterminant is an absolutely irreducible integer polynomial. By analogy, $Det_{n+1,p}() - u$ is irreducible in $\bar{\mathbb{F}}_p[a_{i_0,i_1,i_2}, 0 \leq i_0, i_1, i_2 \leq n]$. The variety $Det_{n+1,p}() - u$ defines has only one component and the Lang-Weil bound implies

$$Prob_A\left(Det_{n+1,p}(A) = u\right) \leq \frac{1}{p} + O_{\deg(Det_{n+1,p}()-u)}\left(\frac{1}{p}\right).$$

But the asymptotic notation $O_{\deg(Det_{n+1,p}()-u)}()$ in the original Lang-Weil paper hides terms depending on n that are too big. Therefore, we look to the effective version of the Lang-Weil bound, optimized for irreducible hypersurfaces in [25, Thm. 2], which for $p > 5\deg(Det_{n+1,p}() - u)^{13/3}$ implies

$$Prob_A\left(Det_{n+1,p}(A) = u\right) \leq \frac{1}{p} + \frac{(\deg(Det_{n+1,p}() - u) - 1)(\deg(Det_{n+1,p}() - u) - 2)}{p^{3/2}} + \frac{5}{p^2}.$$

Therefore, for $p \geq 5(n/2)^{13/3} 2^{\frac{13n}{3}\left(1+\frac{3}{2}\log_2 n\right)} \geq 5\deg(Det_{n+1,p}() - u)^{13/3}$, the second bound claimed in the lemma is true. ◀

In light of this reduction, to prove tensor isomophism hardness of computing the hyperdeteminant, it suffices to answer the following open question in the affirmative.

▶ **Question 9.** *Is the problem of deciding if for two given tensors A and B there exists a triple $(G_0, G_1, G_2) \in (SL_{n+1}(\mathbb{F}_p))^3$ of determinant one matrices such that $f_B = (G_0, G_1, G_2) \circ f_A$ tensor isomorphism hard? In other words, is there a polynomial time reduction from the tensor isomorphism problem with $(GL_{n+1}(\mathbb{F}_p))^3$ action to that with $(SL_{n+1}(\mathbb{F}_p))^3$ action?*

We suspect that the answer to the question is yes, but also advise caution. Tensor isomorphism problems with other matrix group actions such as the orthogonal, symplectic or unitary (over complex numbers) are in practice easier than the general linear group actions [4].

▶ Remark 10. For pairs (n,p) such that $p-1$ divides $deg(Det_{n+1,p}())/(n+1)$, our distinguisher for the $(SL_{n+1}(\mathbb{F}_p))^3$ actually also works as a distinguisher for the $(GL_{n+1}(\mathbb{F}_p))^3$ action. Therefore, restricted to the pairs (n,p) satisfying $p-1$ divides $deg(Det_{n+1,p}())/(n+1)$, the hyperdeteminant is at least as hard as the cryptographically hard problem underlying MEDS.

The reason is that the relative invariance of the hyperdeterminant with respect to the $GL_{n+1}(\mathbb{F}_p)^3$ action takes the following form (c.f. proof of theorem 4.4 in [19]). For all $A \in (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^* \otimes (\mathbb{F}_p^{n+1})^*$ and for all $(G_0,G_1,G_2) \in (GL_{n+1}(\mathbb{F}_p))^3$,

$$Det_{n+1,p}((G_0,G_1,G_2)\circ f_A) = (Det(G_0)Det(G_1)Det(G_2))^{deg(Det_{n+1,p}())/(n+1)}\, Det_{n+1,p}(f_A).$$

But for p such that $p-1$ divides $deg(Det_{n+1,p}())/(n+1)$,

$$(Det(G_0)Det(G_1)Det(G_2))^{deg(Det_{n+1,p}())/(n+1)} = 1,$$

since raising a non zero element in $\mathbb{F}_p$ to the $p-1$-th power is one. Therefore, for (n,p) such that $p-1$ divides $deg(Det_{n+1,p}())/(n+1)$, the hyperdeterminant is actually an invariant of the $GL_{n+1}(\mathbb{F}_p)^3$ action, not merely a relative invariant.

Let us pause to understand the pairs (n,p) for which the reduction applies. By [12, Cor. 2.9], the degree of the cubical hyperdeterminant is

$$\deg(Det_{n+1,p}()) = \sum_{0\le j\le k/2} \frac{(j+k_1)!}{j!^3(k-2j)!}2^{k-2j} \le \sum_{0\le j\le k/2} n^{3j}2^{n-2j} \le \frac{n}{2}2^{n\left(1+\frac{3}{2}\log n\right)}.$$

Further, $\deg(Det_{n+1,p}())$ is divisible by $n+1$, although it is not apparent from the expression ([19, Theorem 4.4]). For a choice of n, there are at most finitely many p satisfying the condition $p-1$ divides $\deg(Det_{n+1,p}())/(n+1)$. Some of these primes may be exponential in n, which is consistent with the large size of primes chosen in MEDS and ALTEQ. The number of pairs (n,p) satisfying the condition should be infinite assuming some widely believed conjectures on the distribution of primes in polynomial values, but is difficult to prove unconditionally.

▶ Remark 11. Recently, Ran and Samardjiska [20] identified a potential weakness in MEDS and ALTEQ signature schemes that rely on the hardness of tensor isomorphism problems. If the public keys chosen turn out to support a certain triple of points they call "triangles", then the isomorphism problem may be easier than the generic case. They further describe Grobner basis based algorithms for detecting and finding triangles. If such triangles exist, their algorithms can strip several bits of security off the schemes. Therefore, careful analysis of the weak key issue they identified is warranted. We observe that in the language of hyperdeterminants these weak keys correspond to singular tensors and the triangles are solutions to the homogeneous multilinear equations in 1 modulo p. Further, hyperdeterminants play a curious role in analysing this critical weak key security issue. First, $Det_{n+1,p}()$ being irreducible over $\bar{\mathbb{F}}_p$ means that weak keys arise with probability roughly $\frac{1}{p}$. Therefore, increasing p to be exponential in the security parameter is an immediate remedy (at the cost of efficiency, needing slightly larger signature lengths etc.). If zero testing the hyperdeterminant (that is, given a tensor A deciding if $Det_{n+1,p}(A) = 0$) turns out to be easy, then it can be used to test and weed out the weak keys. Further, any algorithm for computing the hyperdeterminant $Det_{n+1,p}()$ can be turned into one for computing the triangles through our tensor Cramer's rule algorithm in § 3.1.

Abstract

Product states, unentangled tensor products of single qubits, are a ubiquitous ansatz in quantum computation, including for state-of-the-art Hamiltonian approximation algorithms. A natural question is whether we should expect to efficiently solve product state problems on any interesting families of Hamiltonians.

We completely classify the complexity of finding minimum-energy product states for Hamiltonians defined by any fixed set of allowed 2-qubit interactions. Our results follow a line of work classifying the complexity of solving Hamiltonian problems and classical constraint satisfaction problems based on the allowed constraints. We prove that estimating the minimum energy of a product state is in P if and only if all allowed interactions are 1-local, and NP-complete otherwise. Equivalently, any family of non-trivial two-body interactions generates Hamiltonians with NP-complete product-state problems. Our hardness constructions only require coupling strengths of constant magnitude.

A crucial component of our proofs is a collection of hardness results for a new variant of the Vector Max-Cut problem, which should be of independent interest. Our definition involves sums of distances rather than squared distances and allows linear stretches.

We similarly give a proof that the original Vector Max-Cut problem is NP-complete in 3 dimensions. This implies hardness of optimizing product states for Quantum Max-Cut (the quantum Heisenberg model) is NP-complete, even when every term is guaranteed to have positive unit weight.

1 Introduction

Product states, unentangled tensor products of single-qubit states, have served as an effective focus for better understanding quantum phenomena. Because general quantum states cannot be described efficiently, approximation algorithms must be restricted to output some subset of states, an ansatz. Mean-field approaches are common as first steps in statistical mechanics, and recent approximation algorithms for extremal energy states of local Hamiltonians have relied on proving that product states provide good approximations in particular regimes [17, 4, 5, 18, 31, 32]. In fact, because in some natural regimes the ground states are rigorously well-approximated by product states [4], optimal approximation algorithms for local Hamiltonians on arbitrary interaction graphs must be capable of finding good product states. Understanding product state optimization is essential for understanding the complexity of Hamiltonian approximation generally.

Product states are a natural intermediate between classical and quantum states, allowing for superposition but not entanglement. Unlike general quantum states, they have succinct classical descriptions: a single-qubit pure state can be specified by two complex numbers, and an n-qubit pure product state can be specified by $2n$ complex numbers. One could consider "more quantum" intermediates, in the form of reduced states of two or more qubits. However, verifying the consistency of a set of quantum marginals is a QMA-complete problem, even for 2-qubit reduced states [27, 10]. Therefore, product states are uniquely useful when optimizing directly over state vectors.

We study the following question: for a family of Hamiltonians defined by a given set of allowed interactions, what is the complexity of computing the extremal energy over product states? Additionally, how does the complexity of optimizing over product states relate to that of optimizing over general states? For example, for a QMA-hard local Hamiltonian, must finding the optimal product state in turn be NP-hard?[1]

This question follows a long line of work classifying the complexity of constraint satisfaction problems (CSPs) based on the sets of allowed constraints, clauses, or interactions between variables. In particular, the dichotomy theorem of Schaefer [35] showed that for any set of allowed Boolean constraints, the family of CSPs is either efficiently decidable or is NP-complete. In the context of quantum problems, Cubitt and Montanaro [14] introduced a similar classification of ground state energy problems for 2-local Hamiltonians, showing that for any fixed set of allowed 2-qubit interactions, the 2-LH problem is either in P or NP-, StoqMA-, or QMA-complete (the StoqMA case relies on the concurrent work of Bravyi and Hastings [6]). We briefly survey some of this line of classical and quantum work in Related Work below.

[1] The product state problem is always in NP since product states have succinct classical descriptions with which we can compute the expected energy contribution from each local Hamiltonian term in time polynomial in the size of the term.

While the complexity of finding the extremal states (e.g. the ground state) of 2-local Hamiltonians is well understood, the complexity of finding optimal product state solutions has been only sparsely studied [22]. The only NP-hardness results for such problems are based on mapping a classical problem to a diagonal 0-1 valued Hamiltonian [39].

An additional motivation for our study is the hope of developing new methods for identifying families of local Hamiltonians for which problems involving *general* ground states are *not* hard. While a complete complexity classification for the general 2-LH problem is known, more refined attempts at classification which take into account restrictions on the sign of the weights or geometry of the system are currently incomplete [33]. Developing algorithms for product states is a "mostly classical" problem that is easier to analyze, and progress involving product states may inform our expectations regarding general states.

In this work, we completely classify the complexity of finding optimal product states for families of 2-local Hamiltonians. In fact, we find the complexity of the product state problem is fully determined by the complexity of the general local Hamiltonian problem: if the general problem is NP-hard, the product state problem is NP-complete, and otherwise it is in P. To arrive at our results, we study a variant of the Vector Max-Cut which should be of independent interest especially to the optimization community. As a corollary to our classification theorem, we give the first published proof that estimating optimal product state energies in the Quantum Max-Cut model is NP-complete, and we show hardness holds even for unweighted Hamiltonians.[2]

1.1 Our Contributions

Formal definitions are given in Section 2. A k-local Hamiltonian is a sum of Hamiltonian terms each of which only acts non-trivially on at most k qubits, analogous to k-variable Boolean clauses. k-LH denotes the problem of estimating the ground state energy (the minimum eigenvalue across all states) of a k-local Hamiltonian to inverse-polynomial additive precision. Given a set of local terms $\mathcal{S}$, $\mathcal{S}$-LH is k-LH restricted to Hamiltonians such that every term belongs to $\mathcal{S}$. Finally, prodLH and $\mathcal{S}$-prodLH are the restrictions of these problems to product states, i.e. to minimize $\langle\phi|H|\phi\rangle$ where H is the Hamiltonian and $|\phi\rangle$ ranges over tensor products of single-qubit states.[3]

2-local $\mathcal{S}$-prodLH

The classification of the general ground state energy problem by Cubitt and Montanaro [14] completely classifies $\mathcal{S}$-LH for any fixed set $\mathcal{S}$ of 2-qubit terms, showing it is either in P or it is one of NP-, StoqMA-, or QMA-complete.

In the same vein, we give a complete classification of product state complexity for families of 2-local Hamiltonians as a function of the set of allowed 2-qubit interactions. For any given set $\mathcal{S}$ of 2-qubit terms, we prove the problem $\mathcal{S}$-prodLH is either in P or is NP-complete. To the best of our knowledge, ours is the first systematic inquiry into the complexity of product state problems.

▶ **Theorem 1.** *For any fixed set of 2-qubit Hamiltonian terms $\mathcal{S}$, if every matrix in $\mathcal{S}$ is 1-local then $\mathcal{S}$-prodLH is in P, and otherwise $\mathcal{S}$-prodLH is NP-complete.*

[2] A more complex unpublished proof based on large graph cycles was known earlier by Wright [40].
[3] An earlier version of this work considered *exact* versions of product state and graph problems. We have now improved our hardness results to hold up to an inverse-polynomial additive gap.

Additionally, our hardness constructions only require coupling strengths (weights) of at most constant magnitude. This is preferable in practice and contrasts with most known QMA-hardness constructions.

The sets for which [14] shows $\mathcal{S}$-LH is in P are the same for which we show $\mathcal{S}$-PRODLH is in P, i.e. those containing only 1-local terms. This immediately implies that a family of 2-local Hamiltonians has efficiently-computable minimum product state energy if and only if it has efficiently-computable ground state energy.

▶ **Corollary 2.** *For any fixed set of 2-qubit Hamiltonian terms $\mathcal{S}$, the problem $\mathcal{S}$-LH is in* P *if and only if $\mathcal{S}$-PRODLH is in* P*.*

▶ **Corollary 3.** *For any fixed set of 2-qubit Hamiltonian terms $\mathcal{S}$, the problem $\mathcal{S}$-LH is* NP*-hard if and only if $\mathcal{S}$-PRODLH is* NP*-complete.*

Our results imply that hardness of product state approximations is not restricted to Hamiltonians for which product states well approximate ground states: for any QMA-hard family of terms, our result implies that (assuming QMA $\neq$ NP) we can construct a family of local Hamiltonians that are NP-hard to product state approximate *and* for which the product states do not well approximate the ground state by constructing Hamiltonians on two systems, each with one of these properties, and taking a disjoint union thereof. This implies that algorithms using product states to approximate the ground states of QMA-hard Hamiltonians face a "double penalty": hardness of approximating product states which themselves imperfectly approximate ground states.

The Stretched Linear Vector Max-Cut problem

Our hardness constructions for product state problems embed an objective function which we prove is NP-complete. This objective function generalizes the classical MAX-CUT problem. Given work on other variations of MAX-CUT, we expect this problem and our reductions should be of independent interest, especially to the optimization and approximation communities.

In MAX-CUT, one is given a graph $G = (V, E)$ and asked to assign to each vertex v a label $\hat{v} = \pm 1$ so as to achieve the maximum number of oppositely labeled adjacent vertices:

$$\mathrm{MC}(G) = \frac{1}{2} \max_{\hat{\imath}=\pm 1} \sum_{ij \in E} (1 - \hat{\imath}\hat{\jmath}) = \frac{1}{2} \max_{\hat{\imath}=\pm 1} \sum_{ij \in E} |\hat{\imath} - \hat{\jmath}|. \tag{1}$$

A problem referred to as VECTOR MAX-CUT, RANK-k-MAX-CUT, or MAX-CUT$_k$ (MC$_k$) has been studied [8, 7, 22] which generalizes MAX-CUT to assigning k-dimensional unit vectors so as to maximize the angles between adjacent vertex labels, or equivalently to maximize the squared distances between adjacent vertex labels:

$$\mathrm{MC}_k(G) = \frac{1}{2} \max_{\hat{\imath} \in S^{k-1}} \sum_{ij \in E} (1 - \hat{\imath} \cdot \hat{\jmath}) = \frac{1}{4} \max_{\hat{\imath} \in S^{k-1}} \sum_{ij \in E} \|\hat{\imath} - \hat{\jmath}\|^2. \tag{2}$$

Our new problem can be seen as a stretched and linear version of MC$_k$. The goal in W-LINEAR-MAX-CUT (MC$^{\mathrm{L}}_W$) is to assign unit vectors so as to maximize the distance between adjacent labels:

$$\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}(G) = \frac{1}{2} \max_{\hat{\imath} \in S^{d-1}} \sum_{ij \in E} \|W\hat{\imath} - W\hat{\jmath}\| = \frac{1}{2} \max_{\hat{\imath} \in S^{d-1}} \sum_{ij \in E} \sqrt{\|W\hat{\imath}\| + \|W\hat{\jmath}\| - 2(W\hat{\imath})^\top (W\hat{\jmath})}, \tag{3}$$

where W is a fixed $d \times d$ diagonal matrix. Comparing MC_k and $\mathrm{MC}^{\mathrm{L}}_W$, our problem sums over un-squared distances and incorporates a linear stretch given by W. We consider the decision version of this problem, in which the objective is to test whether the optimal solution is at least b or no more than a, for $b - a \geq 1/\operatorname{poly}(n)$. Note that, unlike $\mathcal{S}$-LH, this is an unweighted problem – one could naturally define a weighted version but our hardness results will not require this.

Geometrically, MC_k corresponds to embedding a graph into the surface of a unit sphere with the objective of maximizing the sum of the squared lengths of every edge. Likewise, our problem $\mathrm{MC}^{\mathrm{L}}_W$ corresponds to embedding a graph into the surface of a d-dimensional ellipsoid, with radii defined by the entries of W, with the objective of maximizing the sum of the (non-squared) edge lengths.

Despite being generalizations of the NP-complete Max-Cut problem, hardness of neither MC_k nor $\mathrm{MC}^{\mathrm{L}}_W$ is trivial. The Goemans-Williamson approximation algorithm for Max-Cut on an n-vertex graph begins with efficiently computing the solution to MC_n via an SDP. In fact, deciding MC_k is known to be in P for any $k = \Omega(\sqrt{|V|})$, [28, Theorem 8.4] or [3, (2.2)]. And while it has been conjectured by Lovász that MC_k is NP-complete for all constants $k \geq 1$, in [29, p. 236] and earlier, no proof has been given for any $k > 1$.

Our main theorem concerning W-linear-Max-Cut, which is used to prove Theorem 1, is the following.

▶ **Theorem 4.** *For any fixed non-negative $W = \operatorname{diag}(\alpha, \beta, \gamma)$ with at least one of α, β, γ nonzero, W-linear-Max-Cut is NP-complete.*

Quantum Max-Cut Product States and MC_3

As a corollary of our classification theorem, we give the first published proof of the fact that product state optimization in the Quantum Max-Cut (QMC) model is NP-hard. This model, also known as the anti-ferromagnetic Heisenberg model, is equivalent to $\mathcal{S}$-LH with $\mathcal{S} = \{XX + YY + ZZ\}$. We note that a sketch of a different proof for this specific problem was previously known but unpublished [40]. That proof was based on large graph cycles, and our gadgets are simpler to analyze.

However, the proof of Theorem 1 utilizes Hamiltonian gadgets involving negative weights (unlike the aforementioned proof of [40]). This leaves open whether prodQMC remains NP-hard on unweighted graphs. In Section 5, we give a direct proof of hardness using the fact that the unweighted product-state version of QMC is equivalent to MC_3 (Equation (2)). Our work then is also the first published proof that MC_k is NP-complete for some $k > 1$ (in our case, $k = 3$), partially resolving a conjecture of Lovász [29, p. 236]. Note that as with $\mathrm{MC}^{\mathrm{L}}_W$, we consider the decision version in which the goal is to determine whether the value is above b or below a, for b and a with inverse-poly separation.

▶ **Theorem 5.** MC_3 *is NP-complete.*

▶ **Corollary 6.** Quantum Max-Cut *restricted to product states,* prodQMC*, is NP-complete, even when all terms are restricted to have positive unit weight.*

1.2 Proof Overview

2-local $\mathcal{S}$-prodLH

As product states have classical descriptions and their energies can be calculated in polynomial time, $\mathcal{S}$-prodLH is automatically in NP, so we focus on how we show hardness. Our approach is in two parts. We show how to reduce $\mathrm{MC}^{\mathrm{L}}_W$ to $\mathcal{S}$-prodLH, and later we show that $\mathrm{MC}^{\mathrm{L}}_W$

NP-complete (Theorem 4). More precisely, the first part of our approach is to show that for any $\mathcal{S}$ containing a strictly 2-local term, there exists a corresponding weight matrix W meeting the conditions of Theorem 4 so that $\mathrm{MC}^{\mathrm{L}}_W$ is NP-hard. For any instance of $\mathrm{MC}^{\mathrm{L}}_W$ with this fixed W, we show how to construct a Hamiltonian from $\mathcal{S}$ such that the minimum product state energy encodes the $\mathrm{MC}^{\mathrm{L}}_W$ value, yielding Theorem 1.

We interpret problems over product states as optimization problems on the collection of Bloch vectors for each single-qubit state. For example, consider $\mathcal{S}$-PRODLH with the specific set $\mathcal{S} = \{XX + YY + ZZ\}$ (the QMC model). In this case, by writing each qubit v in the Bloch vector representation

$$|\phi_v\rangle\langle\phi_v| = \frac{1}{2}\left(I + v_1 X + v_2 Y + v_3 Z\right),$$

the energy contributed by an interaction between qubits u and v is

$$\mathrm{tr}\left(\left(X^u X^v + Y^u Y^v + Z^u Z^v\right)|\phi_u\rangle\langle\phi_u|\,|\phi_v\rangle\langle\phi_v|\right) = u_1 v_1 + u_2 v_2 + u_3 v_3. \tag{4}$$

So, given a Hamiltonian which is the sum of XYZ interactions between pairs of qubits, the problem of estimating the extremal product state energies is equivalent to optimizing the objective function

$$\sum_{uv} w_{uv}\, u \cdot v$$

over 3-dimensional unit vectors, where each edge uv corresponds to the Hamiltonian's (weighted) interaction graph. Up to constant shifts and scaling, this is equivalent to MC_3, introduced in Equation (2).

More generally, because the Pauli matrices are a basis for all Hermitian matrices, any 2-qubit interaction can be written as $H = \sum_{i,j=1}^{3} M_{ij}\sigma_i\sigma_j + \sum_{k=1}^{3}(*)c_k\sigma_k I + w_k I\sigma_k$, where the σ_i are the Pauli matrices, for some M, c, w. Then, the energy of a given product state is calculated similarly to Equation (4). However, the resulting expression potentially contains many terms.

Our approach is to take an arbitrary 2-qubit term and insert it into gadgets which simplify the energy calculations. First, in the proof of Theorem 1, we borrow a trick of [14] and symmetrize the terms. For any 2-qubit interaction H^{ab} on qubits a, b, the combined interaction $H^{ab} + H^{ba}$ is symmetric, invariant under swapping the qubits. A similar trick handles the case of anti-symmetric terms.

Second, in the proofs of Lemmas 14 and 15, we show how to use a symmetric or anti-symmetric term to embed the $\mathrm{MC}^{\mathrm{L}}_W$ value into the minimum energy of a gadget. We begin by removing the 1-local terms, such as $\sigma_1 I$ or $I\sigma_2$, again taking inspiration from gadgets used by [14]. For two qubits u, v corresponding to two vertices in a $\mathrm{MC}^{\mathrm{L}}_W$ instance, the gadget adds two ancilla qubits and weights each interaction within the gadget to effectively cancel out the 1-local terms. When the two ancilla qubits vary freely, we find the minimum energy contributed by the entire four-qubit gadget is determined by the distance between the states of u and v. Although each individual edge contributes energy proportional to the squared distance between their states, the overall gadget contributes energy proportional to just the distance of the two "vertex qubits", $-\|Mu - Mv\|$. With some massaging, we can treat M as a non-negative diagonal matrix which meets the conditions of Theorem 4.

Therefore, as desired, we have that the $\mathrm{MC}^{\mathrm{L}}_W$ value for an NP-complete instance of $\mathrm{MC}^{\mathrm{L}}_W$ can be embedded into the minimum product state energy of an $\mathcal{S}$-PRODLH instance.

To prove that $\mathrm{MC}^{\mathrm{L}}_W$ is NP-hard for any fixed diagonal non-negative W with at least one nonzero entry, we divide into three cases, in Lemmas 21–23. Our first proof is a reduction from the standard Max-Cut problem, while the other two are reductions from 3-Coloring.

When there is a unique largest entry of W, we reduce from Max-Cut by taking any input graph G and forming G' by adding large star gadgets around each of the vertices of G, each using many ancilla vertices. Because the ancilla vertices in each gadget have just one neighbor (the original vertex at the center of the gadget), their optimal vector labels given any choice of labels for the center vertices are the negation of the center vertex labels. This means they heavily penalize assigning the center vertices any labels that are not along the highest-weight axis. Therefore, when the maximum entry of W is unique, the optimal $\mathrm{MC}^{\mathrm{L}}_W$ assignment to G' will have its vector labels almost entirely along the highest-weight axis. The assignment can trivially earn the maximum possible value on the star gadgets, and the amount additional amount it can earn on the original edges of G corresponds to the Max-Cut value of G.

When all of the entries of W are equal, we reduce from 3-Coloring. Given a graph G, we construct G' by replacing each edge with a 4-clique gadget, made by adding one ancilla vertex per gadget, along with a single ancilla vertex shared by every gadget. We show that G is 3-colorable iff G' has a sufficiently large $\mathrm{MC}^{\mathrm{L}}_W$ value. Specifically, we show this holds iff there is a vector assignment that simultaneously achieves (nearly) the maximum value on all of the clique gadgets. Achieving the maximum objective value on a clique corresponds to maximizing the total distance between each pair of vectors, and this enforces a predictable arrangement.

When weights are equal, assigning these vectors can be viewed as inscribing vectors in the unit sphere, and it is known that maximal perimeter polyhedra inscribed in the sphere must be regular. So for a 4-clique, the vector labels must form a regular tetrahedron. We carefully argue that for regular tetrahedra, fixing two of the vertices (approximately) fixes the other two vertices up to swapping (several of these geometric facts are proved in Section A). This means that the clique gadget corresponding to an edge uv in G shares two vertices with any gadget corresponding to an edge vw incident to the first edge: v and the "global" ancilla shared by all gadgets. This means that, once we fix the vector assigned to the global ancilla, the choice of a vector for v restricts the labels of both u and w to be chosen from a set of two vectors. So simultaneously optimizing every clique gadget is possible iff, for each connected component of G', we can 3-color that component with three vectors (corresponding to, for any v in the component, the vector assigned to v, the vector assigned to the global ancilla vertex, and the two vectors that can share a maximal tetrahedron with those two).

Finally, when the two largest entries of W are equal but distinct from the third, we combine the two previous approaches. Inserting star gadgets effectively reduces the problem from three dimensions to two, by penalizing vector assignments not in the 2d space corresponding to the two largest entries of W. We then add 3-clique gadgets, with one ancilla for each edge in G, and optimizing these over two dimensions corresponds to inscribing maximal perimeter triangles in the unit circle. Now, assigning a vector to one vertex fixes the optimal vectors assigned to the other two vertices (again up to swapping them) and so there is again a one-to-one correspondence between vector assignments simultaneously optimizing every clique gadget and 3-colorings of the connected components of G.

Three-Dimensional Vector Max-Cut

Our proof that MC_k with positive unit weights is NP-complete runs on very similar lines to our 3-Coloring reduction for $\mathrm{MC}^{\mathrm{L}}_W$ with all weights equal. However, there is one additional complication: that proof depended on the fact that the sum of the side lengths of the tetrahedron is uniquely maximized by choosing it to be regular. This is not the case when we instead consider the squared side lengths, for instance assigning half the vectors to one pole of the sphere and half to the other would achieve the same bound. So we use a different gadget: instead of replacing every edge with a 4-clique, we replace every edge with a 4-clique that in turn has its edges replaced with triangles. It turns out that this gadget *does* have a unique optimal MC_k assignment, which in particular assigns the vectors in the 4-clique to a regular tetrahedron, allowing us to proceed along the same lines as the aforementioned proof.

1.3 Related Work

Brandão and Harrow [4] give simple conditions under which 2-local Hamiltonians have product states achieving near-optimal energy, such as systems with high-degree interaction graphs. This suggests that unless NP = QMA, such Hamiltonians cannot be QMA-complete. Since then, there has been a line of work on the relationship between product states and general ground states in other Hamiltonians, in the more general case when the two problems are not equivalent. See e.g. [5, 17, 20].

Product states have especially been studied in the context of the Quantum Max-Cut problem, introduced by Gharibian and Parekh [18]. Briët, de Oliveira Filho, and Vallentin [8] give hardness results conditional on the unique games conjecture for approximating the optimal product state in the QMC model. Related work by Hwang, Neeman, Parekh, Thompson, and Wright [22] also gives tight hardness results for the QMC problem under a plausible conjecture. Parekh and Thompson [32] give an optimal approximation algorithm for QMC when using product states.

See [22] for an exposition of the relationship between QMC restricted to product state solutions and the Vector Max-Cut problem. Studying vector solutions to Max-Cut has a long history [29], including the seminal Goemans-Williamson algorithm [19]. This study is usually with the goal of a solution to the original Max-Cut problem, which relates to approximation ratios of integer and semidefinite programs. Bounding these ratios has been referred to in terms of Grothendieck problems and inequalities: see [7, 2] for further context on this nomenclature. A tight NP-hardness result is known for the non-commutative Grothendieck problem [9] which also generalizes the "little" Grothendieck problem over orthogonal groups [2]. Iterative algorithms (heuristics) for solving MC_k are also well-studied in the literature (see [11] and citing references), since in practice solving MC_k is often faster than solving the corresponding SDP relaxation.

Cubitt and Montanaro [14] classified $\mathcal{S}$-LH for sets $\mathcal{S}$ of 2-qubit terms. This work relies in turn on the work of Bravyi and Hastings [6] to classify the StoqMA case. [14] also examined a variant where $\mathcal{S}$ is assumed to always contain arbitrary single-qubit terms. Follow-up work by Piddock and Montanaro [33] began investigating classifying the complexity of $\mathcal{S}$-LH under the additional restrictions of positive weights (anti-ferromagnetic model) and/or interactions restricted to a spatial geometry such as a 2D grid. [15, 34] continued along these lines, and introduced Hamiltonian simulations rather than computational reductions.

In classical computer science, Schaefer [35] gave a dichotomy theorem showing that given a fixed set of allowed constraints, the family of CSPs is either decidable in P or is NP-complete; but see Section 2 or [14] for some important assumptions that are made in the

quantum versus classical models. In fact, Schaefer's classification offers a more fine-grained classification with classes within P. Later, [12, 25] gave a similar dichotomy theorem for the complexity of Max-SAT and related optimization problems, where the question is not just whether all clauses are simultaneously satisfiable but how many are simultaneously satisfiable. Applying weights to constraints becomes relevant with Max-SAT, and is covered in their work. This work is especially relevant given k-LH is more analogous to Max-SAT than to SAT. Continuing, Jonsson [23] classified these problems when both positive and negative weights are allowed. While arbitrary weights seem natural in the quantum setting, previous classical work simply assumed all weights were non-negative. The book [13] offers an excellent survey of this area. The more recent results of [24, 36] extend classical classification results to problems with non-binary variables (analogous to qu*d*its).

1.4 Open Questions

1. We have shown a relationship between when product state problems and general Hamiltonian problems are hard. This points toward an important question: can some "interesting" class of local Hamiltonians or a Hamiltonian problem for which we do not know an explicit efficient algorithm be proven *not* hard, e.g. neither NP- nor QMA-hard, by showing the corresponding product state problem is in P?
2. Is a more refined classification of the complexity of product state problems, taking into account allowable weights or spatial geometry in the vein of [33], or imposing other promises, possible?
3. While little progress has been made classifying the general $\mathcal{S}$-LH problem for higher-locality families, can we classify $\mathcal{S}$-prodLH for families of k-local Hamiltonians with $k > 2$?
4. Can we relate approximability instead of just complexity? For example, does the ability to α-approximate the product state problem imply the ability to β-approximate the general ground state problem on families defined by some sets of allowed interactions but not others?
5. As mentioned above, we make the first progress towards a conjecture of Lovász [29] that MC_k is NP-hard for any $k = O(1)$. We only focus on $k = 3$ here because of our interest in prodLH. Can our proof be generalized to other values of k?

2 Preliminaries

We assume familiarity with the conventions of quantum computation [38] and complexity theory [1, 26]. See also [16, 14] for surveys of Hamiltonian complexity.

2.1 Notation

I denotes the identity operator. $\lambda_{\min}(H)$ and $\lambda_{\max}(H)$ denote the minimum and maximum eigenvalues of an operator H. In the same manner as with asymptotic $\mathrm{O}(\cdot)$ notation, we use $\mathrm{poly}(n)$ to denote a term that can be bounded by some fixed polynomial in n.

For an operator A, we use superscripts such as A^{abc} to indicate A acts on individual qubits a, b, and c. Unless A is symmetric, the order matters and A^{ab} is different than A^{ba}. If no superscripts are used, then the action is implicit in the ordering of the terms (left versus right).

When clear from context, we will denote the tensor product of two operators $A \otimes B$ simply by AB. All terms implicitly are tensor the identity on any systems not specified.

SWAP will denote the 2-qubit operator exchanging $|01\rangle$ and $|10\rangle$ while $|00\rangle$ and $|11\rangle$ unchanged. We call a 2-qubit term H *symmetric* if $H = \mathrm{SWAP}(H)\,\mathrm{SWAP}$, meaning the ordering of the qubits does not matter. Alternatively, H is *antisymmetric* if $H = -\mathrm{SWAP}(H)\,\mathrm{SWAP}$.

The single-qubit Pauli matrices are denoted X, Y, Z or $\sigma_1, \sigma_2, \sigma_3$. Recall that $\{X, Y, Z, I\}$ is a basis for 2×2 Hermitian matrices. The *Pauli decomposition* of a 2-qubit Hermitian matrix H is H written in the Pauli basis,

$$H = \sum_{i,j=1}^{3} M_{ij}\sigma_i\sigma_j + \sum_{k=1}^{3}(v_k\sigma_k I + w_k I\sigma_k), \tag{5}$$

with all coefficients real and the 3×3 matrix M referred to as the *correlation matrix*. Generally, Equation (5) should include a term wII, but we will work with traceless terms such that $w = 0$.

Unless otherwise stated, all graphs are undirected and simple, meaning there are no self-loops and no multi-edges. We assume all graphs are connected, as it is straightforward to extend any of our constructions to disconnected graphs. When summing over edges, $\sum_{ij\in E}$, we do not double-count ij and ji. Finally, $S^i = \{x \in \mathbb{R}^{i+1} : \|x\| = 1\}$ denotes the unit sphere in $(i+1)$-dimensional space.

2.2 Definitions and Assumptions

A k-local Hamiltonian on n qubits is a Hermitian matrix $H \in \mathbb{R}^{2^n \times 2^n}$ that can be written as $H = \sum_{i=1}^{m} H_i$ such that each H_i is Hermitian and acts non-trivially on at most k qubits. More precisely, each H_i acts on some subset S_i of at most k qubits and each term in the sum is $H_i \otimes I^{[n]\setminus S_i}$, but we generally leave this implicit. We usually consider constant values of k, so each term is of constant size independent of n. The k-qubit terms H_i are often referred to as *interactions* between qubits. We may refer to eigenvalues and expectation values $\langle\psi| H |\psi\rangle$ as the *energy* of the state $|\psi\rangle$ in the system described by H. In particular, the *ground state energy* and *ground state* refer to the minimum eigenvalue and an associated eigenvector.

Estimating the minimum eigenvalue of a Hamiltonian is a natural quantum generalization of estimating the maximum number of satisfiable clauses in a Boolean formula.

▶ **Definition 7** (k-LH). *Given a k-local Hamiltonian $H = \sum_{i=1}^{m} H_i$ acting on n qubits with $m = \mathrm{poly}(n)$, the entries of each H_i specified by at most $\mathrm{poly}(n)$ bits, and the norms $\|H_i\|$ polynomially bounded in n, and two real parameters b, a such that $b - a \geq 1/\mathrm{poly}(n)$, decide whether $\lambda_{\min}(H)$ is at most a (YES) or at least b (NO), promised that one is the case.*

In this work, we are interested in k-LH restricted to families of local Hamiltonians, where the families are determined by sets of allowed interactions. In particular, we will be interested in sets of 2-qubit interactions.

▶ **Definition 8** ($\mathcal{S}$-LH). *For $\mathcal{S}$ any fixed set of Hamiltonian terms, define $\mathcal{S}$-LH as the problem k-LH with the additional promise that any input is of the form $\sum_{i=1}^{m} w_i H_i$ where each H_i is an element of $\mathcal{S}$ assigned to act on some subset of qubits and the* weights $w_i \in \mathbb{R}$ *have magnitude polynomially-bounded in n.*

▶ Remark 9. There are several standard assumptions implicit in our definition of $\mathcal{S}$-LH. Some are not physically realistic in the context of the condensed-matter literature but allow us to precisely characterize the complexity of these problems. First, although classical CSPs generally allow a constraint to take as input multiple copies of the same variable, this makes

less sense in the quantum setting and we do not allow it. Second, the definition of k-local only restricts the dimension of each term, it does not imply any spatial locality or geometry. Therefore, any term in H may be applied to any subset of qubits with the qubits arranged in any order. In particular this means that, if $\mathcal{S}$ contains a directed term H^{ab}, then the family of Hamiltonians allowed as input to $\mathcal{S}$-LH is equivalent to the family allowed to $\mathcal{S}'$-LH for $\mathcal{S}' = \mathcal{S} \cup \{H^{ba}\}$. Third, for the purpose of classifying the complexity of $\mathcal{S}$-LH, we may assume $I \in \mathcal{S}$, since adding or removing a term wI is equivalent to simply shifting the input parameters a, b by w. For $\mathcal{S}$ containing 2-qubit terms, this fact also implies we may assume all terms in $\mathcal{S}$ are traceless. Fourth, except when noted, we allow both positive and negative weights.

Classifying the complexity of systems under additional, more physically natural restrictions appears to be a significantly more difficult problem [14, 33].

Given this setup, our interest will be in the problems k-LH and $\mathcal{S}$-LH restricted to product states.

▶ **Definition 10** (Product state). *A state $\rho = \bigotimes_{i=1}^{n} \rho^i$ where each ρ^i is a single-qubit state.*

▶ **Definition 11** (PRODLH). *Given a k-local Hamiltonian $H = \sum_{i=1}^{m} H_i$ on n qubits with $m = \text{poly}(n)$, the entries of each H_i specified by at most $\text{poly}(n)$ bits, and the norms $\|H_i\|$ polynomially bounded in n, and two real parameters $b \geq a$, decide whether there exists a product state ρ with $\text{tr}(\rho H) \leq a$ (YES) or all product states satisfy $\text{tr}(\rho H) \geq b$ (NO), promised that one is the case.*

The problem $\mathcal{S}$-PRODLH is defined analogously. In both definitions, the fact that product states have concise classical descriptions allows us to naturally consider any choice of parameters, even an exact decision problem with $b = a$, in contrast to k-LH.

By convexity, a product state ρ achieves an extreme value of $\text{tr}(\rho H)$ if and only if there exists a pure product state $|\psi\rangle$ which achieves that value. Similarly, mixtures of product states, known as separable states, reduce to considering pure product states.

▶ Remark 12. In the context of $\mathcal{S}$-LH or $\mathcal{S}$-PRODLH given some fixed set S, we will describe $\mathcal{S}$ as "containing" a Hamiltonian term H, or that we "have access to" H, even when formally $H \notin \mathcal{S}$. As previously referenced in Remark 9, given a set $\mathcal{S}$, the family of Hamiltonians allowed as input to $\mathcal{S}$-LH may be equivalent to the family allowed given some other set $\mathcal{S}'$. For example, $\mathcal{S}'$ may include $\{PHP^\dagger\}$ for $H \in \mathcal{S}$ and any permutation of the qubits P. Similarly, adding constant multiples of the terms in $\mathcal{S}$ or any linear combinations of terms from $\mathcal{S}$ does not change the family of allowed Hamiltonians. So, when discussing $\mathcal{S}$-LH, we may implicitly refer to elements of the largest set $\mathcal{S}'$ such that $\mathcal{S}$-LH and $\mathcal{S}'$-LH each have the same family of allowed inputs.

Additionally, we note that $\mathcal{S}$-LH is reducible to $\mathcal{S}'$-LH for any $\mathcal{S}'$ which can be used to implement all elements of $\mathcal{S}$ – whether because formally $\mathcal{S} \subseteq \mathcal{S}'$ or through other means. In the opposite direction, if the terms in a set $\mathcal{S}$ can be used to construct some term H and we wish to show hardness of $\mathcal{S}$-LH, then it is sufficient to show hardness of $\{H\}$-LH.

Finally, for a 2-local Hamiltonian, we may refer to the *interaction graph*, with vertices associated with each qubit such that vertex i is adjacent to vertex j whenever a nonzero interaction exists on qubits i and j. When all interactions are symmetric, then the graph is undirected. Notably, when $\mathcal{S}$-LH is defined with $\mathcal{S}$ a singleton, then an input is fully specified by its weighted interaction graph.

3 Classification of $\mathcal{S}$-prodLH

In this section, we prove a dichotomy theorem classifying the complexity of estimating the minimum expectation of product states for given families of 2-local Hamiltonians. In particular, we show that for any set $\mathcal{S}$ of 2-qubit terms such that at least one term is not 1-local,[4] the problem $\mathcal{S}$-prodLH is NP-complete. These are precisely those 2-local families such that (as shown in [14]) $\mathcal{S}$-LH is QMA-, StoqMA-, or NP-complete. Conversely, if all terms are 1-local, then both $\mathcal{S}$-LH and $\mathcal{S}$-prodLH are in P.

▶ **Theorem 1.** *For any fixed set of 2-qubit Hamiltonian terms $\mathcal{S}$, if every matrix in $\mathcal{S}$ is 1-local then $\mathcal{S}$-prodLH is in P, and otherwise $\mathcal{S}$-prodLH is NP-complete.*

Our NP-hardness results hold with coupling strengths of at most constant magnitude.

For comparison with our classification, we recall the tetrachotomy theorem of Cubitt and Montanaro [14] classifying $\mathcal{S}$-LH for families of 2-local Hamiltonians. They proved that for every set of 2-qubit Hamiltonian terms $\mathcal{S}$, the problem $\mathcal{S}$-LH is either in P or NP-, StoqMA-, or QMA-complete, and described properties of the set $\mathcal{S}$ which determine the problem's complexity. We note that both Theorem 13 and our Theorem 1 classify the complexity of *all* sets of 2-qubit terms.

▶ **Theorem 13** (Theorem 7 of [14])**.** *For $\mathcal{S}$ any fixed set of 2-qubit Hamiltonian terms:*

- *If every matrix in $\mathcal{S}$ is 1-local, then $\mathcal{S}$-LH is in P.*
- *Otherwise, if there exists a single-qubit unitary U such that U locally diagonalizes all elements of $\mathcal{S}$ (i.e. $U^{\otimes 2} H U^{\dagger \otimes 2}$ is diagonal for each 2-qubit $H \in \mathcal{S}$), then $\mathcal{S}$-LH is NP-complete.*
- *Otherwise, if there exists a single-qubit unitary U such that for each 2-qubit $H \in \mathcal{S}$,*

$$U^{\otimes 2} H U^{\dagger \otimes 2} = \alpha Z^{\otimes 2} + A \otimes I + I \otimes B$$

for some $\alpha \in \mathbb{R}$ and 1-local Hermitian matrices A, B, then $\mathcal{S}$-LH is StoqMA-complete.

- *Otherwise, $\mathcal{S}$-LH is QMA-complete.*

Combining our classification of $\mathcal{S}$-prodLH with the classification of $\mathcal{S}$-LH gives us Corollaries 2 and 3.

To prove Theorem 1, showing containment in P and NP are straightforward, and our effort is to prove NP-hardness. In the proof, we will use a simple symmetrization trick that allows us to consider only antisymmetric or symmetric Hamiltonian terms. We then prove two lemmas, one for each case.

▶ **Lemma 14.** *If $\mathcal{S}$ contains a 2-qubit antisymmetric term that is not 1-local, then $\mathrm{MC}^{\mathrm{L}}_W$ with $W = \mathrm{diag}(1, 1, 0)$ is polynomial-time reducible to $\mathcal{S}$-prodLH.*

▶ **Lemma 15.** *If $\mathcal{S}$ contains a 2-qubit symmetric term that is not 1-local, then there exists a fixed non-negative $W = \mathrm{diag}(\alpha, \beta, \gamma)$ with at least one of α, β, γ nonzero such that $\mathrm{MC}^{\mathrm{L}}_W$ is polynomial-time reducible to $\mathcal{S}$-prodLH.*

In Section 4 we prove Theorem 4, that $\mathrm{MC}^{\mathrm{L}}_W$ is NP-complete for any $W = \mathrm{diag}(\alpha, \beta, \gamma)$ that is nonzero and non-negative.

We state some helpful facts in Section 3.1 below and then prove the two lemmas in Section 3.2. We will now use these lemmas to prove our main theorem.

[4] We would prefer a more concise name for 2-qubit terms that are not 1-local, but are unaware of any. One option is 2-qubit terms with *Pauli degree* 2. Alternatively, these are 2-qubit terms which have nonzero *Pauli rank*, referring to the rank of the correlation matrix M in the Pauli decomposition (Equation (5)).

Proof of Theorem 1. First consider the case where $\mathcal{S}$ only contains 1-local terms. Then we can write $H = \sum_i H_i$, where H_i acts only on the i^{th} qubit. If $|\psi_i\rangle$ is the single-qubit state minimizing $\langle\psi_i|H_i|\psi_i\rangle$, then $|\psi\rangle = \bigotimes_i |\psi_i\rangle$ minimizes $\langle\psi|H|\psi\rangle$, and so $\mathcal{S}$-prodLH can be solved by finding the ground state of n single-qubit Hamiltonians, which takes $O(n)$ time.

Now suppose $\mathcal{S}$ is a set of of 2-qubit Hamiltonian terms such that at least one element of $\mathcal{S}$ is not 1-local. Let H be any such element. As previously mentioned, $\mathcal{S}$-prodLH $\in$ NP for any fixed $\mathcal{S}$, as product states have concise classical descriptions which can be used to efficiently calculate expectation values for a given local Hamiltonian. If H is antisymmetric, then MC^{L}_W with fixed $W = \text{diag}(1, 1, 0)$ is reducible to $\mathcal{S}$-prodLH by Lemma 14, and MC^{L}_W with such a W is NP-hard by Theorem 4, so $\mathcal{S}$-prodLH is NP-complete. If H is symmetric, then by Lemma 15 there exists a non-negative nonzero matrix $W = \text{diag}(\alpha, \beta, \gamma)$ such that MC^{L}_W is reducible to $\mathcal{S}$-prodLH, it is NP-hard by Theorem 4, and so $\mathcal{S}$-prodLH is NP-complete. If H is neither of these, then we use our freedom to permute the direction H is applied to any pair of qubits a, b to apply both H^{ab} and H^{ba}, which is equivalent to implementing the symmetric term $H' = H + \text{SWAP}\,(H)\,\text{SWAP}$. So, we can say $\mathcal{S}$ effectively contains H', or formally that hardness of $\{H'\}$-prodLH implies hardness of $\mathcal{S}$-prodLH, and again referring to Lemma 15 concludes the proof. ◀

3.1 Closure Properties of $\mathcal{S}$-prodLH

Before proving the two lemmas required in the proof of Theorem 1, we review several more facts regarding 2-qubit Hamiltonian terms and operations under which the complexities of $\mathcal{S}$-LH and $\mathcal{S}$-prodLH are unaffected. This section mostly reviews observations made in [14].

First, for a single-qubit unitary U and an operator H, define *simultaneous conjugation* by U to mean $U^{\otimes n} H U^{\dagger \otimes n}$. When discussing sets $\mathcal{S}$ of k-qubit terms, we define simultaneous conjugation to mean $\{U^{\otimes k} H U^{\dagger \otimes k} | H \in \mathcal{S}\}$.

▶ **Fact 16.** *For any single-qubit unitary U, the complexities of $\mathcal{S}$-LH and $\mathcal{S}$-prodLH are equal to the complexities of $\mathcal{S}'$-LH and $\mathcal{S}'$-prodLH, respectively, where $\mathcal{S}'$ is $\mathcal{S}$ simultaneously conjugated by U.*

Observe that $U^{\otimes n} \left(\sum_{i=1}^m H_i\right) U^{\dagger \otimes n} = \sum_{i=1}^m U^{\otimes k} H_i U^{\dagger \otimes k}$. Simultaneous conjugation by U gives a bijection between Hamiltonians allowed in $\mathcal{S}$-LH and $\mathcal{S}'$-LH as well as $\mathcal{S}$-prodLH and $\mathcal{S}'$-prodLH. The above fact follows from observing that this bijection preserves expectation values, and that $U^{\otimes n} |\phi\rangle$ is a product state iff $|\phi\rangle$ is.

As an application of Fact 16, the following is based on an observation in [14].

▶ **Fact 17.** *For any choice of permutation π on $\{1, 2, 3\}$ and any choice of* two *of $c_1, c_2, c_3 = \pm 1$, there exists a single-qubit unitary U and corresponding third coefficient s.t. simultaneous conjugation by U maps the Pauli matrices $\{\sigma_1, \sigma_2, \sigma_3\}$ to $\{c_{\pi(1)}\sigma_{\pi(1)}, c_{\pi(2)}\sigma_{\pi(2)}, c_{\pi(3)}\sigma_{\pi(3)}\}$. So, writing every element of $\mathcal{S}$ in the Pauli basis, relabeling all σ_i with $c_{\pi(i)}\sigma_{\pi(i)}$ in the decompositions of each element of $\mathcal{S}$ does not change the complexity of $\mathcal{S}$-LH or $\mathcal{S}$-prodLH, where π and two of the coefficients can be chosen arbitrarily.*

To justify the above fact, consider simultaneously rotating the three axes of the Bloch sphere. Next, we quote the following, more involved, fact without proof.

▶ **Fact 18** ([14, 21]). *Let H be a 2-qubit Hamiltonian term with Pauli decomposition $H = \sum_{i,j=1}^{3} M_{ij}\sigma_i\sigma_j + \sum_{k=1}^{3}(v_k\sigma_k I + w_k I\sigma_k)$. For any single-qubit unitary U,*

$$U^{\otimes 2}H(U^\dagger)^{\otimes 2} = \sum_{i,j=1}^{3}(RMR^T)_{ij}\sigma_i\sigma_j + \sum_{k=1}^{3}((Rv)_k\sigma_k I + (Rw)_k I\sigma_k) \tag{6}$$

for some $R \in SO(3)$. Likewise, for any $R \in SO(3)$, there exists a single-qubit U such that the Pauli decomposition of $U^{\otimes 2}H(U^\dagger)^{\otimes 2}$ matches Equation (6).

A further straightforward observation from [14] is that in the Pauli decomposition (Equation (5)), if H is symmetric then the correlation matrix M is symmetric, and if H is antisymmetric then M is skewsymmetric, meaning $M = -M^\top$.

Finally, the below observation combines some of the above facts to establish a "normal form" for symmetric and antisymmetric terms.

▶ **Fact 19.** *If a 2-qubit Hamiltonian term H is symmetric, and so the associated correlation matrix M is symmetric, there exists $R \in SO(3)$ which diagonalizes M. Combining Facts 16 and 18, for any 2-qubit symmetric term H, there exists a symmetric term of the form $H' = \sum_{i=1}^{3} u_i\sigma_i\sigma_i + \sum_{j=1}^{3} v_j(\sigma_j I + I\sigma_j)$ such that the complexities of $\{H\}$-LH and $\{H\}$-prodLH are respectively the same as $\{H'\}$-LH and $\{H'\}$-prodLH.*

If H is a 2-qubit antisymmetric term that is not 1-local, then M is skewsymmetric and nonzero. Such an M may be block diagonalized via some $R \in SO(3)$ such that H is mapped to $a(\sigma_i\sigma_j - \sigma_j\sigma_i) + \sum_{k=1}^{3} v_k(\sigma_k I - I\sigma_k)$ [37, 14]. In particular, by Fact 17, H can be mapped to $a(XZ - ZX) + \sum_{k=1}^{3} v'_k(\sigma_k I - I\sigma_k)$. Therefore, the complexities of $\{H\}$-LH and $\{H\}$-prodLH are unaffected by assuming H has this form.

3.2 Proofs of Antisymmetric and Symmetric Lemmas

We now prove the two lemmas required in the proof of the main theorem, respectively handling the cases that $\mathcal{S}$ contains an antisymmetric term and that $\mathcal{S}$ contains a symmetric term. In both cases, it is sufficient for $\mathcal{S}$ to contain just a single term. Interestingly, our construction in Lemma 14 for antisymmetric terms is unweighted, meaning all weights are $+1$. In this case, the final Hamiltonian is fully determined by the specification of a single 2-qubit term and the interaction graph. Our construction in Lemma 15 uses positive and negative unit weights, ± 1. Intuitively, antisymmetric terms inherently allow negativity by simply permuting the qubits they act on, while for symmetric terms we must use negative weights.

Proof of Lemma 14. Consider an arbitrary instance of the problem $\mathrm{MC}^{\mathrm{L}}_W$ with $W = \mathrm{diag}(1, 1, 0)$. For a given graph $G = (V, E)$, the objective function is

$$\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}(G) = \frac{1}{2}\max_{i\in S^2}\sum_{ij\in E}\|W\hat{\imath} - W\hat{\jmath}\|.$$

Given a parameter C, we must decide whether $\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}(G)$ is at least C or at most $C - \varepsilon$. To reduce $\mathrm{MC}^{\mathrm{L}}_W$ to $\mathcal{S}$-prodLH, we first construct a gadget using the promised antisymmetric term. Then, we apply this gadget according to the graph G such that the minimum energy of a product state in our final Hamiltonian will equal $-\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}(G)$.

Denote the assumed 2-qubit antisymmetric term that is not 1-local in $\mathcal{S}$ by H. By Fact 18, our antisymmetric term H may be mapped to a term of the form

$$w\left(X^aZ^b - Z^aX^b\right) + \sum_{k=1}^{3} v_k\left(\sigma_k^a I^b - I^a\sigma_k^b\right)$$

where all coefficients are real, and we have $w \neq 0$ since the term is not 1-local. As explained in Remark 12 and Section 3.1, the complexity of $\{H\}$-PRODLH is equivalent to that of $\{H'\}$-PRODLH for H' derived using a variety of operations, including permutations and linear combinations. If w is negative, then we redefine the direction the term acts in, H^{ab} versus H^{ba}, so that w is positive. Finally, we scale[5] the term so that $w = 1$ and define a single-qubit Hermitian matrix $A = \sum_{k=1}^{3} v_k \sigma_k$. Given the complexity is unchanged using H or H', we simply redefine the original term, so that

$$H^{ab} = X^a Z^b - Z^a X^b + A^a I^b - I^a A^b.$$

Next, we use a symmetrization gadget to remove the 1-local terms $AI - IA$. For four qubits a, b, c, d, define

$$B = H^{ab} + H^{bc} + H^{cd} + H^{da}.$$

Note that here the direction of the interaction matters, since the terms are asymmetric. Then

$$B = (X^a - X^c)(Z^b - Z^d) - (Z^a - Z^c)(X^b - X^d).$$

Now we consider how B interacts with product states on four qubits. For $e = a, b, c, d$, define

$$\rho^e = \frac{1}{2}(I + r^e \cdot v^e)$$

with $v^e = (X^e, Y^e, Z^e)$ the Pauli operators and $r^e = (x^e, y^e, z^e)$ the Bloch vector. Then, writing any product state on qubits a, b, c, d as $\rho^a \rho^b \rho^c \rho^d$, the expectation value on B is $\operatorname{tr}\left(B \rho^a \rho^b \rho^c \rho^d\right)$. After eliminating terms, we find this equals

$$(r^a - r^c)^\top W' (r^b - r^d) \quad \text{for} \quad W' = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{bmatrix}.$$

It is helpful to note that $W'^\top = -W'$.

Now, consider the graph G given as input to $\mathrm{MC}^{\mathrm{L}}_W$. Associate a qubit with each vertex and call these the "vertex qubits". For each edge ij, construct a copy of B such that it acts on qubits ij and two ancilla qubits. The vertex qubits may be shared among several gadgets, while the ancilla qubits are part of only one gadget. In particular, we choose to associate the vertex qubits with qubits a and c in each copy of B, letting b and d be the ancilla. We will refer to the copy of B which acts on vertex qubits i and j as B^{ij}. Our Hamiltonian is then

$$H_{\text{final}} = \sum_{ij \in E} B^{ij}.$$

Before analyzing the full Hamiltonian H_{final}, consider the minimum expectation of a single gadget B^{ij} if the two vertex qubits are fixed, i.e. $\min_{r^b, r^d} (r^i - r^j)^\top W' (r^b - r^d)$. The minimum is achieved when $r^b = -W'^\top (r^i - r^j) / \left\| W'^\top (r^i - r^j) \right\|$ and $r^d = -r^b$, which yields an expectation of

$$-2 \left\| W'' (r^i - r^j) \right\| \quad \text{for} \quad W'' = \operatorname{diag}(1, 0, 1).$$

[5] If we want the terms to have unit weights, we could forgo scaling the term and reduce to $w\,\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}$ instead. As $w > 0$ this problem has the same complexity as $\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}$.

Therefore, given an arbitrary graph $G = (V, E)$, applying our gadget to every edge constructs a Hamiltonian such that the minimum expectation of any product state is equal to

$$2 \min_{r^i \in S^2} \sum_{ij \in E} -\left\|W''(r^i - r^j)\right\| = -2 \max_{r^i \in S^2} \sum_{ij \in E} \left\|W''(r^i - r^j)\right\|.$$

For any graph G, the objective $\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}(G)$ is equal for $W = \mathrm{diag}(1, 1, 0)$ and $W'' = \mathrm{diag}(1, 0, 1)$. Alternatively, we may use our freedom to relabel Paulis to redefine the 2-qubit term H such that the final weight matrix is W.

Finally, multiplying the full Hamiltonian H_{final} by $\frac{1}{2}$ gives us that the minimum expectation of any product state equals

$$-\max_{r^i \in S^2} \sum_{ij \in E} \left\|W(r^i - r^j)\right\| = -\,\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}(G).$$

We conclude deciding $\mathrm{MC}^{\mathrm{L}}_{W}$ reduces to deciding PRODLH on H_{final}. Since H_{final} is entirely constructed from the antisymmetric term $H \in \mathcal{S}$, this completes the desired reduction of $\mathrm{MC}^{\mathrm{L}}_{W}$ with $W = \mathrm{diag}(1, 1, 0)$ to $\mathcal{S}$-PRODLH. ◀

Next we prove the lemma dealing with $\mathcal{S}$ containing a symmetric term. The construction is nearly the same as the in the previous proof, but requires negative weights to implement the symmetrization gadget removing 1-local terms.

Proof of Lemma 15. Given fixed $\mathcal{S}$, we will show there exists some fixed W such that $\mathrm{MC}^{\mathrm{L}}_{W}$ reduces to $\mathcal{S}$-LH. But, before describing W, we must analyze $\mathcal{S}$.

Denote the assumed 2-qubit symmetric term that is not 1-local in $\mathcal{S}$ by H. As in the previous proof, without changing the complexity of $\{H\}$-PRODLH we may conjugate and scale as necessary so that

$$H^{ab} = \alpha^- X^a X^b + \beta^- Y^a Y^b + \gamma^- Z^a Z^b + \sum_{j=1}^{3} v_j(\sigma_j^a I^b + I^a \sigma_j^b),$$

where all coefficients are real and at least one of $\alpha^-, \beta^-, \gamma^-$ is nonzero since H is nonzero. The superscripts in the above equations are to differentiate the coefficients of H from the entries of W, which must be non-negative.

We again use a symmetrization gadget to remove the 1-local terms, but now require negative weights. Given four qubits a, b, c, d, define $B = H^{ab} + H^{cd} - H^{bd} - H^{ac}$. This is a rectangle with two positive edges and two negative edges. Then

$$B = \alpha(X^a - X^d)(X^b - X^c) + \beta(Y^a - Y^d)(Y^b - Y^c) + \gamma(Z^a - Z^d)(Z^b - Z^c).$$

Now we see how B interacts with product states on four qubits. For $e = a, b, c, d$, we again define $\rho^e = \frac{1}{2}(I + r^e \cdot v^e)$ with $v^e = (X^e, Y^e, Z^e)$ and $r^e = (x^e, y^e, z^e)$. Then, writing any product state on a, b, c, d as $\rho^a \rho^b \rho^c \rho^d$, the expectation value on B is $\mathrm{tr}\left[B \rho^a \rho^b \rho^c \rho^d\right]$, which equals

$$\alpha^-(x^a - x^d)(x^b - x^c) + \beta^-(y^a - y^d)(y^b - y^c) + \gamma^-(z^a - z^d)(z^b - z^c)$$

which is in turn equal to

$$\left(r^b - r^c\right)^\top W' \left(r^a - r^d\right) \quad \text{for} \quad W' = \mathrm{diag}\left(\alpha^-, \beta^-, \gamma^-\right).$$

If we fix the state of qubits a and d and minimize the expectation on B, the minimum is achieved when $r^b = -W'(r^a - r^d)/\|W'(r^a - r^d)\|$ and $r^c = -r^b$. This minimum expectation is $-2\|W'(r^a - r^d)\|$. Observe this expectation value is equivalent to $-2\|W(r^a - r^d)\|$ for $W = \mathrm{diag}(\alpha, \beta, \gamma)$ where $\alpha = |\alpha^-|, \beta = |\beta^-|, \gamma = |\gamma^-|$.

Now we are prepared to set up our reduction. For $W = \mathrm{diag}(\alpha, \beta, \gamma)$, which is non-negative and nonzero, consider an arbitrary instance of $\mathrm{MC}^{\mathrm{L}}_W$. For a given graph $G = (V, E)$, the objective function is again $\mathrm{MC}^{\mathrm{L}}_W(G)$, and given a parameter C, we must decide whether $\mathrm{MC}^{\mathrm{L}}_W(G)$ is at least C or at most $C - \varepsilon$.

Associate a "vertex qubit" with each vertex and construct a copy of the gadget B for each edge ij, such that it acts on i, j and two ancilla qubits, and denote it B^{ij}. The vertex qubits may be shared among several gadgets, while the ancilla qubits are part of only one gadget. In particular, we choose a and d in each gadget to be the vertex qubits.

Substituting our gadget for every edge constructs a Hamiltonian H_{final} such that the minimum expectation of any product state is equal to

$$2 \min_{r^i \in S^2} \sum_{ij \in E} -\|Wr^i - Wr^j\| = -2 \max_{r^i \in S^2} \sum_{ij \in E} \|Wr^i - Wr^j\|.$$

Simply multiplying H_{final} by $\frac{1}{2}$ makes this equal to $-\mathrm{MC}^{\mathrm{L}}_W(G)$.

We conclude that given $\mathcal{S}$ contains a 2-qubit symmetric term H that is not 1-local, there exists some non-negative $W = \mathrm{diag}(\alpha, \beta, \gamma)$ with at least one nonzero entry such that $\mathrm{MC}^{\mathrm{L}}_W(G)$ reduces to $\textsc{prodlh}(H_{\text{final}})$. Since H_{final} was constructed using only the symmetric term $H \in \mathcal{S}$, this is also a reduction to an instance of $\mathcal{S}$-$\textsc{prodlh}$, as desired. ◀

4 The Stretched Linear Max-Cut Problem

We study a generalization of the classical Max-Cut problem which arises naturally from our study of product states and which is likely of independent interest. Both Max-Cut and its generalization

$$\mathrm{MC}_k(G) = \frac{1}{2} \max_{\hat{\imath} \in S^{k-1}} \sum_{ij \in E} 1 - \hat{\imath} \cdot \hat{\jmath} = \frac{1}{4} \max_{\hat{\imath} \in S^{k-1}} \sum_{ij \in E} \|\hat{\imath} - \hat{\jmath}\|^2$$

were introduced in Section 1. As the above equation emphasizes, maximizing the distance between vectors is equivalent to maximizing the angle, optimally being anti-parallel.

Our new problem is defined with two significant changes. First, the sum is over distances rather than squared distances. Second, the distances are allowed to incorporate a linear stretch.

▶ **Definition 20** (W-linear-Max-Cut ($\mathrm{MC}^{\mathrm{L}}_W$)). *For a fixed $d \times d$ diagonal matrix W, given an n-vertex graph $G = (V, E)$ and thresholds $b > a \geq 0$ with $b - a \geq 1/\mathrm{poly}(n)$, decide whether*

$$\mathrm{MC}^{\mathrm{L}}_W(G) = \frac{1}{2} \max_{\hat{\imath} \in S^{d+1}} \sum_{ij \in E} \|W\hat{\imath} - W\hat{\jmath}\| = \frac{1}{2} \max_{\hat{\imath} \in S^{d+1}} \sum_{ij \in E} \sqrt{\|W\hat{\imath}\| + \|W\hat{\jmath}\| - 2(W\hat{\imath})^\top (W\hat{\jmath})}$$

is at least b or at most a.

A comparison of the geometric interpretations of MC_k and $\mathrm{MC}^{\mathrm{L}}_W$ was given in Section 1. A further interpretation comes from treating the edges of the graph as springs or rubber bands. As explored in [29], the potential energy of a spring is quadratic in its length, so the MC_k value represents the total potential energy of the system given a particular embedding. On

the other hand, the force or tension of each spring is linear in its length. So, $\mathrm{MC}^{\mathrm{L}}_W$ gives the total force, tension, or pressure such an arrangement of springs would apply to the surface of the sphere (or ellipsoid, more generally).

In both problems, the objective is a linear sum, of either the distances or the inner products. Both problems generalize the traditional Max-Cut problem, since when restricted to ± 1 labels, distances are directly proportional to squared distances. Previous work was likely motivated to focus on squared distances because approximation algorithms like SDPs naturally apply to inner products but not to square roots of inner products.

Our main theorem concerning W-linear-Max-Cut is the below.

▶ **Theorem 4.** *For any fixed non-negative $W = \mathrm{diag}(\alpha, \beta, \gamma)$ with at least one of α, β, γ nonzero, W-linear-Max-Cut is NP-complete.*

Our hardness proofs do not require any edge weights (unlike our Hamiltonian constructions in the previous section).

Containment in NP is immediate, and we break the proof of NP-hardness into three cases based on the entries of W. The three cases depend on how many entries of W are equal, requiring different approaches for dealing with degenerate solutions. We assume throughout that $1 = \alpha \geq \beta \geq \gamma$; as we show in the final proof of Theorem 4, this suffices by scaling and symmetry. Lemma 21 considers the case when all three entries are equal. Lemma 22 considers the case when the largest entry is unique. Lemma 23 finally considers the case when the two largest entries are equal and distinct from the third, combining techniques from the previous two proofs. Note that these cases are not entirely disjoint.

When $W = \mathrm{diag}(1, 1, 1)$, we prove hardness by reducing from the NP-complete 3-Coloring problem. We replace every edge in the graph with a 4-clique, or tetrahedron. To deal with the symmetry created by equally weighted axes, all of the gadgets are connected to a new *sink* vertex, removing a degree of freedom. We then argue that there is an assignment to the new graph that simultaneously (nearly) maximizes all of these cliques iff the original graph is 3-colorable.

▶ **Lemma 21.** *For $W = \mathrm{diag}(1, 1, 1)$, W-linear-Max-Cut is NP-hard.*

Proof. We will reduce from 3-Coloring. Consider an arbitrary graph $G = (V, E)$ on n vertices and m edges. We construct $H = (V', E')$ as follows: Start with G. For each edge $ij \in E$, add vertices k_{ij}, t_{ij} and connect i, j, k_{ij}, t_{ij} to form a 4-clique. Then add a *sink* vertex t and an edge tt_{ij} for each t_{ij}. H therefore consists of m edge-disjoint 4-cliques, each containing one edge from G, and m additional edges from vertices t_{ij} to t.

We claim that if G is 3-colorable, then $\mathrm{MC}^{\mathrm{L}}_W(H) \geq m\mathrm{MC}^{\mathrm{L}}_W(K_4) + m$. Conversely, we claim that if $\mathrm{MC}^{\mathrm{L}}_W(H) \geq m\mathrm{MC}^{\mathrm{L}}_W(K_4) + m - \varepsilon$, for an $\varepsilon = \Omega\big(1/m^2\big)$ we will choose later, then G is 3-colorable.

First, suppose G is 3-colorable. We will show how to derive a vector assignment to H attaining $m\mathrm{MC}^{\mathrm{L}}_W(K_4) + m$ from a 3-coloring of G. Define

$$\Delta_W(u, v, w, r) = \frac{1}{2} \sum_{ij \in \{uv, uw, ur, vw, vr, wr\}} \|Wi - Wj\|$$

Let u, v, w, r be vectors corresponding to a regular tetrahedron inscribed in the unit sphere, known to achieve the maximum perimeter of any inscribed tetrahedron at $4\sqrt{6}$ [30]. We 3-color G (and therefore the vertices of H other than $(k_{ij})_{ij \in E}$, $(t_{ij})_{ij \in E}$, and t) with u, v, w, assigning each vertex the vector matching its color. Then for each $ij \in E$, we assign k_{ij}

the vector in $\{u, v, w\}$ not assigned to i or j, and r to t_{ij}. Finally, we assign $-r$ to t. By construction, this assignment will yield a value of $\mathrm{MC}^{\mathrm{L}}_W(K_4)$ on each 4-clique gadget, and the edges tt_{ij} will each contribute exactly 1. Thus $\mathrm{MC}^{\mathrm{L}}_W(H) \geq m\mathrm{MC}^{\mathrm{L}}_W(K_4) + m$, as desired.

Now we will show the converse. Suppose there exists an assignment $(\hat{k})_{k\in V'}$ of vectors achieving greater than $m\mathrm{MC}^{\mathrm{L}}_W(K_4)+m-\varepsilon$ on H. We construct a 4-coloring of each connected component of $H \setminus \{t\}$ as follows: Choose an edge ij in the corresponding component of G (note that there is a 1-to-1 correspondence between components of G and $H \setminus \{t\}$). Let $\hat{\imath}, \hat{\jmath}, \hat{k}_{ij}, \hat{t}_{ij}$ be the vectors assigned to the vertices of the corresponding clique in H. Our coloring will use these four vectors as colors, which we denote as the set $\mathcal{C}$. We assign each vertex v the color corresponding to the element of $\mathcal{C}$ that is closest to the vector assigned to v in the $\mathrm{MC}^{\mathrm{L}}_W$ assignment. We will show that this is a proper coloring, and that it assigns the same color to every t_{ij}, and therefore gives a 3-coloring of G.

To show that this is a proper coloring, we need to show that every pair of adjacent vertices in $H \setminus \{t\}$ are assigned different colors, i.e. that the closest elements of $\mathcal{C}$ to the vectors assigned to them in the $\mathrm{MC}^{\mathrm{L}}_W$ assignment are distinct. As every edge in $H \setminus \{t\}$ is contained in some 4-clique corresponding to some edge xy of G, it will suffice to show the following: for every edge xy in the component of G containing ij, if d is the smallest number of edges in a path in G starting with ij and ending with xy, each of $\hat{x}$, $\hat{y}$, $\hat{k}_{xy}$ and $\hat{t}_{xy}$ is within $\mathrm{O}(d\sqrt{\varepsilon})$ of a *different* element of $\mathcal{C}$.

First we note that, as H consists of m edge-disjoint 4-cliques and m other edges, and the maximum any assignment can earn on an edge is 1, the lower bound on the total amount the assignment earns implies that every 4-clique earns at least $\mathrm{MC}^{\mathrm{L}}_W(K_4) - \varepsilon$ and the other edges $(t_{xy}t)_{xy\in E}$ earn at least $1-\varepsilon$ each. So by trigonometry we immediately have that every $\hat{t}_{xy}$ is within $\mathrm{O}(\sqrt{\varepsilon})$ of $-\hat{t}$, and therefore within $\mathrm{O}(\sqrt{\varepsilon})$ of each other, and $\hat{t}_{ij}$ in particular.

For the other vertices, we proceed by induction on d. We have the desired result trivially for $d = 1$, as in this case $ij = xy$. Now suppose it holds for d. Let xy be the end of a $(d+1)$-edge path starting with ij. Without loss of generality let y be the vertex of xy earlier in the path, and let z be the immediately prior vertex in the path, so by the inductive hypothesis $\hat{y}$, $\hat{z}$, $\hat{k}_{yz}$, and $\hat{t}_{yz}$ are within $\mathrm{O}(d\sqrt{\varepsilon})$ of different elements of $\mathcal{C}$. Furthermore, as both $\{\hat{x}, \hat{y}, \hat{k}_{xy}, \hat{t}_{xy}\}$ and $\{\hat{y}, \hat{z}, \hat{k}_{yz}, \hat{t}_{yz}\}$ are vertices of tetrahedra with perimeters at least $4\sqrt{6} - \varepsilon$, by Lemma 29 the edge lengths of these tetrahedra are all in the interval $[\frac{4\sqrt{6}}{6} - \mathrm{O}(\sqrt{\varepsilon}), \frac{4\sqrt{6}}{6} + \mathrm{O}(\sqrt{\varepsilon})]$. So as we have already shown that $\hat{t}_{yz}$, $\hat{t}_{xy}$, and $\hat{t}_{ij}$ are all within $\mathrm{O}(\sqrt{\varepsilon})$ of each other, then the criteria of Lemma 30 are satisfied with $ABCD = \hat{y}\hat{t}_{xy}\hat{x}\hat{k}_{xy}$ and $AEFG = \hat{y}\hat{t}_{yz}\hat{z}\hat{k}_{yz}$ and so $\hat{x}$ and $\hat{k}_{xy}$ are each within $\mathrm{O}(\sqrt{\varepsilon})$ of (different) elements of $\{\hat{z}, \hat{k}_{yz}\}$. So then the result follows by the triangle inequality.

We now have that every vertex in H is assigned a vector within $\mathrm{O}(m\sqrt{\varepsilon})$ of an element of $\mathcal{C}$, and so taking ε to be a sufficiently small constant times $1/m^2$, we can take these distances to be at most 0.1. Moreover, for any two adjacent vertices, the choice of color will be different, and so as by Lemma 29 the distances between these four vectors are at least $4/\sqrt{6} - \mathrm{O}(\varepsilon)$, this implies any two adjacent vertices are assigned different colors, and so we have a proper 4-coloring of $H \setminus \{t\}$. Finally, note that, as every $\hat{t}_{xy}$ is within $\mathrm{O}(\varepsilon)$ of every other one, this implies all the t_{xy} were assigned the same color, and so no vertex in G uses this color. So this gives us a proper 3-coloring of G. ◀

Next, in Lemma 22 we consider the case $W = \mathrm{diag}(1, \beta, \gamma)$ and $1 > \beta, \gamma \geq 0$, in which the maximum weight is unique. The approach in the proof of Lemma 21, reducing from 3-Coloring, can in fact be modified to cover this case, but analyzing triangles inscribed in ellipses instead of circles is more technical. Instead, we take a different approach and in the case of a unique maximum (whether β equals γ or not) give a reduction from Max-Cut instead of 3-Coloring.

We insert ancilla vertices so that every vertex in the original graph is the center of a large star. These star gadgets amplify any deviation from the highest-weight axis such that any near-optimal solution must approximate a standard 1-dimensional labeling, as in Max-Cut.

▶ **Lemma 22.** *For any* $W = \mathrm{diag}(1, \beta, \gamma)$ *with* $1 > \beta \geq \gamma \geq 0$, W-linear-Max-Cut *is* NP*-hard.*

Proof. We reduce from the standard NP-complete Max-Cut problem. For any graph $G = (V, E)$ with n vertices and m edges, we construct a graph $H = (V', E')$ with $V \subseteq V'$ and $E \subseteq E'$ by, for each $v \in V$, adding $K = m^3 n$ ancilla vertices v_i, and then adding an edge from each of these vertices to v so that v is the center of a K-star. Now $|V'| = n(1+K)$ and $|E'| = m + Kn$.

We claim that, for any $C > 1$ and for large enough n, $\mathrm{MC}(G) \geq C$ implies $\mathrm{MC}^{\mathrm{L}}_W(H) \geq C + Kn$ and $\mathrm{MC}^{\mathrm{L}}_W(H) > C + Kn - 1/2$ implies $\mathrm{MC}(G) \geq C$.

First, suppose there is a cut of G with value at least C. We construct a corresponding assignment of vectors to vertices in V'. First assign the vector $(1, 0, 0)$ to all vertices in V which are labeled $+1$ in G and $(-1, 0, 0)$ to those with labels -1. Then, for every vertex in $v \in V$, which by construction is at the center of a star of ancilla qubits in H, assign the vector opposite the one assigned to v to each of the ancilla vertices. This assignment of vectors gives an objective value of at least C on the edges from the original graph and Kn on the edges of the star gadgets, and so the $\mathrm{MC}^{\mathrm{L}}_W$ value of this assignment is $C + Kn$.

Now suppose there exists an assignment of vectors achieving $\mathrm{MC}^{\mathrm{L}}_W$ value greater than $C + Kn - 1$ on H. We will show that the cut given by $\mathrm{sgn}(\hat{v}_1)$ for each $v \in V$ (i.e. projecting $\hat{v}$ to the x-axis and checking whether it is ≥ 0 or < 0) has value at least C.

First, for each $v \in V$, let $\widehat{\mathrm{sgn}}(\hat{v}) = (\mathrm{sgn}(\hat{v}_1), 0, 0)$. We will show that this is close to $\widehat{v}$. Because the original graph can contribute at most m to the $\mathrm{MC}^{\mathrm{L}}_W$ objective, and each star gadget can contribute at most K, each star gadget must contribute at least $K + (C - 1/2 - m) \geq K - 1/2 - m > K\big(1 - \frac{2m}{K}\big)$. By Lemma 26, for the K-star to achieve at least $K\big(1 - \frac{2m}{K}\big)$, the vector $\hat{v}$ assigned to v must satisfy

$$\|W\hat{v} - \widehat{\mathrm{sgn}}(v)\| \leq \delta \quad \text{for} \quad \delta = 2\sqrt{\frac{2m}{K}}\sqrt{\frac{1+\beta^2}{1-\beta^2}}.$$

We will use this fact to show that the $\mathrm{MC}^{\mathrm{L}}_W$ value earned by the vector assignment on the original graph G is close to the value of the cut we defined. We have

$$\left|\sum_{ij\in E} \|W\hat{\imath} - W\hat{\jmath}\| - \sum_{ij\in E} \|\widehat{\mathrm{sgn}}(\hat{\imath}) - \widehat{\mathrm{sgn}}(\hat{\jmath})\|\right| = \left|\sum_{ij\in E} (\|W\hat{\imath} - W\hat{\jmath}\| - \|\widehat{\mathrm{sgn}}(\hat{\imath}) - \widehat{\mathrm{sgn}}(\hat{\jmath})\|)\right|$$
$$\leq \left|\sum_{ij\in E} (\|W\hat{\imath} - \widehat{\mathrm{sgn}}(\hat{\imath})\| + \|W\hat{\jmath} - \widehat{\mathrm{sgn}}(\hat{\jmath})\|)\right| \leq 2m\delta = 4\sqrt{\frac{2}{n}}\sqrt{\frac{1+\beta^2}{1-\beta^2}} = \mathrm{O}\big(1/\sqrt{n}\big)$$

which is $< 1/2$ for large enough n.

Using for a second time the fact that the edges of the star gadgets can contribute at most Kn to the $\mathrm{MC}^{\mathrm{L}}_W(H)$, the vector assignment must achieve at least $C - 1/2$ on G, and so

$$C - 1/2 \leq \frac{1}{2}\sum_{ij\in E} \|W\hat{\imath} - W\hat{\jmath}\| \leq \frac{1}{2}\sum_{ij\in E} |\widehat{\mathrm{sgn}}(\hat{\imath}) - \widehat{\mathrm{sgn}}(\hat{\jmath})| + \mathrm{O}\big(1/\sqrt{n}\big)$$

implying that the value of our cut is strictly greater than $C - 1$ for sufficiently large n. Therefore, as it is integer-valued it is at least C, concluding the proof. ◀

Finally, we give Lemma 23, in which $W = \mathrm{diag}(1, 1, \gamma)$ and $1 > \gamma$. Our proof combines the techniques in the previous two proofs. Similar to the proof of Lemma 21, we show hardness by reducing from 3-Coloring. Our construction begins by replacing every edge in the graph with a 3-clique. Then, as in the proof of Lemma 22, we insert large star gadgets on every vertex, forcing solutions away from the low-weight z-axis. With solutions restricted to two dimensions, we are able to argue there is an assignment to the new graph that simultaneously (nearly) maximizes all of the cliques iff the original graph was 3-colorable.

▶ **Lemma 23.** *For any $W = \mathrm{diag}(1, 1, \gamma)$ with $1 > \gamma \geq 0$, W-linear-Max-Cut is* NP*-hard.*

Proof. Consider an arbitrary instance of 3-Coloring on a graph $G = (V, E)$ with n vertices and m edges. Construct a new graph $H' = (V', E')$ by taking G and, for each edge $ij \in E$, adding a vertex k_{ij} and edges ik_{ij} and jk_{ij}, so that each edge in G corresponds to a 3-clique (K_3) in H'. Note that the m cliques constructed this way are edge-disjoint. Next, for each vertex v in H', add $K = m^6$ ancilla vertices v_i, each connected to v so that v is the center of a K-star. Call the final graph $H'' = (V'', E'')$, for which we have $(K + 1)(n + m)$ vertices and $3m + K(n + m)$ edges.

We claim that if G is 3-colorable, then $\mathrm{MC}^{\mathrm{L}}_W(H'') \geq K(n + m) + 3\sqrt{3}m$. Conversely, we claim that if $\mathrm{MC}^{\mathrm{L}}_W(H'') > K(n + m) + 3\sqrt{3}m - \varepsilon$, for an $\varepsilon = \Omega(1/m^2)$ we will choose later, then G is 3-colorable. As testing 3-colorability is NP-hard, this will prove the theorem.

First, suppose G is 3-colorable. Let C be any set of three vectors in the xy-plane achieving the maximum value of $\mathrm{MC}^{\mathrm{L}}_W(K_3) = 3\sqrt{3}$. Given any 3-coloring of G, we assign one of these vectors to each color, and thus assign vectors from C to G with no two adjacent vertices having the same vector. We extend this assignment to H' by, for each of our constructed 3-cliques i, j, k_{ij}, assigning the vector in C that was not assigned to either i or j to k_{ij}. Now each of these cliques contributes $3\sqrt{3}$ to the objective, and as there are m of them and they are edge-disjoint, this contributes $3\sqrt{3}m$ to the objective. To extend to H'' and its star gadgets, every edge of a star centered on vertex v can trivially contribute $\|v\|$ to the objective value. Because all vectors are in the xy-plane, and so the unit circle, this means they all contribute 1. So in total, there exists an assignment with value $3\sqrt{3}m + K(n + m)$.

Now suppose there exists a vector assignment achieving greater than $K(n+m)+3\sqrt{3}m-\varepsilon$ on H''. For a vector $\hat{v} = (\hat{v}_x, \hat{v}_y, \hat{v}_z)$, let $\widehat{\mathrm{sgn}}(\hat{v})$ denote the vector $(\hat{v}_x, \hat{v}_y, 0)/\|(\hat{v}_x, \hat{v}_y, 0)\|$. We assign colors as follows. Choose any of the K_3 gadgets i, j, k_{ij} in H'' corresponding to an edge ij in the original graph. Let $\hat{\imath}, \hat{\jmath}, \hat{k}_{ij}$ be the vectors assigned to the vertices, respectively. Assign three colors to the vertices. Then, choose any K_3 gadget $i, \ell, k_{i\ell}$ adjacent to the first. For each vertex in the second clique, consider its assigned vector and round it via $\widehat{\mathrm{sgn}}$, determine which of the rounded vectors $\widehat{\mathrm{sgn}}(\hat{\imath}), \widehat{\mathrm{sgn}}(\hat{\jmath}), \widehat{\mathrm{sgn}}(\hat{k}_{ij})$ it is closest to, and assign the same color. We continue coloring adjacent cliques in this way, comparing rounded vectors to the original set $\widehat{\mathrm{sgn}}(\hat{\imath}), \widehat{\mathrm{sgn}}(\hat{\jmath}), \widehat{\mathrm{sgn}}(\hat{k}_{ij})$, until the coloring is propagated to the entire graph. This colors all of the vertices in H', which are the centers of star gadgets in H''. We will show no adjacent vertices in H' were assigned the same color. Since G is a subgraph of H', this also implies a proper coloring of G, as desired.

We first show that just as the assigned vectors must achieve a large objective value on the clique gadgets, the star gadgets force the rounded vectors to achieve a similar score. Because the m clique gadgets can each contribute at most $3\sqrt{3}$ to the objective value, the star gadgets in H'' must contribute at least $K(n + m) - \varepsilon$. Similarly, because the edges of each star can contribute at most K, each star must achieve at least $K - \varepsilon$. For any vertex in s in H', consider the star gadget centered on it in H''. As shown in Lemma 26, for the star to achieve $K(1 - \varepsilon/K)$, the vector $\hat{s}$ assigned to s must satisfy

$$\|W\hat{s} - \widehat{\operatorname{sgn}}(\hat{s})\| \leq \delta \quad \text{for} \quad \delta = 2\sqrt{\frac{\varepsilon}{K}}\sqrt{\frac{1+\gamma^2}{1-\gamma^2}}.$$

On the other hand, because the star gadgets can contribute at most $K(n+m)$ to the objective value, the vector assignment must achieve at least $3\sqrt{3}m - \varepsilon$ on the remaining edges, the ones in H'. Given the vectors are close, we have that

$$\left|\sum_{ij\in E'} \|W\hat{\imath} - W\hat{\jmath}\| - \sum_{ij\in E'} \|\widehat{\operatorname{sgn}}(\hat{\imath}) - \widehat{\operatorname{sgn}}(\hat{\jmath})\|\right| = \left|\sum_{ij\in E'} \|W\hat{\imath} - W\hat{\jmath}\| - \|\widehat{\operatorname{sgn}}(\hat{\imath}) - \widehat{\operatorname{sgn}}(\hat{\jmath})\|\right|$$

$$\leq \left|\sum_{ij\in E'} \|W\hat{\imath} - \widehat{\operatorname{sgn}}(\hat{\imath})\| + \|W\hat{\jmath} - \widehat{\operatorname{sgn}}(\hat{\jmath})\|\right| \leq 2|E'|\delta = 12\sqrt{\varepsilon}m^{-2}.$$

Therefore, for $\mu = \varepsilon + 12\sqrt{\varepsilon}m^{-2}$, the set of rounded vectors must achieve at least $3\sqrt{3}m - \mu$ on the rest of H'. Because each of the m clique gadgets can contribute at most $3\sqrt{3}$, the rounded vectors must achieve at least $3\sqrt{3} - \mu$ on each individual clique.

The rounded vectors exist in the xy-plane, which means they are inscribed in the unit circle. Maximizing the sum of the edge lengths on a K_3 gadget is equivalent to maximizing the perimeter of a triangle. For a triangle in the unit circle to have nearly maximal perimeter, it must be nearly regular; as shown in Lemma 27, if the perimeter is at least $3\sqrt{3} - \mu$, then each edge length must be in the interval $\sqrt{3} \pm 4\sqrt{\mu}$.

Now, consider any two adjacent vertices u, v in H', which are at the center of star gadgets in H''. We must show they were assigned different colors. The two vertices exist in some K_3 gadget in H', and the coloring procedure, starting from i, j, k_{ij}, must have reached them in at most m rounds. At each step in the procedure, there is a colored clique and a successive adjacent clique which share a clique. Two nearly regular triangles which share a vertex must nearly share their other vertices; as shown in Lemma 28, the distance between the first clique's rounded vectors and the second clique's is at most $\mathrm{O}\big(\sqrt{\mu}\big)$.

After m rounds of the coloring procedure, we conclude u and v must be assigned colors such that $\widehat{\operatorname{sgn}}(\hat{u}), \widehat{\operatorname{sgn}}(\hat{v})$ are each at distance at most $m \times \mathrm{O}\big(\sqrt{\mu}\big) = \mathrm{O}\big(\varepsilon^{1/4}\big)$ away from the same-colored rounded vectors in the initial clique. Both the initial clique and the clique containing u and v must have vectors separated by at least $\sqrt{3} - \varepsilon$. For sufficiently small ε ($\varepsilon = \Theta\big(1/m^2\big)$ with a sufficiently small constant suffices), $\widehat{\operatorname{sgn}}(\hat{u}), \widehat{\operatorname{sgn}}(\hat{v})$ cannot also be within $\mathrm{O}(\sqrt{\varepsilon})$ of the same initial vector, so we conclude they must be associated with different colors, and this is a proper coloring. ◀

We now conclude with a proof of the main theorem of this section, that W-LINEAR-MAX-CUT is NP-complete for any fixed diagonal 3×3 non-negative nonzero W.

Proof of Theorem 4. The containment of W-LINEAR-MAX-CUT for any diagonal W is straightforward. With W a constant, given a claimed vector assignment, the value $\mathrm{MC}^{\mathrm{L}}_W(G)$ can be verified in time linear in the number of edges.

To show hardness, we make two simplifications. First, because $\mathrm{MC}^{\mathrm{L}}_{cW} = c\mathrm{MC}^{\mathrm{L}}_W$ for a constant c, we can easily reduce to an instance in which we assume the largest entry of W equals 1. Second, although rearranging the entries of diagonal W requires changing any vector assignment, it does not change the objective value. So $\mathrm{MC}^{\mathrm{L}}_{\mathrm{diag}(\alpha,\beta,\gamma)} = \mathrm{MC}^{\mathrm{L}}_{\mathrm{diag}(\beta,\alpha,\gamma)}$ and any other rearrangement of W, and we can assume the entries are ordered $1 \geq \alpha \geq \beta \geq \gamma \geq 0$. With this, the theorem follows by Lemmas 21–23. ◀

5 NP-Hardness of Unweighted Quantum Max-Cut

Our lower bounds elsewhere in this paper are for local Hamiltonian problems in which terms can be given positive *or* negative weight. They apply in the model where all weights are restricted to being of constant weight but require some terms with negative weight to work. In this section we show that this restriction can be removed for one of the best-studied local Hamiltonian problems: the Quantum Max-Cut (or QMC) problem.

The Quantum Max-Cut problem can be defined as $\mathcal{S}$-LH with $\mathcal{F} = \{XX + YY + ZZ\}$. We will write h for $XX + YY + ZZ$.[6]

▶ **Definition 24** (Quantum Max-Cut (QMC)). *Given a Hamiltonian $H = \sum_{ij}^{n} w_{ij} H_{ij}$ acting on n qubits where each $H_{ij} = I - h_{ij}$, all w_{ij} are real, polynomially-bounded, and specified by at most* $\mathrm{poly}(n)$ *bits, and two real parameters b, a such that $b - a \geq 1/\mathrm{poly}(n)$, decide whether $\lambda_{\max}(H)$ is at least b (YES) or at most a (NO).*

Note that we have written QMC as a *maximum* eigenvalue problem (with a flip and shift of the local terms) rather than in terms of the minimum eigenvalue as for k-LH in Definition 7. This is to follow the norm in previous work; note that as both the terms *and* the objective function are flipped, an instance of the problem defined this way will be equivalent to an instance of the corresponding k-LH problem with the same weights.

When minimizing (maximizing) the eigenvalue and the weights are restricted to be non-negative (non-positive), it is referred to as the anti-ferromagnetic Heisenberg model. Flipping the restrictions, e.g. minimizing with non-positive weights, is referred to as the ferromagnetic Heisenberg model. The latter case is trivial when viewed as an optimization problem (as $|00\rangle$ earns 0 on the local term, and so the problem is optimized by assigning $|0\rangle$ to every qubit), so we will be interested in hardness results for the former.

It is straightforward to verify that for two qubits a, b with *pure* states ρ^a, ρ^b,

$$\mathrm{tr}\left(\rho^a \otimes \rho^b \; h\right) = r^a \cdot r^b = 1 - \frac{1}{2}\left\|r^a - r^b\right\|^2,$$

where r^a, r^b are the corresponding Bloch vectors. This shows that deciding QMC restricted to product states, which we denote prodQMC, is equivalent to the standard Vector Max-Cut problem in three dimensions:

▶ **Definition 25** ($\text{Max-Cut}_k(\text{MC}_k)$). *Given an n-vertex graph $G = (V, E)$ and thresholds $b > a \geq 0$ such that $b - a \geq 1/\mathrm{poly}(n)$, decide whether*

$$\text{MC}_k = \frac{1}{2} \max_{\hat{\imath} \in S^{k-1}} \sum_{ij \in E} 1 - \hat{\imath} \cdot \hat{\jmath} = \frac{1}{4} \max_{\hat{\imath} \in S^{k-1}} \sum_{ij \in E} \left\|\hat{\imath} - \hat{\jmath}\right\|^2$$

is at least b or less than a.

Note that this is different from the W-linear-Max-Cut we studied in Section 4 as it considers *squared* distances. Furthermore, while Max-Cut is a classic NP-complete problem, MC_k is not expected to be hard for all values of k, and in particular is tractable when $k = n = |V|$.

Our main result classifying $\mathcal{S}$-prodLH immediately implies $\{h\}$-prodLH, and therefore also prodQMC and MC_3, is NP-complete. However, the proof of Lemma 15 utilizes Hamiltonian gadgets involving negative weights. This leaves open whether prodQMC and

[6] Other work frequently includes a multiplicative factor, e.g. 1/2, in the definition of h and/or of QMC.

MC_3 remain NP-hard on unweighted graphs. We now prove that MC_3 is NP-hard even when restricted to positive unit weights. This is the first published proof of this fact, although we note that a sketch of a different proof was previously known for this specific problem [40].

Our approach is similar to the proof of Lemma 21, which demonstrated hardness of $\mathrm{MC}_W^{\mathrm{L}}$ for $W = I$ by replacing every edge with a 4-clique (with one vertex connected to a source vertex), and showing that the resulting graph could simultaneously optimize all of these 4-cliques (by assigning vectors corresponding to a regular tetrahedron) if and only if the original graph was 3-colorable.

However, the change in objective function from distances to *squared* distances causes a problem: while the regular tetrahedron is the unique optimal solution for $\mathrm{MC}_W^{\mathrm{L}}(K_4)$, in the case of $\mathrm{MC}_3(K_4)$, setting $v_1 = v_2 = (1, 0, 0), v_3 = v_4 = (-1, 0, 0)$ would also be optimal. So we replace each edge of the 4-cliques with triangles, which penalize the degenerate solution and forces the vectors assigned to the vertices of the 4-cliques toward regular tetrahedra.

▶ **Theorem 5.** MC_3 *is* NP*-complete.*

Proof of Theorem 5. Clearly MC_3 is in NP. To show hardness, we reduce 3-Coloring to MC_3. Given an instance $G = (V, E)$ on n vertices and m edges, we first replace every edge with a copy of K_4. That is, for each edge $ij \in E$, we add vertices q_{ij}, t_{ij} and add edges to form a 4-clique. Call the new graph $H' = (V', E')$. Then in H', we replace every edge with a copy of K_3. That is, for all $ij \in E'$ we add a vertex r_{ij} and edges ir_{ij} and jr_{ij}. Finally, we add a *sink* vertex t and for every edge $ij \in E$, in the original graph, add edge tt_{ij}. Call the resulting graph $H'' = (V'', E'')$. For future reference, let R denote a copy of K_4 with each edge replaced by a copy of K_3, which we may call a "tetrahedron with adjoined triangles".

We claim that if G has a proper 3-coloring then $\mathrm{MC}_3(H'') \geq m\,\mathrm{MC}_3(R) + m$. Conversely, we claim that if $\mathrm{MC}_3(H'') \geq m\,\mathrm{MC}_3(R) + m - \varepsilon$, for an $\varepsilon = \Omega\big(1/m^2\big)$ we will choose later, then there is a 3-coloring of G. Later, we will show $\mathrm{MC}_3(R) = 10 + 2\sqrt{3}$.

First, suppose G is 3-colorable. Let S consist of the following three unit vectors in $\mathbb{R}^3$:

$$\left(\sqrt{8/9}, 0, -1/3\right), \left(-\sqrt{2/9}, \sqrt{2/3}, -1/3\right), \left(-\sqrt{2/9}, -\sqrt{2/3}, -1/3\right).$$

Along with $(0, 0, 1)$, these are the four vertices of a regular tetrahedron inscribed in the unit sphere. Assign each one of the vectors of S to each color, such that every vertex in G is assigned a vector and no adjacent vertices have the same vector. We copy those vectors to the vertices of H', and for each vertex q_{ij} we assign the vector in S not assigned to i or j. We assign $(0, 0, 1)$ to each vertex t_{ij}. We copy these vectors to the vertices of H''. In H'' we assign $(0, 0, -1)$ to t. Finally, for each edge $ij \in E'$ and 3-clique i, j, r_{ij}, the only uncolored vertex is r_{ij}, and we assign the unique unit vector that is antiparallel to the sum of the vectors assigned to i and j.

Now we calculate the objective value that this assignment achieves. For vertex i, let $\hat{\imath}$ denote the assigned vector. For any edge ij in G, the vectors assigned to the associated K_4 gadget correspond to vertices of a regular tetrahedron, and it can be directly calculated that for any of the six edges ab, we have $\hat{a} \cdot \hat{b} = -1/3$. For edges tt_{ij}, we have $t \cdot t_{ij} = -1$. For edges ir_{ij}, given $\hat{\imath} \cdot \hat{\jmath} = -1/3$ and $\hat{r}_{ij} \propto -(\hat{\imath} + \hat{\jmath})$, the inner product is $\hat{\imath} \cdot \hat{r}_{ij} = \hat{\jmath} \cdot \hat{r}_{ij} = -1/\sqrt{3}$. In total, for each edge ij in G, the graph H'' has a gadget with six edges in a K_4 gadget, twelves edges in K_3 gadgets, and one edge incident on t. Plugging the inner products we calculated into the definition of MC_k gives a total objective value of $m(10 + 2\sqrt{3}) + m$.

Second, suppose there is a set of unit vectors $\hat{\imath}$ for $i \in V''$ such that $\mathrm{MC}_3(H'') \geq m\,\mathrm{MC}_3(R) + m - \varepsilon$. We color the vertices of H', comprised of the K_4 gadgets, as follows. Pick some color and assign it to all of the vertices t_{ab}. Then, choose any K_4 gadget i, j, k_{ij}, t_{ij}

in H' corresponding to an edge ij in the original graph. Let $\hat{\imath}, \hat{\jmath}, \hat{k}_{ij}, \hat{t}_{ij}$ be the vectors assigned to the vertices, respectively. Assign three colors to the uncolored vertices arbitrarily. Then, choose any K_4 gadget $i, \ell, k_{i\ell}, t_{i\ell}$ adjacent to the first. For each uncolored vertex in the second clique, consider its assigned vector, determine which of $\hat{\imath}, \hat{\jmath}, \hat{k}_{ij}$ it is closet to, and assign the same color. We continue coloring adjacent cliques in this way, comparing vectors to the original set $\hat{\imath}, \hat{\jmath}, \hat{k}_{ij}$, until the coloring is propagated to the entire graph.

Although we assigned four colors, one of them is used exclusively by the vertices t_{ab}. Since these vertices are not in G, if this is a proper 4-coloring of H', then it gives a proper 3-coloring of the subgraph G. So, in the remainder of the proof we will show that no two adjacent vertices in H' were assigned the same color.

The graph H'' is comprised of m edge-disjoint gadgets R as well as m edges tt_{ab}. In order for the total objective value to be greater than $m\,\mathrm{MC}_3(K_3) + m - \varepsilon$, each gadget R must contribute at least $\mathrm{MC}_3(R) - \varepsilon$ and each edge tt_{ab} must contribute at least $1 - \varepsilon$. As shown in Lemma 31, the sum of squared edge lengths of a "tetrahedron with adjoined triangles" is nearly maximized iff the lengths of the edges forming the tetrahedron are nearly regular. Specifically, for a gadget R to achieve at least $10 + 2\sqrt{3} - \varepsilon$, each side of the tetrahedron must be in the interval $4/\sqrt{6} \pm \mathrm{O}(\sqrt{\varepsilon})$.

Now consider any two adjacent vertices v, u in H'. The two vertices exist in some K_4 gadget in H', and the coloring procedure must have reached it after at most m rounds. At each step in the procedure, there is a colored clique and a successive adjacent clique. There are two copies of R in H'' which contain those two 4-cliques from H'. The gadgets share one vertex. Additionally, each gadget has a vertex adjacent to the sink t, whose assigned vectors must be at distance at least $2 - 2\varepsilon$ from $\hat{t}$. Since all of these are in the unit sphere, standard trigonometry shows those two assigned vectors must themselves be within $\mathrm{O}(\varepsilon)$ of each other. As verified in Lemma 30, considering two nearly regular tetrahedra which share one vertex and have a pair of similar vertices, the other vertices of the tetrahedra must each be within $\mathrm{O}(\sqrt{\varepsilon})$ of each other.

After m rounds of the coloring procedure, we conclude that $\hat{v}, \hat{u}$ are each at distance at most $m \times \mathrm{O}(\sqrt{\varepsilon})$ away from the same-colored vectors in the original set $\hat{\imath}, \hat{\jmath}, \hat{k}_{ij}$. Since all of the edges of the 4-clique gadgets must be at least $4/\sqrt{6} - \mathrm{O}(\sqrt{\varepsilon})$, for $\varepsilon = \Theta(1/m^2)$ sufficiently small the vectors $\hat{v}, \hat{u}$ cannot be near the same original vector. Therefore, they must been colored differently, as desired. ◀

By the correspondence described earlier in the section, we immediately have the desired bound on $\mathcal{S}$-prodLH.

▶ **Corollary 6.** Quantum Max-Cut *restricted to product states,* prodQMC*, is* NP*-complete, even when all terms are restricted to have positive unit weight.*

A Geometry Lemmas

First, we give a simple lemma regarding star graphs. Our goal is to show that inserting star gadgets into a graph forces maximal solutions to $\mathrm{MC}^{\mathrm{L}}_W$ to be close to the highest weighted axes.

▶ **Lemma 26.** *Consider a star graph S_K with center vertex v and K neighbors. Consider any $0 \leq \varepsilon \leq 1$ and any $W = \mathrm{diag}(1, w_2, w_3)$ with $1 \geq w_2 \geq w_3 \geq 0$ and $w_3 < 1$.*

Let Π *denote the projector onto the axes for which* $w_i = 1$ *(so the projector onto the* x*-axis or the* xy*-plane). Similarly, let* λ *be the largest* w_i *which is not equal to 1 (either* w_2 *or* w_3*). Let* $\widehat{\operatorname{sgn}}(\hat{v}) = \Pi v / \|\Pi v\|$.

If vectors are assigned to S_K *which achieve at least* $\mathrm{MC}^{\mathrm{L}}_{\mathrm{W}}(S_K) \geq K(1-\varepsilon)$*, and* $\hat{v}$ *is the vector assigned to* v*, then*

$$\|W\hat{v} - \widehat{\operatorname{sgn}}(\hat{v})\| \leq \delta \quad \textit{for} \quad \delta = 2\sqrt{\varepsilon}\sqrt{\frac{1+\lambda^2}{1-\lambda^2}}.$$

Proof. Suppose to the contrary that $\|W\hat{v} - \widehat{\operatorname{sgn}}(\hat{v})\| > \delta$. We know that

$$\begin{aligned}
&\|W\hat{v} - \widehat{\operatorname{sgn}}(\hat{v})\| = \sqrt{(\widehat{\operatorname{sgn}}(\hat{v})_x - \hat{v}_x)^2 + (\widehat{\operatorname{sgn}}(\hat{v})_y - w_2\hat{v}_y)^2 + w_3^2\hat{v}_z^2} \\
&= \sqrt{(\widehat{\operatorname{sgn}}(\hat{v})_x - \hat{v}_x)^2 + (\widehat{\operatorname{sgn}}(\hat{v})_y - w_2\hat{v}_y)^2 + w_3^2\left(1 - \hat{v}_x^2 - \hat{v}_y^2\right)} \\
&\leq \sqrt{\left(1 - \hat{v}_x^2 - \hat{v}_y^2\right) + \lambda^2(1 - \hat{v}_x^2 - \hat{v}_y^2)} = \sqrt{(1+\lambda^2)(1 - \hat{v}_x^2 - \hat{v}_y^2)},
\end{aligned}$$

where the inequality holds for $\hat{v}_x, \hat{v}_y \in [0,1]$. Combining, we have that $(1+\lambda^2)(1-\hat{v}_x^2-\hat{v}_y^2) > \delta^2$, which implies $\hat{v}_x^2 + \hat{v}_y^2 < 1 - \delta^2/(1+\lambda^2)$. Now we are ready to find that the maximum objective value earned on the star is less than half of

$$\begin{aligned}
&K(1 + \|W\hat{v}\|) = K + K\sqrt{\hat{v}_x^2 + \hat{v}_y^2 + \lambda^2\hat{v}_z^2} = K + K\sqrt{\hat{v}_x^2 + \hat{v}_y^2 + \lambda^2(1 - \hat{v}_x^2 - \hat{v}_y^2)} \\
&= K + K\sqrt{(\hat{v}_x^2 + \hat{v}_y^2)(1-\lambda^2) + \lambda^2} \leq K + K\sqrt{\left(1 - \frac{\delta^2}{1+\lambda^2}\right)(1-\lambda^2) + \lambda^2} \\
&= K + K\sqrt{1 - 4\varepsilon} \leq K + K(1 - 4\varepsilon) = K(2 - 4\varepsilon).
\end{aligned}$$

So, the objective value is less than $K(1-2\varepsilon)$, which is less than $K(1-\varepsilon)$, a contradiction. ◀

Next, we study the geometry of triangles. For a triangle ABC, let $\mathrm{L}(ABC)$ denote the sum of the edge lengths. It is straightforward to show that for a triangle inscribed in a circle of radius r, $\mathrm{L}(ABC) \leq 3\sqrt{3}r$, which is uniquely achieved by an equilateral triangle [30].

▶ **Lemma 27.** *Consider a triangle* ABC *inscribed in the unit circle and any* $0 \leq \varepsilon < 1$*. If* $\mathrm{L}(ABC) \geq 3\sqrt{3} - \varepsilon$*, then each edge length is in the interval* $\left[\sqrt{3} - 4\sqrt{\varepsilon}, \sqrt{3} + 4\sqrt{\varepsilon}\right]$.

Proof. For the sake of contradiction, suppose $\mathrm{L}(ABC) \geq 3\sqrt{3} - \varepsilon$ and that there exists an edge length outside the interval $\sqrt{3} \pm 4\sqrt{\varepsilon}$.

First suppose that some edge length is greater than $\sqrt{3} + 4\sqrt{\varepsilon}$. Because the maximum value of L is $3\sqrt{3}$, this implies at least one edge length is less than $\sqrt{3} - 2\sqrt{\varepsilon}$. So whether an edge length is above or below the interval, some edge length is less than $\sqrt{3} - 2\sqrt{\varepsilon}$.

Given $\mathrm{L}(ABC) \geq 3\sqrt{3} - \varepsilon$ and some edge length is less than $\sqrt{3} - 2\sqrt{\varepsilon}$, some edge length must be greater than $(3\sqrt{3} - \varepsilon - \sqrt{3} + 2\sqrt{\varepsilon})/2 \geq \sqrt{3} + \sqrt{\varepsilon}$, so there exists a pair of edge lengths whose difference is greater than $3\sqrt{\varepsilon}$.

We relabel the triangle so that $\|AC\| \geq \|AB\| \geq \|BC\|$ and $\|AC\| - \|BC\| > 3\sqrt{\varepsilon}$. We can rotate the unit circle as necessary so that ABC is of the form

$$A = (a, b) \quad B = (-a, b) \quad C = (c_x, c_y).$$

Define $C' = (0, -1)$. We will show $\mathrm{L}(ABC') - \mathrm{L}(ABC) > \varepsilon$, implying $\mathrm{L}(ABC)$ is less than $3\sqrt{3} - \varepsilon$, a contradiction.

Both $\mathrm{L}(ABC)$ and $\mathrm{L}(ABC')$ are sums of 3 edge lengths. The edge AB is shared and we have that $\|AC'\| = \|BC'\|$, so we are interested in $2\|AC'\| - \|BC\| - \|AC\|$. We may calculate

$$\|AC'\| = \sqrt{2+2b}, \quad \|BC\| = \sqrt{2+2bc_y+2ac_x}, \quad \|AC\| = \sqrt{2+2bc_y-2ac_x}.$$

From here, we may verify

$$4\|AC'\|^2 = (\|BC\| + \|AC\|)^2 + (\|BC\| - \|AC\|)^2,$$

and so

$$(2\|AC'\| + \|BC\| + \|AC\|)(2\|AC'\| - \|BC\| - \|AC\|) \geq (\|BC\| - \|AC\|)^2,$$

and

$$2\|AC'\| - \|BC\| - \|AC\| \geq (\|BC\| - \|AC\|)^2 (2\|AC'\| + \|BC\| + \|AC\|)^{-1}.$$

To lower bound the left-hand side, we use our lower bound on the difference between the edge lengths and the upper bound that all lengths in the unit circle are less than 2. We find

$$2\|AC'\| - \|BC\| - \|AC\| > \left(3\sqrt{\varepsilon}\right)^2 8^{-1} = 9\varepsilon/8.$$

Overall, we have found that $\mathrm{L}(ABC') - \mathrm{L}(ABC) > \varepsilon$. ◀

▶ **Lemma 28.** *Consider triangles ABC and ADE inscribed in the unit circle. If all edges of the triangle have lengths in the interval $\sqrt{3} \pm \delta$, then the points $\{B, C\}$ are each within $\mathrm{O}(\delta)$ distance of (different) points in $\{D, E\}$.*

Proof. Because these are vectors restricted to a unit circle, we can assume $A = (1, 0, 0)$. Given A is fixed, we can characterize the constraints on the other points as follows. B, C, D, E must lie in the intersection of the unit circle with a circular shell bounded by radii $\sqrt{3} - \delta$ and $\sqrt{3} + \delta$ centered at A. Given $\sqrt{3} + \delta < 2$, it is clear this intersection is two disjoint segments of the unit circle.

We wish to upper bound the distance between points in either of these regions. This is the distance between the ends of the regions, along a chord from the point at distance $\sqrt{3} - \delta$ to the point at distance $\sqrt{3} + \delta$.

The length of the chord can be bound as follows. Given a chord length d, the internal angle is $2\arcsin(d)$. Given an angle θ, the chord length is $2\sin(\theta/2)$. So, we can convert the known distances to angles, take the difference, and convert back to a distance: $2\sin(\arcsin((\sqrt{3} + \delta)/2) - \arcsin((\sqrt{3} - \delta)/2))$. This is equivalent to $2\sin\left(\arcsin(d/2) - \arcsin\left((d - 2\delta)/2\right)\right)$ for $d = \sqrt{3} + \delta$. Observing this function is increasing in d, we can upper bound the value by taking $d < \sqrt{3} + 0.1$. The Taylor series of $2\sin(\arcsin(\frac{\sqrt{3}+0.1}{2}) - \arcsin(\frac{\sqrt{3}+0.1-\delta}{2}))$ gives that this is at most 2.5δ. ◀

Next, we transition to considering tetrahedra. For a tetrahedron $ABCD$, let $\mathrm{L}(ABCD)$ denote the sum of the edge lengths. It is known that for a tetrahedron inscribed in a sphere of radius r, $\mathrm{L}(ABCD) \leq 4\sqrt{6}r$, and the maximum is uniquely achieved by a regular tetrahedron [30].

▶ **Lemma 29.** *Consider a tetrahedron $ABCD$ inscribed in the unit sphere and any $\varepsilon \geq 0$. If $\mathrm{L}(ABCD) \geq 4\sqrt{6} - \varepsilon$, then each edge length is in the interval $\left[\frac{4\sqrt{6}}{6} - \frac{50\sqrt{2\varepsilon}}{3}, \frac{4\sqrt{6}}{6} + \frac{50\sqrt{2\varepsilon}}{3}\right]$.*

Proof. For the sake of contradiction, suppose $\mathrm{L}(ABCD) \geq 4\sqrt{6} - \varepsilon$ and that there exists an edge length outside the given interval.

First consider the case that some edge length is greater than $\frac{4\sqrt{6}}{6} + \frac{50\sqrt{2\varepsilon}}{3}$. Because the maximum of L in the unit sphere is $4\sqrt{6}$, at least one of the other edge lengths must be less than $\frac{4\sqrt{6}}{6} - \frac{10\sqrt{2\varepsilon}}{3}$. So, whether an edge length is above or below the interval, in both cases some edge length is less than $\frac{4\sqrt{6}}{6} - \frac{10\sqrt{2\varepsilon}}{3}$.

If $\mathrm{L}(ABCD) \geq 4\sqrt{6} - \varepsilon$ and some edge length is less than $\frac{4\sqrt{6}}{6} - \frac{10\sqrt{2\varepsilon}}{3}$, then some edge length must be greater than $\left(4\sqrt{6} - \varepsilon - \frac{4\sqrt{6}}{6} + \frac{10\sqrt{2\varepsilon}}{3}\right)/5 \geq \frac{4\sqrt{6}}{6} + \frac{2\sqrt{2\varepsilon}}{3}$. So, there exists a pair of edges such that the difference in their lengths is greater than $\frac{12\sqrt{2\varepsilon}}{3} = 4\sqrt{2\varepsilon}$.

If two edge lengths e_1, e_2 in a tetrahedron differ by more than $4\sqrt{2\varepsilon}$, then there must exist a pair of adjacent edges which differ by more than $2\sqrt{2\varepsilon}$. This is because either the two edges are adjacent, or they are both adjacent to a third edge e_3 and that length must be closer to e_1 or to e_2, i.e. $\min\{\|e_3 - e_1\|, \|e_2 - e_1\|\} \leq \|e_1 - e_2\|/2$ We relabel the tetrahedron so that $\|AC\| - \|BC\| > 2\sqrt{2\varepsilon}$.

Next, without changing the value of L, we can rotate $ABCD$ such that A, B are of the form $A = (a, -b, 0) \quad B = (-a, -b, 0)$. Let $C = (c_x, c_y, c_z) \quad D = (d_x, d_y, d_z)$ and $C' = (0, c_y, \sqrt{1 - c_y^2}) \quad D' = (0, d_y, \sqrt{1 - d_y^2})$, We will show $\mathrm{L}(ABC'D') - \mathrm{L}(ABCD) > \varepsilon$, implying $\mathrm{L}(ABCD)$ must in fact be less than $4\sqrt{6} - \varepsilon$.

Both $\mathrm{L}(ABCD)$ and $\mathrm{L}(ABC'D')$ are sums of 6 edge lengths. We can ignore AB. We can directly verify that $\|C'D'\| - \|CD\|$ is

$$\sqrt{(c_y - d_y)^2 + (c_x - d_x)^2 + (c_z - d_z)^2 + 2c_x d_x + 2c_z d_z + 2\sqrt{c_x^2 + c_z^2}\sqrt{d_x + d_z^2}} - \sqrt{(c_x - d_x)^2 + (c_y - d_y)^2 + (c_z - d_z)^2},$$

and so is clearly non-negative. We may calculate

$$\|AC'\| = \|BC'\| = \sqrt{2 + 2bc_y}$$
$$\|BC\| = \sqrt{2 + 2bc_y + 2ac_x}$$
$$\|AC\| = \sqrt{2 + 2bc_y - 2ac_x}$$

and similar expressions for $\|AD'\|, \|BD'\|, \|BD\|, \|AD\|$.

Just as in the proof of Lemma 27, we may verify

$$\begin{aligned} 2\|AC'\| - \|BC\| - \|AC\| &= (\|BC\| - \|AC\|)^2 \left(2\|AC'\| + \|BC\| + \|AC\|\right)^{-1} \\ &> \left(2\sqrt{2\varepsilon}\right)^2 8^{-1} \\ &= \varepsilon. \end{aligned}$$

Similarly, $2\|AD'\| - \|AD\| - \|BD\|$ is twice the difference of the quadratic mean and arithmetic mean of $\|AD\|, \|BD\|$, which is non-negative by the generalized mean inequality.

Overall, we have found that $\mathrm{L}(ABC'D') - \mathrm{L}(ABCD) > \varepsilon$. ◀

▶ **Lemma 30.** *Consider tetrahedra $ABCD$ and $AEFG$ inscribed in the unit sphere with $\|B - E\| \leq \varepsilon$. If all edges of the tetrahedra have lengths in the interval $\frac{4\sqrt{6}}{6} \pm \delta$, then the points $\{C, D\}$ are each within $\mathrm{O}(\delta + \varepsilon)$ distance of (different) points in $\{F, G\}$.*

Proof. Because this is the unit sphere, we can rotate so that A, B are in the xy-plane and equidistant from the y-axis.

Given A, B, E are fixed, we can characterize the constraints on the other points as follows. Let R_1 denote the region bounded by a spherical shell centered at A with radii $\frac{4\sqrt{6}}{6} - \delta$ and $\frac{4\sqrt{6}}{6} + \delta$. Similarly, let R_2 denote a region of the same size and shape but centered at B. The points C, D must exist in the intersection of R_1, R_2, and the unit sphere. The constraints imply the intersection is two disjoint sectors of the unit sphere opposite A and B, call them S_1, S_2. Similarly, the points F, G must exist within ε of S_1 and S_2.

We wish to show that any two points in S_1 must be close, and similarly for S_2. Consider any two points P_1, P_2 in S_1. Fixing P_1 and letting $d(P_2) = \|P_1 - P_2\|$, the function d is convex in P_2 over S_1. Therefore, the extremes of the distance $\|P_1 - P_2\|$ will occur at the four extremal points of S_1, identified by their distances $\frac{4\sqrt{6}}{6} \pm \delta$ from A and B.

If P_1 is at $\frac{4\sqrt{6}}{6} + \delta$ from A and from B, then $d(P_2)$ is maximized with P_2 at $\frac{4\sqrt{6}}{6} - \delta$ from A and B. From point P_1, moving 2δ towards A and then 2δ towards B is an upper bound on the distance to P_2, so $\|P_1 - P_2\| \leq 4\delta$.

The other extreme may occur with $\frac{4\sqrt{6}}{6} + \delta$ and $\frac{4\sqrt{6}}{6} - \delta$ as the distances from P_1 to A and B, respectively, and as the distances from P_2 to B and A, respectively. Recalling that we were able to assume A, B are in the xy-plane and symmetric about the z-axis, it is clear that P_1, P_2 must be symmetric such that $P_1 = (0, P_y, P_z), P_2 = (0, -P_y, P_z)$. This implies A, B, P_1, P_2 are coplanar, and so ABP_1P_2 is a cyclic quadrilateral inscribed in a circular cross-section of the unit sphere. We know the lengths of three sides and the diagonals of this quadrilateral and want to know the fourth side, $\|P_1P_2\|$. Ptolmey's Theorem for cyclic quadrilaterals gives us that

$$\|AP_1\| \times \|BP_2\| = \|AB\| \times \|P_1P_2\| + \|AP_2\| \times \|BP_1\|.$$

Simplifying, we find

$$\|P_1P_2\| \leq \frac{\left(4\sqrt{6} + \delta\right)^2 - \left(4\sqrt{6} - \delta\right)^2}{4\sqrt{6} - \delta} = \frac{8\sqrt{6}\delta}{2\sqrt{6} - 3\delta} \leq \frac{8\sqrt{6}\delta}{2\sqrt{6}} = 4\delta.$$

Overall, we conclude that given any two points in S_1, the distance between the points is at most $\mathrm{O}(\delta)$, and similarly for S_2.

Finally, we return to the shapes $ABCD$ and $AEFG$. Since the distance $\|CD\|$ must be in $\frac{4\sqrt{6}}{6} \pm \delta$, one point must be in S_1 and one point in S_2. Similarly, one of F, G must be near S_1 and one near S_2. So arbitrarily, C, F are within ε of S_1 and D, G are within ε of S_2. We can conclude $\|C - F\|$ and $\|D - G\|$ are at most $\mathrm{O}(\delta + \varepsilon)$, as desired. ◀

We will use the name "tetrahedron with adjoined triangles" to refer to a three-dimensional tetrahedron such that for each edge there is an additional point with which the ends of the edge are joined to form a triangle. In total, there are 10 vertices and 12 edges. The shape will be assumed to be inscribed in the unit sphere, so a vector describing any vertex of the tetrahedron or a triangle is a unit vector. For some instance R of this shape with assigned vertex locations, let $\mathrm{L}(R)$ denote the sum of the *squared* edge lengths. The following lemma says that for $\mathrm{L}(R)$ to be maximized, the edges of the tetrahedron must approximate a regular tetrahedron.

▶ **Lemma 31.** *Given a tetrahedron with adjoined triangles R, $\mathrm{L}(R) \leq 10 + 2\sqrt{3}$. Furthermore, If any edge of the tetrahedron has a length outside of the interval $[\frac{4}{\sqrt{6}} - \varepsilon, \frac{4}{\sqrt{6}} + \varepsilon]$, then*

$$\mathrm{L}(R) < 10 + 2\sqrt{3} - \Omega\left(\varepsilon^2\right).$$

Proof. Suppose the vertices of the tetrahedron are V_1, V_2, V_3, V_4, and the additional vertex forming a triangle with edge V_iV_j is v_{ij}. Let s_{ij} denote the length of edge ij.

Note that the optimal location (which maximizes L) of a vertex v_{ij} is entirely determined by the locations of V_i and V_j, since it has no other neighbors. Given V_i, V_j, the point which maximizes the squared distances is proportional to $-(V_i + V_j)$. Moreover, because we are in the unit sphere, the maximum objective achieved by a triangle $V_iV_jv_{ij}$ when V_i, V_j are fixed is entirely determined by the length of V_iV_j alone; their exact coordinates do not matter, due to rotational symmetry. Combining these two facts and applying trigonometry, we may calculate that given an edge length of the tetrahedron s_{ij}, the maximum objective value of the triangle $V_iV_jv_{ij}$ is

$$\mathrm{t}(s_{ij}) = 1 + \frac{s_{ij}^2}{4} + \sqrt{1 - \frac{s_{ij}^2}{4}}.$$

Now, because R is the disjoint union of the six triangles which each have one of the tetrahedron's edges as a side, we can express

$$\mathrm{L}(R) = \sum_{i<j}^{4} t(s_{ij}).$$

A regular tetrahedron inscribed in the unit sphere has edge lengths equal to $4/\sqrt{6}$. So, if R is formed by a regular tetrahedron and the ideal points for the triangles, then $\mathrm{L}(R) = 6\,\mathrm{t}(4/\sqrt{6}) = 10 + 2\sqrt{3}$.

Now, we suppose the tetrahedron is not regular and some side length is not in the interval $\frac{4}{\sqrt{6}} \pm \varepsilon$. As noted in prior lemmas, it is known that the maximum sum of the (unsquared) edge-lengths of a tetrahedron is $4\sqrt{6}$ [30], so we have $\sum_{i<j} s_{ij} \leq 4\sqrt{6}$. If any edge length is greater than $\frac{4}{\sqrt{6}} + \varepsilon$, then the sum of the other five sides must be greater $5 \times \frac{4}{\sqrt{6}} - \varepsilon$ (otherwise, $\mathrm{L}(R)$ could be trivially increased, meaning our assumption gives a lower bound on the difference), so some side is less than $\frac{4}{\sqrt{6}} - \varepsilon/5$. So whether some side is above or below the interval, there exists a side $s_{ij} < \frac{4}{\sqrt{6}} - \varepsilon/5$.

Analyzing $\mathrm{t}(s)$, we see it is increasing and concave down on the interval $[1.22, 2)$. The maximum occurs at $\mathrm{t}(\sqrt{3})$. We can assume all edge lengths are at least 1.22 and in the concave-down region, as otherwise the total edge length is less than $\mathrm{t}(1.22)+5\,\mathrm{t}(\sqrt{3}) = 13.4145$, which is bounded away from the optimum $10 + 2\sqrt{3} \approx 13.464$. Therefore, the sum of t over the edges of a regular tetrahedron are greater than over a non-regular tetrahedron:

$$6\,\mathrm{t}\left(\frac{4}{\sqrt{6}}\right) > \sum_{i<j}^{4} \mathrm{t}(s_{ij}).$$

In particular,

$$6\,\mathrm{t}\left(\frac{4}{\sqrt{6}}\right) - \sum_{i<j}^{4} \mathrm{t}(s_{ij}) \geq 2\,\mathrm{t}\left(\frac{4}{\sqrt{6}}\right) - \mathrm{t}\left(\frac{4}{\sqrt{6}} - \frac{\varepsilon}{5}\right) - \mathrm{t}\left(\frac{4}{\sqrt{6}} + \frac{\varepsilon}{5}\right).$$

After extensive calculation, the difference of the sum over a regular tetrahedron (the LHS) minus the sum over the non-regular tetrahedron (the RHS) is $\Omega(\varepsilon^2)$. ◀

A Universal Sequence of Tensors for the Asymptotic Rank Conjecture

Abstract

The *exponent* $\sigma(T)$ of a tensor $T \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ over a field $\mathbb{F}$ captures the base of the exponential growth rate of the tensor rank of T under Kronecker powers. Tensor exponents are fundamental from the standpoint of algorithms and computational complexity theory; for example, the exponent ω of square matrix multiplication can be characterized as $\omega = 2\sigma(\mathrm{MM}_2)$, where $\mathrm{MM}_2 \in \mathbb{F}^4 \otimes \mathbb{F}^4 \otimes \mathbb{F}^4$ is the tensor that represents 2×2 matrix multiplication.

Strassen [FOCS 1986] initiated a duality theory for spaces of tensors that enables one to characterize the exponent of a tensor via objects in a dual space, called the *asymptotic spectrum* of the primal (tensor) space. While Strassen's theory has considerable generality beyond the setting of tensors – Wigderson and Zuiddam [*Asymptotic Spectra: Theory, Applications, and Extensions*, preprint, 2023] give a recent exposition – progress in characterizing the dual space in the tensor setting has been slow, with the first universal points in the dual identified by Christandl, Vrana, and Zuiddam [*J. Amer. Math. Soc.* 36 (2023)]. In parallel to Strassen's theory, the algebraic geometry community has developed a geometric theory of tensors aimed at characterizing the structure of the primal space and tensor exponents therein; the latter study was motivated in particular by an observation of Strassen (implicit in [*J. Reine Angew. Math.* 384 (1988)]) that matrix-multiplication tensors have limited universality in the sense that $\sigma(\mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d) \leq \frac{2\omega}{3} = \frac{4}{3}\sigma(\mathrm{MM}_2)$ holds for all $d \geq 1$. In particular, this limited universality of the tensor MM_2 puts forth the question whether one could construct explicit universal tensors that exactly characterize the worst-case tensor exponent in the primal space. Such explicit universal objects would, among others, give means towards a proof or a disproof of Strassen's asymptotic rank conjecture [*Progr. Math.* 120 (1994)]; the former would immediately imply $\omega = 2$ and, among others, refute the Set Cover Conjecture (cf. Björklund and Kaski [STOC 2024] and Pratt [STOC 2024]).

Our main result is an explicit construction of a *sequence* $\mathcal{U}_d$ of zero-one-valued tensors that is universal for the worst-case tensor exponent; more precisely, we show that $\sigma(\mathcal{U}_d) = \sigma(d)$ where $\sigma(d) = \sup_{T \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d} \sigma(T)$. We also supply an explicit universal sequence $\mathcal{U}_\Delta$ localised to capture the worst-case exponent $\sigma(\Delta)$ of tensors with support contained in $\Delta \subseteq [d] \times [d] \times [d]$; by combining such sequences, we obtain a universal sequence $\mathcal{T}_d$ such that $\sigma(\mathcal{T}_d) = 1$ holds if and only if Strassen's asymptotic rank conjecture holds for d. Finally, we show that the limit $\lim_{d\to\infty} \sigma(d)$ exists and can be captured as $\lim_{d\to\infty} \sigma(D_d)$ for an explicit sequence $(D_d)_{d=1}^{\infty}$ of tensors obtained by diagonalisation of the sequences $\mathcal{U}_d$.

As our second result we relate the *absence* of polynomials of fixed degree vanishing on tensors of low rank, or more generally asymptotic rank, with upper bounds on the exponent $\sigma(d)$. Using this technique, one may bound asymptotic rank for all tensors of a given format, knowing enough specific tensors of low asymptotic rank.

1 Introduction

1.1 Exponents of Tensors and the Quest for Universality

For an infinite field $\mathbb{F}$ and a positive integer constant d, the *exponent* of a nonzero tensor $T \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ is the least nonnegative real $\sigma(T)$ such that the sequence of tensor (Kronecker) powers

$$T^{\boxtimes \mathbb{N}} = (T^{\boxtimes p} : p = 1, 2, \ldots) \tag{1}$$

has its sequence of tensor ranks bounded by $\mathrm{R}(T^{\boxtimes p}) \leq d^{\sigma(T)p+o(p)}$. Exponents of specific *constant-size* tensors T are of fundamental significance in the study of algorithms and algebraic complexity theory [16, 76]. For example, Strassen showed that the exponent ω of square matrix multiplication satisfies $\omega = 2\sigma(\mathrm{MM}_2)$ [71, 67], where MM_2 is the $4 \times 4 \times 4$ tensor representing the multiplication map for two 2×2 matrices. Recently, it was shown that the Set Cover Conjecture [29, 30, 40] fails if the exponent of a specific $7 \times 7 \times 7$ tensor Q is sufficiently close to one [7, 59].

The study of exponents of tensors – or, what is the same up to exponentiation, the study of *asymptotic rank*[1] [34] of tensors – is difficult. The exponent ω of square matrix multiplication is perhaps the best studied nontrivial exponent, and even in its case the best current lower bound $\omega \geq 2$ remains the trivial one (but see [8, 43, 52, 47, 24]), and the best current upper bound $\omega \leq 2.371866$ [31] is a result of extensive work spanning decades (e.g. [70, 58, 6, 62, 61, 25, 71, 26, 65, 75, 53, 2]) and relying on increasingly sophisticated techniques. In parallel to the study of exponents of individual tensors, research effort has been invested into developing a structural theory for spaces of tensors and their exponents, a theory to which the present paper also contributes. Two rough lines of research most relevant to our present work are as follows.

Strassen's duality theory – the asymptotic spectrum of tensors. The first line of research, announced by Strassen [71] in his 1986 FOCS paper and developed in a sequence of papers [66, 67, 68] and PhD theses [15, 74, 54] (cf. [72]), builds a duality theory for asymptotic rank of tensors based on the theory of preordered commutative semirings, with the direct sum and tensor (Kronecker) product of tensors as the pertinent semiring operations, and the preorder defined by a rank-capturing tensor restriction relation. Wigderson and Zuiddam [76] give a recent comprehensive exposition of Strassen's theory and the preorder-theoretic topological dual spaces – the *asymptotic spectrum* of a space of tensors – which enable a tight characterization of the asymptotic rank of a tensor via the preorder-monotone homomorphisms in the dual. Yet, progress in terms of understanding the structure and identifying explicit points in the asymptotic spectrum of tensors has been slow. Beyond Strassen's original construction of support functionals, which are restricted to the subspace of oblique tensors, only recently Christandl, Vrana, and Zuiddam [18] constructed a family

[1] The *asymptotic rank* of $T \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ is $\tilde{\mathrm{R}}(T) = \lim_{p\to\infty} \mathrm{R}(T^{\boxtimes p})^{1/p}$ and we have $\tilde{\mathrm{R}}(T) = d^{\sigma(T)}$.

of explicit *universal* spectral points – called quantum functionals – using theory of quantum entropy and covariants; however, also this dual family is far from yielding broadly tight lower bounds on asymptotic rank.

Viewed from the standpoint of Strassen's duality theory, rather than working in a dual space, in this paper we seek and obtain as our main result an explicit and universal *primal* characterization of tensor exponents and thus asymptotic rank in $\mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ – before proceeding to our results, let us review a second pertinent line of prior research and motivation.

Geometry of tensors and the asymptotic rank conjecture. The second line of research seeks to study spaces of tensors to identify the *worst-case* behaviour in the space using tools from algebraic geometry, in particular building on the seminal concept of *border rank* of a tensor due to Bini, Capovani, Romani, and Lotti [6] (see also Schönhage [62]) and its geometric characterization via secant varieties of Segre and Veronese varieties (e.g. [13, 14, 50, 42, 45, 78]). For a space $\mathcal{F}$ of tensors, let $\sigma(\mathcal{F}) = \sup_{T\in\mathcal{F}} \sigma(T)$; as a special case, for $d = 1, 2, \ldots$ let $\sigma(d) = \sigma(\mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d)$. It is immediate that $1 \leq \sigma(d) \leq 2$ and that $\sigma(1) = 1$. Over the complex numbers, it is a nontrivial consequence of the geometry of tensors that $\sigma(2) = 1$. Already the value $\sigma(3)$ is open and would be of substantial interest to determine. For example, it is known that $\sigma(3) = 1$ implies $\omega = 2$ by the application of the Coppersmith–Winograd method [26] to a specific $3 \times 3 \times 3$ tensor. It appears very difficult to prove lower bounds on $\sigma(d)$ apart from the trivial $\sigma(d) \geq 1$. Indeed, any tensor $T \in (\mathbb{F}^d)^{\otimes 3}$ with $\sigma(T) > 1$ would yield an explicit sequence of tensors, namely its Kronecker powers, such that for any constant $C > 0$ for $k \gg 0$ we have rank and border rank of $T^{\boxtimes k}$ greater than Cd^k. Currently, we do not know explicit examples of such sequences for $C = 3$ with the current world record lower bound on rank in [1]. One of the main obstacles is lack of methods to prove that a given tensor has high rank or border rank. In case of rank, the state of the art is the substitution method, based on linear algebra. In case of border rank, one looks for polynomial witnesses that vanish on tensors of given bounded border rank. However in this case, most known equations, not found via explicit computations, also vanish on so-called cactus varieties, which fill the ambient space quickly and thus known methods cannot provide super-linear lower bounds on tensor rank [4, 5, 12, 32, 38]. The state of the art for border rank is based on mixture of different methods, barely breaking the bound for $C = 2$ [48]. As the rank of the generic tensor grows quadratically with d the problem is often referred to as an instance of the *hay in a haystack* problem (phrase due to H. Karloff): find an explicit object that behaves generically. There is hope in the new introduced method of border apolarity [13], still there is currently no clear path of getting past $C = 3$.

The difficulty of lower bounds and progressively improving upper bounds for specific exponents, the exponent ω in particular, has prompted bold conjectures on worst-case exponents for broad families of tensors. Most notably, writing $\mathcal{T}_d$ for the space of all tight tensors in $\mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$, *Strassen's asymptotic rank conjecture* (cf. [69, Conjecture 5.3]) states that the worst-case exponent for this space is the least possible:

▶ **Conjecture 1** (Strassen's asymptotic rank conjecture). *For all $d \geq 1$ it holds that $\sigma(\mathcal{T}_d) = 1$.*

Strassen's asymptotic rank conjecture, if true, immediately implies the algorithmically serendipitous corollary $\omega = 2$ in particular; cf. also [7, 59] for further consequences to algorithms. A yet stronger conjecture (cf. Bürgisser, Clausen, and Shokrollahi [16, Problem 15.5]; also e.g. Conner, Gesmundo, Landsberg, Ventura, and Wang [23, Conjecture 1.4] as well as Wigderson and Zuiddam [76, Section 13, p. 122]) states that the least possible exponent is shared by all concise tensors in $\mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$:

▶ **Conjecture 2** (Extended asymptotic rank conjecture). *For all $d \geq 1$ it holds that $\sigma(d) = 1$.*

A key result supporting Conjecture 1 and Conjecture 2, implicit in Strassen [67, Proposition 3.6] and highlighted by Christandl, Vrana, and Zuiddam [17, Proposition 2.12] as well as Conner, Gesmundo, Landsberg, and Ventura [22, Remark 2.1], is that tensor rank is known to be nontrivially submultiplicative under Kronecker products; stated in terms of worst-case tensor exponents, Strassen proved that for all $d \geq 1$ it holds that $\sigma(d) \leq \frac{2\omega}{3}$.

Viewed in terms of exponents of tensors and universality, we can rephrase Strassen's result as stating that the exponent of the matrix multiplication tensor MM_2 controls from above the exponent of all other tensors, namely we have $\sigma(d) \leq \frac{4}{3}\sigma(\mathrm{MM}_2) = \frac{2\omega}{3}$. This rephrasing suggests that one should seek explicit constructions of tensors $U \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ that are worst-case *universal* for the class with $\sigma(d) = \sigma(U)$. In rough analogy with computational complexity theory, such explicit tensors capture the "hardest" tensors in a class of tensors and, for example, would provide an explicit object of study towards resolving Conjectures 1 and 2.

1.2 Our Results – Explicit Universal Sequences of Zero-One-Valued Tensors

While we do not present explicit individual tensors U that are universal, as our main result we present an explicit *sequence* $\mathcal{U}$ of tensors that is universal and consists of zero-one-valued tensors in coordinates. Towards this end, let us extend the definition of the exponent of a tensor T to a sequence

$$\mathcal{T} = (T_j \in \mathbb{F}^{s_j} \otimes \mathbb{F}^{s_j} \otimes \mathbb{F}^{s_j} : j = 1, 2, \ldots) \tag{2}$$

of nonzero tensors. The *exponent* of the sequence $\mathcal{T}$ is the least nonnegative real $\sigma(\mathcal{T})$ such that $\mathrm{R}(T_j) \leq s_j^{\sigma(\mathcal{T})+o_j(1)}$. From (1) and (2) we immediately have $\sigma(T^{\boxtimes\mathbb{N}}) = \sigma(T)$ for all tensors $T \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$. Our main result is that there is an explicit sequence of tensors that characterizes the exponent of $\mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ and thus enables an approach towards resolving Strassen's conjecture.

▶ **Theorem 3** (Main; A universal sequence of tensors for d fixed). *For all $d \geq 1$ there is an explicit sequence $\mathcal{U}_d$ of zero-one-valued tensors with $\sigma(\mathcal{U}_d) = \sigma(d)$.*

In coordinates, the q^{th} tensor in the sequence $\mathcal{U}_d$ admits explicit combinatorial expression as a union of orbit-indicator tensors under a particular action of the symmetric group $\mathfrak{S}_q$. This combinatorial structure enables us to study the exponent $\sigma(\Delta)$ of the space of tensors spanned by $\{e_i \otimes e_j \otimes e_k : (i,j,k) \in \Delta\} \subseteq \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ for a nonempty $\Delta \subseteq [d] \times [d] \times [d]$; when equality holds, we have $\sigma(\Delta) = \sigma(d)$.

▶ **Theorem 4** (Support-localized universal sequences of tensors). *For all nonempty $\Delta \subseteq [d] \times [d] \times [d]$ there is an explicit sequence $\mathcal{U}_\Delta$ of zero-one-valued tensors with $\sigma(\mathcal{U}_\Delta) = \sigma(\Delta)$.*

From Theorem 4 we obtain the following corollary for tight tensors and Strassen's conjecture (Conjecture 1). We need short preliminaries. We say that the set Δ is *tight* if there exist injective functions $\alpha, \beta, \gamma : [d] \to \mathbb{Z}$ such that $\alpha(i) + \beta(j) + \gamma(k) = 0$ for all $(i,j,k) \in \Delta$. A tensor $T \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ is *tight* if it admits a coordinate-representation whose support is contained in a tight set.

▶ **Theorem 5** (A universal sequence of tensors for Strassen's conjecture). *For all $d \geq 1$ there is an explicit sequence $\mathcal{T}_d$ of tight zero-one-valued tensors with $\sigma(\mathcal{T}_d) = \sigma(\mathcal{T}_d)$.*

Further, by diagonalising the sequences $\mathcal{U}_d$ for increasing d we obtain a universal sequence providing worst possible exponent irrespective of d; that is, a universal sequence for the extended asymptotic rank conjecture (Conjecture 2):

▶ **Theorem 6** (A universal sequence of tensors for the extended asymptotic rank conjecture)**.** *There is an explicit sequence* $\mathcal{D} = (D_d : d = 1, 2, \ldots)$ *of zero-one-valued tensors with* $\lim_{d\to\infty} \sigma(D_d) = \lim_{d\to\infty} \sigma(d)$.

We note that the limit in the theorem above exists and is the supremum of all $\sigma(d)$; cf. Lemma 19. The above theorem may be regarded as a solution to the aforementioned hay in the haystack problem for the exponent of tensors.

1.3 Overview of Techniques

Before proceeding to review our further results, it will be convenient to give an overview of our main techniques and concepts underlying Theorem 3. In particular, a basis induced from integer compositions for the linear span of the image of the Kronecker power map $S \mapsto S^{\boxtimes q}$ will be our key tool.

The Kronecker power map $\mathbf{K_{d,q}}$ in coordinates. For a field $\mathbb{F}$ and positive integers d and q, our key object of study is the *Kronecker power map*

$$\mathrm{K}_{d,q} : \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d \to \mathbb{F}^{d^q} \otimes \mathbb{F}^{d^q} \otimes \mathbb{F}^{d^q}$$

that takes a tensor $S \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ to its q^{th} tensor (Kronecker) power $\mathrm{K}_{d,q}(S) = S^{\boxtimes q}$.

It will be convenient to study the Kronecker power map $\mathrm{K}_{d,q}$ by working with tensors in coordinates, so let us set up conventions accordingly. Let us write $[d] = \{1, 2, \ldots, d\}$ and identify the spaces $\mathbb{F}^{d\times d\times d} = \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$. For a tensor $S \in \mathbb{F}^{d\times d\times d}$ in the domain of $\mathrm{K}_{d,q}$, we write $S_{i,j,k} \in \mathbb{F}$ for the entry of S at position $i, j, k \in [d]$. For a tensor $T \in \mathbb{F}^{d^q\times d^q\times d^q}$ in the codomain of $\mathrm{K}_{d,q}$, it is convenient to index the entries $T_{I,J,K} \in \mathbb{F}$ of T with q-tuples $I = (i_1, i_2, \ldots, i_q) \in [d]^q$, $J = (j_1, j_2, \ldots, j_q) \in [d]^q$, $K = (k_1, k_2, \ldots, k_q) \in [d]^q$. Indeed, with this convention, the image $\mathrm{K}_{d,q}(S) = S^{\boxtimes q}$ of a tensor $S \in \mathbb{F}^{d\times d\times d}$ can be defined entrywise for all $I, J, K \in [d]^q$ by

$$S^{\boxtimes q}_{I,J,K} = S_{i_1,j_1,k_1} S_{i_2,j_2,k_2} \cdots S_{i_q,j_q,k_q} \,. \tag{3}$$

An explicit basis for the linear span of the image of $\mathbf{K_{d,q}}$. Next we embed the image $\mathrm{K}_{d,q}(\mathbb{F}^{d\times d\times d})$ in the least-dimensional subspace of $\mathbb{F}^{d^q\times d^q\times d^q}$ possible, so-called linear span, and provide an explicit basis for this subspace in the assumed coordinates. Towards this end, working with integer compositions that capture the distinct right-hand sides of (3) for a generic S with support in a nonempty set $\Delta \subseteq [d] \times [d] \times [d]$ will be convenient. In precise terms, a function $g : \Delta \to \mathbb{N}_{\geq 0}$ with $\sum_{\delta\in\Delta} g(\delta) = q$ is a *composition* of the positive integer q with domain Δ. Let us write $\mathcal{C}^{\Delta}_q$ for the set of all compositions of q with domain Δ. The distinct right-hand sides of (3) for a generic S are now enumerated by the compositions $g \in \mathcal{C}^{\Delta}_q$; explicitly, associate with g the product

$$S^g = \prod_{i,j,k\in[d]} S^{g(i,j,k)}_{i,j,k} \in \mathbb{F} \,. \tag{4}$$

Writing $\mathbb{F}^{\Delta}$ for the subspace of all tensors in $\mathbb{F}^{d\times d\times d}$ with support in Δ, we next provide a basis $(T^{(g)} \in \mathbb{F}^{d^q\times d^q\times d^q} : g \in \mathcal{C}^{\Delta}_q)$ that enables us to express the Kronecker power $S^{\boxtimes q}$ of an arbitrary tensor $S \in \mathbb{F}^{\Delta}$ as the linear combination

$$S^{\boxtimes q} = \sum_{g \in \mathcal{C}_q^\Delta} S^g T^{(g)} \,. \tag{5}$$

We need short preliminaries to define the tensors $T^{(g)}$ in the assumed coordinates. For $I, J, K \in [d]^q$, define the triple-counting composition $\Phi_{I,J,K} \in \mathcal{C}_q^{[d]\times[d]\times[d]}$ for all $u, v, w \in [d]$ by

$$\Phi_{I,J,K}(u,v,w) = |\{\ell \in [q] : i_\ell = u,\ j_\ell = v,\ k_\ell = w\}| \,. \tag{6}$$

We use *Iverson's bracket notation*; for a logical proposition P, we write $[\![P]\!]$ to indicate a 0 if P is false and a 1 if P is true.

▶ **Definition 7** (Composition basis for the linear span of the image $\mathrm{K}_{d,q}(\mathbb{F}^\Delta)$)**.** *For $g \in \mathcal{C}_q^\Delta$, define the tensor $T^{(g)} \in \mathbb{F}^{d^q \times d^q \times d^q}$ in coordinates for all $I, J, K \in [d]^q$ by*

$$\big(T^{(g)}\big)_{I,J,K} = [\![\Phi_{I,J,K} = g]\!] \,. \tag{7}$$

The tensors $(T^{(g)} : g \in \mathcal{C}_q^\Delta)$ are the composition basis *for the linear span of $\mathrm{K}_{d,q}(\mathbb{F}^\Delta)$.*

We provide various equivalent characterisations of these tensors $T^{(g)}$ in Lemma 9 (on page 10). The characterisation via integer compositions in Definition 7 in particular enables an immediate verification via (7), (4), and (3) that (5) holds. In particular, the linear span of the image $\mathrm{K}_{d,q}(\mathbb{F}^\Delta)$ is contained in the linear span of the composition basis. What is less immediate is that the reverse containment holds under mild assumptions on the field $\mathbb{F}$ by identifying the Kronecker power map with the Veronese map on homogeneous Δ-variate polynomials of degree q. In coordinates, by relying on homogeneous polynomial interpolation we show in Corollary 13 and Proposition 15 that for every $g \in \mathcal{C}_q^\Delta$ there exist tensors $S_f \in \mathbb{F}^\Delta$ and scalars $\lambda_{f,g} \in \mathbb{F}$ indexed by $f \in \mathcal{C}_q^\Delta$ such that

$$T^{(g)} = \sum_{f \in \mathcal{C}_q^\Delta} \lambda_{f,g} S_f^{\boxtimes q} \,. \tag{8}$$

Now (5) and (8) imply the composition basis spans exactly the linear span of $\mathrm{K}_{d,q}(\mathbb{F}^\Delta)$.

Sublinearity and serendipity of polynomial dimensionality of the span. By subadditivity of tensor rank, from the linear combination (5) we have immediately for an arbitrary tensor $S \in \mathbb{F}^\Delta$ that

$$\mathrm{R}\big(S^{\boxtimes q}\big) \le \sum_{g \in \mathcal{C}_q^\Delta} \mathrm{R}\big(T^{(g)}\big) \,.$$

Conversely, for an arbitrary $g \in \mathcal{C}_q^\Delta$, we have from (8) that

$$\mathrm{R}\big(T^{(g)}\big) \le \sum_{f \in \mathcal{C}_q^\Delta} \mathrm{R}\big(S_f^{\boxtimes q}\big) \,.$$

Recalling from combinatorics of integer compositions that $|\mathcal{C}_q^\Delta| = \binom{|\Delta|-1+q}{|\Delta|-1} \le (|\Delta| - 1 + q)^{|\Delta|-1}$, we observe that dimension of the linear span of $\mathrm{K}_{d,q}(\mathbb{F}^\Delta)$ grows only polynomially in q when Δ is fixed. Theorem 3 and Theorem 4 follow essentially immediately by taking $\mathcal{U}_\Delta = (U_{\Delta,q} : q = 1, 2, \ldots)$ with $U_{\Delta,q} = \bigoplus_{g \in \mathcal{C}_q^\Delta} T^{(g)}$ as the universal sequence.

Structure and description of the tensors $T^{(g)}$. The tensors $T^{(g)}$ admit several descriptions, e.g. a group-theoretic description can be given using orbit-indicators of the group $\mathfrak{S}_q$, see Lemma 9, and an alternative description can be given via type decompositions [76, Section 9.3] (see also [28]). There are several important applications of group theory in the study or tensor rank and asymptotic rank. We note that when G is an Abelian group then the structure tensor S_G of the group algebra is an orbit-indicator of the group G^2 identified with $\{(g_1, g_2, g_3) \in G^3 : g_1 + g_2 = g_3\}$; in this case, the tensor S_G has also minimal rank, equal to $|G|$, via the Discrete Fourier Transform. When G is not Abelian, the representation theory of G allows for nontrivial bounds on the rank of S_G; similar observations have been leveraged in the study of fast matrix multiplication; e.g. Cohn and Umans [20], Cohn, Kleinberg, Szegedy, and Umans [19], Cohn and Umans [21], Blasiak, Cohn, Grochow, Pratt, and Umans [10]. We expect this structure to enable further work towards an eventual proof or disproof of the (extended) asymptotic rank conjecture.

A win-win dichotomy. In addition to enabling worst-case characterisation of tensor exponents for families of tensors, the tensors $T^{(g)}$ enable the following "win-win" dichotomy (cf. Corollary 21 for a precise statement) that motivates their further study:

Either the extended asymptotic rank conjecture (Conjecture 2) holds, implying $\omega = 2$ and a disproof of the Set Cover Conjecture;

or the tensors $T^{(g)}$ form an explicit sequence of tensors with superlinear border rank growth, providing substantial progress for the "hay in the haystack" problem for rank and border rank.

A remark on explicitness. We stress that we here view explicitness as the property of not only a single tensor but rather a sequence of tensors; cf. e.g. [48, Section 3]. Both the tensors $T^{(g)}$ and the tensors in our universal sequences have zero-one entries in coordinates, and these entries may be computed fast. Indeed, from (7) it is immediate that we have linear-time algorithms that output $T^{(g)}_{I,J,K}$ given I, J, K, g as input. Similarly, listing (or ranking/unranking) integer compositions $g \in \mathcal{C}_q^\Delta$ for given Δ, q admit fast algorithms.

Invariant Specht tensors. Our techniques reduce the question about asymptotic ranks to questions about ranks of specific tensors, where $T^{(g)}$ is only one possible choice. Another one is to apply representation theory of the symmetric group $\mathfrak{S}_p$. It turns out that ranks of very special tensors, precisely invariants in the tensor product of three Specht modules $(S^\alpha \otimes S^\beta \otimes S^\gamma)^{\mathfrak{S}_p}$, where α, β, γ are partitions of p with at most d parts, govern the exponent $\sigma(d)$. Precise results are given in Section 4.

1.4 Further Results

Our second result relates extended Strassen's conjecture to equations of varieties, in particular secant varieties. We tacitly assume sufficient background in algebraic geometry and geometry of tensors (e.g. [27, 42, 55]). Also, unless otherwise mentioned, we assume that the field $\mathbb{F}$ is the field of complex numbers.

To set the context, it is a well-established method to prove that tensors have high border rank by exhibiting polynomials vanishing on the k^{th} secant variety of the Segre variety $X = (\mathbb{P}^{d-1})^{\times 3}$ and evaluating it on a given tensor T. Among the state of the art theoretical equations in this context are the Koszul flattenings and the Young flattenings, which can provide border rank bounds up $(2 - \epsilon)d$ for any $\epsilon > 0$ for $d \gg 0$. The degree of those equations grows as a polynomial in d for fixed ϵ, however the degree of this polynomial also

grows as $\epsilon \to 0$. The second method to obtain equations of secant varieties is computational, based on representation theory and linear algebra. This is an exhaustive method, finding all equations in the given degree and partitioning them into so-called isotypic components [11, 36]. Still of course its scope is limited due to computational obstacles. For border rank $k < d$, the smallest degree of a polynomial vanishing on the k^{th} secant variety is exactly $k + 1$ [46]. However, for border rank above d, one observes fast grow of the minimal degree in which equations exist; for example, the smallest degree of an equation vanishing on the 6^{th} secant variety of $(\mathbb{P}^3)^{\times 3}$ is 19 and on the 18^{th} secant variety of $(\mathbb{P}^6)^{\times 3}$ is at least 187000 [36]. The lack of low-degree (or otherwise easy) equations has been perceived so far as an obstacle in proving that tensors have high border rank, in particular in disproving Strassen's conjecture or its extensions. In this paper, we proceed in the *opposite* direction, namely that *absence* of low-degree equations of secant varieties implies upper bound on $\sigma(d)$.

▶ **Theorem 8** (Absence of low-degree equations implies low asymptotic rank)**.** *Let $X \subseteq \mathbb{P}((\mathbb{F}^d)^{\otimes 3})$ be a variety contained in the locus of tensors of asymptotic rank at most r. Suppose that no polynomial of degree p vanishes on X. Then every tensor in $(\mathbb{F}^d)^{\otimes 3}$ has asymptotic rank at most*

$$r\binom{d^3 - 1 + p}{d^3 - 1}^{\frac{1}{p}}.$$

We note that the theorem above implies that bounds on asymptotic rank of special tensors may imply bounds for all tensors. As the variety X may be always assumed to be $GL(d)^{\times 3}$ invariant one may combine the computational method of finding isotypic decomposition of homogeneous polynomials with obtaining good bounds on p, in order to obtain new bounds on $\sigma(d)$. We leave this line of research for the future.

1.5 Related Work

It is known that computing the tensor rank of a given tensor is NP-hard [35]; see also [37, 60, 63] for pertinent hardness results. It is also difficult in practice to determine the rank and border rank of small tensors; for example, the rank, border rank and border support rank of MM_2 are known to be seven [9, 36, 41, 70].

There has been extensive interest in constructing explicit tensors of high rank or border rank [1, 44, 48, 51]. This study is motivated by the need for new methods to provide lower complexity bounds. Currently, we do not know how to construct sequences of explicit tensors $T \in \mathbb{F}^d \otimes \mathbb{F}^d \otimes \mathbb{F}^d$ of rank or border rank above $3d$. In fact, there are no known examples of tensors with entries 0 or 1 and rank or border rank greater than $3d$. The only method to construct such tensors, is by making the entries incomparable in size, i.e. each entry is of different order of magnitude then other entries, or making them algebraically independent, which makes the tensors very far from explicit. However, it is easy to prove that tensors of super-linear border rank, with respect to their size exist. Precisely, for any constant $C > 0$ and d sufficiently large there exists a tensor $T \in (\mathbb{F}^d)^{\otimes 3}$ of border rank greater than Cd. Even more: general tensors will have greater border rank than Cd for d sufficiently large and the growth of maximal border rank is quadratic in d. We simply do not know how to provide explicit examples of such tensors, as the methods we have do not allow to prove that particular tensors have large rank. These obstructions are related to the fact that the cactus variety, that contains the secant variety, fills the whole ambient space, while most of the equations we know for secant varieties, also vanish on cactus varieties [12, 33, 32, 38, 49, 73]. We even do not know how to provide a sequence of explicit tensors so that infinitely many elements of the sequence would have high rank, say above $3d$.

The families of tensors with fixed support are also studied. An important concept is that of support rank [21], which has given rise to other support-based algorithm-design techniques (e.g. [3, 39]). Further, bounding asymptotic rank of special tensors was recently tied to NP-hard problems; in particular, Strassen's conjecture (Conjecture 1) would imply unexpected (but not polynomial) upper bounds on complexity of (randomized) algorithms for NP-hard problems [7, 59].

Beyond the present invariant Specht tensors, representation theory of the symmetric and general linear groups has extensive connections to algebraic complexity theory via Strassen's theory of asymptotic spectra (e.g. [18]) as well as the geometric complexity theory program (e.g. [56, 57]).

1.6 Organization of This Paper

Section 2 reviews notational preliminaries and definitions. Section 3 studies the composition basis and proves our main theorems on explicit universal sequences of tensors (Theorems 3 to 6). Section 4 introduces invariant Specht tensors and shows their universality for the exponent $\sigma(d)$ (Corollary 38). Section 5 relates the equations of varieties to bounds on asymptotic rank and proves Theorem 8.

2 Preliminaries

Recall that we write $[d] = \{1, 2, \ldots, d\}$. The set $[d]^q$ consists of sequences of length q of integers in $[d]$. We fix the canonical basis $e_1, e_2, \ldots, e_m \in \mathbb{F}^m$.

In this article, we exclusively work with tensors of format $a \times b \times c$, where in most cases $a = b = c$. These are elements of the vector space $\mathbb{F}^a \otimes \mathbb{F}^b \otimes \mathbb{F}^c \simeq \mathbb{F}^{a\times b\times c}$. In analogy to the case of matrices, the reader may freely think about tensors as three dimensional arrays filled with elements of $\mathbb{F}$. For a vector $v \in \mathbb{F}^a$ we write $v_i := e_i^*(v) \in \mathbb{F}$ for $1 \leq i \leq a$. We write $S_{i,j,k} \in \mathbb{F}$ for the entry of $S \in \mathbb{F}^a \otimes \mathbb{F}^b \otimes \mathbb{F}^c$ at position $(i, j, k) \in [a] \times [b] \times [c]$.

For three vectors $v_1 \in \mathbb{F}^a, v_2 \in \mathbb{F}^b$ and $v_3 \in \mathbb{F}^c$ we define the tensor $v_1 \otimes v_2 \otimes v_3 \in \mathbb{F}^a \otimes \mathbb{F}^b \otimes \mathbb{F}^c$ where the (i, j, k) coordinate equals $(v_1)_i(v_2)_j(v_3)_k$. Tensors of this form are called *rank one* tensors. The *rank* of a tensor T is the smallest r such that T is sum of r rank one tensors.

In case $\mathbb{F} = \mathbb{R}$ or $\mathbb{F} = \mathbb{C}$ we define the *border rank* of a tensor T as the smallest r such that in any neighbourhood of T there exists a tensor of rank r. For more details about rank and border rank we refer to [16, 42, 55]. The Kronecker power of a tensor is defined as in formula (3). *Asymptotic rank* [34] of a tensor T is defined as $\lim_{n\to\infty} \mathrm{R}(T^{\boxtimes n})^{\frac{1}{n}}$. We write $\langle s\rangle$ to be the unit tensor $\langle s\rangle = \sum_{i=1}^{s} e_i \otimes e_i \otimes e_i$.

3 Universal Sequences of Tensors for the Asymptotic Rank Conjecture

In this section we prove that the tensors $T^{(g)}$ in the composition basis (Definition 7) form a universal family for the asymptotic rank conjecture. We start with a more detailed analysis of the structure of the composition basis for fixed d (Section 3.1), and follow with an analysis for increasing d (Section 3.2); in particular, we establish the existence of the limit exponent $\lim_{d\to\infty} \sigma(d)$. Theorem 3 and Theorem 6 are restated and proved next (Section 3.3). Using techniques of Strassen, we then show that the universal sequences have nontrivially low tensor rank (Section 3.4). We end this section by setting up our techniques for support-localization (Section 3.5) as well as restate and prove Theorem 5, our main result for tight tensors (Section 3.6).

3.1 Properties of the Composition Basis

We start with the following easy lemma that provides various alternative characterisations of tensors $T^{(g)}$ in Definition 7.

We note that the symmetric group $\mathfrak{S}_q$ acts by permutations on $\mathbb{F}^{[d]^q}$ and diagonally on $(\mathbb{F}^{[d]^q})^{\otimes 3}$.

▶ **Lemma 9** (Equivalent definitions of the composition basis). *We have the following equivalent definitions of tensors $T^{(g)}$ for any $g \in \mathcal{C}_q^{[d]^3}$.*

1. *The tensors $T^{(g)}$ are precisely sums of $\mathfrak{S}_q$ orbits of canonical basis tensors in $(\mathbb{F}^{[d]^q})^{\otimes 3}$.*
2. *The tensors $T^{(g)}$ are coefficients of monomials for the Kronecker map $K_{d,q}$, explicitly:*

$$K_{d,q}(S) = \sum_{g \in \mathcal{C}_q^{[d]^3}} S^g T^{(g)} .$$

   In particular, the linear span of the image is contained in the linear span of tensors $T^{(g)}$.
3. *If $|\mathbb{F}| > q$, then the tensors $T^{(g)}$, up to scaling by a constant, are precisely tensors with inclusion minimal supports in the linear span of the image of $K_{d,q}$.*

Proof. We note that the condition $\Phi_{I,J,K} = g$ from Definition 7 determines the triple (I, J, K) up to simultaneous action by an element of $\mathfrak{S}_q$. This proves equivalence of point (1) with the original definition.

The coordinates of $K_{d,p}(S)$ in the canonical basis are monomials of degree q in the coordinates of S. A monomial S^g appears exactly on the entries indexed by such (I, J, K)'s that $\Phi_{I,J,K} = g$. This proves equivalence of point (2) with Definition 7.

In Proposition 15, we show that the linear span of the image of $K_{d,q}$ coincides with the linear span of $T^{(g)}$'s for $g \in \mathcal{C}_q^{[d]^3}$ and $|\mathbb{F}| > q$. As $T^{(g)}$'s have disjoint supports, we obtain point (3). ◀

▶ Remark 10 (Invariant subspaces defined by marginals of g). It is immediate that $T^{(g)} \in (\mathbb{F}^{[d]^q})^{\otimes 3}$, however the tensor $T^{(g)}$ also belongs to smaller invariant subspace defined by g. Namely, for $g \in \mathcal{C}_q^{[d]^3}$ let $g_1 : [d] \to \mathbb{N}$ be the first marginal of g; that is, let $g_1(j) = \sum_{a,b \in [d]} g(j, a, b)$ for all $j \in [d]$. In the same way, define the second marginal g_2 and third marginal g_3. For $i = 1, 2, 3$, let $U_i \subseteq [d]^q$ be the set of all q-tuples $I \in [d]^q$ such that the value j appears in I exactly $g_i(j)$ times for all $j \in [d]$. We have $|U_i| = \binom{q}{g_i(1), g_i(2), \ldots, g_i(d)}$ as well as $T^{(g)} \in \mathbb{F}^{U_1} \otimes \mathbb{F}^{U_2} \otimes \mathbb{F}^{U_3}$. Clearly, the ambient space is $\mathfrak{S}_q$ invariant.

▶ **Example 11** (The small Coppersmith–Winograd tensor). Let $d = 2$, $q = 3$ and g assign value 1 on $(0, 0, 1)$, $(0, 1, 0)$ and $(1, 0, 0)$. The tensor $T^{(g)}$ is the small Coppersmith–Winograd tensor in $(\mathbb{F}^3)^{\otimes 3}$, that is:

$$e_0 \otimes e_1 \otimes e_2 + e_0 \otimes e_2 \otimes e_1 + e_1 \otimes e_0 \otimes e_2 + e_1 \otimes e_2 \otimes e_0 + e_2 \otimes e_0 \otimes e_1 + e_2 \otimes e_1 \otimes e_0 .$$

▶ **Definition 12** (Linear span of the composition basis). *Let $L_{d,q}$ be the linear span of the tensors $T^{(g)}$ for $g \in \mathcal{C}_q^{[d]^3}$. As the tensors $T^{(g)}$ have disjoint supports they are linearly independent and hence form a basis of $L_{d,q}$. We note that $\dim L_{d,q} = \binom{d^3+q-1}{q}$ which is the cardinality of $\mathcal{C}_q^{[d]^3}$.*

▶ **Corollary 13** (Span coincides with the space of invariants). *The tensors $T^{(g)}$ for $g \in \mathcal{C}_q^{[d]^3}$ form a basis of the invariants space $((\mathbb{F}^{[d]^q})^{\otimes 3})^{\mathfrak{S}_q}$, which coincides with $L_{d,q}$. Up to rescaling, it is the unique basis of that space made of tensors with disjoint supports.*

From now on we will assume that the cardinality of the field is greater than q.

▶ **Lemma 14** (Dual space of homogeneous polynomials). *There is an isomorphism of vector spaces: $L^*_{d,q}$ of linear forms and functions on $(\mathbb{F}^d)^{\otimes 3}$ given by homogeneous polynomials of degree q. The isomorphism sends a linear form l to the polynomial function $l \circ K_{d,q}$.*

Proof. Let $T^{(g)*}$ be the basis of $L^*_{d,q}$ dual to $T^{(g)}$. The image of the linear function $\sum \lambda_g T^{(g)*}$ is $\sum \lambda_g S^g$. Surjectivity is obvious.

By induction on the number n of variables, one proves that no polynomial of degree q may vanish identically on $\mathbb{F}^n$, when $|\mathbb{F}| > q$. Hence, no linear form l is mapped to the zero function and the linear map $l \mapsto l \circ K_{d,p}$ is injective. This finishes the proof. ◀

▶ **Proposition 15** (Span of the image of the Kronecker power map). *The space $L_{d,q}$ is the linear span of the image of $K_{d,q}$.*

Proof. Clearly $L_{d,q}$ contains the image of $K_{d,q}$. If the containment was strict, there would exist a nonzero linear function $l \in L_{d,q}$ vanishing on the image. Then $l \circ K_{d,q} = 0$. This is not possible by Lemma 14. ◀

▶ Remark 16 (The Veronese map of degree q). Up to isomorphism, $K_{d,q}$ may be identified with the q^{th} Veronese map, that is a map defined by all degree q monomials. However, in coordinates each monomial may appear more than once, as each monomial represented by $g \in \mathcal{C}_q^{[d]^3}$ appears on the support of $T^{(g)}$.

▶ **Lemma 17** (Maximum rank in the composition basis controls rank in $L_{d,q}$). *Let r be the maximum rank (respectively, asymptotic rank) of $T^{(g)}$ over $g \in \mathcal{C}_q^{[d]^3}$. Every tensor in $L_{d,q}$ has rank (respectively, asymptotic rank) at most*

$$r|\mathcal{C}_q^{[d]^3}| = r\binom{d^3-1+q}{d^3-1}.$$

In particular, every tensor in $(\mathbb{F}^d)^{\otimes 3}$ has asymptotic rank at most

$$\left(r\binom{d^3-1+q}{d^3-1}\right)^{\frac{1}{q}}.$$

Proof. Fix $T \in (\mathbb{F}^d)^{\otimes 3}$. By Lemma 9 the tensor $K_{d,q}(T)$ is a linear combination of $T^{(g)}$'s for $g \in \mathcal{C}_q^{[d]^3}$. As $|\mathcal{C}_q^{[d]^3}| = \binom{d^3-1+q}{d^3-1}$ we obtain:

$$\mathrm{R}(K_{d,q}(T)) \leq r\binom{d^3-1+q}{d^3-1}.$$

The statement under the assumption of asymptotic rank r for $T^{(g)}$'s is proved in the same way, noting that asymptotic rank is subadditive and submultiplicative (e.g. [76]). ◀

3.2 The Extended Asymptotic Rank Conjecture and the Limit Exponent

We are now ready to connect the composition-basis tensors $T^{(g)}$ to the extended asymptotic rank conjecture (Conjecture 2).

▶ **Corollary 18** (The composition basis suffices for the extended asymptotic rank conjecture). *If there exists an infinite set $S = \{d_1, d_2, \ldots\} \subseteq \mathbb{Z}_{\geq 1}$ such that for any d_i there exist infinitely many $q_{i,j} \in \mathbb{Z}_{\geq 1}$ such that Conjecture 2 holds for the tensor $T^{(g)}$ for all $g \in \mathcal{C}_{q_{i,j}}^{[d_i]^3}$, then Conjecture 2 holds for all tensors.*

Proof. First fix d_i. By Lemma 17 we see that any $T \in ((\mathbb{F}^{d_i})^{\otimes 3})$ has asymptotic rank at most:

$$(d_i^q)^{\frac{1}{q}} \binom{d_i^3 - 1 + q}{d_i^3 - 1}^{\frac{1}{q}}.$$

Note that for fixed d_i we have

$$\lim_{q\to\infty} \binom{d_i^3 - 1 + q}{d_i^3 - 1}^{\frac{1}{q}} = 1\,.$$

This confirms Conjecture 2 for any $T \in (\mathbb{F}^{d_i})^{\otimes 3}$. We conclude that it must hold for each d from the next Lemma 19. ◀

▶ **Lemma 19** (Existence of the limit exponent). *The limit* $\lim_{d\to\infty} \sigma(d)$ *exists and equals the supremum of the set* $\{\sigma(d) : d \in \mathbb{Z}_{\geq 1}\}$.

Proof. As the sequence $\sigma(d)$ is bounded it is enough to prove:

$$\forall_{d_0\in\mathbb{Z}_{\geq 1}} \forall_{\epsilon>0} \exists_{D\in\mathbb{Z}_{\geq 1}} \forall_{d>D} \quad \sigma(d) > \sigma(d_0) - \epsilon\,.$$

Fix $\epsilon > 0$ and $d_0 \in \mathbb{Z}_{\geq 1}$. For contradiction assume there are infinitely many d_i such that $\sigma(d_i) \leq \sigma(d_0) - \epsilon$. Hence, we also obtain infinitely many k_i such that $d_0^{k_i} \leq d_i < d_0^{k_i+1}$.

We note that we have $\sigma(d_0^{k_i}) \geq \sigma(d_0)$ as taking Kronecker power of a tensor does not change the exponent. Hence, for any $\delta > 0$ there exists $T_\delta \in (\mathbb{F}^{d_0^{k_i}})^{\otimes 3}$ of asymptotic rank at least $d_0^{k_i(\sigma(d_0)-\delta)}$. As we may embed T_δ in larger space, we see that its asymptotic rank is at most $d_i^{\sigma(d_i)} \leq d_0^{(k_i+1)(\sigma(d_0)-\epsilon)}$. We obtain:

$$k_i(\sigma(d_0) - \delta) \leq (k_i + 1)(\sigma(d_0) - \epsilon).$$

As this holds for any $\delta > 0$ we obtain:

$$k_i\sigma(d_0) \leq (k_i + 1)(\sigma(d_0) - \epsilon),$$

which is a contradiction for k_i sufficiently large. ◀

The following more precise result shows that the exponent governing the asymptotic rank is completely determined via asymptotic ranks of the tensors $T^{(g)}$.

▶ **Corollary 20** (The composition bases govern tensor exponents). *For all* $\tau \geq 0$ *it holds that each tensor* $T^{(g)} \in (\mathbb{F}^m)^{\otimes 3}$ *(where* m *is uniquely determined by* g*) has asymptotic rank at most* m^τ *if and only if any tensor* $T \in (\mathbb{F}^d)^{\otimes 3}$ *(where* d *is arbitrary) has asymptotic rank at most* d^τ*. In particular, for any tensor* T *we have* $\sigma(T) \leq \sup_g \sigma(T^{(g)})$.

Proof. The implication "⇐" is immediate. For the implication "⇒", assume that a tensor T has asymptotic rank greater than $d^{\tau+\epsilon}$ for fixed $\epsilon > 0$. By applying Lemma 17 for $q \gg 0$ such that $\binom{d^3-1+q}{d^3-1}^{\frac{1}{q}} < d^\epsilon$ we obtain a contradiction. ◀

We note that there are countably many tensors $T^{(g)}$ and they form a sequence of explicit tensors. This sequence gives rise to the following dichotomy.

▶ **Corollary 21** (A dichotomy on improved algorithms or explicit rank lower bounds). *We have the following dichotomy. Either*

- **(i)** *the extended asymptotic rank conjecture (Conjecture 2) holds; that is, for all tensors T we have $\sigma(T) \leq 1$, which implies $\omega = 2$ and disproves the Set Cover Conjecture; or*
- **(ii)** *the tensors $T^{(g)}$ form a sequence of explicit tensors such that for any constant $C \in \mathbb{Z}_{\geq 1}$ there exist infinitely many $T^{(g)} \in (\mathbb{F}^m)^{\otimes 3}$, such that rank, border rank, and asymptotic rank is greater than Cm.*

It is clear that for special g the rank of $T^{(g)}$ can be small. For example if g is supported at one element, then $T^{(g)}$ has support of cardinality one and thus is of rank one.

3.3 Explicit Universal Sequences and Main Results

We first prove our main theorem for fixed d, and define the universal sequence accordingly.

▶ **Definition 22** (Universal sequence for a fixed d). *For a fixed positive integer d, we define the sequence $\mathcal{U}_d = (U_{d,q} : q = 1, 2, \ldots)$ of tensors, where we set*

$$U_{d,q} = \bigoplus_{g \in \mathcal{C}_q^{[d]^3}} T^{(g)}.$$

We are now ready to prove our main theorem; Theorem 3 is restated below for convenience.

▶ **Theorem 23** (Main; Explicit universal sequences of tensors). *For all $d \geq 1$ we have $\sigma(\mathcal{U}_d) = \sigma(d)$.*

Proof. We prove the equality by proving both inequalities.

First, suppose that $\sigma(\mathcal{U}_d) < \sigma$ for some constant σ. Fix an $\epsilon > 0$ so that for q sufficiently large $\mathrm{R}(U_{d,q}) < (|\mathcal{C}_q^{[d]^3}| d^q)^{\sigma-\epsilon}$. Then, for q sufficiently large and all $g \in \mathcal{C}_q^{[d]^3}$ we have $\mathrm{R}(T^{(g)}) \leq \mathrm{R}(U_{d,q}) < (|\mathcal{C}_q^{[d]^3}| d^q)^{\sigma-\epsilon}$. As $\lim_{q\to\infty} |\mathcal{C}_q^{[d]^3}|^{1/q} = 1$ we see that for q sufficiently large and all $g \in \mathcal{C}_q^{[d]^3}$ we have $\sigma(T^{(g)}) \leq \sigma$. Applying Lemma 17 and taking limit, as $q \to \infty$ we see that $\sigma(T) \leq \sigma$ for all $T \in (\mathbb{F}^d)^{\otimes 3}$.

Suppose now that for all $T \in (\mathbb{F}^d)^{\otimes 3}$ we have $\sigma(T) < \sigma$. Fix $\epsilon > 0$, such that $\sigma(T) < \sigma - \epsilon$ for all $T \in (\mathbb{F}^d)^{\otimes 3}$. By Proposition 15 for any $g \in \mathcal{C}_q^{[d]^3}$ the tensor $T^{(g)}$ is a sum of at most $|\mathcal{C}_q^{[d]^3}|$-many tensors of type $K_{d,q}(T)$. Hence, for q sufficiently large we have:

$$\mathrm{R}(T^{(g)}) \leq |\mathcal{C}_q^{[d]^3}| d^{q(\sigma-\epsilon)}.$$

It follows that:

$$\mathrm{R}(U_{d,q}) \leq |\mathcal{C}_q^{[d]^3}|^2 d^{q(\sigma-\epsilon)}.$$

As $\lim_{q\to\infty} |\mathcal{C}_q^{[d]^3}|/d^{\epsilon q} = 0$ we see that $\mathrm{R}(U_{d,q}) \leq (|\mathcal{C}_q^{[d]^3}| d^q)^{\sigma}$ for $q \gg 0$. Thus $\sigma(\mathcal{U}_d) \leq \sigma$, which finishes the proof. ◀

Next, we construct one universal sequence realizing the worst possible exponent, irrespective of d via a diagonal argument on the sequences $\mathcal{U}_d$. Accordingly, recalling Definition 22, define the diagonal sequence $\mathcal{D} = (D_d : d = 1, 2, \ldots)$ of tensors for all positive integers d by setting $D_d = U_{d,d^4}$. It is immediate that the sequence is explicit. Theorem 6 is restated below for convenience.

▶ **Theorem 24** (An explicit universal sequence for the extended asymptotic rank conjecture). *The sequence $\mathcal{D}$ satisfies $\lim_{d\to\infty} \sigma(D_d) = \lim_{d\to\infty} \sigma(d)$.*

Proof. By Lemma 19 it is enough to prove that for every $\epsilon > 0$, for all d sufficiently large we have $\sigma(U_{d,d^4}) > \sigma(d) - \epsilon$. For any (concise) $T \in (\mathbb{F}^d)^{\otimes 3}$ we have:

$$d^{d^4\sigma(T)} = \tilde{\mathrm{R}}(T)^{d^4} \leq \sum_{g \in \mathcal{C}_{d^4}^{[d]^3}} \tilde{\mathrm{R}}(T^{(g)}) \leq |\mathcal{C}_{d^4}^{[d]^3}| \tilde{\mathrm{R}}(U_{d,d^4}) \leq |\mathcal{C}_{d^4}^{[d]^3}| (|\mathcal{C}_{d^4}^{[d]^3}| d^{d^4})^{\sigma(U_{d,d^4})}.$$

After taking root of order d^4 we only need to prove that $\lim_{d\to\infty} |\mathcal{C}_{d^4}^{[d]^3}|^{1/d^4} = 1$. We have:

$$\lim_{d\to\infty} |\mathcal{C}_{d^4}^{[d]^3}|^{1/d^4} = \lim_{d\to\infty} \binom{d^4 + d^3 - 1}{d^3 - 1}^{1/d^4} \leq \lim_{d\to\infty} (2d^4)^{d^3/d^4} = 1,$$

which finishes the proof. ◀

3.4 Upper Bounds on Tensor Rank in the Universal Sequences

A natural question arises: what are ranks of the tensors $T^{(g)}$. In order to provide upper bounds, we recall the following lemma due to Strassen (implicit in [67, Proposition 3.6]).

▶ **Lemma 25** (Limited universality of matrix multiplication tensors)**.** *The matrix multiplication tensor* MM_{d^2} *degenerates to* $T^{\boxtimes 3}$ *for any tensor* $T \in (\mathbb{F}^d)^{\otimes 3}$*. In particular,* $\sigma(T) \leq 2\omega/3$*.*

Proof. Let us write in coordinates $T = (\lambda_{p,q,r})$ and

$$\mathrm{MM}_{d^2} = \sum_{i_1,i_2,j_1,j_2,k_1,k_2 \in [d]} e_{j_1,j_2}^{i_1,i_2} \otimes e_{k_1,k_2}^{j_1,j_2} \otimes e_{i_1,i_2}^{k_1,k_2}.$$

For $i = 1, 2, 3$, define $l_i : \mathbb{F}^{d^4} \to \mathbb{F}^{d^3}$ as follows:

$$l_1(e_{j_1,j_2}^{i_1,i_2}) = \sum_{a \in [d]} \lambda_{a,j_1,i_1} e_{a,j_2,i_2},$$
$$l_2(e_{k_1,k_2}^{j_1,j_2}) = \sum_{b \in [d]} \lambda_{j_2,b,k_1} e_{j_1,b,k_2},$$
$$l_3(e_{i_1,i_2}^{k_1,k_2}) = \sum_{c \in [d]} \lambda_{i_2,k_2,c} e_{i_1,k_1,c}.$$

We have $l_1 \otimes l_2 \otimes l_3(\mathrm{MM}_{d^2}) = T^{\boxtimes 3}$. ◀

In a similar way we obtain:

▶ **Lemma 26** (Limited universality of matrix multiplication under powers)**.** *The matrix multiplication tensor* $\mathrm{MM}_{d^{2k}}$ *degenerates to* $T^{\boxtimes 3k}$ *for any tensor* $T \in (\mathbb{F}^d)^{\otimes 3}$*.*

We obtain the following corollary, which currently is asymptotically in $k \gg 0$ the best one we know, that works for arbitrary $g \in \mathcal{C}_{3k}^{[d]^3}$.

▶ **Corollary 27** (Upper bound on rank via matrix multiplication)**.** *For any* $g \in \mathcal{C}_{3k}^{[d]^3}$ *the tensor* $T^{(g)}$ *has rank at most* $\mathrm{R}(\mathrm{MM}_{d^{2k}}) \cdot \binom{d^3-1+3k}{d^3-1}$.

▶ Remark 28 (Note on special g). We note that Corollary 27 may be improved for many special g. For any $g \in \mathcal{C}_{3k}^{[d]^3}$ we have three marginal distributions on $[d]$. If such a distribution is close to uniform, then we obtain about d^k compatible sequences of length k; that is, asymptotically every sequence is compatible. However, if the distribution is far from uniform, we obtain less sequences, say d^{ck} for some $c < 1$. In such a case $\mathrm{MM}_{d^{2k}}$ in Lemma 26 may be changed into smaller matrix multiplication.

3.5 Support-Localized Universality

Many of our results remain true if we consider tensors $T \in (\mathbb{F}^d)^{\otimes 3}$ with support contained in a nonempty $\Delta \subseteq [d]^3$. Let us write $\mathbb{F}^\Delta$ be the linear space of tensors with such a support. As before $K_{d,q}$ restricted to $\mathbb{F}^\Delta$ is still a Veronese map, simply in variables corresponding to elements from Δ. The image of $K_{d,q}|_{\mathbb{F}^\Delta}$ has a basis made of tensors $T^{(g)}$ for $g \in \mathcal{C}_q^\Delta$. Below we present a variant of Lemma 17, which proof is analogous.

▶ **Lemma 29** (Maximum rank in the support-localized composition basis controls rank in $\mathbb{F}^\Delta$)**.** *Let r be the maximum rank (respectively, asymptotic rank) of $T^{(g)}$ over $g \in \mathcal{C}_q^\Delta$. The q^{th} Kronecker power of every tensor in $\mathbb{F}^\Delta$ has rank (respectively, asymptotic rank) at most*

$$r|\mathcal{C}_q^\Delta| = r\binom{|\Delta|-1+q}{|\Delta|-1}.$$

In particular, every tensor in $(\mathbb{F}^d)^{\otimes 3}$ with support contained in Δ has asymptotic rank at most

$$\left(r\binom{|\Delta|-1+q}{|\Delta|-1}\right)^{\frac{1}{q}}.$$

Next, we present a variant of Strassen's result for tensors with fixed support. For $\Delta \subseteq [d]^3$, we will use the following notation: $\Delta_{1,2} = \{(i,j) : \exists_k (i,j,k) \in \Delta\}$, $\Delta_{1,3} = \{(i,k) : \exists_j (i,j,k) \in \Delta\}$, and $\Delta_{2,3} = \{(j,k) : \exists_i (i,j,k) \in \Delta\}$.

Consider the following support-localized restriction of the matrix multiplication tensor MM_{d^2}:

$$\mathrm{MM}_\Delta := \sum_{\substack{(j_1,i_1)\in\Delta_{2,3}\\(j_2,k_1)\in\Delta_{1,3}\\(i_2,k_2)\in\Delta_{1,2}}} e_{j_1,j_2}^{i_1,i_2} \otimes e_{k_1,k_2}^{j_1,j_2} \otimes e_{i_1,i_2}^{k_1,k_2}.$$

We obtain the following version of Lemma 25.

▶ **Lemma 30** (Limited universality of support-localized matrix multiplication)**.** *The tensor MM_Δ degenerates to $T^{\boxtimes 3}$ for any tensor $T \in (\mathbb{F}^d)^{\otimes 3}$ with support contained in Δ.*

▶ **Corollary 31** (Upper bound on rank via support-localized matrix multiplication)**.** *For any $g \in \mathcal{C}_{3k}^\Delta$ the tensor $T^{(g)}$ has rank at most $\mathrm{R}(\mathrm{MM}_\Delta) \cdot \binom{|\Delta|-1+3k}{|\Delta|-1}$.*

Next we present the proof of Theorem 4.

▶ **Theorem 32** (Support-localized universal sequences of tensors)**.** *For all nonempty $\Delta \subseteq [d] \times [d] \times [d]$ there is an explicit sequence $\mathcal{U}_\Delta$ of zero-one-valued tensors with $\sigma(\mathcal{U}_\Delta) = \sigma(\Delta)$.*

Proof. Let $\mathcal{U}_\Delta = (U_{\Delta,q} : q = 1, 2, \dots)$ for

$$U_{\Delta,q} = \bigoplus_{g\in\mathcal{C}_q^\Delta} T^{(g)}.$$

As the image of $K_{d,q}|_{\mathbb{F}^\Delta}$ has a basis made of tensors $T^{(g)}$ for $g \in \mathcal{C}_q^\Delta$ the proof is analogous to the proof of Theorem 23 where we replace reference to Lemma 17 by reference to Lemma 29. ◀

3.6 Tight Tensors and Strassen's Conjecture

We now proceed to our main theorem for tight tensors and fixed d; we start by defining a corresponding universal sequence.

▶ **Definition 33** (Universal sequence for tight tensors and fixed d). *For a fixed positive integer d, we define the sequence $\mathcal{T}_d = (T_{d,q} : q = 1, 2, \ldots)$ of tensors, where we set*

$$T_{d,q} = \bigoplus_{\substack{\Delta \subseteq [d]^3 \\ \Delta \text{ tight}}} U_{\Delta,q} = \bigoplus_{\substack{\Delta \subseteq [d]^3 \\ \Delta \text{ tight}}} \bigoplus_{g \in \mathcal{C}_q^\Delta} T^{(g)} .$$

Next we prove Theorem 5, which we restate below for convenience.

▶ **Theorem 34** (A universal sequence of tensors for Strassen's conjecture). *We have $\sigma(\mathcal{T}_d) = \sigma(\mathcal{T}_d)$ and each $T_{d,q}$ is tight.*

Proof. First, we prove that for $g \in \mathcal{C}_q^\Delta$, where Δ is tight, the tensor $T^{(g)}$ is tight. Indeed, if we take any tensor T with support Δ, it is tight, thus so is $T^{\boxtimes q}$. As $T^{(g)}$ has smaller support it is tight. As direct sum of tight tensors is tight, we see that each $T_{d,q}$ is tight.

Next we note that for fixed d each $T_{d,q}$ is a sum of a fixed number of tensors $U_{\Delta,q}$. Thus, there exists a constant C such that:

$$\max_{\substack{\Delta \subseteq [d]^3 \\ \Delta \text{ tight}}} \mathrm{R}(U_{\Delta,q}) \leq \mathrm{R}(T_{d,q}) \leq C \max_{\substack{\Delta \subseteq [d]^3 \\ \Delta \text{ tight}}} \mathrm{R}(U_{\Delta,q})$$

and the same inequalities hold for the size of the tensors. For every tight T, we may find tight Δ such that $\sigma(T) \leq \sigma(\Delta)$. By Theorem 4 this equals $\sigma(\mathcal{U}_\Delta)$ and by the inequality above this is upper bounded by $\sigma(\mathcal{T}_d)$.

For the other inequality, we see that $\sigma(\mathcal{T}_d)$ is upper bounded by $\sigma(\mathcal{U}_\Delta)$ for some tight Δ. Clearly, $\sigma(\mathcal{U}_\Delta) \leq \sigma(\mathcal{T}_d)$ which finishes the proof. ◀

4 Representation Theory and Universality of Specht Tensors

Let us now take a representation-theoretic view to the invariant subspace $(\mathbb{C}^{[d]^p \times [d]^p \times [d]^p})^{\mathfrak{S}_p}$ and start by observing that the $\mathfrak{S}_p$-module $\mathbb{C}^{[d]^p \times [d]^p \times [d]^p}$ is isomorphic to the $\mathfrak{S}_p$-module $\mathbb{C}^{d^p} \otimes \mathbb{C}^{d^p} \otimes \mathbb{C}^{d^p}$. A k-tuple $\lambda = (\lambda_1, \lambda_2, \ldots, \lambda_k)$ of integers $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_k \geq 1$ is an *(integer) partition* of the integer $p = \lambda_1 + \lambda_2 + \ldots + \lambda_k$ into k *parts*. We write $\mathcal{I}(p)$ for the set of all integer partitions of p and $\mathcal{I}(p, d)$ for the set of all integer partitions with at most d parts. For $\lambda \in \mathcal{I}(p)$ we write $\lambda! = (\lambda_1!)(\lambda_2!)\cdots(\lambda_k!)$. For $\lambda \in \mathcal{I}(p, d)$ we write $D(\lambda) = (d-k)! \prod_{\ell=1}^{p} (|\{j \in [k] : \lambda_j = \ell\}|!)$. For $\lambda \in \mathcal{I}(p)$, let us write M^λ for the $\mathfrak{S}_p$-permutation module on Young tabloids of shape λ. Recall that the dimension of M^λ is $p!/\lambda!$. We have the $\mathfrak{S}_p$-module isomorphism

$$\mathbb{C}^{d^p} \cong \bigoplus_{\lambda \in \mathcal{I}(p,d)} \frac{d!}{D(\lambda)} M^\lambda$$

and thus

$$\mathbb{C}^{d^p} \otimes \mathbb{C}^{d^p} \otimes \mathbb{C}^{d^p} \cong \bigoplus_{\mu,\nu,\lambda \in \mathcal{I}(p,d)} \frac{d!}{D(\mu)} \frac{d!}{D(\nu)} \frac{d!}{D(\lambda)} M^\mu \otimes M^\nu \otimes M^\lambda . \tag{9}$$

For $\alpha \in \mathcal{I}(p)$, let us write S^α for the Specht module associated with α. For $\alpha, \mu \in \mathcal{I}(p)$, let us write $m_{\alpha,\mu}$ for the Kostka numbers so that the $\mathfrak{S}_p$-module isomorphism

$$M^\mu \cong \bigoplus_{\alpha \in \mathcal{I}(p)} m_{\alpha,\mu} S^\alpha \tag{10}$$

holds. We have the following elementary lemma that puts a strong restriction on the Specht modules that need to be considered for small values of d in (9) and (10). Recall that a partition $(\alpha_1, \alpha_2, \dots)$ is greater or equal to a partition $(\mu_1, \mu_2, \dots)$ in the *dominance order* if and only if for any i, we have $\sum_{j=0}^{i} \alpha_j \geq \sum_{j=0}^{i} \mu_j$. Here, if one of partitions, say α, has k parts, we let $\alpha_j = 0$ for $j > k$.

▶ **Lemma 35** (Restriction to at most d parts)**.** *For $\alpha, \mu \in \mathcal{I}(p)$ we have $m_{\alpha,\mu} \neq 0$ if and only if α is larger than μ in the dominance order. In particular, for all $\mu \in \mathcal{I}(p,d)$ we have $m_{\alpha,\mu} = 0$ unless $\alpha \in \mathcal{I}(p,d)$.*

Proof. See e.g. [64, p. 315]. ◀

From (9), (10), and Lemma 35 we thus have

$$\mathbb{C}^{d^p} \otimes \mathbb{C}^{d^p} \otimes \mathbb{C}^{d^p} \cong \bigoplus_{\mu,\nu,\lambda \in \mathcal{I}(p,d)} \frac{d!}{D(\mu)} \frac{d!}{D(\nu)} \frac{d!}{D(\lambda)} \bigoplus_{\alpha,\beta,\gamma \in \mathcal{I}(p,d)} m_{\alpha,\mu} m_{\beta,\nu} m_{\gamma,\lambda} S^\alpha \otimes S^\beta \otimes S^\gamma \,. \tag{11}$$

Writing $K(\alpha,\beta,\gamma)$ for the Kronecker coefficient of $\alpha, \beta, \gamma \in \mathcal{I}(p)$, we have that the invariant space $(S^\alpha \otimes S^\beta \otimes S^\gamma)^{\mathfrak{S}_p}$ has dimension $K(\alpha,\beta,\gamma)$. Since $(\mathbb{C}^{[d]^p \times [d]^p \times [d]^p})^{\mathfrak{S}_p}$ has dimension $\binom{d^3-1+p}{d^3-1}$, from (11) we immediately have

$$\binom{d^3-1+p}{d^3-1} = \sum_{\mu,\nu,\lambda \in \mathcal{I}(p,d)} \frac{d!}{D(\mu)} \frac{d!}{D(\nu)} \frac{d!}{D(\lambda)} \sum_{\alpha,\beta,\gamma \in \mathcal{I}(p,d)} m_{\alpha,\mu} m_{\beta,\nu} m_{\gamma,\lambda} K(\alpha,\beta,\gamma) \,. \tag{12}$$

Assuming that d is fixed and p grows, we observe that the left-hand side of (12) grows at most polynomially in p, and all summands on the right-hand side are nonnegative, implying that every summand on the right-hand grows at most polynomially in p. The above observations motivate the following definition.

▶ **Definition 36.** *For any three Specht modules $S^\alpha, S^\beta, S^\gamma$, where α, β, γ are partitions of p, we call any element of $(S^\alpha \otimes S^\beta \otimes S^\gamma)^{\mathfrak{S}_p}$ an* invariant Specht tensor *with* margin α, β, γ *and* degree p*.*

▶ Remark 37. For fixed α, β, γ the dimension of the space of invariant Specht tensors equals the Kronecker coefficient $K(\alpha,\beta,\gamma)$.

By Lemma 35 and Equation (11) only invariant Specht tensors with margins that have at most d parts appear in the decomposition of $(\mathbb{C}^{[d]^p \times [d]^p \times [d]^p})^{\mathfrak{S}_p}$ and each such tensor does appear. Further, for fixed d the dimension of all invariant Specht tensors with arbitrary margins $\alpha, \beta, \gamma \in \mathcal{I}(p,d)$ is polynomial in p. Thus, we can equivalently define $\sigma(d)$ as the infimum of all positive real numbers such that for all $\alpha, \beta, \gamma \in \mathcal{I}(p,d)$ the maximum tensor rank in $(S^\alpha \otimes S^\beta \otimes S^\gamma)^{\mathfrak{S}_p}$ is at most $d^{\sigma(d)p+o(p)}$. We obtain the following corollary.

▶ **Corollary 38.** *Fix an integer $d \geq 2$. Then $\sigma(d)$ is the infimum of all positive real numbers such that for all $\alpha, \beta, \gamma \in \mathcal{I}(p,d)$ the maximum tensor rank of an invariant Specht tensor is at most $d^{\sigma(d)p+o(p)}$.*

The above corollary motivates the following questions:

- What is the maximum tensor rank for an invariant Specht tensor of degree p with margins in $\mathcal{I}(p,d)$ as p grows?
- Which margins witness this maximum?

Specht modules and tensor products of Specht modules have considerable structure; e.g. [77]. As highlighted above, already the case $d = 3$ is interesting.

▶ Remark 39. Our results allow to translate between asymptotic rank and rank of invariant Specht tensors. As $\sigma(d) \leq \frac{2\omega}{3} < 2$, we see that in the range $\alpha, \beta, \gamma \in \mathcal{I}(p,d)$ one indeed obtains nontrivial upper bounds on ranks of invaiant Specht tensors; that is, such tensors in general do not have generic ranks in their ambient spaces $S^\alpha \otimes S^\beta \otimes S^\gamma$.

5 Equations of Secant Varieties and Asymptotic Rank

In this section we relate existence of polynomials vanishing on special varieties, like secant varieties, and asymptotic rank. In particular, we obtain upper-bound control on $\sigma(d)$ via the *absence* of low-degree equations of secants.

5.1 Equations and Bounds on $\sigma(d)$

We start with a generalization of Proposition 15.

▶ **Proposition 40** (Span of the image of a subset). *For any subset $S \subseteq (\mathbb{F}^d)^{\otimes 3}$, the following are equivalent:*

1. *no homogeneous polynomial of degree p vanishes on S,*
2. *$K_{d,p}(S)$ linearly spans $L_{d,p}$.*

Proof. The second condition is equivalent to the fact that no linear form in $L_{d,p}^*$ vanishes on $K_{d,p}(S)$. By Lemma 14 this is also equivalent to the first condition. ◀

▶ **Corollary 41** (Absence of low-degree equations implies low asymptotic rank). *Let X be the Segre variety of rank one tensors in $(\mathbb{F}^d)^{\otimes 3}$. Suppose that for fixed n no polynomial of degree p vanishes on the n^{th} secant variety $\sigma_n(X)$. Then every tensor in $L_{d,p}$ has rank at most*

$$\binom{d^3-1+p}{d^3-1} n^p .$$

Every tensor in $(\mathbb{F}^d)^{\otimes 3}$ has asymptotic rank at most

$$n \binom{d^3-1+p}{d^3-1}^{\frac{1}{p}} .$$

Proof. Note that $\dim L_{d,p} = \binom{d^3-1+p}{d^3-1}$ and by Proposition 40 we have a basis of $L_{d,p}$ made of tensors of rank at most n^p. The last statement follows. ◀

A more general, but less explicit version is given by Theorem 8, which we derive as the following corollary.

▶ **Corollary 42** (Absence of low-degree equations implies low asymptotic rank; implicit version). *Let $Y \subseteq (\mathbb{F}^d)^{\otimes 3}$ be a subset with the property that for all $T \in Y$ the asymptotic rank of T is at most n. Suppose that no homogeneous polynomial of degree p vanishes on Y. Then, every tensor in $(\mathbb{F}^d)^{\otimes 3}$ has asymptotic rank at most*

$$n \binom{d^3-1+p}{d^3-1}^{\frac{1}{p}} .$$

▶ Remark 43. The dimension component $\binom{d^3-1+p}{d^3-1}$ may be improved (by going to border rank) by the smallest s, such that $\sigma_s(K_{d,p}(\sigma_n(X))) = L_{d,p}$. The latter number is in most cases much smaller then $\dim L_{d,p}$. Each particular case may be exactly studied by the Teraccini Lemma.

Alternatively we could greedily, starting from rank one and going up, take tensors T_i such that $K_{d,p}(T_i)$ are linearly independent, building a basis of $L_{d,p}$.

For tensors belonging to a fixed subspace $W \subseteq (\mathbb{F}^d)^{\otimes 3}$ we also have the following variant.

▶ **Theorem 44.** *Let $Y \subseteq W \subseteq (\mathbb{F}^d)^{\otimes 3}$ be a subset with the property that for all $T \in Y$ the asymptotic rank of T is at most n. Suppose that no homogeneous polynomial on W of degree p vanishes on Y. Then every tensor in W has asymptotic rank at most*

$$n\binom{\dim W - 1 + p}{\dim W - 1}^{\frac{1}{p}}.$$

Proof. We recall that the restriction of the Veronese map of degree p to any linear subspace is still a Veronese map of degree p; that is, a map defined by polynomials spanning the space of degree p polynomials, simply in smaller number of variables.

We restrict $K_{d,p}$ to W. The linear span of $K_{d,p}(W)$ is spanned by $K_{d,p}(Y)$ and has dimension $\binom{\dim W-1+p}{\dim W-1}$. Hence for any tensor $T \in W$ the asymptotic rank of $K_{d,p}(T)$ is at most:

$$n^p\binom{\dim W - 1 + p}{\dim W - 1}.$$

As $K_{d,p}(T)$ is the p^{th} Kronecker power of T, the statement follows. ◀

The previous result could be particularly useful if we can provide many examples of low rank tensors inside a linear subspace.

5.2 Equations of Secant Varieties and Applications

We note that deciding if there exists a nonzero polynomial of degree p on $(\mathbb{F}^d)^{\otimes 3}$ vanishing on tensors of rank r is a question in linear algebra. The naïve approach is a as follows.

Consider $3r$ vectors $v_{i,j} \in \mathbb{F}^d$ where $1 \leq i \leq 3$ and $1 \leq j \leq r$ with coordinates $(v_{i,j})_k$ treated as variables. The tensor $T := \sum_{j=1}^r v_{1,j} \otimes v_{2,j} \otimes v_{3,j}$ is a general tensor of rank r. We have:

$$T_{a,b,c} = \sum_{j=1}^{r} (v_{1,j})_a (v_{2,j})_b (v_{3,j})_c \,.$$

If we assign the weight $(1,0,0) \in \mathbb{Z}^3$ to each $(v_{1,j})_a$, the weight $(0,1,0)$ to each $(v_{2,j})_b$, and the weight $(0,0,1)$ to each $(v_{3,j})_c$, we see that an evaluation of a degree p polynomial P on T is a degree (p,p,p) polynomial. Furthermore, P vanishes on all tensors of rank at most r if and only if $P(T) = 0$ as a polynomial. To check the last condition we may build a matrix $N_{d,r,p}$ with:

1. $\binom{p+d^3-1}{p}$ columns indexed by $\mathcal{C}_p^{[d]^3}$, equivalently monomials of degree p,
2. $\binom{p+dr-1}{p}^3$ rows indexed by monomials of degree (p,p,p) in variables $(v_{i,j})_k$,
3. the entry in a column indexed by a monomial $g \in \mathcal{C}_p^{[d]^3}$ and a row indexed by a monomial m is the coefficient of m in the polynomial $g(T)$.

The kernel of $N_{d,r,p}$ is naturally identified with the space of homogeneous degree p polyomials vanishing on rank r tensors. In particular, the kernel is trivial if and only if there are no such polynomials. While this approach is very general, it is also not applicable in most cases due to the large sizes of the matrices $N_{d,r,p}$.

A better approach to understand the equations of secant varieties is to exploit group actions. For this, one decomposes the space $S^p(\mathbb{C}^d \otimes \mathbb{C}^d \otimes \mathbb{C}^d)$ of homogeneous degree p polynomials on the tensor space as a direct sum of irreducible $G := GL(n) \times GL(n) \times GL(n)$ representations. The irreducible polynomial representations of G are indexed by triples of Young diagrams, in our case each one in the triple will have p elements:

$$S^p(\mathbb{C}^d \otimes \mathbb{C}^d \otimes \mathbb{C}^d) = \bigoplus V_{\lambda,\mu,\nu}^{\bigoplus g_{\lambda,\mu,\nu}},$$

where $V_{\lambda,\mu,\nu}$ is the triple corresponding to three Young diagrams λ, μ, ν with p boxes each and $V_{\lambda,\mu,\nu}$ is the Kronecker coefficient. The vector space of homogeneous polynomials of degree p that vanish on the n^{th} secant variety is a subrepresentation and hence also may be decomposed as:

$$\bigoplus V_{\lambda,\mu,\nu}^{\bigoplus a_{\lambda,\mu,\nu}},$$

where now the coefficients $a_{\lambda,\mu,\nu} \leq g_{\lambda,\mu,\nu}$ are unknown. One way to determine them is to consider highest weigh space $HWS_{\lambda,\mu,\nu}$, that is a vector space of dimension $g_{\lambda,\mu,\nu}$ inside $V_{\lambda,\mu,\nu}^{\bigoplus g_{\lambda,\mu,\nu}}$. It turns out that $a_{\lambda,\mu,\nu}$ equals the dimension of the subspace of $HWS_{\lambda,\mu,\nu}$ consisting on those polynomials that vanish on the n^{th} secant variety. Finding the basis of $HWS_{\lambda,\mu,\nu}$ and efficiently evaluating it on points of the secant variety is an art on its own. However, in many examples, the procedure above was successfully carried out in practice. We refer to [11, 36] for details.

▶ **Example 45.** The generic rank in $\mathbb{C}^7 \otimes \mathbb{C}^7 \otimes \mathbb{C}^7$ is 19. Tensors of border rank 18 form a hypersurface with the defining equation of degree at least 187000 [36, Section 3.2]. Applying Corollary 41 we see that every tensor in that space has asymptotic rank smaller than 18.25.

We believe that many further results on asymptotic rank may be obtained in a similar way, through Corollary 41 and 42, especially in combination with Remark 43. We leave this for future work.

Online Versus Offline Adversaries in Property Testing

Abstract

We study property testing with incomplete or noisy inputs. The models we consider allow for *adversarial* manipulation of the input, but differ in whether the manipulation can be done only *offline*, i.e., before the execution of the algorithm, or *online*, i.e., as the algorithm runs. The manipulations by an adversary can come in the form of erasures or corruptions. We compare the query complexity and the randomness complexity of property testing in the offline and online models. Kalemaj, Raskhodnikova, and Varma (Theory Comput. '23) provide properties that can be tested with a small number of queries with offline erasures, but cannot be tested at all with online erasures. We demonstrate that the two models are incomparable in terms of query complexity: we construct properties that can be tested with a constant number of queries in the online corruption model, but require querying a significant fraction of the input in the offline erasure model. We also construct properties that exhibit a strong separation between the randomness complexity of testing in the presence of offline and online adversaries: testing these properties in the online model requires exponentially more random bits than in the offline model, even when they are tested with nearly the same number of queries in both models. Our randomness separation relies on a novel reduction from randomness-efficient testers in the adversarial online model to query-efficient testers in the standard model.

1 Introduction

Property testing [31, 15] aims to lay algorithmic foundations for processing big data. It is a formal study of fast algorithms that accept objects with a given property and reject objects that are far. The goal of this work is to compare models of property testing that address the situations when the data that needs to be analyzed is not only large, but also incomplete or noisy. The models we consider allow for adversarial manipulation of the input, but differ in whether the manipulation can be done only *offline*, i.e., before the execution of the algorithm, or *online*, i.e., as the algorithm runs. The manipulations by an adversary can come in the

form of erasures or corruptions. The offline erasure-resilient property testing model was proposed by Dixit et al. [9]. The model that captures offline corruptions is called *tolerant testing* and was introduced by Parnas et al. [25]. The online analogues of these models were recently defined by Kalemaj et al. [21].

We compare the query complexity and the randomness complexity of property testing in the offline and online models. In the offline-erasure model, a constant fraction of the input is erased adversarially before the execution of the algorithm, whereas in the online-erasure model, the adversary is allowed to make a fixed number of erasures after each query. It may seem that the online adversary has strictly more power, and thus testing in the online models should require more queries. Indeed, [21] justify this intuition and show that simple properties – sortedness and the Lipschitz property of sequences – cannot be tested at all with online erasures[1], even though they are testable using a small number of queries when erasures are offline. Intuitively, [21] show that testing in the presence of one online erasure per query (performed by an adversary with the knowledge of previous queries) can be harder than testing when a constant fraction of the input is adversarially erased offline (in advance). The following natural open question is stated in [21]: "Is there a property that has smaller query complexity in the online-erasure-resilient model than in the (offline) erasure-resilient model of [9]?" We answer this question in the affirmative: specifically, we construct a property that can be tested with a constant number of queries in the online-erasure model (and even in the (harder) online-corruption model), but requires a nearly linear number of queries in the offline-erasure model. We conclude that the two adversarial erasure models are incomparable.

Our second result concerns the randomness complexity of testing in the online and offline manipulation models. Randomness is an important tool in the design of a wide variety of algorithms, and extensive research has been conducted to understand the power of randomness in computation. The investigation of the randomness complexity of property testing algorithms was initiated by Goldreich and Sheffet [18]. They showed that all property testers in the standard model can be derandomized to a large extent: they can be converted to testers that use the number of random bits that is logarithmic in the size of the input, while incurring at most a constant factor blowup in query complexity. The result of [18] easily extends to all offline testing models, but does not apply in the online setting. Moreover, the existing testers in the online model [21, 24, 6, 33, 3] use lots of randomness to fool the adversary. A natural question that arises is how much derandomization is possible in the online setting. We show that a lot of randomness is sometimes indeed necessary to test in the presence of an online adversary. In particular, we exhibit a property that requires exponentially more random bits to test in the online manipulation model than in the offline manipulation model. This result provides a natural converse to the statement of [24] that "the (online) adversary cannot foil our plan if there is no plan" – i.e., random queries are robust to online manipulation of the input.

1.1 Our results

We represent the input to our property testing algorithm as a string. The algorithm is given access to its input string via queries (specifically, of the form "what is the character at index i?"). For each proximity parameter $\varepsilon \in (0, 1)$, the algorithm has to distinguish between strings that have a specified property and strings that are ε-far from having the property – i.e., strings that need to be changed on at least an ε-fraction of indices in order to satisfy

[1] In contrast, in the offline models, testing is always possible when the entire input is read.

the property. The query complexity (the number of queries to the input) of the tester is measured in terms of ε and the input length n. In this section, for simplicity, ε is considered to be a constant and omitted from the statements.

1.1.1 Query complexity: Model Incomparability

We show that the online and offline adversarial models of property testing are incomparable in terms of the query complexity. Recall that [21] prove that sortedness and Lipschitzness of sequences are efficiently testable with offline erasures, but cannot be tested at all even with one online erasure per query[2]. We complement this result with the following theorems, which show that testing in the presence of a small fraction of offline erasures can be harder than testing with online erasures. The first of this theorems (Theorem 1.1) considers the regime with many online erasures per query; the second (Theorem 1.1) considers the regime with one erasure per query. The former exhibits a logarithmic gap in query complexity, where as the latter exhibits a nearly linear gap.

▶ **Theorem 1.1** (Informal version of Corollary 3.2)**.** *There exists a property that can be tested using a* constant number of queries *in the presence of an online adversary that makes $O\left(\frac{n}{\log n}\right)$ erasures per query; but requires $\widetilde{\Omega}(\log n)$* queries[3] *to test when the characters at $\Theta\left(\frac{n}{\log\log n}\right)$ indices are erased offline (in advance).*

We cannot expect to prove an analogue of Theorem 1.1 for the case when the number of online erasures per query is the same as the total number of offline erasures. This is because, after the first query, an online adversary can erase the same part of the input that the offline adversary would have erased in advance.

▶ Remark 1.2. Although the online erasure rate in Theorem 1.1 is very large, the total number of erasures available to the online adversary is smaller than the number of offline erasures we considered. It is an intriguing open question whether there exists a property for which every tester in the online model accumulates at least as many erasures as the best tester in the offline model, but also requires fewer queries to test in the online model than in the offline model.

At the other end of the spectrum, we show that if the number of erasures is much smaller in the online model than in the offline model, then there is an exponentially large gap – i.e., there are properties that can be tested with a constant number of queries when the erasures are online but require a nearly linear number of queries in the offline erasure model.

▶ **Theorem 1.3** (Informal version of Corollary 3.3)**.** *There exists a property that can be tested with a constant number of queries in the presence of an online adversary that makes one erasure per query, but requires $\widetilde{\Omega}(n)$ queries to test when the characters at $\Theta\left(\frac{n}{\log n}\right)$ indices are erased offline (in advance).*

---

[2] We note that there is an even simpler property than sortedness and Lipschitzness of sequences that is easily testable with offline erasures or corruptions, but is not testable at all with online erasures. Moreover, this property is over the alphabet $\Sigma = \{0,1\}$. Specifically, $\mathcal{P} = \{ww : w \in \{0,1\}^*\}$. We can estimate the distance to this property within additive error ε using $O(\frac{1}{\varepsilon^2})$ queries (and therefore it is easily tolerantly testable). However, we cannot test it with online erasures because, whenever the tester queries some position p in an input string of length $2n$, the adversary can erase the corresponding position ($n+p$ if $p \le n$ and $p-n$ if $p > n$).

[3] The notation $\widetilde{\Omega}(f(n))$ hides polylog $f(n)$ factors, e.g., $\widetilde{\Omega}(\log n) = \Omega(\log n/\operatorname{polyloglog} n)$.

In fact, the query complexity separations in Theorems 1.1 and 1.3 hold even if the online adversary can make *corruptions* instead of erasures.

To prove Theorems 1.1 and 1.3, we show that any property that separates the offline model from the standard one, i.e., a property that is easy to test in the standard model but hard in the offline model, can be "lifted" to separate the offline and online models. We can then leverage the state of the art separation (between the standard and offline-manipulation testing models) of [5] to obtain strong separations between the online and offline manipulation models.

Our "lifting" operation is simply encoding the property with a repetition code. Intuitively, repetition won't make the property easier to test in the presence of offline erasures since the same erasures can be made on all copies. Our main technical proof for this part is to show that repetition code is robust against online adversaries. We prove the following general result.

▶ **Lemma 1.4** (Informal version of Lemma 3.5)**.** *If a property $\mathcal{P}$ is testable when no adversary is present then the repeated version $\mathcal{P}^r$, given by concatenating each string in $\mathcal{P}$ with itself r times, is testable in the presence of an online adversary (as long as the number of erasures per query is not too large).*

1.1.2 Randomness complexity separations

As discussed earlier, the investigation of the randomness complexity of property testing algorithms was initiated by Goldreich and Sheffet [18] who showed that every property that is testable in the standard model using q queries can be tested using $O(q)$ queries and $O(\log n)$ random bits. We build on their investigation by studying the randomness complexity of the erasure models. Though their result easily extends to the offline models, the same extension does not work in the online model. Indeed, we show that the derandomization of [18] cannot be extended to the online testing model – that is, we construct a property that requires $\omega(\log n)$ random bits to test in the online model.

Note that a randomness separation trivially holds for properties which are not testable with online erasures, or when the offline-erasure-resilient tester is allowed to query the entire input[4]. Prior to our work it was not clear if there is a randomness separation that applies to properties that are testable in the online model, and still holds if we require that the testers in both models to have a sublinear (in n) query complexity.

We demonstrate such a separation. In particular, we show that there exists a property that is testable in both models using a sublinear number of queries, and, moreover, testing this property in the online erasure model requires exponentially more random bits than testing it in the offline erasure model.

▶ **Theorem 1.5** (Informal version of Corollary 4.2)**.** *There exists a property that can be tested using $O(\sqrt{n})$ queries in the presence of either an online or an offline adversary. The tester against the offline adversary uses $O(\log n)$ random bits, whereas every tester in the presence of an online adversary that makes one erasure per query requires $\widetilde{\Omega}(\sqrt{n})$ random bits to succeed with constant probability.*

Theorem 1.5 follows easily from a more general result, Theorem 4.1, which we prove in Section 4 and which yields meaningful separations for larger online erasure rates as well. The main technique we develop to prove a lower bound on the randomness complexity of testing

[4] In this case, the tester in the offline model is deterministic. Note that it is impossible to deterministically test any nontrivial property in the online model, since the adversary can erase all but the first query made by a deterministic tester.

with an online adversary is a transformation from randomness-efficient testers in the online model to query efficient testers in the standard model. A special case of the guarantees of our transformation is stated in Lemma 1.6. (The general version appears in Lemma 4.3.)

To prove Theorem 4.1, we combine our transformation with existing results regarding the property of strings called τ-Distinct-Elements, which is parametrized by $\tau \in \mathbb{N}$, and consists of strings that have at most τ distinct characters. Testing τ-Distinct-Elements was recently investigated in [17, 2, 1, 20], and it is a natural testing version of the distinct elements approximation problem studied in [28, 32]. For a more detailed exposition regarding the history of the τ-Distinct-Elements property and its variants see [20].

▶ **Lemma 1.6** (Special case of Lemma 4.3 for one online erasure per query)**.** *Fix $r \in \mathbb{N}$. If a property $\mathcal{P}$ can be tested using r random bits in the presence of an online adversary that makes one erasure per query, then $\mathcal{P}$ can be tested in the standard model (with the same proximity parameter ε) using at most r queries.*

The technique from Lemma 1.6, combined with the derandomization results of [18], immediately yields a separation for $\varepsilon = o(\frac{1}{\log n})$: Consider the property $\mathcal{P} \subseteq \{0,1\}^n$ of being the zero string. By the folklore property testing bound, $\Theta(\frac{1}{\varepsilon})$ queries are necessary and sufficient to test $\mathcal{P}$. By [18], there exists a tester in the offline erasure model that uses $O(\log n)$ random bits. However, by Lemma 1.6, every tester in the online model must use $\Omega(\frac{1}{\varepsilon}) = \omega(\log n)$ random bits. While this works for small ε, the separation we show in Theorem 1.5 (and the more general Theorem 4.1) holds for constant ε as well.

1.2 Related work

Relationship between offline and standard models

In terms of query complexity, testing with offline erasures lies between standard and tolerant testing. By definition, an offline-erasure-resilient tester is also a property tester in the standard model, because it has to work on the inputs with no erasures. Not surprisingly, offline testing with erasures is no harder than offline testing with corruptions. This is formalized in [9, Theorem 1.4] that shows that the existence of a tolerant tester for a property implies the existence of an offline-erasure-resilient tester for that property for a comparable setting of parameters. There are also separations that show that standard testing is strictly easier than offline-erasure-resilient testing, which in turn is strictly easier than tolerant testing. Specifically, Dixit et al. [9] showed that a property defined by Fischer and Fortnow [13] can be tested in the standard model with a constant number of queries, but requires $n^{\Omega(1)}$ queries in the offline-erasure-resilient model. This separation was strengthened by Ben-Eliezer et al. [5], improving $n^{\Omega(1)}$ to $\widetilde{\Omega}(n)$. Finally, Raskhodnikova et al. [29] prove a separation similar to that of [9] between offline-erasure-resilient testing and tolerant testing. Thus, at a high level, we have a complete picture in terms of the relative difficulty of testing in the three offline models.

Relationship between offline and online testing

Kalemaj et al. [21] exhibit two properties of strings for which testing with online erasures is impossible for every proximity parameter $\varepsilon \leq \frac{1}{2}$, whereas testing in the offline models is easy. The first property, *sortedness*, consists of sorted arrays, i.e., strings x of length n such that $x_i \leq x_{i+1}$ for all $i \in [n-1]$. The query complexity of testing sortedness (for constant ε) is $\Theta(\log n)$ in both the standard and the offline erasures model (when the erased part is at most a constant fraction of the input) [11, 10, 26, 12, 7, 8, 27, 4, 9]. The second property, Lipschitzness, consists of strings $x \in \{0,1,2\}^n$ satisfying $|x_i - x_{i+1}| \leq 1$ for all $i \in [n-1]$. It can be tested with $\Theta(\frac{1}{\varepsilon})$ queries in both the standard and the offline models [19, 9].

2 Preliminaries

Notation

We use $[n]$ to denote the set of integers $\{1, 2, \ldots, n\}$, and $\mathbb{N}$ to denote the set of positive integers.

Property testing

We start by stating standard property testing definitions. We represent an input to a property testing algorithm as a string of length n over some alphabet Σ_n that might depend on n. For example, Σ_n might be $\{0, 1\}$ or $[n]$.

▶ **Definition 2.1** (Relative Hamming distance, property, ε-far)**.** *The* relative Hamming distance *between two strings x, y of length n is $\delta_H(x, y) = \Pr_{i\sim[n]}[x_i \neq y_i]$ where i is uniformly random index from $[n]$. For a set $\mathcal{S}$ of strings of length n, define $\delta_H(x, \mathcal{S}) = \min_{y\in\mathcal{S}} \delta_H(x, y)$. A property $\mathcal{P}$ is a subset of Σ^* given by $\bigcup_{n\in\mathbb{N}} \mathcal{P}_n$, where each $\mathcal{P}_n$ consists of strings of length n over some alphabet Σ_n. A string x of length n is* ε-far *from $\mathcal{P}$ if $\delta_H(x, \mathcal{P}_n) \geq \varepsilon$.*

▶ **Definition 2.2** (ε-tester in the standard model [31, 15])**.** *For every property $\mathcal{P} \subseteq \Sigma^*$ and proximity parameter $\varepsilon \in (0, 1)$, an algorithm $\mathcal{T}$ is an* ε-tester *for $\mathcal{P}$ if, given a parameter $n \in \mathbb{N}$ and oracle access to input $x \in \Sigma^n$, the algorithm $\mathcal{T}$ accepts with probability at least $\frac{2}{3}$ whenever $x \in \mathcal{P}$ and rejects with probability at least $\frac{2}{3}$ whenever x is ε-far from $\mathcal{P}$. A tester has a one-sided error if it always accepts inputs $x \in \mathcal{P}$.*

Offline manipulations

The offline model with erasures was introduced by [9] and subsequently studied in [30, 29, 5, 23]. The definition we use here is adapted from [23] and only differs from the original definition in how the parameter ε is interpreted. We use $\perp$ to denote an erased symbol in the input.

▶ **Definition 2.3** (α-erased string, completion)**.** *For each $\alpha \in (0, 1)$, a string $x \in (\Sigma \cup \{\perp\})^n$ is α-erased if at most an α fraction of symbols in it are $\perp$. The indices of the $\perp$ symbols in the string are called* erased*. A string $y \in \Sigma^n$ that differs from a string $x \in (\Sigma \cup \{\perp\})^n$ only on indices erased in x is called a* completion *of x.*

▶ **Definition 2.4** (Offline-erasure-resilient tester [9])**.** *For every property $\mathcal{P} \subseteq \Sigma^*$ and parameters $\alpha \in [0, 1)$ and $\varepsilon \in (0, 1)$, an algorithm $\mathcal{T}$ is an* α-offline-erasure-resilient ε-tester *for $\mathcal{P}$ if, given a parameter $n \in \mathbb{N}$ and oracle access to an α-erased input $x \in \Sigma^n$, the algorithm $\mathcal{T}$ accepts with probability at least $\frac{2}{3}$ whenever there exists a completion $y \in \mathcal{P}$ of x and rejects with probability at least $\frac{2}{3}$ whenever every completion y of x is ε-far from $\mathcal{P}$.*

When $\alpha = 0$, the α-offline-erasure-resilient model is the same as the standard model. Another generalization of property testing is tolerant testing, introduced by [25] and extensively studied over the last decades. It can be viewed as guaranteeing resilience to an α fraction of the input being corrupted by an offline adversary.

▶ **Definition 2.5** ((α, ε)-tolerant tester [25])**.** *For every property $\mathcal{P} \subseteq \Sigma^*$ and parameters $\alpha, \varepsilon \in (0, 1)$, an algorithm $\mathcal{T}$ is an* (α, ε)-tolerant tester *for $\mathcal{P}$ if, given a parameter $n \in \mathbb{N}$ and oracle access to input $x \in \Sigma^n$, the algorithm $\mathcal{T}$ accepts with probability at least $\frac{2}{3}$ whenever x is α-close to $\mathcal{P}$ and rejects with probability at least $\frac{2}{3}$ whenever x is ε-far from $\mathcal{P}$.*

When we want to stress comparison to other models we study, we call an (α, ε)-tolerant tester an *α-offline-corruption-resilient ε-tester*.

Online manipulations

In this model, the input string $x \in \Sigma^n$ is accessed via an adversarial oracle $\mathcal{O}$. After answering each query made by the algorithm, the adversary can erase or corrupt a small number of data points. At the beginning of the execution of the algorithm, $\mathcal{O}(i) = x_i$ for all $i \in [n]$. So, the first query is always answered correctly. The number of queries the adversary can manipulate *after* answering each query is parameterized by $t \in \mathbb{N}$. The manipulated values are used by the oracle to answer future queries to the corresponding indices. The algorithm does not know which input locations have been tempered with. As stated in [21], "the actions of the oracle can depend on the input, the queries made so far, and even on the publicly known code that the algorithm is running, but *not* on future coin tosses of the algorithm."

▶ **Definition 2.6** (Adversarial oracle, online testers [21]). *Fix $t \in \mathbb{N}$. A* t-online-erasure *oracle can replace values $\mathcal{O}(i)$ on up to t indices $i \in [n]$ with the erasure symbol $\perp$ after answering each query. A* t-online-corruption *oracle is defined analogously, except that it replaces each symbol with an arbitrary symbol from Σ instead of erasing it. For each $t \in \mathbb{N}$, a* t-online-erasure-resilient ε-tester $\mathcal{T}$ *is defined as in the standard model (Definition 2.2), except that it accesses its input via a t-online-erasure oracle as opposed to querying the input directly. The* t-online-corruption-resilient ε-tester *is defined analogously.*

The standard property testing model is a special case of this enhanced model and corresponds to the case when $t = 0$. Moreover, it is clear from the definition that testing with online erasures is no harder than testing with online corruptions. Specifically, every t-online-corruption-resilient tester can be simulated by a tester that accesses its input via a t-online-erasure oracle – the tester can simply replace each $\perp$ with an arbitrary value from Σ.

3 Query complexity separation

In this section, we prove that testing with an offline adversary can require more queries than testing with an online adversary.

▶ **Theorem 3.1** (Query complexity separation). *Fix $\ell \in \mathbb{N}$ and let $r = r(n) < n$ be a function of the input length n. There exists a property $\mathcal{P} \subseteq \{0,1\}^*$ and a constant $\varepsilon_1 = \varepsilon_1(\ell) \in (0,1)$ such that:*[5]

1. *For all $\varepsilon \in (0,1)$ and $t = (\frac{\varepsilon}{2})^{O(\ell)} \cdot r$, the property $\mathcal{P}$ is t-online-corruption-resiliently ε-testable using $(\frac{2}{\varepsilon})^{O(\ell)}$ queries.*
2. *For all $n \in \mathbb{N}$, $\varepsilon \in (0, \varepsilon_1)$, and $\alpha = \Omega\left(\frac{1}{\log^{(\ell)}(n/r)}\right)$ such that $\varepsilon + \alpha < 1$, every α-offline-erasure-resilient ε-tester for $\mathcal{P}$ must make $\Omega\left(\frac{n}{r \cdot \mathrm{polylog}^{(\ell)}(n/r)}\right)$ queries on inputs of length n.*

For $\ell = 1$ and $r = \frac{n}{\log n}$, we obtain the following corollary.

▶ **Corollary 3.2.** *There exist a property $\mathcal{P}$ such that for all $\varepsilon \in (0,1)$ and $t \leq \mathrm{poly}(\varepsilon) \cdot \frac{n}{\log n}$, the property $\mathcal{P}$ is ε-testable using $\mathrm{poly}(\frac{1}{\varepsilon})$ queries in the t-online-corruption model. However, for all $\alpha = \Omega\left(\frac{1}{\log \log n}\right)$ such that $\alpha + \varepsilon < 1$, every α-offline-erasure-resilient ε-tester requires $\widetilde{\Omega}(\log n)$ queries.*

[5] We use $\log^{(\ell)}$ to denote the log function applied ℓ times.

While Corollary 3.2 shows that testing in the α-offline-erasure model can be harder than testing in the t-online-model for large t and small α, the difference in query complexity is quite mild. To obtain a large gap in query complexity from Theorem 3.1, we fix $\ell \in \mathbb{N}$ and constant proximity parameter $\varepsilon \leq \varepsilon_1(\ell)$, and $r = r(\varepsilon, \ell)$ such that $t = 1$. This yields the following corollary.

▶ **Corollary 3.3.** *Fix $\ell \in \mathbb{N}$ and a constant $\varepsilon = \varepsilon(\ell)$. There exists a property $\mathcal{P}$ such that $\mathcal{P}$ is ε-testable in the 1-online-corruption model using constantly many queries. But, for all $\alpha = \Omega\left(\frac{1}{\log^{(\ell)} n}\right)$ such that $\alpha + \varepsilon < 1$, every α-offline-erasure-resilient ε-tester requires $\Omega(n/\operatorname{polylog}^{(\ell)} n)$ queries.*

One feature of the results in Theorem 3.1 (as well as Corollaries 3.2 and 3.3) is that they hold even when the adversary in the online model is allowed to make corruptions, while the adversary in the offline model is restricted to erasures.

To prove Theorem 3.1, we introduce the following "lifting" result (Lemma 3.5). Informally, the lemma states that every property $\mathcal{P}$ that is testable in the standard model has an encoding $\mathcal{P}'$ that is testable with the same query complexity even in the presence of an online-corruption adversary. This result allows us to transfer existing separations between the standard model and the offline-erasure model to a separation between the online-corruption model and the offline-erasure model.

To "lift" a property $\mathcal{P}$, we simply encoded it with a repetition code, that is, repeat the corresponding input string.

▶ **Definition 3.4** (r-concatenated string x^r and property $\mathcal{P}^r$)**.** *For all $r \in \mathbb{N}$ and strings x, let x^r denote the concatenation of r copies of x, written $x^r[1] \circ x^r[2] \circ \cdots \circ x^r[r]$. Additionally, for a property $\mathcal{P}$ of strings, let $\mathcal{P}^r$ denote the property $\{x^r : x \in \mathcal{P}\}$.*

Our lifting lemma holds for properties of strings over any alphabet.

▶ **Lemma 3.5** (Lifting lemma)**.** *Let Σ be an alphabet and $\delta \in (0,1)$ be a sufficiently small constant. Let $\mathcal{P} \subseteq \Sigma^*$ be a property of strings that is ε-testable in the standard model using $q(m,\varepsilon)$ queries on inputs of length m, where $q(m,\varepsilon) = \Omega\left(\frac{1}{\varepsilon}\right)$. Then, for all $r \in \mathbb{N}$ and $t \leq \frac{\delta \cdot r}{[q(m,\frac{\varepsilon}{2}) \log q(m,\frac{\varepsilon}{2})]^2}$, the property $\mathcal{P}^r$ is t-online-corruption-resiliently ε-testable using $\widetilde{O}(q(m,\frac{\varepsilon}{2}))$ queries on inputs of length $n = m \cdot r$.*

Next we use Lemma 3.5 to prove Theorem 3.1, deferring the proof of Lemma 3.5 to Section 3.1. We leverage the following result of Ben-Eliezer, Fisher, Levi, and Rothblum [5], which separates the offline-erasure-resilient model from the standard model.

▶ **Theorem 3.6** ([5, Theorem 6.2])**.** *For all constant $\ell \in \mathbb{N}$, there exist a property $\mathcal{Q}^{(\ell)} \subseteq \{0,1\}^*$ and a constant $\varepsilon_1 = \varepsilon_1(\ell) \in (0,1)$ such that the following hold:*

1. *For every $\varepsilon \in (0,1)$, the property $\mathcal{Q}^{(\ell)}$ can be ε-tested using $(\frac{2}{\varepsilon})^{O(\ell)}$ queries.*
2. *For all $m \in \mathbb{N}$, $\varepsilon \in (0, \varepsilon_1)$, and $\alpha = \Omega(1/\log^{(\ell)} m)$ satisfying $\varepsilon + \alpha < 1$, every α-erasure resilient ε-tester for $\mathcal{Q}^{(\ell)}$ must make $\Omega(m/(10^\ell \cdot \operatorname{polylog}^{(\ell)} m))$ queries on inputs of length m.*

Proof of Theorem 3.1. Fix $\ell \in \mathbb{N}$ and let $m, r \in \mathbb{N}$ be sufficiently large. Let $\mathcal{P}$ denote the property $\mathcal{Q}^{(\ell)}$ of strings of length m given by Theorem 3.6. By Theorem 3.6, the property $\mathcal{P}$ can be ε-tested using $\left(\frac{2}{\varepsilon}\right)^{O(\ell)}$ queries. Thus, Lemma 3.5 guarantees that for all $t = (\frac{\varepsilon}{2})^{O(\ell)} \cdot r$, the property $\mathcal{P}^r$ is t-online-corruption-resiliently ε-testable using $\left(\frac{2}{\varepsilon}\right)^{O(\ell)}$ queries on inputs of length $n = mr$.

Now we prove that $\mathcal{P}^r$ requires $\Omega\left(\frac{n}{r\,\mathrm{polylog}^{(\ell)}(n/r)}\right)$ queries to ε-test in the α-offline-erasure-resilient model. To do that, we show how to use any α-offline-erasure-resilient ε-tester $\mathcal{T}_r$ for $\mathcal{P}^r$ to construct an α-offline-erasure-resilient ε-tester $\mathcal{T}$ for $\mathcal{P}$ with the same query complexity as $\mathcal{T}_r$. Given a string x^r, let $x^r[i]_j$ denote index j of the i-th copy of x. Observe that for every α-erased input x, the string x^r is also α-erased and the distance of x from $\mathcal{P}$ is the same as the distance of x^r from $\mathcal{P}^r$; moreover, for all $i \in [r]$ and $j \in [m]$, we have $x^r[i]_j = x_j$. Thus, the tester $\mathcal{T}$, given query access to x, can simulate $\mathcal{T}_r$ executed with query access to x^r and output the result given by $\mathcal{T}_r$. By Theorem 3.6, the tester $\mathcal{T}_r$ has query complexity $\Omega\left(\frac{m}{\mathrm{polylog}^{(\ell)}\, m}\right) = \Omega\left(\frac{n}{r\,\mathrm{polylog}^{(\ell)}(n/r)}\right)$ whenever $\alpha = \Omega\left(\frac{1}{\log^{(\ell)}(n/r)}\right)$. ◀

3.1 Proof of the lifting lemma (Lemma 3.5)

Recall that Lemma 3.5 states that if a property $\mathcal{P}$ is testable in the standard model, then the property $\mathcal{P}^r$ is testable in the online-corruption model. Let $\mathcal{T}$ be an ε-tester for $\mathcal{P}$ that has failure probability $\frac{1}{12}$, and query complexity $c_0 \cdot q(m, \varepsilon)$ for some constant $c_0 > 0$ (we can obtain such a tester via standard amplification techniques). We construct a tester $\mathcal{T}'$ for $\mathcal{P}^r$ (Algorithm 1) and show that it is t-online-corruption-resilient. The tester $\mathcal{T}'$ consists of two phases: first, $\mathcal{T}'(s)$ calls REPETITION-TEST (Algorithm 2) to test that s is a repetition of some string, w, and second, $\mathcal{T}'(s)$ simulates $\mathcal{T}$ with query access to w.

For a string s of length $n = r \cdot m$ composed of r substrings each of length m, we use the notation $s[i]_j$ to denote index j, in the i-th substring of s.

Algorithm 1 t-online-corruption-resilient ε-tester $\mathcal{T}'$.

Parameters: length parameter m, repetition parameter r, proximity parameter $\varepsilon \in (0, 1)$
Input: query access to string $s = s[1] \circ \cdots \circ s[r]$ such that $|s[i]| = m$ for each $i \in [r]$
Subroutines: REPETITION-TEST (Algorithm 2) and $c_0 \cdot q(m, \varepsilon)$-query tester $\mathcal{T}$ for $\mathcal{P}$

1: $c_1 \leftarrow 24 \cdot c_0$
2: **if** REPETITION-TEST$(s, \frac{\varepsilon}{2})$ rejects **then reject**
3: simulate $\mathcal{T}$ with proximity parameter $\frac{\varepsilon}{2}$, answering each query j made by $\mathcal{T}$ as follows:
   sample a set of $d = \log(c_1 \cdot q(m, \frac{\varepsilon}{2}))$ uniform indices $i_1, \ldots, i_d \in [r]$
   if there exists a pair of indices $k, k' \in [d]$ such that $s[i_k]_j \neq s[i_{k'}]_j$ **then reject**
   else provide the answer $s[i_1]_j$ to $\mathcal{T}$
4: **if** the simulation of $\mathcal{T}$ rejects **then reject**
5: **else accept**

Algorithm 2 REPETITION-TEST.

Parameters: length parameter m, repetition parameter r, proximity parameter $\varepsilon \in (0, 1)$
Input: query access to string $s = s[1] \circ \cdots \circ s[r]$ such that $|s[i]| = m$ for each $i \in [r]$

1: **repeat** $\frac{2}{\varepsilon}$ times:
   sample $i_1, i_2 \sim [r]$ and $j \sim [m]$ uniformly and independently at random
2: **if** $s[i_1]_j \neq s[i_2]_j$ **then reject**
3: **else accept**

We start by analyzing REPETITION-TEST (Algorithm 2).

▷ Claim 3.7. For all alphabets Σ and parameters $\varepsilon \in (0,1)$ and $r, m \in \mathbb{N}$, REPETITION-TEST is a one-sided error ε-tester for the repetition code defined as $\mathcal{C}_{m,r} = \{s^r : s \in \Sigma^m\}$. It makes $O(\frac{1}{\varepsilon})$ queries and has error probability at most $\frac{1}{6}$.

Proof. Let $s = s[1] \circ \cdots \circ s[r]$, where $s[i] = s[i]_1 \dots s[i]_m$ for all $i \in [r]$, be the input string over the alphabet Σ. If $s \in \mathcal{C}_{m,r}$, then REPETITION-TEST always accepts s.

Suppose that string s is ε-far from $\mathcal{C}_{m,r}$. Let $\text{plurality}_{i\in[r]}(a_i)$ denote a function that takes inputs $a_1, \dots, a_r \in \Sigma$ and outputs the most frequent among them, resolving ties arbitrarily. Let $\hat{w}$ be the string of length m defined by $\hat{w}_j = \text{plurality}_{i\in[r]}\, s[i]_j$ for all $j \in [m]$. Since s is ε-far from $\mathcal{C}_{m,r}$, we can bound the distance between the input string and $\hat{w}$ repeated r times:

$$\delta_H(s, \hat{w}^r) \geq \varepsilon. \tag{1}$$

For all $j \in [m]$ and $a \in \Sigma$, let $p_j(a)$ denote $\Pr_{i\in[r]}[s[i]_j = a]$, the probability that a randomly chosen repetition of the j-th character in s is equal to a. The probability that one iteration of the loop in REPETITION-TEST accepts s is

$$\begin{aligned}
\Pr_{\substack{i_1,i_2\in[r]\\ j\in[m]}}\left[s[i_1]_j = s[i_2]_j\right] &= \frac{1}{m}\sum_{j\in[m]}\sum_{a\in\Sigma}[p_j(a)]^2 && \text{by law of total probability}\\
&\leq \frac{1}{m}\sum_{j\in[m]} p_j(\hat{w}_j)\sum_{a\in\Sigma} p_j(a) && \text{as } p_j(a) \leq p_j(\hat{w}_j)\ \forall j \in [m], a \in \Sigma\\
&= \frac{1}{m}\sum_{j\in[m]} p_j(\hat{w}_j) && \text{since } \sum_{a\in\Sigma} p_j(a) = 1\ \forall j \in [m]\\
&= \Pr_{\substack{i\in[r]\\ j\in[m]}}[s[i]_j = \hat{w}_j] && \text{by law of total probability}\\
&= 1 - \delta_H(s, \hat{w}^r) && \text{by definition of } \delta_H\\
&\leq 1 - \varepsilon && \text{by (1).}
\end{aligned}$$

Hence, each iteration of the loop in REPETITION-TEST rejects with probability at least ε. Therefore, REPETITION-TEST accepts s with probability at most $(1-\varepsilon)^{2/\varepsilon} \leq e^{-\varepsilon\cdot 2/\varepsilon} \leq \frac{1}{6}$. ◁

Next, we analyze the tester $\mathcal{T}'$.

▷ Claim 3.8 ($\mathcal{T}'$ is a tester in the standard model). For all $\varepsilon \in (0,1)$,$r \in \mathbb{N}$, alphabets Σ, and properties $\mathcal{P} \in \Sigma^*$, Algorithm 1 is an ε-tester for $\mathcal{P}^r$ in the standard model (without any adversary). Moreover, it accepts ε-far inputs with probability at most $\frac{1}{6}$, and has one-sided error whenever $\mathcal{T}$ has one-sided error.

Proof. If the input s is in $\mathcal{P}^r$ then $s = w^r$ for some string $w \in \mathcal{P}$. In this case, REPETITION-TEST accepts with probability 1, and $\mathcal{T}'$ accepts with the same probability as $\mathcal{T}$. Next, suppose s is ε-far from $\mathcal{P}^r$. Consider the string $\hat{w} \in \Sigma^m$, where $\hat{w}_j = \text{plurality}_{i\in[r]}\, s[i]_j$ for all $j \in [m]$. Recall that the repetition code is defined as $\mathcal{C}_{m,r} = \{s^r : s \in \Sigma^m\}$. Observe that the distance from s to $\mathcal{C}_{m,r}$ is equal to $\delta_H(s, \hat{w}^r)$. If this distance is at least $\frac{\varepsilon}{2}$ then, by Claim 3.7, REPETITION-TEST accepts with probability at most $\frac{1}{6}$, completing the proof.

Now assume $\delta_H(s, \hat{w}^r) < \frac{\varepsilon}{2}$. We will show that, in this case, the simulation of $\mathcal{T}$ in Algorithm 1 accepts with probability at most $\frac{1}{6}$. Specifically, we consider two failure events: let E_1 be the event that the simulation of $\mathcal{T}$ feeds $\mathcal{T}$ at least one query answer inconsistent with $\hat{w}$, and E_2 be the event that the simulation of $\mathcal{T}$ accepts string $\hat{w}$. We will show that $\Pr[E_1] \leq \frac{1}{12}$ and $\Pr[E_2] \leq \frac{1}{12}$. Then a union bound over E_1 and E_2 completes the proof.

Since s is ε-far from $\mathcal{P}^r$ and $\delta_H(s, \hat{w}^r) < \frac{\varepsilon}{2}$, we get

$$\varepsilon \leq \delta_H(s, \mathcal{P}^r) \leq \delta_H(s, \hat{w}^r) + \delta_H(\hat{w}^r, \mathcal{P}^r) \leq \frac{\varepsilon}{2} + \delta_H(\hat{w}, \mathcal{P}),$$

implying that $\delta_H(\hat{w}, \mathcal{P}) \geq \frac{\varepsilon}{2}$. Since $\mathcal{T}$ is a tester for $\mathcal{P}$ with amplified success probability, and $\hat{w}$ is $\frac{\varepsilon}{2}$-far from $\mathcal{P}$, algorithm $\mathcal{T}$ accepts with probability at most $\frac{1}{12}$ when run on input $\hat{w}$ and with proximity parameter $\frac{\varepsilon}{2}$; that is, $\Pr[E_2] \leq \frac{1}{12}$.

Next we analyze $\Pr[E_1]$. Fix $j \in [m]$, and let a_j denote the answer provided by $\mathcal{T}'$ to query j in the simulation. If $\mathcal{T}'$ does not reject while simulating this query, then

$$\begin{aligned}
\Pr[a_j \neq \hat{w}_j] &= \Pr_{i_1,\ldots,i_d \in [r]}[s[i_k]_j = s[i_{k'}]_j \wedge s[i_k]_j \neq \hat{w}_j \ \forall k, k' \in [d]] \\
&= \Pr_{i_1,\ldots,i_d \in [r]}[s[i_k]_j = s[i_1]_j \ \forall k \in \{2,\ldots,d\} \mid s[i_1]_j \neq \hat{w}_j] \cdot \Pr_{i_1 \in [r]}[s[i_1]_j \neq \hat{w}_j] \\
&\leq 2^{-d+1} \qquad (2) \\
&= 2(c_1 \cdot q(m, \varepsilon/2))^{-1}.
\end{aligned}$$

The inequality in (2) follows from the following simple observation: once $s[i_1]_j$ has been sampled, if it is not the plurality, then for each $k \in \{2,\ldots,d\}$, every subsequent $s[i_k]_j$ is equal to $s[i_1]_j$ with probability at most $\frac{1}{2}$. By our choice of c_1, and a union bound over all the $c_0 \cdot q(m, \varepsilon/2)$ queries made by $\mathcal{T}$, the probability of E_1 is at most $\frac{1}{12}$.

Since $\mathcal{T}'$ can accept only if $E_1 \cup E_2$ occurs, a union bound over E_1 and E_2 implies that $\mathcal{T}'$ is indeed a tester for $\mathcal{P}^r$, and has error probability at most $\frac{1}{6}$ when no adversary is present. ◁

Finally, we prove the lifting lemma.

Proof of Lemma 3.5. First, we argue that the probability $\mathcal{T}'$ (Algorithm 1) queries a corrupted index is small. Recall that $n = m \cdot r$ is the length of the input to $\mathcal{T}'$ and that $c_0 \cdot q(m, \varepsilon)$ is the query complexity of $\mathcal{T}$ with proximity parameter ε. Let $q' = q'(n, \varepsilon) = \frac{8}{\varepsilon} + c_0 \cdot q(m, \frac{\varepsilon}{2}) \log(c_1 \cdot q(m, \frac{\varepsilon}{2}))$ be the number of queries made by $\mathcal{T}'$. Then, there are at most $q't$ corruptions at any point during the execution. Moreover, each query made by $\mathcal{T}'$ is an index that is uniform over the set of corresponding indices in the r different segments of s. It follows that each query made by $\mathcal{T}'$ is corrupted with probability at most $\frac{q't}{r}$. By a union bound over the q' queries,

$$\Pr[\mathcal{T}' \text{ queries a corrupted index}] \leq \frac{(q')^2 t}{r} \leq \frac{1}{6}. \qquad (3)$$

The upper bound follows from the hypothesis that $t \leq \frac{\delta \cdot r}{[q(m,\varepsilon/2) \log q(m,\varepsilon/2)]^2}$, that $q(m, \varepsilon) = \Omega(\frac{1}{\varepsilon})$, and that δ is a sufficiently small constant. By a union bound, the probability that $\mathcal{T}'$ errs in the presence of the adversary is at most the probability $\mathcal{T}'$ errs when no adversary is present plus the probability $\mathcal{T}'$ queries a corrupted index. By Claim 3.8 and (3), this probability is at most $\frac{1}{3}$, which completes the proof of Lemma 3.5. ◀

4 Randomness complexity separation

In this section, we prove our result separating the randomness complexity of testing in the online and offline models.

▶ **Theorem 4.1** (Randomness separation). *For all $\tau = \tau(n)$, there exist a property $\mathcal{P}^{(\tau)} = \bigcup_{n\in\mathbb{N}} \mathcal{P}_n^{(\tau)}$, where $\mathcal{P}_n^{(\tau)} \subseteq [n]^n$, and an algorithm $\mathcal{T}$ that takes $\varepsilon \in (0,1)$ as an input and, for all $\varepsilon \in (0,1)$, is a one-sided error ε-tester for $\mathcal{P}^{(\tau)}$ that make $O(\frac{\tau}{\varepsilon})$ queries. Additionally, the following hold:*

1. *For all $\varepsilon, \alpha \in (0,1)$, tester $\mathcal{T}$ is an α-offline-erasure-resilient ε-tester for $\mathcal{P}^{(\tau)}$. Moreover, $\mathcal{T}$ can be simulated using $O(\log n)$ random bits and no additional queries.*
2. *For all $\varepsilon \in (0,1)$ and $t \leq \left(\frac{0.01\varepsilon\sqrt{n}}{\tau}\right)^2$, tester $\mathcal{T}$ is a t-online-erasure-resilient ε-tester for $\mathcal{P}^{(\tau)}$.*
3. *There exists a constant $\varepsilon > 0$ such that for all $t \in \mathbb{N}$ and $\tau \leq \frac{0.01\sqrt{n}}{\log n}$, every t-online-erasure-resilient ε-tester for $\mathcal{P}^{(\tau)}$ uses $\Omega\left(\frac{\tau \log(t+1)}{\log \tau}\right)$ random bits. Moreover, if the tester has one-sided error, then it uses $\Omega(\tau \log(t+1))$ random bits.*

Theorem 4.1 yields meaningful separations for all settings of τ between $\Omega(\log n)$ and $O\left(\frac{\sqrt{n}}{\log n}\right)$. As an example, the following corollary is derived by setting $\tau = \frac{0.01\varepsilon\sqrt{n}}{\log n}$ and $t = 1$.

▶ **Corollary 4.2.** *There exists a property that can be ε-tested (for every constant ε) using $O\big(\frac{\sqrt{n}}{\log n}\big)$ queries in the presence of either an online or offline adversary. The offline-erasure-resilient tester uses $O(\log n)$ random bits, but there exists a constant ε such that every 1-online-erasure-resilient ε-tester, requires $\Omega\big(\frac{\sqrt{n}}{\operatorname{polylog} n}\big)$ random bits to succeed with constant probability. Moreover, if the 1-online-erasure-resilient tester has one-sided error then it requires $\Omega(\sqrt{n})$ random bits.*

To prove our randomness lower bound, we present a general reduction from randomness-efficient testers in the online-erasure model to query-efficient testers in the standard model.

▶ **Lemma 4.3** (Generalization of Lemma 1.6). *For all $r, t \in \mathbb{N}$ and properties $\mathcal{P}$, if $\mathcal{P}$ is ε-testable in the presence of a t-online-erasure adversary using only r bits of randomness then $\mathcal{P}$ is ε-testable in the standard model using at most $\frac{r}{\log(t+1)}$ queries.*

Proof. Let $\mathcal{T}$ be a t-online-erasure-resilient ε-tester for $\mathcal{P}$ that uses at most r random bits. We construct an adversary that allows $\mathcal{T}$ to make at most $\frac{r}{\log(t+1)}$ non-erased queries. Consider the following random seed elimination adversary $\mathcal{A}$. Given an input x, the description of algorithm $\mathcal{T}$, and query-answer history of $\mathcal{T}$ on input x, the adversary simulates the next query of $\mathcal{T}$ on every random seed $s \in \{0,1\}^r$ that is consistent with the query-answer history of $\mathcal{T}$ thus far and erases the t most queried indices of x. Intuitively, these are the indices that are most likely to be queried by the tester at this step, based on the random seeds that are consistent with the current query-answer history. Each index that the oracle decides not to erase at this step can appear in at most $\frac{1}{t+1}$ fraction of currently relevant random seeds. If $\mathcal{T}$ queries such an index, all random seeds that would have lead to a different query can be eliminated. Thus, each time $\mathcal{T}$ makes a non-erased query, at most a $\frac{1}{t+1}$ fraction of the relevant random seeds remain. Consequently, $\mathcal{T}$ can make at most $\frac{r}{\log(t+1)}$ non-erased queries before $\mathcal{A}$ can exactly determine the random seed being used. Once $\mathcal{A}$ determines the random seed, it can exactly predict the queries of $\mathcal{T}$ and erase all of them.

Next, we use the adversary strategy $\mathcal{A}$ to construct an $\frac{r}{\log(t+1)}$-query tester for $\mathcal{P}$. Let $\mathcal{T}^*$ be defined as follows. Draw a random seed $s^* \in \{0,1\}^r$ and simulate $\mathcal{T}$ with random seed s^*. After making each query, $\mathcal{T}^*$ simulates $\mathcal{A}$ with the query-answer history of $\mathcal{T}$. If $\mathcal{A}$ erases the next query of $\mathcal{T}$, then $\mathcal{T}^*$ answers the query with $\perp$ and continues the simulation (the algorithm $\mathcal{T}^*$ need not make any queries in this case). Otherwise, if $\mathcal{A}$ does not erase

the next query of $\mathcal{T}$, then $\mathcal{T}^*$ queries x, provides $\mathcal{T}$ with the answer, and continues the simulation. Since $\mathcal{T}$ makes at most $\frac{r}{\log(t+1)}$ non-erased queries and successfully tests $\mathcal{P}$, the algorithm $\mathcal{T}^*$ makes at most $\frac{r}{\log(t+1)}$ queries and also successfully tests $\mathcal{P}$. ◀

4.1 The τ-Distinct-Elements property

The property testing problem we use to prove Theorem 4.1 is a version of support size approximation. In support size approximation, one is given sample access to a distribution $\mathcal{D}$ over the domain $[n]$ and asked to approximate $|\text{supp}(\mathcal{D})|$ up to additive error ε. We study the analogous testing problem over strings: Given parameters $\tau \in \mathbb{N}$ and $\varepsilon \in (0,1)$, and a string x of length n, we wish to ε-test whether $|\{x_1, x_2, \ldots, x_n\}| \leq \tau$, that is, to determine whether x has at most τ distinct elements or x is ε-far from every x' (of length n) with at most τ distinct elements.

▶ **Definition 4.4** (τ-Distinct-Elements). *For all $n \in \mathbb{N}$ and $\tau = \tau(n)$, let $\mathcal{P}_n^{(\tau)}$ be the set of strings in $[n]^n$ with at most τ distinct symbols. The property* τ-Distinct-Elements *is defined as $\mathcal{P}^{(\tau)} = \bigcup_{n\in\mathbb{N}} \mathcal{P}_n^{(\tau)}$.*

The following tester for τ-Distinct-Elements appeared in [17]. We include the analysis of its guarantees here for completeness.

▷ Fact 4.5 (A tester for τ-Distinct-Elements). For all $\varepsilon \in (0,1)$, there exists a one-sided error tester for $\mathcal{P}^{(\tau)}$ that uses $O(\frac{\tau}{\varepsilon})$ samples and fails with probability at most $\frac{1}{10}$.

Proof. We first make the following observation: if x is ε-far from $\mathcal{P}^{(\tau)}$, then every collection of τ distinct elements occupies at most a $1-\varepsilon$ fraction of the indices in x. Suppose we sample uniformly random elements from x until we have seen $\tau+1$ distinct elements. Notice that while we have seen at most τ distinct elements, our next sample is a new distinct element with probability at least ε (the at most τ distinct elements we have seen can have probability mass at most $1-\varepsilon$). Let X_i be the number of samples to get the i-th distinct element given we have seen $i-1$ distinct elements, and set $X = \sum_{i=1}^{\tau+1} X_i$. Then $\mathbb{E}[X] \leq (\tau+1)/\varepsilon$, and hence, by Markov's inequality, the probability we need more than $3(\tau+1)/\varepsilon$ samples is at most $\frac{1}{3}$. This analysis inspires the following simple tester:

Sample $s = 3(\tau+1)/\varepsilon$ elements from x and accept if and only if there are at most τ distinct symbols from $[n]$ in the sample (not counting the erasure symbol $\perp$).

Repeating the tester constantly many times suffices to make the failure probability smaller than $\frac{1}{10}$. ◁

Recall that Lemma 4.3 states that to prove a lower bound on the randomness complexity of testing in the online model, it suffices to prove a lower bound on the query complexity of testing in the standard model. In Lemma 4.6, we show a lower bound on the query complexity of testing τ-Distinct-Elements. Our lower bound is a direct corollary of the lower bound of [32].

▶ **Lemma 4.6** (Query lower bound for testing τ-Distinct-Elements). *There exists $\varepsilon \in (0,1)$ such that for all input lengths n, if $\tau \leq \frac{\sqrt{n}}{\log n}$, then the query complexity of ε-testing $\mathcal{P}^{(\tau)}$ is $\Omega(\frac{\tau}{\log \tau})$. Moreover, the query complexity of ε-testing $\mathcal{P}^{(\tau)}$ with one-sided error is $\Omega(\tau)$.*

Proof. We use the following fact to argue that we can assume the tester is sample-based with no loss of generality.

▷ Fact 4.7 (Theorem 6.1 [16]). A property of strings is *symmetric* if it is closed under permutations of the string indices (that is, under reordering of the characters in the string). Let $\mathcal{P}$ be a symmetric property of strings that is ε-testable with query complexity q. Then there exists a sample-based tester for $\mathcal{P}$ with sample complexity $O(q)$.

Since $\mathcal{P}^{(\tau)}$ is symmetric, we can without loss of generality consider sample-based testers. First, we prove the lower bound for two-sided error testers. The essence of our proof is a reduction from the hard instances used in [32] for estimating the support size of a distribution. While we cannot use the lower bound of [32] as a black box, we can nonetheless leverage their hard instances. Indeed, combining Theorem 1, Fact 5, and the remarks regarding the support size of their hard distributions (following Definition 12) from [32], we obtain the following immediate corollary.

▷ Fact 4.8 (Support size approximation lower bound [32]). Let $\alpha > 0$ be a sufficiently small constant. There exist distributions $\mathcal{D}^+$ and $\mathcal{D}^-$ over $[m]$ such that

1. Every element in the support of $\mathcal{D}^+$ or $\mathcal{D}^-$ has probability mass at least $\frac{1}{m}$.
2. $|\mathrm{supp}(\mathcal{D}^+)| \leq m\left(\frac{1}{2}+\alpha\right)$, and $\mathcal{D}^-$ is $\left(\frac{1}{2}-2\alpha\right)$-far from every distribution with support size at most $m\left(\frac{1}{2}+\alpha\right)$.

Moreover, every algorithm that successfully distinguishes $\mathcal{D}^+$ from $\mathcal{D}^-$ with constant probability requires $\Omega\left(\frac{m}{\log m}\right)$ samples.

While the distributions in [32] are defined over $\mathbb{R}$, they all have support size at most m. Thus, we can, without loss of generality, consider distributions over $[m]$. Indeed, given a distribution $\mathcal{D}$ over $\mathbb{R}$, the distribution $\mathcal{D}^\pi$ obtained by choosing a uniformly random permutation π of $[m]$, and then mapping the i-th element in the support of $\mathcal{D}$ to $\pi(i)$, has domain $[m]$ and the same support size as $\mathcal{D}$. Moreover, if two distributions $\mathcal{D}_0$ and $\mathcal{D}_1$ each have support size at most m, then for $b \in \{0,1\}$, the distribution $\mathcal{D}_b^\pi$ can be generated by first, sampling a random permutation π of $[m]$, second, sampling from $\mathcal{D}_b$, and third, sending each distinct sample to the first available element of π. Thus, any algorithm which distinguishes $\mathcal{D}_1^\pi$ and $\mathcal{D}_0^\pi$ can be used to distinguish $\mathcal{D}_0$ and $\mathcal{D}_1$ with the same sample complexity.

To apply Fact 4.8 in our setting, we note that whenever $m \leq \frac{\sqrt{n}}{\log n}$, there exists $x \in [m]^n$ such that the distribution obtained by sampling a uniform index in x has total variation distance at most $\frac{m}{n} = \frac{1}{\sqrt{n}\log n}$ from $\mathcal{D}$. Thus, for sufficiently large n, there exist strings $x^+, x^- \in [m]^n$ such that x^+ has at most $m(\frac{1}{2}+\alpha)$ distinct symbols, and the distributions generated by sampling from x^+ and x^- have total variation distance $\frac{1}{\sqrt{n}\log n}$ from $\mathcal{D}^+$ and $\mathcal{D}^-$, respectively. Let $\tau = m(\frac{1}{2}+\alpha)$ and $\varepsilon = \frac{1}{2} - 2\alpha - o(1)$, then $x^+ \in \mathcal{P}^{(\tau)}$ and x^- is ε-far from $\mathcal{P}^{(\tau)}$. By Fact 4.8, every algorithm for distinguishing x^+ from x^- uses $\Omega\left(\frac{m}{\log m}\right) = \Omega\left(\frac{\tau}{\log \tau}\right)$ samples. By Fact 4.7, every tester for $\mathcal{P}^{(\tau)}$ has query complexity $\Omega\left(\frac{\tau}{\log \tau}\right)$.

To prove the one-sided error lower bound, it suffices to note that every one-sided error algorithm must accept if its sample contains at most τ symbols. Thus, every one-sided error tester requires $\Omega(\tau)$ samples. This completes the proof of Lemma 4.6. ◀

4.2 Proof of the randomness separation (Theorem 4.1)

To complete the proof of the theorem, we argue that the tester given by Fact 4.5 is a valid tester for τ-Distinct-Elements in both the online and offline erasure models. To prove the lower bound on the randomness complexity of testing τ-Distinct-Elements in the online model, we combine the query lower bound of Lemma 4.6 with the reduction stated in Lemma 4.3. To

prove the upper bound on the randomness complexity of testing τ-Distinct-Elements in the offline model, we argue that the offline tester can be simulated with few bits of randomness at a small cost in error probability.

We first prove the part of the theorem regarding testing τ-Distinct-Elements in the offline erasure model.

Proof of Theorem 4.1, Item 1. First, for all $\tau \in \mathbb{N}$, we construct an offline-erasure-resilient tester for τ-Distinct-Elements, and second, we argue that the tester can be simulated with $O(\log n)$ random bits and no additional queries. Let $\mathcal{T}$ be the tester given by Fact 4.5. Recall that $\mathcal{T}$ accepts if and only if the number of nonerased symbols in the sample is at most τ. Below, we argue that $\mathcal{T}$ is an α-offline-erasure-resilient ε-tester.

Let x be an α-erased string in $[n]^n$. If some completion of x is in $\mathcal{P}^{(\tau)}$, then the number of nonerased symbols in the sample drawn by $\mathcal{T}$ is at most τ, so the algorithm accepts. Next we argue that $\mathcal{T}$ accepts with probability at most $\frac{1}{4}$ when every completion of x is ε-far from $\mathcal{P}^{(\tau)}$. Let $x^{\perp}$ denote the erased portion of x, and $x^{\top}$ denote the nonerased portion of x. Notice that $|x^{\top}| = (1-\alpha)n$, and thus if $x^{\top}$ is $\frac{\varepsilon}{1-\alpha}$-close to $\mathcal{P}^{(\tau)}$, then there is a completion of x that is ε-close to $\mathcal{P}^{(\tau)}$ (change εn symbols in $x^{\top}$ and fill out $x^{\perp}$ with an arbitrary symbol from $x^{\top}$). Thus, if every completion of x is ε-far from $\mathcal{P}^{(\tau)}$, then $x^{\top}$ is $\frac{\varepsilon}{1-\alpha}$-far from $\mathcal{P}^{(\tau)}$. By the proof of Fact 4.5, a set of $O\left(\frac{\tau(1-\alpha)}{\varepsilon}\right)$ uniform and independent samples from $x^{\top}$ contains at least $\tau+1$ distinct symbols with probability at least $\frac{9}{10}$. Moreover, a sample of $O\left(\frac{\tau}{\varepsilon}\right)$ elements from x contains $\Omega\left(\frac{\tau(1-\alpha)}{\varepsilon}\right)$ such samples from $x^{\top}$ with probability at least $\frac{9}{10}$. By the union bound, $\mathcal{T}$ accepts x with probability at most $\frac{1}{4}$.

It remains to show that $\mathcal{T}$ can be simulated by a tester $\mathcal{T}'$ that uses $O(\log n)$ random bits and has the same query complexity as $\mathcal{T}$. Fact 4.9 states that any randomized oracle machine that solves a promise problem can be simulated using $\log n + \log\log|\Sigma| + O(1)$ random bits, where $|\Sigma|$ is the size of the alphabet. This fact was originally proven by Goldreich and Sheffet [18] and is stated as an exercise in [14]. We use the statement from the exercise since it is more convenient for our setting.

▷ Fact 4.9 (Exercise 1.21 [14]). Fix $n \in \mathbb{N}$ and let Π be a promise problem regarding strings in Σ^n. Suppose that $\mathcal{M}$ is a randomized q-query oracle machine that solves Π with error probability at most $\frac{1}{4}$. Then there exists a randomized q-query oracle machine $\mathcal{M}'$ that solves Π with error probability at most $\frac{1}{3}$ and $\log n + \log\log|\Sigma| + O(1)$ random bits.

Let Π be the promise problem defined by α-offline-erasure-resilient ε-testing $\mathcal{P}^{(\tau)}$. By the first part of the proof, there exists a randomized oracle machine $\mathcal{T}$ that solves Π with error probability at most $\frac{1}{4}$. Applying Fact 4.9 directly, we see that $\mathcal{T}$ can be simulated by a tester $\mathcal{T}'$ using $\log n + \log\log|\Sigma| + O(1)$ random bits; since $\Sigma = [n]$, tester $\mathcal{T}'$ uses $O(\log n)$ random bits, and has error probability at most $\frac{1}{3}$. To complete the proof, it suffices to note that $\mathcal{T}'$ has the same query complexity as $\mathcal{T}$. ◀

Next, we prove the part of the theorem regarding testing τ-Distinct-Elements in the online erasure model.

Proof of Theorem 4.1, Items 2 and 3. We will show that for all $\tau \in \mathbb{N}$, the tester given by Fact 4.5 is online-erasure-resilient. Let $\mathcal{T}$ be the tester for τ-Distinct-Elements given by Fact 4.5. Recall that $\mathcal{T}$ accepts if and only if the number of nonerased symbols in its sample is at most τ. We show that $\mathcal{T}$ can test in the presence of a t-online-erasure-oracle, by arguing that with high constant probability, none of the queries made by $\mathcal{T}$ are erased. Notice that with proximity parameter ε, the tester makes $O\left(\frac{\tau}{\varepsilon}\right)$ queries. Thus, there are

$O\left(\frac{t\cdot\tau}{\varepsilon}\right)$ erasures at every point during the execution of $\mathcal{T}$. Since $\mathcal{T}$ makes uniform and independent queries, the probability that any particular query is erased is $O\left(\frac{t\cdot\tau}{n\varepsilon}\right)$. Since $\mathcal{T}$ makes $O\left(\frac{\tau}{\varepsilon}\right)$ queries, we can apply the union bound to see that some query is erased with probability at most $O\left(\frac{t\cdot\tau^2}{n\varepsilon^2}\right)$. By the hypothesis that $t \leq \left(\frac{.01\varepsilon\sqrt{n}}{\tau}\right)^2$, we have $O\left(\frac{t\cdot\tau^2}{n\varepsilon^2}\right) \leq .01$ – that is, $\mathcal{T}$ sees an erasure with probability at most .01. By Fact 4.5, the algorithm $\mathcal{T}$ is a t-online-erasure-resilient ε-tester for $\mathcal{P}^{(\tau)}$. Moreover, since an erasure cannot increase number of distinct nonerased symbols in x, tester $\mathcal{T}$ has one-sided error. This completes the proof of Item 2.

To see why Item 3 holds, recall that by Lemma 4.6, there exists $\varepsilon \in (0,1)$ such that for all $n, \tau \in \mathbb{N}$ with $\tau \leq \frac{\sqrt{n}}{\log n}$, every ε-tester for $\mathcal{P}^{(\tau)}$ has query complexity $\Omega\left(\frac{\tau}{\log \tau}\right)$. Similarly every tester with one-sided error has query complexity $\Omega(\tau)$. Thus, applying Lemma 4.3, the reduction from query complexity to randomness complexity, suffices to complete the proof. ◀

Graph Reconstruction via MIS Queries

Abstract

In the Graph Reconstruction (GR) problem, a player initially only knows the vertex set V of an input graph $G = (V, E)$ and is required to learn its set of edges E. To this end, the player submits queries to an oracle and must deduce E from the oracle's answers.

Angluin and Chen [Journal of Computer and System Sciences, 2008] resolved the number of Independent Set (IS) queries necessary and sufficient for GR on m-edge graphs. In this setting, each query consists of a subset of vertices $U \subseteq V$, and the oracle responds with a boolean, indicating whether U is an independent set in G. They gave algorithms that use $O(m \cdot \log n)$ IS queries, which is best possible.

In this paper, we initiate the study of GR via Maximal Independent Set (MIS) queries, a more powerful variant of IS queries. Given a query $U \subseteq V$, the oracle responds with any, potentially adversarially chosen, maximal independent set $I \subseteq U$ in the induced subgraph $G[U]$.

We show that, for GR, MIS queries are strictly more powerful than IS queries when parametrized by the maximum degree Δ of the input graph. We give tight (up to poly-logarithmic factors) upper and lower bounds for this problem:

1. We observe that the simple strategy of taking uniform independent random samples of V and submitting those to the oracle yields a non-adaptive randomized algorithm that executes $O(\Delta^2 \cdot \log n)$ queries and succeeds with high probability. This should be contrasted with the fact that $\Omega(\Delta \cdot n \cdot \log(\frac{n}{\Delta}))$ IS queries are required for such graphs, which shows that MIS queries are strictly more powerful than IS queries. Interestingly, combining the strategy of taking uniform random samples of V with the probabilistic method, we show the existence of a deterministic non-adaptive algorithm that executes $O(\Delta^3 \cdot \log(\frac{n}{\Delta}))$ queries.
2. Regarding lower bounds, we prove that the additional Δ factor when going from randomized non-adaptive algorithms to deterministic non-adaptive algorithms is necessary. We show that every non-adaptive deterministic algorithm requires $\Omega(\Delta^3/\log^2 \Delta)$ queries. For arbitrary randomized adaptive algorithms, we show that $\Omega(\Delta^2)$ queries are necessary in graphs of maximum degree Δ, and that $\Omega(\log n)$ queries are necessary, even when the input graph is an n-vertex cycle.

1 Introduction

Query algorithms for graph problems have recently received significant attention. In this setting, algorithms are granted access to the input graph solely via a (usually easy-to-compute) subroutine, which is referred to as the oracle, and the complexity of an algorithm is measured by the number of subroutine/oracle calls.

In the literature, a large number of different query models have been considered. Queries can either be *local* or *global*, depending on whether they reveal only local information, e.g., vertex degree queries [13] or queries that, for any i, reveal the ith neighbour of a vertex [17], or global information, e.g., (bipartite) independent set queries [7, 10, 1, 3] or maximal

matching queries [12, 20]. Depending on the application, it is generally desirable to obtain *non-adaptive* query algorithms, i.e., algorithms where the different queries do not depend on each other's outcomes, since such queries can be executed simultaneously and therefore admit straightforward parallel implementations. We also say that a query algorithm requires k *rounds of adaptivity*, for some integer k, if the queries executed by the algorithm can be partitioned into k groups such that the queries in the ith group only depend on the outcomes of the queries in groups $1, \ldots, i-1$.

Graph Reconstruction. In this work, we consider query algorithms for the Graph Reconstruction (GR) problem. In GR, a player initially only knows the vertex set V of a graph $G = (V, E)$ and is tasked with learning the edge set E, by submitting a sequence of adaptive or non-adaptive queries to the oracle, and by deducing the edge set E from the oracle's answers.

Query algorithms for GR have been extensively studied under various query models, including Independent Set (IS) queries [18, 11, 6, 5, 7, 1], Distance queries [24, 19, 21, 25], Betweenness queries [2, 26], and in the setting where an algorithm receives random vertex-induced subgraphs or submatrices of the adjacency matrix [22]. Very relevant to our work are IS queries, where a query consists of a subset of vertices $U \subseteq V$, and the oracle returns a boolean, indicating whether U is an independent set in G. IS queries for GR were originally studied for recovering simple graphs, such as matchings and Hamiltonian cycles [18, 11, 6], since these settings have direct applications to genome sequencing. Angluin and Chen [7] were the first to consider general graphs and showed that m-edge graphs can be reconstructed with $O(m \cdot \log n)$ IS queries via an adaptive deterministic algorithm or a randomized algorithm with limited adaptivity (see also [1] who reduced the number of adaptive rounds), and this is also best possible.

MIS Queries. In this work, we initiate the study of GR under Maximal Independent Set (MIS) queries. In this setting, similar to IS queries, a query also consists of a subset of vertices $U \subseteq V$. The oracle, however, responds with any, potentially adversarially chosen, maximal independent set $I \subseteq U$ in the subgraph induced by the queried vertices $G[U]$.

MIS queries are global queries and are similar in spirit to the Maximal Matching queries considered in [12, 20], where the oracle returns a maximal matching in the subgraph induced by the query vertices [12], or in the subgraph spanned by the queried edges that are also contained in the input graph [20]. They are at least as powerful as IS queries since an IS query $U \subseteq V$ can be answered by an MIS oracle by exploiting the connection:

$$\text{IS-Query}(U) = \texttt{true} \iff \text{MIS-Query}(U) = U \ .$$

We observe that computing an MIS is a simple task that can be solved in linear time by a Greedy algorithm and even in sublinear time on graphs of bounded-neighborhood independence [9]. The MIS problem can also be solved efficiently in many restricted computational models, e.g., an MIS can be computed in $O(\log\log\Delta)$ rounds in the Congested-Clique model [16], in $O(\log\Delta)$ rounds in the LOCAL model of distributed computing [15, 27], and in $O(\log\log n)$ passes in the semi-streaming model [4, 8]. This task can therefore be regarded as a building block of more elaborate algorithms and may be outsourced to an oracle that maintains an efficient implementation.

Our key motivation is to answer the question as to whether MIS queries are strictly more powerful than IS queries, i.e., whether enhancing the oracle answer by providing a maximal independent set rather than just indicating whether the query set is independent yields significant savings in the number of queries required.

Table 1 Overview of our results. Our results are parametrized by the maximum degree Δ of the input graph. Both our algorithms are non-adaptive and require knowledge of Δ in advance. We also give adaptive counterparts with similar query complexity that do not require advanced knowledge of Δ. The lower bounds for randomized algorithms hold for adaptive algorithms. The lower bound for deterministic algorithms holds for non-adaptive algorithms.

	Algorithm	Lower Bound
Randomized	$O(\Delta^2 \log n)$ (**Theorem 1**)	$\Omega(\Delta^2 + \log n)$ (**Theorems 13 and 14**)
Deterministic	$O(\Delta^3 \log(\frac{n}{\Delta}))$ (**Corollary 7**)	$\Omega(\Delta^3/\log^2 \Delta)$ (**Corollary 12**)

1.1 Our Results

In this paper, we show that MIS queries can be strictly more powerful than IS queries, but this is also not always the case.

As previously mentioned, Angluin and Chen showed that $O(m \log n)$ IS queries are sufficient for reconstructing a graph on m edges. One of our lower bound results (**Theorem 14**) implies that there are m-edge graphs that require $\Omega(m)$ MIS queries to be reconstructed, which show that, up to a logarithmic factor, MIS queries are not more powerful than IS queries on the class of m-edge graphs. However, when considering the class of graphs with maximum degree Δ, for some integer Δ, significant savings can be achieved:

Algorithms. We give a randomized algorithm for reconstructing an n-vertex graph with maximum degree Δ that uses $O(\Delta^2 \log n)$ non-adaptive queries and succeeds with high probability[1] (**Theorem 1**). This result shows that, for the class of graphs of maximum degree Δ, MIS queries are stronger than IS queries since an information-theoretic lower bound similar to the one given in [7] shows that $\Omega(\Delta n \log(\frac{n}{\Delta}))$ IS queries are needed to reconstruct a graph with maximum degree Δ (**Corollary 16** in Appendix A). Observe that, for the class of constant degree graphs, $O(\log n)$ MIS queries are sufficient, but $\Omega(n \log n)$ IS queries are necessary.

We also investigate whether randomization is necessary to obtain algorithms with low query complexity. Using the probabilistic method, we show that there exists a non-adaptive deterministic query algorithm that executes $O(\Delta^3 \log(\frac{n}{\Delta}))$ queries (**Corollary 7**).

Our non-adaptive randomized and deterministic algorithms assume that the maximum degree Δ is known in advance. This cannot be avoided since, as proved in Theorem 14, any algorithm that executes $o(n^2)$ queries cannot solve all instances with $\Delta = \Theta(n)$. We show that the non-adaptive algorithms above can be turned into adaptive algorithms with query complexities that are by at most a constant factor larger. These adaptive algorithms do not require any information about Δ in order to operate and only require $O(\log \Delta)$ rounds of adaptivity (**Corollary 9**).

Lower Bounds. We give lower bounds on the number of queries required by both non-adaptive deterministic algorithms and adaptive randomized algorithms.

First, we show that every non-adaptive deterministic query algorithm requires $\Omega(\Delta^3/\log^2 \Delta)$ queries (**Corollary 12**), which renders our deterministic algorithm optimal, up to poly-logarithmic factors. This result together with our non-adaptive randomized

[1] As it is standard, we say that an event related to the input graph $G = (V, E)$ occurs *with high probability* if the probability is $1 - \frac{1}{\text{poly } n}$, where $n = |V|$.

algorithm (**Theorem 1**) establishes a separation result between non-adaptive randomized and non-adaptive deterministic algorithms since our randomized algorithm only requires $O(\Delta^2 \log n)$ queries.

Next, we show that every adaptive randomized query algorithm requires $\Omega(\log n)$ queries, even if the input graph is guaranteed to be an n-vertex cycle (**Theorem 13**). Furthermore, we show that every adaptive randomized query algorithm requires $\Omega(\Delta^2)$ queries, for any Δ (**Theorem 14**). These lower bounds show that the number of queries executed by our randomized algorithm is optimal, up to a logarithmic factor, and that the logarithmic dependency on n cannot be avoided entirely.

For an overview of our results, see Table 1.

1.2 Techniques

Algorithms. The starting point for all our algorithms is an algorithm by Angluin and Chen [7] for GR that uses IS queries. Our randomized algorithm is in fact identical to their algorithm, up to the use of a different sampling probability. It works as follows:

The key idea is to learn all the non-edges rather than all the edges of the input graph. To this end, we sample sufficiently many random vertex-induced subgraphs $G[V_i] \subseteq G$, for integers i, such that, for every non-edge $uv \in (V \times V) \setminus E(G)$, the probability that both u and v are contained in V_i and are isolated in $G[V_i]$ is $\Theta(\frac{1}{\Delta^2})$. This is achieved by including every vertex in V_i with probability $\frac{1}{\Delta+1}$. Observe that when u and v are isolated in $G[V_i]$ then the oracle necessarily needs to include both u and v in the returned maximal independent set. The returned maximal independent set therefore serves as a witness that proves that the potential edge uv is not contained in the input graph. We then argue that, after repeating this process $O(\Delta^2 \log n)$ times, we have learnt all non-edges with high probability, which allows us to identify the edges of the input graph by complementing the set of non-edges.

Angluin and Chen use this idea in the context of IS queries for graphs with maximum degree Δ, where the significantly lower inclusion probability of each vertex into each sample V_i of $\frac{1}{\sqrt{\Delta n}}$ needs to be used.

Our deterministic algorithm is built on a similar idea. We show that, when taking $\ell = \Theta(\Delta^3 \log(\frac{n}{\Delta}))$ random subsets $V_1, \ldots, V_\ell \subseteq V$ as above, i.e., by inserting every vertex $v \in V$ into any subset V_i with probability $\frac{1}{\Delta+1}$, then, for any tuple $(\{u, v\}, \{w_1, \ldots, w_{2\Delta}\})$ of $2\Delta + 2$ disjoint vertices, which we also refer to as a *witness*, there exists a set V_i such that $u, v \in V_i$ but $w_1, \ldots, w_{2\Delta} \notin V_i$ with positive probability. Since this event happens with non-zero probability, such a family of subsets $V_1, \ldots, V_\ell$ exists. Our deterministic algorithm then queries all of these subsets $(V_i)_{1 \leq i \leq \ell}$. We now claim that our algorithm learns every non-edge $uv \in (V \times V) \setminus E$: We know that there exists a set V_i such that $u, v \in V_i$ but $(\Gamma(v) \cup \Gamma(u)) \cap V_i = \varnothing$ since $|\Gamma(v) \cup \Gamma(u)| \leq 2\Delta$ holds. The vertices u and v are thus isolated in $G[V_i]$ and therefore necessarily reported in the oracle answer, which provides a proof to the algorithm that the edge uv is not contained in the input graph.

Both our non-adaptive randomized and deterministic algorithms require advanced knowledge of Δ, which, as previously argued, is unavoidable. We turn both of these algorithms into adaptive algorithms that require only $O(\log \Delta)$ rounds of adaptivity and whose total number of queries executed is only by a constant factor larger. This is achieved by successively running our algorithms for the guesses $D = 1, 2, 4, 8, \ldots$ for the maximum degree Δ until a final guess $\Delta < D \leq 2\Delta$ is used, in which case it is easy to see that the graph is correctly reconstructed. While this is a standard doubling argument, the non-trivial part of the argument is to identify when the condition $\Delta < D \leq 2\Delta$ is reached since Δ is now unknown. Denoting by F the set of non-edges learnt by the execution of one of our algorithms when

invoked on the current guess D, we show that if the maximum degree in the graph spanned by the edges $(V \times V) \setminus F$ is at least D then we have indeed learnt all the non-edge of the input graph, and thus also reconstructed the graph.

Lower Bounds. We first discuss our $\Omega(\Delta^3/\log^2 \Delta)$ lower bound for deterministic non-adaptive algorithms. Witnesses, i.e., tuples $(\{u,v\},\{w_1,\ldots,w_{2\Delta}\})$ of $2\Delta+2$ disjoint vertices, play a key role in our lower bound argument. We argue that any deterministic non-adaptive query algorithm must be such that, for every witness $(\{u,v\},\{w_1,\ldots,w_{2\Delta}\})$ of disjoint $2\Delta+2$ vertices, there exists a query Q_i such that $u,v \in Q_i$ and $\{w_1,\ldots,w_{2\Delta}\} \cap Q_i = \varnothing$. We call a set of ℓ queries that fulfills this property a Δ-*Query-Scheme of size* ℓ. To see that the previous property is true, for the sake of a contradiction, suppose that this is not the case and there exists a witness $(\{u,v\},\{w_1,\ldots,w_{2\Delta}\})$ that does not fulfill these properties, i.e., whenever u,v is included in a query then at least one of the vertices $w_1,\ldots,w_{2\Delta}$ is included in this query as well. We claim that the two graphs G_1 and G_2, where, in both graphs, $w_1,\ldots,w_\Delta$ are incident on u and $w_{\Delta+1},\ldots,w_{2\Delta}$ are incident on v, and uv is an edge in G_1 but not in G_2 cannot be distinguished[2]. Indeed, we claim that, for any query executed, the oracle can always report an independent set that contains at most one of the two vertices u,v, even on graph G_2. This is because whenever u,v is included in a query then at least one of the vertices $(w_i)_{1\le i\le 2\Delta}$ is also included in this query. The oracle can therefore include w_i in the oracle answer, which implies that at most one of u and v will also be included. Both graphs G_1 and G_2 are therefore consistent with all oracle answers and are thus indistinguishable, a contradiction.

Our task, therefore, is to prove that any Δ-Query-Scheme must be of size at least $\Omega(\Delta^3/\log^2 \Delta)$. We achieve this by combining two separate arguments that address small queries, i.e., queries $V_i \subseteq V$ of size at most $|V_i| \le t := C \cdot \frac{n \ln(\Delta)}{\Delta}$ and large queries of size larger than t, respectively: For any pair of vertices $\{u,v\}$, small queries are such that they cover many witnesses $(\{u,v\},\{w_1,\ldots,w_{2\Delta}\})$, for many different vertices $(w_i)_{1\le i\le 2\Delta}$, since the vertices $(w_i)_{1\le i\le 2\Delta}$ are chosen from $V \setminus V_i$, however, on average, vertex pairs $\{u,v\}$ cannot be included in many small queries (at most $\binom{t}{2}$). In contrast, vertex pairs $\{u,v\}$ can be included in many large queries, however, those queries do not cover many witnesses $(\{u,v\},\{w_1,\ldots,w_{2\Delta}\})$, for vertices $(w_i)_{1\le i\le 2\Delta}$. We obtain our result by combining these observations, see the proof of Lemma 10.

Next, we discuss our $\Omega(\log n)$ queries lower bound for adaptive randomized algorithms on n-vertex cycles. Observe that, in an n-vertex cycle $G=(V,E)$, every pair of vertices $u,v \in V$ is such that $\Gamma(u) \neq \Gamma(v)$. Hence, for a query algorithm to be able to distinguish any two vertices of the input graph, the algorithm is required to obtain oracle answer maximal independent sets such that u and v do not behave the same in all returned independent sets. We show that $\Omega(\log n)$ queries are needed to distinguish between all the vertices. Our argument is based on the observation that, given a set of vertices $U \subseteq V$ that are so far indistinguishable and a query set $V_i \subseteq V$, the returned maximal independent set I_i only allows us to differentiate between the vertices of U that are not queried, queried and contained in I_i, and queried and not contained in I_i. Every query thus allows us to partition any set of vertices that is still indistinguishable into only three subsets, which implies that $\Omega(\log_3 n) = \Omega(\log n)$ queries are needed to distinguish between all the vertices.

[2] This construction generates a maximum degree of $\Delta+1$ in G_1, which is technically not allowed since we consider algorithms that run on graphs of maximum degree Δ. To circumvent this issue, in our actual proof we therefore relate algorithms that operate on maximum degree Δ graphs to $(\Delta-1)$-Query-Schemes.

Last, we discuss our $\Omega(\Delta^2)$ queries lower bound for arbitrary randomized adaptive algorithms. We work with the family of graphs $\mathcal{G}$ obtained from the family of all balanced bipartite graphs $G = (A, B, E)$ with $|A| = |B| = \Theta(\Delta)$, where the two bipartitions A and B are turned into two separate cliques. Observe that each such graph has a maximum independent set size of 2. We now claim that, for every non-edge $ab \in (V \times V) \setminus E(G)$ in the input graph G, there must exist an independent set I_i returned by the oracle such that $I_i = \{a, b\}$. This needs to be the case since otherwise the algorithm cannot distinguish between G and the graph $G' = G \cup \{ab\}$, i.e., G with the edge ab added, since all query responses are then consistent with both G and G'. However, since at most one non-edge can be learnt per query, and $\mathcal{G}$ contains many graphs with $\Omega(\Delta^2)$ non-edges, the result follows. Our actual lower bound is proved for randomized algorithms via an application of Yao's Lemma, which makes the argument slightly more complicated.

1.3 Recent Developments

Since a preprint of our work was released on arXiv in early 2024, Michael and Scott [23] improved some of our lower bounds by poly-logarithmic factors. They show that, for arbitrary adaptive randomized algorithms, $\Omega(\Delta^2 \log(n/\Delta)/\log\Delta)$ queries are needed, improving our $\Omega(\Delta^2)$ lower bound by a $\log(n/\Delta)/\log\Delta$ factor. They further strengthen this bound to $\Omega(\Delta^2 \log(n/\Delta))$ for non-adaptive randomized algorithms. For deterministic non-adaptive algorithms, they give a $\Omega(\Delta^3 \log n/\log\Delta)$ lower bound, improving over our $\Omega(\Delta^3/\log^2\Delta)$ lower bound.

Their improvements for randomized algorithms are obtained by using different and more involved graph constructions. Their lower bound for non-adaptive deterministic algorithms is obtained by establishing a connection between what we refer to as Δ-Query-Schemes (which are equivalent to non-adaptive deterministic algorithms) and cover-free families, which are well-studied mathematical objects. They give an improved lower bound for a cover-free family with certain parameters, which, by the novel connection identified, translates to a lower bound for deterministic non-adaptive algorithms.

1.4 Outline

We give our algorithms in Section 2 and our lower bounds in Section 3. We conclude with open problems in Section 4.

2 Algorithms

We give our randomized non-adaptive algorithm that executes $O(\Delta^2 \log n)$ queries in Subsection 2.1, and our deterministic non-adaptive algorithm that executes $O(\Delta^3 \log(\frac{n}{\Delta}))$ queries in Subsection 2.2. Both these algorithms require the maximum degree Δ as part of their inputs. In Subsection 2.3, we show how these algorithms can be turned into adaptive algorithms with a similar number of queries that do not require advanced knowledge of Δ.

2.1 Randomized Algorithm

Our algorithm, Algorithm 1, executes $\Theta(\Delta^2 \log n)$ queries on random subsets $V_i \subseteq V$, where each vertex is included in V_i with probability $\frac{1}{\Delta+1}$, and outputs every pair $uv \in V \times V$ as an edge of the input graph if $\{u, v\}$ is not contained in any maximal independent set I_i, for all i, returned by the oracle.

In the analysis, we prove that, for every non-edge $uv \in (V \times V) \setminus E(G)$ in the input graph G, both u and v are reported in any independent set I_i with probability $\Theta(\frac{1}{\Delta^2})$. Since $\Theta(\Delta^2 \log n)$ independent sets are computed, any non-edge will be detected with high probability, and by the union bound, this then applies to all non-edges.

Algorithm 1 Randomized graph reconstruction using a MIS oracle.

Require: Vertex set V, maximum degree Δ, large enough constant C
  for $i = 1 \dots C \cdot (\Delta+1)^2 \cdot \log n$ **do**
    $V_i \subseteq V$ random sample such that every $v \in V$ is included in V_i with probability $\frac{1}{\Delta+1}$
    $I_i \leftarrow \text{query}(V_i)$
  end for
  $E \leftarrow \{uv \in V \times V \ : \ \nexists i \text{ such that } \{u,v\} \subseteq I_i\}$
  return (V, E)

▶ **Theorem 1.** *Algorithm 1 is a non-adaptive randomized algorithm that executes $O(\Delta^2 \log n)$ MIS queries and correctly reconstructs a graph of maximum degree Δ with high probability.*

Proof. Let $G = (V, E)$ denote the input graph, Δ the maximum degree, and let $\overline{E} = (V \times V) \setminus E$ denote the set of non-edges. We will prove that, with high probability, every non-edge can be identified by the algorithm in that, for a non-edge $uv \in \overline{E}$, there exists an independent set I_i such that $\{u, v\} \in I_i$ with high probability.

Consider thus any non-edge $uv \in \overline{E}$. Then, for every i, the probability that both u and v are reported in independent set I_i is at least:

$$\Pr[u, v \in I_i] \geq \Pr[u, v \in V_i \text{ and } (\Gamma(u) \cup \Gamma(v)) \cap V_i = \varnothing] \ ,$$

since both u and v need to be included in a maximal independent set if they are isolated vertices in $G[V_i]$.

Next, observe that the events "$u, v \in V_i$" and "$(\Gamma(u) \cup \Gamma(v)) \cap V_i = \varnothing$" are independent since u and v are not adjacent and are thus not contained in $\Gamma(u) \cup \Gamma(v)$. Furthermore, observe that $|\Gamma(u) \cup \Gamma(v)| \leq 2\Delta$. Then:

$$\begin{aligned}
\Pr[u, v \in V_i \text{ and } (\Gamma(u) \cup \Gamma(v)) \cap V_i = \varnothing] &= \Pr[u, v \in V_i] \cdot \Pr[(\Gamma(u) \cup \Gamma(v)) \cap V_i = \varnothing] \\
&\geq \frac{1}{(\Delta+1)^2} \cdot (1 - \frac{1}{\Delta+1})^{2\Delta} \\
&\geq \frac{1}{(\Delta+1)^2} \cdot e^{-\frac{\frac{1}{\Delta+1}}{1-\frac{1}{\Delta+1}} \cdot 2\Delta} = \frac{1}{(\Delta+1)^2} \cdot \frac{1}{e^2} \ , \quad (1)
\end{aligned}$$

where we used the bound $1 - x \geq e^{-\frac{x}{1-x}}$, which holds for every $x < 1$.

Next, we compute the probability that both endpoints of the non-edge uv are never reported together:

$$\begin{aligned}
\Pr[\{u, v\} \not\subseteq I_i, \text{ for all } i] &= \prod_{i=1}^{C(\Delta+1)^2 \cdot \log n} \Pr[\{u, v\} \not\subseteq I_i] \\
&= \prod_{i=1}^{C(\Delta+1)^2 \cdot \log n} (1 - \Pr[u, v \in I_i]) \\
&\leq (1 - \frac{1}{(\Delta+1)^2} \cdot \frac{1}{e^2})^{C(\Delta+1)^2 \cdot \log n} \\
&\leq \exp\left(-\frac{1}{(\Delta+1)^2} \cdot \frac{1}{e^2} \cdot C(\Delta+1)^2 \cdot \log n\right) \leq \frac{1}{n^3} \ ,
\end{aligned}$$

where we used the inequality $1 + x \leq \exp(x)$, and the last inequality holds when C is chosen to be large enough.

By the union bound, the probability that the endpoints of at least one of the $O(n^2)$ non-edges are not reported in any independent set I_i is therefore at most $\frac{1}{n}$, which completes the proof. ◀

2.2 Deterministic Algorithm

Central to our deterministic algorithm is the notion of a Δ-*Query-Scheme* and a *Witness*:

▶ **Definition 2** (Witness). *Let V be a set of n vertices and let $2 \leq \Delta \leq n/2-1$ be an integer. Then, the tuple $(\{u,v\},\{w_1,\ldots,w_{2\Delta}\})$ with $u,v,w_1,\ldots,w_{2\Delta} \in V$ being distinct vertices is called a* Witness*, and we denote by $\mathcal{W}$ the set of all witnesses.*

As it will be important in the proof of Lemma 6, we give an upper bound on the number of witnesses:

▶ **Lemma 3.** *The number of witnesses $|\mathcal{W}|$ is bounded by:*

$$|\mathcal{W}| \leq n^2 \cdot (e \cdot \frac{n-2}{2\Delta})^{2\Delta} .$$

Proof. We use the bound $\binom{a}{b} \leq \left(e \cdot \frac{a}{b}\right)^b$ and obtain:

$$|\mathcal{W}| = \binom{n}{2} \cdot \binom{n-2}{2\Delta} \leq n^2 \cdot (e \cdot \frac{n-2}{2\Delta})^{2\Delta} .$$ ◀

▶ **Definition 4** (Δ-Query-Scheme). *Let V be a set of n vertices and let $2 \leq \Delta \leq n/2-1$ be an integer. The set $\mathcal{Q} = \{Q_1,\ldots,Q_\ell\}$ is denoted a* Δ-Query-Scheme *of size ℓ if, for every witness $(\{u,v\},\{w_1,\ldots,w_{2\Delta}\}) \in \mathcal{W}$, there exists a query $Q_i \in \mathcal{Q}$ such that:*

1. *$u,v \in Q_i$, and*
2. *$\{w_1,\ldots,w_{2\Delta}\} \cap Q_i = \varnothing$.*

In the following, we say that a query Q_i considers *a witness $W \in \mathcal{W}$ if Items 1 and 2 hold for Q_i and W.*

We show in Lemma 5 that a Δ-Query-Scheme of size ℓ immediately yields a non-adaptive deterministic query algorithm for GR for graphs of maximum degree Δ that executes ℓ queries. Our task is thus to design a Δ-Query-Scheme of small size, which we do in the proof of Lemma 6.

▶ **Lemma 5.** *Let $\mathcal{Q}$ be a Δ-Query-Scheme of size ℓ. Then, there exists a non-adaptive deterministic algorithm for GR that executes ℓ queries on graphs of maximum degree Δ.*

Proof. Let $G=(V,E)$ be the input graph, and let $\mathcal{Q}$ be a Δ-Query-Scheme of size ℓ. The algorithm executes every query $Q_i \in \mathcal{Q}$. Let I_i denote the query answer to Q_i.

We now claim that, for every non-edge $uv \in (V \times V) \setminus E$ in the input graph, there exists an independent set I_i such that $u,v \in I_i$. To see this, denote by $w_1,\ldots,w_{\deg(u)}$ the neighbours of u in G and by $w_{\Delta+1},\ldots,w_{\Delta+\deg(v)}$ the neighbours of v in G. Then, since $\mathcal{Q}$ is a Δ-Query-Scheme, there exists a query Q_i such that $u,v \in I_i$, but none of u's and v's neighbours are included. Hence, both u and v are necessarily included in I_i and the algorithm therefore observes a witness that proves that the edge uv does not exist in the input graph.

Since the argument applies to every non-edge, the algorithm learns all non-edges of the input graph and thus also learns all of the input graph's edges by complementing the set of non-edges. ◀

▶ **Lemma 6.** *There exists a Δ-Query-Scheme of size $O(\Delta^3 \log \frac{n}{\Delta})$.*

Proof. For an integer ℓ whose value we will determine later, let $\mathcal{Q} = \{Q_1, Q_2, \ldots, Q_\ell\}$ be such that, for every i, $Q_i \subseteq V$ is the subset of V obtained by including every vertex with probability $\frac{1}{\Delta+1}$. We use the probabilistic method and prove that $\mathcal{Q}$ is a Δ-Query-Scheme with positive probability, which in turn implies that such a scheme exists.

To this end, let $u, v, w_1 \ldots, w_{2\Delta} \in V$ be distinct vertices. Then, for any i, we obtain (the derivation is identical to Inequality 1 and therefore not repeated here)

$$\Pr[u, v \in Q_i \text{ and } w_1, \ldots, w_{2\Delta} \notin Q_i] = \frac{1}{(\Delta+1)^2} \cdot (1 - \frac{1}{\Delta+1})^{2\Delta} \geq \frac{1}{(\Delta+1)^2} \cdot \frac{1}{e^2} \ .$$

Furthermore, the probability that there does not exist a query Q_i, for any $i \in [\ell]$, such that $u, v \in Q_i$ and $w_1, \ldots, w_{2\Delta} \notin Q_i$ is at most:

$$\begin{aligned}\Pr[\nexists i \text{ such that } u, v \in Q_i \text{ and } w_1, \ldots, w_{2\Delta} \notin Q_i] &\leq \left(1 - \frac{1}{(\Delta+1)^2 e^2}\right)^\ell \\ &\leq \exp(-\frac{\ell}{(\Delta+1)^2 e^2}) \ .\end{aligned}$$

Hence, by the union bound over all witnesses $u, v, w_1, \ldots, w_{2\Delta}$ (see Lemma 3), the probability that there exists a witness that is not considered by the Δ-Query-Scheme is at most:

$$n^2 \cdot (e \cdot \frac{n-2}{2\Delta})^{2\Delta} \cdot \exp(-\frac{\ell}{(\Delta+1)^2 e^2}) \ .$$

For this probability to be strictly below 1, it is enough to set

$$\ell = \Theta(\Delta^3 \cdot \log(\frac{n}{\Delta})) \ ,$$

which in turn implies that such a scheme exists. ◀

Combining Lemma 5 and Lemma 6, we obtain the main result of this section.

▶ **Corollary 7.** *There exists a deterministic algorithm for GR that executes $O(\Delta^3 \log \frac{n}{\Delta})$ non-adaptive MIS queries for graphs with maximum degree Δ.*

2.3 Adaptive Algorithms without Knowledge of Δ

We will now show how the randomized and deterministic algorithms from the previous sections can be turned into adaptive algorithms with similar query complexity that do not require knowledge of Δ in order to operate. More specifically, let $\mathcal{A}$ be a non-adaptive query algorithm that, given an integer D, identifies with high probability in $R(D)$ rounds all non-edges uv such that $\deg(u) \leq D$ and $\deg(v) \leq D$ hold. It immediately follows from our analyses that both our randomized and deterministic query algorithms have this property when executed with parameter D instead of the true value of Δ. For our randomized algorithm, we have $R(D) = O(D^2 \log n)$, and, for our deterministic algorithm, we have $R(D) = O(D^3 \log(\frac{n}{D}))$. We will show how $\mathcal{A}$ can be turned into an adaptive algorithm that does not require knowledge of Δ and requires overall $O(\mathcal{R}(\Delta))$ rounds.

This is achieved via the doubling strategy displayed in Algorithm 2.

The algorithm uses the notation $\Delta(E')$, which is to be interpreted as the maximum degree in the graph spanned by the edges E'.

Algorithm 2 Adaptive algorithm that does not require advanced knowledge of Δ.

Require: Vertex set V, non-adaptive algorithm $\mathcal{A}$ that identifies all non-edges whose endpoints are of degree at most D, for some integer D
$D \leftarrow 1$, $E' \leftarrow V \times V$
while $\Delta(E') > D$ **do**
$D \leftarrow 2 \cdot D$
$F \leftarrow \mathcal{A}(D)$ {Set of non-edges identified}
$E' \leftarrow (V \times V) \setminus F$
end while
return (V, E')

▶ **Lemma 8.** *Let $\mathcal{A}$ be a non-adaptive MIS-query algorithm that, given an integer D, in $R(D)$ rounds identifies with high probability all non-edges $uv \in (V \times V) \setminus E$ of the input graph $G = (V, E)$ that have the property that $\deg(u) \leq D$ and $\deg(v) \leq D$. We assume that $R(D)$ is at least linear in D, i.e., $R(D) = \Omega(D)$. Then, there exists an adaptive algorithm for GR that succeeds with high probability, does not require advanced knowledge of Δ, runs in $O(R(\Delta))$ rounds, and requires $O(\log \Delta)$ rounds of adaptivity.*

Proof. Let $G = (V, E)$ denote the input graph and Δ the maximum degree.

We will argue that when exiting the last iteration of the while loop of the algorithm, the inequalities

$$\Delta \leq D < 2\Delta \tag{2}$$

hold. The lower bound $\Delta \leq D$ establishes correctness since the last run of $\mathcal{A}$ is executed with a guess $\Delta \leq D$, which implies that all non-edges are correctly identified. The upper bound is required in order to bound the query complexity of the algorithm.

We first argue the lower bound in Inequality 2. Observe that, in any iteration of the loop, $E' \supseteq E$ holds since F is a subset of the non-edges and $E' = (V \times V) \setminus F$. Thus, we have $\Delta(E') \geq \Delta(E) = \Delta$. When exiting the last iteration of the algorithm, we have $\Delta(E') \leq D$ since otherwise this would not be the last iteration of the algorithm. Combining these two inequalities yields $\Delta \leq D$.

Regarding the upper bound, we have just proved that, when exiting the last iteration, $\Delta \leq D$ holds. It is then also clear that a run with $\Delta \leq D < 2\Delta$ is executed since the guess D is doubled in each iteration. We claim that this run with $\Delta \leq D < 2\Delta$ is indeed the last iteration of the algorithm. Indeed, in this iteration, all non-edges F are correctly identified since $D \geq \Delta$, which implies that E' constitutes the edge set E of the input graph. This further implies that $\Delta(E') = \Delta$. The condition in the while loop then ensures that this is indeed the last iteration of the algorithm.

Last, regarding the runtime of the algorithm, let $D' = 2^i$ be the guess used in the last iteration. We then have that $\Delta \leq D' < 2\Delta$. Then, under the assumption that $R(D) = \Omega(D)$, we have:

$$R(2) + R(4) + \cdots + R(D') \leq 2 \cdot R(D') \ ,$$

which establishes the query complexity of the algorithm. Last, since the while loop is executed $O(\log \Delta)$ times, the algorithm requires only $O(\log \Delta)$ rounds of adaptivity. ◀

The previous lemma together with our randomized and deterministic algorithms from the previous sections yield the following corollary.

▶ **Corollary 9.** *There are randomized and deterministic adaptive MIS-query algorithms for GR that execute $O(\Delta^2 \cdot \log n)$ and $O(\Delta^3 \cdot \log \frac{n}{\Delta})$ queries, respectively, require $O(\log \Delta)$ rounds of adaptivity, and do not require advanced knowledge of Δ in order to operate. The randomized algorithm succeeds with high probability.*

3 Lower Bounds

In this section, we give three lower bound results. First, in Subsection 3.1, we consider the class of non-adaptive deterministic query algorithms and we prove that such algorithms require $\Omega(\Delta^3/\log^2 \Delta)$ queries. This result renders our deterministic query algorithm optimal, up to poly-logarithmic factors, and it also establishes a separation result between deterministic and randomized query algorithms, since, as demonstrated by our randomized query algorithm, $O(\Delta^2 \log n)$ non-adaptive randomized queries are sufficient.

Next, in Subsection 3.2, we show that $\Omega(\Delta^2)$ queries are needed for query algorithms that may be adaptive and randomized, and that $\Omega(\log n)$ queries are needed for such algorithms, even if the input graph is an n-vertex cycle.

3.1 Lower Bound for Non-adaptive Deterministic Algorithms

We will first show in Lemma 10 that any Δ-Query-Scheme must be of size at least $\Omega(\frac{\Delta^3}{\log^2 \Delta})$. Then, we argue in Lemma 11 that the queries executed by any non-adaptive deterministic query algorithm must constitute a $(\Delta - 1)$-Query-Scheme. These two lemmas together then imply our main result of this section as stated in Corollary 12, i.e., that non-adaptive deterministic query algorithms require $\Omega(\frac{\Delta^3}{\log^2 \Delta})$ queries.

▶ **Lemma 10.** *For every $\Delta \leq n^{2/3}$, every Δ-Query-Scheme is of size $\Omega(\frac{\Delta^3}{\log^2(\Delta)})$.*

Proof. Let C be a suitably large constant, and suppose that there exists a Δ-Query-Scheme $\mathcal{Q}$ of size $\ell = \frac{1}{6 \cdot C^2} \cdot \frac{\Delta^3}{\ln^2(\Delta)}$. We will show by contradiction that a Δ-Query-Scheme of this size does not exist. Furthermore, we define a relevant query size threshold t by $t := C \cdot \frac{n \ln(\Delta)}{\Delta}$.

Given $\mathcal{Q}$, we will first argue that there exists a pair of disjoint vertices $x, y \in V$ such that there is no query $Q \in \mathcal{Q}$ with $Q = \{x, y\}$, and there are at most $\Delta/2$ queries of size at most t that contain both x, y. Then, once we have established that such a pair $\{x, y\}$ exists then we use the probabilistic method to show that there exist 2Δ disjoint vertices $w_1, \ldots, w_{2\Delta}$ different to x, y such that the witness $(\{x, y\}, \{w_1, \ldots, w_{2\Delta}\}$ is not considered in $\mathcal{Q}$, a contradiction to the fact that $\mathcal{Q}$ is a Δ-Query-Scheme. This implies that a query scheme of size ℓ cannot exist.

Denote by $\mathcal{X}$ the set of subsets of V of size 2, i.e., $\mathcal{X} = \{\{u, v\} \ : \ u, v \in V, u \neq v\}$, where V denotes the set of n vertices of the input graph, and observe that $|\mathcal{X}| = \binom{n}{2}$.

First, observe that at most ℓ queries in $\mathcal{Q}$ are of size exactly 2. Hence, as long as $\ell \leq \binom{n}{2}/10$, at most a (1/10)-fraction of $\mathcal{X}$ is part of queries of size 2. Observe that, since the statement of the lemma assumes that $\Delta \leq n^{2/3}$, we have

$$\ell = \frac{1}{6 \cdot C^2} \cdot \frac{\Delta^3}{\ln^2(\Delta)} \leq \frac{\Delta^3}{6 \cdot C^2} \leq \frac{n^2}{6 \cdot C^2} \leq \frac{n^2}{40} \leq \frac{1}{10} \binom{n}{2} ,$$

where we assumed that C is large enough, and the last inequality holds for every $n \geq 2$. Observe that a query $Q = \{u, v\}$ of size 2 immediately considers all witnesses of the form $(\{u, v\}, \{w_1, \ldots, w_{2\Delta}\})$, for any vertices $(w_i)_{1 \leq i \leq 2\Delta}$. The previous argument shows that this can happen for at most a (1/10)-fraction of pairs $\{u, v\} \in \mathcal{X}$.

Next, we argue that at least a (1/4)-fraction of the pairs $\{u,v\} \in \mathcal{X}$ are such that $\{u,v\}$ is contained in at most $\frac{1}{2}\Delta$ queries of size at most t in $\mathcal{Q}$. To this end, observe that any query of size at most t contains at most $\binom{t}{2} \leq t^2$ distinct pairs $\{u,v\}$, and since there are overall ℓ queries, at most

$$\ell \cdot t^2 = \frac{1}{6C^2} \cdot \frac{\Delta^3}{\ln^2(\Delta)} \cdot \left(C \cdot \frac{n \ln(\Delta)}{\Delta} \right)^2 = \frac{1}{6} \cdot n^2 \cdot \Delta$$

pairs appear overall in all queries of size at most t. If less than a (1/4)-fraction of pairs $\{u,v\}$ were contained in at most $\frac{1}{2}\Delta$ queries of size at most t in $\mathcal{Q}$, then at least a (3/4)-fraction of pairs were contained in more than $\frac{1}{2}\Delta$ queries of size at most t. But this implies that the following inequality must hold:

$$(3/4) \cdot \binom{n}{2} \frac{1}{2}\Delta \leq \ell \cdot t^2 = \frac{1}{6} \cdot n^2 \cdot \Delta \ .$$

This inequality, however, does not hold for $n \geq 10$, a contradiction. Hence, we have proved that at least a (1/4)-fraction of pairs $\{u,v\} \in \mathcal{X}$ are such that $\{u,v\}$ is contained in at most $\frac{1}{2}\Delta$ queries of size at most t in $\mathcal{Q}$.

Consider thus a pair $\{u,v\} \in \mathcal{X}$ that is included in at most $\Delta/2$ queries of size at most t, and that is not included in a query of size 2. The arguments above ensure that such a pair exists. Denote by $Q_1, \ldots, Q_k$ the set of queries that contain both u and v, and suppose that $Q_1, \ldots, Q_j$ are the queries of size at most t (which implies $j \leq \Delta/2$). We now claim that there is a witness $W = (\{u,v\}, \{w_1, \ldots, w_{2\Delta}\})$, for some vertices $(w_i)_{1 \leq i \leq 2\Delta}$, that is not considered by the queries $Q_1, \ldots, Q_k$, contradicting the assumption that $\mathcal{Q}$ is a Δ-Query-Scheme, which then completes the proof.

The witness is constructed as follows. For $1 \leq i \leq j$, let $\tilde{w}_i \in Q_i \setminus \{u,v\}$ be any element. Recall that $\{u,v\}$ is not contained in any query of size exactly 2, hence, $\tilde{w}_i$ is well-defined. Furthermore, let $\tilde{W} = \{\tilde{w}_1, \tilde{w}_2, \ldots, \tilde{w}_j\}$. We observe that the elements $(\tilde{w}_i)_{1 \leq i \leq j}$ are not necessarily disjoint, and, hence, $|\tilde{W}| \in \{1, \ldots, j\}$. Next, let $R \subseteq V \setminus \left(\{u,v\} \cup \tilde{W}\right)$ be a random subset of size $2\Delta - |\tilde{W}|$. Then, our witness W is obtained as $W = \{\{u,v\}, \tilde{W} \cup R\}$, and we will prove in the following that, with positive probability, this witness is indeed not considered by $\mathcal{Q}$. This implies that there exists a witness that is not considered by $\mathcal{Q}$, which completes the proof.

Consider now any query Q_i, for $i \geq j+1$. Then, the probability that Q_i considers W is bounded as follows:

$$\begin{aligned}
&\Pr[Q_i \text{ considers } W] \leq \Pr[|Q_i \cap R| = \varnothing] \\
&\quad = \frac{n - |Q_i| - |\tilde{W}|}{n - 2 - |\tilde{W}|} \cdot \frac{n - |Q_i| - |\tilde{W}| - 1}{n - 2 - |\tilde{W}| - 1} \cdot \ldots \cdot \frac{n - |Q_i| - |\tilde{W}| - (2\Delta - |\tilde{W}|) + 1}{n - 2 - |\tilde{W}| - (2\Delta - |\tilde{W}|) + 1} \\
&\quad \leq \left(\frac{n - |Q_i| - |\tilde{W}|}{n - 2 - |\tilde{W}|} \right)^{2\Delta - |\tilde{W}|} \leq \left(\frac{n - |Q_i|}{n - 2} \right)^{2\Delta - |\tilde{W}|} \leq \left(\frac{n - |Q_i|}{n - 2} \right)^{1.5\Delta} \\
&\quad = \left(\frac{n - 2 + 2 - |Q_i|}{n - 2} \right)^{1.5\Delta} = \left(1 - \frac{|Q_i| - 2}{n - 2} \right)^{1.5\Delta} \leq \left(1 - \frac{|Q_i| - 2}{n} \right)^{1.5\Delta} \\
&\quad \leq \exp\left(-\frac{(|Q_i| - 2)1.5\Delta}{n} \right) \leq \exp\left(-1.5C \ln(\Delta) + \frac{3\Delta}{n} \right) \leq \frac{2}{\Delta^{1.5C}} \ .
\end{aligned}$$

Since C is a large enough constant, by the union bound, the probability that at least one query of the queries $Q_{j+1} \ldots, Q_k$ considers W is therefore strictly below 1 (recall that there are at most $k \leq \ell \leq \Delta^3$ queries, and $\Delta^3 \cdot \frac{2}{\Delta^{1.5C}} < 1$ holds, for large enough C). Hence, there exists a witness that is not considered by these queries, which completes the proof. ◀

▶ **Lemma 11.** *Let $\mathcal{A}$ be a non-adaptive deterministic query algorithm for GR on graphs of maximum degree Δ. Then, the queries executed by $\mathcal{A}$ form a $(\Delta-1)$-Query-Scheme.*

Proof. For the sake of a contradiction, suppose that there exists a sequence of queries $Q_1, \ldots, Q_k$ that does not form a $(\Delta-1)$-Query-Scheme but still allows the algorithm $\mathcal{A}$ to learn the input graph exactly. Since the queries do not form a $(\Delta-1)$-Query-Scheme, there exists a witness $W = (\{u, v\}, \{w_1, \ldots, w_{2\Delta-2}\})$ that is not considered by the queries. Consider now any two input graphs G_1 and G_2 of maximum degree Δ that have the following properties: u's neighbours are $w_1, \ldots, w_{\Delta-1}$, and v's neighbours are $w_\Delta, \ldots, w_{2\Delta-2}$. In G_1, there is also an edge between u and v, and in G_2 there is no edge between u and v. Observe that the degrees of u and v in G_1 and G_2 are Δ and $\Delta-1$, respectively. The maximum degrees in G_1 and G_2 are therefore at most Δ.

Now, we claim that, for every query Q_i, the oracle can respond with an independent set I_i that does not include both vertices u and v. Observe that the algorithm therefore cannot learn whether the edge uv exists since both G_1 and G_2 are consistent with all query answers. The algorithm therefore cannot distinguish between the two graphs G_1, G_2, which then completes the argument.

Since Q_i does not consider W, there exists a vertex $w \in \{w_1, \ldots, w_{2\Delta-2}\}$ such that $w \in Q_i$. Hence, the oracle can construct an independent set starting with vertex w (e.g., by running the Greedy maximal independent set algorithm where w is the first vertex picked), which implies that either u or v cannot be included in the independent set. This completes the proof. ◀

▶ Remark. The proof of the previous lemma assumes that the oracle can identify a witness not considered by the queries submitted by the algorithm. This is only possible if all queries are submitted simultaneously to the oracle. Observe that this is a valid assumption since we consider the class of non-adaptive algorithms, and such algorithms equally work when all queries are submitted simultaneously.

Combining Lemma 10 with Lemma 11, we obtain the main lower bound result of this section as a corollary:

▶ **Corollary 12.** *Every deterministic non-adaptive query algorithm for GR requires $\Omega(\Delta^3/\log^2(\Delta))$ queries.*

3.2 Lower Bounds for Adaptive Randomized Algorithms

We first prove that, even on an n-vertex cycle, any randomized adaptive algorithm requires $\Omega(\log n)$ queries to solve GR. Our proof is based on an indistinguishability argument: At least $\Omega(\log n)$ queries are needed so that, for each pair of vertices $u, v \in V$, different outcomes from the oracle are observed, which is needed to distinguish all possible cycles from each other.

▶ **Theorem 13.** *Every possibly randomized query algorithm with success probability strictly above $1/2$ for Graph Reconstruction using a Maximal Independent Set oracle on an n-vertex cycle requires $\Omega(\log n)$ queries.*

Proof. Denote by $\mathcal{C}$ the family of n-vertex cycles on the vertex set V with $|V| = n$, which serve as the input to our algorithm.

Let $\mathbf{A}$ be a randomized query algorithm that executes $\ell := \log_3(n) - 1$ rounds and that, on any input $C \in \mathcal{C}$, succeeds with probability strictly above $\frac{1}{2}$. Then, by Yao's lemma, there exists a deterministic query algorithm $\mathbf{A}_{\text{det}}$ that succeeds on strictly more than half of the inputs in $\mathcal{C}$ and also runs in ℓ rounds.

We first observe that, since $\mathbf{A}_{\text{det}}$ is deterministic, and we also assume that the oracle answers are deterministic, for every $C \in \mathcal{C}$, there exists a unique execution of $\mathbf{A}_{\text{det}}$, i.e., a sequence of query vertices $V_1, \ldots, V_\ell$, query answers $I_1, \ldots, I_\ell$, and output $C_{\text{out}} \in \mathcal{C}$ produced by the algorithm. We observe that C_{out} may be different from C if the algorithm errs on input C.

Denote by $\mathcal{C}_1 \subseteq \mathcal{C}$ the subset of inputs on which the algorithm succeeds, and let $\mathcal{C}_0 = \mathcal{C} \setminus \mathcal{C}_1$ denote the inputs on which the algorithm fails. We will now argue that, for every input $C \in \mathcal{C}_1$ on which the algorithm succeeds, there exists a unique input $C' \in \mathcal{C}_0$ on which the algorithm fails, i.e., there exists an injective mapping from $\mathcal{C}_1$ into $\mathcal{C}_0$, which implies that $|\mathcal{C}_1| \leq |\mathcal{C}_0|$. This is a contradiction to the fact that $\mathbf{A}_{\text{det}}$ is correct on strictly more than half of the instances in $\mathcal{C}$, which in turn implies that the algorithm $\mathbf{A}$ does not exist.

Let $C \in \mathcal{C}_1$ be an input on which $\mathbf{A}_{\text{det}}$ succeeds. Denote by $V_1, \ldots, V_\ell$ the vertices queried by the algorithm in the ℓ query rounds and by $I_1, \ldots, I_\ell$ the query responses. We associate the following complete ternary tree $\mathcal{T}$ with $\ell + 1$ layers to the query vertices and responses in an execution of $\mathbf{A}$:

- The root (layer 1) is labelled with $V = [n]$.
- For an internal node in layer $1 \leq i \leq \ell$ with label $U \subseteq V$, the node has three children with labels U_1, U_2, U_3 such that $U = U_1 \dot\cup U_2 \dot\cup U_3$, and

$$\begin{aligned} U_1 &= (U \cap V_i) \cap I_i \ , && \text{queried and reported} \\ U_2 &= (U \cap V_i) \setminus I_i \ , && \text{queried and not reported} \\ U_3 &= U \setminus V_i \ . && \text{not queried} \end{aligned}$$

Denote by $L_1, L_2, \ldots$ the leaves of $\mathcal{T}$ from left-to-right. We observe that, by construction, the leaves are disjoint and their union equals V, i.e., $\dot\cup_i L_i = V$. Consider now a leaf L_i that contains at least two vertices u, v. The vertices u, v are indistinguishable as they behaved exactly the same throughout the execution of the algorithm. Indistinguishable here means that the cycle C' obtained from the cycle C by swapping the positions of u and v leads to the exact same execution of the algorithm as the execution for C. The algorithm, however, fails on C' as the output produced is $C_{\text{out}} = C$. Hence, as long as there exists a leaf that contains at least two vertices, we can identify an input on which the algorithm fails and establish our injective mapping from $\mathcal{C}_1$ to $\mathcal{C}_0$. To avoid that there are no leaves that contain two vertices, the number of leaves in $\mathcal{T}$ must be at least n. Since $\mathcal{T}$ is ternary and of depth $\ell + 1$, we obtain that $\ell \geq \log_3(n)$ must hold, a contradiction to the assumption that $\ell = \log_3(n) - 1$. This completes the proof. ◀

Last, we give our $\Omega(\Delta^2)$ queries lower bound for graphs of maximum degree Δ. The key observation in our proof is that, for every non-edge uv in the input graph G, there must exist an oracle response maximal independent set that contains both vertices u and v, since, if the opposite was true then the algorithm could not distinguish between the input graph G and the graph $G \cup \{uv\}$.

▶ **Theorem 14.** *For any $\Delta > 0$, every possibly randomized query algorithm with success probability strictly greater than $1/2$ for Graph Reconstruction using a Maximal Independent Set oracle requires $\Omega(\Delta^2)$ queries on graphs of maximum degree Δ.*

Proof. For integers $N > 0$, let $\mathcal{H}_N$ denote the set of all bipartite graphs $H = (A, B, E)$ with $|A| = |B| = N$. Then, let $\mathcal{G}_N$ be the family of graphs obtained from $\mathcal{H}_N$ by turning the bipartitions A and B of each of its graphs $H = (A, B, E) \in \mathcal{H}_N$ into (disjoint) cliques.

Let $\mathbf{A}$ denote a randomized query algorithm that succeeds with probability strictly above $1/2$ on each input $G \in \mathcal{G}_N$, and for the sake of a contradiction, we assume that $\mathcal{A}$ executes at most $\ell = N^2 - 1$ queries. Then, by Yao's lemma, there exists a deterministic query algorithm $\mathcal{A}_{\text{det}}$ that also executes at most ℓ queries and succeeds on strictly more than half of the inputs in $\mathcal{G}_N$.

First, observe that $\alpha(G) \leq 2$, for every $G \in \mathcal{G}_N$ since at most one vertex from A and at most one vertex from B can be included in any independent set. Hence, every independent set reported by $\mathbf{A}_{\text{det}}$ on any of the input graphs $G \in \mathcal{G}_N$ is of size at most 2.

Denote by $\mathcal{G}_N^1 \subseteq \mathcal{G}_N$ the subset of inputs on which $\mathcal{A}_{\text{det}}$ succeeds, and let $\mathcal{G}_N^0 = \mathcal{G}_N \setminus \mathcal{G}_N^1$. We will show that there exists an injective map from $\mathcal{G}_N^1$ to $\mathcal{G}_N^0$, which implies that $|\mathcal{G}_N^1| \leq |\mathcal{G}_N^0|$, a contradiction to the fact that $\mathcal{A}_{\text{det}}$ succeeds on strictly more than half of the instances. This in turn implies that algorithm $\mathbf{A}$ does not exists, which establishes the theorem.

To this end, let $G \in \mathcal{G}_N^1$ be any instance and consider the execution of $\mathcal{A}_{\text{det}}$ on G, i.e., let $V_1, \ldots, V_\ell$ denote the queries submitted in the ℓ query rounds, let $I_1, \ldots, I_\ell$ denote the query responses, and let $G_{\text{out}} = G$ denote the output produced by the algorithm.

Let

$$F = \{(a,b) \in A \times B \mid \{a,b\} \neq I_i, \text{ for all } i\} ,$$

i.e., the set of pairs of vertices a, b that do not constitute a response from the oracle. We observe that every graph G' obtained from G by flipping the edge ab, i.e., by introducing ab in G' in case it is not contained in G or by removing it from G' in case it is contained in G, leads to the exact same execution of $\mathbf{A}_{\text{det}}$ as all oracle answers are consistent with both G and G'. The algorithm however fails on G' since the answer produced by the execution is $G_{\text{out}} = G$. Hence, as long as $F \neq \varnothing$, we can identify a graph G' on which the algorithm fails and map the input G to G' in our injective map. To ensure that $F = \varnothing$, we require at least $|A| \cdot |B| = N^2$ queries. This however is a contradiction to the assumption that only $\ell = N^2 - 1$ queries are executed.

Last, the result follows by observing that the maximum degree Δ of any graph in $\mathcal{G}_N$ is $2N - 1$, which implies that at least $(\frac{\Delta+1}{2})^2$ query rounds are required. ◀

We remark that Theorem 14 also shows that $\Omega(m)$ queries are needed for reconstructing graphs on m edges. Observe that every graph of the family of graphs used in Theorem 14 has $O(\Delta^2)$ edges.

4 Conclusion

In this paper, we initiated the study of the GR problem using an MIS oracle. We gave a non-adaptive randomized algorithm that reconstructs a graph with maximum degree Δ using $O(\Delta^2 \log n)$ queries, and a non-adaptive deterministic query algorithm that uses $O(\Delta^3 \log(\frac{n}{\Delta}))$ queries. Both these algorithms require advanced knowledge of Δ in order to operate, which is unavoidable. We showed that both algorithms can be turned into adaptive algorithms with $O(\log \Delta)$ rounds of adaptivity and a similar number of queries that do not require advanced knowledge of Δ. We also proved that, for adaptive randomized algorithms, $\Omega(\Delta^2)$ queries are necessary, and that such algorithms require $\Omega(\log n)$ queries even if the input graph is an n-vertex cycle. Furthermore, we showed that non-adaptive deterministic query algorithms require $\Omega(\Delta^3/\log^2(\Delta))$ queries, which renders our deterministic algorithm optimal up to poly-log factors.

While, up to lower order terms, the MIS query complexity of GR is settled for randomized algorithms and for non-adaptive deterministic algorithms, it is unclear whether there are adaptive deterministic algorithms that are stronger than non-adaptive deterministic algorithms. More concretely, is there an adaptive deterministic query algorithm that requires fewer than $O(\Delta^3 \log(\frac{n}{\Delta}))$ queries?

A Independent Set Queries for Graph Reconstruction

For completeness, we will now prove that the number of Independent Set queries (or, in fact, any type of query that yields a binary answer) needed for GR on graphs of maximum degree $\Delta \in \Omega(\log n)$ is $\Omega(n\Delta \log(\frac{n}{\Delta}))$.

Angluin and Chen [7] observe that, since an independent set query has a binary output, at least $\log|\mathcal{G}|$ queries are needed to distinguish any two graphs in a graph family $\mathcal{G}$.

We will now prove that the number of n-vertex graphs with maximum degree Δ is $2^{\Omega(n\Delta\log(n/\Delta))}$, which, by the previous argument, implies that $\Omega(n\Delta\log(n/\Delta))$ Independent Set queries are needed to distinguish these graphs.

Our proof uses entropy-based arguments. We refer the reader to [14] for an excellent overview of how entropy is connected to counting problems.

▶ **Lemma 15.** *The number of bipartite $2n$-vertex graphs with bipartitions A and B each of size n and with maximum degree $\Delta = \Omega(\log n)$ is at least:*

$$2^{\frac{1}{2}n\Delta\log(\frac{n}{\Delta})-2} .$$

Proof. We consider the following probabilistic process: Let $G = (A, B, E)$ be a bipartite $2n$-vertex graph with $|A| = |B| = n$ obtained by inserting every potential edge $ab \in A \times B$ into G with probability $\frac{\Delta}{2n}$. Denote by E the indicator random variable of the event that G does not contain a vertex of degree larger than Δ.

We will now bound the quantity $|\text{range}(G|E = 1)|$ from below, which constitutes a set of bipartite graphs with maximum degree Δ.

To this end, first, observe that:

$$\log(|\text{range}(X|E = 1)|) \geq H(X|E = 1) ,$$

which implies that it is enough to bound $H(X|E = 1)$. To bound this quantity, we apply the chain rule for entropy twice on the expression $H(XE)$:

$$H(XE) = H(X) + H(E|X) , \text{ and}$$
$$H(XE) = H(E) + H(X|E) = H(E) + \Pr[E = 0]H(X|E = 0) + \Pr[E = 1]H(X|E = 1) ,$$

which implies:

$$\begin{aligned} H(X|E=1) &= \frac{H(X)+H(E|X)-H(E)-\Pr[E=0]H(X|E=0)}{\Pr[E=1]} \\ &\geq H(X)+H(E|X)-H(E)-\Pr[E=0]H(X|E=0) \\ &\geq H(X)-1-\Pr[E=0]H(X|E=0)\ , \end{aligned} \tag{3}$$

using the fact that entropy is non-negative, and that the inequality $H(E|X) \leq H(E) \leq 1$ holds.

Before bounding Inequality 3 further, we first prove that $\Pr[E=0]$ is small and we give a bound on $H(X)$.

To see that $\Pr[E=0]$ is small, consider any vertex $v \in A \cup B$. Then, the expected degree of v in G is $\Delta/2$, and, by a Chernoff bound, the probability that the degree of v is larger than Δ is at most $\frac{1}{2 \cdot n^4}$ (using the assumption that $\Delta = \Omega(\log n)$). By the union bound, the probability that there exists a vertex of degree larger than Δ is thus at most $\frac{1}{n^3}$, or, equivalently, $\Pr[E=0] \leq \frac{1}{n^3}$.

Next, we bound $H(X)$. Since each of the n^2 potential edges is included in G independently of all other edges, we obtain:

$$\begin{aligned} H(X) &= n^2 \cdot H_2(\frac{\Delta}{2n}) \\ &\geq n^2 \log(\frac{2n}{\Delta})\frac{\Delta}{2n} \geq \frac{1}{2} n\Delta \log(\frac{n}{\Delta})\ , \end{aligned}$$

where we bounded the binary entropy function by considering only one of its the two terms.

We are now ready to further simplify Inequality 3, which then yields the result:

$$\begin{aligned} H(X|E=1) &\geq H(X)-1-\Pr[E=0]H(X|E=0) \\ &\geq \frac{1}{2} n\Delta \log(\frac{n}{\Delta}) - 1 - \frac{1}{n^3} \cdot \log(\text{range}(X|E=0)) \\ &\geq \frac{1}{2} n\Delta \log(\frac{n}{\Delta}) - 1 - \frac{1}{n^3} \cdot n^2 \\ &\geq \frac{1}{2} n\Delta \log(\frac{n}{\Delta}) - 1 - \frac{1}{n} \\ &\geq \frac{1}{2} n\Delta \log(\frac{n}{\Delta}) - 2\ . \end{aligned}$$

◀

▶ **Corollary 16.** *The number of Independent Set queries needed for GR on n-vertex graphs of maximum degree $\Delta = \Omega(\log n)$ is $\Omega(n\Delta \log(\frac{n}{\Delta}))$.*

Error-Correcting Graph Codes

Abstract

In this paper, we construct *Error-Correcting Graph Codes*. An error-correcting graph code of distance δ is a family C of graphs, on a common vertex set of size n, such that if we start with any graph in C, we would have to modify the neighborhoods of at least δn vertices in order to obtain some other graph in C. This is a natural graph generalization of the standard Hamming distance error-correcting codes for binary strings.

Yohananov and Yaakobi were the first to construct codes in this metric. We extend their work by showing

1. Combinatorial results determining the optimal rate vs distance trade-off nonconstructively.
2. Graph code analogues of Reed-Solomon codes and code concatenation, leading to positive distance codes for all rates and positive rate codes for all distances.
3. Graph code analogues of dual-BCH codes, yielding large codes with distance $\delta = 1 - o(1)$. This gives an explicit "graph code of Ramsey graphs".

Several recent works, starting with the paper of Alon, Gujgiczer, Körner, Milojević, and Simonyi, have studied more general graph codes; where the symmetric difference between any two graphs in the code is required to have some desired property. Error-correcting graph codes are a particularly interesting instantiation of this concept.

1 Introduction

In this paper, we studi *Error-Correcting Graph Codes*. These are large families of undirected graphs on the same vertex set such that any two graphs in the family are "far apart" in a natural graph distance. Informally, the graph distance between two graphs on the same vertex set of size n measures the minimum number of vertices one needs to delete to make the resulting graphs identical (not just isomorphic). This can also be thought of as (1) the number of vertices whose neighborhoods one has to modify to go from one graph to another, (2) the vertex cover number of the symmetric difference of the two graphs, or (3) n minus the largest independent set in the symmetric difference of the two graphs.

Definition (Graph Distance). Given two graphs G and H on vertex set $[n]$, the graph distance $\mathrm{d}_{\mathrm{graph}}(G, H)$ is the size of the smallest set $S \subseteq [n]$ such that $G[\overline{S}] = H[\overline{S}]$.

This is a very natural metric and encompasses deep information about graphs. For example, note the following two simple facts (1) the graph distance of a graph from the empty graph is n minus the independence number of the graph. (2) the graph distance of a graph from the complete graph is n minus the clique number of the graph. Thus the answer to the question: "how far can a graph be from both the empty graph and the complete graph?" is precisely the question of finding the right bound for the diagonal Ramsey numbers; the answer is $n - O(\log n)$.

Additionally, the notion of graph distance arises in the definition of node differential privacy (see for example [5, 8, 11, 9]). One instantiation of this setting is a graph encoding a social network where vertices correspond to people and edges correspond to social connections. The goal for node differential privacy is to design an algorithm $\mathcal{A}$ that approximately computes certain statistics of the graph (such as counting edges, triangles, and connected components) while maintaining each individual's privacy. Here, privacy is ensured by requiring that the output distribution on a certain graph does not change by much with any one vertex is deleted. In other words, for any graphs G, H of graph distance 1, the output distribution of $\mathcal{A}$ on the G and H should be similar. Graph distances of greater than 1 are then considered in the continual release model where the graph varies over time as studied in [9].

Codes in the graph-distance metric were initially studied by Yohananov, Efron, and Yaakobi [19, 18], who gave several optimal and near-optimal constructions in a variety of parameters. Their setting allows for arbitrary symbols $\alpha \in_q$ to be written on the edges, and the graph is allowed to have self-loops. We provide several new constructions for the binary setting, and the graph is not allowed to have self-loops. We show that random codes are asymptotically optimal codes in this metric and so focus our attention on explicit constructions.

Error-correcting graph codes also fall into the general framework of graph codes defined by Alon, Gujgiczer, Körner, Milojević, and Simonyi [3], where for a fixed family $\mathcal{F}$ of graphs, one seeks a large code C of graphs on the same n-vertex set such that the symmetric difference of any two graphs in C does not lie in $\mathcal{F}$. This class of problems was studied for a wide variety of natural $\mathcal{F}$ in a number of recent works [3, 2, 1]. As discussed in [2], for a suitable choice of $\mathcal{F}$, graph codes become equivalent to classical Hamming distance codes.

Finally, we note that error-correcting codes are pseudorandom objects, and the connection to Ramsey graphs suggests that error-correcting graph codes might be closely related to pseudorandom graphs. Thus, the problem of studying and explicitly constructing a pseudorandom family of pseudorandom graphs is interesting in its own right.

1.1 Related work

Similar to the Hamming setting, we briefly define the dimension, rate, and distance of a graph code C on n vertices where each edge is allowed to have an arbitrary symbol $\alpha \in \mathbb{F}_q$ written on it.

- **Dimension.** $k = \log_q(|C|)$.
- **Rate.** $R = \log_q(|C|)/\binom{n}{2}$.
- **Distance.** The distance of a code is the largest d such that $\mathrm{d}_{\mathrm{graph}}(G, H) \geq d$ for each $G, H \in C$ such that $G \neq H$. The relative distance δ is d/n.

Unless specified otherwise , we will always be interested in asymptotics of the above parameters as $n \to \infty$.

As noted in [19], an argument similar to the Singleton bound states that for a graph code of dimension k, and distance d, we have

$$k \leq \binom{n-d+1}{2}. \tag{1}$$

In terms of and rate R, and relative distance δ, we have

$$R \leq (1-\delta)^2 + o(1). \tag{2}$$

A code is called optimal if it $R \sim (1-\delta)^2$, equivalently, $\delta \sim 1 - \sqrt{R}$.

The relevant constructions in [19], [18] are summarized in Table 1. Note that all of the constructions in Table 1 are for undirected graphs where self-loops are allowed. One can impose n linear constraints to get codes with no self-loops (zeros on the diagonals of the adjacency matrix). Since the block length of these codes is $\binom{n}{2}$, adding these these constraints changes the rate by $o(1)$.

Table 1 Summary of constructions in [19], and [18].

Name	δ	Field	Tradeoff
[19] (Construction 1)	$= 2/n$	$_2$	Optimal
[19] (Construction 3)	≤ 1	$_q, q \geq n-1$	Optimal
[19] (Construction 5)	$\leq 1/2$	$_2$	$R = 1 - 2\delta$
[18] (Construction 1)	$= 3/n$	$_2$	Optimal
[18] (Construction 2)	$= 4/n$	$_2$	Optimal

Construction 5 of [19] leverages a connection to symmetric array codes and construction by Schmidt [15]. The trade-off achieved, $R \sim 1 - 2\delta$ is close to optimal for δ very small.

Construction 3 of [19] translates Hamming distance into graph distance using the tensor product. Although this construction doesn't directly imply anything about binary codes due to the requirement on field size, a similar code will be an important ingredient in our constructions.

1.2 Results

Our main results are:

1. We show that there are optimal binary codes for any constant $\delta \in (0,1)$.
2. We give constructions of graph codes that have positive constant R for all constant $\delta < 1$. In particular, we give a quasi-polynomial time explicit construction achieving $\delta = 1 - O(R^{1/4})$, while optimal codes have $\delta = 1 - R^{1/2}$. We also give an explicit construction with $\delta = 1 - O(R^{1/6})$, and a strongly explicit construction with $\delta = 1 - O(R^{1/8})$. Although these codes are not optimal, they are the first binary error-correcting graph codes achieving $\delta > 1/2$ with a constant rate.
3. We give (strongly) explicit constructions of graph codes with very high $\delta = 1 - O(n^{-\epsilon})$ and $R = \Omega(n^{\epsilon - 1/2})$ for constant $\epsilon > 0$. This gives a "graph code of Ramsey graphs" as will be discussed later.

Independent work

Pat Devlin and Cole Franks [6] independently proposed the study of graph error-correcting codes under this metric, determined the optimal R vs δ tradeoff, and gave some weaker explicit constructions of graph codes that worked for certain ranges of R and δ.

1.3 Techniques

We now discuss our techniques. We will often specify graphs by their adjacency matrices, viewed as matrices with $_2$ entries.

Our nonconstructive existence result is a straightforward application of the probabilistic method. We consider a uniformly random $_2$-linear subspace of the $_2$-linear space of symmetric 0-diagonal $n \times n$ matrices (i.e., the space of all adjacency matrices of graphs); this turns out to give a good graph code with optimal R vs δ tradeoff. Such graph codes can be specified by an $_2$ basis for it. We say that a construction is *explicit* if this basis can be produced in poly(n) time. We say it is *strongly explicit* if, given (i, j, k), the (i, j) entry of the k'th basis element can be computed in poly$(\log(n))$ time.

To get asymptotically good codes for any constant $\delta \in (0, 1)$ we take a longer detour.

1. We start with a slight variation of [19] (Construction 3), which gives a way to get a good graph code from a classical Hamming-distance linear code $C \subseteq_2^n$. We first consider the tensor code $C \otimes C$, where the elements are matrices all of whose rows and columns are codewords of C. A-priori, C could contain matrices that are neither symmetric, not have a 0 diagonal. But interestingly, if we consider the set C^* of all matrices in $C \otimes C$ that are symmetric and have 0 diagonal, then C^* is a linear space with quite large dimension. In particular, if the classical Hamming distance code C has positive rate, then so does the graph code C^*. We call this construction $C^* = \text{STCZD}(C)$ (Symmetric Tensor Code with Zero Diagonals).
   It turns out that if C has good relative distance (in the Hamming metric), then STCZD(C) has good distance in the graph metric. However the relative graph distance of STCZD(C) such a code is bounded by the relative distance of C – and since C is a binary code, this is at most $1/2$.
2. Now, we bring in another idea from the Hamming code world: code concatenation. Instead of constructing a graph code of symmetric zero-diagonal matrices over $_2$, we instead construct a "large-alphabet graph code" of symmetric zero-diagonal matrices over $_q$ for some large $q = 2^t$ and then try to reduce the alphabet size down to 2 by replacing the q-ary symbols with $_2$-matrices with suitable properties.
   Applying the analog of STCZD to a large alphabet code allows one to get large-alphabet graph codes with large δ, approaching 1 (since over large alphabets Hamming distance codes can have length approaching 1). Using Reed-Solomon codes as these large alphabet codes also allows us to make the STCZD construction strongly explicit. Furthermore, when applied to Reed-Solomon codes, these codes have a natural direct description: these are the evaluation tables of low-degree bivariate polynomials $P(X, Y)$ on product sets $S \times S$ that are (1) symmetric (to get a symmetric matrix), and (2) multiples of $(X - Y)^2$ (to get zero diagonal).
3. What remains now is to develop the right kind of concatenation so that the resulting graph code has good distance. This turns out to be subtle and requires an "inner code" with a stronger "directed graph distance" property with δ nearly 1. Fortunately, this inner code we seek is of very slowly growing size, and we may find this by brute force search. This concludes our description of our explicit construction of graph codes with δ approaching 1 and positive constant R.

Finally, we discuss our constructions for very high distances, $\delta = 1 - o(1)$. In this regime, as mentioned earlier, this is related to constructions of Ramsey graphs, a difficult problem in pseudorandomness with a long history. Our constructions work up to $\delta = 1 - \Omega\left(\frac{1}{\sqrt{n}}\right)$; concretely, we get a large linear space of graphs such that all graphs in the family have no

clique or independent set of size $\Omega(\sqrt{n})$. The construction is based on polynomials over finite fields of characteristic 2: When $n = 2^t$, we consider a linear space of certain low degree univariate polynomials $f(X)$ over $_{2^t}$, and create the $_2$ matrix with rows and columns indexed by $_{2^t}$ whose x, y entry is $\mathsf{Tr}(f(x+y))$. Here Tr is the finite field trace map from $_{2^t}$ to $_2$. The use of Tr of polynomials is inspired by the construction of dual-BCH codes. We then show that any such matrix has no large clique or independent set unless $\mathsf{Tr} \circ f$ is identically 0 or identically 1 (corresponding to the empty and complete graphs respectively). The proof uses the Weil bounds on character sums and a Fourier analytic approach to bound the independence number for the graphs. Our constructions are listed in Table 2.

Table 2 A list of constructions of error-correcting graph codes in this paper. All except Concatenated RS Tensor Codes are explicit. Note that the last four constructions are interesting in the regime where δ is close to 1.

Name	Approximate Tradeoffs	Strongly Explicit?
Random Linear Codes (Proposition 4)	$R = (1-\delta)^2 - o(1)$	No
Concatenated RS Tensor Codes (Code 19)	$R = (1-\sqrt{\delta})^4 - o(1)$	No
Double Concatenated RS Tensor Codes	$R = (1-\delta^{1/3})^6 - o(1)$	No
Triple Concatenated RS Tensor Codes (Code 22)	$R = (1-\delta^{1/4})^8 - o(1)$	Yes
Dual BCH Codes (Code 28)	$R = \log(n)(1-\delta)/\sqrt{n}$	Yes

1.4 Concluding thoughts and questions

The most interesting question in this context is to obtain explicit constructions of graph codes with optimal R vs δ tradeoff. While we have several constructions achieving nontrivial parameters in various regimes, it would even be interesting to get the right asymptotic behavior for the endpoints with δ approaching 1. The setting of large δ (including $\delta = 1 - o(1)$) seems especially challenging, given the connection with the notorious problem of constructing Ramsey graphs.

Another interesting question is to get decoding algorithms for graph codes. For a certain graph code C, if we are given a graph that is promised to be close in graph distance to some graph G in C. Then, can we efficiently find G?

A more general context relevant to error-correcting graph codes is the error correction of strings under more general error patterns. Suppose we have a collection of subsets $S_i \subseteq [m]$ for $i \in [t]$, where $\bigcup_i S_i = [m]$. These S_i denote the corruption zones; a single "corruption" of a string $z \in \{0,1\}^m$ entails, for some $i \in [t]$, changing $z|_{S_i}$ to something arbitrary in $\{0,1\}^{S_i}$. We want to design a code $C \subseteq \{0,1\}^m$ such that starting at any $x \in C$ if we do fewer than d corruptions to x, we do not end up at any $y \in C$ with $y \neq x$. When the S_i are all of size b and form a partition of $[m]$ into $t = m/b$ parts, then such a code is exactly the same as a classical Hamming distance code an alphabet of size 2^b. Error-correcting graph codes give a first step into the challenging setting where the S_i all pairwise intersect - here we have $m = \binom{n}{2}$, $t = n$, the S_i (which correspond to all edges incident on a given vertex) all have size $n-1$, and every pair S_i and S_j intersect in exactly 1 element. It would be interesting to develop this theory – to both find the limits of what is achievable and to develop techniques for constructing codes against this error model.

Finally, there are many other themes from classical coding theory that could make sense to study in the context of graph codes and graph distance, including in the context of sublinear time algorithms. It would be interesting to explore this.

Organization of this paper

We set up basic notions in Section 2. We show the existence of optimal graph codes in Section 3. In Section 4 we construct asymptotically good codes. Finally, in Section 5, we show explicit constructions of graph codes with very high distance.

2 Graph codes: Basics

Definitions and notations

All graphs will be simple, undirected graphs on the vertex set $[n]$ unless otherwise noted. For any graph G, use A_G to denote the adjacency matrix of G, and view A_G as an element of the vector space $\binom{n}{2}_2$. For two graphs G, H, let $G\Delta H$ be the symmetric difference of the two graphs, i.e. $A_{G\Delta H} = A_G - A_H$. For a subset $S \subseteq [n]$, we use $G[S]$ to denote the subgraph of G induced by the vertex set S. If A is a $n \times n$ matrix and $S, T \subset [n]$, let $A_{S,T}$ be the sub-matrix indexed by S on the rows and T on the columns. For $x \in [0,1]$, we use $h_2(x) = -x\log_2 x - (1-x)\log_2(1-x)$ to denote the binary entropy function.

▶ **Definition 1** (Graph distance and relative graph distance).

- *The* graph distance *between two graphs G and H, denoted by $\mathrm{d}_{\mathrm{graph}}(G,H)$, is the smallest $d \in \mathbb{N}$ such that there is a set $S \subseteq [n]$, $|S| = d$, and $G[[n] \setminus S] = H[[n] \setminus S]$.*
- *The* relative graph distance*, or simply relative distance, between G and H is denoted by $\delta_{graph}(G,H)$, and is the quantity $\frac{\mathrm{d}_{\mathrm{graph}}(G,H)}{n}$.*

In the above definition, we require that the graphs $G[\overline{S}]$ and $H[\overline{S}]$ be identical and not just isomorphic. Lemma 2 describes several equivalent characterizations of graph distance.

▶ **Proposition 2** (Alternate characterizations of $\mathrm{d}_{\mathrm{graph}}$). *Suppose G and H are graphs on the same vertex set. Then*

1. *$\mathrm{d}_{\mathrm{graph}}(G,H)$ is the minimum vertex cover size of $G\Delta H$.*
2. *$\mathrm{d}_{\mathrm{graph}}(G,H)$ is the minimum number of vertices whose neighborhoods you need to edit to transform G into H*
3. *$\mathrm{d}_{\mathrm{graph}}(G,H)$ is the minimum number of vertices whose neighborhoods you need to edit to transform $G\Delta H$ into the empty graph.*

Note that $\mathrm{d}_{\mathrm{graph}}$ is a metric (see [19], Lemma 5).

▶ **Definition 3** (Graph code). *We say that a set $C \subseteq 2^{\binom{[n]}{2}}$ is a* graph code *on $[n]$ with distance d if for every pair of graph $G, H \in C$, we have that $\mathrm{d}_{\mathrm{graph}}(G,H) \geq d$.*

- *The* rate *of C, denoted by R_C, is the quantity $\frac{\log_2(|C|)}{\binom{n}{2}} \geq \frac{2\log_2(|C|)}{n^2}$.*
- *The* distance *(resp.* relative distance*) of C, denoted by d_C (resp. δ_C), is the quantity $\min_{\substack{G,H\in C\\ G\neq H}} \mathrm{d}_{\mathrm{graph}}(G,H)$ (resp. $\min_{\substack{G,H\in C\\ G\neq H}} \delta_{graph}(G,H)$).*

Upper bound

As noted in [19], the Singleton bound can be used to obtain an upper bound on the rate of a graph code. We include a proof here for completeness.

▶ **Proposition 4.** *Any graph code with relative distance δ has dimension at most $\binom{n(1-\delta)+1}{2}_2$.*

Proof. Consider any graph code C of relative distance δ. Let $A \subset [n]$ be any subset of at most $\delta n - 1$ vertices. For any two distinct $G_1, G_2 \in C$, we have that the graphs induced on the vertices outside A, $G_1[[n] \setminus A]$ and $G_2[[n] \setminus A]$, are different. Indeed, since otherwise, A is a vertex cover of $G_1 \Delta G_2$, contradicting the relative distance assumption. So, we have that

$$|C| \leq 2^{\binom{n(1-\delta)+1}{2}}.$$ ◀

Expressed in terms of rate and distance, Proposition 4 implies that for constant relative distance δ, $R \leq (1-\delta)^2 + O(1/n)$.

3 Existence of optimal graph codes

As with other objects in the theory of error-correcting codes, the first question we seek to answer relates to the optimal rate-distance tradeoff.

In contrast to the Hamming world, we find that, in the graph distance, random linear codes meet the Singleton bound.

▶ **Proposition 5.** *Let $\delta \in (0,1)$. Then, there exists a linear graph code with distance greater than δ and dimension at least*

$$\max\left\{\binom{n(1-\delta)}{2} - h_2(\delta)n - 2, 0\right\}.$$

Proof. We only consider the case when $\binom{n(1-\delta)}{2} - h_2(\delta)n - 2 > 0$, and prove this by a probabilistic construction. Let $\mathbf{G}_{n,1/2}$, be the Erdös-Rényi random graph distribution where the vertices are $[n]$, and each of the $\binom{n}{2}$ possible edges are selected independently with probability $1/2$. Let $k = \binom{n(1-\delta)}{2} - h_2(\delta)n - 2$, and let $G_1, ..., G_k$ be graphs chosen independently from $\mathbf{G}_{n,1/2}$. Consider the $\mathbb{F}_2$-linear space $C = \text{span}\{A_{G_1}, \ldots, A_{G_k}\}$. We wish to show that C has distance at least δn with high probability.

For $\vec{\alpha} \in \mathbb{F}_2^k$, let $H_{\vec{\alpha}}$ be the graph with the adjacency matrix $\sum_{i=1}^{k} \alpha_i A_{G_i}$. Recalling the definition of graph distance, we need that for any distinct $\vec{\alpha}, \vec{\beta} \in \mathbb{F}_2^k$, $H_{\vec{\alpha}} \Delta H_{\vec{\beta}}$ must have minimum vertex cover size at greater than δn. Since $H_{\vec{\alpha}} \Delta H_{\vec{\beta}} = H_{\vec{\alpha}-\vec{\beta}}$, it suffices to show that for any non-zero $\vec{\alpha} \in \mathbb{F}_2^k$, that $H_{\vec{\alpha}}$ has no vertex cover of size δn.

For any $\vec{\alpha} \in \mathbb{F}_2^k \setminus \{\vec{0}\}$, $H_{\vec{\alpha}}$ has the same law as $\mathbf{G}_{n,\frac{1}{2}}$. Let $B_{\vec{\alpha}}$ be the event that $H_{\vec{\alpha}}$ has a vertex cover of size δn. We have

$$\begin{aligned}
\Pr(B_{\vec{\alpha}}) &= \Pr\left(\exists S \in \binom{[n]}{\delta n} : G[[n] \setminus S] = \text{ is the empty graph}\right) \\
&\leq \binom{n}{\delta n} \cdot 2^{-\binom{n(1-\delta)}{2}} \\
&\leq 2^{-\binom{n(1-\delta)}{2} + h_2(\delta)n},
\end{aligned}$$

where the first inequality uses the union bound over subsets of size δn, and the fact that there are $\binom{n(1-\delta)}{2}$ edges outside of a vertex cover that all have to be unselected. Then, union bounding over the choices of $\vec{\alpha}$, we get

$$\Pr\left(\bigcup_{\alpha \in \mathbb{F}_2^k \setminus \{\vec{0}\}} B_{\vec{\alpha}}\right) \leq 2^{k - \binom{n(1-\delta)}{2} + h_2(\delta)n} \leq 1/4.$$

Therefore, with probability at least $3/4$, there does not exist $\alpha \in \mathbb{F}_2^k$, such that $\alpha \neq \vec{0}$, and H_α has a vertex cover of size δn, and hence C is a code with relative distance greater than δ.

Finally, note that if H_α does not have a vertex cover of size δn, then H_α is not the empty graph. Thus, the fact that there does not exist $\alpha \in_2^k$, $\alpha \neq \vec{0}$ such that H_α has a vertex cover of size δn implies that $G_1, ..., G_k$ are linearly independent. Hence, the dimension of C is $k = \binom{n(1-\delta)}{2} - h_2(\delta)n - 2$, as required. ◀

As a result, we have the following corollaries.

▶ **Corollary 6.** *For any constant $\delta \in (0, 1)$, there exist optimal linear graph codes with relative distance at least δ.*

▶ **Corollary 7.** *For any constant $c > 2$, there exists a linear graph code with dimension at least $\Omega(\log^2 n)$ and relative distance at least $\delta = 1 - c \cdot \frac{\log n}{n}$.*

4 Explicit graph codes for high distance: Concatenated Codes

To get explicit codes of distance $\delta > 1/2$, we start with Construction 3 of [19]. The construction utilizes the tensor product code introduced by [17], where elements of the code are matrices where all rows and columns are codewords over some base Hamming code. The elements of the tensor code are then the adjacency matrices of graphs. Since we consider undirected graphs and do not allow self-loops, we take the subcode of the tensor code containing only symmetric matrices with zeros on the diagonal.

▶ **Definition 8** (Symmetric Tensor Code with Zeros on the Diagonal)**.** *Let C be a code over $_q$. The symmetric tensor code with zeros on the diagonal built on C denoted* $\mathrm{STCZD}(C)$ *is the set of matrices A over $_q^{n\times n}$ such that (1) A is symmetric, (2) the rows and columns of A are codewords of C, and (3) the entries on the diagonal are all 0.*

Properties of elements of Tensor Product Codes that are symmetric and zero-diagonal were also previously studied, in the context of constructing a gap-preserving reduction from SAT to the Minimum Distance of a Code problem, by Austrin and Khot [4].

We will also define another notion of distance that will be useful later on.

▶ **Definition 9** (Directed graph distance)**.** *Let A, and B be $n \times n$ matrices over some field. Define the* directed graph distance *denoted* $\mathrm{d}_{\mathrm{directed}}(G, H)$ *to be the minimum d such that there exists sets $S, T \subset [n]$ of size d where $(A - B)_{\overline{S},\overline{T}} = \mathbf{0}$.*

For weighted, directed graphs, G, and H, abbreviate $\mathrm{d}_{\mathrm{directed}}(A_G, A_H) = \mathrm{d}_{\mathrm{directed}}(G, H)$. To better distinguish between $\mathrm{d}_{\mathrm{directed}}$ and $\mathrm{d}_{\mathrm{graph}}$, we sometimes refer to $\mathrm{d}_{\mathrm{graph}}$ as the *undirected* graph distance.

When G and H are weighted directed graphs, $\mathrm{d}_{\mathrm{directed}}(A_G, A_H)$ can be viewed as the minimum d such that you can go from G to H by editing the incoming edges of d vertices and the outgoing edges of d vertices. The main difference between directed and undirected graph distance is that directed graph distance allows the subset of rows and the subset of columns to be edited to be different. Insisting that $S = T$ in the definition for directed graph distance recovers the undirected graph distance. From this, it easily follows that if G and H are undirected graphs, then $\mathrm{d}_{\mathrm{directed}}(G, H) \leq \mathrm{d}_{\mathrm{graph}}(G, H)$. Thus, to find codes with high graph distance, it suffices to find codes with large directed graph distance, where all the elements are adjacency matrices of undirected, unweighted graphs (i.e., 0/1 matrices that are symmetric and zero diagonal). Note that when discussing rate directed graph codes C, we are referring to the quantity $\log_q(|C|)/n^2$ instead of $\log_q(|C|)/\binom{n}{2}$.

In the next lemma, we show several properties of $\mathrm{STCZD}(C)$. Most importantly, the Hamming distance of C translates to the directed graph distance of $\mathrm{STCZD}(C)$.

▶ **Lemma 10.** *Let C be a linear $[n,k,d]_q$-code, then* $\mathrm{STCZD}(C) \subset_q^{n\times n}$ *is linear, has dimension at least* $\binom{k+1}{2} - n$*, and has directed graph distance d.*

Proof. Let C be a linear $[n,k,d]_q$-code, and let $C' = \mathrm{STCZD}(C)$. C' is linear because C is linear, and the sum of symmetric matrices is symmetric.

WLOG, we assume that C is systematic, i.e., it has $k \times n$ generator matrix $G = [I|A]$, where I is the $k \times k$ identity and A is a $k \times (n-k)$ matrix. Then, for every $X \in_q^{k\times k}$, the following has rows and columns belonging to C

$$G^T X G = \begin{bmatrix} X & XA \\ A^T X & A^T XA \end{bmatrix}.$$

Furthermore, $G^T XG$ is symmetric and has zeros on the diagonal iff X is symmetric, X has zeros on the diagonal, and $A^T XA$ has zeros on the diagonal. This imposes $\binom{k+1}{2} + (n-k)$ linear constraints on the entries of X. Thus, the subspace of X for which $G^T XG \in C'$ has dimension at least $k^2 - \binom{k+1}{2} - (n-k) = \binom{k+1}{2} - n$.

Since C' is linear, to show the distance property, it suffices to show that $\mathrm{d}_{\mathrm{directed}}(A, \mathbf{0}) \geq d$ for every non-zero $A \in C'$. Let $A \in C'$ be a non-zero element of C', we'll show that for any $S, T \subset [n]$, with $|S| < d$, and $|T| < d$, $A_{\overline{S},\overline{T}} \neq \mathbf{0}$.

Since A is non-zero, there is some non-zero entry A_{ij}. Since the rows are elements of a linear code of distance d, the Hamming weight of the ith row is at least d. Since $|T| < d$, there is some $j' \notin T$ such that $A_{ij'}$ is non-zero. Then, the j'th column is also a non-zero codeword of C, so it also has Hamming weight at least d. Since $|S| < d$, there is some $i' \notin S$ such that $A_{i'j'}$ is non-zero. Thus, $A_{\overline{S},\overline{T}} \neq \mathbf{0}$. ◀

▶ Remark 11. A simple calculation shows that if C has constant rate, R, then $\mathrm{STCZD}(C)$ has rate $R^2/2 - o(1)$ as a directed graph code.

Given this lemma (and using the fact that $\mathrm{d}_{\mathrm{graph}} \geq \mathrm{d}_{\mathrm{directed}}$), for any **binary** code $C \subset_2^n$ with rate R and relative distance δ, $\mathrm{STCZD}(C)$ is a (undirected) graph code with rate $R^2 - o(1)$, and relative distance δ. Thus, if C has rate distance tradeoff $R = f(\delta)$, then $\mathrm{STCZD}(C)$ has rate distance tradeoff $R = f(\delta)^2 - o(1)$. Immediately, we get that taking the STCZD of any asymptotically good binary code yields an asymptotically good graph code.

There are two problems with this construction. Firstly, these codes may not be strongly explicit. Secondly, the Plotkin bound [13] implies that any binary code with distance $> 1/2$ has vanishing rate. So this falls short of our goal of obtaining strongly explicit, asymptotically good codes with $\delta > 1/2$.

We will address the first problem by showing that if the base code is a Reed Solomon code [14], then there is a large subcode that is strongly explicit.

▶ **Code 12** (Reed Solomon Code $\mathrm{RS}(n,R,q)$ [14])**.** *The Reed Solomon Code with parameters n, R, and q, where $q \geq n$, is a code over $\mathbb{F}_q^n$ with rate R and distance $1-R$.*

▶ **Lemma 13.** *Let $C \in \mathrm{RS}(n,R,q)$ where $Rn = k-1$. Then, there exists a* strongly explicit *subcode $S \subset \mathrm{STCZD}(C)$ such that the dimension of S is at least $\binom{k-1}{2}$.*

Proof. Essentially, we will evaluate symmetric polynomials that are a multiple of $(X-Y)^2$ on a $n \times n$ grid.

Suppose $h(X,Y)$ is a symmetric polynomial of individual degree at most $k-3$, and let M be the evaluations of $f(X,Y) = (X-Y)^2 h(X,Y)$ on a $n \times n$ grid. M is symmetric and has zeros on the diagonal. Furthermore, for a fixed value, y, $f(X,y)$ is a univariate polynomial

in X of degree at most $k-1$, and hence the column indexed by y is an element of a Reed Solomon code of dimension k, and block length n. Similarly, the rows are also elements of the same code. Thus $M \in \text{STCZD}$.

Let S be the space of bivariate symmetric polynomials of degree at most $k-3$. For $a, b \in \mathbb{N}$, define polynomials $p_{a,b}(X,Y) = X^aY^b + X^bY^a$. Notice that $p_{a,b}$ is symmetric, and furthermore the set

$$\{p_{a,b} : 0 \le a < b \le k-3\} \cup \{X^iY^i : i \in \{0,1,...,k-3\}\},$$

is linearly independent. Thus $\dim(S) = \binom{k-2}{2} + k - 2 = \binom{k-1}{2}$, as desired. ◀

To extend this construction to the setting of $\delta > 1/2$, we use the concatenation paradigm from standard error-correcting code theory, initially introduced by Forney [7].

We will start with a code over a large alphabet and then concatenate with an inner code, which will be an optimal directed graph code.

▶ **Lemma 14.** *For any $\epsilon > 0$, and sufficiently large n, for any $k < \epsilon^2 n^2 - 2n$, there exists a linear directed graph code over $_2$ of dimension k and distance at least $(1-\epsilon)n$.*

The proof is standard and similar to that of Proposition 5. So we will omit it.

▶ **Code 15** (Optimal Directed Graph Code $\text{Opt}(\epsilon, n, k)$)**.** *Require $k < \epsilon^2 n^2 - 2n$. Refer to a code with the properties in Lemma 14 as $\text{Opt}(\epsilon, n, k)$.*

4.1 Symmetric concatenation

Since our inner code is not guaranteed to be symmetric, simply replacing each field element in the outer code with its encoding might result in an asymmetric matrix. To remedy this, we transpose the encoding for entries below the diagonal. This is made formal below.

▶ **Definition 16** (Symmetric Concatenation)**.** *Let q, Q be prime powers, and n, N be positive integers. Let $C_{out} \subset_Q^{N\times N}$ and $C_{in} \subset_q^{n\times n}$ such that $|C_{in}| = Q$. Define $C_{in} \circ C_{out} \subset_q^{nN\times nN}$ to be the code obtained by taking codewords of C_{out} and replacing each symbol of the outer alphabet with by their encodings under C_{in} if they lie above or on the diagonal, and with the transpose of their encodings if they lie below the diagonal.*

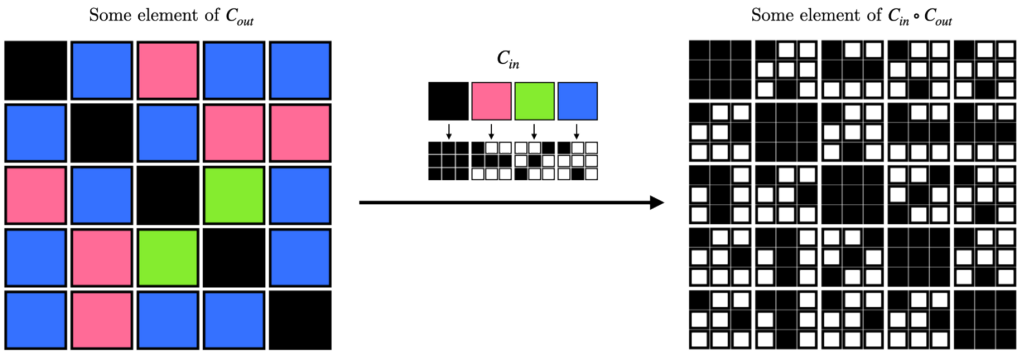

Figure 1 Example of symmetric concatenation. An outer codeword is shown on the left, with field elements represented as different colors. The concatenation with the inner code is shown to the right. Black squares represent 0, and white squares represent 1s.

Figure 1 visualizes an example of symmetric concatenation. We now show that distance and dimension concatenate exactly like it does for standard error-correcting codes.

▶ **Lemma 17.** *Suppose C_{in} and C_{out} are linear codes as in the previous definition with directed graph distance d and D, respectively. Let k be the dimension of C_{in}, and K be the dimension of C_{out}. Note $|C_{in}| = q^k = Q$. Then $C_{in} \circ C_{out}$ is linear and has distance at least dD, and dimension kK.*

Proof. Let $C = C_{in} \circ C_{out}$. First note that $C_{in} \circ C_{out}$ can be made linear by using a ${}_q$-linear map from ${}_{q^k}$ to ${}^k_q$ before encoding with the inner code.

Consider a non-zero outer codeword O, and let A be the codeword after concatenation. Let $S, T \subset [nN]$ be of size less than dD. We'll show that $A_{\overline{S},\overline{T}} \neq \mathbf{0}$. Partition A into $N \times N$ blocks, where the (I, J)'th block for $I, J \in [N]$, is the $n \times n$ matrix encoding the symbol at O_{IJ}. Identify the indices $[nN]$ with $[N] \times [n]$ where the tuple (I, i) corresponds to the i'th index in the I'th block.

For $I \in [N]$, let $S_I = \{i \in [n] : (I, i) \in S\}$ be the set rows in S in the I'th block. Define T_J similarly. Let $S_{\geq} = \{I \in [N] : |S_I| \geq d\}$, be the set of blocks in which there are at least d elements in S, and similarly define $T_{\geq}$, $S_{<}$, and $T_{<}$.

Since $\sum_{I \in [N]} |S_I| < dD$, $\sum_{J \in [N]} |T_J| < dD$, we have $|S_{\geq}| < D$, and $|T_{\geq}| < D$. Since the outer code has directed distance D, $O_{S_{<},T_{<}} \neq \mathbf{0}$, so there exists $I \in S_{<}$, and $J \in T_{<}$ such that $O_{I,J}$ is non-zero. So, the (I, J)'th block of A is a non-zero codeword or the transpose of a non-zero codeword of C_{in}. Let us call it X, and suppose that $X \in C_{in}$.

Since $|S_I| < d$, and $|T_J| < d$, and the inner code has distance at least d, we have that $X_{\overline{S_I},\overline{T_J}} \neq \mathbf{0}$. To finish the proof, note that $\mathrm{d}_{\mathrm{directed}}(X, \mathbf{0}) = \mathrm{d}_{\mathrm{directed}}(X^T, \mathbf{0})$ by switching the roles of S and T in the definition of directed graph distance.

For the claim about dimension, note that the number of codewords in C is the number of codewords in C_{out}, which is Q^K. The dimension of C is then $K \log_q(Q) = Kk$. ◀

Additionally, it is clear from the definition of symmetric concatenation that if C_{out} is symmetric and zero-diagonal, so is $C_{in} \circ C_{out}$.

▶ Remark 18. Lemma 17 also holds for the standard definition of concatenation (without transposing blocks below the diagonal). However, we will not need this fact.

4.2 Concatenated graph codes

We can instantiate the concatenated code using Reed Solomon codes.

▶ **Code 19** (Concatenated Code $C_{\mathrm{RS}}(\epsilon, n, k, N, \rho)$)**.** *Let $Q = 2^k$ be the size of the alphabet of the outer code. Let $\epsilon, \rho \in (0, 1)$, and n, k, N, to be integers satisfying $k < \epsilon^2 n^2 - 2n$, and $N \leq Q$. Then,*

$$C_{\mathrm{RS}} = \mathrm{Opt}(\epsilon, n, k) \circ \mathrm{STCZD}(\mathrm{RS}(N, \rho, Q)).$$

The following theorem follows directly from Lemmas 10 and 17. As a reminder, here we are considering the rate of the codes as a (undirected) graph code.

▶ **Theorem 20.** *Let ϵ, n, k, N, ρ be parameters satisfying the requirements listed in Code 19, then $C_{\mathrm{RS}}(\epsilon, n, k, N, \rho)$ is a graph code with rate $\epsilon^2\rho^2 - o(1)$, and relative distance $(1-\epsilon)(1-\rho)$.*

Note that using this construction, we can get asymptotically good codes for any constant rate and distance - including for distances $> 1/2$, which was not obtained in any of the previous constructions. We get $R = (1 - \sqrt{\delta})^4 - o(1)$ by setting $\epsilon = \rho$.

One drawback of this construction is that it is not strongly explicit or even explicit. The outer code can be made strongly explicit using Lemma 13, however, the inner code was an optimal code which we obtained by a randomized construction. The complexity of searching for such a code by brute force is too large. In particular, the optimal code has dimension $\epsilon^2 n^2$, and block length n^2. Since we need the size of the code to be equal to the size of the outer alphabet, we have $N = 2^{\epsilon^2 n^2}$, so $n = \sqrt{\log(N)}/\epsilon$. Then, there are at least $2^{\epsilon^2 n^4} = 2^{\log(N)^2/\epsilon^2}$ generator matrices to search over. Thus, we cannot find such a code efficiently.

To address this, we reduce the search space by concatenating *multiple times*. The resulting code will have a slightly worse distance/rate tradeoff but will still be asymptotically good for any constant distance or rate.

We also note that C_{RS} can also be made strongly explicit using a Justensen-like construction. However, although this code is again asymptotically good, it has distance bounded away from 1. We present this construction in the Appendix.

4.3 Multiple concatenation

While concatenating twice suffices to obtain an explicit code, it is not clear that the obtained code is strongly explicit. This may be addressed by concatenating three times, at the cost of slightly weaker parameters. Here, we will also use the tensor product code as a building block. For any linear code $C \subset_q^n$ let $\mathrm{TC}(C)$ be the tensor product code of C. As a reminder, $\mathrm{TC}(C)$ is the code consisting of matrices $A \in_q^{n \times n}$ such that each row and each column of A are elements of C.

▶ Remark 21. Suppose C is a linear code with distance d and rate R. Then, it follows from the proof of Lemma 10 that $\mathrm{TC}(C)$ has directed graph distance at least d. It is also well known that $\mathrm{TC}(C)$ has rate R^2.

Below we present the analysis for triple concatenation.

▶ **Code 22** (Triple Concatenation $\mathrm{C}_{\mathrm{Trip}}(\rho, N)$)**.** *For $\rho \in (0,1)$ and an integer N, let C be the subcode of $\mathrm{STCZD}(\mathrm{RS}(N, \rho, N))$ in Lemma 13. Then*

$$\mathrm{C}_{\mathrm{Trip}} = \mathrm{Opt}(N_3, \rho) \circ \mathrm{TC}(\mathrm{RS}(N_2, \rho, N_2)) \circ \mathrm{TC}(\mathrm{RS}(N_1, \rho, N_1)) \circ C,$$

where N_1, N_2 and N_3 are picked to make the concatenation work, i.e., $|\mathrm{Opt}(N_3, \rho)| \geq N_2$, and so on.

Notice that only the outer-most code needs to be symmetric and have zero diagonal since we use the symmetric concatenation operation (entries below the diagonal will be transposed). Thus, using the Tensor Product Code for the two middle codes (instead of STCZD) is sufficient and saves a factor of 2 (each time) on the rate.

▶ **Theorem 23.** *Let N be a positive integer and $\rho \in (0,1)$. Then $\mathrm{C}_{\mathrm{Trip}}(\rho, N)$ has distance at least $(1-\rho)^4$, and rate ρ^8. Furthermore, $\mathrm{C}_{\mathrm{Trip}}(\rho, N)$ is strongly explicit.*

Proof. The claims about rate and distance follow directly from Lemma 17.

We'll now show that this code is strongly explicit. The outermost code C is strongly explicit, and the two codes in the middle built on Reed Solomon codes are also strongly explicit. The idea is that the concatenation steps middle allow us to shrink the alphabet size from N to (less than) $\log(\log(N))$. Searching for optimal codes of this size can be done easily by brute force.

The dimension of $\mathrm{TC}(\mathrm{RS}(N_1, \rho, N_1))$ is $(\rho N_1)^2$, so the number of codewords is $N_1^{(\rho_1 N_1)^2}$, and for the concatenation to work, we need this to be at least N. That is, we need $(\rho_1 N_1)^2 \log(N_1) \geq \log(N)$, which we can get easily by setting $N_1 = O(\log(N))$. For the same reason, we can take $N_2 = O(\log\log(N))$.

This is now small enough to do a brute-force search for an optimal code. The inner-most code has dimension $\rho^2 N_3^2$, so we need $2^{\rho^2 N_3^2} = N_2$, or $N_3 = O(\sqrt{\log(N_2)})$. There are then $\rho^2 N_3^4$ possible generator matrices to search over. So the total number of codes we will need to search over is at most $2^{\rho^2 n^4} = 2^{O(\log\log\log(N)^2)} = 2^{o(\log\log(N))} = O(\log(N))$. ◀

The tradeoff for this code is then

$$R = (1 - \delta^{1/4})^8.$$

Thus, we get *strongly explicit* asymptotically good codes for any constant distance or rate.

If we just wanted explicit codes (instead of strongly explicit), concatenating twice would suffice. In particular, the search space for the inner-most code has size

$$2^{O(\log\log(N)^2)} = 2^{o(\log(N))},$$

which is smaller than any polynomial in N, but not polylogarithmic. The corresponding tradeoff for the double concatenated code is $R = (1 - \delta^{1/3})^6$.

5 Explicit graph codes with very high distance: dual-BCH Codes

In this section, we give explicit constructions of graph codes for the setting of very high distance ($\delta = 1 - o(1)$). As noted earlier, when the complete graph and the empty graph are part of the code, this is a generalization of the problem of constructing explicit Ramsey graphs (i.e., graphs with no large clique or independent set), which corresponds to graph codes of size at least 3.

Our main result here is an explicit construction of a graph code with distance $1 - \frac{n^\epsilon}{n^{1/2}}$ and dimension $\Omega(n^\epsilon \log n)$, for all $\epsilon \in [0, 1/2)$.

▶ **Theorem 24.** *For all d, there is a strongly explicit construction construction of a code with dimension $\Omega(d \log n)$ and distance $n - O(d\sqrt{n})$.*

In analogy with the situation for Hamming-distance codes, these are the dual-BCH codes of the graph-distance world.

5.1 Warmup: a graph code with dimension $\Omega(\log n)$

As a warmup, we first construct code with distance $1 - \frac{1}{n^\epsilon}$ with growing dimension.

Let $n = 2^t$. Let $\mathsf{Tr} :_{2^t} \to_2$ denote the finite field trace map. Concretely, it is given by:

$$\mathsf{Tr}(x) = x + x^2 + x^4 + \ldots + x^{2^i} + \ldots + x^{2^{t-1}}$$

For each $\alpha \in_{2^t}$, consider the matrix $M_\alpha \in_2^{n \times n}$, where the rows and columns of M_α are indexed by elements of $_{2^t}$, given by:

$$(M_\alpha)_{x,y} = \mathsf{Tr}(\alpha \cdot (x + y)^3).$$

Note that each M_α is symmetric. Consider the code

▶ **Code 25.** *For n of the form 2^t, let us define the family of codes*

$$C_{\text{Warmup}} = \{M_\alpha \mid \alpha \in_{2^t}\}.$$

We have that C_{Warmup} is a linear code of dimension $t = \log_2 n$.

▶ **Theorem 26.** *The distance of C_{Warmup} is at least $1 - O(n^{-1/2})$.*

Proof. Fix any $\alpha \in \mathbb{F}_{2^t}$. Let $S \subseteq_{2^t}$ be an arbitrary subset of vertices. It suffices to show that if S is bigger than $\Omega(n^{1/2}) = \Omega(2^{t/2})$, then there exist some $x, y \in S$ such that

$$\mathsf{Tr}(\alpha \cdot (x+y)^3) = 1.$$

Suppose not. Then we have:

$$\sum_{x,y \in S} (-1)^{\mathsf{Tr}(\alpha(x+y)^3)} = |S|^2.$$

By Cauchy-Schwarz, we get:

$$\begin{aligned}
|S|^4 &= \left(\sum_{x\in S}\sum_{y\in S}(-1)^{\mathsf{Tr}(\alpha(x+y)^3)}\right)^2 \\
&\le \left(\sum_{x\in S}\left(\sum_{y\in S}(-1)^{\mathsf{Tr}(\alpha(x+y)^3)}\right)^2\right)\cdot|S| \\
&\le \left(\sum_{x\in_{2^t}}\left(\sum_{y\in S}(-1)^{\mathsf{Tr}(\alpha(x+y)^3)}\right)^2\right)\cdot|S| \\
&= \left(\sum_{x\in_{2^t}}\sum_{y_1,y_2\in S}(-1)^{\mathsf{Tr}(\alpha((x+y_1)^3+(x+y_2)^3))}\right)\cdot|S| \\
&\le \left(\sum_{y_1,y_2}\left|\sum_{x\in_{2^t}}(-1)^{\mathsf{Tr}(\alpha((x+y_1)^3+(x+y_2)^3))}\right|\right)\cdot|S|.
\end{aligned}$$

For $y_1, y_2 \in_{2^t}$, let $P_{y_1,y_2}(X)$ be the polynomial

$$\begin{aligned}
P_{y_1,y_2}(X) &= \alpha\cdot\left((X+y_1)^3 + (X+y_2)^3\right) \\
&= \alpha\cdot\left((y_1+y_2)X^2 + (y_1^2+y_2^2)X + (y_1^3+y_2^3)\right).
\end{aligned}$$

The key observation is that for most $(y_1, y_2) \in S^2$, the trace of the polynomial $P_{y_1,y_2}(X)$ is a nonconstant ${}_2$-linear function, and thus the inner sum:

$$\sum_{x\in_{2^t}}(-1)^{\mathsf{Tr}(P_{y_1,y_2}(x))}$$

equals 0.

▶ **Lemma 27.** *If $P(X) = aX^2 + bX + c \in_{2^t} [X]$, then*

$$\mathsf{Tr}\circ P :_{2^t}\to_2$$

is a nonconstant ${}_2$-linear function unless $a = b^2$.

The proof is standard, and we omit it.

By the lemma, we get that there are at most $4|S|$ choices of (y_1, y_2) such that the inner sum is non-zero (namely those $(y_1, y_2) \in S^2$ for which $\alpha(y_1 + y_2) = \left(\alpha(y_1^2 + y_2^2)\right)^2$, which are few in number by the Schwartz-Zippel lemma).

Thus we get:

$$|S|^4 \leq 4|S|^2 \cdot 2^t,$$

from which we get $|S| \leq O(2^{t/2})$, as desired. ◀

5.2 Larger dimension

We now see how to get graph codes of distance $1 - \frac{1}{n^\epsilon}$ with $\epsilon < \frac{1}{2}$ and larger rate.

For a polynomial $f(X) \in_{2^t} [X]$, let M_f be $n \times n$ matrix with rows and columns indexed by $_{2^t}$ for which:

$$(M_f)_{x,y} = \mathsf{Tr}(f(x + y)).$$

Let W_d be the $_{2^t}$-linear space of all polynomials $f(X)$ of the form:

$$f(X) = \sum_{3 \leq 2i+1 \leq d} \alpha_i X^{2i+1},$$

where the $\alpha_i \in_{2^t}$.

Then, let us define our construction.

▶ **Code 28.** *For n of the form 2^t and $d \leq n^{1/2}$, let us define the family of codes*

$$C_{\text{DualBCH}}(n, d) = \{M_f : f \in W_d\}.$$

▶ **Theorem 29.** *We have that $C_{\text{DualBCH}}(n, d)$ is a linear graph code of distance $1 - O\left(dn^{-1/2}\right)$ and dimension $\Omega(dt) = \Omega(d \log n)$.*

Proof. The proof is very similar to the proof of Theorem 26. Consider any $M_f \in C_{\text{DualBCH}}(n, d)$ with $f \neq 0$. It suffices to show that the independence number[2] of M_f is $O(dn^{1/2})$.

Assume that $S \subseteq_{2^t}$ is an independent set in M_f. Then

$$|S|^2 = \sum_{x,y \in S} (-1)^{\mathsf{Tr}(f(x+y))}. \tag{3}$$

As in the proof of Theorem 26, by the Cauchy-Schwartz inequality and some simple manipulations, we get:

$$|S|^4 \leq \left(\sum_{y_1, y_2 \in S} \left| \sum_{x \in_{2^t}} (-1)^{\mathsf{Tr}(P_{y_1,y_2}(x))} \right| \right) \cdot |S|, \tag{4}$$

where:

$$P_{y_1,y_2}(X) = f(X + y_1) - f(X + y_2).$$

[2] An essentially identical proof shows that the clique number also has the same bound. The only change is to replace the LHS of (3) by $-(|S|^2 - |S|)$, and this sign change does not affect anything later because we immediately apply Cauchy-Schwarz to get (4).
This justifies our referring to this code as a "code of Ramsey graphs".

At this point, we need an upper bound in the inner sum:

$$U_{y_1,y_2} = \left| \sum_{x \in_{2^t}} (-1)^{\mathsf{Tr}(P_{y_1,y_2}(x))} \right|.$$

To get this, we will invoke the deep and powerful Weil bound:

▶ **Theorem 30** ([16], Chapter II, Theorem 2E)**.** *Suppose $P(X) \in_{2^t} (X)$ is a nonzero polynomial of odd degree with degree at most d. Then:*

$$\left| \sum_{x \in_{2^t}} (-1)^{\mathsf{Tr}(P(x))} \right| \leq O(d2^{t/2}).$$

We will use this to show that all but a few pairs $(y_1, y_2) \in S^2$, U_{y_1,y_2} are small.

▶ **Lemma 31.** *For all but $d|S|$ pairs $(y_1, y_2) \in S^2$,*

$$U_{y_1,y_2} \leq O(d2^{t/2}).$$

is at most $d|S|$.

Assuming this for the moment, we can proceed with Equation (4):

$$\begin{aligned} |S|^4 &\leq \left(d|S| \cdot 2^t + |S|^2 \cdot O(d \cdot 2^{t/2}) \right) \cdot |S| \\ &= d|S|^2 2^t + O(d|S|^3 2^{t/2}). \end{aligned}$$

Thus:

$$|S|^2 \leq d2^t + O(d|S|2^{t/2}),$$

which implies that $|S| \leq O\left(d \cdot 2^{t/2}\right)$, as desired. ◀

Proof of Lemma 31

Proof. Theorem 30 only applies to polynomials with odd degree. We first recall a standard trick involving the Tr map to deduce consequences for arbitrary degree polynomials.

Note that $\mathsf{Tr}(a^2) = \mathsf{Tr}(a)$ for all $a \in_{2^t}$, and that every element of $_{2^t}$ has a square root. Thus for any positive degree monomial $M(X) = \alpha X^i$, where $i = j \cdot 2^k$ with j odd, the equality:

$$\mathsf{Tr}(M(x)) = \mathsf{Tr}(\widetilde{M}(x))$$

for each $x \in_{2^t}$, where $\widetilde{M}(X)$ is the odd degree monomial given by:

$$\widetilde{M}(X) = \alpha^{1/2^k} X^j.$$

Extending by linearity, this allows us to associate, to every polynomial $P(X) \in_{2^t} [X]$, a polynomial $\widetilde{P}(X)$ with

$$\mathsf{Tr}(P(x)) = \mathsf{Tr}(\widetilde{P}(x))$$

for all $x \in_{2^t}$, and where every monomial of $\widetilde{P}(X)$ (except possibly the constant term) has odd degree.

The key observation is that whenever $\widetilde{P}_{y_1,y_2}(X)$ is nonconstant, it has odd degree, and so we can apply the Weil bound. In this case, since:

$$\mathsf{Tr}(P_{y_1,y_2}(x)) = \mathsf{Tr}(\widetilde{P}_{y_1,y_2}(x))$$

for each $x \in_{2^t}$, we get:

$$U_{y_1,y_2} = \left| \sum_{x \in_{2^t}} (-1)^{\mathsf{Tr}(\widetilde{P}_{y_1,y_2}(x))} \right| \tag{5}$$

$$\leq O(d \cdot 2^{t/2}), \tag{6}$$

where the last step follows from the Weil bound (Theorem 30).

Thus we simply need to show that there are at most $d|S|$ pairs $(y_1, y_2) \in S^2$ for which $\widetilde{P}_{y_1,y_2}(X)$ is a constant.

Suppose $f(X)$ has degree exactly $2e+1$. Let α be the coefficient of X^{2e+1} in $f(X)$.

Define $\gamma_i(Y) \in_q [Y]$ by:

$$f(X+Y) = \sum_{j=0}^{2e+1} \gamma_i(Y) X^i.$$

Note that $\deg(\gamma_i(Y)) \leq 2e+1-i$. It is easy to check that $\gamma_{2e+1}(Y) = \alpha$ and $\gamma_{2d}(Y) = \alpha Y$.

Then we have:

$$\begin{aligned} P_{y_1,y_2}(X) &= f(X+y_1) - f(X+y_2) \\ &= \sum_{i \leq 2e} \left(\gamma_i(y_1) - \gamma_i(y_2)\right) X^i. \end{aligned}$$

Then by definition,

$$\widetilde{P}_{y_1,y_2}(X) = \sum_{\substack{j \leq 2e-1 \\ j \text{ odd}}} \left(\sum_{\substack{k \geq 0 \\ j 2^k \leq 2e}} \left(\gamma_{j \cdot 2^k}(y_1) - \gamma_{j \cdot 2^k}(y_2)\right)^{\frac{1}{2^k}} \right) X^j.$$

We are trying to show that for most y_1, y_2, this is nonconstant. We will do this by identifying a monomial of positive degree which often has a nonzero coefficient. Let $e = j_0 \cdot 2^{k_0}$ with j odd. We will focus on the coefficient of X^{k_0}. It equals:

$$\left(\gamma_{2e}(y_1) - \gamma_{2e}(y_2)\right)^{1/2^{k_0+1}} + \left(\sum_{0 \leq k \leq k_0} \left(\gamma_{j \cdot 2^k}(y_1) - \gamma_{j \cdot 2^k}(y_2)\right)^{\frac{1}{2^k}} \right).$$

By linearity of the map $a \mapsto a^{1/2^k}$, this can be expressed in the form $Q(y_1^{1/2^{k_0+1}}, y_2^{1/2^{k_0+1}})$, where $Q(Z_1, Z_2)$ is a bivariate polynomial of degree at most $2e$. Furthermore, using the fact that $\gamma_{2e}(Y) = \alpha Y$, the homogeneous part of $Q(Z_1, Z_2)$ of degree 1 exactly equals:

$$\alpha^{1/2^{k_0+1}}(Z_1 - Z_2),$$

which is nonzero. Thus $Q(Z_1, Z_2)$ is a nonzero polynomial.

Thus by the Schwartz-Zippel lemma, for $T = \{y^{1/2^{k_0+1}} \mid y \in S\}$, there are at most $2e|T| \leq d|S|$ values of $(z_1, z_2) \in T^2$ such that $Q(z_1, z_2) = 0$. Thus there are at most $d|S|$ values of $(y_1, y_2) \in S^2$ for which the coefficient of X^{k_0} in $\widetilde{P}_{y_1,y_2}(X)$ is 0. Whenever it is nonzero, Equation (6) bounding U_{y_1,y_2} applies, and we get the desired result. ◀

A Justensen-like code

The construction in this example is inspired by the Justensen code [10], which uses an ensemble of codes for the inner code instead of a single inner code. Justensen uses an ensemble known as the Wozencraft Ensemble [12] with the following properties.

▶ **Theorem 32** (Wozencraft Ensemble). *For every large enough k, there exists codes $C^{(1)}, C^{(2)}, ..., C^{(2^k-1)}$ over $\frac{2}{2}^k$ with rate $1/2$, where $1-\epsilon$ fraction of them have distance at least $H_2^{-1}(1/2-\epsilon)$.*

Since our goal is graph distance, we use the STCZD operation to covert the Wozencraft Ensemble from codes over strings with good Hamming distance to codes of matrices with good graph distance.

▶ **Lemma 33** (Wozencraft Ensemble Modification). *For any $\epsilon > 0$, and large enough k, there exists codes $D^{(1)}, D^{(2)}, ..., D^{(2^k-1)}$ over $\frac{2k\times 2k}{2}$. View these as directed graph codes. Then these codes have rate $1/8$, and at least a $1-\epsilon$ fraction of them have distance at least $H_2^{-1}(1/2-\epsilon)$.*

Proof. Let $C^{(1)}, C^{(2)}, ..., C^{(N)}$ be the Wozencraft Ensemble. For each $I \in [N]$, define $D^{(I)} = \text{STCZD}(C^{(I)})$. Note that each $D^{(I)}$ is a code over $\frac{2k\times 2k}{2}$. Note that by lemma Lemma 10, each of the codes has rate $1/8$. Since the STCZD operation translates Hamming distance to directed graph distance, we also have the same guarantee as the original Wozencraft Ensemble - at least $(1-\epsilon)$ fraction of the codes have distance at least $H_2^{-1}(1/2-\epsilon)$. ◀

Concatenating STCZD(RS) with the modified Wozencraft Ensemble in a particular arrangement yields our next construction.

▶ **Code 34** (Justensen-like $C_{\text{Justensen}}(\epsilon, k, \rho)$). *Require $\epsilon, \rho \in (0,1)$. Let $Q = 2^k$, and $N = 2^k - 1$.*

Let $D^{(1)}, D^{(2)}, ..., D^{2^k-1}$ be the modified Wozencraft Ensemble Lemma 33.

Then $C_{\text{Justensen}}$ is the code where for each element of $A \in \text{STCZD}(\text{RS}(N, \rho, Q))$, for each $I, J \in [N]$, we replace the symbol at A_{IJ} with its encoding under $D^{(\min(I,J))}$. If $J < I$, we transpose the encoding (to keep the matrix symmetric).

Figure 2 shows where each inner code is applied.

$$\begin{bmatrix} - & D^{(1)} & D^{(1)} & D^{(1)} & D^{(1)} & D^{(1)} \\ D^{(1)T} & - & D^{(2)} & D^{(2)} & D^{(2)} & D^{(2)} \\ D^{(1)T} & D^{(2)T} & - & D^{(3)} & D^{(3)} & D^{(3)} \\ D^{(1)T} & D^{(2)T} & D^{(3)T} & - & D^{(4)} & D^{(4)} \\ D^{(1)T} & D^{(2)T} & D^{(3)T} & D^{(4)T} & - & D^{(5)} \\ D^{(1)T} & D^{(2)T} & D^{(3)T} & D^{(4)T} & D^{(5)T} & - \end{bmatrix}$$

Figure 2 Inner code arrangement for $C_{\text{Justensen}}$.

▶ **Theorem 35.** *For any $\epsilon, \rho \in (0,1)$, and k, a sufficiently large integer, $C_{\text{Justensen}}(\epsilon, \rho, k)$ is a strongly explicit linear graph code with rate $\rho^2/8 - o(1)$, and distance at least $(1-\rho-\epsilon)H^{-1}(1/2-\epsilon)$.*

Proof. Let $N = 2^k - 1$, and $n = 2k$ be the side lengths of the inner and outer codes, respectively. First note that $C_{\text{Justensen}}$ is a linear graph code over $\frac{nN\times nN}{2}$, since both the inner and outer codes are linear, and we can apply a $_2$ linear map from $_{2^k} \to \frac{k}{2}$ before encoding with the inner code.

Rate. By Lemma 10, the outer code, STCZD(RS(N, ρ, Q)), has rate $\rho^2/2 - o(1)$, and by Lemma 33, the inner codes have rate $1/8 - o(1)$. Thus, the rate is $\rho^2/8 - o(1)$ as an undirected graph code.

Distance. Let O be a non-zero outer codeword. For convenience, let $d = H^{-1}(1/2 - \epsilon)$, and $n = 2k$ be the side length of the inner code. We claim the distance is at least $(1 - \rho - \epsilon)d$.

Call $I \in [N]$, bad if the distance of $D^{(I)} < d$, and good otherwise. Let $B \subset [N]$ be the subset of bad indices. By the guarantee of the Wozencraft ensemble, we know that $|B| < \epsilon N$. Since O_{IJ} gets encoded with $\min(I, J)$, if $I, J \notin B$, then O_{IJ} is encoded with an inner code of distance at least d.

Define S_I, T_J as in the proof of Lemma 17. Let $S_{\geq} = \{I : |S_I| \geq d_{in} \text{ and } I \notin B\}$. Similarly, define $T_{\geq}$. Then $|S_{\geq}|, |T_{\geq}| < (1 - \rho - \epsilon)N$. Then $|S_{\geq} \cup B|, |T_{\geq} \cup B < (1 - \rho)N$. Since this is less than the outer distance of the code, we have that $O_{IJ} \neq 0$ for some $I \notin S_{\geq} \cup B$, and $J \notin T_{\geq} \cup B$. In other words, $|S_I| < d$, $|T_J| < d_{in}$, and O_{IJ} is encoded with a code of directed graph distance at least d. Thus, by the inner distance, there remains a non-zero element in the (I, J)th block outside of S_I, and T_J. ◀

New Pseudorandom Generators and Correlation Bounds Using Extractors

Vinayak M. Kumar
University of Texas at Austin, TX, USA

Abstract

We establish new correlation bounds and pseudorandom generators for a collection of computation models. These models are all natural generalization of structured low-degree $\mathbb{F}_2$-polynomials that we did not have correlation bounds for before. In particular:

- We construct a PRG for width-2 $\mathsf{poly}(n)$-length branching programs which read d bits at a time with seed length $2^{O(\sqrt{\log n})} \cdot d^2 \log^2(1/\varepsilon)$. This comes quadratically close to optimal dependence in d and $\log(1/\varepsilon)$. Improving the dependence on n would imply nontrivial PRGs for $\log n$-degree $\mathbb{F}_2$-polynomials. The previous PRG by Bogdanov, Dvir, Verbin, and Yehudayoff had an exponentially worse dependence on d with seed length of $O(d \log n + d2^d \log(1/\varepsilon))$.
- We provide the first nontrivial (and nearly optimal) correlation bounds and PRGs against size-$n^{\Omega(\log n)}$ AC^0 circuits with either $n^{.99}$ SYM gates (computing an arbitrary symmetric function) or $n^{.49}$ THR gates (computing an arbitrary linear threshold function). This is a generalization of sparse $\mathbb{F}_2$-polynomials, which can be simulated by an AC^0 circuit with one parity gate at the top. Previous work of Servedio and Tan only handled $n^{.49}$ SYM gates or $n^{.24}$ THR gates, and previous work of Lovett and Srinivasan only handled polynomial-size circuits.
- We give exponentially small correlation bounds against degree-$n^{O(1)}$ $\mathbb{F}_2$-polynomials which are set-multilinear over *some* arbitrary partition of the input into $n^{1-O(1)}$ parts (noting that at n parts, we recover *all* low degree polynomials). This vastly generalizes correlation bounds against degree-d polynomials which are set-multilinear over a fixed partition into d blocks, which were established by Bhrushundi, Harsha, Hatami, Kopparty, and Kumar.

The common technique behind all of these results is to fortify a hard function with the right type of extractor to obtain stronger correlation bounds for more general models of computation. Although this technique has been used in previous work, they rely on the model simplifying drastically under random restrictions. We view our results as a proof of concept that such fortification can be done even for classes that do not enjoy such behavior.

1 Introduction/Outline of Results

Many central questions in complexity theory revolve around proving limitations of various computational models. For example, there are research programs which seek lower bounds against constant depth circuits, low degree polynomials over $\mathbb{F}_2$, and perhaps most famously the complexity class P.

Usually, lower bounds against a simple class of n-bit Boolean functions $\mathcal{C}$ is established by demonstrating an explicit function f such that no $g \in \mathcal{C}$ can compute f on every input. This is referred to as *worst-case hardness*. However, we may not be satisfied with this in practice and stipulate that no $g \in \mathcal{C}$ can even *approximate* f. After all, if there exists a g that agrees with f on all but one point, the difference may be impossible to detect in practice. Furthermore, establishing average case hardness against $\mathcal{C}$ can allow us to create PRGs against $\mathcal{C}$ via the "hardness to randomness" framework introduced by Nisan and Wigderson [24], as well as show hardness results against related function classes, like the majority of functions in $\mathcal{C}$. This *average-case hardness* statement is exactly what the study of correlation bounds capture.

To formally define this, let D a distribution over $\{0,1\}^n$. Define the *correlation* of two Boolean functions $f, g : \{0,1\}^n \to \{0,1\}$ *over* D to be

$$\mathsf{corr}_D(f,g) = |\mathsf{E}_{x\sim D}[(-1)^{f(x)+g(x)}]|.$$

We will usually be concerned with $D = U_n$, the uniform distribution, and should be assumed so if no distribution D is specified. Notice that this quantity is a real number in $[0,1]$. For intuition, note that if $f = g$ or $f = 1 - g$, the correlation is 1, whereas if f and g only match on about half the inputs, the correlation becomes small. This fact allows us to observe correlation is the right notion, as $\mathsf{corr}(f,g)$ being small implies that g cannot predict f much better than a coin flip. For a function f and a function class $\mathcal{C}$, we can define $\mathsf{corr}(f,\mathcal{C}) = \max_{g\in\mathcal{C}} \mathsf{corr}(f,g)$. Hence the notion of f being average-case hard for $\mathcal{C}$ is captured by $\mathsf{corr}(f,\mathcal{C})$ being small.

In this paper, we are most interested in the case $\mathcal{C}$ is the class of low degree $\mathbb{F}_2[x_1,\ldots,x_n]$ polynomials. Establishing correlation bounds against low degree $\mathbb{F}_2$ polynomials is an extremely interesting and central question in complexity theory, as it is either necessary or sufficient to understand a plethora of other problems, some of which concern communication protocols, matrix rigidity, and PRGs for circuits. See Viola's survey [30] for a detailed exposition on this rich program.

Unfortunately, there is a "$\log n$-degree barrier" for PRGs and correlation bounds against low degree polynomials. Current PRGs and correlation bounds are asymptotically tight for constant degree polynomials, but become *trivial* at degree $\log n$ [29]. Getting nontrivial PRGs (or even correlation bounds) against $\log n$-degree polynomials has been a tantalizing and longstanding open problem.

Towards breaking this barrier, researchers have shown strong correlation bounds for *structured* subsets of low degree $\mathbb{F}_2$-polynomials (such as sparse polynomials [20, 26], tensors [3], small-read polynomials, and symmetric polynomials [4]) with the hope of being able to generalize them. In this work, we establish new correlation bounds and PRGs for computation models generalizing some of these polynomials, namely width-2 branching programs reading d bits at a time, AC^0 containing a small number of arbitrary symmetric or linear threshold gates, and set-multilinear polynomials.

Interestingly, all of these correlation bounds are obtained by taking a function hard for a more specific class of polynomials, and then *fortifying* it with a well suited extractor. Although such a fortification technique is not new and has been used for establishing stronger lower bounds for formulas [18, 8], they usually rely on the fact that upon randomly fixing a subset of variables of a formula, there are extremely few possibilities for the resulting function. Our work shows that extractor fortification is a much broader technique that can strengthen lower bounds against function classes even if they do not simplify greatly under a random restriction. In particular, our correlation bounds demonstrate extractor fortification can work if the function class, after a random restriction, has low communication complexity or good algebraic structure.

Inspired by this, we would like to show that extractors will always strengthen correlation bounds, no matter what the proof of the bound is. At a first glance, this may feel intuitive. However, due to technical reasons, this seems challenging to establish.

The remainder of this section is devoted to introducing and motivating each computational model studied, surveying prior work in the topic, and stating all key results proven.

1.1 Better Bounds and PRGs Against AC^0 with More $\{\mathsf{SYM}, \mathsf{THR}\}$ Gates

Our knowledge of hardness and PRG results for AC^0 is far more developed than that of TC^0. Our state of the art PRGs for AC^0 is Lyu's construction [22], which ε-fools polysize AC^0 circuits with seed length $\tilde{O}(\log^{d-1}(n)\log(n/\varepsilon))$, whereas the current best PRG of Hatami, Hoza, Tal, and Tell which (2^{-n^δ})-fools size- $O(n^{1+\delta})$ TC^0 circuits have seed length $O(n^{1-\delta})$ [15]. Due to this stark contrast in parameters, it is natural to gradually work upward from AC^0 by allotting a budget of SYM (calculates an arbitrary symmetric function) or THR (calculates an arbitrary linear threshold function) gates in the circuit. This approach has been explored for more than a decade [28, 20, 26], building upon the study of PRGs for $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuits pioneered by Luby, Velicković, and Wigderson [21]. This context explains why this circuit class a compelling generalization of sparse polynomials (which can be written as a small-size parity of ands). All the mentioned works use the following function introduced by Razborov and Wigderson in 1993 [25] (all arithmetic is over $\mathbb{F}_2$).

$$\mathsf{RW}_{m,k,r}(x) = \sum_{i=1}^{m} \prod_{j=1}^{k} \sum_{\ell=1}^{r} x_{ij\ell} \tag{1}$$

Most recently, Servedio and Tan [26] use $\mathsf{RW}_{m,k,r}$ to uncorrelate against constant-depth size-$n^{O(\log n)}$ AC^0 circuits whose top gate is $\{\mathsf{SYM}, \mathsf{THR}\}$ (denoted as $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$). Their explicit bound is

$$\mathsf{corr}\left(\mathsf{RW}_{\sqrt{\frac{n}{\log n}}, \log n, \sqrt{\frac{n}{\log n}}},\ \{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0\right) \leq 2^{-\Omega(n^{.499})}.$$

Via techniques used in [20], this can be translated to correlation bounds against AC^0 circuits with up to $n^{.499}$ SYM gates or $n^{.249}$ THR gates. As can be surmised by the repeated occurrences of $n^{.499}$, the strength of the correlation bound dictates how many $\{\mathsf{SYM}, \mathsf{THR}\}$ gates we can afford in our budget.

We show that RW is just one of many functions from a general class of hard functions with small correlation against $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuits. For functions $f : (\{0,1\}^r)^k \to \{0,1\}$ and $g : \{0,1\}^m \to \{0,1\}^r$, denote $f \circ g^k(x_1 \ldots, x_k) := f(g(x_1), \ldots g(x_k))$.

▶ **Theorem 1** (informal). *Let g be computable by a size $n^{O(\log n)}$ $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuit. Let f be average-case hard against multiparty protocols*[1]*, and let* Ext *be a suitable extractor. Then*

$$\mathsf{corr}(f \circ \mathsf{Ext}^{\cdot 01 \log n}, g) \leq 2^{-\Omega(n^{.999})}.$$

To our knowledge, this theorem gives the first context where generically precomposing with an extractor boosts correlation bounds whose proof does not rely on simplification under random restriction (indeed parity does not simplify under restriction and is contained in

[1] the formal condition is any function with small "k-party norm" or "cube norm", but this is currently the only technique we know that establishes average case hardness against multiparty protocols.

Table 1 Correlation bounds against $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0_d$ circuits and the PRGs that follow via the [24] framework. In all previous work, the "hard" function used was the RW function, which was first considered by Razborov and Wigderson [25]. Our work uses a better suited function. This table is an extension of the one found in [26].

	Circuit type	Circuit size S	Correlation bound	PRG seed length
[28]	$\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$	$n^{c \log n}$	$n^{-c_d \log n}$	$2^{O(\sqrt{\log(S/\varepsilon)})}$
[20]	$\mathsf{SYM} \circ \mathsf{AC}^0$	$n^{c \log\log n}$	$\exp(-n^{0.999})$	$2^{O\left(\frac{\log S}{\log\log S}\right)} + (\log(1/\varepsilon))^{2.01}$
[20]	$\mathsf{THR} \circ \mathsf{AC}^0$	$n^{c \log\log n}$	$\exp(-n^{0.499})$	$2^{O\left(\frac{\log S}{\log\log S}\right)} + (\log(1/\varepsilon))^{4.01}$
[26]	$\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0_d$	$n^{c \log n}$	$\exp(-\Omega(n^{0.499}))$	$2^{O(\sqrt{\log S})} + (\log(1/\varepsilon))^{4.01}$
This work	$\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$	$n^{c \log n}$	$\exp(-\Omega(n^{0.999}))$	$2^{O(\sqrt{\log S})} + (\log(1/\varepsilon))^{2.01}$

$\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0\}$). Previously, extractors have only been used to boost correlation bounds for classes that heavily simplify under random restriction [18, 8].[2] Our theorem states that extractors can still boost correlation bounds, even if they were proven using communication complexity rather than random restrictions.

Furthermore, our theorem distills out the reason why RW was so effective as a hard function. Quantitatively, we can instantiate the template with a suitable extractor to obtain a new hard function with nearly-optimal correlation bounds.

Due to our strengthened correlation bounds, we can now get correlation bounds and PRGs against size-$n^{O(\log n)}$ AC^0 circuits with up to $n^{.999}$ SYM gates or $n^{.499}$ THR gates. Prior to this, no nontrivial correlation bound or PRG was known to handle such large size *and* number of $\{\mathsf{SYM}, \mathsf{THR}\}$ gates ([20] could handle the same number of $\{\mathsf{SYM}, \mathsf{THR}\}$ gates but only for $n^{O(\log\log n)}$-size circuits, and [26] could handle the same size circuits, but only $n^{.499}$ SYM or $n^{.249}$ THR gates).

Even for $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuits which have only one $\{\mathsf{SYM}, \mathsf{THR}\}$ gate, our correlation bounds yields improved PRGs whose seed length is $2^{O(\sqrt{\log S})} + (\log(1/\varepsilon))^{2.01}$, which has a better dependence on ε, than previous work (see Table 1). In fact, since the best correlation bound one can hope for is $2^{-\Omega(n)}$, this dependence is almost optimal under the Nisan-Wigderson framework, and an alternative approach is needed to reach the optimal dependence of $\log(1/\varepsilon)$. Since any $\log n$-degree $\mathbb{F}_2$ polynomial can be expressed as a $\mathsf{SYM} \circ \mathsf{AND}_{\log n}$ circuit of size $n^{\log n}$, any improvement of the dependence of the seed length on S would give nontrivial PRGs for $\log n$-degree polynomials, a breakthrough result.

1.2 Much Better PRGs Against Width-2 Branching Programs Reading d Bits at a Time

Usually, one constructs PRGs for natural *computational* models, with the idea that we can drastically reduce the randomness we use if the randomized algorithm we are running can be simulated by such a model. Low degree polynomials is an extremely natural mathematical model with applications to circuit complexity, but some may not believe it is well grounded as

[2] There have been uses of extractors as a hard function against classes that do not simplify under restriction, like DNFs of Parities [9] and strongly read-once linear branching programs [12, 19, 7]. However they directly establish a correlation bound against the extractor rather than amplify a weaker hard function by precomposing with an extractor.

a computational one and thus not worth finding a PRG for. However, the work of Bogdanov, Dvir, Verbin, and Yehudayoff [5] showed the beautiful connection that PRGs for degree d polynomials are also PRGs against a particular model described as *width-2 length-*$\mathsf{poly}(n)$ *branching programs which read* d *bits at a time.*

▶ **Definition 2** ((d, ℓ, n)-2BP ([5], adapted)). *A (d, ℓ, n)-2BP (or more colloquially a width-2 length-ℓ branching program over n bits which reads d bits at a time) is a layered directed acyclic graph, where there are ℓ layers and each layer contains two nodes, which we label by 0 and 1. Each vertex in each layer j is associated with an arbitrary d-bit substring $x|_v$ of the input x. Each node in layer j has 2^d outgoing edges to layer $j+1$ that are labelled by all possible values in $\{0,1\}^d$. On input x, the computation starts with the first node v_{start} in the first layer, then follows the edge labelled by $x|_{v_{start}}$ onto the second layer, and so on until a node in the last layer is reached. The identity of this last node is the outcome of the computation.*

Such branching programs are a well motivated computation model which cover computation with only one bit of usable memory, low degree polynomials, and small width DNFs. The survey of unconditional PRGs by Hatami and Hoza refer to this model as a compelling computational model that places low degree polynomials in the computational landscape [14].

Unfortunately, there is a "$\log n$-degree barrier" for PRGs and correlation bounds against low degree polynomials. Current PRGs and correlation bounds are asymptotically tight for constant degree polynomials, but become *trivial* at degree $\log n$, as can be seen by the current best known PRG for degree-d polynomials by Viola which has seed length $O(d \log n + d2^d \log(n/\varepsilon))$ [29]. Getting nontrivial PRGs (or even correlation bounds) against $\log n$-degree polynomials has been a tantalizing and longstanding open problem, and thus PRGs for $(d, \mathsf{poly}(n), n)$-2BPs also seemingly appeared to inherit this "$d = \log n$ barrier" due to the reduction result of [5].

In this work, we construct PRGs against $(d, \mathsf{poly}(n), n)$-2BPs with exponentially better seed length, thereby giving nontrivial PRGs even in the regime $d = n^{1-o(1)}$. Define a d-junta to be a function $\phi : \{0,1\}^n \to \{0,1\}$ which is solely dependent on d input bits (i.e. can be written as $\phi'(x_i)_{i \in S}$ for some subset $S \subset [n]$ of size d). To get our shortened seed length, we evade the $\log n$-degree barrier by instead showing the equivalence between PRGs for $(d, \mathsf{poly}(n), n)$-2BPs and PRGs for the XOR of $\mathsf{poly}(n)$ many d-juntas (denoted as $\mathsf{JUNTA}_{n,d}^{\oplus \mathsf{poly}(n)}$). This class is already interesting in its own right, as it can be seen as a generalization of sparse $\mathbb{F}_2$-polynomials and combinatorial checkerboards (defined by Watson [32] and also studied by Gopalan, Meka, Reingold and Zuckerman [11]), as well as a specific class bounded collusion protocols studied by Chattopadhyay et al. [6]. However, we are not aware of any literature studying $\mathsf{JUNTA}_{n,d}^{\oplus m}$ specifically.

Our main technical contribution is strong correlation bounds for $\mathsf{JUNTA}_{n,d}^{\oplus \mathsf{poly}(n)}$. In particular, we show the following.

▶ **Theorem 3.** *There exists an explicit function f such that*

$$\mathsf{corr}(f, \mathsf{JUNTA}_{n,d}^{\oplus \mathsf{poly}(n)}) \leq \exp\left(-\frac{n}{d2^{O(\sqrt{\log n})}}\right)$$

By combining this with the "hardness-to-randomness" framework of Nisan and Wigderson [24], we construct a PRG of seed length $2^{O(\sqrt{\log n})} d^2 \log^2(1/\varepsilon)$. This is only a quadratic factor away from optimal dependence on d and ε. Improving the dependence on n would be a breakthrough, since if we set $n' = 2^{\sqrt{\log n}}$, a $(d, n, \mathsf{poly}(n))$-2BP can simulate any $\log n'$-degree polynomial over $x_1, \ldots x_{n'}$, and so having seed length $o(n')$ would effectively be breaking the $\log n$-degree barrier for $\mathbb{F}_2$-polynomial PRGs.

Interestingly enough, by combining an "simplification under restriction" approach pioneered by Ajtai and Wigderson [1] with a PRG for sparse $\mathbb{F}_2$-polynomials by Servedio and Tan [27], we are able to construct a PRG against $\mathsf{JUNTA}_{n,d}^{\oplus \mathsf{poly}(n)}$, and thus $(d, \mathsf{poly}(n), n)$-2BPs, with seed length $d2^{O(\sqrt{\log(n/\varepsilon)})}$. This gives us an optimal dependence on d, but an exponentially worse dependence on ε. This suggests perhaps with a combination of these two approaches, one might be able to achieve seed length $2^{O(\sqrt{\log n})} d \log(1/\varepsilon)$.

1.3 Near-Optimal Bounds Against High Degree Set-Multilinear Polynomials

As explained earlier, a central open question in complexity theory is to establish better-than-$O(1/\sqrt{n})$ nontrivial correlation bounds against $\Omega(\log n)$-degree polynomials. In order to make progress on this question, it is natural to consider structured low-degree $\mathbb{F}_2$-polynomials. This is what the work of Bhrushundi et al. does [3].

Define a polynomial $p : \{0,1\}^n \to \{0,1\}$ to be set-multilinear over a partition $X = (X_1, \ldots, X_d)$ of the input bits if every monomial contains *at most one* variable from each X_i (this is slightly more general than the usual definition of *exactly one*). The work of Bhrushundi et al. [3] prove that a random degree d set-multilinear tensor has exponentially small correlation against generic degree $d/2$ $\mathbb{F}_2$-polynomials for $d = \Omega(n)$. Towards making this correlation bound explicit, they defined $\mathsf{FFM}(X_1, \ldots, X_d) = \mathsf{lsb}(X_1 \cdot X_2 \cdots X_d)$, where multiplication is done by treating the X_i as field elements, and lsb outputs the least significant bit of the string. Bhushrundi et al. were able to give exponentially small correlation bounds against polynomials up to degree $o(n/\log n)$ which are set-multilinear over the fixed partition $(X_1, \ldots, X_d)$. However, this leaves more to be wanted. The partition with respect to which the polynomial is set-multilinear over needing to be fixed and dependent on FFM_d feels like an extremely strong and asymmetric condition. Can we uncorrelate against degree $< d$ polynomials set-multilinear over *any* equipartition of X into d parts? Can the parts be unequal? Can we have more than d of them?

We show the affirmative to all the above questions. If we take $\delta > 0$ to be an arbitrarily small constant, we can obtain exponentially small correlation against degree $< n^\delta$ polynomial for which there exists *some* partition of X into up to $n^{1-\delta}$ (not necessarily equal) parts such that p is set-multilinear over it. Notice improving $n^{1-\delta}$ parts to n would be a breakthrough, since all polynomials are set-multilinear over the n-partition of $X = (x_1, \ldots, x_n)$.

To do so, we fortify the hard function FFM with an extractor. Let $\mathsf{Ext}(X, W)$ be a strong linear seeded extractor (for each fixing of W, $\mathsf{Ext}(\cdot, W)$ is linear). For some parameter d, define the function

$$\mathsf{ExtFFM}_d(X_1, \ldots, X_d, W) := \mathsf{lsb}(\mathsf{Ext}(X_1, W) \cdot \mathsf{Ext}(X_2, W) \cdot \ldots \cdot \mathsf{Ext}(X_d, W)),$$

where multiplication is done over a finite field, and lsb outputs the least significant bit of the string. First note that $\mathsf{ExtFFM}_d(X_1, \ldots, X_d, W)$, for a fixed W, is set-multilinear over $X_1, \ldots, X_d$. Hence our intuition that set-multilinear polynomials might correlate the most with the hard function is preserved in ExtFFM as well. Using ExtFFM, we are able to obtain correlation bounds against the more intuitive notion of set-multilinear polynomials, where the structure of the partition does not matter. This gives more leeway since now if we want to implement this approach towards correlation bounds against low-degree polynomials, there is a larger class of set-multilinear polynomials that we can reduce generic polynomials to.

2 Technical Overview Of the Results

In this section, we give the overview of the proofs of the main results we covered above.

2.1 Stronger Correlation Bounds Against $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$

We focus on showing stronger correlation bounds against $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$, since the subsequent arguments turning this into PRGs against AC^0 with a few $\{\mathsf{SYM}, \mathsf{THR}\}$ gates are standard. The blueprint behind this argument follows the "simplification under restrictions" approach of previous works, but most similarly of Tan and Servedio [26]. A random restriction is a random partial assignment where for each variable, it is left unfixed (or "alive") with probability p, and is otherwise set to a uniform bit. [26] shows that under a random restriction, the hard function $\mathsf{RW}_{m,k,r}$ maintains integrity and uncorrelates against multiparty protocols, while the $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ simplifies to a short multiparty protocol. However, the roadblock met in [26] preventing a correlation bound of $2^{-\Omega(n)}$ and only giving one of size $2^{-\Omega(n^{.499})}$ is due to parameters in $\mathsf{RW}_{m,k,r}$ being in contention with each other. To elucidate, if n is the input size, then we must have $mkr = n$. Via the analysis done in [26], the correlation bound ends up being in the form of $2^{-\Omega(m)} + 2^{-\tilde{\Omega}(r)}$, which forces any established correlation bound to be at best $2^{-\Omega(\sqrt{n})}$.

To understand why both conflicting terms show up, we give a quick overview of the argument of [26]. First, $\mathsf{RW}_{m,k,r}$ (as defined in Equation (1)) can be thought of as a fortified version of the *generalized inner product*, $\mathsf{GIP}_{m,k}(x_1, \ldots, x_k) := \sum_{i=1}^{m} \prod_{j=1}^{k} x_{ij}$, where each variable is now replaced by the parity of r new variables. This is effective against random restrictions, since as long as one of the r copies $x_{ij1}, \ldots, x_{ijr}$ survive the restriction, the corresponding term x_{ij} in GIP will survive. They argue that after a random restriction ρ is applied, the $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuit simplifies to a short multiparty protocol, while $\mathsf{RW}_{m,k,r}|_\rho$ is still capable of computing $\mathsf{GIP}_{m/2,k}$ with high probability. Conditioning upon this, previous results of Babai, Nisan, and Szegedy [2] show that $\mathsf{GIP}_{m/2,k}$ has $2^{-\Omega(m/2^k)}$ correlation against these multiparty protocols, explaining the emergence of the $2^{-\Omega(m)}$ term in the correlation. Conditioning on $\mathsf{RW}_{m,k,r}|_\rho$ being able to compute $\mathsf{GIP}_{m/2,k}$ introduces an additive error to the correlation corresponding to the probability $\mathsf{RW}_{m,k,r}|_\rho$ *fails* to simplify. [26] bounds this by the chance all r copies of some variable x_{ij} becomes fixed by a restriction, which will be $(1-p)^r \approx \exp(-pr)$, explaining the occurrence of the $2^{-\Omega(r)}$ term in the correlation.

In summary, the argument of [26] requires r needs to be large to strongly fortify the hard function against random restrictions, while m needs to be large to have a stronger correlation bound against multiparty protocols. However, with the constraint $mr \leq n$, we are forced to compromise and reach the setting $m = r \approx \sqrt{n}$.

We now propose an abstraction of the hard function, which naturally yields a stronger correlation bound. If we define $\oplus_{m,r} : (\{0,1\}^r)^m \to \{0,1\}^m$ to be

$$\oplus_{m,r}(x_1, \ldots, x_m) = \left(\sum_{i=1}^{r} x_{1i}, \ldots, \sum_{i=1}^{r} x_{mi} \right),$$

we observe $\mathsf{RW}_{m,k,r} = \mathsf{GIP}_{m,k} \circ \oplus_{m,r}^k(x_1, \ldots, x_k) := \mathsf{GIP}_{m,k}(\oplus_{m,r}(x_1), \ldots, \oplus_{m,r}(x_k))$. The key insight is that our argument can be generalized to not just RW, but any function

$$f \circ \mathsf{Ext}^k := f(\mathsf{Ext}(x_1), \ldots, \mathsf{Ext}(x_k))$$

where f is average-case hard for multiparty protocols, and Ext is an *oblivious bit-fixing source extractor* (OBF extractor). Informally, an oblivious bit-fixing source extractor for min-entropy k is a function Ext such that if $\mathbf{X}$ is uniform over $\{0,1\}^n$ and ρ is a restriction which leaves $\geq k$ bits alive, the output $\mathsf{Ext}(\mathbf{X}|_\rho)$ is close to uniform. Recall our approach first applies a random restriction to simplify our circuit to a small multiparty protocol, which we then deal with using GIP. If the random restriction leaves sufficiently many variables alive with high probability, then $f \circ \mathsf{Ext}^k$ should still behave like f due to Ext being an OBF extractor. Since the circuit is now a multiparty protocol, the average-case hardness of f gives us a correlation bound.

Notice in the RW construction and the setting of parameters $m = r \approx \sqrt{n}$, $\oplus_{m,r}$ is an OBF extractor which maps n bits to $\sqrt{n}$ bits. But this means the input to the outer GIP function will only have $\approx \sqrt{n}$ bits, and so the best correlation bound we can hope to achieve is $\exp(-\Omega(\sqrt{n}))$. The restrictions used in the proof leave $n^{.99}$ variables alive with high probability, so intuitively we could hope that all these $n^{.99}$ "bits of randomness" could be preserved for GIP (or in general any f) rather than only $\sqrt{n}$, potetially resulting in a $\exp(-\Omega(n^{.99}))$ correlation bound alive. We do just this by using a much better OBF extractor of Kamp and Zuckerman [17]. By making this intuition more formal using techniques developed by Viola and Wigderson [31], we obtain $2^{-\Omega(n^{1-O(1)})}$ correlation bound. The idea of replacing parities with better suited extractors has also appeared in previous work [18, 8].

2.2 PRGs for $\mathsf{JUNTA}^{\oplus t}_{n,d}$ and (d,t,n)-2BPs

Our PRG construction blueprint can be briefly described as follows. We first establish correlation bounds against $\mathsf{JUNTA}^{\oplus t}_{n,d}$. We then put this through the Nisan-Wigderson "hardness vs. randomness" framework to create a PRG against $\mathsf{JUNTA}^{\oplus t}_{n,d}$. We then show that PRGs which fool $\mathsf{JUNTA}^{\oplus t}_{n,d}$ actually fool (d,t,n)-2BPs, making the $\mathsf{JUNTA}^{\oplus t}_{n,d}$ PRG our final construction. We first discuss why PRGs for $\mathsf{JUNTA}^{\oplus t}_{n,d}$ imply PRGs for (d,t,n)-2BPs, and then discuss the techniques needed to show strong correlation bounds against $\mathsf{JUNTA}^{\oplus t}_{n,d}$.

2.2.1 PRGs for $\mathsf{JUNTA}^{\oplus t}_{n,d} \implies$ PRGs for (d,t,n)-2BPs

Adopting the exposition in [14], the previous work of [5] can be outlined as follows. Consider a (d,t,n)-2BP B. By noticing that all transition functions in B are d-juntas, one can derive that $B(x) = B'(\phi_1, \ldots, \phi_{2t}(x))$, where B' is a $(1,t,2t)$ branching program. By Fourier expanding B', this can be decomposed as

$$B(x) = \sum_{S \subset [2t]} \widehat{B}(S)(-1)^{\sum_{i \in S} \phi_i(x)}.$$

[5] shows that $\sum_{S \subset [t]} |\widehat{B}(S)|$ is bounded , so by linearity of expectation and the Triangle Inequality, it suffices to fool the terms $(-1)^{\sum_{i \in S} \phi_i(x)}$. The approach in [5] makes the observation that each ϕ_i, by virtue of being a d-junta, can be written as a degree d polynomial. Consequently, a PRG for degree d polynomials will fool (d,t,n)-2BPs with seed length $O(d \log n + d2^d \log(n/\varepsilon))$. The issue here is that at $d = \log n$, the seed length becomes trivial.

However, we can notice that the $\mathbb{F}_2$-polynomial $p(x) \coloneqq \sum_{i \in S} \phi_i(x)$ has some additional structure. If $t = \mathsf{poly}(n)$, p is the sum of only a polynomial number of d-juntas. If there was a way to leverage this, and get a better PRG that fools $\mathsf{JUNTA}^{\oplus t}_{n,d}$, then we might hope to get nontrivial PRGs even in the regime $d = \Omega(\log n)$.

This observation already yields nontrivial PRGs for $d = \omega(\log n)$. Servedio and Tan [26] provide a PRG fooling $\mathbb{F}_2$-polynomials with S terms with seed length $2^{O(\sqrt{\log S}}\log(1/\varepsilon))$. Since each junta can be written as a polynomial with up to 2^d terms, each $g \in \mathsf{JUNTA}_{n,d}^{\mathsf{poly}(n)}$ can be written as a polynomial with $S = 2^d\mathsf{poly}(n)$ terms, yielding a PRG with seed length $(2^{O(\sqrt{d})}+O(\log n))\log(1/\varepsilon)$. Hence we get nontrivial seed length for $d = o(\log^2 n)$. [3] However, we proceed alternatively to get an exponentially better seed length.

2.3 The Nisan-Wigderson Framework and Correlation Bounds for $\mathsf{JUNTA}_{n,d}^{\oplus\mathsf{poly}(n)}$

We will once again use $f \circ \mathsf{Ext}^k$ as our hard function[4] to establish exponentially small correlation bounds against the class, and then apply the Nisan-Wigderson [24] framework to construct the PRG. The latter portion is straightforward, so we focus on establishing the correlation bounds.

Let $g \in \mathsf{JUNTA}_{n,d}^{\oplus\mathsf{poly}(n)}$. We first show that there exist a subset of variables, S, such that upon arbitrarily fixing bits outside of this set, g can be expressed as a sparse $\mathbb{F}_2$ polynomial, whereas each input block of $f \circ \mathsf{Ext}^k$ heavily intersect S. Hence if we fix $X_{\bar{S}}$ and take the correlation over S, each input block still maintains high min-entropy while g becomes a sparse polynomial, which is a small $\mathsf{SYM} \circ \mathsf{AC}^0$ circuit. Since the hard function is also the same, we can then apply techniques in the previous section to conclude.

2.4 Correlation Bounds against Set-Multilinear Polynomials

Recall that [3] has shown FFM_d uncorrelates against any lower degree polynomial which is set-multilinear over $(X_1, \ldots, X_d)$. The key ingredient behind proving strong correlation bounds against set-multilinear polynomials over arbitrary parititons is to first fortify each input block with extractors, and instead consider ExtFFM_d. This allows us to establish the following structural lemma, which intuitively states that even if you do not start out with a polynomial that is set-multilinear over $(X_1, \ldots, X_d)$, if not too many bits in each input block can be restricted to 1s such that the resulting function is set-multilinear over $(X_1, \ldots, X_d)$ induced by the live variables in each block, exponential correlation bounds can still be obtained.

▶ **Theorem 4.** *Let g be a polynomial of degree $< d$. Let $S_1, \ldots, S_d \subset [n/d]$ be subsets, and let ρ denote the restriction created by fixing the bits in X_i whose index is outside S_i to 1 for each $i \in [d]$. If the restricted function $g|_\rho(X_1, \ldots, X_d)$ becomes set-multilinear in $(X_1, \ldots, X_d)$, then have*

$$\mathsf{corr}(\mathsf{ExtFFM}_d, g) \leq 2^{-\Omega(\frac{n}{cd})}.$$

To explain the proof at a high level, if the sets S_i we leave alive aren't too small, then our strong extractor (conditioned on a good seed) will keep each block $\mathsf{Ext}(X_i, W)$ approximately uniform, and since the restricted function $g|_\rho$ is now set-multilinear over $(X_1, \ldots, X_d)$ we may use a similar approach as [3] to prove the theorem.

It turns out that via a combinatorial argument, one can show that polynomials which are set-multilinear over a large number of blocks can be turned into polynomials set-multilinear over $(X_1, \ldots, X_d)$ by fixing not too many bits per input block X_i. The correlation bounds then follow by the structural lemma.

[3] it is actually the case that a PRG from [21] already gets nontrivial seed length in the same regime, albeit with exponentially worse dependence in ε

[4] we also precompose with parities in the formal argument

3 Preliminaries

For positive integer n, $[n] := \{1, \ldots, n\}$ and $\binom{[n]}{s}$ is the set of all subsets of $[n]$ with $|S| = s$. We denote $e(x) := (-1)^x$.

3.1 Convention About Input Blocks

We will canonically fix a partition of bit strings into d contiguous blocks, each with n/d bits. In particular, any $X \in \{0,1\}^n$ can be written as $X = (X_1, \ldots, X_d)$ where each X_i is the n/d-bit substring. If a string $Y \in \{0,1\}$ is defined, Y_i will be assumed to mean the length n/d substring of Y contained in the ith input block, defined with respect to the canonical partition. Also, we will denote $X_{-i} := (X_1, \ldots, X_{i-1}, X_{i+1}, \ldots, X_d)$ to be the input with the ith block removed.

For a string $X \in \{0,1\}$, we may sometimes identify the n/d bit string X_i as an n-bit string in the following way: the ith block is filled with X, and all other blocks are filled with 0s. Hence, if we interpret bit strings as elements of $\mathbb{F}_2^n$, and we have $X, Y \in \mathbb{F}_2^n$, the expression $X + Y_i$ is well defined.

For parameters $k, d \leq n$ and two functions $f : (\{0,1\}^m)^k \to \{0,1\}$ and $g : \{0,1\}^{n/k} \to \{0,1\}^d$, we will define

$$f \circ g^k = f(g(X_1), \ldots, g(X_d)).$$

3.2 Finite Fields

We will be working with finite fields of characteristic 2. For the finite field over 2^n elements, $\mathbb{F}_{2^n}$, we can naturally identify each element with an n-bit string.

▶ **Definition 5** (character). *A map $\chi : \mathbb{F}_{2^n} \to \mathbb{F}_2$ is called an* additive character *if for all $x, y \in \mathbb{F}_{2^n}$, $\chi(x + y) = \chi(x) + \chi(y)$. It is nontrivial if it is not the zero function.*

Since $\mathbb{F}_{2^n}$ is an n-dimensional vector space, we see the valuations on n basis vectors uniquely define the character. Consequently there are 2^n such characters. Notice we can conveniently characterize all characters either by $\chi_c(x) = \langle x, c \rangle$, or by fixing some character χ, and then defining $\chi_c(x) := \chi(c \cdot x)$. This can be seen by verifying these maps are characters, are distinct, and that there are 2^n of them (the latter is obvious since there are 2^n values of c).

3.3 Models of Computation

▶ **Definition 6** ($\mathbb{F}_2$-polynomials). *An $\mathbb{F}_2$-polynomial (or polynomial for short) is a function of the form $p(x) := \sum_{S \subset [n]} c_S \prod_{i \in S} x_i$ for some $c_i \in \mathbb{F}_2$ (all arithmetic here are over $\mathbb{F}_2$).*

▶ **Definition 7** (set-multilinearity). *An $\mathbb{F}_2$-polynomial p is* set-multilinear *over a partition $(X_1, \ldots, X_d)$ of variables if every monomial of p contains at most one variable from each X_i. Notice that all polynomials are trivially set-multililinear over $(x_1, \ldots, x_n)$.*

▶ **Definition 8** (junta). *Define the class $\mathsf{JUNTA}_{n,k}$ to be a function $\phi : \{0,1\}^n \to \{0,1\}$ which is solely dependent on k input bits (i.e. can be written as $\phi'(x_i)_{i \in S}$ for some subset $S \subset [n]$ of size k). Define $\mathsf{JUNTA}_{n,k}^{\oplus t}$ to be the class of functions which is the parity of t k-juntas.*

▶ **Definition 9** (k-party NOF protocol). *A boolean function $f : (\{0,1\}^{n/d})^d$ can be computed by a k-party NOF protocol with c bits of communication if on input $X = (X_1, \ldots, X_d)$, d players, can take turns writing a bit on the board, where player i's bit can only depend on X_{-d} and the other bits on the board, and the cth bit written is $f(X)$. We denote this class of functions to be Π_k^c.*

Circuits

We measure the size of a circuit by the total number of wires (including input wires) in it. AC^0_d are depth d circuits with unbounded fan-in whose gate set is $\{\mathsf{AND}, \mathsf{OR}, \mathsf{NOT}\}$. SYM is a gate which computes an arbitrary symmetric function, and THR is a gate which computes an arbitrary linear threshold function. In general, if we have a gate G, a subscript G_k will refer to its fan-in (in this case, G is fixed to have fan-in k).

▶ **Definition 10** ($(d, \mathcal{C})$-tree). *Let d be an integer and $\mathcal{C}$ a computational model (e.g. a circuit class). A function is computable by a $(d, \mathcal{C})$-tree if it is computable by a depth t decision tree with $\mathcal{C}$ functions as its leaves. That is, there exists a depth d decision tree T such that for every path π in T, $F|_\pi \in \mathcal{C}$.*

3.4 Probability

We will denote U_m to be the uniform distribution over the finite set $\{0,1\}^m$. We will also denote $S \subset_p T$ to be a random subset of T where each $t \in T$ is added to S independently with probability p.

▶ **Definition 11** (k-wise uniform). *Consider a distribution D over $(\{0,1\}^{n/d})^d$. We say that D is k-wise uniform if for all subsets $S = \{i_1, \ldots, i_k\} \subset [d]$ and all strings $y_1, \ldots, y_k \in \{0,1\}^{n/d}$,*

$$\Pr_{X \sim D}[\forall j, X_{i_j} = y_j] = 2^{-kn/d}.$$

▶ **Definition 12** (ε-close in distribution). *Let D_1 and D_2 be distributions over $\{0,1\}^n$. We say $D_1 \approx_\varepsilon D_2$, or equivalently D_1 is ε-close to D_2, if for all $S \subset \{0,1\}^n$,*

$$|\Pr_{x \sim D_1}[x \in S] - \Pr_{x \sim D_2}[x \in S]| \leq \varepsilon.$$

3.5 Random Restrictions and Partial Assignments

A *partial assignment* or *restriction* is a string $\rho \in \{0,1,\star\}^n$. Intuitively, a $\star$ represents an index that is still "alive" and hasn't been fixed to a value yet.

We also define a composition operation on partial assignments. For two restrictions ρ^1, ρ^2, define $\rho^1 \circ \rho^2$ so that

$$(\rho^1 \circ \rho^2)_i = \begin{cases} \rho^1_i & \rho^1_i \neq \star \\ \rho^2_i & \rho^1_i = \star. \end{cases}$$

Intuitively, one can see this as fixing bits determined by ρ^1 first, and then out of the remaining alive positions, fix them according to ρ^2.

A *random restriction* is simply a distribution over restrictions. A common random restriction we will use is R_p, the distribution where each index will be assigned $\star$ with probability p, and $0, 1$ each with probability $\frac{1-p}{2}$.

The main reason for defining restrictions is to observe their action on functions. Given a restriction ρ and function $f : \{0,1\}^n \to \{0,1\}$, we define $f|_\rho : \{0,1\}^n \to \{0,1\}$ to be the restricted function mapping $f|_\rho(x) := f(\rho \circ x)$.

3.6 Pseudorandomness

Our work will involve working with pseudorandomness primitives, like pseudorandom generators (PRGs) and randomness extractors (or simply extractors).

▶ **Definition 13** (ε-PRG). *A polytime computable function $G : \{0,1\}^s \to \{0,1\}$ is an ε-PRG for a subset $\mathcal{F}$ of functions $\{0,1\}^n \to \{0,1\}$ if for all $f \in \mathcal{F}$,*

$$|\mathsf{E}_{x\sim U_n}[(-1)^{f(x)}] - \mathsf{E}_{s\sim U_s}[(-1)^{f(G(s))}]| \leq \varepsilon.$$

We also say that G ε-fools $\mathcal{F}$. The parameter s is the seed length. In this paper, we will use a PRG of [27] which ε-fools $\mathbb{F}_2$ polynomials with $\leq S$ terms with seed length $2^{O(\sqrt{\log S})}\log(1/eps)$.

▶ **Definition 14** (min-entropy). *Let D be a distribution over $\{0,1\}^n$, and define $supp(D) = \{y \in \{0,1\}^n : \Pr_{x\sim D}[x = y] > 0\}$. Define the min-entropy of D to be the quantity*

$$-\log\left(\max_{x\in\{0,1\}^n} \Pr_{y\sim D}[y = x]\right).$$

It is helpful to note that if for a particular k and all $y \in \{0,1\}^n$, all probabilities $\Pr_{x\sim D}[x = y] \leq 2^{-k}$, then we know D has min-entropy $\geq k$.

▶ **Definition 15** (Strong/Linear/Seeded Extractors). *A (k,ε)-seeded extractor is a function $\mathsf{Ext} : \{0,1\}^n \times \{0,1\}^d \to \{0,1\}^m$ such that for any D with min-entropy $\geq k$, we have for $\boldsymbol{X} \sim D$ and $\boldsymbol{W} \sim U_d$ the following*

$$\mathsf{Ext}(\boldsymbol{X}, \boldsymbol{W}) \approx_\varepsilon U_m.$$

Ext is a strong seeded extractor if we also have

$$\Pr_{w\sim U_d}[\mathsf{Ext}(\boldsymbol{X}, w) \approx_\varepsilon U_m] \geq 1 - \varepsilon$$

Ext is a linear seeded extractor if for every fixed W, $\mathsf{Ext}(\cdot, W)$ is linear over $\mathbb{F}_2$. The Leftover Hash Lemma [16] allows us to construct a strong seeded (k,ε) extractor with seed length $2n$, $\mathsf{Ext} : \{0,1\}^n \cdot \{0,1\}^{2n} \to \{0,1\}^{k-2\log(1/\varepsilon)}$.

▶ **Definition 16** (Oblivious Bit-Fixing Source Extractors). *An (n,k) oblivious bit-fixing source (or OBF) is a distribution D over $\{0,1\}^n$ created by fixing some $n-k$ of the bits, and then filling in the remaining k indices with uniform and independent bits. An (k,ε) oblivious bit-fixing source extractor (or OBF extractor) is a function $\mathsf{Ext} : \{0,1\}^n \to \{0,1\}^m$ such that for every (n,k) OBF D, we have that for $\boldsymbol{X} \sim D$,*

$$\mathsf{Ext}(\boldsymbol{X}) \approx_\varepsilon U_m.$$

For any $k > \sqrt{n}$, Kamp and Zuckerman [17] allows us to construct $(k, 2^{-\Omega(k^2/n)})$ OBF extractors $\mathsf{Ext} : \{0,1\}^n \to \{0,1\}^{\Omega(k^2/n)}$.

3.7 Correlation Bounds

We will need some tools and definitions from the literature of correlation bounds. We first give a formal definition of correlation.

▶ **Definition 17** (correlation). *For two Boolean functions $f, g : \{0,1\}^n \to \{0,1\}$, and a distribution D over $\{0,1\}^n$, define the correlation of f and g over D to be*

$$\mathsf{corr}_D(f,g) = |\mathsf{E}_{x\sim D}(-1)^{f(x)+g(x)}|.$$

If no distribution is mentioned, we always assume $D = U_n$. Furthermore, for a subset of functions $\mathcal{C}$, we define

$$\mathsf{corr}_D(f,\mathcal{C}) = \max_{g\in\mathcal{C}} \mathsf{corr}_D(f,g).$$

Viola and Wigderson defined a convenient quantity R_k, which is very useful in bounding correlations against NOF protocols.

▶ **Definition 18** (k-party Norm). *For a function $f : (\{0,1\}^{n/k})^k \to \{0,1\}$, define the k-party norm of f to be*

$$R_k(f) := \mathsf{E}_{X_1^{(0)},\ldots,X_k^{(0)},X_1^{(1)},\ldots,X_k^{(1)} \sim U_{n/k}} e\left(\sum_{\delta \in \{0,1\}^k} f(X_1^{(\delta_1)},\ldots,X_k^{(\delta_k)})\right).$$

This norm is useful due to the following theorem.

▶ **Theorem 19** ([31]). *Let $f : \{0,1\}^n \to \{0,1\}$ be arbitrary, and let g be computable by a d-party NOF protocol exchanging c bits. Then*

$$R_d(f) \leq \mathsf{corr}(f,g) \leq 2^c R_d(f)^{1/2^d}.$$

We will also use the following theorem of Nisan and Wigderson, which allow us to translate correlation bounds into PRGs.This version is seen in the survey of Hatami and Hoza [14]

▶ **Theorem 20** ([24], [14, Theorem 4.2.2]). *Let $f : \{0,1\}^n \to \{0,1\}$. Suppose $h : \{0,1\}^r \to \{0,1\}$ is ε-hard for $f \circ \mathsf{JUNTA}_{r,k}$ with respect to the uniform distribution. Then there exists a PRG for f with seed length $s = O(n^{\frac{1}{k+1}} \cdot r^2/k)$ and error εn.*

4 Nearly Optimal Correlation Bounds against $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$

We strictly improve upon the result [26] by proving a stronger correlation bound against $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuits. This immediately gives PRGs against this class with improved seed length via the "hardness vs. randomness" framework [24] All previous work [28, 20, 26] looked at the function introduced in [25] created by taking the generalized inner product of parities. We present a new function comprised of field multiplication of extractors in order to prove stronger correlation bounds. Let m, n be parameters, and define $k := n/d$. We now prove the following result:

▶ **Theorem 21.** *Let $\mathsf{Ext} : \{0,1\}^k \to \{0,1\}^{.2k^{.996}}$ be a $(k^{.998}.2^{-.4k^{.996}})$ OBF-source extractor (explicit ones exist due to [17]). Let $f : (\{0,1\}^{.2k^{.996}})^d \to \{0,1\}$ be any function such that $\mathsf{corr}(f, \Pi_d^d) \leq 2^{-\Omega(k^{.996}/2^d)}$. Define $f \circ \mathsf{Ext}^d : (\{0,1\}^k)^d \to \{0,1\}$ to be the function*

$$f \circ \mathsf{Ext}^d(X) := f(\mathsf{Ext}(X_1),\ldots,\mathsf{Ext}(X_d)).$$

Let g be any function implementable by a $n^{O(\log n)}$-size $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuit, and let $m = .0005 \log n$. Then

$$\mathsf{corr}(f \circ \mathsf{Ext}^{m+1}, g) \leq 2^{-\Omega(n^{.995})}.$$

In particular, by instantiating this template, say, with Ext being the extractor of [17] and f being either GIP [2] or FFM [10], we get explicit $f \circ \mathsf{Ext}^{m+1}$. We also note by simple adjusting of constants, we can get any $2^{-\Omega(n^{1-\varepsilon})}$ for constant $\varepsilon > 0$. This gives an improvement of the correlation bound given in [26] of $2^{-\Omega(n^{.499})}$.

Proof. We follow the same approach as done in [26]. The uniform distribution can be expressed as applying a random restriction, and then filling in the remaining bits uniformly. For good random restrictions, we argue that g simplifies to a $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AND}_m$ circuit.

We then argue that even after the random restriction, $f \circ \mathsf{Ext}^{m+1}$ maintains its structural integrity due to the extractor. We then finish the argument by using Hastad and Goldmann's connection between $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AND}_m$ and NOF protocols, and the fact that f has small correlation with $(m+1)$-party protocols.

The proof for the simplification of g is the same as seen in [26] so we merely cite it here. The only change is the tuning of parameters. Here is the lemma restated for our use.

▶ **Lemma 22.** *Let $g \in \{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0_d$ with circuit size $s = n^{\tau \log n}$. Then for $p = \frac{1}{48}(48 \log s)^{-(d-1)}$*

$$\begin{aligned}\Pr_{\rho \leftarrow \mathcal{R}_p}[g|\rho \text{ is not computed by } (.001pk, \{\mathsf{SYM}_{s^2}, \mathsf{THR}_{s^2}\} \circ \mathsf{AND}_{\log s})\text{-tree}] \\ &\leq s \cdot 2^{-.001pk/2^d} \\ &= 2^{-\Omega_d(pk)}\end{aligned}$$

Notice that for constant d this gives a bound of $2^{-\Omega(n/\mathsf{polylog}(n))}$, versus its use in [26] in which a $2^{-\Omega(\sqrt{n/\log n})}$ error was gained. We will see later that we can liberally set parameters here because our hard function maintains integrity even after traversing down a path of size $n/\mathsf{polylog}(n)$ (equivalent to randomly fixing $n/\mathsf{polylog}(n)$ bits), whereas the previous GIP function could only withstand $\sqrt{n}$ bits. This is result of using an OBF extractor with much better parameters than simply taking the XOR of many copies.

The leaves of our tree is now much simpler class of circuits, but it is not simple enough. Our correlation bounds can only handle circuits with fan in $m = O(\log n)$, but we currently have fan in $\log s = O(\log^2 n)$. Fix a leaf ℓ of the tree, and let $\{C_1, \ldots, C_{s^2}\}$ be a collection of subsets of $[n]$ where C_i contains the $\leq \log s$ indices of the variables that feed into the ith $\mathsf{AND}_{\log s}$ gate in the bottom layer. We now use the following basic fact, as in [20] and [26], that there is a large subset of variables that minimally intersect with each C_i.

▷ Claim 23. A random $\mathbf{L} \subset_q [n]$ (add each element to $\mathbf{L}$ with probability q) satisfies

$$\Pr[\exists i \in [s^2] \text{ such that } |C_i \cap \mathbf{L}| > m] \leq s^2 \binom{w}{m} q^m.$$

Instantiating this claim with our parameter setting of m and s, and setting $q = \Theta(n^{-.001})$ tells us

$$\Pr[\exists i \in [s^2] \text{ such that } |C_i \cap \mathbf{L}| > m] \leq \frac{1}{s}.$$

Hence there exists such an $L = L(\ell)$ such that restricting all bits outside L makes only $\leq m$ variables feed into each AND gate as desired.

To summarize, our restriction ρ is sampled by a distribution D specified by these three steps.

1. We first perform restriction $\mathcal{R}_p$,
2. and then randomly restrict $\leq .001pk$ while walking down the depth-$.001pk$ tree to a leaf ℓ,
3. and then randomly restrict all the variables alive in this leaf that is *not* in the $L(\ell)$ set that we showed existed

At the end of this process, we have by the union bound that with all but $2^{-\Omega(-pk)}$ probability, $g|_\rho$ becomes a $\{\mathsf{SYM}_{s^2}, \mathsf{THR}_{s^2}\} \circ \mathsf{AND}_m$ circuit.

We now observe what happens to $f \circ \mathsf{Ext}^{m+1}$ under this restriction ρ. We claim $f \circ \mathsf{Ext}^{m+1}$ retains its structure. Our wish is for at least $k^{.998}$ bits in each block to survive. That way, we will have a high entropy oblivious bit-fixing source fed into each extractor, and the function will be able to continue to strongly uncorrelate with m-party protocols. In Step 1, we draw a restriction from $\mathcal{R}_p$. Notice the live variables are distributed like a set $S \subset_p [n]$. We see that by a simple Chernoff and union bound,

$$\Pr_{\mathbf{S} \leftarrow \mathcal{R}_p} \left[\exists i \in [m+1] \text{ such that } |X_i \cap \mathbf{S}| < \frac{pk}{2} \right] \leq (m+1)2^{-\Omega(pk)}$$

Hence except for probability $m2^{-\Omega(pk)} = 2^{-\Omega(n^{1-o(1)})}$, each block X_i will have $\geq pk/2$ live variables. Conditioned on this, when we follow Step 2 and perform a random walk down the decision tree to a leaf, we will assign at most $.001pk$ bits, so we are guaranteed that each block X_i will contain at least $.499pk$ live variables. Step 3 is to take set $L(\ell)$ and arbitrarily restrict variables outside of it. We showed there exists an $L(\ell)$ which minimally overlaps with the input variables to the $\mathsf{AND}_{\log s}$ gates, but we want it to simultaneously overlap heavily with each block. That way most of the X_i will stay alive after restricting the bits outside of $L(\ell)$ The existence of such an $L(\ell)$ can be established by "completing the probabilistic method" started a few paragraphs above. Conditioning on good restrictions so far, let Y_i denote the variables that survived in X_i (hence $|Y_i| \geq .499pk$). We see that

$$\Pr_{\mathbf{L} \subset_q [n]} \left[\exists i \in [m+1] \text{ such that } |Y_i \cap \mathbf{L}| < \frac{.499pqk}{2} \right] \leq (m+1)2^{-\Omega(pqk)}.$$

Hence, the probability that $\mathbf{L}$ either intersects some C_i too much or some Y_i too little will happen with probability $\leq \frac{1}{s} + (m+1)2^{-\Omega(pqk)} \ll 1$. Thus there exists an $L(\ell)$ such that restricting all variables outside of it will simultaneously simplify g to a $\{\mathsf{SYM}_{s^2}, \mathsf{THR}_{s^2}\} \circ \mathsf{AND}_m$ and also leave at least $\frac{.499pqk}{2} \geq .249k^{.999}/\mathsf{polylog}(n) \gg k^{.998}$ variables alive. Stringing all three steps together, we know that except with probability $2^{-\Omega(-pk)}$, our random restriction ρ reduces g to $\{\mathsf{SYM}_{s^2}, \mathsf{THR}_{s^2}\} \circ \mathsf{AND}_m$, while simultaneously keeping $\geq k^{.998}$ variables in each X_i block alive.

We are now in the final phase of the argument where we now directly bound the correlation against the simplified circuit. We first state the results that will convert our circuits to NOF protocols.

▶ **Theorem 24** ([13]). *Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function computed by a size-s $\mathsf{SYM} \circ \mathsf{AND}_m$ circuit. Then for any partition of the n inputs of f into $m+1$ blocks, there is a deterministic NOF $(m+1)$-party communication protocol that computes f using $O(m \log s)$ bits of communication.*

▶ **Theorem 25** ([23]). *Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function computed by a $\mathsf{THR} \circ \mathsf{AND}_m$ circuit. Then for any partition of the n inputs of f into $m+1$ blocks, there is a randomized NOF $(m+1)$-party communication protocol that computes f with error γ_{err} using $O(m^3 \log n \log(n/\gamma_{err}))$ bits of communication.*

We now need to show an average-case hardness result for $f \circ \mathsf{Ext}^{m+1}|_\rho$ against NOF protocols. To do so, we will first calculate the k-party norm of $f \circ \mathsf{Ext}^{m+1}|_\rho$.

▶ **Lemma 26.** *Let ρ be a restriction which keeps $\geq k^{.998}$ variables in each X_i alive. Then $R_{m+1}(f \circ \mathsf{Ext}^{m+1}|\rho) \leq R_{m+1}(f) + 4(m+1) \cdot 2^{-4k^{.996}}$*

Proof. Now notice that

$$R_{m+1}(f \circ \mathsf{Ext}^{m+1}|_\rho) = \mathsf{E}_{X^{(0)},X^{(1)}} e\left(\sum_{\delta\in\{0,1\}^{m+1}} f(\mathsf{Ext}(X_1^{(\delta_1)}|_\rho),\ldots,\mathsf{Ext}(X_{m+1}^{(\delta_{m+1})}|_\rho))\right) \quad (2)$$

By assumption of ρ, each $X_i^{(\delta_i)}|\rho$ over uniform X_i is an OBF source with min-entropy $k^{.998}$, and so each $\mathsf{Ext}|_\rho(X_i) \approx_{2^{-4k^{.996}}} U_{.2k^{.996}}$. Since all $X_i^{(b)}$ for $i \in [m+1], b \in \{0,1\}$ are mutually independent, it follows by a hybrid argument that

$$(\mathsf{Ext}|_\rho(X_i^{(b)}|_\rho)_{i\in[m+1],b\in\{0,1\}} \approx_{2(m+1)2^{-4k^{.996}}} (U_{.2k^{.996}})_{i\in[m+1],b\in\{0,1\}}.$$

Therefore, we can upper bound Equation 2 by

$$\mathsf{E}_{(Y_i^{(b)})_{i\in[m],b\in\{0,1\}}} e\left(\sum_{\delta\in\{0,1\}^{m+1}} f(Y_1^{(\delta_1)}),\ldots,Y_{m+1}^{(\delta_{m+1})})\right) + 4(m+1)2^{-4k^{.996}}$$
$$\leq R_{m+1}(f) + 4(m+1)2^{-4k^{.996}}$$

as desired. ◀

With this, we can show that $f \circ \mathsf{Ext}^{m+1}|_\rho$ uncorrelates against randomized multiparty protocols.

▶ **Theorem 27.** *Let $g : \{0,1\}^n \to \{0,1\}$ be a Boolean function, and let ρ be a restriction such that $X_i|_\rho$ has $\geq k^{.998}$ live variables for each i, and $g|_\rho$ can be computed by an $(m+1)$-party NOF randomized protocol with with $\leq c$ bits and with error γ. Then*

$$\mathsf{corr}(f \circ \mathsf{Ext}^{m+1}|_\rho, g|_\rho) \leq 2\gamma + 2^{c-\Omega(k^{.996}/2^m)}.$$

This proof is deferred to the full version.

We now have all the ingredients to finish. Say ρ is good if ρ keeps $\geq k^{.998}$ variables alive in each block X_i *and* $g|_\rho$ is computable by $\{\mathsf{SYM},\mathsf{THR}\} \circ \mathsf{AND}_m$. We have shown for $\rho \sim D$, this doesn't happen only with probability $2^{-\Omega(pk)}$. If $g|_\rho$ has a SYM gate at the top, then Theorem 24 says the $\mathsf{SYM} \circ \mathsf{AND}_m$ circuit can be computed by a deterministic NOF protocol over $X_1,\ldots,X_{m+1}$ using $O(m \log s)$ bits. Plugging this in to Theorem 27 tells us

$$\mathsf{corr}(f \circ \mathsf{Ext}^{m+1}|_\rho, g|_\rho) \leq 2^{m\log s - \Omega(k^{.996}/2^m)} \leq 2^{-\Omega(n^{.995})}.$$

If the top gate is a THR, use Theorem 25 with $\gamma_{err} = 2^{-n^{.997}}$ to get that the circuit is a randomized NOF protocol over $X_1,\ldots,X_{m+1}$ using $O(m^3 \log n \log(n/\gamma_{err})) = O(n^{.995})$ bits. Plugging this into Theorem 27 gives us a correlation bound of

$$\mathsf{corr}(f \circ \mathsf{Ext}^{m+1}|_\rho, g|_\rho) \leq 2^{n^{.995} - \Omega(k^{.996}/2^m)} \leq 2^{-\Omega(n^{.996})}.$$

In either case we get the same bound, so we can bound

$$\begin{aligned}\mathsf{corr}(f \circ \mathsf{Ext}^{m+1}, g) &= |\mathsf{E}_{\rho\sim D}\mathsf{E}_X(-1)^{f\circ\mathsf{Ext}^{m+1}|_\rho(X)+g|_\rho(X)}| \\ &\leq 2^{-\Omega(pk)} + \mathsf{E}_{\rho\sim D}[|\mathsf{E}_X(-1)^{f\circ\mathsf{Ext}^{m+1}|_\rho(X)+g|_\rho(X)}||\rho \text{ is good}] \\ &\leq 2^{-\Omega(pk)} + 2^{-\Omega(n^{.995})} = 2^{-\Omega(n^{.995})}.\end{aligned}$$

The theorem is proved. ◀

▶ Remark 28. We note that the original RW function instantiated with different parameters can also get the same strengthened correlation bound. This requires a more nuanced analysis than present in [26], and does not extend to general functions of the form $f \circ \mathsf{Ext}^{m+1}$ as it relies on the specific structure of GIP and $\bigoplus$.

To recap the argument for a size s circuit, we first use the multi-switching lemma to reduce to a depth-2 circuit of fan-in $\log s$. We then restrict more variables so that the fan-in reduces to $\sqrt{\log s}$. We then apply correlation bounds for $\sqrt{\log s}$-party protocols to get an error of $\exp(-n/2^{\sqrt{\log s}})$. If one trusts that this error is the bottleneck in the argument, one can imagine running through the above argument again with $s = n^{\Theta(1)}$ to get a better error.

▶ **Corollary 29.** *Let $g(X)$ be a function implementable by a size $s = n^{O(1)}$-size $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuit, and let $m = 2^{\sqrt{\log n}}$. Define $k := n/(m+1)$, and let $\mathsf{Ext} : \{0,1\}^k \to \{0,1\}^{k/2^{O(\sqrt{\log n})}}$ be a $(k/2^{O(\sqrt{\log n})}, 2^{-k/2^{O(\sqrt{\log n})}})$-extractor constructed from [17]. Then*

$$\mathsf{corr}(f \circ \mathsf{Ext}^{m+1}, g) \leq 2^{-(n/2^{O(\sqrt{\log s})})}.$$

This refinement will be useful for our correlation bounds against branching programs in the next section. As the proof is extremely similar to the above, we defer the sketch to the full version.

From Theorem 21, we derive the following two theorems as well.

▶ **Theorem 30.** *There exists an ε-PRG against size-S $\{\mathsf{SYM}, \mathsf{THR}\} \circ \mathsf{AC}^0$ circuits with seed length $s = 2^{O(\sqrt{\log S})} + (\log(1/\varepsilon))^{2.01}$.*

▶ **Theorem 31.** *There is an efficient ε-PRG which fools $\mathsf{AC}^0[\mathsf{SYM}, n^{.999}, S]$ with seed length $2^{O(\sqrt{\log S})} + (\log(1/\varepsilon))^{2.01}$ and an ε-PRG which fools $\mathsf{AC}^0[\mathsf{THR}, n^{.499}, S]$ with seed length $2^{O(\sqrt{\log S})} + (\log(1/\varepsilon))^{4.01}$.*

The proofs of these theorems follow by applying the Nisan-Wigderson hardness to randomness approach, as well as the decision tree bootstrapping idea of [20]. The details are deferred to the full version of the paper.

5 PRGs against $(d, \mathsf{poly}(n), n)$-2BPs

In this section, we use fortified hard functions to establish strong correlation bounds against the XOR of juntas, $\mathsf{JUNTA}_{n,d}^{\oplus \mathsf{poly}(n)}$. These are then pushed through the Nisan-Wigderson "hardness vs. randomness" framework to create PRGs which can fool $(d, \mathsf{poly}(n), n)$-2BPs. We first establish the correlation bounds, and then we show that this implies our desired PRG.

5.1 Correlation Bounds Against $\mathsf{JUNTA}_{n,d}^{\oplus \mathsf{poly}(n)}$

This subsection is devoted to proving the following result.

▶ **Theorem 32.** *Let $m = d \log n$, let h be the hard function in Corollary 29 instantiated on $k := n/m$ bits, and let $\oplus_m : \{0,1\}^m \to \{0,1\}$ be the parity function on m bits. We then have*

$$\mathsf{corr}(h \circ \oplus_m^k, \mathsf{JUNTA}_{n,d}^{\oplus n^c}) \leq \exp\left(-\frac{n}{d2^{O(\sqrt{\log n})}}\right)$$

Proof. Consider arbitrary $g \in \mathsf{JUNTA}_{n,d}^{\oplus n^c}$. We will show that there exists a subset $T \subset [n]$ of variables such that upon fixing all variables outside T, g simplifies to a sparse polynomial, while at least one input variable in each $\oplus_m$ stays alive. Write $f = \sum_{i=1}^{n^c} \phi_i$, where each ϕ_i is a d-junta. Let $S_i \subset [n]$ be the indices of the variables that ϕ_i depends on. Pick $T \subset_{1/d} [n]$. For a fixed i, we can bound

$$\Pr_T[|T \cap S_i| \geq \ell] \leq \sum_{\substack{S \subset S_i \\ |S|=\ell}} \Pr_T[S \subset T] = \binom{d}{\ell} \left(\frac{1}{d}\right)^\ell \leq \exp(-\Omega(\ell \log \ell)) \leq 0.1 n^{-c}.$$

for $\ell = \Theta(\log n)$. Union bounding over all i, it follows that

$$\Pr_{\rho \sim \mathcal{R}_{1/d}}[\exists i, |T \cap S_i| \geq \ell] < 0.1. \tag{3}$$

Let $X_1, \ldots, X_k$ be the input blocks of size m feeding into h. We can easily calculate

$$\Pr_T[\exists i, X_i \cap T = \emptyset] \leq k(1-1/d)^m \leq k \exp(-m/d) = 1/m = o(1). \tag{4}$$

Union bounding Equation (3) and Equation (4), it follows that there exists a subset $T \subset [n]$ that simultaneously intersects at most ℓ variables alive in each junta ϕ_i, and intersects at least one variable in each X_i. By pruning out elements, we can assume WLOG that there is exactly one variable in each X_i.

Since a function over b bits can be written as an $\mathbb{F}_2$-polynomial with up to 2^b terms, it follows for any restriction ρ with $\rho^{-1}(\star) = T$, $\phi_i|_\rho$ is a polynomial with $2^\ell = n^{\Theta(1)}$ terms. Therefore, $f|_\rho$ is a polynomial with $n^{\Theta(1)}$ terms as well, which can be written as a $n^{\Theta(1)}$-sized $\mathsf{PAR} \circ \mathsf{AND}$ circuit. Furthermore, we know that $h \circ \oplus_m^k|_\rho$ is equivalent to h up to negations of the inputs. As $\mathsf{SYM} \circ \mathsf{AC}^0$ is invariant under shifts of the input, we can appeal to Corollary 29 and observe

$$\begin{aligned}\mathsf{corr}(h \circ \oplus_m^k, g) &= |\mathsf{E}_X(-1)^{h \circ \oplus_m^k(X) + g(X)}| \\ &\leq \mathsf{E}_{X_{\overline{T}}} |\mathsf{E}_{X_T}(-1)^{h \circ \oplus_m^k(X_T, X_{\overline{T}}) + g(X_T, X_{\overline{T}})}| \leq \exp\left(-(n/d)/2^{O(\sqrt{\log n})}\right)\end{aligned}$$ ◀

5.2 Constructing and Analyzing the PRG

With this correlation bound in hand, we can construct good PRGs against the XOR of juntas using the Nisan-Wigderson framework.

▶ **Corollary 33.** *There is an ε-PRG for $\mathsf{JUNTA}_{n,d}^{\oplus n^{\Theta(1)}}$ with seed length $s = 2^{O(\sqrt{\log n})} d^2 \log^2(1/\varepsilon)$*

The proof is a straightforward application of the Nisan-Wigderson framework that we defer to the full version.

Fooling the parity of juntas actually allow us to fool arbitrary functions of juntas as long as the function has low Fourier L_1 norm.

▶ **Theorem 34.** *Let G be an ε-PRG for $\mathsf{JUNTA}_{n,d}^{\oplus m}$, and let $f : \{0,1\}^m \to \{0,1\}$. Then G is an $\varepsilon \cdot L_1(f)$-PRG for $f \circ \mathsf{JUNTA}_{n,d}$.*

We also defer this proof to the full version.

Finally, as an application, we show PRGs against (d, t, n)-2BPs, branching programs over n bits with width 2, length t, and reads d bits at a time. We will use the fact that width-2 branching programs which read one bit at a time have low Fourier L_1 norm (a proof can be found in [14]).

▶ **Lemma 35.** *If f is a $(1,t,n)$-2BP, then $L_1(f) \leq (t+1)/2$.*

We now use the fact that a (d,t,n)-2BP can be represented by a normal width-2 branching program acting on juntas to prove that the PRG from Corollary 33 fools (d,t,n)-2BPs.

▶ **Theorem 36.** *There exists an ε-PRG for (d,n^c,n)-2BPs with seed length $s = 2^{O(\sqrt{\log n})} \cdot d^2 \log^2(n/\varepsilon)$.*

Proof. Given a (d,n^c,n)-2BP B, we note that at each vertex $v \in [2n^c]$ of B, the transition function is some d-junta ϕ_v which will map the d bits read at that vertex to the next vertex to move to. Now consider the $(1,n^c,2n^c)$-2BP B' defined with the same vertex set as B, and define the transition function for $v \in [2n^c]$ in B' to read the vth bit of the input, and then map to the node in the next layer labeled by that bit. It is easy to see by construction that $B(x) = B'(\phi_1(x),\ldots,\phi_{2n^c}(x))$, which is a function in $B' \circ \mathsf{JUNTA}_{n,d}$. By Theorem 34, this can be ε-fooled by an $(\varepsilon/L_1(B'))$-PRG for $\mathsf{JUNTA}_{n,d}^{\oplus 2n^c}$. Using the L_1 bound from Lemma 35 and the construction from Corollary 33, we see that such a PRG has seed length $2^{O(\sqrt{\log n})} d^2 \log^2(1/\varepsilon)$. ◀

▶ Remark 37. There is an alternative PRG construction using the Ajtai-Wigderson framework [1] which gives optimal dependence on d, but exponentially worse dependence on ε. This is presented in the full version of the paper.

6 Correlation Bounds Against Set-Multilinear Polynomials

Our correlation bound for set-multilinear polynomials follows from an instantiation of the following theorem.

▶ **Theorem 38.** *Let $d \leq n$ be an integer. Let $\mathsf{Ext} : \{0,1\}^{n/d} \times \{0,1\}^{2n/d} \to \{0,1\}^{k-2\log(1/\varepsilon)}$ be a strong linear seeded (k,ε)-extractor with seed length $2n/d$ created from the Leftover Hash Lemma [16], and let χ some nontrivial additive character of $\mathbb{F}_{2^{n/d}}$. Define $\mathsf{ExtFFM}_d : \{0,1\}^{n+2n/d} \to \{0,1\}$ to be*

$$\mathsf{ExtFFM}_d(X,W) = \chi\left(\prod_{i=1}^{d} \mathsf{Ext}(X_i,W)\right).$$

Let $g : \{0,1\} \to \{0,1\}^n$ be a function, and let $S_1,\ldots,S_d \subset [n/d]$ be subsets of size $\geq k$ such that for any restriction ρ created by arbitrarily fixing all bits in W and outside S_i in X_i for each i, $g|_\rho$ always becomes set multilinear in $X_1,\ldots,X_d$. We then have

$$\mathsf{corr}(\mathsf{ExtFFM}_d, g) \leq d\varepsilon + (d-1)\left(\frac{1}{2^k\varepsilon^2} + \varepsilon\right).$$

Proof. For brevity, we let $f := \mathsf{ExtFFM}_d$ in this proof. We will first split the correlation expectation into first randomizing over all restrictions ρ of the bits in X outside of $S_1,\ldots,S_d$, then over the seed W, and then over the remaining live variables denoted by the S_i, which we denote $X_1|_\rho,\ldots,X_d|_\rho$. Now let W_ρ be the set of seeds w such that $\mathsf{Ext}(X_i|_\rho,w) \approx_\varepsilon U_k$ for all i. As Ext is strong-seeded, it follows by a union bound that W_ρ cover all but a $d\varepsilon$ fraction of seeds. Thus one can write

$$\begin{aligned}
\mathsf{corr}(f,g) &= |\mathsf{E}_X(-1)^{f'(X)+g(X)}| \\
&\leq \mathsf{E}_{W,\rho}\left|\mathsf{E}_X(-1)^{f|_\rho(X,W)+g|_\rho(X,W)}\right| \\
&\leq d\varepsilon + \mathsf{E}_\rho \mathsf{E}_{w\in W_\rho} |\mathsf{E}_X(-1)^{f|_\rho(X,w)+g|_\rho(X,w)}| \qquad (5)
\end{aligned}$$

Now fix a partial assignment ρ and seed $w \in W_\rho$. For brevity, let $f(\cdot) := f|_\rho(\cdot, w)$, and similarly for g'. By assumption, g' is set-multilinear over X We now apply a similar argument showing up in [3]. Let α be a map taking linear forms $\sum_{i\in[n/d]} c_i X_{d,i}$ in X_d to its vector of coefficients $(c_i) \in \mathbb{F}_2^{n/d}$. Note that by this definition, for any linear form $\ell(X_d)$, $\langle \ell(X_d), X_d\rangle = \ell(X_d)$. Letting $e(x) = (-1)^x$. We then see

$$\begin{aligned}\left|\mathsf{E}_X(-1)^{f'(X)+g'(X)}\right| &= \left|\mathsf{E}_X e\left(f(X_i) + \sum_{i\in[d-1]} g_i(X_{-i}) + g_d(X_d)\right)\right| \\ &\le \mathsf{E}_{X_{[d-1]}}\left|\mathsf{E}_{X_d} e\left(\langle \alpha(f(X_i) + \sum_{i\in[d-1]} g_i(X_{-i})), X_d\rangle + g_d(X_{-d})\right)\right| \\ &\le \Pr_{X_{[d-1]}}\left[\alpha(f'(X) + \sum_{i\in[d-1]} g_i(X_{-i})) = 0\right] \qquad (6)\end{aligned}$$

where we used the facts that f' is linear in X_d (as Ext here is a linear seeded extractor), $g_d(X_{-d})$ is independent of X_d, and linear forms are perfectly unbiased if their coefficient vector is nonzero. We now repeatedly use the simple inequality that for a linear map $h : \mathbb{F}_2^m \to \mathbb{F}_2^k$ and $a \in \mathbb{F}_2^k$, $\Pr_x[h(x) = a] \le \Pr_x[h(x) = 0]$ as follows.

$$\begin{aligned}&\Pr_{X_{[d-1]}}\left[\alpha(f'(X) + \sum_{i\in[d-1]} g_i(X_{-i})) = 0\right] \qquad (7)\\ &= \mathsf{E}_{X_{[d-2]}} \Pr_{X_{d-1}}\left[\alpha(f'(X) + \sum_{i=1}^{d-2} g_i(X_{-i}))) = \alpha(g_{d-1}(X_{-(d-1)}))\right] \\ &\le \Pr_{X_{[d-1]}}\left[\alpha\left(f'(X) + \sum_{i=1}^{d-2} g_i(X_{-i}))\right) = 0\right] \\ &\le \cdots \\ &\le \Pr_{X_{[d-1]}}[\alpha(f'(X)) = 0] \qquad (8)\end{aligned}$$

To analyze this probability, we state a lemma whose proof is deferred to the full version.

▶ **Lemma 39.** *For a linear form $\ell(X_d)$, $\alpha(\ell(X_d)) = 0$ if and only if $\ell(X_d) = 0$ for all X_d.*

Therefore, by Lemma 39,

$$\Pr_{X_{[d-1]}}[\alpha(f'(X)) = 0] = \Pr_{X_{[d-1]}}\left[\forall X_d, \chi\left(\prod_{i=1}^{d} \mathsf{Ext}(X_i|_\rho, w)\right) = 0\right].$$

Clearly if $\prod_{i=1}^{d-1} \mathsf{Ext}(X_i|_\rho, W) = 0$, f' becomes identically zero. When this doesn't happen, the function becomes of the form $\chi(c \cdot \mathsf{Ext}(X_d|_\rho, w))$ for some nonzero $c \in \mathbb{F}_{2^{n/d}}$. We now claim that there must exist some $X_d|_\rho$ such that $\chi(c \cdot \mathsf{Ext}(X_d|_\rho, w))$. Notice that for exactly $2^{n/d-1}$ values of Y, $\chi(cY) = 0$. As $w \in W_\rho$, the probability that a random $X_d|_\rho$ has $\mathsf{Ext}(X_d|_\rho, w)$ hit one of these values must be $\ge 1/2 - \varepsilon > 0$, proving the claim. Therefore, in order for $\alpha(f'(X)) = 0$, it is necessary that $\prod_{i=1}^{d-1} \mathsf{Ext}(X_i|_\rho, W) = 0$. Therefore,

$$\begin{aligned}\Pr_{X_{[d-1]}}[\alpha(f'(X)) = 0] &\leq \Pr_{X_{[d-1]}}\left[\prod_{i=1}^{d-1} \mathsf{Ext}(X_i|_\rho, w) = 0\right] \\ &\leq \sum_{i=1}^{d-1} \Pr_{X_i}[\mathsf{Ext}(X_i|_\rho, w) = 0] \\ &\leq (d-1)\left(\frac{1}{2^{k-2\log(1/\varepsilon)}} + \varepsilon\right)\end{aligned}$$

Stringing the above with inequalities (5), (6), and (8), we find

$$\mathsf{corr}(\mathsf{ExtFFM}_d, g) \leq d\varepsilon + (d-1)\left(\frac{1}{2^k\varepsilon^2} + \varepsilon\right). \qquad \blacktriangleleft$$

As a very nice application of this structural theorem, we show that we can achieve exponentially small correlation against $n^{O(1)}$-degree polynomials which are set-multilinear over some partition of the input into up to $n^{1-O(1)}$ parts.

▶ **Corollary 40.** *Let g be a degree $< d$ polynomial which is set-multilinear over an arbitrary partition $(A_1, \ldots, A_c)$ of X into c parts. Then*

$$\mathsf{corr}(\mathsf{ExtFFM}_d, g) \leq 2^{-\Omega(n/cd)}.$$

Proof. For each $i \in [n/d]$, define S_i to be the largest set among $\{X_i \cap A_1, \ldots, X_i \cap A_c\}$ (arbitrarily pick one if there are ties). Notice that the sets $\{X_i \cap A_j\}_{j\in[c]}$ partition X_i, and $|X_i| = n/d$. Therefore, we know that each $|S_i| \geq \frac{n/d}{c} = \frac{n}{cd}$. We now claim that any restriction ρ formed by arbitrarily fixing all the bits in X_i which are outside S_i, for each i, will make $g|_\rho$ set-multilinear over $(X_1, \ldots, X_d)$. Assume for the sake of contradiction there existed some monomial in $g|_\rho(X)$ that contained 2 variables from some X_i. Since $S_i \subset X_i$ and $S_j \cap X_i = \emptyset$ for $j \neq i$, both of these variables had to have come from S_i. But note that $S_i = X_i \cap A_\ell \subset A_\ell$ for some ℓ, and we know no monomial has 2 terms from the same A_i by our assumption of g. This yields our desired contradiction.

Therefore, we can apply Theorem 38 on the sets (S_i) with $k = n/cd$ and $\varepsilon = 2^{-.1n/cd}$ to deduce that

$$\mathsf{corr}(f, g) \leq d2^{-.1n/cd} + (d-1)(2^{-.8n/cd} + 2^{-.1n/cd}) = 2^{-\Omega(n/cd)}. \qquad \blacktriangleleft$$

Approximate Unitary k-Designs from Shallow, Low-Communication Circuits

Nicholas LaRacuente
Department of Computer Science, University of Indiana Bloomington, IN, USA

Felix Leditzky
Department of Mathematics, University of Illinois Urbana-Champaign, IL, USA
Illinois Quantum Information Science and Technology Center, Urbana, IL, USA

Abstract

Random unitaries are useful in quantum information and related fields but hard to generate with limited resources. An approximate unitary k-design is a measure over an ensemble of unitaries such that the average is close to a Haar (uniformly) random ensemble up to the first k moments. A strong notion of approximation bounds the distance from Haar randomness in relative error: the weighted twirl induced by an approximate design can be written as a convex combination involving that of an exact design and vice versa. The main focus of our work is on efficient constructions of approximate designs, in particular whether relative-error designs in sublinear depth are possible. We give a positive answer to this question as part of our main results:

1. **Twirl-Swap-Twirl:** Let A and B be systems of the same size. Consider a protocol that locally applies k-design unitaries to A^k and B^k respectively, then exchanges ℓ qudits between each copy of A and B respectively, then again applies local k-design unitaries. This protocol yields an ϵ-approximate relative k-design when $\ell = O(k \log k + \log(1/\epsilon))$. In particular, this bound is *independent* of the size of A and B as long as it is sufficiently large compared to k and $1/\epsilon$.
2. **Twirl-Crosstwirl:** Let $A_1, \dots, A_P$ be subsystems of a multipartite system A. Consider the following protocol for k copies of A: (1) locally apply a k-design unitary to each A_p for $p = 1, \dots, P$; (2) apply a "crosstwirl" k-design unitary across a joint system combining ℓ qudits from each A_p. Assuming each A_p's dimension is sufficiently large compared to other parameters, one can choose ℓ to be of the form $2(Pk+1)\log_q k + \log_q P + \log_q(1/\epsilon) + O(1)$ to achieve an ϵ-approximate relative k-design. As an intermediate step, we show that this protocol achieves a k-tensor-product-expander, in which the approximation error is in $2 \to 2$ norm, using communication logarithmic in k.
3. **Recursive Crosstwirl:** Consider an m-qudit system with connectivity given by a lattice in spatial dimension D. For every $D = 1, 2, \dots$, we give a construction of an ϵ-approximate relative k-design using unitaries of spatially local circuit depth

   $$O\big((\log m + \log(1/\epsilon) + k \log k)k \operatorname{polylog}(k)\big) .$$

   Moreover, across the boundaries of spatially contiguous sub-regions, unitaries used in the design ensemble require only area law communication up to corrections logarithmic in m. Hence they generate only that much entanglement on any product state input.

These constructions use the alternating projection method to analyze overlapping Haar twirls, giving a bound on the convergence speed to the full twirl with respect to the 2-norm. Using von Neumann subalgebra indices to replace system dimension, the 2-norm distance converts to relative error without introducing system size. The **Recursive Crosstwirl** construction answers one variant of [1, Open Problem 1], showing that with a specific, layered architecture, random circuits produce relative error k-designs in sublinear depth. Moreover, it addresses [1, Open Problem 7], showing that structured circuits in spatial dimension D of depth $\ll m^{1/D}$ may achieve approximate k-designs.

Facility Location on High-Dimensional Euclidean Spaces

Euiwoong Lee
University of Michigan, Ann Arbor, MI, USA

Kijun Shin
Seoul National University, South Korea

Abstract

Recent years have seen great progress in the approximability of fundamental clustering and facility location problems on high-dimensional Euclidean spaces, including k-Means and k-Median. While they admit strictly better approximation ratios than their general metric versions, their approximation ratios are still higher than the hardness ratios for general metrics, leaving the possibility that the ultimate optimal approximation ratios will be the same between Euclidean and general metrics. Moreover, such an improved algorithm for Euclidean spaces is not known for Uncapaciated Facility Location (UFL), another fundamental problem in the area.

In this paper, we prove that for any $\gamma \geq 1.6774$ there exists $\varepsilon > 0$ such that Euclidean UFL admits a $(\gamma, 1 + 2e^{-\gamma} - \varepsilon)$-bifactor approximation algorithm, improving the result of Byrka and Aardal [3]. Together with the $(\gamma, 1 + 2e^{-\gamma})$ NP-hardness in general metrics, it shows the first separation between general and Euclidean metrics for the aforementioned basic problems. We also present an $(\alpha_{\mathrm{Li}} - \varepsilon)$-(unifactor) approximation algorithm for UFL for some $\varepsilon > 0$ in Euclidean spaces, where $\alpha_{\mathrm{Li}} \approx 1.488$ is the best-known approximation ratio for UFL by Li [15].

1 Introduction

The (metric) Uncapacitated Facility Location (UFL) is one of the most fundamental problems in computer science and operations research. The input of the problem consists of a metric space (X, d), a set of facility locations $\mathcal{F} \subseteq X$, a set of clients $\mathcal{C} \subseteq X$, as well as facility opening costs $\{f_i\}_{i \in \mathcal{F}}$. The goal is open a subset of centers $S \subseteq \mathcal{F}$ to minimize the sum of the *opening cost* $(\sum_{i \in S} f_i)$ and the *connection cost* $(\sum_{j \in \mathcal{C}} \min_{i \in S} d(i, j))$. After intensive research efforts over the years [11, 12, 16, 15], the best approximation ratio is 1.488 [15] and the best hardness ratio is 1.463 [11].

As the objective function is the sum of two heterogeneous terms of the opening cost and the connection cost, the natural notion of *bifactor approximation* has been actively studied as well. Formally, given an instance of UFL, a solution $S \subseteq \mathcal{F}$ is called an (λ_f, λ_c)-approximation for some $\lambda_f, \lambda_c \geq 1$ if, for any solution $T \subseteq \mathcal{F}$, the total cost of S is at most $\lambda_f \cdot F^* + \lambda_c \cdot C^*$, where F^*, C^* denote the opening and connection cost of T respectively. In particular, the case $\lambda_f = 1$, also known as a λ_c-*Lagrangian Multiplier Preserving (LMP)* approximation, has been actively studied due to its connection to another fundamental clustering problem of k-Median. There is a $(2 - \varepsilon)$-LMP approximation for some $\varepsilon > 2 \cdot 10^{-7}$ [8], and any λ_c-LMP approximation for UFL can be translated to $1.307 \cdot \lambda_c$-approximation for k-Median [9].

© Euiwoong Lee and Kijun Shin;
licensed under Creative Commons License CC-BY 4.0

Generalizing the hardness of Guha and Khuller [11], Jain, Mahdian and Saberi [12] proved that no (λ_f, λ_c)-approximation polynomial-time algorithm exists for $\lambda_c < 1 + 2e^{-\lambda_f}$ unless $\mathbf{P} = \mathbf{NP}$. (Guha-Khuller's hardness ratio $\gamma \approx 1.463$ is exactly the solution of $\gamma = 1 + 2e^{-\gamma}$.) While the optimal value for λ_c is not known for small values of λ_f, Byrka and Aardal gave an algorithm that achieves an $(\lambda_f, 1 + 2e^{-\lambda_f})$-approximation for any $\lambda_f \geq 1.6774$ [3].

Euclidean spaces are arguably the most natural metric spaces for facility location and clustering problems. Formally, *Euclidean UFL* is a special case of UFL where the underlying metric is $(\mathbb{R}^k, \|.\|_2)$ for some dimension k. When $k = O(1)$, this problem admits a PTAS [5], while the problem remains APX-hard when k is part of the input [7].[1]

Recent years have seen active studies on related k-Means and k-Median on high-dimensional Euclidean spaces [1, 10, 4], so that the best-known approximation ratios for them are 5.912 and 2.406 respectively. While they are strictly lower than the best-known approximation ratios for general metric spaces (which are 9 and 2.613), they are still larger than the best-known hardness ratios for general metrics (which are $1 + 8/e \approx 3.943$ and $1 + 2/e \approx 1.73$) [12], which means that it is still plausible that the optimal approximation ratios for k-Median and k-Means are the same between Euclidean metrics and general metrics.

Our first result is the first strict separation between Euclidean and general metric spaces for UFL. In particular, we show that Euclidean UFL admits a $(1.6774, 1 + 2e^{-1.6774} - \varepsilon)$ approximation for some universal constant $\varepsilon > 0$, which is NP-hard to do in general metrics.

▶ **Theorem 1.** *There exists a* $(1.6774, 1+2e^{-1.6774}-\varepsilon)$*-approximation algorithm for Euclidean UFL for some* $\varepsilon \geq 3 \cdot 10^{-42}$.

By the result of Mahdian et al. [16], it implies an $(\gamma, 1 + 2e^{-\gamma} - \varepsilon e^{-(\gamma-1.6774)})$-approximation for any $\gamma \geq 1.6774$. Using this result, we are able to slightly improve the approximation ratio for the best-known ($\alpha_{\mathrm{Li}} \approx 1.488$)-unifactor approximation of Li [15].

▶ **Theorem 2.** *There exists a* $(\alpha_{\mathrm{Li}} - \varepsilon)$*-approximation algorithm for Euclidean UFL for some* $\varepsilon \geq 2 \cdot 10^{-45}$.

Recent years also have seen great progress on hardness of approximation for clustering problems in high-dimensional Euclidean spaces, including Euclidean k-Means and k-Median [6, 7]. We show that similar techniques extend to UFL as well, proving the APX-hardness.

▶ **Theorem 3.** *Euclidean UFL is APX-hard.*

2 High-level Plan

Our work is based on the framework of Byrka and Aardal [3] who achieved an optimal $(\lambda_f, 1 + 2e^{-\lambda_f})$-bifactor approximation for $\lambda_f \geq 1.6774$ in general metrics. We first review their framework. It is based on the following standard linear programming (LP) relaxation:

$$\begin{aligned}
\text{Minimize} \quad & \sum_{i \in \mathcal{F}, j \in \mathcal{C}} d(i,j) x_{ij} + \sum_{i \in \mathcal{F}} f_i y_i & \\
\text{subject to} \quad & \sum_{i \in \mathcal{F}} x_{ij} = 1 & \forall j \in \mathcal{C}, \\
& x_{ij} \leq y_i & \forall i \in \mathcal{F}, j \in \mathcal{C}, \\
& x_{ij}, y_i \in [0,1] & \forall i \in \mathcal{F}, j \in \mathcal{C}.
\end{aligned}$$

[1] While the cited paper only studies k-Median and k-Means, the soundness analysis in their Theorem 4.1 (of the arXiv version) can be directly extended to any number of open facilities k, implying APX-hardness of Euclidean UFL.

The dual formulation is as follows:

$$\begin{aligned}
\text{Maximize} \quad & \sum_{j \in \mathcal{C}} v_j & \\
\text{subject to} \quad & \sum_{j \in \mathcal{C}} w_{ij} \leq f_i & \forall i \in \mathcal{F}, \\
& v_j \leq w_{ij} & \forall i \in \mathcal{F}, j \in \mathcal{C}, \\
& w_{ij} \geq 0 & \forall i \in \mathcal{F}, j \in \mathcal{C}.
\end{aligned}$$

A feasible solution (x, y) induces the *support graph*, which is defined as the bipartite graph $G = ((\mathcal{F}, \mathcal{C}), E)$ where nodes $i \in \mathcal{F}$ and $j \in \mathcal{C}$ are adjacent iff the corresponding LP variable $x_{ij} > 0$. Two clients $j, j' \in \mathcal{C}$ are considered *neighbors* in G if they share the same facility.

Let (x^*, y^*) be a fixed optimal solution to the primal program. The overall cost is divided into the facility cost $F^* = \sum_{i \in \mathcal{F}} f_i y_i^*$ and the connection cost $C^* = \sum_{i \in \mathcal{F}, j \in \mathcal{C}} d(i,j) x_{ij}^*$. Our goal is to round this solution to obtain a solution S whose total cost is at most $\lambda_f F^* + \lambda_c C^*$; it is well known that it implies the (λ_f, λ_c)-approximation defined in the introduction by scaling [3], so let us redefine the (λ_f, λ_c)-approximation for the rest of the paper so that S is (λ_f, λ_c)-approximate if its total cost is $\lambda_f F^* + \lambda_c C^*$.

The opening cost and connection cost for individual clients can be further divided using the optimal LP dual solution (v^*, w^*). For each client $j \in \mathcal{C}$, the fractional connection cost is given by $C_j^* = \sum_{i \in \mathcal{F}} d(i,j) x_{ij}^*$, and the fractional facility cost is computed as $F_j^* = v_j^* - C_j^*$. The *irregularity* of the facilities surrounding $j \in \mathcal{C}$ is defined by

$$r_\gamma(j) = \frac{d(j, \mathcal{D}_j) - d(j, \mathcal{D}_j \cup \mathcal{C}_j)}{F_j^*}.$$

Similarly,

$$r'_\gamma(j) = (\gamma - 1) \cdot r_\gamma(j) = \frac{d(j, \mathcal{D}_j \cup \mathcal{C}_j) - d(j, \mathcal{C}_j)}{F_j^*}.$$

If $\sum_{i \in \mathcal{F}'} y_i^* = 0$, we set $d(j, \mathcal{F}') = 0$. Similarly, when $F_j^* = 0$, we define $r_\gamma(j) = 0$ and $r'_\gamma(j) = 0$. According to the definition, the following conditions hold: the irregularity $0 \leq r_\gamma(j) \leq 1$, the average distance to a close facility $C_j = d(j, \mathcal{C}_j) = C_j^* - r'_\gamma(j) \cdot F_j^*$, and the average distance to a distant facility $D_j = d(j, \mathcal{D}_j) = C_j^* + r_\gamma(j) \cdot F_j^*$. The maximum distance to a close facility is bounded by $M_j \leq D_j$.

Clustering of [3]. At a high level, clustering operates based on the support graph $G = ((\mathcal{F}, \mathcal{C}), E)$. For each $c \in \mathcal{C}$, let $N_c := \{c' \in \mathcal{C} : \exists f \in \mathcal{F} \text{ such that } (c, f), (c', f) \in E\}$ be the neighbor of c. The clustering algorithm iteratively selects some client c as a *cluster center*, put all its neighbors into the cluster, and proceed with the remaining clients. Eventually, all clients are partitioned into one of these clusters. After this, for each cluster, exactly one facility adjacent to cluster center is opened. This ensures that every client is connected to a facility that is not too far from them. Therefore, the criteria for choosing cluster centers and opening facilities will determine the quality of solution.

Starting with a fractional solution of the LP (x^*, y^*) and a parameter $\gamma \in (1, 2)$, [3] constructed the *facility-augmented solution* $(\bar{x}, \bar{y})$, where each y_i^* value is multiplied by γ and each client $j \in \mathcal{C}$ reconfigures its x_{ij}^* values to be fractionally connected to as close facilities as possible. (E.g., $\bar{x}_{ij} > 0$ implies $x_{ij}^* > 0$, but not vice versa.) With some postprocessing,

one can also assume that $\bar{x}_{ij} \in \{0, \bar{y}_i\}$ for every $i \in \mathcal{F}, j \in \mathcal{C}$. Then one can categorize every facility near $j \in \mathcal{C}$ into two types: *close* facilities $\mathcal{C}_j = \{i \in \mathcal{F} \mid \bar{x}_{ij} > 0\}$ and *distant* facilities $\mathcal{D}_j = \{i \in \mathcal{F} \mid \bar{x}_{ij} = 0 \text{ and } x^*_{ij} > 0\}$. This implies that as γ increases, the clusters become smaller, and more facilities are opened.

Let the *average distance* from $j \in \mathcal{C}$ to a set of facilities $\mathcal{F}' \subseteq \mathcal{F}$ be defined as $d(j, \mathcal{F}') = \big(\sum_{i \in \mathcal{F}'} d(i,j) y^*_i\big) / \big(\sum_{i \in \mathcal{F}'} y^*_i\big)$. Then Let $C_j := d(j, \mathcal{C}_j)$, $M_j := \max_{i \in \mathcal{C}_j} d(j,i)$, and $D_j := d(j, \mathcal{D}_j)$. We have $C_j \le M_j \le D_j$.

At this point, the support graph is defined by $(\bar{x}, \bar{y})$ solution. Intuitively, we choose the client j with the smallest $C_j + M_j$ as a new cluster center. Given this clustering, the standard randomized rounding procedure is as follows:

1. For each cluster center j, choose exactly one facility from its neighboring facility set $\{i \in \mathcal{F} : (i,j) \in E\}$ according to the $\bar{y}$ values. (Recall that the sum of these values is exactly 1.)
2. For any facility $i \in \mathcal{F}$ that is not adjacent to any cluster center in G, independently open i with probability $\bar{y}_i$.

Algorithm 1 GREEDY: [3]'s clustering algorithm.

Require: Support graph $G = ((\mathcal{F}, \mathcal{C}), E)$
  $L = \{\}$
  while $\mathcal{C} \neq \emptyset$ **do**
    $c \leftarrow \arg\min_{j \in \mathcal{C}} (C_j + M_j)$
    $L \leftarrow L \cup (c, N_c)$
    $\mathcal{C} \leftarrow \mathcal{C} \setminus N_c$
  end while
  return L

Let us consider one client $j \in \mathcal{C}$ and see how its expected connection cost can be bounded under the above randomized rounding. Byrka and Aardal [3] proved the following properties.

- The probability that at least one facility in $\mathcal{C}_j$ is opened is at least $1 - e^{-1}$.
- The probability that at least one facility in $\mathcal{C}_j \cup \mathcal{D}_j$ is opened is at least $1 - e^{-\gamma}$.
- Let client $j' \in \mathcal{C}$ be a neighbor of j in G. Then, either $\mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j) = \emptyset$ or the *rerouting cost* $d(j, \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j)) \le d(j', j) + d(j', \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j)) \le D_j + C_{j'} + M_{j'}$ holds. Especially, when j' is the cluster center of j, it is at most $C_j + M_j + D_j$. (Li [15] refined this bound to $C_j + (3-\gamma)M_j + (\gamma - 1)D_j$.)

Then, one can (at least informally) expect that the expected connection cost of j is at most $(1 - e^{-1})C_j + (e^{-1} - e^{-\gamma})D_j + e^{-\gamma}(D_j + C_j + M_j)$. It turns out that setting $\gamma \approx 1.6774$ (the solution of $e^{-1} + e^{-\gamma} - (\gamma - 1)(1 - e^{-1} + e^{-\gamma}) = 0$) ensures that this value is at most $(1 + 2e^{-\gamma})C^*_j$, proving their $(\gamma, 1 + 2e^{-\gamma})$-bifactor. (See Section 6 for the formal treatment of their analysis as well as our improvement.)

Exploit the Geometry of Euclidean Spaces. In order to strictly improve the approximation ratio, it is natural to attempt to find a cluster N and its center j' where the above inequality holds with some additional slack. Let $cost_{j'}(j) = d(j, \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j))$. Intuitively, our goal is to find a cluster $N \subseteq \mathcal{C}$ with center j' such that

$$\sum_{j \in N} cost_{j'}(j) \le \sum_{j \in N} \big((1 - \varepsilon_1)C_j + (3 - \gamma)M_j + (\gamma - 1)D_j\big). \tag{1}$$

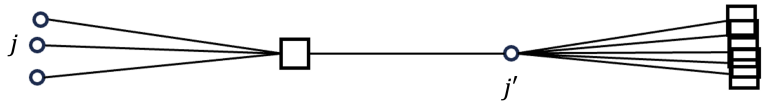

Figure 1 A simple case when $cost_{j'}(j) \approx 3$. There is a client-dense region on the left.

The only requirement from the rounding algorithm is that $N_{j'} \subseteq N$. Compared to [3]'s clustering, we want to shave $\varepsilon_1 \cdot C_j$ on average.

Let us consider the very special case where $C_j = M_j = D_j = 1$ for every $j \in \mathcal{C}$; every facility serving j in the original LP solution (x^*, y^*) is at the same distance from j. Let $j' \in \mathcal{C}$ be a cluster center and $j \in \mathcal{C}$ be in the cluster of j'. Then, a simple *3-hop triangle inequality* (just using $\mathcal{C}_j \cap \mathcal{C}_{j'} \neq \emptyset$) ensures that $cost_{j'}(j) \leq 3$, and our goal is to improve it to $(3 - \varepsilon_1)$. If $cost_{j'}(j) > 3 - \varepsilon_1$, how should the instance look like around j'?

It turns out that the instance around j' must exhibit a very specific structure in order to ensure that the 3-hop triangle inequality is tight for almost every neighbor $j \in N_{j'}$. We must have almost every $j \in N_{j'}$ located around almost the same point at distance 2 from j', where almost all facility neighbors of j' are at the opposite end of the line connecting $N_{j'}$ and j'. See Figure 1 for an example. Intuitively, the existence of such a *dense region* of clients suggests that if we let a client j'' in the region as a new center, many of the 3-hop-triangle inequalities cannot be tight, which implies average rerouting cost $cost_{j''}(j') \leq 3 - \varepsilon_1$. If j'' is again problematic, we can repeat this procedure over and over.

However, if we relax the condition to $C_j = M_j = 1 \leq D_j$, certain exceptions begin to emerge. One possible scenario is as follows: Since $cost_{j'}(j) = d(j, \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j))$ captures the rerouting of j to j''s close facilities $\mathcal{C}_{j'}$ *except the j's facilities* $\mathcal{C}_j \cup \mathcal{D}_j$, if $\mathcal{C}_j \cup \mathcal{D}_j$ is large enough to exclude the facilities of $\mathcal{C}_{j'}$, then $cost_{j'}(j)$ might not behave as expected. However, a large volume of $\mathcal{C}_j \cup \mathcal{D}_j$ implies low C_j^*/F_j^* ratio. If the C^*/F^* ratio is sufficiently low, then this *facility-dominant* instance is actually easier to handle with a completely different algorithm, the JMS algorithm [12], which is known to be $(1.11, 1.7764)$-approximation algorithm.

Therefore, from now on, assume that the cluster centered at j' is connection-dominant. More strictly, assume that for any neighbor j of cluster center j' satisfies that $\mathcal{C}_j \cup \mathcal{D}_j$ cannot cover half of the ball centered at j' with a radius of 1. At this point, we can finally assert that it is impossible to avoid the formation of a dense region of clients.

Assume towards contradiction that there is no dense region and consider j in j''s cluster such that $cost_{j'}(j) > 3 - \varepsilon_1$. Almost all facilities of j' must be placed in one of two locations: on the opposite side of j relative to j', or within $\mathcal{C}_j \cup \mathcal{D}_j$. Since there is no dense region, there must be a neighbor k of j' such that $cost_{j'}(k) > 3 - \varepsilon_1$, and k is located in a different direction from j. This implies that the facilities positioned on the opposite side of j now help reduce $cost_{j'}(k)$, forcing that they are in $\mathcal{C}_k \cup \mathcal{D}_k$; since we assumed that $\mathcal{C}_k \cup \mathcal{D}_k$ cannot cover half of the unit ball around j', it implies the angle $\angle jj'k$ must be strictly greater than $\frac{\pi}{2}$! Ultimately, this process can be simplified to the following situation: inserting unit vectors into a unit sphere with every pairwise angle greater than $\frac{\pi}{2} + \varepsilon$ for some constant $\varepsilon > 0$. It is well known that in the geometry of Euclidean space, there is an upper bound $f(\varepsilon)$ on the number of such vectors, and such an upper bound shows that one of the regions around j (or k) we considered must have been dense. See Figure 2 for an example.

However, there are several technical barriers to extending this notion to the general case without restrictions on C_j, M_j, and D_j. In Section 3, we introduce these barriers and formalize the above concept. We also propose sufficient conditions to satisfy (1). From

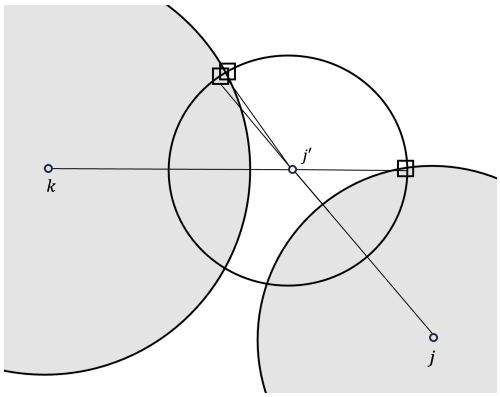

Figure 2 $\mathcal{C}_k \cup \mathcal{D}_k$ contains facilities positioned on the opposite side of j.

Section 3.1 to Section 5, we demonstrate how to remove these conditions, leaving only the connection-dominant instance assumptions. In Section 6, we propose and analyze the full algorithm, which achieves improved bi-factor approximation performance.

3 Finding Good Center via Geometry

In this section, we exploit the geometry of Euclidean spaces to prove the existence of a cluster center strictly better than the greedy choice of [3] under certain conditions (Theorem 10). We first define several concepts and introduce their motivation, including the sketch of our algorithm.

Recall that our goal is to find a cluster that satisfies (1). In all the following propositions, γ is a fixed value in the range $\gamma \in (1.6, 2)$.

▶ **Definition 4.** *Suppose $j' \in \mathcal{C}$ is a cluster center. Let $N_{j'}$ be the set of neighbors of j', and $\varepsilon_1 = 10^{-12}$. Additionally, define two more sets:*

$$N_{j'}^{-} = \{j \in N_{j'} \mid cost_{j'}(j) > (1-\varepsilon_1)C_j + (3-\gamma)M_j + (\gamma-1)D_j\}$$

$$N_{j'}^{+} = \{j \in \mathcal{C} \mid cost_{j'}(j) \leq (1-\varepsilon_1)C_j + (3-\gamma)M_j + (\gamma-1)D_j\}$$

*Moreover, **Saving** and **Spending** of center j' is defined as*

$$Saving(j') = \sum_{j \in N_{j'}^{+}} \{((1-\varepsilon_1)C_j + (3-\gamma)M_j + (\gamma-1)D_j) - cost_{j'}(j)\},$$

$$Spending(j') = \sum_{j \in N_{j'}^{-}} \{cost_{j'}(j) - ((1-\varepsilon_1)C_j + (3-\gamma)M_j + (\gamma-1)D_j)\}.$$

With the goal (1) in mind, $N_{j'}^{+}$ (resp. $N_{j'}^{-}$) contains clients j who meet (resp. do not meet) this goal, and $Saving(j')$ (resp. $Spending(j')$) indicates how much $cost_{j'}(j)$ exceeds (resp. is short of) this goal. Note that $N_{j'}^{-} \subseteq N_{j'} \subseteq N_{j'}^{+} \cup N_{j'}^{-}$ by definition; it is the *best* cluster for center j', which contains all its neighbors (which is required by the algorithm design) and possibly more to increase savings. Therefore, if $Saving(j') \geq Spending(j')$, then j' is considered a *good* center; otherwise, it is a *bad* center.

Now, we will explain some problematic situations that arise when extending the problem to the general case, i.e., without restrictions on C_j, M_j, and D_j's. The first simple concern is that the choice of the center j' will no longer be solely based on $C_{j'} + M_{j'}$ as in Algorithm 1,

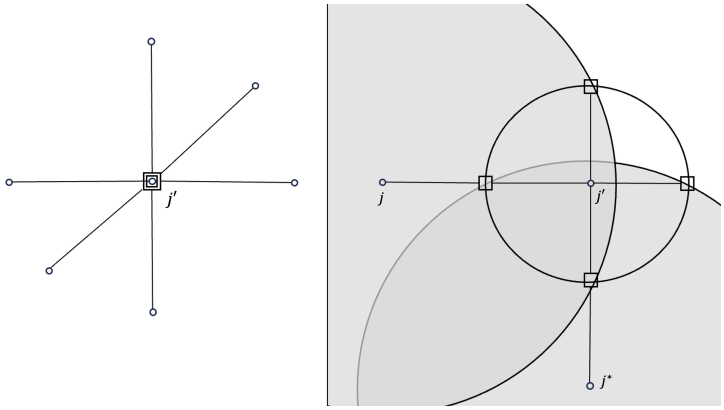

Figure 3 Two examples in a homogeneous network where every neighbor of center j' belongs to $N_{j'}^-$ without creating a dense region.

which breaks the previous arguments. Therefore, to gain more flexibility in selecting a new cluster center, it is beneficial to decompose the entire support graph into several layers, where each layer only concerns clients with roughly the same $C_{j'} + M_{j'}$ values.

▶ **Definition 5.** *A* ***network*** *is a subgraph* $((\mathcal{F}', \mathcal{C}'), E')$ *of the support graph* $G = ((\mathcal{F}, \mathcal{C}), E)$. *A network is called* ***homogeneous*** *if there exists* $s \geq 0$, *such that for any client* $j \in \mathcal{C}'$, $s \leq C_j + M_j \leq (1+\delta)s$ *for* $\delta = 3 \times 10^{-23}$.

However, there are still two more scenarios where the above strategy might not hold, as illustrated in Figure 3. This means that the neighbors in $N_{j'}^-$ are all bad clients, but do not create a dense region.

I. If $C_{j'} \ll s$, the facilities in $\mathcal{C}_{j'}$ are concentrated near j'. In this case, since all the facilities are very close to j', the 3-hop triangle inequality is almost tight for any $j \in N_{j'}$ regardless of where it is.
II. Recall that if $\mathcal{C}_j \cup \mathcal{D}_j$ is large enough to exclude the facilities of $\mathcal{C}_{j'}$, then $cost_{j'}(j)$ might not behave as expected. In particular, a technical problem arises when two facilities from $\mathcal{C}_{j'}$ that are almost antipodal with respect to j' are both contained in $\mathcal{C}_j \cup \mathcal{D}_j$, which is illustrated in Figure 3 (right).

The following definition addresses Scenario I.

▶ **Definition 6.** *For* $K_6 = 1.302$, *let* $\theta = \frac{K_6+1-\gamma}{2K_6+2-\gamma}$. *A client* $j \in \mathcal{C}$ *is* ***normal*** *if* $C_j \geq \theta(C_j + M_j)$, *otherwise* ***weird****.*

The following definition addresses Scenario II. Note that v_j^* is the maximum distance between j and any facility in $\mathcal{C}_j \cup \mathcal{D}_j$. We are interested in the ball around j' of radius $0.998 z_{j'}(j)$ (for sake of analysis), and j having a *small remote arm* with respect to j' means that $\mathcal{C}_j \cup \mathcal{D}_j$ cannot contain two antipodal points in our ball of interest (with some slack depending on α). Let $z_{j'}(j) = d(j', \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j))$. The right-hand side represents the square of the length of the other side of a triangle, where the lengths of the two sides are $d(j', j)$ and $0.998 z_{j'}(j)$, and the included angle between them is $\frac{\pi}{2} - \alpha$.

▶ **Definition 7.** *For normal center* j', *a neighbor* j *of* j' *is said to have a* ***small remote arm*** *if the following holds for* $\alpha = 5 \times 10^{-4}$.

$$(v_j^*)^2 = (C_j^* + F_j^*)^2 < d(j', j)^2 + (0.998 z_{j'}(j))^2 - 2d(j', j) \cdot 0.998 z_{j'}(j) \cdot \cos\left(\frac{\pi}{2} - \alpha\right)$$

Otherwise, j *is said to have a* ***big remote arm****.*

In Section 3.1, we will show that these two scenarios are the only bad cases to worry about. For instance, if we assume that everything is normal and has a small remote arm, each candidate center $j' \in \mathcal{C}$ is either good or contains another candidate center j'' with $Saving(j'') > Saving(j')$ in its dense region.

How can we handle these two bad scenarios? In the following two lemmas, we prove that both the weird center and the big remote arm neighbor imply a high ratio of fractional facility cost $F^*_{j'}$ to fractional connection cost $C^*_{j'}$. The proof appears in the extended version of this paper [14].

▶ **Lemma 8.** *For any weird client j, $C^*_j \le K_6 F^*_j$ holds.*

▶ **Lemma 9.** *When $1.6 < \gamma < 2$, for a normal center j', if $j \in N^-_{j'}$ has a big remote arm, then $C^*_j \le K_6 F^*_j$.*

Therefore, if we consider a (sub)instance that has a low facility-to-connection cost ratio, it is natural to expect to apply this argument, which ultimately leads to a (somewhat) good center. Throughout the paper, we will often express this low facility-to-connection ratio condition will be expressed as $C^* > KF^*$ and use the following values for K: $K_1 = 1.3025 > K_2 = 1.3024 > K_3 = 1.3023 > K_4 = 1.3022 > K_5 = 1.3021 > K_6 = 1.302$. The following theorem is the main result of the section.

▶ **Theorem 10.** *Consider a homogeneous network and let j' be the normal center with the highest saving among all normal centers. Let $c^* = \sum_{j \in N^+_{j'} \cup N^-_{j'}} C^*_j$ and $f^* = \sum_{j \in N^+_{j'} \cup N^-_{j'}} F^*_j$. If $c^* > K_5 f^*$, then this cluster is **good on average** for $\varepsilon_2 = 5 \times 10^{-18}$ and every $\gamma \in (1.6, 2)$. i.e.*

$$\sum_{j \in N^+_{j'} \cup N^-_{j'}} cost_{j'}(j) \le \sum_{j \in N^+_{j'} \cup N^-_{j'}} ((1-\varepsilon_2)C_j + (3-\gamma)M_j + (\gamma-1)D_j).$$

3.1 Geometric Arguments

In this subsection, we prove Theorem 10 using properties of Euclidean geometry. As previously discussed, our goal is to show: When a bad cluster center j' is normal and (many of) its neighbors have a small remote arm, it is possible to find a dense region of clients near j'. When we consider the rerouting of j to j''s close facilities $\mathcal{C}_{j'}$, we can define some *worst* facilities. In the below definition, $B_{j'j} \subseteq \mathcal{C}_{j'}$ is the set of facilities that have the (almost) worst distance from j', and $T_{j'j} \subseteq B_{j'j}$ is the set of facilities with both worst distance and worst angle.

▶ **Definition 11.** *Let $r := 10^{-8}$, and let $\phi_r \approx 2 \times 10^{-4}$ be the minimum angle that satisfies $1 + x^2 + 2x\cos\phi_r \le (1 + (1-r)x)^2$ for $0 \le x \le 2$. For $j \in \mathcal{C}$ and its center j', let*

$$B_{j'j} := \{i \in \mathcal{C}_{j'} \mid 0.999 z_{j'}(j) \le d(i, j') \le M_{j'}\}$$
$$T_{j'j} := \{i \in B_{j'j} \mid \angle jj'i > \pi - \phi_r\}.$$

The following lemma shows that if j' is normal and $j \in N^-_{j'}$ has a bad rerouting through j', then among the facilities in $B_{j'j} \setminus (\mathcal{C}_j \cup \mathcal{D}_j)$, which are the rerouting candidates with worst distance, more than half of them must have a bad angle as well. It is a formalization of the intuition illustrated in Figure 1.

▶ **Lemma 12.** *For any $j \in N^-_{j'}$ of normal center j', $z_{j'}(j) > 0.99 C_{j'}$.*

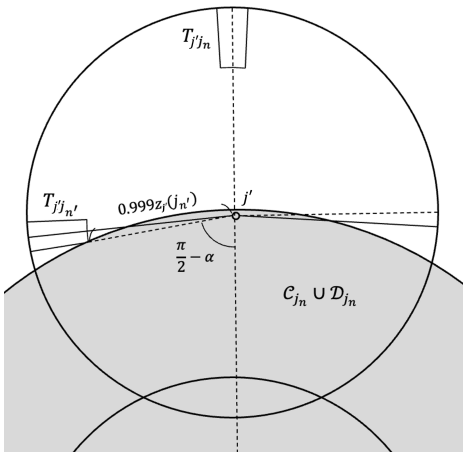

Figure 4 Intersection between a $T_{j'j}$ and a remote arm $\mathcal{C}_j \cup \mathcal{D}_j$.

Proof. By the triangle inequality and the homogeneous condition,

$$\begin{aligned} z_{j'}(j) \geq cost_{j'}(j) - d(j', j) &> (1-\varepsilon_1)C_j + (3-\gamma)M_j + (\gamma-1)D_j - (M_{j'} + M_j) \\ &\geq (1-\varepsilon_1)C_j + (2-\gamma)M_j + (\gamma-1)D_j - ((1+\delta)s - C_{j'}) \\ &\geq -(\varepsilon_1+\delta)s + C_{j'} \geq \left(1 - \frac{\varepsilon_1+\delta}{\theta}\right) C_{j'} \geq 0.99C_{j'}. \end{aligned}$$

◀

▶ **Lemma 13.** *For a normal center j' and any $j \in N_{j'}^-$, let $G_1 = T_{j'j} \cap (\mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j))$, $G_2 = (B_{j'j} \setminus T_{j'j}) \cap (\mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j))$. Then the following holds:*

$$\sum_{i \in G_1} y_i^* > \sum_{i \in G_2} y_i^*.$$

Proof. Assume the nontrivial case: $\mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j) \neq \emptyset$. Let $G_3 = (\mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j)) \setminus (G_1 \cup G_2)$. Let rerouting probability p_n and rerouting length l_n for $1 \leq n \leq 3$ as:

$$p_n = \frac{\sum_{i \in G_n} y_i^*}{\sum_{i \in \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j)} y_i^*}, \quad l_n = \frac{\sum_{i \in G_n} y_i^* \cdot d(i, j')}{\sum_{i \in G_n} y_i^*}$$

Note that $p_1 + p_2 + p_3 = 1$ and $p_1 l_1 + p_2 l_2 + p_3 l_3 = z_{j'}(j)$. Then the goal of this theorem can be written as $p_1 > p_2$.

By Lemma 12, $z_{j'}(j) \geq 0.99C_{j'}$ holds. We derive a lower bound for $p_1 + p_2$ as:

$$z_{j'}(j) = p_1 l_1 + p_2 l_2 + p_3 l_3 \leq (p_1 + p_2) \cdot M_{j'} + (1 - p_1 - p_2) \cdot 0.999 z_{j'}(j)$$

implies that

$$p_1 + p_2 \geq \frac{0.001 z_{j'}(j)}{M_{j'} - 0.999 z_{j'}(j)} \geq \frac{0.001 \cdot 0.99 C_{j'}}{M_{j'}} \geq \frac{0.00099\theta}{1-\theta}$$

since the right-hand side gives the minimum value when $M_{j'}/C_{j'}$ is the maximum. It is bounded because j' is normal.

Denote a position vector as $\vec{v}$. From the definition of ϕ_r, $cost_{j'}(j)$ is at most

$$\begin{aligned} cost_{j'}(j) &= \frac{\sum_{i \in \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j)} y_i^* \, ||(\vec{v_{j'}} - \vec{v_j}) + (\vec{v_i} - \vec{v_{j'}})||}{\sum_{i \in \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j)} y_i^*} \\ &\leq p_1(d(j',j) + l_1) + p_2 \cdot (d(j',j) + (1-r)l_2) + p_3(d(j',j) + l_3) \\ &= d(j',j) + z_{j'}(j) - p_2 r l_2 \\ &\leq C_{j'} + M_{j'} + (2-\gamma)M_j + (\gamma - 1)D_j - p_2 r l_2 \\ &\leq (1 - 0.999 \cdot 0.99 p_2 r) C_{j'} + M_{j'} + (2-\gamma)M_j + (\gamma-1)D_j. \end{aligned}$$

Therefore, since $j \in N_{j'}^-$, $(1-\varepsilon_1)C_j + M_j < (1 - 0.999 \cdot 0.99 p_2 r)C_{j'} + M_{j'} \leq (1 - 0.98 p_2 r)C_{j'} + M_{j'}$ holds. It implies

$$\begin{aligned} \left(1 - \frac{\varepsilon_1}{2}\right)(C_j + M_j) \leq (1-\varepsilon_1)C_j + M_j &< (1 - 0.98 p_2 r)C_{j'} + M_{j'} \\ &\leq ((1 - 0.98 p_2 r)\theta + (1-\theta))(C_{j'} + M_{j'}). \end{aligned}$$

From the homogeneous condition,

$$\left(1 - \frac{\varepsilon_1}{2}\right) < (1 - 0.98 p_2 r \theta)(1 + \delta)$$

which implies

$$p_2 < \frac{1}{0.98\theta r} \cdot \frac{\delta + \frac{\varepsilon_1}{2}}{1+\delta} < \frac{0.00099\theta}{1-\theta} < p_1. \qquad \blacktriangleleft$$

The following argument demonstrates how the positional distribution of facilities in $\mathcal{C}_{j'}$ restricts that of the neighbors in $N_{j'}^-$. Consider two neighbors $j, k \in N_{j'}^-$, both with small remote arms, separated by an angle greater than $2\phi_r$, say $\frac{1}{100}$. Then, $T_{j'j} \cap T_{j'k} = \emptyset$. However, facilities in $T_{j'j}$ reduce $cost_{j'}(k)$ and vice versa, which implies that either $(\mathcal{C}_k \cup \mathcal{D}_k) \cap T_{j'j} \neq \emptyset$ or vice versa. As the small remote arm condition of j puts a limit on how much $(\mathcal{C}_j \cup \mathcal{D}_j)$ can intersect $\mathcal{C}_{j'}$, it is natural to expect that the number of such pairs is small.

▶ **Theorem 14.** *For a normal center j', let S be a subset of $N_{j'}^-$, consisting of clients with a small remote arm. Furthermore, let any two elements $j_1, j_2 \in S$ be separated by an angle greater than $\frac{1}{100}$ with respect to center j', i.e., $\angle j_1 j' j_2 > \frac{1}{100}$. Then, the cardinality of S is bounded by $M = 5 \times 10^6$, independent of the Euclidean space's dimension.*

Proof. Denote $S = \{j_1, j_2, ..., j_{|S|}\}$. Without loss of generality,

$$\sum_{i \in T_{j'j_k} \bigcap (\mathcal{C}_{j'} \setminus (\mathcal{C}_{j_k} \cup \mathcal{D}_{j_k}))} y_i^* \geq \sum_{i \in T_{j'j_{k+1}} \bigcap (\mathcal{C}_{j'} \setminus (\mathcal{C}_{j_{k+1}} \cup \mathcal{D}_{j_{k+1}}))} y_i^*$$

for all $1 \leq k < |S|$. Suppose $T_{j'j_{n'}} \cap (\mathcal{C}_{j_n} \cup \mathcal{D}_{j_n}) = \emptyset$ for some $n' < n$. Additionally, given $j_n \in N_{j'}^-$ and the small arm condition, it implies $T_{j'j_n} \cap (\mathcal{C}_{j_n} \cup \mathcal{D}_{j_n}) = \emptyset$. Therefore, $T_{j'j_{n'}} \cup T_{j'j_n} \subseteq \mathcal{C}_{j'} \setminus (\mathcal{C}_{j_n} \cup \mathcal{D}_{j_n})$. Moreover, $T_{j'j_{n'}} \cap T_{j'j_n} = \emptyset$ since $2\phi_r < \frac{1}{100}$. However, it contradicts to Lemma 13.

We show that two j's in S with similar $z_{j'}(j)$ values form a large angle with j'. Suppose $\angle j_{n'} j' j_n = \beta < \frac{\pi}{2} + \alpha - \phi_r$ for some $n' < n$ with $\frac{z_{j'}(j_n)}{z_{j'}(j_{n'})} \in [\frac{1}{1.001}, 1.001]$. Then for any point $x \in T_{j'j_{n'}}$, it holds that $d(j',x) \geq 0.999 z_{j'}(j_{n'}) > 0.998 z_{j'}(j_n)$ and $\angle j_n j' x < \beta + \phi_r < \frac{\pi}{2} + \alpha$. Also, the quadratic function $d(j',x)^2 - 2d(j',j_n)d(j',x) \cdot \sin(\alpha)$ is shown to be non-decreasing

for $d(j', x) > 0$. It comes from Lemma 12, which ensures that $d(j', x) > 0.998 z_{j'}(j_n) \geq 0.998 \cdot 0.99 C_{j'} \geq 0.98\theta s \geq 2(1+\delta)\sin\alpha \cdot s \geq d(j', j_n) \cdot \sin\alpha$. Therefore, since j_n has a small remote arm,

$$\begin{aligned} d(j_n, x)^2 &= d(j', j_n)^2 + d(j', x)^2 - 2d(j', j_n)d(j', x) \cdot \cos\angle j_n j' x \\ &> d(j', j_n)^2 + d(j', x)^2 - 2d(j', j_n)d(j', x) \cdot \sin\alpha \\ &\geq d(j', j_n)^2 + (0.998 z_{j'}(j_n))^2 - 2d(j', j_n) \cdot 0.998 z_{j'}(j_n) \cdot \sin\alpha \\ &> (C^*_{j_n} + F^*_{j_n})^2 = {v^*_{j_n}}^2 \end{aligned}$$

which implies $T_{j' j_{n'}} \bigcap (\mathcal{C}_{j_n} \cup \mathcal{D}_{j_n}) = \emptyset$, contradicting to the above result. Refer to Figure 4.

According to Rankin [17], the maximum number of disjoint spherical caps, each with an angular radius of $\frac{\pi}{4} + \frac{\alpha - \phi_r}{2}$, is at most $1 + \csc(\alpha - \phi_r)$ in any dimension. Since $0.99 C_{j'} \leq z_{j'}(j) \leq M_{j'}$ holds, it is feasible to segment this range into successive subranges such as $[0.99 C_{j'}, 1.001 \cdot 0.99 C_{j'}]$, $[1.001 \cdot 0.99 C_{j'}, 1.001^2 \cdot 0.99 C_{j'}]$, ..., up to $[M_{j'}/1.001, M_{j'}]$. Thus each subrange can only contain a finite number of clients with a small remote arm. Moreover, the normal center condition ensures a bounded number of such divisions. Consequently, the cardinality of $|S|$ is at most

$$|S| \leq \left(1 + \frac{1}{\sin(\alpha - \phi_r)}\right) \cdot \frac{\log \frac{M_{j'}}{0.99 C_{j'}}}{\log 1.001} \leq \left(1 + \frac{1}{\sin(\alpha - \phi_r)}\right) \cdot \frac{\log \frac{1-\theta}{0.99\theta}}{\log 1.001}. \quad \blacktriangleleft$$

Therefore, if we have a large $S \subseteq N^-_{j'}$ with small remote arms, there must exist a large subset of S whose pairwise angle is small, creating a dense region.

▶ **Lemma 15.** *For a normal center j', let S be a set of clients from $N^-_{j'}$ with a small remote arm. If $S \neq \emptyset$, then there exists a client $j \in S$ for which $Saving(j) \geq \frac{s}{125}\frac{|S|}{M}$.*

Proof. Let S' be a maximal subset of S where any two clients are separated by an angle greater than $\frac{1}{100}$ with respect to the center j'. Then, for any client $j \in S$, there exists a client $z_j \in S'$ such that $\angle j j' z_j \leq \frac{1}{100}$. Therefore, there exists a $z \in S'$ such that the number of clients $j \in S$ for which $z_j = z$ is at least $\frac{|S|}{|S'|}$.

For $1 \leq n \leq 5$, let R_n be a region where

$$R_n = \{x \in \mathbb{R}^l \mid \angle z\, j'\, x \leq \frac{1}{100},\ \frac{2n-2}{5}(1+\delta)s \leq d(j', x) \leq \frac{2n}{5}(1+\delta)s\}.$$

Therefore, there exists an index k such that $|R_k| \geq \frac{|S|}{5|S'|}$. For any two clients $j_1, j_2 \in R_k$, the distance $d(j_1, j_2)$ is bounded by the sum of their radial and angular differences. Hence, $d(j_1, j_2) \leq \frac{2(1+\delta)s}{5} + \frac{2(1+\delta)s}{50} = \frac{11}{25}(1+\delta)s$. From the triangle inequality and the homogeneous condition,

$$\begin{aligned} cost_{j_1}(j_2) &\leq d(j_1, j_2) + M_{j_1} \leq \frac{36}{25}(1+\delta)s \leq \frac{3-\varepsilon_1}{2(1+\delta)}s \\ &\leq (1-\varepsilon_1)C_{j_2} + 2M_{j_2} \leq (1-\varepsilon_1)C_{j_2} + (3-\gamma)M_{j_2} + (\gamma-1)D_{j_2} \end{aligned}$$

which implies $j_2 \in N^+_{j_1}$. By Theorem 14, $|S'| \leq M$. Therefore, the saving of any client $j \in R_k$ is at least

$$\begin{aligned} Saving(j) &\geq \frac{|S|}{5|S'|}\left((1-\varepsilon_1)C_j + (3-\gamma)M_j + (\gamma-1)D_j - \frac{36}{25}(1+\delta)s\right) \\ &\geq \frac{|S|}{5M}\frac{3 - 72\delta - 25\varepsilon_1}{50}s \geq \frac{s}{125}\frac{|S|}{M}. \end{aligned} \quad \blacktriangleleft$$

Given these geometric tools, Theorem 10 follows as the number of big-remote-arm-neighbors of the chosen center j' can be bounded.

▶ **Theorem 10.** *Consider a homogeneous network and let j' be the normal center with the highest saving among all normal centers. Let $c^* = \sum_{j \in N^+_{j'} \cup N^-_{j'}} C^*_j$ and $f^* = \sum_{j \in N^+_{j'} \cup N^-_{j'}} F^*_j$. If $c^* > K_5 f^*$, then this cluster is **good on average** for $\varepsilon_2 = 5 \times 10^{-18}$ and every $\gamma \in (1.6, 2)$. i.e.*

$$\sum_{j \in N^+_{j'} \cup N^-_{j'}} cost_{j'}(j) \leq \sum_{j \in N^+_{j'} \cup N^-_{j'}} ((1-\varepsilon_2)C_j + (3-\gamma)M_j + (\gamma-1)D_j).$$

The proof appears in the extended version of this paper [14].

4 Clustering for Homogeneous Instances

In this section, we present an algorithm that operates on a connection-dominant homogeneous instance, ensuring strictly better performance than a naive greedy clustering strategy. Let $c(i)$ for $i \in \mathcal{C}$ be the center of i when some clustering is given in the context.

▶ **Theorem 16.** *Suppose a homogeneous network $G = ((\mathcal{F}, \mathcal{C}), E)$ satisfies $C^* > K_4 F^*$. Then, the clustering produced by Algorithm 2 is **good on average**. Precisely, for $\varepsilon_3 = 3 \times 10^{-32}$ and every $\gamma \in (1.6, 2)$, the following holds:*

$$\sum_{j \in \mathcal{C}} cost_{c(j)}(j) \leq \sum_{j \in \mathcal{C}} ((1-\varepsilon_3)C_j + (3-\gamma)M_j + (\gamma-1)D_j).$$

Algorithm 2 HOMOGENEOUS: Homogeneous Clustering.

Require: Network $G = ((\mathcal{F}, \mathcal{C}), E)$
  $L = \{\}$
  while $\mathcal{C} \neq \emptyset$ **do**
    if normal client exists in $\mathcal{C}$ **then**
      $c \leftarrow \underset{j \text{ is normal}}{\arg\max}\ Saving(j)$
    else
      $c \leftarrow \underset{j \in \mathcal{C}}{\arg\min}\ (C_j + M_j)$
    end if
    $L \leftarrow L \cup (c, N^+_c \cup N^-_c)$
    $\mathcal{C} \leftarrow \mathcal{C} \setminus (N^+_c \cup N^-_c)$
  end while
  return L

For one of a cluster A made by the algorithm, if the center of A is weird, then the ratio is at most K_6 since all clients within them are weird. If A is not "good", its connection-facility ratio is at most K_5 by Theorem 10. Therefore, the assumed ratio K_4 in this theorem is larger than these values, implying that a constant proportion of clusters are "good" since they satisfy the conditions of Theorem 10. Therefore, by reducing the ε value by that proportion, the desired result can be obtained.

Proof. Divide $\mathcal{C}$ into three groups:

1. Clients clustered by a normal center, where the ratio of that cluster's connection cost to facility cost is greater than K_5.
2. Clients clustered by a normal center, where this ratio is at most K_5.
3. Clients clustered by a weird center.

Let S_n be the set of clients in the n-th group ($1 \le n \le 3$). Here, S_1 and S_2 correspond to clusters formed by the **if** condition, and S_3 is formed by the **else** condition. Define the following values:

$$C_n^* = \sum_{j \in S_n} C_j^*, \quad F_n^* = \sum_{j \in S_n} F_j^*$$

By Theorem 10, $\sum_{j\in S_1} cost_{c(j)}(j) \le \sum_{j\in S_1}((1-\varepsilon_2)C_j+(3-\gamma)M_j+(\gamma-1)D_j)$. The rerouting cost for S_2 is only bounded by the homogeneous condition. For a client j, $cost_{c(j)}(j) \le C_{c(j)}+M_{c(j)}+(2-\gamma)M_j+(\gamma-1)D_j \le (1+\delta)(C_j+M_j)+(2-\gamma)M_j+(\gamma-1)D_j$. Lastly, clients in S_3 are clustered through a greedy strategy. Thus, $cost_{c(j)}(j) \le C_j+(3-\gamma)M_j+(\gamma-1)D_j$. Note that S_3 consists solely of weird clients, meaning $C_3^* \le K_6F_3^* \le K_5F_3^*$.

From above, the total rerouting cost is bounded by:

$$\begin{aligned}
\sum_{j\in\mathcal{C}} cost_{c(j)}(j) &= \sum_{j\in S_1} cost_{c(j)}(j) + \sum_{j\in S_2} cost_{c(j)}(j) + \sum_{j\in S_3} cost_{c(j)}(j) \\
&\le \sum_{j\in S_1}((1-\varepsilon_2)C_j + M_j + (2-\gamma)M_j + (\gamma-1)D_j) \\
&\quad + \sum_{j\in S_2}((1+\delta)(C_j+M_j) + (2-\gamma)M_j + (\gamma-1)D_j) \\
&\quad + \sum_{j\in S_3}(C_j + (3-\gamma)M_j + (\gamma-1)D_j).
\end{aligned}$$

Therefore, it is sufficient to show that

$$(\delta+\varepsilon_3)\sum_{j\in S_2}(C_j+M_j) + \varepsilon_3\sum_{j\in S_3} C_j \le (\varepsilon_2-\varepsilon_3)\sum_{j\in S_1} C_j.$$

Note that $C_2^* + C_3^* \le K_5(F_2^* + F_3^*) < \frac{K_5}{K_4}C^*$ holds, which means $C_1^* > \left(1-\frac{K_5}{K_4}\right)C^*$. Also $C_1^* > K_4F_1^*$, since $C_2^* + C_3^* \le K_5(F_2^* + F_3^*)$. Then the following holds:

$$\begin{aligned}
&(\delta+\varepsilon_3)\sum_{j\in S_2}(C_j+M_j) + \varepsilon_3\sum_{j\in S_3} C_j \\
&\le (\delta+\varepsilon_3)\sum_{j\in S_2\cup S_3}(C_j+M_j) \le (\delta+\varepsilon_3)\sum_{j\in\mathcal{C}}(C_j+D_j) \\
&\le (\delta+\varepsilon_3)(2C^* + (2-\gamma)F^*) \\
&\le \frac{(\delta+\varepsilon_3)(2-\gamma+2K_4)}{K_4}C^* \\
&\le (\varepsilon_2-\varepsilon_3)\frac{(K_5-\gamma+1)(K_4-K_5)}{K_4K_5}C^* \le (\varepsilon_2-\varepsilon_3)\frac{K_5-\gamma+1}{K_5}C_1^* \\
&\le (\varepsilon_2-\varepsilon_3)(C_1^* - (\gamma-1)F_1^*) \le (\varepsilon_2-\varepsilon_3)\sum_{j\in S_1} C_j.
\end{aligned}$$

◀

5 Clustering for Connection-dominant Instances

In this section, we introduce an algorithm that operates on connection-dominant instances without a homogeneous condition. This algorithm uses Algorithm 1 and Algorithm 2 as subroutines. The theorem stated below shows our main result.

▶ **Theorem 17.** *For any connection-dominant instance, i.e. $C^* > K_1 F^*$, there exists an algorithm that finds a clustering configuration whose rerouting cost is at most*

$$\sum_{j\in\mathcal{C}} cost_{c(j)}(j) \le \sum_{j\in\mathcal{C}}((1-\varepsilon_5)C_j + (3-\gamma)M_j + (\gamma-1)D_j)$$

for $\varepsilon_5 = 2\times 10^{-41}$ and every $\gamma \in (1.6, 2)$.

▶ **Definition 18.** *Let B_0 be the set of clients for which $C_j + M_j = 0$. Let $s = \min_{j\in\mathcal{C}\setminus B_0}(C_j + M_j)$. For $\delta' = 7\times 10^{-32}$, let a **Block** B_n be the set of clients such that*

$$B_n = \{j \in \mathcal{C} \mid (1+\delta')^{n-1}s \le C_j + M_j < (1+\delta')^n s\}$$

Note that if $(1+\delta')^m \le (1+\delta)$, then a network composed of at most m consecutive blocks is still homogeneous. However, applying Algorithm 2 directly to each block would be impossible when the block is a facility-dominant or neighbors of the center from some block may belong to a different block. Moreover, the following fact implies that the neighbor relationships between consecutive blocks are the main point.

▶ **Observation 19.** *If two neighbors $j, j' \in \mathcal{C}$ belonging to neither the same block nor consecutive blocks, satisfying $(1+\delta')(C_j + M_j) \le C_{j'} + M_{j'}$, then $j' \in N_j^+$ holds when $Saving(\cdot)$ criteria ε satisfies that $\varepsilon \le \frac{2\delta'}{1+\delta'}$.*

Proof.

$$\begin{aligned} cost_j(j') &\le C_j + M_j + (2-\gamma)M_{j'} + (\gamma-1)D_{j'} \le \frac{C_{j'}+M_{j'}}{1+\delta'} + (2-\gamma)M_{j'} + (\gamma-1)D_{j'} \\ &\le \left(1 - \frac{2\delta'}{1+\delta'}\right)\cdot C_{j'} + (3-\gamma)M_{j'} + (\gamma-1)D_{j'}. \end{aligned}$$

◀

A key idea is that with a sufficiently small δ', the support graph can be segmented almost arbitrarily while still preserving the homogeneous condition, enabling the identification of weak *connections* between consecutive blocks. Notably, even if two clients $j \in B_n$ and $j' \in B_{n+1}$ come from consecutive blocks, the $cost_j(j')$ is not worse than the greedy strategy.

▶ **Definition 20.** *An **interval** I is the set of consecutive blocks, up to a maximum $2L$ for $L = 2\times 10^8$. Precisely, $I = \{B_i, \ldots, B_{i+k}\}$ for $k < L$, where $\sum_{j=i}^{i+k} C^*(B_j) - C^*(B_i) \ge K_3 \sum_{j=i}^{i+k} F^*(B_j)$, except when $k = 0$. The **size** of an interval I is the number of blocks it contains, denoted as $|I|$. The **reward** of interval I is defined as $R(I) = \sum_{j=i}^{i+k} C^*(B_j) - C^*(B_i)$.*

Note that a block is a unique type of interval with a size of 1. Also $(1+\delta')^{2L} \le 1+\delta$ holds. An interval is the basic unit of clustering to which Algorithm 1 and Algorithm 2 are applied. Therefore, the reward of an interval represents the extent to which a guaranteed *Saving* can be obtained when the current interval can be clustered using Algorithm 2, regardless of how the preceding intervals have been clustered. From this perspective, the first block, which does not contribute to the reward, serves as a kind of "buffer".

Given the entire support graph $G = (\mathcal{F} \cup \mathcal{C}, E)$ and a subset $\mathcal{C}' \subseteq \mathcal{C}$, let $G_{\mathcal{C}'}$ be the subgraph (network) induced by $\mathcal{F} \cup \mathcal{C}'$. Consequently, when we call Algorithms 1 or 2 with $G_{\mathcal{C}'}$, the calculations for *Saving* and *Spending* are performed solely with respect to the implicitly defined client set $\mathcal{C}'$. We denote Algorithm 1 as GREEDY and Algorithm 2 as HOMOGENEOUS. For simplicity, when I denotes an interval, we interpret the expression $\sum_{j \in I}$ as $\sum_{B \in I} \sum_{j \in B}$, aggregating over all clients within the interval. The following theorem illustrates how reward is related to *Saving*. The proof appears in the extended version of this paper [14].

▶ **Lemma 21.** *Let J be a set of non-overlapping intervals. Then clustering produced by Algorithm 3 is* ***good on average****. Precisely, for $\varepsilon_4 = 2 \times 10^{-36}$,*

$$\sum_{j \in \mathcal{C}} cost_{c(j)}(j) \leq \sum_{j \in \mathcal{C}} \left(\left(1 - \frac{\sum_{I \in J} R(I)}{\sum_{j' \in \mathcal{C}} C_{j'}} \varepsilon_4 \right) C_j + (3 - \gamma) M_j + (\gamma - 1) D_j \right).$$

Algorithm 3 CONN: Connection-dominant Clustering.

Require: Set of disjoint intervals $J = \{I_1, I_2, \ldots, I_m\}$, arranged in the increasing order of $C_j + M_j$ values of their clients.
  $L = \{\}$
  for $k = 1$ to m **do**
    if $|I_k| \geq 2$ and $\sum_{j \in I_k} C_j^* > K_4 \sum_{j \in I_k} F_j^*$ **then**
      $L \leftarrow L \cup \text{HOMOGENOUS}(G_{I_k})$
    else
      $L \leftarrow L \cup \text{GREEDY}(G_{I_k})$
    end if
    $S := \bigcup_{j \in I_k} \left(N_j^+ \cup N_j^- \right)$
    for $l = k$ to m **do**
      $I_l \leftarrow I_l \setminus S$
    end for
  end for
  return L

In conclusion, it suffices to find a set of non-overlapping intervals J which have a high $R(J)$ value. Here, we will briefly touch on the idea. We will iterate through the blocks in reverse order $(B_N, \ldots, B_0)$, cutting out suitable ranges that satisfy the interval conditions. Fix a point r to be the right end of the interval, and expand the left end of the current range one block to the left until the range is suitable for processing. Suppose, at some point, the C/F value of the current range is less than K_2, which is strictly less ratio of the input instance, K_1. Then, this range can be considered a minor part and can be excluded as there is no need for it to become an interval. Therefore, we only consider cases where the current range has a C/F value of at least K_2.

However, in the situation where the current range's reward is small, meaning that the first block must avoid most of the C^*. In this case, if we keep expanding the range to the left, we will eventually reach the initial block B_0, satisfying the interval condition. There remains a subtle issue of the range's length exceeding $2L$ during the expansion process, but this implies that the C^* value on the left side of the range is always exponentially increasing compared to the right side. This can be resolved by appropriately reducing the right side of the range.

▶ **Lemma 22.** *For any support graph G that is connection-dominant, $C^* > K_1 F^*$, then the set of non-overlapping intervals J obtained by Algorithm 4 satisfies $\sum_{I \in J} R(I) \geq \frac{1}{10^5} C^*$.*

Algorithm 4 CUTINTERVAL: Find a set of non-overlapping intervals J with large rewards.

Require: Network $G = ((\mathcal{F}, \mathcal{C}), E)$.
  $J := \emptyset$
  $r := N$
  while $r > 0$ **do**
    $l := r$
    $c := 0, f := 0$
    while $l \geq 0$ **do**
      if $c \geq K_3(f + F^*(B_l))$ and $C^*(B_l) \leq \frac{K_2 - K_3}{K_2} c$ **then**
        $J \leftarrow J \cup \{[l, r]\}$
        $r \leftarrow l - 1$
        break
      end if
      $c \leftarrow c + C^*(B_l), f \leftarrow f + F^*(B_l)$
      if $c < K_2 f$ **then**
        $r \leftarrow l - 1$
        break
      end if
      if $r - l + 1 = 2L$ **then**
        $c \leftarrow c - \sum_{i=l+L}^{r} C^*(B_i), f \leftarrow f - \sum_{i=l+L}^{r} F^*(B_i)$
        $r \leftarrow r - L$
      end if
      $l \leftarrow l - 1$
    end while
  end while
  Include in J every block (as an interval of size 1) not already part of J
  return J

The proof appears in the extended version of this paper [14].

By directly applying Lemma 21 and Lemma 22, Theorem 17 can be proved.

6 Improved Bifactor Approximation

In this section, we present an improved bifactor approximation algorithm for UFL, proving Theorem 1. To deal with facility-dominant instances, we employ the JMS algorithm [12], which is known to be $(1.11, 1.7764)$-approximation algorithm.

Now, we will show that Algorithm 5 satisfies Theorem 1. Let $\gamma_0 \leq 1.6774$ be a solution of the below equation.

$$\frac{1}{e} + \frac{1}{e^\gamma} - (\gamma - 1)(1 - \frac{1}{e} + (1 - \varepsilon_5)\frac{1}{e^\gamma}) = 0.$$

To prove Theorem 1, we consider two cases. When $C^* \leq K_1 F^*$, the inequality $1.11F^* + 1.7764C^* \leq 1.6774F^* + (1 + 2e^{-1.6774} - \varepsilon_6)C^*$ holds. For the case $C^* > K_1 F^*$, we can employ the same proof structure as the statement proved in [3][2]. The proof appears in the extended version of this paper [14].

[2] Theorem 4.3 of [3]

Algorithm 5 Overall bi-factor clustering process.

Derive $(\bar{x}, \bar{y})$ from the optimal LP primal solution (x^*, y^*).
if $C^* \leq K_1 F^*$ **then**
  Execute the $(1.11, 1.7764)$-approximation algorithm.
else
  Proceed with CONN(CUTINTERVAL(G)) (Algorithm 3 and 4).
  for all cluster centers j **do**
    Open exactly one nearby facility with a probability of $\bar{x}_{ij}$.
  end for
  for all facilities i not close to any cluster center **do**
    Open each facility with a probability of $\bar{y}_i$ independently.
  end for
  Connect each client to the nearest open facility.
end if

7 Improved Unifactor Approximation

In this section, we propose the algorithm that guarantees better unifactor approximation suggested by Li [15], proving Theorem 2.

Framework of [15]. Li showed that a hard instance for a certain γ might not be a hard instance for another value of γ. This suggests that selecting a γ value at random could improve the expected performance of the algorithm.

They introduced a *characteristic function* $h : (0, 1] \to \mathbb{R}$ to represent the distribution of distances between a client and its neighboring facilities. For a client $j \in \mathcal{C}$, assume $i_1, i_2, \ldots, i_k$ are the facilities within $\mathcal{C}_j \cup \mathcal{D}_j$, ordered by increasing distance from j. Then, for $0 < p \leq 1$, $h_j(p)$ is defined as $d(j, i_t)$, where t is the smallest index satisfying $\sum_{l=1}^{t} y^*_{i_l} \geq p$. Also, they improved the bound of the rerouting cost as $d(j, \mathcal{C}_{j'} \setminus (\mathcal{C}_j \cup \mathcal{D}_j)) \leq (2-\gamma)M_j + (\gamma-1)D_j + C_{j'} + M_{j'}$. For fixed γ, the expected connection cost for j for the aforementioned algorithm of [3] is at most

$$\mathbb{E}[C_j] \leq \int_0^1 h_j(p) e^{-\gamma p} \gamma \, dp + e^{-\gamma} \left(\gamma \int_0^1 h_j(p) \, dp + (3-\gamma) h_j(\frac{1}{\gamma}) \right).$$

Therefore, it can be modeled as a 0-sum game to analyze the approximation ratio. The characteristic function for the whole instance is given by $h(p) = \sum_{j \in \mathcal{C}} h_j(p)$. Assuming h is normalized so that $\int_0^1 h(p) \, dp = 1$, the algorithm proceeds as follows: with probability κ, it employs the JMS algorithm [12]. Mahdian [16] proved that the JMS algorithm achieves a $(1.11, 1.7764)$-approximation. Otherwise, γ is sampled randomly from the distribution $\mu : (1, \infty] \to \mathbb{R}^*$, ensuring that $\kappa + \int_1^\infty \mu(\gamma) \, d\gamma = 1$. Thus, the value of the 0-sum game, i.e., the approximation ratio of the algorithm under a fixed strategy (κ, μ), is calculated as follows:

$$\nu(\kappa, \mu, h) = \max\left\{ \int_1^\infty \gamma \mu(\gamma) \, d\gamma + 1.11\kappa, \int_1^\infty \alpha(\gamma, h) \mu(\gamma) \, d\gamma + 1.7764\kappa \right\}$$

where

$$\alpha(\gamma, h) = \int_0^1 h(p) e^{-\gamma p} \gamma \, dp + e^{-\gamma} \left(\gamma + (3-\gamma) h\left(\frac{1}{\gamma}\right) \right).$$

Moreover, for a given probability density function μ for γ, it can be shown that the characteristic function for the hardest instance is a *threshold function*, which defined as

$$h_q(p) = \begin{cases} \frac{1}{1-q}, & \text{for } p > q \\ 0, & \text{for } p \le q \end{cases}$$

for some $0 \le q < 1$. This means that the final approximation ratio for some μ is given by $\max_{0 \le q < 1} \nu(\kappa, \mu, h_q)$. In [15], the suggested distribution for α_{Li} is $\mu(p) = \theta D(p - \gamma_1) + \frac{1-\kappa-\theta}{\gamma_2-\gamma_1}[\gamma_1 < p < \gamma_2]$, where D is Dirac delta function, $\gamma_1 = 1.479311$, $\gamma_2 = 2.016569$, $\theta = 0.503357$, $\kappa = 0.195583$.

Our Improvement. By using Algorithm 5, the expected connection cost for some γ and characteristic function h is given as follows:

$$\alpha'(\gamma, h) = \begin{cases} \int_0^1 h(p) e^{-\gamma p} \gamma \, dp + e^{-\gamma} \left(\gamma(1-\varepsilon_7) + (3-\gamma) h(\frac{1}{\gamma}) \right), & \text{if } 1.6 < \gamma < 2 \\ \int_0^1 h(p) e^{-\gamma p} \gamma \, dp + e^{-\gamma} \left(\gamma + (3-\gamma) h(\frac{1}{\gamma}) \right). & \text{otherwise} \end{cases}$$

Therefore, we define a new 0-sum game value as follows, assuming h is scaled up such that $\int_0^1 h(p)\, dp = 1$.

$$\nu'(\mu, \theta, h) = \max\left\{ \int_1^\infty \gamma \mu(\gamma)\, d\gamma + 1.11\kappa, \int_1^\infty \alpha'(\gamma, h)\mu(\gamma)\, d\gamma + 1.7764\kappa \right\}.$$

Note that α' is still linear for h. Therefore, even if the game definition changes, the adversary's choice of the characteristic function h remains a threshold function h_q for some $0 \le q < 1$. Given that there is a positive probability of sampling γ between 1.6 and 2, it is possible to achieve a lower cost.

▶ **Lemma 23.** *Let $\mu_2(\gamma) = (1-\varepsilon_7)\mu_1(\gamma) + \varepsilon_7(1-\kappa_2)D(\gamma - 1)$, where D is a Dirac-delta function. Then the following holds:*

$$\begin{aligned} &\max_{0 \le q < 1} \max\left\{ \int_1^\infty \gamma \mu_2(\gamma)\, d\gamma + 1.11\kappa_2, \int_1^\infty \alpha'(\gamma, h_q)\mu_2(\gamma)\, d\gamma + 1.7764\kappa_2 \right\} \\ &< \max_{0 \le q < 1} \max\left\{ \int_1^\infty \gamma \mu_1(\gamma)\, d\gamma + 1.11\kappa_2, \int_1^\infty \alpha(\gamma, h_q)\mu_1(\gamma)\, d\gamma + 1.7764\kappa_2 \right\} - \frac{\varepsilon_7}{1000}. \end{aligned}$$

The proof appears in the extended version of this paper [14].

Therefore, we present an improved unifactor approximation algorithm, Algorithm 6.

When $C^* \le K_1 F^*$, an inequality $1.11F^* + 1.7764C^* \le 1.487F^* + 1.487C^*$ is satisfied. For the case $C^* > K_1 F^*$, by Lemma 23, Algorithm 6 shows an improved unifactor approximation with $\varepsilon_8 = \frac{\varepsilon_7}{1000} = 2 \times 10^{-45}$.

8 APX-Hardness

In this section, we prove that UFL is APX-Hard in Euclidean spaces. We use the following result from Austrin, Khot, and Safra [2]. For $\rho \in [-1, +1]$ and $\mu \in [0, 1]$, let $\Gamma_\rho(\mu) := \Pr[X \le \Phi^{-1}(\mu) \wedge Y \le \Phi^{-1}(\mu)]$ where X, Y are standard Gaussian random variables with covariance ρ and Φ is the cumulative density function of the standard normal distribution.

Algorithm 6 Overall uni-factor clustering process.

Derive $(\bar{x}, \bar{y})$ from the optimal LP primal solution (x^*, y^*).
Let X be a random variable that takes the value 1 with probability $1-\kappa_2$, and 0 otherwise.

if $C^* \leq K_1 F^*$ **then**
  Execute the $(1.11, 1.7764)$-approximation algorithm.
else if X $= 1$ **then**
  Execute the $(1.11, 1.7764)$-approximation algorithm.
else
  Takes γ from the distribution $\mu_2(\gamma) = (1-\varepsilon_7)\mu_1(\gamma) + \varepsilon_7(1-\kappa_2)D(\gamma-1)$.
  if $1.6 \leq \gamma \leq 2$ **then**
    Proceed with CONN(CUTINTERVAL(G)) (Algorithm 3 and 4).
  else
    Proceed with GREEDY(G).
  end if
  for all cluster centers j **do**
    Open exactly one nearby facility with a probability of $\bar{x}_{ij}$.
  end for
  for all facilities i not close to any cluster center **do**
    Open each facility with a probability of $\bar{y}_i$ independently.
  end for
  Connect each client to the nearest open facility.
end if

▶ **Theorem 24.** *Assuming the Unique Games Conjecture, for any $q \in (0, 1/2)$ and $\varepsilon > 0$, it is NP-hard to, given a graph $G = (V, E)$, distinguish between the following two cases.*

- *(Completeness) G contains an independent set of size $q|V|$.*
- *(Soundness) For any $T \subseteq V$, the number of edges with both endpoints in T is at least $|E| \cdot (\Gamma_{-q/(1-q)}(\mu) - \varepsilon)$ where $\mu = |T|/|V|$.*

Fix an arbitrary $q \in (0, 1/2)$. Without loss of generality, assume $V = [n]$. Also let $m := |E|$. Our UFL instance has V as the set of facilities and E as the set of clients. The ambient Euclidean space is $\mathbb{R}^n$, and let e_i be the ith standard unit vector (i.e., $(e_i)_i = 1$ and $(e_i)_j = 0$ for every $j \neq i$). Then each facility $i \in V$ is located at e_i and each client $(i, j) \in E$ is located at $e_i + e_j$. Finally, let λ be the common facility cost for every $i \in \mathcal{F}$ to be determined. This finishes the description of the UFL instance.

In the completeness case, there is an independent set U of size qn. We open $V \setminus U$. Since $V \setminus U$ is a vertex cover, every client in E has a facility at distance 1, so the total cost is

$$\lambda(1-q)n + m.$$

In the soundness case, consider any solution that opens $S \subseteq V$ and let $T = V \setminus S$ and $\mu = |T|/n$. By the soundness guarantee, at least $m(\Gamma_{-q/(1-q)} - \varepsilon)$ clients do not have a facility at distance 1. Since every client-facility distance is either 1 or $\sqrt{3}$, the total cost is at least

$$\lambda(1-\mu)n + m\big(1 + (\sqrt{3}-1)(\Gamma_{-q/(1-q)}(\mu) - \varepsilon)\big). \tag{2}$$

For fixed q, the function $\Gamma_{-q/(1-q)}(\mu)$ is a strictly convex function of μ, so if we let λ such that

$$-\lambda n + m(\sqrt{3}-1)\frac{d\Gamma_{-q/(1-q)}(\mu)}{d\mu}|_{\mu=q} = 0,$$

then (2) is minimized when when $\mu = q$, which becomes

$$\lambda(1-q)n + m\big(1 + (\sqrt{3}-1)(\Gamma_{-q/(1-q)}(q) - \varepsilon)\big).$$

Furthermore, we can notice that

$$\lambda = \frac{m}{n} \cdot (\sqrt{3}-1)\frac{d\Gamma_{-q/(1-q)}(\mu)}{d\mu}|_{\mu=q} = \Theta(\frac{m}{n}).$$

Then one can see that the optimal value in the soundness case is at least $m(\sqrt{3}-1)(\Gamma_{-q/(1-q)}(q) - \varepsilon)$ larger than the optimal value in the completeness case. For a fixed q, by choosing ε sufficiently small, one can ensure that this excess is at least a δ fraction of the completeness case optimal value for some constant $\delta > 0$, which proves a $(1+\delta)$-hardness of approximation.

9 Conclusion

The most natural open problem is to get an improved approximation for bifactor or unifactor approximation for UFL. Though we show a strict separation between general and Euclidean metrics for bifactor approximation in a certain regime, it is not achieved for all regimes of bifactor or unifactor approximation.

Whereas our algorithm is based on the *primal rounding* approach of [3] and [15], it might be a fruitful research direction to design a variant of the Jain-Mahdian-Saberi algorithm [12] (greedy algorithm analyzed by the dual fitting method) or Jain-Vazirani [13] (primal-dual algorithm) for a further improvement. In particular, as the best unifactor approximation for UFL in both general and Euclidean metrics employ the $(1.11, 1.7764)$-approximation of the JMS algorithm as a black box, improving the JMS algorithm will directly yield a better result for the best unifactor approximation for UFL. The JV algorithm was already improved in Euclidean spaces [1, 10, 4], but they are not enough for UFL.

Abstract

In this paper, we study the impossibility of constructing perfect complete quantum public key encryption (QPKE) from quantumly secure one-way functions (OWFs) in a black-box manner. We show that this problem is connected to a fundamental conjecture about the roots of low-degree polynomials on the Boolean hypercube. Informally, the conjecture asserts that for every nonconstant low-degree polynomial, there exists a universal (randomized) way to modify a small number of input bits such that, for every input string, the polynomial evaluated on the modified input string avoids 0 with sufficiently large probability (over the choice of how the input string is modified). Assuming this conjecture, we demonstrate the impossibility of constructing QPKE from quantumly secure one-way functions in a black-box manner, by employing the information-theoretical approach recently developed by Li, Li, Li, and Liu (CRYPTO'24). Towards resolving this conjecture, we provide various pieces of evidence supporting it and prove some special cases. In particular, we fully rule out perfect QPKE from OWFs when the key generation algorithm only makes a logarithmic number of quantum queries, improving the previous work, which can only handle classical queries.

1 Introduction

Public-key encryption (PKE) is a fundamental primitive in modern cryptography. It enables secure communication through an insecure channel. A server generates two keys, the secret key and the public key; the secret key is owned only by the server, whereas the public key is broadcasted to everyone else. PKE allows everyone to send messages to the server securely; even if a malicious party, who keeps listening to the channel, has no idea about the actual messages. Its counterpart, secret-key encryption, requires pre-shared keys to conduct secure

communication. Since the first proposal [1] by Diffie and Hellman [13], PKE has become one of the most important cryptographic primitives and concepts, with impacts ranging from theoretical computer science to real-world constructions.

Despite enjoying all the advancements in secret-key encryption (SKE), all PKE schemes have more structures. Therefore, PKE seems to require strictly stronger assumptions than one-way functions. This observation was later confirmed by Impagliazzo and Rudich [16]: there was no black-box construction of PKE solely from one-way functions (or in the random oracle model).

Quantum information has changed the landscape of cryptography, especially weakening the assumptions needed for various cryptographic primitives; for example, quantum key distribution [10], oblivious transfer/multi-party computation [7, 15], commitment [3, 23]. Talking about PKE, first introduced by Morimae and Yamakawa [22], then followed by [12, 17, 19, 6], QPKE with either quantum keys or quantum ciphertext can be constructed from OWFs. However, quantum public keys and quantum ciphertext are often more difficult to broadcast, use and authenticate than their classical counterparts. Thus, the possibility of basing quantum PKE with classical public key, secret key and ciphertext on one-way functions is still intriguing and largely unanswered. In the rest of the work, we will simply denote such QPKE with classical keys and ciphertext by "QPKE". Following the similar questions in [16], in this work, we are interested in the problem:

Question 1: Whether QPKE can be constructed solely in the quantum random oracle model (QROM)?

The direction was investigated first by Austrin, Chung, Chung, Fu, Lin and Mahmoody [5] and later by Li, Li, Li and Liu [18]. Austrin et al. proposed the so-called "polynomial compatible conjecture" (or PCC for short); basing on PCC, they fully rule out QPKE from OWFs. However, their conjecture is tailored to this separation problem; to which we will compare our conjecture later on. Besides, they are able to prove the non-existence of perfect complete QPKE in the QROM when (i) Enc or (ii) both Gen and Dec make only classical queries to a random oracle. Li et al. improved the result (ii) and showed that as long as the key generation algorithm Gen only makes classical queries, perfect correct QPKE can not exist in the QROM.

1.1 Our Results

In this work, we show that Question 1 is closely related to a fundamental conjecture about the roots of low-degree polynomials on the Boolean hypercube. More specifically, we propose the following conjecture, and show that it implies a full impossibility result of perfect complete QPKE in the QROM.

▶ **Conjecture 1.** *For any nonconstant function $f : \{-1,1\}^n \to \mathbb{R}$ with degree d, the following holds. There exists a distribution $\mathcal{D}$ on the set of partial assignments ρ with $|\rho| \leq \mathrm{poly}(d)$ such that: for any $x \in \{-1,1\}^n$,*

$$\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/\mathrm{poly}(d).$$

[1] The UK Government Communications Headquarters proposed and developed the same scheme even earlier than Diffie and Hellman (1973 and 1974), and was later declassified by the British government in 1997.

A partial assignment is denoted by $\rho \in \{-1, 1, \star\}^n$ and $|\rho|$ is defined as the number of non-$\star$ entries. x^ρ is defined as an input string whose i-th bit will be equal to x_i if $\rho_i = \star$, and otherwise equal to ρ_i. In other words, the conjecture asserts that for every degree d nonconstant f, there is a universal (randomized) way to modify $\mathrm{poly}(d)$ bits such that, every input string x has an inverse-polynomial probability of evaluating to non-zero under this randomized modification.

▶ Remark 2 (Comparing PCC in [5] with our conjecture). PCC (Conjecture 1.2) roughly asserts that, for two distributions F, G over low degree polynomials with bounded influences, there always exists $f \in F, g \in G$ and x such that $f(x)g(x) \neq 0$. To the best of our knowledge, there is no obvious connection between PCC and our conjecture. Nonetheless, we hold that our conjecture appears simpler and offers an alternative path towards the ultimate objective; since our conjecture only involves a single polynomial (instead of two distributions) and resembles many fundamental notions in the literature of boolean function analysis. Furthermore, PCC might be too strong to hold: as it will imply attacks with only a polynomial number of classical queries, even if both Alice and Bob make quantum queries; on the other hand, our Eve makes quantum queries.

With the conjecture, we now present our main theorem.

▶ **Theorem 3** (Main Theorem). *If Conjecture 1 is true, then perfect complete QPKE does not exist in the QROM.*

▶ Remark 4. In the proof of Theorem 3, f is treated as a probability and ranges in $[0, 1]$. However, it would not weaken Conjecture 1 if we restrict the range of f to $[0, 1]$. Precisely, in Conjecture 1, it does not lose generality to assume that f is nonnegative, because we can consider f^2 instead; then we can scale the function to fit in the range $[0, 1]$.

Conjecture 1 is closely related to notions like certificate complexity, sensitivity in the literature of boolean function analysis (BFA), and also to the celebrated Combinatorial Nullstellensatz of Alon [2], making it a considerably natural conjecture. With the tools in BFA and the Combinatorial Nullstellensatz, we can provide many pieces of evidence and prove special cases. We mention some of the most important results below while leaving others in the main body.

Special Case 1: Gen makes only classical queries

This is the case that already was analyzed in [18]; there, they did not go through BFA, but rather proved it directly. We demonstrate the versatility of our conjecture and framework, by showing:

▶ **Lemma 5.** *Conjecture 1 holds for all f that can be expressed as the acceptance probability of a (randomized) classical decision tree.*

▶ **Corollary 6** (Recasting [18]). *Perfect complete QPKE does not exist in the QROM, if* Gen *only makes classical queries.*

Evidence 2: The Combinatorial Nullstellensatz

The following relaxed version of Conjecture 1 directly follows from the Combinatorial Nullstellensatz of Alon (Lemma 22).

▶ **Lemma 7.** *For any nonconstant function $f : \{-1,1\}^n \to \mathbb{R}$ with degree d, the following holds. There exists a distribution $\mathcal{D}$ on the set of partial assignments ρ with $|\rho| \leq d$ such that: for any x,*

$$\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/2^d.$$

Somewhat surprisingly, we find that if the probability of $f(x^\rho)$ being non-zero in Lemma 7 can be improved from $1/2^d$ to $1/2^{d^c}$ for an arbitrary $c < 1$, then Conjecture 1 would be affirmed. Formally, the following conjecture is equivalent to Conjecture 1:

▶ **Conjecture 8.** *There is a universal constant $c < 1$, such that for any nonconstant function $f : \{-1,1\}^n \to \mathbb{R}$ with degree d, the following holds. There exists a distribution $\mathcal{D}$ on the set of partial assignments ρ with $|\rho| \leq \mathrm{poly}(d)$ such that: for any x,*

$$\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/2^{d^c}.$$

▶ **Lemma 9.** *Conjecture 8 holds if and only if Conjecture 1 holds.*

Special Case 3: Gen makes $O(\log n)$ quantum queries

With Lemma 7, by following a similar argument in [18], we can directly conclude that when the generation algorithm only makes $O(\log n)$ quantum queries, such QPKE does not exist in the QROM.

▶ **Lemma 10.** *Perfect complete QPKE does not exist in the QROM, if* Gen *only makes $O(\log n)$ quantum queries.*

Thus, we make a step forward by improving the result (ii) in [5] and that in [18].

Table 1 Provable separations in [5, 18] and this work. Q and C denote a polynomial number of quantum and classical queries, respectively.

	[5] (i)	[5] (ii)	[18]	This work
Gen	Q	C	C	log Q
Enc	C	Q	Q	Q
Dec	Q	C	Q	Q

Special Case 4: Gen has "uniform" outputs

Here, by **"uniform"**, we mean that the output of Gen^H has support of the same size for every possible oracle H, and the output distribution is uniform over the support. In other words, $|\mathsf{supp}(\mathsf{Gen}^H)| = |\mathsf{supp}(\mathsf{Gen}^{H'})|$ for every pair of H, H', and Gen^H is uniform over samples with a non-zero probability. To resolve this case, we prove the following special case of Conjecture 1:

▶ **Lemma 11.** *Conjecture 1 holds for all f that takes at most $\mathrm{poly}(d)$ values.*

▶ **Corollary 12.** *Perfect complete QPKE does not exist in the QROM, if* Gen *is "uniform".*

Evidence 5: Other equivalent conjectures

By the min-max principle, Conjecture 1 has the following equivalent form.

▶ **Conjecture 13.** *For any nonconstant function $f : \{-1,1\}^n \to \mathbb{R}$ with degree d, and any distribution X on $\{-1,1\}^n$, there exists a partial assignment with $|\rho| \leq \mathrm{poly}(d)$ such that $\Pr_{x\sim X}[f(x^\rho) \neq 0] \geq 1/\mathrm{poly}(d)$.*

▶ **Lemma 14.** *Conjecture 13 holds if and only if Conjecture 1 holds. Thus, if Conjecture 13 is true, then perfect complete QPKE does not exist in the QROM.*

In the main body, we provide additional evidence for Conjecture 13 (and consequently for Conjecture 1). Conjecture 13 has the advantage of requiring only a single partial assignment that works for the given input distribution, rather than a distribution of partial assignments. This simplifies the reasoning considerably, and much of our evidence supports Conjecture 13.

1.2 Techniques

Here, we give a brief overview of why Conjecture 1 implies a full impossibility result of QPKE in the QROM and the main differences between [18] and this work.

We will be mostly focusing on key agreement protocols in the QROM. In the QROM, all parties can quantumly query a random oracle. A key agreement protocol is an interactive protocol between two query-efficient quantum algorithms Alice and Bob, exchanging classical messages. Their goal is to agree on a key, whereas any query-efficient adversary can not learn the key, even observing all the communication on this channel. It is easy to see that QPKE implies a two-round key agreement protocol:

- Alice sends a single message m_0 to Bob; in this case, m_0 will be the public key.
- Bob sends a message m_1 to Alice; in this case, m_1 will be the encryption of a random key (which will be the agreed key in the two-round key agreement protocol).
- Finally, they both output their own keys k_A, k_B; in this case, Alice decrypts the ciphertext using her secret key, whereas Bob simply outputs the random key.

Thus, to rule out QPKE in the QROM, it is sufficient to rule out the two-round key agreement in the QROM.

Li, Li, Li and Liu [18] proposed the following framework that rules out QPKE with classical-query key generation in the QROM. Let $\mathsf{View}_A, \mathsf{View}_B$ denote the view of Alice and Bob, right after m_1 is received by Alice. They showed that, based on a novel approach called approximate quantum Markov chain, a quantum-query Eve can reconstruct Alice's view View'_A such that

$$\mathsf{View}'_A\mathsf{View}_B \approx \mathsf{View}_A\mathsf{View}_B.$$

More precisely, Eve can reconstruct Alice's register such that the margin of the fake Alice and the real Bob is arbitrarily close to the real Alice and the real Bob. However, this is not sufficient; since to compute the key k_A, Alice potentially needs to perform computation depending on its current state, the random oracle and all the messages m_0, m_1. As the marginal is defined by tracing out the random oracle, we do not know what oracle to work with. For example, a direct attempt is to run fake Alice under the real random oracle H; but it is possible that under real H, conditioned on the messages being m_0, m_1, the view of Alice and Bob will never equal to $\mathsf{View}'_A\mathsf{View}_B$, making the attempt meaningless.

Li et al. solved this by adapting Bob; while perfectly preserving the functionality of the key agreement protocol, the new Bob has one additional nice property (let us call it "stability"):

- if under a random oracle H, input message m_0, Bob outputs certain m_1 with non-zero probability
- then for every H' that has a small Hamming distance to H[2], Bob on H' and m_0 still has non-zero probability to output m_1.

With this property, they show that the two-round key agreement can not exist, when m_0 together with View_A can be computed by a classical decision tree (or Gen only makes classical queries). For any fake Alice view View'_A, it depends on at most d locations of a random oracle; here d is the number of queries made by the classical decision tree. Thus, for any oracle H_0, as long as it is consistent on these d locations, Alice on H_0 can output View'_A and m_0 with non-zero probability. They construct an oracle H' such that: (i) it is almost H, except (ii) on those d locations, H' is reprogrammed to be consistent with these d locations.

It is clear that Alice on H' still outputs m_0, View'_A with a non-zero probability (consistency of these d locations). Moreover, the "stability" ensures that the adapted Bob on H' and m_0 outputs View_B also with a non-zero probability. Thus, there is a non-zero probability, under the oracle H', Alice and Bob will end up with $\mathsf{View}'_A, \mathsf{View}_B$ and transcripts (m_0, m_1). Since we assume the QPKE is perfect, after the whole execution, Alice and Bob should agree on a key. As for Eve, it simply runs Alice with View'_A, m_1 on H' and will recover the key.

The above reasoning in [18] does not work even if Alice only makes a single quantum query, and thus they can only rule out QPKE when Gen makes classical queries. Since a single quantum query can "store" information about exponentially many inputs, it seems that fixing a smaller number of input-output behaviors does not fix Alice's behavior.

We realize that, we do not need to keep Alice's behavior the same; we are only required to keep these probabilities non-zero. More precisely, our solution is to directly look at the polynomial f describing the probability that a quantum Alice on some oracle, outputs (m_0, View'_A),

$$f(x) = \Pr[(m_0, \mathsf{View}'_A) \leftarrow A^x],$$

where we treat x as the random oracle fed into A. As the random oracle will be the input to a polynomial, to be consistent with the literature of BFA, we will denote a random oracle by x. Since A only makes d quantum queries, such a polynomial f has degree at most $2d$. The real random oracle is some x of which we have no knowledge about; the goal is to find another x' such that

- $f(x') > 0$, meaning Alice on the random oracle x' outputs View'_A, m_0 with a non-zero probability, just like the classical case; and,
- x' and x have a small Hamming distance, so that Bob still has non-zero probability to output View_B, m_1.

As we do not know x, the only way we can obtain x' is by locally modifying some locations of x. For example, reprogramming some locations of the real oracle, and running the rest of Alice under the reprogrammed oracle – this is where the partial assignment takes place. If we can find a partial assignment ρ with $|\rho|$ is small, such that for every x, $f(x^\rho) > 0$, then the problem is resolved! This is the high-level intuition why our conjecture (Conjecture 1) implies a full impossibility result of QPKE in the QROM.

[2] We ignore a detail here: H' should be consistent with H on a small set of inputs, whereas on other inputs, their Hamming distance is small. This does not change the reasoning, thus we make the simplification in the introduction.

Towards Conjecture 1, we remark that the Combinatorial Nullstellensatz [2] directly implies the existence of such ρ. More specifically, the Combinatorial Nullstellensatz claims that: given any maximal monomial x_S of f, for any $x \in \{-1,1\}^n$, there exists a ρ with $\mathsf{supp}(\rho) = S$ such that $f(x^\rho) \neq 0$. Therefore, Conjecture 1 holds if we swap the order of quantifiers of ρ and x. Consequently, by letting $\mathcal{D}$ be the uniform distribution on the set of partial assignments ρ with $\mathsf{supp}(\rho) = S$, we have $\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/2^d$ for any x, as claimed by Lemma 7. In particular, when Gen makes only $O(\log n)$ queries and then $\deg(f) = O(\log n)$, we have $\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/\mathrm{poly}(n)$, which implies Lemma 10.

1.3 Related works

In Conjecture 1, we characterize d-query quantum algorithms as degree-$2d$ polynomials [8]. This characterization was further strengthened by Aaronson and Ambainis [1] in terms of bounded degree-$2d$ block-multilinear polynomials. Later, Arunachalam, Briet, and Palazuelos [4] provided an exact characterization of quantum query algorithms in terms of the so-called completely bounded norm.

2 Preliminaries

2.1 Basic notions in Boolean function analysis

Every function $f : \{-1,1\}^n \to \mathbb{R}$ on the hypercube can be uniquely expressed as a multilinear polynomial

$$f(x) = \sum_{S\subseteq[n]} a_S \cdot x_S,$$

where $x_S := \Pi_{i\in S} x_i$. Indeed, this expression is called the *Fourier expansion* of f, where $a_S = 2^{-n}\sum_x f(x)\cdot x_S$. The *degree* of f, denoted $\deg(f)$, is defined as the degree of its multilinear polynomial expression, i.e., $\max\{|S| \mid a_S \neq 0\}$. A monomial x_S is called *maximal* if it has degree $\deg(f)$, i.e., $|S| = \deg(f)$ and $a_S \neq 0$. The *rank* of f, denoted $\mathrm{rank}(f)$, is the maximum number of disjoint maximal monomials.

A *partial assignment* is a function $\rho : [n] \to \{-1, 1, \star\}$. We define the support of ρ as $\mathsf{supp}(\rho) := \{i|\rho_i \neq \star\}$, and the size as $|\rho| := |\mathsf{supp}(\rho)|$. For $x \in \{-1,1\}^n$, we define the modification of x with ρ, denoted x^ρ, as the string $x' \in \{-1,1\}^n$ where $x'_i = \rho_i$ for $i \in \mathsf{supp}(\rho)$ and $x'_i = x_i$ for any other i.

We use $\mathsf{Var}(f) := \mathbb{E}_x[f(x)^2] - \big(\mathbb{E}_x f(x)\big)^2$ to denote f's variance, and define $\|f\|_\infty := \max_x |f(x)|$. A real polynomial p ϵ-approximates f if $|f(x)-p(x)| \leq \epsilon$ for every $x \in \{-1,1\}^n$. The *approximate degree* of f, denoted by $\widetilde{\deg}(f)$, is defined to be the minimum degree needed to 1/3-approximate f.

The following lemma will be used.

▶ **Lemma 15** ([8]). *Suppose a quantum algorithm makes d queries to a Boolean string $x \in \{-1,1\}^n$, and the acceptance probability is denoted by $f(x)$. Then the function $f : \{-1,1\}^n \to \mathbb{R}$ has degree at most $2d$. That is, f can be expressed as*

$$f(x) = \sum_{|S|\leq 2d} a_S \cdot x_S$$

2.2 Quantum public key encryption

In this paper, we will consider constructions in the quantum random oracle model. Given security parameter λ, the oracle H is chosen from the uniformly random distribution over the family of functions $\mathcal{H}_\lambda \colon [2^{n_\lambda}] \to \{0,1\}$, where n_λ is a polynomial of λ. The quantum circuit has access to the oracle unitary U_H that maps $|i,y\rangle$ to $|i, y \oplus H(i)\rangle$. We can also view the oracle unitary in the phase basis $U'_H |i,y\rangle \to (-1)^{H(i)y} |i,y\rangle$.

We will consider quantum public key encryption with classical public key pk and ciphertext ct in this paper. Particularly, we will consider the quantum public key encryption (QPKE) scheme in the quantum random oracle model (QROM) defined as follows:

▶ **Definition 16** (Quantum public key encryption in QROM)**.** *A public key encryption scheme, relative to a random oracle $H \leftarrow \mathcal{H}_\lambda$ consists of the following three bounded quantum query algorithms:*

- $\mathsf{Gen}^H(1^\lambda) \to (\mathsf{pk}, \mathsf{sk})$*: The key generation algorithm that generates a pair of classical public key* pk *and secret key* sk*.*
- $\mathsf{Enc}^H(\mathsf{pk}, m) \to \mathsf{ct}$*: the encryption algorithm that takes a public key* pk*, the plaintext m, produces the ciphertext* ct*.*
- $\mathsf{Dec}^H(\mathsf{sk}, \mathsf{ct}) \to m'$*: the decryption algorithm that takes secret key* sk *and ciphertext* ct *and outputs the plaintext m'.*

The algorithms should satisfy the following requirements:

Perfect Completeness $\Pr\left[\mathsf{Dec}^H\left(\mathsf{sk}, \mathsf{Enc}^H(\mathsf{pk}, m)\right) = m \colon \mathsf{Gen}^H(1^\lambda) \to (\mathsf{pk}, \mathsf{sk})\right] = 1.$

IND-CPA Security For any QPT adversary $\mathcal{E}^H$, for every two plaintexts $m_0 \neq m_1$ chosen by $\mathcal{E}^H(\mathsf{pk})$ we have

$$\Pr\left[\mathcal{E}^H\left(\mathsf{pk}, \mathsf{Enc}^H(\mathsf{pk}, m_b)\right) = b\right] \leq \frac{1}{2} + \frac{\epsilon(\lambda)}{2}.$$

where we call $\epsilon(\lambda)$ as the advantage of the adversary. The scheme is IND-CPA secure if $\epsilon(\lambda)$ is negligible for any adversary $\mathcal{E}^H$.

3 Consequences of our BFA conjecture

In this section, we will show the consequence in cryptography of Conjecture 1. If Conjecture 1 holds, we can obtain a black box separation between post-quantum secure one-way functions and quantum public key encryption schemes.

▶ **Theorem 17** (Restate of Theorem 3)**.** *Assuming Conjecture 1 is true, for any quantum public key encryption scheme in the quantum random oracle model, if* Gen^H *and* Enc^H *make d queries to H in total, and* Dec^H *makes D queries, there exists an adversary Eve $\mathcal{E}^H$ which can break the IND-CPA security with advantage $1/\mathrm{poly}(d)$ by making $O(\mathrm{poly}(d) + D)$ queries.*

It is known that we can use a QPKE scheme for a two-message key agreement protocol, by setting the first message $m_0 = \mathsf{pk}$, and the second message $m_1 = \mathsf{Enc}(\mathsf{pk}, k)$, where k is the key the two parties agree on. We can assume the key k is chosen uniformly random from $\{0,1\}^n$. In the following section, we will refer to the two parties as $\mathcal{A}$ and $\mathcal{B}$, and call the algorithm of $\mathcal{A}$ before sending m_0 as $\mathcal{A}_0$, and the algorithm after receiving message m_1 as $\mathcal{A}_1$. If we can learn the key k with probability p, we can also break the semantic security of the QPKE scheme with advantage p, which implies that we also break the IND-CPA security of the protocol. In the language of key agreement, we are considering the case where $\mathcal{A}_0, \mathcal{A}_1$, and $\mathcal{B}$ can both make quantum queries while only sending classical messages, and we will show how to learn the key k with probability $1/\mathrm{poly}(d)$.

Let us recall the results from [18]. In their paper, they are considering the case where $\mathcal{A}_0$ can only make classical queries. The key part of their analysis is to show how to construct a register A', such that there exists some oracle H', the content View'_A in A' is consistent with H' and transcript $\pi = (m_0, m_1)$. We can think the algorithm $\mathcal{B}$ proceeds as follows: it first receives the message m_0 from $\mathcal{A}$, and after making some queries to the oracle H, it makes a measurement in the computational basis, and generates the key k_B and the second message m_1. The state under consideration in [18] $\sigma_{AB} = \mathbb{E}_H[\sigma_{AB}^H]$ is the state before $\mathcal{B}$ makes the final measurement and sends the second message m_1, where σ_{AB}^H is the state under oracle H, and the expectation is over the posterior distribution of H given the first message m_0.

To construct the register A', they used tools from quantum information theory. They used the following theorem from [14].

▶ **Theorem 18.** *For any state ρ_{AEB} over systems AEB, there exists a channel $\mathcal{T} : \mathsf{E} \to \mathsf{E} \otimes \mathsf{B}'$ such that the trace distance between the reconstructed state $\sigma_{\mathsf{A}'\mathsf{E}'\mathsf{B}'} = \mathcal{T}(\rho_{\mathsf{AE}})$ and the original state ρ_{AEB} is at most*

$$\sqrt{\ln 2 \cdot I(\mathsf{A} : \mathsf{B}|\mathsf{E})_\rho}.$$

The theorem says that if the conditional mutual information $I(\mathsf{A} : \mathsf{B}|\mathsf{E})$ is small, we can generate a consistent copy of A' by a channel only acting on E.

To decrease the conditional mutual information $I(\mathsf{A} : \mathsf{B}|\mathsf{E})$, we have the following lemma from [18].

▶ **Definition 19** (Permutation Invariance)**.** *Let $\mathsf{A}_1, \mathsf{A}_2, \mathsf{A}_3, \ldots, \mathsf{A}_t, \mathsf{B}$ be $(t+1)$-partite quantum system. Given the joint state $\rho_{\mathsf{BA}_1\mathsf{A}_2\cdots\mathsf{A}_t}$, we say $A_1, \ldots, A_t$ are permutation invariant, if for any permutation π on $[t]$, we have*

$$\rho_{\mathsf{BA}_1\mathsf{A}_2\cdots\mathsf{A}_t} = \rho_{\mathsf{BA}_{\pi(1)}\mathsf{A}_{\pi(2)}\cdots\mathsf{A}_{\pi(t)}}.$$

▶ **Lemma 20.** *Let $\mathsf{A}_1, \mathsf{A}_2, \mathsf{A}_3, \ldots, \mathsf{A}_t, \mathsf{B}, \mathsf{E}$ be $(t+2)$-partite quantum system. Suppose the state of the composite system $\rho_{\mathsf{BEA}_1\mathsf{A}_2\cdots\mathsf{A}_t}$ is fully separable. If $\mathsf{A}_1, \mathsf{A}_2, \mathsf{A}_3, \ldots, \mathsf{A}_t$ are permutation invariant, then there is a $0 \le i \le t-1$ such that*

$$I(\mathsf{A}_t : \mathsf{B} \mid \mathsf{E}, \mathsf{A}_1, \ldots, \mathsf{A}_i)_\rho \le S(\mathsf{B})/t.$$

The lemma shows that if Eve parallel repeats multiple copies of $\mathcal{B}$, the mutual information will be decreased.

The following lemma from [9] will also be used.

▶ **Lemma 21.** *Consider a quantum algorithm $\mathcal{B}$ that makes d queries to an oracle H. Denote the quantum state immediately after t queries to the oracle as*

$$|\psi_t\rangle = \sum_{x,w} \alpha_{x,w,t} |x, w\rangle,$$

where w is the content of the workspace register. Denote the query weight q_x of input x as

$$q_x = \sum_{t=1}^{d} \sum_{w} |\alpha_{x,w,t}|^2.$$

For any oracle $\tilde{H}$, denote $|\phi_d\rangle$ as the final state before measurement obtained by running $\mathcal{B}$ with oracle $\tilde{H}$, we have that

$$\||\psi_d\rangle - |\phi_d\rangle\| \le 2\sqrt{d} \sqrt{\sum_{x:\, \tilde{H}(x) \neq H(x)} q_x}.$$

In [18], they defined the heavy query of Bob as $\{x\colon q_x \geq \epsilon^2/d^2\}$. We summarize their adversary Eve's algorithm $\mathcal{E}$ as follows:

1. Eve parallelly simulates Bob's algorithm $\mathcal{B}^H(m_0)$ for multiple times. In this process, Eve records heavy queries of $\mathcal{B}$ under H classically and maintains an input-output pair register $R_E = \{(i_E, H(i_E))\}$.
2. By Lemma 20, if Eve repeat $\mathcal{B}^H(m_0)$ for $\mathrm{poly}(d, 1/\epsilon)$ times, the conditional mutual information $I(\mathsf{A} : \mathsf{B} \mid \mathsf{E})$ of state σ_{ABE} can be reduced to smaller than $O(\epsilon^2)$. By Theorem 18,the channel $\mathcal{T}\colon \mathsf{E} \to \mathsf{A'E}$ provides a state $\mathcal{T}(\sigma_{BE}) = \sigma_{A'BE}$ is ϵ close to the state σ_{ABE}. In the following section, we will choose $\epsilon = 1/\mathrm{poly}(d)$.
3. Eve measures the secret key register as well as the query input-output history register of $\mathsf{A'}$. Note that in their case, we can assume $\mathcal{A}_0^H$ records its classical queries. The measurement will give us some secret key $\mathsf{sk'}$ and input-output pairs $R_{A'} = \{(i_{A'}, H'(i_{A'}))\}$, since $\sigma_{A'BE} \approx_\epsilon \sigma_{ABE}$, with high probability, the measurement result $\mathsf{sk'}$ and $R_{A'}$ are consistent with message m_0 and R_E. Specifically, every query that is both in $R_{A'}$ and R_E should be consistent, meaning $R_{A'}$ is consistent with $\mathcal{B}$'s heavy queries under oracle H.
4. Finally, by the observation beyond, if the oracle H is reprogrammed to H' using the input-output pairs in $R_{A'}$, from $\mathcal{B}$'s view, only $\mathrm{poly}(d)$ light query points under H are modified. Using Lemma 21, it can be shown that w.h.p., $\mathcal{B}^{H'}(m_0)$ will output m_1 with nonzero probability, implying that $\pi = (m_0, m_1)$ is a valid transcript under oracle H'. Thus by perfect completeness, if we simulate $\mathcal{A}_1$ given input $(\mathsf{sk'}, m_1)$ over oracle H', it can still agree with $\mathcal{B}$.

We refer interested readers to their paper for the proof details.

Our observation is that in step 3, we do not need to generate the input-output pair $R_{A'}$ by measuring $\mathsf{A'}$. Given the algorithm of $\mathcal{A}_0$, if we can find some $\mathrm{poly}(d)$-sized assignment $R_{A'}$ that is consistent with R_E and guarantees the output probability of $(\mathsf{sk'}, m_0)$ is still non-zero, by similar arguments, we can see that $\mathcal{B}$ is consistent with the reprogrammed oracle H', and will output m_1 with non-zero probability. From Lemma 15, if we define the algorithm outputs $(\mathsf{sk'}, m_0)$ as acceptance, we can characterize the probability with a $2d$-degree polynomial $f(x)$, viewing the truth table of random oracle H as a $N_\lambda = 2^{n_\lambda}$ length vector x.

Now we show how to leverage Conjecture 1 to prove our main theorem. We use x for the truth table of original oracle H, setting $x_i = (-1)^{H(i)}$, and ρ_E for the restriction given by R_E, and apply Conjecture 1 to polynomial $g(x) = f(x^{\rho_E})$. In an operational meaning, considering $g(x)$ means that we first fix the input-output pairs given by R_E when selecting the random oracle. We now argue $g(x)$ is a non-zero polynomial with high probability. We can obtain the joint view $\mathsf{View}_{A'E} = (\mathsf{sk'}, m_0, R_E)$ of $\mathsf{A'E}$ by performing a computational basis measurement on corresponding registers. Since $\sigma_{A'E}$ is ϵ close to σ_{AE}, we can see that w.p. $1 - \epsilon$, $\mathsf{View}_{A'E} = (\mathsf{sk'}, m_0, R_E)$ is a possible valid view obtained by measuring σ_{AE}.

By Conjecture 1, there exists a distribution of polynomial-sized restrictions $\mathcal{D}$ such that for any x, $\Pr_{\rho\sim\mathcal{D}}[g(x^\rho) \neq 0] \geq 1/\mathrm{poly}(d)$, with $|\rho| \leq \mathrm{poly}(d)$. In our case, this implies that $\Pr_{\rho\sim\mathcal{D}}[f(x^{\rho\cup\rho_E}) \neq 0] \geq 1/\mathrm{poly}(d)$. If we select a polynomial-sized restriction ρ, there is $1/\mathrm{poly}(d)$ probability such that $(\mathsf{sk'}, m_0)$ is still a valid view of $\mathcal{A}_0$ under the new oracle given by $x^{\rho\cup\rho_E}$. The other arguments follow from the original proof.

4 Toward our BFA conjecture: evidences and special cases

In this section, we explore Conjecture 1 by providing some evidence and proving some special cases.

4.1 Main evidence: Combinatorial Nullstellensatz

The main evidence for Conjecture 1 comes from the celebrated Combinatorial Nullstellensatz of Alon [2], which implies Conjecture 1, except with $\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/2^d$ instead of $\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/\mathrm{poly}(d)$. Let us state the special case of the Combinatorial Nullstellensatz for polynomials on the hypercube.

▶ **Lemma 22** ([2]). *Let $f : \{-1,1\}^n \to \mathbb{R}$ be any nonconstant function with degree d, and x_S be any maximal monomial of f. For any $x \in \{-1,1\}^n$, there exists a ρ with $\mathsf{supp}(\rho) = S$ such that $f(x^\rho) \neq 0$.*

Consequently, by letting $\mathcal{D}$ be the uniform distribution on the set of partial assignments ρ with $\mathsf{supp}(\rho) = S$, we have $\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/2^d$ for any x.

We remark that Lemma 22 was also proven by Midrijanis [21]. Even though Lemma 22 has an exponential rather than polynomial dependence on $1/d$, we observe that it already has a nontrivial implication on the separation between QPKE and OWFs. Precisely, it implies that

▶ **Theorem 23** (Restate of Lemma 10). *For any quantum public key encryption scheme in the quantum random oracle model, if Enc^H makes d queries to H, Gen^H makes $O(\log d)$ queries, and Dec^H makes D queries, there exists an adversary Eve $\mathcal{E}^H$ which can break the IND-CPA security with advantage $1/\mathrm{poly}(d)$ by making $O(\mathrm{poly}(d) + D)$ queries.*

The proof of Theorem 23 is the same as Theorem 17 by replacing Conjecture 1 with Lemma 22.

4.2 Proof of Lemma 9

In this subsection, we present the proof of Lemma 9, which claims that Conjecture 1 is equivalent to a seemingly much weaker conjecture, namely Conjecture 8.

▶ **Conjecture 8.** *There is a universal constant $c < 1$, such that for any nonconstant function $f : \{-1,1\}^n \to \mathbb{R}$ with degree d, the following holds. There exists a distribution $\mathcal{D}$ on the set of partial assignments ρ with $|\rho| \leq \mathrm{poly}(d)$ such that: for any x,*

$$\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/2^{d^c}.$$

▶ **Lemma 9.** *Conjecture 8 holds if and only if Conjecture 1 holds.*

Proof. Conjecture 1 implying Conjecture 8 is trivial. Conversely, given any nonconstant function $f : \{-1,1\}^n \to \mathbb{R}$ with degree d, define

$$\tilde{f}(x_1, \ldots, x_t) := \prod_{i=1}^{t} f(x_i)$$

where $x_i \in \{-1,1\}^n$. Note that $\deg(\tilde{f}) = td$. Assuming Conjecture 8 holds for $\tilde{f}$, there exists a distribution $\tilde{\mathcal{D}}_0$ of partial assignment $\tilde{\rho} = (\rho_1, \ldots, \rho_t) \in (\{-1,1,\star\}^n)^t$ with $|\tilde{\rho}| \leq (dt)^{c_1}$ such that

$$\min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}_0}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] \geq \frac{1}{2^{(dt)^{c_2}}}$$

where c_1, c_2 are universal constants satisfying $c_1 \geq 0$ and $0 \leq c_2 < 1$. Observe that

$$\max_{\tilde{\mathcal{D}}} \min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] \geq \min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}_0}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] \geq \frac{1}{2^{(dt)^{c_2}}}$$

where $\tilde{\mathcal{D}}$ is a distribution of partial assignment $\tilde{\rho} = (\rho_1, \ldots, \rho_t) \in (\{-1, 1, \star\}^n)^t$ with $|\rho_i| \leq (dt)^{c_1}$ for all i. Then by Lemma 24, we have

$$\left(\max_{\mathcal{D}} \min_{x} \Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0]\right)^t = \max_{\tilde{\mathcal{D}}} \min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] \geq \frac{1}{2^{(dt)^{c_2}}}$$

where $\mathcal{D}$ is a distribution of partial assignment $\rho \in \{-1, 1, \star\}^n$ with $|\rho| \leq (dt)^{c_1}$. Thus there exists a distribution $\mathcal{D}^*$ such that

$$\left(\min_{x} \Pr_{\rho\sim\mathcal{D}^*}[f(x^\rho) \neq 0]\right)^t \geq \frac{1}{2^{(dt)^{c_2}}}.$$

By setting $t = d^{\frac{c_2}{1-c_2}} \log^{\frac{1}{c_2-1}} d$, we have

$$\min_{x} \Pr_{\rho\sim\mathcal{D}^*}[f(x^\rho) \neq 0] \geq 2^{-(dt)^{c_2}/t} = 2^{-\log d} = 1/d. \qquad \blacktriangleleft$$

▶ **Lemma 24.** *Given positive integers t, K, and function $f : \{-1, 1\}^n \to \mathbb{R}$, let $\tilde{f}(x_1, \ldots, x_t) := \prod_{i=1}^t f(x_i)$. Then*

$$\max_{\tilde{\mathcal{D}}} \min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] = \left(\max_{\mathcal{D}} \min_{x} \Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0]\right)^t$$

where $\mathcal{D}$ is a distribution of partial assignments $\rho \in \{-1, 1, \star\}^n$ with $|\rho| \leq K$, $\tilde{\mathcal{D}}$ is a distribution of partial assignments $\tilde{\rho} = (\rho_1, \ldots, \rho_t) \in (\{-1, 1, \star\}^n)^t$ with $|\rho_i| \leq K$ for all i.

Proof. By the min-max principle, we have

$$\max_{\mathcal{D}} \min_{x} \Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] = \min_{X} \max_{\rho} \Pr_{x\sim X}[f(x^\rho) \neq 0] := p.$$

Let $\mathcal{D}^*$ be the optimal distribution that reaches the maximum, X^* the optimal distribution that reaches the minimum. Let $\tilde{p} := \max_{\tilde{\mathcal{D}}} \min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right]$.

Claim 1: $\tilde{p} \leq p^t$. By min-max principle,

$$\begin{aligned}\max_{\tilde{\mathcal{D}}} \min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] &= \min_{\tilde{X}} \max_{\tilde{\rho}} \Pr_{\tilde{x}\sim\tilde{X}}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] \\ &= \min_{\tilde{X}} \max_{\rho_1,\ldots,\rho_t} \Pr_{(x_1,\ldots,x_t)\sim\tilde{X}}\left[f(x_1^{\rho_1}) \neq 0, \ldots, f(x_t^{\rho_t}) \neq 0\right].\end{aligned}$$

By setting $\tilde{X}$ to be $X^* \times X^* \times \cdots \times X^*$, we have

$$\begin{aligned}\max_{\tilde{\mathcal{D}}} \min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] &\leq \max_{\rho_1,\ldots,\rho_t} \Pr_{x_i\sim X^*}[f(x_1^{\rho_1}) \neq 0, \ldots, f(x_t^{\rho_t}) \neq 0] \\ &= \max_{\rho_1,\ldots,\rho_t} \prod_i \Pr_{x_i\sim X^*}[f(x_i^{\rho_i}) \neq 0] = \prod_t \max_{\rho_i} \Pr_{x_i\sim X^*}[f(x_i^{\rho_i}) \neq 0] = p^t.\end{aligned}$$

Claim 2: $\tilde{p} \geq p^t$. By setting $\tilde{\mathcal{D}}$ to be $\mathcal{D}^* \times \mathcal{D}^* \times \cdots \times \mathcal{D}^*$, we have

$$\begin{aligned}\max_{\tilde{\mathcal{D}}} \min_{\tilde{x}} \Pr_{\tilde{\rho}\sim\tilde{\mathcal{D}}}\left[\tilde{f}(\tilde{x}^{\tilde{\rho}}) \neq 0\right] &\geq \min_{x_1,\ldots,x_t} \Pr_{\rho_i\sim\mathcal{D}^*}[f(x_1^{\rho_1}) \neq 0, \ldots, f(x_t^{\rho_t}) \neq 0] \\ &= \min_{x_1,\ldots,x_t} \prod_i \Pr_{\rho_i\sim\mathcal{D}^*}[f(x_i^{\rho_i}) \neq 0] = \prod_i \min_{x_i} \Pr_{\rho_i\sim\mathcal{D}^*}[f(x_i^{\rho_i}) \neq 0] = p^t.\end{aligned}$$

Thus $\tilde{p} = p^t$ and $\tilde{p}$ can be reached by i.i.d. distribution $\mathcal{D}^* \times \cdots \times \mathcal{D}^*$. $\blacktriangleleft$

▶ Remark 25. By the same technique, the non-zero probability in Conjecture 1 can be further improved from $1/\mathrm{poly}(d)$ to $1 - 1/\mathrm{poly}(d)$, while still keeping $|\rho| \leq \mathrm{poly}(d)$.

4.3 Special cases of boolean functions

We also affirm Conjecture 1 for some special classes of functions.

▶ **Lemma 26.** *Conjecture 1 holds when f satisfies one of the following conditions:*

(a) *f can be expressed as the acceptance probability of a classical randomized decision tree with depth $\leq \mathrm{poly}(d)$ (Lemma 5).*

(b) *f is Boolean-valued, more generally when f takes at most $\mathrm{poly}(d)$ values (Lemma 11).*

(c) *f is a symmetric function.*

Proof.

Part (a). Recall that a randomized decision tree can be viewed as a distribution μ over deterministic decision trees, such that the tree is evaluated by (i) first sampling a deterministic decision tree from μ, and (ii) then evaluating this deterministic decision tree. Since $f(x)$ is the probability that the output of the evaluation is "yes", and f is non-zero, there exists a deterministic decision tree T with $\mu(T) > 0$ such that at least one of its leaves is labeled with "yes". We can set ρ to be the partial assignment corresponding to the path from the root to the leaf. Then $f(x^\rho) \neq 0$ for any x.

Part (b). Without loss of generality, assume $\|f\|_\infty = 1$. Since f takes at most $\mathrm{poly}(d)$ values, there exists a gap $b - a \geq 1/\mathrm{poly}(d)$ such that $f(x) \in [-1, a] \cup [b, 1]$ for all x. Define $f'(x) := \left(1 + \left|\frac{a+b}{2}\right|\right)^{-1} \left(f(x) - \frac{a+b}{2}\right)$. Then $f'(x) \in [-1, -1/\mathrm{poly}(d)] \cup [1/\mathrm{poly}(d), 1]$ for all x. Define a boolean function

$$\tilde{f}(x) := \begin{cases} -1 & \text{if } f'(x) < 0 \\ 1 & \text{if } f'(x) > 0 \end{cases}.$$

Then $\tilde{f}$ is $(1 - 1/\mathrm{poly}(d))$-approximated by f'. f' can be amplified to a degree-$\mathrm{poly}(d)$ polynomial that 1/3-approximates $\tilde{f}$. Thus we have $\widetilde{\deg}(\tilde{f}) \leq \mathrm{poly}(d)$, which further implies $\tilde{f}$ can be computed by a decision tree with depth $\mathrm{poly}(d)$ [11].

(i) If $a < 0 < b$, then $f(x) \neq 0$ alway holds. (ii) If $a \geq 0$, by Part (a), there exists a partial assignment $|\rho| \leq \mathrm{poly}(d)$ such that $\tilde{f}(x) = 1$, which implies $f(x^\rho) \geq b > 0$ for any x. (iii) If $b \leq 0$, by Part (a), there exists a partial assignment $|\rho| \leq \mathrm{poly}(d)$ such that $\tilde{f}(x) = -1$, which implies $f(x^\rho) \leq a < 0$ for any x.

Part (c). Let $x_S = x_{i_1} x_{i_2} \cdots x_{i_d}$ be a maximal monomial of f, and ρ_k be the partial assignment such that $\rho_k(i_1) = \cdots = \rho_k(i_k) = 1$ and $\rho_k(i_{k+1}) = \cdots = \rho_k(i_d) = -1$. By Lemma 22, for any x, there exists a ρ with $\mathsf{supp}(\rho) = S$ such that $f(x^\rho) \neq 0$. Since f is symmetric, we have $f(x^{\rho_j}) = f(x^\rho) \neq 0$ where j is the number of 1's in ρ. Let $\mathcal{D}$ be the uniform distribution over $\{\rho_0, \rho_1, \ldots, \rho_d\}$. Then $\Pr_{\rho\sim\mathcal{D}}[f(x^\rho) \neq 0] \geq 1/(d+1)$ for any x. ◀

The above lemma implies the non-existence of perfect complete QPKE in QROM which the key generation takes special forms, e.g., the special cases 1 and 3 mentioned in the introduction.

▶ **Corollary 27.** *Perfect complete QPKE does not exist in the QROM, if one of the following holds:*

(1) Gen *only makes classical queries. (Corollary 6)*

(2) Gen *is uniform, i.e., it satisfies (i)* $|\mathsf{supp}(\mathsf{Gen}^H)| = |\mathsf{supp}(\mathsf{Gen}^{H'})|$ *for every pair of H, H', and (ii)* Gen^H *is uniform over* $\mathsf{supp}(\mathsf{Gen}^H)$ *with a non-zero probability. (Corollary 12)*

Proof. Consider the polynomial $g(H)$ defined in the proof of Theorem 17, which is defined to be the probability of $\mathsf{Gen}^{H^{\rho_E}}$ outputting (sk', m_0).

(1) g can be expressed as the acceptance probability of a classical randomized decision tree with depth d. Then the proposition follows from Part (a) of Lemma 26.
(2) g takes only two values 0 and $1/|\mathsf{supp}(\mathsf{Gen}^H)|$. Then the proposition follows from Part (b) of Lemma 26. ◀

4.4 More evidences for Conjecture 13

Additionally, we provide evidence for the equivalent form Conjecture 13 (and consequently for Conjecture 1). The first piece of evidence is from the anti-concentration result for low-degree polynomials by Meka, Nguyen and Vu [20], which implies Conjecture 13 when X is uniform distribution on $\{-1,1\}^n$, except that $|\rho|$ is allowed to be as large as d^{8d+4} instead of $|\rho| \leq \mathrm{poly}(d)$.

▶ **Theorem 28** ([20]). *Let $f : \{-1,1\}^n \to \mathbb{R}$ be a nonconstant polynomial with degree d, and U denote the uniform distribution on $\{-1,1\}^n$. If $\mathrm{rank}(f) \geq d^{8d+2}$, then $\Pr_{x\sim U}[f(x) \neq 0] = 1 - o(1)$.*

▶ **Lemma 29.** *For any nonconstant function $f : \{-1,1\}^n \to \mathbb{R}$ with degree d, there exists a partial assignment with $|\rho| \leq d^{8d+4}$ such that $\Pr_{x\sim U}[f(x^\rho) \neq 0] \geq 1 - o(1)$.*

Proof. We construct a partial assignment ρ by the following algorithm, which contains at most d rounds and each round reduces $\deg(f)$ by at least 1. Denote the function at round t by f^t. Initia,lly ρ is empty. At round t,

1. If $\mathrm{rank}(f^t) \geq d^{8d+2}$, the algorithm stops. By Theorem 28, we have
$$\Pr_{x\sim U}[f(x^\rho) \neq 0] = \Pr_{x\sim U}[f^t(x) \neq 0] = 1 - o(1).$$
2. If $\mathrm{rank}(f^t) < d^{8d+2}$, let T be the variables contained a maximum disjoint set of maximal monomials of f^t. The algorithm assigns all the variables in T such that the function after the assignment is still nonconstant and adds them to ρ. This step increases $|\rho|$ by $|T| = \deg(f^t)\mathrm{rank}(f^t) < d^{8d+3}$. For any maximal monomial S of f^t, we have $S \cap T \neq \emptyset$ because otherwise $S \cup T$ is a disjoint set of maximal monomials larger than T. Thus this step reduces $\deg(f^t)$ by at least one.

Because there are at most d rounds, we have $|\rho| \leq d^{8d+4}$. ◀

The second evidence is that Conjecture 13 holds for any function f with large variance when X is uniform.

▶ **Lemma 30.** *For any nonconstant function $f : \{-1,1\}^n \to \mathbb{R}$ with degree d and $\mathsf{Var}(f) \geq \|f\|_\infty^2/\mathrm{poly}(d)$, there exists a partial assignment with $|\rho| \leq \mathrm{poly}(d)$ such that $\Pr_{x\sim U}[f(x^\rho) \neq 0] \geq 1/\mathrm{poly}(d)$.*

Proof. $\mathsf{Var}(f) = \mathbb{E}_x[f^2(x)] - (\mathbb{E}_x f(x))^2 \leq \mathbb{E}_x[f^2(x)] \leq \Pr_x[f(x) \neq 0]\|f\|_\infty^2$. Thus $\Pr_x[f(x) \neq 0] \geq \frac{\mathsf{Var}(f)}{\|f\|_\infty^2} \geq 1/\mathrm{poly}(d)$. ◀

Information Design with Unknown Prior

Tao Lin

Abstract

Classical information design models (e.g., Bayesian persuasion and cheap talk) require players to have perfect knowledge of the prior distribution of the state of the world. Our paper studies repeated persuasion problems in which the information designer does not know the prior. The information designer learns to design signaling schemes from repeated interactions with the receiver. We design learning algorithms for the information designer to achieve no regret compared to using the optimal signaling scheme with known prior, under two models of the receiver's decision-making:

(1) The first model assumes that the receiver knows the prior and can perform posterior update and best respond to signals. In this model, we design a learning algorithm for the information designer to achieve $O(\log T)$ regret in the general case, and another algorithm with $\Theta(\log\log T)$ regret in the case where the receiver has only two actions. Our algorithms are based on multi-dimensional and conservative binary search techniques, which circumvent the $\Omega(\sqrt{T})$ limitation of empirical estimation in previous works.

(2) The second model assumes that the receiver does not know the prior either and employs a no-regret learning algorithm to take actions. Bayesian persuasion and cheap talk are equivalent under this no-regret learning receiver model. We show that the information designer can achieve regret $O(\sqrt{\mathrm{rReg}(T)T})$, where $\mathrm{rReg}(T) = o(T)$ is an upper bound on the receiver's learning regret. The algorithm is based on exploration + robustification. The $O(\sqrt{\mathrm{rReg}(T)T})$ regret bound is tight even when the information designer knows the prior [1].

Our work thus provides a learning foundation for the problem of information design with unknown prior.

Abstract

We consider a generalization of the Learning With Error problem, referred to as the *white-box learning problem*: You are given the code of a sampler that with high probability produces samples of the form $y, f(y) + \epsilon$ where ϵ is small, and f is computable in polynomial-size, and the computational task consist of outputting a polynomial-size circuit C that with probability, say, $1/3$ over a new sample y' according to the same distributions, approximates $f(y')$ (i.e., $|C(y') - f(y')|$ is small). This problem can be thought of as a generalizing of the Learning with Error Problem (LWE) from linear functions f to polynomial-size computable functions.

We demonstrate that worst-case hardness of the white-box learning problem, conditioned on the instances satisfying a notion of computational shallowness (a concept from the study of Kolmogorov complexity) not only *suffices* to get public-key encryption, but is also *necessary*; as such, this yields the first problem whose worst-case hardness characterizes the existence of public-key encryption. Additionally, our results highlights to what extent LWE "overshoots" the task of public-key encryption.

We complement these results by noting that worst-case hardness of the same problem, but restricting the learner to only get black-box access to the sampler, characterizes one-way functions.

1 Introduction

Public-Key Encryption (PKE) [12, 31] is one of the most central cryptographic primitives enabling secure communication on the Internet: it is the primitive that enables entities that have not physically met to engage in confidential conversations and collaborations.

In contrast to private-key primitives, such as symmetric-key encryption and digital signatures, that can be securely build from the minimal primitive of one-way functions (and for which many candidate problems are known), we only know of a handful of candidate

hard problems from which public-key encryption can be constructed. More specifically, these include (a) *number-theory problems* based on either factoring [31, 29] or discrete logarithms [12, 13], (b) coding-theory based problems [27], (c) lattice problems as finding shortest/longest vectors in lattices [1, 30, 8], and (d) noisy linear-algebra based problems [2, 5]. Out of these, the number-theory based problems can be efficiently solved by quantum algorithms [32], and the coding-theory, lattice and noisy linear algebra problems are all very related – in essence, they can all be viewed as different instances of solving noisy systems of *linear* equations (on either particular natural distributions, or even in the worst-case, when restricting attention to systems of equations satisfying the condition that appropriate solutions exist.[1]

The main purpose of this paper is to provide an assumption that generalizes all these assumptions (i.e., is implied by all of them), yet suffices for obtaining secure PKE. Indeed, the main result of this paper is that hardness of a notion of *white-box learning* achieves this goal.

White-box Learning

Perhaps the most common noisy linear algebra-based assumption is the hardness of the *Learning With Error (LWE)* problem [30], which, in essence, stipulates the hardness of recovering a vector $\mathbf{x}$ given $\mathbf{A}, \mathbf{A}\mathbf{x} + \mathbf{e}$, where $\mathbf{A}$ is a matrix, $\mathbf{e}$ is some "small" noise vector and all arithmetic is modulo some prime p. In more detail, we typically require an stronger condition: not only that is hard to recover x, but also that it is hard to compute a value "close" to $\mathbf{a}^T\mathbf{x}$ for a random vector $\mathbf{a}$. In other words, we can think of $\mathbf{x}$ as the description of a function $f_{\mathbf{x}}(\mathbf{a}) = \mathbf{a}^T\mathbf{x}$ that we are trying to *improperly* approximately learn given noisy samples – thus the name "learning with error".

In fact, there is also a different way to think about the LWE problem that will be useful for our purposes (which follows from the construction of Regev's PKE [30]): We are given the code of a sampler P_x that enables providing samples of the form $(\mathbf{a}, f_{\mathbf{x}}(\mathbf{a}) + \mathbf{e})$, and the goal is to approximate $f_{\mathbf{x}}(\mathbf{a}')$ on a new fresh sample $\mathbf{a}'$ according to the same distribution as $\mathbf{a}$.[2] We refer to this alternative way of thinking of LWE as an instance of *(improper) white-box learning*, where, more generally, we are given the code of a sampler P that generates noisy samples of the form $(y, f(y) + \epsilon)$ and the goal is to approximate $f(y')$ for a fresh sample y' according to the same distribution, using a polynomial-size circuit. In essence, this problem is generalizing the LWE problem from (improperly) learning *linear functions* from noisy samples, to (improperly) *learning a polynomial-size circuit* from noisy samples, and given white-box access to the sampler[3]; the white-box access feature can be viewed as a generalization of Valiant classic PAC-learning model [35] to a setting where the learner not only gets random samples, but also gets the code of the sampler.

In more detail, given a sampler circuit P that samples "labeled instances" (y, z) (where we think of $z \in \mathbb{N}$ as a, perhaps, noisy label for y), let $\mathsf{Comp}_\epsilon^\Delta(P)$ denote the set of circuits f that with probability $1 - \epsilon$ over $(y, z) \leftarrow P$ satisfy the property that $|z - f(y)| \leq \Delta$ (when interpreting both z and $f(z)$ as elements in $\mathbb{N}$). For a function $\Delta\colon \{1\}^* \to \mathbb{N}$, let Δ-$\mathsf{WBLearn}$ denote the following learning problem:

---

[1] In more detail, we require worst-case hardness to hold when conditioning on instances that define a lattice where the shortest vector is long compared to amount of noise.

[2] The reason for this is that given $\mathbf{A}, \mathbf{A}\mathbf{x} + \mathbf{e}$, we can generate noisy samples of $f_{\mathbf{x}}(\mathbf{a}')$ by taking linear combinations. See [30] and the full version of this paper for more details.

[3] As we will discuss in more detail later, it is also more general than the LWE problem in the aspect the LWE *sampler* has a particular form, but we here may consider more general classes of samplers.

- **Input:** Circuit $P \in \{0,1\}^n$, with the promise that there exists a circuit $\widehat{C} \in \{0,1\}^n$ such that $\widehat{C} \in \mathsf{Comp}^{\Delta(1^n)/n^{10}}_{n^{-10}}(P)$.
- **Output:** Circuit $C \in \mathsf{Comp}^{\Delta(1^n)}_{1/3}(P)$.[4]

In other words, we are given a sampler that with very high $(1 - n^{-10})$ probability outputs labelled samples where the label is very close $(\Delta(1^n)/n^{10})$ to being correct, and the goal is to, given the code of the sampler P, simply find a circuit C that with probability $2/3$ approximates the label within $\Delta(1^n)$ (i.e., with a factor n^{10} higher error). We use $\mathsf{ExactWBLearn}$ to denote Δ-$\mathsf{WBLearn}$ when $\Delta(1^n) = 0$.

Hardness of Learning v.s. (Public-Key) Cryptography

Roughly speaking, the main result of this paper will be to show that under certain restrictions on samplers P (which come from the study of *time-bounded Kolmogorov complexity* [23, 34, 11, 22, 17, 33] and in particular the notion of *computational depth* [4]), this generalization of the LWE problem not only suffices to realize a PKE, but will also be necessary. In more detail, worst-case hardness of Δ-$\mathsf{WBLearn}$ under these conditions will *characterize* the existence of public-key encryption. As such, our results yield insight on the extent with which LWE "overshoots" the task of public-key encryption.

We highlight that we are not the first ones to consider connections between learning-theory and cryptography; however, as far as we know, all earlier connections were between the hardness of learning and *private-key cryptography* (i.e., the notion of one-way functions), as opposed to public-key cryptography. Indeed, classic results from [21, 7] demonstrate the equivalence of the hardness of a notion of *average-case* PAC-learning of polynomial-size circuits (i.e., black-box learning) and one-way functions.[5] In contrast, our focus here is on PKE, and instead of considering black-box learning, we consider white-box learning. An additional difference is that we consider worst-case hardness, as opposed to average-case hardness, of the learning theory problem. As was recently shown in [18], this issue can be overcome (in the context of characterizing one-way functions) through the use of a (alternative) notion of computational depth (more details on the relationship with this work below). To put out result in context, we additionaly show that exactly the same problem that we demonstrate characterizes PKE, also characterizes one-way functions once modified to only provide the learner black-box access to the sampler.

1.1 Our Results

Towards explaining our results in more detail, let us first recall the notion of *computational depth* [4]. Let the *t-computational depth* of x, denoted $cd^t(x)$, be defined as $cd^t(x) = \mathrm{K}^t(x) - \mathrm{K}(x)$ where $\mathrm{K}(x)$ denotes the Kolmogorov complexity of x and K^t denotes the t-bounded Kolmogorov complexity of x. That is, $cd^t(x)$ measures how much more x could be compressed if the decompression algorithm may be computationally unbounded, as opposed to it running in time bounded by $t(|x|)$.

We will focus on instances P of the Δ-$\mathsf{WBLearn}$ problem having the property that $(P, \widehat{C})$ is "computationally shallow", where $\widehat{C}$ is a circuit that agrees with P with high probability: let $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t}$ denote Δ-$\mathsf{WBLearn}$ with the additional promise that $cd^t(P, \widehat{C}) \leq 2 \log n$.[6]

[4] We remark that for efficient algorithms, outputting a circuit that approximates a function f is essentially equivalent to approximating the value of $f(y')$ on a random sample y'. Indeed, the circuit implementation of an algorithm for the latter task, is a valid output for the first task.

[5] And the results of [20] can be thought of as characterizing one-way functions through a different type of learning.

[6] We note that there is nothing special about the constant 2; it can be anything that is strictly larger

Characterizing PKE through Hardness of White-Box Learning

Our main results is that the hardness of this problem *characterizes* the existence of public-key encryption:

▶ **Theorem 1.** *Let $\epsilon > 0$ be a constant and let $\Delta\colon \{1\}^* \to \mathbb{N}$ be an efficiently computable function such that $\Delta(1^n) \leq 2^{n^{(1-\epsilon)}}$, and $t\colon \mathbb{N} \to \mathbb{N}$ be polynomial such that $t(n) \geq n^{1+\epsilon}$. Then, following are equivalent:*

- *PKE exists.*
- Δ-$\mathsf{WBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$.

Computational depth is typically thought of as measure of "unnaturality" of strings: strings with low computational depth are considered "natural" and those with high computational depth are considered "unnatural".[7] Given this interpretation, our characterization of public key encryption is thus in terms of the worst-case hardness of white-box learning for "natural" instances.

As far as we know, this thus yields the first problem whose worst-case hardness not only suffices for public-key encryption (such as e.g., [30]) but also is *necessary*.

On the Use of Computational Depth

We note that Antunes and Fortnow [3] elegantly used computational depth to connect worst-case hardness of a problem when restricting attention to elements with small computational depth and *errorless* average-case hardness on sampleable distributions; errorless hardness, however, is not sufficient for cryptographic applications. Nevertheless, inspired by the work of [3], worst-case hardness conditioned on instances with small computational depth was used in [26] (and independently using a variant of this notion in [18]) to characterize one-way functions; additionally, an (interactive) variant of such a notion was also implicitly used in [6] to characterize key exchange protocols. Our techniques are similar to those employed in [26, 6] but instead of applying them to study the hardness of a time-bounded Kolmogorov complexity problem (following [25]), we here instead apply them to study a learning theory problem (namely, white-box learning).

We note that learning theory problems conditioned on small computational depth were recently used in [18] to characterize one-way functions, but our techniques here are more similar to [26, 6]. In particular, [18] does not actually use the standard notion of computational depth but instead define a new alternative variant; in contrast, we here rely on just the standard notion.

Relating Exact and Approximate White-Box Learning

Note that in Theorem 1, the equivalence hold for any (sufficiently small) choice of Δ, as such we directly get as a corollary the equivalence of Exact and Approximate White-box Learning:

---

than 1.

[7] The reason why low computational depth captures "natural string" is as follows: random strings are known to have low computational depth; furthermore, known results (c.f. slow growth laws [18]) show (at least under derandomization assumptions) that one needs to have a long running time to even find a string with high computational depth. So strings with high computational depth are rare and "hard to find", which is why they can be thought of as "unnatural".

▶ **Corollary 2.** *Let $\epsilon > 0$ be a constant and let $\Delta\colon \{1\}^* \to \mathbb{N}$ be any efficiently computable function such that $\Delta(1^n) \leq 2^{n^{(1-\epsilon)}}$, and let $t\colon \mathbb{N} \to \mathbb{N}$ be any polynomial such that $t(n) \geq n^{1+\epsilon}$. Then the following are equivalent:*

- $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$
- $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$

Bounded-Degree Learning and LWE

While in the Δ-WBLearn problem, we allow the function we are trying to learn to be any polynomial-size circuit, we may also consider a restricted version of the problem, denoted $\Delta\text{-}\mathsf{WBLearn}^d_q$, where we restrict attention to functions that can be computed by a degree d polynomial, and we assume that arithmetic is now over $\mathbb{Z}_q$.

We first remark that our main theorem can next be generalized (basically using padding) to show that it suffices to use learning of degree-n^ϵ polynomials to characterize PKE:

▶ **Theorem 3.** *Let $\epsilon > 0$ be a constant and let $\Delta, q\colon \{1\}^* \to \mathbb{N}$ be efficiently computable functions with $\Delta(1^n) \leq q(1^n)/4$ and $q(1^n) \leq 2^{n^{(1-\epsilon)}}$, and $t\colon \mathbb{N} \to \mathbb{N}$ be polynomial such that $t(n) \geq n^{1+\epsilon}$. The following are equivalent:*

- *PKE exists.*
- $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$.
- $\Delta\text{-}\mathsf{WBLearn}^n_q|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$.
- $\Delta\text{-}\mathsf{WBLearn}^{n^\epsilon}_q|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$.

Additionally, as informally discussed above, we note that the hardness of the LWE problem, implies hardness of the $\Delta\text{-}\mathsf{WBLearn}^1_q$ problem (i.e., white-box learning of *linear* functions.)

▶ **Lemma 4** (Informal)**.** *Assuming the hardness of LWE, there exists a polynomial t such that $\Delta\text{-}\mathsf{WBLearn}^1_q|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$ where $\Delta = q/4$.*

Lemma 4 thus shows that white-box learning of linear functions is at least as weak an assumption as LWE. At first sight, one would expect that a converse result may also hold due to known worst-case to average-case reductions for the LWE problem [30, 28, 9] and thus that LWE is equivalent to white-box learning of linear functions. However, the problem with proving the converse direction is that the known worst-case to average-case reductions for LWE only work when the LWE instance defines a lattice where the shortest vector is long compared to amount of noise. Instances sampled from P may not necessarily satisfy this promise, and thus is it not clear how to use an LWE oracle to generally solving white-box learning of linear functions. Thus, it would seem that hardness even of just $\Delta\text{-}\mathsf{WBLearn}^1_q|_{\mathsf{CS}^t}$ is seemingly a weaker (and therefore more general) assumption than LWE. (Of course, it may be that a stronger worst-case to average-case reduction can be established for the LWE problem, in which case equivalence would hold.)

We finally investigate what happens in the regime of "intermediate-degree" polynomials. We remark that using standard linearization techniques, the constant-degree problem is equivalent to the case of degree 1:

▶ **Lemma 5.** *For every constant $d \in \mathbb{N}$, and functions $t, q, \Delta\colon \mathbb{N} \to \mathbb{N}$, there exist $t', q', \Delta'\colon \mathbb{N} \to \mathbb{N}$ such that*

$$\Delta\text{-}\mathsf{WBLearn}^d_q|_{\mathsf{CS}^t} \leq_p \Delta'\text{-}\mathsf{WBLearn}^1_{q'}|_{\mathsf{CS}^{t'}},$$

and

$$\Delta\text{-}\mathsf{WBLearn}^d_q \leq_p \Delta'\text{-}\mathsf{WBLearn}^1_{q'}.$$

Black-box Learning

Finally, to put our results in context, we consider the standard PAC learning model [35] where the learner only get access to samples: Let Δ-BBLearn denote identically the same problem as WBLearn with the exception that the learner gets oracle access (i.e., black-box access) to the sampler (as opposed to white-box access to the sampler). This notion is equivalent to the notion of improper Δ-approximate PAC learning for polynomial-size circuits (and when $\Delta = 0$ to simply improper PAC learning).

As before, let $\Delta\text{-BBLearn}|_{\mathsf{CS}^t}$ denote the problem Δ-BBLearn with the additional promise that $cd^t(P, \widehat{C}) \leq 2 \log n$, and let ExactBBLearn and $\text{ExactBBLearn}|_{\mathsf{CS}^t}$ to denote Δ-BBLearn and $\Delta\text{-BBLearn}|_{\mathsf{CS}^t}$ when $\Delta(1^n) = 0$.

The following theorem can be viewed as the worst-case analog of the classic result of [21, 7] characterizing one-way functions through the hardness of *average-case PAC learning*.

▶ **Theorem 6.** *Let $\epsilon > 0$ be a constant and let $\Delta\colon \{1\}^* \to \mathbb{N}$ be any efficiently computable function such that $\Delta(1^n) \leq 2^{n^{(1-\epsilon)}}$, and let $t\colon \mathbb{N} \to \mathbb{N}$ be any polynomial such that $t(n) \geq n^{1+\epsilon}$. Then the following are equivalent:*

- *One-way function exists*
- $\Delta\text{-BBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$

As mentioned, [18] also recently obtained a worst-case characterization of one-way functions through a learning problem, and using a notion of computational depth. The problems, however, are somewhat different. As opposed to [18], we here consider the standard PAC learning problem (whereas they consider a more general learning problem), and condition on the standard notion of low computational depth (whereas they condition on a new notion of low computational depth that they introduce).[8]

We remark that our Theorem 6 differs from [21, 7] not only in the worst-case condition, but also generalizes those results in the sense that we handle the hardness of Δ-approximate learning for any Δ. As a consequence, we again get an equivalence of approximate and exact black-box learning:

▶ **Corollary 7.** *Let $\epsilon > 0$ be a constant and let $\Delta\colon \{1\}^* \to \mathbb{N}$ be any efficiently computable function such that $\Delta(1^n) \leq 2^{n^{(1-\epsilon)}}$, and let $t\colon \mathbb{N} \to \mathbb{N}$ be any polynomial such that $t(n) \geq n^{1+\epsilon}$. Then the following are equivalent:*

- $\text{ExactBBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$
- $\Delta\text{-BBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$

Open Problems

We leave as an intriguing open problem the question of whether white-box learning of polynomial, or even logarithmic-degree polynomials, also can be collapsed down to the case of constant-degree functions (and thus to linear functions); if this were possible, it would show that PKE, in essence, inherently requires the structure of the LWE problem.

Additionally, as discussed above, even when just restricting attention to learning linear functions, our learning problem generalizes LWE. It would appear that despite this, cryptographic applications of LWE (e.g., to obtain fully homomorphic encryption [14, 10]) nevertheless may still be possible from this generalized version; we leave an exploration of this for future work.

[8] Of course, on a conceptual level, these results are similar; the key point we are trying to make here is that exactly the same learning problem characterizes either one-way functions or PKE, depending on whether the learner gets black-box or white-box access to the sampler.

Finally, it is an intriguing open problem to relate black-box and white-box learning. By our results, doing so is equivalent to relating public-key and secret-key encryption. We note that relating black-box and white-box learning is interesting even just for the case of linear functions (which by our results is equivalent to $O(1)$-degree polynomials). Indeed, Regev's construction of a PKE [30] can be thought of a reduction from black-box learning to white-box learning of linear functions for a *specific* distribution; it is possible that a similar reduction may be applicable more generally.

1.2 Proof Overview

We here provide a detailed proof overview for the proof of Theorem 1. For simplicity, we will show the equivalence between PKE and the worst-case hardness of the exact version, $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$. We start with the construction of PKE based on the hardness of $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$.

Weak PKE

First, we use the well-known fact that a PKE is simply a two-rounds key-agreement protocol. Moreover, by the Key-agreement Amplification Theorem of Holenstein [19] and an application of the Goldreich-Levin theorem [15], to obtain (full-fledged) PKE, it suffices to obtain a weak form of two-rounds key-agreemnt, which we simply refer to as *Weak PKE* defined as follows: There exist some $\epsilon = 1/\text{poly}$ such that *agreement* between A and B happens with probability $1 - \epsilon$. *Security* requires that Eve cannot guess the key (output by Alice) with probability better than $1 - 20\epsilon$.

The Weak PKE protocol

We will next define the weak PKE protocol. We note that this construction resembles the universal key-agreement construction from [16], but with some crucial difference that enable our security proof. The parties A and B on input n perform the following steps:

- *Sample random program:* A samples a random length $\lambda \in [2n]$, and a random program Π of length λ.
- *Run random program:* Next, A runs the program Π for at most $t(n)$ steps to get an output, and interprets the output as a pair of circuits $P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell$ and $C\colon \{0,1\}^k \to \{0,1\}^\ell$. (Think of P as the sampler for a white-box learning instance, and of C as a potential solution to the problem.) If the output of Π is not a valid encoding of such a pair, A sets $P = P_0$ and $C = C_0$ for two fixed circuits P_0, C_0 that always output 0.
- *Agreement estimation:* A estimates the "agreement probability" of P and C (i.e., checking whether C indeed is a good solution): it samples n^{20} random inputs $w_1, \ldots, w_{n^{20}}$ for P, and computes $(x_i, s_i) = P(w_i)$. It then lets $\widehat{\alpha} = \Pr_{i \leftarrow [n^{20}]}[C(x_i) = s_i]$. If $\widehat{\alpha} \leq 1 - n^{-9}$, A reset the pair $(P, C) = (P_0, C_0)$.
- *First message:* A sends (the "sampler") P to B.
- *Second message:* B applies P on a random input w, and computes $(x, s) = P(w)$. It then sends x to A.
- *Outputs:* A outputs $C(x)$ and Bob outputs s.

Agreement

We claim that with probability $1 - 1/n^8$, Alice and Bob will agree (i.e., the final outputs are the same). Note that if $(P, C) = (P_0, C_0)$, Alice and Bob always agree. Moreover, let $\alpha = \Pr_{(x,s) \leftarrow P(U_r)}[C(x) = s]$. Then, the probability of Alice and Bob to agree given that

Alice uses (P, C) as the circuits in the protocol, is exactly α. We observe that by the Chernoff bound, the probability that $\widehat{\alpha}$ is far from α is small, and thus Alice uses (P, C) only when α is larger than $1 - n^{-8}$.

Security

We claim that Eve that can guess s with probability $1 - n^{-7}$ can be used to solve $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$. In more detail, consider such Eve, and let P be an input for $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$. The idea is to construct an algorithm Learner, that on input P outputs a circuit C, such that $C(x)$ simply simulates Eve on the messages P and x. C then outputs Eve's output. For simplicity, in the following we assume that Eve (and thus Learner) is deterministic. (We note that this is a *non-black-box* reduction: We are using the code of Eve to generate C – in particular, we are including the code of Eve into this circuit.[9])

Let $\mathbf{P}$ be a random variable distributed according to the same distribution of the first message in the above protocol. By assumption, we have that

$$\Pr[C' = \mathsf{Learner}(\mathbf{P}); (x, s) \leftarrow \mathbf{P}(U_r); C'(x) = s] \geq 1 - n^{-7}.$$

It follows by a simple averaging argument that

$$\Pr_{\mathbf{P}, C' = \mathsf{Learner}(\mathbf{P})}[\Pr_w[(x, s) \leftarrow \mathbf{P}(w); C'(x) = s] \geq 2/3] \geq 1 - 3n^{-7}.$$

Namely, Learner solves ExactWBLearn with probability at least $1 - 3n^{-7}$ over the distribution of $\mathbf{P}$. We next use ideas from [26, 6] to show this implies that Learner solves $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$ in the worst case.

Indeed, assume that Learner fails on some instance P of $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$. By the promise of the problem, there exists a circuit $\widehat{C}$ such that $cd^t(P, \widehat{C}) \leq 2 \log n$, and $\widehat{C}$ agrees with P with probability at least $1 - n^{-10}$. Let $\ell = \mathrm{K}^t(P, \widehat{C})$. Our goal is to show that $\mathrm{K}(P, \widehat{C}) < \ell - 2 \log n$, which is a contradiction.

Toward this goal, let Let $\mathcal{S}_\ell$ be the set of all pairs of circuits $(P', \widehat{C'})$ with $\mathrm{K}^t(P', \widehat{C'}) = \ell$ that agree with probability at least $1 - n^{-10}$, and on which Learner fails, so that $(P, \widehat{C}) \in \mathcal{S}_\ell$. Fix $(P', \widehat{C'}) \in \mathcal{S}_\ell$, and let Π be the length ℓ program that outputs $(P', \widehat{C'})$ in time t. Observe that the probability of A to sample $(P', \widehat{C'})$ in the first step of the above protocol is at least its probability to sample the program Π, which is $1/2n \cdot 2^{-\ell}$. Since $(P', \widehat{C'})$ agree with high probability, the equality test it the third step of the protocol will pass with high probability, and thus A will send P' to B with probability at least $1/4n \cdot 2^{-\ell}$. In other words,

$$\Pr[\mathbf{P} = P'] \geq 1/4n \cdot 2^{-\ell}$$

for every $(P', \widehat{C'}) \in \mathcal{S}_\ell$, and thus

$$\Pr[(\mathbf{P}, \cdot) \in \mathcal{S}_\ell] \geq |\mathcal{S}_\ell| \cdot 1/4n \cdot 2^{-\ell}$$

(here we say that $(P, \cdot) \in \mathcal{S}_\ell$ if there is some C such that $(P, C) \in \mathcal{S}_\ell$).

On the other hand, by definition of $\mathcal{S}_\ell$, Learner fails on every $(P', \widehat{C'}) \in \mathcal{S}_\ell$. Since Learner fails with probability at most $3n^{-7}$ on $\mathbf{P}$, it must holds that

$$3n^{-7} \geq \Pr[(\mathbf{P}, \cdot) \in \mathcal{S}_\ell].$$

[9] This particular non-black usage of Eve is not inherent. We could have considered a different formalization of the learning theory problem which simply requires the attacker to succeed on a randomly sampled instance. Subsequent parts of the argument, however, will use non-black-box access to Eve more inherently.

Combining the above, we get that

$$|\mathcal{S}_\ell| \leq 12n^{-6} \cdot 2^\ell.$$

We can now use the bound on $\mathcal{S}_\ell$ to bound the Kolmogorov complexity of $(P, \widehat{C})$. To describe $(P, \widehat{C})$, it is enough to describe the set $\mathcal{S}_\ell$, and the index of the pair $(P, \widehat{C})$ in this set. That is,

$$\mathrm{K}(P, \widehat{C}) \leq \mathrm{K}(\mathcal{S}_\ell) + \log|\mathcal{S}_\ell| + O(\log\log n) \leq \mathrm{K}(\mathcal{S}_\ell) + \ell - 6\log n + O(\log\log n).$$

We conclude the proof with the observation that to describe $\mathcal{S}_\ell$ it is enough to describe n (which can be done using $\log n + O(\log\log n)$ bits), ℓ ($\log n$ bits) and Eve (that can be described with constant many bits[10]). Thus, $\mathrm{K}(\mathcal{S}_\ell) \leq 3\log n$, and we get that

$$\mathrm{K}(P, \widehat{C}) < \ell - 2\log n,$$

as we wanted to show.

Hardness of ExactWBLearn$|_{\mathsf{CS}^t}$ from PKE

We next show that the existence of PKE implies the hardness of $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$. We now sketch the proof. Let Gen be the algorithm the generate pair (pk, sk) of public and secret key, and let $\mathsf{Enc}, \mathsf{Dec}$ be the encryption and decryption protocols. For a random pair of keys $(pk, sk) \leftarrow \mathsf{Gen}(r)$, we construct two circuits, $P(w, s) = (x = \mathsf{Enc}_{pk}(s; w), s)$, and $\widehat{C}(x) = \mathsf{Dec}_{sk}(x)$.

By the security of the PKE scheme, it follows that with high probability over the randomness of Gen, it is hard to learn the function of C, as the circuit P only uses the public key, and the function C computes is the decryption of a random encryption. This already implies that $\mathsf{ExactWBLearn}$ is hard, but we still need to show that P is inside the promise of the problem $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$.

It follows by the correctness of the PKE scheme that $\widehat{C}$ computes the function that is sampled by P. Thus, to be in the promise of $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$, we only need that $(P, \widehat{C})$ has small computational depth. This, however, is not necessarily the case. To solve this, we simply pad $\widehat{C}$ with the randomness used by Gen. That is, we let $\widehat{C'}$ be a functionally equivalent circuit to $\widehat{C}$, with r encoded to it, where r is such that $\mathsf{Gen}(r) = (pk, sk)$. It follows that when t is large enough, $\mathrm{K}^t(P, \widehat{C'}) \leq |r| + O(1)$ (as we can describe them by simply describing the randomness and the algorithm Gen). On the other hand, $\mathrm{K}(P, \widehat{C'}) \geq \mathrm{K}(r)$ (since r can be obtained from $\widehat{C'}$), which is at least $|r| - O(1)$ with high probability. Together, we conclude that with high probability over the randomness of Gen, the circuits $(P, \widehat{C'})$ are in the promise of $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$.

Comparison with [6]

We remark that at a high-level, our construction of a two-message key-agreement protocol shares many similaries with the key-agreement protocol developing in [6], relying on the hardness of an interactive notion of time-bounded Kolmogorov complexity, conditionned on an analog of computational shallowness. They central difference is that the protocol in [6] requires at least 3 rounds due to the use of an equility check protocol to determine whether

[10] This non-black-box usage of Eve (which is taken from [26, 6]) is seemingly inherent to our proof technique. Note that we are here relying on the fact that Eve is a uniform algorithm, but as we discuss in the formal section, the argument can be extended to work also in the non-uniform setting.

Alice and Bob managed to agree on a key. In contrast, our protocol does not rely on such an equality check step (and thus it can be executed in only two rounds, which is crucial to get PKE); indeed, we replaced the equality protocol with a step where Alice on her own can determine whether the message she sends will enable agreement to happen. Of course, the reason why we can do this is that we are reducing security from a different problem.

Other features of the protocol are quite similar; this is because we also rely on the worst-case hardness of a problem "conditioning on computationally shallow instances". Indeed, as described above, our security proof shares many features with those of [25, 6].

Comparison with Universal Constructions

Universal constructions of PKE are known (see [16]); that is, constructions having the property that they are secure if (any) PKE exist. We emphasize that while the details of the protocol from [16] are somewhat different, the "agreement estimation" step performed there is very similar to what we do. Furthermore, we can interpret our protocol as an alternative (variant) universal PKE protocol in which Alice chooses a random (key-generation) program Gen and executes it to get an encryption scheme Enc_{pk} and description scheme Dec_{sk}, with the keys pk, sk hardcoded to the scheme.[11] Alice then estimates the agreement probability of the encryption, and if it is high enough, she sends the encryption scheme as the public-key, and uses the decryption scheme as the private-key. If PKE exists, with a noticeable probability over the choice of Gen, this scheme will be secure. We emphasize that since we base the security of our protocol (and thus also the above universal one) on the hardness of the white-box learning problem, it enables an approach for measuring the concrete security of the protocol by relating it to the security of the learning theory problem.

2 Preliminaries

2.1 Notations

All logarithms are taken in base 2. We use calligraphic letters to denote sets and distributions, bold uppercase for random variables, and lowercase for values and functions. Let poly stand for the set of all polynomials. Let PPT stand for probabilistic poly-time, and n.u.-poly-time stand for non-uniform poly-time. An n.u.-poly-time algorithm A is equipped with a (fixed) poly-size advice string set $\{z_n\}_{n\in\mathbb{N}}$ (that we typically omit from the notation), and we let A_n stand for A equipped with the advice z_n (used for inputs of length n). For a randomized algorithm A, we denote by $\mathsf{A}(\cdot; r)$ the algorithm A with fixed randomness $r \in \{0,1\}^*$. Let neg stand for a negligible function. Given a vector $v \in \Sigma^n$, let v_i denote its i^{th} entry, let $v_{<i} = (v_1, \ldots, v_{i-1})$ and $v_{\leq i} = (v_1, \ldots, v_i)$. Similarly, for a set $\mathcal{I} \subseteq [n]$, let $v_{\mathcal{I}}$ be the ordered sequence $(v_i)_{i\in\mathcal{I}}$. For $x, y \in \{0,1\}^*$, we use $x||y$ to denote the concatenation of x and y. For a set $\mathcal{S} \subseteq \{0,1\}^*$, we use $\mathcal{S}||y$ to denote the set $\{x||y\colon x \in \mathcal{S}\}$.

2.2 Distributions and Random Variables

When unambiguous, we will naturally view a random variable as its marginal distribution. The support of a finite distribution $\mathcal{P}$ is defined by $\text{Supp}(\mathcal{P}) := \{x\colon \Pr_{\mathcal{P}}[x] > 0\}$. For a (discrete) distribution $\mathcal{P}$, let $x \leftarrow \mathcal{P}$ denote that x was sampled according to $\mathcal{P}$. Similarly, for a set $\mathcal{S}$, let $x \leftarrow \mathcal{S}$ denote that x is drawn uniformly from $\mathcal{S}$. For $m \in \mathbb{N}$, we use $\mathbf{U}_m$ to denote

[11] In the protocol of [16], Alice would instead choose random programs for Alice and Bob to run; we do not know how to prove the security of such a protocol under our assumption.

a uniform random variable over $\{0,1\}^m$ (that is independent from other random variables in consideration). The statistical distance (also known as, variation distance) of two distributions $\mathcal{P}$ and $\mathcal{Q}$ over a discrete domain $\mathcal{X}$ is defined by $\mathrm{SD}(\mathcal{P},\mathcal{Q}) := \max_{\mathcal{S}\subseteq\mathcal{X}}|\mathcal{P}(\mathcal{S}) - \mathcal{Q}(\mathcal{S})| = \frac{1}{2}\sum_{x\in\mathcal{S}}|\mathcal{P}(x) - \mathcal{Q}(x)|$.

The following lemma is proven in the full version of this paper.

▶ **Lemma 8.** *There exists an efficient oracle-aided algorithm* A *such that the following holds. Let* $(\mathbf{X},\mathbf{Y})$ *be a pair of jointly distributed random variables over* $\{0,1\}^* \times \{0,1\}^n$*, and let* $\mathbf{R}$ *be a uniform independent random variable over* $\{0,1\}^n$*. Let* E *be an algorithm such that* $\Pr[\mathsf{E}(\mathbf{X},\mathbf{R}) = \langle \mathbf{Y},\mathbf{R}\rangle] \geq 1-\epsilon$*, for* $0 \leq \epsilon$*. Then* $\Pr\left[\mathsf{A}^{\mathsf{E}}(1^n,\mathbf{X}) = \mathbf{Y}\right] \geq 1 - 8\epsilon - \mathrm{neg}(n)$.

2.3 Circuits

In this paper we consider circuits over the De-Morgan Basis, which contains the following gates: $\wedge$ ("and" gate with fan-in 2), $\vee$ ("or" gate with fan-in 2), and $\neg$ ("not" gate with fan-in one). The size of a circuit C, is the number of gates in C.

We consider encoding of a circuit as a string over $\{0,1\}^*$ in the following natural way: Given a circuit C, we first encode the length of C using a prefix-free encoding, and then for every gate g, according to a topological order, we encode its type (input, output, $\wedge$,$\vee$, or $\neg$), and the (up to two) gates wired into g.

Observe that every circuit C of size s can be encoded to a string of length $O(s\log s)$. Moreover, given the encoding and an input x to C, $C(x)$ can be computed efficiently (in polynomial time in the encoding length).

We identify a string in $\{0,1\}^*$ with the circuit it encodes. For example, for $C \in \{0,1\}^n$ we use $C(x)$ to denote the value of the circuit encoded by C applied on the input x. We denote by $|C|$ the length of the encoding of C.

Finally, by encoding first the size of C, we assume that for every encoding of a circuit C, and for every $z \in \{0,1\}^*$, the string $C||z$ encodes the same circuit as C.[12]

2.4 Entropy

For a random variable $\mathbf{X}$, let $\mathrm{H}(\mathbf{X}) = \mathrm{E}[\log \frac{1}{\Pr[\mathbf{X}=x]}]$ denote the (Shannon) entropy of $\mathbf{X}$, and let $\mathrm{H}_\infty(\mathbf{X}) = \min_{x\in Supp(\mathbf{X})} \log \frac{1}{\Pr[\mathbf{X}=x]}$ denote the *min-entropy* of $\mathbf{X}$.

$$\min_{x\in \mathrm{Supp}(\mathbf{X})} \log \frac{1}{\Pr[\mathbf{X}=x]}.$$

For a random variable $\mathbf{X}$ and an event E, we use $\mathrm{H}_\infty(\mathbf{X} \mid E)$ to denote the min-entropy of the distribution $\mathbf{X}|_E$. We will use the following facts.

▶ **Fact 9.** *Let* $\mathbf{X}$ *and* $\mathbf{Y}$ *be independent random variables. Then* $\mathrm{H}_\infty(\mathbf{X},\mathbf{Y}) = \mathrm{H}_\infty(\mathbf{X}) + \mathrm{H}_\infty(\mathbf{Y})$.

2.5 Complexity Classes

We define the complexity classes FBPP and ioP/poly.

[12] We actually only use the fact that we can encode z into the circuit. This can be done by adding dummy gates that do not change the output of C, where each gate g_i is either $\wedge$ or $\vee$ according to the ith bit of z.

▶ **Definition 10** (Infinitely-often FBPP (ioFBPP)). *A binary relation $\mathcal{R} \subseteq \{0,1\}^* \times \{0,1\}^*$ is in* ioFBPP *if there exists* PPT *algorithms* A *such that the following holds for infinitely many n's:*

For every $x \in \{0,1\}^n$ such that there exists $y \in \{0,1\}^*$ with $(x,y) \in \mathcal{R}$,

$$\Pr\left[(x, \mathsf{A}(x, 1^k)) \in \mathcal{R}\right] \geq 1 - 1/k,$$

for every $k > 0$. $\mathcal{R}$ is in ioP/poly *if the above holds with respect to $n.u. - poly - time$ algorithms* A*.*

2.6 One-Way Function

▶ **Definition 11** (One-way function). *A polynomial-time computable function $f : \{0,1\}^* \to \{0,1\}^*$ is called a* one-way function *if for every polynomial-time algorithm* A*,*

$$\Pr_{x \leftarrow \{0,1\}^n}\left[\mathsf{A}(1^n, f(x)) \in f^{-1}(f(x))\right] = \mathrm{neg}(n)$$

▶ **Definition 12** (Weak one-way function). *Let $m \in$ poly be a polynomial-time computable function. A polynomial-time computable function $f : \{0,1\}^{m(n)} \to \{0,1\}^*$ is called α-*weak one-way function *if for every polynomial-time algorithm* A*, for every large enough n,*

$$\Pr_{x \leftarrow \{0,1\}^{m(n)}}\left[\mathsf{A}(1^n, f(x)) \in f^{-1}(f(x))\right] \leq 1 - \alpha(n)$$

f is a weak one-way function *if it is $1/p$-weak one way function, for some $p \in$ poly.*

▶ **Theorem 13** (Weak to strong OWFs, [36]). *One-way functions exist if and only if weak-one way functions exist.*

2.7 Public-Key Encryption

▶ **Definition 14** (Public-key encryption scheme (PKE)). *A triplet of randomized, efficiently computable functions* $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ *is a* $(\alpha(n), \beta(n))$-public-key encryption scheme (PKE) *if the following holds:*

- *Correctness: For every large enough $n \in \mathbb{N}$ and any $m \in \{0,1\}$,*

$$\Pr_{(sk,pk) \leftarrow \mathsf{Gen}(1^n)}[\mathsf{Dec}(sk, \mathsf{Enc}(pk, m)) = m] \geq 1 - \alpha(n)$$

- *Security: For every* PPT Eve*, for every large enough $n \in \mathbb{N}$,*

$$\Pr_{(sk,pk) \leftarrow \mathsf{Gen}(1^n), m \leftarrow \{0,1\}}[\mathsf{Eve}(pk, \mathsf{Enc}(pk, m)) = m] \leq 1/2 + \beta(n).$$

Such a scheme is a PKE *if it is $(1/n^c, 1/n^c)$-PKE for every $c \in \mathbb{N}$.*

The following lemma shows that it is possible to amplify an 1-bit weak key-agreement protocol into a key-agreement. This lemma is a simple case of the more general result of [19].

▶ **Lemma 15** (PKE amplification, [19]). *The following holds for every constants $c_1 > c_2$. Assume there exists an $(n^{-c_1}, 1/2 - n^{-c_2})$-PKE. Then, there exists a PKE.*

We also define weak-PKE.

▶ **Definition 16** (Weak Public-key encryption scheme (weak-PKE)). *For an efficiently computable function d: $\{1\}^* \to \mathbb{N}$, a triplet of randomized, efficiently computable functions* $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ *is a* $(\alpha(n), \beta(n), \gamma(n))$-weak-public-key encryption scheme (weak-PKE) *if the following holds:*

- *For every $n \in \mathbb{N}$, given pk and randomness r,* $\mathsf{Enc}(pk; r)$ *outputs a message $m(pk; r)$ and an output $o(pk; r) \in \mathbb{N}$.*
- *Correctness: For every large enough $n \in \mathbb{N}$*

$$\Pr_{(sk,pk)\leftarrow \mathsf{Gen}(1^n),r}[|\mathsf{Dec}(sk, m(pk, r)) - o(pk, r)| \leq d(1^n)] \geq 1 - \alpha(n)$$

- *Security: For every* PPT Eve*, for every large enough $n \in \mathbb{N}$,*

$$\Pr_{(sk,pk)\leftarrow \mathsf{Gen}(1^n),r}[|\mathsf{Eve}(pk, m(pk, r)) - o(pk, r)| \leq \gamma(n) \cdot d(1^n)] \leq \beta(n).$$

In the full version of this paper we prove the following lemma, stating that weak-PKE can be used to construct PKE.

▶ **Lemma 17** (Weak-PKE amplification)**.** *The following holds for every constants $c_1 > c_2$. Assume there exists an $(n^{-c_1}/2, 1 - 10n^{-c_2}, 2n^{c_1})$-weak-PKE. Then, there exists a PKE.*

2.8 Kolmogorov Complexity and Computational Depth

Roughly speaking, the *t-time-bounded Kolmogorov complexity*, $\mathrm{K}^t(x)$, of a string $x \in \{0,1\}^*$ is the length of the shortest program $\Pi = (M, y)$ such that, when simulated by an universal Turing machine, Π outputs x in $t(|x|)$ steps. Here, a program Π is simply a pair of a Turing Machine M and an input y, where the output of P is defined as the output of $M(y)$. When there is no running time bound (i.e., the program can run in an arbitrary number of steps), we obtain the notion of Kolmogorov complexity.

In the following, fix universal TM U with polynomial simulation overhead, and let $\mathsf{U}(\Pi, 1^t)$ denote the output of Π when emulated on U for t steps. We now define the notion of Kolmogorov complexity with respect to the universal TM U.

▶ **Definition 18.** *Let t be a polynomial. For all $x \in \{0,1\}^*$, define the* t-bounded Kolmogorov complexity *of x*

$$\mathrm{K}^t(x) = \min_{\Pi \in \{0,1\}^*} \{|\Pi| : \mathsf{U}(\Pi, 1^{t(|x|)}) = x\}$$

where $|\Pi|$ is referred to as the description length *of Π. When there is no time bound, the* Kolmogorov complexity *of x is defined as*

$$\mathrm{K}(x) = \min_{\Pi \in \{0,1\}^*} \{|\Pi| : \exists t \in \mathbb{N} \mathsf{U}(\Pi, 1^t) = x\}.$$

The computational depth *of x [4], denoted by $cd^{t,\infty}(x)$, is defined to be*

$$cd^{t,\infty}(x) = \mathrm{K}^t(x) - \mathrm{K}(x).$$

We use $\mathsf{K}(x, y)$ to denote the Kolmogorov complexity of some generic self-delimiting encoding of the pair x, y. Recall that we use $\mathsf{K}(x||y)$ to denote the complexity of the concatenation of x and y. We will use the following well-known fact:

▶ **Fact 19.** *For every $x, y \in \{0,1\}^*$,*

$$\mathsf{K}(x, y) \leq \mathsf{K}(x) + \mathsf{K}(y) + \log(\mathsf{K}(x)) + 2\log\log(\mathsf{K}(x)) + O(1).$$

We will also use the following bound on the Kolmogorov complexity of strings sampled from distributions with high min-entropy.

▶ **Lemma 20.** *For every $n \in \mathbb{N}$, and every distribution $\mathcal{D}$, it holds that*

$$\Pr_{x \leftarrow \mathcal{D}}[\mathsf{K}(x) \geq \mathrm{H}_\infty(\mathcal{D}) - \log n] \geq 1 - 1/n.$$

Proof. There are at most $2^{\mathrm{H}_\infty(\mathcal{D}) - \log n}$ strings x with $\mathsf{K}(x) < \mathrm{H}_\infty(\mathcal{D}) - \log n$. Thus,

$$\Pr_{x \leftarrow \mathcal{D}}[\mathsf{K}(x) < \mathrm{H}_\infty(\mathcal{D}) - \log n] \leq 2^{\mathrm{H}_\infty(\mathcal{D}) - \log n} \cdot 2^{-\mathrm{H}_\infty(\mathcal{D})} = 1/n. \qquad \blacktriangleleft$$

We will also use the well-known Chernoff bound in our proof.

▶ **Fact 21** (Hoeffding's inequality). *Let $\mathbf{A}_1, ..., \mathbf{A}_n$ be independent random variables s.t. $\mathbf{A}_i \in \{0,1\}$. Let $\widehat{\mathbf{A}} = 1/n \cdot \Sigma_{i=1}^n \mathbf{A}_i$ and $\mu = \mathrm{E}\left[\widehat{\mathbf{A}}\right]$. For every $\epsilon \in [0,1]$ it holds that:*

$$\Pr\left[\left|\widehat{\mathbf{A}} - \mu\right| \geq \epsilon\right] \leq 2 \cdot e^{-\epsilon^2 \cdot n}.$$

3 White-Box Distributional Learning

Let $P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell$ be a circuit that, given r bits of randomness, samples labeled instances (x,s). In the following we view s as a binary representation of a number in $\mathbb{N}$ (and respectively all the operations below are over $\mathbb{N}$, and we use $|\cdot|$ to denote the absolute value). We define the set of all circuits that approximate P with high probability,

$$\mathsf{Comp}_\epsilon^\Delta(P) = \left\{C\colon \{0,1\}^k \to \{0,1\}^\ell \colon \Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|C(x) - s| \leq \Delta] \geq 1 - \epsilon\right\}.$$

We define the following white-box learning problem $\mathsf{WBLearn}$:

▶ **Definition 22** (Δ-$\mathsf{WBLearn}$). *For a function $\Delta\colon \{1\}^* \to \mathbb{N}$, let Δ-$\mathsf{WBLearn}$ be the following learning problem:*

- *Input: Circuit $P \in \{0,1\}^n$, with the promise that there exists a circuit $\widehat{C} \in \{0,1\}^n$ such that $\widehat{C} \in \mathsf{Comp}_{n^{-10}}^{\Delta(1^n)/n^{10}}(P)$.*
- *Output: Circuit $C \in \mathsf{Comp}_{1/3}^{\Delta(1^n)}(P)$*

In this work we are focusing on inputs P for which the circuit $\widehat{C}$ that agree with P with high probability, is such that the description of $\widehat{C}$ and P is computational shallow. Formally, for a time function $t\colon \mathbb{N} \to \mathbb{N}$, we denote by Δ-$\mathsf{WBLearn}|_{\mathsf{CS}^t}$ the problem Δ-$\mathsf{WBLearn}$ with the additional promise that $cd^t(P, \widehat{C}) \leq 2 \log n$.

We use $\mathsf{ExactWBLearn}$ and $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t}$ to denote Δ-$\mathsf{WBLearn}$ and Δ-$\mathsf{WBLearn}|_{\mathsf{CS}^t}$ when $\Delta(1^n) = 0$. Note that $\mathsf{ExactWBLearn}$ and Δ-$\mathsf{WBLearn}|_{\mathsf{CS}^t}$ are incomparable: While in Δ-$\mathsf{WBLearn}|_{\mathsf{CS}^t}$ we only need to find a circuit that approximates P, the promise in $\mathsf{ExactWBLearn}$ is stronger. Yet, there is a simple reduction from $\mathsf{ExactWBLearn}$ to Δ-$\mathsf{WBLearn}|_{\mathsf{CS}^t}$.

▶ **Lemma 23.** *For every $\Delta\colon \{1\}^* \to \mathbb{N}$ such that $\Delta \in 2^{o(n/\log n)}$, it holds that*

$$\mathsf{ExactWBLearn} \leq_p \Delta\text{-}\mathsf{WBLearn}.$$

Similarly, for any such Δ and a function $t\colon \mathbb{N} \to \mathbb{N}$, there exists $t'\colon \mathbb{N} \to \mathbb{N}$, such that

$$\mathsf{ExactWBLearn}|_{\mathsf{CS}^t} \leq_p \Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^{t'}}.$$

Proof. We start with the first reduction $\mathsf{ExactWBLearn} \leq_p \Delta\text{-}\mathsf{WBLearn}$. Given a circuit $P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell$ of length n, the reduction outputs a circuit $P'\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^{\ell+n}$, which is equivalent to P, with additional n output gates that always output 0. That is, $P'(w) = (x, s')$, where $P(w) = (x, s)$ and $s' = 2^n \cdot s$. As we only added n gates to P, P' can be encoded using $O(n \log n)$ bits. Using padding we assume that $|P'| \in \Theta(n \log n)$.

For correctness, observe that if there exists $\widehat{C} \in \mathsf{Comp}^0_{n^{-10}}(P)$, then there exists such $\widehat{C'} \in \mathsf{Comp}^0_{n^{-10}}(P')$ (where $\widehat{C'}$ is defined similarly to P' using $\widehat{C}$). Moreover, an approximation of the output s' of P' within a distance of $2^n/4$ is equivalent to the exact output s of P. Indeed, given an $2^n/4$-approximation of s' we can find s by simply dividing s' by 2^n and rounding to the closest integer.

Finally, to see the second reduction, it is enough to show that $cd^{t'}(P', \widehat{C'}) \leq 2\log|P'|$. Since $P', \widehat{C'}$ can be efficiently constructed given $P, \widehat{C}$, and similarly $P, \widehat{C}$ can be efficiently constructed given $P', \widehat{C'}$, it holds that for large enough (polynomial time t', $cd^{t'}(P', \widehat{C'}) \leq cd^t(P, \widehat{C}) + O(1) \leq 2\log n + O(1) \leq 2\log n + 2\log\log n \leq 2\log|P'|$. ◀

We prove the following theorem.

▶ **Theorem 24.** *Let $\epsilon > 0$ be a constant and let $\Delta\colon \{1\}^* \to \mathbb{N}$ be any efficiently computable function such that $\Delta(1^n) \leq 2^{n^{(1-\epsilon)}}$, and let $t\colon \mathbb{N} \to \mathbb{N}$ be any polynomial such that $t(n) \geq n^{1+\epsilon}$. Then the following are equivalent:*

- *PKE exists*
- $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$

As a corollary, we get a result of independent interest relating exact and approximate white-box learning:

▶ **Corollary 25.** *Let $\epsilon > 0$ be a constant and let $\Delta\colon \{1\}^* \to \mathbb{N}$ be any efficiently computable function such that $\Delta(1^n) \leq 2^{n^{(1-\epsilon)}}$, and let $t\colon \mathbb{N} \to \mathbb{N}$ be any polynomial such that $t(n) \geq n^{1+\epsilon}$. Then the following are equivalent:*

- $\mathsf{ExactWBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$
- $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$

Theorem 24 follows by the following two theorems.

▶ **Theorem 26.** *Let $t(n)$ be a polynomial and $\Delta\colon \{1\}^* \to \mathbb{N}$ an efficiently computable function. Then if $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$, PKE exist.*

▶ **Theorem 27.** *Assume there exists a PKE. Then for any constant $\epsilon > 0$ and any $t(n) \geq n^{1+\epsilon}$ and any efficiently computable $\Delta\colon \{1\}^* \to \mathbb{N}$ such that $\Delta(1^n) \leq 2^{n^{(1-\epsilon)}}$, $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t} \notin \mathsf{ioFBPP}$.*

Theorem 26 is proven in Section 4, and Theorem 27 is proven in the full version of this paper.

4 Worst-Case hardness of $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t} \implies \mathsf{KE}$

In this section we prove Theorem 26, that states that the worst-case hardness of $\mathsf{WBLearn}|_{\mathcal{Q}_t}$ implies the existence of public-key encryption scheme. In the following, let $C_0\colon \{0,1\} \to \{0,1\}$ be the circuit that always outputs 0, and $P_0\colon \{0,1\} \to \{0,1\} \times \{0,1\}$ be the circuit that always outputs $(0,0)$.

To prove the above theorem, fix $t = t(n)$ and $\Delta = \Delta(1^n)$, and consider the following scheme $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$:

▶ **Algorithm 28** (Gen).
Parameter: function $t\colon \mathbb{N} \to \mathbb{N}$.
Input: 1^n.
Operation:
1. *Sample* $\lambda \leftarrow [3n]$ *and* $\Pi \leftarrow \{0,1\}^\lambda$.
2. *Run* Π *for* $t(2n)$ *steps to get circuits* $C\colon \{0,1\}^k \to \{0,1\}^\ell, P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell$ *for some* k, r, ℓ. *If the output of* Π *is not two such circuits, set* $C = C_0$, $P = P_0$, $r = k = \ell = 1$.
3. *Randomly sample* $(x_1, s_1), \ldots, (x_{n^{20}}, s_{n^{20}}) \leftarrow P(U_r)$, *and compute*

$$\widehat{\alpha} = \Pr_{i \leftarrow [n^{20}]}\left[|C(x_i) - s_i| \leq \Delta(1^n)/n^{10}\right].$$

   If $\widehat{\alpha} < 1 - 2n^{-8}$, *reset* $C = C_0$ *and* $P = P_0$.
4. *Output* (k, ℓ, C) *as the secret key, and* (r, k, ℓ, P) *as the public key.*

▶ **Algorithm 29** (Enc).
Input: public-key $(r \in \mathbb{N}, k \in \mathbb{N}, \ell \in \mathbb{N}, P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell)$.
Operation:
1. *Sample randomness* $z \leftarrow \{0,1\}^r$.
2. *Compute* $P(z)$ *to get* (x, s).
3. *Output* $m = x$ *and* $o = s$.

▶ **Algorithm 30** (Dec).
Input: secret-key $(k \in \mathbb{N}, \ell \in \mathbb{N}, C\colon \{0,1\}^k \to \{0,1\})$, *cipher* $x \in \{0,1\}^k$.
Operation:
1. *Compute* $C(x) = s'$.
2. *Output* s'.

Observe that the size of the circuits C and P sampled by $\mathsf{Gen}(1^n)$ is at most $t(2n)$. Thus, all of the above algorithms can be implemented efficiently. Below we bound the correctness and the security of the above scheme. For every $n \in \mathbb{N}$, let $(\mathbf{K}_n, \mathbf{L}_n, \mathbf{C}_n)$ and $(\mathbf{R}_n, \mathbf{K}_n, \mathbf{L}_n, \mathbf{P}_n)$ be the random variables distributed according to the secret and public keys $(k, \ell, C), (r, k, \ell, P)$ in a random execution of $\mathsf{Gen}(1^n)$. Let $\mathbf{M}_n$ and $\mathbf{O}_n$ be the output of $\mathsf{Enc}(\mathbf{R}_n, \mathbf{K}_n, \mathbf{L}_n, \mathbf{P}_n)$ in a random execution.

4.1 Correctness

We start by analyzing the correctness probability of the scheme.

▶ **Lemma 31.** *For every* $n \in \mathbb{N}$, *it holds that*

$$\Pr\left[|\mathsf{Dec}((\mathbf{K}_n, \mathbf{L}_n, \mathbf{C}_n), \mathbf{M_n}) - \mathbf{O}_n| \leq \Delta(1^n)/n^{10}\right] \geq 1 - n^{-7}.$$

To prove Lemma 31 we will use the following simple claim, which is immediate from the Hoffeding bound.

▷ Claim 32. Let $C\colon \{0,1\}^k \to \{0,1\}^\ell$ and $P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell$ be two circuits. Let $\mathbf{A}$ be a random variable distributed according to the following process:

Sample $(x_1, s_1) \ldots, s(x_{n^{20}}, s_{n^{20}}) \leftarrow P(\mathbf{U}_r)$, and let $\mathbf{A} = \Pr_{i \leftarrow [n^{20}]}[|C(x_i) - s_i| \leq \Delta]$.
Let $\mu = \Pr_{(x,s) \leftarrow P(\mathbf{U}_r)}[|C(x) - s| \leq \Delta]$. Then $\Pr\left[|\mathbf{A} - \mu| \geq n^{-9}\right] \leq 2^{-n}$.

Proof. Immediate by Fact 21. ◁

Proof of Lemma 31. When $\mathsf{Gen}(1^n)$ outputs C_0 and P_0, the scheme has perfect correctness. Moreover, when the secret and public key are (k, ℓ, C) and (r, k, ℓ, P), it holds that

$$\Pr\left[|\mathsf{Dec}((k,\ell,C),\mathbf{M})) - \mathbf{O}| \leq \Delta(1^n)/n^{10}\right] = \Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}\left[|C(x) - s| \leq \Delta(1^n)/n^{10}\right].$$

Thus,

$$\begin{aligned}
&\Pr\left[|\mathsf{Dec}((\mathbf{K}_n,\mathbf{L}_n,\mathbf{C}_n),\mathbf{M}_n) - \mathbf{O}_n| \leq \Delta(1^n)/n^{10}\right] \\
&\geq (1-3n^{-8}) \cdot \Pr_{\mathbf{R}_n,\mathbf{K}_n,\mathbf{P}_n,\mathbf{C}_n}\left[\Pr_{(x,s)\leftarrow \mathbf{P}_n(\mathbf{U}_{\mathbf{R}_n})}\left[|\mathbf{C}_n(x) - s| \leq \Delta(1^n)/n^{10}\right] \geq 1-3n^{-8}\right] \\
&\geq 1 - 3n^{-8} - \Pr_{\mathbf{R}_n,\mathbf{K}_n,\mathbf{P}_n,\mathbf{C}_n}\left[\Pr_{(x,s)\leftarrow \mathbf{P}_n(\mathbf{U}_{\mathbf{R}_n})}\left[|\mathbf{C}_n(x) - s| \leq \Delta(1^n)/n^{10}\right] < 1-3n^{-8}\right].
\end{aligned}$$

The lemma now follows since by Lemma 31, the probability of circuits P, C with

$$\Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}\left[|\mathbf{C}_n(x) - s| \leq \Delta(1^n)/n^{10}\right] < 1 - 3n^{-8}$$

to pass the test in Step 3 is at most 2^{-n}. ◀

4.2 Security

We next bound the leakage of the scheme.

▶ **Lemma 33.** *Assume there exists an algorithm* Eve *such that*

$$\Pr[|\mathsf{Eve}(1^n,(\mathbf{R}_n,\mathbf{K}_n,\mathbf{L}_n,\mathbf{P}_n),\mathbf{M_n}) - \mathbf{O}_n| \leq \Delta(1^n)] \geq 1 - n^{-6}$$

for infinitely many n's. Then Δ-$\mathsf{WBLearn}|_{\mathsf{CS}^t} \in \mathsf{ioBPP}$.

In the following, let Eve be an algorithm that uses $r_{\mathsf{Eve}}(n)$ bits of randomness and guesses $\mathbf{M}$ with probability at least $1-n^{-6}$. Recall that for $w \in \{0,1\}^{r_{\mathsf{Eve}}(n)}$, $\mathsf{Eve}(1^n,(r,k,\ell,P),m;w)$ denotes the execution of Eve when its randomness is fixed to be w.

▶ **Algorithm 34.**
Input: $P \in \{0,1\}^n$.
Operation:
1. *Let r, k, ℓ be such that $P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell$.*
2. *Sample $w \leftarrow \{0,1\}^{r_{\mathsf{Eve}}(n)}$ uniformly at random.*
3. *Construct a circuit C' such that $C'(x) = \mathsf{Eve}(1^n,(r,k,\ell,P),x;w)$.*
4. *Return C'.*

We prove the following lemma.

▶ **Lemma 35.** *Assume that*

$$\Pr[|\mathsf{Eve}(1^n,(\mathbf{R}_n,\mathbf{K}_n,\mathbf{L}_n,\mathbf{P}_n),\mathbf{M}_n) - \mathbf{O}_n| \leq \Delta(1^n)] \geq 1 - n^{-6}$$

for infinitely many n's. Then the following holds for infinitely many n's. For every input $P \in \{0,1\}^n \cap \mathcal{Q}_t^\Delta$, Algorithm 34 outputs $C \in \mathsf{Comp}_{1/4}^\Delta(P)$ with probability at least $1/2$.

We prove Lemma 35 below, but first we use it to prove Lemma 33.

Proof of Lemma 33. Assume there exists an algorithm Eve such that

$$\Pr[|\mathsf{Eve}(1^n, (\mathbf{R}_n, \mathbf{K}_n, \mathbf{L}_n, \mathbf{P}_n), \mathbf{M}_n) - \mathbf{O}_n| \leq \Delta(1^n)] \geq 1 - n^{-6}$$

for infinitely many n's.

By Lemma 35, for infinitely many n's, Algorithm 34 outputs $C \in \mathsf{Comp}^{\Delta}_{1/4}(P)$ with probability at least $1/2$, for every $P \in \{0,1\}^n \cap \mathcal{Q}^{\Delta}_t$. We want to construct an algorithm Sol that, given P and $1^{1/\delta}$, outputs $C \in \mathsf{Comp}_{1/3}(P)$ with probability at least $1-\delta$, for every such n.

Let Sol be the algorithm that, given input $(P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell, 1^{1/\delta})$, first run Algorithm 34 on P for $2\lceil \log 1/\delta \rceil$ times, to get circuits $C_1, \ldots, C_{2\lceil \log 1/\delta \rceil}$. Then, for every circuit C_i, Sol samples $(x_1, s_1), \ldots, (x_{(100\lceil \log 1/\delta \rceil)^2}, s_{(100\lceil \log 1/\delta \rceil)^2}) \leftarrow P(\mathbf{U}_r)$, and computes

$$p_i = \Pr_{j \leftarrow [(100\lceil \log 1/\delta \rceil)^2]}[|C_i(x_j) - s_j| \leq \Delta(1^n)].$$

Finally, Sol outputs the circuit C_i for the index i with maximal value of p_i.

We now analyze the success probability of Sol. Using *Fact* 21, for every i, the probability that $\left|p_i - \Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|C_i(x) = s| \leq \Delta(1^n)]\right| \geq 1/25$ is at most

$$2^{-4(\lceil \log 1/\delta \rceil)^2 + 1} \leq 1/(\delta(4\lceil \log 1/\delta \rceil)).$$

Thus, by the union bound, the probability that $\left|p_i - \Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|C_i(x) = s| \leq \Delta(1^n)]\right| \geq 1/25$ for some i is at most $\delta/2$. Next, by the success probability of Algorithm 34, with probability at least

$$1 - (1 - 1/2)^{2\log 1/\delta} \geq 1 - \delta/2,$$

at least one of the circuits $C_1, \ldots, C_{2\log 1/\delta}$ is in $\mathsf{Comp}^{\Delta}_{1/4}(P) \subseteq \mathsf{Comp}^{\Delta}_{1/3}(P)$. Let i^* be the index of such a circuit. Then, with probability at least $1 - \delta/2 - \delta/2 = 1 - \delta$, such i^* exists, and p_{i^*} is at least $(3/4 - 1/25)$, while for every i with $C_i \notin \mathsf{Comp}^{\Delta}_{1/3}(P)$, p_i is at most

$$(2/3 + 1/25) < (3/4 - 1/25) \leq p_{i^*},$$

which implies that the output of Sol is in $\mathsf{Comp}^{\Delta}_{1/3}(P)$. ◀

4.3 Proving Lemma 35

To prove Lemma 35, we start with the following claim.

▷ Claim 36. Let $P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell$ be a circuit, and assume that

$$\Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|\mathsf{Eve}(1^n, (r,k,\ell,P), x) - s| \leq \Delta(n)] \geq 9/10.$$

Then, on input P, Algorithm 34 outputs $C \in \mathsf{Comp}^{\Delta}_{1/4}(P)$ with probability at least $1/2$.

Proof of Claim 36. Let $P\colon \{0,1\}^r \to \{0,1\}^k \times \{0,1\}^\ell$ be a circuit such that

$$\Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|\mathsf{Eve}(1^n, (r,k,\ell,P), x) - s| \leq \Delta(n)] \geq 9/10.$$

Then, by definition it holds that

$$\mathrm{E}_{w\leftarrow\{0,1\}^{r_{\mathsf{Eve}}(n)}}\left[\Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|\mathsf{Eve}(1^n, (r,k,\ell,P), x) - s| > \Delta(n)]\right] \leq 1/10.$$

Using Markov's inequality, we gets that

$$\Pr_{w\leftarrow\{0,1\}^{r_{\mathsf{Eve}}(n)}}\left[\Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|\mathsf{Eve}(1^n, (r,k,\ell,P), x) - s| > \Delta(n)] > 1/4\right] \leq 1/2,$$

which implies that the circuit $C' = \mathsf{Eve}(1^n, (r,k,\ell,P), \cdot; w)$ is in $\mathsf{Comp}^{\Delta}_{1/4}(P)$ with probability at least $1/2$ over the choice of w, as we wanted to show. ◁

Given Claim 36, we are now ready to prove Lemma 35.

Proof of Lemma 35. Assume that Eve is such that

$$\Pr[|\mathsf{Eve}(1^n,(\mathbf{R}_n,\mathbf{K}_n,\mathbf{L}_n,\mathbf{P}_n),\mathbf{M}_n)-\mathbf{O}_n|\leq\Delta(1^n)]\geq 1-n^{-6}$$

for infinitely many n's. In the following, fix such large enough $n\in\mathbb{N}$. We show that

$$\Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|\mathsf{Eve}(1^n,(r,k,\ell,P),x)-s|\leq\Delta(n)]\geq 9/10 \tag{1}$$

for every $P\colon\{0,1\}^r\to\{0,1\}^k\times\{0,1\}^\ell$ with $P\in\mathcal{Q}_t^\Delta\cap\{0,1\}^n$. The proof then follows by Claim 36. To see the above, let $\mathbf{Pk}=(\mathbf{R}_n,\mathbf{K}_n,\mathbf{L}_n,\mathbf{P}_n))$, and notice that

$$\Pr_{\substack{\mathbf{R}_n,\mathbf{K}_n,\mathbf{L}_n,\mathbf{P}_n,\mathbf{C}_n\\ \mathbf{Pk}=(\mathbf{R}_n,\mathbf{K}_n,\mathbf{L}_n,\mathbf{P}_n)}}\left[\Pr_{\mathbf{M}_n,\mathbf{O}_n,\mathbf{W}\leftarrow\{0,1\}^r_{\mathsf{Eve}}}[|\mathsf{Eve}(1^n,\mathbf{Pk},\mathbf{M}_n;\mathbf{W})-\mathbf{O}_n|\leq\Delta(n)]<9/10\right] \tag{2}$$

$$\leq 10n^{-6}.$$

Indeed, it holds that

$$\begin{aligned}
1-n^{-6}&\leq\Pr[|\mathsf{Eve}(1^n,\mathbf{Pk},\mathbf{M}_n)-\mathbf{O}_n|\leq\Delta(n)]\\
&\leq\Pr_{\mathbf{Pk}}[\Pr[|\mathsf{Eve}(1^n,\mathbf{Pk},\mathbf{M}_n)-\mathbf{O}_n|\leq\Delta(n)]\geq 9/10]\\
&\qquad+9/10\cdot\Pr_{\mathbf{Pk}}[\Pr[|\mathsf{Eve}(1^n,\mathbf{Pk},\mathbf{M}_n)-\mathbf{O}_n|\leq\Delta(n)]<9/10]\\
&=(1-\Pr_{\mathbf{Pk}}[\Pr[|\mathsf{Eve}(1^n,\mathbf{Pk},\mathbf{M}_n)-\mathbf{O}_n|\leq\Delta(n)]<9/10])\\
&\qquad+9/10\cdot\Pr_{\mathbf{Pk}}[\Pr[|\mathsf{Eve}(1^n,\mathbf{Pk},\mathbf{M}_n)-\mathbf{O}_n|\leq\Delta(n)]<9/10]\\
&=1-1/10\cdot\Pr_{\mathbf{Pk}}[\Pr[|\mathsf{Eve}(1^n,\mathbf{Pk},\mathbf{M}_n)-\mathbf{O}_n|\leq\Delta(n)]<9/10]
\end{aligned}$$

which implies that Equation (2) holds. Next, we use Equation (2) and the upper bound on the computational depth of instances in $\mathcal{Q}_t^\Delta$, to show that Equation (1) holds for every $P\in\mathcal{Q}_t^\Delta$. To do so, fix $P\in\mathcal{Q}_t^\Delta\cap\{0,1\}^n$ and let $C\in\{0,1\}^n\cap\mathsf{Comp}_{n^{-10}}^{\Delta/n^{10}}(P)$ with $cd^{t,\infty}(C,P)\leq 2\log n$ be the circuit promised by the definition of $\mathcal{Q}_t^\Delta$. Assume towards a contradiction that

$$\Pr_{(x,s)\leftarrow P(\mathbf{U}_r)}[|\mathsf{Eve}(1^n,(r,k,\ell,P),x)-s|\leq\Delta(n)]<9/10.$$

We want to upperbound $\mathsf{K}(P,C)$, to get a lower bound on the computational depth of (P,C). To this end, let $\mathcal{S}$ be the set of all pairs $(P',C')\in\{0,1\}^n\times\{0,1\}^n$, such that $C'\in\mathsf{Comp}_{n^{-10}}^{\Delta/n^{10}}(P')$, $\mathsf{K}^t(P',C')=\mathsf{K}^t(P,C)$, and on which Eve fails to approximate s with probability more than $1/10$.

By our assumption on (P,C), it holds that $(P,C)\in\mathcal{S}$. We next bound the size of $\mathcal{S}$. First, we claim that for every $(P',C')\in\mathcal{S}$,

$$\Pr[\mathbf{P}_n=P',\mathbf{C}_n=C']\geq 1/6n\cdot 2^{-\mathsf{K}^t(C,P)}. \tag{3}$$

Indeed, by definition there exists a program Π of length $\mathsf{K}^t(C,P)$ that outputs (C',P') in at most $t(2n)$ steps. Thus, Gen samples Π with probability at least $1/3n\cdot 2^{-\mathsf{K}^t(C,P)}$. Next, by Claim 32, the test in Step 3 of Gen passes with probability at least $1-2^{-n}>1/2$, since by definition of $\mathsf{Comp}_{n^{-10}}^{\Delta/n^{10}}$, $\Pr_{(x,s)\leftarrow P'(\mathbf{U}_r}\left[|C'(x)-s|\leq\Delta(1^n)/n^{10}\right]-n^{-9}\geq 1-n^{-10}-n^{-9}\geq 1-2n^{-7}$. In this case that the test passes, P' and C' are the output of Gen, and thus Equation (3) holds.

By Equation (3) and the definition of $\mathcal{S}$, we get that

$$\Pr_{\substack{\mathbf{R}_n,\mathbf{K}_n,\mathbf{L}_n,\mathbf{P}_n,\mathbf{C}_n \\ \mathbf{Pk}=(\mathbf{R}_n,\mathbf{K}_n,\mathbf{L}_n,\mathbf{P}_n)}}\left[\Pr_{\mathbf{M}_n,\mathbf{O}_n,\mathbf{W}\leftarrow\{0,1\}^r_{\mathsf{Eve}}}[|\mathsf{Eve}(1^n,\mathbf{Pk},\mathbf{M}_n;\mathbf{W})-\mathbf{O}_n|\leq\Delta(n)]<9/10\right]$$
$$\geq |\mathcal{S}|\cdot 1/6n\cdot 2^{-\mathsf{K}^t(C,P)}.$$

Combining the above with Equation (2) yields that

$$|\mathcal{S}|\leq\frac{10n^{-6}}{1/6n\cdot 2^{-\mathsf{K}^t(C,P)}}\leq 2^{\mathsf{K}^t(C,P)+\log n-6\log n+6}.$$

Observe that $\mathcal{S}$ can be (inefficiently) computed given $n,\mathsf{K}^t(C,P)$ and Eve. Thus, to encode (P,C), it is enough to encode $\mathcal{S}$ and the index of (P,C) in $\mathcal{S}$ (according to the lexicographic order). We conclude that,

$$\begin{aligned}\mathsf{K}(P,C)&\leq\mathsf{K}(n,\lambda,\mathsf{Eve})+2\log(\mathsf{K}(n,\lambda,\mathsf{Eve}))+\log|\mathcal{S}|+O(1)\\&\leq 2\log n+4\log\log n+\mathsf{K}^t(C,P)-5\log n+O(1)\\&<\mathsf{K}^t(C,P)-2\log n,\end{aligned}$$

where the last inequality holds for every large enough n. By the above, $\mathsf{K}^t(C,P)-\mathsf{K}(P,C)>2\log n$, in contradiction to the choice of (P,C). This yields that Equation (1) holds for every $P\in\mathcal{Q}_t$, as we wanted to show. ◀

4.4 Proving Theorem 26

We are now ready to use Lemma 15 in order to prove Theorem 26.

Proof of Theorem 26. By Lemmas 31 and 33, $(\mathsf{Gen},\mathsf{Enc},\mathsf{Dec})$ is a $(n^{-7},1-n^{-6},n^{10})$-weak-PKE (for $d(1^n)=\Delta(1^n)/n^{10}$), and thus it is also a $(n^{-6.9}/2,1-10n^{-6.1},2n^{6.9})$-weak-PKE. Thus, by Lemma 15, $(\mathsf{Gen},\mathsf{Enc},\mathsf{Dec})$ can be amplified into a PKE. ◀

▶ Remark 37 (The non-uniform setting). A similar theorem can be proven when assuming that $\Delta\text{-}\mathsf{WBLearn}|_{\mathsf{CS}^t}\notin\mathsf{ioP}/\mathrm{poly}$, and when the PKE is secure against non-uniform adversaries. In this case, we assume that Eve is a non-uniform algorithm that breaks the PKE protocol, and want to construct a non-uniform (randomized) algorithm that decides $\mathsf{WBLearn}|_{\mathcal{Q}_t}$.

The issue with the above proof is that we cannot simply use Eve to bound the Kolmogorov complexity of (C,P) as done in the proof of Lemma 33, as Eve does not have constant size. However, we can find Eve using a small Turing machine: Let M be the (inefficient) Turing machine that, given a constant c such that n^c is a bound on the size of Eve, and an input for Eve, first find the circuit E'_n of size at most n^c that maximize the advantage in predicting M given an encryption of M by Enc, and then execute E' on the input. Observe that M has prediction advantage at least as the advantage of Eve. The theorem now follows using the same proof, by replacing Eve in the proof of Lemma 33 with M, and replacing Eve in Algorithm 34 with $E'=\{E'_n\}_{n\in\mathbb{N}}$.

Abstract

We study the metric Steiner tree problem in the sublinear query model. In this problem, for a set of n points V in a metric space given to us by means of query access to an $n \times n$ matrix w, and a set of terminals $T \subseteq V$, the goal is to find the minimum-weight subset of the edges that connects all the terminal vertices.

Recently, Chen, Khanna and Tan [SODA'23] gave an algorithm that uses $\widetilde{O}(n^{13/7})$ queries and outputs a $(2-\eta)$-estimate of the metric Steiner tree weight, where $\eta > 0$ is a universal constant. A key component in their algorithm is a sublinear algorithm for a particular set cover problem where, given a set system $(\mathcal{U}, \mathcal{F})$, the goal is to provide a multiplicative-additive estimate for $|\mathcal{U}| - \mathsf{SC}(\mathcal{U}, \mathcal{F})$. Here $\mathcal{U}$ is the set of elements, $\mathcal{F}$ is the collection of sets, and $\mathsf{SC}(\mathcal{U}, \mathcal{F})$ denotes the optimal set cover size of $(\mathcal{U}, \mathcal{F})$. In particular, their algorithm returns a $(1/4, \varepsilon \cdot |\mathcal{U}|)$-multiplicative-additive estimate for this set cover problem using $\widetilde{O}(|\mathcal{F}|^{7/4})$ membership oracle queries (querying whether a set $S \in \mathcal{S}$ contains an element $e \in \mathcal{U}$), where ε is a fixed constant.

In this work, we improve the query complexity of $(2-\eta)$-estimating the metric Steiner tree weight to $\widetilde{O}(n^{5/3})$ by showing a $(1/2, \varepsilon \cdot |\mathcal{U}|)$-estimate for the above set cover problem using $\widetilde{O}(|\mathcal{F}|^{5/3})$ membership queries. To design our set cover algorithm, we estimate the size of a random greedy maximal matching for an auxiliary multigraph that the algorithm constructs implicitly, without access to its adjacency list or matrix. Previous analyses of random greedy maximal matching have focused on simple graphs, assuming access to their adjacency list or matrix. To address this, we extend the analysis of Behnezhad [FOCS'21] of random greedy maximal matching on simple graphs to multigraphs, and prove additional properties that may be of independent interest.

1 Introduction

In the Steiner tree problem, we are given an undirected graph $G = (V, E)$, where each edge e has an associated cost $w(e)$, and a specified set of terminal vertices $T \subseteq V$. Then, the objective is to find a minimum-cost subgraph H of G that connects all terminals in T. The Steiner tree problem is one of the most fundamental problems in combinatorial optimization and has been extensively studied by the TCS community since it was included among Karp's 21 NP-Complete problems [34]. The state-of-the-art approximation factor for the Steiner tree problem is $\ln 4 + \varepsilon < 1.39$ [14], and it is known that approximating it to a factor better than 96/95 is NP-hard [17]. This Steiner tree problem has been studied in various domains, including approximation algorithms [40, 14], online algorithms [29, 3, 37, 26], stochastic algorithms [27, 25, 22], and massive data analysis models [15, 18, 16].

▶ **Definition 1** (Sublinear Metric Steiner Tree). *In the metric Steiner tree problem, we are given a set of points V, a set of terminal points $T \subseteq V$, and query access to an oracle $\mathcal{O}$ to the $|V| \times |V|$ distance matrix of a metric space (V, w), where $\mathcal{O}(u, v)$ returns the weight $w(u, v)$ of the edge (u, v).*

Let $\mathsf{ST}(V, T, w)$ denote the weight of a minimum-weight Steiner tree on instance (V, T, w). Then, the goal is to design an algorithm that estimates $\mathsf{ST}(V, T, w)$ using the fewest possible queries to the distance matrix via the oracle $\mathcal{O}$.

Czumaj and Sohler [18] presented the first sublinear query algorithm for the metric Steiner tree problem, showing a $(2 + \varepsilon)$-approximation using $\tilde{O}(k/\varepsilon^{O(1)})$ queries through their improved algorithm for the minimum spanning tree (MST) problem. Specifically, this follows their sublinear $(1 + \varepsilon)$-approximation for MST together with the well-known result by Gilbert and Pollak [23] showing that an α-approximation for MST over the metric induced on the terminals T is a (2α)-approximation for the metric Steiner tree instance with T as the terminal set.

Recently, Chen, Khanna, and Tan [16] studied the design of sublinear algorithms with strictly better-than-2 approximation for the metric Steiner tree problem. On the lower bound side, they showed that for any $\varepsilon > 0$, estimating the Steiner tree cost to within a $(5/3 - \varepsilon)$-factor requires $\Omega(n^2)$ queries, even when the number of terminals $|T|$ is constant. Moreover, they showed that for any $\varepsilon > 0$, estimating the Steiner tree cost to within a $(2 - \varepsilon)$-factor requires $\Omega(n + |T|^{6/5})$ queries. Additionally, they proved that for any $0 < \varepsilon < 1/3$, any algorithm that outputs a $(2 - \varepsilon)$-approximate Steiner tree (not just its cost) requires $\Omega(n|T|)$ queries. On the upper bound side, they showed that it is possible to achieve a better-than-2 estimate of the Steiner tree cost in sublinear time: there exists an algorithm that, with high probability, computes a $(2 - \eta)$-approximation of the Steiner tree cost using $\widetilde{O}(n^{13/7})$ queries, where $\eta > 0$ is a universal constant. At the core of their sublinear algorithm for metric Steiner tree with improved approximation guarantee, they relate the problem of achieving a better-than-2 estimation for the Steiner tree to a variant of set cover problem with a different objective.

▶ **Definition 2** (Threshold Set Cover). *Given a universe of elements $\mathcal{U}$ and a collection $\mathcal{F}$ of subsets of $\mathcal{U}$, in the Threshold Set Cover problem the goal is to estimate $\mathsf{ThSC}(\mathcal{U}, \mathcal{F}) \coloneqq |\mathcal{U}| - \mathsf{SC}(\mathcal{U}, \mathcal{F})$, where $\mathsf{SC}(\mathcal{U}, \mathcal{F})$ denotes the size of an optimal set cover solution for $(\mathcal{U}, \mathcal{F})$, i.e., the minimal number of sets in $\mathcal{F}$ whose union equals $\mathcal{U}$.*

Following the notation of [16] and for simplicity, in our technical sections, we also refer to this problem as set cover.

Specifically, given access to the adjacency matrix of the graph representation of $(\mathcal{U}, \mathcal{F})$, where there is an edge between $e \in \mathcal{U}$ and $S \in \mathcal{F}$ if and only if $e \in S$, Chen, Khanna, and Tan [16] designed an algorithm that, for any constant $0 < \varepsilon < 1$, with high probability, outputs a *multiplicative-additive* $(1/4, \varepsilon|\mathcal{U}|)$-approximation for estimation of $\mathsf{ThSC}(\mathcal{U}, \mathcal{F})$ using $\widetilde{O}_\varepsilon(|\mathcal{F}|^{3/2} + |\mathcal{F}|^{3/4} \cdot |\mathcal{U}|)$ queries to the adjacency matrix (or, membership queries). An estimate SOL for Threshold Set Cover on $(\mathcal{U}, \mathcal{F})$ is a *multiplicative-additive* (γ_1, γ_2)-approximation, if $\gamma_1 \cdot \mathsf{ThSC}(\mathcal{U}, \mathcal{F}) - \gamma_2 \leq \mathrm{SOL} \leq \mathsf{ThSC}(\mathcal{U}, \mathcal{F})$.

More broadly, there has been a large body of work on solving set cover problems in the massive data models of computation over the past decade [41, 19, 28, 20, 2, 30, 1, 5, 31, 24]. In particular the work of [31, 24] consider the set cover problem in the sublinear query model. However their algorithms assumes that it has an access to the adjacency list model as opposed to the adjacency matrix model, and thus cannot be directly employed here.

1.1 Our Results

Our key contribution is an algorithm for Threshold Set Cover, offering improved approximation guarantees and query complexity, as detailed below:

▶ **Theorem 3** (Our Algorithm for Threshold Set Cover). *There exists an algorithm that, given a set system $(\mathcal{U}, \mathcal{F})$ with oracle access to its adjacency matrix (also known as membership queries), outputs a multiplicative-additive $(1/2, \varepsilon \cdot |\mathcal{U}|)$-approximation to Threshold Set Cover, in $\widetilde{O}(|\mathcal{F}|^{5/3})$ time, with high probability.*

Note that both the query complexity and the running time of the algorithm are bounded by $\widetilde{O}(|\mathcal{F}|^{5/3})$, improving upon the algorithm by Chen, Khanna, and Tan [16] for large values of $|\mathcal{U}|$, which uses $\widetilde{O}_\varepsilon(|\mathcal{F}|^{3/2} + |\mathcal{F}|^{3/4} \cdot |\mathcal{U}|)$ membership queries and provides a multiplicative-additive $(1/4, \varepsilon|\mathcal{U}|)$-approximation for the problem. Notably, when $|\mathcal{U}| = \omega(|\mathcal{F}|^{2/3})$, the algorithm becomes sublinear in $|\mathcal{U}| \cdot |\mathcal{F}|$, making it especially relevant for applications in the metric Steiner tree problem. More specifically, our new algorithm for Threshold Set Cover results in the following improved sublinear query algorithm for the metric Steiner tree problem, which we show in Section 5.

▶ **Theorem 4** (Sublinear Algorithm for Metric Steiner Tree). *There exists an algorithm that, given an instance of metric Steiner tree denoted by (V, T, w) with oracle access $\mathcal{O}$ to the distance matrix of (V, w), outputs a $(2 - \eta)$-estimate of $\mathsf{ST}(V, T, w)$ using $\widetilde{O}(n^{5/3})$ queries to $\mathcal{O}$, where $\eta > 0$ is a universal constant, with high probability.*

Notably, the query complexity of our algorithm improves upon the $\widetilde{O}(n^{13/7})$ query complexity of the algorithm of Chen, Khanna, and Tan [16].

For a detailed overview of our technical contribution, see Section 2.

2 Technical Overview

In this section, we provide a brief overview of the technical challenges involved in designing our algorithms. To design a sublinear time algorithm for the Steiner tree problem, we use the framework developed by Chen, Khanna, and Tan [16]. They demonstrated that breaking the 2-approximation barrier for the Steiner tree problem can be reduced to solving an instance of a set cover problem. We refer the reader to Section 4.1 of [16] for details on this reduction.

We denote the variant of the set cover problem as *Threshold Set Cover*. Given a collection of sets $\mathcal{F}$ over a universe of elements $\mathcal{U}$, we aim to estimate the value of $\mathsf{ThSC}(\mathcal{U}, \mathcal{F}) = |\mathcal{U}| - \mathsf{SC}(\mathcal{U}, \mathcal{F})$, where $\mathsf{SC}(\mathcal{U}, \mathcal{F})$ denotes the size of the optimal set cover of the given instance.

To achieve our goal of breaking the 2-approximation barrier for the Steiner tree problem, we need to estimate $\mathsf{ThSC}(\mathcal{U}, \mathcal{F})$ with a $(\gamma, \varepsilon \cdot |\mathcal{U}|)$ multiplicative-additive error, where γ must be a constant and ε is any (small enough) constant. For this problem, we only have access to a membership oracle of the instance, meaning we can query whether a particular element e is in a particular set S or not. Note that this type of access is generally considered more challenging compared to an adjacency list oracle, where the algorithm can access either the ith element of a set S, or the ith set containing an element e. The reason is that if an element is included in only a constant number of sets, the algorithm is required to spend $\Omega(|\mathcal{F}|)$ queries to find just one set that contains the element. Consequently, we cannot use the results from the literature on sublinear set cover [24, 31] because they all rely on an adjacency list access model.

We will now provide an informal, step-by-step description of our algorithm for Threshold Set Cover, highlighting its differences, innovations, and technical challenges in comparison to the algorithm of [16]. For simplicity, in this technical overview we assume that $|\mathcal{F}| = \widetilde{\Theta}(|\mathcal{U}|)$, since this represents the worst-case scenario for the Steiner tree problem. However, our formal proof does not depend on this assumption. We let $n = |\mathcal{F}|$.

First step: sparsification of the Threshold Set Cover instance. The goal of this step is to produce a new instance where each element and each set has a low degree – specifically, where each element is in only a few sets, and each set contains only a few elements. This step is standard in designing sublinear algorithms for the set cover problem for different access models, and a slightly different version of it is also used in the algorithm by [16]. Our slight modification of the sparsification step allows us to relax some constraints in the reduction from the Steiner tree problem to Threshold Set Cover, enabling us to achieve the same query complexity for both problems.

Let $x > 0$ be some constant that we optimize later. Consider a set $S \in \mathcal{F}$ and suppose we randomly sample $\widetilde{O}(n^{1-x})$ elements from the universe and query the membership of all the sampled elements in S. If the size of S is at least $\widetilde{\Omega}(n^x)$, we expect to see a large intersection. Conversely, if the size of S is much smaller, we expect to see a small intersection. If a large intersection exists, we can remove the set S and all its elements from the instance. Since this event occurs at most $\widetilde{O}(n^{1-x})$ times, we can account for the removed elements and sets using the additive error in our estimation. Similarly, we can show that all elements belonging to more than $\widetilde{\Omega}(n^x)$ sets can be covered by a random subcollection of sets of size $\widetilde{O}(n^{1-x})$. Therefore, without loss of generality, by spending $\widetilde{O}(n^{2-x})$ time, we can assume that each set contains at most $\widetilde{O}(n^x)$ elements, and each element is included in at most $\widetilde{O}(n^x)$ sets.

Second step: constructing an auxiliary graph H and estimating the size of its maximum matching. Similar to [16], we construct a graph H with a vertex set where each vertex corresponds to an element of $\mathcal{U}$. We connect two vertices if their corresponding elements appear together in at least one set from $\mathcal{F}$. It is important to note that we do not construct H explicitly, as doing so would be computationally expensive and require $\Omega(n^2)$ time. As shown by [16], if the size of the maximum matching of H is large, it is evident that $\mathsf{ThSC}(\mathcal{U}, \mathcal{F})$ is significantly smaller than $|\mathcal{U}|$. Conversely, if the size of the maximum matching of H is close to zero, then $\mathsf{ThSC}(\mathcal{U}, \mathcal{F})$ is also close to zero. This is sufficient for our purposes, as our goal is to obtain a constant-factor approximation. Intuitively, each matching edge in H indicates that there are two elements that can be covered together, which increases the value of $\mathsf{ThSC}(\mathcal{U}, \mathcal{F})$.

There is extensive literature on estimating the size of maximum matching in sublinear time [4, 6, 8, 7, 9, 12, 13, 33, 36, 38, 39, 43], with significant progress made in recent years. For our application, we use the algorithm of Behnezhad [6] to estimate the size of a random greedy maximal matching (RGMM) of the graph. In summary, this algorithm can estimate the size of the RGMM of a graph in $\widetilde{O}(\bar{d})$ time if given access to the adjacency list of the graph, where $\bar{d}$ denotes the average degree of the graph. We can now use this algorithm as a black box:

- The average degree of H is $\widetilde{O}(n^{2x})$, since each element is in $\widetilde{O}(n^x)$ sets and each set contains $\widetilde{O}(n^x)$ elements.
- Each time the algorithm visits a vertex in H (corresponding to an element), we can spend $\widetilde{O}(n^{1+x})$ time to find its adjacency list in H. This involves first querying all sets that include the element, and then making queries between those sets and all elements.

Therefore, we can simulate the algorithm from [6] in $\widetilde{O}(\bar{d} \cdot n^{1+x}) = \widetilde{O}(n^{1+3x})$ time. By balancing this with the sparsification step, which requires $\widetilde{O}(n^{2-x})$ time, we can set $x = 1/4$ to achieve an algorithm with a running time of $\widetilde{O}(n^{7/4})$. This is essentially the running time of the algorithm by Chen, Khanna, and Tan [16].

Third step: using the algorithm of Behnezhad [6] in a white-box manner. To improve the running time of our algorithm, we need to open up the RGMM algorithm from [6] and utilize its properties to apply it more effectively. The RGMM algorithm is a local algorithm that explores the neighborhood of a given vertex to determine whether it is matched. A key observation is that during each exploration, the algorithm requires a random neighbor of the vertex that has not been explored yet. However, in the previous approach, we constructed the entire adjacency list of the vertex, which is redundant and inefficient. Intuitively, we only need to randomly identify one of the vertex's neighbors in each step.

However, the first challenge we encounter is that we cannot select a neighbor uniformly at random. To illustrate this, consider the following example. Suppose that we have five elements $\mathcal{U} = \{e_1, \ldots, e_5\}$ and three sets: $S_1 = \{e_1, e_2, e_3\}$, $S_2 = \{e_1, e_2, e_4\}$, and $S_3 = \{e_1, e_2, e_5\}$. Suppose that we want to find a random neighbor of e_1 in H. If we first find all sets that include e_1 and then query between those sets and all elements uniformly at random until we find an edge in H, we are likely to see the edge (e_1, e_2) because it appears in all sets. Consequently, the algorithm has a bias towards finding neighbors that appear in more sets with the element.

To overcome this challenge, rather than defining an auxiliary simple graph H, we define an auxiliary multigraph H. In this multigraph, if two elements appear in the same set multiple times, we add an edge for each of those occurrences. Note that the average degree of H remains at most $\widetilde{O}(n^{2x})$. However, the algorithm and analysis for RGMM from [6] are designed for simple graphs. We extend these results to multigraphs and show that we can estimate the size of RGMM for a multigraph, given access to its adjacency list. This extension may be of independent interest and could be useful for tackling other problems in sublinear time. To establish this, we build on the exquisite approach first introduced by Yoshida, Yamamoto, and Ito [43] and further explored in various settings [6, 10, 11]. We employ techniques such as the analysis of the round-complexity of maximal independent sets [21], double-counting arguments to bound the average complexity of RGMM on multigraphs, and others; we encourage the reader to refer to the arXiv version of the paper for further details.

Now, suppose that for each vertex the RGMM algorithm explores in H, we first query all sets to identify those that include the corresponding element. Since the algorithm explores at most $\widetilde{O}(\bar{d})$ vertices in H, this step will cost at most $\widetilde{O}(\bar{d} \cdot n) = \widetilde{O}(n^{1+2x})$ in total. Let v be a vertex that the RGMM algorithm is exploring at the moment. Define $\mathcal{S}_v$ to be the collection

of sets that include element v. Now, if we query uniformly at random between all elements and the collection $\mathcal{S}_v$, each incident edge of v in the multigraph H has an equal probability of being sampled, which resolves the first challenge. For now, assume that the degree of all vertices in H is $\bar{d}$. Since $|S_v| = \widetilde{O}(n^x)$ and there are $\widetilde{O}(n)$ elements in total, we expect to find an element in one of the sets of S_v every $\widetilde{O}(n^{1+x}/\bar{d})$ queries. Thus, to identify a random neighbor of a vertex in H, we need to spend $\widetilde{O}(n^{1+x}/\bar{d})$ time. The RGMM algorithm queries for a random neighbor of a vertex $\widetilde{O}(\bar{d})$ times, since the exploration size is $\widetilde{O}(\bar{d})$; therefore, the total cost is $\widetilde{O}(n^{1+x})$. Combining this with the cost of sparsification, the total cost of the algorithm is $\widetilde{O}(\max(n^{2-x}, n^{1+2x}))$, which is $\widetilde{O}(n^{5/3})$ if we set $x = 1/3$.

The second challenge arises because the RGMM algorithm may predominantly visit vertices with a very low degree in H. For such vertices, finding a random neighbor can be much more time-consuming. Generally, if a vertex v in H has degree $\deg_H(v)$, then each time the algorithm finds a random neighbor of v, it needs to spend $\widetilde{O}(n^{1+x}/\deg_H(v))$ time. Therefore, if the algorithm frequently encounters vertices with constant degree, each query to find a random neighbor can cost $\widetilde{O}(n^{1+x})$. With the exploration size being $\widetilde{O}(\bar{d})$, this can significantly increase the query complexity of the algorithm. As a property of the local RGMM algorithm, we demonstrate that each vertex is visited by the algorithm in proportion to its degree in H. More formally, we prove that RGMM requires $\widetilde{O}(\deg_H(v)/n)$ neighbors of v on average, for a uniformly random permutation of edges. Thus, the degree-dependent factors cancel each other out, and the average cost of this part can be upper-bounded by $\widetilde{O}(n^{1+x})$, which is enough for us to get the $\widetilde{O}(n^{5/3})$ running time for the Threshold Set Cover.

3 Preliminaries

As is common in the literature, we use the term "with high probability" to refer to a probability of at least $1 - n^{-\alpha}$, for a sufficiently large constant $\alpha \geq 2$. Moreover, we use $\widetilde{O}(\cdot)$, $\widetilde{\Theta}(\cdot)$, and $\widetilde{\Omega}(\cdot)$ to hide the dependency on $\text{poly}(\log n)$. For a maximization problem of estimating some value χ, and for $\gamma_1 \in (0, 1]$ and $\gamma_2 > 0$, we say that $\widetilde{\chi}$ is a multiplicative-additive (γ_1, γ_2)-approximation of the value χ if $\gamma_1\chi - \gamma_2 \leq \widetilde{\chi} \leq \chi$.

3.1 Probabilistic Tools

We use the following standard concentration inequalities in our proof.

▶ **Proposition 5** (Chernoff Bound). *Let $X_1, X_2, \ldots, X_n$ be n independent Bernoulli random variables. Let $X = \sum_{i=1}^{n} X_i$. For any $k > 0$, it holds that*

$$\Pr[|X - \mathbf{E}[X]| \geq k] \leq 2\exp\left(-\frac{k^2}{3\,\mathbf{E}[X]}\right).$$

▶ **Definition 6** (Negative Association [32, 35, 42]). *Let $X_1, X_2, \ldots, X_n$ be a set of random variables. We say this set is negatively associated if for any two disjoint index sets $I, J \subseteq [n]$, and two functions f and g, both either monotonically increasing or monotonically decreasing, the following condition is satisfied:*

$$\mathbf{E}[f(X_i : i \in I) \cdot g(X_j : j \in J)] \leq \mathbf{E}[f(X_i : i \in I)] \cdot \mathbf{E}[g(X_j : j \in J)].$$

▶ **Proposition 7** (Chernoff Bound for Negatively Associated Variables). *Let $X_1, X_2, \ldots, X_n$ be a set of negatively associated Bernoulli random variables. Let $X = \sum_{i=1}^{n} X_i$. Then*

$$\Pr\left[X \geq (1+\alpha)\,\mathbf{E}[X]\right] \leq \left(\frac{e^{\alpha}}{(1+\alpha)^{1+\alpha}}\right)^{\mathbf{E}[X]}$$

and

$$\Pr\left[X \leq (1-\alpha)\,\mathbf{E}[X]\right] \leq \left(\frac{e^{-\alpha}}{(1-\alpha)^{1-\alpha}}\right)^{\mathbf{E}[X]}$$

▶ **Proposition 8** (Markov Inequality). *Let X be a non-negative random variable. For any $\alpha > 0$, it holds that*

$$\Pr[X \geq \alpha] \leq \frac{\mathbf{E}[X]}{\alpha}.$$

3.2 Graph Theory

A *multigraph* is a type of graph in which multiple edges, also known as parallel edges, are allowed between any pair of vertices. A *line graph* of a graph G is a graph that represents the adjacencies between the edges of G. More formally, given a graph G, the line graph $L(G)$ is constructed as follows:

- **Vertices**: Each vertex in $L(G)$ corresponds to an edge in G.
- **Edges**: Two vertices in $L(G)$ are connected by an edge if and only if their corresponding edges in G share a common endpoint (i.e., they are incident to the same vertex in G).

For a graph G, we let $\deg_G(v)$ be the degree of vertex v. In the case of multigraphs, $\deg_G(v)$ counts parallel edges multiple times.

Random Greedy Maximal Matching (RGMM). Given a graph $G = (V, E)$, a random greedy maximal matching is constructed by first selecting a random permutation π of the edges E. The algorithm then iterates over the edges in the order specified by π, adding each edge to the matching if neither of its endpoints is already matched (i.e., if none of its adjacent edges have been included in the matching so far). This process continues until all edges have been considered. The term "random" comes from the fact that the permutation π is chosen uniformly at random among all possible permutations of the edges.

Random Greedy Maximal Independent Set (MIS). Given a graph $G = (V, E)$, a random greedy maximal independent set is constructed by first selecting a random permutation π of the vertices V. The algorithm then iterates over the vertices in the order specified by π, adding each vertex to the independent set if none of its neighbors are already in the set (i.e., it does not share an edge with any vertex already included in the independent set). This process continues until all vertices have been considered. The term "random" comes from the fact that the permutation π is chosen uniformly at random among all possible permutations of the vertices.

Parallel Randomized Greedy Maximal Independent Set. Let G be a graph, and let π be a permutation of its vertices. In each iteration, we select all vertices whose rank is lower than that of all their neighbors and then remove these vertices along with their neighbors from the graph. The number of iterations required for G to become empty is referred to as the round complexity, denoted by $\rho(G, \pi)$. It is not hard to see that the MIS produced by the parallel randomized greedy maximal independent set is the same as the output of the random greedy maximal independent set for a fixed permutation π.

4 Sublinear Algorithm for Set Cover

In this section, we formalize and analyze our algorithm for the set cover variant described above. Throughout this section, we assume that $\mathcal{U}$ denotes the universe and $\mathcal{F}$ denotes the collection of sets. We will slightly abuse notation by letting $k = |\mathcal{U}|$ and $n = |\mathcal{F}|$. Without loss of generality, we can assume that $n \geq k$.[1] We use $\mathsf{SC}(\mathcal{U}, \mathcal{F})$ for the size of the minimum set cover of the input instance. Our goal is to design an algorithm that estimates the value of $\chi = k - \mathsf{SC}(\mathcal{U}, \mathcal{F})$ with at most εk additive error and a constant multiplicative factor. For $\gamma_1 \in (0, 1]$ and $\gamma_2 > 0$, we say that $\widetilde{\chi}$ is a multiplicative-additive (γ_1, γ_2)-approximation of the value χ if $\gamma_1 \chi - \gamma_2 \leq \widetilde{\chi} \leq \chi$. Similar to the reduction from the Steiner tree problem to set cover in [16], we need to estimate $k - \mathsf{SC}(\mathcal{U}, \mathcal{F}_{\neq 2})$ where $\mathcal{F}_{\neq 2}$ denotes the collection of all sets in $\mathcal{F}$ except those of size exactly 2. For simplicity, we focus on estimating χ, and in the final step of this section, we will explain how to handle sets of size 2 in our algorithm. For our application, we need γ_1 to be constant and $\gamma_2 = \varepsilon k$ where ε is a small fixed constant.

A High-Level Description of the Algorithm. Our algorithm for estimating the value of χ is formalized in Algorithm 1. Apart from the collection of sets $\mathcal{F}$ and the universe of elements $\mathcal{U}$, the algorithm runs with two parameters, α and β, both of which can be determined based on the values of x and y, which we optimize in the final step of the analysis. The algorithm has three phases: 1) sparsification of the sets, 2) sparsification of the elements, and 3) estimating the size of a maximum matching of the auxiliary graph H (Definition 9). In the following, we first describe each component in words before moving on to the formal proofs.

(Step 1) Set Sparsification. This component of the algorithm is formalized in Algorithm 2. The algorithm maintains a collection of sets $\hat{\mathcal{F}}$ and a universe of elements $\hat{\mathcal{U}}$ that are initially equal to $\mathcal{F}$ and $\mathcal{U}$, respectively. We iterate over all sets in $\mathcal{F}$ one by one and for each set S, we sample $r_1 = |\hat{\mathcal{U}}|/\alpha$ random elements from $\hat{\mathcal{U}}$. Intuitively, if $|S \cap \hat{\mathcal{U}}| \geq \widetilde{\Omega}(\alpha)$, we expect to have an element of S in the r_1 random sampled elements. Having this in mind, if there is a large enough intersection ($\Omega(\log n)$) between the sampled elements and S, we remove set S and all its elements from $\hat{\mathcal{F}}$ and $\hat{\mathcal{U}}$, respectively (we add this set to our solution). Therefore, after the execution of the algorithm, each remaining set in $\hat{\mathcal{F}}$ has at most $\widetilde{O}(\alpha)$ elements. On the other hand, if $|S \cap \hat{\mathcal{U}}|$ is smaller than α, we expect to see a small intersection with the r_1 sampled elements. Consequently, the number of times the algorithm removes a set and its elements from $\hat{\mathcal{F}}$ and $\hat{\mathcal{U}}$ is at most $k/\alpha = o(k)$, which can be accounted for by the additive error in the estimation. Also, if at any point the size of the maintained universe becomes smaller than some threshold (in the algorithm the value of the threshold is $\widetilde{\Theta}(\alpha)$, the algorithm stops processing the rest of the sets (Algorithm 2) since $\hat{\mathcal{U}} = \widetilde{O}(\alpha)$. This step differs from the algorithm in [16] because we sequentially sparsify the sets, whereas their approach is non-adaptive.

(Step 2) Sparsification of Elements. This part of the algorithm is formalized in Algorithm 3. Similar to the previous step, we want to sparsify our instance such that each element in the remaining instance appears in at most $\widetilde{O}(\beta)$ sets. Let $\hat{\mathcal{U}}$ and $\hat{\mathcal{F}}$ be the output of Algorithm 2. We sample $r_2 = |\hat{\mathcal{U}}|/\beta$ random sets from the collection $\hat{\mathcal{F}}$. With the same intuition as the

[1] For the sake of this problem, for each element in the universe we can add a set that only contains the element. The same assumption is also made in [16].

previous step, if some element is in at least $\widetilde{\Omega}(\beta)$ sets of $\hat{\mathcal{F}}$, we expect to see it in many sampled sets. We partition the elements of $\hat{\mathcal{U}}$ into $\mathcal{U}_{low}$ and $\mathcal{U}_{high}$, depending on whether their intersection with the randomly sampled elements is smaller than a given threshold or not. With high probability, each element in $\mathcal{U}_{low}$ appears in at most $\widetilde{O}(\beta)$ sets of $\hat{\mathcal{F}}$, and each element in $\mathcal{U}_{high}$ appears in at least $\widetilde{\Omega}(\beta)$ sets of $\hat{\mathcal{F}}$. This suffices to show that any random subset of $\hat{\mathcal{F}}$ of size $\varepsilon k/2$ can cover all elements of $\mathcal{U}_{high}$, which can be included in the additive error of the estimation. This step is similar to the approach used in [16].

After steps 1 and 2 of the algorithm, we have the property that each set in the remaining instance has at most $\widetilde{O}(\alpha)$ elements, and each element in the remaining instance is in at most $\widetilde{O}(\beta)$ sets.

(Step 3) Estimating the Maximum Matching of Auxiliary Graph H. We construct an auxiliary multigraph H with vertex set $\mathcal{U}_{low}$. For each set $S \in \hat{\mathcal{F}}$, we add an edge in H between every two elements of S. Note that we do not explicitly construct the multigraph H because doing so would require $\Omega(nk)$ time, which is not feasible. We now estimate the size of the maximum matching in H to produce our final estimate. Intuitively, if χ is very small (close to zero), meaning that nearly k sets are required to cover the universe, then the maximum matching in H will also be small. To see this, note that a matching edge implies that its two endpoints can be covered by the same set. Conversely, if χ is large (almost equal to k), then H will have a large matching because each set in the set cover solution covers many new elements, which can be almost paired up in H. Thus, obtaining a constant approximation for the size of the maximum matching in H is sufficient to achieve our goal, and we do this by estimating the size of a random greedy maximal matching in H. To that end, we modify and analyze the algorithm from [6] for multigraphs and adapt it to our access model for the multigraph H, as discussed in detail in the full version of the paper. The algorithm in [16] constructs a similar graph, but it is not a multigraph in the sense that, for any two elements that appear together in multiple sets, only a single edge is added between them in H.

▶ **Definition 9** (Auxiliary Multigraph H). *Let $\hat{\mathcal{F}}$ and $\mathcal{U}_{low}$ be as defined in Algorithm 1, respectively, of Algorithm 1. We construct an auxiliary graph H with vertex set $\mathcal{U}_{low}$ such that for each set S in $\hat{\mathcal{F}}$ and each two different elements $e, e' \in \mathcal{U}_{low}$, we add an edge (e, e') to H. Note that H is a multigraph: multiple sets may contain both elements e and e', and we add an edge for each of these sets.*

Algorithm 1 Sublinear Time Algorithm for Set Cover.

Input: Collection of sets $\mathcal{F}$ and universe of elements $\mathcal{U}$.
Parameter: $\alpha \leftarrow n^x, \quad \beta \leftarrow 10 \max(k/n^{1-y}, 1) \cdot n \log(n)/k$.
Let $\hat{\mathcal{F}}$ and $\hat{\mathcal{U}}$ be the output of Algorithm 2 with input $\mathcal{F}$, $\mathcal{U}$ and α.
Let $\mathcal{U}_{low}$ and $\mathcal{U}_{high}$ be the output of Algorithm 3 with input $\hat{\mathcal{F}}$, $\hat{\mathcal{U}}$, and β.
Let H be the auxiliary multigraph defined in Definition 9. ▷ We do not build H explicitly.
Let $\widetilde{\mu}$ be the estimate of $\mathbf{E}_\pi |\mathrm{RGMM}(H, \pi)|$.
Let $\widetilde{\chi} \leftarrow \widetilde{\mu} + |\mathcal{U} \setminus \mathcal{U}_{low}| - \varepsilon k/2$.
return $\widetilde{\chi}$.

Algorithm 2 Sparsification of Sets.

Input: Collection of sets $\mathcal{F}$, universe of elements $\mathcal{U}$, and parameter α that controls the sparsification ratio.
$\hat{\mathcal{F}} \leftarrow \mathcal{F}, \quad \hat{\mathcal{U}} \leftarrow \mathcal{U}, \quad c \leftarrow 0.$ ▷ We use c only for the analysis.
for $S \in \mathcal{F}$ **do**
  if $|\hat{\mathcal{U}}| < 10\alpha \log n$ **then**
    break
  $r_1 \leftarrow |\hat{\mathcal{U}}|/\alpha.$
  Let $e_1, e_2, \ldots, e_{r_1}$ be r_1 random elements of $\hat{\mathcal{U}}$.
  Make queries between S and elements $e_1, \ldots, e_{r_1}$.
  if $|\{e_1, \ldots, e_{r_1}\} \cap S| \geq 10 \log n$ **then**
    $\hat{\mathcal{F}} \leftarrow \hat{\mathcal{F}} \setminus \{S\}.$
    $c \leftarrow c + 1.$
    for $e \in \hat{\mathcal{U}}$ **do**
      if $e \in S$ **then**
        $\hat{\mathcal{U}} \leftarrow \hat{\mathcal{U}} \setminus \{e\}.$
return $\hat{\mathcal{F}}, \hat{\mathcal{U}}$

Algorithm 3 Sparsification of Elements.

Input: Collection of sets $\hat{\mathcal{F}}$, universe of elements $\hat{\mathcal{U}}$, and parameter β that controls the sparsification ratio.
$r_2 \leftarrow |\hat{\mathcal{U}}|/\beta.$
if $r_2 < 20 \log n/\varepsilon$ **then**
  $\mathcal{U}_{low} \leftarrow \hat{\mathcal{U}}, \quad \mathcal{U}_{high} \leftarrow \emptyset.$
  return $\mathcal{U}_{low}, \mathcal{U}_{high}.$
Let $\{S_1, S_2, \ldots, S_{r_2}\}$ be r_2 random sets from $\hat{\mathcal{F}}$.
Make queries between all elements in $\hat{\mathcal{U}}$ and sets in $\{S_1, S_2, \ldots, S_{r_2}\}$.
Let $\mathcal{U}_{low}$ be the elements that appeared in at most $20 \log n/\varepsilon$ many sets.
$\mathcal{U}_{high} \leftarrow \hat{\mathcal{U}} \setminus \mathcal{U}_{low}.$
return $\mathcal{U}_{low}, \mathcal{U}_{high}.$

4.1 Proof of Correctness

In this section, we prove the correctness of Algorithm 1.

▷ Claim 10. For any set S such that the condition of Algorithm 2 holds during the execution of Algorithm 2, with high probability it holds that $|S \cap \hat{\mathcal{U}}| \geq \alpha$, where $\hat{\mathcal{U}}$ denotes the universe that Algorithm 2 maintains at the time it processes S.

Proof. Suppose that S is a set such that $|S \cap \hat{\mathcal{U}}| < \alpha$ at the time that Algorithm 2 processes this set. Let X_i be the random variable that indicates $e_i \in S$. Thus, we have $\Pr[X_i] \leq |S \cap \hat{\mathcal{U}}|/|\hat{\mathcal{U}}|$. Let $X = \sum_{i=1}^{r_1} X_i$. By linearity of expectation, we have $\mathbf{E}[X] < r_1\alpha/|\hat{\mathcal{U}}| = 1$. Also, note that X_i's are negatively associated random variables. Let $\lambda = (9 \log n)/\mathbf{E}[X]$. Therefore, using the Chernoff bound for negatively associated random variables (Proposition 7) we have

$$\begin{aligned}\Pr[X \geq (1+\lambda)\,\mathbf{E}[X]] &\leq \left(\frac{e^{\lambda}}{(1+\lambda)^{1+\lambda}}\right)^{\mathbf{E}[X]} \\ &\leq \left(\frac{e^{\lambda}}{\lambda^{\lambda}}\right)^{\mathbf{E}[X]} && \text{(Since } \lambda > 1\text{)} \\ &= \left(\frac{e}{\lambda}\right)^{9\log n} && \text{(Since } \lambda = (9\log n)/\,\mathbf{E}[X]\text{)} \\ &\leq \frac{1}{n^9} && \text{(Since } \lambda > e^2\text{)}\end{aligned}$$

which implies that with probability of at least $1 - n^{-9}$,

$$X < (1+\lambda)\,\mathbf{E}[X] = \mathbf{E}[X] + 9\log n < 10\log n.$$

Since we have n sets, using a union bound, with a probability at least $1 - n^{-8}$, for any set such that the condition of Algorithm 2 holds, we have $|S \cap \hat{\mathcal{U}}| \geq \alpha$. ◁

▷ Claim 11. Let c be the variable used in Algorithm 2. With high probability, we have $c \leq k/\alpha$.

Proof. By Claim 10, for every set S such that the condition on Algorithm 2 of Algorithm 2 holds, with high probability we have that $|S \cap \hat{\mathcal{U}}| \geq \alpha$. Hence, each time the algorithm increases c, the size of $\hat{\mathcal{U}}$ decreases by α. Therefore, the total number of times the algorithm increases c is upper-bounded by k/α. ◁

▷ Claim 12. Let $\hat{\mathcal{F}}$ and $\hat{\mathcal{U}}$ be the output of Algorithm 2. Then, each set $S \in \hat{\mathcal{F}}$ has at most $20\alpha\log n$ elements in $\hat{\mathcal{U}}$ with high probability.

Proof. First, note that if the algorithm stops because of the condition of Algorithm 2 and does not process S, it holds that $|\hat{\mathcal{U}}| < 10\alpha\log n$ and the claim trivially holds.

Let S be a set such that at the time that Algorithm 2 processes S, we have $|S \cap \hat{\mathcal{U}}| \geq 20\alpha\log n$. Similar to the proof of Claim 10, let X_i be the random variable that indicates $e_i \in S$ and $X = \sum_{i=1}^{r_1} X_i$. Hence, $\mathbf{E}[X] \geq 20 r_1 \alpha \log n/|\hat{\mathcal{U}}| = 20\log n$. Since X_i's are negatively associated random variables, using Chernoff bound (Proposition 7) for $\lambda = (9\log n)/\,\mathbf{E}[X]$, we have

$$\begin{aligned}\Pr[X \leq (1-\lambda)\,\mathbf{E}[X]] &\leq \left(\frac{e^{\lambda}}{(1+\lambda)^{1+\lambda}}\right)^{\mathbf{E}[X]} \\ &\leq \left(\frac{e^{\lambda}}{\lambda^{\lambda}}\right)^{\mathbf{E}[X]} && \text{(Since } \lambda > 1\text{)} \\ &= \left(\frac{e}{\lambda}\right)^{9\log n} && \text{(Since } \lambda = (9\log n)/\,\mathbf{E}[X]\text{)} \\ &\leq \frac{1}{n^9} && \text{(Since } \lambda > e^2\text{)}\end{aligned}$$

which implies that with a probability of at least $1 - n^{-9}$,

$$X > (1-\lambda)\,\mathbf{E}[X] = \mathbf{E}[X] - 9\log n \geq 20\log n - 9\log n > 10\log n.$$

Therefore, the condition on Algorithm 2 of Algorithm 2 must hold for all such sets with a probability of at least $1 - n^{-8}$ using union bound. ◁

▶ **Lemma 13** (Sets Sparsification Guarantee). *Let $\hat{\mathcal{F}}$ and $\mathcal{U}_{low}$ be outputs of Algorithm 2 and Algorithm 3. Also, let $S \in \hat{\mathcal{F}}$. Then, with high probability, S contains at most $\widetilde{O}(\alpha)$ elements of $\mathcal{U}_{low}$.*

Proof. Note that $\mathcal{U}_{low} \subseteq \hat{\mathcal{U}}$ where $\hat{\mathcal{U}}$ is the output of Algorithm 2. Also, by Claim 12, we have $|S \cap \hat{\mathcal{U}}| \leq 20\alpha \log n$. Thus, with high probability we have $|S \cap \mathcal{U}_{low}| \leq 20\alpha \log n = \widetilde{O}(\alpha)$. ◀

▶ **Lemma 14** (Elements Sparsification Guarantee). *Let $\mathcal{U}_{low}$ be as output by Algorithm 3 and let $e \in \mathcal{U}_{low}$. Then, with high probability, there are at most $\widetilde{O}(\beta)$ sets of $\hat{\mathcal{F}}$ that contain e.*

Proof. Let e be an element of $\hat{\mathcal{U}}$, where $\hat{\mathcal{U}}$ is the output of Algorithm 2. We show that if at least $40\beta \log n/\varepsilon$ sets in $\hat{\mathcal{F}}$ contain e, then $e \in \mathcal{U}_{high}$ in the output of Algorithm 3 with high probability.

Let X_i be an indicator variable for S_i containing e. Thus, we have $\mathbf{E}[X_i] \geq 40\beta \log n/(\varepsilon n)$. Define $X = \sum_{i=1}^{r_2} X_i$. Hence, $\mathbf{E}[X] \geq r_2 \cdot 40\beta \log n/(\varepsilon n) = 40 \log n/\varepsilon$. Since X_i's are negatively associated random variables, using Chernoff bound (Proposition 7) for $\lambda = (9 \log n)/\mathbf{E}[X]$, we have

$$\Pr[X \leq (1-\lambda)\mathbf{E}[X]] \leq \frac{1}{n^9} \qquad \text{(Similar to the proof of Claim 12)}$$

which implies that $X > 20 \log n$ with a probability of at most $1 - n^{-9}$, since

$$X > (1-\lambda)\mathbf{E}[X] = \mathbf{E}[X] - 9\log n \geq 40 \log n/\varepsilon - 9 \log n > 20 \log n/\varepsilon.$$

Using a union bound for all elements in $\hat{\mathcal{U}}$ that are in at least $40\beta \log n/\varepsilon$ sets of $\hat{\mathcal{F}}$, with high probability all of them are going to be included in $\mathcal{U}_{high}$. As a result, for each $e \in \mathcal{U}_{low}$, e is in at most $\widetilde{O}(\beta)$ sets of $\hat{\mathcal{F}}$. ◀

▷ Claim 15. Let $\mathcal{F}'$ be a random collection of $\varepsilon k/5$ sets of $\hat{\mathcal{F}}$. Then, with high probability, every element in $\mathcal{U}_{high}$ is in one of the sets of $\mathcal{F}'$.

Proof. Let $e \in \hat{\mathcal{U}}$ be such that at most $15\beta \log n/\varepsilon$ sets of $\hat{\mathcal{F}}$ contain e. Similar to the proof of Lemma 14, let X be a random variable that denotes the number of sets S_i (for $i = 1, 2, ..., r_2$) that contain e. Using a Chernoff bound, we can prove that with a probability of at least $1 - n^{-2}$, for all such elements e, we have $X < 20 \log n/\varepsilon$. Therefore, all elements in $\mathcal{U}_{high}$ are in at least $15\beta \log n/\varepsilon$ sets of $\hat{\mathcal{F}}$.

Consequently, when $|\mathcal{F}'| \geq \varepsilon k/5$, the expected number of sets in $\mathcal{F}'$ that cover element $e \in \mathcal{U}_{high}$ is at least

$$\frac{15\beta \log n}{\varepsilon} \cdot \frac{1}{n} \cdot \frac{\varepsilon k}{5} \geq \frac{15n \log n}{\varepsilon k} \cdot \frac{1}{n} \cdot \frac{\varepsilon k}{5} = 3 \log n$$

where we used that $\beta \geq n/k$ (see Algorithm 1 in Algorithm 1). Using Chernoff bounds again, we expect all these elements to be covered by at least one set with high probability, which concludes the proof. ◁

▷ Claim 16. Let $\mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}})$ be the optimal set cover size for the universe of elements $\mathcal{U}_{low}$ and the collection of sets $\hat{\mathcal{F}}$ which are the outputs of Algorithm 3 and Algorithm 2, respectively. Let $\widetilde{\mu}$ be the output of Lemma 21 (i.e., a size estimate of a random greedy maximal matching of H) with $\varepsilon k/2$ additive error. Then, it holds that

$$\frac{1}{2}\left(|\mathcal{U}_{low}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}})\right) - \frac{\varepsilon k}{2} \leq \widetilde{\mu} \leq |\mathcal{U}_{low}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}).$$

Proof. Let M be any maximal matching of H. First, we show that

$$\frac{1}{2}\left(|\mathcal{U}_{low}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}})\right) \leq |M| \leq |\mathcal{U}_{low}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}).$$

If for each edge in M, we take the corresponding set, and for the rest of the elements we take a set that only covers that element, we will have covered all elements of $\mathcal{U}_{low}$ with at most $|\mathcal{U}_{low}| - |M|$ sets, which implies that $|M| \leq |\mathcal{U}_{low}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}})$. On the other hand, no set can cover two elements that are unmatched by M at the same time. Thus, we have $|\mathcal{U}_{low}| - 2|M| \leq \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}})$.

Since the output of *Lemma* 21 can be smaller than the minimum-sized maximal matching by an additive factor of at most $\varepsilon k/2$, we get the claim. ◁

▷ Claim 17. Conditioning on the high-probability events of Claim 11 and Claim 15, it holds that $\mathsf{SC}(\mathcal{U}, \mathcal{F}) \leq \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}) + \varepsilon k/2$.

Proof. All elements of $\mathcal{U} \setminus (\mathcal{U}_{low} \cup \mathcal{U}_{high})$ can be covered using the c sets that are deleted in Algorithm 2. Moreover, by Claim 11, we have $c < o(k)$ since $\alpha > \omega(1)$. On the other hand, the elements of $\mathcal{U}_{high}$ can be covered using $\varepsilon k/5$ sets, as shown in Claim 15. Finally, the elements of $\mathcal{U}_{low}$ can be covered using $\mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}})$ sets. Therefore, the union of these three collections covers all elements, and the size of this solution is at most $\mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}) + \varepsilon k/2$, which completes the proof. ◁

▶ **Lemma 18.** *Conditioning on the high-probability events of Claim 11 and Claim 15, it holds that* $\chi/2 - \varepsilon k \leq \widetilde{\chi} \leq \chi$. *(Recall that* $\chi = k - \mathsf{SC}(\mathcal{U}, \mathcal{F})$ *and* $\widetilde{\chi}$ *is the output of Algorithm 1, defined on its Algorithm 1.)*

Proof. We have that

$$\begin{aligned}
\widetilde{\chi} &= \widetilde{\mu} + |\mathcal{U} \setminus \mathcal{U}_{low}| - \frac{\varepsilon k}{2} && \text{(Output of Algorithm 1)}\\
&\leq |\mathcal{U}_{low}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}) + |\mathcal{U} \setminus \mathcal{U}_{low}| - \frac{\varepsilon k}{2} && \text{(By Claim 16)}\\
&= |\mathcal{U}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}) - \frac{\varepsilon k}{2}\\
&\leq |\mathcal{U}| - \mathsf{SC}(\mathcal{U}, \mathcal{F}) && \text{(By Claim 17)}\\
&= \chi.
\end{aligned}$$

On the other hand,

$$\begin{aligned}
2(\widetilde{\chi} + \varepsilon k) &= 2\left(\widetilde{\mu} + |\mathcal{U} \setminus \mathcal{U}_{low}| + \frac{\varepsilon k}{2}\right)\\
&\geq 2\left(\frac{|\mathcal{U}_{low}|}{2} - \frac{\mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}})}{2} + |\mathcal{U} \setminus \mathcal{U}_{low}|\right) && \text{(By Claim 16)}\\
&\geq |\mathcal{U}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}})\\
&= |\mathcal{U}| - \mathsf{SC}(\mathcal{U}_{low}, \mathcal{F})\\
&\geq |\mathcal{U}| - \mathsf{SC}(\mathcal{U}, \mathcal{F})\\
&= \chi,
\end{aligned}$$

which concludes the proof. ◀

4.2 Time Complexity

▷ Claim 19. Algorithm 2 runs in $O(nk/\alpha)$ time with high probability.

Proof. First note that Algorithm 2 samples at most k/α elements for each set in $\mathcal{F}$ (Algorithm 2). So if we ignore the block of if-condition in Algorithm 2, the runtime is at most $O(nk/\alpha)$. Further, by Claim 11, the condition on Algorithm 2 holds at most k/α times with high probability. Since each time the algorithm enters the if-condition it spends $O(k)$ time to iterate over all elements, the total running time is at most $O(k^2/\alpha + nk/\alpha) = O(nk/\alpha)$. ◁

▷ Claim 20. Algorithm 3 runs in $O(k^2/\beta)$ time.

Proof. The algorithm samples $r_2 = O(k/\beta)$ sets and for each of them makes a membership query between the set and all elements. Hence, the total running time is upper-bounded by $O(k^2/\beta)$. ◁

We defer the proof of the next lemma to the full version of the paper.

▶ **Lemma 21.** *Let H be the multigraph defined in Definition 9. There exists an algorithm with an expected running time of $\widetilde{O}_\varepsilon(k\beta + \alpha\beta n)$ that estimates the value of $E_\pi|\mathrm{RGMM}(H,\pi)|$ with εk additive error with high probability.*

▶ **Lemma 22.** *The total running time of the algorithm is $\widetilde{O}(nk/\alpha + k^2/\beta + n\alpha\beta)$ with high probability.*

Proof. The algorithm runs in expected time $\widetilde{O}(nk/\alpha + n\alpha\beta)$ as shown by Claim 19, Claim 20, Lemma 21, and the fact that $k \le n$. To ensure a high-probability bound on the running time, we execute $\Theta(\log n)$ instances of the algorithm in parallel and use the estimate from the first instance that finishes. Since the expected running time is $\widetilde{O}(kn/\alpha + k^2/\beta + n\alpha\beta)$, the first instance is likely to terminate within $\widetilde{O}(nk/\alpha + k^2/\beta + n\alpha\beta)$ time with probability $1 - 1/\operatorname{poly}(n)$. (We remark that since our approximation guarantees hold with high probability, they also hold with high probability for each of the instances.) ◀

4.3 Putting Everything Together

We combine our ideas to obtain our final theorem for estimating $\chi = k - \mathsf{SC}(\mathcal{U},\mathcal{F})$. Then, we extend our analysis and make slight modifications to the algorithm to estimate $k - \mathsf{SC}(\mathcal{U},\mathcal{F}_{\neq 2})$ which is crucial for designing a sublinear algorithm for the Steiner tree problem.

▶ **Theorem 3** (Our Algorithm for Threshold Set Cover)**.** *There exists an algorithm that, given a set system $(\mathcal{U},\mathcal{F})$ with oracle access to its adjacency matrix (also known as membership queries), outputs a multiplicative-additive $(1/2, \varepsilon\cdot|\mathcal{U}|)$-approximation to Threshold Set Cover, in $\widetilde{O}(|\mathcal{F}|^{5/3})$ time, with high probability.*

Proof. First, if $k \le O(n^{2/3})$, then we can easily query between all elements and sets and compute the estimate in $\widetilde{O}(n^{5/3})$ time since all the steps of the algorithm such as finding the maximal matching can be run in linear time with respect to the size of the input. Now suppose that $k > n^{2/3}$. We use Algorithm 1 to produce the estimate $\widetilde{\chi}$, setting $x = 1/3$ and $y = 1/3$. By Lemma 18, we have that $\widetilde{\chi}$ is a multiplicative-additive $(1/2, \varepsilon k)$-approximation to the value of χ.

Moreover, we have $\alpha = n^{1/3}$ and $\beta = 10\max(k/n^{1-y}, 1)\cdot n\log(n)/k = \widetilde{O}(n^{1/3})$. By Lemma 22, the total runtime of the algorithm is upper-bounded by $\widetilde{O}(kn/\alpha + k^2/\beta + n\alpha\beta) = \widetilde{O}(n^{5/3})$ because of the assumption that $k \le n$. ◀

Now we show how we can estimate $k - \mathsf{SC}(\mathcal{U}, \mathcal{F}_{\neq 2})$ with a slight modification. The only change that is needed in our algorithm is to remove edges of H that are produced by sets of size 2 in $\hat{\mathcal{F}}$. Hence, when the algorithm estimates $\mathbf{E}_\pi[\mathrm{RGMM}(H, \pi)]$ using the vertex oracle, the oracles must not use those edges in the exploration as they do not exist in graph H. Thus, in the implementation of Lemma 21, when the algorithm queries pairs (u, S) where $u \in \mathcal{U}_{low}$ and $S \in \mathcal{F}_v$ to find neighbors of v in H, if $u \in S$, the algorithm starts querying between all elements of $\mathcal{U} \setminus v$ and S until it finds another element in S. If the algorithm finds another element of S, then it accepts the edge (v, u) as a valid edge, and otherwise it continues the random search. So each time the algorithm finds such pair (u, S), it invokes the above procedure to validate the edge. In the next theorem, we demonstrate how to bound the running time of the modified algorithm and discuss its approximation ratio.

▶ **Theorem 23.** *There exists an algorithm that outputs a multiplicative-additive $(1/2, \varepsilon k)$-approximation of value of $\chi = k - \mathsf{SC}(\mathcal{U}, \mathcal{F}_{\neq 2})$ in $\widetilde{O}(|\mathcal{F}|^{5/3})$ time with high probability.*

Proof. We need to show that the new estimation is a multiplicative-additive $(1/2, \varepsilon k)$-approximation of $k - \mathsf{SC}(\mathcal{U}, \mathcal{F}_{\neq 2})$. We follow the same approach as proof of Lemma 18. To follow the same steps, we need analogous claims similar to Claim 16 and Claim 17. The exact same proof of Claim 16 also works to provide a bound on $\mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}_{\neq 2})$. More specifically, we have

$$\frac{1}{2}\left(|\mathcal{U}_{low}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}_{\neq 2})\right) - \frac{\varepsilon k}{2} \leq \widetilde{\mu} \leq |\mathcal{U}_{low}| - \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}_{\neq 2}).$$

Further, to show that $\mathsf{SC}(\mathcal{U}, \mathcal{F}_{\neq 2}) \leq \mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}_{\neq 2}) + \varepsilon k/2$, note that we have $c = o(k)$ (see Algorithm 2 for definition of c) which implies that $\mathcal{U} \setminus (\mathcal{U}_{low} \cup \mathcal{U}_{high})$ can be covered using $o(k)$ sets of size larger than 2 (all sets that are removed in Algorithm 2 have size larger than 2). Additionally, elements of $\mathcal{U}_{high}$ can be covered using $\varepsilon k/5$ sets of $\hat{\mathcal{F}}$ according to Claim 15. Thus, we can cover elements of $\mathcal{U}_{high}$ using $2\varepsilon k/5$ sets of $\hat{\mathcal{F}}_{\neq 2}$ since we can replace each set of size 2 with two sets of size 1 that cover a single element. Finally, elements of $\mathcal{U}_{low}$ can be covered using $\mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}_{\neq 2})$ sets. The union of all these sets is a valid solution for $\mathsf{SC}(\mathcal{U}, \hat{\mathcal{F}}_{\neq 2})$ which has a size of at most $\mathsf{SC}(\mathcal{U}_{low}, \hat{\mathcal{F}}_{\neq 2}) + \varepsilon k/2$. Therefore, the error of our estimation is $(1/2, \varepsilon k)$.

Now it remains to bound the running time of the modified algorithm. We prove that the same bound on the running time as in Lemma 21 holds. Now consider a vertex v that is corresponding to an element in $\mathcal{U}_{low}$. Let $\hat{\mathcal{F}}_v$ be the collection of sets that include v. Also, let $\hat{\mathcal{F}}'_v = \{S | S \in \hat{\mathcal{F}}_v \text{ and } |S| = 2\}$. Let $r = |\hat{\mathcal{F}}_v|$ and $\hat{\mathcal{F}}_v = \{S_1, \ldots, S_r\}$. Also, let $\tau_i = |S_i \cap (\mathcal{U}_{low} \setminus v)|$. Hence, in Lemma 21, when the algorithm queries a pair (u, S) and it returns $u \in S$, the probability that $S = S_i$ is $\tau_i / \sum_{i=1}^{r} \tau_i$. For this set, using a Chernoff bound, the algorithm needs to spend at most $\widetilde{O}(k/\tau_i)$ time to see another element of S_i or explore all elements of $\mathcal{U}$. Therefore, the expected additional time the algorithm needs to spend compared to Lemma 21 is

$$\sum_{i}^{r} \left(\frac{\tau_i}{\sum_{i=1}^{r} \tau_i}\right) \cdot \widetilde{O}\left(\frac{k}{\tau_i}\right) = \widetilde{O}\left(\sum_{i}^{r} \frac{k}{\sum_{i=1}^{r} \tau_i}\right) \leq \widetilde{O}\left(\frac{rk}{\deg_H(v)}\right),$$

where the last inequality follows by the fact that $\deg_H(v) \leq \sum_{i=1}^{r} \tau_i$ since $\deg_H(v) = (\sum_{i=1}^{r} \tau_i) - |\{S | S \in \hat{\mathcal{F}}_v \text{ and } |S| = 2\}|$ after the modification of the graph H. On the other hand, the expected number of times that the oracle calls an adjacent edge of vertex v, is at most $\widetilde{O}(\deg_H(v)/k)$ (for the formal statement and the proof, see the full version of the paper). Also, these two variables have a negative correlation. Therefore, the total cost for all

vertices is at most $\widetilde{O}(rk)$. Combining with the fact that $r = \widetilde{O}(\beta)$ (Lemma 14), the total additional cost is $\widetilde{O}(k\beta)$, which is dominated by other terms in Lemma 22 which implies that the algorithm has the same running time as Theorem 3 if we choose α and β similarly. ◀

5 Connection to Steiner Tree

In this section, we show how our improved algorithm for set cover (from Section 4) implies an improved sublinear algorithm for metric Steiner tree. Formally, we show the following theorem.

▶ **Theorem 4** (Sublinear Algorithm for Metric Steiner Tree). *There exists an algorithm that, given an instance of metric Steiner tree denoted by (V, T, w) with oracle access $\mathcal{O}$ to the distance matrix of (V, w), outputs a $(2-\eta)$-estimate of $\mathsf{ST}(V, T, w)$ using $\widetilde{O}(n^{5/3})$ queries to $\mathcal{O}$, where $\eta > 0$ is a universal constant, with high probability.*

The overall structure of our algorithm is similar to the algorithm of Chen, Khanna and Tan [16]. The main difference in our algorithm compared to [16] is in the set cover component. In the following, we first provide an overview of their algorithm in Section 5.1. We then provide the query-efficient implementation of their algorithm and our modification to it in Section 5.2. We will finally provide the query complexity analysis and the proof of Theorem 4 in Section 5.3. Note that the approximation analysis of our algorithm follows directly from the proof of Theorem 3 in [16].

5.1 Algorithm at a High Level

Step 1: Minimum spanning tree over terminals. The algorithm of [16] as a first step starts with an MST $\mathcal{T}^*$ over the terminals T (whose cost can be estimated in nearly linear time using the sublinear MST algorithm of Czumaj and Sohler [18]). It is known that $w(\mathcal{T}^*)/2 \leq \mathsf{ST}(V, T, w) \leq w(\mathcal{T}^*)$. To get a strictly better-than-2 approximation of $\mathsf{ST}(V, T, w)$, it suffices to detect whether $\mathsf{ST}(V, T, w)$ is closer to $w(\mathcal{T}^*)/2$ or $w(\mathcal{T}^*)$. Hence, the rest of the algorithm is either to provide "significant" local improvements over $w(\mathcal{T}^*)$ using "set cover" like structure (i.e., step 2 in Section 4 of [16]) or "local structure" (i.e., step 3 in Section 4 of [16]), and thus output $(1 - O(\eta))w(\mathcal{T}^*)$ as the estimate of $\mathsf{ST}(V, T, w)$; or conclude that $\mathsf{ST}(V, T, w)$ is closer to $w(\mathcal{T}^*)$ and output it as the estimate of $\mathsf{ST}(V, T, w)$. Then, they show how to implement these steps using sublinear queries to $\mathcal{O}$.

Step 2: Improvement using set cover. First, they partition the edges into $L = O((\log k)/\varepsilon)$ buckets such that the edges of the ith bucket have weights in $[(1+\varepsilon)^{i-1}, (1+\varepsilon)^i)$. Let H_i be the graph built on all the terminals and all the edges upto the ith bucket. They define an instance of set cover corresponding to each level i where *ideally*,

- The elements correspond to the connected components of H_{i-1}.
- The sets correspond to the Steiner vertices.
- A set W_v (corresponding to a Steiner vertex v) contains an element u_S (corresponding to a component S) if the distance between v and some terminal in S is less than a threshold τ (think of it as $\frac{3}{5} \cdot (1+\varepsilon)^i$).

How to use set cover in making a decision about the Steiner tree cost. They show that if one can solve each of these set cover instances approximately, then one can check whether the total contribution of these set cover improvements is more than $O(\eta) \cdot w(\mathcal{T}^*)$. In particular, in that case $\mathsf{ST}(V, T, w)$ is strictly less than $(1 - O(\eta)) \cdot w(\mathcal{T}^*)$. Intuitively, this

is because one can include the Steiner vertices corresponding to the set cover solution and remove a subset of the edges in $\mathcal{T}^*$, while still maintaining a feasible solution to the Steiner tree instance. Hence, this implies that the cost of the constructed solution of the Steiner tree instance is less than $(1 - O(\eta)) \cdot w(\mathcal{T}^*)$.

A challenge and the notion of representatives. The main challenge with the above algorithm is computing the set cover instance. More precisely, in the third bullet point above, in order to check whether a set (corresponding to a Steiner vertex v) contains an element (corresponding to a connected component S), they need to compute the distance of v to all terminals $t \in T$ which could be very costly. Instead, they define a *net* on S which is a maximal subset $\tilde{S} \subseteq S$ such that any pair of terminals in $\tilde{S}$ has distance at least $\varepsilon \cdot (1+\varepsilon)^i$. They call the terminals in $\tilde{S}$ the *representatives*.

Modified set cover instance and the notion of light/heavy levels. Now, to detect if a set contains an element, we only need to check the distance of v to all terminals in $\tilde{S}$. When $|\tilde{S}|$ is small, this can be done efficiently. So, in their algorithm they *only* assign an element to a connected component S if the size of its representatives is *small*. To show that this does not introduce a large error, they define a level i to be *light* if the total sum of the edges of $\mathcal{T}^*$ in bucket i is "small", and define it to be *heavy* otherwise. They show that one can ignore all the levels i that are light, and moreover if a level is heavy, then most of its components have small sets of representatives and thus the error introduced by ignoring the components S with large net size is negligible.

Finally, we note that the notion of representatives will be used in other parts of the overall algorithm such as computing $\mathcal{T}^*$ which we will go over when describing the implementation of this step.

Step 3: Improvement using "local structure". In this step, they consider the hierarchical structure of the connected components. Specifically, they focus on components S that have exactly two child components, S_1 and S_2, where each of these child components also has exactly two child components: S_{11}, S_{12} for S_1 and S_{21}, S_{22} for S_2. Then, they check whether there exists a single Steiner vertex v that can be used to connect components $S_{11}, S_{12}, S_{21}, S_{22}$ and instead remove the corresponding edges in $\mathcal{T}^*$ connecting these components. Similarly to step 2, if the overall advantage of all these 2-level local improvements is more than $O(\eta) \cdot w(\mathcal{T}^*)$, then the algorithm outputs $(1 - O(\eta)) \cdot w(\mathcal{T}^*)$ as its estimate of $\mathsf{ST}(V, T, w)$.

Given that our algorithm does not change this step at all, we refer the reader to [16] for further details. Moreover, the query complexity is exactly the same as in [16].

5.2 Implementation of the Algorithm

Here, we focus on a query-efficient implementation of the algorithm, and particularly highlight where the set cover component was used and how we modify it.

First, we note that one cannot compute H_i exactly, so [16] shows that it suffices to work with an approximate graph H'_i such that $H_i \subseteq H'_i \subseteq H_{i+1}$.

Subroutines. Next, [16] define some useful subroutines for simulating the set cover instance on H'_i:

- $\mathsf{Find}(u, i)$: This receives a terminal u and a level i, and finds some representative terminal u' in the same connected component of H'_i that contains u. Moreover, they show that this subroutine can be implemented using $\widetilde{O}(k)$ queries.

- $\mathsf{BFS}(u, i)$: This subroutine reports all representative terminals that are in the same connected component in H'_i as u, if the total number of such representatives is $\widetilde{O}(L/\varepsilon) = \widetilde{O}(1/\varepsilon)$. Otherwise, the procedure is terminated. This procedure employs Find subroutines and has total query complexity of $\widetilde{O}(k/\varepsilon)$ which is $\widetilde{O}(k)$ given that ε is a constant.

Parameters. The algorithm uses four parameters, whose values will be later set to optimize the query complexity of the algorithm.

- M is a threshold parameter used on the number of components that contain a "small" number of representatives. Note that these are the components to which we assign an element in the universe $\mathcal{U}_i$ of the corresponding set cover instance $(\mathcal{U}_i, \mathcal{F}_i)$.
- R is a threshold parameter defining "low-degree" and "high-degree" elements.
- P is a threshold parameter denoting "low-degree" or "high-degree" sets.
- κ is a threshold parameter on the value of k. At a high level, when $k < \kappa$, we can afford to query all distances between terminals and the Steiner vertices.

Simulation of Step 2 and its query complexity. We now outline the implementation of Step 2 and specify the query complexity of each step, along with potential conditions they impose on the parameters we need to set.

- **The case of small number of terminals: if** $k \leq \kappa$, then we query all distances between terminals and Steiner vertices, which takes $O(n\kappa)$ queries. Then, we estimate $|\mathcal{U}| - \mathsf{SC}(\mathcal{U}, \mathcal{F})$ using our algorithm, but without any further queries.
- **Otherwise,** for each level i, they show that one of the following cases hold:

  Case 1. The total number of representative terminals in all connected components is $\widetilde{O}(M/\varepsilon)$. To detect this case, they use greedy MIS which can be implemented by the BFS and Find subroutines and will take $\widetilde{O}(Mk/\varepsilon)$ queries (for further details, see [43]). If this is the case, then again the set cover instance can easily be computed by querying the distance of all Steiner vertices to all representative terminals which requires $\widetilde{O}(nM/\varepsilon)$ queries. Then, similarly to the case of $k \leq \kappa$, $|\mathcal{U}_i| - \mathsf{SC}(\mathcal{U}_i, \mathcal{F}_i)$ can be estimated using our algorithm, without any further queries.

  Case 2. $|\mathcal{U}_i| \leq M$. In this case they show that level i is in fact light and thus can be ignored. To detect this case, they estimate the size of $|\mathcal{U}_i|$ using calls to BFS starting from $\widetilde{O}(k/M)$ random terminals, which overall takes $\tilde{O}(k^2/M)$ queries. Note that if we are in this case, we take no further action. Also, this step requires $k > M$, which we will ensure in our parameter setup.

  Case 3. The last case is when $|\mathcal{U}_i| \geq M$.
  - **Partitioning of the terminals based on their degree.** First, they partition the terminals into T_{low} and T_{high} based on whether the number of "close-by" Steiner vertices (roughly within distance $(3/5)(1+\varepsilon)^i$) to them is smaller than or larger than R. This partitioning can be computed using $\widetilde{O}(kn/R)$ queries by randomly sampling $\widetilde{O}(n/R)$ Steiner vertices and checking their distance to all the terminals.
  - **Handling high-degree terminals.** Then, by picking $\widetilde{O}(n/R)$ sets uniformly at random, with high probability, all elements corresponding to the components containing at least one terminal in T_{high} are covered. As they can only afford an $\varepsilon|\mathcal{U}_i|$ additive error in their estimate of $|\mathcal{U}_i| - \mathsf{SC}(\mathcal{U}_i, \mathcal{F}_i)$, they require that $n/R < \widetilde{O}(\varepsilon M) = \widetilde{O}(\varepsilon|\mathcal{U}_i|)$.

- **Handling low-degree terminals.** Next, they solve the set cover instance on $\mathcal{U}_{low}$, i.e., the connected components that have no terminal in T_{high}.
  [label=•, leftmargin=*]
  - **Partitioning of the Steiner vertices based on their degree.** They partition the sets of $\mathcal{F}_i$ into $\mathcal{W}_1$ and $\mathcal{W}_2$ based on whether their degree to T_{low} is less than $\Theta(P)$ or higher. This partitioning can be computed using $\widetilde{O}(nk/P)$ queries by randomly sampling k/P terminals from T_{low}. This requires $k > \widetilde{\Omega}(P)$ which we will ensure in our parameter setup. Then, they consider the set cover instances $(\mathcal{U}_{low}, \mathcal{W}_1)$ and $(\mathcal{U}_{low}, \mathcal{W}_2)$ separately, and return the better of the two solutions.

    Our modification to this step: In our set cover algorithm, however, we define $\mathcal{W}_2$ slightly differently, as described in Set Sparsification, see Algorithm 2. More precisely, we iterate over Steiner vertices (i.e., sets in $\mathcal{F}_i$) one by one in an arbitrary order, and at every round $j \leq |\mathcal{F}_i|$, we check whether the degree of the Steiner vertex v_j to T_{low} is more than $\Theta(P)$. If so, we add its corresponding set, W_j, to $\mathcal{W}_2$. Similarly to their test, our test can also be implemented using $\widetilde{O}(nk/P)$ queries. However, each time we add a set W_j to $\mathcal{W}_2$, we find all its "nearby" terminals and remove them from T_{low}, more precisely, $T_{low} \leftarrow T_{low} \setminus W_j$. This step can be simply done by querying the distance of the Steiner vertex v_j and all terminals in T_{low}. Hence, each time a set is added to $\mathcal{W}_2$, we perform an extra $\widetilde{O}(k)$ queries compared to the algorithm of [16]. However, as we can simply bound $|\mathcal{W}_2|$ by k/P, the overall query complexity remains as $\widetilde{O}(nk/P + k^2/P) = \widetilde{O}(nk/P)$.

  - **Handling high-degree Steiner vertices.** To solve $(\mathcal{U}_{low}, \mathcal{W}_2)$, note that by a simple double-counting argument, $|\mathcal{W}_2| \leq kR/P$. So if $kR/P \leq \varepsilon M \leq \varepsilon|\mathcal{U}_i|$, which will be ensured in the parameter setting, we can afford to pick all sets in $\mathcal{W}_2$ and thus, similarly to their argument, we only need to estimate $|\bigcup_{W\in\mathcal{W}_2} W|$ in the set cover instance. This is done by randomly sampling the terminals and using BFS and will take an overall $\widetilde{O}(k^2/M)$ queries.

    Our modification to this step: With the adjusted partitioning of $\mathcal{F}_i$ into $\mathcal{W}_1$ and $\mathcal{W}_2$ in our algorithm, the size of $\mathcal{W}_2$ is at most k/P. Therefore, by setting $k/P \leq \varepsilon M \leq \varepsilon|\mathcal{U}_i|$, we can afford to select all sets in $\mathcal{W}_2$. Notably, this modification relaxes the required condition of [16] from "$kR/P \leq \varepsilon M$" to "$k/P \leq \varepsilon M$".

  - **Handling low-degree Steiner vertices.** Finally, we need to solve $(\mathcal{U}_{low}, \mathcal{W}_1)$. In their approach, this part takes $O(RP \cdot RPk)$ queries, and this is the step where our main improvement comes from.

    Our modification to this step. By our improved bound for set cover (from Section 4), the query complexity of this part reduces to $\widetilde{O}(k^2/M + RP(n+k))$. More precisely, to simulate the algorithm in Lemma 21, we do the following.
    1. To run the RGMM oracle, we need to sample $\widetilde{O}(1)$ elements from $\mathcal{U}_i$ uniformly at random. Note that each element of $\mathcal{U}_i$ corresponds to a small component (a component with a small number of representatives). To find a small component uniformly at random, we first pick a terminal uniformly at random and run a BFS to determine whether it lies in a small component, and if so, whether it is a representative terminal. If the terminal is a representative and lies in a small component, we choose the corresponding connected component with probability $1/z$ where z is the number of representative terminals in that connected component (note that BFS returns this number as well). This approach ensures that each

small connected component has an equal probability of being sampled. Moreover, due to the bound on the number of small connected components, i.e., $|\mathcal{U}_i| \geq M$, we expect to encounter a terminal in a small connected component every $\widetilde{O}(k/M)$ samples. Therefore, the total cost of running all these BFS subroutines is $\widetilde{O}(k^2/M)$, since each BFS takes $\widetilde{O}(k)$ time.

2. For a small component (a vertex in graph H of Lemma 21), we need to identify all the Steiner nodes within a distance of at most τ (which is set roughly as $(3/5)(1+\varepsilon)^i$). This step can be completed in $\widetilde{O}(n)$ time. A similar step with the same time complexity also appears in the proof of Lemma 21.
3. Note that the number of Steiner nodes within this close distance is at most R. Let $\hat{\mathcal{S}}$ be the set of these Steiner nodes. Next, the RGMM algorithm requires a random neighbor of a small component. To get such a neighbor, we keep picking pairs (v,t) in a random order, where $t \in T_{low}$ and $v \in \hat{\mathcal{S}}$, and querying their distance. The first time that we find a pair (v,t) in close distance, we run a BFS from t to check if it is a representative terminal and if it lies in a small component, which takes $\widetilde{O}(k)$ time. If it is not a representative terminal or does not lie in a small connected component, we skip this terminal. Otherwise, we return its small connected component with probability $1/z$, where z is the number of representative terminals in that connected component, ensuring that all neighbors have an equal probability of being selected. We run the above procedure until we find a random neighbor. Therefore, using the running time from Lemma 21 (substituting α and β for R and P), and considering that we run the BFS at most $\widetilde{O}(RP)$ times (which corresponds to the maximum degree of H), we obtain an $\widetilde{O}(RP(n+k))$ time algorithm to estimate the size of the matching.

Simulation of Step 3 and its query complexity. As we are following the exact implementation of [16] for this step, the additional query complexity of this step (compared to the Step 2) is equal to $\widetilde{O}(nk/M)$ for both their algorithm and our algorithm.

5.3 Query Complexity Analysis and Proof of Theorem 4

For completeness, we start with the query complexity analysis of [16].

Analysis of the query complexity of the algorithm of [16]. As computed in Section 5.2, the overall query complexity of their algorithm is bounded by

$$\begin{aligned}&\widetilde{O}(n\kappa + \frac{Mk}{\varepsilon} + \frac{nM}{\varepsilon} + \frac{k^2}{M} + \frac{nk}{R} + \frac{nk}{P} + \frac{k^2}{M} + (RP)^2 k + \frac{nk}{M})\\ &= \widetilde{O}(n\kappa + nM + \frac{nk}{R} + \frac{nk}{P} + (RP)^2 k + \frac{nk}{M}). && \triangleright\ \varepsilon = O(1), k \leq n\end{aligned}$$

Furthermore, the conditions that need to be satisfied are

- $k \leq \kappa$, or
- $k > M$ and $n/R < \widetilde{O}(\varepsilon M)$ and $k > \widetilde{\Omega}(P)$ and $kR/P \leq \varepsilon M$.

The query complexity of their algorithm under the above conditions can be optimized by setting $\kappa = M = n^{6/7}$, $R = n^{1/7}$, and $P = n^{2/7}$, which gives the total query complexity of $\widetilde{O}(n^{13/7})$.

Now, we prove the main theorem of this section.

Proof of Theorem 4. As we are implementing the same algorithm as [16], except replacing their set cover subroutine with a more efficient algorithm, the approximation analysis follows exactly from their proof. It only remains to bound the query complexity of our proposed algorithm for metric Steiner tree using the improved sublinear algorithm for set cover. In Section 5.2, we analyzed the query complexity of the component that is implemented differently in our algorithm. Now, we put the query complexity of all parts together and compute the overall complexity.

Analysis of the query complexity of our algorithm. The overall query complexity of our algorithm is bounded by

$$\begin{aligned}&\widetilde{O}(n\kappa + \frac{Mk}{\varepsilon} + \frac{nM}{\varepsilon} + \frac{k^2}{M} + \frac{nk}{R} + \frac{nk}{P} + \frac{k^2}{M} + RP(k+n) + \frac{nk}{M})\\ &= \widetilde{O}(n\kappa + nM + \frac{nk}{R} + \frac{nk}{P} + RPn + \frac{nk}{M}) \qquad \triangleright\, \varepsilon = O(1), k \le n\end{aligned}$$

Note again that the main difference is that the term P^2R^2k is replaced by RPn. Furthermore, the conditions that need to be satisfied are also slightly more relaxed, as follows:

- $k \le \kappa$, or
- $k > M$ and $n/R < \widetilde{O}(\varepsilon M)$ and $k > \widetilde{\Omega}(P)$ and $k/P \le \varepsilon M$.

Specifically, "$kR/P \le \varepsilon M$" is replaced by "$k/P \le \varepsilon M$". Then, our algorithm can be optimized by setting $\kappa = M = n^{2/3}, R = \widetilde{\Theta}(P) = \widetilde{\Theta}(n^{1/3})$ which gives the total query complexity of $\widetilde{O}(n^{5/3})$. ◀

Abstract

We prove an $\Omega(n/k + k)$ communication lower bound on $(k-1)$-*round distributional complexity* of *the k-step pointer chasing problem* under *uniform input distribution*, improving the $\Omega(n/k - k\log n)$ lower bound due to Yehudayoff (Combinatorics Probability and Computing, 2020). Our lower bound almost matches the upper bound of $\widetilde{O}(n/k + k)$ communication by Nisan and Wigderson (STOC 91).

As part of our approach, we put forth *gadgetless lifting*, a new framework that lifts lower bounds for *a family of restricted protocols* into lower bounds for *general protocols*. A key step in gadgetless lifting is choosing the appropriate definition of restricted protocols. In this paper, our definition of restricted protocols is inspired by the structure-vs-pseudorandomness decomposition by Göös, Pitassi, and Watson (FOCS 17) and Yang and Zhang (STOC 24).

Previously, round-communication trade-offs were mainly obtained by round elimination and information complexity. Both methods have some barriers in some situations, and we believe gadgetless lifting could potentially address these barriers.

1 Introduction

Pointer chasing is a well-known problem [26] that demonstrates the power of interaction in communication and has broad applications in different areas. It was used for proving monotone constant-depth hierarchy theorem [23, 20], lower bounds on the time complexity of distributed computation [22], lower bounds on the space complexity of streaming algorithms [10, 15, 1], adaptivity hierarchy theorem for property testing [5], exponential separations in local differential privacy [16], memory bounds for continual learning [7] and limitations of the transformer architecture [24]. It is a two-party function defined below.

▶ **Definition 1** (k-step pointer chasing function). *For $k \geq 1$, the k-step pointer chasing function $PC_k : [n]^n \times [n]^n \to \{0,1\}$ is defined as follows. Given input $f_A, f_B \in [n]^n$, for $r = 0, 1, \ldots, k$ we recursively define pointers via*

$$pt_r(f_A, f_B) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } r = 0; \\ f_A(pt_{r-1}(f_A, f_B)) & \text{if } r > 0 \text{ is odd}; \\ f_B(pt_{r-1}(f_A, f_B)) & \text{if } r > 0 \text{ is even}. \end{cases}$$

The output of PC_k is the parity of the last pointer, namely, $PC_k(f_A, f_B) \stackrel{\text{def}}{=} pt_k(f_A, f_B) \bmod 2$.

Upper bounds

If Alice and Bob could communicate for k rounds, a simple protocol is the following: Alice and Bob alternatively send $f_A(\mathsf{pt}_{r-1}(f_A, f_B))$ or $f_A(\mathsf{pt}_{r-1}(f_A, f_B))$. The total communication cost for this simple protocol is $O(k \cdot \log n)$. However, if Alice and Bob can only communicate $(k-1)$ rounds, the upper bound then becomes non-trivial. Nisan and Wigderson [23] proposed a randomized $(k-1)$-round protocol with $O((n/k + k) \log n)$ communication bits.

- In the beginning, Alice and Bob use public randomness to pick a set of coordinates $I \subseteq [n]$ of size $10n/k$, and then send $f_A(I)$ and $f_B(I)$ to the other party.
- On the other hand, Alice and Bob also simulate (r rounds) deterministic protocol but skip one round if one party finds that the pointer is located in I.
- If the skip round never happens, Alice and Bob simply abort at the last round. A simple calculation shows the probability of this event is low.

This randomized protocol is indeed very simple. Alice and Bob only share coordinate-wise information. In fact, this is a structured rectangle in our setting.

Lower Bounds

Consider $(k-1)$ round protocols where Alice speaks first. For deterministic protocols, Nisan and Wigderson [23] proved an $\Omega(n - k \log n)$ communication lower bound. In the same paper, they also proved an $\Omega(n/k^2 - k \log n)$ communication lower bound for protocols that achieve $2/3$ accuracy *under uniform input distribution*.

Since then, lower bounds for pointer chasing and its close variants have been substantially studied by a good amount of papers [9, 8, 25, 18, 19, 10, 15, 1]. Finally, Yehudayoff [29] proved an $\Omega(n/k - k \log n)$ lower bound for protocols achieving constant advantage under uniform input distribution.

Now the main gap between the upper bound [23] and the lower bound [29] is the extra $k \log n$ term. This gap becomes significant if $k \geq \sqrt{n}$. In this paper, we further improve the lower bound and close the gap.

1.1 Our results

We prove that any protocol that achieves constant advantage under uniform input distribution must communicate $\Omega(n/k + k)$ bits.

▶ **Theorem 2.** *Let Π be a $(k-1)$-round deterministic protocol for PC_k where Alice speaks first such that*

$$\Pr_{f_A, f_B \leftarrow [n]^n} [\Pi(f_A, f_B) = PC_k(f_A, f_B)] \geq 2/3.$$

Then the communication complexity of Π is $\Omega(n/k + k)$.

By Yao's minimax principle, it implies a lower bound for the $(k-1)$ round randomized communication complexity.

▶ **Corollary 3.** *Every $(k-1)$-round randomized protocol for PC_k with error at most $1/3$ (where Alice speaks first) has communication complexity $\Omega(n/k+k)$.*

We observe there is still a $(\log n)$ gap between our lower bound and the protocol by [23]. We conjecture that our lower bound is tight and there is a chance to remove the $\log n$ factor in the upper bound side. A simple deterministic protocol with $(k-1)$ rounds and $O(n)$ communication bits could be the following: Alice and Bob send the parity of $f_A(x)$ and $f_B(x)$ for all $x \in [n]$ in the beginning. Hence they can skip the last round as they already know the parity. This simple protocol shows that [23]'s protocol is not tight when $k = o(\log n)$. We believe similar ideas could be extended for large k.

Applications

Given the connections between PC_k and diverse applications [10, 22, 5, 16, 7, 24], our improved lower bounds automatically lead to several applications. We list two applications below.

▶ **Corollary 4** (Direct sum extension of pointer chasing)**.** *The $(k-1)$-round randomized communication complexity of PC_k with d pairs of functions is $\Omega(d \cdot n/k^2 + d)$*

This corollary improves the previous $\Omega(d \cdot n/k^3 - dk\log n - 2d)$ lower bound presented in [10], which has applications in BFS trees streaming lower bound.

▶ **Corollary 5** (Exponential separations in local differential privacy)**.** *Let A be a $(k-1)$-round sequentially interactive ε-locally private protocol solving PC_k with error probability $\gamma \le 1/3$. Then the sample complexity of A is $\Omega\left(\frac{1}{e^\varepsilon} \cdot (n/k+k)\right)$ and there is a k round protocol with sample complexity $\widetilde{O}\left(\frac{k\log n}{\varepsilon^2}\right)$.*

This corollary improves the previous $\Omega\left(\frac{n}{e^\varepsilon k^2}\right)$ lower bound for $k < \sqrt{n/\log n}$ given by [16].

1.2 Gadgetless Lifting: A New Framework to Prove Communication Lower Bounds

The following two-step approach for proving communication lower bounds often appears in previous works (e.g., [11, 27]):

1. Identify a family of structured protocols.
2. Simulate general protocols by structured protocols and prove communication lower bounds for structured protocols.

This approach culminates in query-to-communication lifting theorems [12, 13, 6, 21].

Query-to-communication lifting theorems

Let $f : Z^n \to \{0,1\}$ be a function, and let $g : X \times Y \to Z$ be a two-party gadget function. The goal is to prove communication lower bounds for the function $f \circ g^n : X^n \times Y^n \to \{0,1\}$. Indeed, all functions for which lower bounds are proven using the above approach can be written as $f \circ g^n$ for appropriate f and g. For such functions, a communication protocol can always simulate a decision tree that computes f – such protocols consist of a natural family of structured protocols. Communication complexity for such protocols is essentially the query complexity of f, for which lower bounds are often easy to prove. Hence, the primary job is to show how to simulate general protocols by structured ones.

Though query-to-communication lifting is a beautiful framework, it requires a gadget function g since f is a one-party function. As a consequence, this framework only applies to *lifted functions*, namely, functions that can be written as $f \circ g^n$. Many important problems, such as pointer chasing, do not fall into this category; hence, lifting theorems do not apply in those cases.

To address this limitation, we propose a new framework called *gadgetless lifting*. We take a step back to the original approach, reconsidering the choice of structured protocols. In some cases, although the function is not a lifted function, there are simple and natural protocols. The crux of gadgetless lifting is how to decide the structured protocols. In this paper, we capture it as those protocols that "all shared useful information are local information". For example, the protocol by [23] only share local information such as $f_A(x)$ or $f_B(x)$ for some $x \in [n]$. In lemma 11, we show that any protocol for PC_k can be simulated by such protocols. Our proof is inspired by the structure-vs-pseudorandomness decomposition by Göös, Pitassi, and Watson [13] and Yang and Zhang [28], which is a powerful tool that emerged in the study of query-to-communication lifting theorems. Therefore, we call our method "gadgetless lifting".

In the study of lifted functions, it has been shown that query-to-communication lifting theorems bypassed some fundamental barriers from previous methods. Similarly, gadgetless lifting can also bypass obstacles from existing methods. We discuss two of them below.

Avoiding the loss in round elimination method

Previously, the only method to prove round-communication trade-offs is the *round elimination method* [23]. In [23] and [29], the authors studied the pointer chasing problem via the round elimination method. Denote by $\boldsymbol{M}_1, \ldots, \boldsymbol{M}_t$ the messages sent in the first t rounds, and let $\boldsymbol{Z}_i$ be the pointer in the i-th round, i.e., , $Z_i = \mathsf{pt}_i(X, Y)$ where X, Y are uniformly chosen from $[n]^n$. As is standard the round elimination method, [23, 29] analyzed the random variables

$$\boldsymbol{R}_t = (\boldsymbol{M}_1, \ldots, \boldsymbol{M}_t, \boldsymbol{Z}_1, \ldots, \boldsymbol{Z}_{t-1}) \text{ for } t \le k.$$

They proved that $\mathbf{H}(\boldsymbol{R}_k) \ge \Omega(n/k)$. Together with the fact that $\mathbf{H}(Z_1, \ldots, Z_k) = k \log n$, it implies that $\mathbf{H}(\boldsymbol{M}) \ge \Omega(n/k - k \log n)$. The $(k \log n)$ loss (or something similar) appears in many previous works that adopt round elimination-based [23, 18, 19, 14, 10, 29]. In this paper, we avoid the $k \log n$ loss via the gadgetless lifting.

Breaking square-root loss barrier in information complexity

Another popular method in proving communication lower bounds is by way of information complexity. However, as mentioned by Yahudayoff [29], entropy-based analyses are likely to induce a square-root loss barrier. This barrier usually comes from applying Pinsker's inequality (or its variant) to bound statistical distance from a small entropy gap. As a consequence, many results such as [23] can only prove an $\Omega(n/k^2 - k \log n)$ lower bound.

As mentioned in [29], the square-root loss also appears in many works when using the entropy-based method to prove lower bounds. For example, it appears in the parallel repetition theorem and is related to the "strong parallel repetition" conjecture which is motivated by Khot's unique games conjecture [17]. This loss also appears in direct-sum theorems [2] and direct-product theorems [4] in communication complexity.

[29] overcomes this square-root loss barrier by using a non-standard measurement called triangular discrimination. By contrast, our approach overcomes the barrier more naturally without using entropy.

Potential applications

We noticed that our method can also be naturally extended to multiparty settings such as the numbers in hand model. Moreover, some important open problems, such as round-communication tradeoff of bipartite matching problem [3] and set pointer chasing problem [10, 15], are difficult to solve using the round elimination method due to its inherent limitations. Our method offers the potential to solve these challenging problems.

2 Preliminaries

Notations

We use capital letters X to denote a set and use bold symbols like $\boldsymbol{R}$ to denote random variables. Particularly, for a set X, we use $\boldsymbol{X}$ to denote the random variable uniformly distributed over the set X. We use $\leftarrow$ to denote sampling from a distribution or choosing an element from a set uniformly at random.

2.1 Density-Restoring Partition

Min-entropy and dense distribution

For a random variable $\boldsymbol{X}$, we use $\mathrm{supp}(\boldsymbol{X})$ to denote the support of $\boldsymbol{X}$.

▶ **Definition 6** (Min-entropy and deficiency). *The min-entropy of a random variable $\boldsymbol{X}$ is defined by*

$$\mathbf{H}_\infty(\boldsymbol{X}) := \min_{x \in \mathrm{supp}(\boldsymbol{X})} \log\left(\frac{1}{\mathbf{Pr}[\boldsymbol{X} = x]}\right).$$

Suppose that $\boldsymbol{X}$ is supported on $[n]^J$. We define the deficiency of $\boldsymbol{X}$ as

$$\mathbf{D}_\infty(\boldsymbol{X}) := |J| \log n - \mathbf{H}_\infty(\boldsymbol{X}).$$

For $I \subseteq J$, $x \in [n]^J$, let $x(I) \stackrel{\mathrm{def}}{=} (x(i))_{i \in I} \in [n]^I$ be the projection of x on coordinates in I.

▶ **Definition 7** (Dense distribution). *Let $\gamma \in (0,1)$. A random variable $\boldsymbol{X}$ supported on $[n]^J$ is said to be γ-dense if for all nonempty $I \subseteq J$, $\mathbf{H}_\infty(x(I)) \geq \gamma |I| \log n$.*

The following lemma is the crux of the structure-vs-pseudorandomness method by [13]. It essentially says that a flat random variable could be decomposed into a convex combination of flat random variables with disjoint support and dense properties.

▶ **Lemma 8** (Density-restoring partition). *Let $\gamma \in (0,1)$. Let X be a subset of $[n]^M$ and $J \subseteq [M]$. Suppose that there exists an $\beta \in [n]^{\bar{J}}$ such that $\forall x \in X, x(\bar{J}) = \beta$. Then, there exists a partition $X = X^1 \cup X^2 \cup \cdots \cup X^r$ and every X^i is associated with a set $I_i \subseteq J$ and a value $\alpha_i \in [n]^{I_i}$ that satisfy the following properties.*

1. $\forall x \in X^i, x(I_i) = \alpha_i$;
2. $\boldsymbol{X}^i(J \setminus I_i)$ *is γ-dense;*
3. $\mathbf{D}_\infty\left(\boldsymbol{X}^i(J \setminus I_i)\right) \leq \mathbf{D}_\infty\left(\boldsymbol{X}(J)\right) - (1-\gamma)\log n \cdot |I_i| + \delta_i$, *where* $\delta_i \stackrel{\mathrm{def}}{=} \log(|X|/|\cup_{j \geq i} X^j|)$.

The proof of this lemma, simple and elegant, is included in the appendix for completeness.

2.2 Communication Protocols

We recall basic definitions and facts about communication protocols.

Protocol Tree

Let X and Y be the input space of Alice and Bob respectively. A deterministic communication protocol Π is specified by a rooted binary tree. For every internal vertex v,

- it has 2 children, denoted by $\Pi(v,0)$ and $\Pi(v,1)$;
- v is owned by either Alice or Bob – we denote the owner by $\mathsf{owner}(v)$;
- every leaf node specifies an output.

Starting from the root, the owner of the current node cur partitions its input space into two parts X_0 and X_1, and sets the current node to $\Pi(\mathsf{cur}, b)$ if its input belongs to X_b.

▶ **Fact 9.** *The set of all inputs that leads to an internal vertex v is a rectangle, denoted by $\Pi_v = X_v \times Y_v \subseteq X \times Y$.*

The *communication complexity* of Π, denoted by $\mathrm{CC}(\Pi)$, is the depth of the tree. The *round complexity* of Π, is the minimum number k such that in every path from the root to some leaf, the owner switches at most $(k-1)$ times. Clearly, if a protocol has k round, then its communication complexity is at least k. We can safely make the following assumptions for any protocol Π:

- Π has k rounds on every input; and
- Π communicates $\mathrm{CC}(\Pi)$ bits on every input.

Indeed, for any protocol, we can add empty messages and rounds in the end, which boosts the communication complexity by a factor of 2.

3 Proof of Main Theorem

▶ **Theorem 10** (Main theorem, Theorem 2 restated)**.** *Let Π be a $(k-1)$-round deterministic protocol for PC_k where Alice speaks first such that*

$$\Pr_{f_A, f_B \leftarrow [n]^n} [\Pi(f_A, f_B) = PC_k(f_A, f_B)] \geq 2/3.$$

Then the communication complexity of Π is $\Omega(n/k + k)$.

We use a *decomposition and sampling process* DS, as shown in Algorithm 1, in our analysis. DS takes as input a protocol Π, and samples a rectangle R that is contained in Π_v for some leaf node v. Our proof proceeds in three steps:

1. First, Section 3.1 analyzes crucial invariants during the running of DS.
2. Next, Section 3.2 shows that the accuracy of Π is captured by a quantity called *average fixed size*, which is a natural quantity that arises in the running of DS.
3. Finally, Section 3.3 proves that the average fixed size can be bounded from above by $O(\mathrm{CC}(\Pi))$. Consequently, if Π enjoys high accuracy, we get a lower bound of $\mathrm{CC}(\Pi)$.

3.1 The Decomposition and Sampling Process

During the sampling process, we maintain a useful structure of R mainly by a partitioning-then-sampling mechanism: At the beginning, R is set to be the set of all inputs. Walking down the protocol tree, we decompose the rectangle into structured sub-rectangles; then we sample a decomposed rectangle with respect to its size. In the end, we arrive at a leaf node v and a subrectangle of Π_v.

Algorithm 1 The decomposition and sampling process DS.

Input: A protocol Π for the problem PC_k.
Output: A rectangle $R = X \times Y$, and $J_A, J_B \subseteq [n]$.

Initialize $v :=$ root of $\Pi, r := 1, X := Y := [n]^n, J_A := J_B := [n]$, bad := FALSE.
while *v is not a leaf node* **do**
  `//Invariant: (1)` $X \times Y \subseteq \Pi_v$`; (2) there exists some` $z_{r-1} \in [n]$ `such that` $\mathsf{pt}_{r-1}(f_A, f_B) = z_{r-1}$ $\forall (f_A, f_B) \in X \times Y$ `(See Lemma 11).`
  Let $u_0 := \Pi(v, 0), u_1 := \Pi(v, 1)$ be the two children of v.
  if owner(v) = Alice **then**
    Partition X into $X = X^0 \cup X^1$ such that $X^b \times Y \subseteq \Pi_{u_b}$ for $b \in \{0, 1\}$.
    Sample $\boldsymbol{b} \in \{0, 1\}$ such that $\mathbf{Pr}[\boldsymbol{b} = b] = |X^b|/|X|$ for $b \in \{0, 1\}$.
    Update $X := X^{\boldsymbol{b}}, v := u_{\boldsymbol{b}}$.
    if owner($u_{\boldsymbol{b}}$) = Bob **then**
      `// A new round.`
      Further Partition X into $X = X^0 \cup X^1$ where $X^b := \{f_A \in X : f_A(z_{r-1}) \bmod 2 = b\}$.
      Sample $\boldsymbol{b'} \in \{0, 1\}$ such that $\mathbf{Pr}[\boldsymbol{b'} = b] = |X^b|/|X|$ for $b \in \{0, 1\}$.
      Update $X := X^{\boldsymbol{b'}}, r := r + 1$.
    Let $X = X^1 \cup \cdots \cup X^m$ be the decomposition of X promised by Lemma 8 with associated sets $I_1, \ldots, I_m \subseteq J_A$.
    `// Invoking Lemma 8 with` $J = J_A, M = n, \gamma = 1 - \frac{0.1}{\log n}$.
    Sample a random element $\boldsymbol{j} \in [m]$ such that $\mathbf{Pr}[\boldsymbol{j} = j] = |X^j|/|X|$ for $j \in [m]$.
    Update $X := X^j, J_A := J_A \setminus I_j$.
    if owner($u_{\boldsymbol{b}}$) = Bob $\wedge\ z_{r-1} \notin J_B$ **then**
      bad := TRUE.
  if owner(v) = Bob **then**
    Partition Y into $Y = Y^0 \cup Y^1$ such that $X \times Y^b \subseteq \Pi_{u_b}$ for $b \in \{0, 1\}$.
    Sample $\boldsymbol{b} \in \{0, 1\}$ such that $\mathbf{Pr}[\boldsymbol{b} = b] = |Y^b|/|Y|$ for $b \in \{0, 1\}$.
    Update $Y := Y^{\boldsymbol{b}}, v := u_{\boldsymbol{b}}$.
    if owner($u_{\boldsymbol{b}}$) = Alice **then**
      Further Partition Y into $Y = Y^0 \cup Y^1$ where $Y^b := \{f_B \in Y : f_B(z_{r-1}) \bmod 2 = b\}$.
      Sample $\boldsymbol{b'} \in \{0, 1\}$ such that $\mathbf{Pr}[\boldsymbol{b'} = b] = |Y^b|/|Y|$ for $b \in \{0, 1\}$.
      Update $Y := Y^{\boldsymbol{b'}}, r := r + 1$.
    Let $Y = Y^1 \cup \cdots \cup Y^m$ be the decomposition of Y promised by Lemma 8 with associated sets $I_1, \ldots, I_m \subseteq J_B$.
    Sample a random element $\boldsymbol{j} \in [m]$ such that $\mathbf{Pr}[\boldsymbol{j} = j] = |Y^j|/|Y|$ for $j \in [m]$.
    Update $Y := Y^j, J_B := J_B \setminus I_j$.
    if owner($u_{\boldsymbol{b}}$) = Alice $\wedge\ z_{r-1} \notin J_A$ **then**
      bad := TRUE.

▶ **Lemma 11** (Loop invariant). *Set* $\gamma \stackrel{\text{def}}{=} 1 - \frac{0.1}{\log n}$. *Then in the running of* $\mathsf{DS}(\Pi)$, *we have the following loop invariants: After each iteration,*

(♢) $X \times Y \subseteq \Pi_v$;

(♣) $\boldsymbol{X}(J_A), \boldsymbol{Y}(J_B)$ *are* γ*-dense;*

(♡) *there exists some* $\alpha_A \in [n]^{\overline{J_A}}, \alpha_B \in [n]^{\overline{J_B}}$ *such that* $x(\overline{J_A}) = \alpha_A, y(\overline{J_B}) = \alpha_B$ *for all* $x \in X, y \in Y$;

(♠) *there exists some* $z_r \in [n]$ *such that* $\mathsf{pt}_r(f_A, f_B) = z_r$ *for all* $(f_A, f_B) \in X \times Y$.

Proof. Item (♢) is true because every time v is updated, $X \times Y$ is updated accordingly to a sub-rectangle of Π_v and updating $X \times Y$ into its sub-rectangles does not violate this condition.

Since we applied density restoring partition at the end of each iteration, Item (♣) and (♡) is guaranteed by Lemma 8 and the way that X, Y, J_A, J_B are updated.

We prove the last item (♠) by induction. Assume that the statement holds after the first $(t-1)$ iterations. WLOG, assume that at the beginning of the t-th iteration, v is owned by Alice. Consider the following two cases.

- Case 1. Not a new round: Line 13 is not executed in the t-th iteration. Since r remains unchanged and we only update R to be a sub-rectangle of itself, the statement still holds.
- Case 2. A new round begins: Line 13 is executed and r is increased by 1. Let ρ denote the value of r before Line 13, then after this iteration, we have $r = \rho + 1$. The induction hypothesis guarantees that there exists some $z_{\rho-1} \in [n]$ such that

  $$\mathsf{pt}_{\rho-1}(f_A, f_B) = z_{\rho-1} \text{ for all} (f_A, f_B) \in X \times Y.$$

  Due to the partition and the update in Line 11 and Line 12, $|\mathrm{supp}(\boldsymbol{X}(z_{\rho-1}))| \le n/2$. Hence, $\boldsymbol{X}(z_{\rho-1})$ cannot be γ-dense as we set $\gamma = 1 - \frac{0.1}{\log n}$. Observe that after the update in Line 17, $\boldsymbol{X}(J_A)$ is γ-dense. Consequently, we must have $z_{\rho-1} \in \overline{J_A}$, and by item (♡), there exists some $z_\rho \in [n]$ such that $f_A(z_{\rho-1}) = z_\rho \ \forall f_A \in X$. By definition, for all $(f_A, f_B) \in X \times Y$,

  $$\mathsf{pt}_\rho(f_A, f_B) = f_A(\mathsf{pt}_{\rho-1}(f_A, f_B)) = f_A(z_{\rho-1}) = z_\rho.$$

  This is exactly the same statement after the t-th iteration (as we have $r = \rho + 1$). ◀

The restricted rectangles in this loop invariant are inspired by the protocols of Nisan and Wigderson [23]. This lemma aims to capture the fact that Alice and Bob cannot get any additional useful information other than coordinate-wise information during their communication.

3.2 Relating Accuracy and Average Fixed Size

From Lemma 11 we know that the coordinates in $\overline{J_A}$ and $\overline{J_B}$ are fixed if we only look at the inputs in $X \times Y$. Intuitively, the advantage of the protocol comes from such fixed coordinates, since the "alive" coordinates J_A, J_B are dense in the sense that $\boldsymbol{X}(J_A), \boldsymbol{Y}(J_B)$ is γ-dense. This intuition is formalized in the following lemma.

▶ **Lemma 12** (Relating accuracy and avarage fixed size). *Let* Π *be a* $(k-1)$*-round deterministic protocol where Alice speaks first. Then*

$$\Pr_{f_A, f_B \leftarrow [n]^n}[\Pi(f_A, f_B) = PC_k(f_A, f_B)] \le \frac{n^{1-\gamma}}{2} + n^{-\gamma} \cdot (k-1) \cdot \mathop{\mathbf{E}}_{(R, J_A, J_B) \leftarrow \mathsf{DS}(\Pi)} \left[|\overline{J_A}| + |\overline{J_B}| \right].$$

The proof of the lemma is by the following two claims. The first claim readily says that conditioned on the flag bad is not raised, Π has little advantage in the rectangle R output by $\mathsf{DS}(\Pi)$. The second claim shows the probability that the flag is raised is bounded in terms of the average fixed size.

▷ Claim 13. If $\mathsf{DS}(\Pi)$ outputs $(R = X \times Y, J_A, J_B)$ and $\mathsf{bad} = \textsc{False}$ in the end, then

$$\Pr_{(f_A,f_B)\leftarrow R}[\Pi(f_A,f_B) = \mathrm{PC}_k(f_A,f_B)] \le \frac{n^{1-\gamma}}{2}.$$

▷ Claim 14. $\Pr_{\mathsf{DS}(\Pi)}[\mathsf{bad} = \textsc{True}] \le n^{-\gamma}\cdot(k-1)\cdot \mathbf{E}_{(R,J_A,J_B)\leftarrow\mathsf{DS}(\Pi)}\left[|\overline{J_A}| + |\overline{J_B}|\right]$.

Next, we first prove Lemma 12 using the above two claims, and the proof of the claims is followed.

Proof of Lemma 12. Note that in the running of $\mathsf{DS}(\Pi)$, we always update R to a randomly chosen rectangle and the probability of each rectangle being chosen is proportional to its size. Consequently,

$$\begin{aligned}
&\Pr_{f_A,f_B\leftarrow[n]^n}[\Pi(f_A,f_B) = \mathrm{PC}_k(f_A,f_B)]\\
=&\Pr_{(R,J_A,J_B)\leftarrow\mathsf{DS}(\Pi),(f_A,f_B)\leftarrow R}[\Pi(f_A,f_B) = \mathrm{PC}_k(f_A,f_B)]\\
\le&\Pr_{\mathsf{DS}(\Pi)}[\mathsf{bad} = \textsc{True}] + \Pr_{(R,J_A,J_B)\leftarrow\mathsf{DS}(\Pi),(f_A,f_B)\leftarrow R}[\Pi(f_A,f_B) = \mathrm{PC}_k(f_A,f_B)\wedge \mathsf{bad} = \textsc{False}]\\
\le&\frac{n^{1-\gamma}}{2} + n^{-\gamma}\cdot(k-1)\cdot\mathop{\mathbf{E}}_{(R,J_A,J_B)\leftarrow\mathsf{DS}(\Pi)}\left[|\overline{J_A}| + |\overline{J_B}|\right].
\end{aligned}$$

where the last step is by Claim 13 and Claim 14. ◀

It remains to prove the two claims.

Proof of Claim 13. WLOG, assume $k-1$ is odd and the protocol always has k round. Let z_{k-1} be the pointer guaranteed by the loop invariant (Lemma 11), i.e., $\mathsf{pt}_{k-1}(f_A,f_B) = z_{k-1}$ for all $(f_A,f_B)\in R$. Since $\mathsf{bad} = \textsc{False}$, we have $z_{k-1}\in J_A$. Again by the loop invariant, $\mathbf{H}_\infty(\boldsymbol{X}(z_{k-1})) \ge \gamma$. Moreover, since R is contained in some leaf node of Π, Π output the same answer in R, say $b^*\in\{0,1\}$. Consequently,

$$\begin{aligned}
\Pr_{(f_A,f_B)\leftarrow R}[\Pi(f_A,f_B) = \mathrm{PC}_k(f_A,f_B)] &= \Pr_{f_A\leftarrow X}[f_A(z_{k-1}) \bmod 2 = b^*]\\
&\le \sum_{\sigma\in[n]:\sigma \bmod 2 = b^*}\Pr_{f_A\leftarrow X}[f_A(z_{k-1}) = \sigma]\\
&\le \frac{n}{2}\cdot n^{-\gamma}.
\end{aligned}$$

◁

Proof of Claim 14. Let $\mathcal{E}_\ell$ denote the event that the flag bad is raised when $r = \ell+1$ (i.e., when the ℓ-th round ends) for the first time. Clearly, $\Pr[\mathsf{bad} = \textsc{True}] = \sum_{\ell=1}^{k-1}\Pr[\mathcal{E}_\ell]$. It suffices to bound each $\Pr[\mathcal{E}_\ell]$.

Assume ℓ is odd, meaning that Alice speaks in the ℓ-th round. Let coin denote the randomness used for the first $(\ell-1)$ rounds. Let $X^{(\ell-1)}, J_A^{(\ell-1)}, J_B^{(\ell-1)}$ be the sets X, J_A, J_B when executing $\mathsf{DS}(\Pi)$ using coin until the ℓ-th round begins. Let $z_{\ell-1}$ be the pointer promised by the invariant. For $\mathcal{E}_\ell$ to happen, we must have $\mathsf{bad} = \textsc{False}$ until the ℓ-th round begins, meaning that $z_{\ell-1}\in J_A^{(\ell-1)}$.

Note that the random variable $\boldsymbol{z}_\ell$ exactly has the same distribution as $\boldsymbol{X}^{(\ell-1)}(z_{\ell-1})$. This is because, in the ℓ-th round (i.e., until r steps to $\ell+1$), we decompose $X^{(\ell-1)}$ into finer sets and update X to be one of them with probability proportional to their size. Therefore,

$$\begin{aligned}\Pr_{\mathsf{coin}'}[\mathcal{E}_t] = \Pr_{\mathsf{coin}'}\left[z_\ell \notin J_B^{(\ell-1)}\right] &= \Pr_{f_A \leftarrow \boldsymbol{X}^{(\ell-1)}}\left[f_A(z_{\ell-1}) \notin J_B^{(\ell-1)}\right] \\ &= \sum_{\sigma \in \overline{J_B^{(\ell-1)}}} \Pr_{f_A \leftarrow \boldsymbol{X}^{(\ell-1)}}\left[f_A(z_{\ell-1}) = \sigma\right] \\ &\le \left|\overline{J_B^{(\ell-1)}}\right| \cdot n^{-\gamma},\end{aligned}$$

where we fix coin and the probability runs over coin', the randomness used afterward; the last inequality holds because $z_{\ell-1} \in J_A^{(\ell-1)}$ and $\boldsymbol{X}^{(\ell-1)}\left(J_A^{(\ell-1)}\right)$ is γ-dense (by Item (♣) in Lemma 11). Averaging over coin, we get

$$\Pr_{\mathsf{DS}(\Pi)}[\mathcal{E}_\ell] \le \mathop{\mathbf{E}}_{\mathsf{coin}}\left[\left|\overline{J_B^{(\ell-1)}}\right|\right] \cdot n^{-\gamma} \le \mathop{\mathbf{E}}_{(R,J_A,J_B)\leftarrow\mathsf{DS}(\Pi)}\left[|\overline{J_B}|\right] \cdot n^{-\gamma},$$

where the second inequality holds because J_B becomes smaller and smaller during the execution.

For even ℓ's, we analogously have $\mathbf{Pr}[\mathcal{E}_\ell] \le \mathbf{E}\left[|\overline{J_A}|\right] \cdot n^{-\gamma}$, and hence the claim follows from union bound. ◁

3.3 Average Fixed Size is Bounded by Communication

Now that the accuracy of a protocol Π is bounded from above by the average fixed size (i.e., $\mathbf{E}_{(R,J_A,J_B)\leftarrow\mathsf{DS}(\Pi)}\left[|\overline{J_A}| + |\overline{J_B}|\right]$), in what follows we show that the average fixed size is at most $O(\mathrm{CC}(\Pi))$. Formally, we prove that

▶ **Lemma 15.** *Let Π be a $(k-1)$-round deterministic protocol where Alice speaks first. Then*

$$\mathop{\mathbf{E}}_{(R,J_A,J_B)\leftarrow\mathsf{DS}(\Pi)}\left[|\overline{J_A}| + |\overline{J_B}|\right] \le \frac{3\mathrm{CC}(\Pi)}{(1-\gamma)\log n}.$$

▶ Remark 16. We shall set $\gamma := 1 - \frac{0.1}{\log n}$ and hence the right-handed side equals $30\mathrm{CC}(\Pi)$.

Proof. We shall prove this lemma by density increment argument. That is, we study the change of the density function

$$\mathbf{D}_\infty(R) \stackrel{\mathsf{def}}{=} \mathbf{D}_\infty(\boldsymbol{X}(J_A)) + \mathbf{D}_\infty(\boldsymbol{Y}(J_B)). \tag{1}$$

in each iteration. Let $\boldsymbol{\phi_t}$ be the value of $\mathbf{D}_\infty(R)$ at the end of the t-th iteration. Assume without loss of generality Alice speaks (i.e., $\mathsf{owner}(v) = \mathsf{Alice}$) in the t-th iteration.

We fix the random coins used for the first $(t-1)$ iterations and consider the updates in the current iteration.

1. First, X is partitioned into $X = X^0 \cup X^1$ according to Π. Then, X is updated to X^b with probability $\frac{|X^b|}{|X|}$. Consequently, $\mathbf{D}_\infty(\boldsymbol{X}(J_A))$ will increase as $|X|$ shrinks, and in expectation (over the random choice of $\boldsymbol{b}$) the increment is

$$\sum_{b\in\{0,1\}} \frac{|X^b|}{|X|} \log\left(\frac{|X|}{|X^b|}\right) \le 1. \tag{2}$$

2. Next, suppose that updating v leads to the switch of the owner, i.e., Line 13 is triggered. Since we also partition X into two parts and update X with probability proportional to the size of each part, the same argument applies. That is, taking expectation over the random choice of $\boldsymbol{b}'$, $\mathbf{D}_\infty(\boldsymbol{X}(J_A))$ increases by at most 1 in expectation.

3. Finally, we further partition X according to Lemma 8. Say X is partitioned into $X = X^1 \cup \cdots \cup X^m$ and let $I_1, \ldots, I_m$ be the index sets promised by Lemma 8; and for all $j \in [m]$ we have

$$\mathbf{D}_\infty(\boldsymbol{X}^j(J_A \setminus I_j)) \le \mathbf{D}_\infty(\boldsymbol{X}(J_A)) - (1-\gamma)\log n|I_j| + \delta_j,$$

where $\delta_j = \log(|X|/\cup_{v \ge j} X^v)$. With probability $p_j \stackrel{\text{def}}{=} |X^j|/|X|$, we update $X := X^j$ and $J_A := J_A \setminus I_j$. Therefore, taking expectation over the random choice of $\boldsymbol{j}$, the density function will decrease by

$$\mathbf{D}_\infty(\boldsymbol{X}(J_A)) - \mathop{\mathbf{E}}_{j \leftarrow \boldsymbol{j}}\left[\mathbf{D}_\infty(\boldsymbol{X}^j(J_A \setminus I_j))\right] \ge \mathop{\mathbf{E}}_{j \leftarrow \boldsymbol{j}}\left[(1-\gamma)\log n \cdot |I_j| - \delta_j\right]. \tag{3}$$

Note that $\delta_j \stackrel{\text{def}}{=} \log \frac{1}{\sum_{v \ge j} p_v}$ and thus

$$\mathop{\mathbf{E}}_{j \leftarrow \boldsymbol{j}}\left[\delta_j\right] = \sum_{j=1}^{m} p_j \log \frac{1}{\sum_{v \ge j} p_j} \le \int_0^1 \log \frac{1}{1-x}\mathrm{d}x \le 1. \tag{4}$$

Let $\mathcal{F}_{t-1}$ be the σ-algebra generated by the random coins used for the first $(t-1)$ iterations. Let $\boldsymbol{\beta_t}$ be the increment of $|\overline{J_A}|$ and $|\overline{J_B}|$ in the t-th iteration. Observe that $\boldsymbol{\beta_t} = |I_j|$ by definition. By Equation (3) and Equation (4), taking expectation over random choice of $\boldsymbol{j}$, $\mathbf{D}_\infty(\boldsymbol{X}(J_A))$ decrease by at least $(1-\gamma)\log n \cdot \mathbf{E}\left[\boldsymbol{\beta_t} \mid \mathcal{F}_{t-1}\right] - 1$ due to the density restoring partition. Then

$$\mathbf{E}\left[\boldsymbol{\phi_t} - \boldsymbol{\phi}_{t-1}\right] = \mathbf{E}\left[\mathbf{E}\left[\boldsymbol{\phi_t} - \boldsymbol{\phi}_{t-1} \mid \mathcal{F}_{t-1}\right]\right] \le \mathbf{E}\left[1 + \boldsymbol{\eta_t} - ((1-\gamma)\log n \cdot \boldsymbol{\beta_t} - 1)\right], \tag{5}$$

where $\boldsymbol{\eta_t} \stackrel{\text{def}}{=} \mathbb{1}[\text{owner switches in the } t\text{-th iteration}]$.

Write $c \stackrel{\text{def}}{=} \mathrm{CC}(\Pi)$ and assume we always have c iterations. [1] In the beginning, $\boldsymbol{\phi}_0 = \mathbf{D}_\infty([n]^n \times [n]^n) = 0$. Since the density function is always non-negative by definition, we have $\boldsymbol{\phi}_c \ge 0$ and thus $\mathbf{E}\left[\boldsymbol{\phi}_c - \boldsymbol{\phi}_0\right] \ge 0$. On the other hand, by telescoping,

$$\mathbf{E}\left[\boldsymbol{\phi}_c - \boldsymbol{\phi}_0\right] = \sum_{t=1}^{c} \mathbf{E}\left[\boldsymbol{\phi_t} - \boldsymbol{\phi}_{t-1}\right] \le 2c + \sum_{t=1}^{c} \mathbf{E}\left[\boldsymbol{\eta}_t - (1-\gamma)\log n \cdot \boldsymbol{\beta_t}\right],$$

where the inequality follows from Equation (5). Observe that $\sum_{t=1}^{c} \boldsymbol{\eta}_t$ is at most k and $\sum_{t=1}^{c} \boldsymbol{\beta}_t = |\overline{J_A}| + |\overline{J_B}|$ by definition. We conclude that

$$\mathbf{E}\left[|\overline{J_A}| + |\overline{J_B}|\right] = \mathbf{E}\left[\sum_{t=1}^{c} \boldsymbol{\beta}_t\right] \le \frac{2c+k}{(1-\gamma)\log n} \le \frac{3c}{(1-\gamma)\log n},$$

as desired. ◀

Proving the main theorem

Now our main theorem easily follows from the two lemmas.

[1] Namely, Π communicates c bits on all inputs.

Proof of Theorem 2. Set $\gamma \stackrel{\text{def}}{=} 1 - \frac{0.1}{\log n}$. By Lemma 15 and Lemma 12, we get

$$\begin{aligned}\texttt{Accuracy}(\Pi) &\stackrel{\text{def}}{=} \mathop{\mathbf{Pr}}_{f_A, f_B \leftarrow [n]^n}[\Pi(f_A, f_B) = \mathrm{PC}_k(f_A, f_B)] \\ &\le \frac{n^{1-\gamma}}{2} + n^{-\gamma} \cdot (k-1) \cdot \frac{3\mathrm{CC}(\Pi)}{(1-\gamma)\log n} \\ &\le 0.54 + \frac{1.08(k-1)}{n} \cdot 30\mathrm{CC}(\Pi),\end{aligned}$$

where we use $\frac{n^{1-\gamma}}{2} \le 0.54, n^{-\gamma} \le \frac{1.08}{n}$. Since we assumed $\texttt{Accuracy}(\Pi) \ge 2/3$, we conclude that

$$\mathrm{CC}(\Pi) \ge \frac{2/3 - 0.54}{1.08 \cdot 30} \cdot \frac{n}{k-1} > 0.0039 \cdot \frac{n}{k-1} = \Omega(n/k).$$

We also trivially have $\mathrm{CC}(\Pi) \ge k - 1$ as Π has $(k-1)$ rounds; putting it together we conclude that $\mathrm{CC}(\Pi) = \Omega(n/k + k)$. ◀

A Appendix

The following lemma and proof are from Lemma 5 in [13].

▶ **Lemma 17** (Lemma 8 restated). *Let $\gamma \in (0,1)$. Let X be a subset of $[n]^M$ and $J \subseteq [M]$. Suppose that there exists an $\beta \in [n]^{\overline{J}}$ such that $\forall x \in X, x(\overline{J}) = \beta$. Then, there exists a partition $X = X^1 \cup X^2 \cup \cdots \cup X^r$ and every X^i is associated with a set $I_i \subseteq J$ and a value $\alpha_i \in \{0,1\}^{I_i}$ that satisfy the following properties.*

1. $\forall x \in X^i, x(I_i) = \alpha_i$;
2. $\boldsymbol{X}^i(J \setminus I_i)$ *is γ-dense;*
3. $\mathbf{D}_\infty\left(\boldsymbol{X}^i(J \setminus I_i)\right) \le \mathbf{D}_\infty\left(\boldsymbol{X}(J)\right) - (1-\gamma)\log n \cdot |I_i| + \delta_i$, *where* $\delta_i \stackrel{\text{def}}{=} \log(|X|/|\cup_{j \ge i} X^j|)$.

Proof. We prove it by a greedy algorithm as follows.

Algorithm 2 Greedy Algorithm.

Input: $X \subseteq [n]^M$
Output: A partition $X = X^1 \cup X^2 \cup \cdots \cup X^m$
Initialize $i := 1$.
while $X \neq \emptyset$ **do**
  Let $I \subseteq J$ be a maximal subset (possibly $I = \emptyset$) such that $\mathbf{H}_\infty(\boldsymbol{X}(I)) < \gamma|I|\log n$ and let $\alpha_i \in [n]^I$ be a witness of this fact, i.e., $\mathbf{Pr}[\boldsymbol{X}(I) = \alpha_i] > n^{-\gamma|I|}$.
  $X^i := \{x \in X : x(I) = \alpha_i\}$ and $I_i := I$.
  Update $X := X \setminus X^i$, $J := J \setminus I_i$, and $i := i + 1$.

Item 1 is guaranteed by the construction of X^i and I_i.

We prove Item 2 by contradiction. Assume towards contradiction that $\boldsymbol{X}^i(J \setminus I_i)$ is not γ-dense for some i. By definition, there is a nonempty set $K \subseteq J \setminus I_i$ and $\beta \in [n]^K$ violating the min-entropy condition, namely, $\mathbf{Pr}\left[\boldsymbol{X}(K) = \beta\right] > n^{-\gamma|K|}$. Write $X^{\ge i} \stackrel{\text{def}}{=} \cup_{j \ge i} X^i$. Then

$$\mathbf{Pr}\left[\boldsymbol{X}^{\ge i}(I_i \cup K) = (\alpha_i, \beta)\right] = \mathbf{Pr}\left[\boldsymbol{X}^{\ge i}(I_i) = \alpha_i\right] \cdot \mathbf{Pr}\left[\boldsymbol{X}^i(K) = \beta\right] > n^{-\gamma|I_i|} \cdot n^{-\gamma|K|} = n^{-\gamma|I_i \cup K|},$$

where the first equality holds as $(\boldsymbol{X}^{\ge i} | \boldsymbol{X}^{\ge i}(I_i) = \alpha_i) = \boldsymbol{X}^i$. However, this means at moment that I_i is chosen, the set $I_i \cup K \subseteq J$ also violates the min-entropy condition (witnessed by (α_i, β)), contradicting the maximality of I_i.

Finally, Item 3 is proved by straightforward calculation:

$$\begin{aligned}
\mathbf{D}_\infty(\boldsymbol{X}^i(J \setminus I_i)) &= |J \setminus I_i|\log n - \log|X^i| \\
&\le (|J|\log n - |I_i|\log n) - \log\left(\left|X^{\ge i}\right| \cdot n^{-\gamma|I_i|}\right) \\
&= (|J|\log n - \log|X|) - (1-\gamma)|I_i| \cdot \log n + \log\left(\frac{|X|}{|X^{\ge i}|}\right) \\
&= \mathbf{D}_\infty\Big(\boldsymbol{X}(J)\Big) - (1-\gamma)|I_i|\log n + \delta_i.
\end{aligned}$$

A Quantum Unique Games Conjecture

Hamoon Mousavi

Taro Spirig
QMATH, Department of Mathematical Sciences, University of Copenhagen, Denmark

Abstract

After the NP-hardness of computational problems such as 3SAT and MaxCut was established, a natural next step was to explore whether these problems remain hard to approximate. While the quantum nonlocal games extensions of some of these problems are known to be hard – indeed undecidable – their inapproximability remains largely unresolved. In this work, we introduce definitions for the quantum extensions of Label-Cover and Unique-Label-Cover. We show that these problems play a similarly crucial role in studying the inapproximability of quantum constraint satisfaction problems as they do in the classical setting.

1 Introduction

1.1 Motivations

The Label-Cover problem [1, 8, 16], a well-known constraint satisfaction problem (CSP), has been central in the study of hardness of approximation. According to the PCP theorem [2, 3, 4, 5, 8, 15, 19, 45], it is NP-hard to approximate Label-Cover within any additive constant. This result, combined with gap-preserving reductions from Label-Cover, has led to optimal inapproximability results for several other key problems, including 3XOR and 3SAT, due largely to the work of Håstad [24, 25].

An instance of Label-Cover consists of a bipartite graph with left vertex set U and right vertex set V, a large label set (also called an alphabet) $\mathcal{L}$, and maps $\pi_{u,v} : \mathcal{L} \to \mathcal{L}$ associated with each edge (u, v). These maps are usually called projections. A *labelling* $a : U \cup V \to \mathcal{L}$ is said to satisfy an edge (u, v) if it respects the associated projection map, meaning if $\pi_{u,v}(a(u)) = a(v)$. The *value of the instance* is the maximum fraction of satisfied edges over all possible labelings.

In quantum information theory, the quantum extension of Label-Cover, known as *entangled projection games* [14], is a special case of *nonlocal games* [10, 17].[1] The primary distinction lies in the definition of labeling. A *quantum labeling* generalizes probabilistic labeling. In classical probabilistic labeling, each vertex is assigned a probability distribution over labels. In quantum labeling, each edge is assigned a distribution over pairs of labels – one for each vertex incident on the edge.

More formally, a quantum labeling assigns quantum measurements to each vertex, with the measurement outcomes corresponding to labels. When both vertices of an edge are measured, the resulting probability distribution determines the likelihood that the edge is satisfied. The *quantum value* of the instance is the maximum expected fraction of satisfied edges over all possible quantum labelings. A formal definition is given in Section 3.1 of the full version [38].

In the quantum setting, the role of the PCP theorem is played by the $\mathrm{MIP}^* = \mathrm{RE}$ theorem of Ji et al. [29]: it is RE-hard to approximate the quantum value of Label-Cover within any additive constant.[2] Now, as with the classical case, one might expect to derive optimal inapproximability results for other quantum constraint satisfaction problems. O'Donnell and Yuen [41], for instance, extended Håstad's results to the optimal inapproximability of quantum 3XOR. So far, the classical and quantum theories of inapproximability have followed parallel trajectories.

In the classical development, after the initial success of Håstad, researchers discovered some of the limitations of Label-Cover. To address these, Khot [32] introduced a modification to the Label-Cover problem, imposing a uniqueness condition on the projection maps. This modified problem is known as the Unique-Label-Cover and it remains an open question whether it is hard to approximate. However, assuming that Unique-Label-Cover is hard to approximate, researchers showed optimal inapproximability results for a variety of other problems, including MaxCut [34]. This assumption is known as the Unique Games Conjecture (UGC) [32].

A striking divergence arises between the classical and quantum theories of inapproximability with the introduction of Unique-Label-Cover. Kempe et al. [31] showed that the quantum value of Unique-Label-Cover is efficiently approximable. This implies that a *direct* quantum analogue of the UGC does not hold. As a result, none of the classical consequences of the UGC can be straightforwardly extended to the quantum domain. This presents a significant challenge to the development of a comprehensive quantum theory for hardness of approximation.

For instance, understanding the complexity of the anti-ferromagnetic Heisenberg model – a quantum generalization of MaxCut and a problem of great significance in physics and quantum information – remains an open question. While this problem is known to be QMA-hard, the complexity of approximating it is still unresolved.[3] Hwang et al. [26] made significant progress on this question, but their results rely on the classical UGC, which limits them to showing NP-hardness rather than QMA-hardness.

Finding the right candidate for a quantum extension of UGC is key for advancing the theory of inapproximability in the quantum setting. This work proposes such a candidate.

---

[1] We primarily adopt the CSP terminology, while referencing certain naming conventions from the nonlocal games literature for the convenience of readers familiar with that field. See Section 1.2 for a discussion of our terminology.

[2] Recall that RE is the class of recursively enumerable languages. Stating that a problem is RE-hard is another way of saying that it is undecidable.

[3] Recall that QMA is the quantum analogue of NP.

We begin by noting that Kempe et al.'s algorithm for approximating the quantum value of Unique-Label-Cover applies only to some of many possible quantum values that are defined in the literature on nonlocal games. Examples of quantum values include, but are not limited to, the tensor-product, commuting-operator, synchronous, and oracularizable-synchronous values. Label-Cover remains hard across all these models [29, 47, 48], whereas Unique-Label-Cover is efficiently approximable in only some of them [31].

We choose a model where Unique-Label-Cover might still be hard to approximate. This choice forms the basis of our *quantum Unique Games Conjecture* (qUGC). We give an informal overview in Section 1.3. Formal definitions can be found in Section 3.2 of the full version [38].

We then show how classical reductions from Unique-Label-Cover can be "quantized" to prove inapproximability results for quantum CSPs. We illustrate this approach with 2-Lin [32] and MaxCut [34], and we believe the same tools can be applied to Raghavendra's seminal work on CSPs [44]. An informal overview is given in Section 1.4. The proof ideas are sketched in Section 1.5. Detailed statements and proofs are provided in Sections 4 and 5 of the full version [38].

We conclude this section with a few remarks.

Relationship between UGC and qUGC. The cases of 3XOR, 2-Lin, and MaxCut could be instances of a broader principle: any reduction from Label-Cover (or its variants such as Unique-Label-Cover, Smooth-Label-Cover, and 2-to-2 Label-Cover) might be adaptable to the quantum setting. If true, this would imply that the classical UGC implies qUGC. We explore this possibility and related open questions in Section 1.6.

Variants of qUGC. Section 1.3 and Section 3.2 in the full version [38] present several variants of the quantum Unique Games Conjecture. These variants may help in proving hardness for other models, such as the anti-ferromagnetic Heisenberg model or CSPs investigated in [12]. These topics are further detailed as Problems 4, 7, and 8 in Section 1.6.

Alternative Approaches to UGC. Some of the variants of quantum UGC proposed in this paper may be easier to prove hardness for than the classical UGC itself. Proving hardness for any of these variants could strengthen confidence in the UGC. Conversely, some of our UGC variants may be easier to disprove, and doing so could offer insights into disproving UGC. Figure 5, illustrates the reductions between variants of Unique-Label-Cover.

Universality. Label-Cover is exhibiting a remarkable *universality*, remaining hard across all the different quantum and classical models, see Figure 4. In contrast, the brittleness of Unique-Label-Cover aptly mirrors the difficulty in resolving the UGC. From another perspective, however, the constraints encountered in the search for a quantum analogue of the UGC could serve as a guiding principle in identifying the most appropriate model for quantum value from a computational standpoint.

This paper builds on our previous work on noncommutative CSPs [12], exploring how noncommutativity reshapes the landscape of CSPs. One of our motivations is the direct applications of this research to quantum information. We are also equally interested in whether a broader perspective on CSPs might uncover unifying principles that could provide new insights into classical CSPs. Our remarks on alternative approaches to UGC and universality are examples of the insights we are pursuing.

1.2 Quantum Value

We illustrate the concept of *quantum value* of a CSP instance using the example of MaxCut. For formal definitions refer to Section 3 in the full version [38]. Before proceeding, we briefly outline the connection to *nonlocal games*; however, no prior knowledge in quantum information is required to follow this work.

Nonlocal Games. The types of values we introduce for CSPs correspond directly to the values for *nonlocal games* previously studied in quantum information. Every CSP instance can be viewed as a nonlocal game and vice versa and the correspondence between their values is straightforward. This relationship is detailed in Section 10.2 of [12]. The physical, mathematical, and computational considerations for the definitions of the various types of values are extensively explored in the literature on nonlocal games [6, 9, 10, 20, 23, 29, 30, 35, 37, 42, 43, 46, 47, 48, 50, 51]. For readers familiar with this area, Table 1 summarizes the correspondences relevant to this paper. Please also refer to the discussion on previous work at the end of this section for our choice of terminology.

Table 1 Correspondence between types of values for CSPs and nonlocal games. Formal definitions for the values in the left column are given in Section 3 of the full version [38].

CSP terminology	Nonlocal game terminology
classical	classical synchronous
noncommutative [12]	quantum synchronous [43, 23, 35, 37]
quantum	oracularizable quantum synchronous [23, 29, 37]

MaxCut. The objective of MaxCut is to partition the vertices of a given graph $G = (V, E)$ into two subsets, such that the number of edges crossing the partition is maximized (as illustrated in Figure 1).

Classical Value. A (classical) partition can be represented as an assignment $x : V \to \{-1, +1\}$. The value of this partition, meaning the number of edges that cross the partition, is given by $\sum_{(i,j)\in E} \frac{1-x_i x_j}{2}$. The (classical) value of the instance, denoted $\omega_c(G)$, is the maximum partition value over all possible (classical) partitions:

$$\begin{aligned} &\text{maximize:} && \sum_{(i,j)\in E} \frac{1 - x_i x_j}{2} \\ &\text{subject to:} && x_i \in \{-1, +1\}. \end{aligned} \tag{1}$$

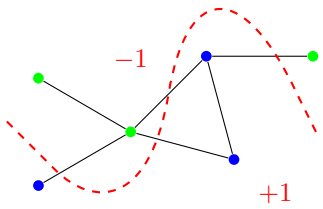

Figure 1 An instance of Max-Cut and an example of a partition (cut).

Noncommutative Value. A *noncommutative partition* assigns an observable to each vertex, i.e. $X : V \to \mathrm{Obs}(\mathcal{H})$, where $\mathcal{H}$ is some finite-dimensional Hilbert space. Observables are unitary operators with eigenvalues in the set $\{-1, +1\}$ (refer to Section 2.2 in the full version [38] for background on quantum measurements and observables). If we substitute observables for ± 1 in (1), we obtain the noncommutative value of the instance, denoted $\omega_{\mathrm{nc}}(G)$:

$$\begin{aligned} \text{maximize:} \quad & \sum_{(i,j)\in E} \frac{1 - \mathrm{tr}(X_i X_j)}{2} \\ \text{subject to:} \quad & X_i \in \mathrm{Obs}(\mathcal{H}), \end{aligned} \tag{2}$$

where tr is the dimension-normalized trace on $\mathcal{H}$. Crucially, the optimization is over all finite-dimensional $\mathcal{H}$. When $\mathcal{H}$ is one-dimensional, we recover the classical value, therefore $\omega_{\mathrm{nc}}(G) \geq \omega_c(G)$.

The noncommutative value has been the focus of our previous work on CSPs [12]. The main focus of this paper, however, is the *quantum value* of CSPs, which we define next.

Quantum Value. A *quantum partition* lies somewhere in between a classical and noncommutative partition: A noncommutative partition X is *quantum* if X_i and X_j commute whenever (i, j) is an edge. In quantum mechanics, commuting observables can be simultaneously measured, emphasizing the physical motivation for this additional commutation relation.

The *quantum value*, denoted $\omega_q(G)$, is therefore obtained from (2) by imposing the extra commutation relations:

$$\begin{aligned} \text{maximize:} \quad & \sum_{(i,j)\in E} \frac{1 - \mathrm{tr}(X_i X_j)}{2} \\ \text{subject to:} \quad & X_i \in \mathrm{Obs}(\mathcal{H}), \\ & X_i X_j = X_j X_i \text{ for all } (i,j) \in E. \end{aligned} \tag{3}$$

Since every classical assignment is a quantum assignment and every quantum assignment is a noncommutative assignment, we obtain the chain of inequalities $\omega_{\mathrm{nc}}(G) \geq \omega_q(G) \geq \omega_c(G)$.

Using the same approach outlined here, we can define the classical and quantum values for all CSPs (refer to Section 3 in the full version [38] for the relevant definitions). However, the noncommutative value is defined only for CSPs where each constraint involves only two variables.[4]

We assume $\omega_c, \omega_q, \omega_{\mathrm{nc}}$ are normalized appropriately so that they are between 0 and 1. So for example in (1),(2), and (3), the normalization amounts to dividing the objective function by the number of edges.

Remark. It is important to note that the commutativity requirement in a quantum assignment does not imply that all observables in the assignment commute with each other, nor does it mean that all observables can be diagonalized in the same basis. Commutativity is not a transitive property: every operator commutes with the identity operator, but not every

[4] This restriction is related to a similar issue for synchronous value of nonlocal games: with current definitions in the literature, the quantum synchronous value of a three-player nonlocal game reduces to the classical synchronous value. See also the remark after Definition 13 in the full version [38].

pair of operators commute with each other. For example, in MaxCut, if two vertices are at a distance of two or more, their observables in a quantum assignment need not commute.

Previous Work. The concept of noncommutative constraint satisfaction problems studied in this work traces its roots to the binary constraint system games introduced by Cleve and Mittal [11]. To the best of our knowledge, the first work to introduce a concept closely related to our notion of quantum assignment – referred to as oracularizable strategies for entangled nonlocal games – is by Ito et al. [27]. Oracularization is also a widely used technique in the study of classical nonlocal games (see references in [27]). Helton et al. [23] later examined oracularizable strategies from a mathematical perspective, employing the term locally commuting algebras (see Sections 7 and 8 of their paper).

Our definition of quantum assignment is the direct translation (for CSPs) of the *oracularizable quantum synchronous strategies* in [37]. The definition in [37] itself dates back to the breakthrough results [40, 29]. In this work, we refer to these assignments as *quantum* because the requirement of *commutativity* stems from *simultaneous measurability in quantum mechanics*. In contrast, we refer to assignments as *noncommutative* when there is no commutation requirement. This terminology originates from our earlier work on noncommutative CSPs [12].[5]

1.3 Quantum Unique Games Conjecture

Before moving on to our conjecture, we first briefly review decision problems and reductions between them. Readers familiar with the terminology can skip the next section.

1.3.1 Reductions

In the context of hardness of approximation, it is often easier to work with a version of a computational problem known as the *decision problem with a promise*. Let $\mathcal{P}$ be any computational problem for which $\omega_c, \omega_q, \omega_{\mathrm{nc}}$ are defined. For example $\mathcal{P}$ could be MaxCut, Label-Cover, or Unique-Label-Cover. For every $s, t \in \{c, q, \mathrm{nc}\}$ and $\zeta, \delta > 0$, the *decision problem* $\mathcal{P}_{s,t}(1-\zeta, \delta)$ is defined as follows: given an instance $\phi \in \mathcal{P}$ that is promised to be either

- $\omega_s(\phi) \geq 1 - \zeta$, called a "yes" instance, or
- $\omega_t(\phi) < \delta$, called a "no" instance,

decide whether the instance is a "yes" or "no" instance. When $s = t$, we simply write $\mathcal{P}_s(1-\zeta, \delta)$ to denote $\mathcal{P}_{s,s}(1-\zeta, \delta)$.

A *reduction* from $\mathcal{P}_{s,t}(\gamma, \delta)$ to $\mathcal{P}'_{s',t'}(\gamma', \delta')$ is any efficient map $\mathcal{P} \to \mathcal{P}'$ that is

- complete: it maps "yes" instances to "yes" instances, and
- sound: it maps "no" instances to "no" instances.

As a simple example, for every choice of $\zeta, \delta > 0$, the decision problem $\mathcal{P}_{q,\mathrm{nc}}(1-\zeta, \delta)$ reduces to $\mathcal{P}_{\mathrm{nc},\mathrm{nc}}(1-\zeta, \delta)$ via the identity map. Soundness is trivial, and completeness holds because $\omega_{\mathrm{nc}}(\phi) \geq \omega_q(\phi)$ for all instances ϕ. This is denoted by $\mathcal{P}_{q,\mathrm{nc}} \longrightarrow \mathcal{P}_{\mathrm{nc},\mathrm{nc}}$ (we often drop the completeness and soundness parameters in our informal discussions in this introduction). There are several other trivial reductions between decision versions of $\mathcal{P}$, and they are illustrated in Figure 2.

[5] Our decision to use *quantum synchronous strategies*, both here and in [12], is driven by the syntactical simplicity they provide compared to tensor-product strategies. While we believe that all of our results can be extended to the tensor-product model, we leave a more detailed exploration of this for future work.

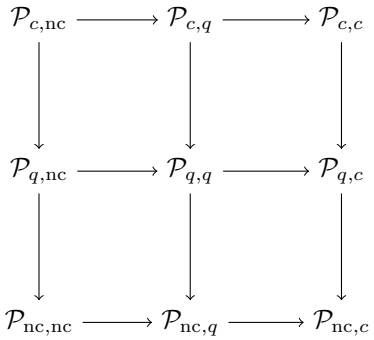

Figure 2 Trivial Reductions: if a problem in this diagram is hard (for some complexity class), then every problem reachable from it is at least as hard.

Lastly, we use the abbreviations LC for Label-Cover and ULC for Unique-Label-Cover.

1.3.2 Label-Cover

The PCP theorem states that the classical value of Label-Cover is NP-hard to approximate, or more precisely:

▶ **Theorem 1** (PCP Theorem). *For every $\delta > 0$, there is a large enough alphabet over which* $\mathrm{LC}_c(1, \delta)$ *is* NP*-hard.*

Since we have the trivial reductions $\mathrm{LC}_{c,c} \longrightarrow \mathrm{LC}_{q,c} \longrightarrow \mathrm{LC}_{\mathrm{nc},c}$, we conclude that both $\mathrm{LC}_{q,c}$ and $\mathrm{LC}_{\mathrm{nc},c}$ are at least NP-hard. This is illustrated in Figure 3.

What can we say about the other variants of Label-Cover in Figure 3? The noncommutative analogue of the PCP theorem is the $\mathrm{MIP}^* = \mathrm{RE}$ theorem. This theorem states that the noncommutative value of Label-Cover is RE-hard to approximate. In fact [29] proves a stronger theorem:

▶ **Theorem 2** ($\mathrm{MIP}^* = \mathrm{RE}$, informal). *For every $\delta > 0$, the decision problem* $\mathrm{LC}_{q,\mathrm{nc}}(1, \delta)$ *is* RE*-hard.*

This immediately implies that the problems in the last two rows in Figure 3 are RE-hard. Our full knowledge of the complexity landscape of Label-Cover is summarized in Figure 4.

1.3.3 Unique-Label-Cover

A Unique-Label-Cover instance is a special case of Label-Cover instance where every projection map is a bijection (i.e. a permutation), see Section 3.2 in the full version [38] for further details. The well-known Unique Games Conjecture asserts that it is hard to approximate the classical value of Unique-Label-Cover:

▶ **Conjecture 3** (UGC [32], informal). *For all $\zeta, \delta > 0$, the decision problem* $\mathrm{ULC}_c(1 - \zeta, \delta)$ *is* NP*-hard.*

Kempe et al. [31] provided an approximation algorithm for the noncommutative value of Unique-Label-Cover (see Theorem 19 in the full version [38] for details), but this result does not address the quantum value. Thus, we propose the following quantum analogue of the Unique Games Conjecture (see Conjecture 20 in the full version [38] for the precise statement):

▶ **Conjecture 4** (qUGC, informal). *For all $\zeta, \delta > 0$, the decision problem* $\mathrm{ULC}_q(1 - \zeta, \delta)$ *is* RE*-hard.*

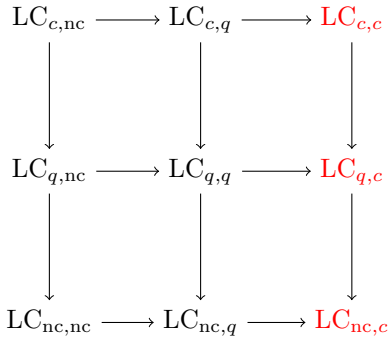

Figure 3 Implication of the PCP theorem: problems in the third column are NP-hard.

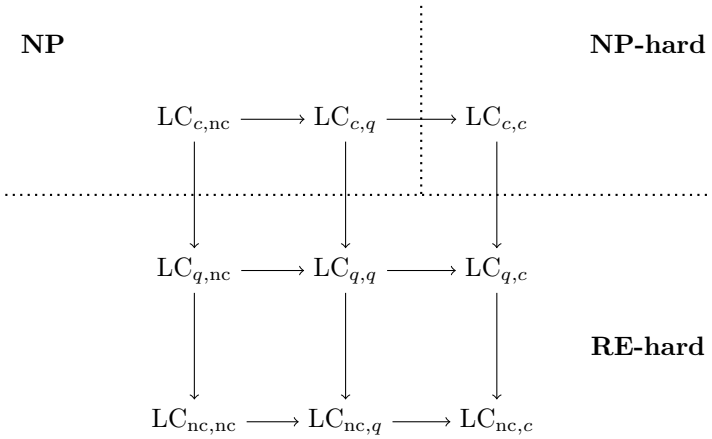

Figure 4 The complexity landscape of Label-Cover.

Assuming both UGC and qUGC, along with the algorithm from Kempe et al., the complexity landscape of Unique-Label-Cover can be summarized as shown in Figure 5.

Assuming that any one of $\mathrm{ULC}_{q,q}, \mathrm{ULC}_{q,c}, \mathrm{ULC}_{\mathrm{nc},q}, \mathrm{ULC}_{\mathrm{nc},c}$ is RE-hard constitutes a variant of the qUGC. The strongest among these variants is the conjecture concerning $\mathrm{ULC}_{q,q}$. As discussed in Section 3.2 in the full version [38], there are many (indeed, infinitely many) variants of qUGC. When we refer to qUGC without additional qualifiers, we are specifically referring to the conjecture stated above.

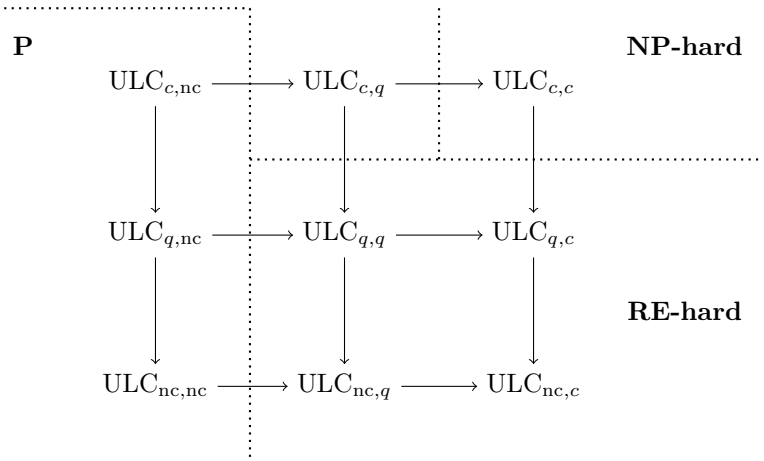
Given the reductions shown in Figure 5, it is likely easier to prove hardness for $\mathrm{ULC}_{q,c}$ or $\mathrm{ULC}_{\mathrm{nc},c}$ than to prove either UGC or qUGC. Conversely, devising a polynomial-time approximation algorithm for $\mathrm{ULC}_{c,q}$ seems more achievable than disproving either UGC or qUGC. Note that $\mathrm{ULC}_{c,q}$ is in NP (since $\mathrm{ULC}_{c,c}$ is in NP).

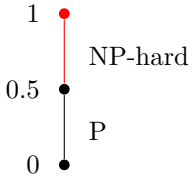
1.3.4 Applications to Hardness of Approximation

The result by O'Donnell and Yuen [41] on the quantum value of 3XOR is stated in the next theorem.

▶ **Theorem 5.** *For every $\delta > 0$, the decision problem $3\mathrm{XOR}_q(1-\delta, \frac{1}{2}+\delta)$ is RE-hard.*

This result was originally proven via a reduction from $\mathrm{LC}_{\mathrm{nc}}$. However, a reduction from LC_q suffices with some straightforward modifications. The hardness of LC_q follows directly from the $\mathrm{MIP}^* = \mathrm{RE}$ theorem (as shown in Figure 4). Since a direct proof of LC_q is likely easier than the full proof of $\mathrm{MIP}^* = \mathrm{RE}$ [29], we propose Problem 5 in Section 1.6.





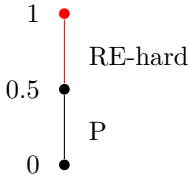


Figure 5 The complexity landscape of Unique-Label-Cover assuming both UGC and qUGC.

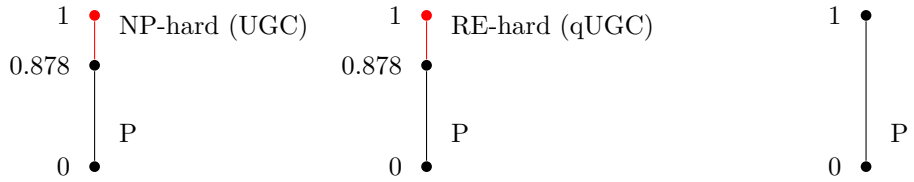
(a) Classical value [25].

(b) Quantum value [41].

Figure 6 Approximability of classical and quantum values of 3XOR: the vertical axis denotes approximation ratios between 0 and 1, with points of sharp transition in hardness (0.5 in both cases) indicated.

This theorem mirrors Håstad's celebrated result on the classical value of 3XOR [25]. Our current understanding of approximability of 3XOR is summarized in Figure 6.

In Sections 4 and 5 in the full version [38], we prove similar results for 2-Lin and MaxCut. Our reductions are from ULC$_q$ rather than LC$_q$. An informal overview of our MaxCut result is provided in the next section.



1.4 Result on MaxCut

How well can the classical, quantum, and noncommutative values of MaxCut be approximated? The current knowledge, including our result, is summarized in Figure 7.

The well-known Goemans-Williamson algorithm [21] for the classical value of MaxCut achieves an approximation ratio of $\alpha_{\mathrm{gw}} \approx 0.878$. More specifically, they showed that $\omega_c(G) \geq \alpha_{\mathrm{gw}}\omega_{\mathrm{sdp}}(G)$, where $\omega_{\mathrm{sdp}}(G)$ is the optimal value of a certain semidefinite programming (SDP) relaxation for MaxCut. Meanwhile, Tsirelson [50, 51] showed that $\omega_{\mathrm{nc}}(G) = \omega_{\mathrm{sdp}}(G)$. Combining these results yields the following chain of inequalities:

$$\alpha_{\mathrm{gw}}\omega_{\mathrm{sdp}}(G) \leq \omega_c(G) \leq \omega_q(G) \leq \omega_{\mathrm{nc}}(G) = \omega_{\mathrm{sdp}}(G). \tag{4}$$

From this chain of inequalities (see also Figure 8), we infer that the Goemans-Williamson algorithm is also a 0.878-approximation algorithm for the quantum value of MaxCut. But can we do better for the quantum value?

(a) Classical value [21, 34]. **(b)** Quantum value (this paper). **(c)** Noncommutative value [50, 51].

Figure 7 Approximability of MaxCut across different types of values.

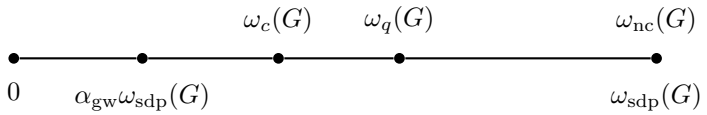


Figure 8 The MaxCut interval.

Under the assumption of the quantum Unique Games Conjecture introduced in this paper, we show:

The classical Goemans-Williamson algorithm is not only the best efficient approximation algorithm for the quantum value; it is the best approximation algorithm for the quantum value–regardless of efficiency.

▶ **Theorem 6** (Theorem 31 in the full version [38], informal)**.** *Assuming the quantum Unique Games Conjecture, it is* RE*-hard to approximate the quantum value of MaxCut to any ratio better than* α_{gw}*.*

Compare this with the following optimal inapproximability result from Khot et al. [34]:

▶ **Theorem 7** (KKMO, informal)**.** *Assuming the Unique Games Conjecture, it is* NP*-hard to approximate the classical value of MaxCut to any ratio better than* α_{gw}*.*

Integrality Gap. Similar to the Goemans-Williamson SDP relaxation, the quantum value–though undecidable–serves as a relaxation to the classical value. A natural question arises: how close is this quantum relaxation to the classical value? Can the quantum value outperform the SDP value in approximating the classical value?

Under the assumption of the quantum Unique Games Conjecture, we show that the SDP and quantum relaxations are incomparable. This is illustrated in Figure 9 and formally established in Theorem 35 in the full version [38]. Constructing examples that exhibit each of the extremes shown in Figure 9 remains an open problem.

1.5 Proof Ideas

In the conventional NP proof system for Label-Cover, the certificate is simply the list of labels for the vertices. This is what we called *classical assignment* in Section 1.2. The verifier's task in this proof system is to check that the assigned labels satisfy the edge constraints.

Håstad's gap-preserving reduction from Label-Cover (used, for instance, in proving the hardness of 3SAT and 3XOR) is best viewed as the construction of a more efficient version of this NP proof system, known as a probabilistically checkable proof (PCP). The PCP certificate for Label-Cover is an encoding of the classical assignment in binary using an error-correcting code, commonly referred to as the Long-Code, pioneered in [7]. In addition

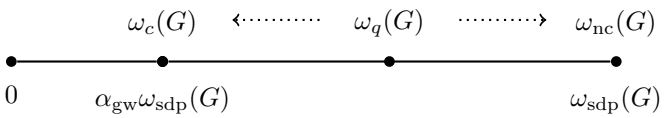

Figure 9 There exist instances realizing both extremes depicted in this picture. That is, among the integrality gap instances of MaxCut (see Feige and Schechtman [18]), i.e. those instances with $\omega_c(G) = \alpha_{\mathrm{gw}}\omega_{\mathrm{sdp}}(G)$, there are instances for which $\omega_q(G) = \omega_c(G)$ and instances for which $\omega_q(G) = \omega_{\mathrm{sdp}}(G)$.

to verifying that the labels in the encoding satisfy the edge constraints, the PCP verifier must also check that the proof consists of valid codewords. The soundness of this PCP relies on Fourier analysis. This was one of the key insights of Håstad's celebrated work.

In our case, we are reducing Unique-Label-Cover to 2-Lin (Section 4 in the full version [38]) and MaxCut (Section 5 in the full version [38]), but the core principles remain the same. Our reductions are based on the classical reductions by Khot [32] and KKMO [34], respectively. There are, however, several key differences, which we discuss in the rest of this section. For concreteness, we focus on the reduction from Unique-Label-Cover to MaxCut.

Completeness. This step requires a generalization of the Long-Code to encode quantum assignments. This is a straightforward generalization of the Long-Code to the operator setting and it is due to O'Donnell and Yuen [41]. The main challenge in proving completeness is ensuring that the encoded quantum assignment satisfies the commutation requirements of a quantum MaxCut assignment.

Soundness. The proof of soundness, as is customary, is done contrapositively. We begin with a quantum assignment for the MaxCut instance that achieves a large value, and from this, we construct a quantum assignment that has a sufficiently large value in the Unique-Label-Cover instance.

The classical proof constructs a probabilistic labeling based on the Fourier coefficients of the MaxCut assignment. Given a MaxCut assignment f, the labeling samples a subset of labels S with probability proportional to the squared Fourier coefficients, $\hat{f}(S)^2$. It then probabilistically selects a label $a \in S$ for each vertex. In the quantum setting, these squared Fourier weights are positive semidefinite operators. Defining $P^a := \sum_{S:a\in S} \frac{1}{|S|}\hat{f}(S)^2$ for each label a results in a *POVM measurement* for each vertex in the Unique-Label-Cover instance (see Section 2.2 in the full version [38] for the definition of POVMs). This is also due to [41].

These measurements satisfy the commutation relations required for a quantum assignment. However, they are not projective measurements, as required by definition of quantum assignment. Naimark's dilation theorem (see, for example, Watrous [52]) is typically used in such cases to convert POVMs into projective measurements. However, due to the commutation requirements (and the use of tracial states), Naimark's theorem is not applicable. Therefore, we need to projectivize these POVMs while preserving the commutation relations, which we accomplish using the projectivization lemma proved in Section 6 in the full version [38].

Classically, the proof of soundness relies on a deep result from Boolean Fourier analysis, known as the Majority-Is-Stablest [36], which relates Boolean functions to their Fourier weights. If the operators in our assignments were simultaneously diagonalizable, we could apply this theorem directly, as in the classical proof. However, the inherent noncommutativity of quantum assignments prevents us from doing so, forcing us to take a new approach.

To explain the problem and our resolution at a high level, recall that our goal is to construct a quantum labeling for an instance of Unique-Label-Cover. Let u be a vertex from the left-vertex set, and let N_u denote its neighbors in the right-vertex set. In the operator setting, while each neighbor's operator individually commutes with u's, the operators assigned to the neighbors may not commute with each other. This noncommutativity is a fundamental obstacle.

We first encountered this issue earlier, when attempting to view quantum assignments as extensions of probabilistic assignments. In a classical probabilistic assignment, each vertex u is assigned a single probability measure P_u over the set of labels. In contrast, a quantum assignment associates two probability measures, $P_{u,e}$ and $P_{v,e}$, with each edge $e = (u, v)$. The crux of the issue is that different edges incident on u – say, e and e' – can impose vastly different probability measures on u, which may conflict with each other.

This same phenomenon arises in the proof of soundness, except it manifests not in the probability measures, but in the Fourier coefficients of the quantum assignment. Classical soundness proofs organize around sets of neighbors, but this approach is too coarse to be applicable to the operator setting. The key to resolving this issue is to structure the proof around individual edges; this allows us to manage the noncommutative nature of the operator assignments without the sort of conflicts we mentioned earlier.

1.6 Future Directions

There are many open problems concerning the quantum value of CSPs and the conjectures we have proposed regarding Unique-Label-Cover:

1. **Quantizing Classical Reductions:** The works of O'Donnell and Yuen [41], as well as this paper, establish straightforward translations of some of the most well-known classical inapproximability results to the quantum setting. Could this indicate a more general phenomenon? More precisely, can any classical gap-preserving reduction from Label-Cover (or its variants like Unique-Label-Cover or Smooth-Label-Cover) be extended to a reduction for the quantum value?
2. **UGC versus qUGC:** What is the relationship between the classical UGC and the quantum UGC? If UGC is proven via a reduction from Label-Cover, can this reduction be "quantized" to prove qUGC? A positive answer to the previous question would also resolve this one affirmatively.
3. **Variants of qUGC:** In the classical setting, several formulations of UGC have been shown to be equivalent (see Section 3 in [33] and references therein). Could similar equivalences hold for the quantum variants discussed in this paper? See Section 3.2 in the full version [38] for further discussion of these qUGC variants.
4. **Noncommutative CSPs:** This work focuses primarily on the quantum value of CSPs. Could variants of qUGC help resolve hardness of approximation questions for the noncommutative value? The noncommutative value, which also plays an important role in quantum information, exhibits some intriguing behavior. As shown in Figure 7, unlike the classical or quantum value, the noncommutative value of MaxCut can be computed in polynomial time. However, it is known that the noncommutative value of Max-3-Cut is undecidable [28, 29]. [12] provides a 0.864-approximation algorithm for the noncommutative value of Max-3-Cut. We suspect that a variant of qUGC could prove useful in establishing the optimality of this algorithm.
5. **Weaker Version of MIP* = RE:** Is there a direct way to prove the hardness of approximating the quantum value of Label-Cover without relying on MIP* = RE? One potential approach is to quantize Dinur's proof of the classical PCP theorem [3, 2, 45, 13].

The commutation relations in LC_q could make this quantization feasible. Could this weaker result also have some of the implications of $\mathrm{MIP}^* = \mathrm{RE}$ such as the resolution of the Connes Embedding Problem?

6. **Integrality Gap Instances for MaxCut:** What is the smallest ratio between the classical and quantum values across all MaxCut instances? Assuming quantum UGC, we show this ratio is the Goemans-Williamson constant $\alpha_{\mathrm{gw}} \approx 0.878$ (Theorem 35 in the full version [38]). Can we construct an instance attaining this ratio?
7. **Label-Cover for QMA:** Approximating the classical value of Label-Cover is NP-complete (PCP theorem). Similarly, approximating the noncommutative and quantum values of Label-Cover is RE-complete ($\mathrm{MIP}^* = \mathrm{RE}$ theorem). What version of Label-Cover or Unique-Label-Cover naturally captures QMA? Could further constraints on the variations of Label-Cover and Unique-Label-Cover explored in this paper lead to suitable candidates? A positive resolution to this problem would answer the Quantum Games PCP Conjecture [39].
8. **Hardness of Approximation in Hamiltonian Complexity:** In quantum information theory, quantum MaxCut often refers to the anti-ferromagnetic Heisenberg model, a special case of the local Hamiltonian problem. Although [26] attempts to prove UGC hardness for the anti-ferromagnetic Heisenberg model, reductions from UGC only establish NP-hardness. Could variations of qUGC yield stronger results?

   While the inapproximability of the anti-ferromagnetic Heisenberg model is one of our motivations for proposing the quantum UGC, our current methods do not yet apply to the inapproximability of local Hamiltonian problems.
9. **Gadget Reductions:** In classical complexity theory, gadgets [25, 49] are widely used to demonstrate hardness of approximation. Can this method be "quantized"? [22, 28] are examples of gadget reductions in the quantum setting.

Organization of the Full Version of the Paper [38]

In Section 2, we present notations, definitions, and some Fourier analytic results that underpin this work. Section 2.1 specifically addresses the notations used throughout the paper. In Section 2.2, we introduce the concept of quantum measurement and discuss several definitions related to projective measurements. Section 2.3 reviews concepts such as reductions and decision problems, and Section 2.4 summarizes results from Fourier analysis.

Section 3.1 offers the most general definition of CSPs necessary for this work. It also covers the classical, quantum, and noncommutative values of a CSP instance, providing definitions which are crucial for the remainder of the paper. In Section 3.2, we discuss variants of quantum UGC. Section 4 contains the proof of our theorem on the quantum value of 2-Lin, and Section 5 presents the proof of our theorem on the quantum value of MaxCut. Finally, two technical lemmas are given in Sections 6 and 7.

Sketching, Moment Estimation, and the Lévy-Khintchine Representation Theorem

Seth Pettie
University of Michigan, Ann Arbor, MI, USA

Dingyu Wang
University of Michigan, Ann Arbor, MI, USA

Abstract

In the d-dimensional turnstile streaming model, a frequency vector $\mathbf{x} = (\mathbf{x}(1), \ldots, \mathbf{x}(n)) \in (\mathbb{R}^d)^n$ is updated entry-wisely over a stream. We consider the problem of *f-moment estimation* for which one wants to estimate

$$f(\mathbf{x}) \stackrel{\text{def}}{=} \sum_{v \in [n]} f(\mathbf{x}(v))$$

with a small-space sketch. A function f is *tractable* if the f-moment can be estimated to within a constant factor using $\text{polylog}(n)$ space.

The f-moment estimation problem has been intensively studied in the $d = 1$ case. Flajolet and Martin estimate the F_0-moment ($f(x) = \mathbb{1}(x > 0)$, incremental stream); Alon, Matias, and Szegedy estimate the L_2-moment ($f(x) = x^2$); Indyk estimates the L_α-moment ($f(x) = |x|^\alpha$), $\alpha \in (0, 2]$. For $d \geq 2$, Ganguly, Bansal, and Dube estimate the $L_{p,q}$ hybrid moment ($f : \mathbb{R}^d \to \mathbb{R}, f(x) = (\sum_{j=1}^d |x_j|^p)^q$), $p \in (0, 2], q \in (0, 1)$. For tractability, Bar-Yossef, Jayram, Kumar, and Sivakumar show that $f(x) = |x|^\alpha$ is *not* tractable for $\alpha > 2$. Braverman, Chestnut, Woodruff, and Yang characterize the class of tractable one-variable functions except for a class of *nearly periodic functions*.

In this work we present a simple and generic scheme to construct sketches with the novel idea of hashing indices to *Lévy processes*, from which one can estimate the f-moment $f(\mathbf{x})$ where f is the *characteristic exponent* of the Lévy process. The fundamental *Lévy-Khintchine representation theorem* completely characterizes the space of all possible characteristic exponents, which in turn characterizes the set of f-moments that can be estimated by this generic scheme.

The new scheme has strong explanatory power. It unifies the construction of many existing sketches (F_0, L_0, L_2, L_α, $L_{p,q}$, etc.) and it implies the tractability of many nearly periodic functions that were previously unclassified. Furthermore, the scheme can be conveniently generalized to multidimensional cases ($d \geq 2$) by considering multidimensional Lévy processes and can be further generalized to estimate *heterogeneous moments* by projecting different indices with different Lévy processes. We conjecture that the set of tractable functions can be characterized using the Lévy-Khintchine representation theorem via what we called the *Fourier-Hahn-Lévy* method.

1 Introduction

Streaming algorithms have been studied for over 40 years, beginning with Morris's [25] *approximate counter* and Munro and Patterson's [26] 1- and 2-pass *selection* algorithms, both from 1978. In 1983 Flajolet and Martin [14] designed and analyzed the first "modern"

sketch called *Probabilistic Counting with Stochastic Averaging* (PCSA). PCSA works only in *incremental* streams whereas all linear sketches, such as the celebrated AMS sketch [1] for estimating L_2-moments, maintain a vector of elements subject to both increments and decrements. In this work we consider a generalized turnstile model, where each element has a value in $\mathbb{R}^d$ for some dimension $d \in \mathbb{Z}_+$.

▶ **Definition 1** ($\mathbb{R}^d$-turnstile model)**.** *Let $[n] = \{1, 2, \ldots, n\}$ be the universe. The frequency vector $\mathbf{x} = (\mathbf{x}(1), \ldots, \mathbf{x}(n)) \in (\mathbb{R}^d)^n$ is initialized as all zeros and gets updated by a stream of pairs of the form of (v, y), where $v \in [n]$ and $y \in \mathbb{R}^d$.*

- Update(v, y), $\mathbf{x}(v) \leftarrow \mathbf{x}(v) + y$.

In this paper we consider the following generic streaming estimation problem.

▶ **Problem 1** (f-moment estimation in the $\mathbb{R}^d$-turnstile model)**.** Fix $d \in \mathbb{Z}_+$. Let $f : \mathbb{R}^d \to \mathbb{C}$ with $f(0) = 0$. Let $\mathbf{x} \in (\mathbb{R}^d)^n$ be the frequency vector of the current stream. Estimate the *f-moment* $f(\mathbf{x})$, where

$$f(\mathbf{x}) \stackrel{\text{def}}{=} \sum_{v \in [n]} f(\mathbf{x}(v)).$$

The f-moment estimation problem was originally posed by Alon, Matias, and Szegedy [1].[1] They estimated the L_2-moment ($f(x) = |x|^2$) with a data structure now commonly known as the AMS sketch, and then asked in general what f-moments can be estimated in polylog space. Indyk [17] designed a class of sketches for estimating the L_p moments, with $p \in (0, 2]$. When $p > 2$, Bar-Yossef, Jayram, Kumar, and Sivakumar [2] proved that estimating the L_p-moment requires $\Omega(\text{poly}(n))$ space. The L_0-moment ($f(x) = \mathbb{1}(x \neq 0)$) has been estimated in two distinct ways. Cormode, Data, Indyk, and Muthukrishnan [10] approximate L_0 by L_α with very small $\alpha > 0$. Kane, Nelson, and Woodruff [20] project each element onto $\mathbb{Z}_p$, $p > \epsilon^{-1} \log n$ being a random prime, which effectively reduces L_0-estimation to cardinality estimation over incremental streams (F_0-estimation).

Apart from the frequency moments L_p, $p \in [0, 2]$, there are other function moments that can be estimated over streams. In particular, a function f is called *tractable* if the f-moment can be approximated to within a $1 \pm \epsilon$ factor in $\text{poly}(\epsilon^{-1}, \log n)$ space. Characterizing the class of tractable functions (the *tractability problem*) has been a central theoretical problem in the streaming literature. Braverman and Ostrovsky [6] managed to characterize all tractable functions $f : \mathbb{Z} \to \mathbb{R}_+$ that are symmetric ($f(x) = f(-x)$) and increasing on $[0, \infty)$. Braverman and Chestnut [3] then charaterized all tractable functions that are symmetric, non-negative, and *decreasing* on $[1, \infty)$. Braverman, Chestnut, Woodruff, and Yang [4] extended the characterization to all symmetric functions, except for a class of "nearly periodic" functions.

The tractability question is closely related to the problem of designing *universal sketches*. A universal sketch specifies a family of functions $\mathcal{F}$ such that for *any* $f \in \mathcal{F}$, the f-moment can be estimated. Sketches in [6, 7, 4] are all universal for their respective classes; they are based on sampling L_2-heavy hitters from subsampled versions of the input vector, then applying f to the samples. Though in this work we focus on the polylog-space regime, there have also been intensive studies for sketching problems in the polynomial-space regime as well, e.g., L_p-moment with $p > 2$ [1, 5, 18, 8, 28, 15], cascaded norms [19], and Schatten norms [24].

[1] Unless specified otherwise, we assume the stream is one-dimensional and integral, i.e., $\mathbf{x} \in \mathbb{Z}^n$, when discussing prior works.

While most of the literature considers the one-dimensional case where $d = 1$, Ganguly, Bansal, and Dube [16] estimate the $L_{p,q}$ hybrid moment, which is defined to be $f(x_1, \ldots, x_d) = (\sum_{j=1}^{d} |x_j|^p)^q$, where $p \in [0, 2], q \in [0, 1]$. The $L_{p,q}$-moment is a meaningful class of multidimensional moments which include, e.g., the Euclidean length $f(x_1, \ldots, x_d) = \sqrt{\sum_{j=1}^{d} x_j^2}$, corresponding to the $L_{2,1/2}$-moment. If the elements are points in $\mathbb{R}^d$ subject to a stream of updates of the form of `(key, displacement)`, then the $L_{2,1/2}$-moment is equal to the sum of the Euclidean distances $\sum_{v\in[n]} |\mathbf{x}(u)|$. Multidimensional inputs can arise when querying *multiple* one-dimensional streams. For example, suppose we have two $\mathbb{R}$-turnstile streams with frequency vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$. A query like "how many elements are non-zero in $\mathbf{x}$ and at least 3 in $\mathbf{y}$" can be written as a two-dimensional f-moment query with $f(x, y) = \mathbb{1}(x \neq 0)\,\mathbb{1}(y \geq 3)$.

Main Contribution

In this work, we uncover an intimate relation between turnstile sketches and *Lévy processes*. Lévy processes have been studied since the early 20th century, and have been used to model phenomena in various fields, e.g., physics (how does a gas particle move?) and finance (how does the stock price change?). We will show that all Lévy processes have *algorithmic* interpretations in the context of streaming sketches, and that the fundamental *Lévy-Khintchine representation theorem* leads to a unified view of sketching for moment estimation.

We give a detailed technical synopsis of Lévy processes in Section 2. For the time being, a Lévy process $(X_t)_{t\geq 0}$, where $X_t \in \mathbb{R}^d$, is defined by having independent, stationary increments. I.e., $(X_{t_1+t_2} - X_{t_1}) \sim X_{t_2}$, for any $t_1, t_2 \in \mathbb{R}_+$, and $X_{t_1}, X_{t_2} - X_{t_1}, \ldots, X_{t_k} - X_{t_{k-1}}$ are mutually independent for any $t_1 < \cdots < t_k$. Some common one-dimensional Lévy processes are

Linear drift. $X_t = \gamma t$ with drift rate γ.
Brownian motion. $X_t \sim \mathcal{N}(0, t\sigma^2)$ with variance σ^2.
Poisson process. $X_t \sim \text{Poisson}(\lambda t)$ with rate λ.
α-stable process. Defined by $X_t/t^{1/\alpha} \sim X_1 \sim \alpha$-stable. (For $\alpha \in (0, 2]$, the α-stable random variable X_1 on $\mathbb{R}$ is defined by its characteristic function $\mathbb{E}e^{izX_1} = e^{-|z|^\alpha}$, for any $z \in \mathbb{R}$.)

These can all be generalized to higher dimensions. The Lévy-Khintchine representation theorem identifies every Lévy process X with its *characteristic exponent* $f_X : \mathbb{R}^d \to \mathbb{C}$, where for any $z \in \mathbb{R}^d$, $\mathbb{E}\exp(i\langle X_t, z\rangle) = \exp(-tf_X(z))$.

1.1 Lévy Processes and Sketching

We briefly explain why Lévy processes naturally lie at the heart of linear sketching. Suppose X is the random memory state of a *linear* sketch[2] of input vector $\mathbf{x}$ and $\hat{f}(X)$ is an estimate of the f-moment $f(\mathbf{x})$. Now consider the situation where the input is repeated w times over disjoint domains. Then by construction, the f-moment becomes $w \cdot f(\mathbf{x})$ and the estimate becomes $\hat{f}(X^{(1)} + \cdots + X^{(w)})$ where $X^{(j)}$ are i.i.d. copies of X.[3] In other words, we should have

$$\frac{\hat{f}(X^{(1)} + \cdots + X^{(w)})}{w} \approx f(\mathbf{x}),$$

[2] It suffices to consider linear sketches in the turnstile model [23].
[3] One can think of this as increasing the vector length from n to wn and letting $X^{(j)}$ be the sketch of $\mathbf{x}^{(j)}$, which is a copy of $\mathbf{x}$ on the index interval $[(j-1)n, jn)$.

for *any* $w \in \mathbb{Z}_+$ and also for the limiting case as $w \to \infty$. Therefore, no matter how complicated the distribution of the linear sketch may be, the sum $X^{(1)} + \cdots + X^{(w)}$ will converge[4] to some well-behaved limiting random process. For the AMS sketch [1], X happens to be sub-gaussian and therefore the normalized sum converges to a Gaussian. For Indyk's [17] stable sketch, X is α-stable, and therefore the normalized sum remains α-stable. These are merely two special cases of Lévy processes. In general, if $X = (X_t)_{t\in\mathbb{R}_+}$ is a Lévy process, then $X^{(1)} + \cdots + X^{(w)} = (X_t^{(1)} + \cdots + X_t^{(w)})_{t\in\mathbb{R}_+} \sim (X_{wt})_{t\in\mathbb{R}_+}$. Thus summing i.i.d. Lévy processes is equivalent to simply *rescaling time*. After normalizing the time scale,[5] we see Lévy processes are stable under i.i.d. sums. Lévy processes therefore form a mathematical closure of linear sketches in terms of their limiting distributions.

In practice it usually suffices to construct some algorithmically simple random projection in the *domain of attraction* of the limiting process. For example, the AMS sketch for estimating L_2 does not need to explicitly use Gaussians in its projection; Rademacher ($\{-1, 1\}$) random variables suffice. For a *prototypical solution*, it is convenient to consider linear sketches with projection sampled directly from Lévy processes. The distribution of the sketch will always lie in the space of Lévy processes and is therefore easier to track.

1.2 Random Projection with Lévy Processes

We now consider linear sketching with Lévy processes and show how different processes can be used to track different function moments. Throughout the paper we work in the *random oracle* model, in which we can evaluate uniformly random hash functions $H : [n] \to [0, 1]$.

Given any Lévy process $X = (X_t)_{t\in\mathbb{R}_+}$ on $\mathbb{R}^d$, by the Lévy-Khintchine representation theorem (Theorem 7), there exists a function $f_X : \mathbb{R}^d \to \mathbb{C}$ such that for any $t \in \mathbb{R}_+$ and $z \in \mathbb{R}^d$,

$$\mathbb{E}e^{i\langle z, X_t\rangle} = e^{-tf_X(z)}. \qquad \text{(Lévy-Khintchine)}$$

Suppose now we aggregate all the input in one register in the following way

$$C_t = \sum_{v\in[n]} \left\langle \mathbf{x}(v), X_t^{(v)} \right\rangle,$$

where the $X_t^{(v)}$ are i.i.d. copies of X_t. Clearly C_t is a linear sketch which can be maintained over a distributed stream. We thus have

$$\begin{aligned}
\mathbb{E}e^{iC_t} &= \mathbb{E}e^{i\sum_{v\in[n]}\left\langle X_t^{(v)}, \mathbf{x}(v)\right\rangle} \\
&= \prod_{v\in[n]} \mathbb{E}e^{i\left\langle X_t^{(v)}, \mathbf{x}(v)\right\rangle} && \text{(by independence)} \\
&= \prod_{v\in[n]} e^{-tf_X(\mathbf{x}(v))} && \text{(by Lévy-Khintchine)} \\
&= e^{-tf_X(\mathbf{x})}, && \text{(recall that } f(\mathbf{x}) = \textstyle\sum_{v\in[n]} f(\mathbf{x}(v))\text{)}
\end{aligned}$$

from which the f_X-moment $f_X(\mathbf{x})$ can be recovered by choosing a suitable time $t \approx \Theta(1/|f(\mathbf{x})|)$. Of course, we do not always know a suitable t, and therefore maintain samples for many t, evenly spaced on a logarithmic scale. This is the key observation that lets us

[4] with a proper normalization depending on X and w

[5] To see how this "time normalization" generalizes the typical scalar normalization of stable variables, note that for α-stable variables, the normalization is $w^{-1/\alpha}(X^{(1)} + \cdots + X^{(w)})$, which is equivalent to scale the time down by w since $w^{-1/\alpha}X_{wt} \sim X_t$ if $(X_t)_{t\in\mathbb{R}_+}$ is α-stable.

estimate every f-moment, where f is the characteristic exponent of a Lévy process. In addition, note that the statistic e^{iC_t} only depends on the value of $C_t \mod 2\pi$. Therefore, it suffices to store $C_t \mod 2\pi$ for the estimation scheme above, which is a *compact value* in the range $[0, 2\pi)$. See Figure 1.[6]

1.3 Stable Projections

A d-dimensional Lévy process X is called α-*stable* if for any $t \in \mathbb{R}_+$, $X_t \sim t^{1/\alpha} X_1$. If the Lévy process X in $C_t = \sum_{v\in[n]} \left\langle \mathbf{x}(v), X_t^{(v)} \right\rangle$ is α-stable, then we have

$$C_t = \sum_{v\in[n]} \left\langle \mathbf{x}(v), X_t^{(v)} \right\rangle \sim \sum_{v\in[n]} \left\langle \mathbf{x}(v), t^{1/\alpha} X_1^{(v)} \right\rangle \sim t^{1/\alpha} C_1.$$

In other words, the projection C_t is also α-stable. Due to this self-similarity, it suffices to consider the projection only at time 1 and there is no need for using multiple time scales. Now let the characteristic exponent be $f_X(z)$. Then we have the characteristic function

$$\mathbb{E} e^{izC_1} = \mathbb{E} e^{iz \sum_{v\in[n]} \left\langle \mathbf{x}(v), X_1^{(v)} \right\rangle} = \prod_{v\in[n]} \mathbb{E} e^{i\left\langle \mathbf{x}(v), zX_1^{(v)} \right\rangle} \qquad \text{(by independence)}$$

Since $X^{(v)}$ is α-stable, we have $zX_1^{(v)} \sim X_{z^\alpha}^{(v)}$

$$\begin{aligned}
&= \prod_{v\in[n]} \mathbb{E} e^{i\left\langle \mathbf{x}(v), X_{z^\alpha}^{(v)} \right\rangle} \\
&= \prod_{v\in[n]} e^{-z^\alpha f(\mathbf{x}(v))} && \text{(by Lévy-Khintchine)} \\
&= e^{-z^\alpha f(\mathbf{x})} = e^{-(z f(\mathbf{x})^{1/\alpha})^\alpha} \\
&= \mathbb{E} e^{iz f(\mathbf{x})^{1/\alpha} Y_\alpha}, && \text{(by Lévy-Khintchine)}
\end{aligned}$$

where Y_α is a *one*-dimensional α-stable random variable with $\mathbb{E} e^{izY_\alpha} = e^{-|z|^\alpha}$. Since the characteristic function uniquely identifies the distribution, we know $C_1 \sim f(\mathbf{x})^{1/\alpha} Y_\alpha$. Note that a register in Indyk's [17] L_α-stable sketch distributes as $(\sum_{v\in[n]} |\mathbf{x}(v)|^\alpha)^{1/\alpha} Y_\alpha$. Thus m i.i.d. copies of C_1 *emulate* the distribution of Indyk's L_α-sketch where the L_α-moment is replaced by the f-moment. Such function moments can be estimated by Indyk's estimator [17] or Li's estimators [22] with the same error guarantee.

Note that such stable projection takes less space than the generic projection considered in Section 1.2 since in general C_t needs to be stored for for many t while stable projection only requires to store C_1. Next, we formally state the new results.

1.4 New Results

The main theorem connects the Lévy-Khintchine representation theorem for generic Lévy processes with f-moment estimation in the $\mathbb{R}^d$-turnstile model. See Table 1 for some notation. Note that for a vector $\mathbf{x} \in (\mathbb{R}^d)^n$ with multidimensional entries ($d \geq 2$), the L_1 and L_∞ norms use the Euclidean norm per entry. For example, $\|\mathbf{x}\|_1 = \sum_{v\in[n]} |\mathbf{x}(v)|$, where $|\mathbf{x}(v)| = \sqrt{\sum_{j=1}^d \mathbf{x}(v)_j^2}$.

[6] Strictly speaking, by wrapping C_t in $[0, 2\pi)$, the sketch becomes non-linear. It is still additive, and therefore allows simple merging of two sketches, but does not permit scalar multiplication.

Table 1 Notation.

Notation	Definition	Notes
$\lvert x\rvert$	$(\sum_{j=1}^{d} x_j^2)^{1/2}$	$x \in \mathbb{R}^d$, Euclidean norm
$\lvert z\rvert$	$(z\bar{z})^{1/2}$	$z \in \mathbb{C}$, modulus
$\lVert\mathbf{x}\rVert_0$	$\sum_{v\in[n]} \mathbb{1}\left(\mathbf{x}(v) \neq 0\right)$	$\mathbf{x} \in (\mathbb{R}^d)^n$, L_0-moment
$\lVert\mathbf{x}\rVert_1$	$\sum_{v\in[n]} \lvert\mathbf{x}(v)\rvert$	$\mathbf{x} \in (\mathbb{R}^d)^n$, L_1-moment
$\mathbb{T}$	complex unit circle	identified by $[0, 2\pi)$
$\mathbb{S}_{d-1}$	$\{x \in \mathbb{R}^d : \lvert x\rvert = 1\}$	unit sphere in $\mathbb{R}^d$
$\mathbb{V}Z$	$\mathbb{E}(Z - \mathbb{E}Z)\overline{(Z - \mathbb{E}Z)}$	variance of Z

▶ **Theorem 2** (generic Lévy-Tower, Section 3). *Let $f : \mathbb{R}^d \to \mathbb{C}$ be any function of the form*

$$f(z) = \frac{1}{2}\langle z, Az\rangle - i\langle\gamma, z\rangle + \int_{\mathbb{R}^d} \left(1 + i\langle z, s\rangle \mathbb{1}\left(|s| < 1\right) - e^{i\langle z,s\rangle}\right) \nu(ds),$$

where A is a covariance matrix, $\gamma \in \mathbb{R}^d$, and ν is a positive measure over $\mathbb{R}^d$ with $\int_{\mathbb{R}^d} \min(|x|^2, 1)\, \nu(dx) < \infty$. There exists a mergeable sketch of $O(\epsilon^{-2} \log n)$ words such that for any input stream $\mathbf{x} \in (\mathbb{R}^d)^n$ with $|f(\mathbf{x})| \in [1, \mathrm{poly}(n)]$, it returns an estimate $\widehat{f(\mathbf{x})}$ that with probability 99/100, where

$$\left|\widehat{f(\mathbf{x})} - f(\mathbf{x})\right| \leq O(\epsilon |f(\mathbf{x})|).$$

▶ Remark 3. The Lévy-Tower sketch improves the understanding of tractability of one-dimension function moments. In particular, it implies the tractability of many nearly periodic functions that were not previously classified. See Section 5 for a discussion of the new result and the existing tractability results. It also implies the tractability of a large class of *multidimensional moments* which have not been considered before.

As discussed in Section 1.3, stable projections form a special subclass of this linear projection method. We prove the following *emulation theorem*, enabling us to extend any analysis of Indyk's [17] classic L_α-stable sketch to the estimation of more general stable moments.

▶ **Theorem 4** (Lévy-Stable, Section 3.3). *Let f be the characteristic exponent of any d-dimensional α-stable process X. When $\alpha = 2$, $f(x) = e^{-\frac{1}{2}t\langle x, Ax\rangle}$, where A is a covariance matrix, and when $\alpha \in (0, 2)$, $f(x) = \int_{\mathbb{S}_{d-1}} |\langle x, \xi\rangle|^\alpha \, \mu(d\xi)$, where μ is a symmetric, positive measure on $\mathbb{S}_{d-1}$.*[7] *Let the Lévy-Stable sketch be parameterized by X. Given any input vector $\mathbf{x} \in (\mathbb{R}^d)^n$ and $\mathbf{x}' \in \mathbb{R}^n$ such that $f(\mathbf{x}) = \sum_{v\in[n]} |\mathbf{x}'(v)|^\alpha$, Lévy-Stable with input $\mathbf{x}$ and Indyk's L_α-stable sketch with input $\mathbf{x}'$ distribute identically.*

Theorem 4 serves as an illuminating example showing how the Lévy-Khintchine theorem helps to understand streaming sketching. Previously, only two classes of stable moments are considered: one dimensional L_α-moments by Indyk [17], and multidimensional $L_{p,q}$-moments by Ganguly et al. [16], which are sketched by *algorithmic tricks* of combining stable random variables. The Lévy-Stable sketch extends such tricks to *all stable processes* in a systematic way. For example, we can now estimate, using any estimator of Indyk's sketch [17, 22], the f-moment of an $\mathbb{R}^3$-turnstile stream with

[7] For the case $\alpha \in (0, 2)$, only symmetric processes are considered here for simplicity.

$$f(x) = \int_{\mathbb{S}_2} \frac{|\langle \xi, x \rangle|}{|\xi_1|^2 + |\xi_2| + |\xi_3|^{1/2}} \, d\xi,$$

where $\mathbb{S}_2$ is the unit $\mathbb{R}^3$-sphere.

Table 2 Sketches and Lévy processes. The target function f_X is the characteristic exponent of the corresponding Lévy process, i.e., $f_X(x) = -\log \mathbb{E} e^{i\langle x, X_1 \rangle}$. Random oracle is assumed (i.e., hash functions are provided externally) and the space is measured in *words* where each word uses $O(\log n)$ bits. $O(\log n)$-size words suffice for the Lévy-Tower and Lévy-Stable sketches under the common assumption that the total number of updates is at most $\text{poly}(n)$. Since F_0 is the cardinality over incremental stream, the space can be compressed to $O(\epsilon^{-2})$ *bits* [20, 21, 27]. In [20], L_0 is approximated by $\sum_{v \in [n]} \mathbb{1}(P | \mathbf{x}(v))$ where P is a random prime. In [10], L_0 is approximated by $\sum_{v \in [n]} |\mathbf{x}(v)|^\alpha$ with a small α. See [17, 20] for space complexity for estimating F_0, L_0, L_α when hash functions are stored explicitly.

Sketch Citation	Target $f(x)$	Space	Corresponding Lévy Process
Flajolet & Martin [14] (F_0)	$\mathbb{1}(x > 0)$	$O(\epsilon^{-2})$	pure killed process
Alon, Matias, and Szegedy [1] (L_2)	$\lvert x \rvert^2$	$O(\epsilon^{-2})$	Brownian motion
Indyk [17] (L_α)	$\lvert x \rvert^\alpha$	$O(\epsilon^{-2})$	α-stable process
Kane, Nelson, and Woodruff [20] (L_0)	$\mathbb{1}(P \mid x)$	$O(\epsilon^{-2} \log n)$	compound Poisson process over $\mathbb{Z}_P$, P random prime
Ganguly, Bansal, and Dube [16] ($L_{p,q}$)	$(\sum_{j \in [d]} \lvert x_j \rvert^p)^q$	$O(\epsilon^{-2})$	per-entry p-stable processes subordinated by per-row q-stable subordinators
Lévy-Tower **(new)**	f_X	$O(\epsilon^{-2} \log n)$	any Lévy process X over $\mathbb{R}^d$
Lévy-Stable **(new)**	f_X	$O(\epsilon^{-2})$	any stable Lévy process X over $\mathbb{R}^d$

Heterogeneous moments

It will become clear in the analysis that both Lévy-Tower and Lévy-Stable will work for *heterogeneous moments* $\sum_{v \in [n]} f_v(\mathbf{x}(v))$, where each element v can have its own function f_v. One only needs to simulate v's process $X^{(v)}$ according to f_v. For Lévy-Tower, f_v can be the characteristic exponent of any Lévy process. For Lévy-Stable with parameter $\alpha \in (0, 2]$, f_v can be the characteristic exponent of any α-stable Lévy process. For example, with $d = 2$ there are many 2-dimensional 1-stable processes to choose from, and one could have $f_1(x, y) = |x| + |y|$, $f_2(x, y) = |x + y|$, $f_3(x, y) = \sqrt{x^2 + y^2}$, each of which corresponds to a 2-dimensional 1-stable process.

1.5 Organization

We first review Lévy processes and the Lévy-Khintchine representation theorem in Section 2. Then present the Lévy-Tower and Lévy-Stable sketches in Section 3. In Section 4, we discuss the connection between previous sketches and Lévy processes in a greater detail (see Table 2 for a summary). In Section 5, we discuss the problem of characterizing the set of *tractable* functions, and describe the *Fourier-Hahn-Lévy* method for expanding the range of the Lévy-Tower beyond Lévy-Khintchine-representable functions. We conclude in Section 6 with a conjectured characterization of the class of tractable functions.

2 Preliminary: Lévy Processes

We use Sato's text [29] as our reference for the theory of Lévy processes.

2.1 Lévy Processes on $\mathbb{R}^d$

▶ **Definition 5** (Lévy processes [29, page 3]). *A random process $X = (X_t)_{t\in\mathbb{R}_+}$ on $\mathbb{R}^d$ is a* Lévy process *if it satisfies*

Stationary Increments. $X_{t+s} - X_t \sim X_s$ *for all* $t, s \in \mathbb{R}_+$.

Independent Increments. *for* $0 \le t_1 < t_2 \ldots < t_k$, $X_{t_1}, X_{t_2} - X_{t_1}, \ldots, X_{t_k} - X_{t_{k-1}}$ *are mutually independent*

Stochastic continuity. $X_0 = 0$ *almost surely and* $\lim_{t\searrow 0} \mathbb{P}(|X_t| > \epsilon) = 0$ *for any* $\epsilon > 0$.

▶ Remark 6. A process that satisfies stationary and independent increments is called *memoryless*.

The primary way to study Lévy processes is through their *characteristic functions*. See Table 1 for notations.

▶ **Theorem 7** (Lévy-Khintchine representation [29, page 37]). *Any Lévy process $X = (X_t)_{t\in\mathbb{R}_+}$ on $\mathbb{R}^d$ can be identified by a triplet (A, ν, γ) where A is a covariance matrix, ν is a measure on $\mathbb{R}$ such that*

$$\nu(\{0\}) = 0 \quad \text{and} \quad \int_{\mathbb{R}^d} \min(|s|^2, 1)\, \nu(ds) < \infty, \tag{1}$$

and $\gamma \in \mathbb{R}^d$. The identification is through the characteristic function. For any $t \in \mathbb{R}_+$ and $z \in \mathbb{R}^d$,

$$\mathbb{E}e^{i\langle X_t, z\rangle} = \exp\left(-t\left(\frac{1}{2}\langle z, Az\rangle - i\langle \gamma, z\rangle + \int_{\mathbb{R}^d} (1 + i\langle z, s\rangle \mathbb{1}(|s| < 1) - e^{i\langle z,s\rangle})\, \nu(ds)\right)\right). \tag{2}$$

Conversely, any triplet (A, ν, γ) where A is a covariance matrix, ν satisfies (1), and $\gamma \in \mathbb{R}^d$ corresponds to a Lévy process satisfying (2).

▶ Remark 8. In the one-dimensional case, the matrix A can be identified by the usual variance σ^2. Then we have for $z \in \mathbb{R}$,

$$\mathbb{E}e^{izX_t} = \exp\left(-t\left(\frac{1}{2}\sigma^2 z^2 - i\gamma z + \int_{\mathbb{R}} (1 + izs\mathbb{1}(|s| < 1) - e^{izs})\, \nu(ds)\right)\right). \tag{3}$$

We call the exponent in (2) the *characteristic exponent*, denoted by $f_X(z) = -\log \mathbb{E}e^{i\langle X_1, z\rangle}$. Let us note some properties of the characteristic exponent f.

▶ **Lemma 9.** *Let X be any Lévy process on $\mathbb{R}^d$ and f be its characteristic exponent.*

- *$\mathfrak{Re} f \ge 0$. $\mathfrak{Re} f = 0$ if and only if X is a deterministic drift, i.e., $X_t = \gamma t$ for all $t \in \mathbb{R}_+$.*
- *For any $x \in \mathbb{R}^d$, $f(-x) = \overline{f(x)}$, the complex conjugate of $f(x)$.*

We list some common one-dimensional Lévy processes in Table 3 that will be frequently used later.

Table 3 Common one-dimensional Lévy processes.

Process	Characteristic Exponent	Notes
linear drift	$i\gamma z$	$\gamma \in \mathbb{R}_+$
α-stable	$\lvert z\rvert^\alpha$	$\alpha \in (0, 2]$
Poisson	$1 - e^{iz}$	
compound Poisson	$\int_{-\infty}^{\infty}(1 - e^{izs})\,\nu(ds)$	$\nu(\mathbb{R}) < \infty$ is the jump rate, $\nu(\mathbb{R})^{-1}\nu$ is the jump distribution
symmetric compound Poisson	$2\int_0^{\infty}(1 - \cos(zs))\,\nu(ds)$	$\nu(\mathbb{R}) < \infty$

3 Infinitely Divisible Sketches

3.1 Lévy-Tower Sketches

We now present a sketch that is induced by a *generic* Lévy process on $\mathbb{R}^d$, which consists of two parameters.

- An accuracy parameter $m \in \mathbb{Z}_+$ which corresponds to the number of subsketches in classic settings.
- A Lévy process $X = (X_t)_{t\in\mathbb{R}_+}$ on $\mathbb{R}^d$ with characteristic exponent $f(z) = -\log \mathbb{E}e^{i\langle X_1, z\rangle}$.

▶ **Definition 10** ((f, m)-Lévy-Tower)**.** *Let f be the characteristic exponent of a Lévy process X on $\mathbb{R}^d$ and $m \in \mathbb{Z}_+$. An (f, m)-*Lévy-Tower *is an infinite vector $S = (S_k^{(j)})_{k\in\mathbb{Z}, j\in[m]} \subset \mathbb{T}^{\mathbb{Z}}$, initialized as all zero. For any element $v \in [n]$ and $y \in \mathbb{R}^d$, a vector update $\mathbf{x}(v) \leftarrow \mathbf{x}(v) + y$ is effected by:*

Update(v, y) **:** *For each $k \in \mathbb{Z}$ and $j \in [m]$, $S_k^{(j)} \leftarrow S_k^{(j)} + \left\langle y, X_{2^{-k}}^{(v,j)}\right\rangle \bmod 2\pi$, where $X^{(v,j)} = (X_t^{(v,j)})_{t\in\mathbb{R}_+}$ is an i.i.d. copy of the Lévy process X with characteristic exponent f.*

▶ Remark 11. If $|f(\mathbf{x})|$ is in the range $[1, \mathrm{poly}(n)]$, then it suffices to store levels $k \in [0, O(\log n)]$. Therefore a Lévy-Tower takes $O(\log n)$ words of space and each word stores a number in $[0, 2\pi)$.

The construction is standard in sketch design: subsample, randomly project, and then sum, but with an important and powerful tweak that the two steps "subsample and random project" are replaced by a single step: sampling at time 2^{-k} of the Lévy process whose characteristic exponent is f. Consequently, such sketches can be used to estimate f-moments. We characterize the distribution of the sketch as follows.

▶ **Lemma 12.** *Fix a frequency vector $\mathbf{x} = (\mathbf{x}(v))_{v\in[n]}$. For any $k \in \mathbb{Z}$, we have*

$$S_k \sim \sum_{v\in[n]} \left\langle X_{2^{-k}}^{(v)}, \mathbf{x}(v)\right\rangle$$

$$\mathbb{E}e^{iS_k} = e^{-2^{-k}f(\mathbf{x})}.$$

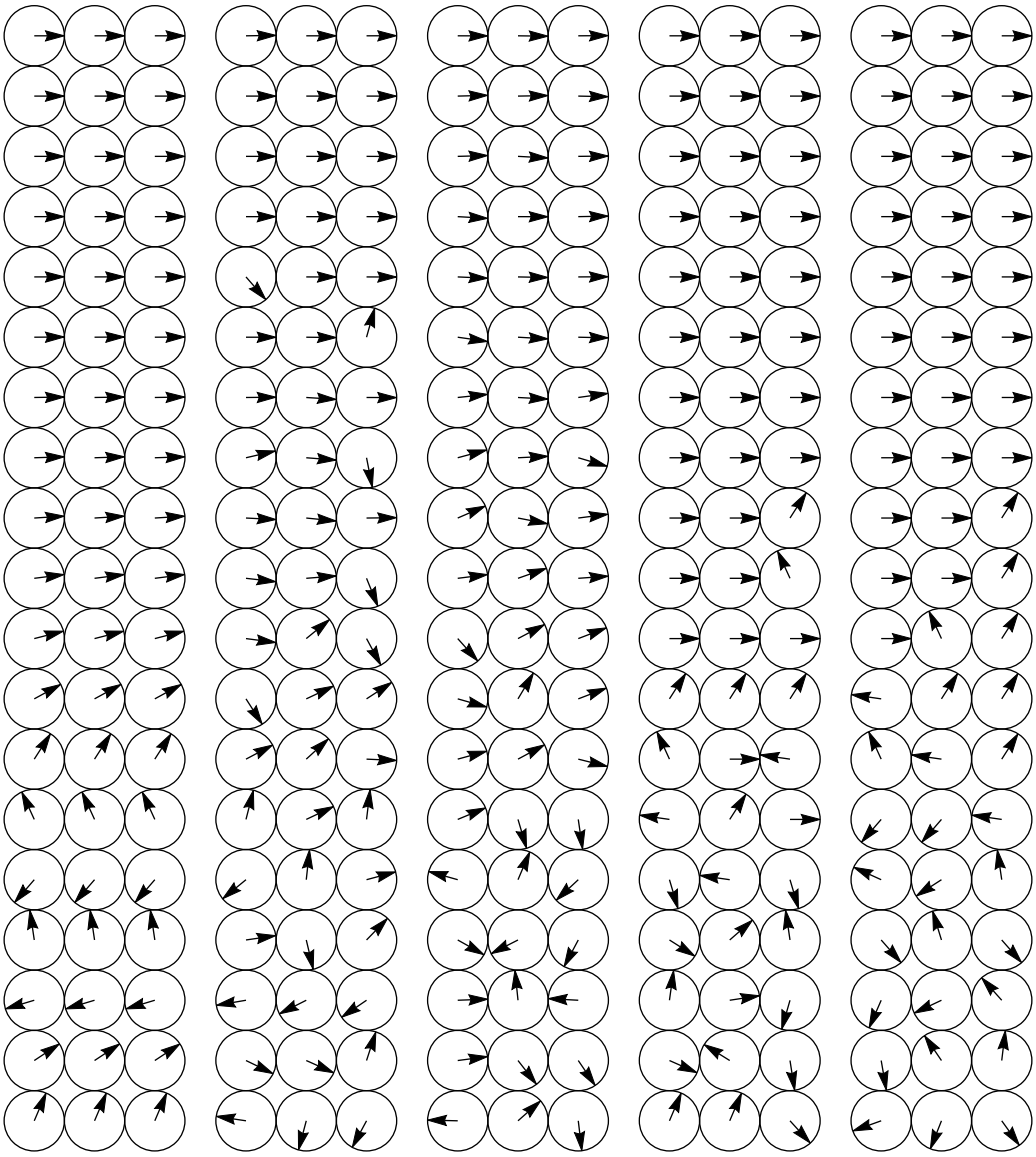

Figure 1 Lévy-Tower with $m = 3$ and $\mathbf{x} = (1, 0, \ldots, 0)$. From left to right: linear drift, Cauchy process, Brownian motion, Poisson process with rate 1, Poisson process with rate 2. Different Lévy processes have different "sensitivities" for a target function-moment. For example, linear drift is only sensitive to the sum of the vector and insensitive to how the values are distributed. The Cauchy process is only sensitive to the L_1-moment, while Brownian motion is only sensitive to the L_2-moment. Poisson processes are sensitive to the *support size* of $\mathbf{x}$ and at the same time leaking information about other f-moments.

Proof. The first statement is trivially true since the sketch is linear. For the second, note that the $X^{(v)}$ are i.i.d., and we have

$$\begin{aligned}
\mathbb{E}e^{iS_k} &= \mathbb{E}e^{i\sum_{v\in[n]}\left\langle X^{(v)}_{2^{-k}},\mathbf{x}(v)\right\rangle} \\
&= \prod_{v\in[n]} \mathbb{E}e^{i\left\langle X^{(v)}_{2^{-k}},\mathbf{x}(v)\right\rangle} && \text{(by independence)} \\
&= \prod_{v\in[n]} e^{-2^{-k}f(\mathbf{x}(v))} && \text{(by Lévy-Khintchine)} \\
&= e^{-2^{-k}f(\mathbf{x})}. && \text{(definition of } f(\mathbf{x})\text{)}
\end{aligned}$$

◀

Note that the f-moment lies exactly in the exponent of $\mathbb{E}e^{iS_k}$. We now formally present the estimation method.

3.2 Estimation of Lévy-Tower

As discussed in Section 1.2, the estimator needs to find a suitable level t and infer the f-moment from C_t. In the Lévy-Tower, we store $S_k = C_{2^{-k}}$ for all $k \in \mathbb{Z}$. We first prove the concentration of the empirical mean at each level.

▶ **Lemma 13.** *For any $t \in \mathbb{R}_+$,*

$$\mathbb{P}\left(\left|\frac{1}{m}\sum_{j=1}^{m} e^{iC_t^{(j)}} - e^{-tf(\mathbf{x})}\right| > \eta\right) \le \frac{2t|f(\mathbf{x})|}{m\eta^2}.$$

Proof. By Chebyshev's inequality, we have

$$\mathbb{P}\left(\left|\frac{1}{m}\sum_{j=1}^{m} e^{iC_t^{(j)}} - e^{-tf(\mathbf{x})}\right| > \eta\right) \le \frac{\mathbb{V}e^{iC_t}}{m\eta^2}.$$

Furthermore, since $\mathbb{E}e^{iC_t} = e^{-tf(\mathbf{x})}$, we have

$$\mathbb{V}e^{iC_t} = \mathbb{E}|e^{iC_t}|^2 - |\mathbb{E}e^{iC_t}|^2 = 1 - e^{-2t\mathfrak{Re}f(\mathbf{x})} \le 2t\mathfrak{Re}f(\mathbf{x}) \le 2t|f(\mathbf{x})|.$$ ◀

▶ **Lemma 14.** *With probability at least 99/100, for any $k \ge \log_2|f(\mathbf{x})|$, we have*

$$\left|\frac{1}{m}\sum_{j=1}^{m} e^{iS_k^{(j)}} - e^{-tf(\mathbf{x})}\right| \le O(1/\sqrt{m}).$$

Proof. By the union bound and Lemma 13,

$$\begin{aligned}
&\mathbb{P}\left(\exists k \ge \log_2|f(\mathbf{x})|, \left|\frac{1}{m}\sum_{j=1}^{m} e^{iS_k^{(j)}} - e^{-tf(\mathbf{x})}\right| > \eta\right) \\
&\le \sum_{k=\log_2|f(\mathbf{x})|}^{\infty} \frac{2\cdot 2^{-k}|f(\mathbf{x})|}{m\eta^2} \\
&= O\left(\frac{1}{m\eta^2}\right).
\end{aligned}$$

Thus it suffices to choose $\eta = O(1/\sqrt{m})$ for the probability above at most $1/100$. ◀

We consider the complex logarithm defined on $\mathbb{C}$ except for the negative real line.

▶ **Lemma 15.** *Let $x, y \in \{z \in \mathbb{C} : |1 - z| < 1/2\}$, then $|\log x - \log y| < 2|x - y|$.*

▶ **Theorem 16.** *With probability at least 99/100, the following procedure returns an estimate $\widehat{f(\mathbf{x})}$ such that $|\widehat{f(\mathbf{x})} - f(\mathbf{x})| \le O(|f(\mathbf{x})|/\sqrt{m})$. Let K be the maximum level and assume $K \ge \log_2 |f(\mathbf{x})| \ge 0$.*

- *Enumerate $k = K, K-1, \ldots, 0$ in the decreasing order, let $Y_k = \frac{1}{m}\sum_{j=1}^{m} e^{iS_k^{(j)}}$.*
  - *If $|1 - Y_k| > 0.2$, then return $-2^k \log Y_k$ and halt.*

Proof. By Lemma 14, with probability at least 99/100, we have $\left|Y_k - e^{-tf(\mathbf{x})}\right| \le O(1/\sqrt{m})$ for all $k \in [\log_2 |f(\mathbf{x})|, K]$. We assume this event happens. Let W be the index selected in the procedure. First note that for $z \in \mathbb{C}$ with $\mathfrak{Re} z \ge 0$, one has $|1 - e^{-z}| \le |z|$. In addition, by Lemma 9, we know $\mathfrak{Re} f(\mathbf{x}) \ge 0$. Thus

$$|1 - Y_k| = |1 - e^{-tf(\mathbf{x})}| + O(1/\sqrt{m}) \le t|f(\mathbf{x})| + O(1/\sqrt{m}).$$

Let m be large enough that $O(1/\sqrt{m}) < 0.01$. Since the times are base 2, one has

$$\begin{aligned} 2^{-W} &\in [(0.2 - 0.01)/|f(\mathbf{x})|, 2(0.2 + 0.01)/|f(\mathbf{x})|] \\ &\subset (0.2/|f(\mathbf{x}))|, 0.45/|f(\mathbf{x}))|). \end{aligned}$$

Thus we have $|1 - Y_W| < 0.45 + O(1/\sqrt{m}) < 0.5$. By Lemma 15, we have

$$|-\log Y_W - 2^{-W} f(\mathbf{x})| \le 2|Y_W - e^{-2^{-W} f(\mathbf{x})}| \le O(1/\sqrt{m}).$$

We conclude that

$$|-2^W \log Y_W - f(\mathbf{x})| \le O(2^W/\sqrt{m}) = O(|f(\mathbf{x})|/\sqrt{m}). \qquad \blacktriangleleft$$

3.3 Lévy-Stable Sketches

Recall that a d-dimensional Lévy process X is *α-stable* if for any $t \in \mathbb{R}_+$, $X_t \sim t^{1/\alpha} X_1$. We call the characteristic exponents of stable processes *stable moments*. Stable moments are of special interest in the context of streaming sketches since there is no need to store the whole tower; only m i.i.d. samples suffice to return an estimate with relative error $O(1/\sqrt{m})$.[8] The only symmetric one-dimensional stable processes are α-stable random processes, which correspond to Indyk's sketches [17]. On the other hand, there is a rich class of higher dimensional stable processes, the one implicit in Ganguly et al. [16] for estimating $L_{p,q}$ hybrid moments being just a single special case.

▶ **Theorem 17** (Lévy-Khintchine for stable processes [29, page 86])**.** *Let X be a Lévy process on $\mathbb{R}^d$ and $x \in \mathbb{R}^d$. X is 2-stable if and only if $\mathbb{E}e^{i\langle x, X_t\rangle} = e^{-\frac{1}{2}t\langle x, Ax\rangle}$ for some covariance matrix A. If X is symmetric, then it is α-stable for $\alpha \in (0, 2)$ if and only if there is a finite, positive measure μ on the sphere $\mathbb{S}_{d-1} = \{x \in \mathbb{R}^d : |x| = 1\}$ such that*

$$\mathbb{E}e^{i\langle x, X_t\rangle} = \exp\left(-t\int_{\mathbb{S}_{d-1}} |\langle x, \xi\rangle|^\alpha \, \mu(d\xi)\right).$$

[8] As discussed in Section 1.3, the Lévy-Towers induced by stable processes are *self-similar*: all registers in the tower are identically distributed with a proper normalization.

▶ Remark 18. For simplicity we only consider symmetric processes here when $\alpha \in (0,2)$ so that the characteristic exponent $f_X(x_1,\ldots,x_d) = f_X(|x_1|,\ldots,|x_d|)$ for any $x \in \mathbb{R}^d$. See [29] for the full characterization.

As discussed in Section 1.3, any multidimensional α-stable moment is as simple to estimate as the one-dimensional L_α-moment, since it is possible to maintain a random variable distributed as $f(\mathbf{x})^{1/\alpha}Y_\alpha$ where Y_α is a unit α-stable random variable. We now give the formal definition of the Lévy-Stable sketch for completeness.

▶ **Definition 19** ((f,m)-Lévy-Stable). *Let f be the characteristic exponent of an α-stable Lévy process X on $\mathbb{R}^d$ and $m \in \mathbb{Z}_+$. An (f,m)-Lévy-Stable sketch is a vector of m registers $T = (T_1,\ldots,T_m) \in \mathbb{R}^m$, initialized as all zero. For any element $v \in [n]$ and $y \in \mathbb{R}^d$, the vector update $\mathbf{x}(v) \leftarrow \mathbf{x}(v) + y$ is effected by:*

Update(v,y) **:** *For each $k \in [m]$, $T_k \leftarrow T_k + \left\langle y, X_k^{(v)} - X_{k-1}^{(v)} \right\rangle$, where $X^{(v)} = (X_t^{(v)})_{t\in\mathbb{R}_+}$ is an independent copy of the Lévy process X with characteristic exponent f, indexed by v.*

▶ Remark 20. By construction, the Lévy-Stable sketches emulates Indyk's sketch, storing m words where each word stores a real number of magnitude at most $\mathrm{poly}(n)$ with high probability, given $f(\mathbf{x}) \le \mathrm{poly}(n)$.

▶ Remark 21. We remark here on the differences between the Lévy-Tower sketch and the Lévy-Stable sketch.

- Lévy-Tower estimates generic function moment f_X where X is the characteristic exponent of *any* Lévy process. Lévy-Tower stores projections at multiple times of the process and each projection is wrapped around within $[0,2\pi)$.
- Lévy-Stable estimates function moment f_X where X is the characteristic exponent of a *stable* Lévy process. Lévy-Stable stores projections at unit time of the process and each projection is in $\mathbb{R}$. Lévy-Stable generalizes the stable sketches of Indyk [17] and Ganguly et al. [16].

4 Previous Sketches and Lévy Processes

In this section, we will discuss in greater detail how previous sketching techniques are equivalent to sampling Lévy processes. The guiding question is: what will happen if the input vector is repeated a large number of times on disjoint supports?

4.1 Single-Level Aggregation and the Central Limit Theorem

We start from the AMS sketch by Alon, Matias, and Szegedy [1], where a cell Q stores

$$Q = \sum_{v\in[n]} \mathbf{x}(v)\xi_v.$$

Here $\mathbf{x}$ is a $\mathbb{Z}$-stream and the $\xi_v \in \{-1,1\}$ are i.i.d. Rademacher random variables.[9] Now suppose the input vector is repeated w times on disjoint supports. Then the final state would be

$$M_w = Q_1 + Q_2 + \cdots + Q_w,$$

[9] Again, in [1]'s analysis, 4-wise independence hashing suffices to guarantee a good enough estimate but we need to assume they are i.i.d. here to talk about the exact distribution of the final state.

where the (Q_j) are i.i.d. copies of Q. Note that $\mathbb{E}Q = 0$ and $\mathbb{V}Q = \sum_{v\in[n]} \mathbf{x}(v)^2$. Thus as $w \to \infty$ the normalized final state $M_w/\sqrt{w}$ converges to a centered Gaussian random variable with variance $\sum_{v\in[n]} \mathbf{x}(v)^2$ in distribution, by the central limit theorem. Thus, in the regime as $w \to \infty$, the AMS sketch eventually becomes the same as a cell in the Lévy-Tower $\sum_{v\in[n]} \left\langle X_1^{(v)}, \mathbf{x}(v) \right\rangle$, where the $(X^{(v)})$ are i.i.d. one dimensional Brownian motion and $X_1^{(v)}$ is the value of the process at time $t = 1$. Of course, since Brownian motions are self-similar, one does not need to sample the Lévy processes at exponentially spaced intervals; samples from m independent processes at time $t = 1$ suffice to approximate $\sum_{v\in[n]} \mathbf{x}(v)^2$ with $O(1/m)$ relative variance. The characteristic exponent of Brownian motion is the target function for the L_2-moment: $f(x) = |x|^2$.

Another illuminating example is Ganguly's [15] L_k-moment estimator for $k \geq 3$. Ganguly randomly projects the elements and stores $S = \sum_{v\in[n]} \mathbf{x}(v)Z^{(v)}$ where each $Z^{(v)}$ is a random root of $x^k = 1$ on the complex unit circle. The statistic S^k seems to be a good estimator for F_k-moment since $\mathbb{E}S^k = \sum_{v\in[n]} \mathbf{x}(v)^k$. However, since this random projection has finite variance, the normalized sum $S/\sqrt{\sum_{v\in[n]} |\mathbf{x}(v)|^2}$ will converge to a complex Gaussian as the input vector is duplicated on disjoint supports. In the limit, the only information remaining in the sketch pertains to the L_2-moment. Indeed, one in fact needs the number of i.i.d. registers to grow polynomially in the support-size for it to work for F_k [15].

By the generalized central limit theorem, for whatever random variable Q that is produced by the current input $\mathbf{x}$, if for some sequences $(a_w)_{w\in\mathbb{N}}$ and $(b_w)_{w\in\mathbb{N}}$, $(M_w - b_w)/a_w$ converges to some non-degenerate random variable Y as $w \to \infty$, then Y has to be α-stable for $\alpha \in (0, 2]$. If in addition, $\mathbb{V}Q < \infty$, then Y is Gaussian. Non-Gaussian stable distributions are discussed later in Section 4.3.

4.2 Multi-Level Subsampling and the Poisson Limit Theorem

Another important sketching technique is *subsampling*. The idea is to devise a sketch that works for $\Theta(m)$ elements and then solve the generic case by subsampling the stream at rates 2^{-k} for $k \in \mathbb{N}$, one of which reduces it down to $\Theta(m)$ elements. Without loss of generality, suppose now we have m non-zero elements with distinct values $\mathbf{x}(1), \ldots, \mathbf{x}(m)$. Let w be the number of times we repeat the input stream and denote the repeated stream as $\mathbf{x}^w$. To obtain a $\Theta(m)$-size set of subsamples, one needs to subsample $\mathbf{x}^w$ with rate $1/w$. Let $Y_{w,j}$ be the indicator that the jth copy of $\mathbf{x}(1)$ is sampled where $\mathbb{E}Y_{w,j} = 1/w$. The number of elements with value $\mathbf{x}(1)$ in the subsampled set is

$$\sum_{j=1}^{w} Y_{w,j} \to \text{Poisson}(1) \text{ in distribution as } w \to \infty,$$

where we have invoked the Poisson limit theorem (see, e.g., [12, Theorem 3.6.1]) because $\mathbb{E}\sum_{j=1}^{w} Y_{w,j} = 1$ and $\max_{j=1}^{w} \mathbb{P}(Y_{w,j} \neq 0) = \frac{1}{w} \to 0$ as $w \to \infty$. Similarly, the number of elements with value $\mathbf{x}(j)$ is also Poisson(1) and the occurrences of different values are independent. It is well known that such a limiting distribution can be simulated algorithmically by duplicating every element a Poisson(1) number of times (see [14, 13, 27, 30]). On the other hand, such limit distributions can be equivalently simulated by hashing each element to a Poisson process and then sampling at different times. Thus all sketches based on subsampling can be simulated by the Lévy-Tower (without mapping to the complex unit circle $\mathbb{T}$) with the corresponding (compound) Poisson processes.

4.3 Stable Random Variables and Stable Processes

Whenever Q has a finite variance, $(Q_1 + Q_2 + \ldots + Q_w)/\sqrt{w}$ goes to Gaussian as $w \to \infty$. Nevertheless, with infinite variance, Q can lie in the domain of attraction of an α-stable distribution for any $\alpha \in (0, 2)$. Indeed, the use of stable random variables is another sketching technique that directly corresponds to Lévy processes: α-stable processes. Similar to the Gaussian case (Section 4.1), α-stable processes are self-similar so there is no need to store the whole tower with exponentially spaced sample times 2^{-k}. Rather, it suffices to sample m independent processes at time $t = 1$.

Indyk [17] uses one-dimensional α-stable random variables for $\alpha \in (0, 2]$ to estimate the L_p-moment, and indeed, the characteristic exponent of the α-stable process is $f(x) = |x|^\alpha$. Ganguly, Bansal, and Dube [16] consider the higher dimensional case, where each element has d attributes. We now show how to reconstruct [16]'s sketch from the perspective of Lévy processes. The target function is

$$f : \mathbb{R}^d \to \mathbb{C}, \quad f(x) = \left(\sum_{j=1}^{d} |x_j|^p \right)^q.$$

Such f-moments are called $L_{p,q}$ hybrid moments in [16]. By the subordination theorem [29, page 197], this function is the characteristic exponent of a vector of d independent p-stable processes that are subordinated by a common q-stable subordinator. That is,

$$X_t = (X^{[1]}_{Z_t}, \ldots, X^{[d]}_{Z_t}),$$

where Z is a q-stable subordinator and the $(X^{[j]})$ are i.i.d. p-stable processes. Note that since $X^{[j]}$ is p-stable, we have $X^{[j]}_{Z_t} \sim Z_t^{1/p} X^{[j]}_1$. Thus, we sample X at time 1 and get

$$X_1 \sim Z_1^{1/p} \left(X^{[1]}_1, \ldots, X^{[d]}_1 \right).$$

Take the inner product and we have, for $x \in \mathbb{R}^d$,

$$\langle x, X_1 \rangle = Z_1^{1/p} \sum_{j=1}^{d} x_j X^{[j]}_1,$$

which is exactly the random projection defined in [16].

4.4 HyperLogLog, PCSA, and Pure Killed Processes

Cardinality sketches like HyperLogLog [13] and PCSA [14] that only allow increments also correspond to Lévy processes in a surprisingly natural way. We consider the number system $\mathbb{R} \cup \{\infty\}$, where for any $x \in \mathbb{R}$, $x + \infty = \infty + x = \infty$ and $\infty + \infty = \infty$. Such definitions extend to multiplication with natural numbers where $0 \cdot \infty = 0$ and $k \cdot \infty = \infty$ for any $k \in \mathbb{Z}_+$.

▶ **Definition 22** (pure killed processes). *A* pure killed process $X = (X_t)_{t \in \mathbb{R}_+}$ *with* kill rate $c > 0$ *is a Lévy process over* $\mathbb{R} \cup \{\infty\}$ *which can be simulated as follows.*

- *Sample a* kill time $Y \sim \mathrm{Exp}(c)$.
- $X_t = 0$ *if* $t < Y$ *and* $X_t = \infty$ *otherwise.*

In particular, we have $\mathbb{P}(X_t = \infty) = \mathbb{P}(Y \le t) = 1 - e^{-ct}$.

Assume the insertion stream is $v_1, \ldots, v_T$, where each v_j is an element in the universe $[n]$. Let $X = (X_t)_{t\in\mathbb{R}_+}$ be a pure killed process with unit kill rate ($c = 1$). Similar to the turnstile case in Section 1.2, one stores the sum at time t,

$$C_t = \sum_{j=1}^{T} X_t^{(v_j)} = \sum_{v\in[n]} \mathbf{x}(v) \cdot X_t^{(v)},$$

where $X^{(v)}$s are i.i.d. copies of X. It is straightforward to see that S_k perfectly simulates a Poissonized PCSA cell [14, 27] (Table 4).

Table 4 HyperLogLog and PCSA can be considered as Lévy-Tower sketches with pure killed processes where the bit-or operation $(\{0,1\}, \vee)$ is simulated with the extended real numbers $(\{0,\infty\}, +)$. Note that, of course, such a reinterpretation does not upgrade HyperLogLog and PCSA to work over turnstile streams. The resulting Lévy-Tower is still incremental-only since $\infty - \infty$ is not defined.

bit operation in cardinality sketches	jumps of a pure killed process
$0 \vee 0 = 0$	$0 + 0 = 0$
$0 \vee 1 = 1$	$0 + \infty = \infty$
$1 \vee 0 = 1$	$\infty + 0 = \infty$
$1 \vee 1 = 1$	$\infty + \infty = \infty$

In fact, one computes

$$\mathbb{E}e^{iC_t} = \prod_{v\in[n]} \mathbb{E}e^{i\mathbf{x}(v)\cdot X_t^{(v)}} = \left(\mathbb{E}e^{iX_t}\right)^{\|\mathbf{x}\|_0} \tag{4}$$

since $0 + \cdots + 0 = 0$ and $\infty + \cdots + \infty = \infty$. By Definition 22, $X_t = 0$ with probability e^{-t}, hence $e^{iX_t} = 1$, and $X_t = \infty$ with probability $1 - e^{-t}$, in which case $e^{iX_t} = 0$.[10] Thus we have $\mathbb{E}e^{iX_t} = e^{-t}$. Inserting this back to Equation (4), we have

$$\mathbb{E}e^{iC_t} = e^{-t\|\mathbf{x}\|_0}.$$

This coincides with the observation in Section 1.2, where the estimation target $\|\mathbf{x}\|_0$ lies right in the exponent of $\mathbb{E}e^{iC_t}$.

We note that HyperLogLog and PCSA both correspond to the pure killed process, with different couplings of cells on different levels. In particular, HyperLogLog stores $(C_1, C_{1/2}, C_{1/4}, \ldots)$ where $C_{2^{-j}}$s are sampled from *a single process* (exactly as in the Lévy-Tower) while PCSA stores $(C_1, C_{1/2}, C_{1/4}, \ldots)$ where $C_{2^{-j}}$s are independent. Since a pure killed process will remain at ∞ after its first jump, for HyperLogLog, $(C_1, C_{1/2}, C_{1/4}, \ldots)$ will always be in the form of a prefix of ones (∞s) followed by all zeros. Therefore, HyperLogLog only needs to store the length of the prefix of ones.

4.5 Uniform Random Projection and the Integral Lévy-Tower

Indyk's L_p-stable sketches [17] are able to estimate the L_p-moment for $p \in (0, 2]$ but do not handle the L_0-moment. Cormode, Datar, Indyk, and Muthukrishnan [10] approximate the L_0-moment by the L_α-moment for very small $\alpha > 0$. This scheme needs a bound on $\|\mathbf{x}\|_\infty$, as a single unbounded update can raise the estimate to infinity. Kane, Nelson, and

[10] Here we take the Cesàro limit $e^{i\infty} = \lim_{T\to\infty} \frac{1}{T}\int_0^T e^{it}\,dt = 0$.

Woodruff [20] take another approach: subsample the stream to a suitable level, randomly project each element within the field $\mathbb{Z}_p$ for a random prime $p > \epsilon^{-1}\log(\|\mathbf{x}\|_\infty)$, and then use an (insertion-only) F_0 estimator. The random projection approach [20] also requires a bound on $\|\mathbf{x}\|_\infty$. As an L_0-moment sketch it has a certain failure probability (e.g., $p|\mathbf{x}(v)$ for many v) but it perfectly estimates a related quantity: the $f_{L_0,p}$-moment for $f_{L_0,p}(x) = \mathbb{1}(p \nmid x)$.

We show how the Lévy-Tower reconstructs [20]'s *trick* by *pure computation*. The target function $f(k) = \mathbb{1}(p \nmid k)$ for $k \in \mathbb{Z}$ can be written as

$$f(x) = \frac{1}{p}\sum_{j=0}^{p-1}(1 - \cos(2\pi jx/p)).$$

The Lévy process with characteristic exponent f is the compound Poisson process with jumps uniformly chosen from $-2\pi(p-1)/p, \ldots, 0, \ldots, 2\pi(p-1)/p$. See Figure 2. The corresponding Lévy-Tower reconstructs [20]'s sketch: subsample through Poisson processes and uniformly project over $\mathbb{Z}_p$ with the uniform random jumps. It is straightforward to see that the resulting Lévy-Tower is *integral* in the sense that $S_k \in \{2j\pi/p : j = 0, \ldots, p\}$ for any k and S_k can be identified by a $\mathbb{Z}_p$-value. Moreover, while [20]'s estimator needs to assume p is a prime, the Lévy-Tower will work no matter whether p is prime or not.

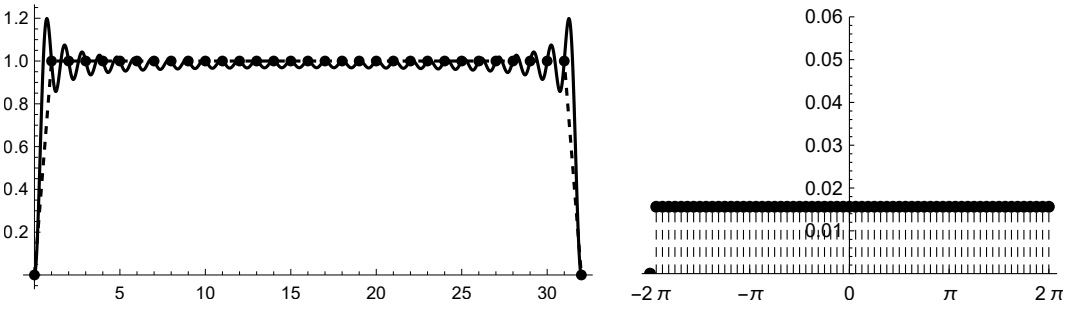

Figure 2 Left: $f_{L_0,32}(x) = \sum_{j=1}^{31}\frac{1}{32}(1-\cos(2\pi jx/32))$. The black dots mark the values at integer xs. Right: The jump distribution of the compound Poisson process X with characteristic exponent $f_{L_0,32}$. The subsampling and uniform random projection tricks used in [20] are recovered from computing the corresponding Lévy process.

5 Tractability and Lévy Processes

A function $f : \mathbb{Z} \to \mathbb{R}$ is *tractable* [4] if the f-moment of any input stream $\mathbf{x} \in \{-M, \ldots, M\}^n$, where $M = O(\text{poly}(n))$, can be $(1 \pm \epsilon)$-approximated with $O(\text{poly}(\epsilon^{-1}, \log n))$ space. Monotonic functions are fully characterized in [6] and all functions except for a class of nearly periodic functions are characterized in [4]. The Lévy-Tower tracks every function f that is the characteristic exponent of a Lévy process, and such exponents are characterized by Lévy-Khintchine. In this section, we investigate the set of tractable functions implied by the Lévy-Khintchine representation.

We start the discussion with a comparison between one-dimensional real characteristic exponents and existing communication complexity lower bounds. Note that by Lévy-Khintchine, such exponents can be written as $f(x) = \frac{1}{2}\sigma^2x^2 + 2\int_0^\infty(1-\cos(xs))\,\nu(ds)$.

▶ **Lemma 23.** *Let $f(x) = \frac{1}{2}\sigma^2x^2 + 2\int_0^\infty(1-\cos(xs))\,\nu(ds)$. The following statements are true.*

- *$f(x) \geq 0$ for any $x \in \mathbb{R}$. [Commentary: functions with both positive and negative values require $\Omega(\text{poly}(n))$-size sketches for constant factor approximations [9].]*

- *For any $z \in \mathbb{Z}$ and $x \in \mathbb{R}$, $f(zx) \le z^2 f(x)$. [Commentary: functions increasing faster than quadratic require $\Omega(\text{poly}(n))$-size sketches for constant factor approxiamtions [1, 2].]*
- *For any $z \in \mathbb{R}_+$, $f(z) = 0$ if and only if $f(x+z) = f(x), \forall x \in \mathbb{R}$, i.e., f is periodic with period z. [Commentary: functions that have zeros other than the origin require $\Omega(\text{poly}(n))$-size sketches, unless the function is periodic with period $\min\{z > 0 : f(z) = 0\}$ [9].]*

Proof. The first statement is obvious. For the second statement, it suffices to prove that with $y = xs$,

$$(1 - \cos(zy)) \le z^2(1 - \cos(y)),$$

for any $y \in \mathbb{R}, z \in \mathbb{Z}$. When $z = 0$, the statement trivially holds. Without loss of generality, assume $z \in \mathbb{Z}_+$ and let $g(y) = z^2(1 - \cos(y)) - (1 - \cos(zy))$. Check that $g'(y) = z^2 \sin(y) - z\sin(zy)$ and $g''(y) = z^2\cos(y) - z^2\cos(zy)$. Clearly for $y \in [0, \pi/z]$, we have $\cos(zy) \le \cos(y)$ and thus $g''(y) \ge 0$. Note $g'(0) = 0$ and therefore $g(y) \ge 0$ for $y \in [0, \pi/z]$. Now consider $y \in [\pi/z, \pi]$, $z^2(1 - \cos(y)) \ge z^2(1 - \cos(\pi/z)) \ge 2 \ge 1 - \cos(zy)$, which implies $g(y) \ge 0$ on $[0, \pi]$. Thus we have $g(y) \ge 0$ for $[\pi, 2\pi]$ too by symmetry. The statement is thus proved since $g(y)$ is periodic in 2π.

For the third statement, $f(z) = 0$ necessarily implies that $\sigma = 0$ and the measure ν concentrates on $2\pi j/z$ for $j \in \mathbb{Z}$. Thus $f(x) = \sum_{j\in\mathbb{Z}}(1 - \cos(2\pi jx/z))\nu(\{2\pi j/z\})$ is periodic with period z. ◀

Braverman, Chestnut, Woodruff, and Yang [4] characterize the tractability of all symmetric functions over $\mathbb{Z}$, except for a class of nearly periodic functions. Specifically, the following example is given in [4, §5] which cannot be solved in the L_2-heavy hitter-based framework, but can be estimated using *ad hoc* algorithmic tricks.

▶ **Definition 24** (g_{np}, a nearly periodic function [4, §5]). *For $x \in \mathbb{N}$, $g_{np}(x) = 2^{-\tau(x)}$, where $\tau(x) = \max\{j \in \mathbb{N} : 2^j | x\}$, i.e., the position of the first "1" in the binary representation of x.*

The reason that g_{np} cannot be tracked by finding L_2-heavy hitters is that $g_{np}(x)$ can occasionally becomes polynomially small in x. In particular, for $k \in \mathbb{N}$, $g_{np}(2^k) = 2^{-k}$. We now demonstrate how the function g_{np} can be estimated *directly* by the Lévy-Tower.

5.1 Estimating g_{np} with the Lévy-Tower

Since it is assumed the element values are at most $\text{poly}(n)$, it suffices to consider a 2^w-periodic version of g_{np} where $w = O(\log(n))$.

▶ **Definition 25** (2^w-periodic g_{np}). *For $x \in \mathbb{N}$,*

$$g_{np,w}(x) = \begin{cases} g_{np}(x), & 2^w \nmid x \\ 0, & 2^w \mid x. \end{cases}$$

We show that, indeed, g_{np} corresponds to a Lévy process, specifically a compound Poisson process. The proof is included in the full version.

▶ **Lemma 26.** *Fix $w \in \mathbb{N}$. For any $x \in \mathbb{N}$,*

$$g_{np,w}(x) = \sum_{j=1}^{2^w-1} \frac{2^{2\tau(j)+1} + 1}{3 \cdot 2^{2w-1}}(1 - \cos(2\pi jx/2^w)).$$

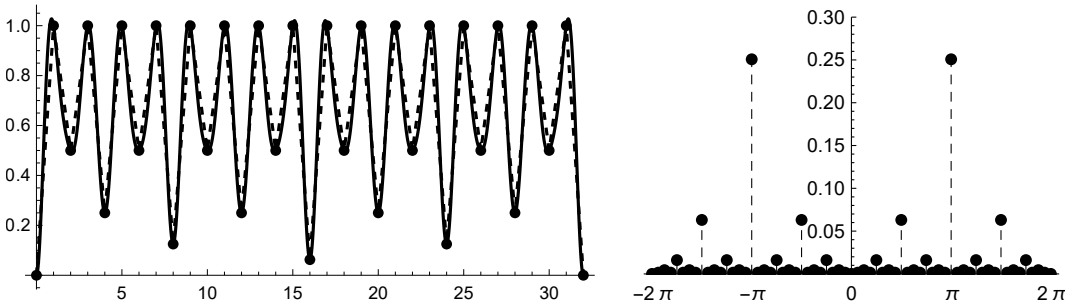

Figure 3 Left: $g_{np,5}(x) = \sum_{j=1}^{31} \frac{2^{2\tau(j)+1}+1}{1536}(1-\cos(2\pi jx/32))$. The black dots mark the values at integer xs. Right: The jump distribution of the compound Poisson process X with characteristic exponent $g_{np,5}$. Such nearly periodic functions do not fit in the L_2-heavy-hitter based framework in [4]. Nevertheless, one may compute the corresponding Lévy process and apply the Lévy-Tower.

The jump rate is

$$\sum_{j=1}^{2^w-1} \frac{2^{2\tau(j)+1}+1}{3\cdot 2^{2w-1}} = \frac{2^{2w}-1}{3\cdot 2^{2w-1}}.$$

By Lévy-Khintchine, $g_{np,w}$ is the characteristic function of a compound Poisson process X with jump rate $\frac{2^{2w}-1}{3\cdot 2^{2w-1}}$ and jump J distributed as

$$\mathbb{P}(J = 2\pi j/2^w) = \mathbb{P}(J = -2\pi j/2^w) = \frac{1}{2}\frac{2^{2\tau(j)+1}+1}{2^{2w}-1}, \quad \text{for } j = 1,\ldots 2^w-1.$$

Moreover, the parameter w for the random jump induced by $g_{np,w}$ has a neat algorithmic interpretation as the max recursion depth if one implements each random jump by a recursive algorithm[11]. The case where $w \to \infty$ corresponds to the algorithm without depth limit. Let $\mathbb{B}$ be the set of all real fractions ($\in [0,1)$) with finite binary representations. Note that the jump distribution converges pointwisely to

$$\mathbb{P}(J = 2\pi x) = \mathbb{P}(J = -2\pi x) = \frac{1}{2}2^{1-2\tau_*(x)},$$

for any $x \in \mathbb{B}$, where $\tau_*(x)$ returns the location of the first one in the binary representation. For example $\tau_*(1/4) = \tau_*((0.01)_2) = 2$. We may thus simulate such jumps by the following algorithm to handle unbounded input streams with dynamically allocated memory.

▶ **Lemma 27.** *Let A, B be two random bit-tapes, embedded on reals with the binary expansion ($A = \sum_{j=1}^{\infty} A[j]2^{-j}, B = \sum_{j=1}^{\infty} B[j]2^{-j}$), and let $\xi \in \{-1,1\}$ be a Rademacher random variable. Then*

$$J \sim 2\pi\,\xi\left(\sum_{j=1}^{\tau_*(B)-1} A[j]2^{-j} + 2^{-\tau_*(B)}\right).$$

[11] (Halt with prob. 1/2; go left and repeat with prob. 1/4; and go right and repeat with prob. 1/4; see Figure 3).

5.2 The Fourier-Hahn-Lévy Method

The example above shows that it is possible to systematically sketch nearly periodic functions by sketching periodic functions and letting the period go to infinity. A natural conjecture is that the class of tractable functions are precisely those with a Lévy-Khintchine representation. This conjecture is *absolutely false*. We refute it with a simple tractable function having no Lévy-Khintchine representation, then attempt to salvage the conjecture via what we call the *Fourier-Hahn-Lévy* method.

▶ **Example 28** (the 0-1-5 problem)**.** Consider the function f where $f(0) = 0$, $f(1) = 1$, $f(k) = 5$ for all $k \geq 2$. The f-moment is easy to estimate to within a $1 \pm \epsilon$ factor in $O(\epsilon^{-2} \operatorname{polylog}(n))$ space, using ℓ_0-sampling [11]. However, no Lévy process has its characteristic function equal to f, for otherwise we would have $f(2 \cdot 1) \leq 2^2 f(1)$ by Lemma 23, which implies $5 \leq 4$ and is absurd.

We now extend our method to handle the *0-1-5 problem*. To be more concrete, we consider an arbitrary symmetric, real function f defined on $\{-p+1, \dots 0, \dots, p-1\}$ where $p > \|\mathbf{x}\|_\infty$ is the range of the values, say 2^{64}. We now describe the three-step *Fourier-Hahn-Lévy method*.

Fourier Transform. Decompose $f(0) - f(x) = \sum_{j=0}^{p-1}(1 - \cos(2\pi xj/p))\hat{f}(j)$ where the coefficient $\hat{f}(j)$ can be computed by taking the Fourier transform of f. Note that $\hat{f}$ is real since we have assumed f to be real and symmetric.

Hahn Decomposition. Decompose $\hat{f} = \hat{f}_+ - \hat{f}_-$ where $\hat{f}_+$ and $\hat{f}_-$ are non-negative real functions.

Lévy Process Simulation. Define functions $f_{\widehat{+}}, f_{\widehat{-}}$ as the inverse Fourier transform of $\hat{f}_+, \hat{f}_-$ respectively. Since the Fourier transform is linear, we have $f = f_{\widehat{+}} - f_{\widehat{-}}$. By construction, $f_{\widehat{+}}, f_{\widehat{-}}$ are all characteristic exponents of some Lévy processes. Estimate those function moments separately with Lévy-Tower sketches and sum to yield an estimate of the f-moment.

▶ **Lemma 29.** *Given any symmetric function $f : \mathbb{Z} \to \mathbb{R}_+$ with $f(0) = 0$ and any stream $\mathbf{x} \in [-p+1, p-1]^n$, the resulting estimator $\widehat{f(\mathbf{x})}$ of the Fourier-Hahn-Lévy method has error*

$$\left|\widehat{f(\mathbf{x})} - f(\mathbf{x})\right| \leq O((|f_{\widehat{+}}(\mathbf{x})| + |f_{\widehat{-}}(\mathbf{x})|)/\sqrt{m}),$$

with probability at least 98/100.

If f is the characteristic exponent of a Lévy process, then $f = f_{\widehat{+}}$ and $f_{\widehat{-}} = 0$. This case was already considered, where we get an asymptotically unbiased estimate with multiplicative error. Clearly, whenever $|f_{\widehat{+}}(\mathbf{x})| + |f_{\widehat{-}}(\mathbf{x})| = O(|f(\mathbf{x})|)$, the Fourier-Hahn-Lévy method *still* returns an estimate with multiplicative error, which handles the *0-1-5 problem*, among others.

6 Conclusion

The design of efficient streaming sketches has traditionally been more *art* than *science*, in which every sketching problem seemed to require a new insight or trick. Some prominent examples are F_0-sketching ($\{0, \infty\}$ projection [14]), L_2-sketching (sub-gaussian projection [1]), L_p-sketching (stable projection [17]), and L_0-sketching ($\mathbb{Z}_p$ uniform projection [20]); see also [16, 13].[12]

[12] There are *universal sketches* [6, 4] which can estimate a large class of function moments with a single sketch. But they consume much more space compared to classic sketches and the ones presented in this paper.

In this work we provide a more systematic method for generating sketches to estimate f-moments, by explicitly using the corresponding Lévy process whose characteristic exponent is f. This scheme mechanically *recreates* many known sketches [14, 1, 17, 16] and provides prototypical solutions to estimating nearly periodic moments, multidimensional moments, and heterogeneous moments. The key idea is to leverage the Lévy-Khintchine representation theorem for Lévy processes in the *design* and *analysis* of sketching algorithms.

Are there any f-moments that are *tractable* [6, 4] (they can be estimated to within a constant factor with a small sketch) but *do not* correspond to Lévy processes? In Section 5 we showed that the answer to this narrow question is *yes*, then introduced the *Fourier-Hahn-Lévy method*, which reduces an f without a Lévy-Khintchine representation to the difference of two functions $f_+^\wedge - f_-^\wedge$ that *can* be estimated by the Lévy-Tower. Does the Fourier-Hahn-Lévy method capture all tractable f-moments? We conjecture the answer is yes.

▶ **Conjecture 30.** *If $f : \mathbb{Z} \to \mathbb{C}$ is tractable, then the f-moment can be estimated to within a constant factor with a Lévy-Tower, either directly or after applying the Fourier-Hahn-Lévy method.*

Randomized Lifting to Semi-Structured Communication Complexity via Linear Diversity

Vladimir Podolskii
Tufts University, Medford, MA, USA

Alexander Shekhovtsov
Moscow Institute of Physics and Technology, Russia

Abstract

We study query-to-communication lifting. The major open problem in this area is to prove a lifting theorem for gadgets of constant size. The recent paper [2] introduces semi-structured communication complexity, in which one of the players can only send parities of their input bits. They have shown that for any $m \geq 4$ deterministic decision tree complexity of a function f can be lifted to the so called semi-structured communication complexity of $f \circ \textsc{Ind}_m$, where $\textsc{Ind}_m$ is the Indexing gadget.

As our main contribution we extend these results to randomized setting. Our results also apply to a substantially larger set of gadgets. More specifically, we introduce a new complexity measure of gadgets, *linear diversity*. For all gadgets g with non-trivial linear diversity we show that randomized decision tree complexity of f lifts to randomized semi-structured communication complexity of $f \circ g$. In particular, this gives tight lifting results for Indexing gadget $\textsc{Ind}_m$, Inner Product gadget IP_m for all $m \geq 2$, and for Majority gadget MAJ_m for all $m \geq 4$. We prove the same results for deterministic case.

From our result it immediately follows that deterministic/randomized decision tree complexity lifts to deterministic/randomized parity decision tree complexity. For randomized case this is the first result of this type. For deterministic case, our result improves the bound in [6] for Inner Product gadget.

To obtain our results we introduce a new *secret sets* approach to simulation of semi-structured communication protocols by decision trees. It allows us to simulate (restricted classes of) communication protocols on truly uniform distribution of inputs.

1 Introduction

In recent years numerous results emerged that lift the complexity of a function in a weak model of computation to the complexity of a modified version of the function in a stronger model of computation [10, 13, 5, 11, 4, 14]. These results proved to be extremely useful for solving open problems in various areas of computational complexity [17, 18, 16, 9, 8]. In this type of results we start with a function $f\colon \{0,1\}^n \to \{0,1\}$ that is hard for a weak computation model (like decision trees) and for a gadget $g\colon \{0,1\}^m \to \{0,1\}$ we consider a function $f \circ g^n\colon \{0,1\}^{nm} \to \{0,1\}$ in which we substitute each variable of f by an output of g applied to fresh variables. Our goal is to show that the resulting function $f \circ g^n$ is hard for a strong computation model (like communication complexity or Boolean formula complexity). We would like the result to hold for as simple g, as possible.

In this paper we are mostly interested in lifting from decision tree complexity to communication complexity, which is sometimes called query-to-communication lifting. This particular type of lifting has seen numerous results [17, 10, 12, 5, 11, 4]. In these papers

the results of this type were obtained and gradually improved for both deterministic and randomized cases and for gradually increasing set of possible gadgets. The size of the gadget is a parameter that is of importance for applications. The smallest known size of the gadget for both deterministic and randomized case is logarithmic. For deterministic case, the results for logarithmic size of gadgets were obtained in [5] and [20]. For randomized case, the first result was obtained in [11] with a gadget of polynomial size. The paper [4] reduced the size of gadget for randomized case to logarithm. Obtaining the lifting results with the gadgets of constant size remains a major open problem.

One of the possible approaches to this problem is to address lifting to restricted models of communication or even simpler computational models and to try to obtain lifting with constant-size gadget in this setting. Some progress in this direction was obtained in recent independent papers [2, 6].

The paper [6] shows lifting from deterministic decision tree complexity $\mathsf{D}^{\mathsf{dt}}(f)$ to deterministic parity decision tree complexity $\mathsf{D}^{\mathsf{dt}}_{\oplus}(f \circ g)$ for a wide range of gadgets g, including gadgets of constant size. More specifically, for each gadget g they introduce a stifling complexity measure k and they show that $\mathsf{D}^{\mathsf{dt}}_{\oplus}(f \circ g) \geq \Omega(k \cdot \mathsf{D}^{\mathsf{dt}}(f))$. In particular, from their result it follows that $\mathsf{D}^{\mathsf{dt}}_{\oplus}(f \circ \textsc{Ind}_m) \geq \Omega(\log m \cdot \mathsf{D}^{\mathsf{dt}}(f))$ and $\mathsf{D}^{\mathsf{dt}}_{\oplus}(f \circ \mathrm{IP}_m) \geq \Omega(\mathsf{D}^{\mathsf{dt}}(f))$ for any positive m, where $\textsc{Ind}_m$ and IP_m are Indexing and Inner Product gadgets that are among the most standard in this field (see Subsection 2.3 for the definition of these functions).

The paper [2] introduces semi-structured communication complexity. In this model one of the players is allowed to send only parities of their input bits. This model is restricted compared to regular communication complexity model, but is more powerful (up to a factor of 2) compared to parity decision trees, as players can easily simulate a parity decision tree with a semi-structured communication protocol. The paper [2] shows lifting from deterministic decision trees to semi-structured communication protocol with $\textsc{Ind}_k$ gadget for any $k \geq 4$.

Our results

We show that for a wide range of gadgets (including constant size) lifting is possible from randomized decision trees to randomized semi-structured communication complexity.

More specifically, we introduce a complexity measure *linear diversity* for gadgets. Informally, it is equal to the number of distinct (up to negation) non-constant linear functions (over $\mathbb{F}_2$) in Bob's variables we can obtain by fixing Alice's variables. We observe that the linear diversity of $\textsc{Ind}_m$ is m and the linear diversity of IP_m is $2^m - 1$.

We show that for any function (or relation) f for any $k \geq 2$ and for any gadget g with linear diversity k randomized semi-structured communication complexity of $f \circ g$ is greater or equal to $\Omega(\log k \cdot \mathsf{R}^{\mathsf{dt}}(f))$, where by $\mathsf{R}^{\mathsf{dt}}(f)$ we denote the minimal depth of probabilistic decision tree computing f. In particular, our result applies to gadgets of constant size. Our result gives tight bounds for both $\textsc{Ind}_m$ and IP_m gadgets. When lifting to probabilistic parity decision trees, our result also gives tight bounds for the MAJ_m gadget using a trick described in Subsection 3.4.

Similarly to [6] we extend our result to give the same lower bound for the logarithm of the size of the randomized semi-structured communication protocol and to a version of communication complexity, in which Bob is allowed to send indicator functions of subspaces of his input bits.

Although our techniques (see below) is designed specifically for randomized case, we translate our results to deterministic case as well. Compared to [2] the deterministic version of our results apply to a wide range of gadgets.

As an immediate corollary, we have the same results (both randomized and deterministic) for lifting to parity decision trees. Compared to [6] the deterministic version of our result for parity decision trees uses linear diversity complexity measure instead of stifling. We discuss the comparison between these two measures below.

Our results can be used to obtain lower bounds on randomized parity decision tree complexity of Boolean functions. We provide a couple of examples of bounds we can obtain.

Linear diversity vs. stifling

A function $g\colon \{0,1\}^m \to \{0,1\}$ is *k-stifled* if for any subset $S \subseteq [m]$ of k input variables and any bit b we can fix all other variables in such a way that g evaluates to b no matter what the values of the variables in the subset S are.

The binary logarithm of linear diversity measure is greater than stifling at least for some functions. A notable example is IP_m function that is a common gadget in lifting results. Its linear diversity is maximal, but its stifling is just 1.

Our techniques

The proof of our results builds on so-called simulation argument in the style of [11, 4]. In this argument, given a randomized communication protocol $\mathbf{\Pi}$ computing $f \circ g^n$ of cost d, we build a randomized decision tree $\mathbf{T}$ computing f of depth $O(d/\log k)$. The tree $\mathbf{T}$ simulates $\mathbf{\Pi}$, querying the necessary information. Next we describe the simulation argument and then explain the new ideas.

For convenience we introduce the following notations:

- The gadget: it is convenient to consider gadgets of the form $g\colon [k] \times \{0,1\}^m \to \{0,1\}$, where $[k]$ corresponds to the inputs of Alice and $\{0,1\}^m$ corresponds to the inputs of Bob, and the linear diversity of g is k; that is, for convenience, we assume that for any fixed first input of g the resulting function on the second input is linear.
- The collection of all gadgets: $G := g^n : [k]^n \times (\{0,1\}^m)^n \to \{0,1\}^n$.
- The input to the i-th gadget: $(x_i, y_i) \in [k] \times \{0,1\}^m$.
- The whole inputs of Alice and Bob: $x = (x_1, \dots, x_n)$, $y = (y_1, \dots, y_n)$.

Simulation argument. The main idea is that $\mathbf{T}$ on input $z \in \{0,1\}^n$ simulates $\mathbf{\Pi}$ on a random input (x, y) that is distributed uniformly on $G^{-1}(z)$. Since $f \circ G(x, y) = f(z)$, $\mathbf{T}(z)$ will output $f(z)$ as long as the simulation of $\mathbf{\Pi}$ performed correctly.

The main difficulty in this approach is to simulate $\mathbf{\Pi}$ on $(x, y) \sim G^{-1}(z)$ without knowing z. To overcome this problem, it was shown in [11, 4] that the distribution $(x, y) \sim G^{-1}(z)$ does not differ substantially (from the perspective of the players) from the uniform distribution on all inputs. Thus, the tree $\mathbf{T}$ can instead simulate $\mathbf{\Pi}$ on (x, y), where (x, y) is distributed uniformly on $[k]^n \times (\{0,1\}^m)^n$, until $\mathbf{\Pi}$ reveals too much information about some block of inputs (x_i, y_i). Once this happens for some i, the tree $\mathbf{T}$ queries z_i and proceeds with the simulation knowing the correct distribution of the pair (x_i, y_i).

However, in this approach the simulation becomes approximate. To be able to assume that the uniform distribution on $G^{-1}(z)$ does not differ too much from the uniform distribution on all inputs, we need that the size of the gadget is at least logarithmic in n (we need this to bound the error probability of the simulation). Thus, it is not clear how to use this approach for gadgets of smaller size.

The key idea of our approach is to simulate $\mathbf{\Pi}$ precisely on the distribution $(x, y) \sim G^{-1}(z)$. This allows us to work with the gadgets of constant size. To address the issue of the simulation with unknown z, we introduce the main key ingredient of our argument, the *secret sets* technique.

Secret sets. Let S_i be some subset of $\{i\} \times [m]$. Assume for now that z_i equals the XOR of variables of y on the positions in S_i. Then we can show that as long as S_i is not in a linear span of linear functions sent by Bob in $\mathbf{\Pi}$, the uniform distribution on $g^{-1}(z_i)$ is indistinguishable (by players) from the uniform distribution on the whole i-th block of input. This allows us to simulate $\mathbf{\Pi}$ as if z_i is known. Once S_i falls into a linear span of functions sent by Bob, we just query z_i and proceed with the simulation. To prove our bound, we must show that Bob needs to send many (about $\log_2 k$) messages in $\mathbf{\Pi}$ on average to force us to query z_i. Recall that S_i is actually random. The intuition is that Bob must send roughly $\log_2 k$ linear functions for their linear span to capture a random S_i.

There are two key ingredients to actually prove that the secret set technique forces Bob to send many messages. Below is the brief description of them.

Narrowing Bob's messages to blocks. For each Bob's message we assign a block which will account for it. For each message assigned in block $\{i\} \times [m]$, we remove the part of it that lies outside of $\{i\} \times [m]$. Denote by L_i this set of truncated messages that assigned to ith block.

Each L_i will admit the following property. S_i is not lying in the linear span of messages sent by Bob as long as it is not lying in the linear span of L_i. At some point, the property can become violated after Bob sends a message, but we will send additional messages for Alice and Bob to restore the property. More precisely, we pick a linear combination of messages assigned to ith block that annulates S_i. We subtract S_i from this linear combination, in which we take untruncated messages, and send this new message for Bob recursively.

Entropy. We use the idea of *fixed/unfixed* blocks that was also used in the previous lifting theorems that utilized entropy. At the beginning, we consider all S_i to be unfixed. Note that, initially, the binary entropy of S_i is $\log_2 k$, since x_i is uniformly distributed on $[k]$. We want to show that S_i rarely lies in the linear span of L_i when a new element is added to L_i. The case when the entropy of S_i is sufficiently larger than $|L_i|$ is favorable for us, since in this case S_i does not lie in the linear span of L_i with a high probability. When the entropy of S_i goes below that level, we fix S_i (Alice sends x_i). Since Alice and Bob must send a lot of messages to decrease the entropy of S_i below the desired level or to increase the size of L_i, the number of fixed S_i is low.

As another feature of our approach we would like to mention that unlike the previous papers our simulation algorithm has a very simple description: we fix Alice's input randomly and maintain the linear space generated by Bob's messages to decide on querying z_is. Correctness of the algorithm easily follows from its description and the most technical part of the proof shifts to the complexity analysis.

For the deterministic version of our result we again use the simulation argument in the style of [11, 4] and more specifically, our general strategy is very similar to the one of [2] (with the necessary generalization to a wide range of gadgets).

Organization

The rest of the paper is organized as follows. In Section 2 we give the necessary preliminary information and introduce key notions and notation. In Section 3 we give a formulation our results. In Subsection 3.5 we show some applications of our results. In Section 4 we introduce additional notation that is used in the proofs. In Subsection 5.1 we begin the proof of our main result and as a first step reformulate the theorem in the form that is convenient for the proof. In Subsection 5.2 we describe the protocol to simulate communication protocol by decision tree. In Subsection 5.3 we proof correctness of the simulation. In Subsection 5.4 we prove the bound on the number of queries in the simulation (this is the most technically heavy part of the proof).

Proofs of the remaining theorems are omitted due to the space constraint and are provided in the full version of the paper. The proofs of our results on lifting to the size of the communication protocols and to the subspace queries are achieved by a slight modification of the proof for the depth complexity. The proof of our results for the deterministic case are similar to the ones for randomized setting with necessary technical modifications.

2 Preliminaries

2.1 Standard Notation

Here we will describe some notation that we use. We denote $[n] := \{1, 2, ..., n\}$ for a non-negative integer n. The addition mod 2 is denoted by XOR or $\oplus$. Sometimes, we view $\{0,1\}^n$ as a vector space $\mathbb{F}_2^n$.

2.2 Computational Models

For functions of the form $f\colon \{0,1\}^n \times \{0,1\}^m \to \{0,1\}$ we consider *semi-structured communication protocols* introduced in [2]. In these protocols Bob is only allowed to send the XOR of some subset of his input bits (and Alice is not restricted). A randomized semi-structured protocol is just a distribution over deterministic semi-structured protocols. We say that such a protocol computes the function f correctly, if on every input the probability of the correct output is at least $\frac{2}{3}$. The complexity $\mathsf{R}^{\mathsf{cc}}_{\to\oplus}(f)$ of f in this model is the minimal depth of a protocol computing f.

We also consider a subspace-query model. Consider communication protocols in which Bob is only allowed to send indicators of whether his input lies in an affine subspace of $\mathbb{F}_2^m$. We denote by $\mathsf{sR}^{\mathsf{cc}}_{\to\oplus}(f)$ the minimum complexity of a randomized protocol computing f, where the protocol is taken from the restricted class.

Additionally, let us introduce a size-complexity of a protocol. A deterministic communication protocol can be represented by a tree in which in every node either Alice or Bob sends a message. We call the size-complexity of the protocol to be the number of leafs in this tree. Denote by $\mathsf{sizeR}^{\mathsf{cc}}_{\to\oplus}(f)$ the minimum size-complexity of a randomized *semi-structured* protocol computing f.

We denote by $\mathsf{D}^{\mathsf{cc}}_{\to\oplus}(f)$, $\mathsf{sizeD}^{\mathsf{cc}}_{\to\oplus}(f)$ and $\mathsf{sD}^{\mathsf{cc}}_{\to\oplus}(f)$ the deterministic versions of these complexity measures.

We can define the semi-structured complexity measures for relations $f \subseteq (\mathcal{X} \times \{0,1\}^m) \times \mathcal{R}$ completely analogously. Here a deterministic protocol Π is said to compute f if for any $(x, y) \in \mathcal{X} \times \{0,1\}^m$ it outputs any z such that $(x, y, z) \in f$, if there is such z (the protocol can give any output if there is no such z).

For a function $f\colon \{0,1\}^n \to \{0,1\}$ we denote by $\mathsf{D}^{\mathsf{dt}}(f)$ the minimal depth of a decision tree computing f. We denote by $\mathsf{D}^{\mathsf{dt}}_{\oplus}(f)$ the minimal depth of a parity decision tree computing f (on each step such a decision tree can query an XOR of a subset of the input bits). Analogously to semi-structured communication complexity, we denote by $\mathsf{D}^{\mathsf{dt}}_{\oplus}(f)$, $\mathsf{sizeD}^{\mathsf{dt}}_{\oplus}(f)$, $\mathsf{sD}^{\mathsf{dt}}_{\oplus}(f)$, $\mathsf{R}^{\mathsf{dt}}_{\oplus}(f)$, $\mathsf{sizeR}^{\mathsf{dt}}_{\oplus}(f)$ and $\mathsf{sR}^{\mathsf{dt}}_{\oplus}(f)$ complexity measures defined by deterministic and randomized parity decision trees.

There is the following standard connection between parity decision trees and communication complexity protocols.

▶ **Lemma 1.** *For any function* $f\colon \{0,1\}^n \times \{0,1\}^m \to \{0,1\}$ *we have*

$$\mathsf{D}^{\mathsf{cc}}_{\to\oplus}(f) \le 2\mathsf{D}^{\mathsf{dt}}_{\oplus}(f),$$

$$\mathsf{R}^{\mathsf{cc}}_{\to\oplus}(f) \le 2\mathsf{R}^{\mathsf{dt}}_{\oplus}(f).$$

Proof. Given a (randomized) parity decision tree for f Alice and Bob can use it to compute the function f by a (randomized) communication protocol. For this they simulate each query one by one computing XOR of their portion of the input and sending them to each other. Simulation of each query requires two bits of communication. ◀

2.3 Gadgets

We first define a class of gadgets that is of use for us.

▶ **Definition 2** (Family of linear functions). *The gadget $g : [k] \times \{0,1\}^m \to \{0,1\}$ is a family of linear functions of order k, if the following is true*

(1) $\forall i \in [k]$ $g(i,\cdot)$ *is a non-trivial linear function as a function of the second argument (that is, it is an XOR of a nonempty subset of its inputs),*

(2) $\forall i,j \in [k], i \neq j$ $g(i,\cdot) \neq g(j,\cdot)$.

For convenience from now on we will use the notation $g_i(y) := g(i,y)$.

We will use the following notion of gadget reduction.

▶ **Definition 3** (Gadget reduction). *Consider two gadgets $g : \mathcal{X} \times \{0,1\}^m \to \{0,1\}, h : \mathcal{Y} \times \{0,1\}^n \to \{0,1\}$. Then g is reducible to h, if there are mappings $\varphi : \mathcal{X} \to \mathcal{Y}, \psi : \{0,1\}^m \to \{0,1\}^n$, such that*

(1) $\forall x \in \mathcal{X}, y \in \{0,1\}^m$ $g(x,y) = h(\varphi(x), \psi(y))$

(2) ψ *is linear, that is* $\forall y_1, y_2 \in \{0,1\}^m$ $\psi(y_1 \oplus y_2) = \psi(y_1) \oplus \psi(y_2)$

Note that gadget reduction relation is transitive.

Gadget reduction is useful for us due to the following lemma.

▶ **Lemma 4.** *Assume that a gadget g reduces to a gadget h. Then for any relation $f \subseteq \{0,1\}^n \times \mathcal{R}$ we have*

$$\mathsf{R}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n) \leq \mathsf{R}^{\mathsf{cc}}_{\to\oplus}(f \circ h^n),$$

$$\mathsf{sizeR}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n) \leq \mathsf{sizeR}^{\mathsf{cc}}_{\to\oplus}(f \circ h^n).$$

$$\mathsf{sR}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n) \leq \mathsf{sR}^{\mathsf{cc}}_{\to\oplus}(f \circ h^n).$$

The same inequalities are true for the deterministic complexities.

Proof. If Alice and Bob would like to compute $f \circ g^n$, they can just compute the mappings $\varphi : \mathcal{X} \to \mathcal{Y}, \psi : \{0,1\}^m \to \{0,1\}^n$ on their inputs individually and use the protocol for $f \circ h^n$. Since $\psi : \{0,1\}^m \to \{0,1\}^n$ is linear, Bob can simulate the protocol for $f \circ h^n$ sending only XORs of his input bits. To see that, denote by $e_i := \{0\}^{i-1} \times \{1\} \times \{0\}^{m-i}$. Thus, ψ is uniquely determined by $\psi(e_1), \ldots, \psi(e_m)$. Let x be Bob's input, and let $y = \psi(x)$. An arbitrary parity message of y can be represented as $\langle y, y' \rangle$ for some y'. Here, $\langle \cdot, \cdot \rangle$ is the dot product modulo 2. Observe that $\langle y, y' \rangle = \langle \psi(x), y' \rangle = \sum_i x_i \cdot \langle \psi(e_i), y' \rangle$. In other words, to compute $\langle y, y' \rangle$, it is enough to take the XOR of all those x_i for which $\langle \psi(e_i), y' \rangle$ equals one. This means that Bob can translate parity messages of y to parity messages of x. ◀

Next we define the main complexity measure for the gadgets.

▶ **Definition 5** (Linear diversity). *We let linear diversity of a function $h : \mathcal{Y} \times \{0,1\}^n \to \{0,1\}$ be the maximal k such that there is a family of linear functions $g : [k] \times \{0,1\}^m \to \{0,1\}$ of order k such that g reduces to h.*

Next we introduce a couple of standard gadgets that will be important for us.

▶ **Definition 6** (Index function). *Let* $\textsc{Ind}_m : [m] \times \{0,1\}^m \to \{0,1\}$ *be the function that on input* (i, y) *outputs* y_i.

▶ **Definition 7** (Inner product function). *Let* $IP_m : \{0,1\}^m \times \{0,1\}^m \to \{0,1\}$ *be the function that on input* (x, y) *outputs* $\bigoplus_{i=1}^{n}(x_i \wedge y_i)$.

▶ **Lemma 8.** $\textsc{Ind}_m$ *is a family of linear functions of order* m. IP_m *has linear diversity* $2^m - 1$.

Proof. The statement of the lemma is almost immediate. For $\textsc{Ind}_m$, note that for any $i \in [m]$ the output of $\textsc{Ind}_m$ is y_i, which is a linear function. For IP_m, note that for any fixed $x \in \{0,1\}^n$ the output of IP_m is $\oplus_{i:x_i=1} y_i$, which is a non-trivial linear function for each $x \neq 0$. The reduction from a family of linear functions is trivial (ψ is an identity function and φ sends an integer to its binary representation). ◀

▶ **Lemma 9.** *With probability approaching* 1 *as* m *tends to infinity, a random gadget* $g : [2^{2^m}] \times \{0,1\}^m \to \{0,1\}$ *has linear diversity at least* $2^{m/2}$. *(The values of* g *on each input are chosen randomly and independently.)*

The proof of this lemma can be found in the full version of the paper.

3 Results Statement

3.1 Randomized Semi-Structured protocols

▶ **Theorem 10.** *Let* $g : [k] \times \{0,1\}^m \to \{0,1\}$ *be a family of linear functions of order* $k \geq 2$. *Then for any relation* $f \subseteq \{0,1\}^n \times \mathcal{R}$ *we have*

$$\mathsf{R}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n) \;=\; \Theta(\log_2 k \cdot \mathsf{R}^{\mathsf{dt}}(f)).$$

We note that big-O part is trivial, since Alice and Bob in communication protocol can simulate a decision tree for f and spend $O(\log_2 k)$ bits of communication for each tree query to compute the function g on the corresponding inputs.

We prove the following stronger versions of Theorem 10.

▶ **Theorem 11.** *Let* $g : [k] \times \{0,1\}^m \to \{0,1\}$ *be a family of linear functions of order* $k \geq 2$. *Then for any relation* $f \subseteq \{0,1\}^n \times \mathcal{R}$ *we have*

$$\log_2 \mathsf{sizeR}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n) \;=\; \Theta(\log_2 k \cdot \mathsf{R}^{\mathsf{dt}}(f)).$$

▶ **Theorem 12.** *Let* $g : [k] \times \{0,1\}^m \to \{0,1\}$ *be a family of linear functions of order* $k \geq 2$. *Then for any relation* $f \subseteq \{0,1\}^n \times \mathcal{R}$ *we have*

$$\mathsf{sR}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n) \;=\; \Theta(\log_2 k \cdot \mathsf{R}^{\mathsf{dt}}(f)).$$

For both theorems big-O part follows since $\mathsf{R}^{\mathsf{cc}}_{\to\oplus}(h) \geq \log_2 \mathsf{sizeR}^{\mathsf{cc}}_{\to\oplus}(h)$ and $\mathsf{R}^{\mathsf{cc}}_{\to\oplus}(h) \geq \mathsf{sR}^{\mathsf{cc}}_{\to\oplus}(h)$ for any function h.

As a corollary of these theorems and Lemma 4 we immediately obtain the following.

▶ **Corollary 13.** *Let* $h : \mathcal{Y} \times \{0,1\}^n \to \{0,1\}$ *have linear diversity at least* k *for* $k \geq 2$. *Then for any relation* $f \subseteq \{0,1\}^n \times \mathcal{R}$ *we have*

$$\mathsf{R}^{\mathsf{cc}}_{\to\oplus}(f \circ h^n) \;=\; \Omega(\log_2 k \cdot \mathsf{R}^{\mathsf{dt}}(f)).$$

The same result is true for $\log \mathsf{sizeR}^{\mathsf{cc}}_{\to\oplus}(f \circ h^n)$ *and* $\mathsf{sR}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n)$.

3.2 Deterministic Semi-structured protocols

We translate our results to deterministic case as well.

▶ **Theorem 14.** *Let $g : [k] \times \{0,1\}^m \to \{0,1\}$ be a family of linear functions of order $k \geq 2$. Then for any relation $f \subseteq \{0,1\}^n \times \mathcal{R}$ we have*

$$\begin{aligned} \mathsf{D}^{\mathsf{cc}}(f \circ g^n) &= \Theta(\log_2 k \cdot \mathsf{D}^{\mathsf{dt}}(f)), \\ \log_2 \mathsf{sizeD}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n) &= \Theta(\log_2 k \cdot \mathsf{D}^{\mathsf{dt}}(f)), \\ \mathsf{sD}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n) &= \Theta(\log_2 k \cdot \mathsf{D}^{\mathsf{dt}}(f)). \end{aligned}$$

▶ **Corollary 15.** *Let $h : \mathcal{Y} \times \{0,1\}^n \to \{0,1\}$ have linear diversity at least k for $k \geq 2$. Then for any relation $f \subseteq \{0,1\}^n \times \mathcal{R}$ we have*

$$\mathsf{D}^{\mathsf{cc}}_{\to\oplus}(f \circ h^n) = \Omega(\log_2 k \cdot \mathsf{D}^{\mathsf{dt}}(f)).$$

The same result is true for $\log \mathsf{sizeD}^{\mathsf{cc}}_{\to\oplus}(f \circ h^n)$ and $\mathsf{sD}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n)$.

3.3 Parity decision trees

Finally, we prove that our results imply the same results for parity decision trees instead of semi-structured communication protocols.

▶ **Theorem 16.** *Let $h : \mathcal{Y} \times \{0,1\}^n \to \{0,1\}$ have linear diversity at least k for $k \geq 2$. Then for any relation $f \subseteq \{0,1\}^n \times \mathcal{R}$ we have*

$$\mathsf{R}^{\mathsf{dt}}_{\oplus}(f \circ h^n) = \Omega(\log_2 k \cdot \mathsf{R}^{\mathsf{dt}}(f)).$$

The same is true for $\log \mathsf{sizeR}^{\mathsf{cc}}_{\to\oplus}(f \circ h^n)$ and $\mathsf{sR}^{\mathsf{cc}}_{\to\oplus}(f \circ g^n)$. The same results are also true for the deterministic complexities.

The part of this theorem concerning $\mathsf{R}^{\mathsf{dt}}_{\oplus}$ is a direct consequence of Lemma 1, Theorem 10, and Lemma 4. The same applies to $\mathsf{D}^{\mathsf{dt}}_{\oplus}$.

The part of this theorem about $\log \mathsf{sizeR}^{\mathsf{dt}}_{\oplus}$ and $\mathsf{sR}^{\mathsf{dt}}_{\oplus}$ does not follow from previous theorems that easily, and we prove them in the full version of the paper.

3.4 More powerful gadget reduction

In this section, we describe a more general version of a gadget reduction than in Definition 3. We apply the reduction to the MAJ gadget, obtaining tight bounds for lifting to parity decision trees.

More specifically, we can consider the domain $\{0,1\}^m$ of a gadget as a vector space $\mathbb{F}_2^m$ and input variables $x_1, \ldots, x_m$ as coordinates in the standard basis. The idea is that we can switch to another basis in this vector space, consider new coordinates as variables and apply the reduction in Definition 3 after that. Since the transformation to the new variables is linear, new variables can be expressed as an XOR of old variables and vice versa. Thus, the parity decision trees in new and old variables can simulate each other (this does not hold for communication complexity setting, since switching to the new basis mixes up the variables belonging to Alice and Bob).

We illustrate this idea on a MAJ gadget. Recall that MAJ_m is a function that returns 1 iff at least $m/2$ of its m variables are equal to 1.

▶ **Lemma 17.** *For any relation $f \subseteq \{0,1\}^n \times \mathcal{R}$ and $m \geq 4$, $\mathsf{R}^{\mathsf{dt}}_{\oplus}(f \circ MAJ^n_m) = \Omega(m \cdot \mathsf{R}^{\mathsf{dt}}(f))$.*

This method can be applied to gadgets other than MAJ. We formulate this approach in a theorem.

▶ **Theorem 18.** *Let $r : \{0,1\}^m \to \{0,1\}$, $h : \mathcal{X} \times \{0,1\}^l \to \{0,1\}$, $g : \mathcal{Y} \to \{0,1\}$ – be functions such that linear diversity of h is at least $k \geq 2$. Suppose that $r \circ h^m$ reduces to g after a change of basis. Then, for any relation $f \subseteq \{0,1\}^n \times \mathcal{R}$,*

$$\mathsf{R}^{\mathsf{dt}}_{\oplus}(f \circ g^n) = \Omega(\mathsf{R}^{\mathsf{dt}}(f \circ r^n) \log k)$$

By reduction we mean Definition 3. Here g depends on x, and we consider some linear change of basis $x \to y$. We also decide on some way to split variables y between Alice and Bob before applying Definition 3.

Proofs of these results are provided in the full version of the paper.

3.5 Applications

A more detailed description of applications can be found in the full version of the paper.

Recursive majority function

Let $\mathrm{MAJ}_3^{\otimes 1} := \mathrm{MAJ}_3$ be the majority function that returns 1 if at least two of its three input bits equal to 1, otherwise it returns 0.

For $k > 1$, define $\mathrm{MAJ}_3^{\otimes k}$ to be MAJ_3 in which each argument is substituted by $\mathrm{MAJ}_3^{\otimes k-1}$. Thus, $\mathrm{MAJ}_3^{\otimes k}$ takes 3^k inputs.

In [15], it is shown that

$$\Omega(2.57143^k) \leq \mathsf{R}^{\mathsf{dt}}(\mathrm{MAJ}_3^{\otimes k}) = O(2.64944^k).$$

It is easily observed that $\mathrm{MAJ}_3^{\otimes 2}$ is at least 2 linear diverse. By using it as a gadget, our lifting theorem imply that $\mathsf{R}^{\mathsf{dt}}_{\oplus}(\mathrm{MAJ}_3^{\otimes k}) = \Omega(\mathsf{R}^{\mathsf{dt}}(\mathrm{MAJ}_3^{\otimes k}))$. Thus, parity queries do not help in computing $\mathrm{MAJ}_3^{\otimes k}$ as compared to single variable queries.

The same approach can be applied to formulas having the form of complete binary AND-OR-tree. In other words, this function is obtained by repeated iteration of $f(x) = (x_1 \vee x_2) \wedge (x_3 \vee x_4)$. It was shown in [19] that R^{dt} of this function is at least $n^{0.7537\ldots}$, where n is the number of inputs. Since f can be used as a gadget, we translate this result to parity decision trees.

Quantum Complexity

Our lifting theorem can be applied to exhibit a separation between randomized parity decision tree complexity and bounded-error quantum complexity. Let $k \leq \log n$. It was shown in [1] that there is a $\lceil k/2 \rceil$ versus $\widetilde{\Omega}(n^{1-\frac{1}{k}})$ separation between the quantum and randomized query complexity. The separation was shown for a partial function f called k-fold Forrelation.

Using our result, we can lift this separation to randomized parity query complexity. Consider the function $f \circ \textsc{Ind}_2^n$. On the one hand, its quantum complexity is the same as the quantum complexity of f (up to a factor), since a quantum protocol can extract inputs to f from $\textsc{Ind}_2$ in constant number of additional queries. On the other hand, by Theorem 10, the randomized parity query complexity of $f \circ \textsc{Ind}_2^n$ is no less than its randomized query complexity. Hence, we obtain the same separation even if our query model can ask parity queries.

An alternative method to obtain separation between randomized parity query and quantum complexity was given in [3]. They also relied on the result of [1]. They used Fourier analysis and properties of k-Fold Forrelation to derive their result. In contrast, our lifting theorem can lift any function f that exhibits the separation.

4 Notation for proving main theorems

In this section we introduce notation and facts about entropy that will be used for proving the main theorems in the subsequent sections. Recall that in a semi-structured communication protocol, Bob can send only parities of its input. In a lifting setting, Bob is given $n \cdot m$ boolean variables. For each of n variables of the initial function, there are m gadget's variables. To analyze Bob's messages, we introduce the following definitions.

4.1 Notation

▶ **Definition 19** (XOR of a subset). *For a set $S \subseteq [m]$ and $y \in \{0,1\}^m$, we define*

$$y_S := \bigoplus_{j \in S} y_j.$$

Analogously, we define y_S if $y \in (\{0,1\}^m)^n$ and $S \subseteq [n] \times [m]$.

If $y \in (\{0,1\}^m)^n$ is the Bob's input, then each of his messages can be represented as y_S for some $S \subseteq [n] \times [m]$.

▶ **Definition 20** (Subsets of $[n] \times [m]$ as a linear space). *We view subsets of $[n] \times [m]$ as vectors in a linear space over $\mathbb{F}_2$ (where addition (+) corresponds to symmetric difference).*

With this notation, for any $S, T \subseteq [n] \times [m], y \in (\{0,1\}^m)^n$, $y_{S+T} = y_S \oplus y_T$.

▶ **Definition 21** (Linear Order on $[n] \times [m]$). *We introduce a lexicographic linear order on $[n] \times [m]$. A pair $(i,j) \in [n] \times [m]$ is said to be lower than (i',j') if $i < i'$ or $i = i', j < j'$.*

▶ **Definition 22** (Principal variable of a non-empty subset). *For a non-empty set $S \subseteq [n] \times [m]$, denote by $p(S)$ its lowest element.*

▶ **Definition 23** (Block). *We refer to $\{i\} \times [m]$ as i-th block. A non-empty subset $S \subseteq [n] \times [m]$ touches i-th block if $p(S) \in \{i\} \times [m]$.*

▶ **Definition 24** (Bernoulli distribution). *Denote by $Bern(p)$ a distribution of a random variable that takes value 0 with probability $1-p$ and 1 with probability p.*

▶ **Definition 25** (Entropy). *For a random variable x, denote by $H(x)$ its binary entropy. If X is a set, then we define its entropy as $H(X) := \log_2 |X|$. If p is a number, then $H(p)$ denotes the binary entropy of the distribution $Bern(p)$.*

Recall that the binary entropy of a random variable taking n values with non-zero probabilities $p_1, ..., p_n$ equals to

$$\sum_{i=1}^{n} -p_i \log_2 p_i$$

4.2 Entropy theorems

We state well-known results that will be used for proving our main theorems.

▶ **Lemma 26** (Gibbs' inequality [7]). *Let $0 \le p \le 1, 0 < q < 1$. Then,*

$$H(p) \le p \log_2 \frac{1}{q} + (1-p) \log_2 \frac{1}{1-q}$$

▶ **Lemma 27** (Fano's Inequality [7]). *Let X, Y be random variables. Let $\varepsilon = P(X \neq Y) \le 1/2$. Then,*

$$H(X|Y) \le H(\varepsilon) + \varepsilon \log_2(|\mathcal{X}| - 1),$$

where $\mathcal{X}$ denotes the support of X.

5 Proof of Theorem 10

5.1 Reformulation of Theorem 10

As we noted in Section 3, the $\le$-direction is simple. Thus, it remains to prove the other direction.

Let $\mathbf{\Pi}$ be a randomized semi-structured protocol computing $f \circ g^n$. Denote by d the depth of $\mathbf{\Pi}$. Our goal is to construct a randomized tree $\mathbf{T}$ of depth $O(d/\log_2 k)$, that computes $f(z)$ for any given z.

The idea is to simulate $\mathbf{\Pi}$ on a randomly uniformly chosen pair (x, y) satisfying $g^n(x, y) = z$. For convenience, denote $P_z = \{(x, y) \mid g^n(x, y) = z\}$. For any pair $(x, y) \in P_z$ we have that $\mathbf{\Pi}(x, y) = f(z)$ with probability at least $2/3$. Thus, if we sample $(x, y) \sim U(P_z)$, the protocol $\mathbf{\Pi}(x, y)$ will also be equal to $f(z)$ with probability at least $2/3$.

We use the following general strategy for $\mathbf{T}$: sample $(x, y) \sim U(P_z)$, sample $\Pi \sim \mathbf{\Pi}$ (recall that $\mathbf{\Pi}$ is a random distribution on deterministic protocols), and output $\Pi(x, y)$. Note that the choice of the pair (x, y) is independent from the choice of Π, and thus it does not matter in which order we sample Π and (x, y). As a result, what is left to do is to simulate the given deterministic semi-structured protocol Π on a random pair $(x, y) \sim U(P_z)$.

We are going to prove the following intermediate theorem.

▶ **Theorem 28.** *Let Π be a deterministic semi-structured protocol with inputs from $[k]^n \times (\{0,1\}^m)^n$. Let d be equal to the depth of Π. Then, there exists a randomized decision tree $\mathbf{T}$ which, on input $z \in \{0,1\}^n$, outputs a random variable that is destributed as $\Pi(x, y)$ for $(x, y) \sim U(P_z)$. The expected number of queries to z made by $\mathbf{T}$ is $O(d/\log_2 k)$, where the expectation is taken over (x, y) for a fixed z.*

Before proceeding to the proof of Theorem 28 we show how to prove Theorem 10 based on Theorem 28.

Proof of Theorem 10. The computation of f on input z proceeds as follows. We choose a random $\Pi \sim \mathbf{\Pi}$ and run $\mathbf{T}$ provided by Theorem 28 on input z. By definition, $\mathbf{T}(z)$ has the same distribution as $\mathbf{\Pi}(x, y)$ for $(x, y) \sim U(P_z)$. Thus, $\mathbf{T}$ computes $f(z)$ with probability at least $\frac{2}{3}$.

The average number of queries made by $\mathbf{T}$ is at most $O(d/\log_2 k)$. To achieve this number of queries in the worst case, we halt $\mathbf{T}$ if it makes 10 times more queries than the expected number. By Markov's inequality, this only happens with probability at most $\frac{1}{10}$, the probability of the correct answer is still a constant greater than $1/2$ and it can be increased to $2/3$ by the standard argument for error reduction. ◀

Now we proceed to the proof of Theorem 28. For this we need to describe how $\mathbf{T}$ simulates Π. In the subsequent sections we will heavily use the notation introduced in Section 4.

5.2 Simulation algorithm for T

In this section we describe the algorithm for $\mathbf{T}$.

$\mathbf{T}$ starts by sampling a random $a \sim U([k]^n)$ and assuming that $x = a$.

After that, $\mathbf{T}$ starts the simulation of Π. Since x is fixed ($\mathbf{T}$ knows x but for Π it is a random variable), Alice's messages are easily simulated. Next, we describe how $\mathbf{T}$ simulates Bob's parity messages on the (unknown) variables y.

Recall that we can view g as a family of linear functions $\{g_1, \dots, g_k\}$ of order k (one function for each value of x). Since $g_1, ..., g_k$ are linear functions, we can represent them as $g_j(x) = x_{G_j}$ for some $G_j \subseteq [m]$.

Let $S_i := \{i\} \times G_{x_i}$. Note that all S_is are linearly independent since they are in distinct blocks. From now on we will call $S_1, ..., S_n$ *the secret sets*.

Consider an arbitrary step of simulation and assume Bob has already sent the parities of his inputs for the sets $Q_1, ..., Q_t \subseteq [n] \times [m]$ and is now supposed to send the parity of y's in the set $Q_{t+1} \subseteq [n] \times [m]$. Note, that it can be assumed that Q_{t+1} is linearly independent of $Q_1, ..., Q_t$: otherwise, the message Q_{t+1} does not reveal any new information and can be omitted from the protocol. There are two cases:

(1) There is a linear combination of Q_is that includes Q_{t+1} and equals to some linear combination of the secret sets:

$$Q_{i_1} + Q_{i_2} + ... + Q_{i_k} + Q_{t+1} = S_{j_1} + ... + S_{j_l}.$$

In this case, the value $y_{Q_{t+1}}$ is uniquely determined since

$$y_{Q_{t+1}} = y_{Q_{i_1}} + y_{Q_{i_2}} + ... + y_{Q_{i_k}} + z_{j_1} + ... + z_{j_l}.$$

The y's parities on the sets $Q_{i_1}, ..., Q_{i_k}$ are already known from the previous messages of Bob. Therefore, $\mathbf{T}$ queries $z_{j_1}, ..., z_{j_l}$ (if it hasn't already), and we calculate the value $y_{Q_{t+1}}$ that Bob sends in this vertex.

(2) Such a linear combination does not exist. In this case, $\mathbf{T}$ sends a random bit $Bern(1/2)$ as an XOR of y on the set Q_{t+1}. In terms of the protocol Π, this corresponds to proceeding to one of the left and right children with equal probabilities.

Thus, we have described how to simulate each Bob's message. Once $\mathbf{T}$ reaches a leaf of Π, it outputs the value written in this leaf.

5.3 Correctness of the simulation of Π done by T

Next, we need to show that $\mathbf{T}(z)$ indeed simulates Π on a random pair $(x, y) \sim U(P_z)$, and that $\mathbf{T}(z)$ makes $O(d/\log_2 k)$ queries on average. We start with the correctness of the simulation.

It is easy to see that for any z the projection of $U(P_z)$ onto x is the uniform distribution on $U([k]^n)$, therefore fixing $x = a \sim U([k]^n)$ correctly corresponds to the distribution of (x, y) we would like to simulate the protocol on.

Note that once x is fixed the only constraints on y are of the form $g_j(y_i) = z_i$, where $j = x_i$. In particular, any variable in y, not included in $\{i\} \times G_{x_i}$, has a $Bern(1/2)$ distribution.

Next, we justify why the algorithm can send $Bern(1/2)$ as an XOR of Q_{t+1} if no linear combination exists (Case 2 above). Indeed, the y's parities of $Q_1, ..., Q_t, S_1, ..., S_n$ define an affine subspace in our linear space. Since Q_{t+1} is linearly independent of $Q_1, ..., Q_t, S_1, ..., S_n$, each of the conditions $y_{Q_{t+1}} = 0$ and $y_{Q_{t+1}} = 1$ is satisfied by exactly half of the points of the affine subspace.

If there exists a linear combination of Q_is that includes Q_{t+1} and equals a linear combination of S_is (Case 1 above), then given the previous messages and the value of z there is only one possible value for $y_{Q_{t+1}}$, which $\mathbf{T}$ indeed sends in our simulation.

Thus, the distribution of $\mathbf{T}(z)$ matches $\Pi(x, y)$ for $(x, y) \sim U(P_z)$.

5.4 Upper bound on the average number of queries made by T

Next we show that $\mathbf{T}(z)$ makes $O(d/\log_2 k)$ queries to the variables z on average. For this we introduce some complexity measures and study their behaviour during the execution of the protocol. To make this analysis cleaner we first modify the protocol Π to add more messages to it. This does not change the output of the protocol, but it allows us to simplify the exposition of time analysis. In the next section we describe the modified protocol. Next we discuss its connection to $\mathbf{T}$. Finally, in Subsubsection 5.4.3, we derive the upper bound on the number of queries made by $\mathbf{T}$.

Since we need to show the upper bound on the number of queries of $\mathbf{T}(z)$ for any z, we fix z for the whole argument.

5.4.1 Description of the modified protocol $\overline{\Pi}_z$

Here we describe $\overline{\Pi}_z$, a refined version of Π. Note that the protocol depends on z, which is fixed throughout the whole argument. We will be interested only in the behaviour of the protocol on inputs in P_z.

We modify the protocol in two ways. First, we modify the messages sent by Bob into equivalent messages. This does not actually change the information transmitted by Bob, this modification is needed only for the purpose of the analysis of the protocol. Next, at some moments of time we add additional messages sent by the players. The information transmitted in these messages is not affecting the following messages in the protocol. One can think of this in the following way: at some points of the protocol the players pause the execution of the protocol, exchange some extra information, and then resume the execution of the protocol as if nothing happened. These extra messages are needed just to introduce new intermediate vertices in communication tree that will allow us to analyse the complexity of $\mathbf{T}$ in a cleaner way.

The pseudocode for the algorithm $\overline{\Pi}_z$ is provided in Figure 1. Next we describe the protocol and introduce some important notation related to it.

First of all, observe that if Bob sends b_1, b_2 as parities on the sets $Q_1, Q_2 \subseteq [n] \times [m]$ respectively, this is equivalent to sending b_1, $b_1 \oplus b_2$ as parities on $Q_1, Q_1 + Q_2$ respectively. More generally, applying an invertible linear transformation to Bob's messages does not change the information transmitted.

Recall that by $S_i = \{i\} \times G_{x_i}$ we denote the secret sets. Note that S_i depends on x and, thus, initially is only known to Alice. Initially, all S_i are *unrevealed*, and over the course of the simulation, they will be gradually *revealed*. We also introduce a separate notion that of S_i being *fixed*. Initially, all S_i are *unfixed* and then will change status to fixed over the course of the simulation. A revealed S_i will also be fixed, but not necessarily vice versa.

Suppose that at the current moment of simulating Π, Bob has sent parities on the sets $Q_1, ..., Q_t \subseteq [n] \times [m]$ and now he wants to send the parity on the set $Q \subseteq [n] \times [m]$. We will maintain the *principle variable invariant*: all $p(Q_i)$ are distinct and, if $i < j$, then $p(Q_i)$ is *lower* than $p(Q_j)$. The variables $p(Q_i)$ will be referred to as *principal*. In particular, from this invariant, it follows that $Q_1, ..., Q_t$ are linearly independent.

Define the procedure *sift*, which will transform Q to an equivalent message. The procedure *sift* iterates over $i = 1, \dots, t$ and replaces Q with $Q + Q_i$ if $p(Q_i) \in Q$. Note that after this procedure for any i we have that $p(Q_i) \notin Q$.

We run the procedure *sift* on Q. If it turns into an empty set, then Bob's message does not provide any new information. In this case we finish its processing and move on to further simulation of Π. If the resulting Q is not empty, then it contains a principal variable. Since after *sift*, Q does not contain principal variables of previous messages, the principal variable of Q does not coincide with the principal variable of previous messages. We insert a copy of Q into the sequence $Q_1, ..., Q_t$ in such a way that the principle variable invariant is maintained. That is, now the length of the sequence is $t + 1$. Assume that $p(Q)$ is in the i-th input block. Let $L_i := \{Q_j \cap \{i\} \times [m] \mid p(Q_j) \in \{i\} \times [m]\}$. In other words, we consider all sets whose principal variables are in the i-th block and intersect them with the i-th block. Note that sets in L_i are linearly independent. Denote by $\mathcal{L}_i$ the linear span of L_i with the zero vector (empty set) removed.

At this point, we apply the second modification to the protocol. If the binary entropy of S_i is less than $\frac{1}{10}\log_2 k + \log_2 |\mathcal{L}_i| + \frac{1}{3}$, Alice sends S_i, and S_i is considered fixed. Here the protocol views S_i to be a random variable of the distribution $(x, y) \sim U(P_z)$ conditioned on the information about (x, y) that the protocol has learnt so far. Note that we fixed z in advance, and we assume that the inputs given to the players are indeed in P_z (we are not interested in the behaviour of the protocol on other inputs). As a result, both players can compute the entropy of S_i and compare it to $\frac{1}{10}\log_2 k + \log_2 |\mathcal{L}_i| + \frac{1}{3}$ without communication.

After that Alice sends a message indicating if S_i lies in $\mathcal{L}_i$[1]. If this is not the case or if S_i has already been revealed on one of the previous steps, we finish processing the message Q and proceed with the further simulation of the protocol Π. If S_i lies in $\mathcal{L}_i$, then we consider S_i to be revealed. In this case Alice sends S_i, and we fix S_i if it was not already fixed before. Bob sends y_{S_i}. Next, let $Q_{j_1}, ..., Q_{j_l}$ be the sets whose linear combination, when intersected with the i-th block, equals the secret set S_i. The set Q must be present among them: otherwise, S_i would have been revealed at an earlier step. Without loss of generality we can assume that $Q_{j_1} = Q$. We update Q to $Q \leftarrow Q + Q_{j_2} + ... + Q_{j_l} + S_i$ and perform the same procedure with the updated Q starting with *sift* (note that from this players can compute y_Q for the new Q without additional communication since y_{S_i} is known). Note, that during this iteration we removed from Q all elements in the i-th block without introducing anything to Q in the previous blocks (all sets in the combinations had their principle variables in the i-th block). As a result, the updated Q lies within the blocks that are higher than i-th block and the whole procedure of updating Q will be finished eventually.

5.4.2 Connection between T and $\overline{\Pi}_z$

The protocol $\overline{\Pi}_z$ is useful for upper bounding the complexity of $\mathbf{T}$ due to the following lemmas.

[1] Note that this might be redundant if we just communicated the whole S_i. We choose to keep this step even if it is redundant to make the pseudocode in Figure 1. In the analysis below the redundancy of these messages is reflected in Observation 35.

Refined protocol $\overline{\Pi}_z$ ***on input*** $(x, y) \sim U(P_z)$**:**

1: Initialize: v = root of Π, $Q_1, ..., Q_t \subseteq [n] \times [m]$ – sets which parities Bob sends, initially $t = 0$
2: **while** v is not a leaf [invariant: $p(Q_i)$ is lower than $p(Q_j)$ when $i < j$]
3: Let v_0, v_1 be children of v
4: **if** Bob speaks at v **then**
5: Let $Q \subseteq [n] \times [m]$ be the set which parity Bob sends at v
6: Let $b = y_Q$
7: ▷ Bob sends b and we update $v \leftarrow v_b$ ▷ (B1)

8: **for** $i = 1..t$ **do**
9: **if** $p(Q_i) \in Q$ **then**
10: $Q \leftarrow Q + Q_i$
11: **end if**
12: **end for**
13: **if** $Q \neq \varnothing$ **then**
14: Insert a copy of Q in $Q_1, ..., Q_t$ so that invariant holds
15: Let $i \in [n]$ be the block containing $p(Q)$
16: // $L_i = \{Q_j \cap \{i\} \times [m] \mid p(Q_j) \in \{i\} \times [m]\}$
17: // $\mathcal{L}_i$ denotes linear span of L_i without null vector
18: // $S_i = \{i\} \times G_{x_i}$ – a *secret* set in ith block
19: **if** $H(S_i) < \frac{1}{10} \log_2 k + \log_2 |\mathcal{L}_i| + \frac{1}{3}$ **then**
20: ▷ Alice sends S_i; S_i is *fixed* now ▷ (A3)
21: **end if**
22: ▷ Alice communicates whether S_i is in $\mathcal{L}_i$ ▷ (A2)
23: **if** $S_i \in \mathcal{L}_i$ and S_i is not *revealed* **then**
24: ▷ Alice sends S_i; S_i is *fixed* now ▷ (A3)
25: S_i is considered to be *revealed*
26: ▷ Bob sends y_{S_i} ▷ (B2)
27: Find distinct $j_1, ..., j_l$, s.t. $Q = Q_{j_1}$ and $(Q_{j_1} + ... + Q_{j_l}) \cap \{i\} \times [m] = S_i$
28: $Q \leftarrow Q + Q_{j_2} + ... + Q_{j_l} + S_i$
29: Go to 8−th line
30: **end if**
31: **end if**

32: **else** Alice speaks at v
33: Let b be the bit she sends
34: ▷ Alice sends b and we update $v \leftarrow v_b$ ▷ (A1)
35: **end if**
36: **end while**
37: return the value of the leaf v

Figure 1 The modified (deterministic) protocol $\overline{\Pi}_z$. The original protocol Π can be recovered by ignoring lines 8–31 and the **red** text. Lines 8–31 are used to maintain the invariant and prove the estimate on the number of *revealed* sets. The classification (A1), (A2), (A3), (B1), (B2) of the actions made by Alice and Bob is used in Section 5.4.3. Note that Alice can send more than 1-bit of information for the message of type (A3).

▶ **Lemma 29.** *The following is a while-loop invariant in $\overline{\Pi}_z$: If a linear combination of $Q_1, ..., Q_t$ equals a linear combination of $S_1, ..., S_n$, then all S_is in this linear combination are revealed.*

Proof. First note that for all i such that S_i is unrevealed, S_i does not lie in $\mathcal{L}_i$. Otherwise, at the line 25 of the algorithm, S_i would have been revealed.

Assume that this invariant is violated. Let this linear combination be $Q_{j_1} + ... + Q_{j_l} = I$, where $j_1 < ... < j_l$. If there are many linear combinations that violate invariant, then choose the one with the greatest j_1. Let i be the block of the variable $p(Q_{j_1})$. Then, $I \cap \{i\} \times [m]$ must be equal to S_i, since $I \cap \{i\} \times [m] \neq \varnothing$. It follows that S_i must be revealed, since it lies in $\mathcal{L}_i$. At the line 28 of the algorithm, it is ensured that a linear combination $Q_{j_1} + ... + Q_{j_l} + S_i = I + S_i$ is added to the set of Qs. $I + S_i$ is contained in blocks strictly higher than i-th block and, by assumption, is equal to a linear combination of $S_1, ..., S_n$ containing an unrevealed secret set. Therefore, we obtained a contradiction with the maximality of j_1. ◀

Next we establish the connection between $\mathbf{T}$ and $\overline{\Pi}_z$. By construction, $\mathbf{T}(z)$ simulates Π on a random input $(x, y) \sim U(P_z)$. Fix r to be the outcome of the random bits of the tree $\mathbf{T}$. Then $\mathbf{T}_r(z)$ will simulate Π on some pair $(x_r, y_r) \in P_z$.

We show the following.

▶ **Lemma 30.** *The number of queries to z made by $\mathbf{T}_r(z)$ is less or equal than the number of revealed sets in protocol $\overline{\Pi}_z$ on input (x_r, y_r).*

Proof. By definition of $\mathbf{T}$, it queries z_i only if there is some linear combination of $S_1, ..., S_n$ containing S_i that equals a linear combination of $Q_1, ..., Q_t$. By Lemma 29, we get that z_i is queried by $\mathbf{T}$ only if S_i is revealed. Hence, the statement of the lemma follows. ◀

The lemma holds for all r. In particular, if we average over r, then we get that the expected number of queries made by $\mathbf{T}$ is bounded by the expected number of revealed sets in protocol $\overline{\Pi}_z$ on a random $(x, y) \sim U(P_z)$. Therefore, it remains to obtain an upper bound on the expected number of revealed sets.

5.4.3 Upper bound on the expected number of revealed sets in $\overline{\Pi}_z$

For each vertex v of the protocol $\overline{\Pi}_z$, define

$$P_{z,v} = \{(x, y) \mid \overline{\Pi}_z \text{ reaches vertex } v \text{ on input } (x, y) \text{ and } g^n(x, y) = z\}$$

In other words, if $X_v \times Y_v$ is the rectangle corresponding to the vertex v in the protocol $\overline{\Pi}_z$, then $P_{z,v} = X_v \times Y_v \cap (g^n)^{-1}(z)$.

Essentially, if the protocol $\overline{\Pi}_z$ has reached the vertex v, then (x, y) can be any element of the set $P_{z,v}$. Now consider the uniform distribution $U(P_z)$ and run $\overline{\Pi}_z$ on a random pair (x, y) from this distribution. Then $U(P_{z,v})$ is precisely the conditional distribution of the pair (x, y), given that $\overline{\Pi}_z$ has reached v. In what follows, we consider $(x, y) \sim U(P_{z,v})$. We will be interested in the entropy of the projection of this distribution onto x, hence we introduce the following notation

$$H^v = H(x),$$

$$H^v_i = H(x_i).$$

Let S_i be the secret set in the i-th block. The set S_i depends on x_i and, moreover, there is a one-to-one correspondence between S_is and x_is. Therefore, their entropies are equal: $H(S_i) = H(x_i) = H_i^v$. Denote by L_i^v the set L_i corresponding to the vertex v, and by $\mathcal{L}_i^v$ its linear span with the zero vector removed. That is, $|\mathcal{L}_i^v| = 2^{|L_i^v|} - 1$.

Using Fano's inequality, we can show the following.

▶ **Lemma 31.** *Let v be a vertex of the protocol $\overline{\Pi}_z$ in which Alice sends a message revealing whether S_i lies in the linear span L_i^v (this is (A2) type of message on Figure 1). Then, if $H_i^v \geq \log_2 |\mathcal{L}_i^v| + \frac{1}{10}\log_2 k + \frac{1}{3}$, then S_i does not lie in $\mathcal{L}_i^v$ with probability at least $\frac{1}{100}$.*

Proof. Define Y to be equal to S_i if $S_i \in \mathcal{L}_i^v$, and to be equal to any element in $\mathcal{L}_i^v$ otherwise. Note that with this definition, $P(S_i \notin \mathcal{L}_i^v) = P(S_i \neq Y)$. Denote this probability by ε. Then, by Fano's inequality we have

$$H(S_i) - \log_2 |\mathcal{L}_i^v| \leq H(S_i) - H(Y) \leq H(S_i|Y) \leq H(\varepsilon) + \varepsilon \log_2 k.$$

Assume that $\varepsilon < 1/100$. Then

$$H(S_i) < \frac{1}{10}\log_2 k + \log_2 |\mathcal{L}_i^v| + H(1/100).$$

Since $H(1/100) < 1/3$, we get at a contradiction with the statement of the lemma. ◀

Now let's show that if at vertex v Alice or Bob sends one-bit message, then the entropy $H(x)$ on average does not decrease significantly.

▶ **Lemma 32.** *Let $I_v : P_{z,v} \to \{0,1\}$ denote the bit of information that Alice or Bob sends at vertex v. Then*

$$H(x|I_v) \geq H(x) - H(I_v) \geq H(x) - 1.$$

Proof. We have that

$$H(x|I_v) + H(I_v) = H(x, I_v) \geq H(x)$$

and

$$H(x|I_v) \geq H(x) - H(I_v) \geq H(x) - 1.$$ ◀

In other words, the entropy H of the distribution of x drops by no more than 1 on average on one step of the protocol. Next, we introduce the deficiency of the distribution. Let

$$U_i^v = \begin{cases} \log_2 k, & \text{if } S_i \text{ is not fixed;} \\ 0, & \text{if } S_i \text{ is fixed,} \end{cases}$$

and let the deficiency be

$$D^v = \left(\sum_{i=1}^n U_i^v\right) - H^v.$$

Note that $H(S_i) = 0$ if S_i is fixed. Thus, $D^v \geq 0$ for any v, as $\sum_{i=1}^n U_i^v \geq \sum_{i=1}^n H_i^v \geq H^v$. We will omit the superscript v if the vertex is clear from the context.

Now we consider $(x, y) \sim U(P_z)$ and introduce some random variables for various types of messages of $\overline{\Pi}_z$ on the input (x, y).

For this we consider a finer classification of the messages sent by Alice, compared to the one in Figure 1:

(A1) A message that Alice sends in Π.

(A2') A message $S_i \overset{?}{\in} \mathcal{L}_i$, such that we have $H_i \geq \log_2 |\mathcal{L}_i| + 1/3 + \frac{1}{10}\log_2 k$ before sending this message. In other words, in these messages S_i was not previously fixed.

(A2") A message $S_i \overset{?}{\in} \mathcal{L}_i$, such that we have $H_i < \log_2 |\mathcal{L}_i| + 1/3 + \frac{1}{10}\log_2 k$ before sending this message. In other words, in these messages S_i was previously fixed.

(A3') A message that Alice sends to find out the exact value of S_i, and S_i was not fixed before sending this message.

(A3") Same as (A3') but S_i was fixed before sending this message.

For Bob we use the same classification of messages as in Figure 1:

(B1) A message that Bob sends in Π.

(B2) A message in which Bob communicates the value y_{S_i}

Let $A_1, A'_2, A''_2, A'_3, A''_3, B_1, B_2$ denote the number of messages of the corresponding type sent by the protocol during the whole computation. All of these are random variables depending on (x, y), which we draw randomly: $(x, y) \sim U(P_z)$.

The following inequality hold.

▶ **Observation 33.** $\mathbb{E}A'_2 \leq 100 \cdot \mathbb{E}B_1$.

Proof. When Alice sends a message of type (A2'), by Lemma 31 the secret set S_i does not lie in $\mathcal{L}_i$ with probability at least $\frac{1}{100}$. If it does not lie in $\mathcal{L}_i$, the processing of the Bob's message is over. Thus, for each query of type (B1), there will be no more than 100 queries of type (A2') on average. ◀

▶ **Observation 34.** *At the end of the computation, the number of fixed S_i is greater or equal than A'_3. In particular, there are at least A'_3 coordinates i such that U_i decreased from $\log_2 k$ to 0. During each of these decreases of U_is, D decreases by at least $\max\{0, \frac{9}{10}\log_2 k - 1/3 - \log_2 |\mathcal{L}_i|\}$ on average.*

Proof. By definition, A'_3 is precisely equal to the number of the fixed secret sets S_i. When the status of S_i changes from unfixed to fixed, U_i drops from $\log_2 k$ to 0. Since U_i changes to 0 only when H_i becomes less than $\log_2 |\mathcal{L}_i| + 1/3 + \frac{1}{10}\log_2 k$ (as ensured by if's on lines 19 and 23), sending S_i transmits no more than $\log_2 |\mathcal{L}_i| + 1/3 + \frac{1}{10}\log_2 k$ information. Thus, we get the required decrease of D by at least $\max\{0, \frac{9}{10}\log_2 k - 1/3 - \log_2 |\mathcal{L}_i|\}$ on average. ◀

▶ **Observation 35.** *Messages of types (B2), (A2"), and (A3") do not affect D.*

Proof. A message of the type (B2) does not change D since pairs $(x, y) \in P_z$ have a property that $g(x_i, y_i) = z_i$. Thus, message y_{S_i} does not decrease the entropy of the distribution.

Just before a message M of type (A2") is sent, by definition, we have that $H_i < \log_2 |\mathcal{L}_i| + 1/3 + \frac{1}{10}\log_2 k$. But in lines $19 - 21$ it is ensured that if H_i is lower than this threshold, then S_i will be fixed. Thus, H_i is not only lower than $\log_2 |\mathcal{L}_i| + 1/3 + \frac{1}{10}\log_2 k$, but also equals to 0. Thus, $(A2'')$ does not influence D.

By definition, S_i is fixed before sending a message of type (A3"). Thus, $H_i = 0$ and sending S_i does not reveal any information. ◀

▶ **Observation 36.** *At the end of the protocol's execution, $\sum_i |L_i| \leq B_1 + B_2$.*

Proof. A new set Q is generated and added to the list of Q_is either when a message of type (B1) is sent, or after a message of type (B2) is sent. ◀

Let's show how the desired bound follows from these lemmas. Note that if S_i is revealed, then it must be fixed. As a consequence, we get $B_2 \le A'_3$ since B_2 equals the number of revealed sets and A'_3 equals the number of fixed ones. Our goal is to upper bound the number of revealed sets. Thus, we only need to upper bound $\mathbb{E}A'_3$ by $\mathbb{E}(A_1 + B_1)/\log_2 k$, as $A_1 + B_1$ is exactly the number of messages sent by the protocol Π.

▶ **Lemma 37.** $\mathbb{E}A'_3 = O(\mathbb{E}(A_1 + B_1)/\log_2 k)$

Proof. By Lemma 32 messages of type (A1) and (B1) increase D by no more than 1 on average. The same is true for messages of type (A2'). As a result, due to Observation 34 and Observation 35,

$$\mathbb{E}\left(-A'_3 \cdot \left(\frac{9}{10}\log_2 k - 1/3\right) + \sum_i \log_2 |\mathcal{L}_i| + A_1 + B_1 + A'_2\right) \ge 0,$$

since D is always greater or equal than than 0. Applying Observation 33 and rearranging we get

$$\mathbb{E}\left(\sum_i \log_2 |\mathcal{L}_i| + 101 \cdot B_1 + A_1\right) \ge \mathbb{E}A'_3 \cdot \left(\frac{9}{10}\log_2 k - 1/3\right).$$

Now we consider two cases.

1. $k \ge 3$
   Note that $\sum_i \log_2 |\mathcal{L}_i| \le \sum_i |L_i| \le B_1 + B_2$. Using the fact that $B_2 \le A'_3$ and the inequality above, we obtain

   $$\mathbb{E}\left(102 \cdot B_1 + A_1\right) \ge \mathbb{E}A'_3 \cdot \left(\frac{9}{10}\log_2 k - 4/3\right).$$

   Since $\frac{9}{10} \cdot \log_2 k > 4/3$, we get $\mathbb{E}A'_3 = O\left(\frac{\mathbb{E}A_1 + B_1}{\log_2 k}\right)$.
2. $k = 2$
   Note that if we are sending a message of type (A3') and it is true that $|L_i| \le 1$, then D decreases by at least $1 - (1/10 + 1/3) \ge \frac{1}{2}$ on average. The number of is such that $|L_i| \ge 2$ does not exceed $\frac{B_1+B_2}{2}$ by Observation 36. As a result,

   $$\mathbb{E}\left(-\frac{1}{2} \cdot \left(A'_3 - \frac{B_1 + B_2}{2}\right) + A_1 + B_1 + A'_2\right) \ge 0.$$

   Using $B_2 \le A'_3$, we get

   $$\mathbb{E}\left(5/4 \cdot B_1 + 100 \cdot B_1 + A_1\right) \ge \mathbb{E}A'_3 \cdot 1/4.$$

   Thus, we again obtain $\mathbb{E}A'_3 = O(\mathbb{E}(A_1 + B_1))$. ◀

Abstract

The study of space-bounded computation has drawn extensively from ideas and results in the field of communication complexity. Catalytic Computation (Buhrman, Cleve, Koucký, Loff and Speelman, STOC 2013) studies the power of bounded space augmented with a pre-filled hard drive that can be used non-destructively during the computation. Presently, many structural questions in this model remain open. Towards a better understanding of catalytic space, we define a model of *catalytic communication complexity* and prove new upper and lower bounds.

In our model, Alice and Bob share a blackboard with a tiny number of free bits, and a larger section with an arbitrary initial configuration. They must jointly compute a function of their inputs, communicating only via the blackboard, and must always reset the blackboard to its initial configuration. We prove several upper and lower bounds:

1. We characterize the simplest nontrivial model, that of one bit of free space and three rounds, in terms of $\mathbb{F}_2$ rank. In particular, we give natural problems that are solvable with a minimal-sized blackboard that require near-maximal (randomized) communication complexity, and vice versa.
2. We show that allowing constantly many free bits, as opposed to one, allows an exponential improvement on the size of the blackboard for natural problems. To do so, we connect the problem to existence questions in extremal graph theory.
3. We give tight connections between our model and standard notions of non-uniform catalytic computation. Using this connection, we show that with an arbitrary constant number of rounds and bits of free space, one can compute all functions in TC^0.

We view this model as a step toward understanding the value of filled space in computation.

1 Introduction

Communication complexity has proven an essential tool in analyzing the power of *space* in computation. For the well-studied problem of derandomizing space-bounded computation, i.e. proving $\mathsf{BPL} = \mathsf{L}$, the frontier pseudorandom generators of [36, 31] are analyzed by considering the space-bounded algorithm as a communication protocol. There has been extensive work analyzing restricted classes of space-bounded algorithms, again relying on this connection [9, 40, 16]. Other works have tightly characterized the space required to solve fundamental problems such as estimating the bias of a coin [10, 7, 8], using sophisticated measures of information complexity.

Concurrently, a new model of bounded-space computation known as *catalytic* computation was introduced by Buhrman, Cleve, Koucký, Loff and Speelman [13], and used to solve fundamental computational problems more efficiently. In the Catalytic Logspace (CL) model, an algorithm receives an n-bit input, $O(\log n)$ bits of standard working space, and an auxiliary $\mathsf{poly}(n)$ bit catalytic tape τ. This tape has an arbitrary initial configuration, and must be reset to that starting configuration at the end of the computation. Despite a possible intuition that such a tape would not be useful, they showed that CL is likely to be *strictly* stronger than L – in particular, it contains logspace-uniform TC^1, and thus nondeterministic logspace (NL). Recently, Cook and Mertz used catalytic algorithms to show that the tree-evaluation problem, a candidate problem for separating L and P, can in fact be solved by an algorithm running in space $O(\log n \log\log n)$, contradicting long-standing prior beliefs [18, 19, 21]. Due to the striking power of this model, there have been many followup papers studying its structure [22, 15, 28, 39]. In the other direction, [17] used tools from the space-bounded literature (in particular, communication bottlenecks) to unconditionally *derandomize* CL. However, many basic questions remain open – it is consistent with current knowledge that $\mathsf{P} \subseteq \mathsf{CL}$, or that $\mathsf{CL} \subseteq \mathsf{NC}^2$, and there is no conditional evidence in either direction.

We aim to understand the power of access to a full memory by developing and studying the phenomenon in the setting of *communication complexity* – to what extent can such un-erasable extra memory be useful in exchanging information between two (computationally unbounded) parties?

1.1 Our Contribution: Catalytic Communication Complexity

We develop a natural model of catalytic communication complexity and prove several results, including maximal separations from the standard model of (randomized) communication complexity, a characterization of efficient protocols for the equality function in terms of extremal graph theory, and a strong equivalence between certain settings of the model and (nonuniform) catalytic computation itself.

Our model is defined as follows. There are two parties, Alice and Bob (perhaps graduate students coming to work on alternating days), sharing a single blackboard. Each party is computationally unbounded, but has no persistent memory between days, except what is written on the blackboard. Unfortunately, all but a tiny corner of the blackboard is currently full of someone else's important research, with instructions not to erase. Are Alice and Bob limited to sharing information through the tiny blank space, or can they do better by temporarily modifying the "Do Not Erase" section in such a way that still allows them to restore it when they're done? If they want to compute some function together, how big does the blackboard need to be, and how many days will they need? Such a model naturally captures the flow of information in a catalytic algorithm. The formal definition is as follows:

▶ **Definition 1** (Catalytic Communication Protocol). *Fix a function $f : \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$.*[1] *A **catalytic protocol computing f with r rounds, s bits of clean space, and c bits of catalytic space** consists of r many transition functions and one output function,*

$$A_1 : \{0,1\}^{n_a} \times \{0,1\}^c \times \{0,1\}^s \to \{0,1\}^c \times \{0,1\}^s$$

$$B_2 : \{0,1\}^{n_b} \times \{0,1\}^c \times \{0,1\}^s \to \{0,1\}^c \times \{0,1\}^s$$

[1] We will typically be concerned with the case $n_a = n_b = n$, but will also consider functions with asymmetric input lengths

$\dots$

$A_r : \{0,1\}^{n_a} \times \{0,1\}^c \times \{0,1\}^s \to \{0,1\}^c \times \{0,1\}^s$

$B_{out} : \{0,1\}^{n_b} \times \{0,1\}^c \times \{0,1\}^s \to \{0,1\}.$

(If r is even, we will instead have $B_r : \{0,1\}^{n_b} \times \{0,1\}^c \times \{0,1\}^s \to \{0,1\}^c \times \{0,1\}^s$ and $A_{out} : \{0,1\}^{n_a} \times \{0,1\}^c \times \{0,1\}^s \to \{0,1\}$.) For the protocol to be valid, for any $\tau \in \{0,1\}^c$, $x \in \{0,1\}^{n_a}$, $y \in \{0,1\}^{n_b}$, letting $A_i^{(x)} = A_i(x, \cdot)$ and $B_i^{(y)} = B_i(y, \cdot)$, these functions must satisfy

$$A_r^{(x)} \circ \dots \circ B_2^{(y)} \circ A_1^{(x)}(\tau, 0^s) = (\tau, w)$$

for some w with

$$B_{out}^{(y)}(\tau, w) = f(x, y).$$

In words, Alice and Bob's blackboard consists of c bits of arbitrarily-initialized catalytic space and s bits of initially-empty clean space. In a given round, the active party modifies the blackboard according to some arbitrary function of its current contents, the input visible to the active party, and the current timestep, then passes the blackboard to the other party. At the end of the protocol, the catalytic part of the blackboard must have been reset to its starting configuration, and the party with the blackboard must be able to announce the answer. Readers familiar with catalytic computing may observe that such a protocol could be described as an **amortized bipartite branching program**; this interpretation is the motivation for the particulars of our definition, and will be discussed in more detail in Section 6.

This model induces a corresponding measure of communication complexity:

▶ **Definition 2** (Catalytic Communication Complexity). *The **r-round s-clean catalytic communication complexity** of a function $f : \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$, denoted $\mathsf{CC}_{r,s}(f)$, is the minimum value of c such that f has an r-round catalytic protocol with s bits of clean space and c bits of catalytic space.*

The following three propositions represent simple observations about catalytic communication, demonstrating that this complexity measure is both well-defined and interesting. We give only the statements here; the associated proofs can be found in Section A. First note that with fewer than 3 rounds, the catalytic space is provably useless – in particular, this means that $\mathsf{CC}_{1,s}(f)$ and $\mathsf{CC}_{2,s}(f)$ are not well-defined for every f, since there may be no amount of catalytic space that suffices:

▶ **Proposition 3.** *Any function computable by a catalytic protocol with 1 or 2 rounds is computable by such a protocol with no catalytic space (i.e. there exists a memoryless protocol with the same amount of clean space, so without loss of generality only the clean space is used).*

For $r \geq 3$, $s \geq 1$, however, with enough catalytic space it is possible to compute any function, so $\mathsf{CC}_{r,s}(f)$ is always well-defined:

▶ **Proposition 4.** *Every function $f : \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$ has a 3-round catalytic protocol with 1 bit of clean space and $2^{\min(n_a, n_b)}$ bits of catalytic space.*

Proposition 4 represents an upper bound on catalytic communication complexity in general, but it is far from tight for some functions. Recall the inner product function (over $\mathbb{F}_2$) $\mathsf{IP}_n : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$, defined as $\mathsf{IP}_n(x,y) = \langle x, y\rangle$. We show that IP can be computed with one bit of clean space and n bits of catalytic space:

▶ **Proposition 5.** *We have $\mathsf{CC}_{3,1}(\mathsf{IP}_n) \leq n$, i.e. the inner product function has a 3-round catalytic protocol with 1 bit of clean space and n bits of catalytic space.*

Note that this protocol is roughly as efficient as a catalytic protocol can possibly be: as long as f is left-injective (i.e. no two values of x result in the same function $f(x,\cdot)$), it is clear for information theoretic reasons that the catalytic space cannot be made much less than n bits, and certainly the clean space required for any non-constant f must be at least 1 bit – so inner product is essentially the *easiest possible* function for this model. This is in contrast to standard notions of communication complexity: inner product has, up to constant factors, maximal deterministic and randomized communication complexity [41]. Such a separation even for a single bit of clean space indicates that the "picture" of catalytic communication can diverge widely from that of standard models.

Furthermore, unlike deterministic and randomized communication complexity, there does not appear to be a direct counting argument showing that a random function requires any amount of catalytic space larger than the trivial bound of n. Despite this barrier, we give a tight characterization of protocols with one bit of clean space and three rounds. As our first main result, we show that $\mathsf{CC}_{3,1}$ is characterized up to a constant factor by $\mathbb{F}_2$ rank:

▶ **Theorem 6.** *For any $f\colon \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$,*

$$\frac{\mathrm{rk}(f)}{6} - o(1) \leq \mathsf{CC}_{3,1}(f) \leq \mathrm{rk}(f),$$

where $\mathrm{rk}(f)$ denotes the rank of the communication matrix over $\mathbb{F}_2$.

The proof of the upper bound of Theorem 6 is an explicit protocol, while the lower bound involves an application of Harper's vertex-isoperimetric theorem on an appropriate subspace of the Boolean hypercube. We remark that several standard communication complexity measures are suspected to be closely controlled by appropriate notions of the rank of the communication matrix, but this case is unusual in that it is the rank over $\mathbb{F}_2$, as opposed to $\mathbb{R}$, that is relevant.

This establishes catalytic communication complexity as a very different measure from standard ones. In particular, if one compares catalytic communication complexity against standard randomized communication complexity[2], there are maximal separations for natural functions in *both* directions. Inner product has a maximally efficient 3-round 1-clean catalytic communication protocol but no standard randomized communication protocol with communication less than the trivial $\Omega(n)$. On the other hand, the equality function EQ_n has $\mathsf{CC}_{3,1}(\mathsf{EQ}_n) = \Omega(2^n)$ but randomized communication complexity $O(1)$ [41].

The lower bound approach we use for $\mathsf{CC}_{3,1}$ does not extend to $\mathsf{CC}_{3,2}$, i.e. protocols with a single extra bit of clean space. This is not simply a consequence of technical limitations – we show that for equality, allowing a single additional bit of clean space enables an exponentially more efficient protocol:

[2] Comparing against *deterministic* standard communication complexity, we would instead find that catalytic communication is strictly stronger, in the sense that $\log(\mathsf{CC}_{3,1}(f))$ is always at most the deterministic communication complexity of f.

▶ **Theorem 7.** *We have that* $\mathsf{CC}_{3,2}(\mathsf{EQ}_n) \leq O(n \log n)$.

Our protocol for equality follows from a connection to a new variant we propose of the well-known Ruzsa–Szemerédi problem in extremal graph theory. We demonstrate that efficient 3-round catalytic protocols for equality can be obtained generically from constructions of "full Ruzsa–Szemerédi graphs", a special case of Ruzsa–Szemerédi graphs. We show that the current frontier Ruzsa–Szemerédi construction can be modified to satisfy our stronger condition, and hence obtain an efficient protocol. We also show a reverse implication – that is, that efficient protocols imply dense Ruzsa–Szemerédi constructions – enabling us to obtain nontrivial lower bounds for the complexity of equality:

▶ **Theorem 8.** *For any constant* s*, we have* $\mathsf{CC}_{3,s}(\mathsf{EQ}_n) \geq n + \Omega(\log^*(n))$.

In addition to this unconditional lower bound, the connection to Ruzsa–Szemerédi graphs also gives a barrier result: improving our upper bound to $\mathsf{CC}_{3,O(1)}(\mathsf{EQ}_n) = O(n)$ would yield (among other things) a polynomial query *lower* bound for testing monotonicity of Boolean functions over general posets.

Towards obtaining lower bounds stronger than $n + \Omega(\log^* n)$, we propose considering protocols for the **indexing problem** $\mathsf{IND}_n : \left([2^n] \times \{0,1\}^{2^n}\right) \to \{0,1\}$, $\mathsf{IND}_n(x, y) = y[x]$. Here, Alice's input is a length-n bitstring representing an index, and Bob's input is a length-2^n bitstring, with the output of the function being the bit of Bob's input corresponding to Alice's index. Another description of this problem is that Alice is given some n-bit input, and Bob is given the truth table of some arbitrary boolean function on n-bit inputs, and they must compute the evaluation of Bob's function on Alice's input. It is clear from this phrasing that proving a complexity lower bound on any function in terms of Alice's input length would require proving at least as strong a lower bound on IND_n, as any other function is a special case. We find a graph theoretic characterization of protocols for this problem, which allows us to show a non-trivial lower bound via the Kővári-Sós-Turán theorem.

▶ **Theorem 9.** *We have* $\mathsf{CC}_{3,s}(\mathsf{IND}_n) \geq (1 + \varepsilon)n$*, for some constant* ε *depending on* s.

While we suspect Theorem 9 is far from tight, it remains open to show super-linear lower bounds even for 2 clean bits.

Finally, we study protocols with more rounds. We note that our measure of catalytic communication complexity corresponds directly to the minimum amount of amortization required in an amortized bipartite branching program of bounded length. Since an ordinary branching program is in particular a bipartite branching program, this immediately lets us translate known results from nonuniform catalytic computing to show statements such as $\mathsf{CC}_{\mathsf{poly}(n),O(1)}(f) \leq O(n)$ for all f. By a more specialized analysis of Buhrman, Cleve, Koucký, Loff and Speelman's algebraic proof of $\mathsf{TC}^1 \subseteq \mathsf{CL}$, we are also able to show the following:

▶ **Theorem 10.** *Let* $f\colon \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$ *be any function computable by a size* S*, depth* d *majority circuit with arbitrary input preprocessing – that is, there exists a depth-*d *circuit* C *composed of* S *many majority gates, and arbitrary functions* g, h*, such that* $f(x, y) = C(g(x), h(y))$*. Then,* $\mathsf{CC}_{4^d,1}(f) \leq \mathsf{poly}(S, 2^d)$.

This implies in particular that any TC^0 function family has constant-round, 1-clean catalytic protocols with $\mathsf{poly}(n)$ catalytic space.

We view these results as indicating that catalytic communication complexity is both an interesting model in its own right, and one that can shed light on reusing space more generally. We remark that our model addresses a question raised in prior work on variants of communication complexity, which we now discuss.

1.2 Related Work

Identifying an interesting communication analogue of catalytic computing was posed as an open problem by Arunachalam and Podder in a paper on space-bounded communication [2]. Space-bounded communication complexity was first studied by Brody, Chen, Papakonstantinou, Song and Sun, who proposed a model in which the two parties in a standard communication protocol are in addition required to compress each of their states into a small number of bits after each message is sent [11]. Subsequent work by Papakonstantinou, Scheder, and Song considered a one-way model, in which Alice (a party with unbounded memory) sends messages of length s to Bob (a party with zero, or only constant, memory) – they showed that when Bob is memoryless, this model can be characterized in terms of a combinatorial notion of rectangle overlays, and when Bob has only 5 available memory states and $s = \mathsf{polylog}(n)$ this model computes exactly PSPACE^{cc} [37]. Arunachalam and Podder suggested instead letting both Alice and Bob be memoryless, and measuring complexity in terms of the size of a block of memory they pass back and forth [2]. They noted that this model aligns closely with bipartite branching program complexity, and that variants could capture the aforementioned models of Brody, Chen, Papakonstantinou, Song and Sun [11] and Papakonstantinou, Scheder and Song [37], as well as the "garden hose" model of Buhrman, Fehr, Schaffner and Speelman [14]. Our model can be thought of as a version of Arunachalam and Podder's memoryless framework where the size of the block of memory passed back and forth is *amortized*, in a sense analogous to the way workspace usage is amortized across inputs in a catalytic algorithm.

2 Preliminaries

We will by convention denote a setting of the catalytic portion of the blackboard by τ (for "transparent registers"), a setting of the initially-clean portion by ω (for "work registers"), and a setting of the entire blackboard by γ (for no particular reason). We will let $x \in \{0,1\}^{n_a}$ be the input given to Alice, and $y \in \{0,1\}^{n_b}$ be the input given to Bob. We now define a few terms and notations which appear in the statements and proofs.

▶ **Definition 11.** *For any n, we denote by IP_n the inner product function over $\mathbb{F}_2^n$. That is,*

$$\mathsf{IP}_n : \{0,1\}^n \times \{0,1\}^n \to \{0,1\},$$

$$\mathsf{IP}(x,y) = \sum_{i\in[n]} x_i y_i \mod 2.$$

▶ **Definition 12.** *For any n, we denote by EQ_n the equality function on n-bit inputs. That is,*

$$\mathsf{EQ}_n : \{0,1\}^n \times \{0,1\}^n \to \{0,1\},$$

$$\mathsf{EQ}(x,y) = \begin{cases} 1 \text{ if } x = y \\ 0 \text{ if } x \neq y \end{cases}.$$

▶ **Definition 13.** *For any n, we denote by IND_n the function taking an n-bit index and a 2^n-bit bitstring to the value of that bitstring at that index. That is,*

$$\mathsf{IND}_n : [2^n] \times \{0,1\}^{2^n} \to \{0,1\},$$

$$\mathsf{IND}_n(x,y) = y[x].$$

▶ **Definition 14.** *For a function $f : \{0,1\}^{n_a} \to \{0,1\}^{n_b} \to \{0,1\}$, let the **communication matrix** of f be the $2^n \times 2^n$ matrix M where $M_{x,y} = f(x,y)$, and let $\mathrm{rk}(f)$ be the rank of M over $\mathbb{F}_2$.*

For a function on two inputs $f\colon X, Y \to Z$, we will use $f(x,\cdot)$ to denote the application $f(x,\cdot)\colon Y \to Z$. We say a function $f\colon X, Y \to Z$ is **left-injective** if there do not exist $x \neq x' \in X$ such that $f(x,\cdot)$ and $f(x',\cdot)$ are identical functions. For integers n, we will write $[n]$ to denote $\{1,\dots,n\}$. To denote to a multiset with elements $a_1,\dots,a_n$, we will use the "bag" notation $\wr a_1,\dots,a_n\int$.

3 Characterizing 3-Round 1-Clean Complexity

In this section, we prove Theorem 6.

▶ **Theorem 6.** *For any $f\colon \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$,*

$$\frac{\mathrm{rk}(f)}{6} - o(1) \leq \mathsf{CC}_{3,1}(f) \leq \mathrm{rk}(f),$$

where $\mathrm{rk}(f)$ denotes the rank of the communication matrix over $\mathbb{F}_2$.

We first give the upper bound, showing that any function with small rank has an efficient catalytic protocol.

▶ **Lemma 15.** *For any $f\colon \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$, we have $\mathsf{CC}_{3,1}(f) \leq \mathrm{rk}(f)$.*

Proof. By definition of rank, the rows of f's communication matrix span a $\mathrm{rk}(f)$-dimensional subspace of $\mathbb{F}_2^n$. Both parties fix ahead of time a basis $v_1,\dots v_{\mathrm{rk}\, f}$ for this subspace, and define a protocol as follows:

1. On the first round, Alice finds $T \subseteq [\mathrm{rk}\, f]$ such that $\bigoplus_{i\in T} v_i$ is the xth row of the communication matrix (i.e., is equal to the truth table of the function $y \mapsto f(x,y)$), and sets the catalytic portion of the blackboard to $\tau \oplus 1_{i\in T}$.
2. Bob computes $\bigoplus_{i\in[\mathrm{rk}\, f]} \tau_i v_i$, and writes the yth entry of the result to the clean portion.
3. Alice XORs out the same string she XORed in, resetting the catalytic portion.
4. Bob finds the new yth entry of $\bigoplus_{i\in[\mathrm{rk}\, f]} \tau_i v_i$, and outputs its XOR with the clean bit.

The correctness of this protocol is straightforward. After the second round of the protocol, Bob sets the clean bit to

$$b_1 = \left(\bigoplus_{i\in[\mathrm{rk}\, f]} (\tau_i \oplus 1_{i\in T}) v_i \right)_y,$$

and so his final output will be

$$b_1 \oplus \left(\bigoplus_{i\in[\mathrm{rk}\, f]} \tau_i v_i \right)_y = \left(\bigoplus_{i\in T} v_i \right)_y = f(x,y),$$

as desired. The resource consumption is immediate from the protocol definition. ◀

We would like to show that it is impossible to do substantially better than the above protocol. Note that the protocol described in Lemma 15 follows a simple pattern: Alice modifies only the catalytic portion of the blackboard, performing some bijective map on all possible settings, Bob uses only the clean portion of the blackboard to "remember" one bit

about the result, and then Alice undoes her bijection and Bob makes his output decision based on his remembered bit in addition to that initial catalytic configuration. For the purposes of showing lower bounds, it would be helpful first to claim that without loss of generality all 3-round protocol must be of that form. However, this is not *quite* true. For one, Alice could use the clean portion of the blackboard to send Bob an additional bit of information about her input on the first round, which is provably helpful sometimes. Another rather more substantial concern is that there's room for "amortization" in the amount of information that Bob remembers: it could, for instance, be possible that, on some particular settings of Alice's input x and the initial catalytic setting C, Alice can on her first round encode all of the catalytic information in a small prefix of the tape – in such cases, Bob could use the rest to send Alice a large amount of information about *his* input, which would then inform her in choosing a single bit send him back in the clean space of the final setting. However, we expect that this latter sort of behaviour should only happen rarely, since most initial catalytic settings can't be compressed. In the full version, we address these concerns formally, guaranteeing that any 3-round 1-clean catalytic protocol can be converted into a protocol that *almost* follows the simple pattern we noted. Specifically, we show the following:

▶ **Lemma 16.** *Every left-injective function $f : \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$ with $\mathsf{CC}_{3,1}(f) = c$ has a protocol of the following form, which we'll call a* ***mostly-one-way-catalytic protocol****:*

1. *For every $x \in \{0,1\}^{n_a}$, Alice has an injective function $\alpha^{(x)} : \{0,1\}^c \to \{0,1\}^c \times \{0,1\}^3$.*
2. *For every $y \in \{0,1\}^{n_b}$, Bob has two functions, $\beta^{(y)}_{rem} : \{0,1\}^c \times \{0,1\}^3 \to \{0,1\}$ and $\beta^{(y)}_{out} : \{0,1\}^c \times \{0,1\} \to \{0,1\}$.*
3. *Call a pair $(x,\tau) \in \{0,1\}^{n_a} \times \{0,1\}^c$* ***bad*** *if, for some $y \in \{0,1\}^{n_b}$, we have*

$$\beta^{(y)}_{out}(\tau, \beta^{(y)}_{rem}(\alpha^{(x)}(\tau))) \neq f(x,y).$$

Then, at most 2^{c+1} many pairs are bad.

Additionally, we may assume that, for every τ, y, we have $\beta^{(y)}_{out}(\tau,0) \neq \beta^{(y)}_{out}(\tau,1)$.

This observation will allow us to associate a communication protocol with a structured collection of vectors in $\mathbb{F}_2^{2^{n_b}}$, whose size we can bound using standard combinatorial facts.

Proof of Theorem 6. The upper bound was shown in Lemma 15; it remains to show the lower bound. Note that removing duplicate rows from the communication matrix of a function can change neither its rank, nor the catalytic communication complexity (since a protocol for the function on the larger domain could simply treat several of its inputs identically). So, it suffices to show the claim for left-injective functions. Also, note that, given the $o(1)$ term in the statement, it suffices to only consider the case where $\mathrm{rk}(f) \geq 1000$. We fix an arbitrary left-injective $f\colon \{0,1\}^{n_a} \times \{0,1\}^{n_b}$ with $\mathrm{rk}(f) \geq 1000$, and assume for contradiction that $\mathsf{CC}_{3,1}(f) < \mathrm{rk}(f)/6$.

By Lemma 16, we have a mostly-one-way-catalytic protocol for f with $c < \mathrm{rk}(f)/6$. We will use this protocol to define three multi-subsets $U, V, W \subseteq \{0,1\}^{n_b}$. For every $\gamma \in \{0,1\}^{c+3}$, let $u_\gamma \in \{0,1\}^{n_b}$ be the truth table of $y \mapsto \beta^{(y)}_{\mathrm{rem}}(\gamma)$, and let $U = \{\!\{u_\gamma \colon \gamma \in \{0,1\}^{c+3}\}\!\}$. For every $\tau \in \{0,1\}^c$, let $v_\tau \in \{0,1\}^{n_b}$ be the truth table of $y \mapsto \beta^{(y)}_{\mathrm{out}}(\tau,0)$, and let $V = \{\!\{v_\tau \colon \tau \in \{0,1\}^c\}\!\}$. Finally, for every bad $(x,\tau) \in \{0,1\}^{n_a} \times \{0,1\}^c$, let $w_{(x,\tau)}$ be the truth table of $y \mapsto f(x,y) \oplus \beta^{(y)}_{\mathrm{out}}(\tau,0)$, and let $W = \{\!\{w_{(x,\tau)} \colon (x,\tau) \text{ is bad}\}\!\}$.

Note that $|U| = 2^{c+3}$, $|V| = 2^c$, and $|W| \leq 2^{c+1}$. The idea of the proof will be to show that $U \cup W$ contains the neighbours in an appropriate Boolean hypercube of every element of V (with appropriate multiplicity) – since small subsets of the hypercube have large vertex

boundary compared to their volume, but we know that $|U| + |W|$ is only a constant factor larger than $|V|$, this will allow us to give a lower bound on c. This approach is formalized as follows.

Imagine placing red and blue pebbles on $\mathbb{F}_2^{n_b}$, such that each element of $\mathbb{F}_2^{n_b}$ gets a number of red pebbles equal to the number of times it appears in $U \cup W$, and a number of blue pebbles equal to the number of times it appears in V. We claim that the following must hold:

▷ Claim 17. For any such pebbling constructed from a valid protocol, for any $k \in \mathbb{N}$, if $v \in \mathbb{F}_2^{n_b}$ has at least k blue pebbles and $r \in \mathbb{F}_2^{n_b}$ is a row of f's communication matrix (i.e. r is the truth table of $y \mapsto f(x, y)$ for some x), then $v \oplus r$ has at least k red pebbles.

Proof of Claim 17. Because v has at least k blue pebbles, there are at least k distinct initial catalytic configurations $\tau_1, \ldots, \tau_k \in \{0,1\}^c$ such that $v_{\tau_i} = v$. Let x be the input such that r is the truth table of $y \mapsto f(x, y)$. For every bad τ_i, we have $w_{(x,\tau_i)} = r \oplus v_{\tau_i} = v \oplus r$, so each of these will contribute a red pebble to $v \oplus r$. Then, since $\alpha^{(x)}$ is injective, each of $\alpha^{(x)}(\tau_1), \ldots, \alpha^{(x)}(\tau_k)$ must be distinct. So, to obtain the remainder of the red pebbles, we'll show that whenever (x, τ_i) is not bad, $u_{\alpha^{(x)}(\tau_i)} = v \oplus r$.

Note that r is the truth table of $y \mapsto f(x, y) \oplus v$, that $v = v_{\tau_i}$ is the truth table of $y \mapsto \beta^{(y)}_{\text{out}}(\tau_i, 0)$, and that $u_{\alpha^{(x)}(\tau_i)}$ is the truth table of $y \mapsto \beta^{(y)}_{\text{rem}}(\alpha^{(x)}(\tau_i))$. So, to conclude that $r = v \oplus u_{\alpha^{(x)}(\tau_i)}$, we need to show that, for all y, we have $f(x, y) = \beta^{(y)}_{\text{out}}(\tau_i, 0) \oplus \beta^{(y)}_{\text{rem}}(\alpha^{(x)}(\tau_i))$.

Since (x, τ_i) is not bad, we have $f(x, y) = \beta^{(y)}_{\text{out}}(\tau, \beta^{(y)}_{\text{rem}}(\alpha^{(x)}(\tau)))$. If $\beta^{(y)}_{\text{rem}}(\alpha^{(x)}(\tau)) = 0$, this gives $f(x, y) = \beta^{(y)}_{\text{out}}(\tau, 0) = \beta^{(y)}_{\text{out}}(\tau, 0) \oplus 0$, so the claim holds. If, on the other hand, $\beta^{(y)}_{\text{rem}}(\alpha^{(x)}(\tau)) = 1$, we have $f(x, y) = \beta^{(y)}_{\text{out}}(\tau, 1)$. But then, since we always have $\beta^{(y)}_{\text{out}}(\tau, 0) \neq \beta^{(y)}_{\text{out}}(\tau, 1)$, we know that $\beta^{(y)}_{\text{out}}(\tau, 1) = \beta^{(y)}_{\text{out}}(\tau, 0) \oplus 1$. ◁

This will be sufficient to prove that there must be many blue pebbles, contradicting the assumption that c is small. Consider the graph on $\mathbb{F}_2^{n_b}$ where an edge (u, v) exists whenever $u \oplus v$ is a row of f's communication matrix. This graph consists of $2^{n_b}/2^{\text{rk}(f)}$ many identical connected components. If we fix some subset $X \subseteq \{0,1\}^{n_a}$ such that the corresponding rows of the communication matrix form a basis for the row-space, and consider only the edges generated by those rows, each of these connected components will be isomorphic to the $\text{rk}(f)$-dimensional hypercube. At least one of these connected components must contain a blue pebble; we will restrict our attention to one such connected component.

Claim 17 ensures that each vertex of this hypercube has at least as many red pebbles as the maximum number of blue pebbles among its neighbours. Consider the set S of vertices with at least one blue pebble. All vertices adjacent to a vertex of S must have at least one red pebble; we claim that there are many such vertices.

▷ Claim 18. For any subset $S \subseteq \mathbb{F}_2^{\text{rk}(f)}$ with $|S| \leq 2^{\text{rk}(f)/6}$, we have $|N(S)| > 10 \cdot |S|$, where $N(S)$ denotes the set of all Hamming neighbours of elements of S.

Proof of Claim 18. Take S to be a set of the smallest possible size such that $|N(S)| \leq 10 \cdot |S|$. Harper's theorem states that, among all subsets of the Boolean hypercube of a given size, the vertex boundary is minimized by a Hamming ball. That is, for any ℓ, if $|S| = \sum_{i=0}^{\ell} \binom{\text{rk}(f)}{i}$, then $|N(S) \setminus S| \geq \binom{\text{rk}(f)}{\ell+1}$ [29, 6]. Let ℓ be the radius of the smallest Hamming sphere larger than our fixed set S; i.e., the smallest integer such that $|S| \leq \sum_{i=0}^{\ell} \binom{\text{rk}(f)}{i}$. Since $\min_{S:\,|S|=s} \left(\frac{|N(S)|}{|S|} \right)$ is monotonically nonincreasing in s for small s[3], the surface-area-to-volume ratio of this Hamming sphere lower bounds that of S:

[3] As long as s is small enough that a Hamming ball of that size can't have vertex boundary less than

$$\frac{|N(S)|}{|S|} \geq \frac{\binom{\mathrm{rk}(f)}{\ell+1}}{\sum_{i=0}^{\ell}\binom{\mathrm{rk}(f)}{i}}.$$

By minimality of S, we know that $\sum_{i=0}^{\ell'}\binom{\mathrm{rk}(f)}{i} \leq \binom{\mathrm{rk}(f)}{\ell'+1}$ for all $\ell' < \ell$, since otherwise the Hamming ball of radius ℓ' would be a smaller example. So, $\sum_{i=0}^{\ell}\binom{\mathrm{rk}(f)}{i} \leq \binom{\mathrm{rk}(f)}{\ell} + \sum_{i=0}^{\ell-1}\binom{\mathrm{rk}(f)}{i} \leq 2\binom{\mathrm{rk}(f)}{\ell}$. Thus,

$$\frac{|N(S)|}{|S|} \geq \frac{\binom{\mathrm{rk}(f)}{\ell+1}}{2\binom{\mathrm{rk}(f)}{\ell}} = \frac{\frac{\mathrm{rk}(f)!}{(\ell+1)!(\mathrm{rk}(f)-\ell-1)!}}{\frac{2\,\mathrm{rk}(f)!}{\ell!(\mathrm{rk}(f)-\ell)!}} = \frac{(\mathrm{rk}(f)-\ell)}{2(\ell+1)}.$$

Since we assumed that $\frac{|N(S)|}{|S|} \leq 10$, this gives $\ell \geq \frac{\mathrm{rk}(f)-19}{20}$. Now, we have

$$|S| \geq \sum_{0}^{\ell-1}\binom{\mathrm{rk}(f)}{i} \geq \binom{\mathrm{rk}(f)}{\ell-1} \geq 2^{\mathrm{rk}(f)\cdot H\left(\ell/\,\mathrm{rk}(f)\right)-\log\left(\mathrm{rk}(f)\right)} \geq 2^{\mathrm{rk}(f)\cdot H\left(1/20-1/\,\mathrm{rk}(f)\right)-\log\left(\mathrm{rk}(f)\right)},$$

where $H\colon p \mapsto -p\log(p) - (1-p)\log(1-p)$ is the binary entropy function. For all values of $\mathrm{rk}(f) \geq 1000$, we have $\mathrm{rk}(f)H\big(1/20 - 1/\,\mathrm{rk}(f)\big) - \log\big(\mathrm{rk}(f)\big) > \frac{\mathrm{rk}(f)}{6}$, so this implies that $|S| > 2^{\left(\mathrm{rk}(f)/6\right)}$. ◁

We can't immediately a derive contradiction from Claim 17 and Claim 18, because V is a multiset (i.e. some vertices may have more than one red pebble). However, this is not a serious obstacle.

▷ Claim 19. Suppose a pebbling satisfies the conditions of Claim 17 – i.e., that $v \oplus r$ always has at least as many blue pebbles as v has red pebbles for any row r of the communication matrix. Then, if we remove one blue pebble from every vertex with at least one blue pebble, and one red pebble from any vertex with at least one red pebble, that condition still holds.

Proof. Consider any v and any r. Before removal, $v \oplus r$ had at least as many blue pebbles as v had red pebbles. If v had 0 blue pebbles, then after removal this will remain the case, so $v \oplus r$ will still be at least as pebbled. Otherwise, we will remove the same number of blue pebbles from v as we remove red pebbles from $v \oplus r$. ◁

If we remove a single blue pebble from every vertex with at least one blue pebble, and a single red pebble from every vertex with at least one red pebble, Claim 18 ensures that we will remove strictly more than ten times as many red pebbles as blue pebbles. After removing those pebbles, there are still at most 2^c vertices with blue pebbles, and we've just shown that Claim 17 still holds – so, we can repeatedly perform such removals until all pebbles are gone, always removing strictly more than ten times as many red pebbles as blue pebbles. This means that the graph overall has *strictly* more than ten times as many red pebbles as blue pebbles, contradicting the fact that $|U| + |W| = 2^{c+3} + 2^{c+1} = 10 \cdot 2^c = 10 \cdot |V|$. ◀

One interesting consequence of Theorem 6 is that the equality function, which has constant randomized communication complexity, requires the maximal $\Omega(2^n)$ blackboard size in this catalytic model. On the other hand, as noted, the inner product function can

twice the volume (which, as we show, is true here), one can observe that adding a new point at the boundary will always increase the surface-area-to-volume ratio.

be communicated with only n bits of catalytic space, despite requiring (up to constant factors) maximal standard communication complexity even with randomness [41]. Catalytic communication complexity seems to be quantifying a very different notion from standard communication complexity measures.

A natural question at this stage is whether our choice to restrict to only a single bit of clean space was roughly without loss of generality, or whether protocols with more clean space can look substantially different. Having more free space is definitely at least moderately helpful: for instance, equality can be computed with 2 bits of free space and $2 \cdot 2^{n/2}$ bits of catalytic space, by simply running two copies of the 1-bit protocol on the two halves of the inputs simultaneously, and having Bob output the AND of the answers. But one might suspect that, with only a little more clean space, there is not too much more that can be done – perhaps for any constant s it's possible to show that $\mathsf{CC}_{3,s}(\mathsf{EQ}_n) \geq 2^{\Omega(n)}$. As we will show in the next section, this intuition turns out to be false – even with two just bits of clean space, it's possible to communicate equality very efficiently.

4 The 3-Round Complexity of Equality

In this section, we prove the following upper bound on 3-round 2-clean catalytic complexity of equality.

▶ **Theorem 7.** *We have that* $\mathsf{CC}_{3,2}(\mathsf{EQ}_n) \leq O(n \log n)$.

The key to the proof of Theorem 7 comes from a long line of research on graphs representable as the union of many large induced matchings, known as Ruzsa–Szemerédi graphs. We will provide background on the Ruzsa–Szemerédi problem in Section 4.1, where we will also introduce a variant important for our application. In Section 4.2, we will demonstrate how any such construction can be generically converted into a catalytic protocol for equality, which will in particular prove Theorem 7.

In Section 4.3 we will demonstrate a reverse implication – that is, that efficient 3-round equality protocols give dense Ruzsa–Szemerédi protocols – which will allow us to state catalytic communication complexity lower bounds. We will show unconditionally that there exists no 3-round $O(1)$-clean protocol for equality using $n + O(1)$ bits of catalytic space, and show that finding any stronger upper bound than $O(n \log n)$ would require improved graph theoretic constructions that would in turn prove new *lower* bounds in areas such as property testing and streaming algorithms.

4.1 Background on the Ruzsa–Szemerédi Problem

We give the following definition:

▶ **Definition 20.** *A graph G is an (r, t)-**Ruzsa–Szemerédi graph** if there exists a partition of its edges into t sets of size r, such that each set constitutes an induced matching in G.*

In 1976, motivated by a problem of Brown, Erdős and Sós on 3-uniform hypergraphs containing no 6 vertices sharing 3 edges [12], Ruzsa and Szemerédi proposed studying such graphs, with the goal of finding examples where both r and t are large compared to number of vertices of G. They showed that Behrend's construction of sets without 3-term arithmetic progression [4] gives $\left(\frac{n}{2^{O(\sqrt{\log(n)})}}, \frac{n}{3}\right)$-Ruzsa–Szemerédi graphs, and used regularity methods to show that r and t cannot both be made $\Omega(n)$ [43]. The best known upper bounds still go through graph regularity: Fox's improved bounds for triangle removal imply that if $r = \Theta(n)$, then $t \leq \frac{n}{2^{\Omega(\log^*(n))}}$ [24].

Ruzsa–Szemerédi graphs have since seen several applications in computational and communication complexity [30, 5, 35]. In particular, constructions where $r = \Theta(n)$ and t is large have been used to obtain a number of lower bounds in streaming algorithms and property testing [23, 27, 33, 32, 3]. The best known lower bound on t when $r = \Theta(n)$ is due to Fischer, Lehman, Newman, Raskhodnikova, Rubinfeld and Samorodnitsky, giving a construction where $r = n/3$ and $t \geq n^{\Omega\left(\frac{1}{\log\log(n)}\right)}$ – eliminating the gap between this bound and the $t \leq \frac{n}{2^{\Omega(\log^*(n))}}$ upper bound is a major open problem in combinatorics [23].

For our application, we also give the following more restrictive definition:

▶ **Definition 21.** *A graph G is a (k,t)-**full Ruzsa–Szemerédi graph** if there exists a partition of its edges into t perfect matchings, and a partition of each of those matchings into k partial matchings, such that each partial matching is induced in G.*

Note that a (k,t)-full Ruzsa–Szemerédi graph is in particular a $(n/2k, kt)$-Ruzsa–Szemerédi graph, but that here we are imposing an additional constraint by requiring that the induced matchings can be grouped together to form perfect matchings in G. The construction presented by Fischer, Lehman, Newman, Raskhodnikova, Rubinfeld and Samorodnitsky is not a full Ruzsa–Szemerédi graph, but we show in the full version that it can easily be made so:

▶ **Lemma 22.** *As long as $n = 2\ell^\ell$ for some integer ℓ, there exists a $\left(3, n^{\Omega\left(\frac{1}{\log\log n}\right)}\right)$-full Ruzsa–Szemerédi graph.*

4.2 Equality Protocols from Full Ruzsa–Szemerédi Graphs

We now show that full Ruzsa–Szemerédi graphs can be generically converted to catalytic protocols.

▶ **Lemma 23.** *If there exists a (k,t)-full Ruzsa–Szemerédi graph on 2^c vertices, then there exists a 3-round, $\lceil\log(k)\rceil$-clean catalytic protocol for equality on $\lfloor\log(t)\rfloor$-bit inputs with c bits of catalytic space*[4]*.*

We first note that this will immediately give us our desired upper bounds on $\mathsf{CC}_{3,2}(\mathsf{EQ}_n)$.

Proof of Theorem 7 given Lemma 23. For some constant $0 < \delta < 1$, by Lemma 22, there exists a $(3, N^{\frac{\delta}{\log\log N}})$-full Ruzsa–Szemerédi graph on N vertices. Plugging this in to Lemma 23, we obtain a $\lceil\log(3)\rceil = 2$-clean catalytic protocol for equality on $\lfloor\log(t)\rfloor = \lfloor\delta\log(N)/\log\log(N)\rfloor$ bit inputs, requiring $\log(N)$ bits of catalytic space. Defining $n = \lfloor\log(t)\rfloor$, this is a 3-round 2-clean protocol with $O(n\log n)$ bits of catalytic space[5]. ◀

Proof of Lemma 23. Let G be such a graph, with vertices $V(G) = v_1, \ldots, v_{2^c}$, composed of perfect matchings $M_1 \sqcup \cdots \sqcup M_t = E(G)$. The full-Ruzsa–Szemerédi property gives, for each $i \in [t]$, a vertex partition $M_i^{(1)} \sqcup \cdots \sqcup M_i^{(k)} = V(G)$ such that the edges of M_i are the union

[4] Observe though, if one cares about such things, that unless that Ruzsa–Szemerédi graph can be constructed explicitly, the resulting protocol may not be computationally efficient. In order to get a computationally effective protocol from our construction, one would have to plug in an explicit code as opposed to just citing Gilbert-Varshanov.

[5] Note that this construction is only defined when both N is a power of two, and $N = 2\cdot\ell^\ell$ for some integer ℓ. However, if we let ℓ be the smallest power of two such that $2\cdot\ell^\ell \geq N$, and let $N' = 2\cdot\ell^\ell$, then note that $\log(N') \leq 4\cdot\log(N)$. So, for other values of n, Alice and Bob can simply pad their inputs with zeroes and run the equality protocol for a value of n where this is defined, losing only a constant factor in the amount of catalytic space required.

over j of the edges induced by $M_i^{(j)}$. Fix an arbitrary bijection $\pi\colon \{0,1\}^c \to \{v_1,\dots,v_N\}$, and arbitrary injections $\sigma\colon \{0,1\}^{\lfloor \log(t)\rfloor} \to \{M_1,\dots,M_t\}$, $\mu\colon [k] \to \{0,1\}^{\lceil \log k\rceil}$. The protocol is as follows.

1. $A_1(x,\tau,\omega) = (\pi^{-1}(v),\omega)$, where v is the neighbour of $\pi(\tau)$ in the matching $\sigma(x)$.
2. $B_2(y,\tau,\omega) = (\tau,\mu(w))$, where w is the unique value such that $\pi(\tau) \in \sigma(y)^{(w)}$.
3. $A_3(x,\tau,\omega) = (\pi^{-1}(v),\omega)$, where v is the neighbour of $\pi(\tau)$ in the matching $\sigma(x)$.
4. $B_{\text{out}}(y,\tau,\omega)$ accepts if and only if $\omega = \mu(w)$, where w is the unique value such that $\pi(\tau) \in \sigma(y)^{(w)}$.

Correctness of this protocol follows from the definition of a full Ruzsa–Szemerédi graph. If $x = y$, then the matchings $\sigma(x)$ and $\sigma(y)$ are the same. Since every edge of $\sigma(x)$ is induced by some part of the partition $\sigma(x)^{(1)},\dots,\sigma(x)^{(k)}$, this means that both endpoints of that edge belong to the same $\sigma(y)^{(w)}$, and so Bob will accept. If, on the other hand, $x \neq y$, then the two endpoints of an edge in $\sigma(x)$ cannot belong to the same $\sigma(y)^{(k)}$, because $\sigma(y)^{(k)}$ induces only the edges belonging to $\sigma(y)$. ◀

4.3 Lower Bounds on Equality Protocols

In this section, we will show that, as long as we are content with a not-necessarily-full Ruzsa–Szemerédi graph, the conversion in Lemma 23 can be done in reverse. That is, the existence of dense Ruzsa–Szemerédi graphs is necessary for efficient equality protocols. This will allow us to deduce both conditional and unconditional communication lower bounds.

▶ **Lemma 24.** *For any s, if there exists a 3-round, s-clean catalytic protocol for equality on n-bit inputs with c bits of catalytic space, there exists an $(\Omega(2^{c-s}),\Omega(2^{n-s}))$-Ruzsa–Szemerédi graph on $O(2^{c+4^s})$ vertices.*

For the purposes of proving this lemma, it would simplify matters to know that Alice only ever modifies the catalytic portion of the blackboard, and Bob only ever modifies the clean portion[6]. As in Section 3, although we cannot claim such behaviour without loss of generality, we can at least claim that, a substantial fraction of the time, Bob only remembers s bits.

▶ **Lemma 25.** *For any $s > 0$, any function $f : \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$ with $\mathsf{CC}_{3,s}(f) = c$ has a protocol of the following form, which we'll call a **sometimes-one-way-catalytic protocol**:*

1. *For every $x \in \{0,1\}^{n_a}$, Alice has an injective function $\alpha^{(x)} : \{0,1\}^c \to \{0,1\}^c \times \{0,1\}^{s\cdot(2^s+1)}$.*
2. *For every $y \in \{0,1\}^{n_b}$, Bob has two functions, $\beta_{rem}^{(y)} : \{0,1\}^c \times \{0,1\}^{s\cdot(2^s+1)} \to \{0,1\}^s$ and $\beta_{out}^{(y)} : \{0,1\}^c \times \{0,1\}^s \to \{0,1\}$.*
3. *Call a pair $(x,\tau) \in \{0,1\}^{n_a} \times \{0,1\}^c$ **bad** if, for some $y \in \{0,1\}^{n_b}$, we have $\beta_{out}^{(y)}(\tau,\beta_{rem}^{(y)}(\alpha^{(x)}(\tau))) \neq f(x,y)$. Then, at most a $2^s/(2^s+1)$ fraction of all pairs are bad.*

[6] In fact, in this case we note that an analysis similar to the one we present here would give a *full*-Ruzsa–Szemerédi graph, as opposed to just a Ruzsa–Szemerédi graph, demonstrating (up to some quantitative loss) an equivalence between full Ruzsa–Szemerédi graphs and this kind of "well-behaved" 3-round catalytic protocol for equality. We suspect that such an equivalence should also exist without the well-behavedness condition – perhaps even that full Ruzsa–Szemerédi graphs can be generically constructed from Ruzsa–Szemerédi graphs – however we do not know a proof.

Proof of Lemma 24. By Lemma 25, we have a sometimes-one-way catalytic protocol for f with c bits of catalytic space. From this protocol, we will construct a bipartite graph G whose 2^c many left vertices are identified with $\{0,1\}^c$, and whose $2^{c+s\cdot(2^s+1)}$ many right vertices are identifed with $\{0,1\}^c \times \{0,1\}^{s\cdot(2^s+1)}$. The edge set will consist of, for every non-bad $(x,\tau) \in \{0,1\}^n \times \{0,1\}^c$, an edge from τ on the left to $\alpha^{(x)}(\tau)$ on the right.

Now, for every $z \in \{0,1\}^n$, $\omega \in \{0,1\}^s$, we'll define a vertex subset $M_z^{(\omega)} \subseteq V(G)$. A left vertex $\tau \in \{0,1\}^c$ will be included in $M_z^{(\omega)}$ if and only if both (z,τ) is non-bad, and $\beta_{\text{rem}}^{(z)}(\alpha^{(z)}(\tau)) = \omega$. A right vertex $\gamma \in \{0,1\}^c \times \{0,1\}^{s\cdot(2^s+1)}$ will be included in $M_z^{(\omega)}$ if and only if $\beta_{\text{rem}}^{(z)}(\gamma) = \omega$.

We claim that every edge of G is induced by one of these subsets, and that each subset induces a matching. The first part of this is immediate: both endpoints of the edge generated by a pair (x,τ) must belong to $M_x^{(\beta_{\text{rem}}^{(x)}(\alpha^{(x)}(\tau)))}$. To see the second part, consider some edge $(\tau,\gamma) \in E(G)$, generated by a non-bad (x,τ), and suppose it belongs to some M_z^{ω} with $z \neq x$. (Note that, by definition of $M_x^{(\omega)}$, this edge it cannot belong to $M_x^{(\omega)}$ for any $\omega \neq \beta_{\text{rem}}^{(x)}(\alpha^{(x)}(\tau))$.) But now, suppose the protocol is run with Alice given input x, Bob given input z, and the catalytic tape initialized to τ. The output of the protocol will be $\beta_{\text{out}}^{(z)}(\tau, \beta_{\text{rem}}^{(z)}(\alpha^{(x)}(\tau))) = \beta_{\text{out}}^{(z)}(\tau, \beta_{\text{rem}}^{(z)}(\gamma)) = \beta_{\text{out}}^{(z)}(\tau,\omega) = \beta_{\text{out}}^{(z)}(\tau, \beta_{\text{rem}}^{(z)}(\alpha^{(z)}(\tau)))$. However, since both (x,τ) and (z,τ) are non-bad, we know $\beta_{\text{out}}^{(z)}(\tau, \beta_{\text{rem}}^{(z)}(\alpha^{(x)}(\tau))) = \mathsf{EQ}_n(x,z) = 0$ and $\beta_{\text{out}}^{(z)}(\tau, \beta_{\text{rem}}^{(z)}(\alpha^{(z)}(\tau))) = \mathsf{EQ}_n(z,z) = 1$, so this is contradiction.

Now, oberve that since there are at least $(2^c \cdot 2^n)/(2^s+1)$ many non-bad pairs, G has at least this many edges. Since we've partitioned these edges into $2^n \cdot 2^s$ many induced matchings, each of which has at most 2^c many edges, we must have at least $2^n/2^{s+1}$ many induced matchings each with at least $2^c/2^{s+1}$ many edges. Letting $G' \subseteq G$ be the graph on only those edges, this is a $2^c + 2^{c+s\cdot(2^s+1)} = O(2^c)$-vertex $(\Omega(2^c), \Omega(2^n))$-Ruzsa–Szemerédi graph. ◀

This characterization immediately allows us to show that no 3-round $\Theta(1)$-clean catalytic protocol for equality can use only $n + O(1)$ bits of catalytic space – although we have found a surprisingly efficient protocol, equality is at least somewhat more difficult for this model than, for instance, inner product.

▶ **Corollary 26.** *For any constant s, we have $\mathsf{CC}_{3,s}(\mathsf{EQ}_n) \geq n + \Omega(\log^*(n))$.*

Proof. It is known by the triangle removal lemma that for any constant k, a $(N/k, t)$-Ruzsa–Szemerédi graph on N vertices must satisfy $t \leq \frac{N}{2^{\Omega(\log^*(N))}}$ [24]. Since, by Lemma 24, a 3-round s-clean protocol on n-bit inputs with c bits of catalytic space gives a $(\Omega(2^c), \Omega(2^n))$-Ruzsa–Szemerédi graph on $O(2^c)$ vertices, this means that $2^n \leq O\left(\frac{2^c}{2^{\Omega(\log^*(2^c))}}\right)$. Rearranging gives $c \geq n + \Omega(\log^* n)$. ◀

Of course, this doesn't rule out a protocol with linear catalytic space – and in fact, the second author believes that such a protocol likely exists. However, it does provide evidence that constructing such a protocol may be difficult: doing so would improve known Ruzsa–Szemerédi constructions, yielding improvements to state-of-the-art bounds in property testing, streaming algorithms, and information theory. We mention a few such implications; the reader is referred to the cited works for definitions of terms.

▶ **Corollary 27.** *If, for some constant s, $\mathsf{CC}_{3,s}(\mathsf{EQ}_n) \leq O(n)$, then*

1. *Any non-adaptive tester for monotonicity over general N-element posets requires query complexity $\Omega(N^c)$ for some $c > 0$.*

2. *Any randomized semi-streaming algorithm for* $(1-\varepsilon)$*-approximate maximum bipartite matching requires* $\Omega(\log(1/\varepsilon))$ *passes over the stream.*
3. *There exist constant-rate centralized coding caching schemes, in which each file is divided into a number of pieces polynomial in the number of participants.*

Proof. By Lemma 24, if $\mathsf{CC}_{3,s}(\mathsf{EQ}_n) \leq O(n)$, then for some $c > 0$ there exist $(\Theta(N), N^c)$-Ruzsa–Szemerédi graphs on N vertices. The property testing lower bounds of Fischer, Lehman, Newman, Raskhodnikova, Rubinfeld and Samorodnitsky [23], the streaming lower bounds of Assadi and Sundaresan [3], and the centralized coding caching scheme construction of Shangguan, Zhang and Ge [44] all rely on constructions of Ruzsa–Szemerédi graphs where the partial matchings are of linear size. Plugging in a construction with $t = N^c$ to those arguments would immediately yield the strengthened bounds in the statement of the corollary. ◀

A more optimistic interpretation of Corollary 27 is that designing catalytic protocols for equality could provide an approach towards improved Ruzsa-Semerédi constructions. There is some evidence that the language of communication complexity can be useful in this area: Linial, Pitassi, and Shraibman have shown a close relationship between Ruzsa–Szemerédi graphs and protocols for high-dimensional permutations in the Number On the Forehead model, which Alon and Shraibman used to give simple communication theoretic descriptions of a couple of known Ruzsa–Szemerédi constructions [35, 1]. 3-round catalytic protocols for equality offer another distinct communication-theoretic interpretation of the problem that may prove useful.

5 The 3-Round Complexity of Indexing

The fact that $\mathsf{CC}_{3,2}(\mathsf{EQ}_n)$ is exponentially smaller than $\mathsf{CC}_{3,1}$ raises the question of whether perhaps *every* function has an efficient 3-round s-clean protocol for some constant s. One might suspect that most functions should require exponential complexity, but there is no clear counting argument to this effect. In fact, even for functions of unbalanced input lengths – i.e. when $n_b \gg n_a$ – there's no obvious way to rule out a protocol with catalytic space close to n_a [7]. We propose considering the following function:

▶ **Definition 13.** *For any* n*, we denote by* IND_n *the function taking an* n*-bit index and a* 2^n*-bit bitstring to the value of that bitstring at that index. That is,*

$$\mathsf{IND}_n : [2^n] \times \{0,1\}^{2^n} \to \{0,1\},$$

$$\mathsf{IND}_n(x, y) = y[x].$$

This indexing function is often considered in one-way communication complexity contexts, where the party holding the index cannot send messages, so all information must be sent by the party with the longer input. Note that in our case, however, we consider the reverse: we're giving Alice the index, and by Lemma 25 our protocol can be largely thought of as one-way from Alice to Bob. The reason we're particularly interested in this setting is that a protocol for IND_n can be thought of as a protocol for all functions simultaneously: Bob has to be able to determine any Boolean function on Alice's input. So, for fixed value of Alice's input length $n_a = n$, IND_n is the hardest possible function, in the sense that a protocol for IND_n gives a protocol with the same parameters for every other function with the same n_a.

[7] The other direction of asymmetry – that is, when $n_a \gg n_b$ – is less interesting for 3-round protocols, since Bob can without loss of generality communicate very little information to Alice, and so there are easily functions requiring at least n_a bits of catalytic space for information theoretic reasons.

By Proposition 4, we know $\mathsf{CC}_{3,s}(\mathsf{IND}_n) \leq 2^n$. We suspect that this is close to the correct answer for any constant s, but the results we've shown thus far haven't ruled out the possibility that $\mathsf{CC}_{3,2}(\mathsf{IND}_n) = n + O(\log^*(n))$. In this section, we will prove a somewhat stronger lower bound – still far away from the upper bound, but enough to suggest for instance that it's unlikely that some sort of Ruzsa–Szemerédi construction as in Section 4 will work directly. We show the following:

▶ **Theorem 9.** *We have $\mathsf{CC}_{3,s}(\mathsf{IND}_n) \geq (1+\varepsilon)n$, for some constant ε depending on s.*

As in our lower bounds for equality, our proof comes from a graph theoretic interpretation. We will show that a protocol for IND_n corresponds to a graph composed of a union of matchings, with the property that any subset of the matchings are separable from the rest of the graph. We will then show that such a graph cannot have too high density, bounding the efficiency of the catalytic protocol. We make the following definitions:

▶ **Definition 28.** *Let E_1 and E_2 be disjoint edge sets on a common set of vertices, and let $k \in \mathbb{N}$. We say E_1 and E_2 are **k-separable** if there exists a k-edge colouring of $E_1 \cup E_2$ such that*

- *each colour appears in only one of E_1 or E_2, and*
- *for every 3-edge path, if the first and last edges share the same colour, so does the middle edge.*

▶ **Definition 29.** *We call an n-vertex graph **k-divisive** if its edges can be partitioned into matchings $M_1, \ldots, M_m$ such that for all $S \subseteq [m]$, the edge sets $\bigcup_{i\in S} M_i$ and $\bigcup_{j\notin S} M_j$ are k-separable.*

▶ **Lemma 30.** *For any constant s, there is a family $\{G_n\}_{n\in\mathbb{N}}$, with $|V(G_n)| \leq O(2^c)$ and $|E(G_n)| \geq \Omega(2^{c+n})$ for $c = \mathsf{CC}_{3,s}(\mathsf{IND}_n)$, and where each G_n is 2^{2^s+s}-divisive.*

Proof. As in Section 4.3, we begin by invoking Lemma 25 to obtain a sometimes-one-way-catalytic protocol. In fact, we'll define the same graph: let G consist of 2^c many left vertices identified with $\{0,1\}^c$, $2^{c+s\cdot(2^s+1)}$ many right vertices identified with $\{0,1\}^c \times \{0,1\}^{s\cdot(2^s+1)}$, and an edge $(\tau, \alpha^{(x)}(\tau))$ for each x whenever (x,τ) is non-bad. This graph has $2^c + 2^{c+s\cdot(2^s+1)} \leq O(2^c)$ many vertices, and $2^{n+c}/(2^s+1) \geq \Omega(2^{c+n})$ many edges.

For any $x \in [2^n]$, let $M_x \subseteq E(G_n)$, $M_x = \{(\tau, \alpha^{(x)}(\tau))\colon (x,\tau) \text{ is not bad}\}$. Note that each M_x is a matching, since $\alpha^{(x)}$ is injective. We claim that, for any $S \subseteq [2^n]$, the edge sets $\bigcup_{i\in S}$ and $\bigcup_{i\notin S} M_i$ are $\left(2^{2^s+s}\right)$-separable. Fix any $S \subseteq [2^n]$, and let $1_S \in \{0,1\}^{2^n}$ denote the indicator vector of S. Now, to separate $\bigcup_{i\in S}$ and $\bigcup_{i\notin S} M_i$, we will "colour" each edge (τ,γ) with the pair $\left(\beta^{(1_S)}_{\text{out}}(\tau,\cdot), \beta^{(1_S)}_{\text{rem}}(\gamma)\right) \in (\{0,1\}^s \to \{0,1\}) \times \{0,1\}^s$. If (τ,γ) and (τ',γ') have the same colour, it means that $\beta^{(1_S)}_{\text{out}}(\tau,\cdot)$ and $\beta^{(1_S)}_{\text{out}}(\tau',\cdot)$ are the same function, and $\beta^{(1_S)}_{\text{rem}}(\gamma)$ and $\beta^{(1_S)}_{\text{rem}}(\gamma')$ are the same bitstring – so, (τ,γ') and (τ',γ) will also share this colour.

We now just need to show that no edge $(\tau,\gamma) \in \bigcup_{i\in S} M_i$ can share a colour with an edge $(\tau',\gamma') \in \bigcup_{i\notin S} M_i$. Fix any $x, x' \in [2^n]$, and any edges $(\tau,\gamma) \in M_x$ and $(\tau',\gamma') \in M_{x'}$ with the same colour. In order for these edges to be present, both (x,τ) and (x',τ') must be good. So,

$$\begin{aligned} f(x,1_S) &= \beta^{(1_S)}_{\text{out}}(\tau, \beta^{(1_S)}_{\text{rem}}(\alpha^{(x)}(\tau))) \\ &= \beta^{(1_S)}_{\text{out}}(\tau, \beta^{(1_S)}_{\text{rem}}(\gamma)) \\ &= \beta^{(1_S)}_{\text{out}}(\tau', \beta^{(1_S)}_{\text{rem}}(\gamma')) \\ &= \beta^{(1_S)}_{\text{out}}(\tau', \beta^{(1_S)}_{\text{rem}}(\alpha^{(x')}(\tau'))) \\ &= f(x',1_S), \end{aligned}$$

meaning that either both x and x' belong to S, or neither do. ◀

We now demonstrate that any such graph cannot contain a large complete bipartite subgraph, which will allow us to bound its density by the KST theorem.

▶ **Lemma 31.** *For any $k \in \mathbb{N}$, if a graph G is k-divisive, then G does not contain the complete bipartite graph $K_{3k^2,3k^2}$ as a subgraph.*

Proof. We proceed by contradiction: suppose we've found a copy H of $K_{3k^2,3k^2}$ in G. Let $M_1 \sqcup \cdots \sqcup M_m = E(G)$ be the partition into matchings guaranteed by the divisiveness condition. We claim that we can find some set of M_i and some smaller complete bipartite subgraph of H whose intersection with the union of those M_i is a perfect matching.

▷ Claim 32. There exists a set $S \subseteq [m]$, and a subgraph $H' \subseteq H \subseteq G$, such that H' is isomorphic to $K_{k+1,k+1}$, and $\bigcup_{i\in S}(H \cap M_i)$ is a matching with $k+1$ edges.

Proof of Claim 32. First, suppose some single M_i contains at least $k+1$ edges of H. Then, the claim follows immediately by taking $S = \{i\}$, and letting H' be the subgraph induced by the edges of $H \cap M_i$. So, we will assume each M_i contains at most k edges of H.

We construct S greedily, starting with $S = \emptyset$ and adding indices one-at-a-time. Suppose $\bigcup_{i\in S}(H \cap M_i)$ currently consists of a matching with $\ell < k+1$ many edges. The number of edges of H that contain any endpoint of an edge in $\bigcup_{i\in S}(H \cap M_i)$ is therefore no more than $2 \cdot \ell \cdot (3k^2)$. Since no M_i contains more than k edges of H, and H has $(3k^2)^2$ edges, there must be at least $\frac{(3k^2)^2}{k} = 9k^3 > 2 \cdot \ell \cdot (3k^2)$ distinct M_i with at least one edge in H. Thus, we can find some i^* such that $M_{i^*} \cap H$ contains at least one edge, but contains no edge sharing an endpoint with an edge of $\bigcup_{i\in S}(H \cap M_i)$ – this implies that $\bigcup_{i\in(S\cup\{i^*\})}(H \cap M_i)$ is a matching with at least $\ell + 1$ many edges. The claim follows by repeating this procedure until $|\bigcup_{i\in S}(H \cap M_i)| \geq k+1$, and then taking H' to be the subgraph induced by those edges. ◁

Now, we use H' and S to contradict the k-separability assumption. By assumption on G, the edge sets $\bigcup_{i\in S} M_i$ and $\bigcup_{i\notin S} M_i$ are k-separable – fix an edge colouring that k-separates them. Since $\bigcup_{i\in S}(H \cap M_i)$ contains $k+1$ edges, by pigeonhole principle it must contain two edges (u_1, u_2) and (v_1, v_2) that are given the same colour. Since H' is a complete bipartite graph, the edge (u_1, v_2) must also be present, and since $\bigcup_{i\in S}(H \cap M_i)$ is a matching it cannot belong to any M_i, $i \in S$. Since (u_1, u_2) and (v_1, v_2) have the same colour, the definition of a k-separation requires (u_1, v_2) to share that colour – but (u_1, v_2) does not belong to $\bigcup_{i\in S} M_i$, so that colour cannot be used on (u_1, v_2). This is contradiction. ◀

Theorem 9 now follows directly from Lemma 30 and Lemma 31.

Proof of Theorem 9. Lemma 30 gives a family $\{G_n\}_{n\in\mathbb{N}}$ of 2^{2^s+s}-divisive graphs, where each G_n has $N = O(2^{\mathsf{CC}_{3,s}(\mathsf{IND}_n)})$ many vertices and $\Omega(2^{\mathsf{CC}_{3,s}(\mathsf{IND}_n)+n}) = \Omega(N^{1+n/\mathsf{CC}_{3,s}(\mathsf{IND}_n)})$ many edges. Then, Lemma 31 ensures that no G_n in this family can contain a copy of $K_{t,t}$, for $t = 3\left(2^{2^s+s}\right)^2$. The Kővári–Sós–Turán theorem guarantees that an N-vertex graph without $K_{t,t}$ as a subgraph must have at most $O(N^{2-1/t})$ many edges [34, 45], so we must have $n/\mathsf{CC}_{3,s}(\mathsf{IND}_n) \leq 1 - 1/t$ for sufficiently large n. Rearranging, this gives that $\mathsf{CC}_{3,s}(\mathsf{IND}_n) \geq n + \left(\frac{1}{t-1}\right) n$ for all sufficiently large n. ◀

This is not an especially strong lower bound – it seems plausible that $\mathsf{CC}_{3,s}(\mathsf{IND}_n)$ is exponential in n for any constant s, but do not even know that $\mathsf{CC}_{3,s}(\mathsf{IND}_n) \geq 2n$. However, the proof does at least give some evidence that the sort of direct application of Ruzsa–Szemerédi constructions we saw in Section 4 is unlikely to work here – Ruzsa–Szemerédi

graphs can contain complete bipartite graphs of any constant size, and we expect that bounds of the form $t \leq n^{1-\Omega(1)}$ for $r = \Theta(n)$ on (r,t)-Ruzsa–Szemerédi graphs, if true, will be difficult to prove [25]. We note also that the graph theoretic property of k-divisiveness, in which any subset of matchings must be k-separable from the rest of the graph, is a strictly stronger property than that of being a Ruzsa–Szemerédi graph, and may be interesting to study in its own right.

6 More Rounds and Connections to Catalytic Computing

We've restricted attention thus far to protocols of only 3 rounds, as the design and analysis of such protocols has proven to already be quite theoretically rich. In this section, we consider what can be said for protocols with more rounds. We observe a close relationship between standard models of nonuniform catalytic computation and our model of catalytic communication, and show that by a communication analogue of Buhrman, Cleve, Koucký, Loff and Speelman's results on CL [13], there exist constant-round constant-clean protocols with polynomial catalytic space for all of TC^0.

6.1 Amortized Bipartite Branching Programs

The notion of catalytic space introduced by Buhrman, Cleve, Koucký, Loff and Speelman is a uniform model of computation: it consists of a space-bounded algorithm, with an additional resource of catalytic space that must be reset at the end of computation [13]. One can also define a natural *nonuniform* catalytic model:

▶ **Definition 33.** *An **amortized branching program**[8] of amortized width w and length ℓ computing m copies of a function f is a directed acyclic multigraph consisting of ℓ layers, where*

- *The first layer has m vertices, the last layer has 2 vertices, and all other layers have mw vertices.*
- *Each layer except the last is labeled with an index $i \in [n]$.*
- *Each vertex except in the last layer has exactly two outgoing edges, labeled 0 and 1 respectively.*
- *The two vertices in the last layer are labeled "accept" and "reject", and the vertices in the second-to-last layer are labeled with the names of vertices in the first layer, such that each name appears exactly w times.*

To compute the function on an input x, the program starts at an arbitrary vertex in the first layer, and then for each layer reads the associated index of x and follows the edge labeled with the resulting value. Correctness of the program entails that, for every input and every starting vertex, the program ends in the vertex with the correct acceptance behaviour, and the second-to-last vertex visited has the same label as the starting vertex.

Amortized branching programs were introduced by Girard, Koucký and McKenzie, who showed examples where direct sum theorems succeeded and failed for the model [26]. Since then, there has been interest in determining the minimum amount of amortization needed to compute a function with small amortized width and length. Potechin showed that every

[8] We remark that our definition is slightly nonstandard, as the last layer is usually defined to have width $2m$ with labels (v,b), where $v \in [m]$ and $b \in \{0,1\}$. However, the definitions are easily seen to be equivalent (up to a unit change in length).

function has an amortized branching program of length $O(n)$ and amortized width $O(1)$ computing 2^{2^n} copies [38]. Robere and Zuiddam showed that this amount of amortization could be reduced for bounded-degree functions over $\mathbb{F}_2$ [42]. Cook and Mertz showed a trade-off in both of these results between length and amortization, allowing them to show in the former case that any function has an amortized branching program of length $O(n)$ and amortized width $O(1)$ computing $2^{2^{\varepsilon n}}$ copies, where the constant in the program length depends on ε [20]. In a recent breakthrough work on the tree evaluation problem, Cook and Mertz showed that the ideas of this tradeoff could be strengthened to give length $\mathsf{poly}(n)$, amortized width $O(1)$ branching programs computing $2^{O(n)}$ copies of any function [21].

In their work on memoryless communication complexity, Arunachalam and Podder observed that the model was closely related to a notion of **bipartite** branching programs [2]. We define a similar notion in the amortized sense, which we note exactly describes our model of catalytic communication, and can be seen as an alternate definition.

▶ **Definition 34.** *A **bipartite amortized branching program** of amortized width w and length ℓ computing m copies of a function f is a directed acyclic multigraph consisting of ℓ layers, where*

- *The first layer has m vertices, the last layer has 2 vertices, and all other layers have mw vertices.*
- *Each layer except the last is labeled either x or y.*
- *Each vertex except in the last layer has exactly 2^n outgoing edges, labeled with the values of $\{0,1\}^n$.*
- *The two vertices in the last layer are labeled "accept" and "reject", and the vertices in the second-to-last layer are labeled with the names of vertices in the first layer, such that each name appears exactly w times.*

To compute the function on an input (x, y), the program starts at an arbitrary vertex in the first layer, and then for each layer follows the edge labeled with the value of the associated input. Correctness of the program entails that, for every input and every starting vertex, the program ends in the vertex with the correct acceptance behaviour, and the second-to-last vertex visited has the same label as the starting vertex.

The equivalence between such programs and catalytic communication protocols is immediate.

▶ **Proposition 35.** *$\mathsf{CC}_{r,s}(f) \leq c$ if and only if there exists a bipartite amortized branching program of amortized width 2^s and length $r + 2$ computing 2^c copies of f.*

Proof. Given such a branching program, we define a catalytic protocol by thinking of the initial catalytic setting as giving the index of a starting vertex of the program, and then on subsequent steps having the blackboard store the index of the current node within its layer. The fact that vertices in the second-to-last layer are labeled by vertices in the first layer means that, with an appropriate ordering of the indexing, the condition of second-to-last vertex having the same label as the starting vertex corresponds exactly to the catalytic portion of the blackboard being reset after r rounds. The final layer corresponds to the output function.

Given a r-round s-clean catalytic protocol with catalytic space c, we can perform the reverse transformation. Each layer except the first and last contains one vertex for each blackboard state, and the transition functions between pairs of layers are determined by how the active player would update the blackboard (with the transition function to the last layer determined by the output function). ◀

Note that any amortized branching program is also a bipartite amortized branching program, so a consequence of this equivalence is that any result known for amortized branching programs trivially extends to catalytic communication. For instance, the results of [20] and [21] give the following, respectively:

▶ **Corollary 36.** $\mathsf{CC}_{O(n),O(1)}(f) \leq 2^{\varepsilon n}$ *for all* $f\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$, $\varepsilon > 0$.

▶ **Corollary 37.** $\mathsf{CC}_{\mathsf{poly}(n),O(1)}(f) \leq O(n)$ *for all* $f\colon \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$.

However, there are cases where bipartite amortized branching programs can be much more efficient than amortized branching programs. Note that an amortized branching program of length less than n is uninteresting (it is effectively solving a problem on a smaller input length), whereas we've seen that bipartite amortized branching programs of length 5 can be quite powerful. In the full version, we give a result making use of this power: Buhrman, Cleve, Koucký, Loff and Speelman's CL algorithm for threshold circuit evaluation gives an amortized branching program of length $\mathsf{poly}(n)$ even when the circuit has constant depth, but we note that by appropriate rearranging it can be converted to a bipartite amortized branching program of only constant length, yielding the following:

▶ **Theorem 10.** *Let* $f\colon \{0,1\}^{n_a} \times \{0,1\}^{n_b} \to \{0,1\}$ *be any function computable by a size* S*, depth* d *majority circuit with arbitrary input preprocessing – that is, there exists a depth-*d *circuit* C *composed of* S *many majority gates, and arbitrary functions* g, h*, such that* $f(x,y) = C(g(x), h(y))$*. Then,* $\mathsf{CC}_{4^d,1}(f) \leq \mathsf{poly}(S, 2^d)$.

A Proof of Results In Introduction

First, catalytic protocols with two or fewer rounds cannot meaningfully make use of the catalytic space.

Proof of Proposition 3. In a one-round protocol, the blackboard is only modified once, so if the catalytic portion is ever changed it will end up in a different state from how it started. Since the catalytic state is an arbitrary string that can't be changed, Alice and Bob could just as well do without it.

In a two-round protocol, Alice and Bob each only get to modify the blackboard once. So, Bob must have a function (independent of x) that lets him recover the original state of the catalytic portion for every message Alice can send. There are 2^{s+c} many possible messages for Alice to send, each of which Bob returns to a single fixed catalytic state – so, by pigeonhole principle, the protocol has some catalytic state that's associated with at most 2^s many Alice messages. This gives a new protocol with no catalytic space: the two parties pretend the catalytic portion started in that state, Alice gives Bob the index of which of the 2^s associated messages she would have wanted to send in the original protocol, and Bob determines what bits he would have sent back in the clean space. ◀

Next, we show that every function has a three-round protocol:

Proof of Proposition 4. First, suppose $n_a \leq n_b$. In this case, the protocol is as follows:

1. Alice flips the xth bit of the catalytic portion.
2. Based on his own input, Bob computes the truth table of $x \mapsto f(x, y)$, which he thinks of as a 2^{n_a}-entry bitvector. He takes the inner product of this truth table and the current catalytic space, and writes the result to the clean space.
3. Alice flips the xth bit of the catalytic portion again, resetting it.
4. Bob once again takes the inner product of his truth table and the catalytic space, and outputs the XOR of the result and the clean bit.

If, on the other hand, $n_a > n_b$, the roles are reversed: Alice XORs in the truth table of $y \mapsto f(x, y)$, and Bob reads off the yth bit. In either case, this can be seen as an application of the inner product protocol of Proposition 5 to compute the inner product of a truth table and the indicator vector of the index on which it's being evaluated. ◀

Finally, we present our protocol for inner product.

Proof of Proposition 5. We will describe a protocol. Let x be Alice's input, y be Bob's input, and τ be the initial state of the catalytic space.

1. For the first round of the protocol, Alice replaces the catalytic portion of the blackboard with $\tau \oplus x$, where $\oplus$ denotes bitwise XOR.
2. For the second round, Bob computes the inner product of the catalytic portion and his input, writing the resulting bit $\langle \tau \oplus x, y \rangle$ to the clean space.

3. For the third round, Alice once again bitwise XORs her input into the catalytic portion, resetting it to $(\tau \oplus x) \oplus x = \tau$.
4. To output the answer, Bob computes the inner product of the new catalytic portion and his input, and adds this to the bit stored in the clean space, resulting in $\langle \tau, y \rangle \oplus \langle \tau \oplus x, y \rangle = \langle x, y \rangle$. ◀

1 Results

We consider the dynamics imposed by natural selection on the populations of two competing, sexually reproducing, haploid species. In this model genomes acquire time-varying fitnesses as a result of the changing mix of species in the population; this is in contrast to most previous works in this area, which impose external rules for varying fitnesses over time. Previous work on our model [2] showed that, in the special case where each of the two species exhibits just two phenotypes, genetic diversity is maintained at all times. This finding supported the tenet that sexual reproduction is advantageous because it promotes phenotype diversity.

In the present paper we consider the more realistic case where there are more than two phenotypes available to each species. The conclusions about diversity in general turn out to be very different from the two-phenotype case. For simplicity, we consider two species with n and m genes respectively, each of which may take two allele values, 0 and 1. Game-theoretically, we think of two teams, A and B, with $|A| = n$ and $|B| = m$. The players within each team play a coordination game, but the two teams between them play a competitive, zero-sum game. Thus for each choice of actions $x \in \{0,1\}^n$, $y \in \{0,1\}^m$ by the $m+n$ players, all players in team A receive common payoff $u(x,y)$ and all players in team B receive $-u(x,y)$, where u is a $2^n \times 2^m$ payoff matrix. Players within a team are not allowed to coordinate their actions, so the strategies of each team are constrained to be product distributions.

Writing $p = (p_1, \ldots, p_n)$ and $q = (q_1, \ldots, q_m)$ for the (time dependent) mixed strategies of teams A, B respectively, where p_i denotes the probability of player i in team A choosing allele 0 (and q_j similarly for player j in team B), the replicator dynamics under weak selection [1] can be written as

$$\dot{p}_i = p_i\big(\widehat{u}_{i,0}(p,q) - \widehat{u}(p,q)\big)\,; \qquad \dot{q}_j = q_j\big(-\widehat{u}_{j,0}(p,q) + \widehat{u}(p,q)\big)\,, \tag{1}$$

© Yuval Rabani, Leonard J. Schulman, and Alistair Sinclair;
licensed under Creative Commons License CC-BY 4.0

where $\widehat{u}(p,q)$ is the average payoff to team A under the current strategies p, q, and $\widehat{u}_{i,0}(p,q)$ (resp., $\widehat{u}_{j,0}(p,q)$) is this same average conditioned on player i of team A (resp., player j of team B) choosing allele 0.

We consider first the following strong notion of preservation of genetic diversity:

▶ **Property A.** *For any initial populations* $(p(0),q(0)) \in (0,1)^{n+m}$ *(i.e., all genotypes are initially represented),*

$$\exists \varepsilon > 0, t_0 \geq 0 \text{ s.t. } \forall t \geq t_0, \quad H(p(t)) + H(q(t)) \geq \varepsilon, \tag{2}$$

where $H(p) = \sum_i H(p_i)$ *and* $H(p_i) = -p_i \log p_i - (1-p_i)\log(1-p_i)$ *is Shannon entropy. I.e., at all times the two-species system maintains diversity (not necessarily within a particular species).*

Our first result is negative: namely, we show that sexual reproduction does not guarantee the maintenance of diversity at all times:

▶ **Theorem 1.** *There exist replicator dynamics with no weak pure Nash equilibrium for which Property A fails. In fact, inequality* (2) *holds only on a set of initial conditions of measure zero.*

Our concrete example used in the proof of Theorem 1 consists of species with three phenotypes each. This is in sharp contrast to the result of [2], which shows that Property A does hold with only two phenotypes per species.

Our main result is a complementary positive statement, which says that in any non-degenerate example, diversity *is* maintained in the following weaker, "infinitely often" sense.

▶ **Property B.** *For any initial populations* $(p(0),q(0)) \in (0,1)^{n+m}$,

$$\exists \varepsilon > 0 \text{ s.t. } \int_0^\infty \max\{0, H(p(t)) + H(q(t)) - \varepsilon\}\, dt = \infty. \tag{3}$$

I.e., during an infinite span of time the entropy is uniformly bounded away from 0.

We also identify the following slightly weaker version of this property:

▶ **Property C.** *For any initial populations* $(p(0),q(0)) \in (0,1)^{n+m}$,

$$\int_0^\infty (H(p(t)) + H(q(t)))\, dt = \infty. \tag{4}$$

The following theorem summarizes the maintenance of diversity in general replicator dynamics, according to whether or not a pure Nash equilibrium exists:

▶ **Theorem 2.** *The following results hold for general replicator dynamics:*

- **(i)** *If the dynamics has no pure Nash equilibrium, then Property B holds.*
- **(ii)** *If the assumption in (i) is weakened to assume only that the dynamics has no* strict *pure Nash equilibrium, then Property C holds.*
- **(iii)** *If the dynamics has a strict pure Nash equilibrium, then Property C (and therefore also Property B) fails on a set of initial populations* $(p(0),q(0)) \in (0,1)^{n+m}$ *of positive measure.*

In summary, our results refute the supposition that sexual reproduction ensures diversity at all times, but affirm a weaker assertion that extended periods of high diversity are necessarily a recurrent event.

Online Balanced Allocation of Dynamic Components

Rajmohan Rajaraman
Northeastern University, Boston, MA, USA

Omer Wasim
Northeastern University, Boston, MA, USA

Abstract

We introduce Online Balanced Allocation of Dynamic Components (OBADC), a problem motivated by the practical challenge of dynamic resource allocation for large-scale distributed applications. In OBADC, we need to allocate a dynamic set of at most $k\ell$ vertices (representing processes) in $\ell > 0$ clusters. We consider an over-provisioned setup in which each cluster can hold at most $k(1+\varepsilon)$ vertices, for an arbitrary constant $\varepsilon > 0$. The communication requirements among the vertices are modeled by the notion of a *dynamically changing component*, which is a subset of vertices that need to be co-located in the same cluster. At each time t, a request r_t of one of the following types arrives:

1. *insertion* of a vertex v forming a singleton component $\{v\}$ at unit cost.
2. *merge* of (u, v) requiring that the components containing u and v be merged and co-located thereafter.
3. *deletion* of an existing vertex v at zero cost.

Before serving any request, an algorithm can migrate vertices from one cluster to another, at a unit migration cost per vertex. We seek an online algorithm to minimize the total migration cost incurred for an arbitrary request sequence $\sigma = (r_t)_{t>0}$, while simultaneously minimizing the number of clusters utilized. We analyze competitiveness with respect to an optimal clairvoyant *offline* algorithm with identical (over-provisioned) capacity constraints.

We give an $O(\log k)$-competitive algorithm for OBADC, and a matching lower-bound. The number of clusters utilized by our algorithm is always within a $(2+\varepsilon)$ factor of the minimum. Furthermore, in a resource augmented setting where the optimal offline algorithm is constrained to capacity k per cluster, our algorithm obtains $O(\log k)$ competitiveness and utilizes a number of clusters within $(1+\varepsilon)$ factor of the minimum.

We also consider OBADC in the context of machine-learned predictions, where for each newly inserted vertex v at time t: i) with probability $\eta > 0$, the set of vertices (that exist at time t) in the component of v is revealed and, ii) with probability $1-\eta$, no information is revealed. For OBADC with predictions, we give a $O(1)$-*consistent* and $O(\min(\log \frac{1}{\eta}, \log k))$-*robust* algorithm.

1 Introduction

Modern large-scale applications are distributed over multiple physical machines or computing clusters in data centers, generating a considerable amount of network traffic. In a typical setting, a cloud service provider provisions computational resources (such as CPU, memory, storage) in the form of virtual machines (VMs) to users who pay a cost proportional to their resource requirements which varies over time. However, operating and allocating these resources in a "demand-aware" manner to minimize cost, and optimize performance and energy utilization while fulfilling service-level agreements (SLAs) for various users is technically challenging. This has garnered a surging interest in resource allocation strategies in cloud computing frameworks in recent years [7, 9, 1, 31].

© Rajmohan Rajaraman and Omer Wasim;
licensed under Creative Commons License CC-BY 4.0

Consider the setting where a massively distributed application attributed to a single cloud user may be spread across multiple VMs, necessitating inter-VM communication. If such VM's are allocated in the same cluster, inter-VM communication consumes little network bandwidth, leading to low *communication cost* and potential energy savings [31, 32]. However if inter-VM communication happens over physically separated clusters, this may compromise quality of service, responsiveness, and incur a large consumption of network resources. Almost all virtualization systems support "live-migration" of VMs between various clusters with the aim of reducing latency, improving resource-allocation and energy savings [12, 16, 17]. However, VM migration must be performed sparingly, as it creates network overhead and may compromise the responsiveness of the VM being migrated.

In addition to inter-process communication patterns that evolve over time, another challenge is to provision resources *dynamically* to users under varying resource requirements. This leads to the removal of existing virtual machines and the insertion of new virtual machines [6]. Thereafter, new communication patterns emerge between newly re-allocated VMs. Such re-allocations also incur a cost for the cloud service provider which is inevitable, in addition to future defragmentation of resources caused by multiple re-allocations over time [30].

Finally, *energy consumption* of data centers due to an ever-increasing need for large-scale cloud computing is well documented [19]. In practice, migration of VMs together with other load-balancing strategies have been exploited to reduce the number of "active" physical machines to save energy [16, 19, 17]. For example, VMs on under-loaded clusters are migrated so that such clusters can save energy by moving to an idle state. Thus, it is highly desirable to ensure that the number of "active" clusters *dynamically scales* with the workload.

In this paper, we address the challenges posed by unknown communication patterns, dynamic resource requirements, and energy consumption by introducing the problem of **Online Balanced Allocation of Dynamic Components** (OBADC). We model the scenario where clusters and VMs are homogeneous, and migration and inter-VM communication costs are uniform across different clusters, while the communication patterns and dynamic allocation requests are unknown.

1.1 Problem Formulation and Main Results

Our problem formulation is inspired by the online balanced graph partitioning (OBGR) problem, introduced by Avin, Bienkowski, Loukas, Pacut and Schmid [2], and considers additional technical aspects including the dynamics of VMs, and a secondary goal of minimizing the number of active clusters. In OBADC, we have a set V of at most $n \leq k\ell$ vertices (representing VMs) at any given point in time, and $\ell > 0$ clusters denoted by $S_1, S_2, ..., S_\ell$, each with capacity k. Initially $V = \emptyset$ and S_i for all $i \in [\ell]$ is empty. We model the communication requirements among the vertices using the notion of a dynamically changing *component*, which is a subset of vertices that need to be co-located in the same cluster. The request sequence $\sigma = \{r_t\}_{t \geq 1}$ is revealed online, such that each request r_t is of the following type:

1. *Insertion of a vertex v*: Insert v (and a corresponding singleton component $\{v\}$) at unit cost, to any cluster which can accommodate it. The cost of insertion models a one-time "startup" cost to initialize a VM in a cluster.
2. *Deletion of a vertex v*: Delete existing vertex v from its component C. The cost of deletion is zero; all vertices in $C \backslash \{v\}$ are still required to be co-located.
3. *Merge vertices u and v* : Merge the components containing u and v into a single component so that vertices in the resulting component are co-located thereafter.

Insertions and deletions of vertices model VM allocation and de-allocation, while merge requests model the scenario when frequently communicating VM's dedicated to a single application or a customer are consolidated for efficiency or energy savings [28].

The request sequence σ induces a unique set of components denoted by $\mathcal{C}$, over time. The migration cost of a single vertex is unit. All vertices of a single component are required to be assigned to the same cluster. Thus, we assume that the size of any component $C \in \mathcal{C}$ is most k at all times, and that there exists a component assignment to clusters such that each cluster is assigned a maximum of k vertices.

Competitive Analysis. We adopt the competitive analysis framework to analyze OBADC algorithms. A deterministic (resp. randomized) online algorithm $\mathcal{A}$ is said to be ρ-competitive (alternatively, ρ is the competitive ratio of $\mathcal{A}$) if for any input sequence σ, the cost (resp. expected cost) $c(\mathcal{A}, \sigma)$ incurred by $\mathcal{A}$ in σ satisfies $c(\mathcal{A}, \sigma) \leq \rho \mathrm{OPT}(\sigma) + \gamma$ where γ is a constant independent of the length of σ and $\mathrm{OPT}(\sigma)$ is the cost of an optimal offline algorithm denoted by OPT, which has complete information about the request sequence σ in advance. Abusing notation slightly, we refer to $\mathrm{OPT}(\sigma)$ as OPT when σ is clear from context.

Resource Competitiveness. To capture the practical objective of utilizing a number of clusters proportional to the total resource requirement (which varies over time), we seek algorithms which are also *competitive* with respect to the *number of clusters* utilized by OPT. Let n_t denote the number of vertices at any time t, and let α_t, β_t denote the number of clusters used to assign all n_t vertices at time t by OPT and an online algorithm $\mathcal{A}$. We say that $\mathcal{A}$ is μ-resource competitive if for all time t, $\beta_t \leq \mu \alpha_t$.

OBADC with Over-Provisioning. For the sake of obtaining polynomial-time online algorithms, we consider an overprovisioned setting, similar to the one considered in a recent work [23]. Here, each cluster C_i for $i \in [\ell]$ has capacity $(1+\varepsilon)k$ for some $\varepsilon \in (0, 1)$. While seemingly similar to a $(1+\varepsilon)$ resource-augmented model, we emphasize that in the over-provisioned setup, both the online algorithm and the optimal offline algorithm OPT are constrained to an *identical* cluster capacity of $(1+\varepsilon)k$ for any cluster C_i. As a result, competitiveness is analyzed on a stricter benchmark, in that the optimal offline and online algorithm have access to the same amount of resources, in strong contrast to resource augmentation where competitiveness is analyzed with respect to an unaugmented offline algorithm (see Chapter 4 of [25]).

Our main result is a $O(\log k)$-competitive algorithm for OBADC in the over-provisioned setting. We show that the competitive ratio of our algorithm is asymptotically optimal by establishing a lower bound. Furthermore, our algorithm is $(2+\varepsilon)$-resource competitive.

▶ **Theorem 1.** *Consider any instance of OBADC with ℓ clusters each of capacity $(1+\varepsilon)\ell$ and arbitrary sequence of insertion, deletion, and merge requests such that at any time the resulting components can be allocated to the ℓ clusters using capacity at most k. There exists an online algorithm that achieves cost at most $O(\log k)$ times the optimal, while utilizing at most $(2+\varepsilon)$ times more clusters than the minimum required at each time step.*

Furthermore, every online algorithm incurs cost $\Omega(\log k)$ times the optimal for the worst-case instance.

In a resource augmented setting where the optimal offline algorithm is constrained to capacity k per cluster, our algorithm obtains $O(\log k)$ competitiveness, while utilizing a number of clusters within $(1+\varepsilon)$ factor of the minimum. The proof of resource-competitiveness is deferred to the full version of the paper.

OBADC with Machine-Learned Predictions. We next investigate OBADC in the context of "algorithms with predictions" which is a growing research area [25, 15] with the over-arching goal of circumventing pessimistic limitations of lower and upper bounds for various problems in online, dynamic and approximation algorithms.

Prediction Model: At any time step t when a vertex v is inserted, with probability $\eta \geq 0$, we also receive a set P_v consisting of all vertices in V_t that lie in the same component as v, where V_t denotes the set of vertices at the beginning of time step t. Note that with probability $1-\eta$, we do not receive any information on the component of v. Furthermore, P_v only consists of vertices in v's component which exist at time t, and contains no information about future vertices in v's component which may arrive after time t.

Our "prediction error" is quantified by the confidence $\eta > 0$ of the predictions, similar to [11] and we analyze the performance of a learning-augmented online algorithm for OBADC in a standard *consistency-robustness* framework [11, 15, 24]. An algorithm $\mathcal{A}$ for OBADC with predictions is said to be α-consistent and β-robust if it is α-competitive when $\eta = 1$, and β-competitive where β is a non-increasing function of η. Roughly speaking if $\eta = 1$, and we have perfect predictions, then one would desire constant-factor competitiveness. On the other hand, as η approaches 0, the performance of the algorithm should gracefully degrade to the competitive ratio obtained by the best-known online algorithm for the problem. Our second result provides a near-tight consistency-robustness tradeoff for OBADC.

▶ **Theorem 2.** *There exists an $O(1)$-consistent and $O(\min(\log \frac{1}{\eta}, \log k))$-robust algorithm for OBADC with predictions in the over-provisioned setting.*

1.2 Technical Overview

In this section, we present a high level overview of our techniques towards obtaining our algorithms. We ignore several intricacies in the following discussion.

1.2.1 Overview of the Algorithms

Our algorithm for OBADC classifies components in terms of their volume (which refers to their size). A component is said to be *small* if it has volume at most Dk where $D = \Omega(\varepsilon)$, and large otherwise. Let $\mathcal{C}_S, \mathcal{C}_L$ denote the set of small and large components maintained at all times. Component volumes are rounded up to the nearest power of $(1 + \frac{\varepsilon}{4})$, such that components whose size is in the interval $[(1 + \frac{\varepsilon}{4})^{i-1}, (1 + \frac{\varepsilon}{4})^{i})$ belong to component class i. Thus, the total number of *small* component classes is $O(\log k)$ while the number of *large* component classes is $O(1)$. Our algorithm *assigns* volume to each component C on a cluster such that the assigned volume is upper bounded by $(1 + \frac{\varepsilon}{4})|C|$. The precise volume assigned by our algorithm is more fine-grained to further distinguish components within the same component class.

The assignment of large components is accomplished by solving an integer linear program (ILP) whose objective function seeks to minimize the number of clusters utilized. We remark that large components are assigned *independently* of small components. Since the number of large component classes is $O(1)$, the ILP can be solved in polynomial time. Invoking a result from [26] allows us to limit the total "change" in large component assignments after component merges (resp. vertex deletions), which lead to increase (resp. decrease) in a component's class. Small components are assigned in a *first-fit* fashion. Our algorithm maintains a "tight" assignment of components throughout time which guarantees $(2+\varepsilon)$-resource competitiveness.

The main challenge arises in maintaining these assignments *dynamically*, while simultaneously minimizing the total migration cost and clusters utilized. To accomplish this, our algorithm maintains several invariants. We give an overview of our algorithm as follows.

Insertion of singleton components are handled by provisioning volume on a cluster, with sufficient residual volume whenever possible. For a merge request (u, v), if u, v are in the same component C, the algorithm does nothing; else distinct components C_i, C_j containing u and v respectively, are merged into a new component C_m where w.l.o.g. $|C_i| \geq |C_j|$.

When C_m is *small* and the volume assigned to C_i is at least $|C_m|$, the smaller component C_j is migrated (unless it is assigned on the same cluster as C_i). Otherwise, if there is sufficient residual volume on the cluster to which C_i is assigned, C_m is assigned volume and vertices in C_j are migrated (if necessary). If the residual volume is insufficient, this implies that at least k vertices are assigned to this cluster. Thereafter, vertices in C_i and C_j are migrated to another cluster with sufficient residual volume. This may lead to a reduction in the assigned volume of C_j's cluster. Whenever the residual volume of a cluster decreases below a certain threshold, our algorithm migrates small components as necessary from other clusters to ensure resource-competitiveness.

On the other hand, if C_m is large such that C_m belongs to a higher component class than C_i, our algorithm solves an ILP; otherwise, vertices in C_j are migrated (if necessary). If the ILP is solved, this may lead to multiple components (both large and small) being reassigned and migrated. We give a greedy procedure to assign large components, which together with the sensitivity analysis result from [26], allows us to bound the total migration cost by $O(f(\varepsilon)k)$. If the request sequence consists of only vertex insertions and component merges (i.e. only monotonic increases in component sizes), we can establish $O(\log k)$-competitiveness by a relatively elegant charging argument (see Section 3).

However, for non-monotonic changes in component sizes a major challenge arises towards ensuring resource-competitiveness, since vertex deletions in one component may necessitate migration of other unrelated components to maintain a *tight* packing. To this end, our algorithm always maintains the property that the assigned volume of any component C is within a $(1 + \frac{\varepsilon}{4})$ factor of $|C|$ under both component merges and vertex deletions. For small components undergoing vertex deletions, volume reassignment can be done after a constant fraction of vertices in C are deleted. This may require migration of small components to C's cluster. On the other hand, if vertex deletions in C lead to a drop in C's component class we solve an ILP to reassign large components. This may be prohibitive in general because repeated vertex insertions and deletions can lead to a cost of $O(f(\varepsilon)k)$ every time an ILP is solved. To circumvent this, our algorithm works with a *relaxed* volume threshold (and component class categorization) when "deciding" whether to re-solve an ILP under vertex deletions. Thus, for example, certain large components may be treated as class i components by our algorithm even when their volume is less than $(1 + \frac{\varepsilon}{4})^{i-1}$. However, once at least $\Omega(\varepsilon^2 k)$ vertices are deleted from such components, our algorithm re-solves the ILP. We show that treating certain components in this manner does not violate resource competitiveness, since the total number of large components which can be assigned to any cluster is $O(\frac{1}{\varepsilon})$.

For the learning-augmented model, we enhance our algorithm of Theorem 1 by executing the merges indicated by the predictions at the time of insertion. That is, on the insertion of a vertex v whose predicted set $P(v)$ is non-empty, our algorithm issues merge requests of the form (v, u) for all $u \in P(v)$. This allows us to inherit several desirable properties of our algorithm of Theorem 1 while minimizing the total migration cost when augmented with predictions. The resulting algorithm also yields a smooth interpolation between our algorithm without predictions and one with full predictions.

We present an overview of our analyses in Section 3 and Section 4 for our $O(\log k)$-competitive algorithm and learning-augmented algorithm, respectively.

1.3 Related Work

Online graph partitioning problems. At a high-level, OBADC is related to previous work on online partitioning of dynamically changing graphs. Related problems include variants of online graph coloring and the OBGR problem. In recent work, Azar et al. [3] introduce an online graph recoloring problem in which edges of a graph arrive online and an algorithm needs to distribute the vertices among ℓ clusters such that for any edge, the two endpoints must be in different clusters. Subsequent work [23] considers a capacitated variant of online recoloring. A key distinction between such coloring problems and OBADC is that while an edge in the former requires the endpoints to be *separated*, an edge in the latter requires the endpoints to be *co-located*, leading to different technical considerations.

OBADC is perhaps most closely related to OBGR [2], in which there is a *static* set V of $n = kl$ vertices and a set of $l > 0$ clusters each holding k vertices initially. An online sequence $\sigma = \{(u_t, v_t)\}_{t>0}$ of communication requests arrives over time. The cost of serving request (u_t, v_t) is 1 if u_t and v_t are in distinct clusters and 0 otherwise. Prior to serving any request, a vertex can be migrated at a cost of $\alpha \in \mathbb{Z}^{>0}$. The cost incurred by an online algorithm is the total communication and migration cost to serve all requests in σ. OBGR has a $O(k^2l^2)$-competitive algorithm [2] in the non-augmented setting while a lower bound of $\Omega(kl)$ is known. In recent work, a $O(kl2^{O(k)})$-competitive algorithm was given in [4], which is optimal for constant k. In the resource augmented setting, with $(2+\varepsilon)$-augmented cluster capacity an $O(k \log k)$-competitive deterministic algorithm was given in [2]. For the same setting, a polynomial time algorithm was recently presented in [10]. A lower bound of $\Omega(l)$ holds even in the $(1+\varepsilon)$-augmented setting where $\varepsilon < 1/3$ [20].

In [14], Henzinger et al. introduced the learning model of the problem in which the vertex set of the graph G_σ induced by the request sequence σ can be partitioned into $V_1, ...V_l$ such that $|V_i| = k$ for all i and there are no inter-cluster requests (u, v) where $u \in V_i.v \in V_j$ for $j \neq i$. For the learning model, the lower bound of $\Omega(kl)$ holds in the non-augmented setting. Allowing $(1+\varepsilon)$-augmentation, the best deterministic and randomized algorithms are $\Theta(l \log k)$ and $\Theta(\log k + \log l)$-competitive respectively which are shown to be tight[13].

OBADC vs. OBGR. We describe the similarities and differences between OBADC and OBGR. OBADC resembles a "fully dynamic" version of OBGR in the learning model, but differs as follows. In OBADC, vertices arrive and depart over time, and hence the online algorithm has to adapt to communication patterns which evolve over time between both existing vertices and new vertices. The migration costs are identical between the two models; however in OBADC, an insertion of a new vertex incurs a cost of 1 and we aim to have the total number of clusters utilized by an online algorithm to adapt with the number of vertices. This may incur strategic migrations of vertices to satisfy this additional objective, in contrast to OBGR where migrations are performed to solely minimize communication overhead.

Resource-augmentation and over-provisioning. To circumvent pessimistic lower-bounds and obtain polyonomial time algorithms, many online algorithmic problems have been studied in the *resource-augmented* model (e.g., see [21, 33, 34]), going back as far as the earliest work on caching [29]. OBGR has also been studied in the resource-augmentation model [13, 22, 10, 2], where OPT is constrained to a capacity of k on each cluster, while an online algorithm can utilize capacity $(1+\varepsilon)k$ for some $\varepsilon > 0$. In contrast, we study OBADC in an *over-provisioned* setting, which yields stronger guarantees than resource-augmentation since the algorithm and the optimal have the same resources. Any competitive ratio in

the over-provisioned model immediately implies the same bound in the resource augmented model; for the measure of number of clusters utilized, we are able to get stronger bounds in the resource-augmentation model (see the remark after Theorem 1 in Section 1.1).

Learning-augmented algorithms. Another approach toward addressing pessimistic bounds in online and approximation algorithms is to incorporate the growing availability of machine-learned predictions in the design of algorithms [11, 18, 15, 5]. A central theme in this area is the following: given access to an imperfect machine-learned oracle which can "predict" characteristics of future request sequences or actions (in the context of online algorithms [24, 15]), edge updates (in the context of dynamic algorithms [5]) or optimal solutions (in the context of approximation algorithms [8]), can improved competitive ratios, running/update times, or approximation ratios be obtained? The imperfection of predictions is quantified by prediction error, which is problem and instance dependent, or a confidence parameter [11]. There is a great variation in terms of various prediction models and prediction errors which have been utilized and there is no singular notion of either, which can be useful or applicable to wide variety of problems.

Our study of online OBADC with predictions is also inspired from prior empirical work in VM allocation and migration, in which various predictions on resource utilization in clusters [17], future VM requests and migrations [19], and communication traffic from historically collected data have been utilized towards efficient provisioning of resources.

1.4 Outline and Preliminaries

Section 2 presents our main algorithm for OBADC. In Section 3, we give a proof sketch of the competitive ratio of our algorithm. The proofs of resource competitiveness and correctness are deferred to the full version of the paper. Finally, Section 4 presents a learning-augmented algorithm for OBADC with predictions, together with a proof sketch of Theorem 2.

We present some useful notation. Let V_t denote the set of vertices at any given point in time t such that $n_t = |V_t| \leq kl$. We use the notation $[i]$ for any $i \in \mathbb{Z}^+$ to refer to the set $\{1, 2, \ldots, i\}$. The volume of a component C is simply its size, and denoted by $|C|$.

Our algorithms maintain a set of components $\mathcal{C} = \{C_1, C_2, ...\}$ induced on V_t for all time t. We use $\mathcal{S} = \{S_1, S_2, \ldots, S_\ell\}$ to denote the set of all clusters. When there is merge a request (u, v) between distinct components C_i and C_j, our algorithms merge C_i and C_j into C_m. A merge is viewed as deletion of components C_i and C_j from $\mathcal{C}$ and an insertion of C_m to $\mathcal{C}$.

2 An $O(\log k)$-competitive algorithm

In this section, we present an *asymptotically* optimal deterministic $O(\log k)$-competitive algorithm for OBADC. We begin by giving some definitions and invariants that our algorithm maintains.

2.1 Definitions and Invariants

Component Classes. Our algorithm classifies components according to their size. For a component $C \in \mathcal{C}$, we say that C is in class i if $|C| \in [(1 + \frac{\varepsilon}{4})^{i-1}, (1 + \frac{\varepsilon}{4})^{i})$, where $1 \leq i \leq \lfloor \ln_{(1+\frac{\varepsilon}{4})} k \rfloor$. We say that a component is small if it is in class i where $i \leq c_s$ where $c_s \leq \lfloor \ln_{(1+\frac{\varepsilon}{4})} \frac{\varepsilon k}{4} \rfloor$. Thus, any small component has size at most Dk where $\frac{\varepsilon}{5} \leq D \leq \frac{\varepsilon}{4}$. All the other components are said to be large.

A large component is understood to be in class i if it is in class $i + c_s$. By the above definitions, it follows that a large component of class i has size in $[Dk(1+\frac{\varepsilon}{4})^{i-1}, Dk(1+\frac{\varepsilon}{4})^{i})$. The following lemma bounds the number of large component classes.

▶ **Lemma 3.** *The number of large component classes is* $c_l \leq \frac{26}{\varepsilon^2} = O(1)$.

Proof. Note that a large component has volume at least $\frac{\varepsilon k}{5}$ and at most k. Thus, $c_l \leq \frac{\ln(\frac{5}{\varepsilon})}{\ln(1+\frac{\varepsilon}{4})} + 1$. Since $1 - \frac{1}{x} \leq \ln x \leq x - 1$ for any $x \in \mathbb{R}^{\geq 0}$, it follows that $c_l \leq \frac{(5/\varepsilon)}{1/(1+\varepsilon/4)} \leq \frac{4+\varepsilon}{\varepsilon} \cdot \frac{5}{\varepsilon} + 1 \leq \frac{26}{\varepsilon^2}$ since $\varepsilon < 1$. ◀

Assigned Volume. For every component $C \in \mathcal{C}$, our algorithm provisions volume on some cluster $S_i \in \mathcal{S}$ to which it is assigned, which we refer to as the assigned volume and denote it by $A(C)$.

For any cluster $S_i \in \mathcal{S}$ let $A(S_i)$ denote the total assigned volume for all components assigned to S_i. Let R_i denote the residual *unassigned* volume of S_i, where $R_i = (1+\varepsilon)k - A(S_i)$. We present a fine-grained scheme to assign volumes to components as follows.

Let $A_{ij} = (1 + j\frac{\varepsilon}{16})(1+\frac{\varepsilon}{4})^{i-1}$, for $j \in \{0, 1, 2, 3, 4\}$. Thus, $A_{i0} = (1+\frac{\varepsilon}{4})^{i-1}$ and $A_{i4} = (1+\frac{\varepsilon}{4})^{i}$. Our algorithm maintains the following invariant for assigned volumes at all times.

▶ **Invariant 1** (Assigned Volume). *For all classes i, and any class i component such that $|C| \in [(1+\frac{\varepsilon}{4})^{i-1}, (1+\frac{\varepsilon}{4})^{i})$, one of the following statements holds:*

1. *if $A_{i0} \leq |C| < A_{i1}$, then $|C| \leq A(C) \leq A_{i3}$.*
2. *if $A_{i1} \leq |C| < A_{i2}$, then $|C| \leq A(C) \leq A_{i4}$.*
3. *if $A_{i2} \leq |C| < A_{i3}$, then $|C| \leq A(C) \leq (1+\frac{\varepsilon}{16})(1+\frac{\varepsilon}{4})^{i} = A_{i+1,1}$.*
4. *if $A_{i3} \leq |C| < A_{i4}$, then $|C| \leq A(C) \leq (1+\frac{\varepsilon}{8})(1+\frac{\varepsilon}{4})^{i} = A_{i+1,2}$.*

The following lemma is immediate based on the invariant above.

▶ **Lemma 4.** *If Invariant 1 is maintained, then for any component C, $|C| \leq A(C) \leq (1+\frac{\varepsilon}{4})|C|$.*

Active Clusters. A cluster is said to be *active* if there is at least one component assigned to it. The set of all active clusters is denoted by $\mathcal{S}_A$.

Marked Clusters. Our algorithm marks and un-marks active clusters over time. If a cluster is marked, then its residual volume is small. We denote the set of marked clusters by $\mathcal{S}_M$, where $\mathcal{S}_M \subseteq \mathcal{S}_A$. Initially, all clusters are unmarked, i.e. $\mathcal{S}_M = \emptyset$. Our algorithm maintains the following invariant at all times.

▶ **Invariant 2.** *For a cluster $S_j \in \mathcal{S}_M$, $R_j \leq \frac{\varepsilon k}{3}$.*

Furthermore, let $\mathcal{S}_S$ denote the set of clusters on which only small components (and no large components) are assigned and let $\mathcal{S}_L$ denote the set of clusters to which at least one large component is assigned. To ensure that the number of active clusters is at most $(2+\varepsilon)$ times the minimum needed, our algorithm maintains the following invariant.

▶ **Invariant 3.** *At any time t, if $|\mathcal{S}_S| > 0$ then both of the following hold: i) either $\mathcal{S}_L = \emptyset$ or $\mathcal{S}_L \subseteq \mathcal{S}_M$ (i.e. all clusters in $\mathcal{S}_L$ are marked) and, ii) exactly one cluster in $\mathcal{S}_S$ is unmarked.*

Marked Components. Our algorithm marks and un-marks certain components when their component class decreases due to vertex deletions. If a large component of class $i \in [c_l - 1]$, (resp. a small component of class c_s) is marked, then it is treated as a large component of class $i+1$ (resp. a large component of class 1). Intuitively, we mark a component to ensure that the ILP is not solved too frequently if its volume shrinks only slightly due to deletions. The set of marked components at any time is denoted by $\mathcal{C}_M$. Note that all marked components are *treated* as large components by our algorithm, thus $\mathcal{C}_M \subseteq \mathcal{C}_L$. Our algorithm maintains the following invariant for marked components.

▶ **Invariant 4.** *At any point in time, a marked component $C \in \mathcal{C}_L$ satisfies one of the following conditions:*

1. *C is a small component of class c_s, such that $|C| \geq Dk - \frac{\varepsilon^2 k}{100}$.*
2. *C is a large component of class $i \in [c_l - 1]$, such that $|C| \geq Dk(1+\frac{\varepsilon}{4})^i - \frac{\varepsilon^2 k}{100}$.*

Data Structures. Our algorithms maintain the sets $\mathcal{C}_S$ and $\mathcal{C}_L$ of small and large components, respectively, together with the set $\mathcal{C}_M$ of marked components. For a component C, the assigned volume $A(C)$ is maintained, and for all $S_i \in \mathcal{S}$, $A(S_i)$ and R_i are maintained. Furthermore, the sets of clusters $\mathcal{S}_A, \mathcal{S}_M, \mathcal{S}_S$ and $\mathcal{S}_L$ are maintained.

In the following section, we outline our approach for assigning large components which is completely independent of the assignment of small components.

2.2 An Approach to Assign Large Components

We first define the notion of a signature, similar to [22, 13]. Intuitively, a signature encodes the number of large components of each component class that can be assigned to a single cluster while respecting cluster capacity.

▶ **Definition 5.** *A signature $\tau = (\tau_1, \tau_2, ..., \tau_{c_l})$ is a non-negative vector of dimension c_l where τ_i denotes the number of large components of class i such that $\sum_{i=1}^{c_l}(Dk(1+\frac{\varepsilon}{4})^{i-1} - \frac{\varepsilon^2 k}{100})\tau_i \leq k$.*

Let $\mathcal{T} = \{T_1, T_2, ...\}$ denote the set of all possible signatures. The following lemma bounds the size of $\mathcal{T}$.

▶ **Lemma 6.** *The total number of signatures, $|\mathcal{T}|$ is bounded by $(\frac{6}{\varepsilon})^{\frac{26}{\varepsilon^2}} = O(1)$.*

Proof. We first note that $Dk(1+\frac{\varepsilon}{4})^{i-1} - \frac{\varepsilon^2 k}{100} \geq Dk - \frac{\varepsilon^2 k}{100} \geq \frac{\varepsilon k}{5} - \frac{\varepsilon^2 k}{100} \geq \frac{\varepsilon k}{6}$ for any $i > 0$. Thus, any entry τ_i is upper bounded by $\frac{k}{\varepsilon k/6} = \frac{6}{\varepsilon}$. Since the number of large component classes is $\frac{26}{\varepsilon^2}$ by Lemma 3, the total number of signatures is at most $(\frac{6}{\varepsilon})^{\frac{26}{\varepsilon^2}} = O(1)$. ◀

We solve an integer linear program (ILP) in polynomial time, and obtain signatures which guide the placement of large components. Let T_{ij} denote the j^{th} entry of a signature $T_i \in \mathcal{T}$. For each signature T_i, we let $x_i \in [0, \ell]$ denote the number of clusters which are assigned signature T_i. Let σ_j denote the number of class j large components at any given point in time. Our ILP is as follows.

ILP.

$$\min \quad \sum_{i=1}^{|\mathcal{T}|} x_i \quad \text{s.t.} \quad \sum_{i=1}^{|\mathcal{T}|} T_{ij} x_i = \sigma_j \ \forall j \in [c_l], \quad x_i \in [0, \ell] \ \forall i \in [\mathcal{T}].$$

In matrix form, our ILP has $n_r = O(c_l) = O(1)$ rows and $n_c = O(|\mathcal{T}|) = O(1)$ columns. Thus, the ILP can be solved in polynomial time.

Our algorithm solves this ILP whenever σ_j changes for any $j \in [c_l]$. This could be after components are merged leading to a larger component with a higher component class or, vertex deletions from a component leading to a decrease in its component class. In both cases, at most three components in $\mathcal{C}$ change, and as a result, at most three component classes change. We invoke a well-known result in sensitivity analysis from [27], which quantifies the *change* in optimal solutions of the ILP.

▶ **Theorem 7** ([27]). *Let A be an integral $n_r \times n_c$ matrix, such that each subdeterminant of A is at most Δ in absolute value; let b' and b'' be column n_r-vectors, and let c be a row n_c-vector. Suppose $\max\{cx|Ax \leq b' : x \text{ integral}\}$ and $\max\{cx|Ax \leq b'' : x \text{ integral}\}$ are finite. Then for each optimum solution z' of the first maximum there exists an optimum solution z'' of the second maximum such that $\|z' - z''\|_\infty \leq n_c\Delta(\|b' - b''\|_\infty + 2)$.*

We prove the following lemma.

▶ **Lemma 8.** *After a merge request or deletion request, the number of signatures which change in the optimal solution to the ILP is $f(\varepsilon) = \frac{|\mathcal{T}|^{2+|\mathcal{T}|}}{\varepsilon^{|\mathcal{T}|}} = O(1)$ for constant $\varepsilon > 0$.*

Proof. Whenever two components are merged or a deletion causes a large component's size class to decrease, the RHS vector in our ILP changes by at most 1 in the infinity norm. To bound the sub-determinant, we use the Hadamard inequality to derive that $\Delta \leq (n_c A_{\max})^{n_c/2}$ where $A_{\max}$ denotes the maximum entry (in absolute value) of the constraint matrix A. Each entry in the constraint matrix of our ILP has value either 1 or T_{ij} so that $A_{\max} \leq \frac{k}{Dk} = O(\frac{1}{\varepsilon})$. As a result, $\Delta = O((\frac{|\mathcal{T}|}{\varepsilon})^{|\mathcal{T}|})$. Thus, the optimal solution to the ILP changes by $O(|\mathcal{T}|\Delta)$ in the infinity norm. Since x has dimension $|\mathcal{T}|$, the number of signatures which change between any two optimal solutions is $O(|\mathcal{T}|^2\Delta) = O(1)$. ◀

Greedy Assignment of Signatures to Clusters. Given the solution $x = (x_1, x_2, ..., x_{|\mathcal{T}|})$ from the ILP, we perform a *greedy* assignment of signatures to clusters which minimizes the number of clusters whose assigned signatures change. Let $x' = (x'_1, x'_2, ..., x'_{|\mathcal{T}|})$ denote the current signature, such that there are exactly x'_i clusters which are assigned signature T_i. Our algorithm for greedy assignment, `Assign-Signatures` works as follows.

Let $z_i = x_i$ for all $i \in [|\mathcal{T}|]$ and $\mathcal{S}' := \mathcal{S}_A$ denote the set of active clusters. We iterate over all $i \in [|\mathcal{T}|]$: while $z_i > 0$, if there exists an active cluster S_j in $\mathcal{S}'$ which is currently assigned signature T_i, z_i is decremented, S_j is removed from $\mathcal{S}'$ and we continue. Else if no cluster in $\mathcal{S}'$ is assigned signature T_i, we pick an arbitrary active cluster S_j in $\mathcal{S}_A$ and assigns T_i to S. If $\mathcal{S}' = \emptyset$, our algorithm picks an arbitrary inactive cluster $S_j \in \mathcal{S} \backslash \mathcal{S}_A$, adds S_j to $\mathcal{S}_A$ and assigns T_i to S.

Let $\mathcal{S}_N \subseteq \mathcal{S}_A$ denote the set of clusters which are assigned a new signature after the call to `Assign-Signatures`. Any cluster $S \in \mathcal{S}_N$ satisfies one of the following conditions prior to the call to `Assign-Signatures`: i) S was inactive, ii) S was active but its signature changed after the call to `Assign-Signatures` or iii) S was active and was not assigned any signature prior to the call to `Assign-Signatures`.

Let $\mathcal{S}_O \subseteq \mathcal{S}$ denote the set of clusters which were assigned a signature prior to solving the ILP, and are no longer assigned a signature. Finally, let $\mathcal{S}_I$ denote the set of clusters whose assigned signatures are identical before and after the call to `Assign-Signatures`. Our algorithm returns sets $\mathcal{S}_N, \mathcal{S}_O$ and $\mathcal{S}_I$. Clearly, the assigned signatures change only for clusters which are in $\mathcal{S}_N \cup \mathcal{S}_O$.

By virtue of subroutine `Assign-Signatures` and Lemma 8, the following lemma is immediate.

Algorithm 1 `Assign-Signatures`.

Let $x' = (x'_1, x'_2, ..., x'_{|\mathcal{T}|})$ denote the current signature.
$\mathcal{S}' \leftarrow \mathcal{S}_A$, $\mathcal{S}_N \leftarrow \emptyset$, $\mathcal{S}_I \leftarrow \emptyset$.
Solve the ILP and let $x = (x_1, x_2, ..., x_{|\mathcal{T}|})$ denote the obtained signature
for $i \in [|\mathcal{T}|]$ **do**
    $z_i = x_i$.
    while $z_i > 0$ **do**
        if there exists $S_j \in \mathcal{S}'$ assigned a signature T_i **then**
            $z_i \leftarrow z_i - 1$, $\mathcal{S}' \leftarrow \mathcal{S}' \backslash \{S_j\}$, $\mathcal{S}_I \leftarrow \mathcal{S}_I \cup \{S_j\}$.
        else
            if $\mathcal{S}' = \emptyset$ **then**
                Pick an arbitrary cluster $S_j \in \mathcal{S} \backslash \mathcal{S}_A$, and assign T_i to S_j.
                $\mathcal{S}_N \leftarrow \mathcal{S}_N \cup \{S_j\}$.
            else
                Pick an arbitrary active cluster S_j in $\mathcal{S}'$ and assign T_i to S_j.
                $\mathcal{S}_N \leftarrow \mathcal{S}_N \cup \{S_j\}$, $\mathcal{S}' \leftarrow \mathcal{S}' \backslash \{S_j\}$.
$\mathcal{S}_O \leftarrow \mathcal{S}_L \backslash (\mathcal{S}_I \cup \mathcal{S}_N))$.
$\mathcal{S}_L \leftarrow \mathcal{S}_N \cup \mathcal{S}_I$.
Return $(\mathcal{S}_N, \mathcal{S}_O, \mathcal{S}_I)$.

▶ **Lemma 9.** *After a call to* `Assign-Signatures`, $|\mathcal{S}_N \cup \mathcal{S}_O| = f(\varepsilon) = O(1)$.

For all clusters $S_i \in \mathcal{S}_I$ whose assigned signatures do not change, our algorithm does not modify the assignment of large components. Let $\mathcal{C}'_L$ denote the set of all large components in $\mathcal{C}_L$ which are not assigned to any cluster in $\mathcal{S}_I$. It follows from Lemma 9 that the total volume of all large components in $\mathcal{C}'_L$ is $O(kf(\varepsilon))$.

Components in $\mathcal{C}'_L$ are assigned to clusters in $\mathcal{S}_N$, corresponding to the newly assigned signatures. Let $\mathcal{C}'_S$ denote the set of all small components previously assigned to $\mathcal{S}_N \cup \mathcal{S}_O$. From Lemma 9, it follows that the total volume of all components in $\mathcal{C}'_S$ is $O(kf(\varepsilon))$. Our algorithm re-assigns small components in $\mathcal{C}'_S$ in a *first-fit* fashion, explained in the next section. The following Lemma is immediate from Lemma 8, Lemma 9 and our preceding discussion.

▶ **Lemma 10.** *The total volume of components in* $\mathcal{C}'_L \cup \mathcal{C}'_S$ *is bounded by* $O(kf(\varepsilon) = O(k)$.

2.3 The Full Algorithm

In this section, we present our algorithm which takes as input a request r_t at time t, and maintains an assignment of components to clusters while satisfying Invariants 1 through 4. Our algorithm relies on various subroutines, which we present in the following.

Subroutine `Assign-Volume`. This subroutine takes as input a component C, and a cluster $S_j \in \mathcal{S}_A$ and assigns volume for C on S_j. In the case when C is a class $i-1$ marked component, it is treated as a class i component and assigned volume A_{i2}.

Observe that Invariant 1 is satisfied for any component C after a call to `Assign-Volume`.

Subroutine `Assign-Small`. The subroutine `Assign-Small` is invoked whenever a small component C needs to be assigned volume on a cluster. We iterate over active unmarked clusters $S_j \in \mathcal{S}_A \backslash \mathcal{S}_M$, and if $R_j \geq (1 + \frac{\varepsilon}{4})|C|$, C is assigned to S_j. Else, S_j is marked and added to $\mathcal{S}_M$.

Algorithm 2 `Assign-Volume`(C, S_j).

if $C \notin \mathcal{C}_M$ **then**
  Let $i > 0$ s.t. $|C| \in [(1+\frac{\varepsilon}{4})^{i-1}, (1+\frac{\varepsilon}{4})^{i})$.
  $A(C) \leftarrow 0$.
  if $A_{i0} \leq |C| < A_{i1}$ **then**
    $A(C) \leftarrow A_{i2}$.
  else if $A_{i1} \leq |C| < A_{i2}$ **then**
    $A(C) \leftarrow A_{i3}$.
  else if $A_{i2} \leq |C| < A_{i3}$ **then**
    $A(C) \leftarrow A_{i,4}$.
  else
    $A(C) \leftarrow A_{i+1,1}$.
  $A(S_j) \leftarrow A(S_j) + A(C)$, $R_j \leftarrow R_j - A(C)$.
else ▷ If C is marked.
  Let $i \geq 0$ s.t. $|C| \in [Dk(1+\frac{\varepsilon}{4})^{i-1} - \frac{\varepsilon^2 k}{100}, Dk)$.
  $A(C) \leftarrow A_{i2}$.

If all clusters are marked, i.e. $\mathcal{S}_M = \mathcal{S}_A$ we add an arbitrary cluster in $\mathcal{S} \backslash \mathcal{S}_A$ to $\mathcal{S}_A$ and assign volume for C.

Algorithm 3 `Assign-Small`(C).

is-assigned=false.
for all $S_j \in \mathcal{S}_A \backslash \mathcal{S}_M$ **do**
  if $R_j \geq (1+\frac{\varepsilon}{4})|C|$ **then**
    `Assign-Volume`(C, S_j).
    is-assigned=true.
    break
  else
    $\mathcal{S}_M \leftarrow \mathcal{S}_M \cup \{S_j\}$.
if is-assigned=false **then**
  Pick an arbitrary cluster $S_j \in \mathcal{S} \backslash \mathcal{S}_A$.
  $\mathcal{S}_A \leftarrow \mathcal{S}_A \cup \{S_j\}$.
  `Assign-Volume`(C, S_j).
  $\mathcal{S}_S \leftarrow \mathcal{S}_S \cup \{S_j\}$.

Subroutine `Handle-Insertion`. The subroutine `Handle-Insertion` is called whenever a request r_t at time t corresponds to a vertex insertion v. Subroutine `Assign-Small` is invoked to assign the singleton component $\{v\}$.

Algorithm 4 `Handle-Insertion`(v).

$C \leftarrow \{v\}$.
$\mathcal{C}_S \leftarrow \mathcal{C}_S \cup \{C\}, \mathcal{C} \leftarrow \mathcal{C} \cup \{C\}$.
`Assign-Small`(C).

Subroutine `Unassign-Volume`. This subroutine takes as input a component C which is currently assigned to a cluster S_i. The quantity $A(S_i)$ is decremented by $A(C)$ and $A(C)$ is set to 0. If $S_i \in \mathcal{S}_M$ and $R_i \geq \frac{\varepsilon k}{3}$, S_i is unmarked. The reason why S_i is unmarked is that if $R_i \geq \frac{\varepsilon k}{2}$, a small component can be assigned volume on S_i, since the assigned volume for a small component is bounded by $\frac{\varepsilon k}{4}(1+\frac{\varepsilon}{4}) < \frac{\varepsilon k}{3}$ by Invariant 1. The pseudo-code is given as follows.

Algorithm 5 `Unassign-Volume`(C, S_i).

1: $A(S_i) \leftarrow A(S_i) - A(C)$, $R_i \leftarrow R_i + A(C)$.
2: $A(C) \leftarrow 0$.
3: **if** $S_i \in \mathcal{S}_M$ and $R_i \geq \frac{\varepsilon k}{2}$ **then**
4: $\quad \mathcal{S}_M \leftarrow \mathcal{S}_M \backslash \{S_i\}$.

Subroutine `Handle-Unmarked`. This subroutine takes as input a newly unmarked cluster S_i. If the assigned volume $A(S_i) = 0$, then S_i is removed from the sets $\mathcal{S}_A$ and $\mathcal{S}_S$. If $|\mathcal{S}_S| > 0$, an arbitrary cluster $S \in \mathcal{S}_S$ is chosen and unmarked.

Else, if $A(S_i) > 0$, Invariant 3 is restored as follows. Note that if $S_i \in \mathcal{S}_L$ and $\mathcal{S}_S = \emptyset$ or $S_i \in \mathcal{S}_S$ and $|\mathcal{S}_S| = 1$, nothing needs to be done since Invariant 3 is already maintained. Else, let $S \in \mathcal{S}_S$ denote an unmarked cluster where $S \neq S_i$. While the residual volume of S_i is sufficient (and S_i is unmarked and $|\mathcal{S}_S| > 0$) small components from S are migrated to S_i. If the residual volume of S_i is insufficient, S_i is marked and added to $\mathcal{S}_M$. If at any point $A(S) = 0$, S is removed from $\mathcal{S}_A$ and $\mathcal{S}_S$. Thereafter, if $S_i \in \mathcal{S}_L$, and $|\mathcal{S}_S| > 0$, an arbitrary cluster S in $\mathcal{S}_S$ is unmarked. If $S_i \in \mathcal{S}_S$, and $|\mathcal{S}_S| > 1$, an arbitrary cluster in $\mathcal{S}_S$ is unmarked. The procedure continues while the residual volume of S_i is sufficient. On the other hand, if S_i is the only cluster in $\mathcal{S}_S$ it is unmarked and the process terminates.

Subroutine `Reassign-Large`. We give a subroutine `Reassign-Large` which is invoked whenever the number of large components σ_i of any class $i \in [c_l]$ change. In `Reassign-Large`, the subroutine `Assign-Signatures` is invoked which returns the sets $\mathcal{S}_N, \mathcal{S}_O$ and $\mathcal{S}_I$ of clusters (see Section 2.2).

Let $\mathcal{C}'_S$ denote the set of all small components assigned to clusters in $\mathcal{S}_O \cup \mathcal{S}_N$. Small components currently assigned to clusters in $\mathcal{S}_O \cup \mathcal{S}_N$ are unassigned. Clusters in $\mathcal{S}_O \cup \mathcal{S}_N$ are unmarked and the set of active clusters $\mathcal{S}_A$ is updated by removing clusters in $\mathcal{S}_O$ and adding clusters in $\mathcal{S}_N$.

Next, let $\mathcal{C}'_L$ denote the set of large components which are not assigned to any cluster in $\mathcal{C}_I$. For all clusters $S \in \mathcal{S}_N$, let T_s be the signature assigned to cluster S. For all non-zero T_{sa} where $a \in [c_l]$, a class a large component C is chosen from $\mathcal{C}'_L$, and `Assign-Volume`(S, C) is invoked, concluding the the assignment of large components.

For small components $C \in \mathcal{C}'_S$, `Assign-Small`(C) is invoked. Finally, for all unmarked clusters S in $\mathcal{S}_N \notin \mathcal{S}_M$, `Handle-Unmarked`$(S)$ is invoked. The pseudo code of `Reassign-Large` is deferred to the full version of the paper.

Subroutine `Handle-Deletion`. We present a subroutine `Handle-Deletion` which takes as input a vertex v to be deleted. We assume that Invariant 1 holds prior to the deletion request. Let C denote the component containing v prior to v's deletion s.t. $|C| \in [(1+\frac{\varepsilon}{4})^{i-1}, (1+\frac{\varepsilon}{4})^{i})$ and S_j denote the cluster to which C is assigned. We consider two cases.

Algorithm 6 `Handle-Unmarked`(S_i).

if $A(S_i) = 0$ **then**
  $\mathcal{S}_A \leftarrow \mathcal{S}_A \backslash \{S_i\}, \mathcal{S}_S \leftarrow \mathcal{S}_S \backslash \{S_i\}$.
  if $|\mathcal{S}_S| > 0$ **then** Pick an arbitrary cluster $S \in \mathcal{S}_S$, $\mathcal{S}_M \leftarrow \mathcal{S}_M \backslash \{S\}$.
else
  if ($S_i \in \mathcal{S}_L$ and $\mathcal{S}_S \neq \emptyset$) or ($S_i \in \mathcal{S}_S$ and $|\mathcal{S}_S| > 1$) **then**
    Let $S \neq S_i$ be an unmarked cluster in $\mathcal{S}_S$.
    while $S_i \notin \mathcal{S}_M$ and $\mathcal{S}_S \neq \emptyset$ **do**
      Let C be an arbitrary small component assigned to S.
      if $R_i \geq (1 + \frac{\varepsilon}{4})|C|$ **then**
        `Assign-Volume`(C, S_i).
        `Unassign-Volume`(C, S).
      else
        $\mathcal{S}_M \leftarrow \mathcal{S}_M \cup \{S_i\}$. ▷ S_i is marked
      if $A(S) = 0$ **then**
        $\mathcal{S}_A \leftarrow \mathcal{S}_A \backslash \{S\}$, $\mathcal{S}_S \leftarrow \mathcal{S}_S \backslash \{S\}$. ▷ S is made inactive.
        if $S_i \in \mathcal{S}_L$ and $|\mathcal{S}_S| > 0$ **then**
          Let S be an arbitrary cluster in $\mathcal{S}_S$.
          $\mathcal{S}_M \leftarrow \mathcal{S}_M \backslash \{\mathcal{S}\}$. ▷ S is unmarked.
        if $S_i \in \mathcal{S}_S$ **then**
          if $|\mathcal{S}_S| > 1$ **then**
            Let $S \neq S_i$ be an arbitrary cluster in $\mathcal{S}_S$.
            $\mathcal{S}_M \leftarrow \mathcal{S}_M \backslash \{S\}$. ▷ S is unmarked.
          else
            break. ▷ S_i is the only unmarked cluster in $\mathcal{S}_S$ in this case.

1. C is small and unmarked: Vertex v is removed from C. There are five sub-cases to consider.
   a. If $A(C) = A_{i+1,2}$ and $|C| < A_{i3}$, then $A(C)$ is set to $A_{i+1,1}$.
   b. If $A(C) = A_{i+1,1}$ and $|C| < A_{i2}$, then $A(C)$ is set to A_{i4}.
   c. If $A(C) = A_{i4}$ and $|C| < A_{i1}$, then $A(C)$ is set to A_{i3}.
   d. If $A(C) = A_{i3}$ and $|C| < A_{i0} = (1 + \frac{\varepsilon}{4})^{i-1}$, then C has become a class $i-1$ component. $A(C)$ is set to A_{i2}.
   e. If $C = \emptyset$, $A(C)$ is set to 0.

   In all of the above cases, $A(S_j)$ and R_j are updated. If $S_j \in \mathcal{S}_M$ and $R_j \geq \frac{\varepsilon k}{2}$, S_j is removed from $\mathcal{S}_M$ and `Handle-Unmarked`(S_j) is invoked.
2. C is large or marked: We first remove v from C. We consider the following cases.
   a. C is large and unmarked (i.e. $C \in \mathcal{C}_L \backslash \mathcal{C}_M$): Our algorithm considers the following cases.
      i. If $A(C) = A_{i+1,2}$ and $|C| < A_{i3}$, then $A(C)$ is set to $A_{i+1,1}$.
      ii. If $A(C) = A_{i+1,1}$ and $|C| < A_{i2}$, then $A(C)$ is set to A_{i4}.
      iii. If $A(C) = A_{i4}$ and $|C| < A_{i1}$, then $A(C)$ is set to A_{i3}.
      iv. If $|C| < A_{i0}$, C is marked. If $A(C) = A_{i3}$ then $A(C)$ is set to A_{i2}.

      In the above cases, if $S_j \in \mathcal{S}_M$ and $R_j \geq \frac{\varepsilon k}{2}$, S_j is removed from $\mathcal{S}_M$ and `Handle-Unmarked`(S_j) is invoked.

b. C is marked: There are two cases to consider depending on whether C is large or small (after the deletion of v).

i. Let C be a marked large component of class c where $c = i - c_s$, such that $c \in [c_l - 1]$. If $|C| \geq Dk(1+\frac{\varepsilon}{4})^c - \frac{\varepsilon^2 k}{100}$, there is nothing to be done. Else, if $|C| < Dk(1+\frac{\varepsilon}{4})^c - \frac{\varepsilon^2 k}{100}$, C is unmarked. The counter σ_{c+1} is decremented since C is now considered a class c component, and σ_c is incremented. Then, the subroutine `Reassign-Large` is invoked.

ii. Let C be a marked small component of class c_s. If $|C| \geq Dk - \frac{\varepsilon^2 k}{100}$, nothing is done. Else, if $|C| < Dk - \frac{\varepsilon^2 k}{100}$, C is first unmarked. Then, C is removed from $\mathcal{C}_L$ and added to $\mathcal{C}_S$. The counter σ_1 is decremented. Then, the subroutine `Reassign-Large` is invoked.

The pseudo-code of `Handle-Deletion` is deferred to the full version of the paper.

`Merge-Components`. The subroutine `Merge-Components` is invoked by our algorithm to handle a merge request (u, v). Let C_i, C_j denote the components of u and v respectively. If $C_i = C_j$, nothing needs to be done. Otherwise, w.l.o.g., let $|C_j| \leq |C_i|$ and S_i and S_j denote the clusters on which C_i and C_j are currently assigned. Let $C_m = C_i \cup C_j$.

1. C_m is small: The subroutine `Handle-Small` is called and considers two cases.

a. C_i is marked: We note that C_j cannot be a marked component since this would contradict that C_m is small. This is because if C_j is marked, then $|C_m| \geq 2(Dk - \frac{\varepsilon^2 k}{100}) = Dk + Dk - \frac{\varepsilon^2 k}{50} > Dk$ since $Dk - \frac{\varepsilon^2 k}{50} > \frac{\varepsilon k}{5} - \frac{\varepsilon k}{50} > 0$. Thus, the only possibility is that C_i is marked. Since any marked small component must have volume at least $Dk - \frac{\varepsilon^2 k}{100}$, and C_m is small it follows that $|C_m| \leq Dk$. In this case we note that $A(C_i) = A_{i2} \geq Dk$ so that $A(C_m)$ can be set to $A(C_i)$. C_i is removed from $\mathcal{C}_M$ and C_m is added to $\mathcal{C}_M$. If $|C_m| < Dk$, C_m is added to $\mathcal{C}_M$. As such, C_m is still treated by our algorithm as a large marked component. If $S_i = S_j$ nothing needs to be done. Else, vertices in C_j are migrated to S_i, and `Unassign-Volume`(C_j, S_j) is invoked. Subroutine `Handle-Unmarked`(S_j) is invoked to handle the case when S_j becomes unmarked.

b. C_i and C_j are not marked: In this case, there are two cases to consider.

i. If $A(C_i) \geq |C_m|$, we set $A(C_m)$ to $A(C_i)$ and $A(C_i), A(C_j)$ to 0. If $S_j = S_i$, nothing needs to be done. If $S_j \neq S_i$, vertices in C_j are migrated to S_i, and `Unassign-Volume`(C_j) is invoked. Subroutine `Handle-Unmarked`(S_j) is invoked to handle the case if S_j becomes unmarked.

ii. If $A(C_i) < |C_m|$, we invoke `Unassign-Volume`(C_i, S_i) and `Unassign-Volume`(C_j, S_j). If $R_i \geq (1 + \frac{\varepsilon}{4})|C_m|$, we call `Assign-Volume`$(C_m, S_i)$. If $S_i \neq S_j$, we migrate vertices in C_j to S_i. We invoke `Handle-Unmarked`(S_j) and `Handle-Unmarked`(S_i).
On the other hand, if $R_i < (1 + \frac{\varepsilon}{4})|C|$, S_i is marked and `Assign-Small`(C_m) is invoked.

2. C_m is large: The subroutine `Handle-Large` is invoked which adds C_m to the set of large components.
Let $m' \in [c_l]$ be an integer such that $|C_m| \in [Dk(1 + \frac{\varepsilon}{4})^{m'-1}, Dk(1 + \frac{\varepsilon}{4})^{m'})$. If C_i is marked, i.e. $C_i \in \mathcal{C}_M$, let $i' \coloneqq a + 1$ be the integer where a is an integer such that $|C_i| \in [Dk(1 + \frac{\varepsilon}{4})^a - \frac{\varepsilon^2 k}{100}, Dk(1 + \frac{\varepsilon}{4})^a)$, else we let $i' \coloneqq a$ be the integer where a is an integer such that $|C_i| \in [Dk(1 + \frac{\varepsilon}{4})^{a-1}, Dk(1 + \frac{\varepsilon}{4})^a)$. We consider the following cases.

a. C_j is large or C_j is marked or $m' > i'$: If C_j is marked, we let $j' \coloneqq a + 1$ be the integer where a is an integer such that $|C_j| \in [Dk(1 + \frac{\varepsilon}{4})^a - \frac{\varepsilon^2 k}{100}, Dk(1 + \frac{\varepsilon}{4})^a)$. Else if C_j is unmarked, we let $j' \coloneqq a$ be the integer where a is an integer such that

$|C_j| \in [Dk(1+\frac{\varepsilon}{4})^{a-1}, Dk(1+\frac{\varepsilon}{4})^{a})$. We decrement $\sigma_{j'}$ and $\sigma_{i'}$ by 1, and increment $\sigma_{m'}$ by 1. We remove C_i, C_j from $\mathcal{C}_M$ to make sure that the set of marked components is updated. Thereafter, we update the component sets $\mathcal{C}_S, \mathcal{C}_L$ and call subroutine `Reassign-Large` to handle the assignment of large components.

b. C_j is small and C_j is unmarked and $m' \leq i'$: In this case, we note that $\sigma_{i'}, \sigma_{m'}$ do not change. Thus, the ILP is not solved. We assign volume for the merged component as follows.

In the case when $A(C_i) \geq A(C_m)$, vertices in C_j are migrated to S_i if $S_i \neq S_j$. We invoke `Unassign-Volume`(C_j, S_j), and `Handle-Unmarked`(S_j). Else, nothing needs to be done. The assigned volumes $A(C_i), A(C_j)$ are set to 0. If C_i is marked and $|C_m| < Dk(1+\frac{\varepsilon k}{4})^{i'-1}$, then C_i is removed from $\mathcal{C}_M$ and C_m is added to $\mathcal{C}_M$. We note that in this case, $A(C_i) = A_{i'2} \geq A(C_m)$.

If $A(C_i) < |C_m|$, then we invoke `Unassign-Volume`(C_i, S_i) and `Unassign-Volume`(C_j, S_j).

If $R_i \geq (1+\frac{\varepsilon}{4})|C_m|$, we assign volume for C_m on S_i by invoking `Assign-Volume`(C_m, S_i). If $A(S_j) = 0$, we call `Handle-Unmarked`(S_j). Next, we call `Handle-Unmarked`(S_i). In the case when $A(S_j) \neq 0$ (and $S_j \in \mathcal{S}_A$ as a result), we invoke `Handle-Unmarked`(S_j).

If $R_i < (1+\frac{\varepsilon}{4})|C_m|$, we do the following. While $R_i < (1+\frac{\varepsilon}{4})|C_m|$, we call `Unassign-Volume`$(C, S_i)$ where C is an arbitrary small component assigned on S_i, and add it to a set $\mathcal{C}'_S$. Once $R_i \geq (1+\frac{\varepsilon}{4})|C_m|$, we invoke `Assign-Volume`$(C_m, S_i)$ and migrate vertices in C_j to S_i if needed (in the case when $S_i \neq S_j$) together with a call to `Unassign-Volume`(C_j, S_j). Next, we assign components in $\mathcal{C}'_S$ to S_i as long as there is sufficient volume and S_i is not marked. If all components in $\mathcal{C}'_S$ have been assigned and S_i is unmarked, we call `Handle-Unmarked`(S_i).

If S_j is unmarked, we invoke `Handle-Unmarked`(S_j). All remaining unassigned components C in $\mathcal{C}'_S$ (if any) are assigned by invoking `Assign-Small`(C). Finally, the component sets $\mathcal{C}_S, \mathcal{C}_L$ are updated.

The pseudo-code of subroutines `Merge-Components`, `Handle-Small` and `Handle-Large` are deferred to the full version of the paper.

We present the pseudo-code of our final online algorithm `OBA` that utilizes the aforementioned subroutines as follows.

Algorithm 7 `OBA`.

$\mathcal{C}_S, \mathcal{C}_L, \mathcal{C}_M, \mathcal{C}_C \leftarrow \emptyset$.
for all $S_i \in \mathcal{S}$ **do** $A(S_i) \leftarrow 0, R_i = (1+\varepsilon)k$
$\mathcal{S}_S, \mathcal{S}_L, \mathcal{S}_M, \mathcal{S}_A \leftarrow \emptyset$.
for r_t at time t **do**
    if r_t is an insertion request for vertex v **then**
        `Handle-Insertion`(v).
    else if r_t is a deletion request for vertex v **then**
        `Handle-Deletion`(v).
    else
        Let r_t be a merge request between vertices (u, v).
        `Merge-Components`(u, v).

3 Analysis of OBA

In this section, we give a proof sketch towards $O(\log k)$-competitiveness of our algorithm. Technical details of our proof, together with proofs of correctness and resource competitiveness are deferred to the full version of the paper.

Our analysis is intricate and relies on various charging arguments. At a high level, we show that a vertex can be assigned sufficient credit on insertion such that the total amount of credit on it at any point in time is sufficient to pay for the cost charged against it. The total credit on a vertex is the sum of its *direct* and *indirect* credits. *Direct* credit is a one-time credit assigned to v on its insertion. *Indirect* credit on v is credit passed on to it by other vertices which get deleted from v's component.

Warm up: An insertions-only case. Let us first consider a (finite) request sequence σ which only consists of insertion and merge requests. For this sequence, the assigned volume of any component containing a vertex v monotonically increases over time, and no components are ever marked. We show that it suffices to charge each vertex an amount $O(\log k + \frac{f(\varepsilon)}{\varepsilon^3})$ on its insertion. On v's insertion, our algorithm assigns $\{v\}$ to an active cluster in $\mathcal{S}_A$, or makes a new cluster active and assigns $\{v\}$ to it. On a merge request between components C_i and C_j which are merged into a *small* component C_m, where w.l.o.g., $|C_i| \geq |C_j|$ our algorithm always migrates vertices in C_j to C_i (in the case when $S_i \neq S_j$) as long as the cluster S_i containing C_i has sufficient residual volume. The first key observation is that for such a merge, all vertices in C_j are now part of a component (i.e. C_m) with a larger component class. Thus, if $A(C_i) \geq |C_m|$ or $R_i \geq (1 + \frac{\varepsilon}{4})|C_m|$, only vertices in C_j are migrated. Potentially some other vertices may be migrated to S_j if S_j becomes unmarked after volume is un-assigned due to the migration of C_j (we ignore these costs for now). For any vertex v, and the component C containing v, note that C's component class increases monotonically over time due to merge requests. The number of component classes, which is $O(c_s + c_l) = O(\log k + \frac{1}{\varepsilon^2})$ bounds the number of times the component class can increase.

On the other hand, if R_i is insufficient to accommodate vertices in C_j (i.e. in the case when $A(C_i) < |C_m|$ and $R_i < (1 + \frac{\varepsilon}{4})k$), vertices in both C_i and C_j are migrated to another cluster. Note that in this case, $A(C_m) > A(C_i)$. Since there are at most $4(c_s + c_l) = O(\log k + \frac{1}{\varepsilon^2}) = O(\log k)$ possible values that assigned volumes can take, and assigned volume increases monotonically for any component, each vertex v can migrate only $O(\log k + \frac{1}{\varepsilon^2})$ times in this manner.

Crucially, we note that if the component C containing v becomes large (or C is large and its component class increases), a total of $O(f(\varepsilon)k)$ migration cost may be incurred, by Lemma 10. This migration cost can be incurred a total of $c_l = O(\frac{1}{\varepsilon^2})$ times. By definition, a C has size at least $Dk \geq \frac{\varepsilon k}{5}$; we charge the migration cost to all $\Omega(\varepsilon k)$ vertices in C. Thus, each vertex in C contributes at least $O(\frac{f(\varepsilon)}{\varepsilon})$ credit a total of $O(\frac{1}{\varepsilon^2})$ times. Therefore, a credit of $O(\frac{f(\varepsilon)}{\varepsilon^3})$ on a vertex is sufficient to pay for migrations of this type.

We now analyze the potential migration costs incurred when a component C migrates from one cluster (say S_i) to S_j, which may lead to a call to `Handle-Unmarked`(S_i) leading to components migrations to S_i. To account for these costs, a cluster credit $\Theta(|C|)$ is left on S_i when C migrates to S_j, and each vertex in C is charged an amount $O(1)$. As a result, each time the residual volume of a cluster increases, there is enough cluster credit to pay for successive migrations (as part of `Handle-Unmarked`). Note that in subroutine `Handle-Unmarked`, only small components are migrated from an unmarked cluster, and the total amount of migrated components is proportional to the increase in residual volume.

Thus, a vertex is charged for cluster credit each time its component is promoted to a higher class or its assigned volume increases. Since the number of choices for assigned volumes (and component classes) is $O(\log k + \frac{1}{\varepsilon^2})$, any vertex is charged $O(\log k + \frac{1}{\varepsilon^2})$ in this manner.

By the above, it follows that assigning a one-time direct credit of $O(\frac{1}{\varepsilon^3} f(\varepsilon) + \log k)$ on each vertex v on its insertion is sufficient. Since OPT is lower bounded by the number of vertex insertions, this yields $O(\log k)$ competitiveness.

The General Case. Let us consider the case when the request sequence consists of insertions, merges and deletions. In this case, the component class of any component C and its assigned volume $A(C)$ do not necessarily increase over time, in general. Thus, direct credit on v is insufficient, and our analysis crucially relies on *indirect* credit. Indirect credit is assigned to any vertex in the following manner: whenever a vertex u is deleted from v's component C, an amount of indirect credit is distributed to all remaining vertices in C. Some credit is also left as cluster credit on the cluster containing C on u's deletion. Cluster credit is used to pay for re-balancing and migrating components as in the previous case. The total indirect credit assigned to vertices in C, together with cluster credit that is left on u's deletion is charged against vertex u. On the other hand, the total credit assigned to a vertex is the sum of the direct credit and indirect credit distributed to it by other vertices. Let C denote the component containing v. We show that even in the case of deletions, it suffices to assign a direct credit of $O(\frac{1}{\varepsilon^3} f(\varepsilon) + \log k)$ to vertex v upon insertion, which is used to pay for:

1. the unit migration cost incurred each time C is promoted to a component class for the *first* time, or the assigned volume of C increases for the first time as in the previous case.
2. indirect credit assigned to vertices in C upon the deletion of v.
3. cluster credit assigned to the cluster containing C, upon v's deletion.
4. cluster credit assigned to the cluster containing C, before C is migrated to another cluster as a result of C being promoted to either a component class for the first time, or an increase in its assigned volume for the first time.

Consider a vertex v and let C denote an (unmarked) component containing v with assigned volume $A(C)$. Upon vertex deletions from C, $A(C)$ may decrease. Suppose $A(C) = A_{ij}$ for some $j \in \{1, 2, 3, 4\}$. Consider a set of deleted vertices C_D which lead to a reduction in C's assigned volume to $A_{i,j-1}$. For this to happen, $|C_D| \geq \frac{\varepsilon}{16}(1 + \frac{\varepsilon}{4})^{i-1}$. On the other hand, $|C| \leq (1 + \frac{j-1}{16}\varepsilon)(1 + \frac{\varepsilon}{4})^{i-1} \leq (1 + \frac{3\varepsilon}{16})(1 + \frac{\varepsilon}{4})^{i-1}$, after vertices in C_D are deleted. For each vertex u in C_D, we distribute a total indirect credit of $O(\frac{1}{\varepsilon^2} f(\varepsilon))$ uniformly to all remaining vertices in C. As a result, the total indirect credit gained by each remaining vertex in $C \backslash C_D$ is at least $O(|C_D| \cdot \frac{O(\frac{f(\varepsilon)}{\varepsilon^2})}{(1+\frac{3\varepsilon}{16})(1+\frac{\varepsilon}{4})^{i-1}}) = O(\frac{f(\varepsilon)}{\varepsilon})$ after all vertices in C_D are deleted. The *indirect* credit gained by any vertex v in $C \backslash C_D$ is used to pay for: i) a single *future* migration of a vertex $v \in C \backslash C_D$ which leads to an increase in either the assigned volume of v's component or the component class of v's component and ii) leave $O(1)$ cluster credit when the aforementioned migration happens.

Next, consider the time when a component C is marked, such that $|C| < Dk(1 + \frac{\varepsilon}{4})^{i-1}$ where $i \geq 1$. Once $|C| < Dk(1 + \frac{\varepsilon}{4})^{i-1} - \frac{\varepsilon^2 k}{100}$, this leads to either a call to `Reassign-Large` (if C is large) or C is treated as a small component thereafter (see `Handle-Deletion`). Since C has size at most k, this implies that at least $\frac{\varepsilon^2}{100} = \Omega(\varepsilon^2)$ fraction of vertices in C are deleted before either of these events happen. The total migration and reassignment cost incurred due to `Reassign-Large` is $O(f(\varepsilon)k)$ by Lemma 10. To pay for this cost, leave an indirect credit of $O(\frac{f(\varepsilon)}{\varepsilon})$ on each remaining vertex in C, and assign a cluster credit of $O(1)$, it suffices to charge each deleted vertex from C an amount $O(\frac{1}{\varepsilon^3} f(\varepsilon))$. The cluster credit is used to pay for the migration cost of vertices to S_i if S_i becomes unmarked. The amount charged against a deleted vertex u is paid by the direct credit assigned to u upon its insertion.

By the above, it follows that assigning a direct credit of $O(\log k + \frac{f(\varepsilon)}{\varepsilon^3})$ to a vertex upon its insertion is sufficient. Since OPT is lower bounded by the number of vertices inserted over all time, this yields $O(\log k)$ competitiveness for constant $\varepsilon > 0$.

4 OBADC with Predictions

In this section, we present our algorithm for OBADC which is augmented with machine learned predictions. The problem formulation and objectives are identical as in the standard un-augmented setup. At each time step t, a request r_t which corresponds to either a vertex insertion, deletion or a merge between two components is issued. At any given point in time, an online algorithm is required to maintain an assignment of components to clusters, while respecting the over-provisioned cluster capacity of $(1+\varepsilon)k$, such that all vertices in any component are assigned to the same cluster. In light of the $\Omega(\log k)$ lower bound on the competitiveness of any randomized algorithm, it is natural to ask whether this barrier can be circumvented given oracle access to machine-learned predictions to guide the assignment of components. To this end, we recap our prediction model.

Prediction Model. Let V_{t-1} denote the set of vertices at the beginning of time $t-1$. For a request r_t at time t which corresponds to an insertion of vertex v, we obtain:

1. with probability $\eta > 0$, a predicted set $P(v)$ of all vertices in V_{t-1} which will be in the same component as v.
2. with probability $1-\eta$, a *null* prediction, i.e. $P(v) = \emptyset$. Thus no information is revealed on the insertion of v.

We present an algorithm `Predicted-OBA` which is $O(1)$-consistent and $\min\{\log \frac{1}{\eta}, \log k\}$-robust. This algorithm is similar in many ways to our $O(\log k)$ competitive algorithm `OBA`. We utilize identical data structures, definitions and subroutines as detailed in Section 2. We also maintain Invariants 1 through 4 as in Section 2.

Our algorithm `Predicted-OBA` is as follows.

Algorithm 8 `Predicted-OBA`.

$\mathcal{C}_S, \mathcal{C}_L, \mathcal{C}_M, \mathcal{C}_C \leftarrow \emptyset$.
for all $S_i \in \mathcal{S}$ **do** $A(S_i) \leftarrow 0, R_i = (1+\varepsilon)k$
$\mathcal{S}_S, \mathcal{S}_L, \mathcal{S}_M, \mathcal{S}_A \leftarrow \emptyset$.
for r_t at time t **do**
    if r_t is an insertion request for vertex v **then**
        `Predicted-Insertion`$(v, P(v))$.
    else if r_t is a deletion request for vertex v **then**
        `Handle-Deletion`(v).
    else
        Let r_t be a merge request between components C_i and C_j.
        `Merge-Components`(C_i, C_j).

We give an additional subroutine, `Predicted-Insertion` as follows.

Subroutine `Predicted-Insertion`. This subroutine takes as input a vertex v inserted at time t and a predicted set $P(v)$ consisting of vertices at time t that will be in the same component as v. If $P(v) = \emptyset$, the subroutine `Handle-Insertion`(v) is invoked. Else, a set σ_I of merge requests is created where $\sigma_I = \{(u, v) |\ u \in P(v)\}$. For each merge request in σ_I, the subroutine `Merge-Components`(u, v) is invoked.

The following lemma bounds the competitive ratio of Algorithm `Predicted-OBA`.

▶ **Lemma 11.** *Algorithm `Predicted-OBA` is $O(\min\{\log(1/\eta), \log k\})$-competitive.*

We build towards a proof of Lemma 11 in the following. We first analyze the probability of a merge request being incident to vertices in distinct components C_i, C_j as a function of component sizes.

▶ **Lemma 12.** *Let r_t be a merge request between components C and C' at time t, such that $s = |C| \leq |C'|$ without loss of generality. Then, the probability that $C' \neq C$ is bounded by $e^{-\eta s}$.*

Proof. We note that if $C \neq C'$, then for at least $s = |C|$ insertions of vertices w, $P(w) = \emptyset$. Since the probability that $P(w) = \emptyset$ for any w is $(1-\eta)$, it follows that for s vertex insertions, the probability that all predicted sets are empty is bounded by $(1-\eta)^s \leq e^{-\eta s}$. ◀

We define monotonic merges as follows.

▶ **Definition 13** (Monotonic Merge)**.** *Let C be the component containing vertex v at any point in time throughout v's lifetime. Let t_1 and t_2 be time-steps s.t. v is inserted at time t_1 and deleted at time t_2. A merge request involving components C and C' at time $t \in [t_1, t_2)$ is said to be a monotonic merge for v if $|C| \leq |C'|$ and one of the following holds:*

1. *The assigned volume of C is set to A_{ij} by our algorithm where $i \in [c_s + c_l], j \in \{1, 2, 3, 4\}$ for the first time during time interval $[t_1, t_2)$.*
2. *The component class of C is set to $i \in [c_s + c_l]$ by our algorithm for the first time during time interval $[t_1, t_2)$.*

A merge request for v is non-monotonic if it is not monotonic.

▶ **Lemma 14.** *The expected number of monotonic merge requests for any vertex v including merge requests created by Subroutine `Predicted-Insertion` is bounded by $O(\log(\frac{1}{\eta}))$.*

Proof. Let C denote the component of v, such that v is inserted at time t_1 and deleted at time t_2. Let $d = (1 + \frac{\varepsilon}{4})$, so that a class i component has volume in $[d^{i-1}, d^i)$. By Lemma 12, the probability that a merge request involving C where C is the smaller of the two components and belongs to class i, is bounded by $e^{-\eta \cdot d^{i-1}}$. Thus, the expected number of monotonic merge requests for v is bounded by

$$\sum_{i=0}^{\log k} e^{-d^i \eta} = \sum_{i=0}^{\log(1/\eta)} e^{-d^i \eta} + \sum_{i=\log(1/\eta)+1}^{\log k} e^{-d^i \eta} \leq \log(1/\eta) + O(1) = O(\log(1/\eta)).$$ ◀

Proof Sketch of Lemma 11. Let us recall the analysis of $O(\log k)$-competitiveness of our algorithm `OBA`. We argued that it suffices to leave a direct credit of $O(\log k + \frac{f(\varepsilon)}{\varepsilon^3})$ on any vertex v upon its insertion, which is sufficient to pay for: i) migration costs and cluster credits charged against v for both monotonic and non-monotonic merges and, ii) cluster and indirect credits charged against v upon its deletion. The $O(\log k)$ term comes from the fact a vertex v can be part of monotonic merges for a total of $c_s + c_l = O(\log k)$ times, and is charged $O(\log k)$ times for merges while C is small. On the other hand, for a non-monotonic merge, v is charged an amount $O(1)$ to pay for its migration cost and leave cluster credit if the residual volume of the cluster C is assigned to, is no longer sufficient to accommodate an increase in $A(C)$. Since the number of choices for assigned volumes is $O(c_s + c_l) = O(\log k + \frac{1}{\varepsilon^2})$, the total cost charged against v for non-monotonic merges is $O(\log k + \frac{1}{\varepsilon^2})$.

We modify our charging argument for non-monotonic merges as follows. Ignoring the reassignment of components that takes place as a result of subroutine `Handle-Unmarked` for the sake of clarity, we crucially observe that whenever the residual volume of C's cluster (denoted by S_i) decreases, it is due to either: i) vertices in a smaller component involved in a merge request migrate to S_i, or ii) new vertices are inserted to S_i's cluster. We modify our charging argument such that the migrated or inserted vertex in the above cases leaves $O(1)$ extra cluster credit on S_i. Thus, whenever the residual volume of S_i decreases by $\Omega(k)$, these extra cluster credits can be used to pay for non-monotonic merges involving vertices already assigned on S_i. As a result, we focus on the cost charged for monotonic merges in the remainder of the analysis.

By Lemma 14, it follows that the expected number of monotonic merges for a vertex is bounded by $O(\log(\frac{1}{\eta}))$. By our analysis of `OBA`, it follows that the expected cost charged to a vertex for monotonic merges is $O(\frac{f(\varepsilon)}{\varepsilon})$. Thus, an expected credit of $O(\log(1/\eta)\frac{f(\varepsilon)}{\varepsilon})$ is sufficient for monotonic merges. On the other hand, when a vertex v is deleted, we charge an amount $O(\frac{f(\varepsilon)}{\varepsilon^3})$ to it which is assigned as indirect credit and cluster credit. As a result, it follows that a total direct credit of $O(\log(1/\eta)\frac{f(\varepsilon)}{\varepsilon} + \frac{f(\varepsilon)}{\varepsilon^3})$ in expectation, is sufficient to pay for all costs charged against v throughout its lifetime.

This yields $O(\log(1/\eta))$-competitiveness. On the other hand, as $\eta \to 0$, the behavior of algorithm `Predicted-OBA` resembles the behavior of algorithm `OBA`, and thus, the competitiveness of `Predicted-OBA` is bounded by $O(\log k)$ in the worst-case. This yields $O(\min(\log(1/\eta), \log k))$-competitiveness. The following lemma establishes $O(1)$ competitiveness when $\eta = 1$. The proof is deferred to the full version of the paper.

▶ **Lemma 15.** *Algorithm `Predicted-OBA` is $O(1)$ consistent.*

Theorem 2 follows from Lemmas 11 and 15.

5 Future Work

Our model for OBADC is restrictive in the sense that component sizes decrease only as a result of vertex deletions; in particular, our model does not allow for splitting of existing components. We believe that such a model will be much more challenging to handle; indeed, it could be considered as a generalization of the general model of OBGR, for which there is a significant gap between the upper and lower bounds for the best competitive ratio achievable.

In this work, we introduced the OBADC and studied it in the context of machine-learned predictions. It would be interesting to extend our prediction model to the case when predictions are always available but may be erroneous. Other prediction models for online balanced allocation problems would be worth exploring.

Tight Bounds on List-Decodable and List-Recoverable Zero-Rate Codes

Nicolas Resch
Informatics' Institute, University of Amsterdam, The Netherlands

Chen Yuan
School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University, China

Yihan Zhang
Institute of Science and Technology Austria, Klosterneuburg, Austria

Abstract

In this work, we consider the list-decodability and list-recoverability of codes in the *zero-rate regime*. Briefly, a code $\mathcal{C} \subseteq [q]^n$ is (p, ℓ, L)-list-recoverable if for all tuples of input lists $(Y_1, \ldots, Y_n)$ with each $Y_i \subseteq [q]$ and $|Y_i| = \ell$, the number of codewords $c \in \mathcal{C}$ such that $c_i \notin Y_i$ for at most pn choices of $i \in [n]$ is less than L; list-decoding is the special case of $\ell = 1$. In recent work by Resch, Yuan and Zhang (ICALP 2023) the zero-rate threshold for list-recovery was determined for all parameters: that is, the work explicitly computes $p_* := p_*(q, \ell, L)$ with the property that for all $\varepsilon > 0$ (a) there exist positive-rate $(p_* - \varepsilon, \ell, L)$-list-recoverable codes, and (b) any $(p_* + \varepsilon, \ell, L)$-list-recoverable code has rate 0. In fact, in the latter case the code has *constant* size, independent on n. However, the constant size in their work is quite large in $1/\varepsilon$, at least $|\mathcal{C}| \geqslant (\frac{1}{\varepsilon})^{O(q^L)}$.

Our contribution in this work is to show that for all choices of q, ℓ and L with $q \geqslant 3$, any $(p_* + \varepsilon, \ell, L)$-list-recoverable code must have size $O_{q,\ell,L}(1/\varepsilon)$, and furthermore this upper bound is complemented by a matching lower bound $\Omega_{q,\ell,L}(1/\varepsilon)$. This greatly generalizes work by Alon, Bukh and Polyanskiy (IEEE Trans. Inf. Theory 2018) which focused only on the case of binary alphabet (and thus necessarily only list-decoding). We remark that we can in fact recover the same result for $q = 2$ and even L, as obtained by Alon, Bukh and Polyanskiy: we thus strictly generalize their work.

Our main technical contribution is to (a) properly define a linear programming relaxation of the list-recovery condition over large alphabets; and (b) to demonstrate that a certain function defined on a q-ary probability simplex is maximized by the uniform distribution. This represents the core challenge in generalizing to larger q (as a binary simplex can be naturally identified with a one-dimensional interval). We can subsequently re-utilize certain Schur convexity and convexity properties established for a related function by Resch, Yuan and Zhang along with ideas of Alon, Bukh and Polyanskiy.

1 Introduction

Given an error-correcting code $\mathcal{C} \subseteq [q]^n$, a fundamental requirement is that the codewords are sufficiently well-spread in order to guarantee some non-trivial correctability properties. This is typically enforced by requiring that the minimum distance of the code $d = \min\{d_{\mathrm{H}}(\boldsymbol{c}, \boldsymbol{c}') :$

© Nicolas Resch, Chen Yuan, and Yihan Zhang;
licensed under Creative Commons License CC-BY 4.0

$\boldsymbol{c} \neq \boldsymbol{c}' \in \mathcal{C}\}$, where $d_{\mathrm{H}}(\cdot,\cdot)$ denotes the Hamming distance (i.e. the number of coordinates on which two strings differ). Note that minimum distance d is equivalent to the following "packing" property: if we put a ball of radius $r := \lfloor d/2 \rfloor$ around any point $\boldsymbol{z} \in [q]^n$ – i.e. we consider the Hamming ball $\mathcal{B}_{\mathrm{H}}(\boldsymbol{y}, r) := \{\boldsymbol{x} \in [q]^n : d_{\mathrm{H}}(\boldsymbol{x}, \boldsymbol{y}) \leqslant r\}$ – then all these balls contain at most 1 codeword from $\mathcal{C}$.

This latter viewpoint can easily be generalized to obtain *list-decodability*, where we now require that such Hamming balls do not capture "too many" codewords. That is, for $p \in [0,1]$ and $L \in \mathbb{N}$ a code is called (p, L)-*list-decodable* if every Hamming ball of radius pn contains less than L codewords from $\mathcal{C}$. In notation: for all $\boldsymbol{y} \in [q]^n$, $|\mathcal{B}_{\mathrm{H}}(\boldsymbol{y}, pn) \cap \mathcal{C}| \leqslant L - 1$.[1] This notion was already introduced in the 50's by Elias and Wozencraft [10, 30, 11] but has in the past 20 years seen quite a bit of attention due to its connections to other parts of theoretical computer science [13, 2, 21, 19, 18, 26].

One can push this generalization further to obtain *list-recoverability*. Here, we consider a tuple of input lists $\boldsymbol{Y} = (Y_1, \ldots, Y_n)$, where each $Y_i \subseteq [q]$ has size at most ℓ (for some $\ell \in \mathbb{N}$). The requirement is that the number of codewords that "disagree" with $\boldsymbol{Y}$ in at most pn coordinates is at most $L - 1$. More formally, if for all $\boldsymbol{Y} = (Y_1, \ldots, Y_n)$ the number of codewords $\boldsymbol{c} \in \mathcal{C}$ such that $|\{i \in [n] : c_i \notin Y_i\}| \leqslant pn$ is at most $L - 1$, the code is called (p, ℓ, L)-*list-recoverable*. Note that (p, L)-list-decodability is nothing other than $(p, 1, L)$-list-recoverability. Initially, list-recoverability was abstracted as a useful stepping stone towards list-decoding concatenated codes. However, in recent years this notion has found many connections to other parts of computer science, e.g. in cryptography [15, 16], randomness extraction [14], hardness amplification [8], group testing [17, 23], streaming algorithms [9], and beyond.

Rate versus noise-resilience. Having fixed a desired "error-tolerance" as determined by the parameters p, ℓ and L we would also like the code $\mathcal{C}$ to be as large as possible: intuitively, this implies that the code contains the minimal amount of redundancy possible. A fundamental question in coding theory is to understand the achievable tradeoffs between the rate $R := \frac{\log_q |\mathcal{C}|}{n}$ and some "error-resilience" property of the code, e.g., minimum distance, list-decodability, or list-recoverability.

This question in full generality is wide open. Even for the special case of $q = 2$ and $L = 2$ (i.e. determining the optimal tradeoff between rate and distance for binary codes) is unclear: on the possibility side we have the Gilbert-Varshamov bound [12, 28] showing $R \geqslant 1 - H_2(p/2)$ is achievable (here, $H_2(x) = -x \log_2 x - (1-x)\log_2(1-x)$ is the binary entropy function), while bounds of Elias and Bassalygo [3] and the linear programming bound [29, 22, 7] give incomparable and non-tight upper bounds. None of these bounds have been substantially improved in at least 40 years. The situation is even more complicated for larger q: for $q = 49$ (and larger prime powers) the celebrated algebraic geometry codes of Tsafsman, Vladut and Zink [27] provide explicit codes of higher rate in certain regimes than those promised by the Gilbert-Varshamov bound.

When one relaxes the question to allow an asymptotically growing list size L then we do have a satisfactory answer: the answer is provided by the list-decoding/-recovery theorem, which states that for all $\varepsilon > 0$ there exist $(p, \ell, O(1/\varepsilon))$-list-recoverable codes of rate $1 - H_{q,\ell}(p)$ where

[1] Typically the upper bound is L, rather than $L - 1$. However, for "impossibility" arguments this parametrization is more common, as it leads to less cumbersome computations.

$$H_{q,\ell}(x) := p \log_q \left(\frac{q-\ell}{p} \right) + (1-p) \log_q \left(\frac{\ell}{1-p} \right)$$

is (q, ℓ)-ary entropy function [24].[2] On the other hand, any code of rate $R \geqslant 1 - h_{q,\ell}(p)$ fails to be (p, ℓ, L)-list-recoverable unless $L \geqslant q^{\Omega(\varepsilon n)}$. However, this does not provide very meaningful bounds if one is interested in, say, $(p, 2, 5)$-list-recoverable codes.

Positive versus zero-rate regimes. Thus far, we have implicitly been discussing the *positive-rate regime*. However, one can also ask questions about the behaviour of codes in the *zero-rate regime*. For context, recent work by Resch, Yuan and Zhang [25] computed the zero-rate threshold for list-recovery: that is, for all alphabet sizes $q \geqslant 2$, input list sizes ℓ and output list size L, they determine the value $p_*(q, \ell, L)$ such that (a) for all $p < p_*(q, \ell, L)$ there exist infinite families of positive rate (p, ℓ, L)-list-recoverable codes over the alphabet $[q]$, and (b) for all $p > p_*(q, \ell, L)$ there does not exist such an infinite family.

Having now delineated the "positive rate" and the "zero-rate" regimes depending on how p compares to $p_*(q, \ell, L)$, in this work we study the zero-rate regime for list-recoverable codes for all alphabet sizes q. In [25], it is shown that (p, ℓ, L)-list-recoverable codes $\mathcal{C} \subseteq [q]^n$ with $p = p_*(q, \ell, L) + \varepsilon$ have constant size (that is, independent of the block length n); however, this constant is massive in the parameters due to the use of a Ramsey-theoretic bound. In particular, the dependence on ε is at least $(1/\varepsilon)^{2q^L}$, and this is additionally multiplied by a tower of 2's of height roughly L.

To the best of our knowledge, prior work on this question focuses exclusively on the $q = 2$ case. For example, in the case of $L = 2$ (i.e., unique-decoding) we have $p_*(2, 1, 2) = 1/4$, and work by Levenshtein [20] shows that a code construction based on Hadamard matrices corrects a $1/4 + \varepsilon$ fraction of errors and has size $1/(4\varepsilon) + O(1)$. A particularly relevant prior work is due to Alon, Bukh and Polyanskiy [1]. Herein the authors consider this question for the special case of $q = 2$ (and thus, necessarily, only for list-decoding). In particular, they show that when L is even if $p = p_*(2, 1, L) + \varepsilon$ then such a (p, L)-list-decodable code $\mathcal{C} \subseteq [2]^n$ has size at most $O_L(1/\varepsilon)$, and moreover provide a construction of such a code with size $\Omega_L(1/\varepsilon)$.[3] They observe some interesting behaviour in the case of odd L; in particular, the maximum size of a $(p_*(2, 1, 3) + \varepsilon, 3)$-list-decodable code is $\Theta(1/\varepsilon^{3/2})$.[4]

Our motivations for this investigation are three-fold. Firstly, the zero-rate regime offers combinatorial challenges and interesting behaviours that we uncover in this work. Secondly, many codes that find applications in other areas of theoretical computer in fact have subconstant rate. Lastly, the zero-rate regime appears much more tractable than the positive rate regime – indeed, we can obtain tight upper and lower bounds on the size of a code, as we will soon see. It would be interesting to determine to what extent such techniques could be useful for understanding the positive rate regime as well.

[2] Note that setting $\ell = 1$ recovers the standard q-ary entropy function, which itself reduces to the binary entropy function upon setting $q = 2$.

[3] Note that for the special case of $q = 2$, the zero-rate threshold for list-decoding had already been established by Blinovsky [4].

[4] This argument in fact shows a flaw in an earlier claimed proof of Blinovsky that claimed such codes have size $O_L(1/\varepsilon)$ for all $L \in \mathbb{N}$.

1.1 Our results

Our main result in this work is a tight bound on the size of a (p, ℓ, L)-list-recoverable code over an alphabet of size $q \geqslant 3$ when $p > p_*(q, \ell, L)$. The main technical challenge is to compute the following upper bound on the size of such a code.

▶ **Theorem 1.** *Let $q, \ell, L \in \mathbb{N}$ with $q \geqslant 3$. $\ell < q$ and $L > \ell$ be fixed constants. Let $\varepsilon > 0$ and put $p = p_*(q, \ell, L) + \varepsilon$. Suppose $\mathcal{C} \subseteq [q]^n$ is (p, ℓ, L)-list-recoverable. Then $|\mathcal{C}| \leqslant O_{q,\ell,L}(1/\varepsilon)$.*

We complement the above negative result with the following code construction, showing the upper bound is tight.

▶ **Theorem 2.** *Let $q, \ell, L \in \mathbb{N}$ with $q \geqslant 3$ and $\ell < q$ be fixed constants. Let $\varepsilon > 0$ and put $p = p_*(q, \ell, L) + \varepsilon$. There exists a (p, ℓ, L)-list-recoverable code $\mathcal{C} \subseteq [q]^n$ such that $|\mathcal{C}| \geqslant \Omega_{q,\ell,L}(1/\varepsilon)$.*

We emphasize that in the above theorems the implied constants may depend on q, ℓ and L.

Note that our results explicitly *exclude* the case of $q = 2$. As [1] prove, the binary alphabet behaves in subtle ways: the bound on the code size depends on the parity of L. Intriguingly, our work demonstrates that such behaviour does not arise over larger alphabets.

1.2 Technical Overview

The double-counting argument. Since our focus is on zero-rate list-decodable/-recoverable codes, it helps to first review the proof of the zero-rate threshold $p_*(q, \ell, L)$. A lower bound can be easily obtained by a random construction that attains a positive rate for any $p \leqslant p_*(q, \ell, L) - \varepsilon$. For the upper bound, let us first consider the list-decoding case, i.e., $\ell = 1$. The proof in [5, 6, 25], at a high-level, proceeds via a double-counting argument.[5] For any (p, ℓ, L)-list-decodable code $\mathcal{C} \subset [q]^n$, the proof aims to upper and lower bound the *radius* of a list averaged over the choice of the list from $\mathcal{C}$:

$$\frac{1}{M^L} \sum_{(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L) \in \mathcal{C}^L} \mathrm{rad}_{\mathrm{H}}(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L). \tag{1}$$

Comparing the bounds produces an upper bound on $|\mathcal{C}|$. Here $\mathrm{rad}_{\mathrm{H}}(\cdot)$, known as the Chebyshev radius of a list, is the relative radius of the smallest Hamming ball containing all codewords in the list. A lower bound on Equation (1) essentially follows from list-decodability of $\mathcal{C}$. Indeed, each term (corresponding to lists consisting of distinct codewords) is lower bounded by p, otherwise a list that fits into a ball of radius at most np is found, violating list-decodability of $\mathcal{C}$. Therefore Equation (1) is at least $p - o(1)$, where $o(1)$ is to account for lists with not-all-distinct codewords.

On the other hand, it is much more tricky to upper bound Equation (1) as, in general, $\mathrm{rad}_{\mathrm{H}}$ admits no analytically closed form and can only be computed by solving a min-max problem. Previous proofs [25] then first extracts a subcode $\mathcal{C}'$ with highly-regular list structures via the hypergraph Ramsey's theorem. This allows one to assert that all lists have essentially the same radius and all codewords in each list have essentially the same distance to the center of the list. As a result, the min-max expression is "linearized" and Equation (1) can be upper bounded when restricted to $\mathcal{C}'$. The downside is that the Ramsey reduction step is rather lossy for code size.

[5] A characterization of $p_*(q, 1, L)$ was announced in [5, 6] whose proof was flawed. The work [25] filled in the gaps therein and characterized $p_*(q, \ell, L)$ for general ℓ.

Weighted average radius. The effect of the Ramsey reduction, put formally, is to enforce the *average radius*:

$$\overline{\mathrm{rad}}_{\mathrm{H}}(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L) \coloneqq \frac{1}{n} \min_{\boldsymbol{r} \in \{0,1\}^n} \frac{1}{L} \sum_{i=1}^{L} d_{\mathrm{H}}(\boldsymbol{c}_i, \boldsymbol{r}) \tag{2}$$

of every list in the subcode to be approximately equal. To extract the regularity structures in lists without resorting to extremal bounds from Ramsey theory, [1] introduced the notion of *weighted average radius* which "linearizes" the Chebyshev radius in a *weighted* manner:

$$\overline{\mathrm{rad}}_{\omega}(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L) \coloneqq \frac{1}{n} \min_{\boldsymbol{r} \in \{0,1\}^n} \sum_{i=1}^{L} \omega(i) d_{\mathrm{H}}(\boldsymbol{c}_i, \boldsymbol{r})$$

where ω is a distribution on L elements. For any weighting ω, $\overline{\mathrm{rad}}_{\omega}$ of lists from the code forms a suite of succinct statistics of the list distribution. It turns out $\overline{\mathrm{rad}}_{U_L} = \overline{\mathrm{rad}}$ (where U_L denotes the uniform distribution on $[L]$) is maximal under all ω. Recall that the double-counting argument suggests that in an optimal zero-rate code, the behaviour of the ensemble average of rad is essentially captured by that of $\overline{\mathrm{rad}}$. In particular, list-decodability ensures that $\overline{\mathrm{rad}}$ of *most* lists should be large. However, not too many lists in an optimal code are expected to have large $\overline{\mathrm{rad}}_{\omega}$ for any $\omega \neq U_L$. [1] then managed to quantify the gap between $\overline{\mathrm{rad}} = \overline{\mathrm{rad}}_{U_L}$ and $\overline{\mathrm{rad}}_{\omega}$ (with $\omega \neq U_L$), which yields improved (and sometimes optimal) size-radius trade-off of zero-rate codes.

Generalization to q-ary list-decoding. Our major technical contribution is in extrapolating the above ideas to list-recovery. The challenge lies particularly in defining a proper notion of weighted average radius and proving its properties. Our definition relies crucially on an embedding φ from $[q]$ to the simplex in $\mathbb{R}^q$ and relaxes the center $\boldsymbol{r}$ of the list to be a fractional vector. Specifically, denoting by $\Delta = \left\{\boldsymbol{a} \in \mathbb{R}^q_{\geqslant 0} : \sum_{i=1}^{q} a_i = 1\right\}$ the simplex in $\mathbb{R}^q$ and $\partial\Delta = \{\boldsymbol{e}_1, \cdots, \boldsymbol{e}_q\}$ its vertices (i.e., the standard basis of $\mathbb{R}^q$), we let the embedding φ map each symbol $x \in [q]$ to the standard basis vector $\boldsymbol{e}_x \in \partial\Delta$. Denoting by $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L \in (\partial\Delta)^n$ the (element-wise) images of a list $\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L \in [q]^n$, we define the *weighted average radius* of $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L$ as:

$$\overline{\mathrm{rad}}_{\omega}(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) = \frac{1}{n} \min_{\boldsymbol{y} \in \Delta^n} \frac{1}{2} \mathop{\mathbb{E}}_{i \sim \omega} \left[\|\boldsymbol{x}_i - \boldsymbol{y}\|_1\right], \tag{3}$$

where ω is any distribution on $[L]$.

The notriviality and significance of the above notion, especially the embedding used therein, is three-fold.

- First, as the weighting ω varies, $\overline{\mathrm{rad}}_{\omega}$ serves as a bridge between the standard average radius in Equation (2) and the Chebyshev radius. Indeed, $\omega = U_L$ recovers the former, and the maximum $\overline{\mathrm{rad}}_{\omega}$ over ω recovers the latter. However, we caution that the second statement does not hold without the embedding since the Hamming distance between q-ary symbols per se is not and cannot be interpolated by a convex function, which makes the minimax theorem inapplicable. Fortunately, our embedding affinely extend the q-ary Hamming distance to the simplex therefore brings back the applicability of the minimax theorem and connects $\max_{\omega} \overline{\mathrm{rad}}_{\omega}$ to rad.
- Second, our definition in Equation (3) allows $\boldsymbol{y}$ to take any value on the simplex, instead of only its vertices, i.e., the image of $[q]$ under φ. Though embedding naively to the hypercube $[0,1]^q$ seems convenient, upon solving the expression with fractional $\boldsymbol{y}$ one

does not necessarily obtain a notion that is guaranteed to closely approximate the original version with integral $\boldsymbol{y}$. In contrast, using linear programming duality, we show that our embedding yields relaxed notion of radius which closely approximates the actual Chebyshev radius. Indeed, upon rounding the fractional center $\boldsymbol{y}$ and taking its pre-image under φ, our results guarantee that the resulting radius must have negligible difference from the Chebyshev radius. Precisely speaking, we want to find a vector $\boldsymbol{y} = (y(i,j))_{[n]\times[q]} \in \Delta$ close to the L images of the codewords $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_L$ by linear programming. Meanwhile, we want $\boldsymbol{y}(i) := (y(i,1), \ldots, y(i,q))$ to belong to $\partial\Delta$ so that we can find a preimage of $\boldsymbol{y}(i)$ in $[q]$. Since $\boldsymbol{y}(i) \in \Delta$, the components in $\boldsymbol{y}(i)$ are subject to $\sum_{j=1}^{q} y(i,j) = 1$. This implies that at least one component of $\boldsymbol{y}(i)$ is nonzero. The basic feasible solution guarantees that there exists a feasible solution such that most of $y(i,j)$ are 0. Combining with the fact $\sum_{j=1}^{q} y(i,j) = 1$ forces $(y(i,1), \ldots, y(i,q)) \in \partial\Delta$ for almost all $i \in [n]$. Thus, we obtain a negligible loss in the conversion between Hamming distance and Euclidean distance.

- Finally, under the embedding φ, the weighted average radius $\overline{\mathrm{rad}}_\omega$ still retains the appealing feature that the minimization can be analytically solved, therefore giving rise to an explicit expression (see Equation (14)) which greatly facilitates our analysis.

We then show, via techniques deviating from those in [1], three key properties that are required by the subsequent arguments.

1. For any fixed distribution P, if entries of codewords in the list are generated i.i.d. using P, then

$$f(P,\omega) := \mathop{\mathbb{E}}_{(X_1,\cdots,X_L)\sim P^{\otimes L}} \left[1 - \max_{x\in[q]} \sum_{\substack{i\in[L] \\ X_i = x}} \omega(i) \right]$$

   is maximized when $\omega = U_L$. Moreover, the equality holds if and only if $\omega = U_L$ for $q \geqslant 3$ and any L. Our approach is different from [1] as we can not explicitly represent function $f(P,\omega)$.
2. Furthermore, if entries of codewords in the list are generated i.i.d. using a certain P, then $f(P, U_L)$ is upper bounded by $f(P_{q,p}, U_L)$ with $P_{q,p} = (\frac{1-p}{q}, \ldots, \frac{1-p}{q}, p)$ and $p = \max_{i\in[q]} P(i)$. This follows from the Schur convexity property proved in [25].
3. Finally, denoting by P_i the distribution of the i-th components of codewords in code $\mathcal{C}$, Schur convexity promises $f(P_i, U_L) \leqslant f(P_{q,p_i}, U_L)$. In [25], it is proved that $f(P_{q,p}, U_L)$ is convex for $p \in [1/q, 1]$. Thus, we can conclude that

$$\frac{1}{n} \sum_{i\in[n]} f(P_i, U_L) \leqslant f(P_{q,p}, U_L)$$

   with $p = \frac{1}{n}\sum_{i\in[n]} p_i$.

   The remaining part of our proof is similar to [1]. We show that a code $\mathcal{C}$ either has radius

$$\mathrm{rad}(\mathcal{C}) = \frac{1}{n} \min_{\boldsymbol{x}\in[q]^n} \max_{\boldsymbol{c}\in\mathcal{C}} d_{\mathrm{H}}(\boldsymbol{c},\boldsymbol{x}) \leqslant 1 - \frac{1}{q} - \delta$$

or most of L-tuples with distinct codewords in $\mathcal{C}$ are distributed close to uniform,. For the former case, we use the convexity property to show that the list-decodability of $\mathcal{C}$ can not exceed $f(U_q, U_L) = p_*(q, L)$ by much. For the latter case, since most of L-tuples of distinct codewords in $\mathcal{C}^L$ looks uniformly at random, we can show that the list-decodablilty of $\mathcal{C}$ is very close to that of random codes which is $f(U_q, U_L)$.

Generalization to list-recovery. For list-recovery, i.e., $\ell > 1$, we find an embedding φ_ℓ that maps each element in $[q]$ to a superposition of ℓ vertices of the simplex in $\mathbb{R}^q$, i.e., we map the element in $[q]$ to a vector space $[0,1]^{\mathcal{X}}$ where $\mathcal{X} = \binom{[q]}{\ell}$ is the collection of all ℓ-subsets in $[q]$. Concretely, we define $\varphi_\ell(i) := \sum_{A \in \mathcal{X}, i \in A} \boldsymbol{e}_A$ where $(\boldsymbol{e}_A)_{A \in \mathcal{X}}$ is a standard basis of $\mathbb{R}^{\mathcal{X}}$. The intuition behind this map is that if $i \in X$, we have $\|\varphi_\ell(i) - \boldsymbol{e}_X\|_1 = \binom{q}{\ell} - 1$ and otherwise $\|\varphi_\ell(i) - \boldsymbol{e}_X\|_1 = \binom{q}{\ell} + 1$. Similar to the list decoding, given L codewords in $[q]^n$, we obtain L vectors $\boldsymbol{x}_1, \dots, \boldsymbol{x}_L$ under the map φ_ℓ. Our goal is to find a vector $\boldsymbol{y} = (y(i,A))_{[n] \times \mathcal{X}}$ close to these L vectors subject to the constraint that $\sum_{A \in \mathcal{X}} y(i,A) = 1$ for any $i \in [n]$. This constraint combined with the basic feasible solution argument forces that for almost all $i \in [n]$, $(y(i,A))_{A \in \mathcal{X}}$ is of the form $\boldsymbol{e}_X$. For such i, we can find an ℓ-subset $X \in \mathcal{X}$ preserving the distance, i.e.,

$$d_{\mathrm{LR}}(i, X) = \mathbb{1}\{i \notin X\} = \frac{1}{2}\left(\|\varphi_\ell(i) - \boldsymbol{e}_X\|_1 - \binom{q}{\ell} + 1\right).$$

Besides the linear programming relaxation, further adjustments for the proof of properties analogous to Items 1–3 above are required.

Code construction. As alluded to before, a code that saturates the optimal size-radius trade-off should essentially saturate both the upper and lower bounds on the quantity

$$\frac{1}{M^L} \sum_{(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L) \in \mathcal{C}^L} \overline{\mathrm{rad}}_{\mathrm{H}}(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L)$$

considered in the double-counting argument. Indeed, our impossibility result implies that any optimal zero-rate code must contain a large fraction of random-like L-tuples $(\boldsymbol{c}_1, \dots, \boldsymbol{c}_L)$, i.e., for every $\boldsymbol{u} \in [q]^L$

$$\sum_{i=1}^{n} \mathbb{1}\{(\boldsymbol{c}_1(i), \dots, \boldsymbol{c}_L(i)) = \boldsymbol{u}\} \approx \frac{n}{q^L} \tag{4}$$

where $\boldsymbol{c}_j = (\boldsymbol{c}_j(1), \dots, \boldsymbol{c}_j(n)) \in [q]^n$. To match such an impossibility result, an optimal construction should contain as many such L-tuples as possible. A simplex-like code then becomes a natural candidate. This is a natural extension of the construction in [1] to larger alphabet. An $M \times n$ codebook $\mathcal{C}$ consisting of M codewords each of length n is constructed by putting as columns all possible distinct length-M vectors that contains identical numbers of $1, 2, \cdots, q$. It is not hard to see by symmetry that (4) becomes equality for every L-tuple with distinct codewords in $\mathcal{C}$. Thus, $\mathcal{C}$ is the most regular code.

We also remark that, unlike for positive-rate codes, the prototypical random construction (with expurgation) does not lead to favorable size-radius trade-off since the deviation of random sampling is comparatively too large in the zero-rate regime. In contrast, the simplex code is deterministically regular and has no deviation.

1.3 Organization

The remainder is organized as follows. First, Section 2 provides the necessary notations and definitions, together with some preliminary results which will be useful in the subsequent arguments. Sections 3.1–3.4 contain our argument establishing Theorem 1 for list-decoding (i.e. the case $\ell = 1$); in Section 4 we elucidate the changes that need to be made to establish the theorem for general ℓ. Next, Section 5 provides the code construction establishing Theorem 2.

2 Preliminaries

Firstly, for convenience of the reader we begin by summarizing the notation that we use. This is particularly relevent as we will often be in situations where we need multiple indexes for, e.g., lists of vectors where each coordinate lies in a probability simplex, so the reader is encouraged to refer to this table whenever it is unclear what is intended.

Table 1 Notation for list-decoding.

English letter in boldface	$[q]^n$-valued vector
Greek letter in boldface	$\Delta([q])$-valued vector
$\Delta := \Delta([q])$	Simplex in $[0,1]^q$, i,e., $\Delta = \{(x_1, \dots, x_q) \in [0,1]^q : \sum_{i=1}^q x_i = 1\}$
$\partial\Delta$	Set of vertices of Δ
$\boldsymbol{e}_x \in \partial\Delta$	The image of $x \in [q]$ under φ, i.e., the x-th vertex of Δ
$\boldsymbol{c}_i \in [q]^n$	The i-th codeword in a list
$\boldsymbol{x}_i \in \Delta^n$	Image of $\boldsymbol{c}_i$ under φ (applied component-wise)
$\boldsymbol{y} \in \Delta^n$	Relaxed center of a list
$\boldsymbol{x}(j) \in \partial\Delta, \boldsymbol{y}(j) \in \Delta$	The j-th block (of length q) in $\boldsymbol{x} \in (\partial\Delta)^n, \boldsymbol{y} \in \Delta^n$, respectively
$x(j,k) \in \{0,1\}, y(j,k) \in [0,1]$	The (j,k)-th element of $\boldsymbol{x} \in (\partial\Delta)^n, \boldsymbol{y} \in \Delta^n$, respectively
$\mathrm{rad}_{\mathrm{H}}$	(Standard) Chebyshev radius
rad	Relaxed Chebyshev radius
$\overline{\mathrm{rad}}$	Average radius
$\overline{\mathrm{rad}}_{\omega}$	Average radius weighted by $\omega \in \Delta([L])$
$f(P,\omega)$	Expected average radius (weighted by ω) of P-distributed symbols
$(X_1, \cdots, X_L) \sim P^{\otimes L}$	A list of i.i.d. P-distributed symbols
U_k	Uniform distribution on $[k]$

For a finite set S and an integer $0 \leqslant k \leqslant |S|$, we denote $\binom{S}{k} := \{T \subset S : |T| = k\}$. Let $[q] = \{1, \dots, q\}$.

2.1 List-Decoding

Fix $q \in \mathbb{Z}_{\geqslant 3}$ and $L \in \mathbb{Z}_{\geqslant 2}$. Let $d_{\mathrm{H}}(\boldsymbol{c}, \boldsymbol{r})$ denote the *Hamming distance* between $\boldsymbol{c}, \boldsymbol{r} \in [q]^n$, i.e., the number of coordinates on which the strings differ. For $t \in [0,n]$, let $\mathcal{B}_{\mathrm{H}}(\boldsymbol{y}, t) := \{\boldsymbol{c} \in [q]^n : d_{\mathrm{H}}(\boldsymbol{c}, \boldsymbol{y}) \leqslant t\}$ denote the *Hamming ball* centered around $\boldsymbol{y}$ of radius $\lfloor t \rfloor$.

▶ **Definition 3** (List-decodable code). *Let $p \in [0,1]$. A code $\mathcal{C} \subseteq [q]^n$ is $(p, L)_q$-*list-decodable *if for any $\boldsymbol{y} \in [q]^n$,*

$$|\mathcal{C} \cap \mathcal{B}_{\mathrm{H}}(\boldsymbol{y}, np)| \leqslant L - 1.$$

In [25] the zero-rate regime for list-decoding was derived, which is the supremum over $p \in [0,1]$ for which $(p - \varepsilon, L)_q$-list-decodable codes of positive rate exist for all $\varepsilon > 0$. This value was shown to be

$$p_*(q, L) = 1 - \frac{1}{L} \mathop{\mathbb{E}}_{(X_1, \cdots, X_L) \sim U_q^{\otimes L}} [\mathsf{pl}(X_1, \cdots, X_L)], \tag{5}$$

where the function pl outputs the number of times the most popular symbol appears. In [25] it is shown that $(p_*(q, L) + \varepsilon, L)$-list-decodable codes have size $O_{\varepsilon,q,L}(1)$, i.e., some constant independent of n. Our target in this work is to show that the correct dependence on ε is $O_{q,L}(1/\varepsilon)$, except for the case of $q = 2$ with odd L.

A "dual" definition of list-decodability is proffered by the Chebyshev radius.

▶ **Definition 4** (Chebyshev radius). *The* Chebyshev radius *of a list of distinct vectors* $\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L \in [q]^n$ *is defined as*

$$\mathrm{rad}_{\mathrm{H}}(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L) \coloneqq \frac{1}{n} \min_{\boldsymbol{r} \in [q]^n} \max_{i \in [L]} d_{\mathrm{H}}(\boldsymbol{c}_i, \boldsymbol{r}).$$

Observe that a code $\mathcal{C} \subseteq [q]^n$ is (p, L)-list-decodable if and only if

$$\min\{\mathrm{rad}_{\mathrm{H}}(\boldsymbol{c}_1, \ldots, \boldsymbol{c}_L) : \boldsymbol{c}_1, \ldots, \boldsymbol{c}_L \in \mathcal{C} \text{ distinct}\} > p \ . \tag{6}$$

In particular, to show a code fails to be list-decodable, it suffices to upper bound the Chebyshev radius of L distinct codewords.

Recall that our main target is an upper bound on the size of list-decodable/-recoverable codes (in the zero-rate regime). A natural approach is to derive from Equation (6) the desired bound on the code; however, this quantity is quite difficult to work with directly. We therefore work with a *relaxed* version, which we now introduce.

We require the following definitions. Let us embed $[q]^n$ into the simplex $\Delta([q])$ via the following map φ:

$$\begin{array}{rccc} \varphi\colon & [q] & \to & \Delta([q]) \\ & x & \mapsto & \boldsymbol{e}_x \end{array} \tag{7}$$

where $\boldsymbol{e}_x$ is the q-dimensional vector with a 1 in the x-th location and 0 everywhere else. Denote by $\Delta = \Delta([q])$ the simplex and $\partial\Delta = \{\boldsymbol{e}_1, \cdots, \boldsymbol{e}_q\}$ its vertices. For $\boldsymbol{\chi} = \boldsymbol{e}_x \in \partial\Delta$ and $\boldsymbol{\eta} \in \Delta$, let

$$d(\boldsymbol{\chi}, \boldsymbol{\eta}) \coloneqq \frac{1}{2} \|\boldsymbol{\chi} - \boldsymbol{\eta}\|_1 = \frac{1}{2} \left(1 - \boldsymbol{\eta}(x) + \sum_{x' \in [q] \setminus \{x\}} \boldsymbol{\eta}(x') \right). \tag{8}$$

Note that if $\boldsymbol{\eta} = \boldsymbol{e}_y \in \partial\Delta$, then

$$d(\boldsymbol{\chi}, \boldsymbol{\eta}) = d_{\mathrm{H}}(x, y).$$

From now on we will only work with Δ^n-valued vectors and will still denote such length-qn vectors by boldface letters, abusing the notation. For $\boldsymbol{y} \in \Delta^n$, we use $y(j,k) \in [0,1]$ to denote its (j,k)-th element and use $\boldsymbol{y}(j) = (y(j,1), \ldots, y(j,q)) \in \Delta$ to denote its j-th block of size q. For $\boldsymbol{c} \in [q]^n$, we use $\boldsymbol{c}(j) \in [q]$ to denote its j-th element.

For $\boldsymbol{x} \in (\partial\Delta)^n$ and $\boldsymbol{y} \in \Delta^n$, the definition of $d(\cdot,\cdot)$ can be extended to length-qn vectors in the natural way. Specifically,

$$d(\boldsymbol{x}, \boldsymbol{y}) = \sum_{j=1}^{n} d(\boldsymbol{x}(j), \boldsymbol{y}(j)). \tag{9}$$

We may now define the *relaxed Chebyshev radius*.

▶ **Definition 5.** *The* relaxed Chebyshev radius *of a list of distinct vectors* $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L \in (\partial\Delta)^n$ *is*

$$\mathrm{rad}(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) \coloneqq \frac{1}{n} \min_{\boldsymbol{y} \in \Delta^n} \max_{i \in [L]} d(\boldsymbol{x}_i, \boldsymbol{y}). \tag{10}$$

Observe that

$$\mathrm{rad}(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) \leqslant \mathrm{rad}_{\mathrm{H}}(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L). \tag{11}$$

where $\varphi(\boldsymbol{c}_i) = \boldsymbol{x}_i$ (here we extend the definition of φ to length-n inputs in a similar way as in Equation (9)). This justifies the "relaxation" terminology.

As a last piece of terminology, we define the radius of a code.

▶ **Definition 6.** *For any code* $\mathcal{C} \in [q]^n$*, we define the* Chebyshev radius *of* $\mathcal{C}$ *as*

$$\mathrm{rad}(\mathcal{C}) = \frac{1}{n} \min_{\boldsymbol{x} \in [q]^n} \max_{\boldsymbol{c} \in \mathcal{C}} d_{\mathrm{H}}(\boldsymbol{c}, \boldsymbol{x}).$$

3 Zero-Rate List-Decoding

3.1 Linear Programming Relaxation

We have shown in Equation (11) that rad is smaller than $\mathrm{rad}_{\mathrm{H}}$. Conversely, Lemma 7 below establishes that rad and $\mathrm{rad}_{\mathrm{H}}$ do not differ much. That is, for any list, if a center $\boldsymbol{y} \in \Delta^n$ achieves a relaxed radius t, then there must exist $\boldsymbol{r} \in [q]^n$ attaining approximately the same t for sufficiently large n.

▶ **Lemma 7** (rad is close to $\mathrm{rad}_{\mathrm{H}}$)**.** *Let $\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L \in [q]^n$. Denote by $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L \in (\partial\Delta)^n$ the images of $\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L$ under the embedding φ. Then*

$$\mathrm{rad}_{\mathrm{H}}(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L) \leqslant \mathrm{rad}(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) + \frac{L}{n}.$$

Proof. Suppose $\mathrm{rad}(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) = t$. Then there exists $\boldsymbol{y} \in \Delta^n$ such that for every $i \in [L]$,

$$d(\boldsymbol{x}_i, \boldsymbol{y}) = \frac{1}{2}\sum_{j=1}^{n}\left(1 - y(j, c_i(j)) + \sum_{x \in [q]\setminus\{c_i(j)\}} y(j,x)\right) \leqslant t,$$

where the first equality is by Equations (8) and (9). That is, the following polytope is nonempty:

$$\begin{aligned}&\{\boldsymbol{y} \in \Delta^n : \forall i \in [L],\ d(\boldsymbol{x}_i, \boldsymbol{y}) \leqslant t\}\\ &= \left\{ (y(j,k))_{(j,k)\in[n]\times[q]} : \begin{array}{l} \forall (j,k) \in [n]\times[q],\ y(j,k) \geqslant 0,\\ \forall j \in [n],\ \sum_{k=1}^{q} y(j,k) = 1,\\ \forall i \in [L],\ \frac{1}{2}\sum_{j=1}^{n}\left(1 - y(j,\boldsymbol{c}_i(j)) + \sum_{x\in[q]\setminus\{\boldsymbol{c}_i(j)\}} y(j,x)\right) \leqslant t \end{array} \right\}.\end{aligned}$$

Equivalently, the following linear program (LP) is feasible:

$$\begin{array}{ll} \max\limits_{(y(j,k))_{(j,k)\in[n]\times[q]}} & 0\\ \text{s.t.} & \forall (j,k) \in [n]\times[q],\ y(j,k) \geqslant 0,\\ & \forall j \in [n],\ \sum_{k=1}^{q} y(j,k) = 1,\\ & \forall i \in [L],\ \frac{1}{2}\sum_{j=1}^{n}\left(1 - y(j,\boldsymbol{c}_i(j)) + \sum_{x\in[q]\setminus\{\boldsymbol{c}_i(j)\}} y(j,x)\right) \leqslant t. \end{array}$$

Since the equality $\langle \boldsymbol{a}, \boldsymbol{y}\rangle \leqslant b$ is equivalent to the equality $\langle \boldsymbol{a}, \boldsymbol{y}\rangle + z = b, z \geqslant 0$, the above LP can be written in equational form:

$$\begin{array}{ll} \max\limits_{(y(j,k))_{(j,k)\in[n]\times[q]}, (z(i))_{i\in[L]}} & 0\\ \text{s.t.} & \forall (j,k) \in [n]\times[q],\ y(j,k) \geqslant 0,\\ & \forall i \in [L],\ z(i) \geqslant 0,\\ & \forall j \in [n],\ \sum\limits_{k=1}^{q} y(j,k) = 1,\\ & \forall i \in [L],\ \frac{1}{2}\sum\limits_{j=1}^{n}\left(1 - y(j,\boldsymbol{c}_i(j)) + \sum\limits_{x\in[q]\setminus\{\boldsymbol{c}_i(j)\}} y(j,x)\right) + z(i) \leqslant t, \end{array} \tag{12}$$

or more compactly in matrix form:

$$\begin{array}{ll} \max\limits_{\boldsymbol{y}\in\mathbb{R}^{nq}, \boldsymbol{z}\in\mathbb{R}^L} & 0\\ \text{s.t.} & \begin{bmatrix} A & I_L \\ B & 0 \end{bmatrix}\begin{bmatrix} \boldsymbol{y} \\ \boldsymbol{z} \end{bmatrix} = \begin{bmatrix} t\mathbf{1}_L \\ \mathbf{1}_n \end{bmatrix},\\ & \boldsymbol{y}, \boldsymbol{z} \geqslant \mathbf{0}. \end{array}$$

Here $A \in \mathbb{R}^{L\times(nq)}$ and $B \in \mathbb{R}^{n\times(nq)}$ encode respectively the fourth and third constraints in Equation (12), and $I_L \in \mathbb{R}^{L\times L}, \mathbf{1}_L \in \mathbb{R}^L$ denote respectively the $L \times L$ identity matrix and the all-one vector of length L. It is clear that $\mathrm{rk}\left(\begin{bmatrix} A & I_L \\ B & 0 \end{bmatrix}\right) \leqslant n+L$. This implies that there exists a feasible solution $\boldsymbol{y}, \boldsymbol{z}$ that has at most $n+L$ nonzeros and thus $\boldsymbol{y} = (y(j,k))_{(j,k)\in[n]\times[q]}$ has at most $n+L$ nonzeros. Indeed, such solutions are known as the *basic feasible solutions*. Note that for every block $j \in [n]$, $\sum_{k=1}^{q} y(j,k) = 1$. This implies that $y(j,1),\dots,y(j,q)$ cannot be simultaneously 0. Moreover, if $q-1$ out of them are 0, the remaining one is forced to be 1. Since there are n blocks in total, by the pigeonhole principle, there are at least $n-L$ choices of $j \in [n]$ such that $\boldsymbol{y}(j) = (y(j,1),\dots,y(j,q)) \in \partial\Delta$. Without loss of generality, we assume that these $n-L$ indices are $1,\dots,n-L$. Let $\boldsymbol{r} \in [q]^n$ be such that $\varphi(\boldsymbol{r}(j)) = \boldsymbol{y}(j)$ for $j = 1,\dots,n-L$ and $r(j)$ is any value in $[q]$ for $j = n-L+1,\dots,n$. Since $d(\boldsymbol{x}_i(j), \boldsymbol{y}(j)) \in [0,1]$ and $d_{\mathrm{H}}(\boldsymbol{c}_i(j), \boldsymbol{r}(j)) \in \{0,1\}$, the difference between $d(\boldsymbol{x}_i, \boldsymbol{y})$ and $d_{\mathrm{H}}(\boldsymbol{c}_i, \boldsymbol{r})$ is at most L. The proof is completed. ◀

We further relax rad by defining the *weighted average radius*. For $\boldsymbol{x}_1,\cdots,\boldsymbol{x}_L \in (\partial\Delta)^n$ and $\omega \in \Delta([L])$, let

$$\overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1,\cdots,\boldsymbol{x}_L) \coloneqq \frac{1}{n}\min_{\boldsymbol{y}\in\Delta^n} \mathop{\mathbb{E}}_{i\sim\omega}\left[d(\boldsymbol{x}_i,\boldsymbol{y})\right] = \frac{1}{n}\min_{\boldsymbol{y}\in\Delta^n}\sum_{i\in[L]}\omega(i)d(\boldsymbol{x}_i,\boldsymbol{y}).$$

In words, weighted average radius is obtained by replacing the maximization over $i \in [L]$ in the definition of relaxed radius (see Equation (10)) with an average with respect to a distribution ω.

Since the objective of the minimization is separable, one can minimize over each $y(j)$ individually and obtain an alternative expression. Suppose $\boldsymbol{x}_1,\cdots,\boldsymbol{x}_L \in (\partial\Delta)^n$ are the images of $\boldsymbol{c}_1,\cdots,\boldsymbol{c}_L \in [q]^n$ under the embedding φ. Then

$$\begin{aligned}
\overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1,\cdots,\boldsymbol{x}_L) &= \frac{1}{n}\min_{\boldsymbol{y}\in\Delta^n}\sum_{i\in[L]}\omega(i)d(\boldsymbol{x}_i,\boldsymbol{y}) \\
&= \frac{1}{2n}\min_{(\boldsymbol{y}_1,\cdots,\boldsymbol{y}_n)\in\Delta^n}\sum_{j=1}^{n}\left[\sum_{i\in[L]}\omega(i)\left(1-\boldsymbol{y}_j(\boldsymbol{c}_i(j))+\sum_{x\in[q]\setminus\{\boldsymbol{c}_i(j)\}}\boldsymbol{y}_j(x)\right)\right] \\
&= \frac{1}{2n}\sum_{j=1}^{n}\min_{\boldsymbol{y}_j\in\Delta}\left[\sum_{i\in[L]}\omega(i)\left(1-2\boldsymbol{y}_j(\boldsymbol{c}_i(j))+\sum_{x\in[q]}\boldsymbol{y}_j(x)\right)\right] \qquad (13) \\
&= \frac{1}{2n}\sum_{j=1}^{n}\min_{\boldsymbol{y}_j\in\Delta}\left[\sum_{i\in[L]}\omega(i)\left(2-2\boldsymbol{y}_j(\boldsymbol{c}_i(j))\right)\right] \\
&= \frac{1}{n}\sum_{j=1}^{n}\min_{\boldsymbol{y}_j\in\Delta}\left[1-\sum_{i\in[L]}\omega(i)\boldsymbol{y}_j(\boldsymbol{c}_i(j))\right] = 1-\frac{1}{n}\sum_{j=1}^{n}\max_{x\in[q]}\sum_{\substack{i\in[L]\\ \boldsymbol{c}_i(j)=x}}\omega(i). \qquad (14)
\end{aligned}$$

Equation (13) holds since the objective in brackets only depends on $\boldsymbol{y}_j$, not on other $(\boldsymbol{y}_{j'})_{j'\in[n]\setminus\{j\}}$. To see Equation (14), we note that a maximizer $\boldsymbol{y}^* \in \Delta$ to the following problem $\max_{\boldsymbol{y}\in\Delta}\sum_{i\in[L]}\omega(i)y(x_i)$, where $\omega \in \Delta([L])$ and $(x_1,\cdots,x_L) \in [q]^L$ are fixed, is given by $\boldsymbol{y}^* = \boldsymbol{e}_{x^*}$ where $x^* \in [q]$ satisfies $x^* \in \mathrm{argmax}_{x\in[q]}\sum_{i\in[L]}\omega(i)\mathbb{1}\{x_i = x\}$.

Obviously, by definition, for any $\boldsymbol{x}_1,\cdots,\boldsymbol{x}_L \in (\partial\Delta)^n$ and $\omega \in \Delta([L])$, $\overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1,\cdots,\boldsymbol{x}_L) \leqslant \mathrm{rad}(\boldsymbol{x}_1,\cdots,\boldsymbol{x}_L)$. In fact, the following lemma shows that rad is equal to the maximum $\overline{\mathrm{rad}}_\omega$ over ω.

▶ **Lemma 8** (rad equals maximum $\overline{\mathrm{rad}}_\omega$)**.** *For any* $\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L \in (\partial\Delta)^n$,

$$\mathrm{rad}(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) = \max_{\omega \in \Delta([L])} \overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L).$$

Proof. Note that

$$\mathrm{rad}(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) \coloneqq \frac{1}{n} \min_{\boldsymbol{y} \in \Delta^n} \max_{i \in [L]} d(\boldsymbol{x}_i, \boldsymbol{y}) = \frac{1}{n} \min_{\boldsymbol{y} \in \Delta^n} \max_{\omega \in \Delta([L])} \sum_{i \in [L]} \omega(i) d(\boldsymbol{x}_i, \boldsymbol{y}),$$

since the inner maximum is anyway achieved by a singleton distribution. Note also that the objective function

$$\sum_{i \in [L]} \omega(i) d(\boldsymbol{x}_i, \boldsymbol{y}) = \frac{1}{2} \sum_{i \in [L]} \omega(i) \sum_{j=1}^{n} \left(1 - y(j, \boldsymbol{c}_i(j)) + \sum_{x \in [q] \setminus \{\boldsymbol{c}_i(j)\}} y(j, x) \right)$$

is affine in ω and linear in $\boldsymbol{y}$. Therefore, von Neumann's minimax theorem allows us to interchange min and max and obtain

$$\mathrm{rad}(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) = \frac{1}{n} \max_{\omega \in \Delta([L])} \min_{\boldsymbol{y} \in \Delta^n} \sum_{i \in [L]} \omega(i) d(\boldsymbol{x}_i, \boldsymbol{y}) = \max_{\omega \in \Delta([L])} \overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L),$$

as claimed by the lemma. ◀

In fact, we can say something stronger: it is not necessary to maximize over the entire (uncountable) probability simplex $\Delta([L])$. Instead, we can extract a finite subset $\Omega_L \subset \Delta([L])$ and maximize over this set to recover rad. The following lemma is analogous to [1, Lemma 6].

▶ **Lemma 9** (rad is achieved by finitely many ω)**.** *For every L, there exists a finite set of probability measures $\Omega_L \subseteq \Delta([L])$ such that*

$$\mathrm{rad}(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_L) = \max_{\omega \in \Omega_L} \overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_L).$$

for all $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_L \in \partial\Delta^n$.

Proof. The idea is to view the computation of $\max_{\omega \in \Omega_L} \overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_L)$ as finding the maximum among some finite set of linear program maxima over some convex polytopes, and then to take Ω_L to be the set of vertices of the defined convex polytopes.

First, we define the convex polytopes based on a (q-ary version of a) signature. For each $\omega \in \Delta([L])$, we define a *signature* for ω which is a function $S_\omega : [q]^L \to [q]$ such that

$$S_\omega(\boldsymbol{u}) \in \operatorname*{argmax}_{x \in [q]} \sum_{i : \boldsymbol{u}(i) = x} \omega(i)$$

for $\boldsymbol{u} \in [q]^L$. Define further the q halfspaces $H_{\boldsymbol{u},x} \coloneqq \{\omega \in \Delta([L]) : \sum_{i:\boldsymbol{u}(i)=x} \omega(i) \geqslant 1/q\}$ for $x \in [q]$. Observe that if $S(\boldsymbol{u}) = x$ where S is a signature for ω then $\omega \in H_{\boldsymbol{u},x}$. Thus, by ranging over the choices for $\boldsymbol{u} \in [q]^L$ and $x \in [q]$ we obtain q^{L+1} halfspaces that partition the $(L-1)$-dimensional space $\Delta([L])$ into at most $\sum_{j \leqslant L-1} \binom{q^{L+1}}{j}$ regions.

For each possible signature $S : [q]^L \to [q]$, let $\Omega_S = \{\omega \in \Delta([L]) \colon S \text{ is a signature for } \omega\}$, and note that Ω_S is a convex polytope. Indeed, it is an intersection over $\boldsymbol{u} \in [q]^L$ of the convex polytopes

$$\{\omega \in \Delta([L]) \colon \exists \text{ signature } \ S_\omega \text{ for } \omega \text{ s.t. } S_\omega(\boldsymbol{u}) = S(\boldsymbol{u})\}$$
$$= \bigcap_{y \in [q] \setminus S(\boldsymbol{u})} \left\{ \omega \in \Delta([L]) \colon \sum_{i : \boldsymbol{u}(i) = S(\boldsymbol{u})} \omega(i) \geqslant \sum_{i : \boldsymbol{u}(i) = y} \omega(i) \right\}$$

where S_ω is a signature for ω. Now, to maximize

$$\overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) = \frac{1}{n} \min_{\boldsymbol{y} \in \Delta^n} \sum_{i \in [L]} \omega(i) d(\boldsymbol{x}_i, \boldsymbol{y})$$

over $\omega \in \Omega_L$, consider the set $T_{\boldsymbol{u}} = \{i \in [n] : (\boldsymbol{x}_1(i), \ldots, \boldsymbol{x}_L(i)) = \boldsymbol{u}\}$ for $\boldsymbol{u} \in [q]^L$ and let $a_{\boldsymbol{u}} = \frac{|T_{\boldsymbol{u}}|}{n}$. We claim it suffices to find the maximum of the following linear function:

$$\sum_{\boldsymbol{u} \in [q]^L} a_{\boldsymbol{u}} y_{\boldsymbol{u}}, \quad \text{s.t.} \quad y_{\boldsymbol{u}} = \sum_{i : \boldsymbol{u}(i) = S(\boldsymbol{u})} \omega(i) \tag{15}$$

over all $\omega \in \Omega_S$. Indeed, by Equation (14), we have

$$\overline{\mathrm{rad}}_\omega(\boldsymbol{x}_1, \cdots, \boldsymbol{x}_L) = 1 - \frac{1}{n} \sum_{j=1}^{n} \max_{x \in [q]} \sum_{\substack{i \in [L] \\ c_i(j) = x}} \omega(i).$$

This implies that a maximizer only depends on the index set $T_{\boldsymbol{u}}$, and furthermore that its value is determined by the $a_{\boldsymbol{u}}$'s as in Equation (15).

We can thus take the union of all vertex sets of all polytopes Ω_S for all signatures S. Multiplying this by the $O_{q,L}(1)$ regions defined by all the halfspaces $H_{\boldsymbol{u},x}$ we obtain a finite set of vertices, as desired. ◀

3.2 Properties of $f(P, \omega)$

Now, we consider the expected weighted average radius of a sequence of i.i.d. symbols. Specifically, for $P \in \Delta([q])$ and $\omega \in \Delta([L])$, let

$$f(P, \omega) \coloneqq \mathop{\mathbb{E}}_{(X_1, \cdots, X_L) \sim P^{\otimes L}} \left[\overline{\mathrm{rad}}_\omega(\boldsymbol{e}_{X_1}, \cdots, \boldsymbol{e}_{X_L}) \right].$$

[1] studies $f(P, \omega)$ for $q = 2$ and even L. In this case, one can take advantage of the fact that $P \in \Delta([2])$ may be parametrized by a single real number, and thereby yield a fairly simple expression for $f(P, \omega)$.

Nonetheless, in this subsection, we will show that all properties of $f(P, \omega)$ in [1] holding for $q = 2$ and even L can be generalized to any $q \geqslant 3$ and any L. Let us first provide a more explicit expression for $f(P, \omega)$ using Equation (14):

$$\begin{aligned} f(P, \omega) &\coloneqq \mathop{\mathbb{E}}_{(X_1, \cdots, X_L) \sim P^{\otimes L}} \left[1 - \max_{x \in [q]} \sum_{\substack{i \in [L] \\ X_i = x}} \omega(i) \right] \\ &= 1 - \sum_{(x_1, \cdots, x_L) \in [q]^L} \left(\prod_{i=1}^{L} P(x_i) \right) \max_{x \in [q]} \sum_{i \in [L]} \omega(i) \mathbb{1}\{x_i = x\}. \end{aligned}$$

We define the shorthand notation

$$\max_\omega(x_1, \cdots, x_L) \coloneqq \max_{x \in [q]} \sum_{\substack{i \in [L] \\ x_i = x}} \omega(i) \tag{16}$$

for any $\omega \in \Delta([L])$ and $(x_1, \ldots, x_L) \in [q]^L$.

The first property that we would like to establish is that $f(P,\omega)$ only increases if ω is replaced by U_L, and furthermore that the maximum is uniquely obtained at U_L if $P(x) > 0$ for all $x \in [q]$. In order to do this, we will regularly "average-out" coordinates of ω and then show that the function value increases (or at least, does not decrease). To be introduce some terminology, for $S \subseteq [L]$ we say that $\overline{\omega}$ is obtained from ω by *averaging-out* the subset S of coordinates if $\overline{\omega}$ is defined as

$$\overline{\omega}(i) = \begin{cases} \frac{\sum_{j\in S}\omega(j)}{|S|} & i \in S \\ \omega(i) & i \notin S \end{cases}.$$

The following lemma gives a simple criterion for establishing that, if $\overline{\omega}$ is obtained from ω by averaging two coordinates, then $f(P,\overline{\omega}) \leqslant f(P,\omega)$, and it furthermore gives a criterion for the inequality to be strict. The main thrust of the proof of Lemma 11 is thus to show that this criterion is always satisfied.

▶ **Lemma 10.** *Let $P \in \Delta([q])$ and $\omega \in \Delta([L])$. Suppose $\omega(L-1) \neq \omega(L)$ and that $\overline{\omega} \in \Delta([L])$ is obtained by averaging-out the last two coordinates of ω. Suppose that for all $(x_1,\ldots,x_L) \in [q]^L$ we have*

$$\frac{1}{2}\left(\max_\omega(x_1,\cdots,x_{L-1},x_L) + \max_\omega(x_1,\cdots,x_L,x_{L-1})\right) \geqslant \max_{\overline{\omega}}(x_1,\cdots,x_{L-1},x_L). \quad (17)$$

Then $f(P,\overline{\omega}) \geqslant f(P,\omega)$.

Furthermore, suppose that additionally there exists $(x_1,\ldots,x_L) \in [q]^L$ with $\prod_{i=1}^L P(x_i) > 0$ such that the inequality in Equation (17) is strict. Then $f(P,\overline{\omega}) > f(P,\omega)$.

Proof. Define $\omega' \in \Delta([L])$ as

$$\omega'(i) = \begin{cases} \omega(i), & i \in [L]\backslash\{L-1,L\} \\ \omega(L), & i = L-1 \\ \omega(L-1), & i = L \end{cases}.$$

That is, ω' is obtained by swapping the last two components of ω. By symmetry, we have $f(P,\omega) = f(P,\omega')$ and so

$$\begin{aligned} f(P,\omega) &= \frac{1}{2}(f(P,\omega) + f(P,\omega')) \\ &= \frac{1}{2}\left(1 - \sum_{(x_1,\cdots,x_L)\in[q]^L}\left(\prod_{i=1}^L P(x_i)\right)\max_\omega(x_1,\ldots,x_{L-1},x_L)\right. \\ &\qquad \left. +1 - \sum_{(x_1,\cdots,x_L)\in[q]^L}\left(\prod_{i=1}^L P(x_i)\right)\max_{\omega'}(x_1,\ldots,x_{L-1},x_L)\right) \\ &= 1 - \sum_{(x_1,\cdots,x_L)\in[q]^L}\left(\prod_{i=1}^L P(x_i)\right)\frac{1}{2}\left(\max_\omega(x_1,\ldots,x_{L-1},x_L) + \max_\omega(x_1,\ldots,x_L,x_{L-1})\right)) \\ &\leqslant 1 - \sum_{(x_1,\cdots,x_L)\in[q]^L}\left(\prod_{i=1}^L P(x_i)\right)\max_{\overline{\omega}}(x_1,\ldots,x_{L-1},x_L) \\ &= f(P,\overline{\omega}), \end{aligned}$$

where the inequality follows from Equation (17). From the above sequence of inequalities, it is also clear that if additionally there exists $(x_1,\ldots,x_L) \in [q]^L$ with $\prod_{i=1}^L P(x_i) > 0$ for which the inequality in Equation (17) is strict, then $f(P,\overline{\omega}) > f(P,\omega)$. ◀

We now establish that the function value cannot decrease if ω is replaced by U_L.

▶ **Lemma 11.** *For any $P \in \Delta([q])$ and $\omega \in \Delta([L])$, $f(P,\omega) \leqslant f(P,U_L)$.*

Proof. Fix any $(x_1,\cdots,x_L) \in [q]^L$. Let $\omega \in \Delta([L])$ be non-uniform. Without loss of generality, assume $\omega(L-1) \neq \omega(L)$. Let $\overline{\omega} \in \Delta([L])$ be obtained by uniformizing the last two components of ω, i.e.,

$$\overline{\omega}(i) = \begin{cases} \omega(i), & i \in [L]\backslash\{L-1,L\} \\ \frac{1}{2}(\omega(L-1)+\omega(L)), & i \in \{L-1,L\} \end{cases}.$$

We claim $f(P,\overline{\omega}) \geqslant f(P,\omega)$. By Lemma 10, we just need to establish Equation (17).

Equation (17) trivially holds if $x_{L-1} = x_L$. We therefore assume below $x_{L-1} \neq x_L$. Let $x_{L-1} = a$ and $x_L = b$. Let

$$\omega^{(a)} = \sum_{\substack{i\in[L-2]\\ x_i=a}} \omega(i), \qquad \omega^{(b)} = \sum_{\substack{i\in[L-2]\\ x_i=b}} \omega(i)\ .$$

Then, we have

$$\sum_{\substack{i\in[L]\\ x_i=a}} \overline{\omega}(i) = \omega^{(a)} + \frac{1}{2}(\omega(L-1)+\omega(L)), \qquad \sum_{\substack{i\in[L]\\ x_i=b}} \overline{\omega}(i) = \omega^{(b)} + \frac{1}{2}(\omega(L-1)+\omega(L)).$$

We first assume that there exists $c \notin \{a,b\}$ such that

$$\max_{\overline{\omega}}(x_1,\cdots,x_L) = \sum_{\substack{i\in[L]\\ x_i=c}} \overline{\omega}(i) = \sum_{\substack{i\in[L]\\ x_i=c}} \omega(i)$$

where the second equality follows since the set $\{i \in [q] : x_i = c\}$ does not contain $L-1, L$. Equation (17) therefore holds as

$$\max_{\omega}(x_1,\cdots,x_{L-1},x_L) \geqslant \sum_{\substack{i\in[L]\\ x_i=c}} \omega(i), \qquad \max_{\omega}(x_1,\cdots,x_L,x_{L-1}) \geqslant \sum_{\substack{i\in[L]\\ x_i=c}} \omega(i).$$

We proceed to the case that

$$\max_{\overline{\omega}}(x_1,\cdots,x_L) = \max\left\{\frac{1}{2}(\omega(L-1)+\omega(L)) + \omega^{(a)}, \frac{1}{2}(\omega(L-1)+\omega(L)) + \omega^{(b)}\right\}.$$

Equation (17) holds as

$$\max_{\omega}(x_1,\cdots,x_{L-1},x_L) \geqslant \max\left\{\omega^{(a)} + \omega(L-1), \omega^{(b)} + \omega(L)\right\}$$

and

$$\max_{\omega}(x_1,\cdots,x_L,x_{L-1}) \geqslant \max\left\{\omega^{(a)} + \omega(L), \omega^{(b)} + \omega(L-1)\right\}.$$

Thus, Lemma 10 implies $f(P,\overline{\omega}) \geqslant f(P,\omega)$, as desired.

We can then continue averaging components of ω and in this way obtain a sequence $(\omega_i)_{i\in\mathbb{N}}$ of distributions with $\omega_1 = \omega$. This sequence converges in ℓ_∞-norm to the uniform distribution U_L and satisfies $f(P,\omega_{i+1}) \geqslant f(P,\omega_i)$ for all $i \in \mathbb{N}$. Observing that $\omega \mapsto f(P,\omega)$ is a continuous function – the term $\max_{x\in[q]} \sum_{i\in[L]} \omega(i)\mathbb{1}\{x_i = x\}$ is a maximum over linear functions of ω, hence linear, implying that $f(P,\cdot)$ is a linear combination of continuous functions – it follows that $f(P,U_L) = \lim_{i\to\infty} f(P,\omega_i)$, and in particular that $f(P,U_L) \geqslant f(P,\omega_1) = f(P,\omega)$, as desired. ◀

We now strengthen the conclusion of Lemma 11 by showing that for all $q \geqslant 3$ and $L \geqslant 2$ the function $\omega \mapsto f(P,\omega)$ is *uniquely* maximized by the setting $\omega = U_L$, except for degenerate cases where $P(x) = 0$ for some $x \in [q]$.

Before stating and proving this fact, we note that the proof of Lemma 11 in fact shows that we can average out any subset of coordinates of ω and only increase the value of $f(P,\omega)$. We formalize this fact in the following lemma, which will be useful in the following arguments.

▶ **Lemma 12.** *Let $P \in \Delta([q])$, $\omega \in \Delta([L])$ and $S \subseteq [L]$. Let $\overline{\omega}$ be obtained from ω by averaging-out the subset S of coordinates. Then $f(P,\overline{\omega}) \geqslant f(P,\omega)$.*

▶ **Theorem 13.** *Let $q \geqslant 3$, $L \geqslant 2$ and let $P \in \Delta([q])$ be such that $P(x) > 0$ [6] for all $x \in [q]$. Then for all $\omega \in \Delta([L])$, $f(P,\omega) \leqslant f(P,U_L)$ with equality if and only if $\omega = U_L$.*

Proof. The inequality was already established in Lemma 11, so we focus on showing $\omega = U_L$ when $f(P,\omega) = f(P,U_L)$. As $q \geqslant 3$, let a, b and c denote 3 distinct elements of $[q]$. Let $\omega \neq U_L$ and suppose for a contradiction that $f(P,\omega)$ is a maximum of the function $\omega \mapsto f(P,\omega)$. The proof proceeds via a number of cases.

1. ***L* is even.** Without loss of generality, $\omega(L-1) < \omega(L)$. If $L \geqslant 4$, let ω' be obtained from ω by averaging-out the first $L-2$ coordinates; by Lemma 12, $f(P,\omega') \geqslant f(P,\omega)$. If $L = 2$, set $\omega' = \omega$.
   If $L \geqslant 4$, since $2|(L-2)$, we can set $x_1 = \cdots = x_{L/2-1} = a$ and $x_{L/2} = \cdots = x_{L-2} = b$. Set further $x_{L-1} = a$ and $x_L = b$. We observe that for this $(x_1,\ldots,x_L) \in [q]^L$ and $\overline{\omega}$ obtained from ω' by averaging-out the last two coordinates, Equation (17) strictly holds. Indeed,

$$\max_{\omega'}(x_1,\ldots,x_{L-1},x_L) + \max_{\omega'}(x_1,\ldots,x_L,x_{L-1}) = 2\sum_{j=1}^{(L-2)/2}\omega(i) + 2\omega(L)$$

   and

$$2\max_{\overline{\omega}}(x_1,\ldots,x_{L-1},x_L) = 2\sum_{j=1}^{(L-2)/2}\omega(i) + \omega(L-1) + \omega(L).$$

   Thus Lemma 10 implies $f(P,\overline{\omega}) > f(P,\omega') \geqslant f(P,\omega)$, a contradiction.
2. ***L* is odd and at least three components of *ω* take distinct values, or the components in *ω* only take two different values and at least two of them take the minimum value.** Without loss of generality $\omega(L-2) \leqslant \omega(L-1) < \omega(L)$. If $L \geqslant 5$, let ω' be obtained from ω by averaging-out the first $L-3$ coordinates; by Lemma 12, $f(P,\omega') \geqslant f(P,\omega)$. If $L = 3$, set $\omega' = \omega$.
   Since $2|(L-3)$, if $L \geqslant 5$, we set $x_1 = \cdots = x_{(L-1)/2-1} = a$ and $x_{(L-1)/2} = \cdots = x_{L-3} = b$. Let $x_{L-2} = c$, $x_{L-1} = a$ and $x_L = b$. We observe that for this $(x_1,\ldots,x_L) \in [q]^L$ and $\overline{\omega}$ obtained from ω' by averaging-out the last two coordinates, Equation (17) strictly holds. Indeed, since $\omega(L-2) < \omega(L)$ we have

$$\max_{\omega'}(x_1,\ldots,x_{L-1},x_L) + \max_{\omega'}(x_1,\ldots,x_L,x_{L-1}) = 2\sum_{j=1}^{(L-2)/2}\omega(i) + 2\omega(L)$$

[6] In fact, our proof only apply with $P = U_q$ which clearly satisfies the condition.

and

$$2\max_{\overline{\omega}}(x_1,\ldots,x_{L-1},x_L) = 2\sum_{j=1}^{(L-3)/2}\omega(i)+\omega(L-1)+\omega(L).$$

Thus Lemma 10 implies $f(P,\overline{\omega}) > f(P,\omega') \geqslant f(P,\omega)$, a contradiction.

3. ***L* is odd and only one component takes the minimum value.** That is, $\omega(1) = \omega(2) = \cdots = \omega(L-1) < \omega(L)$. Let ω' be obtained from ω' by averaging-out the subset $\{L-1, L_2\}$. Then $f(P,\omega') \geqslant f(P,\omega)$ by Lemma 12 and moreover ω' is such that at least two coordinates take on the minimum value, as $\omega'(1) = \cdots = \omega'(L-2) > \omega'(L-1) = \omega'(L)$. The argument from the previous case can now be applied to derive a contradiction. ◀

Thus, except for degenerate choices for $P \in \Delta([q])$, it follows that the function $\omega \mapsto f(P,\omega)$ is maximized by the choice of $\omega = U_L$. The next step is to determine the distribution $P \in \Delta([q])$ maximizing $P \mapsto f(P,U_L)$. At this point, we can rely on a main result of [25], as the function $P \mapsto 1 - f(P,U_L)$ is the same as the function $f_{q,L}(P)$ defined in [25, Equation (17)]. It is shown therein that $f_{q,L}(P)$ is *strictly Schur convex*, which in particular means that $f_{q,L}(P)$ has a unique minimum at $P = U_q$. That is, $f(P,U_L)$ has a unique maximum at $P = U_q$.

The (strict) Schur convexity also implies the following: if $p = \max_{x\in[q]} P(x)$, then $f_{q,L}(P) \geqslant f_{q,L}(P_{q,p})$ where

$$P_{q,p}(x) = \begin{cases} \frac{1-p}{q-1} & x \in \{1,2,\ldots,q-1\} \\ p & x = q \end{cases} . \tag{18}$$

That is, we can conclude that $f(P,U_L) \leqslant f(P_{q,p},U_L)$. We encapsulate these facts in the following proposition.

▶ **Proposition 14** (Theorem 1,2 [25]). *Let $q \geqslant 2$, $L \geqslant q$ and $P \in \Delta([q])$. Suppose $p = \max_{x\in[q]} P(x)$. Then $f(P,U_L) \leqslant f(P_{q,p},U_L)$. Furthermore, $f(P_{q,p},U_L) \leqslant f(U_q,U_L)$ is monotone decreasing for $p \geqslant 1/q$. Lastly, $f(P_{q,p},U_L)$ is concave for $p \in [1/q,1]$, i.e., $\frac{1}{n}\sum_{i=1}^n f(P_{q,p_i},U_L) \leqslant f(P_{q,p},U_L)$ with $p = \frac{1}{n}\sum_{i=1}^n p_i$.*

A further fact that we have from [25] is that

$$p_*(q,L) = f(U_q,U_L) .$$

In fact, this was taken as the definition of $p_*(q,L)$. To end this subsection, we prove the following theorem by utilizing the concavity of $f(P_{q,p},U_L)$.

▶ **Theorem 15.** *Assume $\mathrm{rad}_{\mathrm{H}}(\mathcal{C}) \leqslant p$, then we have*

$$\mathop{\mathbb{E}}_{(\boldsymbol{c}_1,\ldots,\boldsymbol{c}_L)\in\mathcal{C}^L}[\mathrm{rad}_\omega(\varphi(\boldsymbol{c}_1),\ldots,\varphi(\boldsymbol{c}_L))] \leqslant f(P_{q,p},U_L).$$

Proof. Let $\boldsymbol{y}$ be the center attaining $\mathrm{rad}_{\mathrm{H}}(\mathcal{C})$. Without loss of generality, we can assume $\boldsymbol{y}$ is a all zero vector. Let P_i be the distribution of symbols in the i-th index of $\mathcal{C}$, i.e., $P_i(j) = \Pr[\boldsymbol{c}(i) = j]$ with the distribution taken over $\boldsymbol{c} \in \mathcal{C}$. Let $p_i = \max_{x\in[q]} P_i(x)$ and $p' = \frac{1}{n}\sum_{i=1}^n p_i$. Clearly, $p_i \geqslant 1/q$. Then, we have

$$\begin{aligned}\mathop{\mathbb{E}}_{(\boldsymbol{c}_1,\ldots,\boldsymbol{c}_L)\in\mathcal{C}^L}[\mathrm{rad}_\omega(\varphi(\boldsymbol{c}_1),\ldots,\varphi(\boldsymbol{c}_L))] &= \frac{1}{n}\sum_{i=1}^n f(P_i,\omega) \\ \leqslant \frac{1}{n}\sum_{i=1}^n f(P_i,U_L) &\leqslant \frac{1}{n}\sum_{i=1}^n f(P_{q,p_i},U_L) \leqslant f(P_{q,p'},U_L) \leqslant f(P_{q,p},U_L).\end{aligned}$$

The first inequality is due to Lemma 11 and the second and third inequalities are due to Proposition 14. The last inequality is due to $\mathrm{rad}_{\mathrm{H}}(\mathcal{C}) \leqslant p$ and the center $\boldsymbol{y}$ is all zero vector. The proof is completed. ◀

3.3 Abundance of Random-Like L-tuples

Recall the notations

$$\mathrm{rad}(\mathcal{C}) = \frac{1}{n} \min_{\boldsymbol{y}\in[q]^n} \max_{\boldsymbol{c}\in\mathcal{C}} d_{\mathrm{H}}(\boldsymbol{c}, \boldsymbol{y})$$

and

$$\mathsf{type}_{\boldsymbol{u}}(\boldsymbol{c}_1, \ldots, \boldsymbol{c}_L) = \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}\{(\boldsymbol{c}_1(i), \ldots, \boldsymbol{c}_L(i)) = \boldsymbol{u}\}$$

where $\boldsymbol{c}_i = (\boldsymbol{c}_i(1), \ldots, \boldsymbol{c}_i(n)) \in [q]^n$ and $\boldsymbol{u} \in [q]^L$. In this subsection, we prove a code $\mathcal{C} \subseteq [q]^n$ either contains a large subcode $\mathcal{C}' \subseteq \mathcal{C}$ with radius $\mathrm{rad}(\mathcal{C}') \leqslant 1 - \frac{1}{q} - \varepsilon$, or most of its L-tuples are of type close to the uniform distribution (for all $\boldsymbol{u} \in [q]^L$).

We first show that for any projection π_A with $|A| \geqslant \mu n$ (for some parameter $\mu \in [0, 1]$), the projection $\pi_A(\mathcal{C})$ almost preserves the radius $\mathrm{rad}(\mathcal{C})$ with small loss. Then, if $\mathrm{rad}(\mathcal{C}') > 1 - \frac{1}{q} - \varepsilon$ for any subcode $\mathcal{C}'$ with large size, we find a codeword $\boldsymbol{c}_1$ in $\mathcal{C}$ whose symbols' distribution is close to the uniform. In fact, most codewords in $\mathcal{C}$ satisfies this requirement. Let A_i be the index set of $\boldsymbol{c}_1$ taking value i. We apply π_{A_i} to $\mathcal{C}$ and claim that $\pi_{A_i}(\mathcal{C})$ preserves the radius. Thus, we can find a codeword $\boldsymbol{c}_2$ such that for every $i \in [q]$, the symbol's distribution of $\pi_{A_i}(\boldsymbol{c}_2)$ is close to uniform. Moreover, most of codewords in $\mathcal{C}$ satisfy this requirement. The proof is the completed by induction.

▶ **Lemma 16.** *Let $\pi_A : [q]^n \to [q]^A$ be the projection on a set A of size m. Suppose $\mathcal{C} \subseteq [q]^n$ is a code of size qs satisfying $\mathrm{rad}_{\mathrm{H}}(\pi_A(\mathcal{C})) \leqslant 1 - \frac{1}{q} - \varepsilon$. Then, there exists a subcode $\mathcal{C}' \subseteq \mathcal{C}$ of size at least s such that $\mathrm{rad}_{\mathrm{H}}(\mathcal{C}') \leqslant 1 - \frac{1}{q} - \frac{m}{n}\varepsilon$.*

Proof. The proof is omitted due to the limited space. ◀

▶ **Theorem 17.** *Let L be fixed. For every $\varepsilon > 0$, there exists a $\delta > 0$ with the following property. If s is a natural number, there exist constants $M_0 = M_0(s)$ and $c(s)$ such that for any code $\mathcal{C} \subseteq [q]^n$ with size $M \geqslant M_0$, at least one of the following must hold:*

1. *There exists $\mathcal{C}' \subseteq \mathcal{C}$ such that $|\mathcal{C}'| \geqslant s$ and $\mathrm{rad}_{\mathrm{H}}(\mathcal{C}') \leqslant 1 - \frac{1}{q} - \delta$.*
2. *There exist at least $M^L - c(s)M^{L-1}$ many L-tuples of distinct codewords $(\boldsymbol{c}_1, \ldots, \boldsymbol{c}_L)$ in $\mathcal{C}$ such that for all $\boldsymbol{u} \in [q]^L$ we have*

$$|\mathsf{type}_{\boldsymbol{u}}(\boldsymbol{c}_1, \ldots, \boldsymbol{c}_L) - q^{-L}| \leqslant \varepsilon$$

and thus

$$|\overline{\mathrm{rad}}_{\omega}(\varphi(\boldsymbol{c}_1), \cdots, \varphi(\boldsymbol{c}_L)) - f(U_q, \omega)| \leqslant q^L\varepsilon.$$

Proof. The proof is omitted due to the limited space. ◀

3.4 Putting Everything Together

The argument follows the same line of reasoning as [1]. We provide the proof for completeness. Define $\rho_L(\mathcal{C}) = \min \mathrm{rad}(\varphi(\boldsymbol{c}_1), \ldots, \varphi(\boldsymbol{c}_L))$ with minimum taken over all L-tuples $(\boldsymbol{c}_1, \ldots, \boldsymbol{c}_L) \in \mathcal{C}^L$ with distinct elements, where we recall that rad denotes the *relaxed* Chebyshev radius (Definition 5).

▶ **Theorem 18.** *Let $L \geqslant 2$ and $q \geqslant 3$. If $\mathcal{C} \subseteq [q]^n$ is $(p_*(q, L) + \varepsilon, L)$-list-decodable, then $|\mathcal{C}| = O_{q,L}(\frac{1}{\varepsilon})$.*

Proof. The proof is omitted due to the limited space. ◀

4 Zero-Rate List-Recovery

In this section, we show how our results on list-decoding can naturally be extended to list-recovery. Due to the page limit, we refer the reader to the full version. The result is summarized in Theorem 1.

5 Code Construction

In this section, we present a simple simplex-like code construction and show that it attains the optimal size-radius trade-off by analyzing its list-decoding and -recovery radius.

Our construction will be identical for list-decoding and -recovery and therefore we will directly analyze its list-recovery radius. Before presenting the construction and its analysis, let us define the average radius $\overline{\mathrm{rad}}_\ell$. This is a standard notion that "linearizes" the Chebyshev radius rad and often finds its use in the analysis of list-recoverable codes in the literature. The definition reads as follows: for any $\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L \in [q]^n$,

$$\overline{\mathrm{rad}}_\ell(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L) \coloneqq \frac{1}{L} \min_{\boldsymbol{Y} \in \mathcal{X}^n} \sum_{i=1}^{L} d_{\mathrm{LR}}(\boldsymbol{c}_i, \boldsymbol{Y}).$$

It is well-known and easy to verify (by, e.g., following the derivations leading to Equation (14)) that the above minimization admits the following explicit solution:

$$\overline{\mathrm{rad}}_\ell(\boldsymbol{c}_1, \cdots, \boldsymbol{c}_L) \coloneqq \sum_{j=1}^{n} \left(1 - \frac{1}{L} \mathsf{pl}_\ell(\boldsymbol{c}_1(j), \cdots, \boldsymbol{c}_L(j))\right), \tag{19}$$

Equation (19) should be interpreted as the average distance from each $\boldsymbol{c}_i$ to the "centroid" $\boldsymbol{Y}^* \in \mathcal{X}^n$ of the list defined as[7]

$$\boldsymbol{Y}^*(j) \coloneqq \operatorname*{argmax}_{A \in \mathcal{X}} \sum_{i=1}^{L} \mathbb{1}\{\boldsymbol{c}_i(j) \in A\}.$$

for each $j \in [n]$.

Finally, for integers $q \geqslant 1$ and $L \geqslant 0$, denote by

$$\mathcal{A}_{q,L} = \left\{(a_1, \cdots, a_q) \in \mathbb{Z}_{\geqslant 0}^q : \sum_{i=1}^{q} a_i = L\right\}$$

[7] If there are multiple maximizers, take an arbitrary one and the value of $\overline{\mathrm{rad}}_\ell$ remains the same.

the set of q-partitions of L, i.e., a_i is the number of indices taking value i. For $\boldsymbol{a} \in \mathcal{A}_{a,L}$, we shorthand $\binom{L}{\boldsymbol{a}} = \binom{L}{a_1,\ldots,a_q}$ where $\boldsymbol{a} = (a_1, \ldots, a_q)$. Define $\max_\ell\{\boldsymbol{a}\} = \max_{A\in\mathcal{X}} \sum_{i\in A} a_i$, i.e., the sum of ℓ largest components in $\boldsymbol{a}$.

▶ **Theorem 19** (Construction of zero-rate list-recoverable codes). *Fix any integers $q \geqslant 3$, $\ell \geqslant 1$ and $L \geqslant 2$. For any sufficiently large m, there exists a (p, ℓ, L)-list-recoverable code $\mathcal{C}$ with blocklength*

$$n = \binom{qm}{\underbrace{m, \cdots, m}_{q}}, \tag{20}$$

and the trade-off between code size M and (relative) radius p given by:

$$M = qm, \quad p = p_*(q, \ell, L) + c_{q,\ell,L} m^{-1} + O(m^{-2}),$$

where

$$c_{q,\ell,L} \coloneqq q^{-L} \sum_{\boldsymbol{a}\in\mathcal{A}_{q,L}} \frac{\max_\ell\{\boldsymbol{a}\}}{L} \binom{L}{\boldsymbol{a}} \left[\sum_{i=1}^{q} \binom{a_i}{2} - \frac{1}{q}\binom{L}{2}\right] > 0. \tag{21}$$

Proof. The proof is omitted due to the page limit. ◀

Abstract

Integer Linear Programming with n binary variables and m many 0/1-constraints can be solved in time $2^{\tilde{O}(m^2)}\text{poly}(n)$ and it is open whether the dependence on m is optimal. Several seemingly unrelated problems, which include variants of Closest String, Discrepancy Minimization, Set Cover, and Set Packing, can be modelled as Integer Linear Programming with 0/1 constraints to obtain algorithms with the same running time for a natural parameter m in each of the problems. Our main result establishes through fine-grained reductions that these problems are equivalent, meaning that a $2^{O(m^{2-\varepsilon})}\text{poly}(n)$ algorithm with $\varepsilon > 0$ for one of them implies such an algorithm for all of them.

In the setting above, one can alternatively obtain an $n^{O(m)}$ time algorithm for Integer Linear Programming using a straightforward dynamic programming approach, which can be more efficient if n is relatively small (e.g., subexponential in m). We show that this can be improved to ${n'}^{O(m)} + O(nm)$, where n' is the number of distinct (i.e., non-symmetric) variables. This dominates both of the aforementioned running times.

1 Introduction

The study of parameterized complexity for Integer Linear Programming has a long history: classical works by Lenstra [15] and Kannan [12] and very recently Rothvoss and Reis [19] provide FPT algorithms in the number of variables n of an ILP of the form $Ax \leq b,\ x \in \mathbb{Z}^n$. In an orthogonal line of research, Papadimitriou [17] gave an FPT algorithm in the number of constraints and the size of the coefficients of A and b for an ILP in the standard form $Ax = b,\ x \in \mathbb{Z}^n_{\geq 0}$. Interest in the second line of work has been renewed by the improved algorithms due to Eisenbrand, Weismantel [9] and Jansen, Rohwedder [11], which give essentially optimal running times $(m\Delta)^{O(m)}\,\text{poly}(n)$ due to a conditional lower bound based on the Exponential Time Hypothesis (ETH) [14]. Here, Δ is the maximum absolute size

of an entry in A. The work by Eisenbrand and Weismantel also considers a version where variables are subject to box-constraints, which will be the primary focus of this work, see the definition below.

Integer Linear Programming
Input: Constraint matrix $A \in \{-\Delta, \dots, \Delta\}^{m \times n}$, right-hand side $b \in \mathbb{Z}^m$, variable bounds $\ell, u \in \mathbb{Z}^n_{\geq 0}$.
Task: Find $x \in \mathbb{Z}^n$ with

$$Ax = b$$
$$\ell_i \leq x_i \leq u_i \qquad i = 1, 2, \dots, n.$$

We refer to the variant where $\ell = (0, \dots, 0)^\mathsf{T}$ and $u = (1, \dots, 1)^\mathsf{T}$ as *binary* Integer Linear Programming.

Binary Integer Linear Programming
Input: Constraint matrix $A \in \{-\Delta, \dots, \Delta\}^{m \times n}$, right-hand side $b \in \mathbb{Z}^m$.
Task: Find $x \in \{0, 1\}^n$ with

$$Ax = b.$$

The running times obtained in [9] for either variant is $(m\Delta)^{O(m^2)} \operatorname{poly}(n)$. Also for matrices with only 0/1 coefficients nothing better than $2^{\tilde{O}(m^2)} \operatorname{poly}(n)$ is known. It is an intriguing question whether the slightly unusual exponent of $\tilde{O}(m^2)$ is necessary, which is in the spirit of *fine-grained complexity*. Since the dominant complexity-theoretic assumption of P≠NP is not powerful enough to show precise lower bounds on running times, the field of fine-grained complexity is concerned with finding lower bounds via stronger conjectures, see e.g., [2, 20, 6]. A number of such conjectures exist by now, often with interesting connections between them. Even if one doubts these conjectures, the reductions still provide insights into how problems relate to each other.

Based on existing conjectures, the best lower bound known on the exponent of Integer Linear Programming is $\Omega(m \log m)$ from the easier unbounded setting [14], which is of course not tight in this setting. In this paper, we take another path: we assume that Integer Linear Programming cannot be solved faster than the state-of-the-art and present several other natural parameterized problems that are all equivalent with respect to improvements on their running time.

▶ **Hypothesis 1** (ILP Hypothesis). *For every fixed $\varepsilon > 0$, there is no $2^{O(m^{2-\varepsilon})} \operatorname{poly}(n)$ time algorithm for Integer Linear Programming with $\Delta = O(1)$.*

In all of the problems below, the symbol m is chosen for the parameter of interest.

Closest String with Binary Alphabet
Input: Alphabet $\Sigma = \{0, 1\}$, strings $s_1, s_2, \dots, s_m \in \Sigma^n$
Task: Find string $t \in \Sigma^n$ minimizing

$$\max_i d(t, s_i),$$

where $d(t, s_i)$ is the Hamming distance between t and s_i, i.e., the number of positions the two strings differ in.

We refer to the generalization with arbitrary Σ simply as Closest String.

Discrepancy Minimization
Input: Universe $U = \{1, 2, \ldots, n\}$, set system $S_1, S_2, \ldots, S_m \subseteq U$
Task: Find coloring $\chi : U \to \{-1, 1\}$ minimizing

$$\max_i \left| \sum_{u \in S_i} \chi(u) \right|.$$

Set Multi-Cover
Input: Universe $U = \{1, 2, \ldots, m\}$, set system $S_1, S_2, \ldots, S_n \subseteq U$, $b \in \mathbb{N}$
Task: Find $I \subseteq \{1, 2, \ldots, n\}$ of minimal cardinality such that for each $v \in U$ there are at least b sets S_i with $i \in I$ and $v \in S_i$.

Set Multi-Packing
Input: Universe $U = \{1, 2, \ldots, m\}$, set system $S_1, S_2, \ldots, S_n \subseteq U$, $b \in \mathbb{N}$
Task: Find $I \subseteq \{1, 2, \ldots, n\}$ of maximal cardinality such that for each $v \in U$ there are at most b sets S_i with $i \in I$ and $v \in S_i$.

Many of these problems are well-known applications of ILP techniques. For example, Knop et al. [13] provided $m^{O(m^2)} \cdot \text{poly}(n)$ algorithms for Closest String and Set Multi-Cover. Discrepancy Minimization is usually considered within the context of approximation algorithms (see, e.g., [3]).

As mentioned above, our main result is the following equivalence.

▶ **Theorem 2.** *The following statements are equivalent:*
(1) *There exists an* $2^{O(m^{2-\varepsilon})} \text{poly}(n)$ *algorithm for Integer Linear Programming with* $\Delta = O(1)$ *with* $\varepsilon > 0$.
(2) *There exists an* $2^{O(m^{2-\varepsilon})} \text{poly}(n)$ *algorithm for Binary Integer Linear Programming with* $A \in \{0, 1\}^{m \times n}$ *and* $n \leq m^{O(m)}$ *with* $\varepsilon > 0$.
(3) *There exists an* $2^{O(m^{2-\varepsilon})} \text{poly}(n)$ *algorithm for Closest String with Binary Alphabet with* $\varepsilon > 0$.
(4) *There exists an* $2^{O(m^{2-\varepsilon})} \text{poly}(n)$ *algorithm for Discrepancy Minimization with* $\varepsilon > 0$.
(5) *There exists an* $2^{O(m^{2-\varepsilon})} \text{poly}(n)$ *algorithm for Set Multi-Cover with* $\varepsilon > 0$.
(6) *There exists an* $2^{O(m^{2-\varepsilon})} \text{poly}(n)$ *algorithm for Set Multi-Packing with* $\varepsilon > 0$.

Note that Item 1 is the negation of Hypothesis 1. All problems in Theorem 2 are easily transformed into the first problem, i.e., Integer Linear Programming with $\Delta = O(1)$, while maintaining the same value of m. Hence, the more interesting aspect of the theorem is that all these problems are as expressive as the first one.

Hypothesis 1 considers Integer Linear Programming with relatively small entries, i.e., $\Delta = O(1)$. One can also ask the question of whether there is any parameter regime for Δ for which the state-of-the-art can be improved. In this spirit, a stronger variant of the conjecture is the following.

▶ **Hypothesis 3** (Strong ILP Hypothesis). *For every fixed* $\varepsilon > 0$ *and* $\delta \geq 0$, *there is no* $2^{O(m^{\delta+2-\varepsilon})} \text{poly}(n)$ *time algorithm for Integer Linear Programming with* $\Delta = 2^{m^\delta}$.

Note that Hypothesis 1 is a special case of Hypothesis 3 for $\delta = 0$. Another interesting regime is the complexity of Integer Linear Programming with $\Delta = 2^m$, because of a connection to block-structure integer programming, which we elaborate on later. There, the state-of-the-art algorithm requires time $m^{O(m^3)} \text{poly}(n)$, Integer Linear Programming with large entries can be reduced to an equivalent instance with a 0/1 matrix as seen in the following theorem, but the reduction is not strong enough to show equivalence between the two hypotheses.

▶ **Theorem 4.** *There is a polynomial time algorithm that transforms an instance of* Integer Linear Programming *with* $\Delta > 1$ *into an equivalent one with* $A' \in \{0,1\}^{m' \times n'}$ *for* $m' = O(m \log \Delta)$ *and* $n' \leq {m'}^{O(m')}$.

This implies that if there is an algorithm with running time $2^{O(m^{1.5-\varepsilon})} \operatorname{poly}(n)$ for Integer Linear Programming with $A \in \{0,1\}^{m \times n}$, then there is a $2^{O(m^{3-\varepsilon'})} \operatorname{poly}(n)$ time algorithm for Integer Linear Programming with $\Delta = 2^m$.

One might hope to improve the theorem to $m' = O(m\sqrt{\log \Delta})$, since then a $2^{O(m^{2-\varepsilon})} \operatorname{poly}(n)$ time algorithm for 0/1 matrices would imply a $2^{O(m^{3-\varepsilon'})} \operatorname{poly}(n)$ time algorithm for $\Delta = 2^m$. However, such a reduction would imply the strong result that under ETH is equivalent to Hypothesis 1. This is because under ETH the Subset Sum problem, i.e., the case when $m = 1$, cannot be solved in $\Delta^{o(1)} \operatorname{poly}(n)$ time [1] and the hypothetical reduction would be able to encode an instance of Subset Sum into an ILP with $m = O(\sqrt{\log \Delta})$. We are not aware of any meaningful reduction in the other direction, i.e., from large m and small Δ to smaller m and larger Δ. It is possible to aggregate m constraints into a single one with entries bounded by $\Delta' = \Delta^{O(m^2)}$, but this reduction seems useless since the resulting parameter range requires $\operatorname{poly}(\Delta') \cdot \operatorname{poly}(n)$ time due to the ETH lower bound mentioned above.

Assuming Hypothesis 3, we derive a tight lower for a form of block-structured integer linear programs that has been studied extensively in recent literature. For simplicity, we consider here the basic setting with $m \times m$ submatrices.

n-Fold Integer Linear Programming
Input: Square matrices $A_1, \ldots, A_n, B_1, \ldots, B_n \in \{-\Delta, \ldots, \Delta\}^{m \times m}$, right-hand sides $b^{(0)}, \ldots, b^{(n)} \in \mathbb{Z}^m$.
Task: Find $x^{(1)}, \ldots, x^{(n)} \in \mathbb{Z}^m_{\geq 0}$ with

$$\begin{aligned} A_1 x^{(1)} + \ldots + A_n x^{(n)} &= b^{(0)} \\ B_1 x^{(1)} &= b^{(1)} \\ &\vdots \\ B_n x^{(n)} &= b^{(n)} \end{aligned}$$

▶ **Theorem 5.** *For every* $\delta > 0$*, there is no algorithm with running time* $2^{O(m^{3-\delta})} \operatorname{poly}(n)$ *for* n*-Fold Integer Linear Programming when the maximum absolute entry is bounded by* $\Delta = O(1)$*, unless Hypothesis 3 is false.*

This matches the best algorithms known for the problem, see [5] and references therein. The reduction follows the same idea as used in [10], where the authors show a non-tight quadratic lower bound for the exponent based on ETH. Our lower bound is stronger simply because the conjecture we base it on is stronger.

1.1 Tightness of more general problems

There are several other, more general problems to the ones mentioned above, for which known algorithms would be tight assuming that one cannot improve the running time for the class of problems in Theorem 2. However, we do not know if these are all equivalent.

The algorithm by Eisenbrand and Weismantel [9] also works for the optimization version of ILP, i.e.,

$$\max c^\mathsf{T} x,\ Ax = b,\ \ell \le x \le u,\ x \in \mathbb{Z}^n.$$

This leads to the same running time of $(m\Delta)^{O(m^2)}\operatorname{poly}(n)$ except for a slightly higher constant in the exponent. Notably, the coefficients of c do not increase the number of arithmetic operations.

Given a matrix $A \in \{-\Delta, \dots, \Delta\}^{m\times n}$ and a convex function $g : \mathbb{R}^m \to \mathbb{R} \cup \{\infty\}$, Dadush, Léonard, Rohwedder, and Verschae [7] have shown that one can find the minimizer of $g(Ax),\ x \in \{0,1\}^n$ in time $(m\Delta)^{O(m^2)}\operatorname{poly}(n)$ (assuming polynomial time to evaluate g). This problem is a generalization of Binary Integer Linear Programming, since one can take $g(b') = 0$ if $b' = b$ and $g(b') = \infty$ otherwise.

Given a linear matroid $M = (E, \mathcal{I})$, where $|E| = n$, a matrix $A \in \{-\Delta, \dots, \Delta\}^{n\times m}$ and a right-hand side $b \in \mathbb{Z}^m$, Eisenbrand, Rohwedder, and Węgrzycki [8] gave an algorithm that finds a basis B of M such that $Ax_B = b$ in time $O(m\Delta)^{O(m^2)}\operatorname{poly}(n)$, where x_B is the incidence vector of B. This generalizes Binary Integer Linear Programming, since one can take E as the set of binary variables and n additional dummy variables and then take M as the uniform matroid of rank n.

Finally, Closest String (with arbitrary alphabet) can still be solved in time $m^{O(m^2)}\operatorname{poly}(n)$ for example by casting it as the previous matroid problem [8] or as a block structured ILP, see [13].

1.2 Algorithm for few distinct variables

We show that the running time of $2^{\tilde{O}(m^2)}\operatorname{poly}(n)$ for Integer Linear Programming with $\Delta = O(1)$, i.e., the subject of Hypothesis 1, can be improved if the number of distinct variables is low. For the sake of generality, we state the algorithmic result for the optimization variant and any range of Δ.

▶ **Theorem 6.** *Consider the integer programming problem*

$$\begin{aligned} &\max\ c^\mathsf{T} x \\ &\quad Ax = b \\ &\ell_i \le x_i \le u_i && i = 1, \dots, n \\ &\quad x \in \mathbb{Z}^n\ . \end{aligned} \tag{1}$$

Let Δ be an upper bound on the absolute value of entries of A. The problem (1) can be solved in time

$$n^{m+1} \cdot O(m\Delta)^m \cdot \log(\|u - \ell\|_\infty).$$

Using standard reductions, see e.g. Section 2.5.2, one may reduce $\|u - \ell\|_\infty$ to $(m\Delta)^{O(m)}$, making the logarithmic factor insignificant.

We will now interpret this running time and point out interesting special cases.

Binary ILP with $A \in \{0,1\}^{m\times n}$

Here, the running time above implies an $n'^{O(m)} + O(nm)$ time algorithm, where n' is the number of distinct variables, i.e., variables that differ either in their entry of c or in their column of A: one can merge identical variables in time $2^{O(m)} + O(nm)$ time, after which

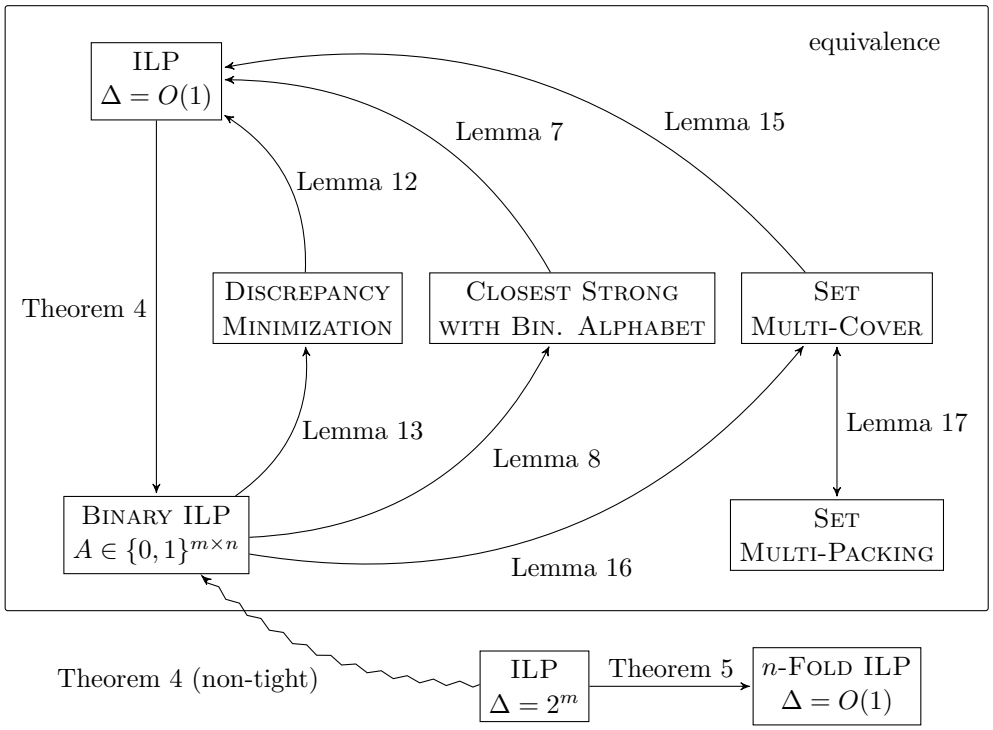

Figure 1 Overview of reductions in this paper.

$\|u\|_\infty \leq n$. Furthermore, without loss of generality, the rows of A are linearly independent, thus $m \leq n'$. Hence, the overall running time is

$$\begin{aligned} 2^{O(m)} + O(nm) + {n'}^{m+1} \cdot O(m)^m \cdot \log n &\leq {n'}^{O(m)} \cdot \log n + O(nm) \\ &\leq {n'}^{O(m)} + O(nm). \end{aligned}$$

Here, the last inequality follows from a case distinction whether $\log n$ is greater than ${n'}^{O(m)}$ or not. Note that in the setting without objective function we have $n' \leq 2^m$. Thus, this running time is at least as good as the known $2^{\tilde{O}(m^2)} \operatorname{poly}(n)$ time algorithms. It also dominates the running time of $n^{O(m)}$ one would get by simple dynamic programming over the right-hand sides b' that are feasible (for which there can be at most n^m).

Binary ILP with $A \in \{0,1\}^{m \times n}$ and a constant number of 1s in each column

Here, the number of distinct columns is polynomial in m and the previous case implies a running time of $m^{O(m)} + O(nm)$, meaning that Hypothesis 1 does not extend to this special case.

2 Reductions

The basic idea of all reductions for Theorem 2 is that we transform one problem with parameter m into another problem with parameter $m' = O(m \cdot \log^{O(1)} m)$. Additionally the size of the instance may only increase from n to $2^{O(m^{2-\delta})} \operatorname{poly}(n)$ for some $\delta > 0$. The concrete reductions we prove can be seen in Figure 1.

2.1 Closest String

Let d be the bound on the maximum hamming distance in the decision version of Closest String with Binary Alphabet. For a string $s \in \Sigma^n$ we denote by $s[i]$ the ith character. For $i \leq j$ we write $s[i \dots j]$ for the substring from the ith to the jth character.

▶ **Lemma 7.** *Theorem 2, Statement 1 implies Statement 3*

Proof. The following is an ILP model for Closest String with Binary Alphabet.

$$\sum_{i=1}^{n} x_i \cdot \mathbb{1}_{\{s_j[i]=0\}} + (1-x_i) \cdot \mathbb{1}_{\{s_j[i]=1\}} \leq d \qquad \text{for all } j \in \{1,2,\dots,m\}$$

$$x \in \{0,1\}^n$$

One may add slack variables to turn the inequalities into equalities. ◀

▶ **Lemma 8.** *Theorem 2, Statement 3 implies Statement 2*

Proof. We want to transform the following ILP

$$\begin{aligned} Ax &= b \\ x &\in \{0,1\}^n \end{aligned} \tag{2}$$

where $A \in \{0,1\}^{m \times n}$, into an equivalent instance of Closest String. We first rewrite (2) into a more convenient form.

▷ Claim 9. One can in polynomial time construct a matrix $C \in \{-1,1\}^{(2m+2)\times 2n}$ and some $c \in \mathbb{Z}^{2m+2}$ such that (2) is feasible if and only if there is a solution to

$$\begin{aligned} Cx &\leq c \\ x &\in \{0,1\}^{2n}. \end{aligned} \tag{3}$$

Furthermore, every feasible x for (3) has $x_1 + \dots + x_{2n} = n$.

This follows from simple transformations. We defer the proof until later and first show how the reduction follows from it. By comparing to the ILP formulation of Closest String we observe that (3) corresponds to a "non-uniform" variant of Closest String. It can be reformulated as: given strings $s_1, \dots, s_{2m+2} \in \{0,1\}^{2n}$ and bounds $d_1, \dots, d_{2m+2} \in \mathbb{Z}$, find a string $t \in \{0,1\}^{2n}$ such that for each $j = 1, \dots, m$ we have $d(t, s_j) \leq d_j$. This follows from the ILP model given in the proof of Lemma 7. Furthermore, we have the guarantee that any solution has exactly n ones. To transform this into a regular instance, we add two more strings r_1, r_2 and to each string s_j we add $4n$ more characters, which makes a total of $6n$ characters per string. The strings of this instance $s'_1, \dots, s'_{2m+2}, r_1, r_2$ are defined as

$$\begin{aligned} r_1 &= (\ 0,\dots,0,\ 0,\dots,0,\ 0,\dots,0,\ 0,\dots,\dots,0\ ), \\ r_2 &= (\ 1,\dots,1,\ 1,\dots,1,\ 1,\dots,1,\ 0,\dots,\dots,0\ ), \\ s'_j &= (\ \underbrace{s_j}_{2n \text{ chars}},\ \underbrace{1,\dots,1}_{n \text{ chars}},\ \underbrace{0,\dots,0}_{n \text{ chars}},\ \underbrace{1,\dots,1}_{2n-d_j \text{ chars}}\ \underbrace{0,\dots,0}_{d_j \text{ chars}}\ ). \end{aligned}$$

Here, we assume without loss of generality that $d_j \in \{0,\dots,2n\}$. We claim that there is a solution to this instance with maximum Hamming distance $2n$ if and only if there is a solution to the non-uniform instance.

▷ Claim 10. If there is a string $t' \in \{0,1\}^{6n}$ with distance at most $2n$ to r_1, r_2, and s'_j, $j = 1, 2, \ldots, 2m+2$, then there is also a string $t \in \{0,1\}^{2n}$ with distance at most d_j to s_j, $j = 1, 2, \ldots, 2m+2$.

▷ Claim 11. If there is a string $t \in \{0,1\}^{2n}$ with distance at most d_j to s_j, $j = 1, 2, \ldots, 2m+2$, then there is also a string $t' \in \{0,1\}^{6n}$ with distance at most $2n$ to r_1, r_2, and s'_j, $j = 1, 2, \ldots, 2m+2$.

From these claims, the lemma follows immediately. ◀

Proof of Claim 9. We add variables $\bar{x}_1, \ldots, \bar{x}_n$ and force a solution to take exactly n many ones

$$\begin{aligned} Ax &= b \\ x_1 + \cdots + x_n + \bar{x}_1 + \cdots + \bar{x}_n &= n \\ x, \bar{x} &\in \{0,1\}^n. \end{aligned}$$

Next, we change the equality constraints into inequalities and A into a $-1, 1$ matrix

$$\begin{aligned} A'x - \mathbf{1}\bar{x} &\leq b' \\ -A'x + \mathbf{1}\bar{x} &\leq -b' \\ x_1 + \cdots + x_n + \bar{x}_1 + \cdots + \bar{x}_n &\leq n \\ -x_1 - \cdots - x_n - \bar{x}_1 - \cdots - \bar{x}_n &\leq -n \\ x, \bar{x} &\in \{0,1\}^n \end{aligned}$$

where $A' = 2A - \mathbf{1}$ with $\mathbf{1}$ being the all-ones $m \times n$ matrix and $b' = 2b - (n, \ldots, n)^\mathsf{T}$. ◁

Proof of Claim 10. Suppose there is a string $t' \in \{0,1\}^{6n}$ with distance at most $2n$ to each of the strings $s'_1, \ldots, s'_{2m+2}, r_1, r_2$. Because $d(r_1, r_2) = 4n$, string t' must match r_1 and r_2 on characters where r_1 and r_2 match. More precisely, $t'[i] = 0$ for $i \in \{4n, \ldots, 6n\}$. Formally, this follows because of

$$\begin{aligned} 4n &\geq d(t', r_1) + d(t', r_2) \\ &= d(t'[1 \ldots 4n], r_1[1 \ldots 4n]) + d(t'[1 \ldots 4n], r_2[1 \ldots 4n]) \\ &\quad + 2d(t'[4n+1 \ldots 6n], (0, \ldots, 0)) \\ &\geq d(r_1[1 \ldots 4n], r_2[1 \ldots 4n]) + 2d(t'[4n+1 \ldots 6n], (0, \ldots, 0)) \\ &\geq 4n + 2d(t'[4n+1 \ldots 6n], (0, \ldots, 0)). \end{aligned}$$

Let us now analyze the distance between $t := t'[1 \ldots 2n]$ and s_j for some j. Since the last $2n$ characters of t' are zero, we have $d(t'[4n+1 \ldots 6n], s'_j[4n+1 \ldots 6n]) = 2n - d_j$. Thus,

$$\begin{aligned} d(t, s_j) &\leq d(t', s'_j) - d(t'[4n+1 \ldots 6n], s'_j[4n+1 \ldots 6n]) \\ &\leq 2n - (2n - d_j) = d_j. \end{aligned}$$

Thus, string t is a solution for the non-uniform instance. ◁

Proof of Claim 11. Let $t \in \{0,1\}^{2n}$ with $d(t[1 \ldots 2n], s_j) \leq d_j$ for all j. We extend it to a string $t' \in \{0,1\}^{6n}$ by setting $t'[1 \ldots 2n] = t$, $t[2n+1 \ldots 3n] = (1, \ldots, 1)$, and $t[3n+1 \ldots 6n] = (0, \ldots, 0)$. Let us now verify that t' has a distance at most $2n$ to each string. For r_1, r_2 note that $t[1 \ldots 2n]$ has exactly n ones by guarantee of the non-uniform instance. Thus, the distance to r_1 and r_2 is exactly $2n$. Consider some $j \in \{1, \ldots, 2m+2\}$. Then

$$d(s'_j, t) = d(s_j, t[1 \ldots 2n]) + 2n - d_j \leq 2n.$$ ◀

2.2 Discrepancy Minimization

▶ **Lemma 12.** *Theorem 2, Statement 1 implies Statement 4*

Proof. Let d be a bound on the objective in the decision version of Discrepancy Minimization. Let A be the incidence matrix of the given set system. Then the colorings of discrepancy at most d are exactly the solutions of

$$\begin{pmatrix} A \\ -A \end{pmatrix} y \leq \begin{pmatrix} d \\ d \\ \vdots \\ d \end{pmatrix}$$
$$y \in \{-1,1\}^n.$$

This can be equivalently formulated as

$$\begin{pmatrix} 2A \\ -2A \end{pmatrix} x \leq \begin{pmatrix} A \\ -A \end{pmatrix} \begin{pmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{pmatrix} + \begin{pmatrix} 2d \\ 2d \\ \vdots \\ 2d \end{pmatrix}$$
$$x \in \{0,1\}^n.$$

where $x_i = (1+y_i)/2$. One may translate the inequalities into equalities by introducing slack variables. Therefore, an algorithm for Integer Linear Programming can be used to solve Discrepancy Minimization. ◀

▶ **Lemma 13.** *Theorem 2, Statement 4 implies Statement 2.*

Proof. Consider an ILP of the form

$$Ax = b \tag{4}$$
$$x \in \{0,1\}^n$$

for $A \in \{0,1\}^{m \times n}$ and $n \leq m^{O(m)}$. We will construct an instance of Discrepancy Minimization which has discrepancy zero if and only if the ILP has a feasible solution. Towards this, we first reformulate the ILP above as

$$Ay = b' \tag{5}$$
$$y \in \{-1,1\}^n$$

where $b' = 2b - A\,(1,\dots,1)^\mathsf{T}$. Note that x is feasible for (4) if and only if $y = 2x - (1,\dots,1)^\mathsf{T}$ is feasible for (5). Also, if $b' = (0,\dots,0)^\mathsf{T}$, then (5) is already equivalent to an instance of Discrepancy Minimization that tests for discrepancy zero. To handle the general case, we transform it into an equivalent system with right-hand size $(0,\dots,0)^\mathsf{T}$. We first construct a gadget of elements that have the same color.

▷ Claim 14. For any $k \in \mathbb{N}$ we can construct a pair of matrices $B, \bar{B} \in \{0,1\}^{(2k-1)\times 2^k}$ such that there are exactly two solutions to

$$Bz + \bar{B}\bar{z} = \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix}$$
$$z, \bar{z} \in \{-1,1\}^{2^k}$$

namely $z = (1,\dots,1)^\mathsf{T}, \bar{z} = (-1,\dots,-1)^\mathsf{T}$ and $z = (-1,\dots,-1)^\mathsf{T}, \bar{z} = (1,\dots,1)^\mathsf{T}$.

We will defer the proof to the end of the section. Using this gadget with $k = \lceil \log_2 n \rceil = O(m \log m)$ we now replace each coefficient b'_j in the previous system by the variables from the gadget. Note that (5) is infeasible if $\|b'\|_\infty > n$. Thus assume without loss of generality that $\|b'\|_\infty \leq n \leq 2^k$. Let $C, \bar{C} \in \{0,1\}^{2^k \times m}$ be defined as follows. The jth row of C has b'_j many ones at arbitrary positions if $b'_j \geq 0$ and is all zero otherwise; contrary, the jth row of $\bar{C}$ has $-b'_j$ many ones at arbitrary positions if $b'_j < 0$ and is all zero otherwise.

Now consider the system

$$\begin{aligned} Ay + Cz + \bar{C}\bar{z} &= \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix} \\ Bz + \bar{B}\bar{z} &= \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix} \\ y &\in \{-1,1\}^n \\ z, \bar{z} &\in \{-1,1\}^{2^k}. \end{aligned} \tag{6}$$

We claim that (6) has a solution if and only if there is a solution to (5). Let $y, z, \bar{z}$ be a solution to the former. Notice that the negation of a solution is also feasible. Due to Claim 14 we may assume without loss of generality that $z = (-1, \ldots, -1)^\mathsf{T}$ and $\bar{z} = (1, \ldots, 1)^\mathsf{T}$, negating the solution if necessary. It follows that

$$Cz + \bar{C}\bar{z} = -b'.$$

Thus, $Ay = b'$, which concludes the first direction. For the other direction, assume that there is a solution y to (5). We set $z = (-1, \ldots, -1)^\mathsf{T}$, $\bar{z} = (1, \ldots, 1)^\mathsf{T}$, which by Claim 14 satisfies $Bz + \bar{B}\bar{z} = (0, \ldots, 0)^\mathsf{T}$. As before we have that $Cz + \bar{C}\bar{z} = -b'$. Thus, $y, z, \bar{z}$ is a solution to (6). This establishes the equivalence of the initial ILP instance to (6), which corresponds to an instance of Discrepancy Minimization where we test for discrepancy zero with $m' = O(m \log m)$ sets. ◀

Proof of Claim 14. The existence of such a matrix can be proven by induction: for $k = 1$, we simply take $B = \bar{B} = (1)$. Now suppose that we already have a pair of matrices $B, \bar{B} \in \{0,1\}^{(2k-1)\times 2^k}$ as above. Then we set

$$B' = \begin{pmatrix} B & 0 \\ 1\cdots 1 & 0\cdots 0 \\ 0\cdots 0 & 1\cdots 1 \end{pmatrix} \text{ and } \bar{B}' = \begin{pmatrix} \bar{B} & 0 \\ 0\cdots 0 & 1\cdots 1 \\ 1\cdots 1 & 0\cdots 0 \end{pmatrix} \in \{0,1\}^{(2k+1)\times 2\cdot 2^k}.$$

It can easily be checked that choosing either $z = z' = (1, \ldots, 1)^\mathsf{T}, \bar{z} = \bar{z}' = (-1, \ldots, -1)^\mathsf{T}$ or $z = z' = (-1, \ldots, -1)^\mathsf{T}, \bar{z} = \bar{z}' = (1, \ldots, 1)^\mathsf{T}$ satisfies

$$B' \begin{pmatrix} z \\ z' \end{pmatrix} + \bar{B}' \begin{pmatrix} \bar{z} \\ \bar{z}' \end{pmatrix} = \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix}. \tag{7}$$

Now take any $z, z', \bar{z}, \bar{z}' \in \{-1,1\}^{2^{k+1}}$ that satisfy (7). Then we have that $Bz + \bar{B}\bar{z} = (0, \ldots, 0)^\mathsf{T}$. Hence by induction hypothesis either $z = (1, \ldots, 1)^\mathsf{T}, \bar{z} = (-1, \ldots, -1)^\mathsf{T}$ or $z = (-1, \ldots, -1)^\mathsf{T}, \bar{z} = (1, \ldots, 1)^\mathsf{T}$. Assume for now the first case holds. Then because of the second-to-last rows of $B, \bar{B}$ we have

$$2^k + \sum_{i=1}^{2^k} \bar{z}'_i = \sum_{i=1}^{2^k} z_i + \bar{z}'_i = 0.$$

Hence, $\bar{z}' = (-1, \dots, -1)^\mathsf{T} = \bar{z}$. Similarly, the last row of $B, \bar{B}$ implies that $z' = (1, \dots, 1)^\mathsf{T} = z$. Analogously, if $z = (-1, \dots, -1)^\mathsf{T}, \bar{z} = (1, \dots, 1)^\mathsf{T}$ then $z' = z$ and $\bar{z}' = \bar{z}$. ◁

2.3 Set Multi-Cover

▶ **Lemma 15.** *Theorem 2, Statement 1 implies Statement 5.*

Proof. An instance of the decision version of Set Multi-Cover with a bound d on the cardinality can be formulated as

$$\begin{aligned} x_1 + \cdots + x_n &\leq d \\ Ax &\geq \begin{pmatrix} b \\ \vdots \\ b \end{pmatrix} \\ x &\in \{0,1\}^n \end{aligned}$$

where $A \in \{0,1\}^{m \times n}$ is the incidence matrix of the given set system. This can easily be translated to the form of (1) by introducing slack variables. Notice that this ILP has $m + 1$ constraints. Thus, a faster algorithm for ILP would imply a faster algorithm for Set Multi-Cover. ◀

In the remainder, we show that the converse is also true.

▶ **Lemma 16.** *Theorem 2, Statement 5 implies Statement 2.*

Proof. First, we reduce to a "non-uniform" version of Set Multi-Cover where each element v has a different demand b_v. Let $A \in \{0,1\}^{m \times n}$ and $b \in \mathbb{Z}^m_{\geq 0}$ and consider the solutions to

$$\begin{aligned} Ax &= b \\ x &\in \{0,1\}^n. \end{aligned}$$

First, we add n additional binary variables $\bar{x}$ and the requirement that exactly n variables are equal to one, i.e.,

$$\begin{aligned} Ax &= b \\ x_1 + \cdots + x_n + \bar{x}_1 + \cdots + \bar{x}_n &= n \\ x &\in \{0,1\}^n \\ \bar{x} &\in \{0,1\}^n. \end{aligned}$$

This system is equivalent to the previous one, by setting $n - x_1 - \cdots - x_n$ arbitrary variables $\bar{x}_i$ to 1. Next, we transform the equality constraints $Ax = b$ into inequalities:

$$
\begin{aligned}
Ax &\geq b \\
(\mathbf{1} - A)x + \mathbf{1}\bar{x} &\geq \begin{pmatrix} n \\ \vdots \\ n \end{pmatrix} - b \\
x_1 + \cdots + x_n + \bar{x}_1 + \cdots + \bar{x}_n &= n \\
x &\in \{0,1\}^n \\
\bar{x} &\in \{0,1\}^n.
\end{aligned}
$$

Here, $\mathbf{1}$ denotes the $n \times n$ all-ones matrix. Note that the second constraint is equivalent to $Ax \leq b$, since we fixed the number of ones in the solution. This ILP is feasible if and only if the optimum of the following ILP is n.

$$
\begin{aligned}
\min\ & x_1 + \cdots + x_n + \bar{x}_1 + \cdots + \bar{x}_n \\
& Ax \geq b \\
& (\mathbf{1} - A)x + \mathbf{1}\bar{x} \geq \begin{pmatrix} n \\ \vdots \\ n \end{pmatrix} - b \\
& x_1 + \cdots + x_n + \bar{x}_1 + \cdots + \bar{x}_n \geq n \\
& x \in \{0,1\}^n \\
& \bar{x} \in \{0,1\}^n.
\end{aligned}
$$

This ILP corresponds to an instance of non-uniform Set Multi-Cover with $2m+1$ elements.

To reduce a non-uniform instance $S_1, \ldots, S_n$, $(b_v)_{v \in U}$, to a uniform instance of Set Multi-Cover we proceed as follows: add one new element and n many new sets to the instance. The coverage requirement of each element is n. The new element is contained in each of the new sets and in none of the old ones. Thus, each new set has to be taken. Furthermore, we add each old element v to $n - b_v$ many arbitrary new sets. ◀

2.4 Set Multi-Packing

▶ **Lemma 17.** *Theorem 2, Statements 5 and 6 are equivalent.*

Proof. Notice the following duality between Set Multi-Cover and Set Multi-Packing. Let $U = \{1, 2, \ldots, m\}$, $S_1, S_2, \ldots, S_n$, and $b \in \mathbb{N}$ be an instance of Set Multi-Cover. Now consider the instance of Set Multi-Packing with universe U, set system $\bar{S}_1 = U \setminus S_1, \bar{S}_2 = U \setminus S_2, \ldots, \bar{S}_n = U \setminus S_n$, and bounds $\bar{b} = n - b$. This is a bipartition between instances of Set Multi-Cover and Set Multi-Packing, i.e., it can be performed in both ways.

For one pair of such instances, a solution I for Set Multi-Cover is feasible if and only if $\bar{I} = \{1, 2, \ldots, n\} \setminus I$ is feasible for Set Multi-Packing. Thus, if the optimum of Set Multi-Cover is k, then the optimum of Set Multi-Packing is $n - k$. ◀

2.5 Integer Linear Programming

In this section, we prove Theorem 4, i.e., we show how to reduce an ILP with large coefficients into a (larger) ILP with only 0/1 coefficients.

▶ **Theorem 4.** *There is a polynomial time algorithm that transforms an instance of* Integer Linear Programming *with* $\Delta > 1$ *into an equivalent one with* $A' \in \{0,1\}^{m' \times n'}$ *for* $m' = O(m \log \Delta)$ *and* $n' \leq {m'}^{O(m')}$.

Furthermore, we show how to reduce an ILP with arbitrary upper and lower bounds into one with at most $(m\Delta)^{O(m)}$ binary variables. Note that this implies that Statements 1 and 2 are equivalent and concludes the proof of Theorem 2.

2.5.1 From large coefficients to zero-one

We will transform an ILP of the form

$$\begin{aligned} Ax &= b \\ \ell \leq x &\leq u \\ x &\in \mathbb{Z}^n \end{aligned}$$

where $A \in \{-\Delta, \dots, \Delta\}^{m \times n}$ into an equivalent one with $A' \in \{0,1\}^{m' \times n'}$ for $m' = O(m \log \Delta)$. Let $k = \lceil \log_2(\Delta) \rceil$. For the jth row of A we introduce $4(k+1)$ rows in A', denoted by $r_0^+(j), {r'}_0^+(j), \dots, r_k^+(j), {r'}_k^+(j), r_0^-(j), {r'}_0^-(j), \dots, r_k^-(j), {r'}_k^-(j)$. Intuitively, the rows $r_i^+(j), {r'}_i^+(j)$ are symmetric rows that each stand for a value of 2^i in row j. Similarly, $r_i^-(j), {r'}_i^-(j)$ stand for a value of -2^i in row j. The right-hand sides of the new ILP are b_j for row $r_0^+(j)$ and zero for all other rows affiliated with j.

For each column A_i we derive a column of A' as follows: for row j we consider the binary encoding of A_{ji} and have the column in A' use this binary encoding in $r_0^+(j), r_1^+(j), \dots, r_k^+(j)$ if $A_{ji} \geq 0$ and in $r_0^-(j), r_1^-(j), \dots, r_k^-(j)$ if $A_{ji} < 0$. All other entries of this column are zero.

We now add auxiliary variables to shift the values from one power to another. For each row j and each $i = 0, \dots, k-1$ we add:

- a variable $x(i,j)$ with a one in row $r_i^+(j), {r'}_i^+(j)$ and $r_{i+1}^-(j)$ and
- a variable $\bar{x}(i,j)$ with a one in row $r_i^-(j), {r'}_i^-(j)$ and $r_{i+1}^+(j)$.

Furthermore, for each row j and each $i = 0, \dots, k$ we add:

- a variable $x_a(i,j)$ with a one in row ${r'}_i^+(j)$ and $r_i^-(j)$,
- a variable $x_b(i,j)$ with a one in row ${r'}_i^-(j)$ and $r_i^+(j)$, and
- a variable $x_c(i,j)$ with a one in row $r_i^-(j)$ and $r_i^+(j)$.

Note that each auxiliary variable does not alter the total value for row j, i.e., the sum of 2^i times $r_i^+(j)$ and ${r'}_i^+(j)$ minus 2^i times $r_i^-(j)$ and ${r'}_i^-(j)$ across all i.

Thus, any solution to the new ILP must correspond to a solution of the original ILP. The converse is also true: the auxiliary variables can be adjusted to preserve the original value of the ILP. This is because any value for one of the rows of j can always be shifted to $r_0^+(j)$ using the auxiliary variables, while still satisfying the constraints. Therefore, we can enforce the value of the unchanged variables.

2.5.2 From bounded to binary variables

Consider an ILP of the form

$$\begin{aligned} Ax &= b \\ \ell \leq x &\leq u \\ x &\in \mathbb{Z}^n \end{aligned}$$

where $A \in \{-\Delta, \dots, \Delta\}^{m \times n}$. We will first transform this into an equivalent ILP of the form

$$\begin{aligned} A'x &= b' \\ x &\in \{0,1\}^{n'} \end{aligned} \tag{8}$$

where $A' \in \{-\Delta, \dots, \Delta\}^{m \times n'}$ for $n' \leq (m\Delta)^{O(m)}$. Assume without loss of generality that each column of A is different. Otherwise, we can merge identical columns together by adding the respective upper and lower bounds. This implies that $n \leq (2\Delta+1)^m$. Next, we compute a vertex solution x^* to the continuous relaxation $\{Ax = b, \ell \leq x \leq u, x \in \mathbb{R}^n\}$. The proximity bound by Eisenbrand and Weismantel [9] shows that there is an integer solution z with $\|z - x^*\|_1 \leq m(2m\Delta+1)^m$ if any integer solution exists. Thus, choosing $\ell'_i = \max\{\ell_i, \lceil x^*_i \rceil - (2\Delta+1)^m\}$ and $u'_i = \min\{u_i, \lfloor x^*_i \rfloor + (2\Delta+1)^m\}$ for $i = 1, 2, \dots, n$, we can replace ℓ, u by ℓ', u' without affecting feasibility. By shifting the solution, we can reduce the lower bound to zero and we arrive at the following ILP that is equivalent to the original one.

$$\begin{aligned} Ax &= b - A\ell' \\ x_i &\in \{0, 1, \dots, u'_i - \ell'_i\} \qquad\qquad \text{for all } i = 1, 2, \dots, n \end{aligned}$$

Note that $u'_i - \ell'_i \leq 2m(2m\Delta+1)^m$. Thus replacing each variable by $u'_i - \ell'_i$ binary variables we arrive at an ILP with $n' \leq 2m(2m\Delta+1)^m \cdot n \leq 2m(2m\Delta+1)^{2m}$ binary variables.

2.6 n-Fold Integer Linear Programming

In this section, we prove Theorem 5.

▶ **Theorem 5.** *For every $\delta > 0$, there is no algorithm with running time $2^{O(m^{3-\delta})}\operatorname{poly}(n)$ for n-Fold Integer Linear Programming when the maximum absolute entry is bounded by $\Delta = O(1)$, unless Hypothesis 3 is false.*

Consider the ILP

$$\begin{aligned} Ax &= b \\ x &\in \{0,1\}^n \end{aligned} \tag{9}$$

with $A \in \{-2^m, \dots, 2^m\}^{m \times n}$. We will show that this can be formulated as an equivalent n-Fold Integer Linear Program with parameter m and $\Delta = O(1)$. The reduction follows a similar idea as one in [10], which derives a lower bound based on Subset Sum. Note that if (9) had arbitrary variables (not necessarily binary) then we can use the reduction of the previous section to transform it into a binary one. For $m \geq 3$, define

$$B = \begin{pmatrix} 1 & 0 & & \cdots & 0 & 1 \\ 0 & & & \cdots & & 0 \\ 2 & -1 & & \cdots & & \\ & 2 & -1 & \cdots & & \vdots \\ & & & \ddots & & \\ & & & 2 & -1 & 0 \end{pmatrix} \in \{-1, 0, 1, 2\}^{m \times m}.$$

This matrix has the property that the system $Bx = (1, 0, \dots, 0)^\mathsf{T}, x \in \mathbb{Z}^m_{\geq 0}$ has exactly two solutions, namely $x = (0, \dots, 0, 1)$ and $x = (1, 2^1, 2^2, \dots, 2^{m-2}, 0)$. Our n-Fold Integer Linear Program has one block A'_i, B'_i for each column A_i of A. Matrix B'_i is defined as B above with right-hand side $b'^{(i)} = (1, 0, \dots, 0)^\mathsf{T}$. Matrix A'_i is derived from A_i as follows: consider a coefficient A_{ji}. We rewrite

$$A_{ji} = \lambda_0 \cdot 2^0 + \lambda_1 \cdot 2^1 + \cdots + \lambda_{m-2} \cdot 2^{m-2} \text{ with } \lambda \in \{-2, \dots, 2\}^{m-1}.$$

Such a λ exists since $|A_{ji}| \leq 2^m$. Then we set the jth row of A'_i as $(\lambda^\mathsf{T}, 0)$. Let $x^{(i)}$ be the variables corresponding to block A'_i, B'_i. By choice of $B'_i, b'^{(i)}$ there are exactly two settings of $x^{(i)}$ that satisfy $B'_i x^{(i)} = b'^{(i)}$, namely $x^{(i)} = (0, \dots, 0, 1)$ and $x^{(i)} = (2^0, 2^1, \dots, 2^{m-2}, 0)$. Thus $A'_i x^{(i)} \in \{(0, \dots, 0)^\mathsf{T}, A_i\}$. Hence, the n-Fold Integer Linear Program with $b^{(0)} = b$ is equivalent to (9).

3 Algorithm for few distinct variables

In this section, we prove Theorem 6.

▶ **Theorem 6.** *Consider the integer programming problem*

$$\begin{aligned} &\max\ c^\mathsf{T} x \\ &\quad Ax = b \\ &\ell_i \leq x_i \leq u_i \qquad\qquad i = 1, \dots, n \\ &\quad x \in \mathbb{Z}^n\ . \end{aligned} \tag{1}$$

Let Δ be an upper bound on the absolute value of entries of A. The problem (1) can be solved in time

$$n^{m+1} \cdot O(m\Delta)^m \cdot \log(\|u - \ell\|_\infty).$$

We assume without loss of generality that in (1) we have $\ell = (0, 0, \dots, 0)$. Note that otherwise, one may obtain an equivalent ILP with $\ell = (0, 0, \dots, 0)$, $u' = u - \ell$, and $b' = b - A\ell$. We first decompose each u_i into a sum of powers of two with the properties described in the following lemma. Such a construction is well-known in literature, see e.g. [18, 4, 16].

▶ **Lemma 18** (Cover). *For every integer $k \in \mathbb{N}$ and $h \geq \lfloor \log k \rfloor$, there exist integers $c_0(k), \dots, c_h(k) \in \{0, 1, 2\}$ such that*

$$\left\{ \sum_{i=0}^{h} 2^i x_i : 0 \leq x_i \leq c_i(k) \text{ for all } 0 \leq i \leq h \right\} = \{0, 1, \dots, k\}.$$

We call such a set $c_0(k), \dots, c_h(k)$ a cover *of k. This set can be found in polynomial time in h.*

Proof. For $n \in \mathbb{N}$, let $\mathrm{bin}_i(n) \in \{0, 1\}$ denote the ith bit of the binary representation of n. Let $B := 2^h - 1$ be the *bottom* bits, and let $T = k - B$ represent the *top* bits of k. Now, consider the sets

$$S_B := \left\{ \sum_{i=0}^{h-1} 2^i x_i : 0 \leq x_i \leq \mathrm{bin}_i(B) \text{ for all } 0 \leq i \leq h-1 \right\} \text{ and}$$

$$S_T := \left\{ \sum_{i=0}^{h} 2^i x_i : 0 \leq x_i \leq \mathrm{bin}_i(T) \text{ for all } 0 \leq i \leq h \right\}.$$

We will set $c_i(k) := \mathrm{bin}_i(B) + \mathrm{bin}_i(T) \in \{0,1,2\}$. Showing that these numbers are a cover of k is equivalent to

$$S_B \oplus S_T := \{b + t \mid b \in S_B, t \in S_T\} = \{0, 1, \ldots, k\}.$$

First, observe that $S_B = \{0, 1, \ldots, 2^h - 1\}$. Moreover, there is no gap of length at least 2^h in the set S_T, that is, for every nonzero $a \in S_T$, there exists a smaller $b \in S_T$ such that $a - b < 2^h$. This b can be constructed by flipping an arbitrary bit of a to 0. Therefore, $S_B \oplus S_T$ consists of consecutive numbers. The smallest number in $S_B \oplus S_T$ is clearly 0, and the largest is $B + T = k$. ◀

We set $h = \lfloor \log_2(\|u\|_\infty) \rfloor$. Using the lemma above, for each i, we decompose $u_i = c_0(u_i) \cdot 2^0 + c_1(u_i) \cdot 2^1 + \cdots + c_h(u_i) \cdot 2^h$ with its cover. We can now naturally rewrite (1) as

$$\begin{aligned}
&\max \sum_{i=0}^{h} 2^i c^\mathsf{T} z^{(i)} \\
&\sum_{i=0}^{h} 2^i A z^{(i)} = b \\
&0 \le z_i^{(k)} \le c_k(u_i) && k \in \{0, \ldots, h\} \\
&z^{(0)}, \ldots, z^{(h)} \in \mathbb{Z}^n \ .
\end{aligned}$$

Each $z^{(j)}$ produces a partial solution for some unknown right-hand side $b^{(j)} = 2^j A z^{(j)}$. We write $b^{(\le j)} = 2^0 A z^{(0)} + 2^1 A z^{(1)} + \cdots + 2^j A z^{(j)}$.

Our approach is now to compute, for $j = 0, 1, \ldots, h$ and for every potential value of $b^{(\le j)}$, a solution $z^{(0)}, z^{(1)}, \ldots, z^{(j)}$. To do this, we first reduce the search space of relevant vectors $b^{(\le j)}$.

▶ **Lemma 19.** *Consider $A \in \mathbb{Z}^{m \times n}$ and $b \in \mathbb{Z}^m$ with $\|A\|_\infty \le \Delta$. Suppose that $y = y^{(0)} \cdot 2^0 + y^{(1)} \cdot 2^1 + \cdots + y^{(h)} \cdot 2^h$ satisfies $Ay = b$ and $0 \le y^{(j)} \le u^{(j)}$ with $u^{(j)} \in \{0,1,2\}^n$ for each $j \in \{0, \ldots, \ell\}$. Then for $b^{(\le j)} = 2^0 A y^{(0)} + 2^1 A y^{(1)} + \cdots + 2^j A y^{(j)}$, we have*

$$b^{(\le j)} \equiv b \mod 2^{j+1}$$

and furthermore

$$b^{(\le j)} \in \{-2^{j+2} mn\Delta, \ldots, 2^{j+2} mn\Delta\}^m \ .$$

Proof. The first property follows from the observation that $b^{(>j)} := b - b^{(\le j)}$ is a vector with each component being a multiple of 2^{j+1}. Hence, $b^{(\le j)} \equiv b - b^{(>j)} \equiv b \mod 2^{j+1}$.

For the second property, observe that $\|y^{(h)}\|_1 \le \|u^{(h)}\|_1 \le 2n$ for each h. Therefore, $\|b^{(\le j)}\|_\infty \le \sum_{h=0}^{j} 2^{h+1} n\Delta \le 2^{j+2} nm\Delta$. ◀

We say that a vector $b' \in \mathbb{Z}^m$ is *relevant* for j if $b' \equiv b \mod 2^{j+1}$ and $\|b'\|_\infty \le 2^{j+2} mn\Delta$. Clearly, the following holds:

▷ Claim 20. For every j, the number of relevant vectors for j is $O(mn\Delta)^m$.

We will now iteratively compute solutions for all vectors relevant for $j+1$ from the solutions for all relevant vectors for j with $j \ge 0$. Note that this will immediately establish Theorem 6.

▶ **Lemma 21.** *Let $\mathcal{S}_j$ be a set of optimal solutions to (1) for all $b' \in \mathbb{Z}^m$ that are relevant for j. Then, in time $n^{m+1} \cdot O(m\Delta)^m$, we can compute a set $\mathcal{S}_{j+1}$ of optimal solutions for all $b'' \in \mathbb{Z}^m$ relevant for $j+1$.*

Proof. Let V be the set of all vectors $b' \in \mathbb{Z}^m$ with $b' \equiv b \mod 2^{j+1}$ and $\|b'\|_\infty \leq 2^{j+2}mn\Delta$.

We define an edge-weighted directed acyclic graph with vertices $\{s\} \cup V^{(0)} \cup V^{(1)} \cup \ldots \cup V^{(n)}$, where $V^{(0)}, V^{(1)}, \ldots, V^{(n)}$ are $n+1$ copies of V, and s is a distinguished source vertex.

If $j \geq 0$, there is an edge from s to every vertex $v_{b'} \in V^{(0)}$ such that the vector $v_{b'}$ corresponds to a relevant vector $b' \in \mathbb{Z}^m$ for j for which (1) has a solution $x_{b'}$. This edge indicates feasibility, and the weight of the edge from s to $v_{b'}$ is the value $c^\mathsf{T} x_{b'}$ for the optimal solution $x_{b'}$. In the base case where $j < 0$, there is exactly one edge of weight 0 to the vertex in $V^{(0)}$ that corresponds to the all-zero vector.

For each vertex in $V^{(i-1)}$ for $0 < i \leq n$, there is an edge to the corresponding vertex in $V^{(i)}$ with weight zero. Further, if $c_{j+1}(u_i) \geq 1$, for every vertex corresponding to b' in $V^{(i-1)}$, there is an edge to the vertex in $V^{(i)}$ that corresponds to $b' + 2^j A_i$ (if it exists). The weight of this edge is $2^j c_i$.

Similarly, if $c_{j+1}(u_i) \geq 2$, then for every vertex in $V^{(i-1)}$ that corresponds to a relevant b', there is an edge to a vertex in $V^{(i)}$ that corresponds to $b' + 2^{j+1} A_i$ (if it exists), with a cost of $2^{j+1} c_i$.

Finally, we compute the longest path from s to each vertex in $V^{(n)}$, and we store these as the values of the solutions to all the relevant right-hand sides for $j+1$.

For the running time, observe that by Claim 20, we have $|V| \leq O(mn\Delta)^m$. Hence, the graph has $n^{m+1} \cdot O(m\Delta)^m$ vertices and edges. Thus, the longest path problem can be solved in time $n^{m+1} \cdot O(m\Delta)^m$.

For correctness, consider a path in the graph from vertex $v_{b_1} \in V^{(0)}$ to vertex $v_{b_2} \in V^{(n)}$ (corresponding to vectors b_1 and b_2 respectively). The edges of this path define a vector $z^{(j+1)}$ such that $0 \leq z^{(j+1)} \leq c_{j+1}(u)$. Moreover, by construction, it holds that $2^j A z^{(j+1)} + b_1 = b_2$. Finally, the weight of this path corresponds to the value $2^j c^\mathsf{T} z^{(j+1)}$. ◀

Quantum Communication Complexity of Classical Auctions

Aviad Rubinstein

Department of Computer Science, Stanford University, CA, USA

Abstract

We study the fundamental, classical mechanism design problem of single-buyer multi-item Bayesian revenue-maximizing auctions under the lens of communication complexity between the buyer and the seller. Specifically, we ask whether using quantum communication can be more efficient than classical communication. We have two sets of results, revealing a surprisingly rich landscape – which looks quite different from both quantum communication in non-strategic parties, and classical communication in mechanism design.

We first study the expected communication complexity of approximately optimal auctions. We give quantum auction protocols for buyers with unit-demand or combinatorial valuations that obtain an arbitrarily good approximation of the optimal revenue while running in exponentially more efficient communication compared to classical approximately optimal auctions. However, these auctions come with the caveat that they may require the seller to charge exponentially large payments from a deviating buyer. We show that this caveat is necessary - we give an exponential lower bound on the product of the expected quantum communication and the maximum payment.

We then study the worst-case communication complexity of exactly optimal auctions in an extremely simple setting: additive buyer's valuations over two items. We show the following separations:

- There exists a prior where the optimal classical auction protocol requires infinitely many bits, but a one-way message of 1 qubit and 2 classical bits suffices.
- There exists a prior where no finite one-way quantum auction protocol can obtain the optimal revenue. However, there is a barely-interactive revenue-optimal quantum auction protocol with the following simple structure: the seller prepares a pair of qubits in the EPR state, sends one of them to the buyer, and then the buyer sends 1 qubit and 2 classical bits.
- There exists a prior where no multi-round quantum auction protocol with a finite bound on communication complexity can obtain the optimal revenue.

1 Introduction

We study the quantum communication complexity of classical problems with strategic constraints. The communication problems we study differ from traditional ("cooperative") problems in communication complexity like Set Disjointness due to Incentive Compatibility

(IC) constraints. Informally speaking, one can think of the goal of a traditional communication problem is to design a protocol for both parties that optimizes some common objective function.

For instance, in Set Disjointness, the common goal is to maximize the probability of outputing the correct answer. By contrast, in strategic communication, each party optimizes a different objective; we seek protocols that are communication-efficient, and at the same time don't expect strategic parties to take actions that are mis-aligned with their objectives.

Specifically, we study the quantum communication complexity of a fundamental setting in mechanism design: a monopolistic, revenue-maximizing seller with Bayesian prior auctioning n items to a single buyer; this setting has proved very attractive to researchers in theoretical computer science (e.g. [6, 18, 5, 40, 44, 70] and references therein).

It is known that even with seemingly benign Bayesian priors, revenue-optimality requires complex auctions, e.g. ones that allow the buyer to choose among lotteries [73, 55, 16, 62, 48]. This realization has sparked a fruitful line of work on the simplicity-vs-complexity of (approximately) optimal auctions. Understanding the tradeoffs of simplicity vs. complexity requires formal definitions of complexity.

Perhaps the most well-studied notion of complexity for this problem is the number of distinct lotteries offered to the buyer ("menu-size complexity" [47]). The measure exactly characterizes the *deterministic communication* complexity of the interaction between a buyer and seller who both know the rules of the auction[1] [5].

We study the communication complexity of auctions subject to an Incentive Compatibility (IC) constraint: it is crucial that a strategic buyer must not be able to gain from deviating from the protocol. (As is standard in the literature, we assume that the seller is non-strategic and follows the protocol faithfully. See Section 4 for formal definition, and e.g. [34, 29, 70, 69] for further discussion.) Under this IC constraint, [70] show that it is possible to obtain dramatic savings in communication by considering (classical) *randomized communication*. The main question we ask in this work is whether *quantum communication* can be even more efficient than classical randomized communication complexity for this problem:

Can quantum auction protocols achieve super-classical performance?

Specifically, [70] show that even though randomized auction protocols can be much more efficient than deterministic ones, they still have limitations:

- **Worst-case vs expected CC barrier:** [70] improve the communication complexity in expectation (over the randomness of the protocol), but the worst-case communication complexity of randomized protocols is still characterized by the menu-size complexity.
- **Combinatorial valuations barrier:** For buyers with combinatorial valuations over the items, [70] prove exponential lower bounds even for the expected communication of randomized auction protocols. These lower bounds hold even for approximately optimal mechanisms, and even against restricted classes of valuations (e.g. monotone submodular valuations).

In this paper, we investigate to what extent quantum communication can break these classical barriers.

[1] Specifically, deterministic-CC $= \log\big(\lceil$menu-size complexity$\rceil\big)$.

1.1 Our Contributions

We formalize a model of *quantum auction protocols* (Definition 7) that extends the randomized auction protocols of [70] by allowing the buyer and seller to send, receive, operate on, and measure qubits. We then provide two sets of results, centered around the two barriers for classical auction protocols mentioned above.

1.1.1 (Un)expected Quantum CC with Combinatorial Valuations

Our first result is an exponential quantum speed-up for auction protocols. It is stated in a general form for a mechanism that chooses an allocation among B possible allocations. Specifically, it gives a near-equivalent IC quantum auction protocol that uses only $O(\log(B))$ qubits – matching the cost of naively encoding the allocation (without strategic considerations).

▶ **Theorem 1** (Efficient in-expectation quantum auction protocols). *Let $\mathcal{D}$ be a prior over buyer's combinatorial valuations over n items; assume all valuations are in the range*[2] *$[0, U]$. Let $\mathcal{M}$ be any mechanism that can only possibly allocate one of B subsets of the items. Finally, let $\delta > 0$ be any parameter (δ may be a function of n or B). Then there is an IC quantum auction protocol that guarantees a $(1-\delta)$-fraction of $\mathcal{M}$'s expected revenue using $O(\log(B))$ qubits in expectation.*

As a corollary, we only need $O(\log(n))$ qubits for unit-demand, or $O(n)$ qubits for arbitrary combinatorial valuations. On the contrary, [70] shows that any randomized classical communication protocol requires at least $\Omega(n)$ bits for unit-demand, and $\Omega(2^n)$ bits for combinatorial valuations. To the best of our knowledge, this is the first exponential separation of quantum and classical communication in algorithmic game theory.

The positive result in Theorem 1 has a caveat: the protocol may require large payments. Specifically, we need the ability to inflict a large penalty on buyers who deviate from the intended quantum strategy. However, the probability of catching deviating buyers may be exponentially small, so we use exponentially large payments. Even though buyers who follow the protocol can never be penalized, to be accountable for a potentially large payment the buyer may need significant collateral to participate in the auction. Our second result shows that unfortunately without exponentially large payments all the lower bounds from [70] extend to quantum communication.

▶ **Theorem 2** (Efficient protocols require large payments - short version). *Let n be the number of items, P be an upper bound on the payments in the quantum auction protocol (when the valuations are normalized to $[0, 1]$), and $\hat{K}$ an upper bound on the expected communication complexity. Then for a buyer with combinatorial (XOS) valuations, any quantum auction protocol that obtains $\Omega(1)$-approximation to the optimal revenue must satisfy $\hat{K}P = 2^{\Omega(n)}$. See Theorem 8 for full statement and additional results.*

Interestingly, we are not aware of any classical analogs of such tradeoffs between maximum payment and communication complexity. In particular, the exponential lower bounds against classical auction protocols in [70] hold even with arbitrarily large payments.

[2] Our protocol assumes that we're given some finite upper bound U on valuations, but the communication complexity does not depend on U.

1.1.2 Worst-Case Quantum CC with Two Items

Our second set of results focuses on the particularly simple case of a buyer with additive valuations over only two items, and the Bayesian prior for these values is independent. In this case, classical protocols of [70] already achieve $O(1)$ expected communication, but their worst-case communication is infinite. Note that this is for exactly optimal mechanisms – for approximately optimal mechanisms, worst-case can be reduced to expected communication.

We show that on one hand, a *single qubit* can sometimes replace an *infinite* stream of classical bits.

▶ **Theorem 3** (Separating one-way quantum vs classical)**.** *For the problem of auctioning two items to a single buyer, there is a Bayesian prior over independent item values, such that there is a revenue-optimal and IC one-way quantum auction protocol where the buyer sends 1 qubit and 2 classical bits; yet no finite classical auction protocol can achieve the optimal revenue.*

Furthermore, interactive quantum protocols are even more powerful:

▶ **Theorem 4** (Separating interactive quantum vs one-way quantum)**.** *For the problem of auctioning two items to a single buyer, there is a Bayesian prior over independent item values, such that there is an IC revenue-optimal quantum auction protocol where the seller sends 1 qubit to the buyer, who replies with 1 qubit and 2 classical bits; yet no finite classical or one-way quantum auction protocol can achieve the optimal revenue.*

However, in the worst case, even fully interactive quantum auction protocols cannot achieve optimal revenue in finite worst-case communication.

▶ **Theorem 5** (Limitations of finite interactive quantum auction protocols)**.** *For the problem of auctioning two items to a single buyer, there is a Bayesian prior over independent item values, such that there is a revenue-optimal classical auction protocol that requires a constant number of bits* in exepctation*; yet no worst-case finite IC quantum auction protocol can achieve the optimal revenue.*

1.2 Key Takeaway: Thinking About Quantum and Incentives Together

Communication complexity in game-theoretic setting and quantum communication complexity have each been studied extensively over the past few decades, but in separate lines of work, and to a large extent in disjoint communities. The key takeaway from our work is that we can unlock significant advantages by thinking of both together - advantages that are not possible by composing disjoint results for classical-strategic communication and quantum-cooperative communication.

In particular, it is important to note that our quantum speed-ups are not achievable by a generic quantum speed-up on communication (for example, Holevo's theorem states that an n-qubit quantum state, even with infinite precision, can only carry up to n classical bits accessible information [49]). In fact, they cannot be derived from a quantum speed-up on any non-strategic communication problem.

We further note that our infinite separations require quantum operations with infinite precision. While this is clearly not practical, it is the standard textbook model of quantum computing, and, to the best of our knowledge, no previous work on quantum-cooperative communication complexity exhibits infinite separations[3].

[3] Compared with quantum advantages in interactive proofs, e.g. the celebrated $\mathsf{MIP}^* = \mathsf{RE}$ [51], it is

Surprises for the quantum side:

- **Exponential quantum speedup on a natural problem (Theorem 1).** For combinatorial and unit-demand auctions, we find quantum protocols that are exponentially more efficient than any classical protocol. Existing exponential quantum-classical separations (in cooperative communication complexity) are for problems like Hidden Matching Problem [10] that were designed for the purpose of exhibiting a separation. In contrast, the strategic communication problem we study here was considered before in classical algorithmic game theory [5, 70].
- **Infinite 1-way vs. 1-way + entanglement separation (Theorem 4).** Specifically, we show that a one-way protocol with pre-shared entanglement (an EPR pair) is infinitely more efficient than any one-way protocol with no shared entanglement. This unique separation does not exist in the cooperative quantum communication environment as the honest sender can always prepare the EPR pair and send one half through the channel.
- **Infinite quantum-classical separation (Theorem 3).** We construct an example where we can implement the optimal auction with a one-way quantum communication protocol with 3 qubits in the worst case. However, no worst-case finite classical protocol can implement it.

Figure 1 Summary of most surprising aspects of our results from quantum perspective.

We highlight some of the ways in which our results are distinct from previous work in either line of work in Figure 1 and Figure 2.

Core conceptual idea: Efficient, samplable and verifiable distribution encodings

At a high level, the communication protocol of Bayesian auction boils down to the following task: The seller has a set $\mathcal{S}$ consisting of valid distributions of auction outcomes (allocation and payment). The buyer then selects a distribution D from $\mathcal{S}$ that maximizes his utility. Subsequently, the seller draws a sample from the chosen distribution D and outputs it as the outcome. In general, the complexity of describing a distribution is exponentially higher than specifying an outcome. It is worth noting that this task is completely trivial in a fully cooperative environment as the buyer can simply draw the outcome himself and send only this outcome to the seller. A natural quantum solution to this problem is that the buyer can efficiently encode D in state $\sum_x \sqrt{D_x}\,|x\rangle$. To draw an element from the distribution, the seller only needs to measure this quantum state in the computational basis. However, this simple approach has a caveat – in general it is information theoretically impossible for the seller to verify that this quantum state indeed encodes a valid distribution in set $\mathcal{S}$. To overcome this issue, our paper proposes two solutions. The first one is a general spot-check method – with a small probability, after receiving the quantum state, the seller asks the buyer to send the whole classical description of the distribution; the seller verifies that the classical description is valid and the quantum state is close enough to this classical description. By imposing an exponentially large penalty, we ensure that the buyer is always

worth noting that the latter is only an "unbounded" separation, i.e. that separation still needs the complexity of the MIP^* provers to go to infinity. In contrast, we show separation of 3 qubits vs infinitely many classical bits.

Surprises for the AGT side:

- **Infinite 1-way vs. interactive separation (Theorem 4).** We show an example where an interactive two-way quantum protocol is infinitely better than any one-way quantum protocol. This unique separation does not exist in the classical setting. Since with a trusted party (the seller in our setting), any classical protocol can be "flattened" to a one-way protocol incurring an exponential overhead in the worst-case communication complexity, yet this overhead remains finite.
- **Exponential lower bound on CC $\times$ payment (Theorem 8).** We prove that our exponentially more efficient quantum protocol in Theorem 1 necessitates an exponentially large payment, by establishing an exponential lower bound on the product of payment and communication complexity. This characteristic is distinctive to the quantum setting, as the exponential lower bounds for classical protocols [70] apply even with arbitrarily large payments.

Figure 2 Summary of most surprising aspects of our results from AGT perspective.

incentivized to prepare a quantum state corresponding to a valid distribution while keeping the *expected* communication complexity low. The other solution works for the worst case communication complexity under some specific assumptions on the set of valid distribution of auction outcomes. These assumptions are satisfied for example by the canonical classically-hard example of [24], but not in general (see Theorem 5). By carefully tailoring the quantum protocol to the desired auction, we can ensure that the space of distributions that the buyer can encode coincides with the desired valid space.

1.3 Additional Related Works

Our work extends a rich tradition of studying mechanism design and game theory under the lens of communication complexity – including auctions [61, 12, 4, 31, 28, 26, 27, 14, 2, 15, 33, 3, 5, 76], and also stable matching [41], voting rules [22, 64, 17, 71], fair division [13, 63], computation of equilibria [21, 46, 68, 43, 35, 7, 8, 36, 9], and interdomain routing [53]. In particular, the communication complexity of IC implementing a mechanism vs that of (non-IC) computing the outcome was the focus of [34, 29, 69, 30].

We show exponential separations (and for worst-case complexity – infinite separations) between quantum and classical communication complexity of auctions. Earlier works on separating the two measures (in non-strategic settings) include general boolean functions (constructed for obtaining separations) [65, 10, 37, 38, 66], sampling [1, 57], and very recently also linear regression [58, 72].

Our work is also related to works on quantum game theory – including nonlocal games [19, 20], quantization of classical games [32, 56], quantum equilibria [25, 75], and quantum interactive games [45]. In particular, quantum interactive strategies are also studied in quantum interactive proofs [74, 11, 50, 59, 51].

1.4 Organization

We begin with a review of the quantum communication model and mechanism design in Section 2 and 3, and then introduce our main model of quantum auction protocols in Section 4. Part I brings our results for expected communication: Our quantum auction protocol for

combinatorial valuations in Section 5, and our lower bound against quantum auction protocols with bounded maximum payment in Section 6. Part II focuses on worst-case communication: we begin with preliminaries of optimal 2-item auctions in Section 7; in Section 9 we construct an example separating one-way quantum auction protocols from finite classical; in Sections 8 and 10 we separate interactive quantum auction protocols from one-way; and finally in Section 11 we show that in general no finite quantum auction protocol can guarantee optimal revenue.

2 Preliminaries I: Quantum

Bra-ket notation

In this paper, we may occasionally use bra-ket notation. Specifically, within an N-dimensional complex vector space, we represent each unit-length column vector as a ket, denoted as $|\phi\rangle$. Correspondingly, for every unit-length vector $|\phi\rangle$, a bra $\langle\phi|$ is defined as an N-dimensional row vector that is the conjugate transpose of $|\phi\rangle$.

Moreover, we use the notation $|a\rangle$ for $a \in \{1, \ldots, N\}$ to indicate the column vector with a value of 1 at the a-th coordinate and 0 in all other positions. We refer to $|1\rangle, \ldots, |N\rangle$ as the computational basis.

We employ the notation $|\phi\rangle$ to represent a pure quantum state associated with the density matrix $|\phi\rangle\langle\phi|$. Inversely, a quantum state described by the density matrix ρ is considered a pure state if there exists a $|\phi\rangle \in \mathbb{C}^N$ such that $\rho = |\phi\rangle\langle\phi|$.

Closeness of states

Given two positive semidefinite matrices $\rho, \sigma \in \mathbb{C}^{N\times N}$, the trace distance between them is defined as

$$T(\rho,\sigma) = \max_F \frac{1}{2}\sum_\ell \left|\mathrm{Tr}(F_\ell\rho) - \mathrm{Tr}(F_\ell\sigma)\right|,$$

where $\{F_\ell\}$ is maximized over all possible POVMs[4].

In particular, when ρ and σ are density matrices, $T(\rho,\sigma)$ is equal to the total variation distance between classical distributions obtained by measuring two states maximized over all possible measurements.

Below is an important property of the trace distance:

$$T(\rho,\sigma) \le \sqrt{1-\mathrm{Tr}(\rho\sigma)}. \tag{1}$$

2.1 (Non-Strategic) Quantum Communicatiom Protocols

We give an overview of multi-party quantum communication protocols. For readers who are familiar with quantum communication, this model is equivalent to the ones used in the literature (e.g. [77]). A formal description of two-party strategic communication model is given in Section 4. A multi-party quantum communication protocol is defined over a system of qubits, that are initially partitioned between the parties. The protocol proceeds in rounds; in each round, one party can locally manipulate or measure her qubits, and then send a

[4] a positive operator-valued measure (POVM) is a finite set of positive semidefinite Hermitian matrices that sum to identity.

subset of them to other parties. The *communication complexity* of a protocol is the total number of qubits sent by parties across all rounds. We now provide more detail on each of those components.

Quantum systems

Let m be an upper bound on the number of qubits in the system.[5] The state $\rho^{(r)}$ of the system at the beginning of round r can be mathematically represented as a *density matrix*[6] $\rho^{(r)} \in (\mathbb{C}^{2\times 2})^{\otimes m}$. Note that $(\mathbb{C}^{2\times 2})^{\otimes m} = \mathbb{C}^{2^m \times 2^m}$, i.e. it is just a 2^m-by-2^m complex matrix; however, the former tensor product notation will be useful when we consider the qubits held by each party.

Initial state of the system

Initially, each party holds $m_i^{(0)}$ qubits ($\sum_i m_i^{(0)} = m$). Because we're concerned with quantum protocols for mechanisms with classical inputs, we assume that initially all the qubits are not entangled (e.g. the initial state is $\rho^{(0)} = (|0\rangle\langle 0|)^{\otimes m}$). In particular, it is important that qubits held by different parties are initially non-entangled.

Local histories

A party's local history consists of the number of qubits that she sent and received in each round so far in the protocol, as well as the outcomes of measurements that she locally performed on her qubits (see more on measurements below).

Local manipulations: unitary operators and measurements

In each round, before sending any qubits, the active party can locally apply quantum operations and measurements to the qubits that she currently holds. If $m_i^{(r)}$ is the number of qubits held by party i at the beginning of round r, we can represent the state $\rho^{(r)}$ as a density matrix in $(\mathbb{C}^{2\times 2})^{\otimes m_i^{(r)}} \otimes (\mathbb{C}^{2\times 2})^{\otimes m - m_i^{(r)}}$. Party i's operations can transform the state into

$$\rho^{(r+1/2)} = (U \otimes I_{2^{m-m_i^{(r)}}})^\dagger \rho^{(r)} (U \otimes I_{2^{m-m_i^{(r)}}}),$$

where $I_{2^{m-m_i^{(r)}}}$ is the identity operator on qubits held by other parties, U is a unitary operator of i's choice, acting only on i's qubits, and $\rho^{(r+1/2)}$ is the new state of the quantum system after applying the operator (but before the measurement).

Similarly, party i can measure her qubits. A POVM is defined by L matrices $\{A_\ell\}_{\ell=1}^L \in \mathbb{C}^{2^{m_i^{(r)}} \times 2^{m_i^{(r)}}}$ such that $\sum_\ell A_\ell^\dagger A_\ell = I_{2^{m_i^{(r)}}}$. After applying the measurement, with probability

$$\mathrm{Tr}\left(\left(A_\ell \otimes I_{2^{m-m_i^{(r)}}}\right)^\dagger \left(A_\ell \otimes I_{2^{m-m_i^{(r)}}}\right) \rho^{(r+1/2)}\right),$$

[5] We assume for simplicity of notation that there is a finite upper bound on the total number of qubits. Our results can be generalized e.g. to a setting where each party can add qubits in each round of the protocol, and a setting where local operators are defined by general quantum channels.

[6] A matrix is a *density matrix* if it is a positive semidefinite, trace 1 Hermitian matrix. *Hermitian* means that $A^\dagger = A$, where $A^\dagger$ is the conjugate transpose of A.

the state of the system is updated to

$$\rho^{(r+1)} = \frac{\left(A_\ell \otimes I_{2^{m-m_i^{(r)}}}\right)^\dagger \rho^{(r+1/2)} \left(A_\ell \otimes I_{2^{m-m_i^{(r)}}}\right)}{\mathrm{Tr}\left(\left(A_\ell \otimes I_{2^{m-m_i^{(r)}}}\right)^\dagger \left(A_\ell \otimes I_{2^{m-m_i^{(r)}}}\right) \rho^{(r+1/2)}\right)}.$$

It is wlog for each party to perform the measurement after all the unitary operators in a given round.

Sending and receiving qubits

After applying local operations, the active party sends exactly one of the qubits she holds to another party. Sending qubits does not change the state of the quantum system, but it changes which party can operate on the sent qubits.

Note that it is wlog to send e.g. the last qubit, because locally qubits can be swapped by unitary operators.

Termination of the protocol

The protocol may terminate after a pre-determined number of rounds, or by any party as a function of her private inputs and/or local history.

Complexity of the protocol

The main metric of complexity of the protocol that we use is the total number of qubits sent by different parties. We give bounds for the complexity of both in-expectation (over the outcome of quantum measurements) and worst-case communication. In addition to the total number of qubits, we will show that: (i) In some cases it is possible to simplify protocols by replacing some qubits with classical bits, and (ii) we also consider the effect of restricting the number of rounds of the protocol.

2.1.1 Conventions

We make the following conventions to simplify both our notation and analysis:

- There is no seperate channel for classical information. For convenience, when we say a message is intended to be classical, it means the receiver immediately measures the qubit in the computational basis $(|0\rangle, |1\rangle)$.
- For convenience, in a 2-party protocol, when we mention that the a player sends m consecutive qubits to the other, it technically means that this player sends these qubit over m rounds and the other player responds with a dummy qubit in each round.

2.1.2 Choi-Jamiołkowski representation of protocols and strategies

Consider a quantum protocol with a fixed number of rounds R and a fixed number of qubits sent in each round. A *strategy* s_i of a party i who is active in R_i rounds is a sequence of R_i mappings applied to the qubits that it holds at each round, together with a measurement of its qubits at the end of the protocol. A *co-strategy* s_{-i} is a sequence of mappings by other parties at their rounds (and finally a measurement). Notice that the tuple of protocol, strategy, and co-strategy, fully determine the distribution of measurement realizations at the end of the protocol.

Suppose that party i's measurements have L_i possible outcomes and the other parties have L_{-i} possible outcomes. [45] show that any strategy (resp, co-strategy) can be represented as L_i (resp. L_{-i}) matrices of dimension that depend only on the communication complexity, and not on the additional (possibly very large) quantum memory of the parties. For ease of presentation, we state only the simplest form of the theorem that we need; in particular, we avoid the notation necessary for actually defining the Choi-Jamiołkowski representation.

▶ **Theorem 6** (Choi-Jamiołkowski representation of strategies in interactive quantum protocols [45])**.** *Consider any R-round quantum protocol with communication complexity K, a party i in the protocol, and strategy s_i for i and co-strategy s_{-i} for the rest of the parties. Let $\Phi^{(s_i)}, \Psi^{(s_{-i})}$ denote the respective Choi-Jamiołkowski representation. Then the probability of measuring outcome (a_i, a_{-i}) is given by*

$$2^K \cdot \mathrm{Tr}\left(\Phi^{(s_i)}_{a_i} \Psi^{(s_{-i})}_{a_{-i}}\right).$$

Moreover, each of $\Phi^{(s_i)}_{a_i}$, $\Psi^{(s_{-i})}_{a_{-i}}$ is a 2^{2K} by 2^{2K} positive semidefinite Hermitian matrix, and $\sum_{a_i=1}^{L_i} \mathrm{Tr}\left(\Phi^{(s_i)}_{a_i}\right) = \sum_{a_{-i}=1}^{L_{-i}} \mathrm{Tr}\left(\Phi^{(s_{-i})}_{a_{-i}}\right) = 1$[7]*.*

3 Preliminaries II: Mechanism Design

We consider the mechanism (auction) design for selling n indivisible items to a single risk-neutral buyer. A buyer has a *type* (valuation function) $v : 2^{[n]} \to \mathbb{R}_{\geq 0}$ specifying his value for each bundle (subset). We use X to denote the type set, which contains all possible types of the buyer. For our purposes, it is important to define the two simplest and most widely studied class valuations:

- **Additive** If there exists a value of each item $v_1, \ldots, v_n$ such that $v(S) = \sum_{i \in S} v_i$.
- **Unit-demand** If there exists a value of each item $v_1, \ldots, v_n$ such that $v(S) = \max_{i \in S} v_i$.

Some of our results also hold for more general classes of valuations[8], which satisfy the following hierarchy of increasing generality:

$$\text{additive, unit-demand} \subset \text{gross-substitutes} \subset \text{submodular} \subset \text{XOS} \subset \text{subadditive} \subset \text{combinatorial}.$$

In addition to satisfying these structures, valuations are usually assumed to be monotone; our results hold for both monotone and non-monotone valuations.

Without loss of generality, we consider direct mechanisms. The buyer reports a type $v' \in X$ to the mechanism, and the mechanism then allocates a (randomized) bundle to the buyer and charges the buyer a price. $\mathcal{M}$ consists of two functions.

- An allocation function $\mathcal{A} : X \to [0,1]^{2^{[n]}}$ gives the probability of allocating each bundle to the buyer declares to have each possible type.
- A payment function $\mathcal{Q} : X \to \mathbb{R}_{\geq 0}$ gives the price the buyer needs to pay for each declared type of the buyer.

Let D be a distribution over bundles. With a slight abuse of notation, we denote by $v(D) = \mathbb{E}_{S \sim D} v(S)$ the expected value of the buyer with type v.

---

[7] In the original definition of [45], Choi-Jamiołkowski representations $\Phi^{(s_i)}, \Psi^{(s_{-i})}$ are not normalized. Here, we normalize all Choi-Jamiołkowski representations (now they are all density matrices), that is why we have an additional 2^K factor in the probability of outcome compared to the original paper.

[8] See e.g. [52] for definitions; they are not necessary for understanding our paper.

We say a mechanism $\mathcal{M} = (\mathcal{A}, \mathcal{Q})$ is *incentive compatible* (IC) if

$v(\mathcal{A}(v)) - \mathcal{Q}(v) \geq v(\mathcal{A}(v')) - \mathcal{Q}(v') \quad \forall v, v' \in X.$

We say a mechanism $\mathcal{M} = (\mathcal{A}, \mathcal{Q})$ is ε-*incentive compatible* (ε-IC) if

$v(\mathcal{A}(v)) - \mathcal{Q}(v) \geq v(\mathcal{A}(v')) - \mathcal{Q}(v') - \varepsilon \quad \forall v, v' \in X.$

We say a mechanism $\mathcal{M} = (\mathcal{A}, \mathcal{Q})$ is *individually rational* (IR) if

$v(\mathcal{A}(v)) - \mathcal{Q}(v) \geq 0 \quad \forall v \in X.$

We say a mechanism $\mathcal{M} = (\mathcal{A}, \mathcal{Q})$ is ε-*individually rational* (ε-IR) if

$v(\mathcal{A}(v)) - \mathcal{Q}(v) \geq -\varepsilon \quad \forall v \in X.$

For a mechanism $\mathcal{M} = (\mathcal{A}, \mathcal{Q})$, we denote by $u : X \to \mathbb{R}$ the expected utility of the buyer when he truthfully reports the valuation function. It follows from the definition that $u(v) = v(\mathcal{A}(v)) - \mathcal{Q}(v)$.

Revenue Maximization

In this paper, we primarily focus on the revenue-optimal Bayesian mechanism design. In this setting, the buyer knows his type v for sure. However, the seller only knows the probability distribution over X. Let $f : X \to \mathbb{R}$ be the probability density function of this distribution.

The goal of revenue-optimal Bayesian mechanism design is to find an IC and IR mechanism $\mathcal{M} = (\mathcal{A}, \mathcal{Q})$ that maximizes the revenue of the seller:

$$Rev = \int_X \mathcal{Q}(v) f(v) \mathrm{d}v.$$

4 Quantum Communication Model with a Strategic Player

We now introduce the main strategic communication model of this work, which formally defines the elements of a two-player quantum communication protocol subject to strategic manipulation. In essence, when the length of the protocol is fixed, this model is equivalent to the one used in the literature of quantum games and quantum interactive proofs (see e.g. [45]). The communication is between one strategic player (we call it the buyer), and a truthful player (we call it the seller). In this setup, the seller initially possesses n qubits, while the buyer has m qubits, with S representing the finite set of possible communication outcomes. Initially, the joint state is $|0\rangle^{\otimes(n+m)}$. The communication proceeds in rounds (or steps). Since we will cover protocols with infinite worst-case communication complexity (but bounded expected communication), we do not specify the total number of rounds in our model. In each round, one of the player performs a local operation on qubits in their hand and then sends *one* qubit to the other player. Or you can alternatively think there is a one-qubit register shared by both players. We assume the seller takes the first round and then they alternate in the following rounds.

The seller's operations

Without loss of generality, we assume the seller only performs general measurements in her rounds[9]. For round i, let $\{A_x^i\}_{x \in S \cup \{\perp\}}$, such that $\sum_{x \in S \cup \{\perp\}} (A_x^i)^\dagger A_x^i = I_{2^n}$, be the seller's

[9] If the seller simply want to apply a unitary U, she can do it by letting $A_\perp^i = U$, and $A_x^i = 0$ for any $x \in S$.

measurements. Let $h_i \in S \cup \{\perp\}$ be the measurement outcome of round i. For each round i, if $h_i = \perp$ then communication continues, otherwise the seller terminates the communication and outputs h_i as the outcome[10].

The buyer's operations

In our model, only seller can terminate the protocol and output an outcome. Therefore, by the principle of deferred measurement (see e.g. Chapter 4.4 of [60]), we wlog assume the buyer makes no measurement[11], and his only local operation in round i is a unitary U_i with dimension 2^{m+1}, for $i = 2, 4, \ldots$.

The seller's strategy

A seller's strategy includes the following elements:

- Set of communication outcomes: S.
- The size of initial local quantum memory: n.
- General measurements: $\{A_x^i\}_{x \in S \cup \{\perp\}}$, for $i = 1, 3, 5, \ldots$.

The buyer's strategy

A buyer's strategy s^{buy} includes the following elements:

- The size of initial local quantum memory: m.
- Unitary operators: U_i, for $i = 2, 4, 6, \ldots$.

Quantum auction protocols

Our objective is to implement an auction using the strategic quantum communication model previously outlined. Our quantum auction protocols are a generalization of classical auction protocols defined in [70]. The classical auction protocols are also a special case of Bayesian incentive compatibility (BIC)-incentivizable binary dynamic mechanism (BDM) defined in [34]. For simplicity, here we only define the quantum analog for auctions, but exploring the quantum communication complexity of mechanisms more broadly is an interesting direction for future work.

▶ **Definition 7** (Quantum auction protocols). *A* quantum auction protocol $\mathcal{P}$ *that sells* n *items to a single buyer with type space* X *consists of:*

- *A seller's strategy* $s^{\mathcal{P}}_{seller}$ *such that the outcomes in the outcome set* S *are in the form* (B, p)*, where* $B \subseteq [n]$ *is a subset of items and* $p \in \mathbb{R}_{\geq 0}$ *is the price.*
- *A suggested strategy function* $s^{\mathcal{P}}_*$ *that maps each valuation in the type space* X *to a buyer's strategy.*

[10] By the principle of deferred measurement (see e.g. Chapter 4.4 of [60]), any non-terminating measurements outcomes can be removed by adding more qubits to the system. Therefore, it is wlog to only consider measurement with at most one non-terminiating outcome($\perp$) each round.

[11] By the principle of deferred measurement, the buyer can always obtain the same outcome distribution by adding more qubits to his local memory and removing measurements. Since the buyer is allowed to choose an arbitrarily large memory size m (we will discuss it later), it is wlog not to consider buyer's measurement.

Given a seller's strategy s_{seller}, and a buyer's strategy s_{buyer} let $D(s_{\text{seller}}, s_{\text{buyer}})$ be the outcome distribution of the communication[12]. Let $\mathcal{A}(s_{\text{seller}}, s_{\text{buyer}})$ be the marginal distribution of the first component of $D(s_{\text{seller}}, s_{\text{buyer}})$. So, $\mathcal{A}(s_{\text{seller}}, s_{\text{buyer}})$ is a distribution over subsets of $[n]$. Let $\mathcal{Q}(s_{\text{seller}}, s_{\text{buyer}})$ be the expected value of the second component (price) of $D(s_{\text{seller}}, s_{\text{buyer}})$.

With definitions above, we say a quantum auction protocol $\mathcal{P}$ *implements* the mechanism

$$\mathcal{M}^{\mathcal{P}} = \left(\mathcal{A}(s^{\mathcal{P}}_{\text{seller}}, s^{\mathcal{P}}_{*}(\cdot)), \mathcal{Q}((s^{\mathcal{P}}_{\text{seller}}, s^{\mathcal{P}}_{*}(\cdot)))\right).$$

Further, we say a quantum auction protocol $\mathcal{P}$ is ε-IC if for any type $v \in X$, and any buyer's strategy $\hat{s}$, the following holds,

$$v\left(\mathcal{A}(s^{\mathcal{P}}_{\text{seller}}, s^{\mathcal{P}}_{*}(v))\right) - \mathcal{Q}(s^{\mathcal{P}}_{\text{seller}}, s^{\mathcal{P}}_{*}(v)) \geq v\left(\mathcal{A}(s^{\mathcal{P}}_{\text{seller}}, \hat{s})\right) - \mathcal{Q}(s^{\mathcal{P}}_{\text{seller}}, \hat{s}) - \varepsilon.$$

By definition, the mechanism implemented by an ε-IC quantum auction protocol is an ε-IC mechanism.

We say quantum auction protocol $\mathcal{P}$ is ε-IR if for any type $v \in X$ the following holds,

$$v\left(\mathcal{A}(s^{\mathcal{P}}_{\text{seller}}, s^{\mathcal{P}}_{*}(v))\right) - \mathcal{Q}(s^{\mathcal{P}}_{\text{seller}}, s^{\mathcal{P}}_{*}(v)) \geq -\varepsilon.$$

By definition, the mechanism implemented by an ε-IR quantum auction protocol is an ε-IR mechanism.

Exactly IC and IR quantum protocols are defined similarly.

The main goal of our paper is to find an (ε-)IC and (ε-)IR quantum auction protocol that implements the revenue-optimal mechanism.

Part I
Expected communication

5 ε-IC Quantum Protocols for General Valuations

Consider selling n items to a single buyer with combinatorial valuations drawn from prior $\mathcal{D}$. We will show that for any direct IC mechanism $\mathcal{M}$ that only ever allocates B different deterministic bundles, there is an ε-IC quantum protocol with the same expected payment for every type using $O(\log B)$ qubits of communication in expectation. Note that our protocol holds for arbitrarily small ε, and the constant factor in $O(\log B)$ does not depend on ε.

Moreover, by employing a standard ε-IC-to-IC reduction that discounts all the payments by $(1-\sqrt{\varepsilon})$-factor, we can transform an ε-IC quantum protocol into an exactly IC quantum protocol that has the same expected communication complexity, while incurring only a negligible loss in revenue (see e.g. [42, Theorem 7]).

▶ **Theorem** (Theorem 1 restated). *Let $\mathcal{D}$ be a prior over buyer's combinatorial valuations over n; assume all valuations are in the range $[0, U]$. Let $\mathcal{M}$ be any mechanism that can only possibly allocate one of B subsets of the items. Finally, let $\delta > 0$ be any parameter (δ may be a function of n or B). Then there is an IC auction quantum protocol that guarantees a $(1-\delta)$-fraction of $\mathcal{M}$'s expected revenue using $O(\log(B))$ qubits in expectation.*

[12] Throughout the paper we only consider seller's strategies which guarantee termination within finite steps with probability 1 for any buyer's strategy.

We first present a modification of an $O(B\log(B))$-bits classical protocol given in [70]. Then, we augment it with a single quantum message from the buyer to the seller that gives an exponential improvement in the expected communication.

5.1 Warm-up: An Inefficient Classical Protocol [70]

First note that if the maximum value of the buyer over any bundle is at most U, any IC and IR direct mechanism $\mathcal{M}$ that only ever allocates B different bundles can be converted into an equivalent direct mechanism $\mathcal{M}'$ that only ever allocates B different bundles and always charges either 0 or U. This implies the new mechanism $\mathcal{M}'$ has $2B$ different deterministic outcomes (each deterministic outcome is a bundle-payment pair). Suppose B different bundles allocated in $\mathcal{M}$ are $\pi_1, \ldots, \pi_B$, then $\mathcal{M}'$ creates 2 outcomes $(\pi_j, 0), (\pi_j, U)$ for each bundle in $\mathcal{M}$. For each type, v, $\mathcal{M}$ has a distribution over B bundles and an expected payment P (by IR, $P \leq U$). Then $\mathcal{M}'$ defines a distribution over $2B$ outcomes for each type v: suppose in $\mathcal{M}$ the proability of receiving π_j is p_j, $\mathcal{M}'$ gives outcome (π_j, U) with probability $p_j \cdot \frac{P}{U}$ and outcome $(\pi_j, 0)$ with probability $p_j \cdot (1 - \frac{P}{U})$.

We first present a classical (randomized) IC protocol that implements $\mathcal{M}'$ with $O(B \log B)$ expected communication complexity. This protocol differs slightly from the one in [70] and serves as a more straightforward foundation for constructing a quantum protocol. A probability distribution over $2B$ outcomes can be represented by $2B$ non-negative real numbers $p_1, \ldots, p_{2B}$ such that $\sum_{i=1}^{2B} p_j = 1$. We call a distribution *feasible* if it is a distribution over $2B$ outcomes for some type in mechanism $\mathcal{M}'$. At each round, the buyer sends $2B$ bits, and the seller either terminates the protocol with an allocation and a payment or continues by moving to the next round and letting the buyer send more bits.

Buyer's suggested strategy

Given the buyer's type and mechanism $\mathcal{M}'$, we denote by $p_1, \ldots, p_{2B}$ the probability of each outcome. The buyer sends $2B$ bits each round. The suggested strategy is to send, in the r-th Buyer round, the r-th bit of the binary representation of $p_1, \ldots, p_{2B}$, respectively.

Seller's strategy

After receiving each bit, the seller first checks if all buyer's messages so far are consistent with some feasible distributions, which means messages are binary prefixes of probabilities corresponding to some feasible distributions. When there is only one possible value for the next bit that is consistent with some feasible distribution, then the seller sets the value of the next bit of the message to be the only feasible value and ignores the original bit of the message.

Let $m_j^{(r)}$ be the j-th bit of message receives at round r. For round r, we denote by $\tau^{(r)}$ the total probability revealed so far.

In addition, we define $\tau^{(0)} = 0$. After receiving all $2B$ bits of message at round r, the protocol terminates with probility $\frac{\tau^{(r)} - \tau^{(r-1)}}{1 - \tau^{(r-1)}}$. Conditioned on terminating, the protocol assigns allocation and payment of outcome j of $\mathcal{M}'$ with probability $\frac{m_j^{(r)} \cdot 2^{-r}}{\tau^{(r)} - \tau^{(r-1)}}$ for each j. Finally, with probability $1 - \frac{\tau^{(r)} - \tau^{(r-1)}}{1 - \tau^{(r-1)}}$, the protocol continues. It is important to note that the protocol terminates in no longer than r rounds with probability $\tau^{(r)}$.

IC

The suggested strategy is optimal for the buyer.

Communication complexity

The overall expected communication complexity is $O(B \log B)$.

5.2 Quantum Protocol

The idea of our quantum protocol is to replace all classical bits the buyer sends in the first $2 \log B$ rounds (total of $O(B \log B)$ bits) with a single message with $\log(B)+1$ qubits and $2 \log B$ classical bits. Note that $\log(B)+1$ qubits can encode an arbitrary distribution with support size $2B$ (see details below). The buyer is supposed to encode the distribution associated with his type into a quantum state. Then the seller can measure the quantum state and decide the allocation and payment according to the outcome. Here, the problem with this approach is that the buyer might encode an infeasible distribution (not associated with any type), and the seller has no way to tell if a quantum state encodes a feasible distribution.

To overcome this challenge, the seller will, with high probability, blindly trust the buyer and determine the allocation and payment according to the measurement outcome. However, with a small probability, rather than measuring the qubits, the seller asks the buyer to reveal the probability distribution he encoded by sending its full description classically. Subsequently, the seller can perform a measurement to verify if the quantum state accurately encodes the given distribution. Specifically, any quantum state that unfaithfully encodes the distribution will fail the test with a non-zero probability. As a result, the protocol can penalize the buyer with a big payment once she observes that the test has failed.

Seller's strategy

In the first round, the seller expects a quantum message of $(\log(B)+1)$ qubits, which we denote by m_Q, and a $\log(B+1)$-bit classical message that represents an integer $\hat{\tau} \in [0, B]$.

With probability $\gamma(\hat{\tau}) = 1 - \frac{1}{2B} - (1 - \frac{1}{2B})\frac{\hat{\tau}}{B^2}$, the seller measures the quantum message m_Q in the computational basis $(|1\rangle, |2\rangle, \ldots, |2B\rangle)$ and terminates the protocol. Suppose the measurement outcome is $|a\rangle \in \{|1\rangle, |2\rangle, \ldots, |2B\rangle\}$, the allocation and payment are determined according to outcome a of mechanism $\mathcal{M}'$.

With probability $1 - \gamma(\hat{\tau}) = \frac{1}{2B} + (1 - \frac{1}{2B})\frac{\hat{\tau}}{B^2}$, the seller asks the buyer to send $4B \log B$ classical bits to represent $2B$ binary numbers, $\widehat{p_1}, \ldots, \widehat{p_{2B}}$, each consisting of $2 \log B$ bits (we denote by m_C this classical message). Applying the same correction procedure as described in Subsection 5.1, we can assume that $\widehat{p_1}, \ldots, \widehat{p_{2B}}$ is the rounding-down to nearest multiple of $1/B^2$ of a feasible distribution $p_1, \ldots, p_{2B}$. The seller then verifies that $\hat{\tau} = B^2 \cdot (1 - \sum_i \widehat{p_i})$; if it isn't, the protocol terminates with the empty allocation and payment $2BU^3\varepsilon^{-2}$. Next, the seller measures the quantum message she receives earlier m_Q in a way such that the measurement has two outcomes $0, 1$, and the probability of outcome 1 is given by $\mathrm{Tr}(\rho |\psi\rangle \langle\psi|)$, where ρ is the reduced density matrix that represents the state of m_Q at the time of measurement, and $|\psi\rangle$ is the canonical state of classical message m_C that is given by $|\psi\rangle = \frac{B}{\sqrt{B^2 - \hat{\tau}}} \sum_{i=1}^{2B} \sqrt{\widehat{p_i}}\, |i\rangle$.

If the measurement outcome is 0, the protocol terminates with empty allocation and payment $2BU^3\varepsilon^{-2}$. Otherwise, the protocol continues as a purely classical protocol in the following manner: for each $i \in \{1, \ldots, 2B\}$, with probability $\frac{1}{2B(1-\gamma(\hat{\tau}))}\widehat{p_i}$, the protocol terminates with outcome i of mechanism $\mathcal{M}'$. Finally, with probability $1 - \frac{1}{2B(1-\gamma(\hat{\tau}))}\sum_i \widehat{p_i}$, the seller starts to run the classical protocol from round $2 \log B + 1$ and let $\widehat{p_1}, \ldots, \widehat{p_{2B}}$ be the message she received in the first $2 \log B$ rounds.

Buyer's suggested strategy

Given the buyer's type and mechanism $\mathcal{M}'$, we denote by $p_1, \ldots, p_{2B}$ the probability of each outcome. Let $\widetilde{p_1}, \ldots, \widetilde{p_{2B}}$ be the numbers such that for any i, the binary representation of $\widetilde{p_i}$ consists of first $2 \log B$ bits of the binary representation of p_i. The suggested strategy is to send, for quantum message m_Q whose density matrix is given by $|\varphi\rangle\langle\varphi|$, where $|\varphi\rangle$ is defined as $|\varphi\rangle = \frac{B}{\sqrt{B^2-\tilde{\tau}}} \sum_{i=1}^{2B} \sqrt{\widetilde{p_i}}\,|i\rangle$, and send integer $\tilde{\tau} = B^2(1 - \sum_i \widetilde{p_i})$. In addition, when the protocol asks the buyer to send classical message m_C, the suggested strategy sends $\widetilde{p_1}, \ldots, \widetilde{p_{2B}}$. Finally, as for the classical protocol part, for round corresponding to the r-th round of the classical protocol, the suggested strategy is to send the r-th bit of the binary representation of $p_1, \ldots, p_{2B}$, respectively.

ε-IC

We demonstrate that this protocol is ε-IC.

Communication complexity

The overall expected communication complexity is $O(\log B)$.

6 Lower Bounds for Quantum Protocols with Small Payments

Throughout this section, we normalize the valuations so that the upper bound on the highest value is $U = 1$.

▶ **Theorem 8** (Full version of Theorem 2). *Let n be the number of items, P be the upper bound on the payments and in the quantum auction protocol, and $\hat{K}$ an upper bound on the expected communication complexity. Then we have the following lower bounds on $\hat{K}P$:*

- *For unit-demand valuations, any quantum auction protocol that obtains $\Omega(1)$-approximation to the optimal revenue must satisfy $\hat{K}P = \Omega(n)$.*
- *For Gross-substitutes valuations, any quantum auction protocol that obtains $\Omega(1)$-approximation to the optimal revenue must satisfy $\hat{K}P = 2^{\Omega(n^{1/3})}$.*
- *For XOS valuations, any quantum auction protocol that obtains $\Omega(1)$-approximation to the optimal revenue must satisfy $\hat{K}P = 2^{\Omega(n)}$.*
- *For XOS valuations over independent items, any quantum auction protocol that obtains $4/5 + \Omega(1)$-approximation to the optimal revenue must satisfy $\hat{K}P = 2^{\Omega(n)}$.*

6.1 A List-Decodable Code of Bayesian Priors

The lower bounds of [70] against approximately optimal classical auction protocols construct, for each valuation class (unit-demand, submodular, etc.), a family of Bayesian priors over valuations from this class. Each family has the following "list-decodability" guarantee: no mechanism can simultaneously obtain high revenue on a "list" of $\omega(1)$ priors from the family. We now state the results from [70], with different parameters for family size and approximability for different valuation classes.

▶ **Lemma 9** (Family of hard priors [70]). *For each of the following combinations of valuation class X over n items, family size ζ, and approximability factor γ, there exists a family of ζ Bayesian priors over valuations from X, and a small constant $\varepsilon > 0$ such that no single ε-IC and ε-IR mechanism can simultaneously obtain a γ-approximation of the optimal revenue from $\omega(1)$ distinct priors from the family.*

- X = *unit-demand;* $\zeta = 2^{2^{\Omega(n)}}$; γ = *arbitrarily small constant.*
- X = *gross-substitute;* $\zeta = 2^{2^{2^{o(n^{1/3})}}}$; γ = *arbitrarily small constant.*
- X = *XOS;* $\zeta = 2^{2^{2^{\Omega(n)}}}$; γ = *arbitrarily small constant.*
- X = *XOS over independent items;* $\zeta = 2^{2^{2^{\Omega(n)}}}$; $\gamma = 4/5 + \tau$ *for arbitrarily small constant* τ.

6.2 Approximate Cover over Efficient Quantum Auction Protocols

Our next objective is to demonstrate the existence of a finite set of protocols capable of approximating any (almost) IC and (almost) IR quantum protocol with bounded worst-case communication complexity. Formally speaking, we have the following lemma.

▶ **Lemma 10** (Approximate cover over efficient quantum auction protocols). *Let X be a type space with n items, B an upper bound of number of feasible bundles, P an upper bound of payments and values of types in X, $\varepsilon > 0$ as an approximation parameter, and K an upper bound on the communication complexity, there exists a set $\mathcal{S} = \mathcal{S}(n, B, P, \varepsilon, K)$ of mechanisms such that the following hold:*

- *Small cover:* $|\mathcal{S}| = 2^{2^{O(K+\log B+\log\log P+\log n)}}$.
- *Mechanisms in $\mathcal{S}$ are $2\sqrt{\varepsilon}$-IC and $2\sqrt{\varepsilon}$-IR.*
- *Approximate covering property: For any ε-IC and ε-IR quantum protocol $\mathcal{P}$ with a worst-case communication complexity bounded by K, let $\mathcal{M}_{\mathcal{P}} = (\mathcal{A}_{\mathcal{P}}, \mathcal{Q}_{\mathcal{P}})$ be the mechanism induced by $\mathcal{P}$. Then there exists a mechanism $\mathcal{M} = (\mathcal{A}, \mathcal{Q}) \in \mathcal{S}$ such that for every type $v \in X$, we have*

$$\mathcal{Q}(v) \geq (1 - \sqrt{\varepsilon})\mathcal{Q}_{\mathcal{P}}(v).$$

Part II
Worst-case communication

7 Preliminaries III: Optimal Mehchanisms for Selling 2 Items

In this section, we introduce a special case of framework of [24, 39] to characterize optimal auctions for selling two goods to a single additive buyer with independent valuations. We will first give a picture of their framework and then discuss how to apply duality theory to show that infinite menu complexity (aka infinite worst-case classical communication complexity) is inevitable for the optimal mechanisms of some prior distributions.

For simplicity, we only consider the case where the buyer's type space X is $[0,1]^2$, and each coordinate represents the buyer's value of each good. We assume the prior distribution has a density function $f(x,y) = f_1(x)f_2(y)$. Further, we assume f_1, f_2 are continuous and differentiable with bounded derivatives.

It is well-known (see e.g. [67, 54], that for any IC and IR mechanism the utility function $u : [0,1]^2 \to \mathbb{R}$ is convex, non-negative, non-decreasing, and 1-Lipschitz with respect to the ℓ_1 norm. Also, given any $u : [0,1]^2 \to \mathbb{R}$ with these conditions, the utility function uniquely[13] defines an IC and IR mechanism $\mathcal{M}$ with allocation function $\mathcal{A}(v) = \nabla u(v)$ and payment function $\mathcal{Q}(v) = \mathcal{A}(v) \cdot v - u(v)$.

[13] Up to measure zero.

At a high level, the mechanisms established in [24, 39] partition $[0,1]^2$ into 4 regions $Z, \mathcal{A}, \mathcal{B}, \mathcal{W}$ induced by a convex area Z defined by two concave functions s_1, s_2 and a straight line $x + y = P_{\text{crit}}$ for some $P_{\text{crit}} \in [0,2]$. Moreover, [24] calls $Z, \mathcal{A}, \mathcal{B}, \mathcal{W}$ *the canonical partition with respect to* Z, and P_{crit} *the critical price*. For ease of exposition, we only consider the case that the line $x + y = P_{\text{crit}}$ intersects both curves $x = s_1(y)$ and $y = s_2(x)$.

More precisely, let $s_1, s_2 : [0,1] \to [0,1]$ be two 1-Lipschitz, concave and non-increasing function, and $P_{\text{crit}} \in [0,2]$. Let x_{crit} be the solution to $s_2(x) = P_{\text{crit}} - x$, and y_{crit} be the solution to $s_1(y) = P_{\text{crit}} - y$. We can always find such solutions since we assume the line $x + y = P_{\text{crit}}$ intersects both curves.

Region $Z \subseteq [0,1]^2$ is defined as the region enclosed by s_1, s_2, and line $x + y = P_{\text{crit}}$. Formally, $Z = \{(x,y) \in [0,1]^2 : x \le s_1(y), y \le s_2(x), x + y \le P_{\text{crit}}\}$. The other three regions are defined as follows:

$$\mathcal{A} = \{(x,y) \in [0,1]^2 : x < x_{\text{crit}}\} \backslash Z; \quad \mathcal{B} = \{(x,y) \in [0,1]^2 : y < y_{\text{crit}}\} \backslash Z; \quad \mathcal{W} = [0,1]^2 \backslash (Z \cup \mathcal{A} \cup \mathcal{B}).$$

▶ **Definition 11** (GK conditions [39]). *Let* $\mu(x,y) = 3f_1(x)f_2(y) + xf_1'(x)f_2(y) + yf_2'(y)f_1(x)$. *Given a canonical partition of* $[0,1]^2$ *induced by* s_1, s_2, *and* P_{crit}, *we say that it satisfies* GK conditions with respect to f_1, f_2 *if it satisfies the following conditions:*

- $\mu(x,y) > 0$ *for all* $(x,y) \in [0,1]^2$, *and*
- $\int_Z \mu(x,y) = 1$, *and*
- $\int_{s_1(y)}^1 \mu(x,y)\mathrm{d}x = f_1(1)f_2(y)$, *for all* $y \in [0, y_{crit}]$, *and*
- $\int_{s_2(x)}^1 \mu(x,y)\mathrm{d}y = f_1(x)f_2(1)$, *for all* $x \in [0, x_{crit}]$.

Finally by [39] (specifically, their Theorem 1 and duality discussions in Section 2.2), we have the following characterization of the optimal mechanism.

▶ **Theorem 12** (Uniqueness and characterization of optimal auction [39]). *Given probability density functions* f_1, f_2 *over* $[0,1]$. *Suppose that canonical partition* $(Z, \mathcal{A}, \mathcal{B}, \mathcal{W})$ *induced by* 1*-Lipschitz, concave and non-increasing functions* s_1, s_2, *and* $P_{\text{crit}} \in [0,2]$ *satisfies the GK conditions. The utility function* $u(x,y)$ *of the optimal IC and IR mechanism for selling two items to a single additive buyer with independent prior distributions* f_1, f_2 *is given by*

$$u(x,y) = \max(0, x - s_1(y), y - s_2(x), x + y - P_{\text{crit}}).$$

Specifically,

- *if* $(x,y) \in Z$, $u(x,y) = 0$;
- *if* $(x,y) \in \mathcal{A}$, $u(x,y) = y - s_2(x)$;
- *if* $(x,y) \in \mathcal{B}$, $u(x,y) = x - s_1(y)$;
- *if* $(x,y) \in \mathcal{W}$, $u(x,y) = x + y - P_{\text{crit}}$.

Moreover, the optimal utility function $u(x,y)$ *is unique in regions* $\mathcal{A}, \mathcal{B}, Z$.

8 Limitations of One-Way Quantum Protocols

[24] studies the optimal auction of selling two items to a single additive buyer with i.i.d. valuations from Beta$(1,2)$. It characterizes the unique utility function $u(\cdot)$ for any optimal mechanism. In particular they show that in the region $y = 1$ and $x \in [0, 0.06]$, the unique utility function for optimal mechanism is given by $u(x,1) = \frac{2-2x}{4-5x}$.

In this section, we show that no finite one-way quantum mechanism can implement this utility function for $x \in [0, 0.06]$ and $y = 1$. It it worth noting that, although only one qubit is exchanged in a single round per definition of our main model, the following negative result applies to any one-way quantum protocol with an arbitrarily large (but finite) message size.

▶ **Theorem 13.** *Given the two-item additive type space $[0,1]^2$, for any non-linear rational function $R(x)$, for any $r > 0$, there is no IC quantum one-way protocol $\mathcal{P}$ has utility function $u(x,1) = R(x)$ for $x \in [0,r)$.*

9 A Quantum One-Way Mechanism for An Uncountable Menu

In this section, we are going to construct an example of a prior over two additive, independent items, where the corresponding optimal auction can: (i) be implemented by a one-way protocol in 1 qubit and 2 classical bits; but (ii) requires an uncountably infinite menu.

▶ **Theorem** (Theorem 3 restated)**.** *For the problem of auctioning two items to a single buyer, there is a Bayesian prior over independent item values, such that there is a revenue-optimal one-way quantum auction protocol where the buyer sends 1 qubit and 2 classical bits; yet no finite classical auction protocol can achieve the optimal revenue.*

At a high level, we construct the example in the following steps:

1. First, we want to apply Theorem 12 to identify the utility function for optimal mechanisms. To simplify the verification of GK conditions, we choose $f_1(x) = 1$, for $x \in [0,1]$, aka the value for item 1 is drawn uniformly from $[0,1]$. By choosing $f_1(x) = 1$, the measure $\mu(x,y)$ defined in GK conditions can be simplified to $\mu(x,y) = 3f_2(y) + yf_2'(y)$.
2. Next, we choose a non-increasing, 1-Lipschitz, concave function s_1. In addition, we require s_1 to be a non-piecewise-linear function, so the utility function in the region $\mathcal{B}$ of the canonical partition $u(x,y) = x - s_1(y)$ is non-piecewise-linear, which implies no finite menu can characterize it. Moreover, as we discussed in the last section, to be able to be implemented by a one-way quantum protocol, $s_1(y)$ has to be a function in the form $\|Ay + B\|$ for some Hermitian matrices A and B. After some trial and error, it turns out that $s_1(y) = \frac{49}{24} - \frac{1}{4}(3y + \sqrt{121/4 - 10y + y^2})$ is a good idea.
3. With the chosen s_1, the next step is to reverse-engineer Theorem 12 to obtain a probability density function $f_2(y)$, function s_2 and critical price P_{crit} such that the canonical partition induced by $s_1, s_2, P_{\text{crit}}$ satisfies GK conditions. In particular, By the third bullet of Definition 11, $f_2(y)$ has to satisfy the following ODE:

$$(1 - s_1(y))\,(3f_2(y) + yf_2'(y)) = f_2(y).$$

4. Finally, we construct a one-way quantum protocol whose utility function is exactly the one given by Theorem 12.

By solving the ODE in bullet 2, we obtain

$$f_2(y) = \frac{c \cdot \left(-6g(y) + 12y + \sqrt{5737} + 5\right)^{-\frac{75}{58} - \frac{7551}{58\sqrt{5737}}} (g(y) - 2y + 10)^3 \left(6g(y) - 12y + \sqrt{5737} - 5\right)^{\frac{7551}{58\sqrt{5737}} - \frac{75}{58}}}{(11 - 2y + g(y))^{99/29}}, \quad (2)$$

where $g(y) = \sqrt{4y^2 - 40y + 121}$, and c is the normalization factor such that

$$\int_0^1 f_2(y)\,\mathrm{d}y = 1.$$

9.1 Optimal Mechanisms

In this subsection, we will further define another non-increasing, 1-Lipschitz, concave function s_2 and critical price $P_{\text{crit}} \in [0,2]$. Next, we verify the canonical partition induced by s_1, s_2, and P_{crit} satisfy GK conditions and give the characterization of the optimal mechanism by applying Theorem 12.

First, one can verify that $\mu(x,y) = 3f_2(y) + yf_2'(y)$ is negative for all $(x,y) \in [0,1]^2$.

Next, given $f_1(x) = 1$, by the last bullet of Definition 11, we set $s_2(x) \approx 0.558$ as a constant function such that $\int_{s_2(x)}^{1}(3f_2(y) + yf_2'(y))\mathrm{d}y = f_2(1)$.

Finally, we set $P_{\text{crit}} \approx 0.669$ such that $\int_Z (3f_2(y)+yf_2'(y)) = 1$. Moreover, line $x+y = P_{\text{crit}}$ intersects both curves $x = s_1(y)$ and $y = s_2(x)$. With s_1, s_2 and P_{crit} we now have $x_{\text{crit}} \approx 0.111$ and $y_{\text{crit}} \approx 0.005$. By definition, the canonical partition induced by s_1, s_2 and P_{crit} satisfies GK conditions. Therefore, by Theorem 12, we give the following characterization of the optimal mechanism for selling two items to a single additive buyer with values independently distributed according to $f_1 = 1$ and f_2 given by (2).

▶ **Lemma 14.** *The optimal mechanism for selling two items to a single additive buyer with values independently distributed according to $f_1 = 1$ and f_2 defined by (2) is given by the utility function*

$$u(x,y) = \max(0, x - s_2(y), y - s_1(x), x + y - P_{\text{crit}}).$$

Specifically, $u(x,y) = x - s_2(y)$ in region B is not a piecewise linear function, and it is the unique utility function for all optimal mechanisms in region B.

9.2 Exact One-Way Quantum Protocol

In this subsection, we give an IC one-way quantum protocol with exactly the same utility as the one characterized in Lemma 14.

Protocol implementation

In the first (and the only) round, the buyer send a single qubit with reduced density matrix ρ, and two classical bits b_1, b_2. If $b_1 = b_2 = 0$, then the seller terminates the protocol with empty allocation and payment 0. If $b_1 = b_2 = 1$, then the seller terminates the protocol with allocation $\{1,2\}$ and payment $P_{\text{crit}} \approx 0.669$. If $b_1 = 0, b_2 = 1$, then the seller terminates the protocol with alloation $\{2\}$ and payment $s_2(0) \approx 0.558$. Finally, if $b_1 = 1, b_2 = 0$, the seller measures the qubit using the following POVM and terminates the protocol with allocation and payment associated with each measurement outcome.

$$A_1 = \begin{pmatrix} 2/5 & \sqrt{21}/16 \\ \sqrt{21}/16 & 1/4 \end{pmatrix}, \quad a_1 = \{1,2\}, \quad p_1 = 2,$$

$$A_2 = \begin{pmatrix} 2/5 & -\sqrt{21}/16 \\ -\sqrt{21}/16 & 1/4 \end{pmatrix}, \quad a_2 = \{1,2\}, \quad p_2 = 0,$$

$$A_3 = \begin{pmatrix} 1/5 & 0 \\ 0 & 0 \end{pmatrix}, \quad a_3 = \{1,2\}, \quad p_3 = \frac{299}{24},$$

$$A_4 = \begin{pmatrix} 0 & 0 \\ 0 & 1/2 \end{pmatrix}, \quad a_4 = \{1\}, \quad p_4 = \frac{7}{12}.$$

We define the buyer's suggested strategy as the optimal response to the seller's strategy, given his private value x and y.

10 (Barely) interactive one-way quantum auction protocols

In Section 8 we see an example of a prior whose optimal mechanism cannot be implemented by a finite one-way quantum auction protocol. In this section, we introduce a barely interactive multi-round quantum auction protocol which is optimal for this example, i.e. $f_1(x) = 2(1-x), f_2(y) = 2(1-y)$ for $(x,y) \in [0,1]^2$.

▶ **Theorem 15** (Theorem 4). *For the problem of auctioning two items to a single buyer, there is a Bayesian prior over independent item values, such that there is a revenue-optimal quantum auction protocol where the seller sends 1 qubit to the buyer, who replies with 1 qubit and 2 classical bits; yet no finite classical or one-way quantum auction protocol can achieve the optimal revenue.*

Due to [24] Section 8.2.1, the (unique) optimal mechanism for this example can be characterized by the following lemma.

Protocol implementation

The seller's strategy is as follows.

In this protocol, the seller first prepares an EPR pair: $\frac{1}{\sqrt{2}}(|0\rangle|0\rangle + |1\rangle|1\rangle)$ and sends one qubit of the EPR pair to the buyer.

The density matrix of an EPR pair is $\rho_{\text{EPR}} = \begin{pmatrix} \frac{1}{2} & 0 & 0 & \frac{1}{2} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \frac{1}{2} & 0 & 0 & \frac{1}{2} \end{pmatrix}$.

Next, the seller receives one qubit from the buyer (and two classical bits). We denote by b_1, b_2 the two classical bits. If $b_1 = b_2 = 0$, the protocol terminates with empty allocation and payment 0. If $b_1 = b_2 = 1$ the protocol terminates with allocation $\{1, 2\}$ and payment $P_{\text{crit}} \approx 0.5535$ defined in [24]. If $b_1 \neq b_2$, the seller measures the joint state (two qubits) of his half of the EPR pair and the qubit she receives from the buyer. The seller will use the following POVM and corresponding allocation and payments. For convenience, we define bundle $\pi = \{1\}$ if $b_1 = 1$, and $\pi = \{2\}$ if $b_2 = 1$.

$$A_1 = \begin{pmatrix} \frac{3}{20} & 0 & 0 & \frac{1}{10} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{2}{5} & 0 \\ \frac{1}{10} & 0 & 0 & \frac{2}{5} \end{pmatrix}, \quad a_1 = \pi, \quad p_1 = 3,$$

$$A_2 = \begin{pmatrix} \frac{23}{80} & 0 & 0 & -\frac{1}{10} \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \frac{3}{5} & 0 \\ -\frac{1}{10} & 0 & 0 & \frac{3}{5} \end{pmatrix}, \quad a_2 = \pi, \quad p_2 = 0,$$

$$A_3 = \begin{pmatrix} \frac{9}{16} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad a_3 = \{1, 2\}, \quad p_3 = 0.$$

We can verify by calculation that this is a valid POVM as all three matrices are positive semidefinite and $A_1 + A_2 + A_3 = I$.

We define the buyer's suggested strategy as the optimal response to the seller's strategy, given his private value x and y.

11 Limitations of finite-round quantum protocols

In this section we give an example where no finite IC and IR protocol obtains optimal revenue.

▶ **Theorem** (Theorem 5 restated). *For the problem of auctioning two items to a single buyer, there is a Bayesian prior over independent item values, such that there is a revenue-optimal classical auction protocol that requires a constant number of bits* in exepctation*; yet no finite quantum auction protocol can achieve the optimal revenue.*

Below are definitions of semialgebraic sets and semialgebraic functions. (See e.g. [23] for reference.)

▶ **Definition 16** (semialgebraic sets). *A subset of $\mathbb{R}^n$ is semialgebraic if it can be represented as a finite union of sets of the form:*

$$\{x \in \mathbb{R}^n : f(x) = 0, g_1(x) > 0, \ldots, g_m(x) > 0\},$$

where f and g_is are real polynomials in x.

▶ **Definition 17** (Semialgebraic functions). *A function $f : \mathbb{R}^n \to \mathbb{R}$ is semialgebraic if its graph $\{(x, y) \in \mathbb{R}^{n+1} : f(x) = y\}$ is a semialgebraic set.*

11.1 The utility function of finite round IC protocol is semialgebraic

▶ **Lemma 18.** *Given an IC an IR finite-round quantum auction protocol, its utility function $u(x)$ is semialgebraic.*

11.2 A mechanism with a non-semialgebraic utility function

[39] characterizes the optimal mechanism for selling two items to an additive buyer with i.i.d. priors $\frac{e^{-x}}{1-1/e}$ (i.e. $f_1(x) = \frac{e^{-x}}{1-1/e}$ and $f_2(y) = \frac{e^{-y}}{1-1/e}$). In particular, they show that the utility function of the optimal mechanism satisfies $u(x, 1) = 2x + W(e^{1-x}(2-x)) - 1$ for $x \in [0, 0.1]$, where $W(\cdot)$ is the Lambert W function[14]. Furthermore, by Theorem 12, we also know this utility function is unique in this region ($y = 1, x \in [0, 0.1]$).

Next, we show that the unique utility function $g(x) = 2x + W(e^{1-x}(2-x)) - 1$ is not a semialgebraic function. Together with Lemma 18, this implies that no finite quantum IC protocol achieves exactly optimal revenue (aka completing the proof of Theorem 5).

▶ **Lemma 19.** *Let $f : \mathbb{R} \to \mathbb{R}$ be a semialgebraic function. $f(x)$ cannot be equal to $g(x) = 2x + W(e^{1-x}(2-x)) - 1$ on $[0, r)$ for any $r > 0$.*

Abstract

Despite the fundamental role the Quantum Satisfiability (QSAT) problem has played in quantum complexity theory, a central question remains open: At which local dimension does the complexity of QSAT transition from "easy" to "hard"? Here, we study QSAT with each constraint acting on a d_A-dimensional and d_B-dimensional qudit pair, denoted $(d_A \times d_B)$-QSAT. Our first main result shows that, surprisingly, QSAT on qubits can remain QMA_1-hard, in that (2×5)-QSAT is QMA_1-complete. (QMA_1 is a quantum analogue of MA with perfect completeness.) In contrast, (2×2)-QSAT (i.e. Quantum 2-SAT on qu*b*its) is well-known to be poly-time solvable [Bravyi, 2006]. Our second main result proves that $(3\times d)$-QSAT on the 1D line with $d \in O(1)$ is also QMA_1-hard. Finally, we initiate the study of $(2\times d)$-QSAT on the 1D line by giving a frustration-free 1D Hamiltonian with a unique, entangled ground state.

As implied by our title, our first result uses a *direct embedding*: We combine a novel clock construction with the 2D circuit-to-Hamiltonian construction of [Gosset and Nagaj, 2013]. Of note is a new simplified and *analytic* proof for the latter (as opposed to a partially numeric proof in [GN13]). This exploits Unitary Labelled Graphs [Bausch, Cubitt, Ozols, 2017] together with a new "Nullspace Connection Lemma", allowing us to break low energy analyses into small patches of projectors, and to improve the soundness analysis of [GN13] from $\Omega(1/T^6)$ to $\Omega(1/T^2)$, for T the number of gates. Our second result goes via *black-box* reduction: Given an *arbitrary* 1D Hamiltonian H on d'-dimensional qudits, we show how to embed it into an effective 1D $(3\times d)$-QSAT instance, for $d \in O(1)$. Our approach may be viewed as a weaker notion of "analog simulation" (*à la* [Bravyi, Hastings 2017], [Cubitt, Montanaro, Piddock 2018]). As far as we are aware, this gives the first "black-box simulation"-based QMA_1-hardness result.

1 Introduction

Boolean satisfiability problems have long served as a testbed for probing the boundary between "easy" (i.e. poly-time solvable) and "hard" (e.g. NP-complete) computational problems. A striking early example of this is the fact that while 3-SAT is NP-complete [12, 33, 28], 2-SAT is in P [38, 15, 31, 18, 5, 36]. Despite this, *MAX*-2-SAT (i.e. what is the *maximum* number of satisfiable clauses of a 2-CNF formula?) remains NP-complete [20]! Thus, the border between tractable and intractable can often be intricate, hiding abrupt transitions in complexity.

In the quantum setting, generalizations of k-SAT and MAX-k-SAT have similarly played a central role, additionally due to their strong physical motivation. The input here is a *k-local Hamiltonian* $H = \sum_i H_i$ acting on n qubits, which is a $2^n \times 2^n$ complex Hermitian matrix (a quantum analogue of a Boolean formula on n bits), given via a succinct description $\{H_i\}$. Here, each H_i is a $2^k \times 2^k$ operator acting on[2] k out of n qubits (i.e. a local quantum clause). Given H, the goal is to compute the smallest eigenvalue $\lambda_{\min}(H)$ of H, known as the *ground state energy*. The corresponding eigenvector, in turn, is the *ground state*. This k-local Hamiltonian problem (k-LH) generalizes MAX-k-SAT, and formalizes the question: If a many-body quantum system is cooled to near absolute zero, what energy level will the system relax into? The complexity of k-LH is well-understood, and analogous to MAX-2-SAT, even 2-LH is complete for[3] Quantum Merlin-Arthur (QMA) [30, 29, 14].

The quantum generalization of k-SAT (as opposed to *MAX*-k-SAT), on the other hand, is generally *less* understood. In contrast to k-LH, one now asks whether there exists a ground state of H which is simultaneously a ground state for *each local term* H_i (analogous to a string satisfying *all* clauses of a k-SAT formula). Formally, in Quantum k-SAT (k-QSAT), each H_i is now a projector, and one asks whether $\lambda_{\min}(H) = 0$. As in the classical setting, it is known that the locality k leads to a complexity transition: On the one hand, Gosset and Nagaj [24] proved that 3-QSAT is[4] QMA$_1$-complete, while on the other hand, Bravyi gave [8] a poly-time classical algorithm for 2-QSAT (in fact, 2-QSAT is solvable in linear time [4, 16]).

Systems of higher local dimension. In the quantum setting, however, there is an additional, physically motivated direction to probe for complexity transitions for 2-QSAT – *systems of higher local dimension*. Perhaps the most striking example of this is that, while Boolean satisfiability problems in 1D are efficiently solvable via dynamic programming (even for

[2] Formally, if H_i acts on a subset $S \subseteq [n]$ of qubits, to make the dimensions match we consider $(H_i)_S \otimes I_{[n]\setminus S}$.
[3] QMA is the bounded-error quantum analogue of NP, now with poly-size quantum proof and quantum verifier [30].
[4] QMA$_1$ is QMA but with perfect completeness; see Definition 2.1. Note that while MA = MA$_1$ [43], whether QMA$_1$ = QMA remains a major open question.

Table 1 Summary of the known complexity results for $(a\times b)$-QSAT. Rows denote values of d_A, columns values of d_B. New results from this work are bold.

d-level systems instead of bits), Aharonov, Gottesman, Irani and Kempe showed [2] that 2-LH on the line remains QMA-complete, *so long as* one uses local dimension $d = 12$! An analogous result for 2-QSAT with $d = 11$ was subsequently given by Nagaj [34]. This raises the guiding question of this work:

What is the smallest local dimension that can encode a QMA_1*-hard problem?*

There are three results we are aware of here. Define $(d_A\times d_B)$-QSAT as 2-QSAT where each constraint acts on a qu-d_A-it and a qu-d_B-it, i.e. on $\mathbb{C}^{d_A}\otimes\mathbb{C}^{d_B}$. (When $d_A \neq d_B$, for this to be well-defined, the interaction graph of the instance must be bipartite.) Not only is 2-QSAT on qubits (i.e. (2×2)-QSAT) in P, Chen, Chen, Duan, Ji, and Zheng showed [11] that a YES instance always has a witness that is a product of single- and two-qubit states. On the other hand, Bravyi, Caha, Movassagh, Nagaj, and Shor gave a frustration-free[5] qutrit construction (i.e. on local dimension $d = 3$) on the 1D line[6] [9] with a *unique*, *entangled* ground state. While this construction does not encode a computation (and thus does not give QMA_1-hardness), it is an important first step in that it shows even such low dimensional systems can encode entangled witnesses (entanglement is necessary, otherwise an NP witness is possible). Together, these works [11] and [9] suggest that qu*b*it systems are a no-go barrier for QMA_1-hardness. Prior to these, Eldar and Regev [17] came closest to establishing a result about qubit systems, showing that (3×5)-QSAT is QMA_1-hard (on general graphs).[7] But the key question remains open – *Can qubit systems support* QMA_1*-hardness for Quantum* 2*-SAT, i.e. is* $(2\times d)$-QSAT QMA_1*-hard for some* $d \in O(1)$*?*

Our results. We show two main results, along with a third preliminary one.

1. QMA_1*-hardness for qubit systems.* The complexity of $(d_A\times d_B)$-QSAT including our new results is summarized in Table 1. The first main result is as follows.

▶ **Theorem 1.1.** (2×5)-QSAT *is* QMA_1*-complete with soundness* $\Omega(1/N^2)$.

Here, N denotes the number of gates[8] used by the QMA_1-verifier. Thus, qubit systems *can* encode QMA_1-hardness. Let us be clear that the surprising part of this is *not* that this setting is intractable – indeed, even classical (2×3)-SAT is known to be NP-hard (e.g. [34]).

[5] A *frustration-free* Hamiltonian is a YES instance of QSAT, i.e. a local Hamiltonian $H \succeq 0$ with $\lambda_{\min}(H) = 0$.

[6] "On the line" means $H = \sum_{i=1}^{m} H_{i,i+1}$, i.e. the qudits can be depicted as a sequence with each consecutive constraint acting on the next pair of qudits in the sequence.

[7] QMA_1-hardness of (4×9)-QSAT is claimed without proof in a footnote in [35] (see Reference 12 therein).

[8] As an aside, we assume in this paper that the QMA_1 verifier utilizes the standard "Clifford + T" gate set. See also [39] for an in-depth discussion of the "gate set issue" of QMA_1.

What *is* surprising is that one can encode *quantum* verifications in such low dimension, for two reasons. First, *a priori* a 2-dimensional space for 2-local constraints appears too limited to *exactly*[9] encode a computation – a two-dimensional space only appears to suffice to encode a "data qubit", so where does one encode the "clock" tracking the computation? Second, the entanglement of $(2\times d)$ systems is generally easier to characterize than that of $(d\times d)$ systems. For example, whether a (2×2) or (2×3) system is entangled is detectable via Peres' Positive Partial Transpose (PPT) criterion [37], whereas detecting entanglement for $(d\times d)$ systems (for polynomial d) becomes strongly NP-hard [25, 27, 21]. And recall that a "sufficiently entangled" ground space is necessary to encode QMA$_1$-hardness.

As a complementary result, we show that one can "trade" dimensions in the construction above if one is careful, i.e. the 5 in (2×5) can be reduced to 4 at the expense of increasing 2 to 3.

▶ **Theorem 1.2.** (3×4)-QSAT *is* QMA$_1$*-complete with soundness* $\Omega(1/N^2)$.

One can also consider general Quantum 2-SAT on qu-d-its of identical dimension d, which is QMA$_1$-complete for $d = 5$ [17]. Theorem 1.2 improves this to $d = 4$.

We remark that obtaining Theorems 1.1 and 1.2 is significantly more involved than the previous best QMA$_1$-hardness for (3×5)-QSAT [17] (details in "Techniques" below), and in particular requires (among other ideas) a simplified analysis of the advanced 2D-Hamiltonian framework of Gosset and Nagaj for $(2\times 2\times 2)$-QSAT (i.e. 3-QSAT on qubits) [24][10], a new clock construction, and the Unitary Labelled Graphs of Bausch, Cubitt and Ozols [6]. One of the payoffs is that we obtain a "tight"[11] soundness gap of $\Omega(1/N^2)$ for Theorem 1.1, compared to the $\Omega(1/N^6)$ gap of [24]. This allows us to recover the 3-QSAT hardness results of [24], but with improved soundness[12]:

▶ **Theorem 1.3.** 3-QSAT *is* QMA$_1$*-complete with soundness* $\Omega(1/N^2)$.

2. Low dimensional systems on the line. Our next main result is the following.

▶ **Theorem 1.4.** $(3\times d)$-QSAT *on a line is* QMA$_1$*-complete with* $d = O(1)$.

This improves significantly on the previous best 1D (11×11)-QSAT QMA$_1$-hardness construction of Nagaj [34], showing that frustration free Hamiltonians on qutrits can encode not just entangled ground states (*cf.* [9]), but also QMA$_1$-hard computations.

For clarity, there is a trade-off in the parameter, d, which we now elaborate. A key novelty of Theorem 1.4 is its proof via *black-box* reduction (see "Techniques" below), as opposed to a direct embedding of a QMA$_1$ computation. Specifically, given an *arbitrary* 1D Hamiltonian H on d'-dimensional qudits, we embed it into an effective 1D $(3\times d)$-QSAT instance with $d \in O((d')^4)$ (i.e. $d \in O(1)$ for constant d'). On the not-so-positive side, the generality of

[9] An *exact* encoding appears needed by definition of QSAT. This is in strong contrast to 2-LH, where *approximate* encodings are allowed (since all constraints need not be simultaneously satisfiable) via perturbation theory [29, 10].

[10] At a first glance, it seems like $(2\times 2\times 2)$-QSAT can be reinterpreted as (2×4)-QSAT-QSAT by combining two qubits into a qu-4-dit. Indeed, a *single* $(2\times 2\times 2)$-constraint can be embedded straightforwardly into a (2×4)-constraint. However, the interactions between a *set* of $(2\times 2\times 2)$-constraints seems difficult to directly reproduce via a set of (2×4)-constraints.

[11] By "tight", we mean that it is not currently known for either QSAT or LH how to get a promise gap larger than $\Omega(1/N^2)$ [42].

[12] For clarity, this improved soundness is not necessary for our results, but an added bonus of our new analysis.

this approach means that an input 1D Hamiltonian H on d'-dimensional qudits is mapped to a 1D Hamiltonian on constraints of dimension $(3 \times O((d')^4))$, i.e. the first dimension drops to 3 at the expense of the second dimension increasing. Thus, for example, if we plug in the 1D (11×11) QMA_1-hardness construction [34], Theorem 1.4 gives QMA_1-hardness for (2×76176)-QSAT.

On the positive side, however, our technique is the first use of (a weaker notion) of the influential idea of *local simulation* (Bravyi and Hastings [7], Cubitt, Montanaro, and Piddock [13]; see Definition 4.1 of [22] for a simpler statement) in the study of QSAT. Roughly, in such simulations, given a local Hamiltonian H on n qubits, one typically applies a local isometry V to each qubit, i.e. maps $H \mapsto V^{\otimes n} H (V^\dagger)^{\otimes n}$, blowing up the input space A into a larger, "logical" space B. By cleverly choosing an appropriate Hamiltonian H' on B, one forces the low-energy space of H' to approximate H. Traditionally, the drawback of this approach is its reliance on perturbation theory, which necessarily gives rise to[13] *frustrated* Hamiltonians H'. Here, however, we show for the first time that a weaker[14] version of such local embeddings can be designed even for the frustration-free setting, ultimately yielding Theorem 1.4.

3. Towards qubits on the line. Finally, we initiate the study (2×d) on a line by proving that even a frustration-free Hamiltonian on a line of alternating particles with dimensions 2 and 4 can have a unique entangled ground state.

▶ **Theorem 1.5.** *Consider a line of $2n$ particles such that the i-th particle has dimension 2 for even i and 4 for odd i. There exists a Hamiltonian $H = \sum_{i=1}^{n} A_{2i-1,2i} + \sum_{i=1}^{n-1} B_{2i,2i+1} + L_{1,2} + R_{2n-1,2n}$, where A, B, L, R are 2-local projectors, such that the nullspace of H is $\mathcal{N}(H) = \mathrm{Span}\{|\psi\rangle\}$ and $|\psi\rangle$ is entangled across all cuts.*[15]

Techniques. We focus on our main results, Theorem 1.1 and Theorem 1.4.

QMA_1*-hardness for* (2×5)-QSAT. The basic idea behind most (if not all) QMA_1-hardness constructions for QSAT is to embed a so-called *history state* $|\psi_{\mathrm{hist}}\rangle$ encoding the QMA_1 verifier's circuit U into the nullspace of a local Hamiltonian H. Specifically, let $U = U_T \cdots U_1$ be a sequence of 1- and 2-qubit gates. Then, the Feynman-Kitaev history state [19, 30] is given by

$$|\psi_{\mathrm{hist}}\rangle = \frac{1}{\sqrt{T+1}} \sum_{t=0}^{T} \big(U_t \cdots U_1 |\psi_{\mathrm{proof}}\rangle_A |0 \cdots 0\rangle_B \big) |t\rangle_C, \tag{1}$$

for register A the proof register, B the ancilla register, and C the clock register. This should be thought of as the quantum analogue of a Cook-Levin tableau, where the steps of the computation are now encoded in *superposition* over time t. While this basic idea is simple, the challenge lies in implementing it when restricted to certain local dimensions, clause/interaction localities, or interaction geometries. Progress for QSAT in particular has largely been difficult, since in contrast to the setting of LH, one does not have access to the tools of perturbation theory, which necessarily create Hamiltonians with frustrated ground spaces (i.e. empty nullspaces). Instead, QSAT hardness constructions must carefully stitch together rather involved gadgets to logically effect the history state idea above.

[13] In words, perturbation theory is only known to be able to show QMA-hardness for k-LH, as opposed to QMA_1-hardness for k-QSAT.

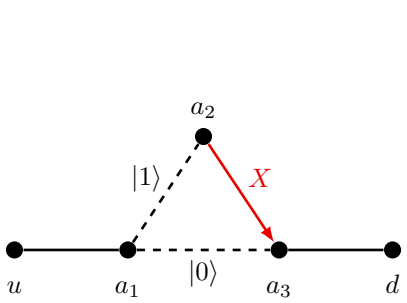
[14] For clarity, the simulations of [7, 13] reproduce the whole target Hamiltonian H, whereas our approach is weaker in that we prove simulation of only H's nullspace. A similar notion of simulation is discussed by Aharonov and Zhou [3], called *gap simulation*, where only the ground space is approximately simulated.

[15] The Schmidt rank is $\Theta(1)$, but we do not explicitly analyze it here.

To this end, we begin by discussing our approach for Theorem 1.1. We wish to encode local Hamiltonian constraints which force any potential null state to repeatedly update the current time in the clock register from t to $t+1$, along with applying the tth gate of U, as sketched above. However, even embedding a clock (never mind the full computation of U!) into the nullspace of a $(2\times d)$-Hamiltonian is non-trivial, as we only have qubit-systems at our disposal to act as "auxiliary particles" (as opposed to qutrits in [17]). Thus, our first challenge is to break this "qutrit barrier". We illustrate our techniques in a toy example.

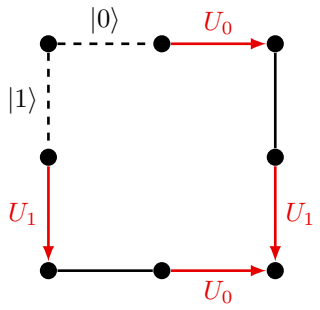
Our starting point is to embed a simple clock into the null-space of a (3×3)-Hamiltonian, and subsequently logically simulate this clock by pairing "indicator qubits" (i.e. qubit auxiliary particles) with 6-dimensional qudits as follows. It is straightforward to write down a (3×3)-Hamiltonian encoding the simple sequence of clock states (e.g. on 3 qutrits) $(|100\rangle, |200\rangle, |210\rangle, |220\rangle, |221\rangle, |222\rangle)$ in its nullspace, where note that only a single qutrit changes in each step. To break the "qutrit barrier", we thus now implement each qutrit in this clock *logically* in a larger space consisting of a 6-dimensional qudit and a triple of "indicator qubits". Formally, qutrit $|x\rangle \in \{|0\rangle, |1\rangle, |2\rangle\}$ is encoded via

$$|x\rangle \mapsto |x\rangle_\alpha |000\rangle_\beta + |x'\rangle_\alpha |0^x 10^{2-x}\rangle_\beta \quad \text{for } x \in \{0,1,2\} \text{ and } x' = x+3 \in \{3,4,5\}, \tag{2}$$



where α is 6-dimensional, and β consists of three qubits labelled $\beta_0, \beta_1, \beta_2$. To illustrate the idea behind this encoding, consider a projector that enforces equality (i.e. applies an identity gate) between the first two clock states (we also call this a $|100\rangle \leftrightarrow |200\rangle$ transition). In (3×3), we can use the projector onto $|10\rangle - |20\rangle$ (i.e. $\frac{1}{2}(|1\rangle - |2\rangle)(\langle 1| - \langle 2|) \otimes |0\rangle\langle 0|$) acting on the first two qutrits, where $|0\rangle\langle 0|$ on the second qutrit ensures that the projector only acts on the first two timesteps. Using our encoding, we can realize this transition with a (2×6)-projector onto $|11\rangle_{\alpha,\beta_0} - |21\rangle_{\alpha,\beta_0}$. This uses two features of the encoding: (1) a transition on a logical qutrit can be implemented with a 1-local projector on qudit α (here $\frac{1}{2}(|1\rangle - |2\rangle)(\langle 1| - \langle 2|)_\alpha$), and (2) a projection onto a standard basis state $|i\rangle \in \{|0\rangle, |1\rangle, |2\rangle\}$ of a logical qudit can be implemented with a 1-local projector onto an indicator qubit β_i (here $|1\rangle\langle 1|_{\beta_i}$).

This qutrit encoding (Equation (2)) generalizes to qudits of any dimension, and combined with the (3×5)-Hamiltonian of [17], gives QMA$_1$-hardness of (2×10)-QSAT. We can remove some unused indicator qubits to improve this to (2×7)-QSAT (see [40]) as the indicator requires an extra qudit dimension ($|x\rangle$ and $|x'\rangle$).[16]



Further improvement to (2×5)-QSAT requires much more work. In order to directly enforce the application of a gate $U_t \neq \mathbb{I}$ in a history state (Equation (1)) with a 2-local projector, we can only use a single qudit from the proof register and a single qudit from the clock register. Hence, we need to be able to project onto clock states with a 1-local qudit projector. For that, Eldar and Regev [17] introduce the notion of "*u*nborn", "*d*ead", and "*a*live" states, where non-trivial transitions only happen on the "alive" states, which uniquely identify a single timestep. Having separate "unborn" and "dead" states allows the clock states to have the general structure $d \cdots d\, a\, u \cdots u$, which is easy to enforce with 2-local constraints.[17] In fact, [17] uses three "alive states" a_1, a_2, a_3 to implement a CNOT gate via a "triangle gadget", which routes states with $|0\rangle$ and $|1\rangle$ in the control register along two different paths, only applying the X gate on the path of $|1\rangle$ (see Figure 1.1a).

[16] We need both and $|x\rangle_\alpha$ and $|x'\rangle_\alpha$ so that logical $|x\rangle$ and $|y\rangle$ differ only in a single qudit (on a subspace), which allows for a 1-local transition. Since the indicator qubits are "off" on $|x\rangle_\alpha$, we need a unique $|x'\rangle_\alpha$ to "turn on" the correct indicator via a transition.

[17] A natural question is if we can reduce the alphabet $\{a, u, d\}$ to a simpler binary alphabet $\{0, 1\}$, so that

(a) Effective implementation of a CNOT gate from u to d. Conditioned on a control bit being $|1\rangle$ (respectively $|0\rangle$), the gadget takes transition $|a_1\rangle \leftrightarrow |a_2\rangle$ (respectively $|a_1\rangle \leftrightarrow |a_3\rangle$). Only the former path applies the X gate (indicated by edge $|a_2\rangle \to |a_3\rangle$).

(b) In this case, when the control bit is $|0\rangle$ (respectively $|1\rangle$), U_1U_0 (respectively U_0U_1) is applied. A suitable choice of non-commuting U_0, U_1 implements CNOT (up to 1-local unitaries) from top left to bottom right. In contrast to the triangle gadget in (a), this gadget in (b) is only the "effective Hamiltonian" and the actual construction is more involved due to geometric limitations.

Figure 1.1 Graphical representation of the 2-local gate gadgets of (a) [17], and (b) [24] as well as this work. Vertices represent clock states, black (solid) edges identity transitions, red (directed) edges unitary transitions, dashed edges conditional identity transitions.

Gosset and Nagaj [24] (see Figure 1.1b) introduce the idea of a 2D-clock with two separate clock registers for the X- and Y-directions. Hence, clock states are vertices in a 2D-grid and therefore can realize separate paths while only requiring transitions between "adjacent" (in one dimension) clock states. The next idea of our construction is to implement this 2D-Hamiltonian of [24] using just two "alive" states in 2-QSAT (compared with three "alive" states in [17] for 2-QSAT; note [24] uses their 2D-clock for 3-QSAT). Figure 1.1b depicts the "effective Hamiltonian" leveraging this idea in order to implement a CNOT gate. Note Figure 1.1b is simplified; the actual implementation with 2-local projectors is significantly more involved (see full version [40]). This is due to complications which arise from geometric limitations: For example, we are not able to restrict the U_0 transition (Figure 1.1b) in the Y-direction (i.e. U_0 would be applied from $x = 2$ to $x = 3$ for all coordinates y).

To implement the ideas of the previous paragraph, we extract the 2D-Hamiltonian of [24] as a generic construction into which we can plug any clock satisfying certain requirements (see Theorem 3.1). Thereby we obtain QMA_1-hardness for (3×4)-QSAT. Then we simulate this (3×4)-clock on a (2×5)-system via the indicator qubit principle (similar to Equation (2)). Note that when implementing a logical 4-dit on a (2×5)-system, we can only use a single indicator qubit. Thus, we need a very carefully crafted (3×4)-clock, and further "technical tricks", which we omit in this introduction.

Finally, to analyze the 2D-Hamiltonian, we prove a novel technical lemma, which we dub the "Nullspace Connection Lemma" (Lemma 3.2). This enables us to split the 2D-Hamiltonian into smaller gadgets (see Figure 1.1b and [40] for the individual gadgets), each of which implements a small part of the history state and is relatively straightforward to analyze. The gadgets are then connected with additional transitions to form the complete Hamiltonian (see [40]), whose nullspace is spanned by superpositions of the gadget's history

clock states look like $\{|100\rangle, |010\rangle, |001\rangle\}$. Unfortunately, there is no set of 2-local projectors whose joint nullspace is the span of $\{|100\rangle, |010\rangle, |001\rangle\}$. The common unary encoding $|100\rangle, |110\rangle, |111\rangle$ cannot be used here because such states cannot be identified 1-locally.

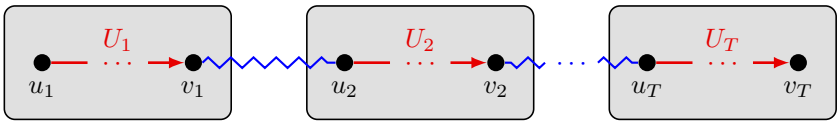


Figure 1.2 Nullspace Connection Lemma: Each box represents a gadget that only acts on a subset of clock states (vertices). Each gadget has an input vertex u_i, and an output vertex v_i. Its nullspace is spanned by history states applying gate U_i from u_i to v_i. Blue zigzag edges connect outputs v_i to inputs u_{i+1} with identity transitions. We show that the entire Hamiltonian has spectral gap $\Omega(1/N^2)$[18] and its nullspace is spanned by history states applying $U_T \cdots U_2 U_1$ from u_1 to v_T.

states. Figure 1.2 gives a visualization and informal statement of the lemma. The Connection Lemma is quite generic and can also be applied to, e.g., the original circuit Hamiltonian of Kitaev [30] (see Remark 3.3), matching the $\Omega(1/N^2)$ soundness (smallest non-zero eigenvalue) therein. Furthermore, the Connection Lemma is proven directly via the Geometric Lemma [30] and does not require transformation to the Laplacian matrix of a random walk, unlike [30]. Our main application of the Connection Lemma is to give a simplified proof for the 2D-Hamiltonian with improved soundness. Since the Connection Lemma requires modifications to the Hamiltonian of [24], we actually use our own variant of [24]'s gadget, which is slightly more compact (using $6M+1$ clock states as opposed to $9M+3$ for M gates). Finally, we do not rely on numerical methods to derive the nullspaces of the individual gadgets (*cf.* the gadget analysis of [24], which required numerics), and instead give a formal proof based on the theory of *unitary labeled graphs* [6]. The upshot is that our overall approach is very flexible – by combining unitary labelled graphs with the Connection Lemma, one can in principle analyze combinations of Hamiltonian gadgets beyond just our 2D setting with relative ease. Therefore, we believe the Connection Lemma will find uses in future works.

QMA$_1$*-hardness for* $(3\times d)$-QSAT *on the line.* As mentioned earlier, in contrast to the direct embedding for Theorem 1.1, for Theorem 1.4 we instead use a black-box simulation. In other words, we do not give a new circuit-to-Hamiltonian mapping, but instead bootstrap the prior QMA$_1$-completeness result of QSAT on a line of qu-d-its with $d = 11$ due to Nagaj [34]. Specifically, we construct a general embedding of *any* 1D-Hamiltonian H on a line of qudits into a Hamiltonian H' on an alternating line of qu-d'-its and qutrits. We then plug the [34] construction into this embedding. To design our embedding, each qu-d'-it is treated as two logical qu-d''-its with $d'' = \sqrt{d'}$ (see Figure 1.3; Figure 4.2 for technical details). We construct a Hamiltonian H'_{logical} that restricts the $(d''\times 3\times d'')$ systems to a d-dimensional subspace, which acts as a logical qu-d-it. This logical subspace has the key feature that, in a sense, the logical qu-d-it can be "accessed" from either its left or right qu-d''-it. This allows us to encode the 2-local terms of H as 1-local terms acting on the qu-d'-its of H'. The rough idea behind the logical subspace is to treat the $(d''\times 3\times d'')$ system as three bins capable of holding two types of balls (red and black) that are exchanged between the bins to move the information between the left and right qu-d''-it in each triple $(d''\times 3\times d'')$. When one d''-bin is full, the other d''-bin must be empty and the total number i of red balls encodes the basis state $|i/2\rangle$ of the corresponding logical qudit (Figure 4.1 depicts the balls and bins). To encode a d-dimensional system, this requires $O(d)$ red balls and $O(d)$ black balls, so that $d'' = \Theta(d^2)$, and thus $d' = \Theta(d^4)$.

[18] This gap is for gadgets of constant size, which suffice for our purposes. However, Lemma 3.2 is more general and even allows gadgets of non-constant size.

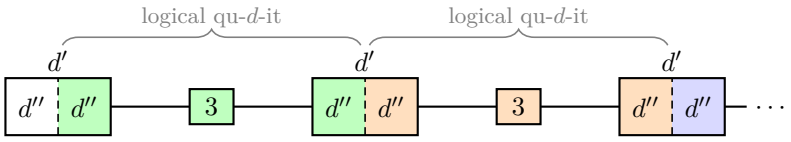

Figure 1.3 Simulation of $(d\times d)$-QSAT with $(3\times d')$-QSAT on the line. Qu-d'-its are split into two qu-d''-its with $d'' = \sqrt{d'}$. Each $(d''\times 3\times d'')$ system implements a logical qu-d-it.

As previously described, our embedding can be seen as a weaker notion of *simulation* in the sense of [7, 13], in that formally our embedding is achieved via application of *local isometries* (i.e. local observables are mapped to local observables), followed by additional constraints on the logical space (Equations (19a) and (19b)). However, in contrast to [7, 13], we do not analyze the structure of higher energy spaces of H', and only show that H' preserves the nullspace of H as well as its smallest non-zero eigenvalue, up to a linear factor (see Lemma 4.3), as this suffices for our purposes.

Open questions. Although we have shown that qubit systems can support QMA_1-hard problems, the frontier for characterizing the complexity transition of local Hamiltonian problems from low to high local dimension remains challenging. In our setting, in particular, the main open question is whether one can obtain QMA_1-hardness even for (2×3)-QSAT? This would complete the complexity characterization for $(d_A\times d_B)$-QSAT, as recall (2×2)-QSAT (i.e. 2-QSAT) is in P [8]. Getting this down to (2×3)-QSAT (even (3×3)-QSAT or (2×4)-QSAT), however, appears difficult, requiring ideas beyond those introduced here.

As for the 1D line, the best hardness results for 2-LH and 2-QSAT are on 8-dimensional [26] and 11-dimensional [34] systems, respectively. Is 1D 2-QSAT on qudits with $2 < d < 11$ QMA_1-hard? We showed that 1D $(3\times d)$-QSAT is QMA_1-hard, but due to our black-box approach we only get $d = 76176$. So it seems likely that this d can be improved significantly. Perhaps more interesting is the question whether 1D $(2\times d)$-QSAT is still QMA_1-hard. We showed that even 1D (2×4)-dimensional constraints can support a unique globally entangled ground state (Theorem 1.5), but this construction alone does not embed a computation, and thus does not yield QMA_1-hardness. Can this be bootstrapped to obtain QMA_1-hardness for 1D $(2\times d)$-QSAT? For 1D 2-LH, the situation is even worse – on qubits, these systems can only be efficiently solved in the presence of a constant spectral gap [32]. In contrast, for inverse polynomial gap, and even with the promise of an NP witness (i.e. via Matrix Product State), the problem is NP-complete [41]. What is the complexity of 1D 2-LH on qudits with $2 < d < 8$?

Organization. Section 2 gives formal definitions for QMA_1, $(d_A\times d_B)$-QSAT, and states the Geometric Lemma with various corollaries. Section 3 proves our main result, the QMA_1-completeness of (2×5)-QSAT. Section 4 proves the QMA_1-completeness of $(3\times d)$-QSAT on a line. Section 5 gives the construction of the (2×4)-Hamiltonian on a line with entangled ground space.

2 Preliminaries

In this section, we formally introduce QMA_1 and elaborate on the Geometric Lemma.

2.1 QMA$_1$

The complexity class QMA$_1$ is defined in the same way as QMA, but with the additional requirement of *perfect completeness*, i.e., in the YES-case, there exists a proof that the verifier accepts with a probability of exactly 1. Consequently, QMA$_1$ is not known to be independent of the gate set [24], as approximate decompositions of arbitrary unitaries generally breaks perfect completeness. Therefore, we have to fix a gate set before we define QMA$_1$, and here we follow [24] in choosing the "Clifford + T" gate set $\mathcal{G} = \{\widehat{H}, T, \mathrm{CNOT}\}$, where $\widehat{H}$ denotes the Hadamard gate. Giles and Selinger [23] have proven that a unitary can be synthesized exactly with gate set $\mathcal{G}$ iff its entries are in the ring $\mathbb{Z}[\frac{1}{\sqrt{2}}, i]$.

▶ **Definition 2.1** (QMA$_1$). *A promise problem $A = (A_{\mathrm{yes}}, A_{\mathrm{no}})$ is in* QMA$_1$ *if there exists a poly-time uniform family of quantum circuits $\{Q_x\}$ with gate set $\mathcal{G}$ such that:*

- *(Completeness) If $x \in A_{\mathrm{yes}}$, then there exists a proof $|\psi\rangle$ with $\Pr[Q_x \text{ accepts } |\psi\rangle] = 1$.*
- *(Soundness) If $x \in A_{\mathrm{no}}$, then then for all proofs $|\psi\rangle$, $\Pr[Q_x \text{ accepts } |\psi\rangle] \leq 1 - 1/\operatorname{poly}(|x|)$.*

▶ **Definition 2.2** ($(d_A \times d_B)$-QSAT). *Consider a system of d_A- and d_B-dimensional particles, denoted $A_i, i \in [n_A]$ and $B_j, j \in [n_B]$, respectively. In the* $(d_A \times d_B)$-QSAT *problem, the input is a $(d_A \times d_B)$-Hamiltonian $H = \sum_{i \in [n_A], j \in [n_B]} \Pi_{A_i, B_j}$ with 2-local projectors Π_{A_i, B_j} acting non-trivially only on particles A_i and B_j. Decide:*

- *(YES) $\lambda_{\min}(H) = 0$.*
- *(NO) $\lambda_{\min}(H) \geq 1/\operatorname{poly}(n_A + n_B)$.*

Note that the projectors of $(d_A \times d_B)$-QSAT need to have a specific form such that the problem is contained in QMA$_1$ with our chosen gate set (see Section 3.4).

2.2 Geometric Lemma

In our proofs, we frequently apply Kitaev's Geometric Lemma [30] as well as its extension to the frustration-free case due to Gosset and Nagaj [24], where we are interested in lower-bounding the smallest non-zero eigenvalue of a Hamiltonian H, denoted $\gamma(H)$. In the following, we also give further refinements of these statements. As in [24], we use the notation $H|_S = \Pi_S H \Pi_S$ for the restriction of the Hamiltonian H to the subspace S, where Π_S is the projector onto S.[19] $\mathcal{N}(H)$ denotes the nullspace of H.

▶ **Lemma 2.3** (Kitaev's Geometric Lemma [30] as stated in [24]). *Let $H = H_A + H_B$ with $H_A \succeq 0$ and $H_B \succeq 0$. Let $S = \mathcal{N}(H_A)$ and Π_B be the projector onto $\mathcal{N}(H_B)$. Suppose $\mathcal{N}(H) = \{0\}$. Then $\gamma(H) \geq \min\{\gamma(H_A), \gamma(H_B)\} \cdot (1 - \sqrt{c})$, where $c = \max_{|v\rangle \in S : \langle v|v\rangle = 1} \langle v|\Pi_B|v\rangle$.*

▶ **Corollary 2.4** ([24, Corollary 1]). *Let $H = H_A + H_B$ where $H_A \succeq 0$ and $H_B \succeq 0$ each have nonempty nullspaces. Let Γ be the subspace of states in $\mathcal{N}(H_A)$ that are orthogonal to $\mathcal{N}(H)$, and let Π_B be the projector onto $\mathcal{N}(H_B)$. Then $\gamma(H) \geq \min\{\gamma(H_A), \gamma(H_B)\} \cdot (1 - \sqrt{d})$, where $d = \|\Pi_B|_\Gamma\| = \max_{|v\rangle \in \Gamma : \langle v|v\rangle = 1} \langle v|\Pi_B|v\rangle$.*

We give a slightly tighter statement of [24, Corollary 2][20]:

▶ **Corollary 2.5.** *Let $H = H_A + H_B$ where $H_A \succeq 0$ and $H_B \succeq 0$ each have nonempty nullspaces. Let $S = \mathcal{N}(H_A)$ and suppose $H_B|_S$ is not the zero matrix. Then*

$$\gamma(H) \geq \min\{\gamma(H_A), \gamma(H_B)\} \cdot \frac{\gamma(H_B|_S)}{2\|H_B|_S\|}. \tag{3}$$

[19] Note, this is not the standard restriction of linear map to a subspace since H does not necessarily map S to itself.

[20] The only difference is that we have $\|H_B|_S\|$ instead of $\|H_B\|$ in the denominator.

Proof. As stated in [24], $\gamma(H_B|_S) = \min_{v\in\Gamma:\langle v|v\rangle=1}\langle v|H_B|v\rangle$ with Γ as defined in Corollary 2.4. Hence for all unit $|v\rangle \in \Gamma \subseteq S$,

$$\gamma(H_B|_S) \leq \langle v|H_B|v\rangle \leq \langle v|(\mathbb{I}-\Pi_B)|v\rangle\|H_B|_S\| \tag{4}$$

and thus $d \leq 1-\gamma(H_B|_S)/\|H_B|_S\|$. The statement then follows from $1-\sqrt{1-x} \geq \frac{x}{2}$ for $x \in [0,1]$. ◀

▶ **Corollary 2.6.** *Let $H = H_A + H_B$ where $H_A \succeq 0$ and $H_B \succeq 0$ each have nonempty nullspaces. Let $S = \mathcal{N}(H_A)$ and suppose $H_B|_S$ is not the zero matrix. Then*

$$\gamma(H) \geq \min\{\gamma(H_A),\gamma(H_B)\} \cdot \min_{|v\rangle\in\Gamma:\langle v|v\rangle=1} \langle v|(\mathbb{I}-\Pi_B)|v\rangle/2. \tag{5}$$

Proof. Follows from Corollary 2.4 and the fact $1-\sqrt{1-x} \geq \frac{x}{2}$ for $x \in [0,1]$. ◀

▶ **Corollary 2.7.** *Let $H_A \succeq 0, H_B \succeq 0$ be Hamiltonians with $\mathcal{N}(H_A) \subseteq \mathcal{N}(H_B)$. Then $\gamma(H_A+H_B) \geq \min\{\gamma(H_A),\gamma(H_B)\}$.*

Proof. In Corollary 2.4, we have $\Gamma = \mathcal{N}(H_A)\cap\mathcal{N}(H_A+H_B)^\perp = \mathcal{N}(H_A)\cap\mathcal{N}(H_A)^\perp = \{0\}$. Thus $d = \|\Pi_B|_\Gamma\| = 0$ and $\gamma(H_A+H_B) \geq \min\{\gamma(H_A),\gamma(H_B)\}$. ◀

3 (2×5)-QSAT is QMA$_1$-complete

Our proof mainly leverages the 2D-Hamiltonian construction of Gosset and Nagaj [24], which gives a circuit-to-Hamiltonian embedding with a set of "simple" projectors that are constructed from a suitable clock encoding. In Section 3.2, we give the main technical tool which we use to analyze the soundness of the aforementioned Hamiltonian, and in Section 3.3 we give our clock construction for (2×5)-QSAT.

3.1 2D-Hamiltonian

The following theorem extracts the 2D-Hamiltonian construction central to [24] so that we can use it in conjunction with our own clock construction. In the full version [40], we give a complete proof with a simplified Hamiltonian construction and improved analysis that gives soundness $\Omega(\gamma(H^{(N)}_{\text{clock}})/N^2)$, as opposed to $\Omega(\gamma(H^{(N)}_{\text{clock}})/N^6)$ from [24]. Our proof is fully analytic, improving on the partially numeric analysis of [24].

Note, our construction is structurally almost the same as [24], which would also work in conjunction with our clock (see Section 3.3), requiring only a slight modification to the H_{init} and H_{end} terms. However, the application of Lemma 3.2 (necessary for improved soundness) to their Hamiltonian is not as straightforward because there is no separate gadget for 1-local gates. So, our contribution to the following theorem are a simplified proof and improved soundness bounds. The intuition of the construction is given in the introduction.

▶ **Theorem 3.1.** *Suppose we are given Hamiltonian terms as follows:*

(1) *Clock Hamiltonian $H^{(N)}_{\text{clock}}$ acting on Hilbert space $\mathcal{H}_{\text{clock}}$ with nullspace $\mathcal{N}(H^{(N)}_{\text{clock}}) = \text{Span}\{|C_1\rangle,\ldots,|C_n\rangle\} =: \mathcal{C}$ for* clock states *$|C_i\rangle$.*

(2) *Projectors $h_{i,i+1}(U)$ acting on $\mathcal{H}_{\text{comp}}\otimes\mathcal{H}_{\text{clock}}$, where U is a unitary acting on $\mathcal{H}_{\text{comp}}$, such that*

$$\begin{aligned}\left(\mathbb{I}\otimes\Pi^{(N)}_{\text{clock}}\right) h_{i,i+1}(U) \left(\mathbb{I}\otimes\Pi^{(N)}_{\text{clock}}\right) = c_1\big((\mathbb{I}\otimes|C_i\rangle\langle C_i| + \mathbb{I}\otimes|C_{i+1}\rangle\langle C_{i+1}|)\\ -(U^\dagger\otimes|C_i\rangle\langle C_{i+1}| + U\otimes|C_{i+1}\rangle\langle C_i|)\big)\end{aligned} \tag{6}$$

for constant[21] *c_1. We write $h_{i,i+1} := h_{i,i+1}(\mathbb{I})$.*

[21] It suffices for our purposes to have the same c for all i. In principle, however, one can also allow different

(3) *Projectors $C_{\geq i}, C_{\leq i}$ acting on $\mathcal{H}_{\text{clock}}$ such that*

$$\Pi^{(N)}_{\text{clock}} C_{\geq i} \Pi^{(N)}_{\text{clock}} = \sum_{j=i}^{N} c_{2,i,j} |C_j\rangle\langle C_j|, \qquad \Pi^{(N)}_{\text{clock}} C_{\leq i} \Pi^{(N)}_{\text{clock}} = \sum_{j=1}^{i} c_{3,i,j} |C_j\rangle\langle C_j|, \tag{7}$$

and $c_{2,i,j}, c_{3,i,j} \geq c_2$ for all $i, j \in [N]$ for some constant c_2.

(4) *All above projectors $(h_{i,i+1}(U), C_{\geq i}, C_{\leq i})$ pairwise commute, besides $h_{i,i+1}(U)$ and $h_{i,i+1}(U')$ for non-commuting U, U'. For all $i \neq j$, $h_{i,i+1}(U) h_{j,j+1}(U') = 0$.*

(5) *If $\Pi_1, \ldots, \Pi_k$ are projectors of the form $C_{\leq i}, C_{\geq i}$, then $\langle C_{j_1}|\Pi_1 \cdots \Pi_k|C_{j_2}\rangle = 0$ for $j_1 \neq j_2$.*

Then any problem in QMA$_1$ *can be reduced to* QSAT *restricted to Hamiltonians H acting on $\mathcal{H}_{\text{comp}} \otimes \mathcal{H}_{\text{clock},1} \otimes \mathcal{H}_{\text{clock},2}$ (operators acting on these spaces are labeled with subscripts Z, X, Y respectively) with terms $(H^{(N)}_{\text{clock}})_X$, $(H^{(N)}_{\text{clock}})_Y$, $\Pi_Z \otimes (h_{i,i+1})_A$, $(C_{\sim j})_A \otimes (h_{i,i+1})_B$, $(h_{i,i+1}(U))_{Z,A}$, $(C_{\leq i})_A \otimes (C_{\geq j})_B$, where $A, B \in \{X, Y\}, A \neq B$, $\sim \in \{\leq, \geq\}$[22], $i, j \in [N]$, $\Pi_Z \in \{|0\rangle\langle 0|, |1\rangle\langle 1|\}$ is a single-qubit projector acting on $\mathcal{H}_{\text{comp}}$, and U is either a 1-local gate from the* QMA$_1$ *circuit or $U \in \{\sigma^Z, B\}$ with $B = \frac{1}{\sqrt{2}}\left(\begin{smallmatrix} 1 & i \\ i & 1 \end{smallmatrix}\right)$, $\sigma^Z = \left(\begin{smallmatrix} 1 & 0 \\ 0 & -1 \end{smallmatrix}\right)$. The soundness is $\Omega(\gamma(H^{(N)}_{\text{clock}})/N^2)$, where $N = \Theta(g)$ and g is the number of gates used by the* QMA$_1$ *verifier.*

Proof. A rough intuition is given in Section 1 and the formal proof in the full version [40]. ◀

Note, this theorem is not explicitly stated in [24], but is implicitly proven, albeit with a soundness of $\Omega(\gamma(H^{(N)}_{\text{clock}}/N^6))$. Thus, as an immediate first consequence we can (using the clock Hamiltonian of [24]) recover QMA$_1$-hardness of 3-QSAT, but with improved soundness:

▶ **Theorem 1.3.** 3-QSAT *is* QMA$_1$*-complete with soundness $\Omega(1/N^2)$.*

Unfortunately its generality makes Theorem 3.1 somewhat difficult to parse. Hence, we sketch its application to the clock of Kitaev's circuit Hamiltonian [30] as a toy example:

(1) Clock states are given by $|C_i\rangle = |1^i 0^{N-i}\rangle$ with $H_{\text{clock}} = \sum_{i=1}^{N-1} |01\rangle\langle 01|_{i,i+1} + |0\rangle\langle 0|_1$.

(2) $h_{i,i+1}(U)$ essentially applies the gate U from timestep $|C_i\rangle$ to $|C_{i+1}\rangle$. Define for $i \in [N-1]$, $h_{i,i+1}(U) = (\mathbb{I} \otimes |100\rangle\langle 100|_{i,i+1,i+2} + \mathbb{I} \otimes |110\rangle\langle 110|) - (U^\dagger \otimes |100\rangle\langle 110| + U \otimes |110\rangle\langle 100|)$. Equation (6) can easily be verified with $c_1 = 1$. In our actual construction we get $c_1 < 1$ because the clock states are superpositions of multiple standard basis states, of which $h_{i,i+1}$ only acts on one (see Section 3.3).

(3) $C_{\leq i}, C_{\geq i}$ just project onto timesteps $\leq i$ or $\geq i$. Define $C_{\leq i} = |0\rangle\langle 0|_{i-1}$ and $C_{\geq i} = |1\rangle\langle 1|_i$. Equation (7) can easily be verified with $c_2 = 1$.

(4) and **(5)** are only used to prove the soundness lower bound and may be dropped, decreasing soundness by a polynomial factor.

Thus, Theorem 3.1 gives QMA$_1$-completeness of 4-QSAT when applied to Kitaev's unary clock.

3.2 Nullspace Connection Lemma

Abstractly, the 2D-Hamiltonian consists of a sequence of gadgets connected together via the blue zigzag edges, as depicted in Figure 1.2. If we remove the zigzag edges, we can analyze the nullspace and gap of the Hamiltonian easily, as gadgets have only constant size and act on orthogonal clock spaces. One can show that the nullspace of each gadget is spanned by history states on the local clock spaces. The "Nullspace Connection Lemma" below then argues that these local history states can be connected via the zigzag edges.

---

constants depending on the choice of index i.

[22] Here we use "$\sim$" as a placeholder for a relation "$\leq$" or "$\geq$".

Our statement is quite general, so that Lemma 3.2 can be applied more broadly. Due to the decomposition into the local gadgets acting on disjoint sets of clock states, one only needs to compute the nullspaces of constant-size gadgets before applying Lemma 3.2. See Remark 3.3 for an application to Kitaev's circuit Hamiltonian. For instance, Rudolph uses Lemma 3.2 to prove correctness of various circuit-to-Hamiltonian embeddings [39] and computes the gadget nullspaces algebraically. In the full version of this work, we compute nullspaces of the 2D-Hamiltonian gadgets via the theory of Unitary Labelled Graphs [6].

▶ **Lemma 3.2** ("Nullspace Connection Lemma"). *Let*

(1) $K = K_1 \cup \ldots \cup K_m = [N]$ *be a disjoint partition of the indices of* N *clock states with* $u_i, v_i \in K_i, u_i \neq v_i$ *for all* $i \in [m]$.

(2) $H_1 = \sum_{i=1}^{m} H_{1,i}$ *be a Hamiltonian on ancilla space* A *and clock space* C*, such that for all* $i \in [m]$*:*

- **(a)** $\mathcal{N}(H_{1,i}|_{\mathcal{K}_i}) = \mathrm{Span}\{|\psi_i(\alpha_j)\rangle \mid j \in [d]\}$*, where* $\mathcal{K}_i = \mathbb{C}^d_A \otimes \mathrm{Span}\{|v\rangle_C \mid v \in K_i\}$*, and* $|\alpha_1\rangle, \ldots, |\alpha_d\rangle$ *is an orthonormal basis of the ancilla space,*
- **(b)** *the local history states* $|\psi_i(\alpha)\rangle$ *are linear in the input* $|\alpha\rangle$*, i.e., there exists a linear map* L_i *with* $L_i|\alpha\rangle = |\psi_i(\alpha)\rangle$ *and* $L_i^\dagger L_i = \lambda_i \mathbb{I}$ *for some constant* λ_i*,*
- **(c)** H_i *has support only on clock space* $\mathcal{K}_i$*,*
- **(d)** $\||\psi_i(\alpha)\rangle\|^2 =: \delta_i \in [1, \Delta]$*,*
- **(e)** $(\mathbb{I}_A \otimes \langle u_i|_C)|\psi_i(\alpha)\rangle = |\alpha\rangle_A$*,*
- **(f)** $(\mathbb{I}_A \otimes \langle v_i|_C)|\psi_i(\alpha)\rangle = U_i|\alpha\rangle_A$ *for some unitary* U_i*.*

(3) $H_2 = \sum_{i=1}^{m-1} h_{v_i,u_{i+1}}(V_i)$ *with* $h_{v_i,u_{i+1}}(V_i) = \mathbb{I}\otimes|v_i\rangle\langle v_i| + \mathbb{I}\otimes|u_{i+1}\rangle\langle u_{i+1}| - V_i^\dagger \otimes |v_i\rangle\langle u_{i+1}| - V_i \otimes |u_{i+1}\rangle\langle v_i|$ *for unitaries* V_i*.*

(4) $|\alpha_{ij}\rangle = V_{i-1}U_{i-1}\cdots V_1U_1|\alpha_j\rangle$*.*

Then for $H = H_1 + H_2$*,* $\mathcal{N}(H) = \mathrm{Span}\{\sum_{i=1}^{m}|\psi_i(\alpha_{ij})\rangle \mid j \in [d]\}$*,* $\gamma(H) = \Omega(\gamma(H_1)/(m^2\Delta))$*.*

Prior to the proof, let us briefly give an intuitive explanation of the parts. (1) just gives a decomposition of the indices of clock states into disjoint components K_i. One can think of these as a generalization of timesteps to a graph, like in the Unitary Labelled Graphs [6]. (2) is the Hamiltonian corresponding to the unitary gadgets without the connection (zigzag) edges. (a) says that the i-th gadget should apply gate U_i, such that it has a "local history state" from input (e) to output (f). The local history state is linear in the "input state" (b). (c) requires the gadgets to only act on their clock states K_i and thus commute. (d) constrains the norm of history states, which is used to compute the gap. (3) is the Hamiltonian corresponding to the connection edges. (4) describes the input states to each gadget.

Proof. Since the $H_{1,i}$ Hamiltonians act on different clock spaces, they commute and it holds $S := \mathcal{N}(H_1) = \mathrm{Span}\{|\psi_i(\alpha_j)\rangle \mid i \in [m], j \in [d]\}$. Next, we derive $\mathcal{N}(H) = S \cap \mathcal{N}(H_2)$. Partition S into orthogonal subspaces $S_1, \ldots, S_d$, where $S_j = \mathrm{Span}\{|\psi_i(\alpha_{ij})\rangle \mid i \in [m]\}$. Orthogonality holds because $\langle\psi_i(\alpha)|\psi_i(\alpha')\rangle = \langle\alpha|L_i^\dagger L_i|\alpha'\rangle = \lambda_i\langle\alpha|\alpha'\rangle$, and $|\psi_i(\alpha)\rangle \in \mathcal{K}_i$, where $\mathcal{K}_i \subseteq \mathcal{K}_{i'}^\perp$ for $i \neq i'$. As H_2 is block diagonal across $S_1, \ldots, S_d$, it suffices to consider the $\mathcal{N}(H_2|_{S_j})$ individually.

Let $|\psi\rangle = \sum_{i=1}^{m} a_i|\psi_i(\alpha_{ij})\rangle \in S_j$. Then $\langle\psi|H|\psi\rangle = \langle\psi|H_2|\psi\rangle = \sum_{i=1}^{m-1}\langle\psi|h_{v_i,u_{i+1}}(V_i)|\psi\rangle$ with

$$\begin{aligned} h_{v_i,u_{i+1}}(V_i)|\psi\rangle &= a_iU_i|\alpha_{ij}\rangle|v_i\rangle + a_{i+1}|\alpha_{i+1,j}\rangle|u_{i+1}\rangle - a_{i+1}V_i^\dagger|\alpha_{i+1,j}\rangle|v_i\rangle - a_iV_iU_i|\alpha_{ij}\rangle|u_{i+1}\rangle \\ &= a_iU_i|\alpha_{ij}\rangle|v_i\rangle + a_{i+1}|\alpha_{i+1,j}\rangle|u_{i+1}\rangle - a_{i+1}U_i|\alpha_{ij}\rangle|v_i\rangle - a_i|\alpha_{i+1,j}\rangle|u_{i+1}\rangle. \end{aligned}$$

Thus, $\langle\psi|h_{v_i,u_{i+1}}(V_i)|\psi\rangle = a_i^*a_i + a_{i+1}^*a_{i+1} - a_i^*a_{i+1} - a_{i+1}^*a_i = |a_i - a_{i+1}|^2$ and $\mathcal{N}(H_2|_{S_j}) = \mathrm{Span}\{\sum_{i=1}^{m}|\psi_i(\alpha_{ij})\rangle\}$.

Figure 3.1 Applying the Nullspace Connection Lemma to Kitaev's circuit Hamiltonian.

Next, we apply Corollary 2.5 to show $\gamma(H) \geq \min\{\gamma(H_1), \gamma(H_2)\} \cdot \gamma(H_2|_S)/(2\|H_2\|)$. The terms $\|H_2\|, \gamma(H_2)$ are constant as the $h_{v_i,u_{i+1}}$ projectors act on distinct clock states. Hence, $\gamma(H) = \Omega(\gamma(H_1)\gamma(H_2|_S))$. Since $H_2|_S$ is block diagonal, we have $\gamma(H_2|_S) \geq \min_{j\in[d]} \gamma(H_2|_{S_j})$, where $\gamma(H_2|_{S_j}) = \min_{|v\rangle\in\Gamma_j:\langle v|v\rangle=1} \langle v|H_2|v\rangle$ and $\Gamma_j = S_j \cap \mathcal{N}(H)^\perp$.

Let $|\psi\rangle = \sum_{i=1}^m a_i|\psi_i(\alpha_{ij})\rangle \in \Gamma_j, \langle\psi|\psi\rangle = 1$ and $|\phi\rangle = \sum_{i=1}^m |\psi_i(\alpha_{ij})\rangle \in \mathcal{N}(H)$. Then $0 = \langle\phi|\psi\rangle = \sum_{i=1}^m a_i\delta_i$ and $\langle\psi|H_2|\psi\rangle = \sum_{i=1}^{m-1} |a_i - a_{i+1}|^2 \geq (\sum_{i=1}^{m-1} |a_i - a_{i+1}|)^2/m$. Also, there exists an l such that $|a_l|^2\delta_l \geq 1/m$. Via a global rotation, we may assume without loss of generality $a_l > 0$. Since $\sum_{i=1}^m a_i\delta_i = 0$, there must exist k with $\Re(a_k) < 0$. Thus $|a_l - a_k| = |a_l\delta_l - a_k\delta_l|/\delta_l > |a_l\delta_l|/\delta_l \geq 1/\sqrt{m\Delta}$. By the triangle inequality, $\langle\psi|H_2|\psi\rangle \geq 1/(m^2\Delta)$. ◀

▶ Remark 3.3. The Nullspace Connection Lemma can also used to prove correctness of Kitaev's original circuit-to-Hamiltonian construction [30] directly without transforming H_{prop} to a random walk. Recall $H_{\text{prop}} = \sum_{j=2}^N H^j_{\text{prop}}$ with

$$H^j_{\text{prop}} = -\frac{1}{2}(U_j)_A \otimes |j\rangle\langle j-1|_C - \frac{1}{2}(U_j^\dagger)_A \otimes +\frac{1}{2}I_A \otimes (|j\rangle\langle j| + |j-1\rangle\langle j-1|)_C,$$

where A denotes the ancilla space where the computation takes place, and C the clock space. Assume that $U_j = \mathbb{I}$ for even j. Figure 3.1 then depicts H_{prop} for $N = 7$. The graph is only a line since H_{prop} uses an ordinary (single) clock. To apply Lemma 3.2, let $K_1 = \{0, 1\}, K_2 = \{2, 3\}, K_3 = \{4, 5\}, K_4 = \{6, 7\}$, $H_1 = \sum_{j\in\{1,3,5,7\}} H^j_{\text{prop}}$ (red edges in Figure 3.1), and $H_2 = \sum_{j\in\{2,4,6\}} H^j_{\text{prop}}$ (blue zigzag edges in Figure 3.1). It is now easy to verify that all the conditions of Lemma 3.2 are satisfied: For example, $\mathcal{N}(H^1_{\text{prop}}|_{\mathcal{K}_1}) = \text{Span}\{|\psi_1(\alpha_j)\rangle \mid j \in [d]\}$, for $|\psi_1(\alpha_j)\rangle = |\alpha_j\rangle_A|0\rangle_C + U_1|\alpha_j\rangle_A|1\rangle_C$. It follows that $\mathcal{N}(H_{\text{prop}}) = \text{Span}\{|\psi_{\text{hist}}(\alpha_j)\rangle \mid j \in [d]\}$, where $|\psi_{\text{hist}}(\alpha)\rangle = \sum_{i=0}^N U_i \cdots U_1|\alpha\rangle|i\rangle_C$.

The Hamiltonian H_{in} is then used to restrict the ancilla space to $|0\rangle$ on timestep 0, so that $\mathcal{N}(H_{\text{in}} + H_{\text{prop}}) = \text{Span}\{|\psi_{\text{hist}}(0)\rangle\}$.

3.3 Clock Hamiltonian

In this section, we define the clock to prove the QMA$_1$-completeness of (2×5)-QSAT (Theorem 1.1) and (4×3)-QSAT (Theorem 1.2) using Theorem 3.1. The main difficulty was the construction of a suitable clock for Theorem 3.1 using just (2×5)-projectors. The hardness of (3×4)-QSAT is obtained almost for free as part of the proof. Since our construction may seem somewhat arbitrary, we give an intuition in the appendix of [40] by sketching a proof for the QMA$_1$-hardness of (2×7)-QSAT.

We begin by defining several logical states. A 5-dit (whose standard basis states are labeled u, a_1, a_2, d, u') and a qubit are combined to construct a logical 4-dit (labeled $\mathbf{U}, \mathbf{A}_1, \mathbf{A}_2, \mathbf{D}$), as shown on the left of Equation (8) (normalization factors omitted). A 5-dit (labeled u, a, d, x, d') and two qubits are combined to construct a logical qutrit (labeled $\mathbf{u}, \mathbf{a}, \mathbf{d}$), as shown on the right of Equation (8). The labels u, a, d maybe be interpreted as "unborn", "alive", and "dead", respectively, following the convention of [1, 8, 17].

$$\begin{aligned} |\mathbf{U}\rangle &= |u,0\rangle + |u',1\rangle & |\mathbf{u}\rangle &= |u,1,0\rangle + |x,0,0\rangle \\ |\mathbf{A}_1\rangle &= |a_1,0\rangle & |\mathbf{a}\rangle &= |a,0,0\rangle + |x,1,0\rangle \\ |\mathbf{A}_2\rangle &= |a_2,0\rangle & |\mathbf{d}\rangle &= |d,0,0\rangle + |d',0,1\rangle \\ |\mathbf{D}\rangle &= |d,0\rangle \end{aligned} \tag{8}$$

▶ **Lemma 3.4.** *There exist 2-local Hamiltonians $H_{\text{logical}_4}, H_{\text{logical}_3}$ of $(2,5)$-projectors with $\mathcal{N}(H_{\text{logical}_4}) = \text{Span}\{|\mathbf{U}\rangle, |\mathbf{A}_1\rangle, |\mathbf{A}_2\rangle, |\mathbf{D}\rangle\}$ and $\mathcal{N}(H_{\text{logical}_4}) = \text{Span}\{|\mathbf{U}\rangle, |\mathbf{A}_1\rangle, |\mathbf{A}_2\rangle, |\mathbf{D}\rangle\}$.*

Proof. In the full version [40]. ◀

The main "feature" of these logical qudits is the fact that a 1-local qubit projector suffices to identify the states $|\mathbf{U}\rangle$, $|\mathbf{d}\rangle$, "$|\mathbf{u}\rangle$ or $|\mathbf{a}\rangle$" (e.g. $|u\rangle\langle u|$), and implement a transition between $|\mathbf{u}\rangle, |\mathbf{a}\rangle$ as $(|0\rangle - |1\rangle)(\langle 0| - \langle 1|)$ (assuming $|\mathbf{d}\rangle$ is already penalized by another projector).

We make use of these properties in the definition of the *clock states* $|C_i\rangle =: |C_{i,1}\rangle + |C_{i,2}\rangle + |C_{i,3}\rangle + |C_{i,4}\rangle$ for $i \in [N]$, where the states $|C_{i,j}\rangle$ are defined as follows:

$$|C_{i,1}\rangle = |\mathbf{dD}\rangle^{\otimes i-2} \otimes |\mathbf{dA}_2, \mathbf{uU}\rangle \otimes |\mathbf{uU}\rangle^{\otimes N-i} \tag{9a}$$
$$|C_{i,2}\rangle = |\mathbf{dD}\rangle^{\otimes i-2} \otimes |\mathbf{dD}, \mathbf{aU}\rangle \otimes |\mathbf{uU}\rangle^{\otimes N-i} \tag{9b}$$
$$|C_{i,3}\rangle = |\mathbf{dD}\rangle^{\otimes i-2} \otimes |\mathbf{dD}, \mathbf{dU}\rangle \otimes |\mathbf{uU}\rangle^{\otimes N-i} \tag{9c}$$
$$|C_{i,4}\rangle = |\mathbf{dD}\rangle^{\otimes i-2} \otimes |\mathbf{dD}, \mathbf{dA}_1\rangle \otimes |\mathbf{uU}\rangle^{\otimes N-i} \tag{9d}$$

Here, the qudits of the clock register are subdivided into groups of five, where the first three (labeled α, β, γ) represent a logical qutrit and the the last two (labeled δ, ε) represent a logical 4-qudit (e.g. the i-th group of (9d) is $|\mathbf{dA}_1\rangle$). With these clock states, a 1-local transition from $|\mathbf{A}_1\rangle$ of $|C_{i,4}\rangle$ to $|\mathbf{A}_2\rangle$ of $|C_{i+1,1}\rangle$ can be implemented on a single 5-dit: $(|a_1\rangle - |a_2\rangle)(\langle a_1| - \langle a_2|)_{\delta_i}|_{\mathcal{C}} = \Omega(1) \cdot (|C_i\rangle - |C_{i+1}\rangle)(\langle C_i| - \langle C_{i+1}|)$ with $\mathcal{C}$ as below.

▶ **Lemma 3.5.** *$\mathcal{N}(H_{\text{clock}}) = \text{Span}\{|C_1\rangle, \ldots, |C_N\rangle\} =: \mathcal{C}$ and $\gamma(H_{\text{clock}}) = 1$.*

Proof sketch. The first step is to enforce the "logical space" using the Hamiltonian $H_{\text{logical}} = \sum_{i=0}^{N-1} \left((H_{\text{logical}_3})_{\alpha_i\beta_i\gamma_i} + (H_{\text{logical}_4})_{\delta_i\varepsilon_i} \right)$. Next, enforce valid clock states using the following Hamiltonian, where the annotations on the left explains the function of each projector.

$$\mathbf{U} \text{ implies } \mathbf{u} \text{ to the right:} \qquad H_{\text{clock},1} = \sum_{i=1}^{N-1} \sum_{v \in \{a,d\}} |1,v\rangle\langle 1,v|_{\varepsilon_i\alpha_{i+1}} \tag{10a}$$
$$\mathbf{d} \text{ implies } \mathbf{d} \text{ to the left:} \qquad + \sum_{i=1}^{N-1} |1,d\rangle\langle 1,d|_{\beta_i\alpha_{i+1}} \tag{10b}$$
$$\mathbf{d} \text{ implies } \mathbf{D} \text{ to the left:} \qquad + \sum_{i=1}^{N-1} \sum_{v \in \{u,a_1,a_2\}} |v,1\rangle\langle v,1|_{\varepsilon_i\gamma_{i+1}} \tag{10c}$$
$$\mathbf{u}, \mathbf{a} \text{ implies } \mathbf{U} \text{ to the right:} \qquad + \sum_{i=1}^{N} \sum_{v \in \{a_1,a_2,d\}} |1,v\rangle\langle 1,v|_{\beta_i\delta_i} \tag{10d}$$
$$\mathbf{U} \text{ or } \mathbf{A}_1 \text{ is last:} \qquad + |a_2\rangle\langle a_2|_{\delta_N} + |d\rangle\langle d|_{\delta_N} \tag{10e}$$

We then have $\mathcal{N}(H_{\text{logical}} + H_{\text{clock},1}) = \text{Span}(\{|C_{i,j}\rangle \mid i \in [N], j \in [4]\} \cup \{|E_{i,j}\rangle \mid i \in \{2,\ldots,N\}, j \in [4]\})$, where the $|E_{i,j}\rangle$ are similar to the $|C_{i,j}\rangle$ but with $|\mathbf{dA}_1, \mathbf{aU}\rangle$, $|\mathbf{dA}_2, \mathbf{aU}\rangle$, $|\mathbf{dD}, \mathbf{uU}\rangle$ in the middle. The $|E_{i,j}\rangle$ are still in the nullspace because $H_{\text{clock},1}$ cannot yet

penalize all logical states that are not valid clock states. Next, we construct $H_{\text{clock},2} = \sum_{i=1}^{N} H_{\text{clock},2,i}$ to enforce the superposition $|C_{i,1}\rangle + \cdots + |C_{i,4}\rangle$, and also penalize the $|E_{i,j}\rangle$ using a similar argument to the *clairvoyance lemma* [2]. The idea is that the transition terms of (11) "evolve" the states $|E_{i,j}\rangle$ to states that are penalized by Equation (10). $H_{\text{clock},2,i}$ is given by

$$(C_{i,1} \leftrightarrow C_{i,2})\ |\mathbf{A}_2, \mathbf{u}\rangle \leftrightarrow |\mathbf{D}, \mathbf{a}\rangle: \quad \begin{cases} (|x,0\rangle - |x,1\rangle)(\langle x,0| - \langle x,1|)_{\alpha_1\beta_1}, & i = 1 \\ (|a_2,0\rangle - |d,1\rangle)(\langle a_2,0| - \langle d,1|)_{\delta_{i-1}\beta_i}, & i > 1 \end{cases} \tag{11a}$$

$$(C_{i,2} \leftrightarrow C_{i,3})\ |\mathbf{a}, \mathbf{U}\rangle \leftrightarrow |\mathbf{d}, \mathbf{U}\rangle: \quad + (|a,1\rangle - |d,1\rangle)(\langle a,1| - \langle d,1|)_{\alpha_i\varepsilon_i} \tag{11b}$$

$$(C_{i,3} \leftrightarrow C_{i,4})\ |\mathbf{d}, \mathbf{U}\rangle \leftrightarrow |\mathbf{d}, \mathbf{A}_1\rangle: \quad + (\sqrt{2}|1,u\rangle - |1,a_1\rangle)(\sqrt{2}\langle 1,u| - \langle 1,a_1|)_{\gamma_i\delta_i}. \tag{11c}$$

Finally, we set $H_{\text{clock}} = H_{\text{logical}} + H_{\text{clock},1} + H_{\text{clock},2}$ and prove $\mathcal{N}(H_{\text{clock}}) = \mathcal{C}$ and $\gamma(H_{\text{clock}}) = \Omega(1)$ in the full version [40]. ◀

The transition and selection operators are then defined as follows, where we give two variants of the $C_{\sim i}$ projectors, one acting on a 5-qudit and the other on a qubit.

$$h_{i,i+1}(U_Z) = \frac{1}{2}\left(\mathbb{I}_Z \otimes |a_1\rangle\langle a_1|_{\delta_i} + \mathbb{I}_Z \otimes |a_2\rangle\langle a_2|_{\delta_i} - U_Z^\dagger \otimes |a_1\rangle\langle a_2|_{\delta_i} - U_Z \otimes |a_2\rangle\langle a_1|_{\delta_i}\right),$$
$$C_{\leq i}^{(5)} = |u\rangle\langle u|_{\delta_i}, \quad C_{\leq i}^{(2)} = |1\rangle\langle 1|_{\varepsilon_i}, \quad C_{\geq i}^{(5)} = |d\rangle\langle d|_{\alpha_i}, \quad C_{\geq i}^{(2)} = |1\rangle\langle 1|_{\gamma_i} \tag{12}$$

Thus, the Hamiltonians from Theorem 3.1 can all be implemented as a (2×5)-projector.

3.4 QMA$_1$-completeness

Our main contribution is certainly the QMA$_1$-hardness (Theorem 1.1), but we still need to discuss containment in QMA$_1$ briefly.

▶ **Lemma 3.6.** *The* (2×5)-QSAT *and* (3×4)-QSAT *instances constructed from* QMA$_1$*-circuits are contained in* QMA$_1$*.*

Proof. To evaluate $(d_A \times d_B)$-QSAT instances with a QMA$_1$-verifier, we embed each qudit into $\lceil \log d \rceil$ qubits, and add additional diagonal projectors to reduce the local dimension as necessary. The lemma then follows from the containment of QSAT in QMA$_1$ [24], which requires projectors of a specific form. Besides (11c), all projectors used in Section 3.3 have entries in $\mathbb{Z}[\frac{1}{\sqrt{2}}, i]$. Measurements with respect to such projectors are implemented with [23]. Recall the projector from (11c), $\Pi = \left(\sqrt{\frac{2}{3}}|1,u\rangle - \sqrt{\frac{1}{3}}|1,a_1\rangle\right)\left(\sqrt{\frac{2}{3}}\langle 1,u| - \sqrt{\frac{1}{3}}\langle 1,a_1|\right)_{\gamma_i\delta_i}$. Under the qubit embedding, there exists a permutation P such that

$$P\Pi P^\dagger = \left(\sqrt{\frac{2}{3}}|0000\rangle - \sqrt{\frac{1}{3}}|0001\rangle\right)\left(\sqrt{\frac{2}{3}}\langle 0000| - \sqrt{\frac{1}{3}}\langle 0001|\right). \tag{13}$$

A measurement algorithm with perfect completeness is given in [24, Appendix A] for a 3-local projector of analogous structure, which can easily be extend to larger projectors. ◀

▶ **Theorem 1.1.** (2×5)-QSAT *is* QMA$_1$*-complete with soundness* $\Omega(1/N^2)$*.*

Proof. Follows from Theorem 3.1 and Lemma 3.5. ◀

▶ **Theorem 1.2.** (3×4)-QSAT *is* QMA$_1$*-complete with soundness* $\Omega(1/N^2)$*.*

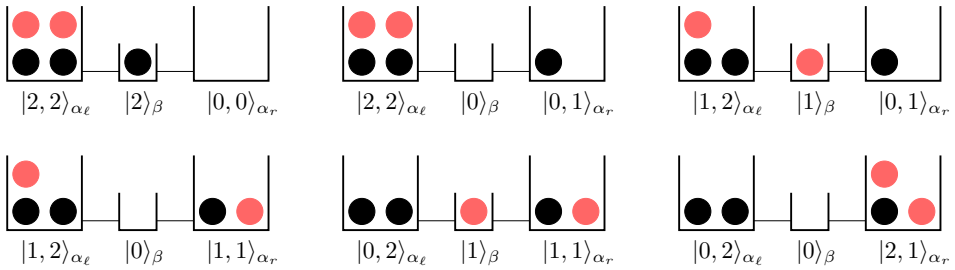

Figure 4.1 Configurations of the balls and bins for $d = 2$. Only configurations in $\mathcal{C}_1$ are depicted ($c_{1,1} = 2$ red balls and $c_{1,2} + 1 = 3$ black balls). The first two are in $\mathcal{C}_1^*$. The configurations evolve according to the transitions of (17b) and (17c). There are $d'' = 15$ possible configurations for the large bins.

Proof. We use the same clock construction operating directly in logical space, though care needs to be taken that everything is realizable with (3×4)-constraints. To implement $H_{\text{clock},1}$ using only (3×4)-terms, we have to replace "**d** implies **d** to the left" with "**D** implies **d** to the left". $H_{\text{clock},2}$ only uses (3×4)-transitions. The $C_{\sim i}$ projectors are implemented as $C^{(4)}_{\leq i} = |U\rangle\langle U|_{\delta_i}, C^{(3)}_{\leq i} = |u\rangle\langle u|_{\alpha_i}, C^{(4)}_{\geq i} = |D\rangle\langle D|_{\delta_{i-1}}, C^{(3)}_{\geq i} = |d\rangle\langle d|_{\alpha_i}$, where α_i, δ_i denote the pairs of (3×4)-qudits as depicted in Equation (9). The computational register is implemented on qutrits restricted to a 2-dimensional subspace. ◀

4 (3×d)-QSAT on a line

▶ **Theorem 1.4.** (3×d)-QSAT *on a line is* QMA$_1$*-complete with* $d = O(1)$.

To prove this theorem, we give a general construction to embed an arbitrary Hamiltonian $H = \sum_{i=1}^{n-1} H_{i,i+1}$ on n qu-d-its with d into a Hamiltonian H' on an alternating line of $n+1$ qu-d'-its ($d' = (d'')^2$) and n qutrits. The qu-d'-its are treated as two qu-d''-its of dimension $d'' \in O(d^2)$. Then each triple (d''×3×d'') logically stores one qu-d-it, which is "sent" between the outer qu-d''-its with a history-state-like construction. Conceptually, we think of this system as three bins with two kinds of balls (say *red* and *black*). The outer bins (qu-d''-its) may contain up to $B = 2d$ balls, and the middle bin only at most a single ball. A valid configuration of the bins has $B + 1$ balls, and the number of red balls is even and positive. We use transition terms to enforce a superposition of all valid configurations that have the same number of red balls. Hence, the (d''×3×d'') system has a nullspace of dimension d.

The standard basis states of the qu-d''-it are written as $|c_1, c_2\rangle$ with $c_1, c_2 \in \mathbb{Z}_{\geq 0}$ and $c_1 + c_2 \leq B := 2d$. Thus, we get $d'' = \sum_{i=0}^{B}(B+1-i) = (B+1)(B+2)/2 = (d+1)(2d+1)$. Semantically, one may think of c_1 as "number of red balls" and c_2 as "number of black balls" (see Figure 4.1). For $i \in [d]$, let $c_{i,1} = 2i, c_{i,2} = B - 2i$ and define the set of valid configurations corresponding to the state $|i\rangle \in \mathbb{C}^d$ as

$$\mathcal{C}_i =: \left\{ (l_1, l_2, m, r_1, r_2) \;\middle|\; \begin{array}{c} l_1, l_2, r_1, r_2 \in \{0, \ldots, B\} \\ m \in \{0, 1, 2\} \\ l_1 + r_1 + \delta_{m,1} = c_{i,1} \\ l_2 + r_2 + \delta_{m,2} = c_{i,2} + 1 \end{array} \right\}, \tag{14}$$

where $\delta_{x,y}$ denotes the Kronecker delta. The constraints in (14) enforce that in total there are $c_{i,1}$ red balls and $c_{i,2} + 1$ black balls (see also Figure 4.1).

We place the local terms of the original Hamiltonian into the dimensions corresponding to $\mathcal{C}_i^* \coloneqq \{(l_1, l_2, m, r_1, r_2) \in \mathcal{C}_i \mid (l_1, l_2) = c_i^* \vee (r_1, r_2) = c_i^*\}$, where $c_i^* \coloneqq (c_{i,1}, c_{i,2})$. These configurations can be identified locally, i.e., one can tell which $\mathcal{C}_i^*$ a configuration corresponds to by only looking at the left or the right bin. Note that $|\mathcal{C}_i^*| = 4$ and $\mathcal{C}_i^* \cap \mathcal{C}_j = \emptyset$ for $j \neq i$. Thus, $\langle c_i^*|_{\alpha_\ell} |\psi_j\rangle = 0$ if $j \neq i$.

A logical $|i\rangle$ is then represented by

$$|\psi_i\rangle = \sum_{x=(l_1,l_2,m,r_1,r_2)\in\mathcal{C}_i} \sqrt{w_x}|l_1, l_2\rangle_{\alpha_\ell}|m\rangle_\beta|r_1, r_2\rangle_{\alpha_r},\ w_x = \begin{cases} \frac{2}{3}\cdot\frac{1}{|\mathcal{C}_i^*|} =: w_i^*, & x \in \mathcal{C}_i^* \\ \frac{1}{3}\cdot\frac{1}{|\mathcal{C}_i\setminus\mathcal{C}_i^*|} =: \overline{w}_i, & x \notin \mathcal{C}_i^* \end{cases}, \tag{15}$$

where α_ℓ, α_r denote the qu-d''-its and β the qutrit. Let

$$V = \sum_{i=1}^{d} |\psi_i\rangle\langle i| \in \mathbb{C}^{3(d'')^2 \times d} \tag{16}$$

be the isometry that maps $|i\rangle$ to $|\psi_i\rangle$. The weights w_x in (15) ensure that the $\mathcal{C}_i^*$ always have the same amplitude ($\sqrt{1/6}$), as the $\mathcal{C}_i$ can have different sizes. The reason for having the additional configurations $\mathcal{C}_i \setminus \mathcal{C}_i^*$ is so that we can use 2-local transitions (see (17b) and (17c)) on the line to enforce a superposition between the $\mathcal{C}_i^*$ states.

Next, we construct a Hamiltonian whose nullspace is spanned by the logical states $|\psi_1\rangle, \ldots, |\psi_d\rangle$. Let $H_{\text{ball}} = (H_{\text{ball}/2})_{\alpha_\ell\beta} + (H_{\text{ball}/2})_{\alpha_r\beta}$, where α_ℓ, α_r denote the qu-d''-its and β the qutrit.

$$H_{\text{ball}/2} = P(|0,0\rangle|0\rangle) + P(|0,B\rangle|2\rangle) + P(|B,0\rangle|1\rangle) + \sum_{c_1+c_2=B, c_1 \text{ odd}} P(|c_1,c_2\rangle|2\rangle) \tag{17a}$$

$$+ \sum_{c_1>0, c_2} \big[T((c_1,c_2,0),(c_1-1,c_2,1)) + T((c_1,c_2,2),(c_1-1,c_2+1,1))\big] \tag{17b}$$

$$+ \sum_{c_1,c_2>0} \big[T((c_1,c_2,0),(c_1,c_2-1,1)) + T((c_1,c_2,1),(c_1+1,c_2-1,2))\big], \tag{17c}$$

where $P(|\psi\rangle) \coloneqq |\psi\rangle\langle\psi|$,

$$T((a_1,a_2,m_a),(b_1,b_2,m_b)) \coloneqq P(\sqrt{w_b}|a_1,a_2\rangle|m_a\rangle - \sqrt{w_a}|b_1,b_2\rangle|m_b\rangle), \tag{18a}$$

$$(w_a, w_b) = \begin{cases} (w_i^*, \overline{w}_i), & (a_1,a_2) = c_i^* \\ (\overline{w}_i, w_i^*), & (b_1,b_2) = c_i^* \\ (1,1), & \text{otherwise} \end{cases}. \tag{18b}$$

One may interpret $P(|\psi\rangle)$ as penalizing $|\psi\rangle$ and $T(\cdot)$ as a transition between the two given configurations, where the weights are chosen according to the weights in the $|\psi_i\rangle$ states.

▶ **Lemma 4.1.** $\mathcal{N}(H_{\text{ball}}) = \text{Span}\{|\psi_i\rangle \mid i \in [d]\} =: \mathcal{L}_{\text{ball}}$.

Proof. In the full version [40]. ◀

The logical states $|\psi_1\rangle, \ldots, |\psi_d\rangle$ are orthonormal and can be "identified" by projecting either qudit onto $|c_i^*\rangle$ as $\langle c_i^*|_{\alpha_r}|\psi_i\rangle = \sqrt{1/6}(|0,0\rangle|2\rangle + |0,1\rangle|0\rangle)_{\alpha_\ell\beta} =: \sqrt{1/3}|\eta\rangle$. $|\eta\rangle$ is the residual state of $|\psi_i\rangle$ after projecting onto $|c_i^*\rangle$ and is the same for all $i \in [d]$. In Figure 4.1, $|\eta\rangle_{\alpha_r\beta}$ is the superposition of the right halves of the first two configurations.

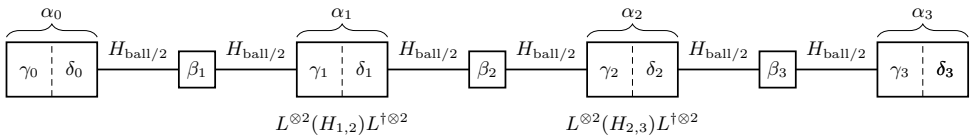

Figure 4.2 Graphical representation of H' embedding an $n = 3$ qudit Hamiltonian. The qu-d'-its $\alpha_0, \ldots, \alpha_3$ are subdivided into qu-d''-its γ_i, δ_i. H' acts trivially on γ_0, δ_3.

We define the isometry $L \coloneqq \sum_{i=1}^{d} |c_i^*\rangle\langle i| \in \mathbb{C}^{d''\times d}$ and finally the complete Hamiltonian H' on qu-d'-its $\alpha_0, \ldots, \alpha_n$ (each logically divided into two qu-d''-its γ_i and δ_i) and qubits $\beta_1, \ldots, \beta_n$ is given by $H' = H'_{\text{logical}} + H'_{\text{sim}}$ with

$$H'_{\text{logical}} = \sum_{i=1}^{n} \underbrace{\left((H_{\text{ball}/2})_{\delta_{i-1}\beta_i} + (H_{\text{ball}/2})_{\gamma_i\beta_i}\right)}_{(H_{\text{ball}})_{\delta_{i-1}\beta_i\gamma_i}} \tag{19a}$$

$$H'_{\text{sim}} = \sum_{i=1}^{n-1} (L\otimes L)(H_{i,i+1})(L\otimes L)^\dagger_{\alpha_i}, \tag{19b}$$

where H'_{logical} contains the terms of H_{ball} to enforce the logical subspace, and H'_{sim} embeds the terms of the original Hamiltonian H. Figure 4.2 gives a graphical representation of H'. Note that H' acts as identity on the first half of the first qu-d'-it (γ_0) and the second half of the last qu-d'-it (δ_n). So we can write

$$H' = \mathbb{I}_{\gamma_0} \otimes H''_{\delta_0\alpha_1\beta_1\ldots\alpha_{n-1}\beta_n\gamma_n} \otimes \mathbb{I}_{\delta_n}. \tag{20}$$

The next lemma shows that H' and H are equal inside the nullspace of H'_{logical}, up to an isometry.

▶ **Lemma 4.2.** *$T^\dagger H'' T = \frac{1}{9} H$ with $T = V^{\otimes n}$, for V and H'' as in Equations (16) and (20).*

Proof. It suffices to check equality for computational basis states $|x\rangle$ with $x \in [d]^n$. Then $T|x\rangle = |\psi_{x_1}\rangle \cdots |\psi_{x_n}\rangle =: |\psi_x\rangle$. Clearly, $H'_{\text{logical}}|\psi_x\rangle = 0$. Consider now the first summand of H'_{sim}, $(L\otimes L)(H_{1,2})(L\otimes L)^\dagger_{\alpha_i} =: M_1$. We have

$$\begin{aligned} V^{\dagger\otimes 2} M_1 |\psi_{x_1}\rangle_{\delta_0\beta_1\gamma_1} |\psi_{x_2}\rangle_{\delta_1\beta_2\gamma_2} &= \frac{1}{3} V^{\dagger\otimes 2} |\eta\rangle_{\delta_0\beta_1} \otimes L^{\otimes 2} H_{1,2} |x_1\rangle_{\varepsilon_1} |x_2\rangle_{\varepsilon_2} \otimes |\eta\rangle_{\gamma_2\beta_2} \\ &= \frac{1}{9} H_{1,2} |x_1 x_2\rangle, \end{aligned} \tag{21}$$

where $\varepsilon_1, \varepsilon_2$ denote the qudits $H_{1,2}$ acts on, and the second equality follows from the fact that $V^\dagger(|\eta\rangle_{\alpha_\ell\beta} \otimes L_{\alpha_r}) = \mathbb{I}/\sqrt{3}$. Since M_1 only acts nontrivially on the first two logical qudits, we have $T^\dagger M_1 T|x\rangle = \frac{1}{9} H|x\rangle$. Applying the same argument to the other summands of H'_{sim} yields $T^\dagger H'' T|x\rangle = \frac{1}{9} H|x\rangle$. ◀

▶ **Lemma 4.3.** *Let H be a Hamiltonian on a line of n qu-d-its with $H_{i,i+1} \succeq 0$ and $\gamma(H_{i,i+1}) \in \Omega(1)$ for all $i \in [n-1]$. There exists an efficiently computable Hamiltonian H' on an alternating chain of $n+1$ qu-d'-its and n qutrits with $d' = ((d+1)(2d+1))^2 \in O(d^4)$, such that $\lambda_{\min}(H') = 0$ iff $\lambda_{\min}(H) = 0$ and $\gamma(H') \in \Omega(\gamma(H)/\|H\|)$.*

Proof. If there exists $|\psi\rangle$ such that $H|\psi\rangle = 0$, then $H'' T|\psi\rangle = 0$ by Lemma 4.2. To prove $\gamma(H') \in \Omega(\gamma(H)/\|H\|)$, apply Corollary 2.5. We have $\mathcal{N}(H'_{\text{logical}}) = \mathcal{L}_{\text{ball}}^{\otimes n} =: S$ and $\gamma(H'_{\text{logical}}), \gamma(H'_{\text{sim}}) \in \Omega(1)$ since $H'_{\text{logical}}, H'_{\text{sim}}$ are sums of commuting Hamiltonians. Since $T^\dagger \Pi_S = T^\dagger$, it follows that $T^\dagger H'' T = \frac{1}{9} H$ is equal to $H''|_S$ up to change of basis. Hence $\gamma(H'|_S) = \frac{1}{9}\gamma(H)$ and $\|H'|_S\| = \frac{1}{9}\|H\|$. ◀

Proof of Theorem 1.4. 2-QSAT one a line of qu-d-its with $d = 11$ is QMA$_1$-complete [34]. Using Lemma 4.3, we can embed this QSAT instance into a $(3\times d')$-QSAT on a line. ◀

▶ Remark 4.4. Care needs to be taken regarding containment in QMA$_1$, since the transition terms of $H_{\text{ball}/2}$ include irrational amplitudes (see (15) and (18a)) for which the techniques of [24] (see Lemma 3.6) do not directly apply. If we allow the QMA$_1$-verifier to use gates with entries from some algebraic field extension (as in [8]), we can easily verify H'. If we are restricted to the "Clifford + T" gate set as in Definition 2.1, we can modify $H_{\text{ball}/2}$ so that the sets $\mathcal{C}_i$ are of equal size for each i. We can do this by adding additional dimensions with transitions to $|c_i^*\rangle$, which increases d' by a constant factor as $|\mathcal{C}_i| = O(d)$. Then we can set all weights in the transitions of H_{ball} to 1 so that the logical states $|\psi_i\rangle$ are just uniform superpositions over the $\mathcal{C}_i$ configurations. Lemma 4.2 then still holds, albeit with a smaller factor that depends on d.

▶ Remark 4.5 (Hamiltonian simulation). Our embedding of the Hamiltonian H into H' is related to the notion of Hamiltonian simulation [7, 13]. In a sense, our embedding is almost a *perfect simulation* [13, Definition 20], but then only the nullspace is really simulated perfectly since H'_{logical} does not commute with H'_{sim}. Our construction takes the form $H' = H'_{\text{logical}} + H'_{\text{sim}}$, such that $T^\dagger H'_{\text{sim}} T = cH$ for some constant c, where T is an isometry with $TT^\dagger = \Pi_{\mathcal{N}(H'_{\text{logical}})}$. This notion of simulation may be helpful for future quantum SAT research.

5 Hamiltonian with unique entangled ground state on a (2×4)-Line

We were only able to prove QMA$_1$-hardness of quantum SAT on a $(3\times d)$-line. This raises the question whether hardness still holds with qubits instead of qutrits. In this section, we show that it is at least possible to construct a (2×4)-QSAT instance on a line with a unique entangled null state. Therefore, the $(2\times d)$-QSAT problem on a line does not necessarily have a product state solution like 2-QSAT.

▶ **Theorem 1.5.** *Consider a line of $2n$ particles such that the i-th particle has dimension 2 for even i and 4 for odd i. There exists a Hamiltonian $H = \sum_{i=1}^{n} A_{2i-1,2i} + \sum_{i=1}^{n-1} B_{2i,2i+1} + L_{1,2} + R_{2n-1,2n}$, where A, B, L, R are 2-local projectors, such that the nullspace of H is $\mathcal{N}(H) = \text{Span}\{|\psi\rangle\}$ and $|\psi\rangle$ is entangled across all cuts.*

▶ Remark 5.1. Observe that besides the left and right boundary (projectors L, R), all (4×2)-projectors have the same form A and all (2×4)-projectors have the same form B. Therefore, H may be considered translation invariant, in a weaker sense. The Hamiltonian with a fully entangled ground state on a line of qutrits [9] also has additional projectors on the boundary.

We begin by explicitly writing the unique ground state of this Hamiltonian on line of 6 particles. The dimensions of these particles are $(4, 2, 4, 2, 4, 2)$, although for the first and second to last particle a qutrit would suffice as the the $|0\rangle/|3\rangle$ dimension is not used.

$$
\begin{aligned}
&|10|00|00\rangle && +|20|20|10\rangle\\
+&|21|00|00\rangle && +|31|20|10\rangle\\
+&|20|10|00\rangle && +|20|31|10\rangle\\
+&|31|10|00\rangle && +|31|31|10\rangle\\
+&|20|21|00\rangle && +|20|20|21\rangle\\
+&|31|21|00\rangle && +|31|20|21\rangle\\
& && +|20|31|21\rangle\\
& && +|31|31|21\rangle
\end{aligned}
\tag{22}
$$

While this state might look complex at a first glance, it can easily be understood semantically. We again think of particles as bins holding balls, but now there is only one kind of ball. A state $|c\rangle$ means that the bin holds c balls. Thus, a qu-d-it can hold at most $d-1$ balls and we have *large* bins of capacity 3 , and *small* bins of capacity 1. Initially, only the first bin contains a ball (first state in the superposition). Then we evolve according to the following rules (also in the reverse):

- If a large bin is not empty and the bin to the right is empty, we can add a ball to both bins ($|c,0\rangle \leftrightarrow |c+1,1\rangle$ for $c \in [1, d-2]$).
- If a small bin contains a ball and the large bin to the right is empty, we can move the ball from the small to the large bin ($|1,0\rangle \leftrightarrow |0,1\rangle$).

We can simplify the transitions by factoring $|*\rangle := \sqrt{1/2}(|20\rangle + |31\rangle)$. To obtain a uniform superposition, we also need to change the amplitudes of the transitions. On $2n$ particles, we obtain the following state.

$$|\phi\rangle := \sum_{i=1}^{n} \begin{pmatrix} |*\rangle^{\otimes i-1} \otimes |\,1\,0\,\rangle \otimes |\,0\,0\,\rangle^{\otimes n-i} \\ +\,|*\rangle^{\otimes i-1} \otimes |\,2\,1\,\rangle \otimes |\,0\,0\,\rangle^{\otimes n-i} \end{pmatrix} \tag{23}$$

Note, $|\phi\rangle$ has a quite similar structure to common clock constructions and can be extended to $2n$ particles. We will show that it is the unique ground state of the following Hamiltonian:

$$H = |0\rangle\langle 0|_1 + |3\rangle\langle 3|_{2n-1} + \sum_{i=1}^{n} A_{2i-1,2i} + \sum_{i=1}^{n-1} B_{2i,2i+1} \tag{24}$$

$$A = \big(|10\rangle - |21\rangle\big)\big(\langle 10| - \langle 21|\big) + \big(|20\rangle - |31\rangle\big)\big(\langle 20| - \langle 31|\big) + |30\rangle\langle 30| + |11\rangle\langle 11| \tag{25}$$

$$B = \big(|10\rangle - \sqrt{2}|01\rangle\big)\big(\langle 10| - \sqrt{2}\langle 01|\big) \tag{26}$$

▶ **Lemma 5.2.** *$|\phi\rangle$ is fully entangled, i.e. $|\phi\rangle \neq |\phi_1\rangle_A \otimes |\phi_2\rangle_B$ for all cuts A/B and $|\phi_1\rangle, |\phi_2\rangle$.*

Proof. Consider the random experiment of measuring $|\psi\rangle$ in standard basis. The outcome is denoted by the string x. Let $S \subset [2n]$ be a subset of particles. If $|\phi\rangle = |\phi_S\rangle|\phi_{\bar{S}}\rangle$, then the random variables x_S and $x_{\bar{S}}$ (substrings of x on particles S and $\bar{S} = [2n] \setminus S$, respectively) are independent. In the following, we argue that this is not the case.

Note for an odd i, $P(x_i = 3, x_{i+1} = 0) = 0$, but $P(x_i = 3)P(x_{i+1} = 0) > 0$. Hence, if there exists odd i such that $|\{i, i+1\} \cap S| = 1$, then $x_S, x_{\bar{S}}$ are not independent.

Otherwise, there exists an odd i such that $|\{i, i+2\} \cap S| = 1$. Again, $x_S, x_{\bar{S}}$ are not independent as $P(x_i = 0, x_{i+2} = 1) = 0$, but $P(x_i = 0)P(x_{i+2} = 1) > 0$. ◀

▶ **Lemma 5.3.** *$|\phi\rangle$ is the unique ground state of H.*

Proof. It is easy to verify $H|\phi\rangle = 0$. Now, assume $H|\psi\rangle = 0$. If there exists a standard basis vector $|x\rangle$ such that $\langle x|\psi\rangle \neq 0$, it corresponds to an illegal state of the ball game (terms of (23) are the legal states). Observe that the transition terms of A and B directly correspond to the allowed moves in the ball game. The illegal states that are not caught directly, are `|10|` or `|21|` not followed by all zeroes. By applying the transition rules, we can go to `|11|`, which is caught by A. Hence, $|\psi\rangle$ and $|\phi\rangle$ overlap the same standard basis vectors. The transition terms ensure the weights are such that $|\phi\rangle$ can be written as in (5.2). ◀

▶ Remark 5.4. $|\phi\rangle$ has only constant entanglement entropy, whereas [9] achieves $\Omega(\log n)$. So it remains an open problem whether logarithmic entanglement entropy can be achieved on the (2×4)-line.

Abstract

We discover a novel connection between two classical mathematical notions, Eulerian orientations and Hadamard codes by studying the counting problem of Eulerian orientations (#EO) with local constraint functions imposed on vertices. We present two special classes of constraint functions and a chain reaction algorithm, and show that the #EO problem defined by each class alone is polynomial-time solvable by the algorithm. These tractable classes of functions are defined inductively, and quite remarkably the base level of these classes is characterized perfectly by the well-known Hadamard code. Thus, we establish a novel connection between counting Eulerian orientations and coding theory. We also prove a #P-hardness result for the #EO problem when constraint functions from the two tractable classes appear together.

1 Introduction

The notion of Eulerian orientations arises from the historically notable *Seven Bridges of Königsberg* problem, whose solution by Euler in 1736 [14] is considered to be the first result of graph theory. Given an undirected graph G, an Eulerian orientation of G is an assignment of a direction to each edge of G such that at each vertex v, the number of incoming edges is equal to the number of outgoing edges. A connected graph has an Eulerian orientation, called an Eulerian graph if and only if every vertex has even degree. This is the well-known Euler's theorem, whose first complete proof was given back in the 1800s [3]. In terms of computational complexity, Euler's theorem implies that the decision problem of Eulerian orientations of a graph is polynomial-time solvable (tractable). While for the counting problem, Mihail and Winkler showed that counting the number of Eulerian orientations of an undirected graph is #P-complete in 1996 [18], more than one hundred years later after Euler's theorem. However, the counting problem becomes tractable when certain particular restrictions are imposed on edges. An intriguing example of such tractable problems comes from computing the partition function of the six-vertex model [19, 22, 20], one of the most intensively studied models in statistical physics. In this example, the graphs are 4 regular graphs and on each vertex exactly one edge incident to it is restricted to take the direction coming into the vertex. Then counting the number of Eulerian orientations obeying restrictions on these edges is proved to be tractable [7].

In this paper, we further study the counting restricted Eulerian orientations (#EO) problem, defined by constraint functions placed at each vertex that represent restrictions on edges incident to the vertex. We consider for which class of constraint functions, the #EO problem is tractable. Before we formally define the problem and describe our results, we first take a detour to another classical notion in coding theory, the Hadamard code. The Hadamard code is an error-correcting code used for error detection and correction when transmitting messages over very noisy or unreliable channels. Because of its plentiful mathematical properties, the Hadamard code is not only used in coding and communication, but also intensely studied in various areas of mathematics and theoretical computer science. However, it is not known how the Hadamard code can be related to Eulerian orientations, and particularly, how it can be used to carve out tractable classes for the #EO problem. Quite surprisingly, in this paper, we establish a novel connection between these two well-studied mathematical notions. We present new tractable classes for the #EO problem and a corresponding algorithm based on a chain reaction. These classes are defined inductively and the base levels of them, defined as kernels are characterized perfectly by the Hadamard code (or more precisely, the balanced Hadamard code).

Now we formally define the #EO problem. A 0-1 valued constraint function (or a signature) f of arity n is a map $\mathbb{Z}_2^n \to \{0,1\}$. The support of f is $\mathscr{S}(f) = \{\alpha \in \mathbb{Z}_2^n | f(\alpha) = 1\}$. A signature f of arity $2n$ is an *Eulerian orientation* (EO) signature if for every $\alpha \in \mathscr{S}(f)$, $\mathrm{wt}(\alpha) = n$. The problem #EO($\mathcal{F}$) specified by a set $\mathcal{F}$ of EO signatures is defined as follows. The input is a graph G where each vertex v of G is associated with some function f_v from $\mathcal{F}$. The incident edges to v are totally ordered and correspond to input variables to f_v. Each edge has two ends, and an orientation of the edge is denoted by assigning 0 to the head and 1 to the tail. Thus, locally at every vertex v, a 0 represents an incoming edge and a 1 represents an outgoing edge. An Eulerian orientation corresponds to an assignment to each edge (01 or 10) where the numbers of 0's and 1's at each v are equal. Then, the local constraint function f_v takes value 1 if the restriction imposed by f_v are satisfied by the local assignment on edges incident to v. Otherwise, $f_v = 0$. Since every f_v is an EO signature, it takes value 1 only if the numbers of input 0's and 1's are equal. Thus, only Eulerian orientations can contribute value 1. An Eulerian orientation contributes value 1 if $f_v = 1$ for every vertex v. The #EO problem outputs the number of Eulerian orientations contributing value 1.

▶ **Example 1.** Let $\mathcal{F} = \{g_2, g_4, \ldots g_{2n}, \ldots\}$, where $\mathscr{S}(g_{2n}) = \{\alpha \in \mathbb{Z}_2^{2n} \mid \mathrm{wt}(\alpha) = n\}$. Then #EO($\mathcal{F}$) counts the total number of all Eulerian orientations of the input graph, which is #P-hard.

▶ **Example 2.** Let f_2 be a signature of arity 4 with support $\mathscr{S}(f_2) = \{1100, 1010, 1001\}$. Then, #EO($\{f_2\}$) computes the partition function of a six-vertex model which is tractable. The reason for naming this function f_2 will be explained in Section 4.

The #EO problem has an intrinsic significance in counting problems. In [5], the framework of #EO problems is formally introduced and is showed to be expressive enough to encompass all Boolean counting constraint satisfaction problems (#CSP) [12, 13, 4, 10] with arbitrary constraint functions that are not necessarily supported on half weighted inputs, although the #EO problem itself requires all constraint functions to be supported on half weighted inputs. Also, the #EO problem encompasses many natural problems from statistical physics and combinatorics, such as the partition function of the six-vertex model and the evaluation of the Tutte polynomial at the point $(3, 3)$ [15]. Cai, Fu and Xia proved a complexity classification of the partition function of the six-vertex model on general 4-regular graphs [7].

Besides these interesting concrete problems expressible as #EO problems, the study of the #EO framework plays a crucial role in a broader picture, the complexity classification program for a much more expressive counting framework, the Holant problem. Significant progress has been made in the complexity classification of Holant problems [9, 8, 1, 11, 2, 16, 6], and a full complexity dichotomy for all real-valued Holant problems is achieved [21]. This dichotomy is crucially based on a complexity dichotomy for the #EO problem [5] with complex-valued signatures assuming a physical symmetry called *arrow reversal symmetry* (ARS) since under a suitable holographic transformation, the ARS property corresponds to precisely real-valued signatures. In this paper, we consider the 0-1 valued #EO problem without assuming ARS, which may serve as a building block for the ultimate classification for all complex-valued Holant problems. For this problem, we give new tractable classes that are not covered by all the previously known tractable classes for Holant problems.

We use $a(f)$ to denote the arity of f, and $A(f) = \{1, 2, ..., a(f)\}$ to denote the indices of variables of f. We use δ_1 and δ_0 to denote the unary signatures where $\mathscr{S}(\delta_1) = \{1\}$ and $\mathscr{S}(\delta_0) = \{0\}$ respectively. Pinning the i-th variable of f to 0 gives the signature $f(x_1, ..., x_{i-1}, 0, x_{i+1}, ..., x_n)$ of arity $n-1$, denoted by f_i^0. Similarly, we define f_i^1. Let f and g be two signatures of support size n and m respectively. Suppose $\mathscr{S}(f) = \{\alpha_1, \alpha_2, ..., \alpha_n\}$ and $\mathscr{S}(g) = \{\beta_1, \beta_2, ..., \beta_m\}$. Then the tensor product $f \otimes g$ of f and g is the signature where $\mathscr{S}(f \otimes g) = \{\alpha_i\beta_j | 1 \le i \le n, 1 \le j \le m\}$. Note that when we take a tensor product of the functions, the variables need not be in the same order of the product. A nonzero signature g is a factor of f, denoted by $g \mid f$, if there is a signature h such that $f = g \otimes h$ or there is a constant λ such that $f = \lambda \cdot g$. Otherwise, g is not factor of f, denoted by $g \nmid f$. In the following, we first state the definition of affine signatures, which are known to be tractable for the #EO problem. Then we give the new tractable classes.

▶ **Definition 3** (Affine). *A signature $f(x_1, x_2, ..., x_n)$ of arity n is affine, denoted by $f \in \mathscr{A}$ if $\mathscr{S}(f) = \{x \in \mathbb{Z}_2^n | AX = 0\}$, where $X = (x_1, x_2, ..., x_n, 1)$ and A is a matrix over $\mathbb{Z}_2$. Note that $f \in \mathscr{A}$ when $\mathscr{S}(f) = \emptyset$, is called a zero signature.*

▶ **Definition 4** (δ_1-affine and δ_0-affine). *An EO signature f is δ_1-affine, denoted by $f \in \mathscr{D}_1$ if $f = \delta_1 \otimes g$ for some g where for every $i \in A(g)$, $g_i^0 \in \mathscr{A} \cup \mathscr{D}_1$. Symmetrically, an EO signature f is δ_0-affine, denoted by $f \in \mathscr{D}_0$ if $f = \delta_0 \otimes g$ for some g where for every $i \in A(g)$, $g_i^1 \in \mathscr{A} \cup \mathscr{D}_0$.*

For example, the 4-ary signature f in Example 2 is an δ_1-affine signature. Note that $\mathscr{D}_1$ (or $\mathscr{D}_0$) does not encompass $\mathscr{A}$, since an affine signature may not have a δ_1 (or δ_0) factor. Thus, our tractable classes are $\mathscr{A} \cup \mathscr{D}_1$ and $\mathscr{A} \cup \mathscr{D}_0$, rather than $\mathscr{D}_1$ and $\mathscr{D}_0$.

▶ **Theorem 5.** *#EO($\mathscr{A} \cup \mathscr{D}_1$) and #EO($\mathscr{A} \cup \mathscr{D}_0$) are tractable.*

The tractability result is established via a chain reaction algorithm, in which the presence of a δ_1 or δ_0 signature plays a role similar to a neutron in a nuclear chain reaction which initializes the reaction and generates a new neutron (a δ_1 or δ_0 signature respectively) by propagation which makes the chain reaction continue. Eventually, the chain reaction terminates when a stable state (a tractable instance of #EO($\mathscr{A}$)) is reached.

Although the reaction algorithm works for δ_1-affine signatures or δ_0-affine signatures alone, it does not work when both of them appear. This is because when both δ_1-affine signatures and δ_0-affine signatures appear, by connecting δ_1 and δ_0 using $\neq$, both of them are killed by each other and no new δ_1 or δ_0 are generated. Thus, the chain reaction is unsustainable. This is somewhat similar to the phenomenon of electron–positron annihilation in nuclear physics. In fact, we can show that the #EO problem is #P-hard when they both appear.

▶ **Theorem 6.** $\#\mathrm{EO}(\mathscr{D}_0 \cup \mathscr{D}_1)$ *is #P-hard.*

Since the classes $\mathscr{D}_1$ and $\mathscr{D}_0$ are defined inductively, it is not an easy task to get explicit expressions for them in a form similar to other known tractable classes for counting problems such as affine signatures. Note that the tractability of $\mathscr{D}_1$ or $\mathscr{D}_0$ is obtained by eventually reducing the problem into a problem where all signatures are affine signatures. Thus, we focus on δ_1-affine (or δ_0-affine) signatures from which by pinning an arbitrary variable to 0 (or 1 respectively), we always get an affine signature. In other words, these δ_1-affine (or δ_0-affine) signatures are at the first level of the inductive hierarchy. We define them as kernels.

▶ **Definition 7** (δ_1-affine and δ_0-affine kernel)**.** *An* EO *signature f is a δ_1-affine kernel, denoted by $f \in K(\mathscr{D}_1)$ if it satisfies the following two properties:*

1. *$f = \delta_1^{\otimes m} \otimes h$, for some $m \in \mathbb{Z}_+$ where h is a signature of positive arity, $\delta_1 \nmid h$ and $h \notin \mathscr{A}$;*
2. *for every $i \in A(h)$, $h_i^0 \in \mathscr{A}$.*

Symmetrically, we define δ_0-affine kernels denoted by $K(\mathscr{D}_0)$ by switching 0 *and* 1 *everywhere. Notice that $h \notin \mathscr{A}$ implies $f \notin \mathscr{A}$. Thus, δ_1-affine and δ_0-affine kernels are not affine.*

A main technical contribution of the paper is a complete characterization of δ_1-affine and δ_0-affine kernels using the Hadamard code. The Hadamard code refers to the code based on Sylvester's construction of Hadamard matrices. A Hadamard matrix H_n is a square matrix of size n such that all its entries are in $\{1, -1\}$ and $H_n H_n^T = nI_n$. Sylvester's construction gives Hadamard matrices H_{2^k} of size 2^k for all $k \geq 0$, where $H_{2^{k+1}} = \begin{bmatrix} H_{2^k} & H_{2^k} \\ H_{2^k} & -H_{2^k} \end{bmatrix}$ and $H_{2^0} = 1$. The Hadamard code $\mathscr{H}_{2^k}^1$ derived from the Hadamard matrices H_{2^k} by Sylvester's construction is a code over the binary alphabet $\{0, 1\}$ of which the 2^k codewords are rows of H_{2^k} where the entry 1 of H_{2^k} is mapped to 1 and the entry -1 is mapped to 0. Symmetrically, we can also get the Hadamard code $\mathscr{H}_{2^k}^0$ by mapping the 1 entry to 0 and -1 to 1. Note that $\mathscr{H}_{2^k}^1$ contains an all-1 codeword and $\mathscr{H}_{2^k}^0$ contains an all-0 codeword. We call the former the 1-Hadamard code and the latter the 0-Hadamard code. In standard coding theory notation for block codes, $\mathscr{H}_{2^k}^1$ and $\mathscr{H}_{2^k}^0$ are $[2^k, k, 2^{k-1}]$-code, which is a binary linear code having block length 2^k, message length k, and minimum Hamming distance $2^k/2$. By removing the all-1 codeword from $\mathscr{H}_{2^k}^1$, we get a balanced code, i.e., each codeword has Hamming weight 2^{k-1}, half of its block length. We call it the balanced 1-Hadamard code, denoted by $\mathscr{H}_{2^k}^{1\mathrm{b}}$. Symmetrically, we can get the balanced 0-Hadamard code, denoted by $\mathscr{H}_{2^k}^{0\mathrm{b}}$. A binary code $\mathscr{C}_n$ of block length n can be viewed equivalently as a 0-1 valued constraint function f of arity n by taking the support $\mathscr{S}(f) = \{\alpha \in \mathbb{Z}_2^n | f(\alpha) \neq 0\}$ to be $\mathscr{C}_n$. An m-multiple of the code $\mathscr{C}_n$ is a code of block length nm, each codeword of which is obtained from a codeword α of $\mathscr{C}_n$ by taking the concatenation of m copies of α.

▶ **Theorem 8.** *An* EO *signature f is a δ_1-affine kernel if and only if $\mathscr{S}(f)$ is an m-multiple of a balanced 1-Hadamard code $\mathscr{H}_{2^k}^{1\mathrm{b}}$ for some $k \geq 3$ and $m \geq 1$, or $\delta_0 \nmid f$ and $|\mathscr{S}(f)| = 3$.*

A symmetric statement holds for the δ_0-affine kernel by switching 0 *and* 1 *everywhere.*

Due to the existence of newly discovered non-trivial tractable classes corresponding to the Hadamard code in the #EO problem without assuming ARS, the complexity classification for the complex-valued Holant problem is much more challenging. It's hard to imagine how many more tractable classes with remarkable properties are yet to be discovered. The results in this paper are a tiny step towards an ambitious goal. Very recently, independent of this work, Meng, Wang and Xia discover new larger tractable classes for the #EO problem [17].

In addition, we note that the presented result in this paper is not the first time that a tractable class for counting problems is found to be related to coding theory. Even in the classification of real-valued Holant problems, a tractable family called local affine [11] was already discovered using the well-known Hamming code. Are there other interesting tractable classes for counting problems that can be carved out with the help of coding theory? In the other direction, it is also worth pursuing whether these new tractability results for counting problems can be applied back to coding theory? We leave the questions in both directions for further study.

The paper is organized as follows. In Section 2, we give some definitions and notations. In Section 3, we give a chain reaction algorithm which establishes the tractability result (Theorem 5) for δ_1-affine and δ_0-affine signatures. In Section 4, we prove the characterization theorem (Theorem 8) for δ_1-affine and δ_0-affine kernels. In Section 5, we prove the hardness result Theorem 6. In fact, the proof of the hardness result highly depends on the characterization of δ_1-affine and δ_0-affine kernels. Omitted proofs can be founded in the full version.

2 Preliminaries

A 0-1 valued signature is determined by its support $\mathscr{S}(f)$. In the paper, we use f and $\mathscr{S}(f)$ interchangeably. We can also view $\mathscr{S}(f)$ as a binary code of block length $a(f)$ where each $\alpha \in \mathscr{S}(f)$ is a codeword. We say $\mathscr{S}(f)$ (or equivalently f) has a constant Hamming weight ℓ if $\mathrm{wt}(\alpha) = \ell$ for every $\alpha \in \mathscr{S}(f)$. For simplicity, we say f is ℓ-weighted or constant-weighted in general. The following fact can be easily checked. Any factor of a constant-weighted signature is still constant-weighted. If a vertex v in a graph is labeled by a signature $f = g \otimes h$, we can replace the vertex v by two vertices v_1 and v_2 and label v_1 with the factor g and v_2 with h, respectively. The incident edges of v become incident edges of v_1 and v_2 respectively according to the partition of variables of f in the tensor product of g and h. This does not affect the evaluation of the instance. We represent f or $\mathscr{S}(f)$ by a matrix which lists all vectors in $\mathscr{S}(f)$ by its rows. All matrices that are equal up to a permutation of rows and columns represent the same signature. Normally, the columns indexing variables are ordered from the smallest index to the largest, and are omitted for convenience when the context is clear. For example, the signature $f = \{1100, 1010, 1001\}$ can be written as $\begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{bmatrix}$.

For $i \in A(f)$, we use $\#_i^0(f)$ and $\#_i^1(f)$ to denote the number of 0s and 1s respectively in the i-th column of $\mathscr{S}(f)$. The complement of a signature f, denoted by $\overline{f}$ is the signature with the support $\mathscr{S}(\overline{f}) = \{\alpha \in \mathbb{Z}_2^n | \overline{\alpha} \in \mathscr{S}(f)\}$ where $\overline{\alpha}$ is the standard complement of α, i.e., $\overline{\alpha} \oplus \alpha = \vec{0}^n$. Let $\widehat{f}(x_1, x_2, ..., x_n) = x_1 x_2 ... x_n \oplus f(x_1, x_2, ..., x_n)$. Then, $\mathscr{S}(\widehat{f}) = \{\vec{1}^n\} \Delta \mathscr{S}(f)$. Similarly, let $\breve{f}(x_1, x_2, ..., x_n) = (1 \oplus x_1)(1 \oplus x_2)...(1 \oplus x_n) \oplus f(x_1, x_2, ..., x_n)$. Then $\mathscr{S}(\breve{f}) = \{\vec{0}^n\} \Delta \mathscr{S}(f)$. We use $\neq$ to denote the binary disequality signature $\{01, 10\}$. Connecting δ_1 with the i-th variable of f using $\neq$ is equivalent to pinning the i-th variable of f to 0, which gives the signature f_i^0. Extracting the i-th variable of f to 0 gives the signature $(x_i \oplus 1) f(x_1, x_2, ..., x_n)$ of arity n, denoted by $f^{x_i=0}$. Clearly $f^{x_i=0} = \delta_0 \otimes f_i^0$. Similarly we define f_i^1 and $f^{x_i=1}$. We use f_{ij}^{ab} to denote the signature $(f_i^a)_j^b = (f_j^b)_i^a$ for distinct $i, j \in A(f)$ and any $a, b \in \mathbb{Z}_2$. The signature $f^{x_i \neq x_j}$ is defined to be $f_{ij}^{01} + f_{ij}^{10}$ which can be obtained by connecting the i-th and j-th variables of f using $\neq$. For a signature f, we define its m-multiple, denoted by $f_{\times m}$ to be the signature $\mathscr{S}(f_{\times m}) = \{\vec{\alpha}^m \mid \alpha \in \mathscr{S}(f)\}$ where $\vec{\alpha}^m \in \mathbb{Z}_2^{nm}$ is obtained from α by taking the concatenation of m copies of α.

Now we give some basic properties of affine signatures. Equivalently, f is affine if and only if it satisfies the property that for any $\alpha, \beta, \gamma \in \mathscr{S}(f)$, $\alpha \oplus \beta \oplus \gamma \in \mathscr{S}(f)$. One can also check that affine signatures are closed under pinning, extracting, tensor product and factoring. Also, $f \in \mathscr{A}$ if and only if $f_{\times m} \in \mathscr{A}$ for any $m \in \mathbb{Z}_+$.

▶ **Lemma 9.** *If a signature $f \in \mathscr{A}$ is constant-weighted and $\delta_0, \delta_1 \nmid f$, then $\#_i^0(f) = \#_i^1(f)$ for any $i \in A(f)$. Moreover, f is an* EO *signature.*

▶ **Definition 10** (Pairwise opposite)**.** *Let f be a signature of arity $2n$. We say f is pairwise opposite if we can partition the $2n$ variables into n pairs such that in $\mathscr{S}(f)$, two variables of each pair always take opposite values.*

▶ **Lemma 11** (Lemma 5.7 in [5])**.** *If f is an affine* EO signature, then f is pairwise opposite.

3 A chain reaction algorithm

In the section, we show $\#\mathrm{EO}(\mathscr{D}_1 \cup \mathscr{A})$ and $\#\mathrm{EO}(\mathscr{D}_0 \cup \mathscr{A})$ are tractable by giving a chain reaction algorithm. We only consider $\#\mathrm{EO}(\mathscr{D}_1 \cup \mathscr{A})$, since the other case is symmetric. Given an instance Ω of $\#\mathrm{EO}(\mathscr{D}_1 \cup \mathscr{A})$, we may assume that there is at least one vertex labelled by a δ_1-affine signature f. Otherwise, all signatures in the instance are affine. Such an instance of $\#\mathrm{EO}(\mathscr{A})$ is tractable.

Since f is δ_1-affine, consider a factor δ_1 of f. This δ_1 is connected to another variable of some signature (which may be f itself) using $\neq_2$. Then, the connected variable is pinned to 0. A key property that ensures our algorithm work is that after connecting δ_1 to another variable no matter whether it is a variable of f itself, an affine signature, or another δ_1-affine signature, either the resulting signature is affine, or we can realize another δ_1. In the later case, we call it a propagation step. After a propagation step, the new realized δ_1 can be used to pin another variable to 0. Thus, we get a chain reaction, and it terminates when an instance of $\#\mathrm{EO}(\mathscr{A})$ is reached. Note that, after each propagation step, the number of edges (total variables) in the instance is reduced by 2. Thus, the chain reaction terminates after at most $|E|/2$ many steps where E is the edge set of the underlying graph in Ω.

▶ **Lemma 12.** *Suppose that $f = \delta_1 \otimes h$ is δ_1-affine and $g \in \mathscr{D}_1 \cup \mathscr{A}$. For any variable x_i of g, by connecting it with δ_1 of f using $\neq_2$, we can get a zero signature or a signature $h \otimes \delta_1 \otimes g_{ij}^{01}$ where $g_{ij}^{01} \in \mathscr{D}_1 \cup \mathscr{A}$ for some $j \in A(g) \backslash \{i\}$.*

Proof. If $g \in \mathscr{A}$, then g is pairwise opposite by Lemma 11. Suppose x_j is opposite to x_i. Then pinning x_i to 0 makes x_j be a δ_1 factor, i.e., $g_i^0 = \delta_1(x_j) \otimes g_{ij}^{01}$, where $g_{ij}^{01} \in \mathscr{A}$. Otherwise $g \in \mathscr{D}_1 \backslash \mathscr{A}$. Suppose $g = \delta_1(x_j) \otimes g'$ for some variable x_j. If $x_i = x_j$, then by connecting the δ_1 factor of f and x_j of g using $\neq$, we get a zero signature. Now assume $x_i \neq x_j$. Then $(g')_i^0 \in \mathscr{A} \cup \mathscr{D}_1$ since $g \in \mathscr{D}_1$. In this case, we get $h \otimes \delta_1(x_j) \otimes g_{ij}^{01}$, where $g_{ij}^{01} = (g')_i^0 \in \mathscr{A} \cup \mathscr{D}_1$. ◀

▶ **Theorem 13.** *$\#\mathrm{EO}(\mathscr{A} \cup \mathscr{D}_1)$ and $\#\mathrm{EO}(\mathscr{A} \cup \mathscr{D}_0)$ are tractable.*

Proof. We only prove $\#\mathrm{EO}(\mathscr{A} \cup \mathscr{D}_1)$ is tractable, the other case is symmetric.

Consider an instance Ω of $\#\mathrm{EO}(\mathscr{A} \cup \mathscr{D}_1)$. If all signatures in Ω are affine, then we are done. Otherwise, there is a vertex u in Ω that is labeled by a δ_1-affine signature $f = \delta_1 \otimes h$. Without loss of generality, we name the variable associated with δ_1 after x_1. Suppose that in Ω, x_1 is connected to another variable x_i of some g labeling the vertex v using $\neq_2$.

- If $u = v$, i.e., f and g are labeled on the same vertex in Ω, then by definition the resulting signature $f^{x_1 \neq x_i} = f_{1i}^{10} = h_i^0$ obtained from f by connecting variables x_1 and x_i is in $\mathscr{D}_1 \cup \mathscr{A}$. Then, the instance is reduced to a smaller instance with two fewer edges where f is replaced by $f^{x_1 \neq x_i}$ of smaller arity. Since $f^{x_1 \neq x_i} \in \mathscr{D}_1 \cup \mathscr{A}$, the reduced instance is still an instance of $\#\mathrm{EO}(\mathscr{A} \cup \mathscr{D}_1)$.
- Otherwise, f and g are labeled on two different vertices. By Lemma 12, connecting δ_1 of f with a variable x_i of g, we get a zero signature or a signature $h \otimes \delta_1 \otimes g'$ where $g' = g_{ij}^{01} \in \mathscr{D}_1 \cup \mathscr{A}$ for some $j \in A(g) \backslash \{i\}$. If a zero signature is realized, then clearly we are done. Otherwise, by renaming variables and decomposing $h \otimes \delta_1 \otimes g'$ into two parts $f = h \otimes \delta_1$ and g', again we can reduce the original instance to a smaller instance with two fewer edges where the edges incident to f is changed and g is replaced by g' of smaller arity. Still, since $g' \in \mathscr{D}_1 \cup \mathscr{A}$, the reduced instance is still an instance of $\#\mathrm{EO}(\mathscr{A} \cup \mathscr{D}_1)$.

Thus, in both cases, the instance can be solved recursively and the number of recursions is bounded by $|E|/2$ where E is the edge set of the underlying graph of Ω. ◀

4 Characterization of δ_1-affine δ_0-affine kernels

In this section, we prove the main characterization theorem for δ_1-affine and δ_0-affine kernels using the Hadamard code. We first give an equivalent definition for the δ_1-affine kernel. Note that in Definition 7 we require $h \notin \mathscr{A}$, while in the following lemma we require $\delta_0 \nmid h$.

▶ **Lemma 14.** *An* EO *signature* $f \in K(\mathscr{D}_1)$ *if and only if it satisfies the following two properties:*

1. $f = \delta_1^{\otimes m} \otimes h$ *for some* $m \in \mathbb{Z}_+$ *where* h *is a signature of positive arity,* $\delta_1, \delta_0 \nmid h$*;*
2. *for every* $i \in A(h)$, $h_i^0 \in \mathscr{A}$*.*

Note that the signature f_2 in Example 2 is a δ_1-affine kernel. Trivially, any EO signature of support size 3 with at least one δ_1 factor and no δ_0 factor is a δ_1-affine kernel, since any signature obtained from it by pinning a variable to 0 has a support of size 1 or 2, which is affine. We say $f \in K(\mathscr{D}_1)$ (or $K(\mathscr{D}_0)$) is a trivial kernel if $|\mathscr{S}(f)| = 3$. Below, we prove the characterization theorem for non-trivial δ_1-affine and δ_0-affine kernels, which is essentially equivalent to Theorem 8.

▶ **Theorem 15.** *An* EO *signature* f *is a non-trivial* δ_1*-affine (or* δ_0*-affine) kernel if and only if* $\mathscr{S}(f)$ *is an* m*-multiple of a balanced 1-Hadamard (or balanced 0-Hadamard respectively) code of size* $2^k - 1$ *for some* $k \geq 3$ *and* $m \geq 1$*.*

We give a proof outline for this theorem. First, we prove δ_1-affine kernels admit certain arities and support sizes by carefully counting the number of 0s and 1s in each column of their supports. More specifically, we prove a non-trivial δ_1-affine kernel f must have support size $2^k - 1$ and arity $m2^k$, for some $m, k \in Z_+, k \geq 3$ (Lemma 17). Then, we define basic δ_1-affine kernels (Definition 18) of support size $2^k - 1$ and arity 2^k. We show every non-trivial δ_1-affine kernel is a multiple of some non-trivial basic kernel (Lemma 19). Finally, we characterize the basic δ_1-affine kernel by the balanced 1-Hadamard code $\mathscr{H}_{2^k}^{1b}$. We define a special affine signature called butterfly (Definition 20), serving as a bridge connecting basic kernels and balanced Hadamard codes. We show $\mathscr{H}_{2^k}^{1}$ (or $\mathscr{H}_{2^k}^{0}$) is just a half of butterfly (Lemma 24). We also define left and right wings of butterfly (Definition 21) by removing the all-0 (or all-1) row from a half of butterfly. Notice $\mathscr{H}_{2^k}^{0b}$ (or $\mathscr{H}_{2^k}^{1b}$) is obtained by removing the all-0 (or all-1) codeword from $\mathscr{H}_{2^k}^{1}$. Thus, wings of butterfly coincide with $\mathscr{H}_{2^k}^{0b}$ and $\mathscr{H}_{2^k}^{1b}$ (Lemma 24). Finally, we prove basic kernels are precisely wings of butterfly (Lemma 26 and Lemma 28). Therefore, basic kernels, balanced Hadamard codes and wings of butterfly are precisely the same things.

▶ **Lemma 16.** *Suppose $f \in K(\mathscr{D}_1)$. If $\delta_0 \nmid f^{x_i=1}$ for some $i \in A(f)$, then $f^{x_i=1} \in K(\mathscr{D}_1)$.*

▶ **Lemma 17.** *Suppose that $f = \delta_1^{\otimes m} \otimes h \in K(\mathscr{D}_1)$ where $m \geq 1, \delta_1, \delta_0 \nmid h$, and $|\mathscr{S}(f)| > 3$. Then there exists some $k \geq 2$ such that $|\mathscr{S}(f)| = 2^{k+1} - 1$ and $a(f) = m2^{k+1}$. Moreover, we have $\delta_1 \nmid h_i^0, \delta_0 \nmid h_i^1$ and $\#_i^0(h) = 2^k$ for every $i \in A(h)$.*

▶ **Definition 18** (Basic δ_1-affine kernel)**.** *A basic δ_1-affine kernel f_k of order k (or a k-th basic δ_1-affine kernel) is a δ_1-affine kernel of arity 2^k and support size $2^k - 1$.*

For example, the basic δ_1-affine kernel of order 1 is $f_1 = \delta_1 \otimes \delta_0$ and the basic δ_1-affine kernel of order 2 is $f_2 = \delta_1 \otimes \{(001), (010), (100)\}$.

▶ **Lemma 19.** *An* EO signature of arity $m2^k$ is a non-trivial δ_1-affine kernel if and only if it is an m-multiple of a non-trivial basic δ_1-affine kernel of arity 2^k.

Proof. First we assume $f = \delta_1 \otimes g$ is a non-trivial basic δ_1-affine kernel. Then $|\mathscr{S}(f_{\times m})| = |\mathscr{S}(f)| > 3$. We want to show $f_{\times m} \in K(\mathscr{D}_1)$. Note that $f_{\times m} = \delta_1^{\otimes m} \otimes g_{\times m}$ and $\delta_1, \delta_0 \nmid g_{\times m}$. Pinning 0 to the i-th variable of one copy of g in $g_{\times m}$, each of the remaining $m-1$ copies contributes a δ_0 factor. i.e, $(g_{\times m})_i^0 = \delta_0^{\otimes(m-1)} \otimes (g_i^0)_{\times m}$. Clearly $(g_{\times m})_i^0 \in \mathscr{A}$ since $g_i^0 \in \mathscr{A}$. It follows that $f_{\times m} \in K(\mathscr{D}_1)$.

Conversely, assume $f = \delta_1^{\otimes m} \otimes h$ is a non-trivial δ_1-affine kernel, where $m \in \mathbb{Z}_+, \delta_1, \delta_0 \nmid h$. We want to show there exists a non-trivial basic δ_1-affine kernel f_0 such that $f = (f_0)_{\times m}$. By Lemma 17, we have $|\mathscr{S}(f)| = 2^k - 1$ and $\#_i^0(h) = 2^{k-1}$ for every $i \in A(h)$. Fix any $i \in A(h)$, consider $f^{x_i=0} = \delta_1^{\otimes m} \otimes h^{x_i=0}$. It is an affine EO signature of support size 2^{k-1}. By Lemma 17, $\delta_1 \nmid h^{x_i=0}$. Factoring out δ_0 in $h^{x_i=0}$, we suppose $h^{x_i=0} = \delta_0^{\otimes m_0} \otimes h'$, $\delta_1, \delta_0 \nmid h'$. At the same time, notice h' is constant-weighted. Thus, h' is an EO signature by Lemma 9. Since $f^{x_i=0} = \delta_1^{\otimes m} \otimes \delta_0^{\otimes m_0} \otimes h'$ is also EO, we have $m = m_0$.

On one hand, if x_j is a variable taking constant 0 in $\mathscr{S}(f^{x_i=0})$, then the values of x_j and x_i must be identical in $\mathscr{S}(h)$, because the j-th column already contributes 2^{k-1} many 0s in $\mathscr{S}(f^{x_i=0})$ and the remaining $2^{k-1} - 1$ rows must be all 1s. On the other, if x_j is a variable of h', then x_j and x_i are not identical in $\mathscr{S}(h)$ since they are not identical in $\mathscr{S}(h^{x_i=0})$. Therefore, there are exactly $m_0 = m$ copies of the i-th column in $\mathscr{S}(h)$. Since $i \in A(h)$ is arbitrary, we have $h = (h_0)_{\times m}$ for some signature h_0. Clearly $\delta_1, \delta_0 \nmid h_0$ since $\delta_1, \delta_0 \nmid h$. Notice for every $i \in A(h_0)$, $(h_0^{x_i=0})_{\times m} = ((h_0)_{\times m})^{x_i=0} = h^{x_i=0} = \delta_0 \otimes h_i^0 \in \mathscr{A}$, so $h_0^{x_i=0} \in \mathscr{A}$ and then $(h_0)_i^0 \in \mathscr{A}$. Therefore, $f_0 = \delta_1 \otimes h_0$ is a basic δ_1-affine kernel and $f = (f_0)_{\times m}$. ◀

Below, we show balanced Hadamard codes characterize basic kernels via the bridge of butterfly.

▶ **Definition 20** (Butterfly)**.** *Let $k \geq 1$. An affine signature g of arity 2^{k+1} is a butterfly and denoted by B_k, if it has exactly k free (linearly independent) variables $x_1, x_2, ..., x_k$ and any two different variables do not always take identical values in $\mathscr{S}(g)$.*

The butterfly B_k is unique up to a permutation of variables. It is precisely the affine signature of k free variables with the maximum arity, assuming any two different variables are not identical.

▶ **Definition 21** (Wings of butterfly)**.** *We represent the butterfly B_k by a matrix in the following way. Let $(x_2, x_3, ..., x_{k+1})$ be free variables of B_k, and x_1 be constant 0. Moreover, let $x_m = \lambda_2 x_2 + \lambda_3 x_3 + ... + \lambda_{k+1} x_{k+1}$ and $x_{m+2^k} = x_m + 1$ for $1 \leq m \leq 2^k$, where $\lambda_2, ..., \lambda_{k+1} \in \mathbb{Z}_2$. Through a permutation of rows, we let the first row be $\vec{0}^{2^k} \vec{1}^{2^k}$.*

Then, B_k can be split into the left half and the right half, each of which consisting of 2^k columns. The left wing of B_k, denoted by L_k is the signature obtained form the left half of B_k by removing the first row $\widetilde{0}^{2^k}$. Symmetrically, we define the right wing of B_k denoted by R_k.

▶ Remark 22. Recall that $\widetilde{L_k}$ and $\widehat{R_k}$ are obtained from L_k and R_k by adding an all-0 or all-1 row respectively. They are the left and right halves of B_k respectively which are affine. In fact, $\widetilde{L_k}$ is precisely the affine signature of k free variables with maximum arity, assuming every variable is a linear combination of free variables and any two variables are not identical. While $\widehat{R_k}$ is the complement of $\widetilde{L_k}$.

▶ **Example 23.** We give a butterfly with 2 free variables x_2, x_3.

$$B_2 = \begin{array}{c} \begin{matrix} x_1 & x_2 & x_3 & x_4 & x_5 & x_6 & x_7 & x_8 \end{matrix} \\ \begin{bmatrix} 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 \end{bmatrix} \end{array}.$$

The other variables are decided by the following linear or affine linear combinations. $x_1 = 0x_2+0x_3, x_4 = x_2+x_3, x_5 = 0x_2+0x_3+1, x_6 = x_2+0x_3+1, x_7 = 0x_2+x_3+1, x_8 = x_2+x_3+1$.

The left and right wings of B_2 are $L_2 = \left[\begin{smallmatrix} 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 \end{smallmatrix}\right]$ and $R_2 = \left[\begin{smallmatrix} 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 \end{smallmatrix}\right]$.

▶ **Lemma 24.** *As a signature, the balanced 1-Hadamard (or 0-Hadamard) code is the right (or left) wing of butterfly up to a permutation of variables.*

Proof. We only need to prove $\mathscr{H}^0_{2^k}$ is the left half of B_k. Note that $\mathscr{H}^0_{2^k}$ is a linear code, then it is affine as a signature. By the definition of Hadamard matrix and Hadamard code, every two different rows of $\mathscr{H}^0_{2^k}$ do not take identical values. By Sylvester's construction, $\mathscr{H}^0_{2^k}$ is symmetic as a matrix. Thus, every two different variables of $\mathscr{H}^0_{2^k}$ do not take identical values in its support. Because $\mathscr{H}^0_{2^k}$ is of arity 2^k, support size 2^k, and has an all-0 vector in its support, it is precisely the affine signature of k free variables with maximum arity, assuming every variable is a linear combination of free variables and any two variables are not identical. Therefore, $\mathscr{H}^{0b}_{2^k} = L_k$ is just removing the all-0 row of $\mathscr{H}^0_{2^k}$. ◀

So far we show the equivalence of balanced Hadamard code and wings of butterfly. Next we focus on the relationship between basic kernels and wings of butterfly. For convenience, we only consider the basic δ_1-affine kernel and the right wing of butterfly in the following. The other case is symmetric.

▶ **Lemma 25.** *Let $k \geq 3$ and R_k be the right wing of B_k, then R_k is an EO signature. Moreover, every two different rows (or columns) of R_k do not take identical or opposite values.*

Proof. Because $\mathscr{H}^{1b}_{2^k}$ is an EO signature and every two different rows and columns do not take identical or opposite values, this lemma is true because $R_k = \mathscr{H}^{1b}_{2^k}$ by Lemma 24. ◀

▶ **Lemma 26.** *Let R_k be the right wing of a butterfly. Then R_k is the k-th basic δ_1-affine kernel.*

Proof. For $k = 1, 2$ it can be checked by definition. Now we assume $k \geq 3$. First by Lemma 25 R_k is EO. Then we show $R_k \in K(\mathscr{D}_1)$. Notice $R_k = \delta_1 \otimes r_k, \delta_0, \delta_1 \nmid r_k$, and $(r_k)^0_i = (\widehat{r_k})^0_i \in \mathscr{A}$, since $\widehat{r_k} \in \mathscr{A}$. Finally, because R_k is of arity 2^k and support size $2^k - 1$, it is a basic δ_1-affine kernel of order k. ◀

Below, we prove the more complicated direction that a basic δ_1-affine kernel of order k is just R_k up to a permutation of variables. We prove this by induction. We first prove certain properties for the $k+1$-th δ_1-affine kernel assuming the k-th δ_1-affine kernel is unique up to a permutation of variables.

▶ **Lemma 27.** *Suppose $k \in \mathbb{Z}_+, k \geq 2$. If the k-th basic δ_1-affine kernel f_k is unique up to a permutation of variables, then any $(k+1)$-th basic δ_1-affine kernel $f = \delta_1 \otimes h$ satisfies the following properties for every $l \in A(h)$.*

1. *$f^{x_l=1} = (f_k)_{\times 2}$ up to a permutation of variables.*
2. *$f^{x_l=0} = B_k$ up to a permutation of variables.*
3. *Two variables x_i and x_j take opposite values in $\mathscr{S}(f^{x_l=0})$ if and only if they take identical values in $\mathscr{S}(f^{x_l=1})$.*

▶ **Lemma 28.** *The k-th basic δ_1-affine kernel f_k is precisely R_k up to a permutation of variables.*

Proof. For $k = 1$, we have $f_1 = \delta_1 \otimes \delta_0$ and this lemma is clear. For $k = 2$, $f_2 = \delta_1 \otimes \{(001), (010), (100)\}$ and this lemma is true by Example 23. Now assume this lemma holds for positive integers less or equal than $k (k \geq 2)$. By Lemma 27, we know any $(k+1)$-th δ_1-affine kernel $f_{k+1} = \delta_1 \otimes h_{k+1}$ satisfies the following three properties:

$f_{k+1} =$

$0 \cdots 0$	$1 \cdots 1$
$\overline{f_k}$	f_k
f'_k	f'_k

1. Extracting any variable of h_{k+1} to 0, up to a permutation of rows, the first 2^k rows of f_{k+1} is butterfly B_k.
2. Extracting any variable of h_{k+1} to 1, up to a permutation of rows, the last $2^k - 1$ rows is $(f_k)_{\times 2}$. However, when we write the above butterfly into the specific form, we fix the order of columns. Then we denote the last $2^k - 1$ rows by two f'_k, where $f'_k = f_k$ up to a permutation of rows and columns.
3. Every two different variables take identical values in $\mathscr{S}((f_{k+1})^{x_i=1})$ if and only if they take opposite values in $\mathscr{S}((f_{k+1})^{x_i=0})$, $i \in A(h_{k+1})$.

Because every two different columns of f_k (as well as f'_k) do not take identical or opposite values by Lemma 25, we can easily check this proposition still holds for f_{k+1}. Next we show the signature $\widehat{f_{k+1}}$ is affine. We first notice $\widehat{f_{k+1}}$ has the following properties, which holds for every $i \in A(\widehat{f_{k+1}})$:

1. $(\widehat{f_{k+1}})^{x_i=0} = (f_{k+1})^{x_i=0} = B_k \in \mathscr{A}$.
2. $(\widehat{f_{k+1}})^{x_i=1} = (\widehat{f_k})_{\times 2} \in \mathscr{A}$, since f_k is the right wing of B_k by induction hypothesis, hence $\widehat{f_k}$ is the right half of B_k, which is affine.

We prove $\widehat{f_{k+1}} \in \mathscr{A}$ by contradiction. If $\widehat{f_{k+1}} \notin \mathscr{A}$, there exists $\alpha', \beta', \gamma' \in \mathscr{S}(\widehat{f_{k+1}})$, such that $\theta' = \alpha' \oplus \beta' \oplus \gamma' \notin \mathscr{S}(\widehat{f_{k+1}})$. If there exists a position j such that $\alpha'_j = \beta'_j = \gamma'_j = 0$, assume $j = 1$ without loss of generality. Then $\alpha' = 0\alpha, \beta' = 0\beta, \gamma' = 0\gamma, \theta' = 0\theta$, where $\alpha, \beta, \gamma \in \mathscr{S}(\widehat{(f_{k+1})}^0_j)$ and $\theta = \alpha \oplus \beta \oplus \gamma$. Because $(\widehat{f_{k+1}})^0_j \in \mathscr{A}$, we have $\theta \in \mathscr{S}((\widehat{f_{k+1}})^0_j)$.

Then $\theta' = 0\theta \in \mathscr{S}(\widehat{f_{k+1}})$, contradiction! Similarly, if there exists a position j such that $\alpha'_j = \beta'_j = \gamma'_j = 1$, we also get a contradiction. Then, by enumerating all possible combinations of $\alpha', \beta', \gamma' \in \mathscr{S}(\widehat{f_{k+1}})$, we can show $\widehat{f_{k+1}} \in \mathscr{A}$. Because $\mathscr{S}(\widehat{f_{k+1}})$ contains an all-1 vector; $|\mathscr{S}(\widehat{f_{k+1}})| = a(\widehat{f_{k+1}}) = 2^{k+1}$; and there is no identical pair in $\mathscr{S}(\widehat{f_{k+1}})$, f_{k+1} is precisely the right wing of B_{k+1}. ◀

So far by Lemma 26 and Lemma 28 we prove the equivalence between basic kernels and wings of butterfly. Combining with Lemma 24 we get the proof of Theorem 15.

5 Hardness result

Recall that the binary disequality signature $(\neq)$ is $\{10, 01\}$. The symbol "$\leq_T$" stands for Turing reduction.

▶ **Definition 29** (ARS). *A signature f satisfies ARS if $f(\alpha) = f(\overline{\alpha})$ for every $\alpha \in \mathscr{S}(f)$.*

First, we show that $\delta_1 \otimes \delta_0$ is always realizable from an EO signature not satisfying ARS.

▶ **Lemma 30.** *If an* EO signature f does not satisfy ARS, then $\#\mathrm{EO}(f, \delta_1 \otimes \delta_0) \leq_T \#\mathrm{EO}(f)$.

With the help of $\delta_1 \otimes \delta_0$, we have the following reduction.

▶ **Lemma 31.** *If an* EO signature f does not satisfy ARS, then $\#\mathrm{EO}(\{f, f^{xi=1}, f^{xi=0}\}) \leq_T \#\mathrm{EO}(f)$ for every $i \in A(f)$.

Next we will prove $\#\mathrm{EO}(f, g)$ is #P-hard if $f \in \mathscr{D}_1 \backslash \mathscr{A}$ and $g \in \mathscr{D}_0 \backslash \mathscr{A}$, which implies that $\#\mathrm{EO}(\mathscr{D}_1 \cup \mathscr{D}_0)$ is #P-hard. We first consider a basic case where f and g are basic δ_1-affine and δ_0-affine kernels of order 2 respectively.

▶ **Lemma 32.** *Let $f_2(x_1, x_2, x_3, x_4) = \left[\begin{smallmatrix} 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{smallmatrix}\right]$ and $g_2(y_1, y_2, y_3, y_4) = \left[\begin{smallmatrix} 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{smallmatrix}\right]$. Then $\#EO(f_2, g_2)$ is #P-hard.*

Proof. Connecting the variables x_1 and y_1, x_2 and y_2 using $\neq$ respectively, we realize a signature h of arity 4 where

$$h = \begin{array}{c} \begin{matrix} x_3 & x_4 & y_3 & y_4 \end{matrix} \\ \left[\begin{matrix} 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{matrix}\right] \end{array}.$$

It is known that $\#\mathrm{EO}(h)$ is #P-hard by the complexity classification for the six-vertex model [7]. Then, $\#\mathrm{EO}(f_2, g_2)$ is #P-hard. ◀

This #P-hardness result can be generalized to any multiples of f_2 and g_2.

▶ **Lemma 33.** *Let $f = (f_2)_{\times a}, g = (g_2)_{\times b}$, where $a, b \in \mathbb{Z}_+$. Then $\#EO(f, g)$ is #P-hard.*

Proof. Connect f and g using $\neq$ block by block. That is, connect variables x_i and y_i using $\neq$ for $1 \leq i \leq 4$, where x_i, y_i are variables of one block f_2 and g_2 as denoted in Lemma 32.

If $a = b = 1$, it is the case in Lemma 32. If $a = b > 1$, we can realize

$$h' = \begin{array}{c} \begin{matrix} x_3 & x_4 & y_3 & y_4 \end{matrix} \\ \begin{bmatrix} 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{bmatrix} \end{array}$$

which is also #P-hard by the complexity classification of the six vertex model.

If $a \neq b$, we may assume $a > b$ without loss of generality. Then we can realize $f' = (f_2)_{\times(a-b)}$. Then connect f' and g block by block and continue this process. We finally realize $(f_2)_{\times d}$ and $(g_2)_{\times d}$ where $d = gcd(a, b)$ is computed by the Euclidean algorithm. Then it is reduced to the case $a = b$. ◀

This #P-hardness result can still be generalized to any basic δ_1-affine and δ_0-affine kernels of support size 3.

▶ **Lemma 34.** *Let $f \in \mathscr{D}_1 \backslash \mathscr{A}, g \in \mathscr{D}_0 \backslash \mathscr{A}$, and $|\mathscr{S}(f)| = |\mathscr{S}(g)| = 3$. Then $\#EO(f, g)$ is #P-hard.*

▶ **Theorem 35.** *If $f \in \mathscr{D}_1 \backslash \mathscr{A}, g \in \mathscr{D}_0 \backslash \mathscr{A}$, then $\#EO(f, g)$ is #P-hard.*

Proof. We first show we can realize a signature $f' \in \mathscr{D}_1 \backslash \mathscr{A}$ of support size 3 if $|\mathscr{S}(f)| > 3$. If $f \in K(\mathscr{D}_1)$, suppose $f = (f_k)_{\times m}$ by Lemma 19, where f_k is the δ_1-affine kernel of order k. we can extract 1 in some variable x_i of f by Lemma 31 and realize $f^{x_i=1}$, which is a multiple of f_{k-1} by Lemma 27. Continuing this process we can finally realize multiple of f_2. If $f \notin K(\mathscr{D}_1)$, suppose $f = \delta_1 \otimes h$. Then there exists $i \in A(h)$ such that $h_i^0 \in \mathscr{D}_1 \backslash \mathscr{A}$. We have $3 < |\mathscr{S}(h_i^0)| < |\mathscr{S}(f)|$. Repeating the process, either $h_i^0 \in K(\mathscr{D}_1)$ or it can realize a signature in $\mathscr{D}_1 \backslash \mathscr{A}$ of smaller support size. Finally we can realize $f' \in \mathscr{D}_1 \backslash \mathscr{A}$ of support size 3. Similarly, we can realize $g' \in \mathscr{D}_0 \backslash \mathscr{A}$ of support size 3. Then by Lemma 34 we prove $\#\mathrm{EO}(f, g)$ is #P-hard. ◀

When to Give up on a Parallel Implementation

Nathan S. Sheffield

Alek Westover
MIT, Cambridge, MA, USA

Abstract

In the Serial Parallel Decision Problem (SPDP), introduced by Kuszmaul and Westover [SPAA'24], an algorithm receives a series of tasks online, and must choose for each between a serial implementation and a parallelizable (but less efficient) implementation. Kuszmaul and Westover describe three decision models: (1) **Instantly-committing** schedulers must decide on arrival, irrevocably, which implementation of the task to run. (2) **Eventually-committing** schedulers can delay their decision beyond a task's arrival time, but cannot revoke their decision once made. (3) **Never-committing** schedulers are always free to abandon their progress on the task and start over using a different implementation. Kuszmaul and Westover gave a simple instantly-committing scheduler whose total completion time is 3-competitive with the offline optimal schedule, and proved two lower bounds: no eventually-committing scheduler can have competitive ratio better than $\phi \approx 1.618$ in general, and no instantly-committing scheduler can have competitive ratio better than 2 in general. They conjectured that the three decision models should admit different competitive ratios, but left upper bounds below 3 in any model as an open problem.

In this paper, we show that the powers of instantly, eventually, and never committing schedulers are distinct, at least in the "massively parallel regime". The massively parallel regime of the SPDP is the special case where the number of available processors is asymptotically larger than the number of tasks to process, meaning that the *work* associated with running a task in serial is negligible compared to its *runtime*. In this regime, we show (1) The optimal competitive ratio for instantly-committing schedulers is 2, (2) The optimal competitive ratio for eventually-committing schedulers lies in $[1.618, 1.678]$, (3) The optimal competitive ratio for never-committing schedulers lies in $[1.366, 1.500]$. We additionally show that our instantly-committing scheduler is also 2-competitive outside of the massively parallel regime, giving proof-of-concept that results in the massively parallel regime can be translated to hold with fewer processors.

1 Introduction

1.1 Background

Many computational tasks can be performed quickly in parallel over a large number of processors – but such parallel implementations may be less work-efficient than a serial implementation on a single processor, requiring substantially more total computation time across all machines. When several different tasks must be completed in as little total time as possible, this trade-off between work and time can necessitate running different tasks in different modes: small tasks can be done in serial to save work, while large tasks must be parallelized to prevent their serial runtimes from dominating the overall computation.

To formalize this problem, Kuszmaul and Westover introduced the **Serial Parallel Decision Problem (SPDP)** [16]. In their model, each task has exactly two possible implementations: an "embarrassingly parallel" implementation which can be worked on by

© Nathan S. Sheffield and Alek Westover;
licensed under Creative Commons License CC-BY 4.0

multiple machines at once (where the rate of progress on the implementation is proportional to the number of processors assigned to it), and a serial implementation which can only be worked on by a single processor at a time. If all tasks are available at time 0, it is easy to efficiently determine the optimal strategy: all jobs with serial completion time smaller than some threshold can be run in serial, and the larger tasks must be run in parallel. The model becomes interesting when previously-unknown tasks are allowed to arrive at arbitrary times, and one wishes to minimize the competitive ratio between the total completion time of an *online* algorithm compared to the offline optimal completion time.

Kuszmaul and Westover define three distinct versions of this model, parameterized by the degree to which the online scheduler is able to reverse its decisions.

1. An **instantly-committing** scheduler must choose an implementation for each task as soon as the task arrives, and is not allowed to revisit this choice.
2. An **eventually-committing** scheduler may delay choosing an implementation, but must choose one irrevocably before assigning its work to a processor.
3. A **never-committing** scheduler can, at any time, discard all as-yet completed work on an implementation and re-start the task with the other implementation.

The distinction between the eventually- and never-committing models is motivated by potential practical concerns: if a task involves mutating an input in memory, it may not be feasible to cancel an implementation once it begins running. Westover and Kuszmaul present an instantly-committing scheduler achieving competitive ratio 3, and show competitive ratio lower bounds of 2 and $\phi \approx 1.618$ in the instantly-committing and eventually-committing models, respectively (for deterministic schedulers). They conjecture that the ability to delay or cancel choices should allow for more competitive online algorithms, but leave open the problem of finding better competitive ratio upper bounds than 3.

1.2 This Work

In this work, we consider Kuszmaul and Westover's SPDP when the number of available processors is much larger than the number of tasks, noting that all of their upper and lower bounds hold in this parameter regime. This is a particularly simple setting, since the work associated to a serial implementation is now negligible compared to its completion time – running a task in serial means accepting a lower bound on completion time, but requires essentially no work. We can think of this setting as an unrelated-machines scheduling problem with an unlimited number of identical "slow" machines, and a single unrelated "fast" machine, representing a massively parallel implementation of the task across many processors – note that this could also describe scenarios with a literal fast machine, such as a single piece of accelerated hardware. Although we consider the number of processors to be large, we won't assume that tasks complete instantly when run on all the processors; instead, we'll let the total parallel work of each tasks be proportional to p.

Our main results are tight bounds on the competitive ratio of instantly-committing schedulers in this regime, and separations between the strength of all 3 models. Our results are summarized in Table 1. Note that we focus on deterministic schedulers (although we briefly discuss randomized schedulers in the appendix).

In each case, the upper bound comes from a simple heuristic in which the algorithm compares its projected completion time to its current estimate of the optimal completion time. More precisely, at each time t, our scheduler computes an offline optimal strategy "$\mathsf{opt}(t)$" on the truncation of the task sequence to tasks that arrive before time t, and makes decisions based on the completion time of $\mathsf{opt}(t)$.

Table 1 Main Results. * = this work.

Model	Lower Bound	Upper Bound
Instantly-Committing Schedulers	2 [16]	**2** *
Eventually-Committing Schedulers	1.618 [16]	**1.678** *
Never-Committing Schedulers	**1.366** *	**1.5** *

Our main technical contribution is the analysis of the schedulers. Working with $\mathsf{opt}(t)$ is challenging, because the schedules $\mathsf{opt}(t)$ and $\mathsf{opt}(t')$ can be quite different for $t \neq t'$. For instantly-committing schedulers we use an invariant-based approach to bound, at all times, the work taken by our scheduler in terms of the minimum work and completion time among all schedulers. For eventually- and never-committing schedulers this approach is no longer feasible: there is no well defined notion of the "work taken" by our scheduler, because the scheduler may not have committed to a decision yet. Instead, these analyses rely on choosing a couple of critical times to observe the state of our scheduler and $\mathsf{opt}(t)$, and then establishing a dichotomy: either (1) "real fast tasks" (tasks that opt runs on the fast machine) arrive quickly, in which case our scheduler prioritizes real fast tasks on the fast machine and will run most other tasks on slow machines, or (2) real fast tasks arrive slowly, in which case our scheduler never falls too far behind opt, despite making suboptimal use of the fast machine.

In addition to these results, we show that with some effort our instantly-committing scheduler can be adapted to work for any number of processors, fully resolving the question of the optimal competitive ratio of instantly-committing schedulers in the general SPDP, and giving a proof-of-concept that results for a large number of processors can be adapted to hold when the work associated with serial tasks is also a concern.

1.3 Related Work

There is a long line of work studying the phenomenon of work-inefficient parallel implementations in multi-processor scheduling. Typically, the models of limited parallelism considered involve one of three types of jobs:

1. **Rigid** jobs, which come with a number p_i specifying a fixed number of processors the job must be run on at each timestep of its execution.
2. **Moldable** jobs, where the scheduler may choose the (fixed) number of processors the job is run on, and the amount of work scales depending on this choice according to some **speedup curve**.
3. **Malleable** jobs, which like moldable jobs have an associated speedup curve, but where the job may be assigned to different numbers of processors at different timesteps (as opposed to the scheduler choosing a fixed value at the start of the task's runtime).

In each of these cases, there is interest in minimizing the total completion time (**makespan**) in both the offline setting – where problems tend to be NP-hard, but may have approximation algorithms [25, 20, 18, 24, 23] – and the online setting, where the goal is to minimize competitive ratio [8, 7, 4, 14, 9, 29, 28]. Kuszmaul and Westover's Serial Parallel Decision Problem is related to this line of work, but doesn't quite fit into the usual framework – in their model, instead of dealing with an arbitrary speedup curve, there is a single binary decision between a completely serial and perfectly parallelizable implementation.

As noted, the massively-parallel regime of the SPDP considered in this paper can be naturally viewed as a scheduling problem with an unlimited number of identical "slow" machines, and a single unrelated "fast" machine. Standard scheduling problems in the

unrelated machines model have also been well-studied, in terms of both offline approximation algorithms and hardness results [13, 17, 22, 26, 19, 21, 10, 15, 6], and online algorithms [3, 2, 22, 5, 1, 11, 12, 30]. We note, however, that since we treat "slow" machines as an unbounded resource, and there is only a single fast machine available, most of the typical difficulties of multi-processor scheduling problems do not arise. In particular, unlike a typical load-balancing problem where NP-hardness follows from a standard set-partition reduction, the One-Fast-Many-Slow Decision Problem (without dependencies) is easily solvable offline, simply by putting all tasks which finish below a certain threshold on distinct slow machines.

1.4 Open Questions

We leave three main open questions as directions for future work.

▶ **Question 1.** What are the optimal competitive ratios for eventually/never-committing schedulers?

In Section A we identify barriers, showing that improving on our eventually/never-committing schedulers will require substantially different algorithms – but we suspect that such improvements may be possible.

▶ **Question 2.** Are randomized schedulers more powerful than deterministic schedulers?

In the main body of the paper we consider only deterministic schedulers; however, for many online problems randomized algorithms can do substantially better than deterministic ones. In Section C we give some lower bounds against randomized schedulers, but these bounds are weaker than those known for deterministic schedulers.

▶ **Question 3.** Is there a general transformation between schedulers for the massively parallel regime (i.e. the One-Fast-Many-Slow Decision Problem) and the general SPDP?

The fundamental difficulty of the SPDP is deciding between implementations which take a lot of work, and implementations which take a lot of time. This tradeoff is absolute in the massively parallel regime, since the large number of processors means the amount of work associated with a serial implementation is negligible, whereas in the general SPDP it is possible for all processors to be saturated with serial implementations to run. Intuitively, one might expect that having work associated to the serial implementations only makes the problem *easier*, since it makes the tradeoff less dramatic – indeed, Kuszmaul and Westover's competitive ratio lower bounds become weaker when the number of processors is small. So, one might hope that algorithms in the massively parallel regime can be generically translated to limited-processor settings. Formalizing this connection is an interesting direction for future research.

2 Preliminaries

2.1 The One-Fast-Many-Slow Decision Problem

In this section we formally define the **One-Fast-Many-Slow Decision Problem**, where the goal is to distribute work between a single **fast machine** and an unlimited number of **slow machines**. An instance of the problem is a **Task Arrival Process (TAP)** $\mathcal{T} = (\tau_1, \ldots, \tau_n)$, where each task τ_i consists of a tuple (σ_i, π_i, t_i) indicating runtime on a slow machine, runtime on the fast machine, and arrival time, respectively, such that $t_1 \leq \cdots \leq t_n$ and such that

$\sigma_i \leq \pi_i$. A valid schedule associates at most one task to each machine at each point in time[1] such that no work is done on any task before its arrival time, each task runs on at most 1 machine, and each task τ_i is either run for a total of σ_i time on some slow machine, or a total of π_i time on the fast machine. The **completion time** (also known as **makespan**) of the schedule is the time when the last task is finished.

We will be interested in online algorithms for this problem. An online scheduler learns about each task only at its arrival time, and at each time t must already have fixed the prefix of the schedule on times less than t. We define three distinct models for how these online decisions are made:

1. For each task τ, an **instantly-committing** scheduler must fix at τ's arrival time the machine that τ will run on.
2. An **eventually-committing** scheduler need not fix a machine for any task until that task begins running.
3. A **never-committing** scheduler is an eventually-committing scheduler with the additional power to, at any time, "cancel" a task from the schedule, erasing all work previously done on the task and allowing it to be re-assigned to a new machine.

In each case, we are interested in minimizing the **competitive ratio** of an online scheduler, which is the supremum over all TAPs of the ratio of the online scheduler's completion time to the completion time of an optimal scheduler on that TAP.

2.2 Connection to the SPDP

In Kuszmaul and Westover's Serial Parallel Decision Problem, a scheduler must allocate work to p equally-powerful processors, where each task is specified by the work of the serial implementation, the work of the parallel implementation, and the runtime. The scheduler must choose whether to run each task in serial or parallel, and then must assign the resulting work to the p processors, where parallel work can run on multiple processors at once but serial work cannot.

We can define the **massively parallel** regime of this problem to be the limit as the number of processors becomes large compared to the number of tasks. Letting n be the number of tasks, if $n \leq \varepsilon p$ then restricting the serial implementations to run on only the first n many processors, and the parallel implementations to run on only the last $p - n$ many processors, the completion time can increase by at most a $\frac{1}{1-\varepsilon}$ factor. This corresponds directly to the One-Fast-Many-Slow Decision Problem: we think of each of these serial processors as a "slow machine", noting that since we have as many processors as we have tasks there are effectively an unlimited number of processors. We think of the parallel processors collectively as a "fast machine", noting that we can assume without loss of generality that, at any point in time, all parallel processors are running the same parallel implementation.

2.3 Notation

We now introduce our notation for describing and analyzing schedulers. For algorithm alg and TAP $\mathcal{T}$, we let $\mathsf{C}_{\mathsf{alg}}^{\mathcal{T}}$ be the completion time of alg on $\mathcal{T}$. Let $\mathcal{T}^t$ be the truncation of TAP $\mathcal{T}$ consisting of the tasks τ_i with $t_i \leq t$. When $\mathcal{T}$ is clear from context we will write $\mathsf{C}_{\mathsf{alg}}^{t}$ to denote $\mathsf{C}_{\mathsf{alg}}^{\mathcal{T}^t}$, and we will write $\mathsf{C}_{\mathsf{alg}}$ to denote $\mathsf{C}_{\mathsf{alg}}^{\infty} = \mathsf{C}_{\mathsf{alg}}^{\mathcal{T}}$. We will also use $\widetilde{\mathsf{C}}_{\mathsf{alg}}$ to denote the completion time of the fast machine – that is, the final time when the fast machine has work.

[1] In order for the notions like "amount of work performed on τ_i" to be well-defined, we must additionally mandate that a schedule be measurable. Alternatively, one can assume that time is discretized into appropriately fine timesteps.

It will be useful to be able to talk about the optimal completion time of a prefix of the TAP. Define the schedule $\mathsf{opt}(t)$ to be a schedule for $\mathcal{T}^t$ with minimal completion time. Note that $\mathsf{opt}(t)$ is only defined as an offline strategy, but that an online algorithm can compute it (efficiently!) at time t, thus obtaining a lower bound on $\mathsf{C}_{\mathsf{opt}}$, which will be useful to inform the algorithm's future decisions. For ease of notation, we'll often abbreviate $\mathsf{C}^t_{\mathsf{opt}(t)}$ as C^t.

There may be many sets of decisions which result in the optimal completion time; as opposed to letting $\mathsf{opt}(t)$ be an arbitrary such scheduler, it will be useful to fix a canonical one, which we will do by letting $\mathsf{opt}(t)$ run as many tasks in serial as possible.

▶ **Scheduler 4.** The scheduler $\mathsf{opt}(t)$, defined on $\mathcal{T}^t$, makes decisions as follows:

- If τ_i has $\sigma_i + t_i \leq \mathsf{C}^t$, run τ_i on a slow machine when it arrives.
- Otherwise, run τ_i on the fast machine. Prioritize tasks with larger $\sigma_i + t_i$, and break ties by taking tasks with smaller i.

Finally, we let $[n] = \{1, \ldots, n\}$, and for a set J of tasks we will write π_J to denote $\sum_{j \in J} \pi_j$.

3 A 2-Competitive Instantly-Committing Scheduler

In this section we present and analyze a 2-competitive instantly-committing scheduler. Kuszmaul and Westover showed that a competitive ratio of $(2 - \varepsilon)$ is impossible for instantly-committing schedulers, so our scheduler is optimal. The scheduler, which we call ins ("*ins*tantly commiting") is defined in Scheduler 5.

▶ **Scheduler 5.** When task τ_i arrives:

- If $\sigma_i + t_i > 2\mathsf{C}^{t_i}$ run τ_i on the fast machine, with the fast machine processing tasks in order of arrival.
- Otherwise run τ_i on a slow machine.

We analyze ins by showing inductively that $\widetilde{\mathsf{C}}_{\mathsf{ins}}$ (the completion time of the fast machine) is small compared to the work and completion time of *any* other schedule. For length n TAP $\mathcal{T}$, scheduler alg, and $i \in [n]$, we define the quantity $\mathsf{K}^t_{\mathsf{alg}}$ to be the sum of π_j for all tasks $\tau_j \in \mathcal{T}^t$ that alg runs on the fast machine. The key to analyzing ins is the following lemma.

▶ **Lemma 6.** *Fix a length n TAP. For all $i \in [n]$, and for all instantly-committing schedulers* alg*,*

$$\widetilde{\mathsf{C}}^{t_i}_{\mathsf{ins}} \leq \mathsf{C}^{t_i}_{\mathsf{alg}} + \mathsf{K}^{t_i}_{\mathsf{alg}}. \tag{1}$$

Proof. We prove the lemma by induction on i. For $i = 1$ the claim is trivial. Now, fix $i \in [n-1]$, alg and assume the lemma for i and for all alg'; we will prove the lemma for $i+1$, alg.

If ins runs τ_{i+1} on a slow machine then $\widetilde{\mathsf{C}}^{t_{i+1}}_{\mathsf{ins}} = \widetilde{\mathsf{C}}^{t_i}_{\mathsf{ins}}$, and $\mathsf{C}^{t_i}_{\mathsf{alg}} + \mathsf{K}^{i}_{\mathsf{alg}} \leq \mathsf{C}^{t_{i+1}}_{\mathsf{alg}} + \mathsf{K}^{i+1}_{\mathsf{alg}}$. Thus, the invariant Equation (1) is maintained. We always have $\widetilde{\mathsf{C}}^{t_{i+1}}_{\mathsf{ins}} \leq \widetilde{\mathsf{C}}^{t_i}_{\mathsf{ins}} + \pi_{i+1}$, so if alg runs τ_{i+1} on the fast machine then the invariant Equation (1) is also maintained, since then $\mathsf{C}^{t_{i+1}}_{\mathsf{alg}} + \mathsf{K}^{t_{i+1}}_{\mathsf{alg}} \geq \mathsf{C}^{t_i}_{\mathsf{alg}} + \mathsf{K}^{t_i}_{\mathsf{alg}} + \pi_{i+1} \geq \widetilde{\mathsf{C}}^{t_i}_{\mathsf{ins}} + \pi_{i+1}$ by the inductive hypothesis.

The final case to consider is when alg runs τ_{i+1} on a slow machine, while ins runs τ_{i+1} on the fast machine. From the definition Scheduler 5 of ins, the fact that ins ran τ_{i+1} on the fast machine implies

$$2\mathsf{C}^{t_{i+1}} < \sigma_{i+1} + t_{i+1}. \tag{2}$$

On the other hand, alg ran τ_{i+1} on the fast machine. Thus,

$$\sigma_{i+1} + t_{i+1} \leq \mathsf{C}_{\mathsf{alg}}^{t_{i+1}}. \tag{3}$$

Now, we use the invariant for $(i, \mathsf{opt}_{t_{i+1}})$ to bound $\widetilde{\mathsf{C}}_{\mathsf{ins}}^{t_{i+1}}$. We have:

$$\widetilde{\mathsf{C}}_{\mathsf{ins}}^{t_{i+1}} \leq \widetilde{\mathsf{C}}_{\mathsf{ins}}^{t_i} + \pi_{i+1} \leq \mathsf{K}_{\mathsf{opt}(t_{i+1})}^{t_i} + \mathsf{C}_{\mathsf{opt}(t_{i+1})}^{t_i} + \pi_{i+1}. \tag{4}$$

Because of Equation (2) we know that $\mathsf{opt}(t_{i+1})$ must run τ_{i+1} on the fast machine. So, we have

$$\mathsf{K}_{\mathsf{opt}(t_{i+1})}^{t_i} + \mathsf{C}_{\mathsf{opt}(t_{i+1})}^{t_i} + \pi_{i+1} = \mathsf{K}_{\mathsf{opt}(t_{i+1})}^{t_{i+1}} + \mathsf{C}_{\mathsf{opt}(t_{i+1})}^{t_i} \leq 2\mathsf{C}^{t_{i+1}}. \tag{5}$$

Stringing together the above inequalities Equation (4), Equation (5), Equation (2), and Equation (3), we get

$$\widetilde{\mathsf{C}}_{\mathsf{ins}}^{t_{i+1}} < \mathsf{C}_{\mathsf{alg}}^{t_{i+1}}.$$

Thus, the invariant Equation (1) holds. ◀

Using Lemma 6 it is easy to show that ins is 2-competitive.

▶ **Theorem 7.** ins *is a 2-competitive instantly-committing scheduler.*

Proof. By Lemma 6 we have $\widetilde{\mathsf{C}}_{\mathsf{ins}}^{t_n} \leq 2\mathsf{C}_{\mathsf{opt}}$. Thus, ins finishes using the fast machine before time $2\mathsf{C}_{\mathsf{opt}}$. Any task that ins runs on a slow machine must have $\sigma_i + t_i \leq 2\mathsf{C}_{\mathsf{opt}}$, so these tasks finish before $2\mathsf{C}_{\mathsf{opt}}$ as well. ◀

4 A 1.678-Competitive Eventually-Committing Scheduler

In this section we present and analyze a ξ-competitive eventually-committing scheduler, where $\xi \approx 1.678$ is the real root of the polynomial $2x^3 - 3x^2 - 1$. Kuszmaul and Westover gave a lower bound of $\phi \approx 1.618$ on the competitive ratio of any eventually-committing scheduler and conjectured that this lower bound is tight. Our scheduler represents substantial progress towards resolving Kuszmaul and Westover's conjecture, improving on their previous best algorithm which had a competitive ratio of 3. Our scheduler, which we call eve ("*eve*ntually committing"), is defined in Scheduler 8.

▶ **Scheduler 8.** At time t:

- If task τ_i, which has arrived but not yet been started, has $\sigma_i + t \leq \xi\mathsf{C}^t$, then start τ_i on a slow machine.
- Maintain up to one **active** task at a time. The fast machine is always allocated to the active task.
- When there is no active task, but there are unstarted tasks present, choose as the new active task the unstarted task with the largest $\sigma_i + t_i$ value (breaking ties arbitrarily).

▶ **Theorem 9.** eve *is a ξ-competitive eventually-committing scheduler.*

Proof. Fix TAP $\mathcal{T}$. Let $\widetilde{\mathsf{C}}_{\mathsf{eve}}$ denote the time when eve completes the last task run on the fast machine. If τ_i is run on a slow machine at any time t, then τ_i finishes before $\xi\mathsf{C}^t \leq \xi\mathsf{C}_{\mathsf{opt}}$. Thus, it suffices to show that $\widetilde{\mathsf{C}}_{\mathsf{eve}} \leq \xi\mathsf{C}_{\mathsf{opt}}$.

For any $x \in [0, \mathsf{C}_{\mathsf{opt}}]$, let $R(x)$ be the first time that an online algorithm becomes aware that the optimal schedule requires at least x completion time – that is, $R(x) = \inf\{t : \mathsf{C}^t \geq x\}$. Let $\mathcal{A}$ ("actual") be the set of tasks that opt runs on the fast machine, and $\mathcal{F}$ ("fake") be the set of tasks that opt runs on a slow machine but eve runs on the fast machine. We can bound the sizes and arrival times of tasks in $\mathcal{F}$ as follows.

▷ Claim 10. All tasks $\tau_i \in \mathcal{F}$ arrive before time $R(\mathsf{C}_{\mathsf{opt}}/\xi)$, and have $\pi_i < \sigma_i/\xi$.

Proof. All tasks $\tau_i \in \mathcal{F}$ are run on the fast machine by eve, and on slow machines by opt. In particular this means

$$\xi \mathsf{C}^{t_i} < \sigma_i + t_i \leq \mathsf{C}_{\mathsf{opt}} \leq \xi \mathsf{C}^{R(\mathsf{C}_{\mathsf{opt}}/\xi)}.$$

Thus, $t_i < R(\mathsf{C}_{\mathsf{opt}}/\xi)$. To show $\pi_i < \sigma_i/\xi$, note that $\pi_i + t_i \leq \mathsf{C}^{t_i} < \frac{\sigma_i + t_i}{\xi}$. ◁

To analyze when tasks in $\mathcal{F}$ get run it will be useful to partition $\mathcal{F}$ into $\mathcal{F}_{\mathsf{big}} = \{\tau_i \in \mathcal{F} \colon \sigma_i + t_i > \mathsf{C}_{\mathsf{opt}}/\xi\}$ and $\mathcal{F}_{\mathsf{small}} = \{\tau_i \in \mathcal{F} \colon \sigma_i + t_i \leq \mathsf{C}_{\mathsf{opt}}/\xi\}$. Now we show that, without loss of generality, eve does not start any tasks in $\mathcal{F}_{\mathsf{small}}$ too late.

▷ Claim 11. If eve starts a task $\tau \in \mathcal{F}_{\mathsf{small}}$ at any time $t \geq R(\mathsf{C}_{\mathsf{opt}}/\xi)$, then $\widetilde{\mathsf{C}}_{\mathsf{eve}} \leq \xi \mathsf{C}_{\mathsf{opt}}$.

Proof. Note that no task $\tau_i \in \mathcal{F}_{\mathsf{small}}$ can be started after time $\mathsf{C}_{\mathsf{opt}}$: since $\mathsf{C}_{\mathsf{opt}} + \sigma_i \leq \mathsf{C}_{\mathsf{opt}} + \mathsf{C}_{\mathsf{opt}}/\xi < \xi \mathsf{C}_{\mathsf{opt}}$, any task $\tau_i \in \mathcal{F}_{\mathsf{small}}$ present but not already running at time $\mathsf{C}_{\mathsf{opt}}$ would be run on a slow machine. Let t_* be the last time after $R(\mathsf{C}_{\mathsf{opt}}/\xi)$ when eve starts a task $\tau \in \mathcal{F}$. If t_* does not exist the claim is vacuously true. In light of our previous observation, $t_* < \mathsf{C}_{\mathsf{opt}}$. Let τ_i be the task that eve starts at time t_*. Because eve prioritizes making tasks with larger $\sigma_j + t_j$ values active, at time t_* there are no tasks $\tau \in \mathcal{F}_{\mathsf{big}} \cup \mathcal{A}$ present. After time t_*, no more tasks from $\mathcal{F}$ can arrive by Claim 10, and at most $\mathsf{C}_{\mathsf{opt}} - t_*$ work in $\mathcal{A}$ can arrive because opt must be able to complete this work. Thus,

$$\widetilde{\mathsf{C}}_{\mathsf{eve}} \leq t_* + (\mathsf{C}_{\mathsf{opt}} - t_*) + \pi_i = \mathsf{C}_{\mathsf{opt}} + \pi_i. \tag{6}$$

Now, because $\tau_i \in \mathcal{F}_{\mathsf{small}}$ we have $\pi_i \leq \mathsf{C}_{\mathsf{opt}}/\xi^2$; using this in Equation (6) we find $\widetilde{\mathsf{C}}_{\mathsf{eve}} \leq (1 + 1/\xi^2)\mathsf{C}_{\mathsf{opt}} \leq \xi \mathsf{C}_{\mathsf{opt}}$. ◁

This means that we can assume that, after time $R(\mathsf{C}_{\mathsf{opt}}/\xi)$, the only tasks that eve runs on the fast machine are $\mathcal{A}$, $\mathcal{F}_{\mathsf{big}}$, and whatever the active task was at time $R(\mathsf{C}_{\mathsf{opt}}/\xi)$. We call the active task at time $R(\mathsf{C}_{\mathsf{opt}}/\xi)$, if one exists, the **stuck** task, denoted τ_s. We split into cases depending on how large this stuck task is.

Case 1. There is no stuck task.

In this case, we in fact have $\widetilde{C}_{\mathsf{eve}} \leq \mathsf{C}_{\mathsf{opt}}$. Since there is no active task at time $R(\mathsf{C}_{\mathsf{opt}}/\xi)$, there are no tasks present but not started on slow machines. By Claim 10, eve will run all tasks $\tau \notin \mathcal{A}$ arriving after time $R(\mathsf{C}_{\mathsf{opt}}/\xi)$ on slow machines. Thus, at all time steps $t \in [R(\mathsf{C}_{\mathsf{opt}}/\xi), \mathsf{C}_{\mathsf{opt}}]$, eve either has no active task on the fast machine, or has some $\tau \in \mathcal{A}$ as the active task on the fast machine, so eve completes $\mathcal{A}$ at least as quickly as opt.

Case 2. There is a stuck task, with $\sigma_s + t_s > \mathsf{C}_{\mathsf{opt}}/\xi$.

Define $\mathcal{A}_{\text{early}} = \{\tau_i \in \mathcal{A} : t_i < R(\mathsf{C}_{\mathsf{opt}}/\xi)\}$ and $\mathcal{A}_{\text{late}} = \mathcal{A} \setminus \mathcal{A}_{\text{early}}$. Let $t < R(\mathsf{C}_{\mathsf{opt}}/\xi)$ be a time when all tasks in $\{\tau_s\} \cup \mathcal{F}_{\mathsf{big}} \cup \mathcal{A}_{\text{early}}$ have already arrived; such a time must exist by Claim 10. Observe that $\mathsf{opt}(t)$ runs all tasks in $\{\tau_s\} \cup \mathcal{F}_{\mathsf{big}} \cup \mathcal{A}_{\text{early}}$ on the fast machine due to $\mathsf{C}^t < \mathsf{C}_{\mathsf{opt}}/\xi$. This further implies that $\pi_{\mathcal{F}_{\mathsf{big}} \cup \{\tau_s\} \cup \mathcal{A}_{\text{early}}} \leq \mathsf{C}_{\mathsf{opt}}/\xi$. Also $\pi_{\mathcal{A}_{\text{late}}} \leq \mathsf{C}_{\mathsf{opt}} - R(\mathsf{C}_{\mathsf{opt}}/\xi)$, simply because opt must complete the work on tasks $\mathcal{A}_{\text{late}}$ after these tasks arrive. By Claim 11 we may assume without loss of generality that, after time

$R(\mathsf{C}_{\mathsf{opt}}/\xi)$, eve is always running a task from $\{\tau_s\} \cup \mathcal{A} \cup \mathcal{F}_{\mathsf{big}}$. Thus,

$$\begin{aligned}\widetilde{\mathsf{C}}_{\mathsf{eve}} &\leq R(\mathsf{C}_{\mathsf{opt}}/\xi) + \pi_{\mathcal{A}\cup\mathcal{F}_{\mathsf{big}}\cup\{\tau_s\}} \\ &= R(\mathsf{C}_{\mathsf{opt}}/\xi) + \pi_{\mathcal{A}_{\mathrm{early}}\cup\mathcal{F}_{\mathsf{big}}\cup\{\tau_s\}} + \pi_{\mathcal{A}_{\mathrm{late}}} \\ &\leq R(\mathsf{C}_{\mathsf{opt}}/\xi) + \mathsf{C}_{\mathsf{opt}}/\xi + (\mathsf{C}_{\mathsf{opt}} - R(\mathsf{C}_{\mathsf{opt}}/\xi)) \\ &\leq \xi\mathsf{C}_{\mathsf{opt}}\end{aligned}$$

Case 3. There is a stuck task, with $\sigma_s + t_s \leq C_{\mathsf{opt}}/\xi$.

This case will be the most difficult to handle of the three. It will be useful to focus now on the tasks of $\mathcal{F}_{\mathsf{big}}$ that arrive after the stuck task is started. Let t_* be the time when eve starts running τ_s, and let $\mathcal{F}_{\mathsf{big}}{}' = \{\tau_i \in \mathcal{F}_{\mathsf{big}} : t_i \geq t_*\}$ be the fake tasks arriving after t_*. We first observe that, if no such tasks arrive, eve performs very well.

▷ Claim 12. If $\mathcal{F}_{\mathsf{big}}{}' = \varnothing$ then $\widetilde{\mathsf{C}}_{\mathsf{eve}} \leq \xi\mathsf{C}_{\mathsf{opt}}$.

Proof. At time $t_\star$ no tasks $\tau_i \in \mathcal{A}\cup\mathcal{F}_{\mathsf{big}}$ can be present, since all such tasks have $\sigma_i + t_i > \mathsf{C}_{\mathsf{opt}}/\xi$, so eve would prioritize running them on the fast machine instead of the stuck task. By Claim 11, we know that after time t_* eve will always be running tasks from $\{\tau_s\} \cup \mathcal{A} \cup \mathcal{F}_{\mathsf{big}}{}'$. The total work on tasks from $\mathcal{A}$ that arrives after time $t_\star$ is at most $\mathsf{C}_{\mathsf{opt}} - t_\star$, so if $\mathcal{F}_{\mathsf{big}}{}' = \varnothing$ we have

$$\widetilde{\mathsf{C}}_{\mathsf{eve}} \leq t_\star + \pi_s + \mathsf{C}_{\mathsf{opt}} - t_\star \leq \sigma_s/\xi + \mathsf{C}_{\mathsf{opt}} \leq \xi\mathsf{C}_{\mathsf{opt}}. \qquad \triangleleft$$

By Claim 12 we may assume $\mathcal{F}_{\mathsf{big}}{}' \neq \varnothing$. So, let $\sigma_{\min} = \min_{\tau_i \in \mathcal{F}_{\mathsf{big}}{}'}(\sigma_i)$; we will be able to control how much work arrives in the TAP by the fact that eve never decides to run the task $\tau_i \in \mathcal{F}_{\mathsf{big}}{}'$ with $\sigma_i = \sigma_{\min}$ on a slow machine. Split $\mathcal{A}$ into $\mathcal{A}_{\mathrm{early}} = \{\tau \in \mathcal{A} : t_\star \leq t_i < R(\sigma_{\min})\}$ and $\mathcal{A}_{\mathrm{late}} = \{\tau \in \mathcal{A} : t_i \geq \max(t_\star, R(\sigma_{\min}))\}$ (note that we use a different threshold to define earliness here than we did in case 2). First we need the following analogue of Claim 11.

▷ Claim 13. If eve starts a task $\tau \in \mathcal{F}_{\mathsf{big}}{}'$ at any time $t \in [R(\mathsf{C}_{\mathsf{opt}}/\xi), \mathsf{C}_{\mathsf{opt}}]$, then $\widetilde{\mathsf{C}} \leq \xi\mathsf{C}_{\mathsf{opt}}$.

Proof. Let t_* be the last time in $[R(\mathsf{C}_{\mathsf{opt}}/\xi), \mathsf{C}_{\mathsf{opt}}]$ when eve starts a task $\tau \in \mathcal{F}'$. If t_* does not exist the claim is vacuously true. Let τ_i be the task that eve starts at time t_*. Because eve prioritizes making tasks with larger $\sigma_j + t_j$ values active, at time t_* there are no tasks $\tau \in \mathcal{A}$ present. After time t_* at most $\mathsf{C}_{\mathsf{opt}} - t_*$ work in $\mathcal{A}$ can arrive because opt must be able to complete this work. Recalling that $\pi_{\mathcal{F}_{\mathsf{big}}{}'} \leq \mathsf{C}_{\mathsf{opt}}/\xi$, we have

$$\widetilde{\mathsf{C}}_{\mathsf{eve}} \leq t_* + \pi_{\mathcal{F}_{\mathsf{big}}{}'} + (\mathsf{C}_{\mathsf{opt}} - t_*) \leq \xi\mathsf{C}_{\mathsf{opt}}. \qquad \triangleleft$$

▷ Claim 14. $t_\star + \pi_{\mathcal{F}_{\mathsf{big}}{}'} + \pi_{\mathcal{A}_{\mathsf{early}}} < (\sigma_{\min} + R(\sigma_{\min}))/\xi$.

Proof. Fix a time $t < R(\sigma_{\min})$ after all tasks in $\mathcal{F}_{\mathsf{big}}{}' \cup \mathcal{A}_{\mathsf{early}}$ have arrived, and fix a task $\tau_i \in \mathcal{F}_{\mathsf{big}}{}'$ with $\sigma_i = \sigma_{\min}$. First, note that by Claim 13 we can assume that eve has not started τ_i by time t. Thus, eve is free to start τ_i on a slow machine, but chooses not to. This implies

$$\xi\mathsf{C}^t < \sigma_i + t < \sigma_{\min} + R(\sigma_{\min}). \tag{7}$$

We also observe that $\mathsf{opt}(t)$ must run $\mathcal{F}_{\mathsf{big}}{}' \cup \mathcal{A}_{\mathsf{early}}$ on the fast machine, since running any of them on the slow machine would finish after time $\sigma_{\min}$. Thus,

$$t_\star + \pi_{\mathcal{F}_{\mathsf{big}}{}'} + \pi_{\mathcal{A}_{\mathsf{early}}} \leq \mathsf{C}^t. \tag{8}$$

Combining Equation (8) and Equation (7) gives the desired statement. $\triangleleft$

The other observation we make is that $R(\sigma_{\min})$ cannot happen too early.

▷ Claim 15. $R(\sigma_{\min}) > (\xi - 1)\sigma_{\min}$.

Proof. Let $\tau_i \in \mathcal{F}_{\mathsf{big}}{}'$ be a task with $\sigma_i = \sigma_{\min}$. Note that $t_i \leq R(\sigma_{\min})$ by Claim 10. Then, by Claim 13 we may assume without loss of generality that at time $R(\sigma_{\min})$ eve is not running τ_i, and does not choose to start τ_i on a slow machine. So,

$$R(\sigma_{\min}) + \sigma_{\min} > \xi \mathsf{C}^{R(\sigma_{\min})} \geq \xi\sigma_{\min}.$$ ◁

Now we conclude the theorem.

▷ Claim 16. $\widetilde{\mathsf{C}}_{\mathsf{eve}} \leq \xi \mathsf{C}_{\mathsf{opt}}$.

Proof. Note that $\pi_{\mathcal{A}_{\text{late}}} \leq \mathsf{C}_{\mathsf{opt}} - R(\sigma_{\min})$. Also, note that since τ_s was not put on a slow machine immediately upon arrival, we must have $\pi_s \leq \sigma_s/\xi \leq \mathsf{C}_{\mathsf{opt}}/\xi^2$. Then, applying Claim 14 and Claim 15 we have

$$\begin{aligned}
\widetilde{\mathsf{C}}_{\mathsf{eve}} &\leq \pi_s + t_\star + \pi_{\mathcal{F}_{\mathsf{big}}{}'} + \pi_{\mathcal{A}_{\mathsf{early}}} + \pi_{\mathcal{A}_{\text{late}}} \\
&\leq \mathsf{C}_{\mathsf{opt}}/\xi^2 + (\sigma_{\min} + R(\sigma_{\min}))/\xi + \mathsf{C}_{\mathsf{opt}} - R(\sigma_{\min}) \\
&\leq (1/\xi^2 + (1 + \xi - 1)/\xi + 1 - (\xi - 1))\mathsf{C}_{\mathsf{opt}} \\
&= (3 + 1/\xi^2 - \xi)\mathsf{C}_{\mathsf{opt}} \\
&= \xi \mathsf{C}_{\mathsf{opt}}.
\end{aligned}$$ ◁

◀

▶ Remark 17. The simple nature of the lower bound in Proposition 32, along with the fact that eve gets a competitive ratio quite close to ϕ might leave the impression that ϕ is clearly the correct competitive ratio, and a slightly better analysis of (a natural variant of) eve would be ϕ-competitive. However, this is not the case: in Section A, we show that no **non-procrastinating** eventually-committing scheduler can achieve competitive ratio better than ξ, where a scheduler is called non-procrastinating if, whenever tasks are present, it always runs at least one task. Thus, if the competitive ratio of eve can be improved upon, doing so will require a substantially different scheduler: one which occasionally decides to do nothing at all despite work being present.

5 A 1.5-Competitive Never-Committing Scheduler

In this section we analyze never-committing schedulers. First we give a simple lower bound.

▶ **Proposition 18.** *Fix $\varepsilon > 0$. There is no deterministic $((1 + \sqrt{3})/2 - \varepsilon)$-competitive never-committing scheduler.*

Proof. We may assume $\varepsilon < .001$. Let $\psi = (\sqrt{3} - 1)/2$. Let $\mathcal{T} = \Big((1, 2\psi, 0), (\infty, 1 - \psi, \psi)\Big)$; that is, τ_1 has $\sigma_1 = 1, \pi_1 = 2\psi, t_1 = 0$, and τ_2 has $\sigma_2 = \infty, \pi_2 = 1 - \psi, t_2 = \psi$. Let $\mathcal{T}' = \Big((1, 2\psi, 0)\Big)$ be the same TAP without the second task. We have $\mathsf{C}^{\mathcal{T}'}_{\mathsf{opt}} = 2\psi$, since opt just runs the single task on the fast machine, and $\mathsf{C}^{\mathcal{T}}_{\mathsf{opt}} = 1$, since opt can run τ_1 on a slow machine and τ_2 on the fast machine.

Suppose that alg is a $(\psi + 1 - \varepsilon)$-competitive scheduler. On TAP $\mathcal{T}'$, at time $\psi - \varepsilon/2$, we claim alg must be running τ_1 on the fast machine. If not, then alg's completion time must be at least $\min(\sigma_1, \psi - \varepsilon/2 + \pi_1) = 1$, with the branch of the min depending on whether τ_1 is ever moved to the fast machine – but this gives competitive ratio $1/(2\psi) = 1 + \psi$.

Before time ψ, it is impossible to distinguish between $\mathcal{T}$ and $\mathcal{T}'$. Thus, alg must be running τ_1 on the fast machine at time $\psi - \varepsilon/2$ on TAP $\mathcal{T}$. Now, we have $\mathsf{C}^{\mathcal{T}}_{\mathsf{alg}} \geq \min(\sigma_1 + \psi - \varepsilon/2, \pi_1 + \pi_2) = 1 + \psi - \varepsilon/2$, with the branch of the min depending on whether τ_1 is ever moved to a slow machine – but this gives competitive ratio $(1 + \psi - \varepsilon/2)/1$. Thus, alg is not actually $(\psi + 1 - \varepsilon)$-competitive. ◀

Now we give a 1.5-competitive never-committing scheduler, which we call nev ("*nev*er committing"). Note that this competitive ratio is smaller than the lower bound of $\phi \approx 1.618$ known for eventually committing schedulers, so this demonstrates a separation between the strengths of schedulers in the two models.

▶ **Scheduler 19.** At time t:

- If task τ_i has $\sigma_i + t \leq 1.5\mathsf{C}^t$ but is not currently running on a slow machine, start τ_i on a slow machine, cancelling its fast machine implementation if necessary.
- Let $\mathcal{P}$ be the set of τ_i that have arrived and are not running on a slow machine. Choose $\tau_i \in \mathcal{P}$ maximizing $\sigma_i + t_i$, breaking ties by choosing the task with the smaller i. Run τ_i on the fast machine during this time step.

▶ **Theorem 20.** nev *is a* 1.5*-competitive never-committing scheduler.*

Proof. Fix TAP $\mathcal{T}$. Let $\widetilde{C}_{\mathsf{nev}}$ denote the final time when nev has work on the fast machine. Observe that if nev ever runs τ_i on a slow machine, then nev finishes τ_i before time $1.5\mathsf{C}_{\mathsf{opt}}$. Thus, to show that nev is 1.5-competitive it suffices to show $\widetilde{C}_{\mathsf{nev}} \leq 1.5\mathsf{C}_{\mathsf{opt}}$.

Let $\mathcal{A} = \{\tau_i : \sigma_i + t_i > \mathsf{C}_{\mathsf{opt}}\}$ be the set of tasks that opt *actually* runs on the fast machine.

▷ Claim 21. nev never runs a task $\tau \in \mathcal{A}$ on the fast machine after time $\mathsf{C}_{\mathsf{opt}}$.

Proof. nev always allocates the fast machine to the present task with the largest value of $\sigma_i + t_i$ among tasks that aren't running on slow machines. Thus, whenever there are tasks from $\mathcal{A}$ that aren't running on slow machines, nev will run one such task on the fast machine. opt is able to complete all tasks in $\mathcal{A}$ on the fast machine by time $\mathsf{C}_{\mathsf{opt}}$. Thus, nev completes or starts on slow machines all tasks $\tau \in \mathcal{A}$ before time $\mathsf{C}_{\mathsf{opt}}$. ◁

This means that the only way to have $\widetilde{\mathsf{C}}_{\mathsf{eve}} > \mathsf{C}_{\mathsf{opt}}$ is if there are tasks with $\sigma_i + t_i \leq \mathsf{C}_{\mathsf{opt}}$ that have yet to be completed at time $\mathsf{C}_{\mathsf{opt}}$; we assume that this is the case for the remainder of the proof. Let $\Pi(x)$ be the total amount of work nev performs on the fast machine after time $\mathsf{C}_{\mathsf{opt}}$ across all tasks with $\sigma_i + t_i \in [x, 1.5x]$. For any $x \leq \mathsf{C}_{\mathsf{opt}}$, let $R(x) = \inf\{t \mid \mathsf{C}^t \geq x\}$ be the first time an online algorithm becomes aware that the optimal schedule requires x completion time; the following key claim allows us to bound this left-over work $\Pi(x)$ in terms of $R(x)$.

▷ Claim 22. For all x, we have $\Pi(x) \leq x - R(x)$.

Proof. Let $\mathcal{J}_x$ denote the set of tasks with $\sigma_i + t_i \leq 1.5x$ that nev runs on the fast machine at some time after $\mathsf{C}_{\mathsf{opt}}$. First, note that all $\tau_i \in \mathcal{J}_x$ must have $t_i < R(x)$, or else τ_i would be placed on a slow machine upon arrival. Choose ε sufficiently small, such that no tasks arrive between times $R(x) - \varepsilon$ and $R(x)$. Since $R(x) - \varepsilon < R(x)$, we know $\mathsf{C}^{R(x)-\varepsilon} < x$, and so $\mathsf{opt}(R(x) - \varepsilon)$ must run all tasks with $\sigma_i + t_i \geq x$ on the fast machine. In order for $\mathsf{opt}(R(x) - \varepsilon)$ to finish these tasks before time $\mathsf{C}^{R(x)-\varepsilon} < x$, $\mathsf{opt}(R(x) - \varepsilon)$ must have at most $x - R(x) + \varepsilon$ fast work remaining across all such tasks.

Now, by the same argument as in Claim 21, because nev prioritizes tasks with $\sigma_i + t_i \geq x$ over tasks with $\sigma_i + t_i < x$ on the fast machine whenever they are present (and not yet started on slow machines), nev has at most $x - R(x) + \varepsilon$ work remaining on tasks in $\mathcal{J}_x$ at time $R(x) - \varepsilon$. Because no more tasks from $\mathcal{J}_x$ arrive after this time, we have $\Pi(x) \leq x - R(x) + \varepsilon$ as well. The claim held for all $\varepsilon > 0$, and so taking $\varepsilon \to 0$ we have $\Pi(x) \leq x - R(x)$. ◁

We now give an observation to control $R(x)$. Let $\tau_{i_\star}$ be the task, among all tasks that nev runs on the fast machine after time $\mathsf{C}_{\mathsf{opt}}$, with the smallest value of $\sigma_i + t_i$. Let $\lambda = \sigma_{i_\star} + t_{i_\star}$.

▷ Claim 23. For all $x \geq \lambda$, we have $R(x) > 1.5x - \lambda$.

Proof. First, note that $t_{i_\star} \leq R(\lambda) \leq \lambda$ or else nev would start $\tau_{i_\star}$ on a slow machine upon arrival. Now, because nev doesn't start $\tau_{i_\star}$ on a slow machine at time $R(x) > t_{i_\star}$, we have $R(x) + \sigma_{i_\star} > 1.5x$. ◁

To prove the theorem, it will now suffice to branch into two cases, based on how large λ is.

Case 1. $\lambda \geq (2/3)\mathsf{C}_{\mathsf{opt}}$.

In this case, since $1.5\lambda \geq \mathsf{C}_{\mathsf{opt}}$, by Claim 21 all left-over work at time $\mathsf{C}_{\mathsf{opt}}$ comes from tasks with $\sigma_i + t_i \in [\lambda, 1.5\lambda]$. By Claim 22, the total amount of such work is at most $\lambda - R(\lambda)$. Then, by Claim 23, we know $R(\lambda) > .5\lambda$. Together, this implies that the total amount of leftover work is at most $.5\lambda \leq .5\mathsf{C}_{\mathsf{opt}}$.

Case 2. $\lambda < 2\mathsf{C}_{\mathsf{opt}}/3$.

First note that $\lambda \geq \mathsf{C}_{\mathsf{opt}}/2$ or else $\tau_{i_\star}$ would be started on a slow machine at time $\mathsf{C}_{\mathsf{opt}}$. So, all left-over work at time $\mathsf{C}_{\mathsf{opt}}$ comes either from tasks with $\sigma_i + t_i \in [\lambda, 1.5\lambda]$, or from tasks with $\sigma_i + t_i \in [1.5\lambda, 1.5^2\lambda]$. By Claim 22, we can therefore bound the total amount of leftover work by $(\lambda - R(\lambda)) + (1.5\lambda - R(1.5\lambda))$. Now, by Claim 23, this quantity can be at most $(\lambda - .5\lambda) + (1.5\lambda - 1.25\lambda) = .75\lambda$. Since $\lambda < 2\mathsf{C}_{\mathsf{opt}}/3$, this is at most $.5\mathsf{C}_{\mathsf{opt}}$. ◀

▶ Remark 24. In Section A we show that Scheduler 19 is optimal among never-committing schedulers that never cancel implementations running on slow machines. This shows that improving on Scheduler 19 will require a substantially different scheduler.

6 Extending Beyond the Massively Parallel Regime

In Theorem 7, we have shown that Scheduler 5 is a 2-competitive instantly-committing scheduler in the Massively Parallel regime of the SPDP. In this section, we will show that in fact, Scheduler 5 is a 2-competitive scheduler even outside of the Massively Parallel regime, although the analysis is slightly more complicated. This result is interesting in its own right, resolving an open question from [16]. However, we think that the main virtue of this proof is that it serves as a proof-of-concept that results from the conceptually simpler Massively Parallel regime can be adapted to apply to the general SPDP: we conjecture that all upper bounds holding in the massively parallel regime should also hold in the general SPDP.

First, recall the setup of the SPDP problem. The input is a sequence of triples $\tau_i = (\sigma_i, \pi_i, t_i)$, where π_i is the work of the parallel implementation of task τ_i, and σ_i is the work of the serial implementation of task τ_i. At each time step, the scheduler allocates its processors to the jobs, giving at most 1 processor to each serial job.

Scheduler 5 is not a defined scheduler in the SPDP, because we specify the decisions for which tasks to run, but do not specify how to schedule the tasks. We extend ins to the general SPDP as follows:

▶ **Scheduler 25.** When task τ_i arrives:
- If $\sigma_i + t_i > 2\mathsf{C}^{t_i}$ parallelize τ_i.
- Otherwise, serialize τ_i.

At every timestep, if there are x serial jobs present, then ins schedules the jobs by allocating a processor to each of the $\min(p, x)$ serial jobs with the most remaining work (or an arbitrary set of p jobs with maximum remaining work if there are more than p serial jobs with maximum remaining work), and then allocating any remaining processors to an arbitrary parallel job (if a parallel job is present).

Now we analyze ins. We say ins is **saturated** at time t if ins has no idle processors at time t.

▶ **Lemma 26.** *If* ins *is unsaturated right before finishing, then* $\mathsf{C}_{\mathsf{ins}} \leq 2\mathsf{C}_{\mathsf{opt}}$.

Proof. We claim that if ins is unsaturated at time t, then for each task τ_i present at time t, τ_i has been run on every time step since it arrived. Suppose this is not the case. Then, there must have been some time step before time t when there were at least p serial jobs with at least as much remaining work as τ_i. But then τ_i will finish at the same time as these other jobs, contradicting the fact that ins is unsaturated at time t. Thus, if ins is unsaturated at time t, then $t \leq \sigma_i + t_i$ for some i such that ins ran τ_i in serial. Thus, $t \leq 2\mathsf{C}_{\mathsf{opt}}$, as desired. ◀

By virtue of Lemma 26 it suffices to consider the case that ins is saturated immediately before finishing. Let t_* be the final time in $[0, \mathsf{C}_{\mathsf{ins}})$ when ins is unsaturated (we set $t_* = 0$ if ins is always saturated). Let $i_* \in [n]$ be the smallest i such that $t_i \geq t_*$; in fact we will have $t_{i_*} = t_*$, since in order to transition from being unsaturated to being saturated, some tasks must arrive. For integer $i \in [i_*, n]$, let $\mathsf{K}^i_{\mathsf{alg}}$ denote the sum of π_j for each τ_j with $i_* \leq j \leq i$ that alg runs in parallel; If alg is an instantly-committing scheduler then $\mathsf{K}^i_{\mathsf{alg}}$ can be computed at time t_i. Now we prove an analogue of Lemma 6.

▶ **Lemma 27.** *Fix a length n TAP. For all $i \in [i_*, n]$, and for all instantly-committing schedulers* alg*,*

$$\mathsf{K}^i_{\mathsf{ins}} \leq (\mathsf{C}^{t_i}_{\mathsf{alg}} - t_*)p + \mathsf{K}^i_{\mathsf{alg}}. \tag{9}$$

Proof. We prove Equation (9) by induction on i. The base case is $i = i_*$. If alg takes π_i work here, then we have $\mathsf{K}^i_{\mathsf{ins}} \leq \mathsf{K}^i_{\mathsf{alg}}$ (and $\mathsf{C}^{t_i}_{\mathsf{alg}} \geq t_*$) so the invariant will hold. If instead alg runs τ_i in serial, then we'll have $\mathsf{C}^{t_i}_{\mathsf{alg}} - t_* \geq \sigma_i \geq \pi_i/p$, in which case we have $\mathsf{K}^i_{\mathsf{ins}} \leq (\mathsf{C}^{t_i}_{\mathsf{alg}} - t_*)p$ so the invariant holds. This establishes the base case.

Now, assume Equation (9) for $i \in [i_*, n)$; we prove Equation (9) for $i + 1$. If alg takes at least as much work as ins on τ_{i+1}, i.e., $\mathsf{K}^{i+1}_{\mathsf{alg}} - \mathsf{K}^i_{\mathsf{alg}} \geq \mathsf{K}^{i+1}_{\mathsf{ins}} - \mathsf{K}^i_{\mathsf{ins}}$, then Equation (9) for (i, alg) implies Equation (9) for $(i + 1, \mathsf{alg})$. It remains to consider the case when alg runs τ_{i+1} in serial, but ins runs τ_{i+1} in parallel. Here, ins thought τ_{i+1} was too large to serialize large, so:

$$\mathsf{C}^{t_{i+1}}_{\mathsf{alg}} \geq \sigma_{i+1} + t_{i+1} > 2\mathsf{C}^{t_{i+1}}. \tag{10}$$

One consequence of Equation (10) is that $\mathsf{opt}(t_{i+1})$ parallelizes τ_{i+1}; a corollary of this is that Equation (9) holds for $(i+1, \mathsf{opt}(t_{i+1}))$. Thus, applying Equation (9) for $(i+1, \mathsf{opt}(t_{i+1}))$ and using Equation (10) gives:

$$\mathsf{K}_{\mathsf{ins}}^{i+1} \leq (\mathsf{C}^{t_{i+1}} - t_*)p + \mathsf{K}_{\mathsf{opt}(t_{i+1})}^{i+1} \leq (2\mathsf{C}^{t_{i+1}} - 2t_*)p \leq (\mathsf{C}_{\mathsf{alg}}^{t_{i+1}} - t_*)p,$$

so the invariant holds in this case as well. ◀

In the Massively Parallel regime Theorem 7 followed immediately from Lemma 6. Slightly more work is required in the general setting, but Lemma 27 is still very useful.

▶ **Theorem 28.** ins *is a 2-competitive instantly-committing scheduler in the SPDP.*

Proof. Recall from Lemma 26 that we need only consider the case that ins ends saturated, and recall the definition of t_*. For any scheduler alg, let $\mathsf{B}_{\mathsf{alg}}$ denote the work that alg has left immediately before time t_*, and let $\mathsf{K}_{\mathsf{alg}}$ be work that alg takes on tasks τ_i with $t_i \geq t_*$. Because ins ends saturated, we have

$$\mathsf{C}_{\mathsf{ins}} = t_* + (\mathsf{K}_{\mathsf{ins}} + \mathsf{B}_{\mathsf{ins}})/p.$$

Applying Lemma 27 gives

$$t_* + (\mathsf{K}_{\mathsf{ins}} + \mathsf{B}_{\mathsf{ins}})/p \leq \mathsf{C}_{\mathsf{opt}} + (\mathsf{K}_{\mathsf{opt}} + \mathsf{B}_{\mathsf{ins}})/p. \tag{11}$$

So, to conclude, it suffices to show that $\mathsf{B}_{\mathsf{ins}} + \mathsf{K}_{\mathsf{opt}} \leq p\mathsf{C}_{\mathsf{opt}}$. Let S be the set of tasks that ins has present immediately before time t_*. Let $W = \sum_{\tau_i \in S} \sigma_i$. Clearly $\mathsf{B}_{\mathsf{ins}} \leq W$. On the other hand, opt must take at least W work on the tasks S, and can have made at most pt_* progress on these tasks by time t_*. Thus,

$$\mathsf{B}_{\mathsf{ins}} \leq W \leq pt_* + \mathsf{B}_{\mathsf{opt}}.$$

Therefore,

$$\mathsf{B}_{\mathsf{ins}} + \mathsf{K}_{\mathsf{opt}} \leq pt_* + \mathsf{B}_{\mathsf{opt}} + \mathsf{K}_{\mathsf{opt}} \leq p\mathsf{C}_{\mathsf{opt}}.$$

Using this in Equation (11) gives $\mathsf{C}_{\mathsf{ins}} \leq 2\mathsf{C}_{\mathsf{opt}}$. ◀

A Barriers Against Improved Schedulers

In this section we show that the schedulers of Section 4 and Section 5 are optimal among natural restricted classes of schedulers. This highlights what changes must be made to the schedulers in order to have hopes of achieving better competitive ratios.

First we show that among **non-procrastinating** eventually-committing schedulers (i.e., eventually-committing schedulers with the property that whenever tasks are present, they will run at least one task), the scheduler Scheduler 8 is optimal.

▶ **Proposition 29.** *Fix $\varepsilon > 0$. Let $\xi \approx 1.677$ denote the real root of the polynomial $2x^3 - 3x^2 - 1$. There is no deterministic $(\xi - \varepsilon)$-competitive non-procrastinating eventually-committing scheduler.*

Proof. It suffices to consider the case that $\varepsilon < .001$. Fix a non-procrastinating eventually-committing scheduler alg. Assume towards contradiction that alg is $(\xi - \varepsilon)$-competitive. We now describe a TAP $\mathcal{T}$ on which $\mathsf{C}_{\mathsf{alg}} \geq \xi \mathsf{C}_{\mathsf{opt}}$. The TAP starts with $\tau_1 = (1/\xi, 1/\xi^2, 0)$. Next, let $\tau_2 = (1 - \varepsilon^2, 1/\xi - \varepsilon^2, \varepsilon^2)$. Finally, at each time $t \in [\xi + 1/\xi - 2, 1 - \varepsilon^2] \cap (\mathbb{N}\varepsilon^2)$, give a task $\tau = (\infty, \varepsilon^2, t)$.

We now argue that alg must run all the tasks on the fast machine. Because alg is a non-procrastinating $(\xi - \varepsilon)$-competitive scheduler, alg must instantly start τ_1 on the fast machine (in case there are no tasks after τ_1). Now we argue that alg runs τ_2 on the fast machine as well. Suppose that alg starts τ_2 on a slow machine at some time t with

$$1 - \varepsilon^2 + t > (\xi - \varepsilon)\mathsf{C}^t. \tag{12}$$

Then, alg would not be $(\xi - \varepsilon)$-competitive on the truncated TAP $\mathcal{T}^t$. Thus, alg must not start τ_2 on a slow machine at any time t satisfying Equation (12). We now show that Equation (12) holds for all $t \geq \varepsilon$, thus proving that alg must run τ_2 on the fast machine. For $t \in [\varepsilon^2, \xi + 1/\xi - 2)$ we have $\mathsf{C}^t \leq 1/\xi$, and $1 - \varepsilon^2 + t \geq 1$, so Equation (12) holds. For $t \geq \xi + 1/\xi - 2$ we have

$$\mathsf{C}^t \leq \min(1, t - \xi + 2 + \varepsilon^2).$$

Thus, it suffices to show:

$$1 - \varepsilon^2 + t > (\xi - \varepsilon)\min(1, t - \xi + 2 + \varepsilon^2). \tag{13}$$

To show Equation (13) it suffices to check Equation (13) for $t = \xi - 1 - \varepsilon^2$ (by monotonicity of the inequality on either side of $t = \xi - 1$). At $t = \xi - 1 - \varepsilon^2$ Equation (13) is:

$$\xi - 2\varepsilon^2 > \xi - \varepsilon,$$

which is true because $\varepsilon < .001$.

We have now shown that alg runs all tasks in $\mathcal{T}$ on the fast machine. Thus, (by definition of ξ)

$$\mathsf{C}_{\mathsf{alg}} \geq 1/\xi^2 + 1/\xi - \varepsilon^2 + 1 - (1/\xi + \xi - 2) - \varepsilon^2 = \xi - 2\varepsilon^2.$$

However, $\mathsf{C}_{\mathsf{opt}} \leq 1$. This contradicts the assumption that alg is $(\xi - \varepsilon)$-competitive. ◀

Now, we show that the 1.5-competitive scheduler of Section 5 is optimal among never-committing schedulers that don't cancel tasks on slow machines.

▶ **Proposition 30.** *Let* alg *be a deterministic never-committing scheduler that never cancels serial tasks. Then, for any $\varepsilon > 0$, there is a TAP $\mathcal{T}$ with $n \leq O(1)$ on which* alg *has is not $(1.5 - \varepsilon)$-competitive.*

Proof. It suffices to consider the case that $\varepsilon < .001$. The TAP is defined as follows. First, $\tau_1 = (2, 1, 0)$. Then, for each time $t \in [\varepsilon^2, 1 - \varepsilon^2] \cap \mathbb{N}\varepsilon^2$, a task $\tau = (\infty, \varepsilon^2, t)$ arrives. We will show that if alg starts τ_1 on a slow machine at any time t then alg is not $(1.5 - \varepsilon)$-competitive on $\mathcal{T}^t$. We show this by considering two cases.

Case 1. alg starts τ_1 on a slow machine at time $t \in [0, 1]$.
If alg does this, then $\mathsf{C}^{\mathcal{T}^t}_{\mathsf{alg}} \geq 2 + t$. However, $\mathsf{C}^t \leq t + 1 + \varepsilon^2$. Thus,

$$\mathsf{C}^{\mathcal{T}^t}_{\mathsf{alg}}/\mathsf{C}^t \geq \frac{2 + t}{t + 1 + \varepsilon^2} \geq \frac{3}{2 + \varepsilon^2} > 1.5 - \varepsilon.$$

So alg cannot start τ_1 on a slow machine at this time.

Case 2. alg starts τ_1 on a slow machine at time $t \geq 1$.
If alg does this, then $\mathsf{C}_{\mathsf{alg}} \geq 2 + t$. However, $\mathsf{C}_{\mathsf{opt}} \leq 2$. Thus,

$$\mathsf{C}_{\mathsf{alg}}/\mathsf{C}_{\mathsf{opt}} \geq 1.5.$$

In conclusion, alg must run τ_1 on the fast machine. But then

$$\mathsf{C}_{\mathsf{alg}} \geq 3 - \varepsilon^2 > (1.5 - \varepsilon)\mathsf{C}_{\mathsf{opt}} = (1.5 - \varepsilon)2,$$

a contradiction. ◀

B Lower Bounds from [16]

In this section we state, for the reader's convenience, the lower bounds from [16] against instantly- and eventually- committing schedulers.

▶ **Proposition 31** (Kuszmaul, Westover [16]). *Fix $\varepsilon > 0$. There is no deterministic $(2-\varepsilon)$-competitive instantly-committing scheduler.*

Proof. Consider an n-task TAP where for each $i \in [n]$, the i-th task has $\sigma_i = 2^i, \pi_i = 2^{i-1}$, and the arrival times are all very close to 0. For each $i \in [n]$, it is possible to handle the first i tasks in the TAP with completion time 2^{i-1}. Thus, a $(2-\varepsilon)$-competitive scheduler cannot afford to run task τ_i on a slow machine. So, a $(2-\varepsilon)$-competitive scheduler must run all tasks on the fast machine, giving completion time at least $2^n - 1$ on this TAP, while $\mathsf{C}_{\mathsf{opt}} \leq 2^{n-1}$. For large enough n this implies that the scheduler is not actually $2-\varepsilon$ competitive. ◀

▶ **Proposition 32** (Kuszmaul, Westover [16]). *Fix $\varepsilon > 0$. There is no deterministic $(\phi-\varepsilon)$-competitive eventually-committing scheduler, where $\phi \approx 1.618$ is the golden ratio.*

Proof. Suppose that alg is a $(\phi-\varepsilon)$-competitive eventually-committing scheduler. Let $\tau_1 = (\phi, 1, 0)$; if there are no further tasks, alg must run τ_1 on the fast machine, starting at some time $t_0 \leq 1/\phi$. Let $\tau_2 = (\infty, \phi - t_0, t_0)$. On this TAP, $\mathsf{C}_{\mathsf{opt}} = \phi$, while $\mathsf{C}_{\mathsf{alg}} \geq \phi + 1 = \phi^2$. So alg is not $(\phi-\varepsilon)$-competitive. ◀

C Randomized Lower Bounds

In this section we give lower bounds against randomized schedulers. Our main tool is Yao's minimax principle [27], which allows us to prove a lower bound on the competitive ratio by exhibiting a distribution over TAPs, and showing that any deterministic scheduler has poor expected cost on a random TAP drawn from the distribution.

▶ **Proposition 33.** *For any $\varepsilon > 0.03$, there is no $(5/3-\varepsilon)$-competitive instantly-committing scheduler, even with randomization.*

Proof. Fix $N = 25$. For $k \in \mathbb{N}$, define $\mathcal{T}_k$ to be a length k TAP with $\sigma_i = 2^{i+1}, \pi_i = 2^i$. Let $\mathcal{D}$ denote the following distribution over TAPs: choose $k \in [N]$ uniformly randomly, and then output TAP $\mathcal{T}_k$. By brute force enumeration of all possible deterministic instantly-committing strategies, one can show that no such strategy is 1.637-competitive on this TAP. ◀

▶ **Proposition 34.** *For any $\varepsilon > 0$, there is no $((3+\sqrt{3})/4-\varepsilon)$-competitive eventually-committing scheduler, even with randomization.*

Proof. In the proof of Proposition 18 we defined two TAPs, and showed that no deterministic eventually-committing scheduler is $((1+\sqrt{3})/2-\varepsilon)$-competitive on both of the TAPs. One can show that if we randomly choose between the two TAPs of Proposition 18, there is no deterministic eventually-committing scheduler with expected competitive ratio $(1+\sqrt{3})/4 - \varepsilon$. ◀

Detecting and Correcting Computationally Bounded Errors: A Simple Construction Under Minimal Assumptions

NTT Research, Sunnyvale, CA, USA

Abstract

We study error detection and error correction in a computationally bounded world, where errors are introduced by an arbitrary polynomial time adversarial channel. We consider codes where the encoding procedure uses random coins and define two distinct variants: (1) in *randomized codes*, fresh randomness is chosen during each encoding operation and is unknown a priori, while (2) in *self-seeded codes*, the randomness of the encoding procedure is fixed once upfront and is known to the adversary. In both cases, the randomness need not be known to the decoding procedure, and there is no trusted common setup between the encoder and decoder. The encoding and decoding algorithms are efficient and run in some fixed polynomial time, independent of the run time of the adversary.

The parameters of standard codes for worst-case (inefficient) errors are limited by the Singleton bound: for rate R it is not possible to detect more than a $1 - R$ fraction of errors, or uniquely correct more than a $(1 - R)/2$ fraction of errors, and efficient codes matching this bound exist for sufficiently large alphabets. In the computationally bounded setting, we show that going beyond the Singleton bound implies *one-way functions* in the case of randomized codes and *collision-resistant hash functions* in the case of self-seeded codes. We construct randomized and self-seeded codes under these respective minimal assumptions with essentially optimal parameters over a constant-sized alphabet:

- Detection: the codes have a rate $R \approx 1$ while detecting a $\rho \approx 1$ fraction of errors.
- Correction: for any $\rho < 1/2$, the codes uniquely correct a ρ fraction of errors with rate $R \approx 1 - \rho$.

Codes for computationally bounded errors were studied in several prior works starting with Lipton (STACS '94), but all such works either: (a) need some trusted common setup (e.g., public-key infrastructure, common reference string) between the encoder and decoder, or (b) only handle channels whose complexity is a prior bounded below that of the code.

1 Introduction

The theory of error detection and error correction goes back to the seminal works of Shannon [21] and Hamming [7]. A sender *encodes* a message and sends the resulting codeword over a noisy channel that may introduce errors by modifying a subset of the codeword symbols. A receiver gets the modified codeword and attempts to *decode* the original message. The goal of *error-detection* is to recover the original message when there are no errors or detect the presence of errors. The goal of *error-correction* is to always uniquely recover the original message. The main parameters of interest are the *rate* R, defined as the ratio of message length to codeword length, and the *relative error tolerance* ρ, defined as the ratio between the number of errors that can be detected/corrected and the codeword length.

Starting with the work of Hamming [7], a large body of research studies codes for worst-case computationally unbounded (adversarial) channels that can introduce arbitrary errors patterns. The error tolerance in this setting is fully determined by the *distance* of the code, which is subject to several well-established fundamental bounds. For example, the *Singleton bound* implies that for any rate $R \geq 0$ the relative error tolerance is $\rho \leq 1 - R$ for error detection and $\rho \leq (1 - R)/2$ for error correction. Furthermore, there are efficient codes matching the Singleton bound for sufficiently large alphabet sizes.

Computationally Bounded Channels

We consider a setting similar to that of Hamming [7], where errors are introduced by a fully adversarial channel, but with the additional natural restriction that the channel is *computationally bounded*, and can run in arbitrary polynomial (or even sub-exponential) time. This restriction is well motivated – if an error pattern takes longer than the lifetime of the universe to compute, then we can safely assume it will not occur. Our goal is to construct efficient codes that can detect/correct errors in this setting with rate vs error-tolerance trade-offs that go beyond the Singleton bound. Many prior works starting with [11] and including [14, 12, 8, 4, 17, 1, 18, 19, 20, 3] have previously considered computationally bounded channels, either to get better parameters, or to achieve other desirable properties such as improved local/list decoding. However, all such prior works suffer from at least one of the following deficiencies:

1. *Trusted setup:* Many works require a trusted coordinated setup between the encoding and decoding algorithms. For example, [11] assumes that they share a secret key, which is unknown to the adversarial channel. Alternatively, [12] require a public-key infrastructure where the encoding algorithm has its own secret key, while the decoding algorithm (as well as the adversarial channel) gets the corresponding public-key. In both cases, the encoding algorithm is also stateful and updates its state between operations. The use of secret keys and state are significant limitations that make such codes inapplicable in many natural settings. The work of Grossman, Holmgren and Yogev [3] introduces the notion of *seeded codes* that only requires a light trusted setup consisting of a *common (uniformly) random seed* shared by the encoder and decoder. They construct such seeded codes correcting $\rho \approx 1 - R$ errors over a large alphabet based on strong and non-standard cryptographic hardness assumptions – namely a certain form of *two-input correlation-intractable hash functions*, which are currently only known to exist in the random-oracle model, but have no known provably secure instantiations under standard cryptographic hardness assumptions.
2. *Codes have higher complexity than adversary:* Many works [4, 17, 18, 19, 20] restrict the complexity (time/size or space) of the adversarial channel to be bounded by some arbitrary polynomial chosen a priori, and the complexity of the encoding/decoding algorithms then

scales accordingly to some sufficiently larger polynomial. In particular, the adversarial channel is not powerful enough to evaluate the encoding/decoding algorithms in these schemes. This is a significant limitation, since we cannot argue that such schemes protect against all errors that can arise in a computationally bounded world – a world that can compute the encoding/decoding algorithms of the scheme can also find error patterns to defeat them! In contrast, we would like to have efficient codes with some fixed polynomial run-time that protect against arbitrary polynomial (or even sub-exponential time) adversarial channels.

The different prior works and their properties are summarized in Table 1.

Table 1 Summary of related work. Seeded codes are also known as Monte-Carlo codes in the literature and require a common random seed shared by the encoder and decoder as a trusted setup. Randomized codes require fresh on-the-fly randomness at each encoding operation. Seeded + randomized codes require both simultaneously. Codes for channels in $\text{SIZE}(n^c)$ have correspondingly larger run-time $\text{poly}(n^c)$, while codes for channels in P/poly have some a priori fixed polynomial run-time independent of the channel. Some works focus on the binary alphabet while others focus on larger alphabets.

1.1 Our Results

In this work we construct error detection and error correction codes for computationally bounded channels, while simultaneously achieving: (1) no trusted setup, (2) a fixed polynomial-time code that protects against arbitrary polynomial (or even sub-exponential) time adversarial channels, (3) provable guarantees under basic/minimal computational hardness assumptions, (4) essentially optimal trade-offs between rate and error tolerance beyond the Singleton bound for sufficiently large constant-sized alphabets.

Randomized/Self-Seeded Codes

Standard deterministic codes cannot achieve better parameters against (non-uniform) computationally bounded channels beyond what they achieve for computationally unbounded channels, and in particular, they cannot go beyond the Singleton bound. This is because a worst-case message and error pattern for which detection/correction fails can simply be hard-coded as non-uniform advice to an efficient adversary. To overcome this limitation, we therefore consider codes (Enc, Dec), where the encoding procedure Enc takes additional

randomness as input. We consider two variants. In the basic variant of *randomized codes*, fresh randomness r for the encoding algorithm is chosen each time on the fly and is unknown to the adversary ahead of time. The adversary chooses a worst-case message m, gets the resulting randomized codeword $c \leftarrow \mathrm{Enc}(m; r)$ for a fresh random r, and then chooses the error e as an arbitrary efficiently computable function of the codeword. We also consider a stronger variant called *self-seeded codes*, where the randomness r of the encoding algorithm is fixed once and for all and known to the adversary a priori. That is, the adversary gets the randomness r and then uses it to adaptively choose the message m (which fully defines the codeword $c = \mathrm{Enc}(m; r)$) along with the error e. In both cases, the fractional Hamming weight of e is bounded by the error tolerance ρ. Error detection ensures that with overwhelming probability the resulting erroneous codeword $c' = c + e$ decodes to m when there are no errors, and decodes to either m or $\perp$ when there are errors. Error correction ensures that with overwhelming probability c' decodes to m.

The main technical difference between randomized and self-seeded codes is adaptivity: in the former the message m to be encoded is chosen by the adversary before the randomness r is chosen, while in the latter the message m can adaptively depend on r.[1] Self-seeded codes allow us to fix the randomness for the code once and for all as a public seed, and afterwards the code is fully deterministic. Moreover, the seed can be chosen by the encoder unilaterally without any coordination with the decoder. For example, different software manufacturers can individually choose their own seeds to be used by the encoding algorithms in their software, while allowing for interoperability with the decoders implemented by other manufacturers without any coordination. Self-seeded codes should be contrasted to the notion of seeded codes in [3], which required a shared random seed as a common trusted setup between the encoder and decoder. Self-seeded codes are the strongest notion and directly imply the seemingly incomparable notions of randomized codes and seeded codes.

Minimal Assumptions

We show that any randomized code that goes beyond the Singleton bound with error detection tolerance $\rho > 1 - R$ or error correction tolerance $\rho > (1 - R)/2$ implies *one-way functions*, while any such seeded (and therefore also self-seeded) code implies *collision-resistant hash functions*.

Main Theorem

We construct randomized and self-seeded codes going beyond the Singleton bound, with essentially optimal parameters for both error detection and error correction, under the above respective minimal assumptions.

▶ **Theorem 1** (Informal). *Assuming one-way functions (resp. collision-resistant hash functions) there exist efficiently computable randomized (resp. self-seeded) error-detection and error-correction codes for arbitrary polynomial-time adversarial errors with the following parameters:*

- *Error Detection: For any constant $0 < \varepsilon < 1$, there is a code over a constant-sized alphabet with rate $R = 1 - \varepsilon$ that detects a $\rho = 1 - \varepsilon$ fraction of errors.*

[1] Randomized codes may also be secret-coin, where the adversary never sees the full randomness r. However, our construction will be public-coin and the randomness r can be easily recovered from the codeword c.

- *Error Correction: For any constants $0 < \varepsilon < 1$ and $0 \leq \rho < 1/2$, there is a code over a constant-sized alphabet with rate $R = 1 - \rho - \varepsilon$ that uniquely corrects from a ρ fraction of errors.*

If we assume sub-exponentially secure one-way functions (resp. collision-resistant hash functions), then the above properties hold even for sub-exponential time adversarial errors.

Recall that, in the case of error-detection, the Singleton bound says that the relative error tolerance $\rho \leq 1 - R$ necessarily degrades as the rate improves when considering worst-case errors; in contrast, for computationally bounded errors, our result simultaneously achieves the best possible error tolerance $\rho \approx 1$ and rate $R \approx 1$. In the case of error correction, the Singleton bound says the maximal error tolerance is $\rho \leq (1 - R)/2$ for worst-case errors, while for computationally bounded errors our result achieves twice as large error tolerance $\rho \approx 1 - R$, subject to the upper limit $\rho < 1/2$.

Our achieved parameters are essentially optimal, up to the arbitrarily small constant ε. This is clear for error detection, where we get the best possible rate $R \approx 1$ and error tolerance $\rho \approx 1$ simultaneously. For error-correction, one cannot tolerate $\rho \geq 1/2$ fraction of errors since an efficient adversarial channel can modify $1/2$ the codeword positions to a fresh encoding of a different message, causing decoding to fail with probability at least $1/2$.[2] Moreover, one cannot have rate $R > 1 - \rho$ since zeroing out the first ρ fraction of positions of the codeword would remove information about the message, causing decoding to fail.

We remark that, not only are one-way functions and collision-resistant hash functions the minimal assumptions needed to achieve the above results, they are considered some of the most standard and well-studied cryptographic assumptions/primitives. In particular, one-way functions are a minimal assumption necessary for essentially any non-trivial task in cryptography and are implied by all concrete cryptographic hardness assumptions. Collision-resistant hash functions are not known to be implied by one-way function, but can be constructed from essentially every concrete cryptographic hardness assumption, such as hardness of factoring, discrete logarithms, learning with errors, etc.

The closest related prior work of [3] achieves essentially the same parameters as our work, but only for the weaker notion of seeded codes, which require trusted setup, and only by assuming a strong form of "two-input correlation-intractable hash functions", which we do not know how to instantiate under any standard cryptographic hardness assumption. Our result for self-seeded codes yields a stronger primitive under significantly weaker minimal assumptions. Comparing the notions of randomized, seeded and self-seeded codes, it is clear that self-seeded codes are the strongest notion easily implying the other two, while randomized and seeded codes are seemingly incomparable. Interestingly, since we show that any non-trivial seeded codes imply collision-resistant hashing, which in turn implies self-seeded codes, we show that seeded and self-seeded codes are equivalent in terms of the needed assumptions.

Simultaneous Correction and Detection

While we stated separate results for error-detection and error-correction above, we can also simultaneously achieve a non-trivial combination of correction and detection. In particular, we can augment the previous theorem statement with the following:

[2] The works of [11, 12] overcome this limitation by having a stateful and secret keyed encoding procedure to ensure that an adversarial channel cannot generate/reuse valid codewords.

For any constants $0 < \varepsilon < 1$ and $0 \leq \rho_c < 1/2$, there is a code over a constant-sized alphabet with rate $R = 1 - \rho_c - \varepsilon$ that simultaneously uniquely corrects from a ρ_c fraction of errors and detects a $\rho_d = 1 - \rho_c - \varepsilon$ fraction of errors.

The above implies both of the previously stated results for error detection (by setting $\rho_c = 0$) and error correction (by ignoring ρ_d). However simultaneous error correction and detection is an interesting property, which is more than the sum of its parts. It gives a single decoding procedure that either outputs a message or $\perp$ (error detection symbol) and is guaranteed to uniquely recover the correct message if the error rate is $\leq \rho_c$ and to never output the wrong message as long as the error rate is $\leq \rho_d$. We can envision scenarios where correcting a small fraction of errors (e.g., $\rho_c = .1$) may suffice. Our result show that for such instances, we can have a code with a correspondingly large rate (e.g., $R \approx .9$) while simultaneously being able to detect a much larger fraction of errors (e.g., $\rho_d \approx .9$) at no additional cost.

Alphabet Size

We note that our results hold for large constant-size alphabets, but do not extend to the case of a binary alphabet. Giving optimal results for binary codes that detect/correct computationally bounded errors under minimal assumptions remains an interesting open problem. The results of [3] for seeded error correcting codes using a strong form of correlation intractable hash functions extend to the binary case and show that one can uniquely decode computationally bounded errors with essentially the same parameters as list-decoding for worst-case errors. It remains an open problem to achieve such results for randomized or self-seeded codes under any assumptions, and/or to to get provably secure seeded codes under standard cryptographic hardness assumptions.

1.2 Our Techniques

Our techniques are quite simple in retrospect. We start by showing how to construct self-seeded codes assuming collision-resistant hashing, and then discuss how to modify these results to get analogous ones for randomized codes from one-way functions. Throughout the introduction, we use "$\approx$" to denote that two values differ by an arbitrarily small constant.

Self-Seeded Error Detection with Sub-Exponential Alphabet

We start with a naive construction of self-seeded error-detection codes that requires a sub-exponentially large alphabet size, and then show how to reduce the alphabet size to some (large) constant. Let $\mathcal{H} = \{h_r \ : \ \{0,1\}^k \to \{0,1\}^\lambda\}_{r \in \{0,1\}^\lambda}$ be a collision-resistant hash function family with output length λ (security parameter), which we can think of as $\lambda = k^\alpha$ for some small constant $\alpha > 0$. Given a random public seed $r \leftarrow \{0,1\}^\lambda$, no polynomial-time adversary can find two messages $m \neq m'$ such that $h_r(m) = h_r(m')$.

The encoding algorithm $\mathrm{Enc}(m; r)$ takes a message $m \in \{0,1\}^k$ and parses it as $n = k/w$ symbols $m = (m_1, \ldots, m_n)$ over an alphabet $\Sigma_{\mathrm{data}} = \{0,1\}^w$ for some large $w = O(\lambda)$. It then "folds in" the seed r and hash of the message $h_r(m)$ into each message symbol to yield the codeword

$$c = (\ [m_1, r, h_r(m)]\ ,\ [m_2, r, h_r(m)]\ ,\ \ldots\ ,\ [m_n, r, h_r(m)]\ ) \in \Sigma^n$$

interpreted as n symbols over the larger alphabet $\Sigma = \{0,1\}^{w+2\cdot\lambda}$. The decoding algorithm $\mathrm{Dec}(c')$ gets

$$c' = (\ [m'_1, r'_1, y'_1]\ ,\ [m'_2, r'_2, y'_2]\ ,\ \ldots\ ,\ [m'_n, r'_n, y'_n]\ ) \in \Sigma^n,$$

which gives a candidate message $m' = (m'_1, \ldots, m'_n)$. It checks that the second part of each codeword symbol has the same common seed value $r'_1 = \cdots = r'_n$ and that the third part of each symbol has the same common hash value $y'_i = h_{r'_i}(m')$; if so it outputs m' else $\perp$. The code achieves rate $R = w/(w + 2\lambda) \approx 1$ by choosing a sufficiently large $w = O(\lambda)$. Moreover, it achieves error-tolerance $\rho = 1 - 1/n$. Unless the adversary changes *every* symbol of the codeword c, or finds a collision, decoding is guaranteed to output the correct message m or $\perp$. To see this, assume at least one symbol of the codeword remains unchanged and decoding outputs $m' \neq m$ for some $m' \neq \perp$. Then it must be the case that $r'_i = r, y'_i = h_r(m') = h_r(m)$ for all i and therefore the this gives a collision $m \neq m'$ such that $h_r(m) = h_r(m')$.

Self-Seeded Error Detection with Constant Alphabet

We reduce the alphabet size to a constant by applying a standard error-correcting code $(\mathrm{Enc}_{\mathrm{ctrl}}, \mathrm{Dec}_{\mathrm{ctrl}})$ over a constant sized alphabet to the small "control" value $(r, h_r(m))$. In particular, for some constants $w > v$, we use a code with alphabet $\Sigma_{\mathrm{ctrl}} = \{0,1\}^v$ such that $\mathrm{Enc}_{\mathrm{ctrl}} : \{0,1\}^{2\lambda} \to \Sigma^n_{\mathrm{ctrl}}$ maps a 2λ-bit message to a codeword of length $n = k/w$. The corresponding rate of the code is very small $R_{\mathrm{ctrl}} = O(\lambda/k) = o(1)$, but we will want large distance $\delta_{\mathrm{ctrl}} \approx 1$. Such codes can be constructed by concatenating Reed-Solomon codes with a brute-force inner code over the alphabet Σ_{ctrl} (see Theorem 13). We do not need efficient error-decoding for now, but only require an efficient way to recognize and valid codewords and invert them without errors. The encoding algorithm of our self-seeded code $\mathrm{Enc}(m; r)$ first computes $c_{\mathrm{ctrl}} = (c_{\mathrm{ctrl},1}, \ldots, c_{\mathrm{ctrl},n}) = \mathrm{Enc}_{\mathrm{ctrl}}((r, h_r(m))) \in \Sigma^n_{\mathrm{ctrl}}$. It interprets $m \in \{0,1\}^k$ as $m = (m_1, \ldots, m_n) \in \Sigma^n_{\mathrm{data}}$ consisting of $n = k/w$ symbols over the alphabet $\Sigma_{\mathrm{data}} = \{0,1\}^w$ and then "folds" the two vectors together to yield the final codeword

$$c = (\ [m_1, c_{\mathrm{ctrl},1}]\ ,\ \ldots\ ,\ [m_n, c_{\mathrm{ctrl},n}]\ ) \in \Sigma^n,$$

interpreted as n symbols in over the alphabet $\Sigma = \Sigma_{\mathrm{data}} \times \Sigma_{\mathrm{ctrl}} = \{0,1\}^{v+w}$. The decoding algorithm $\mathrm{Dec}(c')$ gets

$$c' = (\ [m'_1, c'_{\mathrm{ctrl},1}]\ ,\ \ldots\ ,\ [m'_n, c'_{\mathrm{ctrl},n}]\ ) \in \Sigma^n,$$

and recovers a candidate message $m' = (m'_1, \ldots, m'_n)$ as well as a candidate $c'_{\mathrm{ctrl}} = (c'_{\mathrm{ctrl},1}, \ldots, c'_{\mathrm{ctrl},n})$. It checks that c'_{ctrl} is a valid codeword and if so recovers (r', y') such that $c'_{\mathrm{ctrl}} = \mathrm{Enc}_{\mathrm{ctrl}}(r', y')$. If c'_{ctrl} is not a valid codeword or $h_{r'}(m') \neq y'$, it outputs $\perp$ else it outputs m'. Note that this generalizes the previous naive idea with a sub-exponentially large alphabet, which corresponds to using a repetition code for the control code. The rate of the overall code is $R = w/(w + v)$ which can be made arbitrarily close to 1 by choosing a sufficiently large constant $w > v$. The error-tolerance is $\rho = \delta_{\mathrm{ctrl}} \approx 1$. In particular, if c' is within distance ρ of c and c'_{ctrl} is a valid codeword then it must be the case that $c'_{\mathrm{ctrl}} = c_{\mathrm{ctrl}}$ and hence $r' = r, y' = h_r(m)$. In this case, the only way that that decoding can output some $m' \neq m$ is if the values form a hash collision $h_r(m') = h_r(m)$.

Self-Seeded Error Correction

To achieve error-correction, we use essentially the same construction as before, but additionally encode the data m using an efficiently list-decodable error-correcting code $(\mathrm{Enc}_{\mathrm{data}}, \mathrm{Dec}_{\mathrm{data}})$ over a constant size alphabet $\Sigma_{\mathrm{data}} = \{0,1\}^w$ for some large constant w. For any constant $\rho < 1/2$ we want this code to have rate $R_{\mathrm{data}} \approx 1 - \rho$ and to be list-decodable from a ρ fraction of errors. This can be accomplished using the codes of [5]. Moreover, we will now want the code $(\mathrm{Enc}_{\mathrm{ctrl}}, \mathrm{Dec}_{\mathrm{ctrl}})$ to efficiently uniquely decode from ρ errors, which

can be achieved with the same parameters as previously. Our self-seeded code $\mathrm{Enc}(m;r)$ computes $c_{\mathrm{ctrl}} = (c_{\mathrm{ctrl},1},\ldots,c_{\mathrm{ctrl},n}) = \mathrm{Enc}_{\mathrm{ctrl}}((r,h_r(m))) \in \Sigma_{\mathrm{ctrl}}^n$ as before, and also $c_{\mathrm{data}} = (c_{\mathrm{data},1},\ldots,c_{\mathrm{data},n}) = \mathrm{Enc}_{\mathrm{data}}(m) \in \Sigma_{\mathrm{data}}^n$. It then "folds" the two codewords together to yield the final codeword

$$c = (\ [c_{\mathrm{data},1}, c_{\mathrm{ctrl},1}]\ ,\ \ldots\ ,\ [c_{\mathrm{data},n}, c_{\mathrm{ctrl},n}]\ ) \in \Sigma^n$$

where $\Sigma = \Sigma_{\mathrm{data}} \times \Sigma_{\mathrm{ctrl}} = \{0,1\}^{v+w}$. The decoding algorithm $\mathrm{Dec}(c')$ gets

$$c' = (\ [c'_{\mathrm{data},1}, c'_{\mathrm{ctrl},1}]\ ,\ \ldots\ ,\ [c'_{\mathrm{data},n}, c'_{\mathrm{ctrl},n}]\ ) \in \Sigma^n.$$

It applies list-decoding on the data part c'_{data} of the received value c to recover a polynomial list of candidate messages $\{m^{(i)}\} = \mathrm{Dec}_{\mathrm{data}}(c'_{\mathrm{data}})$. It also uniquely decodes $(r',y') = \mathrm{Dec}_{\mathrm{ctrl}}(c'_{\mathrm{ctrl}})$. Then it outputs the first value $m^{(i)}$ such that $h_{r'}(m^{(i)}) = y'$, or outputs $\perp$ if none is found or if either of the decoding procedures fail. The rate of the overall code is $R = R_{\mathrm{data}} \cdot (w+v)/w \approx 1-\rho$ by choosing sufficiently large constants $w > v$. To analyze the error-correction, first observe that if the received value c' within relative distance ρ of $c = \mathrm{Enc}(m;r)$ then, by the correctness of list-decoding of the "data code", the correct message m will be in the decoded list with $m = m^{(i)}$ for some i, and by the correctness of unique decoding of the "control code" we have $(r',y') = (r,h_r(m))$. So the only way that error correction can fail is if there is another $m^{(j)} \neq m$ in the list such that $h_r(m^{(j)}) = h_r(m)$, but this gives a collision on the hash function.

Randomized Codes from One-Way Functions

Our constructions of *randomized* codes with error-detection and error-correction are identical to the above constructions of *self-seeded* codes, but instead of requiring the hash family h_r to be collision-resistant, we only need it to be a *universal one-way hash function (UOWHF).* A UOWHF ensures that a polynomial time adversary that selectively chooses a message m first and then gets the seed r cannot find a collision $m' \neq m$ such that $h_r(m) = h_r(m')$ except with negligible probability. Such UOWHFs can be constructed from one-way functions [13, 16]. Recall that the only difference between self-seeded and randomized codes is whether the encoded message m can be chosen adaptivley depending on the randomness r or selectively before r is chosen, which exactly matches the difference between collision-resistant hash functions and UOWHFs.

Necessity of Assumptions

We show that self-seeded codes beating the Singleton bound, with error-detection tolerance $\rho > 1-R$ or error-correction tolerance $\rho > (1-R)/2$, imply collision-resistant hash functions (CRHFs). Start by considering a self-seeded error-detection code $(\mathrm{Enc},\mathrm{Dec})$ with error-detection tolerance ρ. We claim that for every fixed subset S of $1-\rho$ fraction of codeword positions, the function $h_r(m) = \mathrm{Enc}(m;r)[S]$ that outputs the codeword symbols of $\mathrm{Enc}(m;r)$ in the positions indexed by S is collision-resistant. In particular, if there is an efficient adversary that, given r, can find a collision $m \neq m'$ such that $h_r(m) = h_r(m')$, it means that $\mathrm{Enc}(m;r)$ and $\mathrm{Enc}(m';r)$ are at distance $< \rho$ and therefore such an adversary can break error detection by choosing the message m and modifying $\mathrm{Enc}(m;r)$ to $\mathrm{Enc}(m';r)$. Moreover, if the rate of the code exceeds the Singleton bound with $R > 1-\rho$, then the functions h_r are compressing, making them CHRFs. To get the analogous result for error-correction, we simply note that ρ-error-correction implies (2ρ)-error-detection. In particular, if an efficient adversary given r can find two messages $m_0 \neq m_1$ such that $\mathrm{Enc}(m_0;r)$ and

$\mathrm{Enc}(m_1; r)$ are within relative distance 2ρ then it can find a "midpoint" c' which is at relative distance ρ from both $\mathrm{Enc}(m_0; r)$ and $\mathrm{Enc}(m_1; r)$. For one of $b \in \{0, 1\}$, modifying $\mathrm{Enc}(m_b; r)$ to c' necessarily causes decoding to output the incorrect message m_{1-b}.

We also show that randomized error-detection and error-correction codes beating the Singleton bound imply one-way functions. The argument is somewhat different from above since we don't want to assume that $\mathrm{Enc}(m; r)$ reveals r in the full. Instead, we rely on the fact that, if one-way functions don't exist, then we can efficiently sample "almost uniform" inverses of any efficient function [9]. Consider a random codeword $c = \mathrm{Enc}(m; r)$ for a random message m and randomness r. For any subset S of $1 - \rho$ fraction of codeword positions we can efficiently find an almost uniform inverse (m', r') of the function $f(m, r) = \mathrm{Enc}(m; r)[S]$ that outputs the codeword symbols in positions S. This means that $c = \mathrm{Enc}(m; r)$ and $c' = \mathrm{Enc}(m'; r')$ agree on the positions in S and therefore have relative distance $\leq \rho$. If the rate of the code exceeds the Singleton bound with $R > 1 - \rho$, then there is a non-negligible probability that $m \neq m'$ since f loses information about m. Therefore the channel that changes c to c' is efficient and defeats error detection by introducing ρ-fraction errors. Similarly the channel that changes a random subset of $\rho/2$ positions outside of S from c to c' defeats error correction since decoding is almost as likely to output m' as m.

Organization of the Paper

In Section 2 we give general notations and state the ingredients that we will use. In Section 3 we give formal definitions for randomized codes and self-seeded codes. In Section 4 we state and prove our main theorems. In Section 5 we show that randomized codes imply one-way functions. Due to space limitations, this extended abstract does not contain the proof that self-seeded codes imply collision resistance hash functions. The reader is referred to [22] for a full version that contains this proof.

2 Preliminaries and Ingredients

2.1 Notations

All logarithms are taken in base 2. Let poly stand for the set of all polynomials. Let PPT stand for non-uniform probabilistic polynomial-time. We note that while we rely on the non-uniform model of computation by default, all our results also hold if we were to define PPT in the uniform model. We use sans-serif (e.g., A) for PPT algorithms. A function $\nu \colon \mathbb{N} \mapsto [0, 1]$ is *negligible*, denoted $\nu(k) = \mathrm{neg}(k)$, if $\nu(k) < 1/p(k)$ for every $p \in \mathrm{poly}$ and large enough k. For a set S, let $x \leftarrow S$ denote that x was drawn uniformly from S. Given a distribution P, we use $x \leftarrow P$ to denote that x is chosen according to P.

Hamming distance

The Hamming distance between $x, y \in [q]^n$ is $\Delta(x, y) = |\{i : x_i \neq y_i\}|$. The relative Hamming distance between $x, y \in [q]^n$ is $\delta(x, y) = \frac{\Delta(x,y)}{n}$.

Distributions and random variables

The statistical distance (also known as, variation distance) of two distributions P and Q over a discrete domain X is defined by $\mathsf{SD}(P, Q) = \max_{S \subseteq X} |P(S) - Q(S)|$.

▶ **Definition 2** (Min-entropy). *A random variable X has min-entropy k, denoted $H_\infty(X) \geq k$, if $\max_x \mathbf{Pr}[X = x] \leq 2^{-k}$.*

We will also use the following lemma about average min-entropy:

▶ **Definition 3** (Average min-entropy). *Let (X, Y) be a pair of random variables. The average min-entropy of X conditioned on Y is:*

$$\tilde{H}_\infty(X|Y) = -\log\left[\mathop{\mathbf{E}}_{y\leftarrow Y}\left[2^{-H_\infty(X|Y=y)}\right]\right]$$

Average min-entropy gives a bound on the probability that an adversary that gets the value of Y will guess the value of X in a single attempt. We will use the following useful lemma that connects average min-entropy and min-entropy.

▶ **Lemma 4** ([2, 15]). *$\tilde{H}_\infty(X|Y) \geq H_\infty(X, Y) - v$, where 2^v is the number of elements in support of Y.*

2.2 One-Way Functions

▶ **Definition 5** (One-way functions). *A* PPT *algorithm* $\mathsf{F}\colon \{0,1\}^* \to \{0,1\}^*$ *is a* **one-way function** *if for every* PPT A *and every sufficiently large $k \in \mathbb{N}$,*

$$\Pr_{x\leftarrow\{0,1\}^k}\left[\mathsf{A}(1^k, \mathsf{F}(x)) \in \mathsf{F}^{-1}(\mathsf{F}(x))\right] \leq \mathrm{neg}(k).$$

Distributional one-way functions

We will also use the classical result of Impagliazzo and Luby on distributional one-way functions implying one-way functions.

▶ **Definition 6** (Distributional One-way functions). *A* PPT *algorithm* $\mathsf{F}\colon \{0,1\}^* \to \{0,1\}^*$ *is a* **distributional one-way function** *if there exists a constant $c > 0$ such that for every* PPT A *and every sufficiently large $k \in \mathbb{N}$,*

$$SD\Big(\big(\mathsf{A}(1^k, \mathsf{F}(X)), \mathsf{F}(X)\big), \big(X, \mathsf{F}(X)\big)\Big) \geq 1/k^c.$$

where X is sampled uniformly from $\{0,1\}^k$.

▶ **Theorem 7** (Distributional one-way functions imply one-way functions, [9]). *If there exists a distributional one-way function then there exists a one-way function.*

2.3 Universal One-Way Hash Functions

▶ **Definition 8** (Universal one-way hash functions). *For a security parameter $k \in \mathbb{N}$. A family of functions $\mathcal{H} = \{h_s\colon \{0,1\}^{n(k)} \to \{0,1\}^{\ell(k)}\}_{s\in\{0,1\}^{\ell(k)}}$ is a family of* **universal one-way hash functions** *(UOWHFs) if it satisfies:*

1. *Efficiency: Given $s \in \{0,1\}^{\ell(k)}$ and $x \in \{0,1\}^{n(k)}$, $h_s(x)$ can be evaluated in time* $\mathrm{poly}(n(k), \ell(k))$.
2. *Shrinking: $\ell(k) < n(k)$.*
3. *Target Collision Resistance: For every* PPT A *and sufficiently large $k \in \mathbb{N}$, if we consider the following randomized experiment:*
   - $(x, \mathrm{state}) \leftarrow \mathsf{A}(1^k) \in \{0,1\}^{n(k)} \times \{0,1\}^*$,
   - *Sampling* $s \leftarrow \{0,1\}^{\ell(k)}$,
   - $x' \leftarrow \mathsf{A}(\mathrm{state}, s)$

   Then, $\mathbf{Pr}\left[x \neq x' \wedge h_s(x) = h_s(x')\right] \leq \mathrm{neg}(k)$.

The notion of universal one-way hash functions (UOWHF) was first introduced by Naor and Yung [13]. Rompel [16] gave the first UOWHF construction from arbitrary one-way functions.

▶ **Theorem 9** (One-way functions imply universal one-way hash function, [13, 16]). *There is a black-box construction of universal one-way hash functions (UOWHFs) from one-way functions (OWFs). In particular, assuming OWFs, for any arbitrarily large constant c and arbitrarily small constant $\delta > 0$ there is a UOWHF with input length $n(k) = k^c$ and output/seed length $\ell(k) = k^\delta$.*

2.4 Collision Resistance Hashing

▶ **Definition 10** (Collision resistance hash functions (CRHF)). *For a security parameter $k \in \mathbb{N}$. A family of functions $\mathcal{H} = \{h_s \colon \{0,1\}^{n(k)} \to \{0,1\}^{\ell(k)}\}_{s \in \{0,1\}^{\ell(k)}}$ is a family of* **collision resistance hash functions (CRHFs)** *if it satisfies:*

1. *Efficiency: Given $s \in \{0,1\}^{\ell(k)}$ and $x \in \{0,1\}^{n(k)}$, $h_s(x)$ can be evaluated in time $\mathrm{poly}(n(k), \ell(k))$.*
2. *Shrinking: $\ell(k) < n(k)$.*
3. *Collision Resistance: For every* PPT A *and sufficiently large $k \in \mathbb{N}$,*

$$\Pr_{\substack{s \leftarrow \{0,1\}^k, \\ x, x' \leftarrow \mathsf{A}(s)}} [x \neq x' \wedge h_s(x) = h_s(x')] \leq \mathrm{neg}(k).$$

We mention that the parameters of CRHFs above do not matter much: any "non-trivial" CRHF implies an "arbitrarily good" CRHF. That is, start with any CRHF with arbitrarily large polynomial seed/output length $\ell(k)$ that has even 1-bit compression $n(k) = \ell(k) + 1$. Then, for any arbitrarily small constant $\delta > 0$ and arbitrarily large constant c, we can also get a CRHF with small seed/output length $\ell(k) = k^\delta$ and large input length $n(k) = k^c$. Therefore, when we assume the existence of CRHFs we without loss of generality assume the above "arbitrarily good" CRHF parameters.[3]

2.5 Standard Correcting/Detecting Codes

We now define error-correcting codes for information-theoretic adversaries also called Hamming channels. In this section, a code is a pair $(\mathrm{Enc}, \mathrm{Dec})$ of deterministic encoding and decoding algorithms, and different notions are obtained by considering the requirements of the decoding algorithm.

▶ **Definition 11** (Standard codes for Hamming channels). *Let k, n, q be parameters and let $\mathrm{Enc} : \{0,1\}^k \to [q]^n$ be a function. We say that* Enc *is an encoding function for a code that:*

- **decodes** *d* **errors**, *if there exists a function $\mathrm{Dec} : [q]^n \to \{0,1\}^k$ such that for every $m \in \{0,1\}^k$ and every $v \in [q]^n$ with $\Delta(\mathrm{Enc}(m), v) \leq d$, we have $\mathrm{Dec}(v) = m$.*
- *L*-**list-decodes** *d* **errors**, *if the function* Dec *is allowed to output a list of size at most L, and for every $m \in \{0,1\}^k$ and every $v \in [q]^n$ with $\Delta(\mathrm{Enc}(m), v) \leq d$, we have $m \in \mathrm{Dec}(v)$.*
- **detects** *d* **errors**, *if there exists a function $\mathrm{Dec} : [q]^n \to \{0,1\}^k \cup \{\perp\}$ such that for every $m \in \{0,1\}^k$, $\mathrm{Dec}(\mathrm{Enc}(m)) = m$ and for every $v \in [q]^n$ such that $v \neq \mathrm{Enc}(m)$ and $\Delta(\mathrm{Enc}(m), v) \leq d$, we have $\mathrm{Dec}(v) = \perp$.*

[3] We can decrease the seed/output length by changing the security parameter from k to k^ε for a sufficiently small ε and noting that poly/negl in k^ε is the same as poly/negl in k. We can increase the input length arbitrarily using the Merkle-Damgard transform.

The rate of the code is the ratio of the message length and output length of Enc*, where both lengths are measured in bits. That is the rate* $R = \frac{k}{n \cdot \log q}$.

*A code (*Enc, Dec*), is* **explicit** *if* Enc *and* Dec *run in polynomial time. (Naturally, this makes sense only for a family of encoding and decoding/detecting functions with varying message length* k *block length* $n(k)$*, and alphabet sizes* $q(k)$*).*[4]

We will also use the following construction by Guruswami and Rudra [5] for optimal list-decodable codes over a constant alphabet.

▶ **Theorem 12** ([5])**.** *For every* $0 < R < 1$*, every sufficiently small* $\varepsilon > 0$*, there is an explicit family of codes over an alphabet of size* $2^{O(\varepsilon^{-4} \log(\frac{1}{\varepsilon}))}$ *that have rate at least* R *and which can be list decoded up to a fraction* $1 - R - \varepsilon$ *of errors in polynomial time, with a list of size* $n^{O(\varepsilon^{-1} \log(\frac{1}{\varepsilon}))}$.[5]

It is folklore that for every $\varepsilon > 0$ by using code concatenation it is possible to construct standard codes with distance $d \geq 1 - \varepsilon$ and rate $R = o(1)$ for any sufficiently large k with an alphabet size that depends on ε. We make this formal in the following Theorem (see for example the book by Guruswami, Rudra, and Sudan [6] for more details).

▶ **Theorem 13.** *For every sufficiently small* $0 < \varepsilon$*, and every computable function* $n : \mathbb{N} \mapsto \mathbb{N}$ *such that for every sufficiently large* k*,* $n(k) > k^c$*, (for a universal constant* $c > 1$*) there exists an explicit standard code* $(\mathrm{Enc}, \mathrm{Dec})$*, for* $\mathrm{Enc}\colon \{0,1\}^k \to [q]^{n(k)}$ *and* $\mathrm{Dec}\colon [q]^{n(k)} \to \{0,1\}^k$ *with alphabet* $q = 2^{(1/\varepsilon^3)}$ *such that the code has distance* $d(k) > n(k) - \varepsilon \cdot n(k)$ *and (uniquely) decodes from* $d(k)/2 - 1$ *errors.*

3 Definitions for Randomized Codes and Self-Seeded Codes

In this section, we formally define randomized codes and self-seeded codes, and their related notions of error detection and correction.

3.1 Randomized Codes

We start by giving a formal definition of randomized encoding and decoding algorithms. This syntax will be also shared with our notion of self-seeded codes defined in the next section.

▶ **Definition 14** (Randomized codes)**.** *Let* $n, q : \mathbb{N} \mapsto \mathbb{N}$ *be poly-time computable functions. An* (n, q)**-randomized** *code is a pair* $(\mathrm{Enc}, \mathrm{Dec})$ *such that:*

- Enc *is a* PPT *algorithm that on input* $m \in \{0,1\}^k$ *outputs a string in* $c \in [q(k)]^{n(k)}$*. We use* $\mathrm{Enc}_r(m)$ *to denote the instantiation of* $\mathrm{Enc}(m)$ *when using the string* r *as random coins.*
- Dec *is a* PPT *algorithm that on input* $z \in [q(k)]^{n(k)}$ *outputs a string* $\widehat{m} \in \{0,1\}^k \cup \{\perp\}$.

[4] We point out that traditionally codes are indexed by the codeword length (that is, k and q are chosen as a function of the codeword size n). However, for the sake of consistency with the rest of our definitions, we chose to define the codeword length n and alphabet q as a function of the input size k.

[5] We remark that while Theorem 12 does not explicitly mention that the rate can be achieved for every sufficiently large message size k, and instead just claims that it holds for infinitely often choices of k. A careful examination of the construction and proof by [5] reveals that the argument and proof hold for every sufficiently large k, given a suitable expander graph. An explicit construction for such graphs were given for every sufficiently large k in [10] (see Lemma 2.7 for a formal proof). Thus, we assume that Theorem 12 holds for every sufficiently large k.

For a fixed $k \in \mathbb{N}$, the rate of the code for k is defined to be $R_k = \frac{k}{\log(q)\cdot n(k)}$. When $R = \lim_{k\to\infty} R_k \in [0,1]$ is well defined we say that R is the rate of the code. We omit all or a subset of the functions n and q when they are clear from the context.

We now define a notion of reliable codes for randomized codes, which essentially states that it is possible to recover the message given a codeword (that was not damaged by error).

▶ **Definition 15** (Codes with reliable decoding). *A randomized code* $(\mathrm{Enc}, \mathrm{Dec})$ *is said to be* **perfectly reliable** *if for every $k \in \mathbb{N}$ and $m \in \{0,1\}^k$,* $\mathbf{Pr}\left[\mathrm{Dec}(\mathrm{Enc}(m)) = m\right] = 1$.

Intuitively, in randomized codes, each time the sender wants to send a message, it samples fresh randomness on the fly and uses it to encode the message. We make this formal in the definition below.

▶ **Definition 16** (Error detection/correction for randomized codes). *Let $n, \ell, d : \mathbb{N} \mapsto \mathbb{N}$ be poly-time computable functions and let* $(\mathrm{Enc}, \mathrm{Dec})$ *be a randomized code. For a* PPT *algorithm* A *and $k \in \mathbb{N}$, consider the following randomized experiment:*

1. $(m, \mathrm{state}) \leftarrow \mathsf{A}(1^k) \in \{0,1\}^k \times \{0,1\}^*$
2. *Compute* $c \leftarrow \mathrm{Enc}(m)$ *(by sampling* $r \leftarrow \{0,1\}^{\ell(k)}$ *and computing* $\mathrm{Enc}_r(m)$*).*
3. $z \leftarrow \mathsf{A}(m, \mathrm{state}, c)$

We say that the code:

- *is* **reliable** *if for every* PPT *algorithm* A *and every sufficiently large $k \in \mathbb{N}$:* $\mathbf{Pr}\left[\mathrm{Dec}(c) \neq m\right] \leq \mathrm{neg}(k)$.[6]
- **detects** *d-errors if it is a* **reliable** *code, and for every* PPT *algorithm* A *and every sufficiently large $k \in \mathbb{N}$:* $\mathbf{Pr}\left[\Delta(c,z) \leq d(k) \wedge \mathrm{Dec}(z) \notin \{\perp, m\}\right] \leq \mathrm{neg}(k)$.
- **corrects** *d-errors if for every* PPT *algorithm* A *and every sufficiently large $k \in \mathbb{N}$:* $\mathbf{Pr}\left[\Delta(c,z) \leq d(k) \wedge \mathrm{Dec}(z) \neq m\right] \leq \mathrm{neg}(k)$.

For a constant $\rho \in [0,1]$, the code detects or corrects ρ-relative errors, if for every sufficiently large $k \in \mathbb{N}$, $\rho \leq d(k)/n(k)$.

Note that by definition if a code corrects d-errors for $d > 0$ then the code is reliable. In addition, our definition of error detection permits also error correction (that is, when errors are induced, the decoding algorithm can either return $\perp$ or successfully decode and return the original message m). By doing so we can achieve simultaneous error detection and correction (that is, the same decoding function can at the same time satisfy the notion of detection and correction defined above).

3.2 Self-Seeded Codes

We now formally, define the notion of self-seeded codes. A self-seeded code is a randomized code that shares the same syntax as defined in 14. However, a self-seeded code provides a strictly stronger notion of security as compared to the notion of error correction and detection for randomized codes stated above in Definition 16.

▶ **Definition 17** (Error detection/correction for self-seeded codes). *Let $n, \ell, d : \mathbb{N} \mapsto \mathbb{N}$ be poly-time computable functions. A randomized code is said to be a* **self-seeded** *code if the following holds: For a* PPT *algorithm* A *and $k \in \mathbb{N}$, consider the following randomized experiment:*

[6] This is a weaker variant of Definition 15. Our construction achieves the stronger variant of perfect reliability. However, our lower bounds results are stronger since they apply to this weaker notion.

1. $r \leftarrow \{0,1\}^{\ell(k)}$
2. $(m, z) \leftarrow \mathsf{A}(r)$

We say that the code:

- *is* **reliable** *if for every* PPT *algorithm* A *and every sufficiently large* $k \in \mathbb{N}$*:* $\mathbf{Pr}\left[\mathrm{Dec}(\mathrm{Enc}_r(m)) \neq m\right] \leq \mathrm{neg}(k)$.
- **detects** *d-errors if it is a* **reliable** *code, and for every* PPT *algorithm* A *and every sufficiently large* $k \in \mathbb{N}$*:* $\mathbf{Pr}\left[\Delta(\mathrm{Enc}_r(m), z) \leq d(k) \wedge \mathrm{Dec}(z) \notin \{\perp, m\}\right] \leq \mathrm{neg}(k)$.
- **corrects** *d-errors if for every* PPT *algorithm* A *and every sufficiently large* $k \in \mathbb{N}$*:* $\mathbf{Pr}\left[\Delta(\mathrm{Enc}_r(m), z) \leq d(k) \wedge \mathrm{Dec}(z) \neq m\right] \leq \mathrm{neg}(k)$.

For a constant $\rho \in [0,1]$*, the code detects or corrects* ρ*-relative errors, if for every sufficiently large* $k \in \mathbb{N}$*,* $\rho \leq d(k)/n(k)$.

Self-seeded code enables the sender to sample its randomness once, fix it, and then use this same randomness for encoding multiple messages (this contrasts with the standard notion of randomized codes, which requires the sender to generate fresh randomness for each message in real time). We stress that after being fixed, this randomness is known to any potential adversary but is *not* given to the decoding algorithm.[7] Still, we require that no efficient adversary can find a message and a close error vector that leads to a decoding error.

Indeed, self-seeded codes offer a stronger adaptive notion of security, where the adversary can choose the message m adaptively based on the randomness fixed by the sender. In contrast, standard randomized codes require the sender to choose fresh randomness after the adversary has decided on the message.

4 Optimal Randomized Codes and Self-Seeded Codes

We now state our main theorems for randomized codes and self-seeded codes. Our results show that it is possible to construct codes that bypass the Singleton bound for computationally bounded channels under minimal cryptographic assumptions. Specifically, for the randomized codes construction, we assume the existence of one-way functions, and for the self-seeded codes construction, we assume the existence of a collision resistance hash function.

Main theorem

We state our result for randomized codes and self-seeded codes together in the following theorem.

▶ **Theorem 18** (Randomized codes [resp., self-seeded codes] with constant alphabet size)**.** *Assuming the existence of one-way functions [resp., collision resistance hash functions], the following holds: For every constant* $0 \leq p < 1/2$ *and every sufficiently small constant* $0 < \varepsilon$*, there exists a* (q, n)*-randomized [resp.,* (q, n)*-self-seeded code] code with rate* $R = 1 - p - \varepsilon$ *that simultaneously (uniquely) corrects* p *relative errors and detects from* $1 - p - \varepsilon$ *relative errors. Moreover, the alphabet size* q *is a constant that depends on* ε*.*

The proof of Theorem 18 appears in Section 4.2 and relies on our construction described in Section 4.1.

[7] We note that our notion of self-seeded codes is strictly stronger than the notion of "seeded codes" defined in [3]. Seeded codes (unlike self-seeded codes), requires the encoding and decoding algorithms to share a random seed. Thus, unlike self-seeded codes, seeded codes necessitate a trusted setup between the encoding and decoding.

▶ Remark 19. If the underlying cryptographic primitives assumed in our theorem statements (that is, one-way functions for randomized codes and collision resistance hash functions for self-seeded codes) have sub-exponential security, then our constructed codes in Theorem 18 will also have sub-exponential failure probability for correction and detection against channels that are computable by sub-exponential size circuits. This follows since all our reductions run in polynomial time and have a polynomial loss in advantage. However, for the sake of simplicity, we focus on the case of polynomial/negligible security in our formal statements and proofs.

4.1 Construction

In this section, we describe the construction that we will use to prove Theorem 18.

We now describe the encoding and decoding algorithms. In Figure 1, we state the parameters and ingredients that are needed to define our encoding and decoding algorithms $(\mathrm{Enc}, \mathrm{Dec})$ that are specified in Figure 2. The encoding and decoding algorithms are essentially the same for randomized codes and for self-seeded codes. In both cases the encoding algorithm Enc takes as input a message m and some value r. For randomized codes, a fresh random r is chosen every time we send a new message, and for the self-seeded codes r is sampled once (and is given to any possible adversary), and this single fixed r could be used in the encoding of multiple messages.

In both cases, the decoding algorithm Dec only takes as input a possibly damaged codeword z. In particular, the decoding algorithm is not provided with the seed r.

4.2 Proof of Theorem 18

In this section, we prove Theorem 18. We make use of the following technical lemma. The proof for the lemma is given below in Section 4.2.1.

▶ **Lemma 20.** *If there are ingredients and parameters that satisfy the conditions stated in Figure 1. Moreover, if the hash family $\mathcal{H}$ specified in Figure 1 is a family of universal one-way hash functions [resp., collision resistance hash functions]. Then, the code* $(\mathrm{Enc}, \mathrm{Dec})$ *as specified in Figure 2 is a (q, n)-randomized code [resp., (q, n)-self-seeded code]. Moreover, the code is perfectly reliable, has alphabet size $q = q_{\mathrm{ctrl}} \cdot q_{\mathrm{data}}$, rate $R = R_{\mathrm{data}} \cdot \frac{\log(q_{\mathrm{data}})}{\log(q_{\mathrm{data}})+\log(q_{\mathrm{ctrl}})}$, and the decoding algorithm simultaneously,*

- *detects from $d_{\mathrm{ctrl}} - d_{\mathrm{data}}$ errors, and*
- *corrects from d_{data} errors.*

Proof of Theorem 18. Note that one-way functions imply universal one-way hash functions that satisfy the conditions stated for the hash family $\mathcal{H}$ in Figure 1 (see, Theorem 9).

Given a sufficiently small $0 < \varepsilon$, let $\hat{\varepsilon} = \varepsilon/4$ and apply Theorem 12 for $\hat{\varepsilon}$ and $R_{\mathrm{data}} = 1 - p - \hat{\varepsilon}$ to get a standard code $(\mathrm{Enc}_{\mathrm{data}}, \mathrm{Dec}_{\mathrm{data}})$ with rate $R_{\mathrm{data}} = 1 - p - \hat{\varepsilon}$, codeword length n_{data} alphabet size $q_{\mathrm{data}} = 2^{O(\hat{\varepsilon}^{-5})}$. Moreover, $(\mathrm{Enc}_{\mathrm{data}}, \mathrm{Dec}_{\mathrm{data}})$ list decodes from $d_{\mathrm{data}} = p \cdot n_{\mathrm{data}}$ errors (that is, from p relative errors) with a list size that depends only on $\hat{\varepsilon}$ and k. Note also that we can increase the alphabet size by bundling symbols together without damaging the list decoding and the rate R_{data} of the code, and so, we can assume that $\log(q_{\mathrm{data}})$ is of size at least $\hat{\varepsilon}^{-5}$. To summarize $(\mathrm{Enc}_{\mathrm{data}}, \mathrm{Dec}_{\mathrm{data}})$ meets the conditions stated in Figure 1 for "data code" for the parameters R_{data} and d_{data} and $\log(q_{\mathrm{data}}) > \hat{\varepsilon}^{-5}$.

Apply theorem 13 for $\hat{\varepsilon}$ to get a code $(\mathrm{Enc}_{\mathrm{ctrl}}, \mathrm{Dec}_{\mathrm{ctrl}})$ with codeword length $n_{\mathrm{data}} = n_{\mathrm{ctrl}}$, alphabet size at most $q_{\mathrm{ctrl}} = 2^{\hat{\varepsilon}^{-3}}$ that has distance $d_{\mathrm{ctrl}} > n_{\mathrm{ctrl}}(1 - \hat{\varepsilon})$ and efficient decoding of up to $d_{\mathrm{ctrl}}/2 - 1$ errors. Note that for a sufficiently small ε (and $\hat{\varepsilon}$) it holds that $d_{\mathrm{ctrl}} > 2d_{\mathrm{data}} + 1$. This means that $(\mathrm{Enc}_{\mathrm{ctrl}}, \mathrm{Dec}_{\mathrm{ctrl}})$ meets the conditions stated in Figure 1 for the "control code" with parameters d_{ctrl} and $\log(q_{\mathrm{ctrl}}) < \hat{\varepsilon}^{-3}$.

List of ingredients and parameters: Let $q, q_{\text{data}}, q_{\text{ctrl}}, d_{\text{data}}, d_{\text{ctrl}}, \ell, n : \mathbb{N} \mapsto \mathbb{N}$ and $R_{\text{data}} : \mathbb{N} \mapsto \mathbb{R}$ be poly-time computable functions.

Data code: A family of standard codes $(\text{Enc}_{\text{data}}, \text{Dec}_{\text{data}})$ such that $\text{Enc}_{\text{data}} \colon \{0,1\}^k \to [q_{\text{data}}]^n$ list-decodes from d_{data} errors with rate R_{data} and polynomial list size.

A hash family: $\mathcal{H} = \{h_s \colon \{0,1\}^k \to \{0,1\}^\ell\}_{s \in \{0,1\}^\ell}$ that is efficiently computable. Where we require that $2\ell := \ell' \leq k^{c_\ell}$ (where $c_\ell < 1$ is a fixed universal constant).

Control code: Code with large distance: A family of standard codes $(\text{Enc}_{\text{ctrl}}, \text{Dec}_{\text{ctrl}})$, such that $\text{Enc}_{\text{ctrl}} \colon \{0,1\}^{\ell'} \to [q_{\text{ctrl}}]^n$ has distance larger than $d_{\text{ctrl}} > 2 \cdot d_{\text{data}} + 1$ and efficiently uniquely decodes from $d_{\text{ctrl}}/2 - 1$ errors. (Note that we require the codeword size n to be the same in Enc_{data} and Enc_{ctrl}).

Figure 1 Parameters and Ingredients for folding construction.

Encoding algorithm

We define an encoding function $\text{Enc} : \{0,1\}^k \times \{0,1\}^\ell \to [q]^n$:
Input: A message $m \in \{0,1\}^k$. And coins $r \in \{0,1\}^\ell$.

Output: A codeword $c \in [q]^n$ for $q := q_{\text{ctrl}} \cdot q_{\text{data}}$.

Operation :

Encode the data: Compute $c_{\text{data}} = \text{Enc}_{\text{data}}(m) \in [q_{\text{data}}]^n$.
Hash the encoded data: Compute $y = h_r(m)$ and set $w := (y, r)$.
Encode the control: Compute $c_{\text{ctrl}} = \text{Enc}_{\text{ctrl}}(w) \in [q_{\text{ctrl}}]^n$
Fold the control and data codes: Compute $c \in ([q_{\text{data}}] \times [q_{\text{ctrl}}])^n$, where for every $i \in [n]$, $c_i = ((c_{\text{data}})_i, (c_{\text{ctrl}})_i)$. That is, c_i contains the i^{th} symbol of c_{data} and c_{ctrl}.
Output: c.

Decoding algorithm

We define a decoding function $\text{Dec} : [q]^n \to \{0,1\}^k \cup \{\perp\}$:
Input: A received word $z \in [q]^n$.

Output: A message $\widehat{m} \in \{0,1\}^k \cup \{\perp\}$.

Operation :

Unfold the control and data: For every $i \in [n]$ we view $z_i = ((z_{\text{data}})_i, (z_{\text{ctrl}})_i) \in [q_{\text{data}}] \times [q_{\text{ctrl}}]$ and compute $z_{\text{data}} = ((z_{\text{data}})_1, \cdots, (z_{\text{data}})_n)$ and $z_{\text{ctrl}} = ((z_{\text{ctrl}})_1, \cdots, (z_{\text{ctrl}})_n)$.
Uniquely decode the control part: $\widehat{w} = (\widehat{y}, \widehat{r}) = \text{Dec}_{\text{ctrl}}(z_{\text{ctrl}})$.
List decode the data part: Compute a list of message candidates $\text{List} = \text{Dec}_{\text{data}}(z_{\text{data}})$, by applying the list decoding for d_{data} errors.
Check control distance: If $\Delta(\text{Enc}_{\text{ctrl}}(\widehat{w}), z_{\text{ctrl}}) > d_{\text{data}}$ then output $\perp$.
Check consistency: Output the first message $\widehat{m} \in \text{List}$ for which $h_{\widehat{r}}(\widehat{m}) = \widehat{y}$. If no such message exists output $\perp$.

Figure 2 Encoding and decoding algorithm.

Thus, we can apply Lemma 20 for $(\mathrm{Enc}_{\mathrm{data}}, \mathrm{Dec}_{\mathrm{data}})$, $(\mathrm{Enc}_{\mathrm{ctrl}}, \mathrm{Dec}_{\mathrm{ctrl}})$ and $\mathcal{H}$ to get a (q, n)-randomized code when we take $\mathcal{H}$ to be a universal one-way hash family and (q, n)-self-seeded code if $\mathcal{H}$ is a collision resistance hash family. In both cases, it follows that

- $n = n_{\mathrm{data}}$
- $q = q_{\mathrm{data}} \cdot q_{\mathrm{ctrl}} = 2^{O(\varepsilon^{-5})}$,
- for every sufficiently small ε (and $\hat{\varepsilon}$), $R = R_{\mathrm{data}} \cdot \frac{\log(q_{\mathrm{data}})}{\log(q_{\mathrm{data}})+\log(q_{\mathrm{ctrl}})} > (1 - p - \hat{\varepsilon}) \cdot \frac{1}{1+\hat{\varepsilon}} > (1 - p - \varepsilon)$.
- The code detects from $d_{\mathrm{ctrl}} - d_{\mathrm{data}} = n(1 - \hat{\varepsilon}) - np > n(1 - p - \varepsilon)$ errors. That is, it detects from $1 - p - \varepsilon$ relative errors.
- The code corrects $d_{\mathrm{data}} = pn$ errors. That is, it corrects up to p relative errors.

This concludes the proof of Theorem 18. ◀

4.2.1 Proof of Lemma 20

Let $\mathrm{Enc}_{\mathrm{data}}, \mathrm{Enc}_{\mathrm{ctrl}}, h_r$, be as defined in Figure 1 and let $(\mathrm{Enc}, \mathrm{Dec})$ be as defined in Figure 2. By construction, $(\mathrm{Enc}, \mathrm{Dec})$ is perfectly reliable. This holds since for every fixed randomness r if no errors are applied, all ingredients in the construction are deterministic, and standard codes are by definition perfectly reliable. Similarly, by construction $q = q_{\mathrm{ctrl}} \cdot q_{\mathrm{data}}$ and

$$R = \frac{k}{n \cdot \log(q)} = \frac{R_{\mathrm{data}} \cdot (n \cdot \log(q_{\mathrm{data}}))}{n \cdot (\log(q_{\mathrm{ctrl}}) + \log(q_{\mathrm{data}}))} = R_{\mathrm{data}} \cdot \frac{\log(q_{\mathrm{data}})}{\log(q_{\mathrm{data}}) + \log(q_{\mathrm{ctrl}})}.$$

We now prove the rest of Lemma 20. For simplicity, we focus on the randomized codes case, the proof for the self-seeded codes is essentially the same and follows along similar lines.[8]

Consider the following randomized experiment for a PPT algorithm A and $k \in \mathbb{N}$:

1. $(m, \mathrm{state}) \leftarrow \mathsf{A}(1^k) \in \{0,1\}^k \times \{0,1\}^*$
2. Compute $c \leftarrow \mathrm{Enc}_r(m)$ (by sampling $r \leftarrow \{0,1\}^{\ell(k)}$).
3. $z \leftarrow \mathsf{A}(m, \mathrm{state}, c)$

We make use of the following notation: Let $c_{\mathrm{data}} = \mathrm{Enc}_{\mathrm{data}}(m)$, $w = (h_r(m), r)$ and $c_{\mathrm{ctrl}} = \mathrm{Enc}_{\mathrm{ctrl}}(w)$. Recall that $z \in ([q_{\mathrm{data}}] \times [q_{\mathrm{ctrl}}])^n$, and define $z_{\mathrm{data}} = ((z_{\mathrm{data}})_1, \cdots, (z_{\mathrm{data}})_n)$ and $z_{\mathrm{ctrl}} = ((z_{\mathrm{ctrl}})_1, \cdots, (z_{\mathrm{ctrl}})_n)$ such that for every $i \in [n]$, $z_i = ((z_{\mathrm{data}})_i, (z_{\mathrm{ctrl}})_i)$. Let $\widehat{w} = (\widehat{y}, \widehat{r}) = \mathrm{Dec}_{\mathrm{ctrl}}(z_{\mathrm{ctrl}})$ and $\mathrm{List} = \mathrm{Dec}_{\mathrm{data}}(z_{\mathrm{data}})$.

Error correction

To prove the error correction property, we need to show that

$$\mathbf{Pr}\left[\Delta(c, z) \leq d_{\mathrm{data}} \wedge \mathrm{Dec}(z) \neq m\right] \leq \mathrm{neg}(k).$$

We make use of the following claims:

▷ Claim 21. If $\Delta(c, z) \leq d_{\mathrm{data}}$ then $m \in \mathrm{List}$ and $w = \widehat{w}$.

Proof of Claim 21. If $\Delta(c, z) \leq d_{\mathrm{data}}$ it follows that $\Delta(c_{\mathrm{ctrl}}, z_{\mathrm{ctrl}}) \leq d_{\mathrm{data}}$ and $\Delta(c_{\mathrm{data}}, z_{\mathrm{data}}) \leq d_{\mathrm{data}}$. Since $(\mathrm{Enc}_{\mathrm{ctrl}}, \mathrm{Dec}_{\mathrm{ctrl}})$ is a standard code that uniquely decodes from $d_{\mathrm{ctrl}}/2 - 1 \geq d_{\mathrm{data}}$ errors it holds that $w = w'$. Similarly, since $(\mathrm{Enc}_{\mathrm{data}}, \mathrm{Dec}_{\mathrm{data}})$ is a standard code that list-decodes from d_{data} errors it follows that $m \in \mathrm{List}$. ◁

[8] The main difference is that we consider an adaptive adversary (that is, first $r \leftarrow \{0,1\}^{\ell(k)}$ and then $(m, z) \leftarrow \mathsf{A}(r)$) and we reduce to the security of the CRH instead of the security of the UOWHF, otherwise, the proof is identical.

▷ Claim 22. $\forall \widehat{m} \in \text{List}$, if $\widehat{m} \neq m$ then $\mathbf{Pr}\left[h_r(\widehat{m}) = y\right] \leq \text{neg}(k)$.

Proof of Claim 22. Follows directly from the security of the universal one-way hash function, as otherwise, we can use A to find collisions in h contradicting the collision resistance property. ◁

By Claim 21, $m \in \text{List}$ and $w = \widehat{w}$. Thus, by Claim 22, with all but negligible probability, m is the only message in List for which $h_r(m) = y$ (passing the "Check consistency" step in the decoding algorithm) which implies $\text{Dec}(z) = m$.

Error detection

To prove the error detection property, we need to show that

$$\mathbf{Pr}\left[\Delta(c, z) \leq d_{\text{ctrl}} - d_{\text{data}} \wedge \text{Dec}(z) \notin \{m, \perp\}\right] \leq \text{neg}(k).$$

We make use of the following Claim.

▷ Claim 23. If $\Delta(c, z) \leq d_{\text{ctrl}} - d_{\text{data}}$ and $\text{Dec}(z) \neq \perp$ then $w = \widehat{w}$.

Proof. Let $\widehat{c}_{\text{ctrl}} = \text{Enc}_{\text{ctrl}}(\widehat{w})$ and note that the by the "Check control distance" step in the decoding algorithm (see Figure 2), if $\text{Dec}(z) \neq \perp$ it follows that $\Delta(z_{\text{ctrl}}, \widehat{c}_{\text{ctrl}}) \leq d_{\text{data}}$. Moreover, by construction, if $\Delta(c, z) \leq d_{\text{ctrl}} - d_{\text{data}}$ it follows that $\Delta(c_{\text{ctrl}}, z_{\text{ctrl}}) \leq d_{\text{ctrl}} - d_{\text{data}}$. Thus, if $\text{Dec}(z) \neq \perp$ and $\Delta(c, z) \leq d_{\text{ctrl}} - d_{\text{data}}$ by the triangle inequality

$$\Delta(c_{\text{ctrl}}, \widehat{c}_{\text{ctrl}}) \leq d_{\text{ctrl}}.$$

Since c_{ctrl} and $\widehat{c}_{\text{ctrl}}$ are both valid codewords of the standard code $(\text{Enc}_{\text{ctrl}}, \text{Dec}_{\text{ctrl}})$ that has distance d_{ctrl}, it follows that $w = \widehat{w}$. ◁

By Claim 23 if $\text{Dec}(z) \neq \perp$ then $w = \widehat{w}$. This concludes the proof, since by Claim 22, if $w = w'$, with all but negligible probability, m is the only valid message that can be outputted by $\text{Dec}(z)$.

5 Randomized Codes Imply One Way Functions

We now show that non-trivial randomized codes imply the existence of one-way functions. For large alphabets, this is indeed optimal since as we have seen in our construction it is possible to construct optimal randomized codes assuming only universal one-way functions (which can be constructed from one-way functions).

The following theorem states that if a randomized code has a rate that bypasses the singleton bound, it implies one-way functions.

▶ **Theorem 24** (Randomized codes with rate beating the Singleton bound imply one way functions). *Let* (Enc, Dec) *be a randomized code with rate* $0 \leq R < 1$. *If one of the following holds:*

- *The code detects* ρ_0*-relative errors and* $\rho_0 > 1 - R + \frac{1}{n}$.
- *The code corrects from* ρ_1*-relative errors and* $2\rho_1 > 1 - R + \frac{2}{n}$.

Then there exists one-way functions.

The proof will make use of the following lemma.

▶ **Lemma 25** (Non-trivial error detection/correction for randomized codes implies one-way functions). *Let* (Enc, Dec) *be an* (n, q)*-randomized code that has at least one of the following properties:*

- *The code detects d-errors.*
- *The code corrects $\lceil d/2 \rceil$-errors.*

Let $s := n - d$, if $v := \lceil \log(q) \cdot s \rceil \leq k - 1$ then $\mathsf{F} \colon \{0,1\}^{k+\ell} \to \{0,1\}^v$ defined so that on input $(m, r) \in \{0,1\}^{k+\ell}$ it computes $\mathrm{Enc}_r(m)$ and outputs a binary representation of the first s symbols is a distributional one-way function.[9] [10]

The proof for the lemma is given below, but first, we will use it to prove Theorem 24.

Proof of Theorem 24. Let $d = Max(\lceil \rho_0 \cdot n \rceil, \lceil 2\rho_1 \cdot n \rceil)$ and note that by definition at least one of the following holds: The code detects d-errors, or corrects $\lceil d/2 \rceil$-errors. Moreover, by our assumption on the rate of the code, it holds that $d > n - R \cdot n + 1$. Let $s = n - d$ and let $v = \lceil \log(q) \cdot s \rceil$ since $R \geq \frac{k}{\log(q) \cdot n}$ it holds that $v \leq k - 1$. Thus, we meet the conditions of Lemma 25 which implies that there exists a distributional one-way function (in fact outputting the binary representation of the first s symbols of Enc is the distributional one-way function), and by Theorem 7 there exists a one-way function. ◀

Proof of Lemma 25. For $k \in \mathbb{N}$, let M_k and R_k denote the random variables sampled uniformly from $\{0,1\}^k$ and $\{0,1\}^{\ell(k)}$ respectively. Let $Y_k = \mathsf{F}(M_k, R_k)$ and assume for contradiction that F is not a distributional one-way function (see Definition 6). That is, for every constant $c > 0$ there exists a PPT algorithm A such that for infinitely many $k \in \mathbb{N}$,

$$\mathsf{SD}\Big(\big(\mathsf{A}(Y_k), Y_k\big), \big((M_k, R_k), Y_k\big)\Big) \leq 1/k^c. \tag{1}$$

For a fixed k for which the above holds, we omit the subscript k from the random variables to avoid clutter.

Let $(M', R') = \mathsf{A}(Y)$ and note that by the definition of average min-entropy (see Definition 3)

$$\mathbf{Pr}\left[M = M'\right] \leq 2^{-\tilde{H}_\infty(M|Y)} \leq 1/2 \tag{2}$$

where the last inequality follows by Lemma 4 that states that $\tilde{H}_\infty(M|Y) \geq H_\infty(M, Y) - v \geq k - v \geq 1$.

Let $C = \mathrm{Enc}_R(M)$ and $C' = \mathrm{Enc}_{R'}(M')$ and recall that by definition, $Y = \mathsf{F}(M, R)$ is just the binary representation of the first s symbols of C. Thus, if $\mathsf{F}(M', R') = \mathsf{F}(M, R) = Y$ it follows that, $\Delta(\mathrm{Enc}_R(M), \mathrm{Enc}_{R'}(M')) \leq n - s = d$, which by Equation 1 implies that:

$$\mathbf{Pr}\left[\Delta(C, C') > d\right] \leq 1/k^c. \tag{3}$$

Note also that by Equation 1,

$$\mathbf{Pr}\left[M' = \perp\right] \leq 1/k^c \tag{4}$$

We first handle the case where the code detects d-error and then the case where the code corrects $\lceil d/2 \rceil$-errors.

[9] Here, ℓ is just the implicitly assumed bound on the number of random bits used by Enc.

[10] The statement of Lemma 25 could be readily extended so that restricting the output of $\mathrm{Enc}_r(m)$ to *any* s symbols (that can be efficiently identified) not just the first s symbols is itself a distributional one-way function. This would be similar to our statement on self-seeded codes made in the full version [22], where we show that restricting the output to any subset of size s is a collision resistance hash family. However, for the sake of simplicity, we restrict our statement and analysis to the simple case where the distributional one-way function is defined to be the first s symbols.

Detection. By Equation 1 and by the reliability of the code,

$$\mathbf{Pr}\left[\mathrm{Dec}(C') = M'\right] \geq \mathbf{Pr}\left[\mathrm{Dec}(C) = M\right] - 1/k^c > 0.9 \tag{5}$$

We now define a PPT algorithm A' (that makes use of A) that contradicts the detection property of the code: On input 1^k, A' samples $m \leftarrow \{0,1\}^k$ and on input $c \in [q]^n$ it runs $(m', r') \leftarrow \mathsf{A}(y)$ where y is just the binary representation of the first s symbols of c (i.e., $y = \mathsf{F}(m, r)$), and outputs $c' = \mathrm{Enc}_{r'}(m')$. It holds that:

- $M = \mathsf{A}'(1^k)$ (where by definition M is sampled uniformly by A').
- Compute $C = \mathrm{Enc}_R(M)$ (by sampling $R \leftarrow \{0,1\}^\ell$).
- $C' = \mathrm{Enc}_{R'}(M') = \mathsf{A}'(M, C)$.

Thus, A' contradicts the d-detection property since

$$\begin{aligned}
&\mathbf{Pr}\left[\mathrm{Dec}(C') \notin \{M, \perp\} \wedge \Delta(C', C) \leq d\right] \\
&\geq \mathbf{Pr}\left[\mathrm{Dec}(C') = M' \wedge M' \notin \{M, \perp\} \wedge \Delta(C', C) \leq d\right] \\
&\geq \mathbf{Pr}\left[\mathrm{Dec}(C') = M'\right] - \mathbf{Pr}\left[M' = M\right] - \mathbf{Pr}\left[M' = \perp\right] - \mathbf{Pr}\left[\Delta(C', C) > d\right] \\
&\geq 0.9 - 0.5 - 2/k^c \geq 0.1
\end{aligned}$$

Where the penultimate inequality follows from Equations 5, 2, 4 and 3.

Correction. We now prove the correction property. Let G be a function defined as follows: On inputs $c, c' \in [q]^n$, G samples a set I of random $(n-s)/2$ indices from the set $[n] \setminus [s]$ (if $n - s$ is an odd number then with probability $1/2$ it sample $\lceil (n-s)/2 \rceil$ indices and with probability $1/2$ it samples $\lceil (n-s)/2 \rceil - 1$ indices), and outputs $c^* \in [q]^n$ where for every $i \in I$, $c^*_i = c'_i$ and for every $i \in [n] \setminus I$, $c^*_i = c_i$. Intuitively, if c and c' agree on the first s indexes then $G(c, c') = c^*$ is a random "mid point" between c and c'.

Recall that $C = \mathrm{Enc}_R(M)$, $C' = \mathrm{Enc}_{R'}(M')$ and let $C^* = G(C, C')$. By Equation 1 and symmetry,

$$\mathsf{SD}((M, R, C, C^*), (M', R', C', C^*)) \leq 2/k^c. \tag{6}$$

Since by assumption $n - s = d$, by the definition of C^* it follows that:

$$\mathbf{Pr}\left[\Delta(C, C^*) > \lceil d/2 \rceil\right] \leq 1/k^c \tag{7}$$

Recall that (M, R) are sampled uniformly at random, thus, by Equations 6 and 7 and the decoding properly of the code

$$\mathbf{Pr}\left[\mathrm{Dec}(C^*) = M'\right] \geq \mathbf{Pr}\left[\mathrm{Dec}(C^*) = M\right] - 3/k^c \geq 0.9. \tag{8}$$

We now define a PPT algorithm A' (that makes use of A) that contradicts the correction property of the code: On input 1^k, A' samples $m \leftarrow \{0,1\}^k$ and on input $c \in [q]^n$ runs $(m', r') \leftarrow \mathsf{A}(y)$ where y is just the binary representation of the first s symbols of c (i.e., $y = \mathsf{F}(m, r)$), computes $c' = \mathrm{Enc}_{r'}(m')$ and outputs $c^* = G(c, c')$. It holds that,

- $M = \mathsf{A}'(1^k)$ (where by definition M is sampled uniformly by A').
- Compute $C = \mathrm{Enc}_R(M)$ (by sampling $R \leftarrow \{0,1\}^\ell$).
- $C^* = \mathsf{A}'(M, C)$ (recall that $C^* = G(C, C')$ for $C' = \mathrm{Enc}_{R'}(M')$ and $(M', R') = \mathsf{A}(\mathsf{F}(M, R))$).

Thus, A' contradicts the $\lceil d/2 \rceil$-correction property since,

$$\begin{aligned}
&\mathbf{Pr}\left[\mathrm{Dec}(C^*) \neq M \wedge \Delta(C^*, C) \leq \lceil d/2 \rceil\right] \\
&\geq \mathbf{Pr}\left[\mathrm{Dec}(C^*) = M' \wedge M \neq M' \wedge \Delta(C^*, C) \leq \lceil d/2 \rceil\right] \\
&\geq \mathbf{Pr}\left[\mathrm{Dec}(C^*) = M'\right] - \mathbf{Pr}\left[M = M'\right] - \mathbf{Pr}\left[\Delta(C^*, C) \leq \lceil d/2 \rceil\right] \\
&\geq 0.9 - 0.5 - 1/k^c \geq 0.1.
\end{aligned}$$

Where the penultimate inequality follows from Equations 2, 7 and 8. This concludes the proof for Lemma 25. ◀

6 Self-Seeded Codes Imply Collision Resistance Hash Functions

We now show that non-trivial self-seeded codes imply the existence of a collision resistance hash family. Loosely speaking, the following theorem states that if a self-seeded code has rate that bypasses the Singleton bound, then it implies collision resistance hash functions (since there are codes with large alphabet that can achieve the Singleton bound, this result means that for large alphabet, any non-trivial self-seeded code implies collision resistance functions).

We note that while the result below is stated with respect to the notion of self-seeded codes, the same exact proof also holds for the weaker notion seeded codes defined in [3] in which the encoding and decoding algorithms both share the random seed. Since our lower bound still holds even if the decoding algorithm is given the random seed as input, the lower bound immediately extends to the weaker notion of seeded codes. However, to avoid confusion and clutter, we present our result with respect to the notion of self-seeded codes defined in this paper.

▶ **Theorem 26** (Self-Seeded codes with rate beating the Singleton bound imply collision resistance hash functions)**.** *Let* $(\mathrm{Enc}, \mathrm{Dec})$ *be a self-seeded code with rate* $0 \leq R < 1$*. If one of the following holds:*

- *The code detects* ρ_0*-relative errors and* $\rho_0 > 1 - R + \frac{1}{n}$*.*
- *The code corrects from* ρ_1*-relative errors and* $2\rho_1 > 1 - R + \frac{2}{n}$*.*

Then there exists an explicit construction for a collision resistance hash family given black-box access to the code.

The proof for Theorem 26 appears in the full version [22].

Optimal Communication Complexity of Chained Index

Janani Sundaresan
Cheriton School of Computer Science, University of Waterloo, Canada

Abstract

We study the CHAIN communication problem introduced by Cormode et al. [ICALP 2019]. For $k \geq 1$, in the $\text{CHAIN}_{n,k}$ problem, there are k string and index pairs (X_i, σ_i) for $i \in [k]$ such that the value at position σ_i in string X_i is the same bit for all k pairs. The input is shared between $k+1$ players as follows. Player 1 has the first string $X_1 \in \{0,1\}^n$, player 2 has the first index $\sigma_1 \in [n]$ and the second string $X_2 \in \{0,1\}^n$, player 3 has the second index $\sigma_2 \in [n]$ along with the third string $X_3 \in \{0,1\}^n$, and so on. Player $k+1$ has the last index $\sigma_k \in [n]$. The communication is one way from each player to the next, starting from player 1 to player 2, then from player 2 to player 3 and so on. Player $k+1$, after receiving the message from player k, has to output a single bit which is the value at position σ_i in X_i for any $i \in [k]$. It is a generalization of the well-studied INDEX problem, which is equivalent to $\text{CHAIN}_{n,2}$.

Cormode et al. proved that the $\text{CHAIN}_{n,k}$ problem requires $\Omega(n/k^2)$ communication, and they used it to prove streaming lower bounds for the approximation of maximum independent sets. Subsequently, Feldman et al. [STOC 2020] used it to prove lower bounds for streaming submodular maximization. However, it is not known whether the $\Omega(n/k^2)$ lower bound used in these works is optimal for the problem, and in fact, it was conjectured by Cormode et al. that $\Omega(n)$ bits are necessary.

We prove the optimal lower bound of $\Omega(n)$ for $\text{CHAIN}_{n,k}$ when $k = o(n/\log n)$ as our main result. This settles the open conjecture of Cormode et al., barring the range of $k = \Omega(n/\log n)$. The main technique is a reduction to a non-standard INDEX problem where the input to the players is such that the answer is biased away from uniform. This biased version of INDEX is analyzed using tools from information theory. As a corollary, we get an improved lower bound for approximation of maximum independent set in vertex arrival streams via a reduction from CHAIN directly.

The author would also like to thank Parth Mittal for useful comments, Christian Konrad for introducing them to the Augmented Chain problem, and the anonymous reviewers of ITCS 2025 for helpful comments and suggestions. The author is very grateful to Mi-Ying Huang, Xinyu Mao, Guangxu Yang and Jiapeng Zhang for an illuminating discussion about the problem. They pointed out an important flaw in an earlier version of this work, and the discussion was instrumental for the new proofs in the current version.

1 Introduction

The INDEX problem is one of the foundational problems in communication complexity. For $n \geq 1$, in the INDEX_n problem, there are two players Alice and Bob. Alice has a string $X \in \{0,1\}^n$ and Bob has an index $\sigma \in [n]$, and Bob has to output the value of X at position σ.

If the communication is one-way from Alice to Bob, it is easy to show that Alice needs to send $\Omega(n)$ bits to get any constant advantage [1, 30]. This problem has been well-studied in multiple settings, and we know tight trade-offs in the two-party communication model for communication complexity [34], information complexity [24], and quantum communication complexity [8, 24].

Among the numerous applications of communication complexity, one that is of interest to us is proving lower bounds for streaming algorithms. INDEX and its variants, in particular, have been quite useful in this context, for example, in [23, 18, 20, 21, 16, 10]. This is by no means an exhaustive list.

In this paper, we study a natural generalization of INDEX, called chained index ($\text{CHAIN}_{n,k}$ for $n, k \geq 1$) introduced by [12]. There are k different instances of INDEX_n, correlated so that they have the same answer. They are "chained" together, where each player holds the index to the previous instance, and also the string for the next instance.

▶ **Definition 1** (Informal). *In $\text{CHAIN}_{n,k}$, there are k instances of INDEX_n, all with the same answer. Players 1 and 2 take on the role of Alice and Bob respectively in the first instance, players 2 and 3 take on the role of Alice and Bob respectively for the second instance, and so on, all the way till players k and $k+1$ for the last instance.*

Communication is one-way from each player to the next in ascending order. The last player has to output the answer. The communication cost is the total number of bits in all the messages sent by the players. See Figure 1 for an illustration.

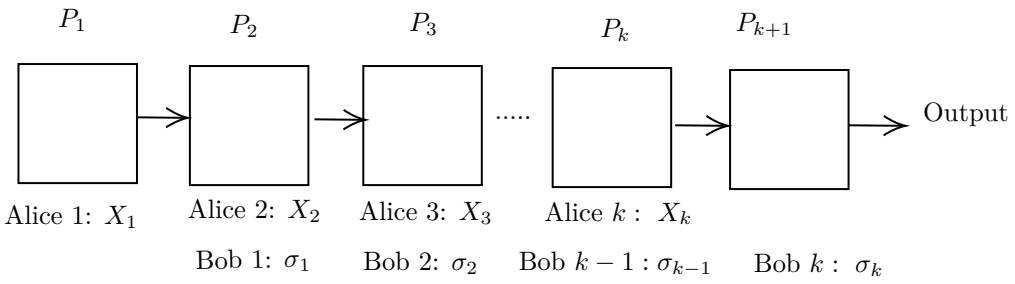

Figure 1 An illustration of the $\text{CHAIN}_{n,k}$ problem with k correlated sub-instances of INDEX_n from Definition 1. The arrows illustrate that the message is from P_i to P_{i+1} for $i \in [k]$.

In [12], a reduction from CHAIN was employed to get a lower bound for approximation of maximum independent sets in vertex arrival streams. Before its introduction, [28] used the problem implicitly to get a lower bound of $(1 - 1/e)$ in the approximation factor for maximum matching in $\tilde{O}(n)$ space in vertex arrival streams.

The problem has been used by the breakthrough result of [19] to study the multi-party communication complexity of submodular maximization. They proved that any randomized p-party protocol which maximizes a monotone submodular function $f : \{0,1\}^N \to \mathbb{R}$, subject to a cardinality constraint of at most p and an approximation factor of at least $(1/2 + \epsilon)$, uses $\Omega(N\epsilon/p^3)$ communication. This also gave a lower bound for streaming submodular maximization. The CHAIN problem was used by [17] also for similar purposes, but subject to stronger matroid constraints. [7] used a reduction from CHAIN to prove lower bounds for interval independent set selection in streams of split intervals.

We do not know tight bounds for the communication complexity of the CHAIN problem, despite finding varied applications of it. There is a trivial protocol of $O(n)$ bits, where any player can send the entire string to the next player who holds the index. Another simple

protocol is for each player to send $O(n/k)$ bits randomly sampled from their strings using public randomness, and with constant probability, in at least one of the k instances, we send the special bit to the player holding the index. However, this still takes $\Omega(n)$ total bits of communication.

In [12], they prove a lower bound of $\Omega(n/k^2)$ for any $k \geq 1$ through a reduction from conservative multi-party pointer jumping problem, introduced by [14]. They state without proof that a stronger lower bound of $\Omega(n/k)$ can be obtained for a restricted range of $k \leq O((n/\log n)^{1/4})$. They posed the following conjecture on the optimal communication lower bound.

▶ **Conjecture 2 ([12]).** *Any protocol that solves* $\textsc{chain}_{n,k}$ *requires* $\Omega(n)$ *bits of communication.*

[19] made some progress on Conjecture 2 by showing that among all the messages sent by the players, there is at least one message with $\Omega(n/k^2)$ bits for every $k \geq 1$. But the original conjecture is still open, and this is the focus of our work.

1.1 Our Results

We settle Conjecture 2 almost fully by proving the optimal lower bound of $\Omega(n)$ barring the corner case of when k is too large. As far as we know, this corner case is not a focus for existing reductions from $\textsc{chain}_{n,k}$.

▶ **Theorem 3.** *For any* $n, k \geq 1$*, any protocol for* $\textsc{chain}_{n,k}$ *with probability of success at least 2/3, requires* $\Omega(n - k\log n)$ *total bits of communication.*

Therefore, as long as $k = o(n/\log n)$, we get the optimal $\Omega(n)$ lower bound from Theorem 3.

The proof of Theorem 3 can be found in Section 3. We prove the lower bound in the more general blackboard model of communication, instead of private messages between players (see Section 2.1 for details). The main idea is to analyze $\textsc{index}_n$ where Alice and Bob already have *some prior advantage* in guessing the answer. We elaborate on our techniques in Section 1.2.

As a direct corollary of Theorem 3, we get improvements in streaming lower bounds in [12, 19] through reductions from CHAIN immediately. In particular, we get that any algorithm which α-approximates the size of a maximum independent set in vertex arrival streams requires $\Omega(n^2/\alpha^5 - \log n)$ space, while the previous bound was $\Omega(n^2/\alpha^7)$ in [12]. We present the implications of our result in Section 4.

A further generalization of CHAIN, called Augmented Chain was defined in [15]. Here, instances of Augmented Index are chained together instead. Our lower bound of $\Omega(n - k\log n)$ can be extended to Augmented Chain also, and the details are covered in Section 3.4.

1.2 Our Techniques

In this subsection, we give an overview of the challenges in proving the lower bound and a summary of our techniques. We start by going over the prior techniques.

Prior Techniques

We will briefly talk about the technique used in [19] to prove that there is at least one player who sends $\Omega(n/k^2)$ bits for any $k \geq 1$. We will argue that these techniques can be extended to proving a lower bound of $\Omega(n/k)$ for the total number of bits, but not all the way to $\Omega(n)$ bits.

The first step in proving a lower bound for $\text{CHAIN}_{n,k}$ in [19] is a decorrelation step – the k instances of INDEX_n have the same answer, and they remove this correlation with a hybrid argument. These arguments have been used extensively in the literature (see e.g., [26, 3, 27, 6]). Intuitively, any protocol that tries to solve $\text{CHAIN}_{n,k}$ may attempt to solve "many" of the instances of INDEX_n, albeit each with a "small" advantage over $1/2$, in the hope that the "small" advantages may accrue to get a constant probability of success overall (taking advantage of the fact that all the instances of INDEX_n have the same answer). The hybrid argument is a way to reduce proving a lower bound on the overall problem, to proving a lower bound for k different INDEX_n problems against these low advantages.

Let us assume, for simplicity, that the protocol tries to get an advantage of $\Omega(1/k)$ in each instance of INDEX_n, to get a constant total advantage. We can prove that any protocol that gets an advantage of $\Omega(1/k)$ for INDEX_n uses $\Omega(n/k^2)$ bits of communication using basic tools from information theory [9] (this is quite standard, see e.g., [2] for a direct proof), and this is known to be tight. Therefore, for k instances, we get a lower bound of $\Omega(n/k)$ bits in total. Now, we will argue why this is not the optimal lower bound.

On one hand, for INDEX_n, it is known that for any $\delta \in (0, 1/2)$, there is a protocol that uses $O(n\delta^2)$ bits of communication to get a probability of success $1/2 + \delta$. This means that INDEX_n can be solved with advantage $\Omega(1/k)$ in $O(n/k^2)$ bits; in other words, each "hybrid step" of the previous lower bound argument is optimal. So, then, why can we not get a good protocol for $\text{CHAIN}_{n,k}$ by running the protocol for INDEX_n with $\delta = 1/k$ on all k instances? This protocol would have $O(n/k)$ bits of communication in total. The reason is that the $1/k$ small advantages do not add up as we would like them to. To illustrate this, we will briefly talk about the protocol that gets δ advantage in $O(n\delta^2)$ bits for INDEX_n.

Protocol for INDEX_n

First, we will sketch a protocol for $\delta = 1/\sqrt{n}$ that uses $O(1)$ bits of communication. Let us imagine that the input X is chosen uniformly at random from $\{0,1\}^n$ and the index σ is chosen uniformly at random from $[n]$. Then, Alice finds the majority bit from her string X and sends it to Bob. Bob just outputs the bit sent by Alice. We know, from simple anti-concentration bounds on the binomial distribution, that the number of indices with the majority bit in X is at least $n/2 + c\sqrt{n}$ with constant probability for some appropriate constant c. The protocol succeeds if Bob holds the index σ to a majority bit, and this happens with probability at least $\frac{1}{2} + \frac{c}{\sqrt{n}}$.

The assumption that the input X is chosen uniformly at random from $\{0,1\}^n$ can be removed using public randomness. Alice and Bob collectively sample a random string $A \in \{0,1\}^n$, and Alice changes her input to $X \oplus A$ so that each bit is 0 or 1 with equal probability. Similarly, the assumption that the index σ is chosen uniformly at random from $[n]$ can be removed by Alice and Bob sampling a random permutation of $[n]$. Alice permutes string X according to this permutation, and Bob changes his input to the index that the permutation maps σ to. This is termed as the self-reducibility property of INDEX.

We can also extend the protocol to any δ by partitioning the string X into $n\delta^2$ blocks at random using public randomness and sending the majority bit in each block. Bob knows the block that his input index σ belongs to as public randomness is used.

Challenges for $\text{CHAIN}_{n,k}$

If we use the protocol we described for $\text{CHAIN}_{n,k}$, we are left with k bits from each instance of INDEX_n, which may be the correct answer to the problem with probability $1/2 + \Theta(1/k)$, but, the variance of each of these bits is $1/4 - \Theta(1/k^2)$. We have a protocol for $\text{CHAIN}_{n,k}$,

where, out of the k instances of INDEX_n, it finds the right answer for $\approx k/2 + \Theta(1)$ instances in expectation. However, the standard deviation of the number of right answers is $\approx \sqrt{k}/2$, which is enough to mask the $\Theta(1)$ improvement over $k/2$ we get in expectation. If we use a hybrid argument over the total variation distance, each of the smaller "hybrid steps" is optimal, whereas the overall lower bound is not optimal. We cannot achieve a lower bound stronger than $\Omega(n/k)$.

Our Solution

Instead of keeping track of progress in terms of advantage gained in guessing the answer, we directly keep track of the "information" the message reveals about the answer. Formally, this translates to the change in entropy of the answer, after each successive message. Initially, the players have no information about the answer, and it is uniform over $\{0,1\}$ (the entropy is 1). Any protocol with a large enough probability of success must reduce the entropy of the answer by a large factor (see Fano's inequality in Proposition 8). We prove that after each message, the entropy is reduced only by an additive factor *linear in the length of the message*, by a reduction to the INDEX problem. This will give us a lower bound on the total length of the messages.

For INDEX_n, in any protocol with probability of success at least ε, the entropy of the answer conditioned on the message is at most $H_2(\varepsilon)$ where $H_2(x) = x\log(1/x)+(1-x)\log(1/(1-x))$ is the binary entropy function. In the standard version where the initial entropy is 1, the reduction in entropy is $1 - H_2(\varepsilon)$, and it is known that the protocol requires $\Omega(n(1 - H_2(\varepsilon)))$ communication [24]. This is not sufficient for our application due to the following reason: after the message of $\mathcal{P}_1$, when $\mathcal{P}_2$ and $\mathcal{P}_3$ attempt to solve INDEX_n, they already have some prior advantage that the message of $\mathcal{P}_1$ gives them. Therefore, we need to analyze INDEX_n when the answer is not uniform over $\{0,1\}$.

Biased Index

We define the biased index problem, parametrized by $\theta \in [-1/2, 1/2]$. Alice and Bob receive input $Y \in \{0,1\}^n$ and $\rho \in [n]$ respectively, such that the value at position ρ in Y (denoted by $Y(\rho)$) is 1 with probability $1/2 + \theta$ and 0 otherwise. Alice sends a message M to Bob and Bob has to output $Y(\rho)$. The initial entropy of the answer is $H_2(1/2 + \theta)$. We prove that entropy of $Y(\rho)$ conditioned on M is smaller by at most $O((|M| + \log n)/n)$ compared to the initial $H_2(1/2 + \theta)$, which is **our main contribution** (see Lemma 14).

We can show that the entropy of input to Alice, i.e. the random string Y, in such a distribution is at least $\Omega(n \cdot H_2(1/2 + \theta))$. Hence, after a message of length s from Alice, the entropy of string Y reduces to $\Omega(n \cdot H_2(1/2 + \theta) - s)$. For a randomly chosen position in Y after conditioning on the message, the entropy is at least $\approx H_2(1/2 + \theta) - s/n$, which gives a lower bound on s.

In the distribution given to Alice and Bob, however, ρ is *not* chosen uniformly at random, and in fact, is correlated with the distribution of Y. Such versions of index where the distributions of Alice and Bob are correlated have been studied before (see Sparse Indexing in Appendix A of [5] and Section 3.3 of [36]). This correlation is the main issue in analyzing biased index with information theoretic tools.

Adapted from the approach in Appendix A of [5], we restrict the randomness in Y to a fixed set of indices of a carefully chosen size (based on θ), and break this correlation. The loss in entropy of Y is not significant enough to hinder us, and the restriction then allows us to use standard information theoretic tools to analyze biased index (see Section 3.3 for more details).

Independent and Concurrent Work

Independently and concurrently of this work, [33] made progress on Conjecture 2. They showed a lower bound of $\Omega(n/k + \sqrt{n})$ for oblivious protocols (where the length of the message sent by each player does not depend on the input), and a lower bound of $\Omega(n/k - k)$ for general protocols. We show a lower bound of $\Omega(n - k \log n)$ for all protocols.[1]

Quantitatively, our lower bounds are a factor of almost k stronger, and are optimal for $k = o(n/\log n)$; moreover, our lower bound also holds for the Augmented Chain problem of [15]. In terms of techniques, however, the two works are entirely disjoint: their proof is based on a new method of analysis through min-entropy and we use information theoretic approaches.

2 Preliminaries

In this section, we will present the required notation and definitions for our proof.

Notation

For any tuple $A = (A_1, A_2, \ldots, A_m)$ of m items, we use $A_{<i}$ to denote the tuple $(A_1, A_2, \ldots, A_{i-1})$ for all $i \in [m]$. We use sans-serif font to denote random variables. For any random variable A, we use $A \sim \mathsf{A}$ to denote any A sampled from the distribution of the random variable A.

For any string $X \in \{0,1\}^n$, we use $X(\sigma)$ to denote the bit at position σ in X for $\sigma \in [n]$. We use $X(< \sigma)$ to denote the string of $\sigma - 1$ bits preceding $X(\sigma)$ in X. We use $X(S)$ for any $S \subseteq [n]$ to denote the bits at positions in set S.

For any $x \in [0,1]$, we use $H_2 : [0,1] \to [0,1]$ to denote the binary entropy function.

$$H_2(x) = -x \log x - (1-x) \log(1-x).$$

We need the following standard approximation of binomial coefficients (see Lemma 7 of Chapter 10 in [32]).

▶ **Fact 4** (c.f. [32]). *For any $p \geq 1$ and any $q \in [p-1]$, we have,*

$$2^{p \cdot H_2(q/p)} \cdot \sqrt{\frac{n}{8\pi q(p-q)}} \leq \binom{p}{q} \leq 2^{p \cdot H_2(q/p)} \cdot \sqrt{\frac{n}{2\pi q(p-q)}}$$

2.1 Communication Complexity Model

We use the standard number-in-hand multi-party model of communication. Only the basic definitions are given in this subsection. More details can be found in textbooks on communication complexity [35, 31].

For any $k \geq 1$, let f be a function from $\mathcal{A}_1 \times \mathcal{A}_2 \times \ldots \times \mathcal{A}_k$ to $\{0,1\}$. There are k players $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_k$ where $\mathcal{P}_i$ gets an input $a_i \in \mathcal{A}_i$ for $i \in [k]$. There is a shared blackboard visible to all the players. The players have access to a shared tape of random bits, along with their own private randomness. In any protocol π for f, the players send a message to the blackboard in increasing order ($\mathcal{P}_1$ sends a message followed by $\mathcal{P}_2$, and so on till

[1] The authors of [33] pointed out an important flaw in the arguments of an earlier version of this work which was posted at around the same time as [33]. This flaw was subsequently fixed in the current version using a global change to the original argument, which now recovers optimal result for $k = o(n/\log n)$.

$\mathcal{P}_k$). The last player $\mathcal{P}_k$, after all the messages are sent, outputs a single bit denoted by $\pi(a_1, a_2, \ldots, a_k)$. Protocol π is said to solve f with probability of success at least $1-\delta$ if, for all $i \in [k]$, for any choice of $a_i \in \mathcal{A}_i$, we have,

$$\Pr[\pi(a_1, a_2, \ldots, a_k) \neq f(a_1, a_2, \ldots, a_k)] \leq \delta.$$

The **communication cost** of a protocol π is defined as the worst case **total communication** of all the players on the blackboard at the end of the protocol.

▶ **Definition 5.** *The* **randomized communication complexity** *of f, with probability of error δ, is defined as the minimum communication cost of any protocol which solves f with probability of success at least $1-\delta$.*

2.2 Information Theoretic Tools

Our proof relies on tools from information theory, and we state the basic definitions and the inequalities we need in this section. Proofs of the statements and more details can be found in Chapter 2 of a textbook on information theory by Cover and Thomas [13].

▶ **Definition 6** (Shannon Entropy)**.** *For any random variable X over support $\mathcal{A}$, the Shannon entropy of X, denoted by $\mathbb{H}(\mathsf{X})$ is defined as,*

$$\mathbb{H}(\mathsf{X}) = \sum_{A \in \mathcal{A}} \Pr[\mathsf{X} = A] \cdot \log(1/\Pr[\mathsf{X} = A]).$$

For any event $\mathcal{E}$ we define $\mathbb{H}(\mathsf{X} \mid \mathcal{E})$ in the same way, as the entropy of distribution of X conditioned on the event $\mathcal{E}$. For any two random variables X and Y, the entropy of X conditioned on Y, denoted by $\mathbb{H}(\mathsf{X} \mid \mathsf{Y})$ is defined as,

$$\mathbb{H}(\mathsf{X} \mid \mathsf{Y}) = \mathop{\mathbb{E}}_{Y \sim \mathsf{Y}} \mathbb{H}(\mathsf{X} \mid \mathsf{Y} = Y).$$

▶ **Fact 7.** *We know the following about entropy and mutual information:*

1. *For any random variable X, the entropy obeys the bound: $0 \leq \mathbb{H}(\mathsf{X}) \leq \log_2(|\mathcal{X}|)$ where $\mathcal{X}$ is the support of X.*
2. *For any two random variables X, Y, $\mathbb{H}(\mathsf{X} \mid \mathsf{Y}) \leq \mathbb{H}(\mathsf{X})$ with equality holding iff $\mathsf{X} \perp \mathsf{Y}$.*
3. *Chain Rule of Entropy: For $m \geq 1$ and any tuple of random variables $\mathsf{X} = (\mathsf{X}_1, \mathsf{X}_2, \ldots, \mathsf{X}_m)$, $\mathbb{H}(\mathsf{X}) = \sum_{i \in [m]} \mathbb{H}(\mathsf{X}_i \mid \mathsf{X}_{<i})$.*
4. *Subadditivity of entropy: For $m \geq 1$ and any tuple of random variables $\mathsf{X} = (\mathsf{X}_1, \mathsf{X}_2, \ldots, \mathsf{X}_m)$, $\mathbb{H}(\mathsf{X}) \leq \sum_{i \in [m]} \mathbb{H}(\mathsf{X}_i)$.*

We also need the following proposition, which relates entropy to the probability of correctness while estimating a random variable.

▶ **Proposition 8** (Fano's inequality)**.** *Given a binary random variable X and an estimator random variable Y and a function g such that $g(Y) = X$ with probability at least $1-\delta$ for $\delta < 1/2$,*

$$\mathbb{H}(\mathsf{X} \mid \mathsf{Y}) \leq H_2(\delta).$$

This concludes our preliminaries section.

3 The Lower Bound

In this section, we will prove our lower bound of $\Omega(n)$ on the communication complexity of the $\text{CHAIN}_{n,k}$ problem for $k = o(n/\log n)$. Let us formally define the $\text{CHAIN}_{n,k}$ communication problem first.

▶ **Definition 9.** *The $\text{CHAIN}_{n,k}$ communication problem is defined as follows. Given $k+1$ players $\mathcal{P}_i$ for $i \in [k+1]$ where,*

- *$\mathcal{P}_i$ has a string $X_i \in \{0,1\}^n$ for each $i \in [k]$, and,*
- *$\mathcal{P}_i$ for $1 < i \leq k+1$ has an index $\sigma_{i-1} \in [n]$,*

such that,

$$X_i(\sigma_i) = z,$$

for some bit $z \in \{0,1\}$. The players have a blackboard visible to all the parties. For $i \in [k]$ in ascending order, $\mathcal{P}_i$ sends a single message M_i, after which the index σ_i is revealed to the blackboard at no cost. $\mathcal{P}_{k+1}$ has to output whether z is 0 or 1. Refer to Figure 2 for an illustration.

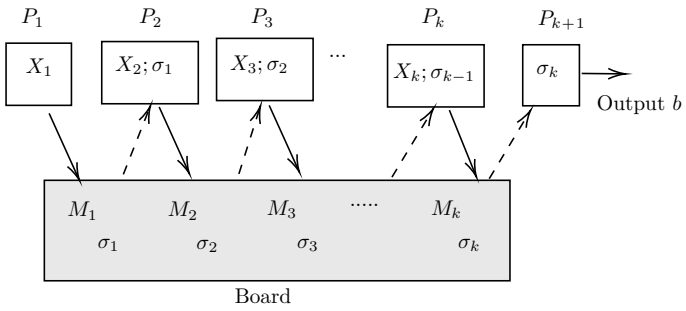

Figure 2 An illustration of the $\text{CHAIN}_{n,k}$ problem from Definition 9. The solid arrows illustrate that player $\mathcal{P}_i$ writes a message M_i to the board. The dashed arrows indicate that $\mathcal{P}_i$ can read the contents of the board. It also shows the order in which the messages are sent by the players and indices are released.

Let us recall the statement of our main result.

▶ **Theorem 3** (restated). *For any $n, k \geq 1$, any protocol for $\text{CHAIN}_{n,k}$ with probability of success at least 2/3, requires $\Omega(n - k\log n)$ total bits of communication.*

We give our hard distribution for $\text{CHAIN}_{n,k}$ in Section 3.1 and give the proof of Theorem 3 in Section 3.2 except for the analysis of biased index, which is given in Section 3.3. Lastly, we extend the arguments to Augmented Chain in Section 3.4.

3.1 Setting Up the Problem

In this subsection, we start by defining the notation for our proof, and we describe the input distributions to $\text{CHAIN}_{n,k}$.

The input hard distribution is as follows. Let $\mathcal{L} \subset \{0,1\}^n$ be the subset of strings where the number of ones is exactly equal to $n/2$.

Distribution $\mathcal{D}$ for $\textsc{chain}_{n,k}$:
1. Pick a bit z uniformly at random from $\{0,1\}$.
2. For each $i \in [k]$, sample (X_i, σ_i) uniformly at random from $\mathcal{L} \times [n]$ and independently conditioned on $X_i(\sigma_i) = z$.

Notation

We use X_i to denote the random variable corresponding to string X_i and $\boldsymbol{\sigma}_i$ to denote the random variable corresponding to index σ_i for $i \in [k]$. To denote the random variable corresponding to the first $i-1$ strings and indices, we use $\mathsf{X}_{<i}$ and $\boldsymbol{\sigma}_{<i}$ respectively.

We use M_i to denote the random variable corresponding to the message M_i sent by $\mathcal{P}_i$ to the blackboard. We use $M = (M_1, M_2, \ldots, M_k)$ to denote the tuple containing the messages of all the players, and M to denote the random variable corresponding to M.

Let π be a deterministic protocol for $\textsc{chain}_{n,k}$ with probability of success at least $2/3$ when the input is distributed according to $\mathcal{D}$. We use Γ to denote the random variable corresponding to the contents of the blackboard (referred to as a **transcript**), and we use γ to also denote transcripts sampled from Γ. We use Γ_i to denote the random variable of the tuple (M^i, σ^i) for $i \in [k]$. We use $\pi(\gamma_{<i}, X_i)$ to denote the output of $\mathcal{P}_i$ when the contents of the blackboard are $\gamma_{<i}$ and the input is X_i for $i \in [k]$.

Let s be the total length of all the messages sent by the players in γ. We assume that the total length of the messages is exactly s by padding. For any random variable A, we use $\mathcal{D}(\mathsf{A})$ to denote the distribution of the random variable A, as the input is distributed according to $\mathcal{D}$. We replace $\mathcal{D}(\mathsf{A} \mid \mathsf{B} = b)$ with $\mathcal{D}(\mathsf{A} \mid b)$ for ease of readability whenever it is clear from context.

Let Z denote the random variable corresponding to bit z. The bit z corresponds to the answer to $\textsc{chain}_{n,k}$. We show the lower bound of $\Omega(n - k \log n)$ for distinguishing between the case when $z = 0$ and $z = 1$ based on the contents of the blackboard.

We need one important observation about the distribution $\mathcal{D}$.

▶ **Observation 10.** *For any $i \in [k]$, random variable $\mathsf{X}_i, \boldsymbol{\sigma}_i$ is independent of $\Gamma_{<i}$ conditioned on Z.*

Proof. For any fixed value of Z, $\mathsf{X}_i, \boldsymbol{\sigma}_i$ are chosen uniformly at random from $\mathcal{L} \times [n]$ such that $\mathsf{X}_i(\boldsymbol{\sigma}_i) = \mathsf{Z}$. This choice is independent of any $\mathsf{X}_j, \boldsymbol{\sigma}_j$ with $j \neq i$, and thus independent of $\Gamma_{<i}$. ◀

We are ready to proceed with the proof of our main theorem.

3.2 Proof of Lower Bound

We start by showing that in any successful protocol, the entropy of the distribution of Z conditioned on the message must be small.

▷ Claim 11 (The transcript reveals information about Z.).

$$\mathbb{H}(\mathsf{Z} \mid \Gamma) \leq 24/25.$$

Proof. We know that $\mathcal{P}_{k+1}$ successfully finds the value of z with probability of success at least $2/3$ using the transcript. Thus, using Fano's inequality in Proposition 8, we have,

$$\mathbb{H}(\mathsf{Z} \mid \Gamma) \leq H_2(2/3) \leq 24/25.$$ ◁

The main part of the proof is that we show a lower bound the entropy of Z conditioned on the transcripts using the entropy of the message.

▶ **Lemma 12.** *For any protocol π,*

$$1 - \frac{12}{n} \cdot (\mathbb{H}(\mathsf{M}) + k \log n) \leq \mathbb{H}(\mathsf{Z} \mid \Gamma).$$

Before we prove Lemma 12, we can easily show that it implies Theorem 3.

Proof of Theorem 3. Combining Lemma 12 with Claim 11, we get,

$$1 - \frac{12}{n} \cdot (\mathbb{H}(\mathsf{M}) + k \log n) \leq \mathbb{H}(\mathsf{Z} \mid \Gamma) \leq \frac{24}{25}.$$

This gives that,

$$\mathbb{H}(\mathsf{M}) \geq \frac{n}{25 \cdot 12} - k \log n.$$

We know from Fact 7-(1) that $\mathbb{H}(\mathsf{M}) \leq \log(2^s) = s$, which proves that the total number of bits $s = \Omega(n - k \log n)$ for any deterministic protocol. By Yao's minimax principle, we get a lower bound of $\Omega(n - k \log n)$ on the randomized communication complexity of $\textsc{chain}_{n,k}$. ◀

The proof of Lemma 12 employs a reduction to the two player $\textsc{index}_n$. However, in these instances of $\textsc{index}_n$, Alice and Bob already have some partial information about the answer. We call this problem the **biased index** problem, and it is defined based on parameter $\theta \in [-1/2, 1/2]$, which is the initial bias known about the answer.

▶ **Definition 13.** *The* **biased index distributional communication problem**, *denoted by* $\textsc{bias-ind}(\theta)$ *for $\theta \in [-1/2, 1/2]$, is defined as follows.*

Sample $W \in \{0, 1\}$ such that $W = 1$ with probability $1/2 + \theta$, and $W = 0$ otherwise. Sample (Y, ρ) uniformly at random from $\mathcal{L} \times [n]$ conditioned on $Y(\rho) = W$. Give string Y to Alice, and index ρ to Bob. Bob has to output $Y(\rho)$ after a single message $M_{\textsc{index}}$ from Alice.

Let $\pi_{\textsc{index}}$ be a deterministic protocol for $\textsc{bias-ind}(\theta)$. Let $\mathsf{W}, \mathsf{Y}, \boldsymbol{\rho}, \mathsf{M}_{\textsc{index}}$ denote the random variables corresponding to W, Y, ρ and $M_{\textsc{index}}$ respectively. Let $\mathcal{D}_\theta$ denote the joint distribution of $\mathsf{W}, \mathsf{Y}, \boldsymbol{\rho}$ and $\mathsf{M}_{\textsc{index}}$ in $\textsc{bias-ind}(\theta)$.

We prove the following lemma about $\textsc{bias-ind}(\theta)$ in Section 3.3.

▶ **Lemma 14** (Biased Index)**.** *For any protocol $\pi_{\textit{INDEX}}$ for $\textsc{bias-ind}(\theta)$,*

$$\mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\textit{INDEX}}, \boldsymbol{\rho}) \geq H_2(1/2 + \theta) - \frac{2}{n} \cdot (\mathbb{H}(\mathsf{M}_{\textit{INDEX}}) + \log n).$$

We can prove Lemma 12 using Lemma 14, but the proof is deferred to the full version.

3.3 Biased Index

In this subsection, we will prove Lemma 14. Let us first recall the input distribution to $\textsc{bias-ind}(\theta)$.

Distribution $\mathcal{D}_\theta$: Sample $W = 1$ with probability $1/2 + \theta$ and set $W = 0$ otherwise. Sample $(Y, \rho) \in \mathcal{L} \times [n]$ conditioned on $Y(\rho) = W$.

In $\mathcal{D}_\theta$, the distribution of Y and $\boldsymbol{\rho}$ are highly correlated. We give an alternate way of sampling Y, ρ so that this correlation is removed partially.

Distribution $\mathcal{D}'_\theta$:
For $\theta \geq 0$:
1. Sample set $T \subset [n]$ of size $b = n/(1+2\theta)$ uniformly at random.
2. Sample a set S of $n/2$ indices from T uniformly at random and set them to 1, and set $[n] \setminus S$ to 0 to get Y.
3. Sample ρ by sampling an index uniformly at random from T.

For $\theta < 0$:
1. Sample set $T \subset [n]$ of size $b = n/(1-2\theta)$ uniformly at random.
2. Sample a set S of $n/2$ indices from T uniformly at random and set them to 0, and set $[n] \setminus S$ to 1 to get Y.
3. Sample ρ by sampling an index uniformly at random from T.

In this section, we assume that $\theta \geq 0$. For the case when $\theta < 0$, the proof follows in the same vein, and is not presented. Let T, S denote the random variables corresponding to set T and set S respectively. We show that distributions $\mathcal{D}_\theta$ and $\mathcal{D}'_\theta$ are in fact identical, and the proofs can be found in the full version.

▷ Claim 15. In distribution $\mathcal{D}_\theta$, for any $(Y, \rho) \in \mathcal{L} \times [n]$,

$$\Pr(\mathsf{Y} = Y, \boldsymbol{\rho} = \rho) = \begin{cases} \frac{1+2\theta}{n \cdot \binom{n}{n/2}} & \text{when } Y(\rho) = 1, \\ \frac{1-2\theta}{n \cdot \binom{n}{n/2}} & \text{when } Y(\rho) = 0. \end{cases}$$

▷ Claim 16. Distribution $\mathcal{D}_\theta$ is the same as $\mathcal{D}'_\theta$.

Using this alternate way of sampling, it is easy to see that random variables Y and $\boldsymbol{\rho}$ are independent of each other conditioned on T. It can also be extended to include random variable $\mathsf{M}_{\text{INDEX}}$, as it is only a function of Y.

▶ **Observation 17.** *In distribution $\mathcal{D}'_\theta$, conditioned on $\mathsf{T} = T$, for any $i \in T$, distribution of random variables $\mathsf{Y}, \mathsf{M}_{INDEX}$ is independent of event $\boldsymbol{\rho} = i$.*

Proof. Conditioned on $\mathsf{T} = T$, string Y is chosen by picking an $n/2$ size set S uniformly at random from T, and setting these indices to 1, and this choice also fixes $\mathsf{M}_{\text{INDEX}}$ as the protocol is deterministic. And index ρ is chosen uniformly at random from T, independently of the choice of S, by definition of $\mathcal{D}'_\theta$. Thus, choice of $\boldsymbol{\rho} = i$ is independent of random variables $\mathsf{Y}, \mathsf{M}_{\text{INDEX}}$. ◀

Next, we will show that even conditioned on T, the entropy of Y remains large.

▷ Claim 18.

$$\mathbb{H}(\mathsf{Y} \mid \mathsf{T}) \geq \frac{n}{(1+2\theta)} \cdot H_2(1/2+\theta) - 2\log n.$$

Proof. We assume that $\theta < 1/2$, as otherwise, the statement is vacuously true. $H_2(1) = 0$ by definition, and entropy is always non-negative by Fact 7-(1).

Conditioned on $\mathsf{T} = T$, we know that Y is fixed by choosing set S uniformly at random. Thus,

$$\mathbb{H}(\mathsf{Y} \mid \mathsf{T}) = \log\left(\binom{b}{n/2}\right) \qquad \text{(by Fact 7-(1))}$$

$$\geq \log\left(2^{bH_2(n/2b)} \cdot \sqrt{\frac{b}{8(n/2)(b-n/2)}}\right) \quad \text{(by Fact 4, and } n/2 < b \text{, as } \theta < 1/2)$$
$$= b \cdot H_2(n/2b) + \frac{1}{2} \cdot \log(\frac{b}{8(n/2)(b-n/2)})$$
$$= \frac{n}{(1+2\theta)} \cdot H_2(1/2+\theta) + \frac{1}{2}\log(\frac{1}{4n \cdot (1/2-\theta)})$$
$$\geq \frac{n}{(1+2\theta)} \cdot H_2(1/2+\theta) + \frac{1}{2}\log(1/4n) \quad \text{(as } 1/2-\theta \leq 1)$$
$$\geq \frac{n}{(1+2\theta)} \cdot H_2(1/2+\theta) - 2\log n. \qquad \lhd$$

We are ready to prove Lemma 14.

Proof of Lemma 14. We can lower bound the entropy of W conditioned on $\mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}$ as,

$$\mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}) \geq \mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}, \mathsf{T}) \quad \text{(as conditioning reduces entropy, Fact 7-(2))}$$
$$= \mathop{\mathbb{E}}_{\mathsf{T}=T}\Big[\frac{1}{b} \cdot \sum_{\rho \in T} \mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho} = \rho, \mathsf{T} = T)\Big] \quad \text{(as } \boldsymbol{\rho} \text{ is uniform over } T)$$
$$= \mathop{\mathbb{E}}_{\mathsf{T}=T}\Big[\frac{1}{b} \cdot \sum_{\rho \in T} \mathbb{H}(\mathsf{Y}(\rho) \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho} = \rho, \mathsf{T} = T)\Big]$$
(as $W = Y(\rho)$ by definition of $\mathcal{D}_\theta$)
$$= \mathop{\mathbb{E}}_{\mathsf{T}=T}\Big[\frac{1}{b} \cdot \sum_{\rho \in T} \mathbb{H}(\mathsf{Y}(\rho) \mid \mathsf{M}_{\text{INDEX}}, \mathsf{T} = T)\Big]$$
(as $\mathsf{Y}, \mathsf{M}_{\text{INDEX}} \perp (\boldsymbol{\rho} = \rho) \mid \mathsf{T} = T$, by Observation 17)
$$\geq \mathop{\mathbb{E}}_{\mathsf{T}=T}\Big[\frac{1}{b} \cdot \mathbb{H}(\mathsf{Y}(T) \mid \mathsf{M}_{\text{INDEX}}, \mathsf{T} = T)\Big]$$
(by subadditivity of entropy, Fact 7-(4))
$$= \mathop{\mathbb{E}}_{\mathsf{T}=T}\Big[\frac{1}{b} \cdot \mathbb{H}(\mathsf{Y} \mid \mathsf{M}_{\text{INDEX}}, \mathsf{T} = T)\Big] \quad \text{(as } Y([n] \setminus T) \text{ is fixed to be 0)}$$
$$= \frac{1}{b} \cdot \mathbb{H}(\mathsf{Y} \mid \mathsf{M}_{\text{INDEX}}, \mathsf{T}).$$

Thus it follows that,

$$\mathbb{H}(\mathsf{Y} \mid \mathsf{M}_{\text{INDEX}}, \mathsf{T}) \leq b \cdot \mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}). \tag{1}$$

We also have,

$$\mathbb{H}(\mathsf{Y} \mid \mathsf{T}) = \mathbb{H}(\mathsf{Y}, \mathsf{M}_{\text{INDEX}} \mid \mathsf{T}) \quad \text{(as } M \text{ is fixed by } Y)$$
$$= \mathbb{H}(\mathsf{M}_{\text{INDEX}} \mid \mathsf{T}) + \mathbb{H}(\mathsf{Y} \mid \mathsf{M}_{\text{INDEX}}, \mathsf{T}) \quad \text{(by chain rule of entropy, Fact 7-(3))}$$
$$\leq \mathbb{H}(\mathsf{M}_{\text{INDEX}} \mid \mathsf{T}) + b \cdot \mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}) \quad \text{(by Eq (1))}$$
$$\leq \mathbb{H}(\mathsf{M}_{\text{INDEX}}) + b \cdot \mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}).$$
(as conditioning reduces entropy, by Fact 7-(2))

Combining with Claim 18, we get,

$$\mathbb{H}(\mathsf{M}_{\text{INDEX}}) + b \cdot \mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}) \geq b \cdot H_2(1/2+\theta) - 2\log n \quad \text{(as } b = n/(1+2\theta))$$
$$b \cdot \mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}) \geq b \cdot H_2(1/2+\theta) - (\mathbb{H}(\mathsf{M}_{\text{INDEX}}) + 2\log n).$$
(rearranging the terms)

Dividing both sides by b, we get,

$$\begin{aligned}\mathbb{H}(\mathsf{W} \mid \mathsf{M}_{\text{INDEX}}, \boldsymbol{\rho}) &\geq H_2(1/2+\theta) - \frac{1}{b} \cdot (\mathbb{H}(\mathsf{M}_{\text{INDEX}}) + 2\log n) \\ &\geq H_2(1/2+\theta) - \frac{2}{n} \cdot (\mathbb{H}(\mathsf{M}_{\text{INDEX}}) + 2\log n), \qquad (\text{as } b \geq n/2)\end{aligned}$$

finishing the proof. ◀

3.4 Extension to Augmented Chain

In this subsection, we will extend our lower bound to the Augmented Chain problem introduced by [15]. We begin by defining Augmented Index.

Augmented Index is a close variant of the INDEX problem. Here, in addition to having the index σ, Bob also has the bits $X(<\sigma)$. We know that this generalization also requires $\Omega(n)$ communication when Alice sends a message to Bob [34]. This problem is particularly useful for proving lower bounds for turnstile streams (see e.g., [11, 25, 16], and references therein). Tight information cost trade-off for this variant in the two-way communication model was proved by [9].

The formal definition of Augmented Chain follows.

▶ **Definition 19** (Augmented Chain). *The* AUG-CHAIN$_{n,k}$ *communication problem is defined as follows. Given $k+1$ players $\mathcal{P}_i$ for $i \in [k+1]$ where,*

- *$\mathcal{P}_i$ has a string $X_i \in \{0,1\}^n$ for each $i \in [k]$,*
- *$\mathcal{P}_i$ for $1 < i \leq k+1$ has an index $\sigma_{i-1} \in [n]$, and a string $X_{i-1}(<\sigma_{i-1})$,*

such that,

$$X_i(\sigma_i) = z,$$

for some bit $z \in \{0,1\}$. The players have a blackboard visible to all the parties. For $i \in [k]$ in ascending order, $\mathcal{P}_i$ sends a single message M_i, after which the index σ_i, and the string $X_{i-1}(<\sigma_{i-1})$ are revealed to the blackboard at no cost. $\mathcal{P}_{k+1}$ has to output whether z is 0 or 1. Refer to Figure 3 for an illustration.

For the chained version of Augmented Index, the lower bound that at least one player sends $\Omega(n/k^2)$ bits holds true, and the proof follows with minimal changes. Using this, [15] proved lower bounds for interval independent set selection in turnstile streams with weighted intervals.

We prove the following result about AUG-CHAIN$_{n,k}$.

▶ **Theorem 20.** *For any $n, k \geq 1$, any protocol for* AUG-CHAIN$_{n,k}$ *with probability of success at least 2/3 requires communication $\Omega(n - k\log n)$.*

A proof sketch detailing the changes needed to prove Theorem 20 is given in the full version. Most parts of the proof are similar to the proof of Theorem 3.

4 Applications to Streaming

In this section we give applications of our main result to independent sets in vertex arrival streams and streaming submodular maximization.

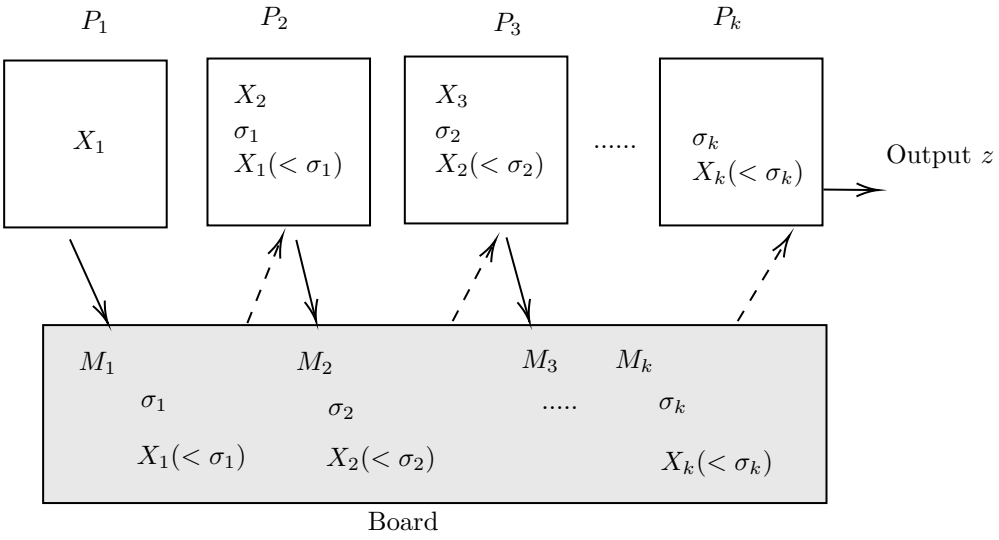

Figure 3 An illustration of the AUG-CHAIN$_{n,k}$ problem from Definition 19. The solid arrows illustrate that player $\mathcal{P}_i$ writes a message M_i to the board. The dashed arrows indicate that $\mathcal{P}_i$ can read the contents of the board. The order in which the messages are sent and indices, strings are released is also shown.

4.1 Independent Sets

In edge arrival streams, for any graph $G = (V, E)$, the vertex set V with n vertices is given, and the edges E arrive in any arbitrary order. We are required to process the graph in limited space.

In vertex arrival streams, for any graph $G = (V, E)$, the edges are grouped by their incident vertices. Vertices from V arrive one by one (in any arbitrary order), and when a vertex arrives, all the edges connecting it to any previously arrived vertices are revealed. This makes the vertex arrival stream a strictly easier model than the edge arrival stream, as the order of edges is restricted.

Indeed, for the maximal independent set problem, we know that finding algorithms in vertex arrival streams is easier; the greedy algorithm produces a maximal independent set in $\widetilde{O}(n)$ space, whereas, in edge arrival streams, any algorithm which finds a maximal independent set requires $\Omega(n^2)$ space [4, 12].

Maximum independent set (MIS), however, is provably hard in both vertex arrival streams and edge arrival streams. It is known that, any algorithm which performs an α-approximation of MIS in edge arrival streams requires $\Omega(n^2/\alpha^2)$ space from [22]. In vertex arrival streams, [12] proved a lower bound of $\Omega(n^2/\alpha^7)$. They also gave the following connection between CHAIN problem and MIS in the proof of Theorem 9 of their paper.

▶ **Proposition 21** (Rephrased from [12]). *For any $\alpha \geq 1$, any algorithm that gives an α-approximation of maximum independent sets in vertex arrival streams for n-vertex graphs using space at most s and probability of success at least 2/3 can be used to solve* CHAIN$_{n^2/64\alpha^4, 2\alpha}$ *with communication at most $2\alpha \cdot s$ bits and success probability at least 2/3.*

Our lower bound Theorem 3, along with Proposition 21 directly gives the following corollary.

▶ **Corollary 22.** *For $\alpha \geq 1$, any α-approximation of maximum independent sets in n-vertex graphs in vertex arrival streams uses $\Omega(n^2/\alpha^5 - \log n)$ space.*

This further reduces the gap between the lower bounds for α-approximation of MIS in vertex arrival streams and edge arrival streams by an α^2 factor.

4.2 Submodular Maximization

In this subsection, we will summarize our slight improvements to lower bounds for streaming submodular maximization.

A function f over ground set V from $f : 2^V \to \mathbb{R}$ is submodular if and only if, for any two sets $A \subset B \subset V$ and for any element $x \in V \setminus B$,

$$f(B \cup \{x\}) - f(B) \leq f(A \cup \{x\}) - f(A).$$

This captures the diminishing returns property of any submodular function.

We are interested in maximization of a monotone submodular function subject to a cardinality constraint. That is, for a given ℓ, we want to find a subset $S \subset V$ with $|S| \leq \ell$ such that for any other set $T \subset V$ with $|T| \leq \ell$, $f(S) \geq f(T)$.

We are given oracle access to function f, however, we do not have access to the entirety of the ground set. The elements of the ground set V arrive one by one, and the algorithm has space s to either store the incoming element or to discard it. The algorithm can query the oracle to f with any subset of the elements currently in storage. We want the storage to be roughly the same as the output size, which is ℓ.

In this model, [29] gave an algorithm which finds a $(1/2 - \epsilon)$-approximation in $O(\ell/\epsilon)$ space. [19] showed that a better approximation was not possible. They proved that any algorithm which gets a $(1/2 + \epsilon)$-approximation uses $\Omega(\epsilon |V| / \ell^3)$. They give the following connection to the CHAIN problem in Theorem 1.3 and Theorem 1.4 of their paper.

▶ **Proposition 23** (Rephrased from [19]). *For any $\epsilon > 0$, there exists a constant ℓ_0 such that for any $\ell \geq \ell_0$, any randomized streaming algorithm which maximizes a monotone submodular function $f : 2^V \to \mathbb{R}$ subject to cardinality constraint of at most ℓ, using space at most s and with approximation factor at least $(1/2 + \epsilon)$ in expectation can be used to solve $\text{CHAIN}_{|V|/\ell,\ell}$ with probability of success at least 2/3 and communication at most $s \cdot O(\ell/\epsilon)$.*

We get an improvement of ℓ factor over the current state-of-art lower bound in [19] as a corollary of Theorem 3.

▶ **Corollary 24.** *For any $\epsilon > 0$, there exists a constant ℓ_0 such that for any $\ell \geq \ell_0$, any streaming algorithm that maximizes a monotone submodular function $f : 2^V \to \mathbb{R}$ subject to a cardinality constraint of at most ℓ, with an approximation factor at least $(1/2 + \epsilon)$, requires $\Omega(|V| \epsilon/\ell^2 - \varepsilon \log(|V|))$ space.*

Abstract

We show how to convert any circuit of poly-logarithmic depth and polynomial size into a functionally equivalent circuit of polynomial size (and polynomial depth) that is resilient to adversarial short-circuit errors. Specifically, the resulting circuit computes the same function even if up to ϵd gates on every root-to-leaf path are short-circuited, *i.e.*, their output is replaced with the value of one of its inputs, where d is the depth of the circuit and $\epsilon > 0$ is a fixed constant.

Previously, such a result was known for formulas (Kalai-Lewko-Rao, FOCS 2012). It was also known how to convert general circuits to error resilient ones whose size is quasi-polynomial in the size of the original circuit (Efremenko et al. STOC 2022). The reason both these works do not extend to our setting is that there may be many paths from the root to a given gate, and the resilient circuits needs to "remember" a lot of information about these paths, which causes it to be large. Our main idea is to reduce the amount of this information at the cost of increasing the depth of the resilient circuit.

1 Introduction

Constructing error-resilient circuits is one of the most fundamental problems in theoretical computer science, dating back to von Neumann [30]. In the study of error resilient circuits, the goal is to convert any circuit C into a circuit C' that computes the same function as C even if some of the gates of C' are faulty. Moreover, the goal is to do so with a small overhead in size, *i.e.*, constructing a circuit C' whose size is bounded by a polynomial in the size of C.

In this paper, we show how to convert any polynomial size circuit of poly-logarithmic depth into a polynomial size circuit that is functionally equivalent and is resilient to short-circuit errors, an error model that was introduced by Kleitman, Leighton, and Ma [20], and was soon adopted as a central model in the study of error-resilient circuits [18, 4, 7]. In this error model, the adversary can replace any gate in the circuit with an arbitrary gate $g : \{0,1\}^2 \to \{0,1\}$ as long as $g(0,0) = 0$ and $g(1,1) = 1$ (and in particular can replace an AND gate with an OR gate, and vice versa)[1]. Equivalently, we can say that the value of the gate g is replaced by the value of one of its children (the wire to the other child is "cut

[1] Note that the restriction that $g(b,b) = b$ for all $b \in \{0,1\}$ is necessary since otherwise an adversary can simply flip the result of the output gate, and thus no circuit can be resilient to even a single error.

out"). This model is motivated by applications; indeed, as noted in [20], "stuck-at" and "power-ground" failures resulting from short-circuits or broken connections are more common than other types of errors.

Similar to the works of [18, 4, 7], we consider omniscient adversaries that have full information about the entire circuit, and can corrupt ϵd of the gates on every root-to-leaf path, where d is the depth of the circuit and $\epsilon > 0$ is some fixed constant. These prior works were either restricted to formulas, *i.e.*, logarithmic depth circuits [18, 4], or incurred a quasi-polynomial blowup to the circuit size [7]. Moreover, it was conjectured in [7] that, unlike the case of formulas [18, 4], a quasi-polynomial blowup in the circuit size is necessary when converting general circuits into noise resilient ones.

1.1 Our Results

We show that how to convert any circuit of polynomial size and poly-logarithmic depth (i.e., any NC circuit) into a functionally equivalent circuit of polynomial size (and polynomial depth) that is error resilient.

▶ **Theorem 1** (Informal, see formal version in Theorem 8)**.** *Let C be a Boolean circuit in the class NC that[2] computes a function f. There exists a Boolean circuit C' whose size and depth are polynomial in the size of C that computes f even when a constant fraction of gates in any input to output path in C' are short-circuited.*

In terms of comparison, Theorem 1 improves on the main result of [18] in the sense that it works for all circuits with polynomial size and poly-logarithmic depth while [18] only works for formulas. It also improves upon [7] in the sense that it gets a polynomial blowup in the size instead of the quasi-polynomial blowup obtained in [7]. However, it does not subsume either of these results. For example, [18] also preserve the depth of the original formula up to constant factors but we do not provide such a guarantee, and [7] works for general circuits, including those not in the class NC.

We also mention that [7] believed that the quasi-polynomial blowup they obtain is inherent and conjectured that a polynomial blowup will not suffice like it does in the case of formulas [18, 4]. Theorem 1 disproves this conjecture for the restricted case of circuits in NC. Proving/disproving the conjecture for general circuits is an amazing problem that we leave open. However, proving this conjecture, even in an existential manner, would imply $\mathsf{P/poly} \not\subseteq \mathsf{NC}$, and thus may be extremely hard. Indeed, if $\mathsf{P/poly} \subseteq \mathsf{NC}$, then a general polynomial size circuit has a functionally equivalent circuit in NC and we can use Theorem 1 to make it error resilient with only a polynomial blowup.

Error-resilient dag-protocols

Computation and communication have a deep connection. Just like prior work [18, 4, 7], the current work also exploits this connection via the Karchmer-Wigderson transformation. Specifically, Karchmer and Wigderson [19] show that any circuit computing a function f can be converted into a communication protocol for a related search problem KW_f such that the depth of the circuit matches the length of the communication protocol, and vice versa.

[2] Thus, if f takes n variables as input, the number of gates in C is bounded by a polynomial in n and the depth of C is bounded by a polynomial in $\log n$. The other constants in the theorem statement depend on the degree of these polynomials; see the formal version of the theorem (Theorem 8) for the precise dependence.

An analogous transformation can be shown in the reverse direction, *i.e.* a transformation that takes error-resilient communication protocols to error resilient circuits, and was used in [18, 4] to build error resilient formulas.

The Karchmer-Wigderson transformation does not preserve the size of the circuit and in fact, blows it up to be exponential in the depth. To circumvent this blowup in size, [25, 29] showed how to convert any circuit into a "**dag**-protocol" that preserves both its size and depth. **dag**-protocols are a generalization of communication protocols, and can be represented by the following pebble game: There is a rooted directed acyclic graph, and each non-sink node in the graph belongs to one of the two parties, while each sink node is associated with an output. The game starts with a "pebble" at the root of graph, that is moved along the edges of the graph. At every step, if the pebble is not already at a sink node, the party who owns that node will move the pebble along one of its out-edges. This will end when the pebble reaches a sink node, and the output will be the output of the sink node.

[25, 29] showed that every circuit computing a function f can be converted to a **dag**-protocol with the same size and depth that solves KW_f with a strong correctness guarantee called rectangular correctness (see Definition 5 for a precise definition). The reverse direction also holds, and in fact even holds in the error-resilient setting. This direction was used to get error-resilient circuits from error-resilient **dag**-protocols in [7]. We adopt a similar approach and use the [25, 29] transformation to go from circuits to **dag**-protocols and back. Indeed, our main technical result is the following theorem about error-resilient **dag**-protocols.

▶ **Theorem 2** (Informal, see formal version in Theorem 9)**.** *Let S be a search problem and Π be a* **dag***-protocol that solves S with rectangular correctness. Assume that the depth of Π is poly-logarithmic in the size. There exists a* **dag***-protocol Π' with a polynomially larger size that solves S with rectangular correctness even if a constant fraction of nodes on any root to leaf path in the protocol Π' are adversarially corrupted.*

1.2 Related Work

The works most closely related to ours are the works [18, 4, 7] cited above. We discuss additional related work below.

Other noise models for circuits

Even though the short-circuit error model we consider is the most studied one, other models have also been considered. For example, von Neumann [30] initiated the study of the stochastic noise model, where the noise flips the value of each gate in the circuit independently with some small fixed probability. Von Neumann's model was studied by a long sequence of works, including [6, 22, 23, 11, 8, 9, 17, 13, 12, 10]. In this model, it is known that a circuit of size s can converted to a noise resilient circuit of size $O(s \log s)$, and that a function with sensitivity s' requires a resilient circuits of size $\Omega(s' \log s')$ [30, 6, 22, 13, 12].

In this paper, we study the short-circuit error model of [20] but there is also a different adversarial model studied by [14], where the adversary may corrupt the output of a small constant fraction of the gates at each layer of the circuit in an arbitrary way. They show how to construct error resilient circuits for symmetric functions in this model, by exploiting interesting connections between their model and probabilistically checkable proofs. However, the obtained circuit is only guaranteed to compute, what they call, a "loose version" of

the function, and may err on many inputs. Lastly, we mention the orthogonal direction of constructing testable circuits which are circuits on which errors can detected (but not necessarily corrected) efficiently [2, 1].

Codes for interactive communication

As our work develops error-resilient circuits via error-resilient **dag**-protocols, it is also connected with the vast literature on codes for interactive communication, or simply "interactive codes", that are used to make communication protocols resilient to noise. This field, initiated by the seminal works [26, 27, 28] has received a lot of attention over the last three decades, and various aspects of interactive codes have been extensively studied. A work loosely related to circuits is [5] but see [16] for an excellent survey. We note that all constructions of error resilient **dag**-protocols are heavily inspired by an underlying interactive coding scheme (recall that **dag**-protocols are a generalization of communication protocols).

dag-protocols

Razborov [25] introduced a model of *PLS communication protocols*, and used it generalize the Karchmer-Wigderson transformation [19] in a way that preserves both the size and the depth of the circuit. This connection was used by Krajícek [21], who introduced the technique of *monotone feasible interpolation*, which became a popular method for proving lower bounds on the refutation size in propositional proof systems such as Resolution, and Cutting Planes [3], by reducing to monotone circuit lower bounds. The notion of PLS communication protocols was simplified by Pudlak [24] and Sokolov [29] to the notion of **dag**-*like communication protocols*, which we call **dag**-protocols. Subsequently, a "converse" to monotone feasible interpolation was established in [15] to prove new lower bounds on monotone circuits by lifting lower bounds on Resolution refutations. To the best of our knowledge, our work is the only work, other than [7], to use the notion of **dag**-protocols in a "positive" manner, namely to construct error-resilient circuits, in contrast to prior work which mainly used this notion to prove lower bounds in proof complexity and circuit complexity.

1.3 Additional Discussion

An obvious problem left open by our work is whether general circuits can be made error resilient with only a polynomial overhead. As mentioned above, the only work in this regard is [7], that showed that general circuits can be made error-resilient by incurring a quasi-polynomial overhead. Specifically, if the original circuit has size s and depth d, they construct a resilient version of this circuit that has size $s^{\mathcal{O}(\log d)}$ and depth $\mathcal{O}(d)$. [7] further say that the power of $\mathcal{O}(\log d)$ seems inherent.

The current work manages to get around the $\mathcal{O}(\log d)$ in the exponent, at the cost of increasing depth to be a polynomial (note that $d = (\log s)^{\mathcal{O}(1)}$ in our setting). It is interesting to see if our techniques can be combined with [7] to shave off a small factor off of this exponent for general circuits, at the expense of a larger depth. We leave this investigation to future work. Another great question for future research is whether the polynomial blowup in depth that we suffer is inherent, or is there a way to make circuits in NC error resilient while preserving their depth up to a constant factor.

Another interesting direction for future work is whether the resilient circuit can be computed efficiently, say in time polynomial in the size of the circuit. The initial work of [18] guaranteed efficiency when the initial circuit is a formula although the later work [7]

was not able to generalize it to circuits[3]. The current work for circuits in NC also leaves this direction open. Finally, even though we get resilience to some constant fraction of adversarial errors, we make no efforts to optimize this constant. Finding the right constant is a great question for future work (see [4]).

2 Technical Overview

We now overview the ideas behind Theorem 1 and contrast it with prior work [18, 4, 7]. Roughly speaking, Theorem 1 says that there exist polynomial sized resilient circuits for every circuit C in NC. We let s and d be the size and the depth of C, respectively, and use f to denote the Boolean function computed by C. We will also assume without loss of generality that the circuit C is layered and alternating. Just like prior work, our construction is in three-steps via **dag**-protocols[4]:

1. **Circuits → dag-protocols.** This step is the same as prior work, and uses the Karchmer-Wigderson transformation [19] to transform the circuit that computes f to a **dag**-protocol that solves the Karchmer-Wigderson game KW_f associated with f with rectangular correctness. This transformation satisfies the property that short-circuit errors in the original circuit correspond to running the protocol over a channel with corruption noise and perfect feedback. We will call such channels feedback channels for simplicity and use this property in the Step 3 below.
2. **dag-protocols → error-resilient dag-protocols.** This is the main step in the proof where the input is a **dag**-protocol and the goal is to output a functionally equivalent **dag**-protocol that works on feedback channels. This is the main contribution of this work and is detailed below.
3. **Error-resilient dag-protocols → error-resilient circuits.** Having constructed a protocol that solves KW_f with rectangular correctness even on feedback channels, we use the "inverse" Karchmer-Wigderson transformation to transform it to a Boolean circuit computing f that is resilient to short-circuit errors. This step in our proof can also be found in prior work.

The main contribution of this work is Step 2 above, which transforms **dag**-protocols to error-resilient **dag**-protocols. Analogous transformations in prior work were usually done using interactive coding schemes, an area of research initiated by the seminal works [26, 27, 28] that is dedicated to making communication protocols resilient to errors. At an extremely high level, this is done by designing mechanisms to detect errors fast and then using rewind mechanisms to rewind to a point in the communication history that was before these errors occurred.

However, to rewind to a point in the communication history before the errors occurred, the resilient protocol needs to remember the state at that point. After the Karchmer-Wigderson transformation, this extra memory shows up as a blowup in the size of the resilient circuit, which we want to minimize. To be more specific, prior work on resilient circuits [7], remembers $\mathcal{O}(\log d)$ different states at every point in the resilient protocol which means that each layer in the resilient circuit is quasi-polynomially larger (*i.e.*, has size $s^{\mathcal{O}(\log d)}$) than each layer in the original circuit. Thus, even though [7] increase the number of layers by only a constant factor, the blowup in the size of each layer makes the overall blowup quasi-polynomial.

[3] Note that the error-resilient circuit of [7] is of quasi-polynomial size, and thus polynomial in this size of this circuit means that it is quasi-polynomial in the size of the original circuit.
[4] Readers not familiar with **dag**-protocols may find it useful to first go over Section 2.1 of [7].

Our approach is to greatly reduce the size of every layer, at the expense of the increasing the total number of layers. This means that we cannot even afford to remember $\mathcal{O}(\log d)$ many states at any point. As any interactive coding scheme we are aware of remembers at least logarithmically many states, they would not suit us, and new ideas are needed.

2.1 Our Approach For NC^1

We start by considering a restricted case where the original circuit C lies in NC^1. Even though circuits in NC^1 can be transformed into formulas with only a polynomial blowup, we will stick with the circuit view as it will allow us to generalize later on. Note that prior work already gives a resilient circuit for this case that has size polynomial in s and has depth $\mathcal{O}(d)$. We construct a different resilient circuit that has the same size guarantee but relaxes the depth guarantee[5]. This alternate construction allows us to extend to all of NC.

Our approach

We devise a way to make **dag**-protocols corresponding to NC^1 circuits resilient while remembering only a constant number (in fact, 2) states at each point, at the cost of blowing up the number of layers exponentially. As the depth of NC^1 circuits is logarithmic in n, this exponential blowup is still polynomial in n. Moreover, as we only remember a constant number of states at each point, the blowup in the size of each layer is also polynomial, and combining this with the blowup in the number of layers still gives a polynomial blowup.

Note that any protocol must at least remember the current state, and thus a protocol that remembers only 2 states actually remembers only 1 extra state! Interestingly, for our protocol, this extra state is not a state in the past but actually the next state in the future that the protocol is considering going to. Specifically, if the protocol is currently in state in layer $i-1$ (for some $i > 0$), and wants to advance to a state in layer i, then instead of jumping to that state directly, it is remembered as a "candidate" state until the protocol has enough "confidence" in the candidate to advance. This confidence is implemented via a variable `cnf` that is incremented every time the parties want to advance and decremented every time they suspect that the states in memory are incorrect. Only after the confidence `cnf` hits a certain threshold $\mathfrak{C}_i$ does the protocol actually advance to the state in layer i.

We will view the thresholds as being cumulative, *i.e.*, $\mathfrak{C}_i$ is the total confidence required to go from layer 0 to layer i. This means that $\mathfrak{C}_i - \mathfrak{C}_{i-1}$ is the additional confidence needed to advance from layer $i-1$ to layer i. With this said, the obvious question is how large does $\mathfrak{C}_i - \mathfrak{C}_{i-1}$ need to be? In other words, how much confidence should the protocol have in the candidate before they advance to a state in layer i? To answer this question, one needs to consider the total "loss" of the protocol in case it advances wrongly and reaches an incorrect state. As no state in the past is remembered, the only way the protocol can recover from this incorrect state is if it starts all over again and reaches the state in layer $i-1$, which requires a total increase in confidence of $\mathfrak{C}_{i-1}$. Thus, the increase (which equals $\mathfrak{C}_i - \mathfrak{C}_{i-1}$) of the confidence required to jump from layer $i-1$ to layer i should be the same order of magnitude as the confidence $\mathfrak{C}_{i-1}$ needed to reach layer $i-1$ from the beginning of the protocol. Solving, we get that $\mathfrak{C}_i$ should be (at least) exponential in i. This is the choice that we make, setting $\mathfrak{C}_i = c^i$ for some suitable constant $c > 1$.

[5] The depth is at most the size, so it must still be polynomial in s.

Protocol details

We now provide more details of our protocol and argue its correctness. The protocol starts at the initial (root) node in layer 0 with confidence $\texttt{cnf} = \mathfrak{C}_0 = 0$. At any given time, the protocol is in some layer, say layer $i-1$ with some confidence $\texttt{cnf}$, and trying to continue the simulation from some state in this layer. For this, the protocol first checks[6] if the current state has any errors. If so, the protocol decreases the confidence $\texttt{cnf}$ by 1. This may cause $\texttt{cnf}$ to hit 0, which is taken as a signal to forget all progress and restart the simulation. If no errors are found, then the current state is assumed to be correct and the action to be taken is determined by the value of the confidence $\texttt{cnf}$.

If we have $\texttt{cnf} < \mathfrak{C}_{i-1}$, then it must be the case that the confidence was decreased after reaching layer $i-1$. The protocol simply increases it by 1 trying to get it back to $\texttt{cnf}_{i-1}$ so that further progress can be made. If the confidence $\texttt{cnf} = \mathfrak{C}_{i-1}$, the confidence in layer $i-1$ is high enough for the protocol to compute a candidate in layer i. A candidate $\texttt{nxt}$ for the state to advance to is computed and the confidence is further increased by 1.

Finally, if the confidence $\texttt{cnf} > \mathfrak{C}_{i-1}$, then the protocol must already have a candidate $\texttt{nxt}$ that it is considering going to. The protocol then checks if this candidate was caused due to errors, and if so, decreases the confidence by 1. If the confidence is lowered all the way back to $\mathfrak{C}_{i-1}$, the protocol "forgets" about the candidate $\texttt{nxt}$ (and will compute a new one in the future if needed). On the other hand, if the candidate $\texttt{nxt}$ was not due to errors, the protocol increases the confidence $\texttt{cnf}$ by 1. If this increased confidence reaches $\texttt{cnf}_i$, it is high enough to advance. The protocol forgets about the current state in layer $i-1$ and continue the rest of the simulation from the state $\texttt{nxt}$ in layer i.

Arguing correctness

We now show that the above protocol indeed simulates the original protocol correctly. For this, we first show that if the protocol has high confidence at the end of the protocol, specifically, if $\texttt{cnf} \geq \mathfrak{C}_d$, where d is the total number of layers (depth) of the original protocol, then the output of the protocol must be correct. Indeed, if the confidence is that high, the protocol is in a state in layer d or higher[7], and the only reason this state would not be correct is if the protocol advanced to it incorrectly. However, this means that there must have been at least $\mathfrak{C}_d - \mathfrak{C}_{d-1}$ errors while this state was the next candidate. As the confidence thresholds are exponential, we have that the total number of errors is at least $\mathfrak{C}_d - \mathfrak{C}_{d-1} = \Omega(\mathfrak{C}_d)$, which is more than a constant fraction and therefore, unaffordable.

Now, all we need to show is that the confidence is indeed high at the end of the protocol. For this, we fix any execution of the protocol and partition the rounds into rounds where the protocol wants to "go back" and decrease the confidence $\texttt{cnf}$ (this happens when either the current state or the next state $\texttt{nxt}$ has any errors) and rounds where it does not. We collect the former type of rounds in the set Back. By definition, the confidence will increase in any round not in Back unless there are errors, and will decrease in any round in Back

[6] As in prior work, assuming that the original **dag**-protocol is rectangular correct is crucial for the protocol to be able to check whether or not there are errors. As this is not a novel idea for the current work, we omit a precise description in this sketch. (Very) roughly speaking (see formal definition in Definition 5), a state is said to be rectangular correct for inputs x and y for Alice and Bob respectively, if there exists inputs x' for Alice and y' for Bob such that the protocol reaches that state when executed with inputs x and y' and also reaches it with inputs x' and y. This means that the parties can go over all possible inputs of the other party in order to check if the state is (rectangular) correct or not.

[7] We append the original protocol with dummy states to get states beyond layer d.

unless there are errors. As the total number of errors is only a small constant fraction, this means that all we need to do to show that the confidence is high at the end of the protocol is to show that the size of Back is small.

To show this, we argue that the size of Back is at most a constant factor more than the number of rounds in Back where the protocol did not go back. To see why, note that the first round in Back must be a round where the protocol added an incorrect next state as their candidate `nxt`. As mentioned above, if the next state is in layer i, this only happens when the confidence is exactly $\mathfrak{C}_{i-1}$.

As long as the protocol does not advance to this next state (in other words, it remains a candidate), the confidence must stay above $\mathfrak{C}_{i-1}$, as otherwise the protocol will forget the incorrect candidate and look for a new one. This means that the total number of rounds where the protocol does not go back and increase the confidence exceeds the total number of rounds where the protocol did go back, and we are done. On the other hand, if the protocol does advance to the candidate, there must have been at least $\mathfrak{C}_i - \mathfrak{C}_{i-1}$ errors, and by definition of $\mathfrak{C}$, these are high enough (up to constant factors) for $\mathfrak{C}_i$ rounds of progress. Thus, the protocol can wait until the confidence hits 0 and restart the simulation from there.

2.2 From NC^1 to NC

We now show how we can extend the ideas above to get a simulation for all of NC. Note that the Karchmer-Wigderson transformation transforms general NC circuits to **dag**-protocols of poly-logarithmic depth. As our arguments above increase the depth exponentially, using them on general NC circuits would make the depth super-polynomial.

To reduce the depth, we extend our protocol above to also remember some states in the past. Specifically, if the current state is layer $i-1$, the protocol also remembers the state it encountered in the most recent layer that was a multiple of $(\log s)^j$, for all $j \in \mathbb{N}$. As the total number of layers we have is poly-logarithmic, we get that when j is larger than some fixed constant, the most recent layer that is a multiple of $(\log s)^j$ is just layer 0. This means that the parties only remember a constant number of distinct states, implying as above that the blowup in the size of each layer is still polynomial.

We now argue why remembering these extra states ("meeting points") in the past will also reduce the total number of layers back to polynomial. The reason is that if the protocol remembers meeting point in the near future, then, when the confidence is too low, the protocol does not have to forget all progress and restart the simulation from scratch. Instead, the protocol only has to forget the progress since the last meeting point and restart the simulation from said meeting point. Because of the loss in progress is now smaller, we can allow the confidence increase (which equals $\mathfrak{C}_i - \mathfrak{C}_{i-1}$) required to advance to also be smaller. As this happens for almost all i, the value of $\mathfrak{C}_d$, the highest confidence threshold is significantly smaller, and we can bound it by a polynomial.

The new confidence thresholds

We are yet to specify the precise increase in confidence (which equals $\mathfrak{C}_i - \mathfrak{C}_{i-1}$) required to advance to a state in layer i. For this, we look at the representation of i as an integer[8] in base $\log s$. If $a_1, a_2, \ldots$ are the digits in this representation, we set $\mathfrak{C}_i - \mathfrak{C}_{i-1}$ to be proportional to $c^{\sum_i a_i}$. As there is a meeting point in memory for every power of $\log s$, it can be seen

[8] The actual proof uses the representation of $i-1$ for technical reasons.

that $c^{\sum_i a_i}$ takes into account the distance from all the meeting points stored in memory, while maintaining the exponential growth required between two meeting points. We defer the remaining details to the proof.

Getting rectangular correctness

Just like prior work, for Step 2 above to work, it is crucial that our simulation protocol is rectangular correct, which is a stronger notion of correctness than standard correctness, and is necessary for Step 3 to work. Without going into the precise definition, this means that we need to account for the errors in the rounds where the parties (Alice and Bob) are talking separately. That is, the errors in rounds where Alice is talking cannot be used to offset the rounds where Bob is going back and decreasing the confidence, and vice versa.

Other than doubling the notation we use (*e.g.*, we now need to remember a pair of meeting points, one for Alice and one for Bob, *etc.*), this also introduces a more subtle challenge regarding the fraction of errors that we can be resilient to. To understand this, recall that the layers in the original circuit, and therefore the layers in the original **dag**-protocol, are alternating. This means that the party controlling the layer changes every time the protocol advances a layer. Now, imagine what happens when the adversary spends $\mathfrak{C}_i - \mathfrak{C}_{i-1}$ errors in a layer controlled by Alice to advance it incorrectly to a layer controlled by Bob.

As the errors for the both the parties are accounted for separately, Bob cannot detect and correct these errors, and the protocol will run as if there were no errors till the next time Alice gets to speak. This happens only after $\mathfrak{C}_{i+1} - \mathfrak{C}_i$ rounds, which due to our definition of $\mathfrak{C}$, may be a factor of c larger than $\mathfrak{C}_i - \mathfrak{C}_{i-1}$, the total number of errors inserted by the adversary. Thus, it is possible for the adversary to waste c rounds of simulation per error, implying that there has to be a multiplicative $1/c$ loss in the overall error resilience. Moreover, c cannot be too small, as then the parties will not be able to correctly maintain their meeting points. We are able to show that this loss is a constant proportional to the total number of meeting points; see the formal version of our main theorem (Theorem 8).

3 Model and Preliminaries

We now describe the model and our result more formally. Note that our description closely follows [7].

3.1 Circuits and dag-protocols

Circuits

We will consider Boolean circuits with negations at the inputs. That is, a Boolean circuit will be a directed acyclic graph C where each non-source node (or gate) is labelled as an $\wedge$ gate or an $\vee$ gate, while each source node is labelled with an input variable or the negation of the input variable. The source nodes are also called input gates and one designated node in C is called the output gate. We use $V_\wedge$ and $V_\vee$ to denote the set of all the nodes in C that are labelled $\wedge$ and $\vee$ respectively. We define how computation over a circuit C takes place by inductively defining the functions $f_{C,v}$ computed at each gate v. We have:

$$f_{C,v} = \begin{cases} z, & \text{if } v \text{ is an input gate with label } z \\ \bigvee_{u:(u,v) \text{ is an edge in } C} f_{C,u}, & \text{if } v \in V_\vee \\ \bigwedge_{u:(u,v) \text{ is an edge in } C} f_{C,u}, & \text{if } v \in V_\wedge \end{cases} . \tag{1}$$

When v is the output gate, we omit it from the notation and simply write f_C, which we call the function computed by C. We will assume that every gate in C that is not an input gate has at least one edge coming to it. We define the size of C to be the number of nodes in C and the depth of C to be the length of the longest path in C starting from an input gate and ending at the output gate. We use $\|C\|$ to denote the size of C.

Note that edges in C are going "up" from the inputs to the output gate. This contrasts with the edges in **dag**-protocols that are going "down" from the root to the leaves as defined below. These two directions, although different, follow the conventions for both circuits and **dag**-protocols.

Search problems and KW-games

Let $\mathcal{X}$ and $\mathcal{Y}$ be input sets for Alice and Bob respectively and $\mathcal{O}$ be a set of outputs. A search problem on these input and output sets is defined by a relation $S \subseteq \mathcal{X} \times \mathcal{Y} \times \mathcal{O}$, and the goal of Alice and Bob is to determine, given inputs $x \in \mathcal{X}$ and $y \in \mathcal{Y}$ respectively, an element $o \in \mathcal{O}$ such that $(x, y, o) \in S$.

KW-games are special type of search problems that are defined using a Boolean function f on n variables (for some n). Here, the set $\mathcal{X}$ is the set $f^{-1}(1)$ of all inputs for which f evaluates to 1, $\mathcal{Y}$ is the set $f^{-1}(0)$ of all inputs for which f evaluates to 0, and $\mathcal{O}$ is the set $[n]$. As $\mathcal{X}$ and $\mathcal{Y}$ are disjoint by definition, for any $x \in \mathcal{X}$, $y \in \mathcal{Y}$, there exists $o \in [n]$ such that $x_o \neq y_o$. The search problem KW_f is the problem of finding such an o, namely, it is the subset:

$$\mathsf{KW}_f = \{(x, y, o) \in \mathcal{X} \times \mathcal{Y} \times \mathcal{O} \mid x_o \neq y_o\}.$$

dag-protocols

We now define the notion of **dag**-protocols. Let $\mathcal{X}$, $\mathcal{Y}$, and $\mathcal{O}$ be input and output sets as above. A **dag**-protocol is defined by a tuple:

$$\Pi = \left(G = (V_A \cup V_B \cup V_O, E), \mathsf{rt}, \{h_v\}_{v \in V_A \cup V_B}, \{o_v\}_{v \in V_O}\right).$$

Here, G is a directed acyclic graph with vertices partitioned into V_A, V_B, and V_O respectively, and edges E. We will use $V = V_A \cup V_B \cup V_O$ to be the set of all vertices in G and $\mathsf{rt} \in V$ is a special vertex called the root. For all $v \in V_A$, the function h_v is a "message function" that maps Alice's input set $\mathcal{X}$ to a vertex in V that v has an edge to. Similarly, for all $v \in V_B$, the function h_v maps Bob's input set $\mathcal{Y}$ to a vertex in V that v has an edge to. We often conflate the two and write $h_v : \mathcal{X} \times \mathcal{Y} \to V$ with the understanding that the second argument is redundant if $v \in V_A$ and the first argument is redundant if $v \in V_B$. Finally, for all $v \in V_O$, the value $o_v \in \mathcal{O}$ is the output value for the vertex v. We will assume that vertices in V_O do not have any out-edges, all other vertices have at least one outgoing edge (as otherwise the message functions will not be defined) and rt does not have any incoming edges. We define the size of Π to be $|V|$, the number of nodes in Π, and the depth of Π to be the length of the longest path in G starting from rt. We use $\|\Pi\|$ to denote the size of Π.

As mentioned above, edges in a **dag**-protocol go "down" from the root to the leaves, and are thus opposite to our convention for circuits. We are explicit about the direction in our exposition whenever there is room for ambiguity.

Execution of a dag-protocol

A **dag**-protocol Π as above is executed by start with inputs $x \in \mathcal{X}$, $y \in \mathcal{Y}$ and a vertex $v = \mathsf{rt}$, and continuing as follows: If $v \in V_A \cup V_B$ then the execution simply uses the message function and updates the current vertex to $h_v(x, y)$[9]. Otherwise, we have $v \in V_O$, and the execution terminates with the output o_v. As this output is determined by x and y, we will denote it using $\Pi(x, y)$. For a search problem $S \subseteq \mathcal{X} \times \mathcal{Y} \times \mathcal{O}$, we say that Π solves S if for all $x \in \mathcal{X}$, $y \in \mathcal{Y}$, we have $(x, y, \Pi(x, y)) \in S$.

3.2 Rectangular Correctness & Equivalence of Circuits and dag-protocols

The models of Boolean circuits and **dag**-protocols described above have a deep connection. To understand this connection, we first define the notion of rectangular correctness for **dag**-protocols.

▶ **Definition 3** (Rectangles for **dag**-protocols). *Let Π be a* **dag***-protocol with input sets $\mathcal{X}$, $\mathcal{Y}$, and output set $\mathcal{O}$. We inductively define the (combinatorial) rectangle associated with each vertex. For the root rt, define the rectangle to $R_{\mathsf{rt}} = \mathcal{X} \times \mathcal{Y}$. For a node $v \neq \mathsf{rt}$, define the (combinatorial) rectangle $R_v \subseteq \mathcal{X} \times \mathcal{Y}$ to be the smallest rectangle containing $\bigcup_{u:(u,v)\in E}\{(x, y) \in R_u \mid h_u(x, y) = v\}$.*

For a combinatorial rectangle $R \subseteq \mathcal{X} \times \mathcal{Y}$, we will use R_A to denote the projection of the rectangle on the set $\mathcal{X}$ and R_B to denote the projection on the set $\mathcal{Y}$. As we defined R_v to be the smallest rectangle in Definition 3, we have the following observation.

▶ **Observation 4.** *Let Π be a* **dag***-protocol with input sets $\mathcal{X}$, $\mathcal{Y}$, and output set $\mathcal{O}$ and $\{R_v\}_{v\in V}$ be the associated rectangles. For all $v \neq \mathsf{rt}$ and all $x \in (R_v)_A$, there exists a $u \in V$ such that $(u, v) \in E$ and $y \in \mathcal{Y}$ such that $(x, y) \in R_u$ and $h_u(x, y) = v$. An analogous claim holds with the roles of x and y reversed.*

Additionally, observe that for all vertices v, the rectangle R_v contains all the pairs (x, y) such that the execution of Π goes to v on inputs x and y. Thus, the following notion of rectangular correctness is stronger than the "standard" notion of correctness.

▶ **Definition 5** (Rectangular Correctness). *Let Π be a* **dag***-protocol with inputs sets $\mathcal{X}$, $\mathcal{Y}$, and output set $\mathcal{O}$, and $\{R_v\}_{v\in V}$ be the associated rectangles. For a search problem $S \subseteq \mathcal{X} \times \mathcal{Y} \times \mathcal{O}$, we say that Π solves S with rectangular correctness if for all $v \in V_O$ and all $(x, y) \in R_v$, we have $(x, y, o_v) \in S$.*

We are now ready to state the equivalence between circuits and **dag**-protocols formally. This theorem can also be found in [7]. We include a proof for completeness.

▶ **Theorem 6** ([25, 29]). *Let $f : \{0, 1\}^n \to \{0, 1\}$ be a Boolean function.*

1. *For any circuit C that computes f, there is a* **dag***-protocol Π with the same size and depth as C that solves KW_f with rectangular correctness.*
2. *For any* **dag***-protocol Π that solves KW_f with rectangular correctness, there is a circuit C with $\|C\| \leq \|\Pi\|$ that computes f.*

[9] Recall that $h_v(x, y)$ is independent of y if $v \in V_A$ and is independent of x if $v \in V_B$.

Proof. We only prove Item 1 as Item 2 is implied by Theorem 7 proved later. Fix a circuit C and define a **dag**-protocol Π for KW_f by setting the graph G to be the same graph as C except that the directions of all the edges are reversed. Let V_A be the set of all $\vee$ gates in C, V_B be the set of all the $\wedge$ gates in C and V_O be the set of all the inputs gates. Let rt be the output gate of C. For all $v \in V_O$, we define o_v to be the variable that (possibly after negation) is input at that gate. It remains to define the message transmission functions $\{h_v\}_{v \in V_A \cup V_B}$.

Fix $v \in V_A \cup V_B$ and recall that the input set $\mathcal{X} = f^{-1}(1)$ and $\mathcal{Y} = f^{-1}(0)$. For $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, we define $h_v(x, y)$ as follows: If $v \in V_A$, then $h_v(x, y)$ is just a function of x. If $f_{C,v}(x) = 1$, then, as v is a $\vee$ gate[10], by Equation (1), there exists a neighbor u (in-neighbor in C and out-neighbor in G) of v such that $f_{C,u}(x) = 1$, and we set $h_v(x, y)$ to be the lexicographically smallest such neighbor u. Otherwise, we set $h_v(x, y)$ to be the lexicographically smallest neighbor u of v. Observe that such a neighbor always exists as v is not an input gate. Similarly, if $v \in V_B$, then $h_v(x, y)$ is just a function of y. If $f_{C,v}(y) = 0$, then, as v is a $\wedge$ gate, by Equation (1), there exists a neighbor u (in-neighbor in C and out-neighbor in G) of v such that $f_{C,u}(y) = 0$, and we set $h_v(x, y)$ to be the lexicographically smallest such neighbor u. Otherwise, we set $h_v(x, y)$ to be the lexicographically smallest neighbor u of v. As before, such a neighbor always exists as v is not an input gate.

We clearly have $\|\Pi\| = \|C\|$ and we just have to show that Π solves KW_f with rectangular correctness. By Definition 5, we have to show that, if $\{R_v\}_{v \in V}$ are the rectangles associated with Π as in Definition 3, then, for all $v \in V_O$ and all $(x, y) \in R_v$, we have $(x, y, o_v) \in \mathsf{KW}_f$. In fact, we will show the stronger statement that for all $v \in V$ and all $(x, y) \in R_v$, we have:

$$f_{C,v}(x) = 1 \qquad \text{and} \qquad f_{C,v}(y) = 0.$$

This is indeed stronger, as if $v \in V_O$, then Equation (1) says that $f_{C,v}$ is just the (possibly negated) input variable o_v implying that $(x, y, o_v) \in \mathsf{KW}_f$. We show this by induction starting from the root rt downwards to the nodes reachable from it[11]. For the root rt, we use the fact that it corresponds to the output gate of C implying that $f_{C,\mathsf{rt}} = f$. The result follows as $\mathcal{X} = f^{-1}(1)$ and $\mathcal{Y} = f^{-1}(0)$.

We now show it for $v \neq \mathsf{rt}$ assuming it holds for all u that have edges to v in Π (equivalently, all u that v has an edge to in the circuit C). Let $(x, y) \in R_v$ be arbitrary. We only show that $f_{C,v}(x) = 1$ as the proof that $f_{C,v}(y) = 0$ is analogous. As $(x, y) \in R_v$, we have by Observation 4 that there exists u that has an edge to v in Π and a $y' \in \mathcal{Y}$ such that $(x, y') \in R_u$ and $h_u(x, y') = v$. Applying the induction hypothesis on u, it follows that $f_{C,u}(x) = 1$. Now, if $u \in V_\wedge$, then the fact that v has an edge to u in C together with Equation (1) implies that $f_{C,v}(x) = 1$, as desired. On the other hand, if $u \in V_\vee$, then, use the fact that $h_u(x, y') = v$ to get that $f_{C,v}(x) = 1$, finishing the proof. ◀

3.3 Error Models

Circuits

We consider short-circuit errors. Let C be a Boolean circuit as above. An error pattern for C is defined by a function $e : V \to V \cup \{*\}$ satisfying the property that $e(v)$ maps v to an in-neighbor of v, *i.e.* to a neighbor of v that is "below" it, or to $*$, for all $v \in V$. In particular,

[10] We abuse notation and use v to denote both the vertices in G and the corresponding vertices in C.
[11] Observe that if v is not reachable from rt, then Definition 3 says that $R_v = \emptyset$ and there is nothing to show.

if $v \notin V_\wedge \cup V_\vee$, we have $e(v) = *$. It will often be convenient to separate e into two functions and write $e = (e_\vee, e_\wedge)$, where $e_\vee$ is the function e restricted to the vertices in $V_\vee$ and $e_\wedge$ is the function e restricted to the vertices in $V_\wedge$. Let C be a circuit and e be an error pattern for C. Let $v \in C$ be a gate. We define how computation takes place in C in the presence of errors e by inductively defining the functions $f_{C,e,v}$ computed at each gate v. We have[12]:

$$f_{C,e,v} = \begin{cases} z, & \text{if } v \text{ is an input gate with label } z \\ \bigvee_{u:(u,v) \text{ is an edge in } C} f_{C,e,u}, & \text{if } v \in V_\vee \text{ and } e(v) = * \\ \bigwedge_{u:(u,v) \text{ is an edge in } C} f_{C,e,u}, & \text{if } v \in V_\wedge \text{ and } e(v) = * \\ f_{C,e,e(v)}, & \text{if } e(v) \neq * \end{cases}. \tag{2}$$

We omit v from the notation if v is the output gate of C. Let C be a circuit and $\mathcal{E}$ be a set of error patterns for C. For a function f, we say that C computes f despite $\mathcal{E}$, if for all $e \in \mathcal{E}$, we have $f_{C,e} = f$. We say that $\mathcal{E}$ is rectangular if viewing every $e \in \mathcal{E}$ as a pair $e = (e_\vee, e_\wedge)$ gives a combinatorial rectangle. When this happens, we use $\mathcal{E}_\vee$ to denote the projection of this rectangle on the first coordinate and $\mathcal{E}_\wedge$ to denote the projection on the second coordinate (thus, $\mathcal{E} = \mathcal{E}_\vee \times \mathcal{E}_\wedge$)

We now define the set of error patterns that we work with. Let $\Theta \geq 0$ be an integer parameter. For a circuit C, define the set $\mathcal{E}_\Theta(C)$ to be the set of all error patterns e such that for any path in C that starts at an input gate and ends the output gate, at most Θ gates $v \in V_\wedge$ on the path satisfy $e(v) \neq *$ and at most Θ gates $v \in V_\vee$ on the path satisfy $e(v) \neq *$. Observe that the set $\mathcal{E}_\Theta(C)$ is rectangular for all $\Theta \geq 0$.

dag-protocols

Let Π be a **dag**-protocol as above. An error pattern ξ for Π is defined by a function $\xi : V \to V \cup \{*\}$ satisfying the property that $\xi(v)$ maps v to an out-neighbor of v, *i.e.* to a neighbor of v that is "below" it[13], or to $*$. In particular, if $v \in V_O$, we have $\xi(v) = *$. It will often be convenient to separate ξ into two functions $\xi = (\xi_A, \xi_B)$, where ξ_A is the function ξ restricted to the vertices in V_A, and ξ_B is the function ξ restricted to the vertices in V_B. The error pattern ξ affects the execution of Π as follows: If the current vertex is v and $\xi(v) = *$, the execution proceeds as before. On the other hand, if $\xi(v) \neq *$ (observe that this can only happen if $v \in V_A \cup V_B$), the execution updates the current vertex to $\xi(v)$ instead of updating using the function h_v as before.

Let Π be a **dag**-protocol and Ξ be a set of error patterns for Π. Similarly to before, we say that Ξ is rectangular if viewing every $\xi \in \Xi$ as a pair $\xi = (\xi_A, \xi_B)$ gives a combinatorial rectangle. When this happens, we use Ξ_A to denote the projection of this rectangle on the first coordinate and Ξ_B to denote the projection on the second coordinate (thus, $\Xi = \Xi_A \times \Xi_B$). For a rectangular Ξ, define the **dag**-protocol Π_Ξ to be the same as Π except that the input sets are now $\mathcal{X} \times \Xi_A$ and $\mathcal{Y} \times \Xi_B$ and the message functions $h_{\Xi,v}$ are defined as (recall that $\xi = (\xi_A, \xi_B)$):

$$h_{\Xi,v}((x, \xi_A), (y, \xi_B)) = \begin{cases} h_v(x, y), & \text{if } \xi(v) = * \\ \xi(v), & \text{if } \xi(v) \neq * \end{cases}. \tag{3}$$

[12] Recall that the label of an input gate is either an input variable or the negation of an input variable.
[13] Recall that our conventions for the directions of edges in circuits is opposite that in **dag**-protocols.

For a search problem $S \subseteq \mathcal{X} \times \mathcal{Y} \times \mathcal{O}$ and a rectangular Ξ, we say that Π solves S with rectangular correctness despite Ξ if Π_Ξ solves S_Ξ with rectangular correctness, where $S_\Xi \subseteq (\mathcal{X} \times \Xi_A) \times (\mathcal{Y} \times \Xi_B) \times \mathcal{O}$ is the search problem satisfying $((x, \xi_A), (y, \xi_B), o) \in S_\Xi \iff (x, y, o) \in S$ for all values of x, y, o, ξ_A, ξ_B.

We now define the set of error patterns that we work with. Let $\Theta \geq 0$ be an integer parameter. For a **dag**-protocol Π, define the set $\Xi_\Theta(\Pi)$ to be the set of all error patterns ξ such that for any path in G that starts at rt and ends at a node in V_O, at most Θ nodes $v \in V_A$ on the path satisfy $\xi(v) \neq *$ and at most Θ nodes $v \in V_B$ on the path satisfy $\xi(v) \neq *$. Observe that the set $\Xi_\Theta(\Pi)$ is rectangular for all $\Theta \geq 0$. For convenience, we will often abbreviate $\Pi_{\Xi_\Theta(\Pi)}$ to Π_Θ.

3.4 Connecting the Error Models

We now show that error resilient **dag**-protocols are stronger than error-resilient circuits. Observe that the theorem below implies Item 2 of Theorem 6 as can be seen by setting $\Theta = 0$. Additionally, note that the theorem below differs from the analogous theorem in [7] in that the number of allowed errors Θ is the same for every path, while in [7], it was a constant fraction of the length of the path. Having it as a constant fraction creates some minor complications while trimming the "empty edges" (in the first paragraph of the proof), that were overlooked in [7]. These complications do not affect the rest of the proof of [7], as [7] actually works even when the allowed number of errors is the same for every path (and equals a constant fraction of the length of the *longest* path). Nonetheless, we flesh out the details of trimming for our model formally in the full version. We also mention that having the same number of errors on all the paths, irrespective of their length, is a stronger error model than having the number of errors on each path be proportional to its length.

▶ **Theorem 7.** *Let $\Theta \geq 0$ be given and $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function. For any* **dag***-protocol Π that solves KW_f with rectangular correctness despite $\Xi_\Theta(\Pi)$, there is a circuit C with size and depth at most that of Π that computes f despite $\mathcal{E}_\Theta(C)$.*

Proof. Fix a protocol Π that solves KW_f with rectangular correctness despite $\Xi_\Theta(\Pi)$. We can assume without loss of generality that there are no empty edges in Π, as defined in the full version. Equivalently, if $\{R_{\Theta,v}\}_{v \in V}$ are the rectangles associated with Π_Θ according to Definition 3 and $\{h_{\Theta,v}\}_{v \in V_A \cup V_B}$ are the message functions, for all edges $e = (u, v) \in E$ we have:

$$R_{\Theta,u} = \emptyset \quad \text{or} \quad \exists ((x, \xi_A), (y, \xi_B)) \in R_{\Theta,u} : \qquad h_{\Theta,u}((x, \xi_A), (y, \xi_B)) = v. \tag{4}$$

As Π that solves KW_f with rectangular correctness despite $\Xi_\Theta(\Pi)$, we have that Π_Θ solves $\mathsf{KW}_{f,\Xi_\Theta(\Pi)}$ with rectangular correctness. From Definition 5, we get that for all $v \in V_O$ and all $((x, \xi_A), (y, \xi_B)) \in R_{\Theta,v}$, we have $((x, \xi_A), (y, \xi_B), o_v) \in \mathsf{KW}_{f,\Xi_\Theta(\Pi)}$. Simplifying using the definition of $\mathsf{KW}_{f,\Xi_\Theta(\Pi)}$, we get:

$$\forall v \in V_O, ((x, \xi_A), (y, \xi_B)) \in R_{\Theta,v} : \quad x_{o_v} \neq y_{o_v}. \tag{5}$$

We now define the circuit C. The gates in the circuit C are exactly the nodes in V and we abuse notation slightly by using u, v *etc.* to refer to both. For any edge $(u, v) \in E$, we add the flipped edge (v, u) to the circuit C. We define all gates in V_A to be $\vee$ gates and all gates in V_B to be $\wedge$ gates while rt is chosen as the output gate. The remaining gates are in V_O are input gates whose labels are defined next. As $R_{\Theta,v}$ in Equation (5) is a combinatorial rectangle, we get that there exists $b \in \{0,1\}$ such that

$$\forall ((x, \xi_A), (y, \xi_B)) \in R_{\Theta,v} : \quad x_{o_v} = b \quad \text{and} \quad y_{o_v} = \overline{b}.$$

If $b = 1$, we label the input gate v by the variable o_v unnegated, and we label it by the negated variable $\overline{o_v}$ otherwise. This finishes the description of C. As the claim about the size $\|C\|$ is straightforward, we focus on showing that C computes f despite $\mathcal{E}_\Theta(C)$. As both C and Π have the same graph upto the directions of the edges, observe that any error pattern for C can also be seen as a pattern for Π and that $\mathcal{E}_\Theta(C) = \Xi_\Theta(\Pi)$. Because of this, we interpret any error pattern $\xi = (\xi_A, \xi_B)$ as an error pattern $e = (e_\vee, e_\wedge)$ for C and we ξ and subscripts A and B to refer to both. We also define the error patterns $*_A$ and $*_B$ to be those that map all gates in V_A (equivalently, $V_\vee$) and V_B (equivalently, $V_\wedge$) respectively to $*$. To show that C computes f despite $\mathcal{E}_\Theta(C)$, we show inductively that for all $u \in V$, we have:

$$\forall((x,\xi_A),(y,\xi_B)) \in R_{\Theta,u}: \quad f_{C,(\xi_A,*_B),u}(x) = 1 \quad \text{and} \quad f_{C,(*_A,\xi_B),u}(y) = 0. \tag{6}$$

This suffices as plugging $v = \mathsf{rt}$ and using the definition of $R_{\Theta,\mathsf{rt}} = \left(f^{-1}(1) \times (\Xi_\Theta(\Pi))_A\right) \times \left(f^{-1}(0) \times (\Xi_\Theta(\Pi))_B\right)$ from Definition 3, we get that:

$$\forall((x,\xi_A),(y,\xi_B)) \in R_{\Theta,\mathsf{rt}}: \quad f_{C,(\xi_A,*_B)}(x) = f(x) \quad \text{and} \quad f_{C,(*_A,\xi_B)}(y) = f(y).$$

As short-circuiting a gate in $V_\wedge$ can never change the output from 1 to 0 and short-circuiting a gate in $V_\vee$ can never change the output from 0 to 1, we get that:

$$\forall((x,\xi_A),(y,\xi_B)) \in R_{\Theta,\mathsf{rt}}: \quad f_{C,\xi}(x) = f(x) \quad \text{and} \quad f_{C,\xi}(y) = f(y).$$

Thus, we get that $f_{C,\xi} = f$ for all $\xi \in \Xi_\Theta(\Pi)$. As $\mathcal{E}_\Theta(C) = \Xi_\Theta(\Pi)$, we get that C computes f despite $\mathcal{E}_\Theta(C)$, as desired. Having shown that Equation (6) is sufficient, we now prove that Equation (6) holds by induction. For the base case, when $u \in V_O$, this follows by our labels and Equations (2) and (5). We show the results for $u \notin V_O$ assuming it holds for all v that have edges to u in C. If $R_{\Theta,u} = \emptyset$, there is nothing to show, so we assume otherwise. As the proof in the other case is similar, assume without loss of generality that $u \in V_A$. From Equation (4), we get that for all v that have edges to u in C, we have that there exists $((x,\xi_A),(y,\xi_B)) \in R_{\Theta,u}$ such that $h_{\Theta,u}((x,\xi_A),(y,\xi_B)) = v$. As $u \in V_A$, the message function is determined by the first argument and we get from Definition 3 that:

$$(R_{\Theta,u})_A \subseteq \bigcup_{v:(v,u) \text{ is an edge in } C} (R_{\Theta,v})_A \quad \text{and} \quad (R_{\Theta,u})_B \subseteq \bigcap_{v:(v,u) \text{ is an edge in } C} (R_{\Theta,v})_B. \tag{7}$$

We now show Equation (6). Fix $((x,\xi_A),(y,\xi_B)) \in R_{\Theta,u}$.

- **Showing that $f_{C,(\xi_A,*_B),u}(x) = 1$ when $\xi(u) \neq *$:** By Equation (3), we get that $h_{\Theta,u}((x,\xi_A),(y,\xi_B)) = \xi(u)$ implying from Definition 3 that $((x,\xi_A),(y,\xi_B)) \in R_{\Theta,\xi(u)}$. By the induction hypothesis on $\xi(u)$, we get that $f_{C,(\xi_A,*_B),\xi(u)}(x) = 1$. From Equation (2), we get:

$$f_{C,(\xi_A,*_B),u}(x) = f_{C,(\xi_A,*_B),\xi(u)}(x) = 1.$$

- **Showing that $f_{C,(\xi_A,*_B),u}(x) = 1$ when $\xi(u) = *$:** We have from $((x,\xi_A),(y,\xi_B)) \in R_{\Theta,u}$ that $(x,\xi_A) \in (R_{\Theta,u})_A$. From Equation (7), there exists an in-neighbor v' of u in C and $(y_{v'},\xi_{B,v'})$ such that $((x,\xi_A),(y_{v'},\xi_{B,v'})) \in R_{\Theta,v'}$. By the induction hypothesis on v', we have $f_{C,(\xi_A,*_B),v'}(x) = 1$. From Equation (2), we get:

$$f_{C,(\xi_A,*_B),u}(x) = \bigvee_{v:(v,u) \text{ is an edge in } C} f_{C,(\xi_A,*_B),v}(x) = 1.$$

- **Showing that $f_{C,(*_A,\xi_B),u}(y) = 0$:** We have from $((x,\xi_A),(y,\xi_B)) \in R_{\Theta,u}$ that $(y,\xi_B) \in (R_{\Theta,u})_B$. It follows from Equation (7) that for all in-neighbors v of u in C, we have that there exists $(x_v,\xi_{A,v})$ such that $((x_v,\xi_{A,v}),(y,\xi_B)) \in R_{\Theta,v}$. From the induction hypothesis on v, we get that $f_{C,(*_A,\xi_B),v}(y) = 0$ for all such v. From Equation (2), we get:

$$f_{C,(*_A,\xi_B),u}(y) = \bigvee_{v:(v,u) \text{ is an edge in } C} f_{C,(*_A,\xi_B),v}(y) = 0. \qquad \blacktriangleleft$$

3.5 Our Results

We are now ready to state our main result formally. We show that:

▶ **Theorem 8** (Formal version of Theorem 1). *Let $c > 1$, $n > 0$ be integers and $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function. Let C be a Boolean circuit of size $\|C\| = s$ and depth*[14] *$d < (\log n)^{c-1}$ that computes f. There exists $\Theta \leq s^{\mathcal{O}(c \log c)}$ and a Boolean circuit C' with size at most $s^{\mathcal{O}(c \log c)}$ and depth $\mathcal{O}(c) \cdot \Theta$ that computes f despite $\mathcal{E}_\Theta(C')$.*

To prove Theorem 8, we need the following result about **dag**-protocols, which forms the technical core of Theorem 8.

▶ **Theorem 9** (Formal version of Theorem 2). *Let S be a search problem and Π be a* **dag***-protocol of size s and depth d that solves S with rectangular correctness. Let $c > 1$ be an integer satisfying*[15] *$d < (\log s)^{c-1}$. There exists $\Theta \leq s^{\mathcal{O}(c \log c)}$ (defined in the full version) and a* **dag***-protocol Π' (as defined in the full version) with size $s' = s^{\mathcal{O}(c \log c)}$ and depth $\mathcal{O}(c) \cdot \Theta$ that solves S with rectangular correctness despite $\Xi_\Theta(\Pi')$.*

We prove Theorem 9 in the full version, but use it here to prove Theorem 8.

Proof of Theorem 8 assuming Theorem 9. Fix a circuit C as in the theorem statement. Applying Theorem 6, we get that there exists a **dag**-protocol Π with size s and depth d that solves KW_f with rectangular correctness. Applying Theorem 9, we get that there exists $\Theta \leq s^{\mathcal{O}(c \log c)}$ and a **dag**-protocol Π' with size $s' = s^{\mathcal{O}(c \log c)}$ and depth $\mathcal{O}(c) \cdot \Theta$ that solves KW_f with rectangular correctness despite $\Xi_\Theta(\Pi')$. Now, applying Theorem 7 on Π', we get that there exists a circuit C' with size at most $s^{\mathcal{O}(c \log c)}$ and depth at most $\mathcal{O}(c) \cdot \Theta$ that computes f despite $\mathcal{E}_\Theta(C')$, as desired. ◀

Simple Norm Bounds for Polynomial Random Matrices via Decoupling

Madhur Tulsiani
Toyota Technological Institute at Chicago, IL, USA

June Wu
University of Chicago, IL, USA

Abstract

We present a new method for obtaining norm bounds for random matrices, where each entry is a low-degree polynomial in an underlying set of independent real-valued random variables. Such matrices arise in a variety of settings in the analysis of spectral and optimization algorithms, which require understanding the spectrum of a random matrix depending on data obtained as independent samples.

Using ideas of decoupling and linearization from analysis, we show a simple way of expressing norm bounds for such matrices, in terms of matrices of lower-degree polynomials corresponding to derivatives. Iterating this method gives a simple bound with an elementary proof, which can recover many bounds previously required more involved techniques.

1 Introduction

For fixed matrices $\mathbf{C_1}, \ldots, \mathbf{C_n}$ and independent scalar random variables $x_1, \ldots, x_n$, consider the problem of analyzing the random matrix

$$\mathbf{M} \;=\; \mathbf{C_1} \cdot x_1 + \cdots + \mathbf{C_n} \cdot x_n \,.$$

Note that the entries of the random matrix $\mathbf{M}$ are not necessarily independent, but are (possibly correlated) linear functions of the independent random variables $x_1, \ldots, x_n$. Such matrices, which arise in a variety of applications in algorithms, statistics, and numerical linear algebra, can often be shown as being concentrated around the mean, using a rich selection of matrix deviation inequalities [34]. Moreover, when the random variables $x_1, \ldots, x_n$ are Gaussian, recent breakthrough results have obtained even sharper concentration guarantees depending on the structure of the matrices $\mathbf{C_1}, \ldots, \mathbf{C_n}$ [5, 9] already leading to applications in discrepancy theory [6] and quantum information theory [20].

In contrast to the above random matrices which are linear functions of independent random variables, several recent applications in spectral algorithms and lower bounds for statistical problems require understanding the (expected) norms of random matrices of the form

$$\mathbf{F} \;=\; \sum_{\substack{S \subseteq [n] \\ |S| \leq d}} \mathbf{C}_S \cdot \prod_{i \in S} x_i \,.$$

The above random matrix, which denote as a matrix-valued function $\mathbf{F}(\mathbf{x})$, is a (multilinear, in the example above) *low-degree polynomial* in the vector of random variables $\mathbf{x} = (x_1, \ldots, x_n)$.

Such matrix-valued polynomial functions arise naturally in a variety of applications, including algorithms for tensor decomposition and completion [13, 12, 18, 10], orbit recovery [24], power-sum decompositions and learning of Gaussian mixtures [4], and lower bounds for Sum-of-Squares hierarchies [2, 7, 16, 28]. In general, such matrices are often an important technical component in the analysis of spectral algorithms, which require understanding the spectrum of some random matrix depending on data obtained as independent samples. Given the expressive power of polynomials, one can often write the matrix entries as low-degree polynomials in the data.

In several applications above, one is interested in obtaining bounds on the spectral norm of the deviation matrix $\mathbf{F}(\mathbf{x}) - \mathbb{E}\,\mathbf{F}(\mathbf{x})$, which hold with high probability over the choice of $\mathbf{x}$. Although matrix-deviation inequalities for nonlinear random matrices have been a subject of active research in recent work [26, 22, 3, 14, 15], the analyses in the applications above have often needed to rely on estimating matrix norms via direct computations of trace moments. While these do yield sharp bounds required for applications, they require somewhat intricate computations and ingenious combinatorial arguments tailored to the applications at hand.

Analyzing concentration via moment estimates. We consider concentration bounds on a *scalar* polynomial $f(\mathbf{x})$ with mean zero. Using Markov's inequality, this can be reduced to computing moment estimates, since

$$\mathbb{P}\left[|f(\mathbf{x})| \geq \lambda\right] \;=\; \mathbb{P}\left[\left(f(\mathbf{x})\right)^{2t} \geq \lambda^{2t}\right] \;\leq\; \lambda^{-2t} \cdot \mathbb{E}\left[\left(f(\mathbf{x})\right)^{2t}\right]$$

Note that while in some cases $\mathbb{E}[(f(\mathbf{x}))^{2t}]$ can be computed by direct expansion, it often involves an intricate analysis of the structure of terms with degrees growing with t, and therefore indirect methods may be more convenient. Methods for obtaining concentration of (scalar) polynomial functions have been the subject of a large body of work, including results by Kim and Vu [17], Latała [21], Schudy and Sviridenko [31, 32], Adamczak and Wolff [1], and Bobkov, Götze and Sambale [8]. A useful comparison to direct computation, is the method of Adamczak and Wolff, which is applicable to functions $f(\mathbf{x})$ of a broad range of random vectors $\mathbf{x}$ (with not necessarily independent coordinates) from a distribution obeying the Poincaré inequality. They obtain such moment bounds by recursive applications of the Poincaré inequality, reducing the computation of the moments of f to that of its derivatives. For a degree-d polynomial function f, one can consider its coefficients as forming a (symmetric) order-d tensor, and their results obtain bounds on the moments of f in terms of the norms of various lower-order tensors "flattening" of this coefficient tensor. Thus, the problem of estimating moments of the random variable $f(\mathbf{x})$, can be reduced in a black-box way, to understanding the norms of a small number (depending on d) of *deterministic* tensors. Any dependence on the problem structure can then be limited to understanding these norms, where often crude estimates can suffice.

The matrix analog of the Markov argument involves the Schatten-$2t$ norm $\|.\|_{2t}$, which is defined for a matrix $\mathbf{M}$ with non-zero singular values $\sigma_1, \ldots, \sigma_r$ as $\|\mathbf{M}\|_{2t}^{2t} := \sum_{j\in[r]} \sigma_j^{2t}$. For a function $\mathbf{F}$ with $\mathbb{E}[\mathbf{F}(Z)] = \mathbf{0}$, we have the following bound using Schatten norms.

$$\mathbb{P}\left[\sigma_1(\mathbf{F}) \geq \lambda\right] \;\leq\; \lambda^{-2t} \cdot \mathbb{E}\,\|\mathbf{F}\|_{2t}^{2t} \;=\; \lambda^{-2t} \cdot \mathbb{E}\,\mathrm{tr}\left[\left(\mathbf{F}(\mathbf{x})\mathbf{F}(\mathbf{x})^\intercal\right)^t\right]$$

Several applications requiring norm bounds for matrix-valued polynomial functions, start with the above inequality, and often rely on direct expansion of the trace for the matrix power $(\mathbf{F}(\mathbf{x})\mathbf{F}(\mathbf{x})^\intercal)^t$. Recall that when $\mathbf{A}$ is the adjacency matrix of a graph, $\mathrm{tr}(\mathbf{A}^{2t})$ can be interpreted as the number of cycles of length $2t$. Similarly, when working with matrices $\mathbf{F}(\mathbf{x})$

where each entry can be interpreted as arising from a combinatorial pattern, $(\mathbf{F}(\mathbf{x})\mathbf{F}(\mathbf{x})^\intercal)^t$ can be viewed as the number of copies of such patterns "chained" together in a certain way. Estimating the trace then amounts to estimating the (expected) number of such chainings [2].

Obtaining bounds on the $\mathbb{E}\,\|\mathbf{F}\|_{2t}^{2t}$ via this method requires first using problem structure to decompose $\mathbf{F}$ into matrices with such combinatorial patterns, and then using (ingenious) combinatorial arguments to understand the expected number of occurrences of such chains of patterns. The focus of this work is understanding alternative general methods for estimating such norm bounds, when the underlying problem may not necessarily have a combinatorial flavor, or when such decompositions may be hard to analyze.

Decoupling. Decoupling inequalities were developed in the study of U-statistics [27], multiple stochastic integration [23], and polynomial chaos [19], and have found important applications in applied mathematics, theoretical computer science, applied probability theory and statistics. Some examples include the study of compressed sensing [30], query complexity [25], the proof of Hanson-Wright inequality [35], learning mixture of Gaussians [11] and so on. Moreover, the inequalities are applicable in both scalar and matrix settings, and even more broadly in Banach spaces.

For a degree-d homogeneous *multilinear* polynomial $f(\mathbf{x})$ in n independent random variables, standard decoupling inequalities (see Section 3) can be used to obtain

$$\mathop{\mathbb{E}}_{\mathbf{x}}\left[(f(\mathbf{x}))^{2t}\right] \;\leq\; C_d^{2t}\cdot \mathop{\mathbb{E}}_{\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)}}\left[\left(f(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)})\right)^{2t}\right],$$

where $f(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)})$ denotes the polynomial in $d\cdot n$ random variables obtained by replacing the d variables in each (ordered) monomial by the corresponding d coordinates coming from the d independent random vectors $\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)}$, and C_d is a constant depending on the degree d. One can now fix the vectors $\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d-1)}$, and consider the expectation

$$\mathop{\mathbb{E}}_{\mathbf{x}^{(d)}}\left[\left(f(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)})\right)^{2t}\right] \;=\; \mathop{\mathbb{E}}_{\mathbf{x}^{(d)}}\left[\left(\sum_{i\in[n]} f_i(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d-1)})\cdot x_i^{(d)}\right)^{2t}\right],$$

where we write $f(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)})$ as a linear form in $\mathbf{x}^{(d)}$ with coefficients $f_i(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d-1)})$. The moments of such a linear form can be understood (for example) using the Khintchine inequality, which bounds it in terms of a polynomial depending only on $\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d-1)}$.

Similarly, in the matrix case, we use decoupling inequalities to reduce the problem of estimating moments for degree-d homogeneous (and multilinear) matrix-valued polynomials, to that of estimating moments for *linear* matrix-valued functions. At this point, one can apply standard and well-known linear matrix concentration inequalities (we use the matrix Rosenthal inequality) which yield a bound in terms of a degree-$(d-1)$ matrix-valued polynomial function of the vectors $\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d-1)}$. Iterating this process gives a simple method for obtaining norm bounds, applicable for *multilinear* polynomial functions on n independent random variables (with any reasonable distribution).

While this method does not immediately apply for non-multilinear polynomials, it suffices for many of the applications mentioned above. Moreover, for arbitrary polynomials in Gaussian random variables, we can also obtain a simple recursion as an immediate consequence of the more recent Poincaré inequalities of Huang and Tropp [15]. Together, these suffice for most applications of interest.

Methods and results: a technical overview

Let $x_1, \ldots, x_n$ be i.i.d real-valued random variables with $\mathbb{E}[x_i] = 0, \mathbb{E}[x_i^2] = 1$ and $|x_i| \leq L$ for each $i \in [n]$. Let $\mathcal{T}_n^d \subseteq [n]^d$ denote the set of ordered d-tuples $\mathbf{i} = (i_1, \ldots, i_d)$ with $i_1, \ldots, i_d$ all distinct. For a fixed sequence of (deterministic) matrices $\{\mathbf{A_i}\}_{\mathbf{i} \in \mathcal{T}_n^d} \subseteq \mathbb{R}^{d_1 \times d_2}$, we consider a matrix-valued multilinear polynomial function defined as

$$\mathbf{F}(\mathbf{x}) \;=\; \sum_{\mathbf{i} \in \mathcal{T}_n^d} \mathbf{A_i} \cdot \prod_{j \in [d]} x_{i_j} \,.$$

We write the polynomial in terms of ordered tuples for decoupling, but since the variables $x_1, \ldots, x_n$ commute, we can assume that for any permutation $\sigma : [d] \to [d]$ permuting the d coordinates of each tuple, $\mathbf{A_i} = \mathbf{A}_{\sigma(\mathbf{i})}$ (this is referred to as *permutation symmetry* of $\mathbf{F}$). We can use the decoupling inequalities from Section 3 to show that

$$\|\mathbf{F}(\mathbf{x})\|_{4t} \;\leq\; C_d \cdot \left\|\mathbf{F}(\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(d)})\right\|_{4t} \;=\; C_d \cdot \left\|\sum_{\mathbf{i} \in \mathcal{T}_n^d} \mathbf{A_i} \cdot \prod_{j \in [d]} x_{i_j}^{(j)}\right\|_{4t} ,$$

where $\|\cdot\|_{4t}$ denotes the (expected) Schatten norm $\left(\mathbb{E}[\mathrm{tr}(\mathbf{F}(\mathbf{x})^\mathsf{T}\mathbf{F}(\mathbf{x}))^{2t}]\right)^{1/4t}$.

We remark that while the constant C_d is of the form d^d in general, this can be improved when the underlying set of indices $[n]$ has more structure. For example, when $[n]$ corresponds to the set of *pairs* in an base set $[r]$ and each of the monomials involves at most k elements of $[r]$ (has *index degree* k), it is possible to improve the constant to k^k. This is essentially the "vertex partitioning" argument used in works on graph matrices, and is discussed in Section 3 in the language of decoupling.

As mentioned earlier, we can now "linearize" the function $\mathbf{F}(\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(d)})$ by fixing $\mathbf{x}^{(d)}, \ldots, \mathbf{x}^{(d-1)}$ and treating it only as a function of $\mathbf{x}^{(d)}$ i.e., we consider

$$\begin{aligned}
\mathbb{E}\left\|\sum_{\mathbf{i} \in \mathcal{T}_n^d} \mathbf{A_i} \cdot \prod_{j \in [d]} x_{i_j}^{(j)}\right\|_{4t}^{4t} &= \mathop{\mathbb{E}}_{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(d-1)}} \mathop{\mathbb{E}}_{\mathbf{x}^{(d)}} \left\|\sum_{k \in [n]} \left(\sum_{\substack{\mathbf{i} \in \mathcal{T}_n^d \\ i_d = k}} \mathbf{A_i} \cdot \prod_{j \in [d-1]} x_{i_j}^{(j)}\right) \cdot x_k^{(d)}\right\|_{4t}^{4t} \\
&= \mathop{\mathbb{E}}_{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(d-1)}} \mathop{\mathbb{E}}_{\mathbf{x}^{(d)}} \left\|\sum_{k \in [n]} \left(\partial_{x_k^{(d)}} \mathbf{F}\right) \cdot x_k^{(d)}\right\|_{4t}^{4t} .
\end{aligned}$$

To bound the inner expectation, we can now use the matrix Rosenthal inequality (Lemma 8) which says that for a collection of centered, independent random matrices $\{\mathbf{Y}_k\}$ with finite moments, we have

$$\mathbb{E}\left\|\sum_k \mathbf{Y}_k\right\|_{4t}^{4t} \leq (16t)^{3t} \cdot \left\{\left\|\left(\sum_k \mathbb{E}\mathbf{Y}_k\mathbf{Y}_k^\mathsf{T}\right)^{1/2}\right\|_{4t}^{4t} + \left\|\left(\sum_k \mathbb{E}\mathbf{Y}_k^\mathsf{T}\mathbf{Y}_k\right)^{1/2}\right\|_{4t}^{4t}\right\} + (8t)^{4t} \cdot \left(\sum_k \mathbb{E}\left\|\mathbf{Y}_k\right\|_{4t}^{4t}\right).$$

Taking $\mathbf{Y}_k = \partial_{x_k^{(d)}} \mathbf{F} \cdot x_k^{(d)}$ we can now compute the expectations (over $\mathbf{x}^{(d)}$) in the RHS as

$$\sum_k \mathbb{E}\mathbf{Y}_k\mathbf{Y}_k^\mathsf{T} = \left[\partial_{x_1^{(d)}}\mathbf{F} \quad \dots \quad \partial_{x_n^{(d)}}\mathbf{F}\right]\left[\partial_{x_1^{(d)}}\mathbf{F} \quad \dots \quad \partial_{x_n^{(d)}}\mathbf{F}\right]^\mathsf{T}$$

$$\sum_k \mathbb{E}\mathbf{Y}_k^\mathsf{T}\mathbf{Y}_k = \left[\partial_{x_1^{(d)}}\mathbf{F}^\mathsf{T} \quad \dots \quad \partial_{x_n^{(d)}}\mathbf{F}^\mathsf{T}\right]\left[\partial_{x_1^{(d)}}\mathbf{F}^\mathsf{T} \quad \dots \quad \partial_{x_n^{(d)}}\mathbf{F}^\mathsf{T}\right]^\mathsf{T}$$

$$\sum_k \mathbb{E}\left\|\mathbf{Y}_k\right\|_{4t}^{4t} = \mathbb{E}\left\|\begin{bmatrix} x_1^{(d)}\cdot\partial_{x_1^{(d)}}\mathbf{F} & & \\ & \ddots & \\ & & x_n^{(d)}\cdot\partial_{x_n^{(d)}}\mathbf{F}\end{bmatrix}\right\|_{4t}^{4t} \le L^{4t}\cdot\left\|\begin{bmatrix}\partial_{x_1^{(d)}}\mathbf{F} & & \\ & \ddots & \\ & & \partial_{x_n^{(d)}}\mathbf{F}\end{bmatrix}\right\|_{4t}^{4t}$$

Iterating the above argument, we can prove a bound in terms of a collection of partial derivative matrices $\mathbf{F}_{a,b,c}$ (see Section 2 for details).

Note that in the above definition, we do not specify the order of differentiation, which can be ignored due to the permutation symmetry of $\mathbf{F}$ and the fact that changing the order does not change the Schatten norms (see Section 2 and Section 4 for details). This argument yields the following bound for all homogeneous multilinear polynomial functions.

▶ **Theorem 1** (Restatement of Theorem 10). *Let $\mathbf{x} = \{x_i\}_{i=1}^n$ be a sequence of i.i.d random variables with $\mathbb{E}x_i = 0$, $\mathbb{E}x_i^2 = 1$ and $|x_i| \le L$ for all $1 \le i \le n$. Let $\{\mathbf{A_i}\}_{\mathbf{i}\in\mathcal{T}_n^d}$ be a multi-indexed sequence of deterministic matrices of the same dimension. Define a permutation symmetric, homogeneous multilinear polynomial random matrix of degree d as*

$$\mathbf{F}(\mathbf{x}) = \sum_{\mathbf{i}\in\mathcal{T}_n^d}\left(\mathbf{A_i}\cdot\prod_{j\in\{i_1,\dots,i_d\}} x_j\right).$$

Let $a, b, c \in \mathbb{Z}_{\ge 0}$ and $d = a+b+c$. Then for $2 \le t \le \infty$,

$$\mathbb{E}\left\|\mathbf{F}(\mathbf{x})\right\|_{4t}^{4t} \le \sum_{\substack{a,b,c:\\ a+b+c=d}} (48dt)^{4dt}\cdot L^{4ct}\left\|\mathbf{F}_{a,b,c}\right\|_{4t}^{4t}.$$

We remark that the condition that $|x_i| \le L$ can be replaced by a condition on the growth of moments of x_i, which is true for subgaussian variables. The above bound is in terms of the norms of a constant number of *deterministic* matrices $\mathbf{F}_{a,b,c}$, as is also the case for general moment bounds on scalar polynomials [1]. We will see later that these deterministic matrices can easily be interpreted in several cases of interest, to recover the bounds obtained via combinatorial methods.

Gaussian polynomial matrices. While the above bounds are only for multilinear polynomials, they can also be extended to *arbitrary* polynomials of independent Gaussian random variables, using standard techniques to approximate them by multilinear polynomials. However, for the case of Gaussian polynomials, the recent Poincaré inequalities of Huang and Tropp [14] directly yield a simple bound, which is easier to apply. They show that for a Hermitian matrix-valued function $\mathbf{H}$ of Gaussian valued random variables

$$\mathbb{E}\left\|\mathbf{H}(\mathbf{x}) - \mathbb{E}\mathbf{H}(\mathbf{x})\right\|_{2t}^{2t} \le (\sqrt{2}t)^{2t}\cdot\mathbb{E}\,\mathrm{tr}\left(\sum_{i=1}^n(\partial_i\mathbf{H}(\mathbf{x}))^2\right)^t.$$

As before, one can apply this argument inductively to obtain a bound in terms of the matrices $\mathbf{F}_{a,b}$ which are defined similarly as the matrices $\mathbf{F}_{a,b,c}$ before, with $c = 0$. Since we no longer have $\mathbb{E}\mathbf{F}_{a,b} = \mathbf{0}$ for $a+b < d$, the bound is in terms of the expected matrices $\mathbb{E}\mathbf{F}_{a,b}$ for all a, b with $a+b \le d$.

▶ **Theorem 2** (Restatement of Theorem 14). *Let $\mathbf{x} \sim \mathcal{N}(0, \mathbb{I}_n)$ and $\{\mathbf{A_i}\}_{\mathbf{i}\in[n]^d}$ be a sequence of deterministic matrices of the same dimension. Define a degree-d homogeneous Gaussian polynomial random matrix as*

$$\mathbf{F}(\mathbf{x}) = \sum_{\mathbf{i}\in[n]^d} \left(\mathbf{A_i} \cdot \prod_{j\in\{i_1,\ldots,i_d\}} x_j \right).$$

Let $a, b \in \mathbb{Z}_{\geq 0}$. Then for $2 \leq t \leq \infty$,

$$\mathbb{E}\,\|\mathbf{F}(\mathbf{x}) - \mathbb{E}\mathbf{F}(\mathbf{x})\|_{2t}^{2t} \;\leq\; (2^d\sqrt{2}t)^{2t} \left(\sum_{1\leq a+b\leq d} \|\mathbb{E}\mathbf{F}_{a,b}\|_{2t}^{2t} \right).$$

While the above theorem is stated for homogeneous polynomials, the proof is identical also for the non-homogeneous ones, with the sum in the definition being over all tuple sizes.

Do try this at home: applying the framework

We now discuss how to interpret the matrices $\mathbf{F}_{a,b,c}$ arising in the bound in Theorem 1 to recover the norm bounds for graph matrices derived via combinatorial methods. This is discussed with more formal details in Section 6, but we present an intuitive (at least for the authors) version of the argument here.

Graph matrices are defined using constant-sized template "shapes" and provide a convenient basis for expressing (large) random matrices where the the entries are low-degree polynomials in the (normalized) indicators of edges in a $G_{n,p}$ random graph. Such matrices and their norm bounds have been used for a large number of applications [2].

Let $N = \binom{n}{2}$ and fix a canonical bijection between the space $[N]$ and $\binom{[n]}{2}$, and let $[N]$ index the space of all possible edges in a random graph on n vertices. For each $e = \{i, j\} \in \binom{[n]}{2}$, for $\Delta_p = \sqrt{(1-p)/p}$ let x_e be independently $1/\Delta_p$ with probability $(1-p)$ and $-\Delta_p$ with probability p, so that $\mathbb{E}x_e = 0$, $\mathbb{E}x_e^2 = 1$, and $|x_e| \leq \Delta_p$.

Let $(V(\tau), E(\tau))$ be a graph on k vertices with d edges, and let U_τ, V_τ be *ordered* subsets of $V(\tau)$ of size k_1 and k_2 respectively. The tuple $\tau = (V(\tau), E(\tau), U_\tau, V_\tau)$ is referred to as a "shape" and is used to define the following graph matrix $\mathbf{M}_\tau$ with rows and columns indexed by $\mathcal{T}_n^{k_1}$ and $\mathcal{T}_n^{k_2}$ respectively

$$\mathbf{M}_\tau[\mathbf{i}, \mathbf{j}] \;:=\; \sum_{\psi\in\mathcal{T}_n^k} \mathbb{1}_{\{\psi(U_\tau)=\mathbf{i}\}} \cdot \mathbb{1}_{\{\psi(V_\tau)=\mathbf{j}\}} \cdot \prod_{e_0\in E(\tau)} x_{\psi(e_0)}\,,$$

where we interpret a tuple $\psi \in \mathcal{T}_n^k$ as an injective function $\psi : V(\tau) \to [n]$ in the canonical way. If the function ψ maps U_τ to $\mathbf{i}$ (the row-index) and V_τ to $\mathbf{j}$ (the column index), we add the monomial to $\mathbf{M}_\tau[\mathbf{i}, \mathbf{j}]$ corresponding to the product of the images of all edges in the "pattern" $E(\tau)$ under ψ. Note that each nonzero entry of the matrix-valued function $\mathbf{M}$ is a multilinear homogeneous polynomial in the variables $\{x_e\}_{e\in\binom{[n]}{2}}$ with degree $d = |E(\tau)|$. We denote $\mathbf{M}_\tau$ by $\mathbf{F}$ for ease of notation in the discussion below.

As will be apparent from the analysis below, the norm bounds for such matrices behave different characterizations in the "dense" regime where $p = \Omega(1)$ and the "sparse" one where $p = o(1)$. This is because the subgaussian norm $L = \Delta_p \approx p^{-1/2}$ is bounded in the first case, and growing in the second case. The bounds for the first case are stated in terms of the size the minimum vertex separator separating U_τ from V_τ in the shape τ. For the second case, one needs to augment the defintion of minimum vertex separator, to use a cost based on the subgaussian norm Δ_p. We will show how to recover both these characterizations, using the matrices $\mathbf{F}_{a,b,c}$ given by Theorem 1.

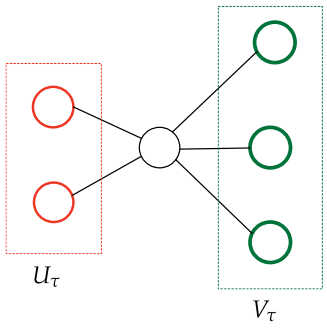

Figure 1 A shape τ.

Dense graph matrices. We start by considering $p = 1/2$ so that the random variables x_e are just independent Rademacher variables. Taking d to be constant, the bound in Theorem 1 involves only a constant number of matrices, and will depend on the dominant term. To understand each of the terms, we first consider the matrices derived after one step of the recursion.

$$\mathbf{F}_{1,0,0} = \begin{bmatrix}\partial_{x_1}\mathbf{F} & \dots & \partial_{x_N}\mathbf{F}\end{bmatrix}^\mathsf{T}, \quad \mathbf{F}_{0,1,0} = \begin{bmatrix}\partial_{x_1}\mathbf{F} & \dots & \partial_{x_N}\mathbf{F}\end{bmatrix} \text{ and } \mathbf{F}_{0,0,1} = \begin{bmatrix}\partial_{x_1}\mathbf{F} & & \\ & \ddots & \\ & & \partial_{x_N}\mathbf{F}\end{bmatrix}.$$

Since $\operatorname{tr}\left(\sum_i \mathbf{A}_i\mathbf{A}_i^\mathsf{T}\right)^{2t} + \operatorname{tr}\left(\sum_i \mathbf{A}_i^\mathsf{T}\mathbf{A}_i\right)^{2t} \geq \sum_i \operatorname{tr}\left(\mathbf{A}_i\mathbf{A}_i^\mathsf{T}\right)^{2t}$ and $L = 1$, we will have that $\|\mathbf{F}_{1,0,0}\|_{4t}^{4t} + \|\mathbf{F}_{0,1,0}\|_{4t}^{4t} \geq L^{4t} \cdot \|\mathbf{F}_{0,0,1}\|_{4t}^{4t}$. This will also be true (up to constant factors) for any constant L, since we interested in the $4t$-th root of the above trace. Using a similar argument, we can ignore terms with $c > 0$ for now (we will come back to these in the sparse case) and focus on matrices $\mathbf{F}_{a,b,0}$.

We now interpret the matrices $\mathbf{F}_{1,0,0}$ and $\mathbf{F}_{0,1,0}$. The row-space of $\mathbf{F}_{1,0,0}$ is now indexed by $(\mathbf{i}, e)$ for $e \in \binom{[n]}{2}$ (respectively $(\mathbf{j}, e)$ for the column space of $\mathbf{F}_{0,1,0}$). We now include terms corresponding to maps ψ for which $\psi(U_\tau) = \mathbf{i}$, $\psi(V_\tau) = \mathbf{j}$ and $\psi(e_0) = e$ for some $e_0 \in E(\tau)$ so that $\partial x_e \mathbf{F}[\mathbf{i}, \mathbf{j}] \neq 0$.

Decomposing $\mathbf{F}_{1,0,0}$ into $|E(\tau)|$ matrices (one for each choice of e_0), we can consider the $\mathbf{F}_{1,0,0,e_0}$ as simply a new graph matrix we have *deleted* the edge e_0 and included both its end points in U_τ (respectively in V_τ for $\mathbf{F}_{0,1,0}$) to obtain a new shape τ'. Similarly, each $\mathbf{F}_{a,b,0}$ can be decomposed into $|E(\tau)|^{a+b}$ graph matrices, where we delete $a+b$ edges in total, and include the endpoints in U_τ for a of them and V_τ for b of them. This is illustrated in Figure 2 where we color the edges red or green depending on their inclusion in U_τ or V_τ.

The bound in Theorem 1 is then in terms of these new graph matrices where we delete all d edges, and split their endpoints between U_τ or V_τ to obtain $U', V' \subseteq V(\tau) = [k]$. For an entry $\mathbf{M}[\mathbf{i}', \mathbf{j}']$ of any such matrix, there is at most one $\psi : V(\tau) \to [n]$ such that $\psi(U') = \mathbf{i}'$ and $\psi(V') = \mathbf{j}'$ (assuming τ has no isolated vertices), and $\mathbf{M}[\mathbf{i}', \mathbf{j}'] = \mathbb{1}_{\{\psi(U')=\mathbf{i}'\}} \cdot \mathbb{1}_{\{\psi(V')=\mathbf{j}'\}}$. Taking $S = U' \cap V'$, this matrix can be simply written as a block-diagonal matrix with $n^{|S|}$ of size $n^{|U'\setminus S|} \times n^{|V'\setminus S|}$. It is easy to check that the spectral norm of such a matrix is $n^{(|U'\setminus S|+|V'\setminus S|)/2} = n^{(k-|S|)/2}$ since $|U' \cup V'| = k$ and $S = U' \cap V'$.

Thus, each of the terms in the bound will correspond to graph matrices with different U' and V' (obtained by coloring edges red or green according to the above process) and the dominant term will be the one with the smallest value of $|U' \cap V'|$. We now claim that

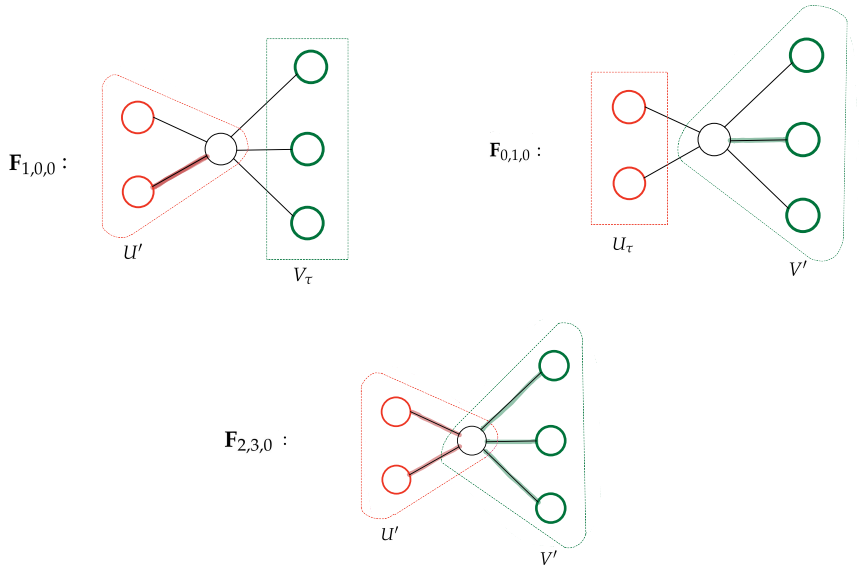

Figure 2 $\mathbf{F}_{1,0,0}$, $\mathbf{F}_{0,1,0}$ and $\mathbf{F}_{2,3,0}$.

$U' \cap V'$ must be a vertex separator separating U_τ and V_τ in the shape τ i.e., any path between them must pass through $U' \cap V'$. If the path contains both red and green edges, then it contains one vertex with both red and green edges incident on it, which is then in $U' \cap V'$ (since U' is obtain by adding endpoint of red edges to U_τ and V' similarly for green edges). If path is entirely red, then we have an endpoint of a red edge in V_τ which is a vertex in $U' \cap V'$, and similarly for green paths.

Thus, we have $n^{(k-|S|)/2} \leq n^{(k-r)/2}$, where r is the size of the minimum vertex separator between U_τ and V_τ, which recovers the known bound for dense graph matrices [2].

Sparse graph matrices. The argument for sparse graph matrices is almost the same as above except now we also need to consider terms of the form $\mathbf{F}_{a,b,c}$ for $c > 0$. Just as we interpreted $\mathbf{F}_{a,b,0}$ as coloring a edges from $E(\tau)$ as red and including in $U' \supseteq U_\tau$ and b green edges in $V' \supseteq V_\tau$, we can now interpret $\mathbf{F}_{a,b,c}$ as having c edges whose endpoints are included in *both* U' and V' (say these edges are colored yellow). This simply reflects the fact that the derivatives in the definition of $\mathbf{F}_{a,b,c+1}$ are placed as diagonal blocks.

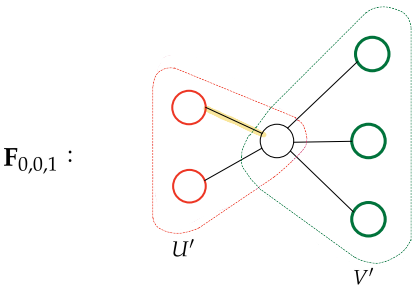

Figure 3 $\mathbf{F}_{0,0,1}$.

As we saw above, increasing the intersection of U' and V' decreases the norm, and so the matrices with $c > 0$ should have a smaller Schatten norm. However, they are now included in the bound with a multiplicative factor of L^c. Thus, we simply look for a vertex separator S maximizing $L^{e(S)} \cdot n^{(k-|S|)/2}$ where $e(S)$ counts the (yellow) edges contained in $S = U' \cap V'$. This is precisely the "sparse vertex separator" which determines the norm bound for such sparse graph matrices [16, 29].

2 Preliminaries and Notation

Vectors are denoted by bold face lower case letters $\mathbf{x}, \mathbf{y}$ and $\mathbf{z}$. Deterministic matrices are denoted by bold face upper case letters $\mathbf{A}$ and $\mathbf{B}$. Matrix-valued functions are denoted by bold face upper case letters $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{F}$, $\mathbf{M}$, $\mathbf{H}$ and $\mathbf{P}$.

Sets and indices. For a set S, let $|S|$ denote the number of distinct elements in S. We denote $[n] = \{1, \ldots, n\}$ for any positive integer n. For $\mathbf{i} := (i_1, \ldots, i_m) \in [n]^m$, define

$$\mathcal{T}_n^m := \{(i_1, \ldots, i_m) : \forall j, k \in [m],\ j \neq k \Rightarrow i_j \neq i_k\}.$$

Matrix norms. Let $\mathbb{R}^{d_1 \times d_2}$ be the space of all $d_1 \times d_2$ real matrices. Let $\mathbb{H}^d$ be the subspace of $\mathbb{R}^{d \times d}$ containing all Hermitian matrices. We write $\|\cdot\|_2$ for the ℓ_2 operator norm, $\|\cdot\|_F$ for the Frobenius norm, and $\mathrm{tr}(\cdot)$ for the trace.

▶ **Definition 3** (Schatten norm). *For $\mathbf{A} \in \mathbb{R}^{d_1 \times d_2}$ and $t \geq 1$, the Schatten $2t$-norm is defined as*

$$\|\mathbf{A}\|_{2t} := (\mathrm{tr}(\mathbf{A}^\mathsf{T}\mathbf{A})^t)^{1/2t}.$$

Polynomial random matrices. Let $(\Omega, \mathcal{F}, \mu)$ be a probability space. Introduce the random vector $\mathbf{x} := (x_1, \ldots, x_n) \in \Omega$ where $x_1, \ldots, x_n$ are independent random variables. A polynomial random matrix $\mathbf{F}(\mathbf{x})$ is a matrix-valued polynomial $\mathbf{F} : \Omega \to \mathbb{R}^{d_1 \times d_2}$. We can construct a polynomial random matrix $\mathbf{F}(\mathbf{x})$ by drawing a copy of $\mathbf{x} \sim \mu$. Note that despite $\mathbf{x}$ having independent entries, the entries of $\mathbf{F}(\mathbf{x})$ can be dependent (or correlated) with each other. Unlike Wigner matrices whose entries are i.i.d., the polynomial random matrices can have dependencies among its entries.

▶ **Definition 4** (Permutation Symmetric Property). *Suppose $\mathbf{F}(\mathbf{x})$ is a degree-d homogeneous multilinear polynomial random matrix, i.e.,*

$$\mathbf{F}(\mathbf{x}) = \sum_{\mathbf{i} \in \mathcal{T}_n^d} \left(\mathbf{A}_\mathbf{i} \cdot \prod_{j \in \{i_1, \ldots, i_d\}} x_j \right),$$

where $\{\mathbf{A}_\mathbf{i}\}_{\mathbf{i} \in \mathcal{T}_n^d}$ is a multi-indexed sequence of deterministic matrices of the same dimension. $\mathbf{F}(\mathbf{x})$ is permutation symmetric if $\mathbf{A}_{i_1, \ldots, i_d} = \mathbf{A}_{i_{\sigma(1)}, \ldots, i_{\sigma(d)}}$ for any permutation $\sigma \in \mathfrak{S}_d$ and any $(i_1, \ldots, i_d) \in \mathcal{T}_n^d$.

Partial derivatives. Let $\mathbf{F}(\mathbf{x})$ be an n-variate polynomial random matrix of degree D. For $a, b, c \in \mathbb{Z}_{\geq 0}$ and $d = a + b + c$, we consider the block matrices $\mathbf{F}_{a,b,c}$ containing all d-th order partial derivatives of $\mathbf{F}(\mathbf{x})$. We define $\mathbf{F}_{a,b,c}$ recursively as $\mathbf{F}_{0,0,0} = \mathbf{F}(\mathbf{x})$ and

$$\mathbf{F}_{a+1,b,c} = \begin{bmatrix} \partial_{x_1} \mathbf{F}_{a,b,c} & \ldots & \partial_{x_n} \mathbf{F}_{a,b,c} \end{bmatrix}^\mathsf{T},$$

$$\mathbf{F}_{a,b+1,c} = \begin{bmatrix} \partial_{x_1}\mathbf{F}_{a,b,c} & \dots & \partial_{x_n}\mathbf{F}_{a,b,c} \end{bmatrix},$$

$$\mathbf{F}_{a,b,c+1} = \begin{bmatrix} \partial_{x_1}\mathbf{F}_{a,b,c} & & \\ & \ddots & \\ & & \partial_{x_n}\mathbf{F}_{a,b,c} \end{bmatrix}.$$

It is evident from the definition that the block matrices $\mathbf{F}_{a+1,b,c}$, $\mathbf{F}_{a,b+1,c}$, $\mathbf{F}_{a,b,c+1}$ are assembled from sub-blocks $\{\partial_{x_i}\mathbf{F}_{a,b,c}\}_{i=1}^n$ arranged vertically, horizontally and diagonally respectively. The order of increment between a and b doesn't affect the resulting matrix, i.e.,

$$\mathbf{F}_{a+1,b+1,c} = \begin{bmatrix} \partial_{x_1}\mathbf{F}_{a,b+1,c} \\ \vdots \\ \partial_{x_n}\mathbf{F}_{a,b+1,c} \end{bmatrix} = \begin{bmatrix} \partial_{x_1}\mathbf{F}_{a+1,b,c} & \dots & \partial_{x_n}\mathbf{F}_{a+1,b,c} \end{bmatrix} = \begin{bmatrix} \partial_{x_1}\partial_{x_1}\mathbf{F}_{a,b,c} & \dots & \partial_{x_1}\partial_{x_n}\mathbf{F}_{a,b,c} \\ & \vdots & \\ \partial_{x_n}\partial_{x_1}\mathbf{F}_{a,b,c} & \dots & \partial_{x_n}\partial_{x_n}\mathbf{F}_{a,b,c} \end{bmatrix}.$$

However, the order of increment involving c affects the resulting matrix, i.e.,

$$\begin{bmatrix} \partial_{x_1}\mathbf{F}_{a,b,c+1} & \dots & \partial_{x_n}\mathbf{F}_{a,b,c+1} \end{bmatrix} \neq \begin{bmatrix} \partial_{x_1}\mathbf{F}_{a,b+1,c} & & \\ & \ddots & \\ & & \partial_{x_n}\mathbf{F}_{a,b+1,c} \end{bmatrix}.$$

Nevertheless, the order of increment doesn't affect the Schatten norm. Since we will only be interested in the Schatten norms of these matrices, we will simply label them as $\mathbf{F}_{a,b+1,c+1}$ without specifying the order. It is easy to see that $\mathbf{F}_{a,b,c}$ is a deterministic matrix if $a+b+c = D$ and $\mathbf{F}_{a,b,c} = \mathbf{0}$ if $a+b+c > D$.

Constants. We denote C for some universal constants and C_a for constants depending only on some parameter a. The values of the constants may differ from one instance to another.

3 Decoupling Inequalities

In this work, we focus on decoupling inequalities for moments, which is fairly elementary and can be interpreted combinatorially as partitioning the random vector $\mathbf{x}$.

▶ **Lemma 5** (see [30] Lemma 6.21). *Let $\mathbf{x} = \{x_j\}_{j=1}^n$ be a sequence of independent random variables with $\mathbb{E}x_j = 0$ for all $j = 1, \dots, n$. Let $\{\mathbf{B}_\mathbf{i}\}_{\mathbf{i}\in\mathcal{T}_n^d}$ be a multi-indexed sequence of deterministic matrices of the same dimension. Then for $1 \le t \le \infty$*

$$\mathbb{E}\left\| \sum_{\mathbf{i}\in\mathcal{T}_n^d} \mathbf{B}_\mathbf{i} \cdot x_{i_1} \dots x_{i_d} \right\|_{2t} \le d^d \cdot \mathbb{E}\left\| \sum_{\mathbf{i}\in\mathcal{T}_n^d} \mathbf{B}_\mathbf{i} \cdot x_{i_1}^{(1)} \dots x_{i_d}^{(d)} \right\|_{2t},$$

where $\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(d)}$ denote d independent copies of $\mathbf{x}$.

Improved Decoupling for Random Variables with Structured Indices

For a generic degree d multilinear polynomial random matrices, an application of Lemma 5 yields a decoupling constant of d^d, which might not be optimal for polynomial random matrices with additional structures. We will show that the additional structures enable us to give a tighter decoupling inequality through a careful partitioning.

Building on Lemma 5, we prove a decoupling inequality for polynomial random matrices, in which the indices of random variables have a graph structure. Let $G = (V, E)$ be a fixed simple graph with $|V| = k$, and $|E| = d$. We denote the vertices by $V(G) = \{v_1, \ldots, v_k\}$ and the ordered edge set by $E(G) = \{(i_1, j_1), \ldots, (i_d, j_d)\}$. For any $\varphi \in \mathcal{T}_n^k$, we write $\varphi(i)$ for the i-th component of φ and $\varphi(E)$ for $\{(\varphi(i_1), \varphi(j_1)), \ldots, (\varphi(i_d), \varphi(j_d))\}$.

▶ **Lemma 6.** *Let $\mathbf{z} = \{Z_{\varphi(i),\varphi(j)}\}_{\varphi \in \mathcal{T}_n^k, (i,j) \in E}$ be a double sequence of independent random variables with $\mathbb{E} Z_{\varphi(i),\varphi(j)} = 0$ for all $(i, j) \in E$ and $\varphi \in \mathcal{T}_n^k$. Let $\{\mathbf{B}_{\varphi(E)}\}_{\varphi \in \mathcal{T}_n^k}$ be a multi-indexed sequence of deterministic matrices of the same dimension. Then for $d \le k(k-1)$ and $1 \le t \le \infty$,*

$$\mathbb{E} \left\| \sum_{\varphi \in \mathcal{T}_n^k} \mathbf{B}_{\varphi(E)} \cdot \prod_{(i,j) \in E} Z_{\varphi(i),\varphi(j)} \right\|_{2t} \le k^k \cdot \mathbb{E} \left\| \sum_{\varphi \in \mathcal{T}_n^k} \mathbf{B}_{\varphi(E)} \cdot Z^{(1)}_{\varphi(i_1),\varphi(j_1)} \cdots Z^{(d)}_{\varphi(i_d),\varphi(j_d)} \right\|_{2t},$$

where $\mathbf{z}^{(1)}, \ldots, \mathbf{z}^{(d)}$ denote d independent copies of $\mathbf{z}$.

▶ Remark 7. It is crucial for the indices of all monomials to share the same structure so that d independent copies of $\mathbf{z}$ suffices. Otherwise, $k(k-1)$ independent copies are needed in general.

Proof. Consider a random partition of the ground set $[n]$ into k parts and let $\mathbf{r}$ be the *vertex partitioner*. Formally, let $\mathbf{r} = (r_1, \ldots, r_n)$ be a sequence of independent random variables with each r_p uniformly distributed on $\{1, \ldots, k\}$, i.e., for $1 \le p \le n$,

$$\mathbb{P}(r_p = 1) = \mathbb{P}(r_p = 2) = \cdots = \mathbb{P}(r_p = k) = 1/k.$$

Define an event $A := \{r_{\varphi(v_1)} = 1, \cdots, r_{\varphi(v_k)} = k\}$ for each $\varphi \in \mathcal{T}_n^k$. Conditioned on $\mathbf{z}$,

$$\mathbb{E}_{\mathbf{r}} \left[\mathbb{1}_A(r_{\varphi(v_1)}, \ldots, r_{\varphi(v_k)}) \right] = 1/k^k.$$

It follows that

$$\begin{aligned} F :&= \mathbb{E}_{\mathbf{z}} \left\| \sum_{\varphi \in \mathcal{T}_n^k} \mathbf{B}_{\varphi(E)} \cdot \prod_{(i,j) \in E} Z_{\varphi(i),\varphi(j)} \right\|_{2t} \\ &= k^k \cdot \mathbb{E}_{\mathbf{z}} \left\| \mathbb{E}_{\mathbf{r}} \left[\sum_{\varphi \in \mathcal{T}_n^k} \mathbb{1}_A(r_{\varphi(v_1)}, \ldots, r_{\varphi(v_k)}) \cdot \mathbf{B}_{\varphi(E)} \cdot \prod_{(i,j) \in E} Z_{\varphi(i),\varphi(j)} \right] \right\|_{2t} \\ &\le k^k \cdot \mathbb{E}_{\mathbf{r}} \mathbb{E}_{\mathbf{z}} \left\| \sum_{\varphi \in \mathcal{T}_n^k} \mathbb{1}_A(r_{\varphi(v_1)}, \ldots, r_{\varphi(v_k)}) \cdot \mathbf{B}_{\varphi(E)} \cdot \prod_{(i,j) \in E} Z_{\varphi(i),\varphi(j)} \right\|_{2t}, \end{aligned}$$

where the last step is due to Jensen's inequality and Fubini's theorem. Since the expectation over $\mathbf{r}$ satisfies the inequality, this implies the existence of an $\mathbf{r}^*$ satisfying the inequality.

Fix $\mathbf{r}^*$ and define the *vertex partitioning* with respect to $\mathbf{r}^*$ as

$$P_1 = \{p \in [n] : r_p^* = 1\}, \ \ldots \ , P_k = \{p \in [n] : r_p^* = k\},$$

which in turn induces an *edge partitioning*,

$$P_e \ := \ \{(P_i, P_j)\}_{(i,j) \in \mathcal{T}_k^2}.$$

Notice that there are $k(k-1)$ elements in P_e, but we only have d edges to partition. So we select d elements out of P_e in the following way. Fix an arbitrary $\varphi^* \in \mathcal{T}_n^k$, choose

$$P_1^* = (P_{\varphi^*(i_1)}, P_{\varphi^*(j_1)}), \ \ldots \ , P_d^* = (P_{\varphi^*(i_d)}, P_{\varphi^*(j_d)}).$$

Let's call $\{P_1^*, \dots P_d^*\}$ a *d-edge partitioning*. In other words, we may select any d elements out of P_e to form a *d-edge partitioning* so long as the pattern of the indices of (P_i, P_j)'s matches that of $E(G)$. Since the elements in P_e have no intersections, the partitions in $\{P_1^*, \dots, P_d^*\}$ also have no intersections. Since $Z_{\varphi(i),\varphi(j)}$'s are independent random variables, replacing $Z_{\varphi(i_1),\varphi(j_1)} \cdots Z_{\varphi(i_d),\varphi(j_d)}$ with $Z^{(1)}_{\varphi(i_1),\varphi(j_1)} \cdots Z^{(d)}_{\varphi(i_d),\varphi(j_d)}$ for any $\varphi(E) \in P_1^* \times \cdots \times P_d^*$ will not change the distribution. Hence

$$F \le k^k \cdot \mathbb{E} \left\| \sum_{\varphi(E) \in P_1^* \times \cdots \times P_d^*} \mathbf{B}_{\varphi(E)} \cdot Z^{(1)}_{\varphi(i_1),\varphi(j_1)} \cdots Z^{(d)}_{\varphi(i_d),\varphi(j_d)} \right\|_{2t}. \tag{1}$$

Denote all variables in $P_1^* \times \cdots \times P_d^*$ by

$$\mathcal{Z} := \left\{ Z^{(1)}_{\varphi(i_1),\varphi(j_1)}, \ \dots, \ Z^{(d)}_{\varphi(i_d),\varphi(j_d)} : \ \forall \ (\varphi(i_1),\varphi(j_1)) \in P_1^*, \ \dots \ , (\varphi(i_d),\varphi(j_d)) \in P_d^* \right\},$$

and denote the rest of the variables by $\mathcal{Z}^c$. It remains to show that the sum on the right-hand side of (1) is over all $\varphi \in \mathcal{T}_n^k$. Observe that

$$\mathbb{E}_{\mathcal{Z}^c} \left[\sum_{\varphi(E) \notin P_1^* \times \cdots \times P_d^*} \mathbf{B}_{\varphi(E)} \cdot Z^{(1)}_{\varphi(i_1),\varphi(j_1)} \cdots Z^{(d)}_{\varphi(i_d),\varphi(j_d)} \ \middle| \ \mathcal{Z} \right] = \mathbf{0}. \tag{2}$$

Denote $P_1^* \times \cdots \times P_d^*$ by $\mathcal{P}$. Since the sum in (2) has conditional expectation zero, we can add it to (1) to get

$$F \le k^k \cdot \mathbb{E}_{\mathcal{Z}} \left\| \sum_{\varphi(E) \in \mathcal{P}} \mathbf{B}_{\varphi(E)} \cdot Z^{(1)}_{\varphi(i_1),\varphi(j_1)} \cdots Z^{(d)}_{\varphi(i_d),\varphi(j_d)} + \mathbb{E}_{\mathcal{Z}^c} \left[\sum_{\varphi(E) \notin \mathcal{P}} \mathbf{B}_{\varphi(E)} \cdot Z^{(1)}_{\varphi(i_1),\varphi(j_1)} \cdots Z^{(d)}_{\varphi(i_d),\varphi(j_d)} \ \middle| \ \mathcal{Z} \right] \right\|_{2t}.$$

Since the two sums on the right-hand side are independent conditioned on $\mathcal{Z}$, conditional application of Jensen's inequality yields the desired inequality,

$$F \le k^k \cdot \mathbb{E}_{\mathbf{z}^{(1)},\dots,\mathbf{z}^{(d)}} \left\| \sum_{\varphi \in \mathcal{T}_n^k} \mathbf{B}_{\varphi(E)} \cdot Z^{(1)}_{\varphi(i_1),\varphi(j_1)} \cdots Z^{(d)}_{\varphi(i_d),\varphi(j_d)} \right\|_{2t}. \qquad \blacktriangleleft$$

4 Multilinear Polynomial Random Matrices

In this section, we prove a moment bound for multilinear polynomial random matrices with bounded, normalized random variables. We follow our recursion framework by decoupling the polynomial random matrices first and then apply the matrix Rosenthal inequality recursively to sums of (conditionally) independent random matrices.

To this end, we derive the non-Hermitian matrix Rosenthal inequality from the Hermitian matrix Rosenthal inequality by Hermitian dilation (see [34] Sec. 2.1.16).

▶ **Lemma 8** (Non-Hermitian Matrix Rosenthal Inequality). *Suppose that $t = 1$ or $t \ge 1.5$. Consider a finite sequence $\{\mathbf{Y}_k\}_{k \ge 1}$ of centered, independent, random matrices, and assume that $\mathbb{E} \|\mathbf{Y}_k\|_{4t}^{4t} < \infty$. Then*

$$\mathbb{E} \left\| \sum_k \mathbf{Y}_k \right\|_{4t}^{4t} \le (16t)^{3t} \cdot \left\{ \left\| \left(\sum_k \mathbb{E} \mathbf{Y}_k \mathbf{Y}_k^{\mathsf{T}} \right)^{1/2} \right\|_{4t}^{4t} + \left\| \left(\sum_k \mathbb{E} \mathbf{Y}_k^{\mathsf{T}} \mathbf{Y}_k \right)^{1/2} \right\|_{4t}^{4t} \right\} + (8t)^{4t} \cdot \left(\sum_k \mathbb{E} \|\mathbf{Y}_k\|_{4t}^{4t} \right).$$

Proof. For a sequence of Hermitian matrices $\{\mathbf{X}_k\}_{k\geq 1}$ satisfying all the assumptions above, we have (Hermitian) matrix Rosenthal inequality [22] Corollary 7.4,

$$\mathbb{E}\left\|\sum_k \mathbf{X}_k\right\|_{4t}^{4t} \leq (16t)^{3t}\cdot\left\|\left(\sum_k \mathbb{E}\mathbf{X}_k^2\right)^{1/2}\right\|_{4t}^{4t} + (8t)^{4t}\cdot\sum_k \mathbb{E}\left\|\mathbf{X}_k\right\|_{4t}^{4t}.$$

We use Hermitian dilation to extend the inequality to non-Hermitian matrices by setting $\mathbf{X}_k = \mathcal{H}(\mathbf{Y}_k)$ and notice that

$$\mathbb{E}\left\|\sum_k \begin{bmatrix}\mathbf{0} & \mathbf{Y}_k\\ \mathbf{Y}_k^\intercal & \mathbf{0}\end{bmatrix}\right\|_{4t}^{4t} = \mathbb{E}\,\mathrm{tr}\left(\begin{bmatrix}((\sum_k \mathbf{Y}_k)(\sum_k \mathbf{Y}_k^\intercal))^{2t} & \mathbf{0}\\ \mathbf{0} & ((\sum_k \mathbf{Y}_k^\intercal)(\sum_k \mathbf{Y}_k))^{2t}\end{bmatrix}\right) = 2\mathbb{E}\left\|\sum_k \mathbf{Y}_k\right\|_{4t}^{4t},$$

$$\left\|\left(\sum_k \mathbb{E}\begin{bmatrix}\mathbf{Y}_k\mathbf{Y}_k^\intercal & \mathbf{0}\\ \mathbf{0} & \mathbf{Y}_k^\intercal\mathbf{Y}_k\end{bmatrix}\right)^{1/2}\right\|_{4t}^{4t} = \mathrm{tr}\left(\begin{bmatrix}\sum_k \mathbb{E}\mathbf{Y}_k\mathbf{Y}_k^\intercal & \mathbf{0}\\ \mathbf{0} & \sum_k \mathbb{E}\mathbf{Y}_k^\intercal\mathbf{Y}_k\end{bmatrix}\right)^{2t}$$

$$= \left\|\left(\sum_k \mathbb{E}\mathbf{Y}_k\mathbf{Y}_k^\intercal\right)^{1/2}\right\|_{4t}^{4t} + \left\|\left(\sum_k \mathbb{E}\mathbf{Y}_k^\intercal\mathbf{Y}_k\right)^{1/2}\right\|_{4t}^{4t},$$

$$\sum_k \mathbb{E}\left\|\begin{bmatrix}\mathbf{0} & \mathbf{Y}_k\\ \mathbf{Y}_k^\intercal & \mathbf{0}\end{bmatrix}\right\|_{4t}^{4t} = 2\sum_k \mathbb{E}\left\|\mathbf{Y}_k\right\|_{4t}^{4t}.$$

Hence, the result follows. ◀

▷ Claim 9. Let $\mathbf{F}(\mathbf{x})$ be a homogeneous multilinear polynomial random matrix of degree D. Let $\mathbf{F}(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(D)})$ be the decoupled $\mathbf{F}(\mathbf{x})$, i.e.,

$$\mathbf{F}(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(D)}) = \sum_{\mathbf{j}\in\mathcal{T}_n^D} \mathbf{A}_{\mathbf{j}}\cdot x_{j_1}^{(1)}\cdots x_{j_D}^{(D)},$$

where $\{\mathbf{A}_{\mathbf{k}}\}_{\mathbf{k}\in\mathcal{T}_n^D}$ is a multi-indexed sequence of deterministic matrices of the same dimension. For some fixed $a,b,c\in\mathbb{Z}_{\geq 0}$ and $k=a+b+c<D$, let $\mathbf{F}_{a,b,c}$ be the block matrix of k-th order partial derivatives of $\mathbf{F}(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(D)})$. Then $\mathbf{F}_{a,b,c}$ is a homogeneous multilinear polynomial random matrix of degree $d=D-k$. Furthermore,

$$\mathbb{E}\left\|\mathbf{F}_{a,b,c}\right\|_{4t}^{4t} \leq (16t)^{3t}\cdot\left(\mathbb{E}\left\|\mathbf{F}_{a+1,b,c}\right\|_{4t}^{4t} + \mathbb{E}\left\|\mathbf{F}_{a,b+1,c}\right\|_{4t}^{4t}\right) + (8t)^{4t}\cdot\mathbb{E}\left\|\mathbf{F}_{a,b,c+1}\right\|_{4t}^{4t}.$$

Proof. Without loss of generality, we differentiate $\mathbf{F}(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(D)})$ with respect to $\mathbf{x}^{(D)}$ first, then $\mathbf{x}^{(D-1)}$, and so on. It is straightforward to see that after $k=a+b+c$ rounds of differentiation, $\mathbf{F}_{a,b,c}(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)})$ is a homogeneous polynomial random matrix of degree $d=D-k$. And

$$\mathbf{F}_{a,b,c}(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)}) = \sum_{\mathbf{i}\in\mathcal{T}_n^d} \mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_d}^{(d)},$$

where $\{\mathbf{B}_{\mathbf{i}}\}_{\mathbf{i}\in\mathcal{T}_n^d}$ is a multi-indexed sequence of deterministic matrices of the same dimension. More specifically, each $\mathbf{B}_{\mathbf{i}}$ is a block matrix whose blocks consist of $\{\mathbf{A}_{\mathbf{j}}\}_{\mathbf{j}\in\mathcal{T}_n^D}$ such that $j_1=i_1,\ldots,j_d=i_d$.

Conditioned on $\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d-1)}$, $\mathbf{F}_{a,b,c}(\mathbf{x}^{(1)},\ldots,\mathbf{x}^{(d)})$ is a sum of centered, (conditionally) independent random matrices in $\mathbf{x}^{(d)}$. It follows that

$$
\begin{aligned}
&\mathbb{E}\left(\left\|\mathbf{F}_{a,b,c}(\mathbf{x}^{(1)},\dots,\mathbf{x}^{(d)})\right\|_{4t}^{4t}\;\middle|\;\mathbf{x}^{(1)},\dots\mathbf{x}^{(d-1)}\right)\\
&=\mathbb{E}\left(\mathbb{E}_{\mathbf{x}^{(d)}}\left(\left\|\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_d}^{(d)}\right\|_{4t}^{4t}\;\middle|\;\mathbf{x}^{(1)},\dots\mathbf{x}^{(d-1)}\right)\right)\\
&\le(16t)^{3t}\cdot\mathbb{E}\left\|\left(\sum_{i_d=1}^{n}\left(\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right)\left(\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right)^{\mathsf{T}}\right)^{1/2}\right\|_{4t}^{4t}\\
&\quad+(16t)^{3t}\cdot\mathbb{E}\left\|\left(\sum_{i_d=1}^{n}\left(\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right)^{\mathsf{T}}\left(\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right)\right)^{1/2}\right\|_{4t}^{4t}\\
&\quad+(8t)^{4t}L^{4t}\cdot\sum_{i_d=1}^{n}\mathbb{E}\left\|\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right\|_{4t}^{4t},
\end{aligned}
$$

where the inequality is due to matrix Rosenthal inequality (Lemma 8). Now we have

$$
\begin{aligned}
&\mathbb{E}\left\|\left(\sum_{i_d=1}^{n}\left(\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right)\left(\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right)^{\mathsf{T}}\right)^{1/2}\right\|_{4t}^{4t}\\
&=\mathbb{E}\left\|\left(\begin{bmatrix}\partial_{x_1^{(d)}}\mathbf{F}_{a,b,c} & \dots & \partial_{x_n^{(d)}}\mathbf{F}_{a,b,c}\end{bmatrix}\begin{bmatrix}\partial_{x_1^{(d)}}\mathbf{F}_{a,b,c}^{\mathsf{T}}\\ \vdots\\ \partial_{x_n^{(d)}}\mathbf{F}_{a,b,c}^{\mathsf{T}}\end{bmatrix}\right)^{1/2}\right\|_{4t}^{4t}=\mathbb{E}\left\|\mathbf{F}_{a,b+1,c}\right\|_{4t}^{4t},
\end{aligned}
$$

$$
\begin{aligned}
&\mathbb{E}\left\|\left(\sum_{i_d=1}^{n}\left(\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right)^{\mathsf{T}}\left(\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right)\right)^{1/2}\right\|_{4t}^{4t}\\
&=\mathbb{E}\left\|\left(\begin{bmatrix}\partial_{x_1^{(d)}}\mathbf{F}_{a,b,c}^{\mathsf{T}} & \dots & \partial_{x_n^{(d)}}\mathbf{F}_{a,b,c}^{\mathsf{T}}\end{bmatrix}\begin{bmatrix}\partial_{x_1^{(d)}}\mathbf{F}_{a,b,c}\\ \vdots\\ \partial_{x_n^{(d)}}\mathbf{F}_{a,b,c}\end{bmatrix}\right)^{1/2}\right\|_{4t}^{4t}=\mathbb{E}\left\|\mathbf{F}_{a+1,b,c}\right\|_{4t}^{4t},
\end{aligned}
$$

$$
\begin{aligned}
&\sum_{i_d=1}^{n}\mathbb{E}\left\|\sum_{\mathbf{i}\in\mathcal{T}_n^d}\mathbf{B}_{\mathbf{i}}\cdot x_{i_1}^{(1)}\cdots x_{i_{d-1}}^{(d-1)}\right\|_{4t}^{4t}\\
&=\mathbb{E}\,\mathrm{tr}\begin{bmatrix}\partial_{x_1^{(d)}}\mathbf{F}_{a,b,c}\cdot\partial_{x_1^{(d)}}\mathbf{F}_{a,b,c}^{\mathsf{T}} & & \\ & \ddots & \\ & & \partial_{x_n^{(d)}}\mathbf{F}_{a,b,c}\cdot\partial_{x_n^{(d)}}\mathbf{F}_{a,b,c}^{\mathsf{T}}\end{bmatrix}^{2t}=\mathbb{E}\left\|\mathbf{F}_{a,b,c+1}\right\|_{4t}^{4t}.
\end{aligned}
$$

◁

We present a moment bound for permutation symmetric, homogeneous multilinear polynomial random matrices of degree d.

▶ **Theorem 10** (Homogeneous Multilinear Recursion). *Let $\mathbf{x} = \{x_i\}_{i=1}^n$ be a sequences of i.i.d random variables with $\mathbb{E}x_i = 0$, $\mathbb{E}x_i^2 = 1$ and $|x_i| \le L$ for all $1 \le i \le n$. Let $\{\mathbf{A_i}\}_{\mathbf{i}\in\mathcal{T}_n^d}$ be a multi-indexed sequence of deterministic matrices of the same dimension. Define a permutation symmetric, homogeneous multilinear polynomial random matrix of degree d as*

$$\mathbf{F}(\mathbf{x}) = \sum_{\mathbf{i}\in\mathcal{T}_n^d} \left(\mathbf{A_i} \cdot \prod_{j\in\{i_1,\ldots,i_d\}} x_j \right).$$

Let $a, b, c \in \mathbb{Z}_{\ge 0}$ and $d = a + b + c$. Then for $2 \le t \le \infty$,

$$\mathbb{E}\left\|\mathbf{F}(\mathbf{x}) - \mathbb{E}\mathbf{F}(\mathbf{x})\right\|_{4t}^{4t} \le \sum_{\substack{a,b,c:\\ a+b+c=d}} (48dt)^{4dt} \cdot L^{4ct} \left\|\mathbf{F}_{a,b,c}\right\|_{4t}^{4t}.$$

Proof. Let $\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(d)}$ be d independent copies of $\mathbf{x}$. We decouple $\mathbf{F}(\mathbf{x})$ by Lemma 5,

$$E := \mathbb{E}\left\|\mathbf{F}((\mathbf{x})\right\|_{4t}^{4t} \le d^{4dt} \cdot \mathbb{E}\left\|\mathbf{F}(\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(d)})\right\|_{4t}^{4t}.$$

We take the partial derivative with respect to $\mathbf{x}^{(d)}$ by applying Lemma 8 to get,

$$E \le d^{4dt}(16t)^{3t} \cdot \left(\mathbb{E}\left\|\mathbf{F}_{1,0,0}\right\|_{4t}^{4t} + \mathbb{E}\left\|\mathbf{F}_{0,1,0}\right\|_{4t}^{4t}\right) + d^{4dt}(8t)^{4t}L^{4t} \cdot \mathbb{E}\left\|\mathbf{F}_{0,0,1}\right\|_{4t}^{4t}.$$

Note that $\mathbf{F}_{1,0,0}$, $\mathbf{F}_{0,1,0}$, and $\mathbf{F}_{0,0,1}$ are functions in variables $\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(d-1)}$. We take the partial derivative with respect to the rest of the variables until $\mathbf{F}_{a,b,c}$'s become deterministic matrices. Apply Claim 9 recursively and use the permutation symmetric property of $\mathbf{F}(\mathbf{x})$, we have

$$E \le \sum_{\substack{a,b,c:\\ a+b+c=d}} (16dt)^{4dt} \cdot L^{4ct} \frac{d!}{a!b!c!} \left\|\mathbf{F}_{a,b,c}\right\|_{4t}^{4t}.$$

Since $\frac{d!}{a!b!c!} \le \frac{d!}{(d/3)!(d/3)!(d/3)!}$ and $\frac{d!}{(d/3)!(d/3)!(d/3)!} \sim \frac{3\sqrt{3}}{2\pi d} \cdot 3^d$,

$$E \le \sum_{\substack{a,b,c:\\ a+b+c=d}} (48dt)^{4dt} \cdot L^{4ct} \left\|\mathbf{F}_{a,b,c}\right\|_{4t}^{4t}. \qquad \blacktriangleleft$$

As a corollary, we derive a moment bound for general multilinear polynomial random matrices of degree D. The polynomials are split into homogeneous parts and each parts are bounded separately. Let $\mathbf{F}^{=d}(\mathbf{x})$ denote the degree-d homogeneous part of $\mathbf{F}(\mathbf{x})$.

▶ **Corollary 11** (Multilinear Recursion). *Let $\mathbf{x} = \{x_i\}_{i=1}^n$ be a sequences of i.i.d random variables with $\mathbb{E}x_i = 0$, $\mathbb{E}x_i^2 = 1$ and $|x_i| \le L$ for all $1 \le i \le n$. Let $\{\mathbf{A_i}\}_{\mathbf{i}\in\mathcal{T}_n^d}$ be multi-indexed sequences of deterministic matrices of the same dimension. Define a degree-D multilinear polynomial random matrix as*

$$\mathbf{F}(\mathbf{x}) = \sum_{d=1}^{D} \sum_{\mathbf{i}\in\mathcal{T}_n^d} \left(\mathbf{A_i} \cdot \prod_{j\in\{i_1,\ldots,i_d\}} x_j \right).$$

Suppose $\mathbf{F}^{=d}(\mathbf{x})$ *is permutation symmetric for* $1 \le d \le D$. *Let* $a, b, c \in \mathbb{Z}_{\ge 0}$ *and* $d = a+b+c$. *Then for* $2 \le t \le \infty$,

$$\mathbb{E}\,\|\mathbf{F}(\mathbf{x}) - \mathbb{E}\mathbf{F}(\mathbf{x})\|_{4t}^{4t} \;\le\; \sum_{d=1}^{D} D^{4t}(48dt)^{4dt} \left(\sum_{\substack{a,b,c:\\ a+b+c=d}} L^{4ct} \left\|\mathbf{F}_{a,b,c}^{=d}\right\|_{4t}^{4t} \right).$$

Proof. We rewrite $\mathbf{F}(\mathbf{x})$ into a formal sum of its homogeneous parts $\mathbf{F}(\mathbf{x}) = \sum_{d=1}^{D} \mathbf{F}^{=d}(\mathbf{x})$. By the trace inequality (see [33] Theorem 3.1), we have

$$\mathbb{E}\,\|\mathbf{F}(\mathbf{x}) - \mathbb{E}\mathbf{F}(\mathbf{x})\|_{4t}^{4t} \le D^{4t} \sum_{d=1}^{D} \mathbb{E}\left\|\mathbf{F}^{=d}(\mathbf{x}) - \mathbb{E}\mathbf{F}^{=d}(\mathbf{x})\right\|_{4t}^{4t}.$$

By Theorem 10,

$$\mathbb{E}\,\|\mathbf{F}(\mathbf{x}) - \mathbb{E}\mathbf{F}(\mathbf{x})\|_{4t}^{4t} \le D^{4t} \sum_{d=1}^{D} (48dt)^{4dt} \left(\sum_{\substack{a,b,c:\\ a+b+c=d}} L^{4ct} \left\|\mathbf{F}_{a,b,c}^{=d}\right\|_{4t}^{4t} \right). \qquad \blacktriangleleft$$

5 Gaussian Polynomial Random Matrices

In this section, we prove a moment bound for polynomial random matrices with Gaussian random variables. While the decoupling technique could work for Gaussian polynomial random matrices as well, we base our recursion framework on the following bound for its simplicity.

▶ **Lemma 12** (Polynomial Moments, see [14] Theorem 7.1). *Let* $\mathbf{H}(\mathbf{x}) : \Omega \to \mathbb{H}^d$ *be a function with* $\mathbf{x} \sim \mathcal{N}(0, \mathbb{I}_n)$. *For* $t = 1$ *and* $t \ge 1.5$,

$$\mathbb{E}\,\|\mathbf{H}(\mathbf{x}) - \mathbb{E}\mathbf{H}(\mathbf{x})\|_{2t}^{2t} \;\le\; (\sqrt{2}t)^{2t} \cdot \mathbb{E}\,\mathrm{tr}\left(\sum_{i=1}^{n} (\partial_i \mathbf{H}(\mathbf{x}))^2 \right)^{t}. \tag{3}$$

The non-Hermitian version of Lemma 12 can be easily obtained by the technique of Hermitian dilation.

▶ **Lemma 13** (Non-Hermitian Polynomial Moments). *Let* $\mathbf{F}(\mathbf{x}) : \Omega \to \mathbb{R}^{d_1 \times d_2}$ *be a function with* $\mathbf{x} \sim \mathcal{N}(0, \mathbb{I}_n)$. *For* $t = 1$ *and* $t \ge 1.5$,

$$\mathbb{E}\,\|\mathbf{F}(\mathbf{x}) - \mathbb{E}\mathbf{F}(\mathbf{x})\|_{2t}^{2t} \;\le\; (\sqrt{2}t)^{2t} \cdot \left(\mathbb{E}\left\| \left(\sum_{i=1}^{n} \partial_i \mathbf{F}(\mathbf{x})\; \partial_i \mathbf{F}^{\mathsf{T}}(\mathbf{x}) \right)^{1/2} \right\|_{2t}^{2t} + \mathbb{E}\left\| \left(\sum_{i=1}^{n} \partial_i \mathbf{F}^{\mathsf{T}}(\mathbf{x})\; \partial_i \mathbf{F}(\mathbf{x}) \right)^{1/2} \right\|_{2t}^{2t} \right).$$

▶ **Theorem 14** (Gaussian Recursion). *Let* $\mathbf{x} \sim \mathcal{N}(0, \mathbb{I}_n)$ *and* $\{\mathbf{A}_\mathbf{i}\}_{\mathbf{i} \in [n]^d}$ *be multi-indexed sequences of deterministic matrices of the same dimension. Define a degree-d homogeneous Gaussian polynomial random matrix as*

$$\mathbf{P}(\mathbf{x}) = \sum_{\mathbf{i} \in [n]^d} \left(\mathbf{A}_\mathbf{i} \cdot \prod_{j \in \{i_1, \ldots, i_d\}} x_j \right).$$

Let $a, b \in \mathbb{Z}_{\geq 0}$. Then for $2 \leq t \leq \infty$,

$$\mathbb{E}\,\|\mathbf{P}(\mathbf{x}) - \mathbb{E}\mathbf{P}(\mathbf{x})\|_{2t}^{2t} \;\leq\; (2^d\sqrt{2}t)^{2t}\left(\sum_{1\leq a+b\leq d}\|\mathbb{E}\mathbf{P}_{a,b}\|_{2t}^{2t}\right).$$

Proof. Start by applying Claim 15 with $k = 0$. Apply Claim 15 recursively until $k = d-1$ to get the desired bound. ◀

▷ Claim 15. Let $\mathbf{x} \sim \mathcal{N}(0, \mathbb{I}_n)$ and $\{\mathbf{A}_\mathbf{i}\}_{\mathbf{i}\in[n]^d}$ be multi-indexed sequences of deterministic matrices of the same dimension. Define a degree-d homogeneous Gaussian polynomial random matrix as

$$\mathbf{P}(\mathbf{x}) = \sum_{\mathbf{i}\in[n]^d}\left(\mathbf{A}_\mathbf{i}\cdot\prod_{j\in\{i_1,\ldots,i_d\}}x_j\right).$$

Let $a, b \in \mathbb{Z}_{\geq 0}$ and $a + b = k < d$. Let $\mathbf{P}_{a,b}(\mathbf{x})$ be the k-th partial derivative block matrix associated to $\mathbf{P}(\mathbf{x})$. Then for $2 \leq t \leq \infty$,

$$\begin{aligned}\mathbb{E}\,\|\mathbf{P}_{a,b} - \mathbb{E}\mathbf{P}_{a,b}\|_{2t}^{2t} \;\leq\; &(2\sqrt{2}t)^{2t}\cdot\left(\mathbb{E}\,\|\mathbf{P}_{a+1,b} - \mathbb{E}\mathbf{P}_{a+1,b}\|_{2t}^{2t} + \|\mathbb{E}\mathbf{P}_{a+1,b}\|_{2t}^{2t}\right)\\ &+ (2\sqrt{2}t)^{2t}\cdot\left(\mathbb{E}\,\|\mathbf{P}_{a,b+1} - \mathbb{E}\mathbf{P}_{a,b+1}\|_{2t}^{2t} + \|\mathbb{E}\mathbf{P}_{a,b+1}\|_{2t}^{2t}\right).\end{aligned}$$

Proof. By the non-hermitian polynomial moment (Lemma 13), we have

$$\begin{aligned}E := \mathbb{E}\,\|\mathbf{P}_{a,b} - \mathbb{E}\mathbf{P}_{a,b}\|_{2t}^{2t} &\leq (\sqrt{2}t)^{2t}\cdot\left(\mathbb{E}\left\|\left(\sum_{i=1}^n\partial_i\mathbf{P}_{a,b}\;\partial_i\mathbf{P}_{a,b}^\mathsf{T}\right)^{1/2}\right\|_{2t}^{2t} + \mathbb{E}\left\|\left(\sum_{i=1}^n\partial_i\mathbf{P}_{a,b}^\mathsf{T}\;\partial_i\mathbf{P}_{a,b}\right)^{1/2}\right\|_{2t}^{2t}\right)\\ &= (\sqrt{2}t)^{2t}\cdot\left(\mathbb{E}\,\left\|\begin{bmatrix}\partial_1\mathbf{P}_{a,b} & \ldots & \partial_n\mathbf{P}_{a,b}\end{bmatrix}\right\|_{2t}^{2t} + \mathbb{E}\left\|\begin{bmatrix}\partial_1\mathbf{P}_{a,b}\\ \vdots\\ \partial_n\mathbf{P}_{a,b}\end{bmatrix}\right\|_{2t}^{2t}\right)\\ &= (\sqrt{2}t)^{2t}\cdot\left(\mathbb{E}\,\|\mathbf{P}_{a+1,b}\|_{2t}^{2t} + \mathbb{E}\,\|\mathbf{P}_{a,b+1}\|_{2t}^{2t}\right),\end{aligned}$$

where the last equality uses our notation for partial derivative block matrices introduced in Section 2. Notice that $\mathbf{P}_{a+1,b}$ and $\mathbf{P}_{a,b+1}$ are homogeneous Gaussian polynomial random matrix of degree $k-1$. Since $\mathbf{P}_{a+1,b}$ and $\mathbf{P}_{a,b+1}$ are not necessarily centered,

$$\begin{aligned}E \;&\leq\; (\sqrt{2}t)^{2t}\cdot\left(\mathbb{E}\,\|\mathbf{P}_{a+1,b} - \mathbb{E}\mathbf{P}_{a+1,b} + \mathbb{E}\mathbf{P}_{a+1,b}\|_{2t}^{2t} + \mathbb{E}\,\|\mathbf{P}_{a,b+1} - \mathbb{E}\mathbf{P}_{a,b+1} + \mathbb{E}\mathbf{P}_{a,b+1}\|_{2t}^{2t}\right)\\ &\leq\; (2\sqrt{2}t)^{2t}\cdot\left(\mathbb{E}\,\|\mathbf{P}_{a+1,b} - \mathbb{E}\mathbf{P}_{a+1,b}\|_{2t}^{2t} + \|\mathbb{E}\mathbf{P}_{a+1,b}\|_{2t}^{2t} + \mathbb{E}\,\|\mathbf{P}_{a,b+1} - \mathbb{E}\mathbf{P}_{a,b+1}\|_{2t}^{2t} + \|\mathbb{E}\mathbf{P}_{a,b+1}\|_{2t}^{2t}\right),\end{aligned}$$

where the last inequality is due to the trace inequality (see [33] Theorem 3.1). ◁

6 Application: Graph Matrices

Denote the Erdős-Rényi random graph on n vertices as $\mathcal{G}_{n,p}$, where each edge is present with probability p independent of all other edges. When $\mathcal{G}_{n,p}$ is viewed as a probability space, it is equal to $(\Omega, \mathcal{F}, \mu)$ where Ω is the sample space of all possible graphs on n vertices. Any $G \in \Omega$ is a random vector representing all edges. Each coordinate in G, denoted by G_{ij}, is an independent random variable representing a single edge. We can construct a

random graph by drawing a copy of $G \sim \mu$. To adopt the convention in p-biased Fourier analysis, we normalize G_{ij} such that $\mathbb{E}G_{ij} = 0$ and $\mathbb{E}G_{ij}^2 = 1$, which leads to the sample space $\Omega = \left\{-\sqrt{\frac{1-p}{p}}, \sqrt{\frac{p}{1-p}}\right\}^{\binom{n}{2}}$.

▶ **Definition 16** (Shape, see e.g. [29] Definition 4.2)**.** *A shape is a tuple $\tau = (V(\tau), E(\tau), U_\tau, V_\tau)$ where $(V(\tau), E(\tau))$ is a graph and U_τ, V_τ are ordered subsets of the vertices.*

▶ **Definition 17** (Graph matrix, see e.g. [29] Definition 4.4)**.** *Given a shape τ, the associated graph matrix $\mathbf{M} : \Omega \to \mathbb{R}^{d_1 \times d_2}$ is a matrix-valued function such that*

$$\mathbf{M}[I, J] = \sum_{\substack{\varphi \in \mathcal{T}_n^k: \\ \varphi(U_\tau)=I, \varphi(V_\tau)=J}} \prod_{(u,v)\in E(\tau)} G_{\varphi(u),\varphi(v)}.$$

In other words, $\mathbf{M}$ maps an input graph $G \in \Omega$ to a $\frac{n!}{(n-|I|)!} \times \frac{n!}{(n-|J|)!}$ matrix whose rows and columns are indexed by I and J respectively.

▶ **Definition 18** (Vertex Separator, see e.g. [29] Definition 4.8)**.** *For any shape τ, a vertex separator is a subset of vertices $S \subseteq V(\tau)$ such that there is no path from U_τ to V_τ in $\tau \setminus S$, which is the shape obtained by deleting S and all edges adjacent to S. We write S_τ for a vertex separator of the minimum size.*

▷ Claim 19. For any shape τ, let $\{E_1, E_2\}$ be an arbitrary cover of $E(\tau)$. Let $S = E_1 \cap E_2$ be the vertex set of the overlapping edges between E_1 and E_2. If S contains $E_1 \cap V_\tau$ and $E_2 \cap U_\tau$, then S is a vertex separator.

Proof. Since $S = E_1 \cap E_2$, there is no path from $E_1 \backslash S$ to $E_2 \backslash S$. Additionally, if S contains $E_1 \cap V_\tau$, then $E_1 \backslash S$ is not adjacent to V_τ and $E_1 \backslash S$ contains $U_\tau \backslash S$. If S also contains $E_2 \cap U_\tau$, then $E_2 \backslash S$ is not adjacent to U_τ and $E_2 \backslash S$ contains $V_\tau \backslash S$. Since there is no path from $U_\tau \backslash S$ to $V_\tau \backslash S$, S is a vertex separator. ◁

▶ **Theorem 20.** *For any shape τ and $2 \le t \le \infty$,*

$$\mathbb{E}\,\|\mathbf{M}\|_{4t}^{4t} \;\le\; \left((48t|V(\tau)|)^{4t|V(\tau)|}(C|E(\tau)|)^{|E(\tau)|}n^{|V(\tau)|}\right)\left(\sqrt{\frac{1-p}{p}}\right)^{4t|E(S_\tau)|} n^{2t(|V(\tau)|-|S_\tau|)}$$

where C is an absolute constant and $E(S_\tau)$ are all edges adjacent to S_τ.

Proof. First, let $|V(\tau)| = k$ and we write $\mathbf{M}$ as a polynomial whose coefficients are matrices,

$$\mathbf{M} = \sum_{\varphi \in \mathcal{T}_n^k} \mathbf{B}_{\varphi(E)} \prod_{(i,j)\in E(\tau)} G_{\varphi(i),\varphi(j)},$$

where the $[I, J]$-entry of $\mathbf{B}_{\varphi(E)}$ is

$$\mathbf{B}_{\varphi(E)}[I, J] = \begin{cases} 1 & \text{if } \varphi(U_\tau) = I \text{ and } \varphi(V_\tau) = J \\ 0 & \text{otherwise.} \end{cases}$$

Note that $\mathbf{B}_{\varphi(E)}$'s have the same dimension as $\mathbf{M}$ and the rows and columns of $\mathbf{B}_{\varphi(E)}$'s are indexed in the same way as $\mathbf{M}$. Since U_τ and V_τ are ordered and each φ assigns one set of value to vertices in U_τ and V_τ, there is only one nonzero entry in each $\mathbf{B}_{\varphi(E)}$. But there might be multiple φ's for which $\mathbf{B}_{\varphi(E)}$'s are identical due to free vertices.

Let $|E(\tau)| = d$ and we rewrite $\mathbf{M}$ in a permutation symmetric way,

$$\begin{aligned}\mathbf{M} &= \sum_{\varphi\in\mathcal{T}_n^k}\left(\frac{1}{d!}\sum_{\sigma\in\mathfrak{S}_d}\mathbf{B}_{\sigma(\varphi(E))}G_{\varphi(i_{\sigma(1)}),\varphi(j_{\sigma(1)})}\ \cdots\ G_{\varphi(i_{\sigma(d)}),\varphi(j_{\sigma(d)})}\right)\\ &= \frac{1}{d!}\sum_{\varphi\in\mathcal{T}_n^k}\mathbf{A}_{\varphi(E)}\cdot G_{\varphi(i_1),\varphi(j_1)}\ \cdots\ G_{\varphi(i_d),\varphi(j_d)},\end{aligned}$$

where $\mathbf{A}_{\varphi(E)} = \sum_{\sigma\in\mathfrak{S}_d}\mathbf{B}_{\sigma(\varphi(E))}$. Notice that the indices of the random variables of $\mathbf{M}$ have the same structure as in Lemma 6, so we can decouple $\mathbf{M}$ using Lemma 6,

$$F := \mathbb{E}\,\|\mathbf{M}\|_{4t}^{4t} \ \le\ |V(\tau)|^{4t|V(\tau)|}\left(\frac{1}{d!}\right)^{4t}\cdot\mathbb{E}\left\|\sum_{\varphi\in\mathcal{T}_n^k}\mathbf{A}_{\varphi(E)}\cdot G^{(1)}_{\varphi(i_1),\varphi(j_1)}\cdots G^{(d)}_{\varphi(i_d),\varphi(j_d)}\right\|_{4t}^{4t},$$

where $\{G^{(1)},\dots,G^{(d)}\}$ denote d independent copies of G. Since $\mathbf{M}$ is a multilinear polynomial random matrix, $\mathbb{E}\mathbf{M} = \mathbf{0}$. An application of Theorem 10 yields,

$$F\ \le\ \sum_{\substack{a,b,c:\\ a+b+c=|E(\tau)|}}(48t|V(\tau)|)^{4t|V(\tau)|}\left(\frac{1}{|E(\tau)|!}\right)^{4t}\left(\sqrt{\frac{1-p}{p}}\right)^{4ct}\|\mathbf{M}_{a,b,c}\|_{4t}^{4t},$$

where $\{\mathbf{M}_{a,b,c}\}$ are partial derivative block matrices associated to $\mathbf{M}$.

Fix a set of a,b,c, $\mathbf{M}_{a,b,c}$ is a block matrix whose blocks are comprised of $\{\mathbf{A}_{\varphi(E)}\}_{\varphi\in\mathcal{T}_n^k}$. More specifically, the $[I,J]$-th block of $\mathbf{M}_{a,b,c}$ is

$$\mathbf{M}_{a,b,c}[I,J] = \partial_{G_{I_1}}\cdots\partial_{G_{I_{a+c}}}\partial_{G_{J_1}}\cdots\partial_{G_{J_b}}\mathbf{M} = \mathbf{A}_{I\cup J} = \sum_{\sigma\in\mathfrak{S}_d}\mathbf{B}_{\sigma(I\cup J)}. \tag{4}$$

Algebraically, the last equality is due to the commutativity of partial derivative operators. Combinatorially, if we fix an arbitrary ordering on the edge set $E(\tau)$, the last expression is summing up all permutations on d edges in $E(\tau)$. Now let's delve into the combinatorics. Let $E(\tau) = E_1\cup E_2$, where E_1 contains $a+c$ edges and E_2 contains $b+c$ edges with c number of overlapping edges. Let $S = E_1\cap E_2$ be the set of vertices shared by E_1 and E_2. The row and column blocks of $\mathbf{M}_{a,b,c}$ are indexed by $\varphi(E_1)$ and $\varphi(E_2)$ respectively. Let's write

$$\mathbf{M}_{a,b,c} = \sum_{\sigma\in\mathfrak{S}_d}\mathbf{M}_{a,b,c,\sigma},$$

where $\mathbf{M}_{a,b,c,\sigma}[I,J] = \mathbf{B}_{\sigma(I\cup J)}$. Applying the trace inequality (see [33] Theorem 3.1), it follows that

$$F\ \le\ \sum_{\substack{a,b,c:\\ a+b+c=|E(\tau)|}}\sum_{\sigma\in\mathfrak{S}_d}(48t|V(\tau)|)^{4t|V(\tau)|}\left(\sqrt{\frac{1-p}{p}}\right)^{4ct}\|\mathbf{M}_{a,b,c,\sigma}\|_{4t}^{4t}. \tag{5}$$

For any two distinct σ_1 and $\sigma_2\in\mathfrak{S}_d$, $\|\mathbf{M}_{a,b,c,\sigma_1}\|_{4t}^{4t} = \|\mathbf{M}_{a,b,c,\sigma_2}\|_{4t}^{4t}$ since $\mathbf{M}_{a,b,c,\sigma_1}$ and $\mathbf{M}_{a,b,c,\sigma_2}$ are identical after permuting rows and columns. So we will focus on bounding $\|\mathbf{M}_{a,b,c,\sigma_0}\|_{4t}^{4t}$ where σ_0 is the identity permutation. For identity permutation, we have $\mathbf{M}_{a,b,c,\sigma_0}[I,J] = \mathbf{B}_{I\cup J}$ by (4). Denote $\mathbf{M}_{a,b,c,\sigma_0}$ by $\mathbf{F}$,

$$\begin{aligned}E &:= \|\mathbf{M}_{a,b,c,\sigma_0}\|_{4t}^{4t} = \|\mathbf{F}\|_{4t}^{4t} = \operatorname{tr}\left(\mathbf{F}^{\mathsf{T}}\mathbf{F}\right)^{2t}\\ &= \operatorname{tr}\sum_{I_1,\dots,I_{2t}\in[n]^{2(a+c)}}\ \sum_{J_1,\dots,J_{2t}\in[n]^{2(b+c)}}\mathbf{F}^{\mathsf{T}}[I_1,J_1]\,\mathbf{F}[I_1,J_2]\,\mathbf{F}^{\mathsf{T}}[I_2,J_2]\,\mathbf{F}[I_2,J_3]\cdots\mathbf{F}^{\mathsf{T}}[I_{2t},J_{2t}]\,\mathbf{F}[I_{2t},J_1]\\ &= \operatorname{tr}\sum_{I_1,\dots,I_{2t}\in[n]^{2(a+c)}}\ \sum_{J_1,\dots,J_{2t}\in[n]^{2(b+c)}}\mathbf{B}^{\mathsf{T}}_{I_1\cup J_1}\,\mathbf{B}_{I_1\cup J_2}\,\mathbf{B}^{\mathsf{T}}_{I_2\cup J_2}\,\mathbf{B}_{I_2\cup J_3}\cdots\mathbf{B}^{\mathsf{T}}_{I_{2t}\cup J_{2t}}\,\mathbf{B}_{I_{2t}\cup J_1}\end{aligned} \tag{6}$$

First of all, $\mathbf{B}_{I_i\cup J_i} \neq \mathbf{0}$ implies that $I_i \cup J_i = \varphi(E_1 \cup E_2)$, for some $\varphi \in \mathcal{T}_n^k$ and $I_i(S) = J_i(S)$ for $1 \le i \le 2t$. Similarly, $\mathbf{B}_{I_i\cup J_{i+1}} \neq \mathbf{0}$ implies that $I_i \cup J_{i+1} = \varphi'(E_1 \cup E_2)$, for some $\varphi' \in \mathcal{T}_n^k$ and $I_i(S) = J_{i+1}(S)$ for $1 \le i \le 2t$ (the additions in the subscripts are in mod $2t$, *i.e.*, $J_{2t+1} = J_1$). Secondly, for each $\mathbf{B}_{I_i\cup J_i} \neq \mathbf{0}$, there is only one nonzero entry, namely $\mathbf{B}_{I_i\cup J_i}[I_i \cup J_i(U_\tau), I_i \cup J_i(V_\tau)] = 1$. So $\mathbf{B}_{I_i\cup J_i}^\mathsf{T}\mathbf{B}_{I_i\cup J_{i+1}} \neq \mathbf{0}$ if $I_i \cup J_i(U_\tau) = I_i \cup J_{i+1}(U_\tau)$ and the only nonzero entry is

$$\mathbf{B}_{I_i\cup J_i}{}^\mathsf{T}\mathbf{B}_{I_i\cup J_{i+1}}[I_i \cup J_i(V_\tau), I_i \cup J_{i+1}(V_\tau)] = 1.$$

It follows that $\mathbf{B}_{I_i\cup J_i}^\mathsf{T}\mathbf{B}_{I_i\cup J_{i+1}} \neq \mathbf{0}$ for $1 \le i \le 2t$ if $J_1(E_2\cap U_\tau) = J_2(E_2\cap U_\tau) = \cdots = J_{2t}(E_2\cap U_\tau)$. Lastly, $\mathbf{B}_{I_i\cup J_i}^\mathsf{T}\mathbf{B}_{I_i\cup J_{i+1}}\mathbf{B}_{I_{i+1}\cup J_{i+1}}^\mathsf{T}\mathbf{B}_{I_{i+1}\cup J_{i+2}} \neq \mathbf{0}$ if $I_i \cup J_{i+1}(V_\tau) = I_{i+1} \cup J_{i+1}(V_\tau)$ and the only nonzero entry is

$$\mathbf{B}_{I_i\cup J_i}^\mathsf{T}\mathbf{B}_{I_i\cup J_{i+1}}\mathbf{B}_{I_{i+1}\cup J_{i+1}}^\mathsf{T}\mathbf{B}_{I_{i+1}\cup J_{i+2}}[I_i \cup J_i(V_\tau), I_{i+1} \cup J_{i+2}(V_\tau)] = 1.$$

It follows that $\mathbf{B}_{I_1\cup J_1}^\mathsf{T}\ \mathbf{B}_{I_1\cup J_2}\ \mathbf{B}_{I_2\cup J_2}^\mathsf{T}\ \mathbf{B}_{I_2\cup J_3}\cdots\mathbf{B}_{I_{2t}\cup J_{2t}}^\mathsf{T}\ \mathbf{B}_{I_{2t}\cup J_1} \neq \mathbf{0}$ if $I_1(E_1 \cap V_\tau) = I_2(E_1 \cap V_\tau) = \cdots = I_{2t}(E_1 \cap V_\tau)$ and the only nonzero entry is

$$\mathbf{B}_{I_1\cup J_1}^\mathsf{T}\ \mathbf{B}_{I_1\cup J_2}\ \mathbf{B}_{I_2\cup J_2}^\mathsf{T}\ \mathbf{B}_{I_2\cup J_3}\cdots\mathbf{B}_{I_{2t}\cup J_{2t}}^\mathsf{T}\ \mathbf{B}_{I_{2t}\cup J_1}[I_1 \cup J_1(V_\tau), I_{2t} \cup J_1(V_\tau)] = 1.$$

Since $I_1(E_1 \cap V_\tau) = I_{2t}(E_1 \cap V_\tau)$, we have $I_1 \cup J_1(V_\tau) = I_{2t} \cup J_1(V_\tau)$. So if the summand is nonzero, it has a 1 on its diagonal.

To summarize, each summand in (6) is nonzero if and only if $I_i \cup J_i = \varphi_i(E_1 \cup E_2), I_i \cup J_{i+1} = \varphi_i'(E_1 \cup E_2)$ for some $\varphi_i, \varphi_i' \in \mathcal{T}_n^k$, I_i's and J_i's agree on S, I_i's agree on $E_1 \cap V_\tau$ and J_i's agree on $E_2 \cap U_\tau$ for $1 \le i \le 2t$. Since each nonzero summand contributes a 1 on the diagonal, we can simply count the number of nonzero summands to compute the trace in (6). Notice that the number of nonzero summands is equal to the number of $\varphi_1, \ldots, \varphi_{2t}, \varphi_1', \ldots, \varphi_{2t}'$ that satisfy all the constraints. Hence

$$E \le n^{|S|}\ n^{|E_1\cap V_\tau|}\ n^{|E_2\cap U_\tau|}\ n^{2t|E_1\setminus V_\tau\setminus S|}\ n^{2t|E_2\setminus U_\tau\setminus S|}. \tag{7}$$

For a fixed set of a, b, c, (7) provides an upper bound for $\|\mathbf{M}_{a,b,c,\sigma}\|_{4t}^{4t}$ for any permutation $\sigma \in \mathfrak{S}_d$. But what is an upper bound for $\|\mathbf{M}_{a,b,c,\sigma}\|_{4t}^{4t}$ among all possible sets of a, b, c? By varying a, b, c, we can always make $S = E_1 \cap E_2$ large enough to contain vertices in $E_1 \cap V_\tau$ and $E_2 \cap U_\tau$. Thus S is a vertex separator by Claim 19. It follows that $E_1\setminus V_\tau\setminus S = E_1\setminus S$ and $E_2\setminus U_\tau\setminus S = E_2\setminus S$. Hence

$$E \ \le\ n^{|V(\tau)|}\ n^{2t|E_1\setminus S|}\ n^{2t|E_2\setminus S|} \ \le\ n^{|V(\tau)|}\ n^{2t(|V(\tau)|-|S_\tau|)}, \tag{8}$$

where S_τ is a vertex separator of minimum size. Substituting (8) into (5) yields the desired bound. ◀

▶ **Corollary 21.** *For any given shape τ, any $\varepsilon > 0$, with probability $1 - \varepsilon$,*

$$\|\mathbf{M}\| \ \le\ |V(\tau)|^{|V(\tau)|}\left(C\log\left(|E(\tau)|^{|E(\tau)|}n^{|V(\tau)|}/\varepsilon\right)\right)^{|V(\tau)|}\left(\sqrt{\frac{1-p}{p}}\right)^{|E(S_\tau)|}\sqrt{n}^{|V(\tau)|-|S_\tau|},$$

where $C > 0$ is an absolute constant.

Proof. By Markov's inequality and Theorem 20, we have

$$\begin{aligned}\mathbb{P}(\|\mathbf{M}\| \ge \theta) \ &\le\ \mathbb{P}(\|\mathbf{M}\|_{4t}^{4t} \ge \theta^{4t}) \ \le\ \theta^{-4t}\mathbb{E}\,\|\mathbf{M}\|_{4t}^{4t} \\ &= \theta^{-4t}\left((48t|V(\tau)|)^{4t|V(\tau)|}(C|E(\tau)|)^{|E(\tau)|}n^{|V(\tau)|}\right)\left(\sqrt{\frac{1-p}{p}}\right)^{4t|E(S_\tau)|}n^{2t(|V(\tau)|-|S_\tau|)}. \end{aligned}\tag{9}$$

Set the right hand side of (9) to ε by taking

$$\theta = \left(\varepsilon^{-\frac{1}{4t}}(48t|V(\tau)|)^{|V(\tau)|}(C|E(\tau)|)^{\frac{|E(\tau)|}{4t}} n^{\frac{|V(\tau)|}{4t}}\right)\left(\sqrt{\frac{1-p}{p}}\right)^{|E(S_\tau)|}\sqrt{n}^{|V(\tau)|-|S_\tau|}.$$

Take

$$t = \frac{1}{4}\log\left(|E(\tau)|^{|E(\tau)|}n^{|V(\tau)|}/\varepsilon\right)$$

to complete the proof. ◀

Listing 6-Cycles in Sparse Graphs

Virginia Vassilevska Williams
MIT, Cambridge, MA, USA

Alek Westover
MIT, Cambridge, MS, USA

Abstract

This work considers the problem of output-sensitive listing of occurrences of $2k$-cycles for fixed constant $k \geq 2$ in an undirected host graph with m edges and t $2k$-cycles. Recent work of Jin and Xu (and independently Abboud, Khoury, Leibowitz, and Safier) [STOC 2023] gives an $O(m^{4/3} + t)$ time algorithm for listing 4-cycles, and recent work by Jin, Vassilevska Williams and Zhou [SOSA 2024] gives an $\widetilde{O}(n^2 + t)$ time algorithm for listing 6-cycles in n node graphs. We focus on resolving the next natural question: obtaining listing algorithms for 6-cycles in the sparse setting, i.e., in terms of m rather than n. Previously, the best known result here is the better of Jin, Vassilevska Williams and Zhou's $\widetilde{O}(n^2 + t)$ algorithm and Alon, Yuster and Zwick's $O(m^{5/3} + t)$ algorithm.

We give an algorithm for listing 6-cycles with running time $\widetilde{O}(m^{1.6} + t)$. Our algorithm is a natural extension of Dahlgaard, Knudsen and Stöckel's [STOC 2017] algorithm for detecting a $2k$-cycle. Our main technical contribution is the analysis of the algorithm which involves a type of "supersaturation" lemma relating the number of $2k$-cycles in a bipartite graph to the sizes of the parts in the bipartition and the number of edges. We also give a simplified analysis of Dahlgaard, Knudsen and Stöckel's $2k$-cycle detection algorithm (with a small polylogarithmic increase in the running time), which is helpful in analyzing our listing algorithm.

1 Introduction

Listing copies of a small pattern graph that occur as subgraphs of a host graph is a fundamental problem in algorithmic graph theory. In this work, we consider the problem of listing C_{2k}'s (i.e., $2k$-cycles) for fixed constant $k \geq 2$. Some examples of applications of C_{2k} listing include analyzing social networks [9], and understanding causal relationships in biological interaction graphs [14]. (See e.g. [19] for further motivation.) In the following discussion we consider an n vertex m edge graph G with t C_{2k}'s (where $k \geq 2$ will be clear from context and t is not necessarily known).

The main reason for focusing on even length cycles is that while there are dense graphs that contain no odd cycles (e.g. bipartite graphs), a classic result of Bondy and Simonovits [6] states that any graph with at least $100kn^{1+1/k}$ edges contains a C_{2k}, for any integer

$k \geq 2$. This fact enables efficient "combinatorial" algorithms for C_{2k} detection, in contrast to the case of odd length cycles where efficient C_{2k+1} detection algorithms are based on matrix multiplication. In fact, very simple reductions (e.g. [16]) show that for any $k \geq 1$, C_{2k+1} detection is at least as hard as triangle detection, and the latter problem is known to be fine-grained subcubically equivalent to Boolean Matrix Multiplication [17]. Thus, fast algorithms for odd cycles cannot avoid matrix multiplication. We focus on even cycles from now on.

A classic result of Yuster and Zwick [19] shows how to determine whether a graph contains a C_{2k} in $O(n^2)$ time for any given constant $k \geq 2$. This quadratic running time is conjectured to be optimal in general (see [2, 15, 8], also discussed below); in particular, [2] gave concrete evidence for the hardness of C_4 detection.

Nevertheless, in the regime of sparser graphs, where $m < o(n^{1+1/k})$ improvements are possible. For C_4's there is a simple $O(m^{4/3})$ algorithm [5] that matches the performance of the $O(n^2)$ algorithm of [19] for $m = \Theta(n^{3/2})$, and improves on the performance for all $m < o(n^{3/2})$. Dahlgaard, Knudsen and Stöckel [8] give an algorithm for C_{2k} detection with running time $O(m^{2k/(k+1)})$ for every constant $k \geq 2$. This matches the $O(n^2)$ running time from [19] for $m = \Theta(n^{1+1/k})$ and improves on it for $m < o(n^{1+1/k})$.

In fine-grained complexity, it is common to assume widely-believed hypotheses and use reductions to obtain conditional lower bounds for fundamental problems. For the special case of cycle detection problems, most conditional lower bounds are based on hypotheses related to triangle detection. One of the most common hypotheses is that triangle detection in n-node graphs does not have a "combinatorial" [1] $O(n^{3-\varepsilon})$ time algorithm for $\varepsilon > 0$ (in the word-RAM model). Vassilevska W. and Williams [17] showed that this hypothesis is equivalent to the so called BMM Hypothesis that postulates that there is no $O(n^{3-\varepsilon})$ time combinatorial algorithm for multiplying two $n \times n$ *Boolean* matrices.

As mentioned earlier, it is easy to show that under the BMM hypothesis, detecting any odd cycle C_{2k+1} requires $n^{3-o(1)}$ time. Dahlgaard, Knudsen and Stöckel [8] gave lower bounds for combinatorial detection of even cycles of fixed length in *sparse* graphs. They show that there is no combinatorial algorithm for C_6 detection, or C_{2k} detection for any $k > 4$, with running time $O(m^{3/2-\varepsilon})$ for $\varepsilon > 0$. Lincoln and Vyas [15] give a similar conditional lower bound under a different hypothesis, extending the lower bounds for potentially non-combinatorial algorithms. Lincoln and Vyas show that, for large enough constant k, a C_{2k} detection algorithm in graphs with $m \leq O(n)$ with running time $m^{3/2-\varepsilon}$ would imply an algorithm for max-3-SAT with running time $2^{(1-\varepsilon')n}n^{O(1)}$.

The problem of *listing* even cycles is less well-understood. Without improving the C_{2k} detection algorithms discussed above, the best result that we could hope for in general is an algorithm with running time $O(n^2 + t)$, where t is the number of $2k$-cycles in the graph, and $O(m^{2k/(k+1)} + t)$ in the sparse setting where $m < o(n^{1+1/k})$. Recently, [3] and [12] gave such an algorithm for C_4 listing. In fact, Jin and Xu's [12] algorithm gives a stronger guarantee: After $O(m^{4/3})$ pre-processing time, they can (deterministically) enumerate 4-cycles with $O(1)$ delay per cycle. Jin and Xu [12] (and concurrently by Abboud, Bringmann, and Fischer [1]) shows that, under the 3SUM Hypothesis, there is no algorithm for C_4 enumeration with $O(n^{2-\varepsilon})$ or $O(m^{4/3-\varepsilon})$ pre-processing time and $n^{o(1)}$ delay, for $\varepsilon > 0$.

[1] The class of combinatorial algorithms is not well defined, but intuitively refers to algorithms that do not use fast matrix multiplication as a subroutine.

For C_6's, Jin, Zhou and Vassilevska Williams [11] give an $\widetilde{O}(n^2+t)$ listing algorithm. For sparse listing algorithms, the previous state of the art is [5] whose work implies an $O(m^{(2k-1)/k}+t)$ time C_{2k} listing algorithm. See also [7] where the complexity of the harder problem of listing H-partite[2] subgraphs is investigated.

1.1 Our contributions

We consider the problem of listing all C_6s in an m-edge graph. The best known result so far is an $O(m^{5/3}+t)$ time algorithm that follows from the work of [5]. Our main result is the first improvement over this 27 year old running time:

▶ **Theorem 23.** *There is an algorithm for listing C_6's in time $\widetilde{O}(m^{1.6}+t)$.*

We now summarize the ideas needed to prove Theorem 23.

Theorem 23 follows easily after establishing a certain bound on the number of **capped k-walks** in a graph. Capped k-walks are a notion introduced by Dahlgaard, Knudsen and Stöckel in [8]. Roughly speaking, a capped k-walk is a walk of length k where the first vertex in the walk has higher degree than the remaining vertices in the walk (handling vertices of equal degree requires a bit of additional care). [8]'s $O(m^{2k/(k+1)})$ time C_{2k} detection algorithm is based on the following fact:

▶ **Theorem 4** ([8]). *Let G be a C_{2k}-free graph with maximum degree $\Delta(G) \leq m^{2/(k+1)}$. Then, there are at most $\widetilde{O}(m^{2k/(k+1)})$ capped k-walks in G.*

One of our main contributions is a *simplified proof* of Theorem 4, although with polylogarithmically worse guarantees than [8]. This simplified analysis of capped k-walks is quite helpful in obtaining Theorem 23. The key lemma used to prove Theorem 4 is a generalization to bipartite graphs of Bondy and Simonovits' classic theorem on the extremal number of C_{2k}'s. Specifically, the result is:

▶ **Theorem 1** ([8]). *Let G be a bipartite graph with vertex parts of sizes L, R and with m edges. If $m > 100k(L+R+(LR)^{(k+1)/(2k)})$ then G contains a C_{2k}.*

In order to use capped k-walks for a listing algorithm, it would be useful to have a **supersaturation** variant of Theorem 1, which would guarantee the presence of *many* C_{2k}'s if the edge density is large; the fact that this supersaturation result could help with listing was communicated to us by Jin and Zhou [13]. The supersaturation analog of Bondy and Simonovits' [6] extremal number for C_{2k}'s is known:

▶ **Theorem 2** ([10]). *For every integer $k \geq 2$, there exist constants c, C such that if G is an n-node graph with $m \geq Cn^{1+1/k}$ edges, then G contains at least $c(m/n)^{2k}$ copies of C_{2k}.*

Jin and Zhou [13] formulated the following conjectured generalization of Theorem 2:

▶ **Conjecture 25.** (The Unbalanced Supersaturation Conjecture [Jin and Zhou'24]) *Let G be an m edge bipartite graph with vertex bipartition $A \sqcup B$, with t C_{2k}'s. Suppose $m \geq 100k(|A|+|B|+(|A||B|)^{(k+1)/2k})$. Then,*

$$t \geq \Omega\left(\frac{m^{2k}}{|A|^k|B|^k}\right).$$

[2] A k-node H is an H-partite subgraph of a k-partite graph G with vertex set $V = \cup_{a\in V(H)} V_a$ if there are k vertices $v_1, \ldots, v_k$ such that $v_a \in V_a$ for each $a \in \{1, \ldots, k\}$ and the mapping $a \to v_a$ is an isomorphism between H and the subgraph of G induced by $v_1, \ldots, v_k$. In other words, instead of looking for an arbitrary subgraph of G isomorphic to H, one only focuses on the subgraphs with exactly one node in each V_a and such that the node picked from V_a corresponds to node a of H.

Jin and Zhou obtained the following conclusion using the approach of [8]:

▶ **Fact 3** ([13]). If the Unbalanced Supersaturation Conjecture is true, then there is an $\widetilde{O}(t + m^{2k/(k+1)})$ time algorithm for $2k$-cycle listing for all $k \geq 2$.

In Corollary 29 we give a simple proof of Jin and Zhou's fact above. Thus, an approach to obtaining the conjectured optimal running time of $\widetilde{O}(t + m^{2k/(k+1)})$ for C_{2k}-listing would be to prove Conjecture 25. Unfortunately, establishing or refuting Conjecture 25 remains a challenging open problem.

Our main technical contribution is a proof of a weaker version of Conjecture 25 for $k = 3$. Then, we show that this partial progress towards Conjecture 25 can be used in our simplified method for analyzing capped k-walks to obtain a bound on the number of capped k-walks, and consequentially an improved C_6 listing algorithm in the sparse setting (namely, Theorem 23).

1.2 Open Questions

Proving or refuting Conjecture 25 is an important open question. It also is valuable to consider other avenues towards obtaining C_{2k} listing algorithms, especially in case Conjecture 25 turns out to be false. The listing algorithms of [11], [12], [3] use a variety of combinatorial insights that could potentially be generalized to larger k. It is also possible that a hybrid approach is productive: one can first use progress towards proving Conjecture 25 to force the instance to have a specific structure, and then use different combinatorial insights to solve the structured version of the problem.

1.3 Paper Outline

In Section 2 we present our simplified analysis of [8]'s C_{2k} detection algorithm. In Section A we show how to modify our simple analysis of [8]'s C_{2k} detection algorithm to get a C_{2k} listing algorithm, assuming the Unbalanced Supersaturation Conjecture. In Section 3 we present progress towards resolving the Unbalanced Supersaturation Conjecture. In Section 4 we show how to use our progress towards Conjecture 25 in our simplified capped k-walk analysis to obtain a listing algorithm for C_6's with running time $\widetilde{O}(m^{1.6} + t)$.

1.4 Notations

We use $\Delta(G)$ to denote the maximum degree of graph G. We write $N(v)$ to denote the neighborhood of vertex v, and for $S \subseteq V(G)$ we write $N_S(v)$ to denote $N(v) \cap S$. For graph G, we will use $V(G), E(G)$ to denote the vertex and edge sets of G. When G is clear from the context we also denote $V(G)$ by V and $E(G)$ by E. We let $n = |V|, m = |E|$ (when the graph being discussed is clear), and assume $m \geq n$. For vertex subsets A, B we write $e(A, B)$ to denote $|E \cap (A \times B)|$. A walk / path of length k will refer to a walk / path with k edges. Given $A, B \subseteq V$, we will write $G[A, B]$ to denote the induced subgraph on A, B, i.e., a graph with vertex set $A \cup B$ and edge set $E(G) \cap (A \times B)$. We will write $G[A]$ to denote $G[A, A]$.

We write $[x]$ to denote the set $\{1, 2, \ldots, \lceil x \rceil\}$. We use log to denote the base-2 logarithm. Define the **dyadic intervals** $\mathcal{I}_n$ as follows: letting n' denote the power of two in $[n, 2n)$, we define $\mathcal{I}_n = (\{0\}, \{1\}, [2, 4), [4, 8), \ldots, [n'/4, n'/2), [n'/2, n'])$. Note that $|\mathcal{I}_n| = 1 + \log n'$. For $j \in [\log n']$, the j-th dyadic interval refers to the j-th set in the list $\mathcal{I}_n$ of dyadic intervals, *starting counting from* $\{1\}$, or in other words *excluding the set* $\{0\}$. That is, the j-th dyadic interval is $[2^{j-1}, 2^j)$ for $j \in [(\log n') - 1]$ and the $(\log n')$-th one is $[n'/2, n']$.

2 A Simpler Analysis of the DKS C_{2k} Detection Algorithm

Dahlgaard, Knudsen and Stöckel [8] define **capped k-walks** and give a sophisticated analysis to bound the number of capped k-walks in C_{2k}-free graphs (assuming $\Delta(G) \leq m^{2/(k+1)}$). In this section we provide a simpler – although quantitatively worse by logarithmic factors – version of their analysis. This will be useful in future sections when we analyze the number of capped k-walks in graphs that are not C_{2k}-free.

Given a total ordering $\succ$ of the vertices in a graph, a **$\succ$-capped k-walk** [8] is a walk $x_0, x_1, \ldots, x_k$ where $x_0 \succ x_i$ for all $i \in [k]$. Throughout the paper we will assume implicitly an ordering $\succ$ of the vertices that satisfies $v_i \succ v_j$ whenever $\deg(v_i) > \deg(v_j)$ (but is otherwise arbitrary). Thus, we will refer simply to capped k-walks (leaving the dependence on $\succ$ implicit). The main result of this section is a simplified proof of the following fact:

▶ **Theorem 4** ([8]). *Let G be a C_{2k}-free graph with maximum degree $\Delta(G) \leq m^{2/(k+1)}$. Then, there are at most $\widetilde{O}(m^{2k/(k+1)})$ capped k-walks in G.*

We note that if G were (m/n)-regular then it would contain $\Theta(n(m/n)^k) \leq O(m^{2k/(k+1)})$ k-walks due to $m \leq O(n^{1+1/k})$ (which holds because G is C_{2k}-free). While a non-regular graph G may have more than $O(m^{2k/(k+1)})$ many k-walks, Theorem 4 states that G does not have more than this many *capped* k-walks (assuming $\Delta(G) \leq m^{2/(k+1)}$). At a high level, the proof of the bound on capped k-walks follows from applying the bipartite generalization of Bondy and Simonovits' extremal number bound [6] (Theorem 1) to a certain **layered organization** of the graph with nice regularity properties. This layered organization of the graph is our contribution.

In [8], the authors took a different approach: they defined the "ϕ-norm" of a vector v as

$$||v||_\phi = \int_0^\infty \sqrt{|\{i \mid |v_i| \geq x\}|}dx.$$

They then related the ϕ-norm of $X_G^k \mathbb{1}$, (where X_G is the graph's adjacency matrix and $\mathbb{1}$ is the all-ones vector) to the number of capped k-walks in G, and analyzed a large set of inequalities using combinatorial insights to bound this ϕ-norm. We find that the layered organization of the graph technique is more helpful than the ϕ-norm approach in elucidating [8]'s elegant result, and that this layered organization technique is easier to use in bounding the number of capped k-walks in graphs which are not C_{2k}-free. Our layered organization of the graph is depicted in Figure 1, and formally defined and analyzed in Lemma 5.

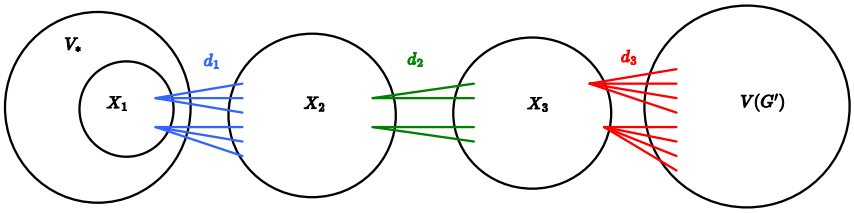

Figure 1 A layer pattern capturing many capped 3-walks.

▶ **Lemma 5.** *Fix graph G. There exists $d_* \in [n]$ such that if we let V_* denote the set of vertices with degree between $[d_*/2, d_*]$ and let G' denote the induced subgraph of G on vertices with degree at most d_*, then there exist $(X_1, \ldots, X_k) \subseteq V_* \times V(G')^{k-1}, (d_1, \ldots, d_k) \in \mathbb{N}^k$ such that letting $X_{k+1} = V(G')$,*

1. *The number of capped k-walks in G is at most $O(\log^{k+1} n)$ times the number of k-walks in $X_1 \times X_2 \times \cdots \times X_k \times V(G')$,*
2. *For each $i \in [k]$, every $v \in X_i$ has $|N_{X_{i+1}}(v)| \in [d_i/2, d_i]$.*

Proof. For $j \in [\log n]$, let V_j denote the set of vertices $v \in V$ with degree lying in the j-th dyadic interval. Fix j maximizing the number of capped k-walks in G that start in a vertex in V_j. Let $V_* = V_j, d_* = 2^j$, and let G' be the induced subgraph on vertices of degree at most d_*. The number of capped k-walks in G is at most $O(\log n)$ times the number of k-walks in G' that start in V_*; this is because the vertices in $V(G) \setminus V(G')$ are of too high degree to participate in a capped k-walk starting in V_*, and because every capped k-walk must start in some V_j.

For each $i_k \in [\log n]$ let $W^{(k)}_{i_k}$ denote the set of vertices in G' whose degree in G' lies in the i_k-th dyadic interval. Now, iteratively for $\ell = k-1, k-2, \ldots, 2$, for each $i_\ell \in [\log n]$ define $W^{(\ell)}_{i_k, i_{k-1}, \ldots, i_\ell}$ to be the set of vertices $v \in V(G')$ such that the number of neighbors of v in $W^{(\ell+1)}_{i_k, i_{k-1}, \ldots, i_{\ell+1}}$ lies in the i_ℓ-th dyadic interval. Finally, for each $i_1 \in [\log n]$ define $W^{(1)}_{i_k, i_{k-1}, \ldots, i_1}$ to be the set of vertices $v \in V_*$ such that the number of neighbors of v in $W^{(2)}_{i_k, i_{k-1}, \ldots, i_2}$ lies in the i_1-th dyadic interval.

Intuitively, looking at Figure 1, we are building up the sets X_ℓ from right to left. Here we think of $W^{(\ell)}_{i_k, i_{k-1}, \ldots, i_\ell}$ as representing X_ℓ for some choice of $i_k, i_{k-1}, \ldots, i_\ell$ that we will fix shortly.

Now, fix a choice $(i_k, \ldots, i_1) \in [\log n]^k$ that maximizes the number of k-walks

$$(x_1, \ldots, x_{k+1}) \in W^{(1)}_{i_k, \ldots, i_1} \times W^{(2)}_{i_k, \ldots, i_2} \times \ldots, W^{(k)}_{i_k} \times V(G'). \tag{1}$$

Note that every k-walk in G' starting in V_* must be of the form described in Equation (1) for *some* $(i_k, \ldots, i_1) \in [\log n]^k$. Thus, for our choice of $(i_k, \ldots, i_1)$, at least an $\Omega(1/\log^k n)$-fraction of the k-walks in G' starting in V_* are of the form Equation (1). For this choice of $(i_k, \ldots, i_1)$, we define for each $j \in [\log n]$,

$$X_j = W^{(j)}_{i_k, \ldots, i_j}, \quad d_j = 2^{i_j}.$$

These are the sets X_j, d_j that we wanted in the lemma statement, and they satisfy the required degree regularity property. Also because an $\Omega(1/\log^k n)$-fraction of the k-walks in G' starting in V_* are of the form Equation (1), and because the number of capped k-walks in G is at most $O(\log n)$ times the number of k-walks in G' starting in V_*, we have that the number of capped k-walks in G is at most $\widetilde{O}(1)$ times the number of k-walks of the form Equation (1). ◀

We have shown in Lemma 5 that in order to bound the number of capped-k walks in G, it suffices to bound the number of k-walks where each vertex of the k-walk is required to belong to a specific "layer" set, where consecutive layers satisfy a degree regularity property. This motivates studying how large an edge density we can have between two such consecutive layers while avoiding C_{2k}'s. First, we need a minor modification of Theorem 1.

▶ **Corollary 6.** *Let G be a C_{2k}-free graph. Fix $A, B \subseteq V(G)$ not necessarily disjoint. Then,*

$$e(A, B) \leq O(|A| + |B| + (|A||B|)^{(k+1)/(2k)}).$$

Proof. A well known fact (see e.g., [20]) in graph theory is that every m-edge graph has a bipartite subgraph with at least $m/2$ edges. Here we can apply the same idea. Let $C = A \cap B, A' = A \setminus C, B' = B \setminus C$. Form a partition of G as follows. Initialize $L = A', R = B'$

and then for every $c \in C$ place c in L with probability $1/2$ and in R otherwise. Then remove all edges not in $L \times R$. In expectation, at least half of the edges in $A \times B$ are preserved. Hence some setting of the random bits gives a bipartite subgraph with at least half the edges from $A \times B$ on which we can apply Theorem 1 to upper-bound $e(A,B)/2$ by $O(|L|+|R|+(|L||R|)^{(k+1)/(2k)})$ which is the desired quantity as $|L| \leq |A|$ and $|R| \leq |B|$. ◀

Now we prove a lemma to explain how consecutive layers in the decomposition of Lemma 5 interact.

▶ **Lemma 7.** *Let G be a C_{2k}-free graph with $\Delta(G) \leq m^{2/(k+1)}$. Fix $A \subseteq V(G)$ and $d \leq \Delta(G)$. Let B denote the set of vertices $v \in V(G)$ with $|N_A(v)| \in [d/2, d]$. Then,*

$$d\sqrt{|B|} \leq O(m^{\frac{1}{k+1}}\sqrt{|A|}).$$

Proof. Define $a = |A|, b = |B|, \Delta = \Delta(G)$. In this proof we will write $x \lesssim y$ to denote $x \leq O(y)$. We aim to show $d^2b/a \lesssim m^{2/(k+1)}$. This will follow from a simple chain of inequalities, with the main combinatorial ingredient being Corollary 6. In the inequalities we will use $\mathbb{1}_{[P]}$ to denote the indicator of whether P is true (i.e., it evaluates to 1 or 0 based on the truth of proposition P).

We have:

$$\begin{aligned}
d^2b/a &= \frac{(db)^2}{ab} \\
&\lesssim \min\left(\frac{d^2b}{a}, \frac{e(A,B)^2}{ab}\right) && B \text{ to } A \text{ degree regularity} \\
&\lesssim \min\left(\frac{d^2b}{a}, \frac{a^2+b^2+(ab)^{1+1/k}}{ab}\right) && \text{Corollary 6} \\
&\lesssim \min\left(\frac{d^2b}{a}, \frac{a}{b}\right) + \frac{b}{a} + \min\left(\frac{d^2b}{a}, (ab)^{1/k}\right) && \text{re-arrange terms} \\
&\lesssim \sqrt{\frac{d^2b}{a}\cdot\frac{a}{b}} + \frac{b}{a} + \min\left(\frac{d^2b}{a}, (ab)^{1/k}\right) && \min(x,y) \leq \sqrt{xy} \\
&\lesssim d + \frac{b}{a} + \min\left(\frac{d^2b}{a}, (ab)^{1/k}\right) && \text{simplify} \\
&\lesssim \Delta + \frac{b}{a} + \min\left(\frac{d^2b}{a}, (ab)^{1/k}\right) && d \leq \Delta \\
&\lesssim \Delta + \frac{\Delta\cdot a}{a} + \min\left(\frac{d^2b}{a}, (ab)^{1/k}\right) && b \leq \left|\bigcup_{v\in A} N(v)\right| \leq \Delta\cdot a \\
&\lesssim m^{2/(k+1)} + \min\left(\frac{d^2b}{a}, (ab)^{1/k}\right) && \Delta \leq m^{2/(k+1)} \\
&\lesssim m^{2/(k+1)} + \mathbb{1}_{[a>dm^{1-2/(k+1)}]}\cdot\frac{d^2b}{a} + \mathbb{1}_{[a\leq dm^{1-2/(k+1)}]}\cdot(ab)^{1/k} && \text{split min} \\
&\lesssim m^{2/(k+1)} + \frac{d^2b}{dm^{1-2/(k+1)}} + (dm^{1-2/(k+1)}b)^{1/k} && \text{monotonicity} \\
&\lesssim m^{2/(k+1)} + \frac{m}{m^{1-2/(k+1)}} + (m^{2-2/(k+1)})^{1/k} && db \leq O(m) \\
&\lesssim m^{2/(k+1)} && \text{simplify.}
\end{aligned}$$

◀

Now we combine Lemma 5 and Lemma 7 to obtain Theorem 4.

Proof of Theorem 4. We apply Lemma 5 to obtain $V_*, d_*, G', X_1, \ldots, X_k \subseteq V(G'), d_1, \ldots, d_k$ with the properties described in Lemma 5. We can easily count the number of k-walks in $X_1 \times \cdots \times X_k \times V(G')$ due to the regularity property that consecutive X_i's enjoy; it is at most

$$|X_1| \cdot \prod_{j=1}^{k} d_j. \tag{2}$$

We now bound Equation (2) using Lemma 7, which implies that for each $i \in [k-1]$,

$$d_i \sqrt{|X_i|} \leq O(m^{1/(k+1)} \sqrt{|X_{i+1}|}). \tag{3}$$

Repeatedly applying Equation (3) to Equation (2) gives:

$$|X_1| \prod_{j=1}^{k} d_j \leq \sqrt{|X_1||X_k|} d_k \cdot O(m^{(k-1)/(k+1)}). \tag{4}$$

To bound Equation (4) we make two observations. First, note that $|X_k| d_k \leq O(m)$ because all $v \in X_k$ have degree at least $d_k/2$. Second, recall that $X_1 \subseteq V_*$, and $d_* \geq d_k$. Thus, $|X_1| d_k \leq |X_1| d_* \leq O(m)$. Applying this in Equation (4) gives

$$|X_1| \prod_{j=1}^{k} d_j \leq O(m^{2k/(k+1)}). \tag{5}$$

By Lemma 5, the number of capped k-walks in G is at most $\widetilde{O}(1)$ times Equation (5); this is the desired bound. ◀

[8] showed that Theorem 4 implies a C_{2k} detection algorithm. The C_{2k} detection algorithm is based on the following slightly more general lemma; this lemma is also the basis of our listing algorithm.

▶ **Lemma 8.** *Fix parameter $\Delta \in \mathbb{N}$, and graph G. Let W be the number of capped k-walks in G that start at a vertex with degree at most Δ. There is a (randomized) algorithm to list the C_{2k}'s in G in time $\widetilde{O}(m^2/\Delta + W + t)$.*

Proof. Label the vertices $v_1, \ldots, v_n$, where $v_i \succ v_j$ iff $i > j$. For each $i \in [n]$, define a subgraph G_i on vertices $\{v_1, \ldots, v_i\}$, consisting of the edges that are part of the k-step BFS out of vertex v_i. For $i = 1, 2, \ldots, n$, we will list the C_{2k}'s in G_i that involve v_i. Note that this will result in listing all C_{2k}'s; in particular, if v_i is the largest (by $\succ$) vertex in some C_{2k}, then we will list this C_{2k} on iteration i of our procedure. Let t_i denote the number of C_{2k}'s in G_i that involve v_i; we now discuss how to list these C_{2k}'s. To list the C_{2k}'s in G_i involving v_i, we use color coding. We color each vertex with a random color from $[2k]$. Then we restrict our search to **colorful** C_{2k}'s: C_{2k}'s with a vertex of every color. Listing the colorful C_{2k}'s involving v_i can be done in time $O(|E(G_i)| + t_i)$. Each C_{2k} becomes colorful with probability $2^{-2k} \geq \Omega(1)$, so by repeating this $\widetilde{O}(1)$ times, we will list all the C_{2k}'s in G_i involving v_i, with high probability.

Now we analyze the cost of our algorithm. Note that $|E(G_i)|$ is at most the number of capped k-walks that start at v_i. Let T be the largest i such that $\deg(v_i) \leq \Delta$. Then, by definition

$$\sum_{i=1}^{T} |E(G_i)| \leq O(W).$$

There are at most m/Δ vertices of degree larger than Δ. Thus,

$$\sum_{i=T+1}^{n} |E(G_i)| \leq O(m^2/\Delta).$$

Finally, we have $\sum_i t_i = O(t)$. Combined, we see that the algorithm runs in time $\widetilde{O}(t + W + m^2/\Delta)$. ◀

▶ **Corollary 9.** *There is a (randomized) $\widetilde{O}(m^{2k/(k+1)})$ time algorithm for C_{2k} detection.*

Proof. This follows by applying Lemma 8 with $\Delta = m^{2/(k+1)}$ (and terminating the algorithm if it runs for too long). ◀

Lemma 8 and Corollary 9 can be derandomized using standard techniques (perfect hash families etc) [4].

3 Progress Towards the Supersaturation Conjecture

Jin and Zhou observed ([13]) that the unbalanced supersaturation conjecture implies sparse listing algorithms for even cycles of any length; we give a simple proof of this in Section A. In this section we present partial progress towards proving the unbalanced supersaturation conjecture. We restrict our attention to **hexagons** (C_6's) because this is the smallest case where sparse listing algorithms are not known. In Section 4 we will show that our partial progress towards the supersaturation conjecture can be translated into partial progress towards listing hexagons in time $O(m^{1.5} + t)$. Before stating our result, we state some simple folklore facts about path supersaturation (see Section B for proofs).

▶ **Fact 10.** Let G be a bipartite graph with parts A, B of sizes L, R. If $m \geq 2R$, then the number of 2-paths in $A \times B \times A$ is at least $L(m/L)(m/R)/2$.

▶ **Fact 11.** Let G be a bipartite graph with parts A, B of sizes L, R. If $m \geq 50(R+L)$, then the number of 4-paths in $A \times B \times A \times B \times A$ is at least $\Omega(L(m/L)^2(m/R)^2)$.

Our partial supersaturation result for hexagons is as follows:

▶ **Theorem 12.** *Let G be a bipartite graph with vertex bipartition $A \sqcup B$ and t hexagons. Let $L = |A|, R = |B|$ with $100 \leq L \leq R$, and let $d_L = m/L, d_R = m/R$. Suppose $m/\lceil \log(L+R) \rceil^{10} > L + R + (LR)^{2/3}$. Then, there is an absolute constant $c > 0$ such that*

$$t \geq d_R^3 d_L^3 \cdot \min(1, d_R^3/L, d_L^2 d_R^2/L^2) \cdot c/\log^{70} n.$$

Proof. Define $n = 2^{\lceil \log(L+R) \rceil}$. The constraint $100(\log n)^{10} \leq m \leq n^2$ implies $n \geq 10^8$.

Organizing the Graph. Our approach is to first organize the graph and then find hexagons via two and three step BFS's. The start of our organization of the graph is the following claim:

▷ Claim 13. There exist disjoint sets $A', A'' \subseteq A$ and $B', B'' \subseteq B$, of sizes $L' = |A'|, L'' = |A''|, R' = |B'|, R'' = |B''|$, and there exist values d'_L, d''_L, d'_R such that:

- Vertices $v \in A'$ have $|N_{B'}(v)| \in [d'_L/4, d'_L]$ and $e(A', B') \geq m/\log^4 n$.
- Vertices $v \in B'$ have $|N_{A''}(v)| \in [d'_R/4, d'_R]$ and $e(B', A'') \geq m/\log^4 n$.
- Vertices $v \in A''$ have $|N_{B''}(v)| \in [d''_L/4, d''_L]$ and $e(A'', B'') \geq m/\log^4 n$.

Proof. Define $Y_1 = Y_3 = A, Y_2 = Y_4 = B$. Form vertex subsets X_1, X_2, X_3, X_4 as follows. Define $X_4 = Y_4$. For $i = 3, 2, 1$ define X_i as follows: Partition $y \in Y_i$ based on which dyadic interval $|N_{X_{i+1}}(y)|$ falls in. Let X_i be a part in this partition with the maximum number of edges to X_{i+1}. The number of parts in our dyadic partition (disregarding the $\{0\}$ part, which does not contribute edges) is $\log n$. Thus,

$$e(X_4, X_3) \geq m/\log n, e(X_3, X_2) \geq m/\log^2 n, e(X_2, X_1) \geq m/\log^3 n. \tag{6}$$

Now, assign each vertex $v \in V(G)$ a uniformly random color from $\{0, 1\}$. For $i = 1, 2$ define X'_i to be the subset of X_i colored 0. For $i = 3, 4$ define X'_i to be the subset of X_i colored 1. Note that the sets X'_1, X'_2, X'_3, X'_4 are disjoint by construction: in particular, even though $X_2 \subseteq X_4$, by the coloring $X'_2 \cap X'_4 = \emptyset$.

We now argue that there exists some coloring such that the sets $\{X'_i \mid i \in [4]\}$ have similar sizes and degree regularity properties to the sets $\{X_i \mid i \in [4]\}$. First, because for each i, $|X_i| \geq 100$, with probability at least .9999 we have $|X'_i| \geq |X_i|/4$ for each i. Now, fix $i \in [3], v \in X_i$. The value $|N_{X'_{i+1}}(v)|$ is is a Bernoulli random variable with $|N_{X_{i+1}}(v)|$ trials, and $p = 1/2$ success probability for each trial. By a Chernoff bound,

$$\Pr[|N_{X'_{i+1}}(v)| \leq |N_{X_{i+1}}(v)|/4] \leq \exp(-|N_{X_{i+1}}(v)|/16). \tag{7}$$

Now, we will argue that $|N_{X_{i+1}}(v)|$ is large enough that we can afford to union bound across Equation (7) for all $i \in [3], v \in X_i$. For $i = 1, 2, 3$ choose d_i such that each vertex $v \in X_i$ has $|N_{X_{i+1}}(v)| \in [d_i/2, d_i]$; the sets X_i were constructed so that this is possible. Now, Equation (6) implies for $i \in [3]$ that

$$d_i \geq \frac{m}{|X_i| \log^3 n} \geq \log^7 n. \tag{8}$$

Therefore, the probability that Equation (7) fails for any $i \in [3], v \in X_i$ is at most

$$3n \exp(-(\log^7 n)/32) \leq .001.$$

Thus with probability at least .99, for each $i \in [4]$, $|X'_i| \geq |X_i|/4$, and if $i \neq 4$ then each vertex $v \in X'_i$ has $|N_{X'_{i+1}}(v)| \in [d_i/4, d_i]$, and finally (using Equation (6))

$$|X'_i| d_i \geq e(X'_i, X'_{i+1}) \geq \frac{1}{16} e(X_i, X_{i+1}) \geq m/\log^4 n.$$

Thus, by the probabilistic method there is some coloring that gives these properties. Fix this coloring, and let $A' = X'_1, A'' = X'_3, B' = X'_2, B'' = X'_4$. These are precisely the sets we wanted to show exist. ◁

We continue to use the sets A', B', A'', B'' introduced in Claim 13 throughout the proof, along with the values L', R', L'', R'' and d'_L, d''_L, d'_R. A useful immediate corollary of Claim 13 is

▶ **Corollary 14.** *$d'_L \geq (L/L')d_L/\log^4 n \geq d_L/\log^4 n$, $d'_R \geq (R/R')d_R/\log^4 n \geq d_R/\log^4 n$, and*
$d''_L \geq (L/L'')d_L/\log^4 n \geq d_L/\log^4 n$.

Now we further organize the vertices. In what follows, we will partition vertices based on the **approximate value** of some quantity associated with the vertex, by which we mean which of the dyadic intervals $\mathcal{I}_n$ the quantity lies in. For vertex v and vertex subset X, define $N^2_X(v)$ to be the set of vertices $w \in X$ that are distance 2 from v.

Fix vertex $v \in A'$. Define (X_v, x_v, δ_v) (visualized in Figure 2) as follows: Partition $w \in N^2_{A''}(v)$ into **buckets** based on the approximate value of $|N_{B'}(v) \cap N_{B'}(w)|$. Let $X_v \subseteq A''$ be a bucket which maximizes the number of edges between X_v and $N_{B'}(v)$. Let $x_v = |X_v|$, and choose $\delta_v \in \{1\} \cup \{4, 8, 16 \ldots, n\}$ such that each $w \in X_v$ has $|N_{B'}(v)| \in [\delta_v/2, \delta_v]$ (this is possible by the definition of $\mathcal{I}_n$, and the fact that the $\{0\}$ bucket does not contribute any edges). Then,

$$\delta_v x_v \geq e(X_v, N_{B'}(v)) \geq \frac{1}{\log n} e(N_{B'}(v), A'') \geq \frac{1}{16 \log n} \cdot d'_L d'_R. \tag{9}$$

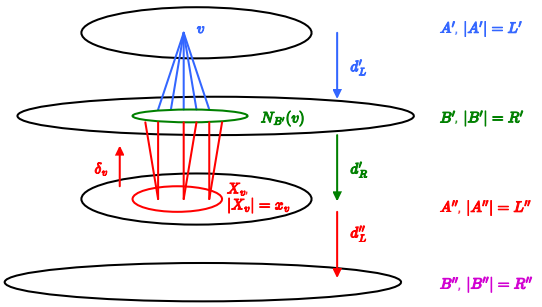

Figure 2 Organizing the graph.

Next, we assign each vertex $r \in N_{B'}(v)$ a tuple $(Y_{rv}, y_{rv}, \lambda_{rv})$ (visualized in Figure 3) as follows: Partition $z \in N^2_{B''}(r)$ into buckets based on the approximate value of $|N_{X_v}(r) \cap N_{X_v}(z)|$. Let $Y_{rv} \subseteq B''$ be a bucket which maximizes the number of edges between Y_{rv} and $N_{X_v}(r)$. Let $y_{rv} = |Y_{rv}|$ and choose $\lambda_{rv} \in \{1\} \cup \{4, 8, 16 \ldots, n\}$ such that each $z \in B''$ has $|N_{X_v}(r) \cap N_{X_v}(z)| \in [\lambda_{rv}/2, \lambda_{rv}]$. Then,

$$\lambda_{rv} y_{rv} \geq e(N_{X_v}(r), Y_{rv}) \geq \frac{1}{\log n} e(N_{X_v}(r), B''). \tag{10}$$

Finally, partition $r \in N_{B'}(v)$ into buckets based on the approximate values of $y_{rv}, \lambda_{rv}, |N_{X_v}(r)|$. Let $B'_v \subseteq B'$ be a bucket which maximizes the number of edges between B'_v and X_v. Choose y_v, λ_v, β_v (visualized in Figure 3) such that each $r \in B'_v$ has $y_{rv} \in [y_v/2, y_v]$, $\lambda_{rv} \in [\lambda_v/2, \lambda_v]$, and $|N_{X_v}(r)| \in [\beta_v/2, \beta_v]$. Then,

$$e(B'_v, X_v) \geq \frac{1}{\log^3 n} e(N_{B'}(v), X_v). \tag{11}$$

Counting Hexagons in the Organized Graph. Let $\mathsf{hex}(G)$ denote the number of hexagons in G. With the graph nicely organized we are prepared to bound $\mathsf{hex}(G)$. For vertex $v \in A'$, let $\mathsf{hex}(v)$ denote the number of hexagons in G where v is the only A' vertex participating in the hexagon. One natural way of bounding $\mathsf{hex}(G)$ is by $\mathsf{hex}(G) \geq \sum_{v \in A'} \mathsf{hex}(v)$. We will split into cases based on the characteristics of the 3-step BFS out of each vertex v and attempt to show that $\mathsf{hex}(v)$ is large. However, in one of the cases we will show $\mathsf{hex}(G)$ is large directly from the 3-step BFS out of a single vertex, rather than bounding $\mathsf{hex}(v)$. We now begin to consider 3-step BFS's based on their characteristics. See Figure 4 and Figure 5 for an illustration of our approach.

▷ Claim 15. Suppose vertex $v \in A'$ has $x_v d''_L/4 > 2R$ and $\delta_v \neq 1$. Then $\mathsf{hex}(v) \geq \Omega(d^3_R d^3_L/L')/\log^{26} n$.

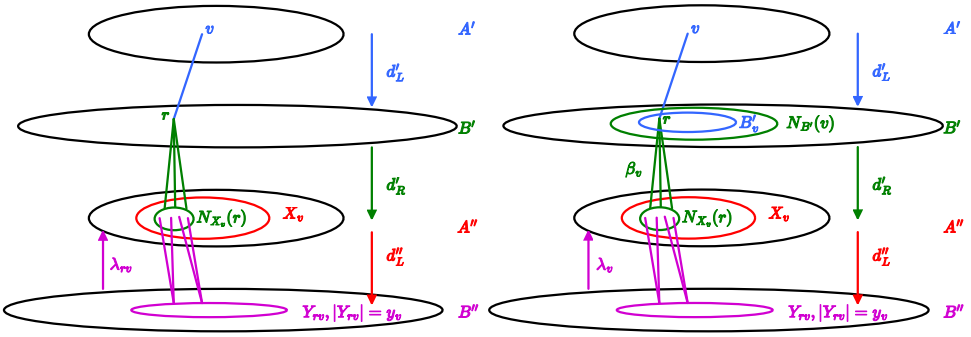

Figure 3 Organizing the graph.

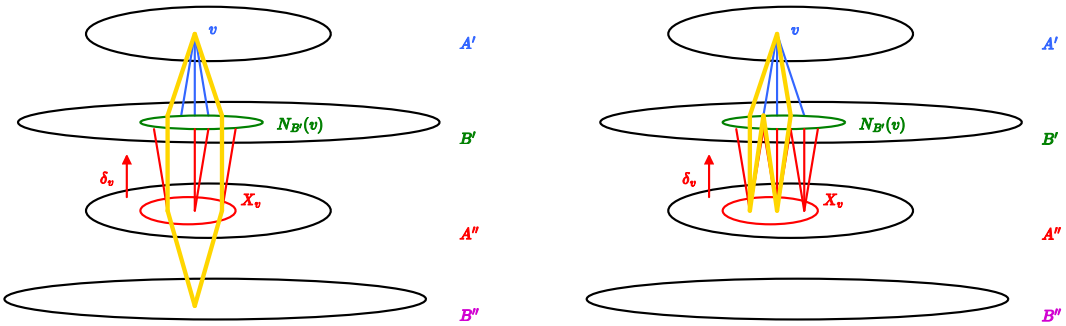
Proof. Recall that $e(X_v, B'') \geq x_v d''_L/4$, which by assumption of the claim is at least $2R$. Thus, Fact 10 implies that the number of 2-paths in $X_v \times B'' \times X_v$ is at least

$$\Omega((x_v d''_L)^2/R). \tag{12}$$



Given a two path $(w_1, z, w_2) \in X_v \times B'' \times X_v$, there are at least $(\delta_v/2)(\delta_v/2-1)$ ways to choose distinct $r_1 \in N_{B'}(w_1), r_2 \in N_{B'}(w_2)$. In this claim we are assuming $\delta_v \neq 1$ and consequentially $\delta_v \geq 4$. Thus, $(\delta_v/2)(\delta_v/2-1) \geq \delta_v^2/8$. Choosing r_1, r_2 in this manner, the vertices $(v, r_1, w_1, z, w_2, r_2)$ form a hexagon containing a single vertex from A'. Combined with Equation (12) this implies

$$\mathsf{hex}(v) \geq \Omega(\delta_v^2 (x_v d''_L)^2/R). \tag{13}$$

Using Equation (9) and Corollary 14 in Equation (13) gives

$$\mathsf{hex}(v) \geq \frac{1}{\log^2 n}\Omega((d'_L d'_R d''_L)^2/R) \geq \frac{1}{\log^{26} n}\Omega(d_R^3 d_L^3/L').$$

◁

(a) Claim 15. **(b)** Claim 19.

Figure 4 Two methods for showing that $\mathsf{hex}(v)$ is large.

Before proceeding to the next case, we make some simple observations.

▶ **Fact 16.** $d_R, d_L \geq \log^{10} n \geq 10^{14}$.

▶ **Corollary 17.** $d'_L d'_R d''_L/R \geq 10^{15} \log n$.

Proof. By Corollary 14 and Fact 16 we have

$$d'_L d''_L d'_R/R \geq (d_L^2 d_R/R)/\log^{12} n \geq (m^3/(LR)^2)/\log^{12} n \geq \log^{18} n \geq 10^{15}\log n. \quad \blacktriangleleft$$

▶ **Corollary 18.** $d'_R \geq 10^7 \log n$.

Proof. By Corollary 14 and Fact 16 we have

$$d'_R \geq d_R/\log^4 n \geq \log^6 n \geq 10^7 \log n. \quad \blacktriangleleft$$

▷ Claim 19. Suppose vertex $v \in A'$ has $x_v d''_L/4 \leq 2R$. Then $\mathsf{hex}(v) \geq \Omega((d_L d_R)^3 d_R^3/(LL'))/\log^{40} n$.

Proof. We claim that if x_v is this small then we have supersaturation of 4-paths between $N_{B'}(v)$ and X_v that start in $N_{B'}(v)$. Indeed, Equation (9), Corollary 17, Corollary 18 and our assumption that x_v is small imply

$$e(N_{B'}(v), X_v) \geq \frac{1}{16\log n} d'_L d'_R \geq 10^{12} R/d''_L + 10^5 d'_L \geq 50(d'_L + 8R/d''_L) \geq 50(d'_L + x_v).$$

Applying Fact 11, Equation (9), the hypothesis that x_v is small, and Corollary 14, the number of such 4-paths is at least

$$\frac{1}{\log^4 n}\Omega\left(\frac{(d'_L d'_R)^4}{d'_L x_v^2}\right) \geq \Omega((d_L d_R)^3 d_R^3/(LL'))/\log^{40} n.$$

Each of these 4-paths paired with v gives a hexagon that contributes to $\mathsf{hex}(v)$. This yields the desired bound on $\mathsf{hex}(v)$. ◁

The remaining two cases for what the BFS out of v looks like will both have $\delta_v = 1$. When $\delta_v = 1$, we have the following interesting property:

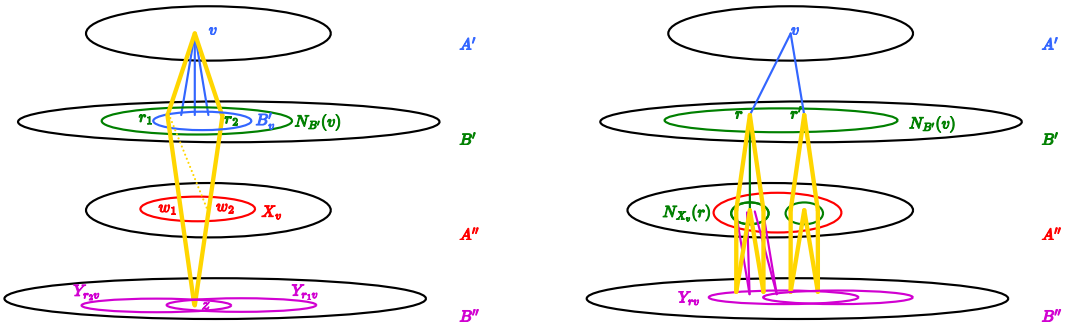
▷ Claim 20. Fix $v \in A'$ with $\delta_v = 1$. Then, $|B'_v| \geq d'_L/\log^5 n$ and $\beta_v \geq d'_R/\log^5 n$.

Proof. We count $e(B_{v'}, X_v)$ in two ways. First,

$$e(B_{v'}, X_v) \leq |B_{v'}|\beta_v. \tag{14}$$

Second, combining Equation (11) and Equation (9) we have

$$e(B_{v'}, X_v) \geq \frac{1}{\log^3 n} x_v \geq \frac{1}{16\log^4 n} d'_L d'_R. \tag{15}$$



Combining Equation (14) and Equation (15) gives

$$|B'_v|\beta_v \geq \frac{1}{\log^5 n} d'_L d'_R. \tag{16}$$

Now we recall upper bounds for $|B_{v'}|, \beta_v$. Applying $\beta_v \leq d'_R$ in Equation (16) gives $|B'_v| \geq d'_L/\log^5 n$. Applying $|B'_v| \leq d'_L$ in Equation (16) gives $\beta_v \geq d'_R/\log^5 n$. ◁

We are now ready to handle the cases where $\delta_v = 1$.

▷ Claim 21. Fix $v \in A'$ and suppose $y_v d'_L > (4\log^5 n)R$ and $\delta_v = 1$. Then $\mathsf{hex}(v) \geq \Omega((d_L^3 d_R^3)/L')/\log^{46} n$.

(a) Claim 21. **(b)** Claim 22.

Figure 5 Handling $\delta_v = 1$.

Proof. We construct an auxiliary graph H between B'_v and B'' as follows: place an edge between $r \in B'_v$ and $z \in B''$ if r, z have a common neighbor in X_v. We have, $|E(H)| \geq |B'_v| y_v/2$. By Claim 20, and the hypothesis of the claim we have

$$|E(H)| \geq \frac{1}{2\log^5 n} d'_L y_v \geq 2R. \tag{17}$$

Thus, applying Fact 10 to Equation (17), the number of 2-paths in H starting in B'_v, is at least

$$\frac{1}{\log^{10} n} \Omega\left((d'_L y_v)^2/R.\right). \tag{18}$$

Now, fix some 2-path $(r_1, z, r_2) \in B'_v \times B'' \times B'_v$ in H. There are at least $\lceil \lambda_v/4 \rceil^2$ pairs $w_1, w_2 \in X_v$ such that $w_i \in N(z) \cap N(r_i)$ for $i = 1, 2$. We claim that for each such w_1, w_2, the tuple $(v, r_1, w_1, z, w_2, r_2)$ is a hexagon. This is not immediately obvious: we need to rule out the possibility of $w_1 = w_2$ (in which case we would have a 4-cycle with a dangling edge rather than a true hexagon). Fortunately, we can rule this out: the fact $\delta_v = 1$ precisely means that for $i = 1, 2$, w_i has only 1 neighbor in B'_v. Thus, we get at least $\lceil \lambda_v/4 \rceil^2$ times the quantity in Equation (18) many hexagons. That is,

$$\mathsf{hex}(v) \geq \frac{1}{\log^{10} n} \Omega((d'_L y_v \lambda_v)^2/R). \tag{19}$$

Now, recall that Equation (10) gives a bound on $y_v \lambda_v$: it asserts that for any $r \in B'_v$ we have

$$y_v \lambda_v \geq y_{rv} \lambda_{rv} \geq \frac{1}{\log n} e(N_{X_v}(r), B'') \geq \frac{1}{\log n} |N_{X_v}(r)| d''_L/4 \geq \frac{1}{\log n} (\beta_v/2) d''_L/4. \tag{20}$$

Now, using Claim 20 we have

$$y_v \lambda_v \geq \frac{1}{\log^6 n} \Omega(d'_R d''_L). \tag{21}$$

Now, we can bound Equation (19) by

$$\mathsf{hex}(v) \geq \frac{1}{\log^{22} n} \Omega((d'_L d'_R d''_L)^2)/R.$$

Now, using Corollary 14 we have

$$\begin{aligned}\mathsf{hex}(v) &\geq \frac{1}{\log^{22} n}\Omega((d'_L d'_R d''_L)^2)/R \\ &\geq \frac{1}{\log^{26} n}\Omega(d'_L(d'_R d''_L)^2(m/L')/R) \\ &\geq \frac{1}{\log^{46} n}\Omega(d_L(d_R d_L)^2(m/L')/R) \\ &= \frac{1}{\log^{46} n}\Omega(d_L^3 d_R^3/L').\end{aligned}$$

◁

The final case is slightly different. Instead of bounding $\mathsf{hex}(v)$ we will directly bound $\mathsf{hex}(G)$.

▷ Claim 22. Fix $v \in A'$ with $\delta_v = 1$, $y_v d'_L \leq (4\log^5 n)R$, and $x_v d''_L > 8R$. Then $\mathsf{hex}(G) \geq \Omega((d_L d_R)^5/L^2)/\log^{67} n$.

Proof. We will find hexagons of the following form: Take $r \in B'_v$, and then let $(x_1, x_2, x_3, x_4, x_5)$ be a 4-path between $N_{X_v}(r)$ and Y_{rv} (starting in $N_{X_v}(r)$). Then, $(r, x_1, x_2, x_3, x_4, x_5)$ is a hexagon. We claim that we have 4-path supersaturation between $N_{X_v}(r)$ and Y_{rv}. Indeed, by Equation (10) we have

$$e(N_{X_v}(r), Y_{rv}) \geq \frac{1}{\log n} e(N_{X_v}(r), B'') \geq \frac{1}{4\log n}|N_{X_v}(r)|d''_L \geq \frac{1}{8\log n}\beta_v d''_L.$$

Then, by Claim 20 we have

$$e(N_{X_v}(r), Y_{rv}) \geq \frac{1}{8\log^6 n} d'_R d''_L. \tag{22}$$

Now, recall that $|N_{X_v}(r)| \leq d'_R$, so Equation (22) together with Corollary 14 and Fact 16 imply $e(N_{X_v}, Y_{rv}) \geq 100|N_{X_v}(r)|$. Next, observe that by Corollary 14, Equation (22) implies

$$|Y_{rv}| \leq y_v \leq (4\log^5 n)R/d'_L \leq \frac{1}{4\log n}\frac{LR}{m} \leq \frac{1}{4\log^{31} n}\frac{m^2}{LR} \leq \frac{d_L d_R}{\log^{31} n} \leq \frac{d'_R d''_L}{800\log^6 n} \leq \frac{e(N_{X_v}(r), Y_{rv})}{100}.$$

Combined, we have

$$e(N_{X_v}(r), Y_{rv}) \geq 50(|Y_{rv}| + |N_{X_v}(r)|),$$

which is the required condition for 4-path supersaturation. Now, applying Fact 11 to Equation (22) the number of 4-paths that we get is:

$$\Omega\left(\frac{e(N_{X_v}(r), Y_{rv})^4}{|N_{X_v}(r)||Y_{rv}|^2}\right) \geq \frac{1}{\log^{24} n}\Omega\left(\frac{(d'_R d''_L)^4}{\beta_v y_v^2}\right) \tag{23}$$

Applying our assumption on y_v and the bound $\beta_v \leq d'_R$ gives

$$\frac{1}{\log^{34} n}\Omega\left(\frac{(d'_R d''_L)^4}{d'_R(R/d'_L)^2}\right) \tag{24}$$

Applying Corollary 14 to Equation (24), the number of such 4-paths is at least

$$\frac{m^9}{L^6 R^5}\Omega(1/\log^{61} n).$$

Each $r \in B'_v$ contributes this many hexagons, and the contributed hexagons are distinct. Applying Claim 20 we have

$$\mathsf{hex}(G) \geq |B'_v|\frac{m^9}{L^6 R^5}\Omega(1/\log^{61} n) \geq \frac{m^{10}}{L^7 R^5}\Omega(1/\log^{67} n) \geq (d_R d_L)^3(d_L d_R/L)^2/\log^{67} n.$$ ◁

Now, we can easily combine Claim 15, Claim 19, Claim 21, Claim 22 to deduce the theorem. Indeed, if any vertex $v \in A'$ falls into the case described by Claim 22 then have the desired bound on $\mathsf{hex}(G)$. Otherwise, each vertex must fall into one of the cases covered in Claim 15, Claim 19, Claim 21. Picking whichever case is most common of these, we can sum over the $\mathsf{hex}(v)$ bounds for at least $|A'|/3 = L'/3$ many $v \in A'$. This gives the desired bound on $\mathsf{hex}(G)$. ◀

4 Progress Towards Listing Algorithms

In this section we describe how our partial progress towards Conjecture 25 in Theorem 12 can be used together with our simplified analysis capped k-walks analysis from Section 2 to give improved listing algorithms for C_6's in sparse graphs. Our main result is:

▶ **Theorem 23.** *There is an algorithm for listing C_6's in time $\widetilde{O}(m^{1.6} + t)$.*

Theorem 23 follows immediately from Lemma 8 with $\Delta = m^{.4}$ and the following lemma:

▶ **Lemma 24.** *Fix G with $\Delta(G) \leq m^{.4}$. The number of capped 3-walks in G is at most $\widetilde{O}(m^{1.6} + t)$.*

Proof. If $n \leq 1000$ the result is trivial; we assume this is not the case. Fix $\lambda = 200\lceil \log n \rceil^{15}$. As in Theorem 4 and Theorem 28 we use Lemma 5 to obtain $\mathcal{B} = (V_*, d_*, G', X_1, X_2, X_3, d_1, d_2, d_3)$ with the properties described in Lemma 5. The number of 3-walks in $X_1 \times X_2 \times X_3 \times V(G')$ is at most $|X_1| \cdot d_1 d_2 d_3$; recall that the number of capped 3-walks in G is at most $\text{polylog}(n)|X_1|d_1d_2d_3$ – thus, in the rest of this proof we'll focus on bounding $|X_1|d_1d_2d_3$. At this point we break into 576 cases (with the help of a computer). A **case** is parameterized by a tuple $(B_{12}, B_{23}, D_{12}, D_{23}, U_{12}, U_{23}, A_{12}, A_{23})$, whose entries can take on the following values:

- $B_{12} \in \{1, 2\}, B_{23} \in \{2, 3\}$. B_{12} indicates which of X_1, X_2 is bigger (B stands for "bigger"). More precisely, $|X_{B_{12}}| = \max(|X_1|, |X_2|)$. B_{23} is defined analogously.
- $D_{12}, D_{23} \in \{1, 2, 3\}$. D_{12}, D_{23} indicate the "density regime" (D stands for "density") that the graphs between (X_1, X_2) and (X_2, X_3) fall into. This means, letting $R = \max(|X_1|, |X_2|), L = \min(|X_1|, |X_2|), m_{12} = e(X_1, X_2)$ and letting $v_1 = 1, v_2 = (d_R^3/L)/\lambda^3, v_3 = (d_L^2 d_R^2/L^2)/\lambda^4$, we have that $v_{D_{12}} = \min(v_1, v_2, v_3)$. D_{23} is defined analogously.
- $U_{12} \in \{0, 1\}, U_{23} \in \{0, 1\}$. U_{12} indicates whether the graph between X_1, X_2 is "balanced" or "unbalanced" (U stands for "unbalanced"). More precisely, U_{12} is 1 if $R \geq (RL)^{2/3}$ and 0 if $R \leq (RL)^{2/3}$. U_{23} is defined analogously.
- $A_{12}, A_{23} \in \{0, 1\}$. A_{12} indicates whether we can charge any hexagons to the graph between X_1, X_2 (A stands for "any"). More precisely, A_{12} is 1 if $m \geq \lambda \max(|X_1|, |X_2|, (|X_1||X_2|)^{2/3})$ and 0 if $m \leq \lambda \max(|X_1|, |X_2|, (|X_1||X_2|)^{2/3})$. A_{23} is defined analogously.

Note that $\mathcal{B}$ falls into at least one case (and the cases are slightly overlapping on the equality cases). Now, let $\mathcal{C} = (B_{12}, B_{23}, D_{12}, D_{23}, U_{12}, U_{23}, A_{12}, A_{23}) \in \{1, 2\} \times \{2, 3\} \times \{1, 2, 3\}^2 \times \{0, 1\}^4$ be a case that describes $\mathcal{B}$. For $i = 1, 2, 3$, let $x_i = \log_m(|X_i|), \delta_i = \log_m(d_i/\lambda)$. Let $\delta_* = \log_m(d_*/\lambda)$, and let τ denote $\log_m(t/c)$ where t is the number of C_6's in G, and c is the constant from Theorem 12. We now outline a series of *linear* constraints that $(x_1, x_2, x_3, \delta_1, \delta_2, \delta_3, \tau)$ must satisfy.

$$x_1, x_2, x_3 \in [0,1] \qquad \forall i, |X_i| \leq n \leq m.$$
$$\delta_*, \delta_1, \delta_2, \delta_3 \in [0, .4] \qquad \Delta(G) \leq m^{.4}.$$
$$\tau \geq 0$$
$$\forall i \in [3], \delta_i \leq \delta_*. \qquad \Delta(G') \leq \delta_*.$$
$$\delta_* + x_1 \leq 1, \qquad |X_1|\delta_* \leq 2m$$
$$\forall i \in [3], \delta_i + x_i \leq 1 \qquad \forall i, |X_i| d_i \leq 2m.$$

Next, based on B_{12}, B_{23} we get ordering relationships between x_1, x_2, x_3. For instance, if $B_{12} = 1, B_{23} = 3$ then we add the constraints

$$x_1 \geq x_2, x_2 \leq x_3.$$

We get more constraints from U_{12}, U_{23}. For instance, if $U_{12} = 0, U_{23} = 1$ we add the following constraints:

$$\max(x_1, x_2) \leq 2\min(x_1, x_2), \max(x_2, x_3) \geq 2\min(x_2, x_3).$$

Note that while these constraints appear non-linear (due to the $\max, \min$) they are actually linear, because B_{12}, B_{23} already specify orders between x_1, x_2, and between x_2, x_3! So, based on the value of B_{12}, B_{23} we could "unroll" these min / max's to the appropriate x_i; we decline to do so here for clarity.

Next, we implement constraints based on A_{12}, A_{23}. If $A_{12} = 1$ the constraint will be

$$x_1 + \delta_1 \geq \max(x_1, x_2, (2/3)(x_1 + x_2)).$$

The constraint would be flipped if $A_{12} = 0$. The constraint is analogous for A_{23}. Again, the max can be unrolled due to the value of the max being determined by B_{12}, U_{12}.

Next we implement constraints based on D_{12}, D_{23}. For instance, if $D_{12} = 1$ we would add constraints (where, as always, the $\max, \min$'s can be unrolled):

$$0 \leq 3(x_1+\delta_1) - 3\max(x_1, x_2) - \min(x_1, x_2), 0 \leq 4(x_1+\delta_1) - 2\max(x_1, x_2) - 4\min(x_1, x_2).$$

Collecting Hexagons. Now, with all these constraints in place, we will use Theorem 12 to obtain a lower bound on the number of hexagons in our graph. Then we'll set up an optimization problem that tells us the slowest possible time for our algorithm, observe that this optimization problem is an LP in each case, and solve the LPs on a computer to find a bound on the performance of our algorithm.

If $A_{12} = 1$, then letting $\ell = \min(x_1, x_2), r = \max(x_1, x_2), e = x_1 + \delta_1$ we add the constraint

$$\tau \geq 6e - 3(r + \ell) + \min(0, 3e - 3r - \ell, 4e - 4\ell - 2r).$$

This constraint is implied by Theorem 12, and we satisfy the pre-condition of Theorem 12 because $A_{12} = 1$. Note that as usual, the min / max's can be unrolled based on the case. If $A_{23} = 1$ we add an analogous constraint on τ.

Bounding capped-3 walks. Now, we want to answer the following question: "subject to $(x_1, x_2, x_3, \delta_*, \delta_1, \delta_2, \delta_3)$ satisfying the above constraints, is it possible that the number of 3-walks in $X_1 \times X_2 \times X_3 \times V(G')$ is larger than $\widetilde{O}(m^{1.6} + t)$? We can answer this question in

the negative by requiring the number of 3-walks to be more than $\Omega(t \log^{45} n)$, and showing that subject to this constraint, the number of 3-walks cannot be larger than $O(m^{1.6})$. In our linear programming formulation, this corresponds to adding the constraint

$$x_1 + \delta_1 + \delta_2 + \delta_3 \geq \tau,$$

and optimizing the following objective function, which is the number of 3-walks (up to $\operatorname{poly}\log n$ factors):

$$x_1 + \delta_1 + \delta_2 + \delta_3.$$

If the objective function optimizes to a number which is at most 1.6, then it will prove that the number of 3-walks of the specified form cannot be larger than $\widetilde{O}(m^{1.6} + t)$.

So, we can prove the lemma by iterating over the 576 possible cases, defining the appropriate linear program in each case, and checking that the optimum of the linear program is at most 1.6. We wrote a simple program [18] to iterate over the cases and solve the linear programs. Running the code we find that the optimum of each linear program is at most 1.6, as desired. We leave developing a human interpretable proof as an open question. ◀

A Listing C_{2k}'s Using the Supersaturation Conjecture

Jin and Zhou [13] observed that the unbalanced supersaturation conjecture would allow one to obtain conditionally optimal sparse / dense listing algorithms for C_{2k}'s. In this section we give a simple proof of this observation, using the techniques of Section 2. Recall the unbalanced supersaturation conjecture:

▶ **Conjecture 25.** (The Unbalanced Supersaturation Conjecture [Jin and Zhou'24]) *Let G be an m edge bipartite graph with vertex bipartition $A \sqcup B$, with t C_{2k}'s. Suppose $m \geq 100k(|A| + |B| + (|A||B|)^{(k+1)/2k})$. Then,*

$$t \geq \Omega\left(\frac{m^{2k}}{|A|^k|B|^k}\right).$$

Conditional on Conjecture 25 we can follow the same proof strategy from Section 2 to obtain a C_{2k} listing algorithm. First, we need a simple consequence of Conjecture 25.

▶ **Corollary 26.** *Assume Conjecture 25. Fix G and $A, B \subseteq V(G)$* not necessarily disjoint. *Then,*

$$m \leq O(|A| + |B| + (|A||B|)^{(k+1)/(2k)} + t^{1/(2k)}\sqrt{|A||B|}).$$

Proof. As in Corollary 6, we pass to a bipartite subgraph with at least $m/2$ edges, while only decreasing $|A|, |B|, t$. Then we bound $m/2$ using Conjecture 25. ◀

Next we prove an analogue of Lemma 7, for analyzing the structure between two layers in the decomposition of Lemma 5.

▶ **Lemma 27.** *Assume Conjecture 25 Let graph G have $\Delta(G) \leq m^{2/(k+1)}$. Fix $A \subseteq V(G)$ and $d \leq \Delta(G)$. Let B denote the set of vertices $v \in V(G)$ that have $|N_A(v)| \in [d/2, d]$. Then,*

$$d\sqrt{|B|}/\sqrt{|A|} \leq O(m^{\frac{1}{k+1}} + t^{1/(2k)}).$$

Proof. The proof is nearly identical to that of Lemma 7. The only difference is that instead of applying the bound

$$e(A,B) \leq O(|A| + |B| + (|A||B|)^{(k+1)/(2k)}),$$

which applied when we assumed the graph was C_{2k}-free, we apply Corollary 26, which gives:

$$e(A,B) \leq O(|A| + |B| + (|A||B|)^{(k+1)/(2k)} + t^{1/(2k)}\sqrt{|A||B|}).$$

Substituting this new bound on $e(A,B)$ into the proof of Lemma 7 and otherwise leaving the analysis unchanged gives the desired bound on $d\sqrt{|B|/|A|}$. ◀

Now we deduce the analog of Theorem 4.

▶ **Theorem 28.** *Assume Conjecture 25. Let G be a graph with $\Delta(G) \leq m^{2/(k+1)}$. Then, the number of capped k-walks in G is at most $\widetilde{O}(m^{2k/(k+1)} + t)$.*

Proof. Just like in the proof of Theorem 4 we apply Lemma 5 to obtain V_*, d_*, G', $X_1, \ldots, X_k \subseteq V(G'), d_1, \ldots, d_k$ with the properties described in Lemma 5. The number of k-walks in $X_1 \times \cdots \times X_k \times V(G')$ is at most $|X_1| \cdot \prod_{j=1}^{k} d_j$. In Theorem 4 we bounded this product by repeatedly applying Lemma 7 (and then using an additional observation to bound $\sqrt{|X_1||X_k|}d_k$). Using Lemma 27 in place of Lemma 7 we have:

$$|X_1| \prod_{j=1}^{k} d_j \leq O((m^{1/(k+1)} + t^{1/(2k)})^{k-1} \cdot m). \tag{25}$$

Applying Hölder's Inequality to Equation (25) proves the desired bound on capped k-walks. ◀

Finally, we have the analog of Corollary 9.

▶ **Corollary 29.** *Assume Conjecture 25. Then, there is an algorithm for listing C_{2k}'s with running time $\widetilde{O}(t + \min(m^{2k/(k+1)}, n^2))$.*

Proof. First, we note that it is sufficient to establish the existence of an $\widetilde{O}(t + m^{2k/(k+1)})$ time algorithm. This is because balanced supersaturation results (Theorem 2) imply that if $m^{2k/(k+1)} > \Omega(n^2)$, meaning $m > \Omega(n^{1+1/k})$, then $t > \Omega(m^{2k/(k+1)})$, and so the t term dominates the running time. Now we give a listing algorithm with running time $\widetilde{O}(t + m^{2k/(k+1)})$.

Set $\Delta = m^{2/(k+1)}$. Assuming Conjecture 25, Theorem 28 implies that there are at most $\widetilde{O}(m^{2k/(k+1)} + t)$ capped-k walks starting at a vertex of degree at most Δ. Then, applying Lemma 8 gives a listing algorithm with the desired running time. ◀

B Folklore Results about Path Supersaturation

▶ **Fact 30.** Let G be a bipartite graph with parts A, B of sizes L, R. If $m \geq 2R$, then the number of 2-paths in $A \times B \times A$ is at least $L(m/L)(m/R)/2$.

Proof. Using Cauchy-Schwarz, the number of 2-paths is at least

$$\sum_{v \in B} \deg(v)(\deg(v) - 1) \geq \frac{1}{R}\left(\sum_{v \in B} \deg(v)\right)^2 - \sum_{v \in B} \deg(v) \geq m(m/R - 1) \geq m^2/(2R). \quad ◀$$

▶ **Fact 31.** Let G be a bipartite graph with parts A, B of sizes L, R. If $m \geq 50(R+L)$, then the number of 4-paths in $A \times B \times A \times B \times A$ is at least $\Omega(L(m/L)^2(m/R)^2)$.

Proof. Throughout the proof we use the notation $\deg_S(v) = |N(v) \cap S|$.

- Let B_1 be the set of vertices $v \in B$ with $\deg_A(v) \geq e(A,B)/(2|B|)$.
- Let A_1 be the set of vertices $v \in A$ with $\deg_{B_1}(v) \geq e(A,B_1)/(2|A|)$.
- Let B_2 be the set of vertices $v \in B_1$ with $\deg_{A_1}(v) \geq e(A_1,B_1)/(2|B_1|)$.

Observe that $e(A,B_1) \geq e(A,B)/2, e(A_1,B_1) \geq e(A,B)/4, e(A_1,B_2) \geq e(A,B)/8$. We now demonstrate that there are a large number of 4-paths starting in A. We can generate such a 4-path as follows:

- Fix an edge $(v_5, v_4) \in A_1 \times B_2$.
- Take $v_3 \in N_{A_1}(v_4)$, $v_2 \in N_{B_1}(v_3), v_1 \in N_A(v_2)$.

The number of such walks is at least:

$$\frac{e(A,B)}{8}\left(\frac{e(A,B)}{8|B_1|}-1\right)\left(\frac{e(A,B)}{4|A|}-1\right)\left(\frac{e(A,B)}{2|B|}-2\right) \geq \Omega(m^4/(LR^2)).$$ ◀

Polynomials, Divided Differences, and Codes

S. Venkitesh
Tel Aviv University, Israel

Abstract

Multiplicity codes (Kopparty et al., J. ACM 2014) are multivariate polynomial codes where the codewords are described by evaluations of polynomials (with a degree bound) and their derivatives up to some order (the multiplicity parameter), on a suitably chosen affine set of points. While efficient decoding algorithms were known in some special cases of point sets, by a reduction to univariate multiplicity codes, a general algorithm for list decoding up to the distance of the code when the point set is an arbitrary finite grid, was obtained only recently (Bhandari et al., IEEE TIT 2023). This required the characteristic of the field to be zero or larger than the degree bound, which is somewhat necessary since list decoding up to distance with small output list size is not possible when the characteristic is significantly smaller than the degree.

In this work, we present an alternative construction based on divided differences of polynomials, that conceptually resembles the classical multiplicity codes but has good list decodability "insensitive to the field characteristic". We obtain a simple algorithm that list decodes this code up to distance for arbitrary finite grids over all finite fields. Our construction can also be interpreted as a *folded Reed-Muller code*, which may be of independent interest.

1 Introduction and overview

Codes based on polynomial evaluations have found widespread applications, both implicitly and explicitly, in theoretical computer science, combinatorics, and allied areas. The prototypical univariate polynomial code is the *Reed-Solomon (RS) code* [57, 58], wherein the codewords are evaluations of degree bounded univariate polynomials on a set of points, and the prototypical multivariate polynomial code is the analogously defined *Reed-Muller (RM) code* [52, 57, 39, 68, 14]. [1] Despite several decades of research, the decodability properties of these codes are far from being well-understood.

[1] The RM code was considered over the binary field by [52, 57], and over larger fields by [39, 68, 14].

1.1 The list decoding problem

In this work, we are specifically interested in the *list decoding problem* [16, 69], where the aim is to output a list of close codewords for any given received word efficiently. The main parameter of interest is the *list decoding radius*, which represents the fraction of disagreements that we can decode from, and we would like it to be as large as possible.

Unique decoding of polynomial codes

To begin with, consider the easier setting where we fix the list decoding radius to be *half the minimum distance* of the code, which is precisely the setting of the *unique decoding problem* – in this case, there could only be at most one codeword this close to any given received word, and the aim is to efficiently find it if it exists. This problem has now been solved completely for RS codes [56, 49, 67], for univariate multiplicity codes [53], for RM codes in a special case [40, 5], and quite recently for RM codes in general [41] and for multivariate multiplicity codes [8]. What is noteworthy is that all of these algorithms are *insensitive to the field characteristic*. We now move on to consider larger list decoding radius.

List decoding of univariate polynomial codes

In the last decade of the 20th century, two classic works [65, 27] showed that all RS codes can be list decoded up to the *Johnson bound* (which is relative radius $1 - \sqrt{R}$, where R is the rate of the code), and also laid an algebraic algorithmic framework that has since been exploited over and over again for several other polynomial codes. Further, we do not know of explicit RS codes that can be list decoded beyond the Johnson bound, but we do know of explicit RS codes that are not list decodable significantly beyond the Johnson bound [7]. Due to recent breakthroughs [11, 26, 2], we now know that random RS codes are list decodable *up to (information theoretic) capacity* (that is, relative radius $1 - R - \epsilon$ for arbitrarily small but fixed $\epsilon > 0$, which represents getting approximately close to the information theoretic limit of list decoding), but we neither know of an explicit construction nor know of an algorithm to achieve this.

It is in this context of list decoding up to the information theoretic capacity that a *folding* trick has been enlightening. The works of [28, 29] showed that *folded Reed-Solomon (FRS) codes* (where the bits of an RS codeword are bunched into blocks of large constant size), and univariate multiplicity codes [43] (wherein the codewords are evaluations of polynomials and their derivatives up to a large constant multiplicity) can be algorithmically list decoded up to capacity! Further improvements to the parameters have been achieved in [44, 61, 63, 12] in different settings.

List decoding of multivariate polynomial codes

Moving on to multivariate polynomial codes, while the list decoding algorithms of [65, 27] generalize easily to RM codes, the decoding radius now worsens as a function of the number of variables, and attaining Johnson bound is no longer possible with these algorithms. While we know of a Johnson bound attaining algorithm [55] for RM codes when the finite grid is the full vector space $\mathbb{F}_q^m$ over the base field $\mathbb{F}_q$, designing a more general algorithm for arbitrary finite grids is still open!

As it turns out, the folding trick helps in the multivariate setting too. The multivariate multiplicity codes [45], which are the obviously defined multivariate analogues of univariate multiplicity codes, were shown to be list decodable *up to distance* (that is, up to radius $\delta - \epsilon$,

where δ is the minimum distance of the code) by [43] when the set of evaluation points is the full vector space $\mathbb{F}_q^m$. However, just as in the case of RM codes, an analogous result for arbitrary finite grids evaded us for quite some time. Very recently, [9] finally bolstered the algebraic algorithmic framework with some simple additional ingredients and managed to design an algorithm for list decoding multivariate multiplicity codes over arbitrary finite grids up to distance.

Sensitivity of list decodability to the field characteristic

Finally, yet another crucial component that could influence the performance of the code (specifically a polynomial code) is the most fundamental underlying algebraic object – the base field over which the polynomials are considered, which is always a finite field in our discussion.

Unlike the unique decoding setting that we mentioned earlier, we do observe sensitivity to the field characteristic in the setting of the list decoding problem. Let us fix the notation that $\mathbb{F}_q$ denotes the base field, and p denotes the characteristic of $\mathbb{F}_q$. On one hand, we know that when q is a large power of p, there are RS codes that cannot achieve anywhere close to list decoding capacity [7] since we can show instances of received words having superpolynomial sized output lists. On the other hand, upon large constant folding, the univariate multiplicity codes achieve capacity when p is larger than the degree parameter [29, 43], or smaller but linear in the degree [44], and the FRS codes achieve list decoding capacity [28, 29] insensitive to p. Thus, the list decodability of the FRS code is insensitive to the field characteristic, whereas the list decodability of the multiplicity code is sensitive to the field characteristic. Indeed, in the case when q is a large power of p, the large output lists shown by [7] for RS codes can be used to construct large output lists for multiplicity codes, and so the list decodability is provably poor.

Things get even more interesting in the multivariate setting, since the multivariate multiplicity codes achieve distance when p is larger than the degree parameter [55, 9], but we do not know of a field characteristic insensitive construction of a multivariate polynomial code that algorithmically achieves distance. Furthermore, we also do not know of an appropriate multivariate analogue of the field characteristic insensitive univariate FRS code. In this work, we answer both questions with a single code construction, along with a list decoding algorithm. In particular, our code subsumes the list decoding performance of the field characteristic sensitive multivariate multiplicity code [9], and also provides a natural *folded Reed-Muller code* construction. The motivation for our construction comes from an extremely simple yet foundational observation within the univariate world itself – the FRS code is also a multiplicity code!

1.2 FRS codes, univariate multiplicity codes, and divided differences

Fix a field $\mathbb{F}_q$. Consider distinct nonzero points $a_1, \ldots, a_n \in \mathbb{F}_q$. Let $\gamma \in \mathbb{F}_q^\times$ be a multiplicative generator, and suppose $s \geq 1$ such that the points $\gamma^j a_i$, $j \in [0, s-1]$, $i \in [n]$ are all distinct. For $k \in [sn]$, the degree-k Folded Reed-Solomon (FRS) code is defined by

$$\mathrm{FRS}_s(a_1, \ldots, a_n; k) = \left\{ [f]_{\mathrm{FRS}} := \begin{bmatrix} f(a_1) \\ f(\gamma a_1) \\ \vdots \\ f(\gamma^{s-1} a_1) \end{bmatrix} \middle| \cdots \middle| \begin{bmatrix} f(a_n) \\ f(\gamma a_n) \\ \vdots \\ f(\gamma^{s-1} a_n) \end{bmatrix} : \begin{array}{l} f(X) \in \mathbb{F}_q[X], \\ \deg(f) < k \end{array} \right\} \subseteq \left(\mathbb{F}_q^s\right)^n.$$

Here, the distance function is the Hamming distance on alphabet $\mathbb{F}_q^s$, that is, the Hamming weight [2] of a codeword $[f]_{\mathrm{FRS}}$ is the number of $i \in [n]$ such that the block $\begin{bmatrix} f(a_i) & f(\gamma a_i) & \cdots & f(\gamma^{s-1} a_i) \end{bmatrix}^{\mathsf{t}}$ is a nonzero vector in $\mathbb{F}_q^s$.

On the other hand, simply assuming $a_1, \ldots, a_n \in \mathbb{F}_q$ are distinct and nothing more about these points, for $k \in [sn]$, the degree-k (univariate) multiplicity code is defined by

$$\mathrm{Mult}_s(a_1, \ldots, a_n; k) = \left\{ [f]_{\mathrm{Mult}} := \begin{bmatrix} f^{(0)}(a_1) \\ f^{(1)}(a_1) \\ \vdots \\ f^{(s-1)}(a_1) \end{bmatrix} \middle| \cdots \middle| \begin{bmatrix} f^{(0)}(a_n) \\ f^{(1)}(a_n) \\ \vdots \\ f^{(s-1)}(a_n) \end{bmatrix} : \begin{array}{l} f(X) \in \mathbb{F}_q[X], \\ \deg(f) < k \end{array} \right\} \subseteq \left(\mathbb{F}_q^s\right)^n.$$

Here $f^{(j)}(X) := \frac{\mathrm{d}^j f(X)}{\mathrm{d}X^j}$ for all $j \in [0, s-1]$. [3] Once again, the Hamming weight of a codeword $[f]_{\mathrm{Mult}}$ is the number of $i \in [n]$ such that the block $\begin{bmatrix} f^{(0)}(a_i) & f^{(1)}(a_i) & \cdots & f^{(s-1)}(a_i) \end{bmatrix}^{\mathsf{t}}$ is a nonzero vector in $\mathbb{F}_q^s$.

Let us begin by looking at an algebraic feature that is intrinsic to multiplicity codes. Consider any $f(X) \in \mathbb{F}_q[X]$ with $\deg(f) < k$. For any $a \in \mathbb{F}_q$, we get the standard Taylor expansion

$$f(X) = f^{(0)}(a) + f^{(1)}(Y)(X-a) + f^{(2)}(a)\frac{(X-a)^2}{2!} + \cdots + f^{(k-1)}(a)\frac{(X-a)^{k-1}}{(k-1)!},$$

provided $p := \mathrm{char}(\mathbb{F}_q) \geq k$. Is there an analogous Taylor expansion in the context of the FRS code? As it turns out, there is such an expansion, and it is even simpler – it is the expansion in terms of the *Newton forward differences*. Precisely, we have

$$f(X) = f^{[0]}(a) + f^{[1]}(a)(X-a) + f^{[2]}(a)(X-a)(X-\gamma a) + \cdots + f^{[k-1]}(a)(X-a)\cdots(X-\gamma^{k-1}a),$$

where

$$f^{[0]}(a) = f(a), \;\; f^{[1]}(a) = \frac{f(\gamma a) - f(a)}{(\gamma-1)a}, \;\; \ldots, \;\; f^{[k-1]}(a) = \frac{f^{[k-2]}(\gamma a) - f^{[k-2]}(a)}{(\gamma^{k-1}-1)a}.$$

Notably, since $\gamma \in \mathbb{F}_q^\times$ is a multiplicative generator, we always have $\mathrm{ord}(\gamma) = q-1 \geq k$, and therefore, this expansion is valid *unconditional on* p.

In the first decade of the 20th century, Jackson [31, 32, 33] (also see [35, 34]) had defined the following specific *divided difference* operator on the polynomial ring,

$$\mathsf{D}_\gamma f(X) := \frac{f(\gamma X) - f(X)}{(\gamma-1)X}, \;\; \text{and} \;\; \mathsf{D}_\gamma^{t+1} := \mathsf{D}_\gamma \circ \mathsf{D}_\gamma^t \;\; \text{for all } t \geq 1.$$

In terms of this operator, the above expansion takes the form

$$f(X) = f(a) + \mathsf{D}_\gamma(a)(X-a) + \mathsf{D}_\gamma^2(a)\frac{(X-a)(X-\gamma a)}{[2]_\gamma!} + \cdots + \mathsf{D}_\gamma^{k-1}(a)\frac{(X-a)\cdots(X-\gamma^{k-1}a)}{[k-1]_\gamma!},$$

[2] We are only concerned with codes that are linear over the base field $\mathbb{F}_q$, and so the Hamming distance between two codewords c_1, c_2 is always equal to the Hamming weight of the codeword $c_1 - c_2$.

[3] Typically, since we are working over finite fields, there will also be a $j!$ scaling factor multiplied with the derivative, to prevent some pathologies arising in finite fields about higher multiplicity vanishing at a point. With this scaling factor, the derivative is usually called the Hasse derivative. We do not consider this, and implicitly assume that the characteristic is large enough so that these pathologies do not arise. Indeed, this is precisely the setting where the multiplicity codes have good list decodability.

where $[t]_\gamma := \frac{\gamma^t - 1}{\gamma - 1} = 1 + \gamma + \gamma^2 + \cdots + \gamma^{t-1}$, and $[t]_\gamma! := [t]_\gamma [t-1]_\gamma \cdots [1]_\gamma$. Returning to the code $\mathrm{FRS}_s(a_1, \ldots, a_n; k)$, it is then immediate by the definition of D_γ that there are invertible lower triangular matrices $U(a_i) \in \mathbb{F}_q^{s \times s}$, $i \in [n]$ such that for any codeword $[f]_{\mathrm{FRS}}$, we have

$$\begin{bmatrix} f(a_i) \\ \mathsf{D}_\gamma f(a_i) \\ \vdots \\ \mathsf{D}_\gamma^{s-1} f(a_i) \end{bmatrix} = U(a_i) \cdot \begin{bmatrix} f(a_i) \\ f(\gamma a_i) \\ \vdots \\ f(\gamma^{s-1} a_i) \end{bmatrix} \qquad \text{for all } i \in [n].$$

In other words, after a specific change of basis (see, for instance, [42, 4] for a proof), the FRS code can be interpreted as a *multiplicity code* with respect to the *derivative-like operator* D_γ.

Note that we have list decoding algorithms for FRS codes [28, 29], with the first one being algebraic and the second one being linear algebraic. If we are given the D_γ*-multiplicity encoding*, we may just change the basis to the usual FRS encoding and run one of these two FRS decoders. However, what is really encouraging is that we can straightforwardly adapt the linear algebraic multiplicity decoder [29] to our D_γ-multiplicity encoding, and the analysis will have a strong resemblance with that in the case of the classical derivatives. In this work, our main contribution is a construction that pushes this resemblance to the multivariate setting.

Our main algorithm will, in fact, work in the more general paradigm of list recovery, as was the case with the previous algorithms mentioned here.

Assumption on the field

Since our intention is to present the basic ideas as clearly and quickly as possible, we will stick to a simpler setting henceforth, where we assume that the evaluation points are contained in a finite field $\mathbb{F}_q$, but the polynomials are over a degree-3 field extension $\mathbb{K} = \mathbb{F}_{q^3}$. (See Remark 4.) We can relax this setting to some extent by tinkering with the parameters involved, but we will not make this effort.

The $\mathtt{Q}$-derivative

We will now forego the use of the symbol γ for the multiplicative generator. Instead we will denote $\mathtt{Q} \in \mathbb{K}^\times$ to be a multiplicative generator, and henceforth refer to the operator $\mathsf{D}_\mathtt{Q}$ as the $\mathtt{Q}$-derivative. This is the more standard terminology in the literature where this operator has appeared before. The $\mathtt{Q}$-derivative [4] is also called the *Jackson derivative*, and is a special case of the *Hahn derivative* [30], as well as the *Newton forward difference* [36, Chapter 1, Section 9]. See [37, Chapter 26] for a discussion on a slightly more general *quantum differential*, as well as some symmetrized variants. These are all instances of a broader notion of *divided difference* in *finite calculus* [46, 10, 54, 64, 36, 59]. The $\mathtt{Q}$-derivative seems to have been used so far only over fields of characteristic zero, particularly in *q-combinatorics* [18, 3, 21, 60, 20] and *quantum calculus* [37, 17, 47]. Further, the $\mathtt{Q}$-derivative does not seem to have made any explicit appearance so far in the *polynomial method* literature. However, as we see in this work, this notion turns out to be useful over fields of positive characteristic, and indeed, as part of the polynomial method.

[4] We use the notation '$\mathtt{Q}$' in $\mathtt{Q}$-derivative in this work instead of the more popular 'q', since we use q to denote the field size.

1.3 Multivariate $\mathtt{Q}$-derivatives, multivariate $\mathtt{Q}$-multiplicity code, and *folded RM code*

Our extension of $\mathtt{Q}$-derivatives from the univariate to multivariate setting is natural, and mimicks the extension of the classical derivatives. Assume indeterminates $\mathbb{X} = (X_1, \ldots, X_m)$, and for any $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ and $\alpha \in \mathbb{N}^m$, we define the α-th $\mathtt{Q}$-derivative as the iterated operator

$$\mathsf{D}^{\alpha}_{\mathtt{Q}} f(\mathbb{X}) := \mathsf{D}^{\alpha_1}_{\mathtt{Q},X_1} \cdots \mathsf{D}^{\alpha_m}_{\mathtt{Q},X_m} f(\mathbb{X}),$$

where $\mathsf{D}_{\mathtt{Q},X_i}$ denotes the univariate $\mathtt{Q}$-derivative in the variable X_i. It is easy to see that the operator $\mathsf{D}^{\alpha}_{\mathtt{Q}}$ is well-defined and invariant under the order of iterations, just as in the case of the classical partial derivatives.

Now consider indeterminates $\mathbb{Y} = (Y_1, \ldots, Y_m)$. For any $t \geq 0$, denote $(X_i - Y_i)^{(t)}_{\mathtt{Q}} := (X_i - Y_i)(X_i - \mathtt{Q}Y_i) \cdots (X_i - \mathtt{Q}^{t-1}Y_i)$, and further, for any $\alpha \in \mathbb{N}^m$, denote $(\mathbb{X} - \mathbb{Y})^{(\alpha)}_{\mathtt{Q}} := \prod_{i=1}^{m} (X_i - Y_i)^{(\alpha_i)}_{\mathtt{Q}}$. Also denote $[\alpha]_{\mathtt{Q}}! := [\alpha_1]_{\mathtt{Q}}! \cdots [\alpha_m]_{\mathtt{Q}}!$, and $\mathtt{Q}^{\alpha}\mathbb{X} = (\mathtt{Q}^{\alpha_1}X_1, \ldots, \mathtt{Q}^{\alpha_m}X_m)$. Then for any $s \geq 1$ and $a \in (\mathbb{F}_q^{\times})^m$, there exists (see Proposition 9) an invertible matrix $U(a) \in \mathbb{K}^{\binom{m+s-1}{s-1} \times \binom{m+s-1}{s-1}}$ such that

$$\left[\mathsf{D}^{\gamma}_{\mathtt{Q}} f(a)\right]_{|\gamma|<s} = U(a) \cdot \left[f(\mathtt{Q}^{\gamma} a)\right]_{|\gamma|<s} \qquad \text{for all } f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]. \tag{1}$$

Fix any $s \geq 1$, and consider any nonempty $A \subseteq \mathbb{F}_q^{\times}$. For any $k \in [s|A|]$, we define the m-variate multiplicity-s degree-k $\mathtt{Q}$-multiplicity code by

$$\begin{aligned}&\mathtt{Q}\text{-Mult}_{m,s}(A;k)\\ &\quad = \left\{[\mathsf{D}_{\mathtt{Q}} \mid f] := \left[\left[\mathsf{D}^{\gamma}_{\mathtt{Q}} f(a)\right]_{|\gamma|<s}\right]_{a \in A^m} : f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}],\, \deg(f) < k\right\} \subseteq \left(\mathbb{K}^{\binom{m+s-1}{s-1}}\right)^{|A|^m}.\end{aligned}$$

Note that the distance function is now the Hamming distance on the alphabet $\mathbb{K}^{\binom{m+s-1}{s-1}}$. Further, by the change of basis that we just saw above, we can define a natural multivariate analogue of the univariate FRS codes. For any $k \in [s|A|]$, we define the s-folded degree k folded Reed-Muller (FRM) code by

$$\begin{aligned}&\mathrm{FRM}_{m,s}(A;k)\\ &\quad = \left\{[\mathtt{Q} \mid f] := \left[\left[f(\mathtt{Q}^{\gamma} a)\right]_{|\gamma|<s}\right]_{a \in A^m} : f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}],\, \deg(f) < k\right\} \subseteq \left(\mathbb{K}^{\binom{m+s-1}{s-1}}\right)^{|A|^m}.\end{aligned}$$

So by (1), we clearly have the change of basis

$$\mathtt{Q}\text{-Mult}_{m,s}(A;k) = \mathrm{diag}(U(a) : a \in A^m) \cdot \mathrm{FRM}_{m,s}(A;k).$$

The rate and distance of our code constructions can be given as follows, which will be immediate from Corollary 11 and Theorem 13.

▶ **Proposition 1.** *For any $k \in [s|A|]$, the codes $\mathtt{Q}$-Mult$_{m,s}(A;k)$ and $\mathrm{FRM}_{m,s}(A;k)$ have*

rate equal to $\dfrac{\binom{m+k-1}{k-1}}{\binom{m+s-1}{s-1}|A|^m}$, *and distance at least* $1 - \dfrac{k-1}{s|A|}$.

1.4 Our result

Our main result is that over *any* field $\mathbb{F}_q$ with sufficiently large q, and for sufficiently large constant multiplicity s, any constant rate multivariate $\mathtt{Q}$-multiplicity code $\mathtt{Q}$-Mult$_{m,s}(A;k)$, can be efficiently list decoded up to distance.

▶ **Theorem 2.** *Consider any $\delta \in (0,1)$, $\epsilon \in (0, 1-\delta)$. For any $A \subseteq \mathbb{F}_q^\times$ and for the choices $s = O(1/\epsilon^{2m+1})$ and $k = \lceil (1-\delta)s|A| \rceil$, the code $\mathtt{Q}$-$\mathrm{Mult}_s^m(A;k)$ is efficiently list decodable up to radius $\delta - \epsilon$ with output list contained in a $\mathbb{K}$-affine space of dimension atmost $O(1/\epsilon^{2m})$.*

Our list decoding algorithm is conceptually simpler than that by [9] for the classical multivariate multiplicity codes. Their algorithm in the classical setting entailed recovering the close enough polynomial messages one homogeneous component at a time, while using the classical *Euler's formula for homogeneous polynomials* (that relates a homogeneous polynomial to its first order derivatives) [5] to fully recover a homogeneous component (or a partial derivative of it) from its further first order partial derivatives. This formula, as well as the Taylor expansion for classical derivatives employed within the recovery step, both require the field characteristic to be large. In our $\mathtt{Q}$-setting, firstly there is no Euler's formula involving $\mathtt{Q}$-derivatives, and interestingly we don't need one! Secondly, the Taylor expansion for $\mathtt{Q}$-derivatives is clearly field characteristic insensitive. These are the only two places in the analysis where conceptually, the field characteristic was relevant in the classical setting, and is now irrelevant in the $\mathtt{Q}$-setting. Further, the short and clean analysis that we obtain encourages us to believe that this construction is the correct way to obtain a folded version of the RM code.

Let us give a quick outline of our algorithm. We make use of a clean *gluing* trick from [9] [6] and then proceed to perform a simpler analysis that is extremely close to the univariate analysis of [29]. The informal takeaway of what we show is that

$$\text{gluing trick} \;+\; \text{univariate list decoding analysis} \;=\; \text{multivariate list decoding analysis}.$$

Suppose we are given the code $\mathtt{Q}$-$\mathrm{Mult}_{m,s}(A;k)$ as in the statement of Theorem 2. Consider any received word

$$w = \Big(w_a := \Big[w_a^{(\gamma)}\Big]_{|\gamma|<s} : a \in A^m\Big) \in \big(\mathbb{K}^{\binom{m+s-1}{s-1}}\big)^{|A|^m}.$$

Consider two fresh sets of indeterminates $\mathbb{Y} = (Y_\gamma)_{|\gamma|<s}$ and $\mathbf{Z} = (Z_1, \ldots, Z_m)$. For a suitably chosen parameter $r \leq s$, we will find a nonzero interpolating polynomial with coefficients in $\mathbb{K}[\mathbf{Z}]$, having the form

$$P(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) = \widetilde{P}(\mathbb{X}) + \sum_{j=0}^{r-1} P_j(\mathbb{X}) \Big(\sum_{|\gamma|=j} Y_\gamma \mathbf{Z}^\gamma \Big),$$

such that the following hold.

(Z1) The polynomials $\widetilde{P}(\mathbb{X}), P_0(\mathbb{X}), \ldots, P_{r-1}(\mathbb{X})$ must have suitably chosen $\mathbb{X}$-degree bounds. We will also simultaneously ensure a good $\mathbf{Z}$-degree bound on the coefficients of these polynomials by performing Gaussian elimination over $\mathbb{K}[\mathbf{Z}]$, as given in [38] or [9, Lemma 3].

(Z2) For any $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$, define a projection

$$P^{[f]}(\mathbb{X}) := \widetilde{P}(\mathbb{X}) + \sum_{j=0}^{r-1} \Big(\sum_{|\gamma|=j} \mathsf{D}_{\mathtt{Q}}^\gamma f(\mathbb{X}) \mathbf{Z}^\gamma \Big).$$

[5] Euler's formula states that for a homogeneous degree-d polynomial $f(\mathbb{X})$ over a field of characteristic greater than d, we have $\sum_{i=1}^m X_i \cdot \frac{\partial f(\mathbb{X})}{\partial X_i} = d \cdot f(\mathbb{X})$.

[6] As mentioned in [9], this gluing trick seems to have first appeared in the construction of a *hitting set generator* in [25].

Further, for every $\alpha \in \mathbb{N}^m$, $|\alpha| < s - r$, define a $\mathbb{K}(\mathbf{Z})$-linear operator $\Delta^{(\alpha)}$ (on an appropriate subspace of $\mathbb{K}(\mathbf{Z})[\mathbb{X}, \mathbb{Y}]$) that satisfies the condition $(\Delta^{(\alpha)}(P))^{[f]}(\mathbb{X}) = \mathsf{D}^{\alpha}_{\mathtt{Q}} P^{[f]}(\mathbb{X})$. The polynomial $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z})$ must now satisfy the vanishing conditions

$$\Delta^{(\alpha)}(P)(a, w_a, \mathbf{Z}) = 0 \qquad \text{for all } \alpha \in \mathbb{N}^m \text{ with } |\alpha| < s - r, \text{ and } a \in A^m.$$

Note that the vanishing conditions in (Z2) define a linear system on the coefficients of $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z})$, and we obtain the interpolating polynomial as a nontrivial solution of this linear system, by having large enough degree bounds as in (Z1). So for any close enough polynomial $f(\mathbb{X})$ (that is, having a large number of agreements with w), the conditions in (Z2) will imply that $P^{[f]}(\mathbb{X})$ vanishes at the agreement points with multiplicity at least $s - r$ (in the sense of multivariate $\mathtt{Q}$-derivatives, which we will define later), and this will imply that $P^{[f]}(\mathbb{X}) = 0$ by a suitable version of Polynomial Identity Lemma for multivariate $\mathtt{Q}$-derivatives. We can then solve this equation to recover $f(\mathbb{X})$. Importantly, the list decoding radius is dependent on the choice of r. We can achieve list decoding up to distance, that is, the claim of Theorem 2 by choosing $s = O(1/\epsilon^{2m})$ and $r = O(1/\epsilon^m)$. In fact, as in the analyses of [29, 9], we will show that the collection of all close enough polynomials is contained in a $\mathbb{K}$-affine subspace having dimension at most $\binom{m+r-2}{r-2}$.

This is a fairly simple strategy, very much within the algebraic algorithmic framework started employed in previous list decoding algorithms [65, 27, 28, 29, 43, 9]. Further, employing the gluing trick with the additional $\mathbf{Z}$-variables as in [9] allows us to formulate what we believe is the correct way to extend the linear algebraic decoding framework from the univariate to the multivariate setting, and our extension turns out to be simpler than the analysis in [9].

There is a subtlety in the recovery step in our multivariate setting vis-à-vis the univariate setting. When we solve the equation $P^{[f]}(\mathbb{X}) = 0$ to recover a close enough polynomial $f(\mathbb{X})$, we will see that the coefficients of $f(\mathbb{X})$ will be captured within the coefficients of some linear relations between monomials in the $\mathbf{Z}$-variables. Using a large enough efficient hitting set (an interpolating set of affine points that is large enough to certify all polynomials with a degree bound) in the $\mathbf{Z}$-variables, we can then recover each of these coefficients. This is similar to what was done in [9] in an analogous situation, but our overall analysis is a bit different and simpler. We will outline this difference now.

Formally, for a vector space $V_d \subseteq \mathbb{K}[\mathbf{Z}]$ of all polynomials having degree at most d, a hitting set is a finite set $H \subseteq \mathbb{K}^m$ such that for any $g(\mathbf{Z}) \in V_d$, if $g(\mathbf{Z}) \neq 0$ then there exists $u \in H$ such that $g(u) \neq 0$. For instance, by the Combinatorial Nullstellensatz [1, Theorem 1.1], every finite grid S^m with $S \subseteq \mathbb{K}$, $|S| > d$ is a hitting set for V_d. (We will precisely use this obvious hitting set in our analysis.) Our departure from the analysis of [9] is that they need to recover the coefficients of $f(\mathbb{X})$ one homogeneous component at a time, by employing the Euler's formula. In our analysis, we will directly recover one coefficient at a time (with respect to a suitable choice of basis), and this is extremely similar to the corresponding step in the linear algebraic list decoding algorithm [29] for classical univariate multiplicity codes. Recall that we intend to obtain an affine subspace of small dimension that contains all close enough polynomials. Assume the form $f(\mathbb{X}) = \sum_{|\alpha|<k} f_\alpha \mathbb{X}^\alpha$ for all *target polynomials* in the affine subspace. We will recover the target polynomials inductively from *lower coefficients to higher coefficients*. In order to kick-start the recovery procedure, as a base case of the induction, we set the coefficients $\big(f_\gamma : |\gamma| \leq r - 2\big)$ arbitrarily. Then for any $\alpha \in \mathbb{N}^m$, $|\alpha| \leq k - r$, the equation $P^{[f]}(\mathbb{X}) = 0$ would imply an equation that has the form

$$\begin{aligned}\mathbb{K}[\mathbf{Z}]\text{-linear combination}\Big(f_{\alpha+\gamma} : |\gamma| = r - 1\Big)& \\ = \ \mathbb{K}[\mathbf{Z}]\text{-linear combination}\Big(f_{\theta+\eta} : (|\eta|, \theta) \leq (r-1, \alpha),\ (|\eta|, \theta) \neq (r-1, \alpha)\Big),&\end{aligned}$$

where the polynomials comprising the above $\mathbb{K}[\mathbf{Z}]$-linear combinations all have a good $\mathbf{Z}$-degree bound due to the $\mathbf{Z}$-degree bound on $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z})$. Note that each of the coefficients $f_{\theta+\eta}$ in the R.H.S. above is *strictly below* (in the usual componentwise partial order) some coefficient $f_{\alpha+\gamma}$ in the L.H.S. above. Since by induction hypothesis, we have already recovered all the coefficients in the R.H.S, we have the $\mathbb{K}[\mathbf{Z}]$-linear combination comprising the L.H.S. above also determined. We then instantiate a hitting set in the $\mathbf{Z}$-variables to recover the individual coefficients in the L.H.S. above, in much the same way as [9] instantiate for their linear combinations.

Thus, the coefficients $\left(f_\gamma : |\gamma| \leq r-2\right)$ are the only possible *free coefficients* in the above procedure, and therefore, the output list is contained in an affine $\mathbb{K}$-subspace having dimension at most $\binom{m+r-2}{r-2}$. We can further adapt the off-the-shelf *pruning* algorithm by [44] and its improved analysis by [66] to the multivariate setting, nearly identically as in [9], to finally end up with a randomized algorithm that guarantees constant output list size. Very recently, two concurrent works [63, 12] improved the output list size guarantee for list decoding FRS codes and univariate multiplicity codes from exponential in $1/\epsilon$ to $O(1/\epsilon^2)$ and the optimal $O(1/\epsilon)$ respectively. It is possible to extend their argument in the obvious way in the multivariate setting to give an even smaller output list size guarantee in the case of list decoding multivariate $\mathtt{Q}$-multiplicity codes. We do not mention the details in this presentation.

We will, in fact, prove a more general list recovery result as in Theorem 19, but stick to only showing polynomial output list size guarantee, for simplicity.

1.5 Further questions

Multivariate multiplicity codes evaluated on the vector space $\mathbb{F}_q^m$ are known to have good locality properties [45], especially when the field characteristic is larger than the degree [43, 44]. It will be interesting to see if similar locality properties hold for the multivariate $\mathtt{Q}$-multiplicity code in a field characteristic insensitive sense.

2 Preliminaries

List decoding and list recovery

Let Σ be a finite alphabet. An input list is any tuple $S = (S_1, \ldots, S_n)$ of subsets $S_i \subseteq \Sigma$. Further, for any $a \in \Sigma^n$, the (relative) Hamming distance between a and S is defined by

$$\mathsf{d}(a, S) = \frac{1}{n}|\{i \in [n] : a_i \notin S_i\}|.$$

We say an input list $S = (S_1, \ldots, S_n)$ is ℓ-sized if $|S_i| \leq \ell$ for all $i \in [n]$.

Let $\mathbb{F}$ be a field, and consider an $\mathbb{F}$-linear code C, that is, Σ is an $\mathbb{F}$-linear space.[7] For $\rho \in [0, 1]$ and $\ell, L \in \mathbb{Z}^+$, we say C is (ρ, ℓ, L)-list recoverable (LR) if there does not exist any ℓ-sized sequence of input lists S that admits $L+1$ distinct codewords $c^{(1)}, \ldots, c^{(L+1)} \in C$ such that

$$\mathsf{d}(c^{(j)}, S) \leq \rho, \qquad \text{for all } j \in [L+1].$$

The case $\ell = 1$ corresponds to list decoding with identical definitions.

[7] The more conventional definition defines C to be a linear code if C is linear over $\Sigma = \mathbb{F}$, but our definition is more relaxed where we allow Σ to be an $\mathbb{F}$-linear space. Our relaxed definition holds for our codes of interest, whereas the conventional definition does not hold. Indeed, we heavily use the relaxed linearity properties of our code constructions, often implicitly.

Field extensions

Fix a finite field $\mathbb{F}_q$, and a finite degree extension $\mathbb{K}/\mathbb{F}_q$ having extension degree κ, that is, $\mathbb{K} = \mathbb{F}_{q^\kappa}$. Also denote $[\kappa]_q = 1 + q + \cdots + q^{\kappa-1}$. Fix a multiplicative generator $\mathtt{Q} \in \mathbb{K}^\times$. We immediately note the following basic observations (see, for instance, [48, Chapter 2]), and also add quick proofs for completeness.

▶ **Proposition 3.**
(a) [48, Theorem 2.10] $\mathbb{K} = \mathbb{F}_q(\mathtt{Q})$.
(b) [48, Lemma 2.3] $\mathtt{Q}^t \notin \mathbb{F}_q$, *for all* $t \in [[\kappa]_q - 1]$.

Proof.
(a) Since $\mathbb{F}_q \subseteq \mathbb{K}$ and $\mathtt{Q} \in \mathbb{K}$, we have $\mathbb{F}_q(\mathtt{Q}) \subseteq \mathbb{K}$. Since $\mathbb{K}^\times = \{\mathtt{Q}^t : t \geq 0\}$, we have $\mathbb{K} \subseteq \mathbb{F}_q(\mathtt{Q})$.
(b) Since $\mathtt{Q}$ is the multiplicative generator of $\mathbb{K}^\times$, and $\mathbb{K} = \mathbb{F}_{q^\kappa}$, the multiplicative order of $\mathtt{Q}$ is $q^\kappa - 1$. Obviously, $\mathtt{Q}^t \neq 0$ for all $t \geq 1$. Now suppose $\mathtt{Q}^t \in \mathbb{F}_q^\times$ for some $t \geq 1$. Then $\mathtt{Q}^{t(q-1)} = 1$, which means $q^\kappa - 1 \leq t(q-1)$, that is, $t \geq (q^\kappa - 1)/(q-1) = 1 + q + \cdots + q^{\kappa-1} = [\kappa]_q$. ◀

▶ Remark 4. Note that in this work, we will assume that the field size $q \to \infty$. We will also consider an additional parameter $s \geq 1$, and always work in the case where $\mathtt{Q}, \ldots, \mathtt{Q}^{s-1} \notin \mathbb{F}_q$. By Proposition 3(b), this is true if $s - 1 < [\kappa]_q = 1 + q + q^2 + \cdots + q^{\kappa-1}$. Further, we will have the degree d of all polynomials that we consider to satisfy $d \leq sq - 1$. Therefore, we will also need $sq - 1 < [\kappa]_q = 1 + q + q^2 + \cdots + q^{\kappa-1}$. Both these requirements are satisfied if we take $\kappa = 3$ and $s \leq q$, and we assume these throughout the rest of this work. In fact, we will only take s to be a constant relative to q. So henceforth, we have $\mathbb{K} = \mathbb{F}_{q^3}$, and $\mathtt{Q}$ is a multiplicative generator of $(\mathbb{F}_{q^3})^\times$.

For any $n \geq k \geq 0$, denote

$$[n]_\mathtt{Q} = \sum_{t=0}^{n-1} \mathtt{Q}^t = \frac{\mathtt{Q}^n - 1}{\mathtt{Q} - 1}, \quad [n]_\mathtt{Q}! = \prod_{t=1}^{n} [t]_\mathtt{Q}, \quad \text{and} \quad \begin{bmatrix} n \\ k \end{bmatrix}_\mathtt{Q} = \frac{[n]_\mathtt{Q}!}{[k]_\mathtt{Q}![n-k]_\mathtt{Q}!}.$$

Note that $[n]_\mathtt{Q} \neq 0$ for all $n \in [q^\kappa - 2]$, and $[0]_\mathtt{Q}! = 1$. The quantity $\begin{bmatrix} n \\ k \end{bmatrix}_\mathtt{Q}$ is called the Gaussian binomial coefficient [22]. We will also have the convention that $[n]_\mathtt{Q}! = 0$ if $n < 0$, and $\begin{bmatrix} n \\ k \end{bmatrix}_\mathtt{Q} = 0$ if $k > n$.

2.1 Univariate $\mathtt{Q}$-derivatives

For any $f(X) \in \mathbb{K}[X]$, the $\mathtt{Q}$-derivative [31, 32, 33, 34, 35] is defined by

$$\mathsf{D}_\mathtt{Q} f(X) = \frac{f(\mathtt{Q}X) - f(X)}{(\mathtt{Q} - 1)X}.$$

Further, we are interested in iterated applications of the operator $\mathsf{D}_\mathtt{Q}$, and so we denote $\mathsf{D}_\mathtt{Q}^0 f(X) = f(X)$, and $\mathsf{D}_\mathtt{Q}^{t+1} f(X) = \mathsf{D}_\mathtt{Q}(\mathsf{D}_\mathtt{Q}^t f)(X)$ for all $t \geq 0$.

▶ Remark 5. We have $\mathsf{D}_\mathtt{Q}^t(X^k) = [k]_\mathtt{Q}[k-1]_\mathtt{Q} \cdots [k-t+1]_\mathtt{Q} X^{k-t+1}$ for all $k, t \geq 0$. Consider any nonconstant $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ and $t \in [0, \deg(f)]$. Then we immediately get $\deg(\mathsf{D}_\mathtt{Q}^t f) \leq \deg(f) - t$ by linearity of $\mathsf{D}_\mathtt{Q}^t$ (see Proposition 6(a) below). More importantly, as a departure from classical derivatives, we get $\deg(\mathsf{D}_\mathtt{Q}^t f) = \deg(f) - t$ if $\deg(f) \leq [\kappa]_q - 1$.

Let us quickly collect a few basic properties of $\mathtt{Q}$-derivatives. For an indeterminate Y and $k \geq 0$, denote $(X - Y)_\mathtt{Q}^{(k)} = \prod_{t=0}^{k-1} (X - \mathtt{Q}^t Y)$. For any $f(X) \in \mathbb{K}[X]$ and $a \in \mathbb{K}^\times$, denote $(f \circ a)(X) = f(aX)$.

▶ **Proposition 6** ([37, 17]).

(a) Linearity. $\mathsf{D}_{\mathtt{Q}}^k$ *is an* $\mathbb{K}$*-linear map on* $\mathbb{K}[X]$*, for all* $k \geq 0$.

(b) Scaling. *For any* $f(X) \in \mathbb{K}[X]$ *and* $a \in \mathbb{K}^\times$,

$$\mathsf{D}_{\mathtt{Q}}^k(f \circ a)(X) = a^k \mathsf{D}_{\mathtt{Q}}^k f(aX) \qquad \text{for all } k \geq 0.$$

(c) Taylor expansion. *For any* $f(X) \in \mathbb{K}[X]$,

$$f(X) = \sum_{k \geq 0} \frac{\mathsf{D}_{\mathtt{Q}}^k f(Y)}{[k]_{\mathtt{Q}}!} (X - Y)_{\mathtt{Q}}^{(k)}.$$

In particular,

- *For any* $a \in \mathbb{K}$*, we have* $f(X) = \sum_{k \geq 0} \frac{\mathsf{D}_{\mathtt{Q}}^k f(a)}{[k]_{\mathtt{Q}}!} (X - a)_{\mathtt{Q}}^{(k)}$.
- *For any* $k \geq 0$*, we have* $\mathsf{D}_{\mathtt{Q}}^k f(0) = [k]_{\mathtt{Q}}! \cdot \mathsf{H}^{(k)} f(0)$*, where* $\mathsf{H}^{(k)} f(0)$ *is the* k-th Hasse derivative[8] *of* $f(X)$ *at* 0.

(d) Product rule. *For any* $f(X), g(X) \in \mathbb{K}[X]$ *and* $k \geq 0$,

$$\mathsf{D}_{\mathtt{Q}}^k(fg)(X) = \sum_{t=0}^{k} \begin{bmatrix} k \\ t \end{bmatrix}_{\mathtt{Q}} \mathsf{D}_{\mathtt{Q}}^{k-t} f(\mathtt{Q}^t X) \mathsf{D}_{\mathtt{Q}}^t g(X) = \sum_{t=0}^{k} \begin{bmatrix} k \\ t \end{bmatrix}_{\mathtt{Q}} \mathsf{D}_{\mathtt{Q}}^{k-t} f(X) \mathsf{D}_{\mathtt{Q}}^t g(\mathtt{Q}^{k-t} X).$$

Change of basis

A simple change of basis shows that $\mathtt{Q}$-derivatives are built out of simple evaluations at correlated points. Define an infinite matrix $\nu(X) \in (\mathbb{K}(X))^{\mathbb{N} \times \mathbb{N}}$ by

$$\nu_{k,t}(X) = \frac{(-1)^t \mathtt{Q}^{\binom{t}{2} - (k-1)t}}{(\mathtt{Q} - 1)^k X^k} \binom{k}{t}, \qquad \text{for all } k, t \geq 0.$$

Clearly, $\nu_{k,t}(X) = 0$ whenever $k < t$, that is, ν lower triangular. Further, we have the diagonal entries $\nu_{k,k}(X) = (-1)^k / (\mathtt{Q}^{\binom{k}{2}} (\mathtt{Q} - 1)^k X^k) \neq 0$ for all $k \geq 0$. So ν is invertible, and $\xi(X) := \nu(X)^{-1}$ is lower triangular, given by

$$\xi_{k,t}(X) = \begin{cases} (-1)^k \mathtt{Q}^{\binom{k}{2}} (\mathtt{Q} - 1)^k X^k & \text{if } k = t \geq 0, \\ \dfrac{(-1)^t (\mathtt{Q} - 1)^t X^t}{\mathtt{Q}^{\binom{k}{2} + (k-1)t}} \binom{k}{t} \left(1 - \left(1 - \dfrac{1}{\mathtt{Q}^{k-t-1}}\right)^{k-t}\right) & \text{if } k > t \geq 0. \end{cases}$$

This can be proven by instantiating, for instance, [62, Theorem 1.2.3].

▶ **Proposition 7** (Change of basis for $\mathtt{Q}$-derivatives). *For any* $f(X) \in \mathbb{K}[X]$ *and* $k \geq 0$*, we have*

$$\mathsf{D}_{\mathtt{Q}}^k f(X) = \sum_{t=0}^{k} \nu_{k,t}(X) f(\mathtt{Q}^t X) \quad [42, 4], \quad \text{and} \quad f(\mathtt{Q}^k X) = \sum_{t=0}^{k} \xi_{k,t}(X) \mathsf{D}_{\mathtt{Q}}^t f(X).$$

Proof. For any $f(X) \in \mathbb{K}[X]$, denote

$$(f \bullet \mathtt{Q}) = \left[f(\mathtt{Q}^k X)\right]_k \in (\mathbb{K}[X])^{\mathbb{N} \times 1} \quad \text{and} \quad (\mathsf{D}_{\mathtt{Q}} \bullet f) = \left[\mathsf{D}_{\mathtt{Q}}^k f(X)\right]_k \in (\mathbb{K}[X])^{\mathbb{N} \times 1}.$$

We have $(\mathsf{D}_{\mathtt{Q}} \bullet f) = \nu \cdot (f \bullet \mathtt{Q})$ by [42, 4]. Further, since $\xi = \nu^{-1}$, this implies $(f \bullet \mathtt{Q}) = \xi \cdot (\mathsf{D}_{\mathtt{Q}} \bullet f)$. ◀

[8] For $f(X) \in \mathbb{K}[X]$, the Hasse derivatives $\mathsf{H}^{(k)} f(Y)$, $k \geq 0$ satisfy: $f(X) = \sum_{k \geq 0} \mathsf{H}^{(k)} f(Y) (X - Y)^k$.

2.2 Multivariate $\mathtt{Q}$-derivatives

Now assume indeterminates $\mathbb{X} = (X_1, \ldots, X_m)$, and for any subset $I \subseteq [m]$, denote $\mathbb{X}_I = (X_i : i \in I)$. For every $i \in [m]$, denote the $\mathbb{K}$-linear $\mathtt{Q}$-derivative map on $\mathbb{K}[X_i]$ by $\mathsf{D}_{\mathtt{Q},X_i}$, and note that it extends in an obvious (and unique) way to a $\mathbb{K}(\mathbb{X}_{[m]\setminus\{i\}})$-linear map on $\mathbb{K}[\mathbb{X}]$. It is also immediate that $\mathsf{D}_{\mathtt{Q},X_1}, \ldots, \mathsf{D}_{\mathtt{Q},X_m}$ commute as $\mathbb{K}$-linear maps on $\mathbb{K}[\mathbb{X}]$. Then for any $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ and $\alpha \in \mathbb{N}^m$, we define the α-th $\mathtt{Q}$-derivative by

$$\mathsf{D}^{\alpha}_{\mathtt{Q}} f(\mathbb{X}) = \mathsf{D}^{\alpha_1}_{\mathtt{Q},X_1} \cdots \mathsf{D}^{\alpha_m}_{\mathtt{Q},X_m} f(\mathbb{X}).$$

For $\alpha, \beta \in \mathbb{N}^m$, $\beta \le \alpha$, denote

$$[\alpha]_{\mathtt{Q}} = \prod_{i=1}^{m} [\alpha_i]_{\mathtt{Q}}, \quad [\alpha]_{\mathtt{Q}}! = \prod_{i=1}^{m} [\alpha_i]_{\mathtt{Q}}!, \quad \text{and} \quad \begin{bmatrix} \alpha \\ \beta \end{bmatrix}_{\mathtt{Q}} = \frac{[\alpha]_{\mathtt{Q}}!}{[\beta]_{\mathtt{Q}}![\alpha-\beta]_{\mathtt{Q}}!} = \prod_{i=1}^{m} \begin{bmatrix} \alpha_i \\ \beta_i \end{bmatrix}_{\mathtt{Q}}.$$

Also, note the usual binomial coefficient $\binom{\alpha}{\beta} := \prod_{i=1}^{m} \binom{\alpha_i}{\beta_i}$. For indeterminates $\mathbb{Y} = (Y_1, \ldots, Y_m)$ and $\alpha \in \mathbb{N}^m$, denote $(\mathbb{X} - \mathbb{Y})^{(\alpha)}_{\mathtt{Q}} = \prod_{i=1}^{m} (X_i - Y_i)^{(\alpha_i)}_{\mathtt{Q}}$. For any $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ and $a \in \mathbb{K}^{\times}$, denote $a\mathbb{X} = (a_1 X_1, \ldots, a_m X_m)$, and $(f \circ a)(\mathbb{X}) = f(a\mathbb{X})$. Also denote $a^{\gamma} = a_1^{\gamma_1} \cdots a_m^{\gamma_m}$. For any $\gamma \in \mathbb{N}^m$, denote $\mathtt{Q}^{\gamma}\mathbb{Y} = (\mathtt{Q}^{\gamma_1} Y_1, \ldots, \mathtt{Q}^{\gamma_m} Y_m)$.

We easily get the following basic properties of multivariate $\mathtt{Q}$-derivatives.

▶ **Proposition 8.**

(a) Linearity. $\mathsf{D}^{\alpha}_{\mathtt{Q}}$ *is a* $\mathbb{K}$*-linear map on* $\mathbb{K}[\mathbb{X}]$*, for all* $\alpha \in \mathbb{N}^m$*.*

(b) Scaling. *For any* $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ *and* $a \in \mathbb{K}^{\times}$*, we have*

$$\mathsf{D}^{\beta}_{\mathtt{Q}}(f \circ a)(\mathbb{X}) = a^{\beta} \mathsf{D}^{\beta}_{\mathtt{Q}} f(a\mathbb{X}) \qquad \text{for all } \beta \in \mathbb{N}^m.$$

(c) Taylor expansion. *For any* $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$*,*

$$f(\mathbb{X}) = \sum_{\alpha \in \mathbb{N}^m} \frac{\mathsf{D}^{\alpha}_{\mathtt{Q}} f(\mathbb{Y})}{[\alpha]_{\mathtt{Q}}!} (\mathbb{X} - \mathbb{Y})^{(\alpha)}_{\mathtt{Q}}.$$

In particular,

- *For any* $a \in \mathbb{K}^m$*, we have* $f(X) = \sum_{\alpha \in \mathbb{N}^m} \frac{\mathsf{D}^{\alpha}_{\mathtt{Q}} f(a)}{[k]_{\mathtt{Q}}!} (\mathbb{X} - a)^{(\alpha)}_{\mathtt{Q}}$*.*
- *For any* $\alpha \in \mathbb{N}^m$*, we have* $\mathsf{D}^{\alpha}_{\mathtt{Q}} f(0^m) = [\alpha]_{\mathtt{Q}}! \cdot \mathsf{H}^{(\alpha)} f(0^m)$*, where* $\mathsf{H}^{(\alpha)} f(0^m)$ *is the* α-th Hasse derivative[9] *of* $f(\mathbb{X})$ *at* 0^m*.*

(d) Product rule. *For any* $f(\mathbb{X}), g(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ *and* $\alpha \in \mathbb{N}^m$*,*

$$\mathsf{D}^{\alpha}_{\mathtt{Q}}(fg)(\mathbb{X}) = \sum_{\beta \le \alpha} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}_{\mathtt{Q}} \mathsf{D}^{\alpha-\beta}_{\mathtt{Q}} f(\mathtt{Q}^{\beta}\mathbb{X}) \mathsf{D}^{\beta}_{\mathtt{Q}} g(\mathbb{X}) = \sum_{\beta \le \alpha} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}_{\mathtt{Q}} \mathsf{D}^{\alpha-\beta}_{\mathtt{Q}} f(\mathbb{X}) \mathsf{D}^{\beta}_{\mathtt{Q}} g(\mathtt{Q}^{\alpha-\beta}\mathbb{X}).$$

Proof. Each item follows easily by induction on m, with the base cases for Item (a), (b), (c), and (d) being Proposition 6(a), (b), (c), and (d) respectively. ◀

Change of basis

Using the infinite matrices defined in Section 2.1, define two infinite matrices $\nu^{(m)}(\mathbb{X}), \xi^{(m)}(\mathbb{X}) : (\mathbb{K}(\mathbb{X}))^{\mathbb{N}^m \times \mathbb{N}^m}$ by

$$\nu^{(m)}_{\alpha,\beta}(\mathbb{X}) = \prod_{i=1}^{m} \nu_{\alpha_i,\beta_i}(X_i), \quad \xi^{(m)}_{\alpha,\beta}(\mathbb{X}) = \prod_{i=1}^{m} \xi_{\alpha_i,\beta_i}(X_i), \qquad \text{for all } \alpha, \beta \in \mathbb{N}^m.$$

[9] For $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$, the Hasse derivatives $\mathsf{H}^{(\alpha)} f(\mathbb{Y})$, $\alpha \in \mathbb{N}^m$ satisfy: $f(\mathbb{X}) = \sum_{\alpha \in \mathbb{N}^m} \mathsf{H}^{(\alpha)} f(\mathbb{Y})(\mathbb{X} - \mathbb{Y})^{\alpha}$.

It is then easy to see (for instance, by induction on m) that $\nu^{(m)}(\mathbb{X})$ is invertible and $\xi^{(m)}(\mathbb{X}) = (\nu^{(m)}(\mathbb{X}))^{-1}$. Also, $\nu^{(m)}_{\alpha,\beta}(\mathbb{X}) = \xi^{(m)}_{\alpha,\beta}(\mathbb{X}) = 0$ for all $\alpha, \beta \in \mathbb{N}^m$, $\alpha \not\geq \beta$, and $\nu^{(m)}_{\alpha,\alpha}(\mathbb{X}) \neq 0 \neq \xi^{(m)}_{\alpha,\alpha}(\mathbb{X})$ as well as $\nu^{(m)}_{\alpha,\alpha}(\mathbb{X}) = 1/\xi^{(m)}_{\alpha,\alpha}(\mathbb{X})$ for all $\alpha \in \mathbb{N}^m$. Further, we obtain the following change of basis, again by induction on m.

▶ **Proposition 9** (Change of basis for multivariate $\mathtt{Q}$-derivatives). *For any $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ and $\alpha \in \mathbb{N}^m$, we have*

$$\mathsf{D}^{\alpha}_{\mathtt{Q}} f(\mathbb{X}) = \sum_{\beta \leq \alpha} \nu^{(m)}_{\alpha,\beta}(\mathbb{X}) f(\mathtt{Q}^{\beta}\mathbb{X}), \quad \textit{and} \quad f(\mathtt{Q}^{\alpha}\mathbb{X}) = \sum_{\beta \leq \alpha} \xi^{(m)}_{\alpha,\beta}(\mathbb{X}) \mathsf{D}^{\beta}_{\mathtt{Q}} f(\mathbb{X}).$$

A monomial basis for function spaces

We assume familiarity with Gröbner basis theory. For definitions and more details, see [13, Chapters 2–5]. For any $A \subseteq \mathbb{F}_q^{\times}$, consider the ideal defined (by appealing to the change of basis in Proposition 9) as

$$\begin{aligned}\mathcal{D}^m_s(A) &= \{f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}] : f(\mathtt{Q}^{\gamma}a) = 0 \text{ for all } a \in A \text{ and } \gamma \in \mathbb{N}^m, |\gamma| < s\} \\ &= \{f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}] : \mathsf{D}^{\gamma}_{\mathtt{Q}} f(a) = 0 \text{ for all } a \in A \text{ and } \gamma \in \mathbb{N}^m, |\gamma| < s\}.\end{aligned}$$

The following is a characterization of a Gröbner basis of $\mathcal{D}^m_s(A)$ that is *universal* (invariant under choice of monomial order) and *reduced* (minimal with respect to divisibility of leading terms).[10] This is an extension of [1, Theorem 1.1] and [6, Theorem 4.1], while being a special case of [23, Theorem 4.7].[11] A similar characterization in the case of classical multivariate derivatives was given in [43, Section 6], and can also be obtained by [23, Theorem 4.7].

▶ **Theorem 10** ([23]). *For any $A \subseteq \mathbb{F}_q^{\times}$, the set of polynomials*

$$\mathcal{G}^m_s(A) := \left\{ \prod_{i=1}^{m} \prod_{t=0}^{\gamma_i - 1} \left(\prod_{a_i \in A} (X_i - \mathtt{Q}^t a_i) \right) : \gamma \in \mathbb{N}^m, |\gamma| = s \right\}$$

is a universal reduced Gröbner basis for $\mathcal{D}^m_s(A)$.

Further, for any $A \subseteq \mathbb{F}_q^{\times}$, define the function spaces

$$V_{m,s}(A) = \left\{ [f] := \left[[f]_a := \left[f(\mathtt{Q}^{\gamma}a) \right]_{|\gamma|<s} \right]_{a \in A^m} : f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}] \right\},$$

$$\text{and} \quad \mathsf{D}_{\mathtt{Q}} V_{m,s}(A) = \left\{ [\mathsf{D}_{\mathtt{Q}} \mid f] := \left[[\mathsf{D}_{\mathtt{Q}} \mid f]_a := \left[\mathsf{D}^{\gamma}_{\mathtt{Q}} f(a) \right]_{|\gamma|<s} \right]_{a \in A^m} : f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}] \right\}.$$

As an immediate corollary of Theorem 10 and the simple properties of Euclidean division for polynomials, we can describe a *monomial basis* (a basis where each vector is the appropriate evaluation of a monomial) for the above vector spaces.

[10] Given any monomial order, a universal Gröbner basis and a reduced Gröbner basis for an ideal both always exist; however, a Gröbner basis that is both universal and reduced may not always exist. A universal reduced Gröbner basis, whenever it exists, is the closest to being *the* Gröbner basis for an ideal, and allows performing Euclidean division *carelessly*.

[11] A related characterization of *standard monomials*, which is a strictly weaker notion than Gröbner basis, was obtained much earlier by [19, 50] via determination of winning strategies of a *lex game*, and a further reinterpretation of these winning strategies using the notion of *compression* for set systems. This reinterpretation was also rediscovered independently by [51].

▶ **Corollary 11.** *The collections of evaluation vectors*

$$\left\{[\mathbb{X}^\alpha] : \alpha \in \triangle^m_{s-1}(|A|)\right\} \quad \text{and} \quad \left\{[\mathsf{D}_\mathtt{Q} \mid \mathbb{X}^\alpha] : \alpha \in \triangle^m_{s-1}(|A|)\right\}$$

are $\mathbb{K}$-linear bases of $V_{m,s}(A)$ and $\mathsf{D}_\mathtt{Q}V_{m,s}(A)$ respectively, where

$$\triangle^m_{s-1}(|A|) = \left\{\alpha \in \mathbb{N}^m : \left\lfloor \frac{\alpha_1}{|A|} \right\rfloor + \cdots + \left\lfloor \frac{\alpha_m}{|A|} \right\rfloor \leq s-1 \right\}.$$

2.3 Counting Q-roots of polynomials with multiplicities

The discussion so far naturally leads us to the question of bounding the number of Q-*roots* of a polynomial with multiplicities.

For any nonzero univariate $f(X) \in \mathbb{K}[X]$ and $a \in \mathbb{K}$, define the Q-multiplicity of $f(X)$ at a by $\mu_\mathtt{Q}(f,a) = \min\left\{k \geq 0 : \mathsf{D}^k_\mathtt{Q} f(a) \neq 0\right\}$. The following claim is easy, by appealing to univariate factorization.

▶ **Proposition 12** (Easy). *For any nonempty set $A \subseteq \mathbb{F}_q^\times$, and nonzero $f(X) \in \mathbb{K}[X]$ with $\deg(f) \leq d < [3]_q$, we have $\sum_{a\in A} \mu_\mathtt{Q}(f,a) \leq d$. In particular, for any $s \geq 1$, we have $|\{a \in A : \mu_\mathtt{Q}(f,a) \geq s\}| \leq \lfloor d/s \rfloor$.*

In the multivariate setting, for any nonzero $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ and $a \in \mathbb{K}^m$, define the Q-multiplicity of $f(\mathbb{X})$ at a by

$$\mu_\mathtt{Q}(f,a) = \min\left\{k \geq 0 : \text{there exists } \gamma \in \mathbb{N}^m,\ |\gamma| = k \text{ such that } \mathsf{D}^\gamma_\mathtt{Q} f(a) \neq 0\right\}.$$

In this section, we will prove the following multivariate extension of Proposition 12, which is analogous to [15, Lemma 2.7] in the setting of classical derivatives.

▶ **Theorem 13.** *For any nonempty set $A \subseteq \mathbb{F}_q^\times$, and any nonzero $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ with $\deg(f) \leq d < [3]_q$, we have*

$$\sum_{a\in A^m} \mu_\mathtt{Q}(f,a) \leq d|A|^{m-1}.$$

In particular, for any $s \geq 1$, we have $|\{a \in A^m : \mu_\mathtt{Q}(f,a) \geq s\}| \leq \lfloor d\,|A|^{m-1}/s \rfloor$.

Towards a proof of Theorem 13, we first consider some simple consequences of the definition of multivariate Q-multiplicity.

▶ **Lemma 14.** *Consider any nonzero $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$.*

(a) *For any $a \in \mathbb{K}^m$, if $\mu_\mathtt{Q}(f,a) \geq k$, then*

$$\mu_\mathtt{Q}(\mathsf{D}^\gamma_\mathtt{Q} f, a) \geq k - |\gamma| \qquad \text{for all } \gamma \in \mathbb{N}^m,\ |\gamma| \leq k.$$

(b) *For any $(a_1,\ldots,a_m) \in \mathbb{K}^m$ and $\gamma \in \mathbb{N}^m$, if $\mathsf{D}^\gamma_\mathtt{Q} f(a_1,\ldots,a_{m-1},X_m) \neq 0$, then*

$$\mu_\mathtt{Q}(\mathsf{D}^\gamma_\mathtt{Q} f, (a_1,\ldots,a_{m-1},a_m)) \leq \mu_\mathtt{Q}(\mathsf{D}^\gamma_\mathtt{Q} f(a_1,\ldots,a_{m-1},X_m), a_m).$$

Proof.

(a) Since $\mu_\mathtt{Q}(f,a) \geq k$, we have

$$\mathsf{D}^\gamma_\mathtt{Q} f(a) = 0 \qquad \text{for all } \gamma \in \mathbb{N}^m,\ |\gamma| \leq k-1.$$

Consider any $\gamma, \beta \in \mathbb{N}^m$, $|\gamma| \leq k$, $|\beta| \leq k - |\gamma| - 1$. So $|\beta+\gamma| \leq k-1$, and therefore $\mathsf{D}^\beta_\mathtt{Q}(\mathsf{D}^\gamma_\mathtt{Q} f)(a) = \mathsf{D}^{\beta+\gamma}_\mathtt{Q} f(a) = 0$. This means $\mu_\mathtt{Q}(\mathsf{D}^\gamma_\mathtt{Q} f, a) \geq k - |\gamma|$.

(b) Suppose $\mu_{\mathtt{Q}}(\mathsf{D}^{\gamma}_{\mathtt{Q}} f, (a_1, \ldots, a_{m-1}, a_m)) = k$. This means

$$\mathsf{D}^{\beta+\gamma}_{\mathtt{Q}} f(a_1, \ldots, a_{m-1}, a_m) = 0 \qquad \text{for all } \beta \in \mathbb{N}^m,\ |\beta| \leq k-1.$$

In particular, restricting our attention to $\beta \in \mathbb{N}^m$ of the form $\beta = (0^{m-1}, t)$, we get

$$\mathsf{D}^{t}_{\mathtt{Q},X_m}(\mathsf{D}^{\gamma}_{\mathtt{Q}} f)(a_1, \ldots, a_{m-1}, a_m) = 0 \qquad \text{for all } t \leq k-1.$$

This means $\mu_{\mathtt{Q}}(\mathsf{D}^{\gamma}_{\mathtt{Q}} f(a_1, \ldots, a_{m-1}, X_m), a_m) \geq k$. ◀

We can now prove Theorem 13.

Proof of Theorem 13. We will prove by induction on m. The base case $m = 1$ is true by Proposition 12. Now suppose the assertion is true for some $m \geq 1$, and now consider indeterminates $\mathbb{X} = (X_1, \ldots, X_m, X_{m+1})$. Without loss of generality, assume $\deg(f) = d$, and write

$$f(X_1, \ldots, X_m, X_{m+1}) = \sum_{t=0}^{\ell} f_t(X_1, \ldots, X_m) \cdot X_{m+1}^t, \quad \text{where } f_\ell(X_1, \ldots, X_m) \neq 0,\ \deg(f_\ell) = d - \ell.$$

For any $a_1, \ldots, a_m \in A$, denote $s_{a_1,\ldots,a_m} = \mu_{\mathtt{Q}}(f_\ell, (a_1, \ldots, a_m))$. So by induction hypothesis, we have

$$\sum_{(a_1,\ldots,a_m)\in A^m} s_{a_1,\ldots,a_m} \leq (d-\ell)|A|^{m-1}. \tag{2}$$

Now fix $a_1, \ldots, a_m \in A$, and let $\gamma = (\gamma_1, \ldots, \gamma_m) \in \mathbb{N}^m$ such that $|\gamma| = s_{a_1,\ldots,a_m}$ and $\mathsf{D}^{\gamma}_{\mathtt{Q}} f_\ell(a_1, \ldots, a_m) \neq 0$. This means

- $\mathsf{D}^{\gamma}_{\mathtt{Q}} f_\ell(X_1, \ldots, X_m) \neq 0$, and so

$$\mathsf{D}^{(\gamma,0)}_{\mathtt{Q}} f(X_1, \ldots, X_m, X_{m+1}) = \sum_{t=0}^{\ell} \mathsf{D}^{\gamma}_{\mathtt{Q}} f_t(X_1, \ldots, X_m) \cdot X_{m+1}^t \neq 0.$$

- $g^{(\gamma)}(X_{m+1}) := \mathsf{D}^{(\gamma,0)}_{\mathtt{Q}} f(a_1, \ldots, a_m, X_{m+1}) \neq 0$, and $\deg(g^{(\gamma)}) = \ell$.

Then, for any $a_{m+1} \in A$, we get

$$\begin{aligned} \mu_{\mathtt{Q}}(f, (a_1, \ldots, a_m, a_{m+1})) &\leq |(\gamma, 0)| + \mu_{\mathtt{Q}}(\mathsf{D}^{(\gamma,0)}_{\mathtt{Q}} f, (a_1, \ldots, a_m, a_{m+1})) && \text{by Lemma 14(a)} \\ &\leq s_{a_1,\ldots,a_m} + \mu_{\mathtt{Q}}(g^{(\gamma)}, a_{m+1}) && \text{by Lemma 14(b)} \end{aligned}$$

So by Proposition 12,

$$\sum_{a_{m+1}\in A} \mu_{\mathtt{Q}}(f, (a_1, \ldots, a_m, a_{m+1})) \leq s_{a_1,\ldots,a_m}|A| + \ell.$$

Then (2) implies

$$\sum_{(a_1,\ldots,a_m,a_{m+1})\in A^{m+1}} \mu_{\mathtt{Q}}(f, (a_1, \ldots, a_m, a_{m+1})) \leq (d-\ell)|A|^m + \ell|A|^m = d|A|^m,$$

which completes the induction. ◀

3 List decoding/recovery of $\mathtt{Q}$-multiplicity codes

We will now move to our main result on list decoding multivariate $\mathtt{Q}$-multiplicity codes. In fact, we will present the algorithm for the more general list recovery paradigm.

3.1 List decoding/recovery of univariate $\mathtt{Q}$-multiplicity codes

Let us see that the classical univariate multiplicity code list decoder [29] can be suitably adapted to list decode $\mathtt{Q}$-Mult$_s(A;k)$, which therefore provides an alternative algorithm to list decode FRS codes. We will, in fact, consider list recovery.

▶ **Theorem 15.** *Consider any $R \in (0,1)$, $\epsilon \in (0, 1-R)$. For any $A \subseteq \mathbb{F}_q^\times$, $|A| = n$ and $\ell \geq 1$, and for the choices $s = \lceil \ell/\epsilon^2 \rceil$ and $k = \lceil Rsn \rceil$, the code $\mathtt{Q}$-Mult$_s(A;k)$ is efficiently list recoverable up to radius $1 - R - \epsilon$ with output list size at most $(\ell/\epsilon)^{O((1+\log \ell)/\epsilon)}$.*

Consider additional indeterminates $\mathbb{Y} = (Y_0, \ldots, Y_{s-1})$, and the $\mathbb{K}$-linear subspace of the polynomial ring $\mathbb{K}[X, \mathbb{Y}]$ defined by

$$\mathsf{L}_s(X, \mathbb{Y}) = \big\{ \widetilde{P}(X) + P_0(X)Y_0 + \cdots + P_{s-1}(X)Y_{s-1} : \widetilde{P}(X), P_0(X), \ldots, P_{s-1}(X) \in \mathbb{K}[X] \big\}.$$

Also, denote $Y_s = 0$. Define a $\mathbb{K}$-linear operator $\Delta : \mathsf{L}_s(X, \mathbb{Y}) \to \mathsf{L}_s(X, \mathbb{Y})$ by

$$\Delta\bigg(\widetilde{P}(X) + \sum_{j=0}^{s-1} P_j(X) Y_j \bigg) = \mathsf{D}_\mathtt{Q} \widetilde{P}(X) + \sum_{j=0}^{s-1} \big(\mathsf{D}_\mathtt{Q} P_j(X) Y_j + P_j(\mathtt{Q}X) Y_{j+1} \big).$$

We will be interested in iterated applications of Δ, and therefore, denote $\Delta^0 = \mathrm{Id}$ and $\Delta^{r+1} = \Delta \circ \Delta^r$ for all $r \geq 0$. For any $P(X, \mathbb{Y}) \in \mathsf{L}_s(X, \mathbb{Y})$ and $f(X) \in \mathbb{K}[X]$, denote $P^{[f]}(X) = P(X, f(X), \mathsf{D}_\mathtt{Q} f(X), \ldots, \mathsf{D}_\mathtt{Q}^{s-1} f(X))$. The following is immediate by the definition of Δ.

▶ **Lemma 16.** *Let $P(X, \mathbb{Y}) \in \mathsf{L}_s(X, \mathbb{Y})$.*

(a) *If $j \in [0, s-1]$ such that $\deg_{Y_{j'}}(P) = 0$ for all $j' \geq j$, then $\deg_{Y_{j'}}(\Delta P) = 0$ for all $j' \geq j+1$.*

(b) *$(\Delta P)^{[f]}(X) = \mathsf{D}_\mathtt{Q}(P^{[f]})(X)$, for all $f(X) \in \mathbb{K}[X]$.*

Proof. Let $P(X, \mathbb{Y}) = \widetilde{P}(X) + P_0(X)Y_0 + \cdots + P_{s-1}(X)Y_{s-1} \in \mathsf{L}_s(X, \mathbb{Y})$.

(a) If $j \in [0, s-1]$ such that $\deg_{Y_j}(P) = 0$ for all $j' \geq j$, this means $P_j(X) = \cdots = P_{s-1}(X) = 0$. Now we have

$$\begin{aligned}(\Delta P)(X, \mathbb{Y}) &= \mathsf{D}_\mathtt{Q} \widetilde{P}(X) + \sum_{j'=0}^{s-1} \big(\mathsf{D}_\mathtt{Q} P_{j'}(X) Y_j + P_{j'}(\mathtt{Q}X) Y_{j'+1} \big) \\ &= \mathsf{D}_\mathtt{Q} \widetilde{P}(X) + \sum_{j'=0}^{s-1} \big(P_{j'-1}(\mathtt{Q}X) + \mathsf{D}_\mathtt{Q} P_{j'}(X) \big) Y_{j'}.\end{aligned}$$

So, $P_{j'-1}(\mathtt{Q}X) + \mathsf{D}_\mathtt{Q} P_{j'}(X) = 0$ for all $j' \geq j+1$. This means $\deg_{Y_{j'}}(\Delta P) = 0$ for all $j' \geq j+1$.

(b) We have

$$\begin{aligned}(\Delta P)^{[f]}(X) &= \mathsf{D}_\mathtt{Q} \widetilde{P}(X) + \sum_{j=0}^{s-1} \big(\mathsf{D}_\mathtt{Q} P_j(X) \mathsf{D}_\mathtt{Q}^j f(X) + P_j(\mathtt{Q}X) \mathsf{D}_\mathtt{Q}^{j+1} f(X) \big) \\ &= \mathsf{D}_\mathtt{Q} \widetilde{P}(X) + \sum_{j=0}^{s-1} \mathsf{D}_\mathtt{Q} \big(P_j \cdot \mathsf{D}_\mathtt{Q}^j f \big)(X) \qquad \text{by Proposition 6(c)} \\ &= \mathsf{D}_\mathtt{Q} P^{[f]}(X).\end{aligned}$$

◀

It is worth noting that a close variant of the operator Δ appears in [24, Definition 8.1] in the context of nearly linear-time list decoding of FRS codes, without the interpretation in terms of $\mathtt{Q}$-derivatives. So it is reasonable to surmise that a nearly linear-time implementation of the list decoding algorithm à la [24] is possible for the univariate $\mathtt{Q}$-multiplicity codes. In order to keep our main presentation short, we limit ourselves here to adapting the more conventional polynomial-time algorithm of [29].

The interpolation step of the list recovery algorithm, which will be used multiple times in this discussion, can be captured as follows.

▶ **Proposition 17.** *Consider any $A = \{\alpha_1, \ldots, \alpha_n\} \subseteq \mathbb{F}_q^\times$, parameters $s \geq r \geq 1$, and $k \in [s|A|]$. Let $\ell \geq 1$, and define*

$$d = \left\lceil \frac{n\ell(s-r+1) - (r+k) + 1}{r+1} \right\rceil.$$

Then for any $S_1, \ldots, S_n \subseteq \mathbb{K}^s$ with $|S_i| \leq \ell$, $i \in [n]$, there exists a nonzero polynomial $P(X, \mathbb{Y}) = \widetilde{P}(X) + \sum_{j=0}^{r-1} P_j(X) Y_j \in \mathsf{L}_s(X, \mathbb{Y})$ with

$$\deg(\widetilde{P}) \leq d + k - 1, \quad \textit{and} \quad \deg(P_j) \leq d \qquad \textit{for all } j \in [0, r-1],$$

such that for any $f(X) \in \mathbb{K}[X]$, $\deg(f) < k$,

$$\textit{if} \quad \mathsf{d}_A^{(s)}(f, S) \geq \frac{\ell}{r+1} + \frac{k}{(s-r+1)n} \qquad \textit{then} \quad P(X, f(X), \mathsf{D}_{\mathtt{Q}} f(X), \ldots, \mathsf{D}_{\mathtt{Q}}^{s-1} f(X)) = 0.$$

Proof. Assume the notation $u = (u^{(0)}, \ldots, u^{(s-1)}) \in \mathbb{K}^s$. We can, in fact, add additional arbitrary elements and assume $|S_i| = \ell$, for all $i \in [n]$. Also enumerate $S_i = \{w_{i,1}, \ldots, w_{i,\ell}\}$, $i \in [n]$. We will construct a nonzero polynomial $P(X, \mathbb{Y}) = \widetilde{P}(X) + \sum_{j=0}^{s-1} P_j(X) Y_j \in \mathsf{L}_s(X, \mathbb{Y})$ such that

(a) $P(X, \mathbb{Y}) = \widetilde{P}(X) + \sum_{j=0}^{r-1} P_j(X) Y_j \in \mathsf{L}_s(X, \mathbb{Y})$, that is, $P_r(X) = \cdots = P_{s-1}(X) = 0$.

(b) $\deg(\widetilde{P}) \leq d + k - 1$, and $\deg(P_j) \leq d$ for all $j \in [0, r-1]$.

(c) $(\Delta^j P)\big(\alpha_i, w_{i,t}^{(0)}, \ldots, w_{i,t}^{(s-1)}\big) = 0$ for all $j \in [0, s-r]$, $t \in [\ell]$, $i \in [n]$.

The number of linear constraints is $n\ell(s-r+1)$, and the number of coefficients is $d + k + r(d+1) = d(r+1) + (r+k)$. So for the choice

$$d = \left\lceil \frac{n\ell(s-r+1) - (r+k) + 1}{r+1} \right\rceil,$$

we indeed have $d(r+1) + (r+k) > n\ell(s-r+1)$, and this ensures a nontrivial solution, that is, $P(X, \mathbb{Y}) \neq 0$.

Now consider any $f(X) \in \mathbb{K}[X]$, and suppose $\mathsf{d}_A^{(s)}(f, S) = 1 - (\nu/n)$. By Lemma 16, this implies $\sum_{a \in A} \mu_{\mathtt{Q}}(P^{[f]}, a) \geq \nu s - r + 1$. But we also have $\deg(P^{[f]}) \leq d + k - 1$. Therefore, by Proposition 12, we can conclude that $P^{[f]}(X) = 0$ if $\nu > \lceil (d+k-1)/(s-r+1) \rceil$. This is equivalent to

$$\nu > \left\lceil \frac{\left\lceil \frac{n\ell(s-r+1)-(r+k)+1}{r+1} \right\rceil + k - 1}{s-r+1} \right\rceil = \left\lceil \frac{n\ell(s-r+1) - (r+k) + (r+1)(k-1) + 1}{(r+1)(s-r+1)} \right\rceil.$$

The above is true if

$$\nu \geq \frac{n\ell}{r+1} + \frac{k}{s-r+1}, \quad \text{that is,} \quad \frac{\nu}{n} \geq \frac{\ell}{r+1} + \frac{k}{(s-r+1)n}.$$ ◀

Once we have an interpolating polynomial that captures the correct codewords, we can extract the output list as follows.

▶ **Proposition 18.** *Consider parameters $s \geq r \geq 1$, and $k, d \geq 1$ such that $d + k - 1 < [3]_q$. If $P(X, \mathbb{Y}) = \widetilde{P}(X) + \sum_{j=0}^{r-1} P_j(X) Y_j \in \mathsf{L}_s(X, \mathbb{Y})$ is a nonzero polynomial with*

$$\deg(\widetilde{P}) \leq d + k - 1, \quad \textit{and} \quad \deg(P_j) \leq d \qquad \textit{for all } j \in [0, r-1],$$

then the solution space

$$\{f(X) \in \mathbb{K}[X] : P^{[f]}(X) = 0\}$$

is an affine $\mathbb{K}$-linear space with dimension at most $r - 1$.

Proof. Consider any $f(X) \in \mathbb{K}[X]$ satisfying $P^{[f]}(X) = 0$. Note that we have $P(X, \mathbb{Y}) \neq 0$. If $P_j(X) = 0$ for all $j \in [0, r-1]$, then $P^{[f]}(X) = \widetilde{P}(X) = 0$, which means $P(X, \mathbb{Y}) = 0$, a contradiction. So there exists $j \in [0, r-1]$ such that $P_j(X) \neq 0$. Without loss of generality, we assume $P_{r-1}(X) \neq 0$. (Otherwise, we work with the largest r' such that $P_{r'-1}(X) \neq 0$.)

Let us also quickly consider another notation. For any $\mathtt{Q}^b \in \mathbb{K}^\times$, $h \geq 0$, and $g(X) \in \mathbb{K}[X]$, denote

$$g_{h,b} := \mathrm{coeff}\left(\frac{(X - \mathtt{Q}^b)_{\mathtt{Q}}^{(h)}}{[h]_{\mathtt{Q}}!}, g \right) = \mathsf{D}_{\mathtt{Q}}^h g(\mathtt{Q}^b) \qquad \text{by Proposition 6(b)}$$

Recall that $\mathbb{K} = \mathbb{F}_{q^3}$. Since $\deg(P_{r-1}) \leq d < [3]_q$, there exists $\mathtt{Q}^b \in \mathbb{K}^\times$ such that $P_{r-1}(\mathtt{Q}^{h+b}) \neq 0$ for all $h \in [0, d+k-1]$. Further, since $\deg(P) \leq d + k - 1 < [3]_q$, we will work with the basis of monomials $\{(X - \mathtt{Q}^b)_{\mathtt{Q}}^{(h)} : h \in [0, d+k-1]\}$. Now we have

$$P^{[f]}(X) \equiv \widetilde{P}(X) + P_0(X) f(X) + P_1(X) \mathsf{D}_{\mathtt{Q}} f(X) + \cdots + P_{r-1}(X) \mathsf{D}_{\mathtt{Q}}^{r-1} f(X) = 0$$

So by Proposition 6(c), for every $h \in [0, d+k-1]$, we have

$$\begin{aligned} 0 = P_{h,b}^{[f]} &= (\widetilde{P})_{h,b} + \sum_{j=0}^{r-1} \sum_{c=0}^{h} \begin{bmatrix} h \\ c \end{bmatrix}_{\mathtt{Q}} (P_j)_{h-c,c+b} (\mathsf{D}_{\mathtt{Q}}^j f)_{c,b} \\ &= (\widetilde{P})_{h,b} + \sum_{j=0}^{r-1} \sum_{c=0}^{h} \begin{bmatrix} h \\ c \end{bmatrix}_{\mathtt{Q}} (P_j)_{h-c,c+b} f_{c+j,b}. \end{aligned}$$

Now for every $h \in [0, d+k-1]$, since $(P_{r-1})_{0,h+b} = P_{r-1}(\mathtt{Q}^{h+b}) \neq 0$, we can rewrite the above

$$f_{h+r-1,b} = -\frac{1}{(P_{r-1})_{0,h+b}} \left((\widetilde{P})_{h,b} + \sum_{\substack{(j,c) \leq (r-1,h) \\ (j,c) \neq (r-1,h)}} \begin{bmatrix} h \\ c \end{bmatrix}_{\mathtt{Q}} (P_j)_{h-c,c+b} f_{c+j,b} \right).$$

So we can set the undetermined coefficients among $f_{0,b}, \ldots, f_{r-2,b} \in \mathbb{K}$ freely, and the remaining coefficients of $f(X)$ are uniquely determined the above equation. This means the solution space is an affine $\mathbb{K}$-linear space having dimension at most $r - 1$. ◀

The final list recovery result can now be proven.

Proof of Theorem 15. Choosing $r = \lceil \ell/\epsilon \rceil$, and plugging in all the parameters into Proposition 17 and Proposition 18 immediately implies that the output list is contained in an affine $\mathbb{K}$-linear space with dimension at most $\lceil \ell/\epsilon \rceil - 1$. The pruning algorithm with the improved analysis [44, 66] then asserts that the output list size is at most $(\ell/\epsilon)^{O((1+\log \ell)/\epsilon)}$. ◀

3.2 List decoding/recovery of multivariate $\mathtt{Q}$-multiplicity codes

We will now see an algorithm to list decode $\mathtt{Q}\text{-Mult}_{m,s}(A;k)$. Even though it is inspired by the classical multivariate multiplicity code list decoder [9], it turns out that we can give a simpler algorithm and analysis that is perhaps the correct multivariate extension of our list decoder in the univariate case. We will, in fact, perform list recovery, and the main theorem statement is the following.

▶ **Theorem 19.** *Consider any $\delta \in (0,1)$, $\epsilon \in (0, 1-\delta)$. For any $A \subseteq \mathbb{F}_q^\times$ and $\ell \geq 1$, and for the choices $s = O(\ell/\epsilon^{2m+1})$ and $k = \lceil (1-\delta)s|A| \rceil$, the code $\mathtt{Q}\text{-Mult}_s^m(A;k)$ is efficiently list recoverable up to radius $\delta - \epsilon$ with output list contained in a $\mathbb{K}$-affine space of dimension atmost $O(\ell^m/\epsilon^{2m})$.*

Note that setting $\ell = 1$ in Theorem 19 gives Theorem 2.

Consider additional indeterminates $\mathbb{Y} = (Y_\gamma)_{|\gamma|<s}$, $\mathbf{Z} = (Z_1, \ldots, Z_m)$, and the $\mathbb{K}$-linear subspace of the polynomial ring $\mathbb{K}[\mathbb{X}, \mathbb{Y}]$ defined by

$$\mathsf{L}_s(\mathbb{X}, \mathbb{Y}) = \left\{ \widetilde{P}(\mathbb{X}) + \sum_{j=0}^{s-1} P_j(\mathbb{X}) \left(\sum_{|\gamma|=j} Y_\gamma \mathbf{Z}^\gamma \right) \in \mathbb{K}(\mathbf{Z})[\mathbb{X}, \mathbb{Y}] \right\}.$$

Also, denote $Y_\gamma = 0$ for all $\gamma \in \mathbb{N}^m$, $|\gamma| \geq s$. For any $\alpha \in \mathbb{N}^m$, define a $\mathbb{K}$-linear operator $\Delta^{(\alpha)} : \mathsf{L}_s(\mathbb{X}, \mathbb{Y}) \to \mathsf{L}_s(\mathbb{X}, \mathbb{Y})$ by

$$\Delta^{(\alpha)} \left(\widetilde{P}(\mathbb{X}) + \sum_{j=0}^{s-1} P_j(\mathbb{X}) \left(\sum_{|\gamma|=j} Y_\gamma \mathbf{Z}^\gamma \right) \right) = \mathsf{D}_\mathtt{Q}^\alpha \widetilde{P}(\mathbb{X}) + \sum_{j=0}^{s-1} \sum_{|\gamma|=j} \left(\sum_{\beta \leq \alpha} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}_\mathtt{Q} \mathsf{D}_\mathtt{Q}^{\alpha-\beta} P_j(\mathtt{Q}^\beta \mathbb{X}) Y_{\beta+\gamma} \right) \mathbf{Z}^\gamma.$$

For any $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) \in \mathsf{L}_s(\mathbb{X}, \mathbb{Y})$ and $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$, denote

$$P^{[f]}(\mathbb{X}) = P\left(\mathbb{X}, \left(\mathsf{D}_\mathtt{Q}^\gamma f(\mathbb{X}) \right)_{|\gamma|<s}, \mathbf{Z} \right) \in \mathbb{K}(\mathbf{Z})[\mathbb{X}].$$

The following is then immediate.

▶ **Lemma 20.** *Let $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) \in \mathsf{L}_s(\mathbb{X}, \mathbb{Y})$.*

(a) *If $j \in [0, s-1]$ such that $\deg_{Y_\gamma}(P) = 0$ for all $\gamma \in \mathbb{N}^m$, $|\gamma| \geq j$, then $\deg_{Y_\gamma}(\Delta^{(\alpha)} P) = 0$ for all $\gamma \in \mathbb{N}^m$, $|\gamma| \geq j + |\alpha|$.*

(b) *$(\Delta^{(\alpha)} P)^{[f]}(\mathbb{X}) = \mathsf{D}_\mathtt{Q}^\alpha (P^{[f]})(\mathbb{X})$, for all $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$.*

▶ Remark 21. A consequence of Lemma 20 is that $\Delta^{(\alpha+\beta)} = \Delta^{(\alpha)} \circ \Delta^{(\beta)}$ for all $\alpha, \beta \in \mathbb{N}^m$. We do not explicitly use this elsewhere.

Proof of Lemma 20. Let $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) = \widetilde{P}(\mathbb{X}) + \sum_{j=0}^{s-1} P_j(\mathbb{X}) \left(\sum_{|\gamma|=j} Y_\gamma \mathbf{Z}^\gamma \right) \in \mathsf{L}_s(\mathbb{X}, \mathbb{Y})$.

(a) If $j \in [0, s-1]$ such that $\deg_{Y_\gamma}(P) = 0$ for all $\gamma \in \mathbb{N}^m$, $|\gamma| \geq j$, this means $P_{j'}(\mathbb{X}) = 0$ for all $j' \geq j$. Now we have

$$\begin{aligned}
(\Delta^{(\alpha)} P)(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) &= \mathsf{D}_\mathtt{Q}^\alpha \widetilde{P}(\mathbb{X}) + \sum_{j'=0}^{s-1} \sum_{|\gamma|=j'} \left(\sum_{\beta \leq \alpha} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}_\mathtt{Q} \mathsf{D}_\mathtt{Q}^{\alpha-\beta} P_{j'}(\mathtt{Q}^\beta \mathbb{X}) Y_{\beta+\gamma} \right) \mathbf{Z}^\gamma \\
&= \mathsf{D}_\mathtt{Q}^\alpha \widetilde{P}(\mathbb{X}) + \sum_{j'=0}^{s-1} \sum_{|\gamma|=j'} \left(\sum_{\beta \leq \alpha} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}_\mathtt{Q} \mathsf{D}_\mathtt{Q}^{\alpha-\beta} P_{j'-|\beta|}(\mathtt{Q}^\beta \mathbb{X}) \mathbf{Z}^{\gamma-\beta} \right) Y_\gamma
\end{aligned}$$

So, $\sum_{\beta \leq \alpha} \mathsf{D}_\mathtt{Q}^{\alpha-\beta} P_{j'-|\beta|}(\mathtt{Q}^\beta \mathbb{X}) \mathbf{Z}^{\gamma-\beta} = 0$ for all $j' \geq j + |\alpha|$. This means $\deg_{Y_{j'}}(\Delta^{(\alpha)} P) = 0$ for all $j' \geq j + |\alpha|$.

(b) We have

$$\begin{aligned}(\Delta^{(\alpha)}P)^{[f]}(\mathbb{X}) &= \mathsf{D}_{\mathtt{Q}}^{\alpha}\widetilde{P}(\mathbb{X}) + \sum_{j=0}^{s-1}\sum_{|\gamma|=j}\Big(\sum_{\beta\le\alpha}\begin{bmatrix}\alpha\\ \beta\end{bmatrix}_{\mathtt{Q}}\mathsf{D}_{\mathtt{Q}}^{\alpha-\beta}P_j(\mathtt{Q}^{\beta}\mathbb{X})\mathsf{D}_{\mathtt{Q}}^{\beta+\gamma}f(\mathbb{X})\Big)\mathbf{Z}^{\gamma}\\ &= \mathsf{D}_{\mathtt{Q}}^{\alpha}\widetilde{P}(\mathbb{X}) + \sum_{j=0}^{s-1}\sum_{|\gamma|=j}\mathsf{D}_{\mathtt{Q}}^{\alpha}\big(P_j\cdot\mathsf{D}_{\mathtt{Q}}^{\gamma}f\big)(\mathbb{X})\mathbf{Z}^{\gamma} \qquad \text{by Proposition 8(d)}\\ &= \mathsf{D}_{\mathtt{Q}}^{\alpha}(P^{[f]})(\mathbb{X}).\end{aligned}$$

◀

The interpolation step of the list recovery algorithm, which will be used multiple times in this discussion, can be captured as follows.

▶ **Proposition 22.** *Consider any $A\subseteq\mathbb{F}_q^{\times}$, parameters $s\ge r\ge 1$, and $k\in[s|A|]$. Let $\ell\ge 1$, and define*

$$d=\left\lceil 5\Big(\frac{\ell}{r+1}\Big)^{1/m}(s-r+1)|A|\right\rceil.$$

Then for any $S_a\subseteq\mathbb{K}^{\binom{m+s-1}{s-1}}$ with $|S_a|\le\ell$, $a\in A^m$, there exists a nonzero polynomial $P(\mathbb{X},\mathbb{Y},\mathbf{Z})=\widetilde{P}(\mathbb{X})+\sum_{j=0}^{r-1}P_j(\mathbb{X})\sum_{|\gamma|=j}Y_{\gamma}\mathbf{Z}^{\gamma}\in\mathsf{L}_s(\mathbb{X},\mathbb{Y})$ with

$$\deg(\widetilde{P})\le d+k-1,\quad \textit{and}\quad \deg(P_j)\le d\qquad \textit{for all } j\in[0,r-1].$$

such that for any $f(\mathbb{X})\in\mathbb{K}[\mathbb{X}]$, $\deg(f)<k$,

$$\textit{if}\quad \mathsf{d}_A^{(m,s)}(f,S)\ge 5\Big(\frac{\ell}{r+1}\Big)^{1/m}+\frac{k}{(s-r+1)|A|^{m-1}}.\qquad \textit{then}\quad P^{[f]}(\mathbb{X})=0.$$

Moreover, we can ensure that $P(\mathbb{X},\mathbb{Y},\mathbf{Z})$ is a polynomial in $\mathbf{Z}$ with $\deg_{\mathbf{Z}}(P)<ms$.

Proof. Assume the notation $u=(u^{(\gamma)}:|\gamma|<s)\in\mathbb{K}^{\binom{m+s-1}{s-1}}$. We can, in fact, add additional arbitrary elements and assume $|S_a|=\ell$, for all $a\in A^m$. Also enumerate $S_a=\{w_{a,1},\dots,w_{a,\ell}\}$, $a\in A^m$. We will construct a nonzero polynomial $P(\mathbb{X},\mathbb{Y},\mathbf{Z})=\widetilde{P}(\mathbb{X})+\sum_{j=0}^{s-1}P_j(\mathbb{X})\big(\sum_{|\gamma|=j}Y_{\gamma}\mathbf{Z}^{\gamma}\big)\in\mathsf{L}_s(\mathbb{X},\mathbb{Y})$ such that

(a) $P(\mathbb{X},\mathbb{Y},\mathbf{Z})=\widetilde{P}(\mathbb{X})+\sum_{j=0}^{r-1}P_j(\mathbb{X})\big(\sum_{|\gamma|=j}Y_{\gamma}\mathbf{Z}^{\gamma}\big)$, that is, $P_r(\mathbb{X})=\cdots=P_{s-1}(\mathbb{X})=0$.

(b) $\deg(\widetilde{P})\le d+k-1$, and $\deg(P_j)\le d$ for all $j\in[0,r-1]$.

(c) $(\Delta^{(\alpha)}P)\Big(a,\big(w_{a,t}^{(\gamma)}\big)_{|\gamma|<s}\Big)=0$ for all $\alpha\in\mathbb{N}^m$ with $|\alpha|\in[0,s-r]$, $t\in[\ell]$, $a\in A^m$.

The number of linear constraints is

$$|A|^m\ell\binom{m+s-r}{s-r}\le\ell\Big(\frac{5(s-r+1)|A|}{m}\Big)^m,$$

and the number of coefficients is

$$\binom{m+d+k-1}{d+k-1}+r\binom{m+d}{d}\ge(r+1)\binom{m+d}{d}\ge(r+1)\Big(\frac{d}{m}\Big)^m.$$

So for the choice

$$d=\left\lceil 5\Big(\frac{\ell}{r+1}\Big)^{1/m}(s-r+1)|A|\right\rceil,$$

we indeed get a nontrivial solution, that is, $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) \neq 0$. Further, since each linear constraint is a polynomial in $\mathbf{Z} = (Z_1, \ldots, Z_m)$ having degree at most $s-1$, we can ensure that $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z})$ is a polynomial in $\mathbf{Z}$ having $\deg_{\mathbf{Z}}(P) < ms$ (see [38] or [9, Lemma 3].)

Now consider any $f(X) \in \mathbb{K}[X]$, and suppose $\mathsf{d}_A^{(m,s)}(f, S) = 1-(\nu/|A|^{m-1})$. By Lemma 20, this implies $\sum_{a \in A^m} \mu_{\mathtt{Q}}(P^{[f]}, a) \geq \nu(s-r+1)$. But we also have $\deg(P^{[f]}) \leq (d+k-1)|A|^{m-1}$. Therefore, by Theorem 13, we can conclude that $P^{[f]}(\mathbb{X}) = 0$ if $\nu > (d+k-1)|A|^{m-1}/(s-r+1)$, which holds if

$$\nu > \left\lceil \frac{5(\ell/(r+1))^{1/m}(s-r+1)|A|^{m-1} + k - 1}{s-r+1} \right\rceil.$$

The above is true if

$$\nu \geq 5\left(\frac{\ell}{r+1}\right)^{1/m} |A|^{m-1} + \frac{k}{s-r+1},$$

$$\text{that is,} \quad \frac{\nu}{|A|^{m-1}} \geq 5\left(\frac{\ell}{r+1}\right)^{1/m} + \frac{k}{(s-r+1)|A|^{m-1}}. \qquad \blacktriangleleft$$

Once we have an interpolating polynomial that captures the correct codewords, we can extract the output list as follows.

▶ **Proposition 23.** *Consider parameters $s \geq r \geq 1$, and $k, d \geq 1$ such that $d + k - 1 < [3]_q$. If $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) = \widetilde{P}(\mathbb{X}) + \sum_{j=0}^{r-1} P_j(\mathbb{X}) \sum_{|\gamma|=j} Y_\gamma \mathbf{Z}^\gamma \in \mathsf{L}_s(\mathbb{X}, \mathbb{Y}, \mathbf{Z})$ is a nonzero polynomial with*

$$\deg(\widetilde{P}) \leq d + k - 1, \quad \textit{and} \quad \deg(P_j) \leq d \qquad \textit{for all } j \in [0, r-1],$$

then the solution space

$$\{f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}] : P^{[f]}(\mathbb{X}) = 0\}$$

is an affine $\mathbb{K}$-linear space with dimension at most $\binom{m+r-2}{r-2}$.

Proof. Consider any $f(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$ satisfying $P^{[f]}(\mathbb{X}) = 0$. Note that we have $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) \neq 0$. If $P_j(\mathbb{X}) = 0$ for all $j \in [0, r-1]$, then $P^{[f]}(\mathbb{X}) = \widetilde{P}(\mathbb{X}) = 0$, which means $P(\mathbb{X}, \mathbb{Y}, \mathbf{Z}) = 0$, a contradiction. So there exists $j \in [0, r-1]$ such that $P_j(\mathbb{X}) \neq 0$. Without loss of generality, we assume $P_{r-1}(\mathbb{X}) \neq 0$. (Otherwise, we work with the largest r' such that $P_{r'-1}(\mathbb{X}) \neq 0$.)

Let us also quickly consider another notation. For any $\mathtt{Q}^\beta \in (\mathbb{K}^\times)^m$, $\alpha \in \mathbb{N}^m$, and $g(\mathbb{X}) \in \mathbb{K}[\mathbb{X}]$, denote

$$g_{\alpha,\beta} := \operatorname{coeff}\left(\frac{(\mathbb{X} - \mathtt{Q}^\beta)_{\mathtt{Q}}^{(\alpha)}}{[\alpha]_{\mathtt{Q}}!}, g\right) = \mathsf{D}_{\mathtt{Q}}^\alpha g(\mathtt{Q}^\beta) \qquad \text{by Proposition 8(b)}$$

Recall that $\mathbb{K} = \mathbb{F}_{q^3}$. Since $\deg(P_{r-1}) \leq d < [3]_q$, there exists $\mathtt{Q}^\beta \in (\mathbb{K}^\times)^m$ such that $P_{r-1}(\mathtt{Q}^{\alpha+\beta}) \neq 0$ for all $\alpha \in \mathbb{N}^m$, $|\alpha| \leq d+k-1$. Further, since $\deg(P) \leq d+k-1 < [3]_q$, we will work with the basis of monomials $\{(\mathbb{X} - \mathtt{Q}^\beta)_{\mathtt{Q}}^{(\alpha)} : \alpha \in \mathbb{N}^m, |\alpha| \leq d+k-1\}$. Now we have

$$P^{[f]}(\mathbb{X}) \equiv \widetilde{P}(\mathbb{X}) + \sum_{j=0}^{r-1} P_j(\mathbb{X}) \sum_{|\gamma|=j} \mathsf{D}_{\mathtt{Q}}^\gamma f(\mathbb{X}) \mathbf{Z}^\gamma = 0.$$

So for every $\alpha \in \mathbb{N}^m$, $|\alpha| \leq d+k-1$, we have

$$\begin{aligned} 0 = P_{\alpha,\beta}^{[f]} &= \widetilde{P}_{\alpha,\beta} + \sum_{j=0}^{r-1} \sum_{|\gamma|=j} \left(\sum_{\theta \leq \alpha} \begin{bmatrix} \alpha \\ \theta \end{bmatrix}_{\mathtt{Q}} (P_j)_{\alpha-\theta,\theta+\beta} \left(\mathsf{D}_{\mathtt{Q}}^\gamma f\right)_{\theta,\beta} \mathbf{Z}^\gamma \right) \\ &= \widetilde{P}_{\alpha,\beta} + \sum_{j=0}^{r-1} \sum_{\theta \leq \alpha} \begin{bmatrix} \alpha \\ \theta \end{bmatrix}_{\mathtt{Q}} (P_j)_{\alpha-\theta,\theta+\beta} \left(\sum_{|\gamma|=j} f_{\theta+\gamma,\beta} \mathbf{Z}^\gamma \right). \end{aligned}$$

Now for every $\alpha \in \mathbb{N}^m$, $|\alpha| \leq d+k-1$, since $P_{r-1}(\mathtt{Q}^{\alpha+\beta}) = (P_{r-1})_{0^m,\alpha+\beta} \neq 0$, we can rewrite the above as

$$\sum_{|\gamma|=r-1} f_{\alpha+\gamma,\beta}\mathbf{Z}^\gamma$$
$$= -\frac{1}{(P_{r-1})_{0^m,\alpha+\beta}}\left((\widetilde{P})_{\alpha,\beta} + \sum_{\substack{(j,\theta)\leq(r-1,\alpha)\\(j,\theta)\neq(r-1,\alpha)}} \begin{bmatrix}\alpha\\ \theta\end{bmatrix}_{\mathtt{Q}} (P_j)_{\alpha-\theta,\theta+\beta}\left(\sum_{|\gamma|=j} f_{\theta+\gamma,\beta}\mathbf{Z}^\gamma\right)\right) \tag{3}$$

So we can set the undetermined coefficients among $f_{\gamma,\beta} \in \mathbb{K}$, $|\gamma| \leq r-2$ freely, and the remaining coefficients of $f(\mathbb{X})$ are uniquely determined the above equation. This means the solution space is an affine $\mathbb{K}$-linear space having dimension at most $\binom{m+r-2}{r-2}$. Further, at any instance of (3), if we know the R.H.S. and determine the L.H.S., then each coefficient $f_{\alpha+\gamma,\beta}$ can be recovered by instantiating an arbitrary finite grid S^m with $S \subseteq \mathbb{K}$, $|S| \geq ms$ as a hitting set for the $\mathbf{Z}$-variables, since we have $\deg_{\mathbf{Z}}(P) < ms$. ◀

We are now ready to complete the proof of our main theorem.

Proof of Theorem 19. Choosing $r = O(\ell/\epsilon^m)$, and plugging in all the parameters into Proposition 17 and Proposition 18 immediately proves the claim. ◀

New Direct Sum Tests

Alek Westover
MIT, Cambridge, MA, USA

Edward Yu

Kai Zhe Zheng
MIT, Cambridge, MA, USA

Abstract

A function $f : [n]^d \to \mathbb{F}_2$ is a **direct sum** if there are functions $L_i : [n] \to \mathbb{F}_2$ such that $f(x) = \sum_i L_i(x_i)$. In this work we give multiple results related to the property testing of direct sums.

Our first result concerns a test proposed by Dinur and Golubev in [13]. We call their test the Diamond test and show that it is indeed a direct sum tester. More specifically, we show that if a function f is ε-far from being a direct sum function, then the Diamond test rejects f with probability at least $\Omega_{n,\varepsilon}(1)$. Even in the case of $n = 2$, the Diamond test is, to the best of our knowledge, novel and yields a new tester for the classic property of affinity.

Apart from the Diamond test, we also analyze a broad family of direct sum tests, which at a high level, run an arbitrary affinity test on the restriction of f to a random hypercube inside of $[n]^d$. This family of tests includes the direct sum test analyzed in [13], but does not include the Diamond test. As an application of our result, we obtain a direct sum test which works in the online adversary model of [20].

Finally, we also discuss a Fourier analytic interpretation of the diamond tester in the $n = 2$ case, as well as prove local correction results for direct sum as conjectured by [13].

1 Introduction

In property testing, one is given query access to a function over a large, typically multidimensional domain, say $f : \prod_{i=1}^{d} S_i \to T$. The goal is to determine whether or not f satisfies some property, $\mathcal{P}$, using as few queries to f as possible. Here, a property $\mathcal{P}$ can be any subset of functions. It is not hard to see that distinguishing between $f \in \mathcal{P}$ and $f \notin \mathcal{P}$ requires querying the entire domain for any nontrivial property $\mathcal{P}$, and so we typically settle for an algorithm with a weaker guarantee, typically called a property tester. A tester for $\mathcal{P}$ is a randomized algorithm, which given input function f, makes queries to f and satisfies the following two properties:

- **Completeness**: If $f \in \mathcal{P}$, the tester accepts with probability 1.
- **Soundness**: If f is δ-far from $\mathcal{P}$, the tester rejects with probability $s(\delta)$.

© Alek Westover, Edward Yu, and Kai Zhe Zheng;

We say that f is δ-far from $\mathcal{P}$, if the minimal fractional hamming distance between f and any $g \in \mathcal{P}$ is at least δ. The function $s(\delta)$ is referred to as the soundness of the tester and oftentimes one repeats the tester in $s(\delta)^{-1}$ times to reject with probability $2/3$ in the soundness case. It is clear that for any property, there is a trivial algorithm that queries f on its entire domain, so oftentimes the goal is to design testers whose query complexity is sublinear in the domain size or even independent of the dimension d.

In this paper we consider two property testing questions related to functions known as direct sums. A function f is called a direct sum if it can be written as a sum of functions on the individual coordinates, that is

$$f(x_1, \ldots, x_d) = \sum_{i=1}^{d} L_i(x_i),$$

for some functions $L_i : S_i \to T$. Direct sums are a natural property to consider in the context of property testing. Indeed, when one takes $f : \mathbb{F}_2^d \to \mathbb{F}_2$, then the direct sum property is equivalent to the classic property of affinity (being a linear function plus a constant) considered by Blum, Luby, and Rubinfeld's seminal work [8]. Property testing of more general versions of direct sums, called low junta-degree functions, has also been considered before in the works of [5, 3]. A junta-degree t function is one that can be written as the sum of t-juntas. Thus, direct sums are junta-degree 1 functions, and direct sum testing is a specialization of the low junta-degree testing problem that appears in [5, 3].

In addition to being a natural property to study, motivation for direct sum testing also comes from its relation to the more widely known direct product testing problem. Historically, direct product testing was first introduced by Goldreich and Safra in [17] due to its potential for application as a hardness amplification step in more efficient PCP constructions [15, 12, 14, 18, 4]. More recently, the related problem of direct sum testing was considered, first by [10] and later by [13]. The motivation for considering direct sums stems in part from the fact that direct sums are similar to direct products in that they can be used to amplify hardness, but with the advantage that the output is a single value, as opposed to an entire tuple. This seems to make direct sum testing more difficult, but has the potential for leading to even more efficient PCPs (in particular, in improving a parameter known as the alphabet size). Analysis of a type of direct sum test is a key piece of Chan's elegant PCP construction in [9].

Direct Sum Testing. In [13], Dinur and Golubev give and analyze a direct sum tester which they call the Square in a Cube test. They propose an additional test which they refer to as the diamond test, but leave its analysis for future work. We call this second test the Diamond Test, and describe both of these tests below.

Let the domain be an arbitrary grid $[\overline{n}; d] = \prod_{i=1}^{d} [n_i]$ where each $[n_i] = \{1, \ldots, n_i\}$. We will let the output be $\mathbb{F}_2$ so that our input function is

$$f : [\overline{n}; d] \to \mathbb{F}_2.$$

Given two points $a, b \in [\overline{n}; d]$ and $x \in \{0,1\}^d$, let **interpolation** $\phi_x(a, b)$ to be the vector obtained by taking a_i whenever $x_i = 0$ and b_i whenever $x_i = 1$. The Square in a Cube test proceeds as follows.

▶ **Test 1** (Square in a Cube)**.** Sample random $a, b \in [\overline{n}; d]$ and $x, y \in \{0,1\}^d$. Accept if and only if

$$f(a) + f(\phi_x(a, b)) + f(\phi_y(a, b)) + f(\phi_{x+y}(a, b)) = 0.$$

The Diamond Test proceeds in a slightly different manner, which essentially fixes $x + y = (1, \ldots, 1)$.

▶ **Test 2** (Diamond). Sample random $a, b \in [\overline{n}; d], x \in \{0,1\}^d$. Accept iff

$$f(a) + f(\phi_x(a,b)) + f(\phi_x(b,a)) + f(b) = 0.$$

In addition to the Diamond test, we also consider a family of tests that generalizes the Square in a Cube test. We call this test the Affine on Subcube test.

▶ **Test 3** (Affine on Subcube). Sample $a, b \in [n]^d$ and run an affinity test on the function $x \mapsto f(\phi_x(a,b))$.

Note that the affinity test can be any arbitrary affinity test for functions $\mathbb{F}_2^d \to \mathbb{F}_2$. The Square in a Cube test is a special case of the above with the classic BLR affinity test as the affinity test. The Diamond Test, however, is not a specialization of the above.

As is usual in property testing, it is clear that both the Diamond and Affine on Subcube test satisfy completeness, so our main interest is with regards to their soundness.

1.1 Main Results

We now describe our main results. Our first result establishes soundness for the Diamond test. As the completeness is clear, this shows that the Diamond test is indeed a Direct Sum tester.

▶ **Theorem 4.** *Suppose $f : [n]^d \to \mathbb{F}_2$ passes the Diamond test with probability $1 - \varepsilon$. Then, f is $C_n \cdot \varepsilon$-close to a direct sum, for some constant C_n independent of d.*

We remark that the theorem above incurs a dependence on n. In contrast, [13] shows a version of the above result with C_n replaced by an absolute constant, C, independent of n. For $n = O(1)$, the soundness we show for the Diamond Test is comparable to what is known for the Square in a Cube test, but for larger n the soundness analysis becomes weaker. This dependence on n in the soundness is not so uncommon in property testing results however. It is comparable to the dependence on field size in the low degree testing results of [2, 21], or on grid size in the junta degree testing results of [5, 3]. We leave it to future work to remove the dependence on n in the soundness.

Our next result is a reformulation of Theorem 4 in the $n = 2$ case. Here the Diamond Test is, to the best of our knowledge, a novel affinity tester. Moreover, we observe that the soundness of the $n = 2$ Diamond Test is equivalent to a succinct Fourier analytic fact regarding a function's distance to affinity, or equivalently its maximum magnitude Fourier coefficient. Interestingly, we were unable to show this fact without appealing to the soundness of the Diamond test. Intuitively, the Fourier analytic fact says "f is close to affine if and only if when you randomly fix or don't fix each coordinate of f to a random value, f becomes close to an even or odd function". Formally, the result is:

▶ **Theorem 5.** *For $f : \mathbb{F}_2^d \to \mathbb{F}_2$, define $\mathcal{R}(f)$ to be a random restriction of f obtained as follows: for each $i \in [d]$ independently, with probability $1/4$ restrict x_i to 0, with probability $1/4$ restrict x_i to 1, and with probability $1/2$ do not restrict x_i. Then, letting* EvenOrOdd *denote the set of functions that are either even or odd, we have:*

$$\mathsf{dist}(f, \mathsf{affine}) = \Theta(\mathbb{E}_{\mathcal{R}}[\mathsf{dist}(\mathcal{R}(f), \mathsf{EvenOrOdd})]).$$

Along with the Diamond Test, we also describe and analyze a family of testers for direct sum which we call the Affine on Subcube test (Test 3).

▶ **Theorem 6.** *Fix $f : [n]^d \to \mathbb{F}_2, \varepsilon \geq 0$ and an affinity test T. If f passes the Affine on Subcube test (instantiated with T) with probability $1 - \varepsilon$, then f is $C\varepsilon$-close to a direct sum, for some constant C independent of n, d.*

By using a suitable erasure-resilient tester as the inner affinity tester in Test 3, we use Theorem 36 obtain direct sum testers in the online-erasure model recently introduced by [20]. We discuss this result as well as the online-erasure model in more detail in Section 4.2.

Finally, we address a second question posed in [13] regarding reconstructing functions which are close to direct sums. They ask if a test that they call the Shapka test can be used to reconstruct, via a "voting scheme", a direct sum given query access to its corrupted version. We show that this is indeed the case, and also give an improved reconstruction method that uses fewer queries.

▶ **Proposition 7.** *Let $f : [n]^d \to \mathbb{F}_2$ be ε close to a direct sum L, with $(n+1)\varepsilon < 1/4$. Then L can be reconstructed using a voting scheme on f using n queries to f.*

We also give lower bounds on the query complexity needed and show that our improved method is asymptotically optimal (up to constant factors) in terms of both query complexity and the fraction of corruptions it can tolerate.

Proof Overview. We give an overview of the proof of Theorem 4. Our analysis here diverges significantly from that of Dinur and Golubev for the Square in a Cube Test. Before discussing our analysis, we first summarize their approach and where it fails for the Diamond Test.

The underlying idea behind the Square in a Cube Test is that after choosing two points $a, b \in [n]^d$, any direct sum restricted to the hypercube-like domain $\prod_{i=1}^{d}\{a_i, b_i\}$ must be an affine function (i.e multivariate polynomial of degree 1). This idea gives way to a natural interpretation of the Square in a Cube Test

- Choose two points $a, b \in [n]^d$ randomly and view the domain $\prod_{i=1}^{d}\{a_i, b_i\}$ as a hypercube of the appropriate dimension d'. Here d' is the number of coordinates on which a and b differ.
- Define the function $f_{a,b} : \{0,1\}^{d'} \to \mathbb{F}_2$ by $f_{a,b}(x) = f(\phi_x(a, b))$.
- Perform the BLR affinity test on $f_{a,b}$. That is, choose $x, y, z \in \{0,1\}^{d'}$ and accept if and only if

$$f_{a,b}(x) + f_{a,b}(x+y) + f_{a,b}(x+z) + f_{a,b}(x+y+z) = 0.$$

From here, the analysis of [13] has two parts. First, they apply BLR to show that if the overall Square in a Cube test passes with high probability, then for many a, b, the function $f_{a,b}$ is close to an affine function (or direct sum), say $F_{a,b}$, on the hypercube $\prod_{i=1}^{d}\{a_i, b_i\}$. These $F_{a,b}$ can be thought of as local direct sums that agree with f locally on hypercubes inside of $[n]^d$. The second step is to show that many of these $F_{a,b}$ are actually consistent with each other and apply a direct product testing result of [16] to conclude that there is in fact a global direct sum F consistent with many $F_{a,b}$'s. As the $F_{a,b}$'s are in turn largely consistent with f, we get that F is a direct sum close to f, concluding the proof of soundness.

Our analysis of the soundness of the Diamond test, however, requires a different approach. Let us first see what happens when we try to naively adapt the above strategy. After choosing $a, b \in [n]^d$, instead of applying BLR, the Diamond test performs the following test on $f_{a,b} : \{0,1\}^{d'} \to \mathbb{F}_2$.

Choose $x \in \{0,1\}^{d'}$ and accept if and only if $f_{a,b}(0) + f_{a,b}(x) + f_{a,b}(x + \mathbb{1}) + f_{a,b}(\mathbb{1}) = 0$.

There is an issue though: the above is not an affinity tester! Indeed one can check that if $f_{a,b}(0) + f_{a,b}(\mathbb{1}) = 0$, resp. 1, then any even, resp. odd, function passes the above test with probability 1. Thus, we would only get that many $f_{a,b}$ are close to even or odd functions, and from here it is not clear how to make the second part of the analysis go through.

We instead combine ideas from the soundness analyses of [10, 7, 3], which use induction. Suppose $f : [n]^d \to \mathbb{F}_2$ is ε-far from a direct sum. We wish to show that the Diamond Test rejects f with some non-trivial probability that is independent of d. The inductive approach of both of the mentioned works consist of three main steps: 1) Restate the test on f as choosing a random subdomain that is one dimension and performing the test on f restricted to this subdomain, 2) analyze the soundness in the ε very small case, 3) on the other hand, show that if ε is large then show that f must also be far from a direct sum on many subdomains.

To execute all of the above steps, we have to draw on ideas from all of the mentioned works. For step 1), we take inspiration from [10] and instead analyze a four-function version of the Diamond Test. The reason is that there is no clear way to view the Diamond Test in the manner described above. It is tempting to describe the Diamond Test as choosing a random coordinate, say $i = 1$, and a random value in $[n]$, say 1, and then performing a $d-1$-dimensional version of the Diamond Test on the function $f(1, x_2, \ldots, x_d)$. Unfortunately this does not work as one has to change the distribution that the points in the $d-1$-dimensional grid are chosen. Indeed, if one chooses the points $a, b \in [n]^{d-1}$ of the one dimension down Diamond Test uniformly at random, then the final d-dimensional points output would agree on $1 + (d-1)/n$ coordinates in expectation instead of d/n.

For the small distance case in step 2), we rely on the a hypercontractivity theorem over grids. However, since we are now working with a four-function version of the Diamond Test some additional care is needed in this analysis.

Finally for step 3), we use techniques from agreement testing in the PCP literature [25, 23]. From [25] we borrow their transitive-consistency graph technique used to analyze the so-called Plane versus Plane test and from [23] we show a version of their hyperplane sampling lemma for $(d-1)$-dimensional grids in $[n]^d$.

Paper Outline. In Section 3 we present and analyze our novel affinity tester (the Diamond test). In Section 4 we give a new class of direct sum tests. In Section 5 we consider the problem of obtaining "corrected" samples from corrupted direct sums.

2 Preliminaries

We now introduce some notations that will be used throughout the paper. We let $[n]$ denote $\{1, 2, \ldots, n\}$. Let $[n; d]$ denote a product space $[n_1] \times \cdots \times [n_d]$. For a set or event X, we write $\overline{X}$ to denote the complement of X.

The notion of distance that we use is fractional hamming distance. That is, given two functions $f : S \to T$ and $g : S \to T$, the distance between them is the fraction of entries on which they differ:

$$\mathsf{dist}(f, g) = \Pr_{x \in S}[f(x) \neq g(x)].$$

Given a property $\mathcal{P} \subseteq \{g : S \to T\}$, the distance from f to the property $\mathcal{P}$ is defined as

$$\mathsf{dist}(f, \mathcal{P}) = \min_{g \in \mathcal{P}} \mathsf{dist}(f, g).$$

We say that f is δ-*far* from $\mathcal{P}$ if $\mathsf{dist}(f, \mathcal{P}) \geq \delta$.

Finally, if we do not explicitly specify the distribution a random variable is drawn from is a probability, then the random variable is meant to be drawn uniformly from the appropriate space (which will be clear from context). The constants hidden in our O-notation are never allowed to depend on d. If there is a parameter k that we think of as constant, we will sometimes use the notation $O_k(\cdot)$ to emphasize that the constant hidden by the O is allowed to depend on k.

Boolean Functions. Define the **interpolation** $\phi_x(a,b)$ to be the vector obtained by taking a_i whenever $x_i = 0$ and b_i whenever $x_i = 1$. A frequently useful property of interpolations is:

▶ **Fact 8.** $\phi_x(a,b) = \phi_{x+\mathbb{1}}(b,a)$.

Given $x \in \prod_i S_i$ and $p \in [0,1]$, let $y \sim \mathsf{T}_p(x)$ denote a vector in $\prod_i S_i$, with each y_i sampled independently as follows: set $y_i = x_i$ with probability p, and otherwise sample y_i uniformly from S_i; T_p is called the **noise operator**. Given $p \in [-1,0]$ and $x \in \mathbb{F}_2^d$, we define the distribution $y \sim \mathsf{T}_p(x)$ as: $y_i = x_i + 1$ with probability $-p$ and y_i is sampled uniformly from $\{0,1\}$ otherwise. For a boolean function $f : \mathbb{F}_2^d \to \mathbb{F}_2$ we will use $\mu(f)$ to denote the fractional size of the support of f (i.e., the fraction of $\mathbb{F}_2^d$ on which f outputs 1). We use $\mathbb{1}$ to denote the all ones vector, and sometimes use 0 to denote the zero-vector (the dimension will be clear from context). For $v, w \in \mathbb{F}_2^d$ we write $\langle v, w\rangle$ to denote $\sum_i v_i w_i$. For boolean functions $f, g : \mathbb{F}_2^d \to \mathbb{F}_2$ we write $\langle f, g\rangle$ to denote $\mathbb{E}_x[f(x)g(x)]$.

When discussing functions $f : [n]^d \to \mathbb{F}_2$ we will always assume $n > 1$.

3 The Diamond Test

We restate the Diamond test, initially proposed by Dinur and Golubev in [13] (recall from Section 2 that ϕ_x is the interpolation function)

▶ **Test 9** (Diamond)**.** Sample random $a, b \sim [n]^d, x \sim \mathbb{F}_2^d$. Accept iff

$$f(a) + f(b) = f(\phi_x(a,b)) + f(\phi_x(b,a)).$$

We will show that Test 9 is a valid tester for direct sum. First, we analyze the case that the test passes with probability 1.

▶ **Lemma 10.** *The function $f : [n]^d \to \mathbb{F}_2$ is a direct sum if and only if f passes the Diamond test with probability* 1*.*

Proof. If f is a direct sum then we can write $f(x) = \sum_i L_i(x_i)$. It follows that for any $a, b \in [n]^d$,

$$f(a) + f(b) = \sum_i (L_i(a_i) + L_i(b_i)) = f(\phi_x(a,b)) + f(\phi_x(b,a)).$$

For the other direction, suppose f passes the Diamond test with probability 1. Then, for all $x \in \mathbb{F}_2^d, a \in [n]^d$ we have

$$f(a) = f(\mathbb{1}) + f(\phi_x(\mathbb{1}, a)) + f(\phi_x(a, \mathbb{1})). \tag{1}$$

Let $e_{i,j} \in [n]^d$ denote a vector which is 1 at all coordinates except coordinate i, where it has value j. Then, repeated application of Equation (1) lets us decompose $f(a)$ as

$$f(a) = f(\mathbb{1}) + \sum_{i=1}^{d} \left(f(e_{i,a_i}) + f(\mathbb{1})\right).$$

Thus, f is a direct sum. ◀

As a simple corollary of Lemma 10 we have:

▶ **Corollary 11.** *If f is ε-close to a direct sum, then f passes the Diamond test with probability at least $1 - 4\varepsilon$.*

Proof. Let g be a direct sum with $\mathsf{dist}(f, g) \leq \varepsilon$. By a union bound, f and g agree on all 4 points queried by the test (because each query is marginally uniformly distributed), in which case the Diamond test accepts. ◀

With completeness done, the remainder of this section is focused on showing the Diamond test's soundness as stated in Theorem 4. We restate the theorem below.

▶ **Theorem 12.** *Suppose $f : [n]^d \to \mathbb{F}_2$ passes the Diamond test with probability $1 - \varepsilon$. Then, f is $C_n\varepsilon$-close to a direct sum, for some constant C_n independent of d.*

We sketch the ideas used in the analysis. First, we will generalize to a "4-function" version of the test, which is more amenable to induction. Then, we use hypercontractivity ([1, 19, 3]) to prove Theorem 17, which establishes a dichotomy for 4-tuples of functions that pass the test with probability $1 - \varepsilon$: if (f, g, k, h) passes the test with probability ε, then either f (and g, h, k as well) is 2ε-close to a direct sum, or f is $\Omega_n(1)$-far from a direct sum. Next, we will relate the pass probability of (f, g, h, k) to the pass probability of 1-variable restrictions of f, g, k, h. This allows us to go down one dimension and apply induction. Crucially, the dichotomy theorem allows us to avoid our closeness factor deteriorating at each step of the induction, which would result in a dependence on the dimension in our result. This dichotomy based approach is inspired by the work of [7, 10], but the details of establishing the dichotomy and performing the induction are quite different.

3.1 The Four Function Diamond Test

In order to facilitate our inductive approach we define a four function version of the diamond test.

▶ **Test 13** (4-Function Diamond)**.** Sample $x \sim \mathbb{F}_2^d$ and $a, b \sim [n]^d$. Accept iff

$$f(a) + g(\phi_x(a, b)) + h(\phi_x(b, a)) + k(b) = 0.$$

The following lemma characterizes what happens when four functions pass with probability 1. It will be used later to establish the base case (in constant dimensions) of our inductive analysis.

▶ **Lemma 14.** *Suppose (f, g, h, k) passes the 4-function Diamond test with probability 1. Then f, g, k, h are direct sums.*

Proof. If (f, g, h, k) passes the 4-function Diamond test with probability 1 then for all a, x, b we have:

$$f(a) + g(\phi_x(a, b)) + h(\phi_x(b, a)) + k(b) = 0 = f(b) + g(\phi_{x+\mathbb{1}}(b, a)) + h(\phi_{x+\mathbb{1}}(a, b)) + k(a).$$

Using Fact 8 to simplify we get that for all a, b,

$$f(a) + k(a) = f(b) + k(b).$$

Again using the fact that (f, g, h, k) passes the test with probability 1 we have that for all a, x, b:

$$f(a) + g(\phi_x(a, b)) + h(\phi_x(b, a)) + k(b) = 0 = f(a) + g(\phi_{x+\mathbb{1}}(a, b)) + h(\phi_{x+\mathbb{1}}(b, a)) + k(b).$$

By Fact 8 this implies

$$g(\phi_x(a,b)) + g(\phi_x(b,a)) = h(\phi_x(a,b)) + h(\phi_x(b,a)).$$

Letting $c = \phi_x(a,b), d = \phi_x(b,a)$, and noting that c, d can be arbitrary (unrelated) elements of $[n]^d$, we have that for all c, d.

$$g(c) + g(d) = h(c) + h(d).$$

Combining our observations so far we conclude that there exist constants α, β such that for all $a \in [n]^d$ we have

$$f(a) = k(a) + \alpha, \quad g(a) = h(a) + \beta.$$

Thus, for all a, b we have

$$f(a) + f(b) = g(\phi_x(a,b)) + g(\phi_x(b,a)) + \alpha + \beta.$$

Taking $x = 0$ we conclude

$$f(a) + f(b) = g(a) + g(b) + \alpha + \beta.$$

Thus, there exists γ such that for all a we have

$$f(a) = g(a) + \gamma.$$

In summary, we have shown that for all a, b, x, we have

$$f(a) + f(b) = f(\phi_x(a,b)) + f(\phi_x(b,a)) + \alpha + \beta.$$

Setting $x = 0$ again shows that $\alpha + \beta = 0$. Thus, we have that f passes the (1-function) Diamond test with probability 1. By Lemma 10 this implies that f is a direct sum. Finally, recall that we have shown in the course of our proof that g, h, k all differ from f by a constant. This concludes the proof. ◀

3.2 A Dichotomy for Functions Passing the Diamond Test

We are now prepared to show Theorem 17, which states that if the 4-function Diamond test accepts (f, g, h, k) with probability exactly $1 - \varepsilon$ then f is either 2ε-close to a direct sum, or $\Omega_n(1)$-far from being a direct sum. To this end, we first establish two lemmas which will useful in the proof.

▶ **Lemma 15.** *Fix $d \in \mathbb{N}$ and functions $f, g, h : [n]^d \to \mathbb{F}_2$. Suppose f, g, h have*

$$\Pr_{a,b \sim [n]^d, x \sim \mathbb{F}_2^d}[f(a) + g(\phi_x(a,b)) + h(\phi_x(b,a)) = 1] < \varepsilon.$$

Then, f, g, h are 3ε-close to constants.

Proof. Fix f, g, h as in the theorem. Performing a union bound and using Fact 8 we have

$$\Pr_{a,b,x}[f(a) + g(\phi_x(a,b)) + h(\phi_x(b,a)) = f(b) + g(\phi_x(a,b)) + h(\phi_x(b,a))] > 1 - 2\varepsilon.$$

Thus, f is 2ε-close to a constant α. Then, by a union bound we have

$$\Pr_{a,b,x}[g(\phi_x(a,b)) + h(\phi_x(b,a)) = \alpha + 1] > 1 - 3\varepsilon.$$

Of course, the distribution of $(\phi_x(a,b), \phi_x(b,a))$ is the same as the distribution of (a,b). Thus, we have

$$\Pr_{a,b}[g(a) + h(b) = \alpha + 1] > 1 - 3\varepsilon.$$

By the probabilistic method this implies that g, h are each 3ε-close to constants. ◀

We will also need the following lemma, which is an extension of the classic **small set expansion** property of the noisy hypercube (see [24]) to *grids*.

▶ **Fact 16** ([24]). Fix $n \in \mathbb{N}$. There exists $\lambda_n > 0$ such that for any d, and any set $S \subseteq [n]^d$ we have

$$\Pr_{a \sim [n]^d, b \sim \mathsf{T}_{1/2}(a)}[a \in S \wedge b \in S] \leq 2\mu(S)^{1+\lambda_n}.$$

Now we are ready to establish the dichotomy theorem.

▶ **Theorem 17.** *Fix $n \in \mathbb{N}$. There exists a constant $c_n > 0$ such that the following is true for any d and any functions $f, g, h, k : [n]^d \to \mathbb{F}_2$. Suppose k has $\mathsf{dist}(k, \mathsf{directsum}) < c_n$. Then, the 4-function Diamond test rejects (f, g, h, k) with probability at least $\mathsf{dist}(k, \mathsf{directsum})/2$.*

Proof. Fix f, g, k, h as described in the theorem statement. Let χ be the closest direct sum to k. Then,

$$\chi(a) + \chi(b) = \chi(\phi_x(a,b)) + \chi(\phi_x(b,a)).$$

Thus, our goal is equivalent to showing that

$$\Pr_{a,x,b}[(\chi+f)(a) + (\chi+g)(\phi_x(a,b)) + (\chi+h)(\phi_x(b,a)) \neq (\chi+k)(b)] \geq \mathsf{dist}(k, \mathsf{directsum})/2.$$

Thus, it suffices to consider the case that the closest direct sum to k is the zero function. We assume this for the remainder of the proof. Then, $\mathsf{dist}(k, \mathsf{directsum}) = \mu(k)$. We are already done unless

$$\Pr_{a,x,b}[f(a) + g(\phi_x(a,b)) + h(\phi_x(b,a)) = 1] \leq 2\mu(k). \tag{2}$$

Thus, we may assume that Equation (2) is true. Now, by Lemma 15 we have that f, g, h are $6\mu(k)$-close to constants. Without loss of generality we may assume g, h are both closer to 0 than to 1; otherwise we can add 1 to both g, h, which does not affect the sum $g(\phi_x(a,b)) + h(\phi_x(b,a))$. If f were closer to 1 than to 0 then we would have

$$\Pr_{(a,x,b)}[f(a) = 1, g(\phi_x(a,b)) = h(\phi_x(b,a)) = 0] \geq 1 - 18\mu(k) > 2\mu(k),$$

with the final inequality holding by our assumption that $\mu(k) < c_n$ (we will choose $c_n < .001$); but this would contradict Equation (2), so it cannot happen. Thus, f, g, h are all $6\mu(k)$-close to 0.

Now, we return to analyzing the probability that the 4-function Diamond test rejects (f, g, h, k); we write $\Pr[\mathsf{rej}]$ to denote the probability. Then,

$$\begin{aligned}
\Pr[\mathsf{rej}] &\geq \Pr_{a,x,b}[k(b) = 1 \wedge f(a) = g(\phi_x(a,b)) = h(\phi_x(b,a)) = 0] \\
&\geq \mu(k) - \Pr_{a,b}[k(b) = f(a) = 1] - \Pr_{a,x,b}[k(b) = g(\phi_x(a,b)) = 1] - \Pr_{a,x,b}[k(b) = h(\phi_x(b,a)) = 1] \\
&\geq \mu(k) - \mu(k)\mu(f) - \Pr_{a,b \sim \mathsf{T}_{1/2}(a)}[k(b) = g(a) = 1] - \Pr_{a,b \sim \mathsf{T}_{1/2}(a)}[k(b) = h(a) = 1].
\end{aligned}$$

Then, using Fact 16 we have

$$\Pr[\mathsf{rej}] \geq \mu(k)(1-\mu(f)) - (\mu(k)+\mu(g))^{1+\lambda_n} - (\mu(k)+\mu(h))^{1+\lambda_n}),$$

where $\lambda_n > 0$ is the constant from Fact 16. Recalling that $\mu(f), \mu(g), \mu(h) \leq 6\mu(k)$ we have:

$$\Pr[\mathsf{rej}] \geq \mu(k)(1-\mu(k)-100\mu(k)^{\lambda_n}).$$

Thus, there is some constant c_n (dependent only on n) such that if $\mu(k) \leq c_n$ then the rejection probability in is at least $\mu(k)/2$, as desired. ◀

3.3 A Lemma Concerning Restrictions

To complete our analysis of the Diamond test, we will relate the Diamond test to lower dimensional Diamond tests, and argue inductively. The Dichotomy lemma just established will be the key to ensuring that our soundness parameter does not deteriorate as we perform the induction. First, we need a lemma that controls the restrictions of a function which is far from a direct sum; namely, we show that a function which is far from a direct sum cannot have too many restrictions which are close to direct sums.

For some set $R \subseteq [n]^d$, we let $f|_R$ denote the restriction of f to R, so that $f|_R : S \to \mathbb{F}_2$ is given by $f|_R(x) = f(x)$ for all $x \in R$. We will specifically be considering restrictions where R is of the form $R = \{x \in [n]^d \mid x_i = j\}$ for some $1 \leq i \leq d$ and some $j \in [n]$. We call such R, *one-variable restrictions*. Throughout this subsection we use $\mathbb{1}$ to denote the indicator of an event. The goal of this subsection is to establish the following Lemma.

▶ **Lemma 18.** *Suppose there are $100n^2/\varepsilon$ one-variable restrictions R such that $f|_R$ is ε-close to a direct sum on R. Then, f is $O(\varepsilon)$-close to a direct sum.*

We will need Dinur and Golubev's result regarding the soundness of the square in the cube test, which we state below.

▶ **Theorem 19** ([13])**.** *Let $f : [n]^d \to \mathbb{F}_2$ satisfy,*

$$\Pr_{a,b\in[n]^d, x,y,z\in\{0,1\}^d}[f(a)+f(\phi_x(a,b))+f(\phi_y(a,b))+f(\phi_{x+y}(a,b))=0] \geq 1-\varepsilon.$$

Then f is $O(\varepsilon)$-close to a direct sum.

At a high level our proof of Lemma 18 follows the strategy of the plane versus point analysis of [25]. Suppose that there are many restrictions R_i with local direct sums $f_i : R_i \to \mathbb{F}_2$ such that f_i and f are close. We will first show that many – in fact at least a constant fraction – of these f_i's are actually consistent with each other. Using these consistent f_i's we can then define a function F on the whole space and argue that 1) F is close to f and 2) F passes the square in the cube test with high probability and is thus close to a direct sum. For both 1) and 2) we are crucially using the fact that F is defined using many consistent direct sums, so for nearly every point x in the domain, there are in fact many of these local direct sums defined on x.

3.3.1 A Sampling Lemma

In order to carry out the mentioned strategy, we must first show a sampling lemma. This lemma roughly states that given a large enough set of restrictions R_i, the measure on $[n]^d$ produced by first choosing a random R_i and then choosing a random $x \in R_i$ is nearly equal to the uniform measure up to constant factors (which will be negligible).

Let $\mathcal{R}$ be a set of one variable restrictions and let $M = |\mathcal{R}|$. Define the measure $\nu_{\mathcal{R}}$ on points $[n]^d$ via the following sampling procedure:

- Choose $R \in \mathcal{R}$.
- Choose $x \in R$.

Letting $N_{\mathcal{R}}(x) = |\{R \in \mathcal{R} \mid R \ni x\}|$, it is clear that,

$$\nu_{\mathcal{R}}(x) = \frac{N_{\mathcal{R}}(x)}{M} \cdot \frac{1}{n^{d-1}}.$$

For a subset of points $S \subseteq [n]^d$, we define

$$\nu_{\mathcal{R}}(S) = \sum_{x \in S} \nu_{\mathcal{R}}(x).$$

We also let μ denote the standard uniform measure on $[n]^d$, so for a set of points $S \subseteq [n]^d$, we have $\mu(S) = \frac{|S|}{n^d}$. At times we will also use μ to denote the uniform measure over grids of dimension other than d. It will be clear from context when this is the case and we remark that one should think of the dimension in this subsection as being arbitrary.

▶ **Lemma 20.** *Let $\mathcal{R}$ be a set of one-variable restrictions of size M. Then,*

$$\mathbb{E}_x[N_{\mathcal{R}}(x)] = \frac{M}{n} \quad \textit{and} \quad \mathsf{Var}(N_{\mathcal{R}}(x)) \leq \frac{M}{n}.$$

Proof. For the first part, we have, by linearity of expectation:

$$\mathbb{E}_x[N_{\mathcal{R}}] = \sum_{R \in \mathcal{R}} \mathbb{E}_x[\mathbb{1}(x \in R)] = \frac{M}{n}.$$

Towards the second part, we write

$$\begin{aligned}
\mathbb{E}[N_{\mathcal{R}}^2] &= \sum_{R_1, R_2 \in \mathcal{R}} \mathbb{E}_x[\mathbb{1}(x \in R_1) \cdot \mathbb{1}(x \in R_2)] \\
&= \sum_{R \in \mathcal{R}} \mathbb{E}_x[\mathbb{1}(x \in R)] + \sum_{R_1 \neq R_2} \mathbb{E}_x[\mathbb{1}(x \in R_1) \cdot \mathbb{1}(x \in R_2)] \\
&\leq \frac{M}{n} + \frac{M^2}{n^2}.
\end{aligned}$$

It follows that,

$$\mathrm{Var}(N_{\mathcal{R}}) = \left(\mathbb{E}_x[N_{\mathcal{R}}]\right)^2 - \mathbb{E}[N_{\mathcal{R}}^2] \leq \frac{M}{n}.$$ ◀

Applying Chebyshev's inequality, we get the following.

▶ **Lemma 21.** *For any $c > 0$, it holds that*

$$\Pr_x\left[\left|N_{\mathcal{R}}(x) - \frac{M}{n}\right| \geq c \cdot \frac{M}{n}\right] \leq \frac{n}{c^2 \cdot M}.$$

Proof. This lemma follows from a direct application of Chebyshev's inequality combined with the variance bound in Lemma 20. ◀

▶ **Lemma 22.** *For any set of points $S \subseteq [n]^d$ and any set $\mathcal{R}$ of one-variable restrictions of size M, we have*

$$\frac{1}{2}\left(\mu(S) - \frac{4n}{M}\right) \leq \nu_{\mathcal{R}}(S) \leq 2\mu(S) + \frac{5n}{M}.$$

Proof. For each integer i, let

$$m_i = \left| \left\{ x \in [n]^d \mid 2^i \frac{M}{n} \leq N_{\mathcal{R}}(x) < 2^{i+1} \frac{M}{n} \right\} \right|.$$

By Lemma 20 we get that

$$\frac{m_i}{n^d} \leq \frac{1}{(2^i - 1)^2 M/n}.$$

Towards the upper bound, we expand $\nu_{\mathcal{R}}(S)$ and perform a dyadic partitioning:

$$\nu_{\mathcal{R}}(S) = \sum_{x \in S} \nu_{\mathcal{R}}(x) = \sum_{x \in S} \frac{N_{\mathcal{R}}(x)}{M n^{d-1}} \leq \frac{1}{M n^{d-1}} \left(2 \cdot \frac{M}{n} \cdot |S| + \sum_{i=1}^{\infty} m_i 2^{i+1} \cdot \frac{M}{n} \right).$$

The first term in the parenthesis contributes $2\mu(\mathcal{S})$, whereas the contribution of the second summand can be upper bounded by

$$\frac{1}{n^d} \cdot \sum_{i=1}^{\infty} m_i 2^{i+1} \leq \frac{n}{M} \cdot \sum_{i=1}^{\infty} \frac{2^{i+1}}{(2^i - 1)^2} \leq \frac{5n}{M}$$

For the lower bound, we have

$$\nu_{\mathcal{R}}(S) = \sum_{x \in S} \nu_{\mathcal{R}}(x) \geq \sum_{x \in S, N_{\mathcal{R}} \geq M/(2n)} \nu_{\mathcal{R}}(x) \geq |\{x \in S \mid N_{\mathcal{R}}(x) \geq M/(2n)\}| \cdot \frac{1}{2n^d}.$$

To lower bound the last term above, we use Lemma 21 to get

$$\Pr_x \left[N_{\mathcal{R}}(x) < \frac{M}{2n} \right] \leq \frac{4n}{M}.$$

It follows that

$$|\{x \in S \mid N_{\mathcal{R}}(x) \geq M/(2n)\}| \geq n^d \left((\mu(S) - \frac{4n}{M} \right).$$

Putting everything together, we get the desired lower bound:

$$\nu_{\mathcal{R}}(S) \geq \frac{1}{2} \left(\mu(S) - \frac{4n}{M} \right).$$ ◀

3.3.2 Proof of Lemma 18

Suppose $\mathcal{R} = \{R_1, \ldots, R_M\}$ is the set of one-variable restrictions on which f is ε-close to a direct sum. For each R_i, let f_i be this direct sum, so

$$\mathsf{dist}(f_i, f|_{R_i}) \leq \varepsilon,$$

for each $1 \leq i \leq M$. By assumption $M \geq 100n^2/\varepsilon$. Note that if ε is large – say $\varepsilon \geq \frac{1}{100}$ – then the result is trivial, so for the remainder of the proof we suppose $\varepsilon < \frac{1}{100}$.

As a useful fact, we show that the set of direct sum functions has minimum distance $\frac{1}{n}$.

▶ **Lemma 23.** *For any two distinct direct sums f and g, we have*

$$\mathsf{dist}(f, g) \geq \frac{1}{n}.$$

Proof. Write $f(x) = \sum_{i=1}^{d} L_i(x_i)$ and $g(x) = \sum_{i=1}^{d} L'_i(x_i)$. First suppose for each i, $L_i - L'_i$ is constant, then since $f(x) \neq g(x)$, we have $\delta(f, g) = 1$ and we are done.

Suppose that there is some i such that $L_i - L'_i$ is not the constant function and without loss of generality, let this i be 1. Then,

$$\Pr_{x \in [n]^d}[f(x) \neq g(x)] = \mathbb{E}_{x_2,\ldots,x_d}\left[\Pr_{x_1}[L_1(x) - L'_1(x) \neq \sum_{i=2}^{d} L_i(x_i) - L'_i(x_i)]\right].$$

To conclude, note that for any $x_2, \ldots, x_d$, the inner probability on the right hand side above is at least $1/n$ since $L_1 - L'_1$ is not the constant function. ◀

We now construct the following graph $G = (V, E)$. The vertex set is $V = \{1, \ldots, M\}$ while the set of edges E consists of all pairs (i, j) such that the functions f_i and f_j are consistent:

$$f_i|_{R_i \cap R_j} = f_j|_{R_i \cap R_j}.$$

If $R_i \cap R_j$ is empty, then we also consider f_i and f_j consistent and have $(i, j) \in E$. We will first show that G contains a large clique. Call a graph is *transitive* if it is an edge disjoint union of cliques. Also define

$$\beta(G) = \max_{(i,j) \notin E} \Pr_{k \in V}[(i, k), (j, k) \in E].$$

Note that G is transitive if and only if $\beta(G) = 0$. The following lemma from [25] gives a sort of approximate version of this fact and states that if $\beta(G)$ is small then G is almost a transitive graph.

▶ **Lemma 24.** *The graph G can be made transitive by removing at most $3\sqrt{\beta(G)}|V|^2$ edges.*

In our next two lemmas we show that G has many edges, and then bound $\beta(G)$. This will establish that G contains a large clique, which corresponds to many local direct sums f_i that are consistent with one another.

▶ **Lemma 25.** *The graph G has at least $0.9M^2$ edges.*

Proof. For each R_i, let $S_i \subseteq R_i$ be the set of points on which f_i and f differ. We have that

$$\frac{|S_i|}{|R_i|} \leq \varepsilon,$$

by assumption.

Now fix an R_i. We will apply Lemma 22 inside of R_i, which is isomorphic to the grid $[n]^{d-1}$. For each j, let $R'_j = R_i \cap R_j$. Let $\mathcal{R}' = \{R'_j \mid \frac{R'_j \cap S_i}{R'_j} \geq 3\varepsilon\}$, and let $M' = |\mathcal{R}'|$. Now consider the size of S_i inside of R_i under the measure $\nu_{\mathcal{R}'}$. We have,

$$\nu_{\mathcal{R}'}(S_i) \geq 3\varepsilon.$$

By Lemma 22

$$3\varepsilon \leq \nu_{R'}(S_i) \leq 2\varepsilon + 5n/M'.$$

It follows that,

$$M' \leq \frac{5n}{\varepsilon}.$$

Thus,

$$\Pr_{R_i,R_j}\left[\frac{|R_i \cap R_j \cap S_i|}{|R_i \cap R_j|} \geq 3\varepsilon\right] \leq \frac{5n}{\varepsilon M}.$$

By a union bound, it follows that with probability at least $1 - \frac{10n}{\varepsilon M}$, we have that both

$$\frac{|R_j \cap R_i \cap S_i|}{|R_j \cap R_i|} \leq 3\varepsilon \quad \text{and} \quad \frac{|R_j \cap R_i \cap S_j|}{|R_j \cap R_i|} \leq 3\varepsilon.$$

For such i, j, we get that

$$\Pr_{x \in R_i \cap R_j}[f_i(x) = f_j(x)] \geq 1 - \Pr_{x \in R_i \cap R_j}[x \in S_i \cup S_j] \geq 1 - 6\varepsilon > \frac{1}{n},$$

and $f_i|_{R_i \cap R_j} = f_j|_{R_i \cap R_j}$ by Lemma 23. Thus choosing i, j randomly, we get that they are adjacent in G with probability at least $1 - \frac{10n}{\varepsilon M} \geq 0.9$. ◀

▶ **Lemma 26.** *Suppose R_i, R_j are distinct one-variable restrictions such that $f_i|_{R_i \cap R_j} \neq f_j|_{R_i \cap R_j}$. Then,*

$$\Pr_{R_k}[f_i|_{R_i \cap R_j \cap R_k} = f_j|_{R_i \cap R_j \cap R_k}] \leq \frac{5n^2}{M} \leq \frac{\varepsilon}{20}.$$

Proof. Let $W = R_i \cap R_j$. For each k let $R'_k = R_k \cap W$, let $f'_i = f_i|_W$, and let $f'_j = f_j|_W$.

Throughout the proof we will consider W as our ambient space and we will apply Lemma 22 inside of W. Note that we may do so because W is isomorphic to the grid $[n]^{d-2}$. Define the following set of one-variable restrictions inside W:

$$\mathcal{R}' = \{W \cap R_k \neq \emptyset \mid R_k \in \mathcal{R}, f'_i|_{R'_k} = f'_j|_{R'_k}\}.$$

We will show that $|\mathcal{R}'|$ cannot be too large. Indeed, let M' denote its size and let $S \subseteq W$ be

$$S = \{x \in W \mid f'_i(x) \neq f'_j(x)\}.$$

We have that $\frac{|S|}{|W|} \geq \frac{1}{n}$. On the other hand, by definition of $\mathcal{R}'$, we have that $\nu_{R'}(S) = 0$. Therefore by Lemma 22:

$$0 \geq \frac{1}{2}\left(\frac{1}{n} - \frac{4n}{M'}\right).$$

It follows that

$$M' \leq 4n^2.$$

Finally there can be up to $2n$ additional restrictions R_k such that $R_k \cap R_i = \emptyset$ or $R_k \cap R_j = \emptyset$. The result follows. ◀

Combining Lemma 25 and Lemma 26, we get that G contains a transitive subgraph with at least $0.8M^2$ edges. Let $\mathcal{C}_1, \ldots, \mathcal{C}_J$ be the edge disjoint union cliques of this transitive subgraph and say $\mathcal{C}_1$ is the largest one. It follows that,

$$0.8M^2 \leq \sum_{I=1}^{J} |\mathcal{C}_i|^2 \leq |\mathcal{C}_1| \cdot M,$$

and G contains a clique of size $M_1 = 0.8M$. From now we let $\mathcal{C}$ denote this clique and let $\mathcal{C} = \{1, \ldots, M_1\}$. We define the following function F using the functions $f_1, \ldots, f_{M_1}$: set $F(x) = f_j(x)$ if there is some $j \in \mathcal{C}_1$ such that $x \in R_j$, and $F(x) = 0$ otherwise.

To conclude, we will show that F is close to f and F is close to a direct sum. This will establish that f is close to a direct sum.

▶ **Lemma 27.** *F is 3ε-close to f.*

Proof. Let $S = \{x \in [n]^d \mid f(x) \neq F(x)\}$. Since f is ε-close to F on the restrictions R_i for all $i \in \mathcal{C}$, we have

$$\nu_{\mathcal{C}}(S) \leq \varepsilon.$$

By Lemma 22, it follows that,

$$\varepsilon \geq \frac{1}{2}\left(\mu(S) - \frac{4n}{0.8M}\right),$$

and

$$\mu(S) \leq 3\varepsilon.$$ ◀

▶ **Lemma 28.** *F is $O(\varepsilon)$-close to a direct sum.*

Proof. We will show that F passes the square in a cube test with high probability. Recall this test operates by choosing $a, b \in [n]^d$, $x, y \in \{0,1\}^d$ and checking if F satisfies,

$$F(a) + F(\phi_x(a,b)) + F(\phi_y(a,b)) + F(\phi_{x+y}(a,b)) = 0.$$

Note that F passes if there is some $i \in \mathcal{C}$ such that $a, b \in R_i$. Indeed, in this case all of the queried points are in R_i, so F and the direct sum f_i agree on all of the queried points and

$$F(a)+F(\phi_x(a,b))+F(\phi_y(a,b))+F(\phi_{x+y}(a,b)) = f_i(a)+f_i(\phi_x(a,b))+f_i(\phi_y(a,b))+f_i(\phi_{x+y}(a,b)) = 0.$$

To bound the probability that $i \in \mathcal{C}$ such that $a, b \in R_i$, let $N'(x) = |\{i \in \mathcal{C} \mid x \in R_i\}|$. By Lemma 21,

$$\Pr_a\left[N'(a) \geq \frac{M}{1.6n}\right] \leq \frac{5n}{M}.$$

Now condition on a satisfying $N'(a) \geq \frac{M}{1.6n}$ and let $\mathcal{C}'' = \{i \in \mathcal{C} \mid a \in R_i\}$. We label $\mathcal{C}'' = \{1, \ldots, M''\}$ where $M'' \geq \frac{M}{1.6n}$ and let $N''(x) = |\{i \in \mathcal{C}'' \mid x \in R_i\}|$. Then by Lemma 21 again,

$$\Pr_b[N''(b) \geq 0] \leq \frac{n}{M''} \leq \frac{1.6n^2}{M}.$$

By a union bound, with probability at least $1 - \frac{7n^2}{M}$ we have that a and b are both contained in some R_i with $i \in \mathcal{C}$. It follows that F passes the square in a cube test with probability at least $1 - \frac{7n^2}{M}$. By Theorem 19, F is $O(\frac{n^2}{M}) = O(\varepsilon)$-close to a direct sum. ◀

Proof of Lemma 18. The result follows by combining Lemma 27, Lemma 28 and using the triangle inequality. ◀

3.4 Soundness of the Diamond Test

Equipped with Theorem 17 we complete the proof of Theorem 4. Ultimately, we wish to conclude that if the 4-function Diamond test rejects (f, g, h, k) with probability exactly ε, then f, g, h, k are all $O(\varepsilon)$-close to direct sums. However, what we have thus far only allows us to to conclude that f, g, k, h are each *either* c_n-far from being a direct sum, *or* 2ε-close to a direct sum. Our next theorem rules out the former possibility.

▶ **Theorem 29.** *Fix $n \in \mathbb{N}$. Let c_n be the constant from Theorem 17. There is a constant δ_n such that the following holds. Fix $d \in \mathbb{N}$, and functions $f, g, h, k : [n]^d \to \mathbb{F}_2$. Suppose f is c_n-far from being a direct sum. Then, the 4-function Diamond test rejects (f, g, h, k) with probability at least δ_n.*

Proof. By Lemma 18 there exists a constant K_n such that if f has at least $100n^2/c_n$ restrictions which are c_n/K_n-close to affine, then f is c_n-close to affine. Define $N_n = \lceil 100n^2/c_n \rceil + 1$ and $\delta_n = \min(c_n/(2K_n), n^{-3N_n})$. We will prove the theorem by induction on the dimension d.

The base case is $d \leq N_n$. If $d \leq N_n$ then by Lemma 10 the 4-function Diamond test rejects (f, g, h, k) with non-zero probability since f is not a direct sum. But, any non-zero probability over events determined by a, b, x is at least $1/n^{3N_n} \geq \delta_n$.

Now, fix $d > N_n$, and assume the theorem for functions on $\mathbb{F}_2^{d-1}$. Let $f|_{i,\sigma} : [n]^{d-1} \to \mathbb{F}_2$ denote the function obtained by taking f and fixing $x_i = \sigma$. Then, there is some $i \in [d]$ such for all $\sigma \in [n]$ the restriction $f|_{i,\sigma}$ is c_n/K_n-far from a direct sum. To analyze the probability that the 4-function Diamond test rejects (f, g, h, k), we consider a partition of the probability space into $2n^2$ disjoint events. The events are the value in $[n]^2 \times \mathbb{F}_2$ that our sampled (a_i, b_i, x_i) takes. Now, consider the probability that the 4-function Diamond test rejects (f, g, h, k), conditional on $(a_i, b_i, x_i) = (\alpha, \beta, \xi)$ for some α, β, ξ. Conditional on this event, we will sample $a, b \in [n]^{d-1}, x \in \mathbb{F}_2^{d-1}$ and check:

$$f|_{i,\alpha}(a) + g|_{i,\phi_\xi(\alpha,\beta)}(\phi_x(a,b)) = h|_{i,\phi_\xi(\beta,\alpha)}(\phi_x(b,a)) + k|_{i,\beta}(b).$$

This is precisely a 4-function Diamond test on $(d-1)$-dimensional functions. Now we consider two cases.

Case 1: $f|_{i,\alpha}$ is c_n-far from being a direct sum.
Then by the inductive hypothesis this $(d-1)$-dimension test will reject with probability at least δ_n.

Case 2: $\mathsf{dist}(f|_{i,\alpha}, \mathsf{directsum}) \in [c_n/K_n, c_n]$.
Then, by Theorem 17 this $(d-1)$-dimensional test rejects with probability at least $c_n/(2K_n) \geq \delta_n$.

We have seen that in all cases, the lower dimensional 4-function Diamond tests reject with probability at least δ_n. Thus, the actual 4-function Diamond test rejects with probability δ_n as well. ◀

Combining Theorem 17 and Theorem 29 we have get the following corollary and conclude the proof of Theorem 4.

▶ **Corollary 30.** *If (f, g, h, k) passes the 4-function Diamond test with probability $1 - \varepsilon$, then f, g, h, k are each $O_n(\varepsilon)$-close to direct sums.*

Proof. The result follows immediately from Theorem 17 and Theorem 29. ◀

We can now conclude the proof of Theorem 4 and establish soundness for the Diamond test.

Proof of Theorem 4. The result follows from Corollary 30 by setting $f = g = h = k$. ◀

3.5 The Fourier Analytic Interpretation of the Diamond Test

In this section, we give a Fourier analytic interpretation of the Diamond test. Let Even denote the class of functions $f : \mathbb{F}_2^d \to \mathbb{F}_2$ satisfying $f(x + \mathbb{1}) = f(x)$ and let Odd denote the class of functions $f : \mathbb{F}_2^d \to \mathbb{F}_2$ satisfying $f(x + \mathbb{1}) = f(x) + 1$. Let $\mathsf{EvenOrOdd} = \mathsf{Even} \cup \mathsf{Odd}$. We note that $\mathsf{EvenOrOdd}$ has a nice Fourier analytic interpretation: $f \in \mathsf{EvenOrOdd}$ implies that $(-1)^f$ has either all its Fourier-mass on even-sized characters, or all of its Fourier-mass on odd-sized characters. Given a function $f : \mathbb{F}_2^d \to \mathbb{F}_2$, define random variable $\mathcal{R}(f)$ to be a random restriction of f obtained as follows: for each $i \in [d]$ independently, with probability $1/4$ restrict x_i to 0, with probability $1/4$ restrict x_i to 1, and with probability $1/2$ do not restrict x_i. We now show that the Diamond test's correctness is equivalent to the following Fourier analytic fact

▶ **Theorem 31.**

$$\mathsf{dist}(f, \mathsf{affine}) \leq O(\mathbb{E}[\mathsf{dist}(\mathcal{R}(f), \mathsf{EvenOrOdd})])$$

In fact, we show something stronger: there is a very tight quantitative relationship between

$$\mathbb{E}[\mathsf{dist}(\mathcal{R}(f), \mathsf{EvenOrOdd})]$$

and the probability that the Diamond test rejects f.

▶ **Lemma 32.** *Fix f. Let ε be the probability that the Diamond test rejects f, and let*

$$\delta = \mathbb{E}[\mathsf{dist}(\mathcal{R}(f), \mathsf{EvenOrOdd})].$$

Then,

$$2\delta \leq \varepsilon \leq 4\delta.$$

Proof. Fix f, ε, δ as in the lemma statement. Given a, b define $C_{a,b} = \left\{\phi_x(a,b) \mid x \in \mathbb{F}_2^d\right\}$ and $f_{a,b}(x) = f(\phi_x(a,b))$. We have:

$$\varepsilon = \Pr_{a,b,x}[f_{a,b}(x) + f_{a,b}(x + \mathbb{1}) \neq f_{a,b}(0) + f_{a,b}(\mathbb{1})]. \tag{3}$$

▷ Claim 33. $\varepsilon \leq 4\delta$.

Let $\delta_{a,b} = \mathsf{dist}(f_{a,b}, \mathsf{EvenOrOdd})$. By a union bound we have

$$\Pr_{z,x}[f_{a,b}(x + \mathbb{1}) + f_{a,b}(x) \neq f_{a,b}(z + \mathbb{1}) + f_{a,b}(z)] \leq 4\delta_{a,b}.$$

By averaging, $\delta = \mathbb{E}_{a,b}[\delta_{a,b}]$. Thus,

$$\Pr_{a,b,z,x}[f_{a,b}(x + \mathbb{1}) + f_{a,b}(x) \neq f_{a,b}(z + \mathbb{1}) + f_{a,b}(z)] \leq 4\delta. \tag{4}$$

Now, observe that for random a, b, z, x the following two distributions are the same:
1. $(\phi_x(a,b), \phi_x(b,a), a, b)$
2. $(\phi_x(a,b), \phi_x(b,a), \phi_z(a,b), \phi_z(b,a))$.

Thus Equation (4) implies $\varepsilon \leq 4\delta$.

▷ Claim 34. $\varepsilon \geq 2\delta$.

For any function g,

$$\Pr_x[g(x) \neq g(x+\mathbb{1})] = 2\mathsf{dist}(g, \mathsf{Even}),$$

$$\Pr_x[g(x) = g(x+\mathbb{1})] = 2\mathsf{dist}(g, \mathsf{Odd}).$$

Thus, for any a, b we have

$$\Pr_x[f_{a,b}(x) + f_{a,b}(x+\mathbb{1}) \neq f_{a,b}(0) + f_{a,b}(\mathbb{1})] \geq 2\mathsf{dist}(f_{a,b}, \mathsf{EvenOrOdd}).$$

Averaging over a, b on both sides gives $\varepsilon \geq 2\delta$. ◀

Proof of Theorem 31. The result follows from the soundness of the Diamond Test, Theorem 4 ◀

4 The Affine on Subcube Test

In this section we consider a class of direct sum tests that generalizes the Square in Cube test of [13]. We call these tests **Affine on Subcube** tests. Indeed, the Square in Cube test can be viewed as performing the BLR affinity test inside of a random induced hypercube inside of $[n]^d$. We show that in fact testing for affinity on a random subcube with *any* affinity tester also works as a direct sum test.

▶ **Test 35** (Affine on Subcube)**.** Sample $a, b \in [n]^d$ and run an affinity test that has soundness function $s(\delta) = \Omega(\delta)$ on the function $x \mapsto f(\phi_x(a, b))$.

The flexibility of being able to use any affinity tester also enables us to obtain a direct sum test with additional properties such as erasure resiliency, which we discuss further in Section 4.2, and less use of randomness, which we discuss in Section 4.1. Furthermore, we believe that our analysis for going from local direct sums to a global direct sum is simpler than that of [13] and thus noteworthy on its own.

One final benefit of our analysis is that it fixes an error in [13]'s analysis. Specifically, they establish that a function f passing the Square in Cube test with probability $1 - \varepsilon$ is *locally* close to a direct sum (this is basically Lemma 39 in our presentation), but they do not show how to combine these local direct sums into a global direct sum.

We now show that the Affine on Subcube test is a valid direct sum tester. Once again, completeness is clear. If f is a direct sum, then the Affine on Subcube test passes with probability 1. Our focus is then on showing soundness.

▶ **Theorem 36.** *Fix $f : [n]^d \to \mathbb{F}_2, \varepsilon \geq 0$ and an affinity test T. If f passes the Affine on Subcube test (instantiated with T) with probability $1 - \varepsilon$, then f is $C\varepsilon$-close to a direct sum, for some constant C independent of n, d.*

Proof. Fix f as in the theorem statement. That is, satisfying

$$\mathbb{E}_{a,b\sim[n]^d}[\mathsf{dist}(x \mapsto f(\phi_x(a, b)), \mathsf{affine})] \leq O(\varepsilon). \tag{5}$$

We re-interpret Equation (5) in three steps. First, observe that Equation (5) is equivalent to

$$\mathbb{E}_{a,b\sim[n]^d, z\sim\mathbb{F}_2^d}[\mathsf{dist}(x \mapsto f(\phi_z(a, b)) + f(\phi_{x+z}(a, b)), \mathsf{linear})] \leq O(\varepsilon). \tag{6}$$

Next, observe that we can rewrite $\phi_{x+z}(a, b)$ as follows:

$$\phi_{x+z}(a, b) = \phi_x(\phi_z(a, b), \phi_z(b, a)).$$

In light of this observation, Equation (6) is equivalent to

$$\mathbb{E}_{a,b\sim[n]^d,z\sim\mathbb{F}_2^d}[\mathsf{dist}(x\mapsto f(\phi_z(a,b))+f(\phi_x(\phi_z(a,b),\phi_z(b,a))),\mathsf{linear})]\leq O(\varepsilon). \tag{7}$$

Of course, the distribution of $(\phi_z(a,b),\phi_z(b,a))$ is the same as the distribution of (a,b). So, we can rewrite Equation (7) as:

$$\mathbb{E}_{a,b\sim[n]^d}[\mathsf{dist}(x\mapsto f(a)+f(\phi_x(a,b)),\mathsf{linear})]\leq O(\varepsilon). \tag{8}$$

This interpretation of the test is more convenient to work with.

For each a,b define f_{ab} to be the function $x\mapsto f(a)+f(\phi_x(a,b))$, and let ε_{ab} be the probability that f_{ab} fails the linearity test. Clearly $\mathbb{E}[\varepsilon_{ab}]=\mathbb{E}[\varepsilon_a]\leq O(\varepsilon)$. Because f_{ab} passes the linearity test with probability $1-\varepsilon_{ab}$, there is vector $F^a(b)\in\mathbb{F}_2^d$ such that

$$\Pr_x[f_{ab}(x)=\langle F^a(b),x\rangle]>1-O(\varepsilon_{ab}), \tag{9}$$

where $\langle v,w\rangle=\sum_i v_iw_i$. We will now show that $b\mapsto F^a(b)$ is close to a direct product, by proving that this function passes a certain direct product test. Dinur and Golubev [13] give the following direct product test (which is slightly more convenient here than the original direct product test of [16]):

▶ **Test 37** (Direct Product Test)**.** Sample $x\in[n]^d$. Sample a set A by including each $i\in[d]$ in A with probability $3/4$. Sample y by setting $y_i=x_i$ if $i\in A$, and otherwise sampling y_i uniformly from $[n_i]$. Accept iff $f(x)_i=f(y)_i$ for all $i\in A$.

Using [11], Dinur and Golubev show

▶ **Fact 38.** If f passes Test 37 with probability $1-\varepsilon$, then f is $O(\varepsilon)$-close to a direct product.

Now, we use Fact 38 to show that $b\mapsto F^a(b)$ is close to a direct product.

▶ **Lemma 39.** *$b\mapsto F^a(b)$ is $O(\varepsilon_a)$-close to a direct product.*

Proof. Given b,b' define $\mathcal{D}_{bb'}$ on $\mathbb{F}_2^d$ as follows. If $x\sim\mathcal{D}_{bb'}$ then for each $i\in[d]$ independently, x_i is determined as follows:

If $b_i\neq b'_i$, then $x_i=0$. If $b_i=b'_i$, then $x_i=1$ with probability $2/3$ and 0 otherwise.

Define $\mathsf{eq}_{3/4}=\mathsf{T}_{(3n/4-1)/(n-1)}$. If $b'\sim\mathsf{eq}_{3/4}(b)$, then for each i independently, $b_i=b'_i$ with probability $3/4$. Now, observe that if we sample $b'\sim\mathsf{eq}_{3/4}(b)$ and $x\sim\mathcal{D}_{bb'}$, then the values x_i are independent uniformly random bits. However, if we choose b',x in this manner, then the joint distribution of (b,b',x) satisfies

$$\phi_x(a,b)=\phi_x(a,b').$$

This is because we select a_i whenever $b_i\neq b'_i$. Then, performing a union bound on Equation (9) (and averaging away the dependence on b) we have that

$$\Pr_{b\sim[n]^d,b'\sim\mathsf{eq}_{3/4}(b),x\sim\mathcal{D}_{bb'}}[\langle F^a(b),x\rangle=f_{ab}(x)=f_{ab'}(x)=\langle F^a(b'),x\rangle]>1-O(\varepsilon_a). \tag{10}$$

For each a,b,b', define

$$\delta_{abb'}=\Pr_{x\sim\mathcal{D}_{bb'}}[\langle F^a(b)+F^a(b'),x\rangle\neq 0].$$

By Equation (10), $\mathbb{E}_{b\sim[n]^d,b'\sim\mathsf{eq}_{3/4}(b)}[\delta_{abb'}]<O(\varepsilon_a)$. Intuitively, if $\delta_{abb'}$ is small then $F^a(b),F^a(b')$ must have some "agreement". More precisely we have:

▷ Claim 40. If $\delta_{abb'} < 1/3$, then for all i where $b_i = b'_i$ we have $F^a(b)_i = F^a(b')_i$

Proof. Suppose to the contrary that there is some $i \in [d]$ with $b_i = b'_i$ but $F^a(b)_i \neq F^a(b')_i$. If $x \sim \mathcal{D}_{bb'}$ then there is a $1/3$ chance of $x_i = 0$ and a $2/3$ chance of $x_i = 1$, and this is independent of the values of x_j for $j \neq i$. This means that $\langle F^a(b) + F^a(b'), x\rangle$ takes on either value in $\mathbb{F}_2$ with probability at least $1/3$, implying that $\delta_{abb'} \geq 1/3$. ◁

Now, by Markov's Inequality we have

$$\Pr_{b\sim[n]^d, b'\sim \mathsf{eq}_{3/4}(b)}[\delta_{abb'} \geq 1/3] \leq 3\mathbb{E}_{b,b'}[\delta_{abb'}] < O(\varepsilon_a). \tag{11}$$

Given b, b' let $\overline{\Delta}(b, b')$ denote the set of coordinates i where $b_i = b'_i$. By Equation (11) we have

$$\Pr_{b\sim[n]^d, b'\sim \mathsf{eq}_{3/4}(b)}[F^a(b)_i = F^a(b')_i \quad \forall i \in \overline{\Delta}(b, b')] > 1 - O(\varepsilon_a).$$

By Fact 38 we conclude that $F^a(b)$ is $O(\varepsilon_a)$-close to a direct product. ◀

Now we conclude the proof of Theorem 36. For each a, let $(g_1(a, b_1), \ldots, g_d(a, b_d))$ be a direct product that is close $O(\varepsilon_a)$-close to $F^a(b)$; the existence of these direct products was shown in Lemma 39. Then,

$$\Pr_{a,x,b}\left[f_{ab}(x) = \sum_i g_i(a, b_i)x_i\right] > 1 - O(\varepsilon). \tag{12}$$

Observe that $\phi_x(a, b) = \phi_{\mathbb{1}+x}(b, a)$. Thus, by Equation (12) and a union bound we have

$$\Pr_{a,b,x}\left[\sum_i g_i(a, b_i)x_i + f(a) = f_{ab}(x) = f_{ba}(x + \mathbb{1}) = f(b) + \sum_i g_i(b, a_i)(1 + x_i)\right] > 1-O(\varepsilon). \tag{13}$$

For each a, b, define

$$\lambda_{ab} = \Pr_x\left[\sum_i (g_i(a, b_i) + g_i(b, a_i))x_i \neq \sum_i g_i(b, a_i) + f(a) + f(b)\right].$$

By Equation (13), $\mathbb{E}_{ab}[\lambda_{ab}] \leq O(\varepsilon)$. If $\lambda_{ab} < 1/2$ then we must have

$$\sum_i g_i(b, a_i) = f(a) + f(b).$$

By Markov's inequality:

$$\Pr_{a,b}[\lambda_{ab} \geq 1/2] \leq 2\mathbb{E}_{a,b}[\lambda_{ab}] \leq O(\varepsilon).$$

Thus, we have:

$$\Pr_{a,b}\left[f(a) = f(b) + \sum_i g_i(b, a_i)\right] > 1 - O(\varepsilon).$$

Then, by the probabilistic method there exists β such that

$$\Pr_a\left[f(a) = f(\beta) + \sum_i g_i(\beta, a_i)\right] > 1 - O(\varepsilon).$$

That is, f is $O(\varepsilon)$-close to the direct sum $a \mapsto f(\beta) + \sum_i g_i(\beta, a_i)$. ◀

4.1 Derandomization

In this section we show how to use Theorem 36 to obtain a more randomness-efficient direct sum tester than the Square in Cube test or Diamond test. In particular, we define the **Diamond in Cube test** as follows: run the Diamond test on the restriction of f to a random subcube (i.e., $f(\phi_x(a,b))$).

We now show that the Direct-Sum Diamond test is more randomness-efficient than the Square in Cube test and the Diamond in Cube test for some parameter regimes. In the following discussion we assume that n is a power of two for convenience.

In the statement of tests like the Square in Cube test we say "sample $a, b \sim [n]^d, x, y \sim \mathbb{F}_2$". This would seem to indicate that the test requires $(2+2\log_2 n)d$ bits of randomness. However, if we look inside the Square in Cube test, we see that this is not the case. The Square in Cube test actually requires sampling from the following distribution:

$$(\phi_0(a,b), \phi_x(a,b), \phi_y(a,b), \phi_{x+y}(a,b)),$$

where $a, b \sim [n]^d$ and $x \sim \mathbb{F}_2^d$. However, sampling from this distribution does not actually require sampling a, b, x, y fully. Instead, we can sample from the distribution as follows. First, sample $a \sim [n]^d, x, y \sim \mathbb{F}_2^d$. Then we partially sample b. Note that we don't need to sample b_i if $x_i = y_i = 0$, because in this case the value of b_i will not be needed in any of the query points. Thus, the average number of random bits required to create a sample for the Square in Cube test is only $(2 + 1.75\log_2 n)d$.

On the surface the Diamond test might appear to be more efficient. Rather than sampling a, b, x, y it only needs to sample a, b, x. However, the Diamond test actually requires more random bits than the Square in Cube test if $n \geq 20$. The number of random bits required to sample from the Diamond in Cube's distribution is $(2\log_2 n + (1 - 1/n))d$.

Now, we claim that the Diamond in Cube test is more randomness-efficient than both the Diamond test and the Square in Cube test, at least for large n. A simple computation shows that we can obtain samples from the Diamond in Cube test's sample distribution using only $(2.5 + 1.5\log_2 n)d$ random bits, vindicating this claim.

4.2 Direct Sum Testing in the Online Adversary Model

In this section we show that an immediate application of the Affine on Subcube test from Theorem 36 yields direct sum testers that are online erasure-resilient. The t-online erasure model was first considered by Kalemaj, Raskhodnikova, and Varma in [20] and was further studied in [22, 6]. The properties that these works consider include linearity, low degree, and various properties of sequences. Let us now describe the model.

We are once again given query access to a function $f : [n]^d \to \mathbb{F}_2$, and the goal is the same as in direct sum testing – to distinguish whether f is a direct sum, or far from a direct sum. The twist is that in the t-online erasure model, there is an adversary who is allowed to erase any t entries of f after each query that the property testing algorithm makes. If a point is queried after it is erased, then the oracle will return $\perp$ instead of the actual value $f(x)$. It is not hard to see that neither the Diamond test that we analyze nor the Square in the Cube test of [13] is erasure resilient. The reason is that in both tests, after the first three queries are made, the adversary knows what the fourth query will be and can erase f at that point.

However, by using the Affine on Subcube test with an erasure resilient affinity tester, we obtain an erasure resilient direct sum tester.

▶ **Theorem 41.** *Fix a distance parameter $\delta > 0$ and erasure parameter t, and take d sufficiently large relative to n, δ, t. Then there is a direct sum tester for $f : [n]^d \to \mathbb{F}_2$ that makes $O(\max(1/\varepsilon, \log t))$-queries in the t-online erasure model that satisfies:*

- ***Completeness:*** *If f is a direct sum, the tester accepts with probability 1.*
- ***Soundness:*** *If f is δ-far from being a direct sum, then the tester rejects with probability $2/3$.*

Proof. The result follows by combining Theorem 36 with Theorem 1.1 of [6]. Specifically we use the Affine on Subcube test where the inner affinity tester is the erasure resilient one of [6]. Technically, Theorem 1.1 of [6] is stated for linearity testing, but it is straightforward to modify their result to obtain an affinity tester. ◀

5 Reconstruction for Direct Sums

In this section we address another question raised in [13] on whether a test, which they call the **Shapka Test** can be used to reconstruct the underlying direct sum. We show that the this is indeed the case in some parameter regimes (i.e with the input function being sufficiently close to a direct sum), and then we give an alternate method for obtaining corrected versions of the direct sum, that is both more query efficient and more error tolerant than the Shapka test. We also give upper bounds that match up to a constant for the fraction of errors that can be tolerated when reconstructing the direct sum. This shows that the new reconstruction method we propose is essentially optimal: it works for essentially the entire range of ε where recovery is information theoretically possible, and there is no asymptotically more query-efficient correction method.

We start with our lower bounds.

▶ **Proposition 42.** *Fix an even n, arbitrary integer d, and some $\epsilon > 0$ such that $n\varepsilon > 1/2$. There exist distinct direct sums $L, Z : [n]^d \to \mathbb{F}_2$, and a function $f : [n]^d \to \mathbb{F}_2$ such that $\mathsf{dist}(f, L) = \mathsf{dist}(f, Z) \leq \varepsilon$.*

Proof. Let Z be the zero function, and let L be the indicator of $x_d = 1$. Let f be any function which is zero if $x_d \neq 1$, and for inputs with $x_d = 1$, f is zero half the time. Then, $\mathsf{dist}(f, L) = \mathsf{dist}(f, Z) = 1/(2n) \leq \varepsilon$. In other words, there is no unique closest direct sum to f, so decoding $f(\mathbb{1})$ is undefined. ◀

▶ **Proposition 43.** *Fix an n divisible by 4, an arbitrary integer d, and $\epsilon > 0$ such that $(0.7)^{d/n} < \varepsilon, n\varepsilon < 1/2$. Then there is a set $\mathcal{F}$ of functions $f : [n]^d \to \mathbb{F}_2$, such that using fewer than $n/4$ queries it is impossible to determine the value of $L(\mathbb{1})$ with probability greater than $1/2$, where L is the closest direct sum to f.*

Proof. Call a point $x \in [n]^d$ **heavy** if more than $2d/n$ coordinates $i \in [d]$ have $x_i = 1$. By a Chernoff bound, the fraction of points in $[n]^d$ which are heavy is less than $(0.7)^{d/n}$. Let L be a uniformly random direct sum. Define $\mathcal{F}$ to be the class of all functions which agree with L on non-heavy inputs. Then, querying $f \in \mathcal{F}$ on a heavy point is useless, because it outputs an arbitrary value unrelated to L. By our assumption that $(0.7)^{d/n} < \varepsilon$ we have that any $f \in \mathcal{F}$ is ε-close to L. Now we argue that $n/4$ non-heavy queries do not suffice to determine $L(\mathbb{1})$ with non-trivial probability. Indeed, there will be a coordinate $i \in [d]$ such that among the $n/4$ non-heavy queries, no queried point x has $x_i = 1$. Thus, we cannot hope to distinguish between the equally likely cases $L_i(1) = 0$ and $L_i(1) = 1$, and thus cannot predict $L(\mathbb{1})$ with non-trivial probability. ◀

Now we give algorithms for reconstructing values from the closest direct sum to a function f. Let us start with the **Shapka Test** of [13] which we now describe. This test is slightly different for odd and even d; for simplicity we only consider the case of odd d. Let $e_i \in \{0,1\}^d$ denote a vector with zeros except at the i-th coordinate. We describe how the Shapka Test can be used to reconstruct a direct sum.

▶ **Test 44** (Shapka [13])**.** Sample $a, b \in [n]^d$. Accept iff

$$f(b) = \sum_{i=1}^{d} f(\phi_{e_i}(a,b)). \tag{14}$$

Thus, to reconstruct a direct sum from a corrupted version, f, we can define,

$$f_{\mathsf{shapka}}(b) = \mathsf{maj}_{a\in[n]^d} \sum_{i=1}^{d} f(\phi_{e_i}(a,b)).$$

Dinur and Golubev show that if f passes the Shapka test with probability ε, then f is $O(n\varepsilon)$-close to a direct sum. Now, instead of checking Equation (14), we use the expression on the right hand side of Equation (14) as our guess for the value of $f(b)$, and take the most common value at each b to define the reconstructed function f_{shapka}. We show that if f is close enough to a direct sum, then f_{shapka} is in fact this direct sum:

▶ **Proposition 45.** *Fix $\varepsilon > 0, n \in \mathbb{N}$, and d odd with $n\varepsilon d < 1/4$. Suppose $f : [n]^d \to \mathbb{F}_2$ is ε-close to the direct sum $L = \sum_i L_i$. Then, for any b,*

$$\Pr_{a\in[n]^d}[f(b) = L(b)] \geq \frac{3}{4}.$$

It follows that $f_{\mathsf{shapka}} = L$.

Proof. We say that a query $f(x)$ **succeeds** if $f(x) = L(x)$. Let

$$\varepsilon_i = \Pr_x[f(x) \neq L(x) \mid x_i = b_i].$$

By a union bound, the Shapka test succeeds with probability at least $1 - \sum_i \varepsilon_i$. For each i,

$$\varepsilon = \Pr[f(x) \neq L(x)] \geq \Pr[f(x) \neq L(x) \wedge x_i = b_i] = \varepsilon_i/n.$$

Thus, $\sum_i \varepsilon_i \leq n\varepsilon d \leq 1/4$, so the Shapka test produces the correct value with probability at least $3/4$. ◀

Now we give a more query efficient method for reconstructing a direct sum. Our method has asymptotically optimal query complexity (by Proposition 43), and still works at essentially all possible values of ε for which the function is guaranteed to be information theoretically recoverable (by Proposition 42). We reconstruct the direct sum via the following voting scheme, where we call the reconstructed function f_{recon}. To make things more convenient, we assume that d is odd. Set

$$f_{\mathsf{recon}}(x) = \mathsf{maj}_{x^{(1)},\ldots,x^{(n)}} \sum_{i=1}^{n} x^{(i)},$$

where the set of queried points $x^{(1)}, \ldots, x^{(n)}$ is weighted in the majority according to the following distribution.

- Randomly partition $[d]$ into n parts, $S_1 \sqcup \cdots \sqcup S_n = [d]$, by choosing putting each $i \in [d]$ independently and uniformly at random in a part S_i.
- Sample R uniformly from $([n] \setminus \{1\})^d$.
- For $i \in [n]$, form query point $x^{(i)} \in [n]^d$ by setting $x^{(i)}_j = 1$ for each $j \in S_i$, and setting $x^{(i)}_j = R_j$ otherwise.

For even, n, we require $n+1$ queries, and use the following voting scheme.

$$f_{\mathsf{recon}}(x) = \mathsf{maj}_{x^{(1)},\ldots,x^{(n)}} \sum_{i=1}^{n} x^{(i)},$$

where the set of queried points $x^{(1)}, \ldots, x^{(n+1)}$ is weighted in the majority according to the following distribution.

- Randomly partition $[d]$ into $n+1$ parts, $S_1 \sqcup \cdots \sqcup S_{n+1} = [d]$, by choosing putting each $i \in [d]$ independently and uniformly at random in a part S_i.
- Sample $R \in [n]^d$ as follows: for each i independently, set $R_i = 1$ with probability $1/n^2$ and otherwise sample R_i uniformly from $[n] \setminus \{1\}$.
- For $i \in [n+1]$, form query point $x^{(i)} \in [n]^d$ by setting $x^{(i)}_j = 1$ for each $j \in S_i$, and setting $x^{(i)}_j = R_j$ otherwise.

We prove that the scheme above correctly reconstructs the underlying direct sum for the case where n is odd, as the case where n is even is similar.

▶ **Proposition 46.** *Fix n, d, ε. Let $f : [n]^d \to \mathbb{F}_2$ be ε close to a direct sum L, with $(n+1)\varepsilon < 1/4$. Then for any point x*

$$\Pr_{x^{(1)},\ldots,x^{(n)}} \left[\sum_{i=1}^{n} f(x^{(i)}) = L(x) \right] \geq \frac{3}{4}.$$

It follows that $f_{\mathsf{recon}} = L$.

Proof. Without loss of generality, let us assume that $x = \mathbb{1}$ – the all ones vector. We again say that a query $f(x)$ **succeeds** if $f(x) = L(x)$.

We claim that $x^{(1)}, \ldots, x^{(n)}$ are uniformly random points in $[n]^d$. Fix $i \in [n]$. For each $j \in [d]$, $x^{(i)}_j$ has a $1/n$ chance of being a 1, and a $1/n$ chance of being j for any $j \in [n] \setminus \{1\}$. Furthermore, the value of $x^{(i)}_j$ is independent of the value of $x^{(i)}_{j'}$ for $j' \neq j$. Thus, the probability that all n queries all succeed is at least $1 - n\varepsilon \geq 3/4$ by a union bound. If the queries all succeed, then because d is odd, we have:

$$\sum_i f(x^{(i)}) = \sum_i L(x^{(i)}) = (d-1)L(R) + L(\mathbb{1}) = L(\mathbb{1}). \qquad \blacktriangleleft$$

Toward Separating QMA from QCMA with a Classical Oracle

Mark Zhandry
NTT Research, Sunnyvale, CA, USA

Abstract

QMA is the class of languages that can be decided by an efficient quantum verifier given a *quantum* witness, whereas QCMA is the class of such languages where the efficient quantum verifier only is given a *classical* witness. A challenging fundamental goal in quantum query complexity is to find a classical oracle separation for these classes. In this work, we offer a new approach towards proving such a separation that is qualitatively different than prior work, and show that our approach is sound assuming a natural statistical conjecture which may have other applications to quantum query complexity lower bounds.

1 Introduction

Do quantum witnesses offer more power than classical witnesses? Slightly more precisely, there are two natural ways to generalize NP from the classical setting to the quantum setting: QMA (for Quantum Merlin-Arthur) is the set of languages decidable by efficient quantum algorithms with quantum witnesses, whereas QCMA (for Quantum *Classical* Merlin-Arthur) is the set of languages decidable by efficient quantum algorithms with *classical* witnesses. A long-standing fundamental question, first raised by [2], is whether or not these two generalizations of NP are the same.

As an unconditional separation between QMA and QCMA is out of reach given the state of complexity theory, the community has focused on proving *oracle* separations. The first such separation [1] gives a *quantum* oracle; that is, an oracle that implements a unitary operation and which can be queried on quantum states. A major open question has been whether there is a *classical* oracle separation; that is, an oracle that implements a classical function, but is accessible in superposition. Classical oracle separations are considered more standard in the community.

An early candidate classical oracle separation was given by [9], but no proof was given. More recently, there have been several results making progress towards this goal by proving separations under different restrictions on how the oracle is accessed. [5] show a separation assuming the classical oracle is an "in-place permutation oracle", a non-standard modeling where the oracle irreversibly permutes the input state. [10] show a separation, assuming the witness is required to be independent of certain choices made in constructing the oracle. A very recent line of work has used quantum advantage relative to unstructured oracles [13] to separate QMA from QCMA: [8, 7] give a separation assuming the verifier can only make classical oracle queries, and more recently [3] give a separation which allows the verifier quantum queries, but assumes the adaptivity of the queries is sub-logarithmic. A standard classical oracle separation that makes no constraints on how the oracle is accessed or how the witness is created still remains open.

The central challenge in separating QMA from QCMA relative to a classical oracle seems to be the following. Consider a language in QMA \ QCMA, and consider measuring the QMA witness in the computational basis. The resulting classical string must *not* be accepted by the QMA verifier, since otherwise we would then have a classical witness for the language, putting it in QCMA. Therefore, in some sense, the QMA verifier needs to verify that the witness is in superposition. In order to allow for such verification using only a classical oracle, existing approaches require highly structured oracles. But then to actually prove the language is outside of QCMA, we need a quantum query complexity lower-bound, and unfortunately the techniques we have are often not amenable to highly structured oracles. Additionally, any witness would naturally be treated as a form of oracle-dependent advice about the oracle, and most quantum query complexity techniques are not very good at distinguishing between quantum advice and classical advice. In other words, if a typical technique succeeded at proving a language is outside of QCMA, then if it cannot distinguish quantum vs classical advice, it would likely also show that the language is outside QMA as well, thus failing to give a separation.

Our Work

We give a new approach for separating QMA from QCMA relative to a classical oracle. Like prior work, we are unable to prove our oracle separation unconditionally. However, our separation appears much less structured than the prior work (though this is an intuitive statement rather than a formal one), and appears much more amenable to existing quantum query complexity techniques. In particular, we prove under a natural conjecture about k-wise independent distributions that our separation indeed works. We believe our work adds to the evidence that QMA and QCMA are indeed distinct relative to classical oracles, and may offer a new path toward a proof.

1.1 Our Separating Oracles

Our basic idea is the following. An instance in our language will correspond to a subset $S \subseteq [N]$ where N is exponentially-sized. S will be chosen to only contain a negligible fraction of $[N]$, but still be super-polynomial sized. We will provide a classical oracle (accessible in superposition) that decides membership in S. We will often simply call this oracle S.

Next, we choose a random state $|\psi\rangle = \sum_{y \in S} \alpha_y |y\rangle$ with support on the set S. The state $|\psi\rangle$ will be our witness state for the QCMA instance. An incomplete verification for $|\psi\rangle$ proceeds by simply checking that $|\psi\rangle$ has support contained in S. Essentially, $|\psi\rangle$ is acting as a QMA witness that S is non-empty. But there is also a simple QCMA witness for this fact: any classical value $y \in S$.

We will instead attempt to turn $|\psi\rangle$ into a witness that S is *super-polynomial* sized. To do so, we will add a second oracle U which essentially attests to $|\psi\rangle$ being a superposition over super-polynomially-many points. Intuitively, we want to show that U can distinguish between $|\psi\rangle$ and any state whose support is only polynomial-sized.

To construct U, let $|\hat{\psi}\rangle$ denote the quantum Fourier transform (QFT) of $|\psi\rangle$. We observe that if $|\psi\rangle$ has support on a single point y, then $|\hat{\psi}\rangle$ will have uniform amplitude on all points in $[N]$ (though with complex phases on these points). On the other hand, for random $|\psi\rangle$ with support on the large set S, the amplitudes on different points will vary. Concretely, while the expected squared-amplitude on any point $z \in [N]$ is $1/N$, there is a reasonable chance that it could be, say, smaller than $1/2N$ or larger than $2/N$.

We will choose U to be a subset of $[N]$ consisting of points where $|\hat{\psi}\rangle$ has squared-amplitude somewhat larger than $1/N$. We can then have, say, the total squared-amplitude of $|\hat{\psi}\rangle$ on points in U be roughly $3/4$ while $|U|/N$ is only roughly $1/2$. In this case, the QFT of a classical string y will have squared-amplitude on U of only $1/2$. Thus, U enables distinguishing $|\psi\rangle$ from a classical input. We will therefore give out an oracle for deciding membership in U. The verifier will first confirm that $|\psi\rangle$ has support only on S using the oracle for S. Then it will compute $|\hat{\psi}\rangle$ via the QFT, and check that the support is in U. Overall the verifier accepts with probability $3/4$. Instances not in the language will consist of S, U pairs where S is very small but non-empty. We show that, for a certain way of choosing U, that there is no QMA witness in the case of such small S. Thus, our language is in QMA relative to the oracles for S, U.

1.2 QCMA hardness

We now need a way to argue that our language does not have QCMA witnesses. While we showed that a classical string $y \in S$ cannot serve as a witness, this alone does not preclude some more clever way of attesting to S being large. In particular, the witness w could contain several points in S. Worse, perhaps queries to U may reveal a significant amount of information about S, which may help deciding if S is large or small. We make progress toward showing QCMA hardness of our oracle problem, as we now describe.

Consider a hypothetical QCMA verifier V which is given a classical witness w and makes quantum queries to S, U, and accepts in the case S is large. We want to show that we can replace S with a small set S', and V will still accept with too-high a probability, meaning it incorrectly claims that (S', U) is in the language, despite S' being small.

Toward that end, we will choose S' to be all points in S that are also "heavy" among the queries V makes to S. That is, points $y \in S$ such that the query amplitude in V's quantum queries to S is above some inverse-polynomial threshold. As the total query amplitude of all points is just the number of queries of V and hence polynomial, the number of heavy y is polynomial. Hence, S' is small. We can also construct S' efficiently: for each heavy y, running V and measuring a random query will have an inverse polynomial chance of producing y. By repeating this process a polynomial number of times, we can collect all heavy queries.

But why should S and S' be indistinguishable to V? By standard quantum query analysis, if V can distinguish S from S', then it's queries must place significant amplitude on $S \setminus S'$. By measuring a random query, we therefore obtain with significant probability a $y \in S \setminus S'$. But since y is not heavy, repeating this process many times will produce many different y. This means that if V can distinguish S from S', it must actually be able to generate essentially arbitrarily large (polynomial) numbers of $y \in S$. Denote the number of y by L.

V that do not query U

Let us first assume that V makes no queries to U. In this case, we can argue that any distinguishing V actually violates known query complexity results for multiple Grover search. In particular, [6] show that an algorithm making polynomially-many queries to a random sparse S cannot produce L points in S except with probability bounded by 2^{-L} (see Lemma 8 for precise statement). Now, this result assumes no advice is provided about S, but the witness w counts as advice. Fortunately, we can handle the advice using the strong exponential lower bound provided by [6]. Consider running the process above with a *random* w' instead of w. In the event $w' = w$, the process will produce L points in S. Moreover, $w' = w$

with probability $2^{-|w|}$. By setting $L \gg |w|$ (recall that we can make L an arbitrarily large polynomial), we therefore obtain an algorithm with no advice which produces L points in S with probability $2^{-|w|} \gg 2^{-L}$, contradicting the hardness of multiple Grover search.

▶ Remark 1. The above strategy inherently uses the fact that w is classical. If V had a quantum witness/advice, running it even once and measuring a random query to find a $y \in S$ would potentially destroy the witness, meaning further runs of V are not guaranteed to produce *any* points in S. This is the key place in the proof where we distinguish between classical and quantum witnesses, hopefully indicating a promising route toward proving a separation between QMA and QCMA.

k-wise independent U

The above strategy does not work for handling queries to U. The problem is that U takes potentially N bits (which is exponential) to describe, meaning treating U as advice would require setting $L \gg N$, at which point the bounds from [6] do not apply.

We will for now assume that U is k-wise independent for a super-polynomial k, and return to justifying this assumption later. We will assume such k-wise independence holds even conditioned on S (but not conditioned on $|\psi\rangle$, whose correlation with U is crucial for the correctness of our QMA verifier). A result of [14] (formally described in Lemma 7) shows that a k-wise independent U is actually perfectly indistinguishable from a uniform U, for all quantum query algorithms making at most $k/2$ queries. Since k is super-polynomial, we thus obtain perfect indistinguishability against all polynomial-query algorithms, including our process above for generating points in S. Consequently, the process above succeeds in generating L points in S even if U is replaced by a uniformly random U independent of S. But such a uniform U can be simulated without knowledge of S at all, and hence the lower-bound of [6] actually applies to algorithms making queries to uniform U. Thus under the assumption that U is k-wise independent, we can justify QCMA hardness.

Our U are "close" to k-wise independent

We show that, by choosing U carefully in a probabilistic way, U is "close" to k-wise independent, even conditioned on S. By "close", we concretely mean that for every subset $T \subseteq [N]$ of size at most k, that $2^{-|T|} \leq \Pr[T \cap U = \emptyset] \leq (1+\epsilon) \times 2^{-|T|}$, for some very small ϵ which depends on $k, |S|, N$. Note that true k-wise independence is equivalent to $\Pr[T \cap U = \emptyset] = 2^{-|T|}$ for all T of size at most k.

Is this "close" enough?

Unfortunately, we do not know how to prove that U which are close to k-wise independent are sufficient to make our approach work. The issue is that [14] only applies to perfect k-wise independence, and there are counterexamples that show that the result does *not* hold when replaced with some approximate notions of k-wise independence.

The good news is that our notion of closeness is quite different from the usual notion of "biased" or "almost" k-wise independence used in the literature. Specifically, those notions allow for an additive error in any of the marginal probabilities, whereas we impose a strong *multiplicative* error bound. This gives us hope that our distribution of U, despite not being truly k-wise independent, may still be close enough to get a separation.

We make progress toward justifying this claim. We make a conjecture that any distribution over U which is "close" to k-wise independent (in our sense) can be turned into a distribution U' that is truly k-wise independent. Importantly, U and U' will agree on almost all points.

More precisely, for any z, the probability that U and U' differ on z is negligible. See Conjecture 10 for the formal statement of this conjecture. Observe that this conjecture is simply a statement about distributions, and has nothing on the surface to do with quantum query complexity.

Under this conjecture, we complete the full oracle separation between QMA and QCMA. Instead of giving out the oracle U, we simply give out the oracle U', and prove QCMA hardness following the above approach. Our statistical conjecture is then used to show that replacing U with U' does not break our QMA verifier. Concretely, by standard query complexity arguments, we show that if our verifier works on U, then it must also work (with negligibly larger error) on U'.

▶ Remark 2. Our statistical conjecture gives *one* way to prove an oracle separation between QMA and QCMA following our approach. Our conjecture could of course turn out to be false. Even in this case, our oracles still seem likely to give a separation, and there may be many other paths toward proving it. Perhaps if the general conjecture is false, our particular U can still be converted into U' as needed. Or maybe being "close" to k-wise independent is directly sufficient for a separation and can be proven via quantum query complexity arguments. Possibly there is a different distribution over $|\psi\rangle$ and associated U where U actually is perfectly k-wise independent. Thus, independent of our particular statistical conjecture, we believe our new approach at a separation gives a promising new approach toward separating QMA from QCMA relative to classical oracles.

2 Preliminaries and notation

A function $f(n) \leq n^{O(1)}$ is *polynomial* and $f(n) \geq n^{-O(1)}$ is inverse polynomial. Functions $f(n) \geq n^{\omega(1)}$ are superpolynomial and $f(n) \leq n^{-\omega(1)}$ are negligible.

Let $\mathsf{Bernoulli}_p$ denote the distribution over $\{0,1\}$ which outputs 1 with probability p. Let $\mathsf{Bernoulli}_p^N$ denote the distribution over $\{0,1\}^N$ consisting of N iid samples from $\mathsf{Bernoulli}_p$. We will associate $\{0,1\}^N$ with subsets of $[N]$, where $S \subseteq [N]$ is associated with the vector $\mathbf{v}$ such that $v_x = 1$ if $x \in S$. We will also associate $\{0,1\}^N$ (and hence also subsets of $[N]$) with functions from $[N]$ to $\{0,1\}$, where S is associated with its indicator function f, where $f(x)$ is 1 if and only if $x \in S$.

A joint distribution $X_1, \cdots X_n$ is k-wise independent if, for each subset T of size at most k, $(X_i)_{i\in T}$ are independent random variables. $X_1, \cdots, X_n$ is k-wise *uniform* independent if each $(X_i)_{i\in T}$ are independent uniform random variables over their respective domains.

Complex Normal Distribution

Let $\mathcal{N}^{\mathbb{C}}_{\mu,\sigma}$ denote complex normal distribution with width σ. The probability density function of this distribution is given by $\Pr[x \leftarrow \mathcal{N}^{\mathbb{C}}_{\mu,\sigma}] = \frac{1}{\pi\sigma^2} e^{-|x-\mu|^2/\sigma^2}$.

Two basic identities that will be useful when computing integrals involving complex normal distributions are the following. Let $\mathbf{v}$ is a vector of n complex numbers, $\mathbf{M}$ is a complex $n \times n$ matrix, and $\int_{\mathbb{C}} d\mathbf{v}$ means to integrate over all complex vectors $\mathbf{v}$. Then

$$\int_{\mathbb{C}} e^{-\mathbf{v}^\dagger \mathbf{M} \mathbf{v}} d\mathbf{v} = \frac{\pi}{\det(\mathbf{M})} \qquad \int_{\mathbb{C}} |v_1|^2 |v_2|^2 e^{-\mathbf{v}^\dagger \mathbf{M} \mathbf{v}} d\mathbf{v} = \frac{\pi^2 \mathsf{Tr}(\mathbf{M})^2}{4 \det(\mathbf{M})^3} \text{ for } n = 2$$

Quantum Computation

We assume the reader is familiar with the basics of quantum computation and quantum query models. Recall that in the standard model for making quantum queries to a classical oracle $\mathcal{O}$, the algorithm submits a state $\sum_{x,y,z} \alpha_{x,y,z} |x,y,z\rangle$, and receives back $\sum_{x,y,z} \alpha_{x,y,z} |x, y \oplus$

$\mathcal{O}(x), z\rangle$. We will make use of the quantum Fourier tranform, denoted QFT_N, defined on computational basis states as $|y\rangle \mapsto \frac{1}{\sqrt{N}} \sum_{z \in \mathbb{Z}_N} e^{i2\pi yz/N} |z\rangle$ for $y \in \mathbb{Z}_N$. We will usually drop the subscript N as it will be clear from context. For a quantum state $|\psi\rangle$, we will typically let $|\hat{\psi}\rangle$ be shorthand for $\mathsf{QFT}|\psi\rangle$.

2.1 Defining QMA and QCMA relative to Oracles

We can consider two types of oracle versions of complexity classes, and in particular QMA/QCMA. The first, and most common, is to specify an infinite oracle $\mathcal{O} : \{0,1\}^* \to \{0,1\}$, and define the classes QMA/QCMA relative to $\mathcal{O}$. The second version, which is typically easier to work with, is to consider a variant of QMA/QCMA where the instance itself is an exponentially-sized oracle $\mathcal{X} : \{0,1\}^n \to \{0,1\}$. Fortunately, we show that a QMA/QCMA separation for one variant immediately gives such a separation for the other variant. Thus, it suffices to prove a separation for whichever variant is most convenient.

▶ **Definition 3** (Oracle-Aided QMA/QCMA)**.** *For a function $\mathcal{O} : \{0,1\}^* \to \{0,1\}$, an oracle decision problem is a subset $\mathsf{L}^{\mathcal{O}} \subseteq \{0,1\}^*$ which depends on $\mathcal{O}$. We say that $\mathsf{L}^{\mathcal{O}}$ is in $\mathsf{QMA}^{\mathcal{O}}$ if there exists a polynomial-time oracle-aided quantum algorithm $V^{\mathcal{O}}$ and polynomial p such that:*

- *For every $x \in \mathsf{L}^{\mathcal{O}}$ of length n, there exists a state $|\psi\rangle$ on $p(n)$ qubits such that $\Pr[V^{\mathcal{O}}(x, |\psi\rangle) = 1] \geq 2/3$. In this case, we say that $V^{\mathcal{O}}$* accepts *x.*
- *For every $x \notin \mathsf{L}^{\mathcal{O}}$ of length n, and for any state $|\psi\rangle$ on $p(n)$ qubits, $\Pr[V^{\mathcal{O}}(x, |\psi\rangle) = 1] \leq 1/3$. In this case, we say that $V^{\mathcal{O}}$* reject *x.*

$\mathsf{QCMA}^{\mathcal{O}}$ is defined analogously, except that the states $|\psi\rangle$ are required to be classical.

▶ **Definition 4** (Oracle-Input QMA/QCMA)**.** *Let $\mathcal{U} = \{\mathcal{U}_n\}_{n \in \mathbb{Z}^+}$ where $\mathcal{U}_n$ are sets of strings $\mathcal{X}$ of length $2^{n^{\Theta(1)}}$, interpreted as functions from $\mathcal{X} : [n^{\Theta(1)}] \to \{0,1\}$. An oracle-input promise language is a subset $\mathsf{OI\text{-}L} \subseteq \mathcal{U}$. An oracle-input promise language $\mathsf{OI\text{-}L} \subseteq \mathcal{U}$ is in $\mathsf{OI\text{-}QMA}$ if there exists a polynomial-time oracle-aided quantum algorithm V and polynomial p such that:*

- *For every $\mathcal{X} \in \mathsf{OI\text{-}L} \cap \mathcal{U}_n$, there exists a $|\psi\rangle$ on $p(n)$ qubits such that $\Pr[V^{\mathcal{X}}(|\psi\rangle) = 1] \geq 2/3$.*
- *For every $\mathcal{X} \in \mathcal{U}_n \setminus \mathsf{OI\text{-}L}$, and for any state $|\psi\rangle$ on $p(n)$ qubits, $\Pr[V^{\mathcal{X}}(|\psi\rangle) = 1] \leq 1/3$.*

$\mathsf{OI\text{-}QCMA}$ is defined analogously, except that the states $|\psi\rangle$ are required to be classical.

Note that the constants $1/3, 2/3$ in Definitions 3 and 4 are arbitrary, and can be replaced with a, b for any a, b such that $a \geq 2^{-\mathsf{poly}(n)}, b \leq 1 - 2^{-\mathsf{poly}(n)}$, and $b - a \geq 1/\mathsf{poly}(n)$.

Given any countable collection of oracles $\mathcal{O}_1, \mathcal{O}_2, \cdots$ which may have finite or infinite domains, we can construct a single oracle $\mathcal{O} : \{0,1\}^* \to \{0,1\}$ by setting $\mathcal{O}(j, x) = \mathcal{O}_i(x)$, where (j, x) is some encoding of pairs $(j, x) \in \{0,1\}^* \times \{0,1\}^*$ into strings in $\{0,1\}^*$. We can likewise convert $\mathcal{O}$ back into $\mathcal{O}_1, \mathcal{O}_2, \cdots$. Therefore, we will take the definitions of $\mathsf{QMA}, \mathsf{QCMA}, \mathsf{OI\text{-}QMA}, \mathsf{OI\text{-}QCMA}$ to allow for verifiers making queries to countable collections of oracles.

This next theorem is proved in Section 4 following a standard diagonalization argument, and shows that is suffices to give a separation for either variant of $\mathsf{QMA}, \mathsf{QCMA}$.

▶ **Theorem 5.** *There exists a classical oracle $\mathcal{O}$ such that $\mathsf{QCMA}^{\mathcal{O}} \neq \mathsf{QMA}^{\mathcal{O}}$ if and only if $\mathsf{OI\text{-}QCMA} \neq \mathsf{OI\text{-}QMA}$.*

The style of oracle separation between QMA and QCMA given in [1] follows that of Definition 3, except that they use a quantum oracle instead of a classical oracle. They do not define the oracle-input versions of $\mathsf{OI\text{-}QMA}$ and $\mathsf{OI\text{-}QCMA}$ or a general result like Theorem 5, but their

proof implicitly uses similar concepts. In particular, they first define a universe of quantum oracles: namely, those that are either the identity or reflect around a Haar random state. They then show that the two cases can be efficiently distinguished via a quantum witness, but not a classical witness. This is effectively showing a separation between OI-QMA and OI-QCMA, except using quantum oracles instead of classical oracles. They then extend this to give a quantum oracle $\mathcal{Q}$ separating $\mathsf{QMA}^{\mathcal{Q}}$ from $\mathsf{QCMA}^{\mathcal{Q}}$. This can be seen as roughly corresponding to a transformation like what we prove in Theorem 5.

One slight non-triviality in generalizing their techniques to give a general equivalence is that a separation between OI-QMA and OI-QCMA only needs to show that, for any potential QCMA verifier, there is *some* instance that the verifier answers incorrectly. This is indeed how our separation is constructed. In contrast, [1] show that almost all instances will fool any QCMA verifier. This stronger separation is crucially used when constructing the oracle $\mathcal{Q}$ separating $\mathsf{QMA}^{\mathcal{Q}}$ from $\mathsf{QCMA}^{\mathcal{Q}}$, as they can basically choose $\mathcal{Q}$ to be random from the appropriate universe of oracles. In order to get a general equivalence for arbitrary separations, including those like ours where the instance depends on the verifier, we have to work a bit harder and incorporate a diagonalization argument. Fortunately, this is standard.

2.2 Some Useful Quantum Lemmas

For an oracle algorithm A making queries to an oracle O and an oracle input r, let the state $\sum_{x,y,z} \alpha^{(i)}_{x,y,z}|x,y,z\rangle$ denote the ith oracle query, and let $M_x(i) = \sum_{y,z} |\alpha^{(i)}_{x,y,z}|^2$, which we will call the **query mass** of x in the i-th query. Let $M_x = \sum_i M_x(i)$, the total query mass of x over all q queries, and for a subset V let $M_V = \sum_{x\in V} M_x$ be the total query mass of points in V.

▶ **Lemma 6** ([4] Theorem 3.1+3.3). *Let A be a quantum algorithm running making q queries to an oracle O. Let $\epsilon > 0$ and let V be a set of inputs. If we modify O into an oracle O' which is identical to O except possibly on inputs in V, then $|\Pr[A^O() = 1] - \Pr[A^{O'}() = 1]| \leq 4\sqrt{qM_V}$.*

▶ **Lemma 7** ([14] Theorem 3.1). *Let A be a quantum algorithm making q queries to an oracle O. For any output z, the probability A outputs z when O is $2q$-wise independent is identical to the probability A outputs z when O is uniformly random.*

▶ **Lemma 8** ([6] Theorem 5.5). *Let $p \in [0,1]$. There is a constant $C \leq 48e$ such that the following is true. The success probability of finding K marked items in a random function $S : [N] \to \{0,1\}$ where $S(x) = 1$ with probability p for each $x \in [N]$ is at most $(Cp(Q/K)^2)^K$ for any algorithm making $Q \geq K$ quantum queries to S.*

3 Our Oracle Separation

Here, we give our conjectured oracle separation between QMA and QCMA. Following Theorem 5, it suffices to focus on the oracle-input variants of QMA and QCMA. We first define our new statistical conjecture. Then we will define a certain "nice" type of distribution, which we call Fourier Independent (FI). We show that our statistical conjecture leads to the existence of such a FI distribution. Finally, we show that an FI distribution gives a separation between OI-QMA and OI-QCMA, and hence an oracle $\mathcal{O}$ such that $\mathsf{QCMA}^{\mathcal{O}} \neq \mathsf{QMA}^{\mathcal{O}}$ (via Theorem 5).

3.1 Our Statistical Conjecture

▶ **Definition 9** (Substitution Distance). *Consider two distributions X_0, X_1 over Σ^ℓ for some alphabet Σ. The* substitution distance *between X_0 and X_1, denoted $\|X_0 - X_1\|_{\mathsf{sub}}$, is the minimum value of $\epsilon \geq 0$ such that there is a joint distribution (Z_0, Z_1) over $(\Sigma^\ell)^2$ where:*

- *The marginal distribution Z_0 is equal to X_0 and the marginal distribution Z_1 is equal to X_1.*
- *For each $i \in [\ell]$, $\Pr[Z_{0,i} \neq Z_{1,i}] \leq \epsilon$, where $Z_{b,i}$ means the ith entry of Z_b.*

Intuitively, a small $\|X_0 - X_1\|_{\mathsf{sub}}$ means that, by changing a few positions X_0 – and each position with tiny probability – we can turn X_0 into X_1.

▶ **Conjecture 10.** *There exist functions $r(N), k(N), \zeta(N), \eta(N)$ subject to the constraints $k(N) \geq (\log N)^{\omega(1)}$, $\eta(N) \leq (\log N)^{-\omega(1)}$, and $N\zeta(N)^3/r(N)^6 \geq (\log N)^{\omega(1)}$ such that the following is true. Suppose X_0 is a distribution over $\{0,1\}^N$ such that for all sets $T \subseteq [N]$ of size of size at most $r(N)$, $2^{-|T|} \leq \Pr_{\mathbf{x} \leftarrow X_0}[x_i = 0 \forall i \in T] \leq (1 + \zeta(N)) \times 2^{-|T|}$. Then there exists a $k(N)$-wise uniform independent distribution X_1 such that $\|X_0 - X_1\|_{\mathsf{sub}} \leq \eta(N)$.*

Think of $\log N$ as the instance size, so that N is exponential. Conjecture 10 starts with a distribution X_0 that is in some sense very close to r-wise uniform independent, and concludes that X_0 must be negligibly-close in substitution error to an actual k-wise uniform independent distribution, for k that may be different than r but is still super-polynomial. Note that without the constraint $N\zeta(N)^3/r(N)^6 \geq (\log N)^{\omega(1)}$, the conjecture is trivially true by setting $\zeta = 0$ and $X_0 = X_1$. The exact constraint we stipulate makes the conjecture non-trivial, and arises for technical reasons in our separation.

3.2 Fourier Independent Distributions

▶ **Definition 11.** *Let $N \in \mathbb{Z}^+$ and $S \subseteq [N]$. We say that a distribution $\mathcal{D}_S$ over pairs $(|\psi\rangle, U)$ is (k, δ, γ)-Fourier-Independent (FI) if the following hold:*

- *$|\psi\rangle$ is a normalized superposition $\sum_{y \in S} \alpha_y |y\rangle$ over elements $y \in S$.*
- *$U \subseteq [N]$, and the marginal distribution of U is k-wise uniform independent.*
- *Let $|\hat{\psi}\rangle = \mathsf{QFT}|\psi\rangle$ be the quantum Fourier transform of $|\psi\rangle$. Then except with probability δ over the choice of $|\psi\rangle$, $\langle\hat{\psi}|\Pi_U|\hat{\psi}\rangle \geq \frac{1}{2} + \gamma$, where Π_U is the projection operator $\sum_{z \in U} |z\rangle\langle z|$.*

We want k to be large (say super-polynomial in $\log N$), δ to be small (say negligible in $\log N$), and γ to be not-too-small (non-negligible in $\log N$). Then a Fourier Independent distribution is one where (1) $|\psi\rangle$ has support on S, (2) U looks like a random set to query-bounded quantum algorithms (by Lemma 7), but (3) $|\hat{\psi}\rangle$ is biased toward elements in U.

We now show the existence of a FI distribution for certain k, δ, γ, assuming Conjecture 10.

▶ **Theorem 12.** *Suppose Conjecture 10 holds. Then there exists functions $p, \epsilon, \delta, \gamma : \mathbb{Z}^+ \to [0,1]$ and functions $N, k : \mathbb{Z}^+ \to \mathbb{Z}^+$ such that (1) $p(n), \epsilon(n), \delta(n) \leq n^{-\omega(1)}$, (2) $N(n) \leq 2^{n^{O(1)}}$ (3) $k(n) \geq n^{\omega(1)}$, (4) $\gamma \geq n^{-O(1)}$, and (5) except with probability $\epsilon(n)$ over the choice of $S \leftarrow \mathsf{Bernoulli}_{p(n)}^{N(n)}$, there exists a distribution $\mathcal{D}_S$ that is (k, δ, γ)-Fourier-Independent.*

Proof. Let $N, \ell \in \mathbb{Z}^+$ be positive integers. For a subset $S \subseteq \mathbb{Z}_N$ of size ℓ, let $\mathcal{D}'_S$ be the distribution over pairs $(|\psi\rangle, U')$ where $|\psi\rangle$ is a quantum state and $U' \subseteq \mathbb{Z}_N$, obtained as follows:

- For each $y \in S$, sample a complex number $\alpha_y \leftarrow \mathcal{N}^{\mathbb{C}}(0, \sigma)$ where $\sigma = 1/\sqrt{\ell}$. Let $|\psi\rangle = \sum_{y \in S} \alpha_y |y\rangle$
- For each $z \in \mathbb{Z}_N$, let $\beta_z = \sum_{y \in S} e^{i2\pi yz/N} \alpha_y$.
- For each $z \in \mathbb{Z}_N$, place z into the output set U' with independent probability $1 - e^{-|\beta_z|^2}$.

Intuition

By choosing $\sigma = 1/\sqrt{\ell}$, we will show that $|\psi\rangle$ is approximately normalized, so we can think of $|\psi\rangle$ as being essentially a random state with support on S. Let $|\hat{\psi}\rangle = \mathsf{QFT}|\psi\rangle$ be the QFT applied to $|\psi\rangle$. Then $|\hat{\psi}\rangle = \sum_{z\in\mathbb{Z}_N}(\beta_z/\sqrt{N})|z\rangle$. Thus, the set U' will be biased toward containing the points z where β_z is large. We will also show that U' is close to k-wise independent in substitution distance, for an appropriate k. Via Conjecture 10, this allows us to replace U' with an appropriate U, giving a distribution $\mathcal{D}_S$ that is truly Fourier Independent.

We state some useful lemmas about $\mathcal{D}'_S$; the proofs will be given in Section 4. Define $\tau_T^S := \Pr_{U'\leftarrow\mathcal{D}_S}[T\cap U' = \emptyset]$, or equivalently, the probability $U'(z) = 0$ for all $z\in T$, once S is chosen.

▶ **Lemma 13.** *For any subsets S, T, $1 + |T| \le (\tau_T^S)^{-1} \le 2^{|T|}$*

Lemma 13 holds for any S, T. In particular, for $|T| = 1$, we have that $\tau_T^S = 1/2$. This means each z is placed in U with probability $1/2$; by linearity of expectation, $\mathbb{E}[|U'|] = N/2$. We can also get a tighter lower-bound for larger T with high probability over the choice of S:

▶ **Lemma 14.** *For any $\epsilon > 0$, except with probability at most $2N^2e^{-\epsilon^2\ell/2}$ over the choice of random subset S of size ℓ, for all subsets T, $(\tau_T^S)^{-1} \ge 2^{|T|}(1 - |T|^2\epsilon)$. In this event, as long as $|T|^2\epsilon \le 1/2$, we can bound $\tau_T^S \le 2^{-|T|}(1 + 2|T|^2\epsilon)$.*

Now we bound $\| |\psi\rangle \|^2$, showing that $|\psi\rangle$ is approximately normalized.

▶ **Lemma 15.** *Fix any set S of size ℓ and $\epsilon \in (0,1)$. Then except with probability $2e^{-\epsilon^2\ell/8}$, $\| |\psi\rangle \|^2 \in [1-\epsilon, 1+\epsilon]$, where $|\psi\rangle$ is generated as in $\mathcal{D}'_S$.*

Now, we bound the probability that (the normalization of) $|\hat{\psi}\rangle$ is accepted by U'. Note that $| |\psi\rangle |^2 = | |\hat{\psi}\rangle |^2$.

▶ **Lemma 16.** *Except with probability at most $3(N^{-1} + \ell^2N^{-2})\epsilon^{-2} + 4N^2e^{-\ell\epsilon^2/32}$ over the choice of S, U', we have $\left|\frac{\langle\hat{\psi}|\Pi_{U'}|\hat{\psi}\rangle}{\| |\psi\rangle \|^2} - 3/4\right| \le \epsilon$. Recall $\Pi_{U'}$ is the projection operator $\sum_{z\in U'}|z\rangle\langle z|$.*

We now return to the proof of Theorem 12. $\mathcal{D}'_S$ is almost Fourier Independent, except that the distributions over U' are not k-wise uniform independent. However, Lemmas 13 and 14 show, in some sense, that U' is very close to being k-wide uniform independent, for somewhat large k. We will then invoke the assumed Conjecture 10 to replace U' with a distribution over U that is actually k-wise uniform independent, for a sufficiently large k, and is close in substitution error to U'. We then show that the small substitution error between U and U' implies that the statements of Lemma 16 still approximately holds, even for U.

In more detail, let X_0 be the distribution over U' stemming from $\mathcal{D}'_S$. Let $r(N)$, $k(N)$, $\zeta(N)$, $\eta(N)$ be the functions guaranteed by Conjecture 10. Define $N = \Theta(2^n)$ and let $p = r(N)^4\zeta(N)^{-2}N^{-1}\log^2 N$. By the conditions Conjecture 10 places on $r(N), k(N), \zeta(N), \eta(N)$, we therefore have that $p \le n^{-\omega(1)}\log^2 N \le n^{-\omega(1)}$. By standard concentration inequalities, the size ℓ of S sampled from $\mathsf{Bernoulli}_p^N$ is very close to $pN = r(N)^4\zeta(N)^{-2}\log^2 N$, except with negligible probability. Then set $\epsilon = \zeta(N)/r(N)^2$, which by the conditions of Conjecture 10 gives that $N^{-1}\epsilon^{-2}$, $\ell^2N^{-2}\epsilon^{-2}$, and $N^2e^{-\ell\epsilon^2/32}$ are all negligible. By Lemma 13 and by invoking Lemma 14 with $\epsilon = \zeta(N)/r(N)^2$, we have except with negligible probability over the choice of S, that $2^{-|T|} \le \tau_S^T \le 2^{-|T|}(1+\zeta)$ for all sets T of size at most $r(N)$. Conjecture 10 then implies for "good" S where the bounds on τ_S^T hold, there is a distribution X_1 that is $k(N)$-wise uniform independent and such that $\|X_0 - X_1\|_{\mathsf{sub}} \le \eta(N)$, with $k(N), 1/\eta(N) \ge (\log N)^{\omega(1)} = n^{\omega(1)}$.

Let S be a good set. Now consider the following distribution $\mathcal{D}_S$. It first uses the fact that $\|X_0 - X_1\|_{\mathsf{sub}} \leq n^{-\omega(1)}$ to derive a joint distribution (Z_0, Z_1) with the marginal Z_0 being equivalent to X_0 and Z_1 being k-wise uniform independent for $k \geq n^{\omega(1)}$. Then we sample $(|\psi\rangle, U') \leftarrow \mathcal{D}'_S$ and sample U from the distribution Z_1 conditioned on $Z_0 = U'$. Let $|\psi'\rangle = |\psi\rangle / \| |\psi\rangle \|$. Output $(|\psi'\rangle, U)$. We then have that U is distributed according to Z_1, and is therefore k-wise uniform independent. We also have by Lemma 16 that except with negligible probability, $\langle\hat{\psi}'|\Pi_{U'}|\hat{\psi}'\rangle \geq 2/3$. In order to justify Fourier Independence, we just need to show that, e.g. $\langle\hat{\psi}'|\Pi_U|\hat{\psi}'\rangle \geq 7/12$.

Toward that end, write $|\hat{\psi}'\rangle = \frac{1}{\sqrt{N}} \sum_{z \in \mathbb{Z}_N} \beta'_z |z\rangle$ where $\sum_z |\beta'_z|^2 = 1$. Then deinfe

$$E := \langle\hat{\psi}'|\Pi_{U'}|\hat{\psi}'\rangle - \hat{\psi}'|\Pi_U|\hat{\psi}'\rangle = \sum_{z \in U'} |\beta'_z|^2 - \sum_{z \in U} |\beta'_z|^2 \leq \sum_{z \in U' \setminus U} |\beta'_z|^2$$

Now let ξ_z denote the variable that is 1 if $z \notin U' \setminus U$ and is 0 otherwise. Then $E \leq \sum_z \xi_z |\beta'_z|^2$. Each ξ_z is a 0/1 random variable with negligible expectation. Therefore, since $\sum_z |\beta'_z|^2 = 1$, we have that $\mathbb{E}[E]$ is negligible. Then by Markov's inequality, we have that $\Pr[E \geq \sqrt{\mathbb{E}[E]}] \leq \sqrt{\mathbb{E}[E]}$. Therefore, since $\mathbb{E}[E]$ and hence $\sqrt{\mathbb{E}[E]}$ are negligible, we have that E is negligible except with negligible probability. This means in particular that $\langle\hat{\psi}'|\Pi_U|\hat{\psi}'\rangle \geq 7/12$, except with negligible probability. Thus $\mathcal{D}_S$ is (k, δ, γ)-Fourier-Independent, thereby proving Theorem 12. ◀

3.3 From FI Distributions to An Oracle Separation

We now show that FI distributions as guaranteed by Theorem 12 give a separation between OI-QCMA and OI-QMA.

▶ **Theorem 17.** *Suppose Conjecture 10 holds. Then* OI-QCMA $\neq$ OI-QMA.

Proof. We first invoke Theorem 12 to obtain distributions $\mathcal{D}_S$ satisfying properties (1) through (5) in the statement of Theorem 12. We now use this to construct our separation. We will invoke the definition of OI-QMA and OI-QCMA with $a = 1/2 + \gamma(n)/2$ and $b = 1/2 + \gamma(n)$. Since $b - a = \gamma(n)/2$ is inverse polynomial, this is equivalent to the standard definition of OI-QMA and OI-QCMA. Thus, a valid verifier will accept YES instances of size n (given a correct witness) with probability at least $1/2+\gamma(n)$, and accept NO instances with probability at most $1/2 + \gamma(n)/2$.

An instance will be a pair of oracles (S, U) where $S, U \subseteq [N(n)]$. Our verifier $V^{S,U}(|\psi\rangle)$ will do the following: V will make a query to S on the witness state $|\psi\rangle$ and measuring the output. If it accepts, then V will apply the QFT to the witness state (which may have changed due to the measurement), and make a query to U, measuring the output. If both queries accept, then V will output 1; if either measurement rejects, then V will output 0.

We define the universe $\mathcal{U}$ as the set of pairs (S, U) for which either (1) there exists a state $|\psi\rangle$ such that $\Pr[V^{S,U}(|\psi\rangle) = 1] \geq 1/2 + \gamma(n)$, or (2) for all states $|\psi\rangle$, $\Pr[V^{S,U}(|\psi\rangle) = 1] < 1/2 + \gamma(n)/2$. Then OI-L $\subseteq \mathcal{U}$ is the set such that $\Pr[V^{S,U}(|\psi\rangle) = 1] \geq 1/2 + \gamma(n)$. By definition, OI-L $\in$ OI-QMA.

We now show that OI-L $\notin$ OI-QCMA. We can always assume without loss of generality that there is, say, a fixed quadratic running time t such that the running time of any OI-QCMA verifier is bounded by $t(|x| + |w|)$ where $|x|$ is the instance length and $|w|$ is the witness length. This is accomplished by padding the witness length with 0's that just get ignored by the verifier.

Now let $q = q(n)$ be a sufficiently small super-polynomial function, which we will take as an upper bound on witness length. Let $Q(n) = q(n)^2$, which we take to be an upper bound on the number of queries when the witness length is at most $q(n)$. Let $v = v(n)$ be another super-polynomial. We will need the following constraints on q, Q, v:

$$Q \ll \gamma p^{-1/2} \qquad v \gg qQ^4\gamma^{-4}$$
$$v \ll \gamma N^{1/12} \qquad Qk/v \leq n^{-\omega(1)}$$

These can be satisfied for a sufficiently-small super-polynomial q, v and for sufficiently large n.

Suppose toward contradiction that there is a $\mathsf{OI\text{-}QCMA}$ verifier V_*. Sample $S \leftarrow \mathsf{Bernoulli}_{p(n)}^{N(n)}$ and $(|\psi\rangle, U) \leftarrow \mathcal{D}_S$, where $\mathcal{D}_S$ is $(k(n), \delta(n), \gamma(n))$-Fourier-Independent. Then we have that with overwhelming probability over the choice of $S, U, |\psi\rangle$, $\Pr[V^{S,U}(|\psi\rangle) = 1] \geq 1/2 + \gamma(n)$. Hence $(S, U) \in \mathsf{OI\text{-}L}$. Therefore, under the assumption that V_* is a verifier for $\mathsf{OI\text{-}L}$, V_* must accept (S, U), meaning there is a classical witness w such that $\Pr[V_*^{S,U}(w) = 1] \geq 1/2 + \gamma(n)$.

We will now construct a different instance S', U, where S' is constructed from the following algorithm $\mathsf{GenSmallSet}^{S,U}(w)$: initialize $S' = \{\}$, and then repeat the following loop for $i = 1, ..., v$:

- Run $V_*^{S,U}(w)$ until a randomly chosen query to S, and measure the query, obtaining a string $y_i \in [N]$.
- If $y_i \in S \setminus S'$, add y_i to S'.

The following is proved in Section 4:

▶ **Lemma 18.** *If U is sampled from a k'-wise uniform independent function and S' is potentially correlated to U but has size at most v, then except with probability $2N^2 \left(\frac{\sqrt{ek'}}{\epsilon\sqrt{N}}\right)^{k'}$ over the choice of U, S', it holds that, for any normalized state $|\phi\rangle$ with support on S', $\langle\hat{\phi}|\Pi_U|\hat{\phi}\rangle \leq 1/2 + v\epsilon$, where $|\hat{\phi}\rangle = \mathsf{QFT}|\phi\rangle$.*

▶ **Corollary 19.** *Except with negligible probability over the choice of S, U, S', $(S', U) \in \mathcal{U} \setminus \mathsf{OI\text{-}L}$.*

Proof. Set $\epsilon = \gamma/3v$, and set $G := 2N^2 \left(\frac{3v\sqrt{ek'}}{\gamma\sqrt{N}}\right)^{k'}$ for a yet-unspecified k'. By Lemma 18, except with probability at most G, $\Pr[V^{S',U}(|\phi\rangle) = 1] \leq 1/2 + \gamma/3 < 1/2 + \gamma/2$ for any state $|\phi\rangle$. In this case, $(S', U') \in \mathcal{U} \setminus \mathsf{OI\text{-}L}$. This event holds regardless of what S' is, just using the fact that it consists of at most v elements. Setting $k' = 5$ and using that $v \leq \gamma N^{1/12}$ we have that $G = O(N^{1/12})$, which is negligible. ◀

We now show, however, that V^* fails to reject S', U:

▶ **Lemma 20.** *Except with negligible probability over the choice of S, U, w, S', $\Pr[V_*^{S',U}(w) = 1] > 1/2 + \gamma(n)/2$*

Proof. Observe that the process $\mathsf{GenSmallSet}^{S,U}(w)$ for constructing S' always generates $S' \subseteq S$. Now consider running $S' \leftarrow \mathsf{GenSmallSet}^{S,U'}(w')$, where w' is a random string and U' is a random boolean function, with both w', U' independent of S. This is an algorithm which makes vQ queries to S (and also to U', but U' us simulatable on its own since it is independent of S). S in turn sampled from $\mathsf{Bernoulli}_p^N$. Finally, the algorithm outputs some subset S' of S. By Lemma 8, there is a universal constant C such that

$$\Pr[|S'| \geq K : w', U' \text{ are uniform and independent of } S] \leq (Cp(vQ/K)^2)^K.$$

Now consider running $S' \leftarrow \mathsf{GenSmallSet}^{S,U}(w')$, replacing U' with U. Recall that U is k-wise independent even conditioned on S, for $k \geq 2vQ$ where vQ is the number of queries made by $\mathsf{GenSmallSet}$. By Lemma 7, the output distribution of $\mathsf{GenSmallSet}^{S,U}(w')$ is identical to that of $\mathsf{GenSmallSet}^{S,U'}(w')$. Thus, we still have

$$\Pr[|S'| \geq K : U' = U, \text{ while } w' \text{ is uniform and independent of } S] \leq (Cp(vQ/K)^2)^K.$$

Finally, consider running $S' \leftarrow \mathsf{GenSmallSet}^{S,U}(w)$. Since $\Pr[w' = w] = 2^{-q}$, this means that with probability 2^{-q}, $\mathsf{GenSmallSet}^{S,U}(w')$ is actually running $\mathsf{GenSmallSet}^{S,U}(w)$. Therefore,

$$\Pr[|S'| \geq K : U' = U, w' = w] \leq (Cp(vQ/K)^2)^K \times 2^q.$$

We now set $K = vQ\sqrt{2Cp} + q + \log_2(v)$. Then we have that $\Pr[|S'| \geq K : U' = U, w' = w] \leq 1/v$. Then in particular since $|S'| \leq v$ always, we have that $\mathbb{E}[|S'|] \leq (K-1)\Pr[|S'| < K] + v\Pr[|S'| \geq K] \leq (K-1) + 1 \leq K$.

Let e_j be the probability that $\mathsf{GenSmallSet}$ adds an element y_i to S' in the ith iteration. Then $\sum_{j=1}^{v} e_j = \mathbb{E}[|S'|] \leq K$. We also have that the e_j are monotonically decreasing since the y_i are identically distributed and thus the probability mass outside of the growing S' can only shrink. Thus $e_v \leq K/v$.

For an input $y \in S$, let M_y denote the total magnitude squared of y in all queries made by $V_*^{S,U}(w)$ to oracle S. Then measuring a random choice of the $\leq Q$ queries by V_*, we will obtain y with probability at least M_y/Q. Since $e_v \leq K/v$, this means that by the end of the loop, the expected total query weight of all points in S but not in S' is at most QK/v. By Markov's inequality, we therefore have that the query weight of points in $S \setminus S'$ is at most $\sqrt{QK/v}$, except with probability at most $\sqrt{QK/v}$. Recall that $\sqrt{QK/v}$ is negligible. Therefore, since this probability is negligible, we will therefore assume the total query weight of points in $S \setminus S'$ is at most $\sqrt{QK/v}$.

Lemma 6 shows that the difference in acceptance probability between $V_*^{S,U}(w)$ and $V_*^{S',U}(w))$ is at most $4\sqrt{Q \times \sqrt{QK/v}} = 4\sqrt[4]{Q^3K/v}$. Observe that $Q^3K/v = Q^4\sqrt{2Cp} + Q^3(q + \log_2(v))/v$. Using that $Q \ll \gamma p^{-1/2}$ and $v \gg qQ^4/\gamma^4$, we therefore have that $Q^3K/v \leq \gamma^4/(12)^4$. Hence the difference in acceptance probability is at most $\gamma/3$, and hence $\Pr[V_*^{S',U}(w)) = 1] > 1/2 + \gamma/2$. ◀

Corollary 19 and Lemma 20 shows that V_* fails to decide $\mathsf{OI\text{-}L}$, contradicting it being a QCMA verifier. Hence, $\mathsf{OI\text{-}L} \notin \mathsf{QCMA}$. This completes the proof of Theorem 17 ◀

4 Missing Proofs

We now prove Lemmas 13, 14, 15, and 16 as well as Theorem 5. To do so, we introduce some extra notation. For a subset $S \subseteq \mathbb{Z}_N$, let $\mathbf{M}^S$ be the $N \times N$ matrix defined as $\mathsf{QFT}^\dagger \circ \Pi_S \circ \mathsf{QFT}$. Define $\tau_T^S := \Pr_{U' \leftarrow \mathcal{D}'_S}[T \cap U = \emptyset]$, or equivalently, the probability $U'(z) = 0$ for all $z \in T$, once S is chosen. Let $\mathcal{M}_T^S$ be the $|T| \times |T|$ sub-matrix of $\mathbf{M}^S$ consisting of rows and columns columns whose indices are in T. The following lemmas will be useful.

▶ **Lemma 21.** *For any $\epsilon > 0$, except with probability at most $2N^2 e^{-\epsilon^2 N^2/8\ell}$ over the choice of random S of size ℓ, $\max_{z \neq z'} |\mathbf{M}^S_{z,z'}| \leq \epsilon$*

Proof. Fix any $z \neq z'$, and consider the random variable $M^S_{z,z'}$ where S is a random set of size ℓ. We write:

$$M^S_{z,z'} = \frac{1}{N}\sum_{y\in S} e^{i2\pi(z-z')y/N} = \frac{1}{N}\sum_{j=1}^{\ell} e^{i2\pi(z-z')y_j/N}$$

where $y_1 \cdots, y_\ell$ range over the elements of S, and are therefore random distinct values in $\mathbb{Z}_N$.

We first look at the real part of $\mathbf{M}^S_{z,z'}$, namely $\frac{1}{N}\sum_{i=1}^{\ell} Y_i$ where $Y_i = \cos(2\pi(z-z')y_i/N)$. For the moment, imagine the y_i being uniform without the distinctness requirement, in which case since $z - z' \neq 0$ the Y_i all become independent random variables bounded to the range $[-1, 1]$. Moreover, the means are zero since $z - z' \neq 0 \bmod N$. Then by Hoeffding's inequality, we have

$$\Pr\left[\left|\sum_{i=1}^{\ell} Y_i\right| \geq t\right] \leq 2e^{-t^2/4\ell}$$

We then observe that switching to distinct y_i cannot make the inequality worse. This is because Hoeffding's inequality still holds when sampling is performed without replacement; in fact even better bounds are possible [11].

We now look at the imaginary part $\frac{1}{N}\sum_{i=1}^{\ell} Y'_i$ where $Y'_i = \sin(2\pi(z-z')y_i/N)$. By identical logic, we have that

$$\Pr\left[\left|\sum_{i=1}^{\ell} Y'_i\right| \geq t\right] \leq 2e^{-t^2/4\ell}$$

Combining the two inequalities with the fact that the real and imaginary parts are orthogonal gives $\Pr[|M^S_{z,z'}| \geq \sqrt{2}t/N] \leq 4e^{-t^2/4\ell}$. Setting $t = \epsilon N/\sqrt{2}$ gives that

$$\Pr\left[\left|M^S_{z,z'}\right| \geq \epsilon\right] \leq 4e^{-\epsilon^2 N^2/8\ell}$$

Taking a union bound over all $\binom{N}{2}$ off-diagonal terms[1] we obtain the lemma. ◀

▶ **Lemma 22.** *Fix subsets S, T with $|S| = \ell$. Then*

$$\tau^S_T = \frac{1}{\det(\mathbf{I} + \frac{N}{\ell}\mathbf{M}^T_S)} = \frac{1}{\det(\mathbf{I} + \frac{N}{\ell}\mathbf{M}^S_T)}$$

Proof. Recall that U' is sampled by first sampling the state $|\psi\rangle$ with support on S where each coefficient α_y is Gaussian distributed from $\mathcal{N}^{\mathbb{C}}(0,\sigma)$. Then each z is excluded from U' with probability $e^{-|\beta_z|^2}$, where $\beta_z/\sqrt{N}$ is the Fourier coefficient of z in $|\psi\rangle$. Thus, the probability that $T \cap U' = \emptyset$, conditioned on $|\psi\rangle$ is just

$$\Pr[T \cap U' = \emptyset |\ |\psi\rangle] = e^{-\sum_{z\in T}|\beta_z|^2} = e^{-N\langle\psi|\mathsf{QFT}^\dagger \Pi_T \mathsf{QFT}|\psi\rangle} = e^{-N\langle\psi|\mathbf{M}^T|\psi\rangle}$$

Now let $\mathbf{v}$ be the vector of the α_y as y varies in S. Then $|\psi\rangle$ is just $\mathbf{v}$ with zeros inserted in each position outside of S. Then we can write

$$\Pr[T \cap U' = \emptyset |\ |\psi\rangle] = e^{-N\mathbf{v}^\dagger \mathbf{M}^T_S \mathbf{v}}$$

[1] Since M^S is Hermitian, we only need to bound, say, the terms above the diagonal.

We now average over the choice of $\mathbf{v}$, which is simply distributed as $\mathcal{N}^{\mathbb{C}}(0,\sigma)^\ell$. This gives us

$$\begin{aligned}\tau_T^S &= \int_{\mathbb{C}^\ell} \Pr[\mathbf{v}] e^{-N\mathbf{v}^\dagger \mathbf{M}_S^T \mathbf{v}} d\mathbf{v} \\ &= \frac{1}{(\pi\sigma^2)^\ell} \int_{\mathbb{C}^\ell} e^{-\frac{|\mathbf{v}|^2}{\sigma^2} - N\mathbf{v}^\dagger \mathbf{M}_S^T \mathbf{v}} d\mathbf{v} \\ &= \frac{1}{(\pi\sigma^2)^\ell} \int_{\mathbb{C}^\ell} e^{-\mathbf{v}^\dagger(\sigma^{-2}\mathbf{I} + N\mathbf{M}_S^T)\mathbf{v}} d\mathbf{v} \\ &= \frac{1}{(\sigma^2)^\ell \det(\sigma^{-2}\mathbf{I} + N\mathbf{M}_S^T)} = \frac{1}{\det(\mathbf{I} + N\sigma^2\mathbf{M}_S^T)} = \frac{1}{\det(\mathbf{I} + \frac{N}{\ell}\mathbf{M}_S^T)}\end{aligned}$$

where in the last inequality we plugged in $\sigma = \sqrt{1/\ell}$. This gives us the first part of Lemma 22. Now, we observe that $\mathbf{M}_S^T = A^\dagger A$, where A is the $|T| \times \ell$ sub-matrix of QFT restricted to column indices in S and row indices in T. Then by the Weinstein–Aronszajn identity, $\det(\mathbf{I} + \frac{N}{\ell}\mathbf{M}_S^T) = \det(\mathbf{I} + \frac{N}{\ell}A^\dagger A) = \det(\mathbf{I} + \frac{N}{\ell}AA^\dagger) = \det(\mathbf{I} + \frac{N}{\ell}\mathbf{M}_T^S)$. This gives the second part of Lemma 22. ◀

Going forward, we will use $\overline{\tau}_T^S$ as shorthand for $\det(\mathbf{I} + \frac{N}{\ell}\mathbf{M}_T^S)$. Lemma 22 says that $\tau_T^S = (\overline{\tau}_T^S)^{-1}$.

We can now prove Lemmas 13, 14, 15, and 16.

4.1 Proof of Lemma 13

▶ **Lemma 13.** *For any subsets S, T, $1 + |T| \le \overline{\tau}_T^S \le 2^{|T|}$*

Proof. We first observe that the diagonal entries in $\mathbf{I} + \frac{N}{\ell}\mathbf{M}^S$ are exactly 2. Indeed, the zth diagonal entry is $1 + (N/\ell)\left(\frac{1}{N}\sum_{x\in S} e^{i2\pi zx}e^{-i2\pi zx}\right) = 2$. Moreover, $\frac{N}{\ell}\mathbf{M}^S$ and hence $\mathbf{I} + \frac{N}{\ell}\mathbf{M}^S$ is PSD. Since $\mathbf{I} + \frac{N}{\ell}\mathbf{M}_T^S$ is just a principle minor of $\mathbf{I} + \frac{N}{\ell}\mathbf{M}^S$, it is also PSD with diagonal entries also equal to 2. The determinant is then bounded by the product of the diagonal entries, giving the upper bound.

For the lower bound, we have that the eigenvalues of $\mathbf{I} + \frac{N}{\ell}\mathbf{M}_T^S$ sum to $2|T|$, and each of the $|T|$ eigenvalues is at least 1. The determinant is the product of the eigenvalues, which is minimized when one of the eigenvalues is $|T| + 1$ and the remaining $|T| - 1$ eigenvalues are 1. This gives the lower bound. ◀

4.2 Proof of Lemma 14

▶ **Lemma 14.** *For any $\epsilon > 0$, except with probability at most $2N^2 e^{-\epsilon^2\ell/2}$ over the choice of S, for all subsets T, $\overline{\tau}_T^S \ge 2^{|T|}(1 - |T|^2\epsilon)$. In this event, as long as $|T|^2\epsilon \le 1/2$, we can bound $\tau_T^S \le 2^{-|T|}(1 + 2|T|^2\epsilon)$.*

Proof. Assume all the off-diagonal entries of M^S are bounded by $2\epsilon\ell/N$, which by Lemma 21 holds except with probability $2N^2e^{-\epsilon^2\ell/2}$. We have already seen that the diagonal entries of $\mathbf{I} + \frac{N}{\ell}\mathbf{M}_T^S$ are exactly 2. The off-diagonal entries of $\mathbf{I} + \frac{N}{\ell}\mathbf{M}_T^S$ are off-diagonal entries from $\mathbf{M}^S$ but scaled by N/ℓ, and are therefore bounded by 2ϵ. By Gershgorin's circle theorem, the eigenvalues are therefore lower-bounded by $2(1 - |T|\epsilon)$. The determinant is therefore lower-bounded by this quantity raised to the $|T|$. We obtain the lemma by bounding $(1 - |T|\epsilon)^{|T|} \ge (1 - |T|^2\epsilon)$. ◀

4.3 Proof of Lemma 15

▶ **Lemma 15.** *Fix any set S of size ℓ and $\epsilon \in (0,1)$. Then except with probability $2e^{-\epsilon^2\ell/8}$, $|\ |\psi\rangle\ |^2 \in [1-\epsilon, 1+\epsilon]$, where $|\psi\rangle$ is generated as in $\mathcal{D}'_S$.*

Proof. First, $\mathbb{E}[|\ |\psi\rangle\ |^2] = \sum_{y\in S}\mathbb{E}[|\alpha_y|^2]$. Since $\alpha_y \leftarrow \mathcal{N}^{\mathcal{C}}(0, 1/\sqrt{\ell})$, the real and imaginary parts are mean-0 normal variables with variance $1/2\ell$. $|\alpha_y|^2$ is therefore distributed as the Chi-squared distribution with two degrees of freedom, scaled by $1/2\ell$, which therefore has expectation $1/\ell$. Summing over all $y \in S$ gives $\mathbb{E}[|\ |\psi\rangle\ |^2] = 1$. We also see that $|\ |\psi\rangle\ |^2$ is distributed as a Chi-squared distribution with 2ℓ degrees of freedom, scaled by $1/2\ell$. Via concentration inequalities for Chi-squared, we have that

$$\Pr\left[\left|\ |\ |\psi\rangle\ |^2 - 1\ \right| \geq 4\sqrt{x/2\ell}\right] \leq 2e^{-x}$$

Setting $\epsilon = 4\sqrt{x/2\ell}$ gives the lemma. ◀

4.4 Proof of Lemma 16

▶ **Lemma 16.** *Except with probability at most $3(N^{-1} + \ell^2 N^{-2})\epsilon^{-2} + 4N^2 e^{-\ell\epsilon^2/32}$ over the choice of S, U', we have $\left|\frac{\langle\hat{\psi}|\Pi_{U'}|\hat{\psi}\rangle}{|\ |\psi\rangle\ |^2} - 3/4\right| \leq \epsilon$. Recall $\Pi_{U'}$ is the projection operator $\sum_{z\in U'}|z\rangle\langle z|$.*

Proof. Fix $|\psi\rangle$. We first compute the expectation of $\langle\hat{\psi}|\Pi_{U'}|\hat{\psi}\rangle$ (as U varies) given $|\psi\rangle$. We will actually compute the complement $\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle$

$$\begin{aligned}
\mathbb{E}[\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle] &= \frac{1}{N}\mathbb{E}[\sum_{z\notin U'}|\beta_z|^2] \\
&= \frac{1}{N}\sum_{z\in\mathbb{Z}_N}\Pr[z\notin U']|\beta_z|^2 \\
&= \frac{1}{N}\sum_{z\in\mathbb{Z}_N}|\beta_z|^2 e^{-|\beta_z|^2}
\end{aligned}$$

Now we include the expectation as we vary $|\psi\rangle$, giving:

$$\mathbb{E}[\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle] = \frac{1}{N}\sum_{z\in\mathbb{Z}_N}\mathbb{E}[|\beta_z|^2 e^{-|\beta_z|^2}]$$

Next, we bound $\mathbb{E}[|\beta_z|^2 e^{-|\beta_z|^2}]$. Since the distribution of α_y are invariant under phase change, we see that β_z is just the sum of ℓ iid variables distributed as $\mathcal{N}^{\mathcal{C}}(0, 1/\sqrt{\ell})$. This means each β_z is distributed as $\mathcal{N}^{\mathcal{C}}(0,1)$. Breaking out the real and imaginary parts lets us write

$$\begin{aligned}
\mathbb{E}[|\beta_z|^2 e^{-|\beta_z|^2}] &= \int_{\mathbb{C}}|\beta|^2 e^{-|\beta|^2}\times\frac{1}{\pi}e^{-|\beta|^2}d\beta \\
&= \frac{1}{\pi}\int_{\mathbb{C}}|\beta|^2 e^{-2|\beta|^2}d\beta = \frac{1}{\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(x^2+y^2)e^{-2(x^2+y^2)}dxdy = \frac{1}{4}
\end{aligned}$$

Thus, we have that $\mathbb{E}[\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle] = 1/4$. Now we bound the variance. By carrying out a similar calculation as before, we have:

$$\begin{aligned}
\mathbb{E}[\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle^2] &= \frac{1}{N^2}\,\mathbb{E}[\left(\sum_{z\notin U'}|\beta_z|^2\right)] \\
&= \frac{1}{N^2}\sum_{z,z'\in\mathbb{Z}_N}\Pr[z,z'\notin U']|\beta_z|^2|\beta_{z'}|^2 \\
&= \frac{1}{N^2}\left(\sum_z \Pr[z\notin U']|\beta_z|^4 + \sum_{z\neq z'}\Pr[z\notin U']\Pr[z'\in U']|\beta_z|^2|\beta_{z'}|^2\right) \\
&= \frac{1}{N^2}\left(\sum_z |\beta_z|^4 e^{-|\beta_z|^2} + \sum_{z\neq z'}|\beta_z|^2|\beta_{z'}|^2 e^{-|\beta_z|^2-|\beta_{z'}|^2}\right)
\end{aligned}$$

We include the expectation as we vary $|\psi\rangle$. The expectation of $|\beta_z|^4 e^{-|\beta_z|^2}$ becomes

$$\mathbb{E}\left[|\beta_z|^4 e^{-|\beta_z|^2}\right] = \int_{\mathbb{C}}|\beta|^4 e^{-|\beta|^2}\times\frac{1}{\pi}e^{-|\beta|^2} = \frac{3}{4}$$

Meanwhile, to compute the expectation of $|\beta_z|^2|\beta_{z'}|^2 e^{-|\beta_z|^2-|\beta_{z'}|^2}$, we use that the co-variance matrix of $\beta_z,\beta_{z'}$ is exactly $\mathbf{M}^S_{\{z,z'\}}$. Thus

$$\begin{aligned}
&\mathbb{E}\left[|\beta_z|^2|\beta_{z'}|^2 e^{-|\beta_z|^2-|\beta_{z'}|^2}\right] \\
&= \int_{\mathbb{C}}\int_{\mathbb{C}}\frac{|\beta|^2|\beta'|^2 e^{-|\beta|^2-|\beta'|^2}}{\pi^2\det(\mathbf{M}^S_{\{z,z'\}})^2}\times e^{-\begin{pmatrix}\beta^* & (\beta')^*\end{pmatrix}\cdot\left(\mathbf{M}^S_{\{z,z'\}}\right)^{-1}\cdot\begin{pmatrix}\beta\\ \beta'\end{pmatrix}}d\beta d\beta' \\
&= \frac{1}{\pi^2\det(\mathbf{M}^S_{\{z,z'\}})^2}\int_{\mathbb{C}}\int_{\mathbb{C}}|\beta|^2|\beta'|^2 e^{-\begin{pmatrix}\beta^* & (\beta')^*\end{pmatrix}\cdot\left[\mathbf{I}+\left(\mathbf{M}^S_{\{z,z'\}}\right)^{-1}\right]\cdot\begin{pmatrix}\beta\\ \beta'\end{pmatrix}}d\beta d\beta' \\
&= \frac{1}{\pi^2\det(\mathbf{M}^S_{\{z,z'\}})^2}\times\frac{\pi^2\mathsf{Tr}(\mathbf{I}+(\mathbf{M}^S_{\{z,z'\}})^{-1})^2}{4\det(\mathbf{I}+(\mathbf{M}^S_{\{z,z'\}})^{-1})^3} \\
&= \frac{\det(\mathbf{M}^S_{\{z,z'\}})\mathsf{Tr}(\mathbf{I}+(\mathbf{M}^S_{\{z,z'\}})^{-1})^2}{4\det(\mathbf{I}+\mathcal{M}^S_{\{z,z'\}})^3}
\end{aligned}$$

Now write $\mathbf{M}^S_{\{z,z'\}} = \begin{pmatrix}1 & \epsilon_{z,z'}\\ \epsilon_{z,z'} & 1\end{pmatrix}$. By Lemma 21, we can now bound $|\epsilon_{z,z'}|$ by $\ell/4N < 1/2$, except with probability $2N^2e^{-\ell/32}$. Then we have that

$$\mathbb{E}[|\beta_z|^2|\beta_{z'}|^2 e^{-|\beta_z|^2-|\beta_{z'}|^2}] = \frac{\left(2-|\epsilon_{z,z'}|^2\right)^2}{\left(1-|\epsilon_{z,z'}|^2\right)\left(4-|\epsilon_{z,z'}|^2\right)^3} \leq \frac{1}{16}(1+|\epsilon_{z,z'}|^2)$$

where the last inequality used that $|\epsilon_{z,z'}|\leq 1/2$.

We therefore have that $\mathbb{E}[\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle^2] \leq \frac{3}{4N}+\frac{1}{16}+\frac{1}{16N^2}\sum_{z\neq z'}|\epsilon_{z,z'}|$. Since the mean is $1/4$, the variance is therefore at most $\frac{3}{4N}+\frac{1}{16N^2}\sum_{z\neq z'}|\epsilon_{z,z'}|^2 \leq \frac{3}{4N}+\frac{1}{16N^2}\sum_{z\neq z'}\left(\frac{\ell}{4N}\right)^2 \leq \frac{3}{4N}+\frac{\ell^2}{256N^2}$. We now apply Chebyshev's inequality, to get that

$$\Pr[|\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle - 1/4| \geq \epsilon/2] \leq \frac{\frac{3}{4N}+\frac{\ell^2}{64N^2}}{(\epsilon/2)^2} + 2N^2e^{-\ell/32}$$

Now we have that

$$\begin{aligned}
\Pr\left[\left|\frac{\langle\hat{\psi}|\Pi_{U'}|\hat{\psi}\rangle}{|\,|\psi\rangle\,|^2} - 3/4\right| \geq \epsilon\right] &= \Pr\left[\left|\frac{\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle}{|\,|\psi\rangle\,|^2} - 1/4\right| \geq \epsilon\right] \\
&= \Pr\left[\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle \notin |\,|\psi\rangle\,|^2 \times \left[\frac{1}{4}-\epsilon, \frac{1}{4}+\epsilon\right]\right] \\
&\leq \Pr\left[\langle\hat{\psi}|(\mathbf{I}-\Pi_{U'})|\hat{\psi}\rangle \notin \left[\frac{1}{4}-\epsilon/2, \frac{1}{4}+\epsilon/2\right]\right] \\
&\quad + \Pr[|\,|\psi\rangle\,|^2 \notin [1-\epsilon/2, 1+\epsilon/2]] \\
&\leq \left(\frac{\frac{3}{4N}+\frac{\ell^2}{64N^2}}{(\epsilon/2)^2} + 2N^2 e^{-\ell/32}\right) + 2e^{-\ell\epsilon^2/32} \\
&\leq 3(N^{-1}+\ell^2 N^{-2})\epsilon^{-2} + 4N^2 e^{-\ell\epsilon^2/32}
\end{aligned}$$

◀

4.5 Proof of Lemma 18

▶ **Lemma 18.** *If U' is sampled from a k'-wise uniform independent function and S' is potentially correlated to U' but has size at most v, then except with probability $2N^2\left(\frac{\sqrt{ek'}}{\epsilon\sqrt{N}}\right)^{k'}$ over the choice of U', S', it holds that, for any normalized state $|\phi\rangle$ with support on S', $\langle\hat{\phi}|\Pi_{U'}|\hat{\phi}\rangle \leq 1/2 + v\epsilon$, where $|\hat{\phi}\rangle = \mathsf{QFT}|\phi\rangle$.*

Proof. For a set U', let $\mathbf{M}^{U'} = \mathsf{QFT}^\dagger\Pi_{U'}\mathsf{QFT}$. Then $(\mathbf{M}^{U'})_{z,z'} = \frac{1}{N}\sum_{y\in\mathbb{Z}_N} e^{i2\pi(z-z')y/N}\xi_y$, where ξ_y is the boolean value that is 1 if $y \in U'$. Then we have that $(\mathbf{M}^{U'})_{z,z} = |U'|/N$. In expectation, $|U'|/N$ is $1/2$. We now bound how far $|U'|/N$ can deviate from $1/2$. Recall that $|U'|/N = \frac{1}{N}\sum_{y\in\mathbb{Z}_N}\xi_y$. The ξ_y are not truly independent so we cannot use standard concentration inequalities such as Hoeffding. However, we can use the following somewhat standard bound (e.g. [12]) for the $[-1,1]$-weighted sum of k'-wise independent boolean random variables:

$$\Pr\left[\left|\frac{1}{N}\sum_{y\in\mathbb{Z}_N}\xi_y - \frac{1}{2}\right| \geq \epsilon/\sqrt{2}\right] \leq 2\left(\frac{\sqrt{ek'}}{\epsilon\sqrt{N}}\right)^{k'}$$

On the other hand, for $z' \neq z'$, taking the expectation over U', we see that $\mathbb{E}_{U'}[(\mathbf{M}^{U'})_{z,z}] = 0$. We now try to bound the deviation from the expectation, by bounding the real and imaginary parts separately. We see that $\Re[(\mathbf{M}^{U'})_{z,z'}] = \frac{1}{N}\sum_{y\in\mathbb{Z}_N}\cos(2\pi(z-z')y/N)\xi_y$, which is the weighted sum of boolean random variables ξ_y, where the weights are all in $[-1,1]$. Using the $[-1,1]$-weighted sum of k'-wise independent boolean random variables again, we have:

$$\Pr[\frac{1}{N}\sum_{y\in\mathbb{Z}_N}\cos(2\pi(z-z')y/N)\xi_y \geq \epsilon/\sqrt{2}] \leq 2\left(\frac{\sqrt{ek'}}{\epsilon\sqrt{N}}\right)^{k'}$$

Combining with an identical bound on the imaginary part of $(\mathbf{M}^U)_{z,z'}$, we have that

$$\Pr[|(\mathbf{M}^{U'})_{z,z'}| \geq \epsilon] \leq 4\left(\frac{\sqrt{ek'}}{\epsilon\sqrt{N}}\right)^{k'}$$

By union-bounding over all entries of $\mathbf{M}^U$ (which only needs to count entries on the diagonal and above since $\mathbf{M}$ is Hermitian), we have except for probability at most $2N^2\left(\frac{\sqrt{ek'}}{\epsilon\sqrt{N}}\right)^{k'}$, both (1) for all z that $(\mathbf{M}^U)_{z,z} \in [1/2-\epsilon, 1/2+\epsilon]$ and (2) for all $z \neq z'$ that $|(\mathbf{M}^U)_{z,z'}| \leq \epsilon$.

Now suppose (1) and (2) hold. Now consider a supposed set S' of size v. Let $\mathbf{M}_{S'}^{U'}$ be the $v \times v$ sub-matrix whose row and column indices are in S'. Then by the Gershgorin circle theorem, all eigenvalues of $\mathbf{M}_{S'}^{U'}$ are bounded from above by $1/2 + v\epsilon$. ◀

4.6 Proof of Theorem 5

▶ **Theorem 5.** *There exists a classical oracle $\mathcal{O}$ such that* $\mathsf{QCMA}^{\mathcal{O}} \neq \mathsf{QMA}^{\mathcal{O}}$ *if and only if* $\mathsf{OI\text{-}QCMA} \neq \mathsf{OI\text{-}QMA}$

Proof. In one direction, assume a classical oracle $\mathcal{O}$ such that $\mathsf{QCMA}^{\mathcal{O}} \neq \mathsf{QMA}^{\mathcal{O}}$. Let $\mathsf{L}^{\mathcal{O}}$ be the separating language, and V a verifier for $\mathsf{L}^{\mathcal{O}}$.

We construct a language $\mathsf{OI\text{-}L}$ as follows. Let $Q(n)$ be a (polynomial) upper bound on the length of queries that V makes to $\mathcal{O}$ when given an instance x of length n. Let $\mathcal{O}_n$ be the portion of $\mathcal{O}$ corresponding to queries of length at most $Q(n)$. Then $|\mathcal{O}_n| \leq 2^{n^{\Theta(1)}}$.

Let $\mathcal{U}_n$ consist of strings of the form $(x, \mathcal{O}_n)$ where x has size n, and let $\mathsf{OI\text{-}L}$ be the set of $(x, \mathcal{O}_n)$ where $x \in \mathsf{L}^{\mathcal{O}}$. We can decide membership in $\mathsf{OI\text{-}L}$ as follows: given a witness state $|\psi\rangle$, first recover x by making n queries to $(x, \mathcal{O}_n)$. Then run $V^{\mathcal{O}_n}(x, |\psi\rangle)$. By our choice of $\mathcal{O}_n$ containing all of $\mathcal{O}$ that gets queried by V, we therefore have that $V^{\mathcal{O}_n}(x, |\psi\rangle)$ is identical to $V^{\mathcal{O}}(x, |\psi\rangle)$. As such, if V correctly decides if $x \in \mathsf{L}^{\mathcal{O}}$, then our verifier correctly decides in $(x, \mathcal{O}_n) \in \mathsf{OI\text{-}L}$. Thus, $\mathsf{OI\text{-}L} \in \mathsf{OI\text{-}QMA}$.

On the other hand, suppose there is a $\mathsf{OI\text{-}QCMA}$ verifier V_* that decides $\mathsf{OI\text{-}L}$. We can then readily obtain a QCMA verifier for $\mathsf{L}^{\mathcal{O}}$. On input instance x and witness w, simulate $V_*^{(x,\mathcal{O}_n)}(w)$ by answering queries to x with the bits of x, and queries to $\mathcal{O}_n$ by forwarding the queries to $\mathcal{O}$. If V_* decides membership in $\mathsf{OI\text{-}L}$, this exactly decides if $x \in \mathsf{L}^{\mathcal{O}}$.

We now turn to the other direction in the statement of Theorem 5. Assume that $\mathsf{OI\text{-}QCMA} \neq \mathsf{OI\text{-}QMA}$. Let $\mathcal{U}$ be the universe and $\mathsf{OI\text{-}L} \subseteq \mathcal{U}$ be the separating language, and V the $\mathsf{OI\text{-}QMA}$ verifier for $\mathsf{OI\text{-}L}$.

We construct our oracle $\mathcal{O}$ and associated language $L^{\mathcal{O}}$ as follows. $\mathcal{O}$ will be interpreted as a countably-infinite family of oracles $(\mathcal{X}_{n_i})_{i \in \mathbb{Z}^+}$ for integers $n_i \in \mathbb{Z}^+$. Let $\mathcal{O}_j = (\mathcal{X}_{n_i})_{i \leq j}$. By padding the witness with 0's size appropriately, we can assume that any potential QCMA verifier runs in quadratic time. Let $T_1, T_2, \cdots$ be an enumeration over all oracle-aided quadratic-time quantum algorithms. $\mathcal{O}$ and $\mathsf{L}^{\mathcal{O}}$ will be constructed by constructing $\mathcal{X}_{n_i}$ for $i = 1, 2, \cdots$ as follows: Consider the $\mathsf{OI\text{-}QCMA}$ verifier $V_i^{\mathcal{X}}(w)$ which has $\mathcal{O}_{i-1}$ hard-coded, and runs $T_i^{\mathcal{O}_{i-1},\mathcal{X}}(w)$. Since $\mathcal{O}_{i-1}$ is constant-sized, $V_i^{\mathcal{X}}(w)$ runs in quadratic time (though with a large constant overhead coming from $\mathcal{O}_{i-1}$). Let n_i be an integer and $\mathcal{X}_{n_i} \in \mathcal{U}_{n_i}$ be an instance such that both:

- V_i incorrectly decides $\mathcal{X}_{n_i}$ given classical witnesses/inputs. That is, either $\mathcal{X}_{n_i} \in \mathsf{OI\text{-}L}$ and $V_i^{\mathcal{X}_{n_i}}(w)$ rejects for all w, or $\mathcal{X}_{n_i} \notin \mathsf{OI\text{-}L}$ and there exists a w such that $V_i^{\mathcal{X}_{n_i}}(w)$ accepts.
- n_i is large enough so that the inputs to the function $\mathcal{X}_{n_i}$ are longer than the running time of $T_j^{\mathcal{O}_j}$ on inputs of length n_j for all $j < i$, meaning $T_j^{\mathcal{O}_j}$, and hence V_j, on inputs of length $n_j, j < i$ never query any input that is an input to $\mathcal{X}_{n_i}$.

Such an $\mathcal{X}_{n_i}$ is guaranteed to exist: that *some* $n_i, \mathcal{X}_{n_i}$ exist satisfying the first criteria follows immediately from the fact that $\mathsf{OI\text{-}L} \notin \mathsf{OI\text{-}QCMA}$. Suppose that there is no $n_i, \mathcal{X}_{n_i}$ satisfying the second criteria. This means there are only a finite number of $\mathcal{X}$ where V_i fails to correctly decide. But by hard-coding these bad instances along with the correct solutions, we can obtain a new verifier V_i' which correctly decides $\mathsf{OI\text{-}L}$, contradicting that $\mathsf{OI\text{-}L} \notin \mathsf{QCMA}$.

We then let $\mathsf{L}^{\mathcal{O}}$ consist of the strings 0^{n_i} such that $\mathcal{X}_{n_i} \in \mathsf{OI\text{-}L}$. We immediately see that $\mathsf{L}^{\mathcal{O}} \in \mathsf{QMA}^{\mathcal{O}}$: by making appropriate queries to $\mathcal{O}$, we can simulate the $\mathsf{OI\text{-}QMA}$ verifier $V^{\mathcal{X}_{n_i}}$, thereby deciding membership of 0^{n_i} in $\mathsf{OI\text{-}L}$.

We now show that $\mathsf{L}^{\mathcal{O}} \notin \mathsf{QCMA}^{\mathcal{O}}$. Consider a supposed QCMA verifier V_*. This corresponds to some T_i according to our enumeration. Then we argue that V_* incorrectly decides membership for 0^{n_i}. Indeed, we know that $T_i^{\mathcal{O}}$ in instance 0^{n_i} never queries on $\mathcal{X}_{n_j}$ for $j > i$, by our choice of n_j. Hence, it can be simulated as $T_i^{\mathcal{O}_i}$, or equivalently $T_i^{\mathcal{O}_{i-1},\mathcal{X}_{n_i}}$. Thus, V_* corresponds exactly to the verifier V_i. But we know that V_i incorrectly decides membership for $\mathcal{X}_{n_i}$. Hence, V_* is not a valid QCMA verifier. ◀

Formulations and Constructions of Remote State Preparation with Verifiability, with Applications

Jiayu Zhang ✉
Zhongguancun Laboratory, Beijing, China

Abstract

Remote state preparation with verifiability (RSPV) is an important quantum cryptographic primitive [20, 41]. In this primitive, a client would like to prepare a quantum state (sampled or chosen from a state family) on the server side, such that ideally the client knows its full description, while the server holds and only holds the state itself. In this work we make several contributions on its formulations, constructions and applications. In more detail:

- We first work on the definitions and abstract properties of the RSPV problem. We select and compare different variants of definitions [8, 20, 41, 19], and study their basic properties (like composability and amplification).
- We also study a closely related question of how to certify the server's operations (instead of solely the states). We introduce a new notion named *remote operator application with verifiability* (ROAV). We compare this notion with related existing definitions [38, 28, 24, 29, 31], study its abstract properties and leave its concrete constructions for further works.
- Building on the abstract properties and existing results [11], we construct a series of new RSPV protocols. Our constructions not only simplify existing results [20] but also cover new state families, for example, states in the form of $\frac{1}{\sqrt{2}}(|0\rangle |x_0\rangle + |1\rangle |x_1\rangle)$. All these constructions rely only on the existence of weak NTCF [12, 5], without additional requirements like the adaptive hardcore bit property [10, 5].
- As a further application, we show that the classical verification of quantum computations (CVQC) problem [2, 27] could be constructed from assumptions on group actions [4]. This is achieved by combining our results on RSPV with group-action-based instantiation of weak NTCF [5], and then with the quantum-gadget-assisted quantum verification protocol [17].

1 Introduction

1.1 Background

Development of quantum computers [6, 42, 9] leads to demands of various quantum cryptographic protocols. In a typical setting, there are a client and a remote quantum server. The client would like to achieve some quantum tasks, but it does not trust the server; thus the client would like to make use of cryptography to achieve its goal. Famous examples include quantum computation verification [27, 41], multiparty quantum computations [7], etc. In this work, we are interested in a basic and very important primitive called *remote state preparation* (RSP) [8], which we introduce below.

1.1.1 Remote state preparation: an overview

In the RSP problem, ideally, the client would like to prepare a quantum state (sampled or chosen from a state family) on the server side; thus in the end the client knows the description of the state, while the server simply holds the state. The trivial solution is to simply send the quantum state through a quantum channel. RSP asks: how could we achieve this task using cheaper resources (for example, only classical communication), possibly under computational assumptions?

Studies of RSP have a long history [32, 8]. One setting of RSP is the fully honest setting [8]. In this work, we are interested in the cryptographic setting where the server could be malicious. Then a formulation of RSP should at least have a correctness requirement and a security requirement.

The natural correctness requirement for RSP says that when the server is honest, the server gets the state while the client gets the state description. For security, there are different security notions, including blindness (or privacy, secrecy) and verifiability (or soundness) [15, 20, 40]. In this paper we focus on RSP with verifiability (RSPV). In RSPV, intuitively, the client is able to verify that in the case of passing (or called acceptance, non-aborting) the server (approximately) really gets the state, as if it is sent through a quantum channel. A malicious server who attempts to get other information by deviating from the protocol would be caught cheating by the client.

As a natural quantum task, the RSPV problem is interesting on its own. What's more, it has become an important building block in many other quantum cryptographic protocols. For example, [20] first constructs a classical channel cryptography-based RSPV and uses it to achieve classical verification of quantum computations; [19] explores more applications of RSPV; [41] takes the RSPV approach to achieve classical verification of quantum computations with linear total time complexity. Many quantum cryptographic protocols rely on the quantum channel and quantum communication, and an RSPV protocol could serve as a compiler: it allows us to replace these quantum communication steps by other cheaper resources, like the classical communication.

On the one hand, there have been many important and impressive results in this direction; on the other hand, there are also various limitations or subtleties in existing works, including formulations and constructions. Below we discuss existing works in more detail and motivate our results.

1.2 Existing Works and Motivating Questions

1.2.1 Formulations and abstract properties of RSPV

We first note that there are many variants of definitions for RSPV. For example, there are two subtlely different types of security notions, the *rigidity-based* (or isometry-based) soundness [15, 19] and *simulation-based* soundness [8, 20, 41]. Existing works do not seem to care about the differences; we note that these differences could have impact on the abstract properties of the definitions and could affect their well-behaveness. For example, we would like RSPV to have sequential composability between independent instances: if the client and the server execute an RSPV protocol for a state family $\mathcal{F}_1$, and then execute an RSPV protocol for a state family $\mathcal{F}_2$, we would like the overall protocol to be automatically an RSPV for $\mathcal{F}_1 \otimes \mathcal{F}_2$. If such a sequential composability property holds, protocols for tensor products of states could be reduced to protocols for each simple state family.

In this background, we argue that:

It's helpful to compare variants of definitions and formalize basic abstract properties.

We would like to have a more well-behaved framework for RSPV, which will lay a solid foundation for concrete constructions.

1.2.2 Definitions of the primitive for certifying the server's operations

RSPV talks about the certification of server-side *states*. A closely related question is: how could the client certify the server-side *operations*?

To address this problem, existing works raise the notion of self-testing [38, 33, 28]. One famous scenario of self-testing is in non-local games [24, 35]. In this scenario, the verifier sends questions to two spatially-separated but entangled quantum provers (or called servers). The verifier's questions and passing conditions are specially designed so that the provers have to perform specific operations to pass. This provides a way to constrain the provers' operations through only classical interactions and spatial separation, which has become a fundamental technique in the study of non-local games.

Recently a series of works [29, 18, 11, 31] study the single-server cryptographic analog of the non-local game self-testing. [29] studies the cryptographic analog of the CHSH game, where the server needs to prepare the Bell states and perform measurements on two of its registers. [30, 18] further extend it to three-qubit and N-qubit; [25, 31] make use of QFHE [26] to formulate and address the problem, where the FHE-encrypted part takes the role of one prover and the unencrypted part takes the role of the other prover.

What's common in these existing works is that they are defining the single-server cryptographic analog of the non-local game self-testing to be a protocol where the single server is playing the roles of *both* of the two provers. In this work we are interested in another viewpoint, which is:

How could we define a single-server cryptographic analog of the non-local game self-testing, where the single server is playing the role of one *of the two provers?*

1.2.3 Existing RSPV constructions

Maybe the most natural question in the direction of RSPV is:

For what state families could we achieve RSPV?

Let's quickly review what state families have been achieved in existing works. [20] achieves RSPV for $\{|+_\theta\rangle := \frac{1}{\sqrt{2}}(|0\rangle + e^{\mathrm{i}\theta\pi/4}|1\rangle), \theta \in \{0, 1, 2 \cdots 7\}\}$; independently [15] gives a candidate RSPV construction for this state family and conjectures its security. [20] achieves RSPV for tensor products of BB84 states: $\{|0\rangle, |1\rangle, |+\rangle, |-\rangle\}^{\otimes n}$. [41] achieves RSPV for tensor products of $|+_\theta\rangle$ states. [11] achieves RSPV for BB84 states.

For a broader viewpoint let's also review some famous self-testing protocols. [29] achieves cryptographic self-testing for Bell states and the corresponding X/Z measurements. [30] achieves self-testing for a 3-qubit magic state and the corresponding measurements. [18] achieves self-testing for multiple Bell pairs and measurements. [31] achieves self-testing for "all-X" and "all-Z" operations.

As a summary, one significant limitations of existing works is that they could only handle simple tensor product states and operators. We consider this situation very undesirable since ideally we want a protocol that is sufficiently powerful to cover all the computationally-efficient state families. The lack of concrete protocols also restricts the applications of RSPV as a protocol compiler: suppose that we have a quantum cryptographic protocol that starts with sending states in (for example) $\{\frac{1}{\sqrt{2}}(|0\rangle |x_0\rangle + |1\rangle |x_1\rangle), x_0, x_1 \in \{0,1\}^n\}$, it's not clear how to use existing RSPV protocols to compile this quantum communication step to the classical communication. (Note that although there are mature techniques for creating this type of states with some other security notions [26, 10, 27], it's not known how to construct RSPV for it.)

Besides the existency problem, it's also desirable if we could weaken the assumptions needed or simplify existing results.

1.2.4 Classical verification of quantum computations and its assumption

We will apply our results on RSPV to the classical verification of quantum computations (CVQC) problem. In this problem a classical client would like to delegate the evaluation of a BQP circuit C to a quantum server, but it does not trust the server; thus it wants to make use of a protocol to verify the results. The first and perhaps the most famous construction is given by Mahadev [27]. Building on Mahadev's work and related results [26, 10, 27], a series of new CVQC protocols are constructed [3, 20, 14, 41, 31, 5].

However, one undesirable situation is that all the existing constructions are either based on LWE [34], or based on the random oracle heuristic, or based on some new conjecture on the reduction between security notions. In more detail:

- Most existing works [27, 14, 20] make use of NTCF with the "adaptive hardcore bit property" (or some stronger variants). The only known instantiation of this primitive from standard assumption is based on LWE.
- [5] gives an instantiation of NTCF with a weaker variant of the adaptive hardcore bit property using cryptographic group actions. However, to achieve the adaptive hardcore bit property it relies on an unproven conjecture on the reduction between these two notions. Alternatively one could make use of the random oracle to construct CVQC without the adaptive hardcore bit property [12, 41] but the instantiation of the random oracle is heuristic.
- If we only make use of NTCF without the adaptive hardcore bit property, we could do RSPV for BB84 states [11], but BB84 states are not known to be sufficient for constructing CVQC.
- [31] makes use of a quantum FHE-based approach to construct CVQC. However instantiations of quantum FHE rely on (variants of) NTCF and the classical FHE [26, 22], which still rely on the LWE assumption.

As mentioned above, a type of cryptographic assumption that is different from LWE is the cryptographic group actions, for example, supersingular isogeny [4, 13]. In this background, we ask:

Could we construct CVQC from cryptographic group actions?

1.3 Our Contributions

In this work we address or make progress to the questions above. Below we give an overview of our contributions; we refer to the full version for details.

1.3.1 Definitions and Abstract Properties of RSPV

We first work on the definitions and abstract properties of RSPV.

1. We first formulate and review the hierarchy of notions for formalizing RSPV. This includes the notions of registers, cq-states, protocols, paradigms of security definitions, etc.
2. We then formalize the notion of RSPV. We formulate the soundness as a simulation-based definition and compare this definition with several other variants (like the rigidity-based soundness, which is also popular).
3. We then study the abstract properties of RSPV including the sequential composability and amplification. This allows us to reduce the constructions of RSPV to primitives that are relatively easier to construct.

In summary, we clarify subtleties and build a well-behaved framework for RSPV, which enables us to build larger protocols from smaller or easier-to-construct components. In later part of this work we will build concrete RSPV constructions under this framework.

1.3.2 Our Cryptographic Analog of Self-testing: Remote Operator Application with Verifiability (ROAV)

We then introduce a new notion called remote operator application with verifiability (ROAV), as our answer to the question in Section 1.2.2.

Let's first review how the self-testing-based protocols typically work in the non-local game setting. Suppose the verifier would like to make use of the prover 1 and prover 2 to achieve some tasks – - for example, testing the ground state energy of a local Hamiltonian. One typical technique is to design two subprotocols π_{test} and π_{comp}. Subprotocol π_{test} is a non-local game with a self-testing property, while subprotocol π_{comp} is to test the Hamiltonian. Furthermore, the games are designed specially so that the prover 2, without communicating with the prover 1, could not decide which subprotocol the verifier is currently performing. Then the setting, the overall protocol and the security proof roughly go as follows:

- (Setting) The prover 1 and prover 2 initially hold EPR states. They receive questions from the verifier, make the corresponding measurements and send back the results.
- (Overall protocol) The verifier randomly chooses to execute either π_{test} or π_{comp} (without telling the provers the choices).
- (Security proof)
  1. To pass the overall protocol the provers have to pass π_{test} with high probability. By the property of π_{test} the operations of the prover 2 has to be close to the honest behavior.
  2. By the design of π_{test} and π_{comp}, and the fact that the prover 2 is close to the honest behavior in π_{test}, we could argue that the prover 2 is also close to the honest behavior in π_{comp}.
  3. Since we already know the prover 2 is close to be honest in π_{comp}, it's typically easy to analyze the execution of π_{comp} directly and show that it achieves the task.

Recall that we would like to define a single-server cryptographic analog of the non-local game self-testing where the single server plays the role of one of the two provers. So what does the "non-local game self-testing" mean here? Our idea is to consider both the step 1 and step 2 in the security proof template above as the "non-local game self-testing". Then let's focus on the prover 2 (as "one of the two provers" in our question) and assume the prover 1 is honest. Then we could do the following simplifications in the non-local game self-testing:

- In π_{test} we could assume the prover 1 first measures its states following the verifier's question; as a result, the joint state of the prover 1 and prover 2 becomes a cq-state where the verifer knows its description. Then the verifier also gets the measurement results from the prover 1's answer; so in the end we only need to consider the joint cq-state between the verifier and the prover 2.
- For π_{comp}, since we do not consider the step 3 above as a part of the self-testing notion, the question to the prover 1 in π_{comp} could be left undetermined. Then π_{comp} is not designed for any specific task any more, which in turn makes the self-testing a general notion.

Now the setting and the first two steps in the security proof could be updated as follows:

- (Setting) In π_{test} the client and the prover 2 initially hold a cq-state, where the verifier holds the classical part and the prover 2 holds the quantum part. In π_{comp} the prover 1 and prover 2 hold EPR states and the verifier does not have access to the prover 1's information.
- (Security proof) To make the first two steps in the security proof template above go through, we should at least require that:
  "The prover could pass in π_{test}" should imply that the prover's operation in π_{comp} is close to the desired one.

This gives us the basic intuition for formalizing our single-server cryptographic analog of the non-local game self-testing. Below we introduce the notion, which we call *reomte operator application with verifiability* (ROAV).

An ROAV for a POVM $(\mathcal{E}_1, \mathcal{E}_2, \cdots, \mathcal{E}_D)$ is defined as a tuple $(\rho_{\text{test}}, \pi_{\text{test}}, \pi_{\text{comp}})$ where:

- The setting contains the following registers. $\boldsymbol{D}$ is a client-side classical register, $\boldsymbol{Q}$ is a server-side quantum register, $\boldsymbol{P}$ is a quantum register in the environment with the same dimension with $\boldsymbol{Q}$.
- ρ_{test} is a cq-state on registers $\boldsymbol{D}$ and $\boldsymbol{Q}$.
- π_{test} is the protocol for the test mode. In the test mode ρ_{test} is used as the input state and $\boldsymbol{P}$ is empty.
- π_{comp} is the protocol for the computation mode (where the operations are applied). Denote the state of maximal entanglement (multiple EPR pairs) between $\boldsymbol{P}$ and $\boldsymbol{Q}$ as Φ. In the comp mode Φ is used as the input state and $\boldsymbol{D}$ is empty. Note that the execution of π_{comp} does not touch $\boldsymbol{P}$.

The soundness of ROAV is defined roughly as follows: for any adversary Adv, at least one of the following is true:

- In the test mode (π_{test} is executed with input state ρ_{test} against adversary Adv), the adversary gets caught cheating with significant probability;
- In the comp mode (π_{comp} is executed with input state Φ against adversary Adv), the final state gives the outcome of the following operations:
  The measurement described by $(\mathcal{E}_1, \mathcal{E}_2, \cdots, \mathcal{E}_D)$ is applied on $\boldsymbol{Q}$, and the client gets the measurement result $i \in [D]$; the corresponding output state (on register $\boldsymbol{P}$ and $\boldsymbol{Q}$) is $(\mathbb{I} \otimes \mathcal{E}_i)(\Phi)$.

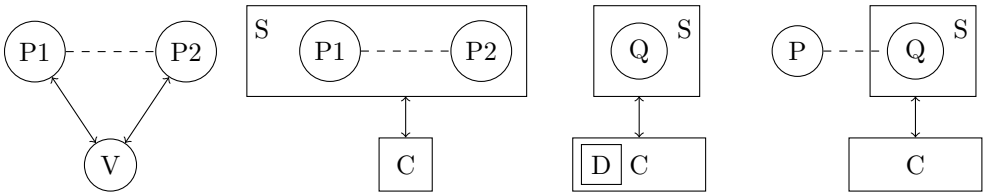

Figure 1 From the left to the right: the non-local game self-testing, previous definitions of its single party analog, and our definition (π_{test} and π_{comp} for the last two diagrams). Here $\leftrightarrow$ stands for interactions, and --- stands for quantum entanglements; C stands for the client and S stands for the server.

We finally note that the definition of ROAV also use the simulation-based security definition paradigm, like RSPV.

ROAV as the operator analog of RSPV

In the previous discussion we focus on the analog between our ROAV primitive and the non-local game self-testing. There is also another intuition that is analogous to the intuition of RSPV (see Section 1.1.1): In the ROAV problem the server is provided an undetermined input state, and the client would like to apply an operation (from an operator family) on it; in the end the client knows the description of the operation, while the server simply holds the output of the operation.

We also note that such a state-operator analog also appears in other directions like [36, 23].

Abstract constructions using ROAV

After giving the abstract definitions, we show several potential applications of our notions. We first show that ROAV is potentially a useful tool for constructing RSPV protocols for more general state families. Then we construct a Hamiltonian ground energy testing protocol based on specific RSPV and ROAV. Our construction shares similarities to Grilo's Hamiltonian verification protocol in the 2-party setting [21]. We note that these constructions are abstract constructions and concrete constructions for nontrivial ROAV remain open.

1.3.3 New RSPV Constructions

Now we introduce a series of new RSPV constructions. Our results not only give arguably simplified constructions for existing results but also cover new state families.

Overall approach

Instead of constructing each protocol directly from cryptographic assumptions, we study how different protocols could be *reduced* to existing ones in a black-box manner. Following this approach, we build a series of RSPV protocols step by step from RSPV for BB84 states $\{|0\rangle, |1\rangle, |+\rangle, |-\rangle\}$. Furthermore, these steps could be classified into two classes:

- In one class of steps, the reduction either has a simple intuition or is an application of the abstract properties in our framework (see Section 1.3.1) (in more detail, sequential composability and amplification).

- In the other class of steps, we could work on an "information-theoretic core" (IT-core) where the analysis is purely quantum information theoretic, and there is no appearance of computational notions like computational indistinguishability.

Our reductions are illustrated in Figure 2. We elaborate details in Section 2. As an example, let's describe the first step of our reductions. We assume an RSPV for BB84 states; then the client would like to prepare a sequence of such states in which there is only one $|+\rangle$ state and no $|-\rangle$ state. Equivalently, this could be written as $\frac{1}{\sqrt{2}}(|x_0\rangle + |x_1\rangle)$ where the hamming weight of $x_0 \oplus x_1$ is exactly 1. What the client needs to do is to repeat the RSPV-for-BB84 protocol for many rounds and tell the server which states it wants to keep. This could be easily understood as a repeat-and-pick process.

We argue that our approach is cleaner and easier to understand compared to the original construction in [20] at least in the following sense: In [20] the computational indistinguishability arguments and quantum information theoretic arguments are mixed together, which could lead to complicated details [1]. By separating two types of steps in the reductions explicitly, each step has a relatively simple intuition and there is much less room for complicated details.

Main results

Among these reductions, we consider the following two results particularly interesting.

▶ **Theorem 1.** *Assuming the existence of RSPV for BB84 states, there exists an RSPV for state family* $\{\frac{1}{\sqrt{2}}(|0\rangle |x_0\rangle + |1\rangle |x_1\rangle), x_0, x_1 \in \{0,1\}^n\}$.

This is an RSPV protocol for a new state family. Note that although there are plenty of works [10, 12] that allow the client to prepare these states with some other types of security (like claw-freeness, etc), as far as we know, this is the first time that an RSPV for it is constructed.

We also recover the results of RSPV for 8-basis states [20].

▶ **Theorem 2.** *Assuming the existence of RSPV for BB84 states, there exists an RSPV for state family* $\{|+_\theta\rangle := \frac{1}{\sqrt{2}}(|0\rangle + e^{\mathrm{i}\pi\theta/4}|1\rangle), \theta \in \{0,1,2\cdots 7\}\}$.

Instantiation of RSPV for BB84

We note that we still need to instantiate the RSPV for BB84 part to get a concrete protocol. Luckily the RSPV for BB84 has been studied relatively thoroughly: there are multiple constructions [19, 11] and we have a better understanding on the assumptions needed [11]. After instantiating the BB84 part by [11], we get RSPV constructions for these state families from weak NTCF, without requiring the adaptive hardcore bit property (elaborated below).

1.3.4 Application: CVQC From Cryptographic Group Actions

Now we apply our results to the classical verification of quantum computations (CVQC) problem.

As the preparation, we give a more detailed review on the variants of NTCF, and their relations to RSPV. We refer to Section 1.2.4 for a CVQC-centric background.

More backgrounds

Noisy trapdoor claw-free functions (NTCF) is a popular and powerful primitive in quantum cryptographic tasks like CVQC and RSPV. Informally, this primitive is defined to be a function family that satisfies the following requirements. Below we use f to denote a function sampled from this function family.

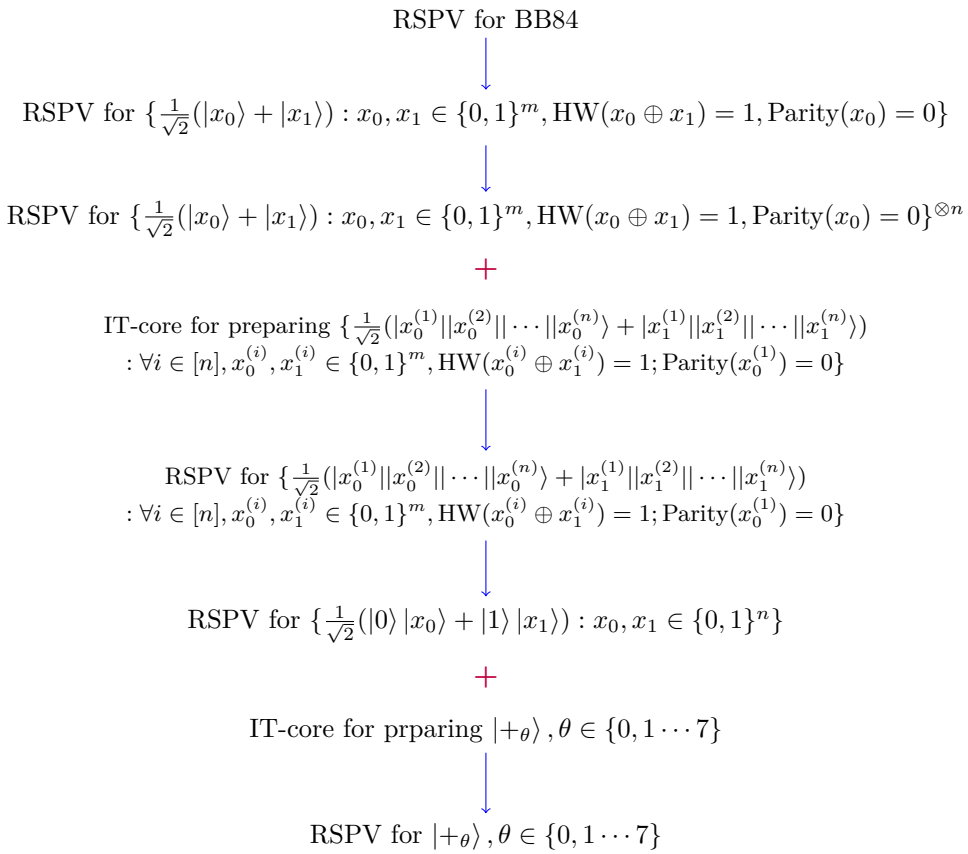

Figure 2 The reduction diagram. Here $\rightarrow$ means this step either has a simple intuition or is from the framework that we describe in Section 1.3.1; $+$ means the analysis of the IT-core below it is purely quantum information theoretic, and the RSPV above it is used to compile the IT-core to a full cryptographic protocol. HW is the hamming weight, Parity is the total parity.

- Trapdoor: this means that all the parties could evaluate f, but only the client, who holds the "trapdoor" information, could invert f.
- Noisy 2-to-1: the un-noisy 2-to-1 means that for each y in the range there exist exactly two preimages x_0, x_1 such that $f(x_0) = f(x_1) = y$. "Noisy" means that the evaluation of the function could be randomized, which makes the instantiation of the primitive easier. Below when we describe other properties we use the un-noisy version to simplify the description.
- Claw-free: the adversary could not efficiently find x_0, x_1 such that $f(x_0) = f(x_1)$.

In practice, we often use some variants of NTCF instead of the standard requirements above, to either make it more powerful or make the instantiation easier. Popular variants or additional requirements of NTCF include:

- Adaptive hardcore bit: the adversary could not find (d, y) with probability better than $\frac{1}{2}$ (the probability of random guessing) such that $d \cdot x_0 \equiv d \cdot x_1 \mod 2 \wedge d \neq 0$, where x_0, x_1 are two preimages of y.
  The RSPV for BB84 states is known to exist without this property [11], but Mahadev's constructions for CVQC [27] and RSPV for $|+_\theta\rangle$ [20] require this property.
- Extended function family: there is another function family g that is injective (instead of 2-to-1) and indistinguishable to f. Existing constructions for CVQC and RSPV for $|+_\theta\rangle$ [27, 20] also require this property.

- Inverse-polynomial correctness error (or weak correctness): this means that the 2-to-1 property is allowed to hold up to an inverse-polynomial error. This is used in [5] to define a primitive called weak TCF.

In our work we build our protocols on weak NTCF, that is, we allow inverse-polynomial correctness error and do not require additional properties like the adaptive hardcore bit property. In other words, we only use a relatively weak assumption from different variants of NTCF/TCF. This assumption could be instantiated from either LWE [10] or assumptions on group actions [5].

Applications of our results on CVQC

We first note that, [11] could be adapted easily to weak NTCF:

▶ **Theorem 3** (By [11]). *There exists an RSPV for BB84 assuming weak NTCF.*

As discussed in Section 1.3.3, this gives us a series of RSPV protocols from weak NTCF.

Then by [17], if the client samples and sends a series of $|+_\theta\rangle$ states to the server, it could do quantum computation verification using these states. Combining Fact 3, Theorem 2 and [17], we get:

▶ **Theorem 4.** *Assuming the existence of weak NTCF, there exists a classical verification of quantum computation protocol.*

Finally we recall the results in [5]:

▶ **Theorem 5** ([5]). *Under certain assumptions on cryptographic group actions, there exists a family of weak TCF.*

Thus we have:

▶ **Theorem 6.** *Under certain assumptions on cryptographic group actions, there exists a CVQC protocol.*

As an additional note, the work in [5] is largely on how to deal with the adaptive hardcore bit property; the fact that we do not need the adaptive hardcore bit may help us simplify the analysis or even construction in [5].

1.4 More Related Works

Previous versions

Compare to the previous versions, the abstract framework parts (described in Section 1.3.1, 1.3.2) of this work are sigfinicantly updated, and the concrete constructions part (described in Section 1.3.3, 1.3.4) are completely new.

RSP with other types of security

There are many works about remote state preparation but with other types of security (instead of RSPV). These works may or may not use the name "remote state preparation". As examples, [22] gives an RSP for the gadgets in [16]; [37] gives an RSP for the quantum money states. When we only consider the honest behavior, RSP is a very general notion.

Other state-operation analog

There are also several notions in quantum cryptography and complexity theory that have a state-operation analog. As examples, [36] studies the complexity of interactive synthesis of states and unitaries. [23] studies pseudorandom states and unitaries. In a sense, the relation of states and unitaries in these works is a "state-operation analog", as the RSPV and ROAV in our work.

1.5 Open Questions and Summary

Our work gives rise to a series of open questions; we consider the following two particularly interesting.

- One obvious open question coming out of this work is to give a construction for ROAV. Our work focuses on its definitions and applications in an abstract sense; an explicit construction of ROAV would allow us to instantiate these applications.
- For RSPV, although our results give new constructions for new state families, this is still far away from a general solution. Ideally we would like to have an RSPV for each computationally efficient state family. Whether this is possible and how to achieve it remain open.

In summary, two major part of this work is the framework and the constructions of RSPV protocols. By formulating and choosing notions and studying their abstract properties, we build an abstract framework for RSPV that is sufficiently well-behaved, which enables us to build more advanced, complicated protocols from more elementary, easy-to-construct components. Building on this framework, we construct a series of new RSPV protocols that not only (in a sense) simplify existing results but also cover new state families. Then we combine our results with existing works to show that the CVQC problem could be constructed from assumptions on cryptographic group actions. We also raised a new notion for certifying the server's operations. We consider our results as a solid progress in the understanding of RSPV; hopefully this will lay the foundation for further works.

2 Overview for Concrete Constructions of RSPV Protocols

We refer to the full version for the details of our contributions. In this section we elaborate our concrete RSPV constructions. As a preparation, we explain several basic notions or theorems in our framework.

- Sequential repetition: it roughly means that if protocol π_1 is an RSPV for state family $\mathcal{F}_1$, protocol π_2 is an RSPV for state family $\mathcal{F}_2$, then the sequential composition of π_1 and π_2 is an RSPV for state family $\mathcal{F}_1 \otimes \mathcal{F}_2$. This implies that, given an RSPV for some state family, its n-fold sequential composition is an RSPV for the n-fold tensor product of the state family.
- RSPV as a protocol compiler: it roughly means that, given a protocol starting with "the client prepares and sends some quantum states", we could replace this step with an RSPV protocol for these states, and the security property of the overall protocol will be preserved (approximately).
- PreRSPV and its amplification to RSPV:
  The preRSPV is defined as a pair of protocols $(\pi_{\text{test}}, \pi_{\text{comp}})$ which could be seen as a generalization of RSPV; it contains a test-mode protocol and a comp-mode protocol. The soundness is defined intuitively as follows: if π_{test} running against an adversary Adv could pass with high probability (that is, close to 1), then π_{comp} running against the same adversary Adv will satisfy the RSPV soundness.

Then a preRSPV defined above could be amplified to an RSPV by a *cut-and-choose* procedure: for each round, the client randomly chooses to execute either π_{test} or π_{comp} with some probabilities (without telling the server the choices). If the server could keep passing in many rounds, then for most of the π_{comp} rounds the target state is prepared as expected.

- PreRSPV-with-score and its amplification to RSPV:
  We also formalize a variant of preRSPV where the client counts *scores* for the server besides the pass/fail flag. The set-up is as follows: in the end of the protocol the client will record a win/lose decision in a ***score*** register, and the honest server could achieve the optimal winning probability. We use OPT to denote the optimal winning probability. (Note that when OPT = 1 the notion downgrades to the original preRSPV notion without the score.) The soundness is roughly defined as follows: if π_{test} running against an adversary Adv could win with probability close to OPT (and also pass with probability close to 1), then π_{comp} running against the same adversary Adv will satisfy the RSPV soundness.
  In the amplification procedure, the client needs to count the number of winning rounds and see whether the total score is close to the expected value of an honest execution.

Below we elaborate each step in the reduction diagram (Figure 2).

2.1 From BB84 to OneBlock and OneBlockTensor

We first build an RSPV for state family

$$\{\frac{1}{\sqrt{2}}(|x_0\rangle + |x_1\rangle : x_0, x_1 \in \{0,1\}^m, \text{HW}(x_0 \oplus x_1) = 1, \text{Parity}(x_0) = 0)\}$$

from the RSPV for BB84 states; this protocol is called OneBlock. The intuition is as described in Section 1.3.3: notice that states in this family could be written as sequence of BB84 states where there is only one $|+\rangle$ state and no $|-\rangle$ state; thus the client only needs to do a repeat-and-pick on RSPV-for-BB84 protocol.

Then we build the RSPV for

$$\{\frac{1}{\sqrt{2}}(|x_0\rangle + |x_1\rangle) : x_0, x_1 \in \{0,1\}^m, \text{HW}(x_0 \oplus x_1) = 1, \text{Parity}(x_0) = 0\}^{\otimes n} \tag{1}$$

which is the tensor products of the state family in OneBlock; this protocol is called OneBlockTensor. This is by taking the sequential repetition of the protocol OneBlock.

2.2 Construction of MultiBlock

Then we go from OneBlockTensor to construct an RSPV for the following state family:

$$\{\frac{1}{\sqrt{2}}(|x_0^{(1)}||x_0^{(2)}||\cdots||x_0^{(n)}\rangle + |x_1^{(1)}||x_1^{(2)}||\cdots||x_1^{(n)}\rangle) :$$

$$\forall i \in [n], x_0^{(i)}, x_1^{(i)} \in \{0,1\}^m, \text{HW}(x_0^{(i)} \oplus x_1^{(i)}) = 1; \text{Parity}(x_0^{(1)}) = 0\} \tag{2}$$

Roughly speaking, the client forces the server to measure the state in (1) to get (2). To see this clearly, we could first consider two blocks as an example. Suppose the server initially holds the state

$$(|x_0^{(1)}\rangle + |x_1^{(1)}\rangle) \otimes (|x_0^{(2)}\rangle + |x_1^{(2)}\rangle), \quad \forall b, i, \text{Parity}(x_b^{(i)}) = b$$

The client asks the server to measure the total parity of the strings it holds. Then if the server performs the measurement honestly, the state will collapse to:

$$\text{outcome} = 0 : |x_0^{(1)}||x_0^{(2)}\rangle + |x_1^{(1)}||x_1^{(2)}\rangle \tag{3}$$

$$\text{outcome} = 1 : |x_0^{(1)}||x_1^{(2)}\rangle + |x_1^{(1)}||x_0^{(2)}\rangle \tag{4}$$

The client could update the keys (that is, the state description) using the reported outcome and the original keys. If the client does the same for each $i = 2, 3 \cdots n$, in the honest setting the state in (1) will collapse to (2).

So what if the server cheats? One possible attack is that the server may not do the measurements and report the total parity honestly. To detect this attack, we will first construct a preRSPV (MultiBlockTest, MultiBlockComp) and use MultiBlockTest to test the server's behavior. In MultiBlockTest after getting the total parities the client will ask the server to measure all the states on the computational basis and report the measurement results; the client could check the results with its keys and see whether the results is consistent with the original keys and the total parities. As a concrete example, in (3) if the client asks the server to measure all the states, the measurement results should be either $x_0^{(1)}||x_0^{(2)}$ or $x_1^{(1)}||x_1^{(2)}$, otherwise the server is caught cheating.

After we get a preRSPV, we could amplify it to get an RSPV for (2).

Let's briefly discuss how the security proof goes through. One desirable property of the security proof of this step is that, we only need to analyze a "information-theoretic core": if we assume the initial state is (1), the analysis of the preRSPV will be purely information-theoretic, which means, the soundness holds against unbounded provers and we do not need to work on computational notions in the security analysis. After we prove the soundness of this information-theoretic part, we could prove the soundness of the overall protocol by calling the abstract properties in our framework.

2.3 Construction of KP

Then we go from MultiBlock to construct an RSPV for state family

$$\{\frac{1}{\sqrt{2}}(|0\rangle |x_0\rangle + |1\rangle |x_1\rangle) : x_0, x_1 \in \{0,1\}^n\} \tag{5}$$

This is by first calling MultiBlock to prepare a sufficiently big state in the form of (2), and then letting the client reveals suitable information to allow the server to transform (2) to (5). Let's explain the intuition.

We first note that by calculating the parity of the first block, (2) could be transformed to

$$\frac{1}{\sqrt{2}}(|0\rangle |x_0^{(1)}||x_0^{(2)}||\cdots\rangle + |1\rangle |x_1^{(1)}||x_1^{(2)}||\cdots\rangle) : \forall i, x_0^{(i)}, x_1^{(i)} \in \{0,1\}^m, \mathrm{HW}(x_0^{(i)} \oplus x_1^{(i)}) = 1 \tag{6}$$

The difference to (5) is that these keys are not sampled uniformly randomly. Note that in (6) we omit some conditions on the keys and focus on the most significant one.

Then the client will reveal lots of information about these keys, which allows the server to transform each two blocks in (6) to a pair of uniform random bits. Let's use the first two blocks as an example. The client will reveal $x_0^{(1)}$ and $x_1^{(2)}$. Then by doing xor between them and the corresponding blocks, (6) becomes:

$$\frac{1}{\sqrt{2}}(|0\rangle |0^m||000\cdots 1000\cdots||\cdots\rangle + |1\rangle |000\cdots 1000\cdots||0^m||\cdots\rangle) \tag{7}$$

Now the $000\cdots1000\cdots$ could be seen as a unary encoding of a random number in $[m]$. By choosing m to be power of 2, converting unary encoding to binary encoding and trimming out extra zeros, this state becomes

$$\frac{1}{\sqrt{2}}(|0\rangle|\gamma_0^{(1)}||\cdots\rangle + |1\rangle|\gamma_1^{(1)}||\cdots\rangle) \tag{8}$$

where $\gamma_0, \gamma_1 \in \{0,1\}^{[\log m]}$ and are uniformly random. Doing this for each two blocks in (6) gives (5).

2.4 Construction of QFac (RSPV for $|+_\theta\rangle$)

Now we have an RSPV for states $\frac{1}{\sqrt{2}}(|0\rangle|x_0\rangle + |1\rangle|x_1\rangle)$ with uniformly random x_0, x_1; we are going to construct an RSPV for the state[1]

$$|+_\theta\rangle = \frac{1}{\sqrt{2}}(|0\rangle + e^{\mathrm{i}\pi\theta/4}|1\rangle), \theta \in \{0,1,2\cdots7\}.$$

We first note that existing work [20] also takes a similar approach: the client first instruct the server to prepare the state $|0\rangle|x_0\rangle + |1\rangle|x_1\rangle$, and then transforms it to $|+_\theta\rangle$.

Let's explain the constructions. The overall ideas for the construction are basically from [20] (adapted to the languages of our framework). We will first construct a preRSPV-with-score, as follows: in both the test mode and comp mode the client will instruct the server to prepare $|+_\theta\rangle$ state, then in the test mode the client will instruct the server to measure $|+_\theta\rangle$, and stores a score based on the reported result; in the comp mode $|+_\theta\rangle$ will be kept. Then once we show this protocol is indeed a preRSPV, we could amplify it to an RSPV as given in our framework.

The first step is to allow the honest server to transform $\frac{1}{\sqrt{2}}(|0\rangle|x_0\rangle + |1\rangle|x_1\rangle)$ to $|+_\theta\rangle$. There are multiple ways to do it, for example:

1. The client will first instruct the server to introduce a phase of $e^{\mathrm{i}\pi\theta_{2,3}/4}, \theta_{2,3} \in \{0,1,2,3\}$ where $\theta_{2,3}$ are hidden in the server's view. This could be done by selecting the xor of the first two bits of x_0, x_1 as θ_2, θ_3. Then on the one hand $\theta_{2,3} = 2\theta_2 + \theta_3$ will be completely hidden; on the other hand using the phase-table-like technique in [39, 41] the honest server could introduce a phase of $e^{\mathrm{i}\pi\theta_{2,3}/4}$ to the x_1 branch up to a global phase.
2. The server does a Hadamard measurement on each bit of the x-part and get a measurement result d; this introduces a phase of $e^{\mathrm{i}\pi(d\cdot(x_0+x_1))}$ to the qubits. Then the server sends back d to the client and the client could calculate $\theta_1 = (d\cdot(x_0+x_1)) \mod 2$. The server holds a single qubit in the state $|+_\theta\rangle, \theta = 4\theta_1 + 2\theta_2 + \theta_3$.

Now in the comp mode we are done. In the test mode the client will continue to ask the server to make measurement on a random basis $|+_\varphi\rangle, |+_{\varphi+4}\rangle, \varphi \leftarrow_r \{0,1,2\cdots7\}$. First we could see that when $\theta = \varphi$ the measurement will collapse to $|+_\varphi\rangle$ with probability 1, and when $\theta = \varphi + 4$ the measurement will collapse to $|+_{\varphi+4}\rangle$ with probability 1. Thus the client could record a "win" score if he has seen such an outcome. But solely doing this does not give us a full control on the server's behavior and states; an important idea is that, when φ is close to θ (or $\theta + 4$), the measurement should also collapse to $|+_\varphi\rangle$ (or $|+_{\varphi+4}\rangle$, correspondingly). This gives some probability of losing even for an honest server; however by analyzing the game it's possible to say "if the server wins with probability close to the optimal winning probability, the state before the testing measurement has to be close to the target state up to an isometry", which is still sufficient for amplification.

[1] The protocol name QFac is from [15].

Security proofs, existing works and their limitations, and our approach

So how could the quoted claim just now be proved? Existing works like [20, 15] has already done a lot of works on this part. In [15] the authors introduce a notion called *blind self-testing*. In more detail, let's denote the server-side state by the time that the comp mode is done corresponding to the client-side phase θ as ρ_θ. (In other words, the overall state is $\sum_\theta |\theta\rangle\langle\theta| \otimes \rho_\theta$.) Then the blind self-testing requires that the state $\rho_{\theta_{2,3}} + \rho_{\theta_{2,3}+4}$ is the same for any $\theta_{2,3}$, which is called (information-theoretic) *basis-blindness* (here $\theta_{2,3}$ is the "basis" and the notion means that the basis is completely hidden after randomization of θ_1). [15] shows that if the initial state satisfies the basis blindness property, the claim "high winning probability $\Rightarrow$ close to the target state up to an isometry" holds.

However, the proof of this claim given in [15] does not generalize to the computational analog of basis blindness. [15] does not solve the problem and leave the security of the whole protocol as a conjecture. [20] makes use of computational indistinguishability between states in the form of $\rho_{\theta_{2,3}} + \rho_{\theta_{2,3}+4}$ together with some quantum information theoretic arguments to prove the claim; in their proofs computational indistinguishability and quantum information theoretic arguments are mixed together, which could be complicated to work on and lead to sophisticated details [1].

Our new hammer for getting rid of this problem is the KP protocol, which is an RSPV for $|0\rangle|x_0\rangle + |1\rangle|x_1\rangle$. (Note that in previous works the preparation of $|0\rangle|x_0\rangle + |1\rangle|x_1\rangle$ is not known to satisfy the RSPV soundness in the malicious setting.) By starting from KP, we are able to prove the security in a much nicer way:

1. The "information-theoretic core": in the security proof we could first simply assume the server holds exactly the state $|0\rangle|x_0\rangle + |1\rangle|x_1\rangle$; then we could prove the ρ_θ generated from it has the (information-theoretic) basis blindness property; then the analysis of the testing on $|+_\theta\rangle$ is basically from existing results [20, 15].
2. Once we complete the analysis of this information-theoretic core, we could compile it using results in our framework to an RSPV.

2.5 A Summary

In summary we have achieve each step of the reductions as shown in Figure 2. The construction of OneBlock is by a repeat-and-pick procedure, OneBlockTensor is by the sequential composition, KP is by revealing some information to allow the server to transform the state to some other forms. For constructions of MultiBlock and QFac, we first analyze an "information-theoretic core" where we only need to work on statistical closeness, and compile the IT-core (IT=information-theoretic) to a full protocol by calling existing soundness properties.
