■ Contents

Preface	
<i>Olaf Beyersdorff, Michał Pilipczuk, Elaine Pimentel, and Nguyễn Kim Thăng</i>	0:xi–0:xii
Conference Organization	
.....	0:xiii–0:xvii
List of Authors	
.....	0:xix–0:xxv

Invited Talks

Proof Complexity and Its Relations to SAT Solving	
<i>Albert Atserias</i>	1:1–1:1
A Strongly Polynomial Algorithm for Linear Programs with at Most Two Non-Zero Entries per Row or Column	
<i>Daniel Dadush, Zhuang Khye Koh, Bento Natura, Neil Olver, and László A. Végh</i> .	2:1–2:1
Algebras for Automata: Reasoning with Regularity	
<i>Anupam Das</i>	3:1–3:1
Some Recent Advancements in Monotone Circuit Complexity	
<i>Susanna F. de Rezende</i>	4:1–4:2

Regular Papers

Parameterized Saga of First-Fit and Last-Fit Coloring	
<i>Akanksha Agrawal, Daniel Lokshtanov, Fahad Panolan, Saket Saurabh, and Shaily Verma</i>	5:1–5:21
Twin-Width One	
<i>Jungho Ahn, Hugo Jacob, Noleen Köhler, Christophe Paul, Amadeus Reinald, and Sebastian Wiederrecht</i>	6:1–6:19
Faster Edge Coloring by Partition Sieving	
<i>Shyan Akmal and Tomohiro Koana</i>	7:1–7:18
Tropical Proof Systems: Between R(CP) and Resolution	
<i>Yaroslav Alekseev, Dima Grigoriev, and Edward A. Hirsch</i>	8:1–8:20
Improved Approximation Algorithms for (1,2)-TSP and Max-TSP Using Path Covers in the Semi-Streaming Model	
<i>Sharareh Alipour, Ermiya Farokhnejad, and Tobias Mömke</i>	9:1–9:17
Monotone Weak Distributive Laws over the Lifted Powerset Monad in Categories of Algebras	
<i>Quentin Aristote</i>	10:1–10:20
Generalized Inner Product Estimation with Limited Quantum Communication	
<i>Srinivasan Arunachalam and Louis Schatzki</i>	11:1–11:17

Results on H -Freeness Testing in Graphs of Bounded r -Admissibility <i>Christine Awofeso, Patrick Greaves, Oded Lachish, and Felix Reidl</i>	12:1–12:16
Hyperbolic Random Graphs: Clique Number and Degeneracy with Implications for Colouring <i>Samuel Baguley, Yannic Maus, Janosch Ruff, and George Skretas</i>	13:1–13:20
Multivariate Exploration of Metric Dilation <i>Aritra Banik, Fedor V. Fomin, Petr A. Golovach, Tanmay Inamdar, Satyabrata Jana, and Saket Saurabh</i>	14:1–14:17
Structure-Guided Automated Reasoning <i>Max Bannach and Markus Hecher</i>	15:1–15:18
Listing Spanning Trees of Outerplanar Graphs by Pivot-Exchanges <i>Nastaran Behrooznia and Torsten Mütze</i>	16:1–16:18
Tight Approximation and Kernelization Bounds for Vertex-Disjoint Shortest Paths <i>Matthias Bentert, Fedor V. Fomin, and Petr A. Golovach</i>	17:1–17:17
Online Disjoint Set Covers: Randomization Is Not Necessary <i>Marcin Bienkowski, Jaroslaw Byrka, and Łukasz Jeż</i>	18:1–18:16
The Complexity of Learning LTL, CTL and ATL Formulas <i>Benjamin Bordais, Daniel Neider, and Rajarshi Roy</i>	19:1–19:20
On Cascades of Reset Automata <i>Roberto Borelli, Luca Geatti, Marco Montali, and Angelo Montanari</i>	20:1–20:22
Computability of Extender Sets in Multidimensional Subshifts <i>Antonin Callard, Léo Paviet Salomon, and Pascal Vanier</i>	21:1–21:19
CMSO-Transducing Tree-Like Graph Decompositions <i>Rutger Campbell, Bruno Guillon, Mamadou Moustapha Kanté, Eun Jung Kim, and Noleen Köhler</i>	22:1–22:18
How to Play the Accordion: Uniformity and the (Non-)Conservativity of the Linear Approximation of the λ -Calculus <i>Rémy Cerda and Lionel Vaux Auclair</i>	23:1–23:21
A Deterministic Approach to Shortest Path Restoration in Edge Faulty Graphs <i>Keerti Choudhary and Rishabh Dhiman</i>	24:1–24:10
Local Density and Its Distributed Approximation <i>Aleksander Bjørn Christiansen, Ivor van der Hoog, and Eva Rotenberg</i>	25:1–25:20
Toward Better Depth Lower Bounds: Strong Composition of XOR and a Random Function <i>Nikolai Chukhin, Alexander S. Kulikov, and Ivan Mihajlin</i>	26:1–26:15
Local Equivalence of Stabilizer States: A Graphical Characterisation <i>Nathan Claudet and Simon Perdrix</i>	27:1–27:18
Can You Link Up With Treewidth? <i>Radu Curticapean, Simon Döring, Daniel Neuen, and Jiaheng Wang</i>	28:1–28:24

Noisy (Binary) Searching: Simple, Fast and Correct <i>Dariusz Dereniowski, Aleksander Łukasiewicz, and Przemysław Uznański</i>	29:1–29:18
Being Efficient in Time, Space, and Workload: a Self-Stabilizing Unison and Its Consequences <i>Stéphane Devismes, David Ilcinkas, Colette Johnen, and Frédéric Mazoit</i>	30:1–30:18
Efficient Approximation Schemes for Scheduling on a Stochastic Number of Machines <i>Leah Epstein and Asaf Levin</i>	31:1–31:18
A Faster Algorithm for Constrained Correlation Clustering <i>Nick Fischer, Evangelos Kipouridis, Jonas Klausen, and Mikkel Thorup</i>	32:1–32:18
Metric Dimension and Geodetic Set Parameterized by Vertex Cover <i>Florent Foucaud, Esther Galby, Liana Khazaliya, Shaohua Li, Fionn Mc Inerney, Roohani Sharma, and Prafullkumar Tale</i>	33:1–33:20
Agreement Tasks in Fault-Prone Synchronous Networks of Arbitrary Structure <i>Pierre Fraigniaud, Minh Hang Nguyen, and Ami Paz</i>	34:1–34:21
Dimension-Free Parameterized Approximation Schemes for Hybrid Clustering <i>Ameet Gadekar and Tanmay Inamdar</i>	35:1–35:20
MaxMin Separation Problems: FPT Algorithms for <i>st</i> -Separator and Odd Cycle Transversal <i>Ajinkya Gaikwad, Hitendra Kumar, Soumen Maity, Saket Saurabh, and Roohani Sharma</i>	36:1–36:21
On the Existential Theory of the Reals Enriched with Integer Powers of a Computable Number <i>Jorge Gallego-Hernández and Alessio Mansutti</i>	37:1–37:18
Two-Dimensional Longest Common Extension Queries in Compact Space <i>Arnab Ganguly, Daniel Gibney, Rahul Shah, and Sharma V. Thankachan</i>	38:1–38:17
A Quasi-Polynomial Time Algorithm for Multi-Arrival on Tree-Like Multigraphs <i>Ebrahim Ghorbani, Jonah Leander Hoff, and Matthias Mnich</i>	39:1–39:19
Identity-Preserving Lax Extensions and Where to Find Them <i>Sergey Goncharov, Dirk Hofmann, Pedro Nora, Lutz Schröder, and Paul Wild</i>	40:1–40:20
Residue Domination in Bounded-Treewidth Graphs <i>Jakob Greilhuber, Philipp Schepper, and Philip Wellnitz</i>	41:1–41:20
Local Enumeration: The Not-All-Equal Case <i>Mohit Gurumukhani, Ramamohan Paturi, Michael Saks, and Navid Talebanfard</i> .	42:1–42:19
Approximating Densest Subgraph in Geometric Intersection Graphs <i>Sariel Har-Peled and Saladi Rahul</i>	43:1–43:17
Independence and Domination on Bounded-Treewidth Graphs: Integer, Rational, and Irrational Distances <i>Tim A. Hartmann and Dániel Marx</i>	44:1–44:19
Forbidden Patterns in Mixed Linear Layouts <i>Deborah Haun, Laura Merker, and Sergey Pupyrev</i>	45:1–45:21

Sampling Unlabeled Chordal Graphs in Expected Polynomial Time <i>Úrsula Hébert-Johnson and Daniel Lokshantov</i>	46:1–46:20
Minimizing the Number of Tardy Jobs with Uniform Processing Times on Parallel Machines <i>Klaus Heeger and Hendrik Molter</i>	47:1–47:17
Subshifts Defined by Nondeterministic and Alternating Plane-Walking Automata <i>Benjamin Hellouin de Menibus and Pacôme Perrotin</i>	48:1–48:15
Cycle Counting Under Local Differential Privacy for Degeneracy-Bounded Graphs <i>Quentin Hillebrand, Vorapong Suppakitpaisarn, and Tetsuo Shibuya</i>	49:1–49:22
Designing Exploration Contracts <i>Martin Hoefer, Conrad Schecker, and Kevin Schewior</i>	50:1–50:19
Protecting the Connectivity of a Graph Under Non-Uniform Edge Failures <i>Felix Hommelsheim, Zhenwei Liu, Nicole Megow, and Guochuan Zhang</i>	51:1–51:21
Polynomial Kernel and Incompressibility for Prison-Free Edge Deletion and Completion <i>Sébane Bel Houari-Durand, Eduard Eiben, and Magnus Wahlström</i>	52:1–52:17
On Read- k Projections of the Determinant <i>Pavel Hrubeš and Pushkar S. Joglekar</i>	53:1–53:7
Multidimensional Quantum Walks, Recursion, and Quantum Divide & Conquer <i>Stacey Jeffery and Galina Pass</i>	54:1–54:16
Modal Separation of Fixpoint Formulae <i>Jean Christoph Jung and Jędrzej Kołodziejcki</i>	55:1–55:20
Transforming Stacks into Queues: Mixed and Separated Layouts of Graphs <i>Julia Katheder, Michael Kaufmann, Sergey Pupyrev, and Torsten Ueckerdt</i>	56:1–56:18
Approximate Minimum Tree Cover in All Symmetric Monotone Norms Simultaneously <i>Matthias Kaul, Kelin Luo, Matthias Mnich, and Heiko Röglin</i>	57:1–57:18
Violating Constant Degree Hypothesis Requires Breaking Symmetry <i>Piotr Kawalek and Armin Weiß</i>	58:1–58:21
Online Matching with Delays and Size-Based Costs <i>Yasushi Kawase and Tomohiro Nakayoshi</i>	59:1–59:18
Modular Counting CSP: Reductions and Algorithms <i>Amirhossein Kazemini and Andrei A. Bulatov</i>	60:1–60:18
Efficiently Computing the Minimum Rank of a Matrix in a Monoid of Zero-One Matrices <i>Stefan Kiefer and Andrew Ryzhikov</i>	61:1–61:22
Faster Algorithms on Linear Delta-Matroids <i>Tomohiro Koana and Magnus Wahlström</i>	62:1–62:19
Approximation of Spanning Tree Congestion Using Hereditary Bisection <i>Petr Kolman</i>	63:1–63:6

Cluster Editing on Cographs and Related Classes <i>Manuel Lafond, Alitzel López Sánchez, and Weidong Luo</i>	64:1–64:21
On Average Baby PIH and Its Applications <i>Yuwei Liu, Yijia Chen, Shuangli Li, Bingkai Lin, and Xin Zheng</i>	65:1–65:19
The Hardness of Decision Tree Complexity <i>Bruno Loff and Alexey Milovanov</i>	66:1–66:13
Commutative N-Rational Series of Polynomial Growth <i>Aliaume Lopez</i>	67:1–67:16
Slightly Non-Linear Higher-Order Tree Transducers <i>Lê Thành Dũng (Tito) Nguyễn and Gabriele Vanoni</i>	68:1–68:20
A Dichotomy Theorem for Ordinal Ranks in MSO <i>Damian Niwiński, Paweł Parys, and Michał Skrzypczak</i>	69:1–69:18
Colorful Vertex Recoloring of Bipartite Graphs <i>Boaz Patt-Shamir, Adi Rosén, and Seeun William Umboh</i>	70:1–70:19
Unfairly Splitting Separable Necklaces <i>Patrick Schneider, Linus Stalder, and Simon Weber</i>	71:1–71:19
Card-Based Protocols Imply PSM Protocols <i>Kazumasa Shinagawa and Koji Nuida</i>	72:1–72:18
Dominating Set, Independent Set, Discrete k -Center, Dispersion, and Related Problems for Planar Points in Convex Position <i>Anastasiia Tkachenko and Haitao Wang</i>	73:1–73:20
Nearly-Optimal Algorithm for Non-Clairvoyant Service with Delay <i>Noam Touitou</i>	74:1–74:21
Canonical Labeling of Sparse Random Graphs <i>Oleg Verbitsky and Maksim Zhukovskii</i>	75:1–75:20
Dynamic Unit-Disk Range Reporting <i>Haitao Wang and Yiming Zhao</i>	76:1–76:19

■ Preface

The International Symposium on Theoretical Aspects of Computer Science (STACS) conference series is an internationally leading forum for original research on theoretical aspects of computer science.

STACS 2025 consists of two tracks, A and B. Track A is dedicated to algorithms and data structures, complexity and games. Track B covers automata, logic, semantics and theory of programming.

STACS is held alternately in France and in Germany. This year's conference, taking place in Jena (Germany) from March 4 to March 7, is the 42nd in the series. Previous meetings took place in Paris (1984), Saarbrücken (1985), Orsay (1986), Passau (1987), Bordeaux (1988), Paderborn (1989), Rouen (1990), Hamburg (1991), Cachan (1992), Würzburg (1993), Caen (1994), München (1995), Grenoble (1996), Lübeck (1997), Paris (1998), Trier (1999), Lille (2000), Dresden (2001), Antibes (2002), Berlin (2003), Montpellier (2004), Stuttgart (2005), Marseille (2006), Aachen (2007), Bordeaux (2008), Freiburg (2009), Nancy (2010), Dortmund (2011), Paris (2012), Kiel (2013), Lyon (2014), München (2015), Orléans (2016), Hannover (2017), Caen (2018), Berlin (2019), Montpellier (2020), Saarbrücken (2021, taking place virtually), Marseille (2022, taking place virtually), Hamburg (2023) and Clermont-Ferrand (2024).

The STACS 2025 call for papers led to 259 submissions (202 for Track A and 57 for Track B). Each paper was assigned to three program committee members who, at their discretion, asked external reviewers for reports. STACS 2025 employed a lightweight double-blind reviewing process and incorporated an author rebuttal period in the reviewing process.

The committee selected 72 papers for presentation at the conference (55 for Track A and 17 for Track B), implying an acceptance rate of approximately 28%. We are thankful to all individuals, institutions, and organizations who contributed to making STACS 2025 a success. We thank all authors for submitting their work to STACS 2025. Our deepest thanks go to all Program Committee members and external expert reviewers for carefully reading the submissions, providing constructive comments, and for participating in extensive discussions that helped in selecting the strongest papers for the technical program of the conference. The very high quality of the submissions made the selection an extremely difficult task. We also thank the Steering Committee members of STACS for providing overall guidance.

We would like to express our gratitude to the three invited speakers: Daniel Dadush (CWI Amsterdam), Anupam Das (University of Birmingham), and Susanna F. de Rezende (Lund University) and to Albert Atserias (UPC Barcelona) as the tutorial speaker.

STACS 2025 was preceded on 3 and 4 March 2025 by a workshop on algorithms, complexity and logic (Theorietag), a workshop under the auspices of the GI interest groups on Algorithms, Complexity and Logic. Invited talks at the workshop were given by Heribert Vollmer (Hanover) and Sebastian Wild (Marburg). We thank Christian Komusiewicz (University of Jena) for co-organising the pre-conference workshop. As in 2024, STACS 2025 was accompanied by an extended stay support program, allowing participants to combine their conference visit with a research trip to a nearby university.

Full versions of selected outstanding papers from STACS 2025 are invited for submission to the journal *TheoretCS*. Further selected papers from Track A are invited to the *ACM Transactions on Computation Theory* and selected papers from Track B to *Logical Methods in Computer Science*.

We thank the LIPIcs team for assisting us in the publication process and the final production of the proceedings. These proceedings contain extended abstracts of the accepted contributions and abstracts of the tutorial and invited talks. The authors retain their rights and make their work available under a Creative Commons license. The proceedings are published electronically by Schloss Dagstuhl – Leibniz-Center for Informatics within their LIPIcs series.

Finally, we would like to thank Friedrich Schiller University of Jena, the Carl Zeiss Foundation, the Interactive Inference project, Inverso, the University Clermont Auvergne and LIMOS for their support. Our special thanks go to Silvia Blaser, Benjamin Böhm, Marlene Gründel, Tim Hoffmann, Kaspar Kasche, Agnes Schleitzer and Luc Spachmann – the local organising team at the University of Jena – for all their help with the organisation, including the webpages, the registration and the social events.

March 2025

■ Conference Organisation

Program Committee – Track A

Antonios Antoniadis	University of Twente
Christian Coester	University of Oxford
Johanne Cohen	CNRS, Université Paris-Saclay
Arnaud de Mesmay	CNRS, Université Gustave Eiffel
Holger Dell	Goethe University Frankfurt and IT University of Copenhagen
Omar Fawzi	Inria, ENS Lyon
Paweł Gawrychowski	University of Wrocław
Carla Groenland	TU Delft
Zhiyi Huang	University of Hong Kong
Bart Jansen	TU Eindhoven
Tuukka Korhonen	University of Copenhagen
Jakub Łącki	Google Research, New York
Hung Le	University of Massachusetts at Amherst
Nguyễn Kim Thăng	Université Grenoble-Alpes, co-chair
Michał Pilipczuk	University of Warsaw, co-chair
Lars Rohwedder	Maastricht University
Rahul Santhanam	University of Oxford
Shay Solomon	Tel-Aviv University
Tatiana Starikovskaya	ENS Paris
Jukka Suomela	Aalto University
Jakub Tarnawski	Microsoft Research
Torsten Ueckerdt	Karlsruhe Institute of Technology
Jan van den Brand	Georgia Tech
Karol Węgrzycki	Saarland University and MPI
Andreas Wiese	Technical University of Munich

Program Committee – Track B

Christoph Berkholz	TU Ilmenau
Olaf Beyersdorff	Friedrich Schiller University Jena, co-chair
Benedikt Bollig	CNRS, ENS Paris-Saclay
Flavien Breuvert	LIPN, Université Sorbonne Paris Nord
Michaël Cadilhac	DePaul University, Chicago, IL
Nofar Carmeli	Inria, LIRMM, Montpellier
Moses Ganardi	MPI-SWS Kaiserslautern
Christoph Haase	University of Oxford
Sandra Kiefer	University of Oxford
Alexander Kurz	Chapman
Dietrich Kuske	TU Ilmenau
Karoliina Lehtinen	CNRS, Aix-Marseille University, LIS
Stefan Mengel	CNRS, CRIL Lens
Cláudia Nalon	University of Brasilia
Elaine Pimentel	University College London, co-chair
Jurriaan Rot	Radboud University, Nijmegen

42nd International Symposium on Theoretical Aspects of Computer Science (STACS 2025).

Editors: Olaf Beyersdorff, Michał Pilipczuk, Elaine Pimentel, and Nguyễn Kim Thăng

Leibniz International Proceedings in Informatics

LIPIC Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Steering Committee

Dietmar Berwanger	LMF, CNRS, Université Paris-Saclay
Marthe Bonamy	LaBRI, CNRS, Université de Bordeaux
Cyril Nicaud	LIGM, Université Paris-Est
Sylvain Schmitz	IRIF, Université de Paris
Luc Segoufin	DI ENS, INRIA, ENS Ulm
Ioan Todinca	LIFO, Université d'Orléans, co-chair
Petra Berenbrink	Hamburg University
Olaf Beyersdorff	Friedrich Schiller University of Jena
Florin Manea	University of Göttingen
Arne Meier	University of Hannover
Heiko Röglin	University of Bonn
Thomas Schwentick	University of Dortmund, co-chair

Local Organising Committee (Friedrich Schiller University Jena)

Olaf Beyersdorff
Silvia Blaser
Benjamin Böhm
Marlene Gründel, chair
Tim Hoffmann
Kaspar Kasche
Agnes Schleitzer
Luc Spachmann

Subreviewers

Abheek Ghosh	Barbara Keller	Eduard Eiben
Adam Karczmarz	Baris Can Esmer	Elena Kirshanova
Adam Polak	Barnaby Martin	Elvira Mayordomo
Aditya Prakash	Bartło Miej Bosek	Emile Anand
Ahmad Biniaz	Bartłomiej Dudek	Emmanouil Vasileios Vlatakis
Akanksha Agrawal	Bartłomiej Dudek	Gkaragkounis
Aleksander Łukasiewicz	Ben Cameron	Eniko Kevi
Aleksandrs Belovs	Ben Lee Volk	Enze Sun
Alessandro Ronca	Benedikt Kolbe	Erik Jan van Leeuwen
Alex Crane	Benjamin Monmege	Erik Paul
Alexander Lindermayr	Benjamin Rossman	Esther Galby
Alexander Rabinovich	Bertrand Simon	Euiwoong Lee
Alexander Skopalik	Blaise Genest	Evangelia Gergatsouli
Alexandra Lassota	Bo Li	Evangelos Kipouridis
Alexandra Wesolek	Bruno Lopes	Faith Ellen
Alexandros Hollender	C. S. Bhargav	Fateme Abbasi
Alexis de Colnet	Ce Jin	Fatiha Bendali
Ali Vakilian	Cédric Bentz	Felix Reidl
Alireza Bagheri	Chenglin Fan	Feng Shi
Alkida Balliu	Chetan Gupta	Florent Foucaud
Aloïs Dufour	Chien-Chung Huang	Florin Manea
Alon Efrat	Chris Köcher	Francesco Dagnino
Ama Koranteng	Christian Ikenmeyer	Franziska Eberle
Amin Shiraz Gilani	Christian Scheideler	Frédéric Magniez
Anastasiia Alokina	Christof Löding	Gabriel Bathie
Anay Mehrotra	Christoph Dürr	Gabriel Istrate
André Nichterlein	Christoph Lenzen	Gaétan Berthe
André Nusser	Christophe Tollu	George Christodoulou
Andreas Björklund	Chung-Shou Liao	George Kenison
Andreas Emil Feldmann	Clemens Thielen	George Manoussakis
Andreas Göbel	Clovis Eberhart	George Mertzios
Andreas Maggiori	Colin Geniet	George Osipov
Andreas Maletti	Corentin Barloy	Giannos Stamoulis
Andrei Krokhin	Corto Mascle	Giorgio Lucarelli
Andrew Ryzhikov	Csaba Toth	Giulia Bernardini
Andris Ambainis	Da Wei Zheng	Graham Leigh
Anish Mukherjee	Damien Busatto-Gaston	Greg Bodwin
Anna Gilbert	Dana Ron	Guillaume Ducoffe
Antonio Casares	Daniel Cordeiro	Guillaume Malod
Argyrios Deligkas	Daniel Neuen	Guillermo Perez
Arindam Khan	Daniel Turetsky	Haitao Wang
Aritra Banik	Davi Silva	Hang Zhou
Arka Ghosh	David Auger	Hans Bodlaender
Arne Meier	David Harris	Harry Vinall-Smeeth
Artem Tsikiridis	David Lidell	Hermann Haeusler
Artur Riazanov	David Mix Barrington	Hermann Wilhelm
Arturo Merino	David R. Wood	Hoai-An Nguyen
Aryan Agarwala	Dedy Septono Catur Putranto	Hsi-Ming Ho
Ashkan Norouzi Fard	Dominik Scheder	Hsin-Hao Su
Athanasios Konstantinidis	Dorit Hochbaum	Hugo Akitaya
Augusto Modanese	Dušan Knop	Ian Pratt-Hartmann
Balagopal Komarath	Édouard Bonnet	Ignaz Rutter

Ioan Todinca	Lior Gishboliner	Michael Poss
Ioannis Psarros	Loes Kruger	Michaela Borzechowski
Isabella Ziccardi	Loïc Dubois	Michal Opler
Jacob Focke	Loukas Georgiadis	Mickael Randour
Jacob Imola	Luc Pellissier	Mikaël Rabie
Jaegun Lee	Luca Pascal Staus	Mikko Koivisto
James Brotherston	Lucas De Meyer	Miriam Münch
Jan Boeckmann	Lucia Draque Penso	Mirza Redzic
Jan Bok	Lukas Plätz	Mohammad Roghani
Janik Huth	Lukasz Kowalik	Morgan Rogers
Jannik Olbrich	Lvzhou Li	Moritz Buchem
Jannis Blauth	Maël Dumas	Moritz Lichter
Jaroslav Byrka	Magnus Berg	Moritz Muehlenthaler
Jędrzej Hodor	Manfred Kufleitner	Naonori Kakimura
Jesper Nederlof	Manoj Gupta	Narek Bojikian
Jianqiang Li	Manolis Vasilakis	Nathan Klein
Jinge Bao	Marc Schroder	Neha Rino
Jingyang Zhao	Marcel Roeloffzen	Nicolas Bonichon
Joachim Gudmundsson	Marcella Anselmo	Nicolas Bousquet
Jochen Koenemann	Marcin Bienkowski	Nicolas Heurtel
Joe Sawada	Marcin Pilipczuk	Niels Kornerup
Joel Rybicki	Marck van der Vegt	Niels van der Weide
Johannes Lengler	Marco Bressan	Nikhil Balaji
Jonas Ellert	Marek Sokółowski	Nikhil Bansal
Jonas Sénizergues	Marin Bougeret	Nikhil Mande
Joseph Landsberg	Mark Bun	Niko Hastrich
Joshua Brakensiek	Markus Anders	Nima Anari
Julien Baste	Markus Hecher	Ninad Rajgopal
Kaave Hosseini	Markus Lohrey	Nir Piterman
Karine Altisen	Martin Böhm	Noam Touitou
Karol Pokorski	Martin Koutecký	Nobutaka Shimizu
Karthik C. S.	Martin Lange	Norbert Zeh
Kazuyuki Amano	Martin S. Krejca	Nutan Limaye
Kevin Schewior	Masayuki Miyamoto	Olivier Idir
Khaled Elbassioni	Massimo Equi	Omrit Filtser
Kiril Bangachev	Massimo Lauria	Pål Grønås Drange
Kirill Simonov	Mateusz Skomra	Pamela Fleischmann
Konstantinos Tsakalidis	Mateusz Wasykiewicz	Pan Peng
Krzysztof Fleszar	Mathieu Mari	Panagiotis Charalampopoulos
Kunihiro Wasa	Matias Korman	Panos Giannopoulos
Kyungjin Cho	Matt Kovacs-Deak	Pasin Manurangsi
Lars Jaffke	Matthew Gray	Paul Duetting
Lasse Wulf	Matthew Kwan	Paulin Jacobé De Naurois
Laurent Bienvenu	Matthias Bentert	Paweł Rzażewski
Laurent Feuilloley	Matthias Kaul	Pei Wu
Laurent Gourves	Matthias Mnich	Peter Kling
Lazar Milenkovic	Max Deppert	Peter Manohar
Lê Thành Dũng Nguyen	Max Dupré La Tour	Petr Golovach
Leo Wennmann	Maximilian Merz	Peyman Afshani
León Bohn	Maximilian Weininger	Philipp Hieronymi
Leonid Barenboim	Meike Neuwohner	Philipp Schepper
Leqi Zhu	Michael Bekos	Pierre Bergé
Leroy Chew	Michael Blondin	Pierre Coucheney
Liam Roditty	Michael Kompatscher	Pierre Ohlmann

Proof Complexity and Its Relations to SAT Solving

Albert Atserias 

Universitat Politècnica de Catalunya, Barcelona, Spain
Centre de Recerca Matemàtica, Bellaterra, Spain

Abstract

Propositional proof complexity is the study of algorithms that recognize the set of tautologies in propositional logic. Initially conceived as an approach to address the “P versus NP” problem in computational complexity, the field has gradually expanded its focus to include new objectives. Among these is the goal of providing a theoretical foundation for comparing the effectiveness of heuristics for algorithms that exhaustively explore the solution spaces of combinatorial problems. Dually, and complementarily, the methods of proof complexity can also be used to assess how to certify that a given exploration path of such an algorithm ultimately leads to a dead end. A notable challenge faced by this methodology lies in the fact that, despite the theoretically proved modelling power of propositional logic, as established by the theory of NP-completeness, propositional logic is not always the best specification language for all application domains. Addressing this challenge involves studying the expressive power of various languages and their associated proof systems through the lens of computational complexity.

The first part of this talk will be a survey of how the emergence of these new objectives for propositional proof complexity came to be, and what the theory’s methods offer in pursuing them. The second part will review the current state of the art on the computational complexity of automating the proof search problem for various proof systems for propositional logic and other languages. While it is now known and well understood that fully automating propositional Resolution as a proof system for propositional logic is NP-hard, it remains an open question whether it is possible to distinguish satisfiable formulas from unsatisfiable ones with short Resolution proofs of unsatisfiability in polynomial time. As of the time of writing, there is no consensus among experts on whether this problem should be considered computationally intractable.

2012 ACM Subject Classification Theory of computation → Proof complexity; Theory of computation → Automated reasoning

Keywords and phrases Propositional logic, proof systems, Resolution, cutting planes, integer linear programming, automatability, NP-hardness, satisfiability, heuristics, search

A Strongly Polynomial Algorithm for Linear Programs with at Most Two Non-Zero Entries per Row or Column

Abstract

We give a strongly polynomial algorithm for minimum cost generalized flow, and hence for optimizing any linear program with at most two non-zero entries per row, or at most two non-zero entries per column. Primal and dual feasibility were shown by Végh (MOR '17) and Megiddo (SICOMP '83) respectively. Our result can be viewed as progress towards understanding whether all linear programs can be solved in strongly polynomial time, also referred to as Smale's 9th problem.

Our approach is based on the recent primal-dual interior point method (IPM) due to Allamigeon, Dadush, Loho, Natura and Végh (FOCS '22). The number of iterations needed by the IPM is bounded, up to a polynomial factor in the number of inequalities, by the *straight line complexity* of the central path. Roughly speaking, this is the minimum number of pieces of any piecewise linear curve that multiplicatively approximates the central path.

As our main contribution, we show that the straight line complexity of any minimum cost generalized flow instance is polynomial in the number of arcs and vertices. By applying a reduction of Hochbaum (ORL '04), the same bound applies to any linear program with at most two non-zeros per column or per row.

To be able to run the IPM, one requires a suitable initial point. For this purpose, we develop a novel multistage approach, where each stage can be solved in strongly polynomial time given the result of the previous stage. Beyond this, substantial work is needed to ensure that the bit complexity of each iterate remains bounded during the execution of the algorithm. For this purpose, we show that one can maintain a representation of the iterates as a low complexity convex combination of vertices and extreme rays. Our approach is black-box and can be applied to any log-barrier path following method.

2012 ACM Subject Classification Theory of computation → Linear programming

Keywords and phrases Linear Programming, Strongly Polynomial Algorithms, Interior Point Methods

Algebras for Automata: Reasoning with Regularity

Anupam Das   

University of Birmingham, UK

Abstract

In the second half of the 20th century various theories of regular expressions were proposed, eventually leading to the notion of a *Kleene Algebra* (KA). Kozen and Krohn independently proved the completeness of KA for the model of regular languages, a now celebrated result that has been refined and generalised over the years. In recent years proof theoretic approaches to regular languages have been studied, providing alternative routes to metalogical results like completeness and decidability.

In this talk I will present a new approach from a different starting point: finite state automata. A notation for non-deterministic finite automata is readily obtained via expressions with least fixed points, leading to a theory of *right-linear algebras* (RLA). RLA is strictly more general than KA, e.g. admitting ω -regular languages as a model too, and enjoys a simpler proof theory than KA. This allows us to recover (more general) metalogical results in a robust way, combining techniques from automata, games, and cyclic proofs. Finally I will discuss extensions of RLA by *greatest* fixed points, comprising a notation for parity automata, to reason about ω -regular languages too.

This talk is based on joint works with Abhishek De [2, 1].

2012 ACM Subject Classification Theory of computation \rightarrow Regular languages; Theory of computation \rightarrow Proof theory

Keywords and phrases Regular languages, Linear grammars, Proof theory, Cyclic proofs, Automata theory, Fixed points, Games

Some Recent Advancements in Monotone Circuit Complexity

Susanna F. de Rezende   

Lund University, Sweden

Abstract

In 1985, Razborov [16] proved the first superpolynomial size lower bound for monotone Boolean circuits for the perfect matching the clique functions, and, independently, Andreev [2] obtained exponential size lower bounds. These breakthroughs were soon followed by further advancements in monotone complexity, including better lower bounds for clique [1, 19], superlogarithmic depth lower bounds for connectivity by Karchmer and Wigderson [12], and the separations $\text{mon-NC} \neq \text{mon-P}$ and that $\text{mon-NC}^i \neq \text{mon-NC}^{i+1}$ by Raz and McKenzie [15]. Karchmer and Wigderson [12] proved their result by establishing a relation between communication complexity and (monotone) circuit depth, and Raz and McKenzie [15] introduced a new technique, now called *lifting theorems*, for obtaining communication lower bounds from query complexity lower bounds,

In this talk, we will survey recent advancements in monotone complexity driven by query-to-communication lifting theorems. A decade ago, Göös, Pitassi, and Watson [10] brought to light the generality of the result of Raz and McKenzie [15] and reignited this line of work. A notable extension is the lifting theorem [8] for a model of DAG-like communication [17, 18] that corresponds to circuit size. These powerful theorems, in their different flavours, have been instrumental in addressing many open questions in monotone circuit complexity, including: optimal $2^{\Omega(n)}$ lower bounds on the size of monotone Boolean formulas computing an explicit function in NP [14]; a complete picture of the relation between the mon-AC and mon-NC hierarchies [6]; a near optimal separation between monotone circuit and monotone formula size [5]; exponential separation between NC^2 and mon-P [8, 11]; and better lower bounds for clique [7, 13], improving on [3]. Very recently, lifting theorems were also used to prove supercritical trade-offs for monotone circuits showing that there are functions computable by small circuits for which any small circuit must have superlinear or even superpolynomial depth [4, 9]. We will explore these results and their implications, and conclude by discussing some open problems.

Abstract

The classic greedy coloring algorithm considers the vertices of an input graph G in a given order and assigns the first available color to each vertex v in G . In the GRUNDY COLORING problem, the task is to find an ordering of the vertices that will force the greedy algorithm to use as many colors as possible. In the PARTIAL GRUNDY COLORING, the task is also to color the graph using as many colors as possible. This time, however, we may select both the ordering in which the vertices are considered and which color to assign the vertex. The only constraint is that the color assigned to a vertex v is a color previously used for another vertex if such a color is available.

Whether GRUNDY COLORING and PARTIAL GRUNDY COLORING admit fixed-parameter tractable (FPT) algorithms, algorithms with running time $f(k)n^{\mathcal{O}(1)}$, where k is the number of colors, was posed as an open problem by Zaker and by Effantin et al., respectively.

Recently, Aboulker et al. (STACS 2020 and Algorithmica 2022) resolved the question for GRUNDY COLORING in the negative by showing that the problem is $W[1]$ -hard. For PARTIAL GRUNDY COLORING, they obtain an FPT algorithm on graphs that do not contain $K_{i,j}$ as a subgraph (a.k.a. $K_{i,j}$ -free graphs). Aboulker et al. re-iterate the question of whether there exists an FPT algorithm for PARTIAL GRUNDY COLORING on general graphs and also asks whether GRUNDY COLORING admits an FPT algorithm on $K_{i,j}$ -free graphs. We give FPT algorithms for PARTIAL GRUNDY COLORING on general graphs and for GRUNDY COLORING on $K_{i,j}$ -free graphs, resolving both the questions in the affirmative. We believe that our new structural theorems for partial Grundy coloring and “representative-family” like sets for $K_{i,j}$ -free graphs that we use in obtaining our results may have wider algorithmic applications.

1 Introduction

A *proper coloring* of a graph G is an assignment of colors to its vertices such that none of the edges have endpoints of the same color. In k -COLORING, we are given a graph G , and the objective is to test whether G admits a proper coloring using at most k colors. The k -COLORING problem is one of the classical NP-hard problems, and it is NP-complete for every fixed $k \geq 3$. The problem is notoriously hard even to approximate. Indeed, approximating k -COLORING within $\mathcal{O}(n^{1-\epsilon})$, for any $\epsilon > 0$, is hard [18]. Also, under a variant of Unique Games Conjecture, there is no constant factor approximation for 3-COLORING [14].

The k -COLORING problem has varied applications ranging from scheduling, register allocations, pattern matching, and beyond [8, 9, 29]. Owing to this, several heuristics-based algorithms have been developed for the problem. One of the most natural greedy strategies considers the vertices of an input graph G in an arbitrary order and assigns to each vertex the first available color in the palette (the color palette for us is \mathbb{N}). In literature, this is called the *first-fit* rule. Notice that there is nothing special about using the “first” available color; one may instead opt for any of the previously used colors, if available, before using a new color; let us call this greedy rule the *any-available* rule. It leads to yet another greedy strategy to properly color a graph, and one can easily prove that this greedy strategy is equivalent to the “last-(available) fit” rule.

For any greedy strategy, one may wonder: *How bad can the strategy perform for the given instance?* The above leads us to the well-studied fundamental combinatorial problems, GRUNDY COLORING and PARTIAL GRUNDY COLORING, that arise from the aforementioned greedy strategies for proper coloring. In the GRUNDY COLORING problem, we are given a graph G on n vertices and an integer k , and the goal is to check if there is an ordering of the vertices on which the first-fit greedy algorithm for proper coloring uses at least k colors. Similarly, we can define the PARTIAL GRUNDY COLORING problem, where the objective is to check if, for the given graph G on n vertices and integer k , there is an ordering of the vertices on which the any-available greedy algorithm uses at least k colors. In this paper, we consider these two problems in the realm of parameterized complexity.

The GRUNDY COLORING problem has a rich history dating back to 1939 [21]. Goyal and Vishwanathan [20] proved that GRUNDY COLORING is NP-hard. Since then, there has been a flurry of results on the computational and combinatorial aspects of the problem both on general graphs and on restricted graph classes, see, for instance [3, 6, 7, 10, 16, 23, 24, 26, 27, 33, 35–39] (this list is only illustrative, not comprehensive). The problem PARTIAL GRUNDY COLORING was introduced by Erdős et al. [16] and was first shown to be NP-hard by Shi et al. [34]. The problem has gained quite some attention thereafter; see, for instance [1, 4, 5, 12, 15, 25, 32, 36].

These problems have also been extensively studied from the parameterized complexity perspective. Unlike k -COLORING, both these problems admit XP algorithms [15, 38], i.e., an algorithm running in time bounded by $|V(G)|^{f(k)}$. The above naturally raises the question of whether they are fixed-parameter tractable (FPT), i.e., admit an algorithm running in time $f(k) \cdot |V(G)|^{\mathcal{O}(1)}$. In fact, these problems have also been explicitly stated as open problems [1, 7, 23, 33].

Havet and Sampaio [23] studied GRUNDY COLORING with an alternate parameter and showed that the problem of testing whether there is a Grundy coloring with at least $|V(G)| - q$ colors is FPT parameterized by q . Bonnet et al. [7] initiated a systematic study of designing parameterized and exact exponential time algorithms for GRUNDY COLORING and obtained FPT algorithms for the problem for several structured graph classes. They gave an exact

algorithm for GRUNDY COLORING running in time $2.443^n \cdot n^{\mathcal{O}(1)}$ and also showed that the problem is FPT on chordal graphs, claw-free graphs and graphs excluding a fixed minor. In the same paper, they stated the tractability status of GRUNDY COLORING on general graphs parameterized by the treewidth or the number of colors as central open questions. Belmonte et al. [6] resolved the first question by proving that GRUNDY COLORING is W[1]-hard parameterized by treewidth, but surprisingly, it becomes FPT parameterized by pathwidth. Later, Aboulker et al. [1] proved that GRUNDY COLORING does not admit an FPT algorithm (parameterized by the number of colors) and obtained an FPT algorithm for PARTIAL GRUNDY COLORING on $K_{t,t}$ -free graphs (which includes graphs of bounded degeneracy, graphs excluding some fixed graph as minor/topological minors, graphs of bounded expansion and nowhere dense graphs). A graph is $K_{i,j}$ -free if it does not have a *subgraph* isomorphic to the complete bipartite graph with i and j vertices, respectively, on the two sides. They concluded their work with the following natural open questions:

Question 1: Does PARTIAL GRUNDY COLORING admit an FPT algorithm?

Question 2: Does GRUNDY COLORING admit an FPT algorithm on $K_{i,j}$ -free graphs?

In this paper, we resolve the questions 1 and 2 in the affirmative by a new structural result and a new notion of representative families for $K_{i,j}$ -free graphs, respectively. In the next section, we give an intuitive overview of both results, highlighting our difficulties and our approaches to overcome them.

1.1 Our Results, Methods and Overview

Our first result is the following.

► **Theorem 1.** *PARTIAL GRUNDY COLORING is solvable in time $2^{\mathcal{O}(k^5)} \cdot n^{\mathcal{O}(1)}$.*

Our algorithm starts with the known “witness reformulation” of PARTIAL GRUNDY COLORING. It is known that (G, k) is a yes-instance of PARTIAL GRUNDY COLORING if and only if there is a vertex subset W of size at most k^2 such that, $(G[W], k)$ is a yes-instance of the problem. In the above, the set W is known as a *small witness set*. Our algorithm is about finding such a set W of size at most k^2 . Observe that this witness reformulation immediately implies that PARTIAL GRUNDY COLORING admits an algorithm with running time $n^{\mathcal{O}(k^2)}$ time. To build our intuition, we first give a simple algorithm for the problem on graphs of bounded degeneracy (or even, nowhere dense graphs). This algorithm has two main steps: (a) classical color-coding of Alon-Yuster-Zwick [2], and (b) independence covering lemma of Lokshtanov et al. [28].

Let (G, k) be a yes instance of PARTIAL GRUNDY COLORING, where G is a d -degenerate graph on n vertices, and W be a small witness set of size at most k^2 . As $(G[W], k)$ must be a yes-instance of the problem, there exists an ordering of the vertices such that when we apply *any-available* greedy rule, it uses at least k colors. Let \hat{c} be this proper coloring of $G[W]$. The tuple $(W_i := \{v \in W \mid \hat{c}(v) = i\})_{i \in [k]}$ is called a *k-partial Grundy witness* for G . Now we apply the color-coding step of the algorithm. That is, we color the vertices of G using k colors independently and uniformly at random, and let Z_1, \dots, Z_k be the color classes of this coloring. The probability that for each $i \in [k]$, $W_i \subseteq Z_i$, is k^{-k^2} . Notice that since G is a d -degenerate graph, we have that $G_i = G[Z_i]$, for each $i \in [k]$, is d -degenerate. Now we exploit this fact and apply the independence covering lemma of Lokshtanov et al. [28]. That is given as input (G_i, k^2) , in time $2^{\mathcal{O}(dk^2)} n^{\mathcal{O}(1)}$ it produces a family \mathcal{F}_i of independent sets of G_i , of size $2^{\mathcal{O}(dk^2)} \cdot \log n$. Furthermore, given any independent set I of G_i of size at most k^2 ,

there exists an independent set $F \in \mathcal{F}_i$, such that $I \subseteq F$ (F covers I). In particular, we know that there is a set $F_i \in \mathcal{F}_i$ that covers W_i . So, the algorithm just enumerates each tuple (F_1, \dots, F_k) of $\mathcal{F}_1 \times \dots \times \mathcal{F}_k$ and checks whether (F_1, \dots, F_k) is a k -partial Grundy coloring of $G[F_1 \cup \dots \cup F_k]$. If (G, k) is a yes instance, our algorithm is successful with probability k^{-k^2} . Moreover, we can convert the described randomized algorithm to a deterministic one by using the standard derandomization technique of “universal sets” [17, 31]. Some remarks are in order; it can be shown that each of $|W_i| \leq k$, and hence we can call the independence covering lemma on (G_i, k) , resulting in an improved running time of $2^{\mathcal{O}(dk^2 \log k)} \cdot n^{\mathcal{O}(1)}$. Aboulker et al. [1] proved that PARTIAL GRUNDY COLORING on $K_{t,t}$ -free graphs is FPT, which includes t -degenerate graphs. Aboulker et al. did not explicitly mention the running time, but their running time is at least $2^{k^t} n$. Our new algorithm improves over this. For general instances, we do not have a bound on the degeneracy of the input graph. However, we can achieve this by using our new structural result.

► **Theorem 2 (Structural result).** *There is a polynomial-time algorithm that given a graph G and a positive integer k , does one of the following:*

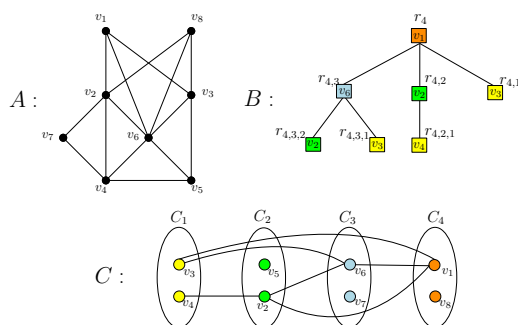

- (i) *Correctly concludes that (G, k) is a yes-instance of PARTIAL GRUNDY COLORING, or*
- (ii) *Outputs at most $2k^3$ induced bicliques A_1, \dots, A_ℓ in G such that the following holds. For any $v \in V(G)$, the degree of v in $G - F$ is at most k^3 , where F is the union of the edges in the above bicliques.*

The structural result (Theorem 2) is one of our main technical contributions. Next, we show how to design an algorithm for PARTIAL GRUNDY COLORING using Theorem 2. We follow the same steps as for the one described for the degenerate case. That is, we have color classes Z_i s and they contain the respective W_i s (the part of the small witness set W). Now, to design a family of independent sets in $G_i = G[Z_i]$, we do as follows. Let (L_j, R_j) be a bipartition of A_j , for each $j \in [\ell]$. Observe that any independent set I (in particular of G_i) intersects L_j or R_j , but *not both*, for any $j \in [\ell]$. Thus, we first guess whether W_i intersects L_j , R_j or none. Let this be given by a function $f_i : [\ell] \rightarrow \{L, R, N\}$, that is, if $f_i(j) = L$, then $W_i \cap L_j = \emptyset$, if $f_i(j) = R$, then $W_i \cap R_j = \emptyset$, else $W_i \cap (L_j \cup R_j) = \emptyset$. Taking advantage of this property, for each guess of which of L_j or R_j is not contained in W_i , we delete the corresponding set (which is one of L_j or R_j , for each $j \in [\ell]$) from G_i . We call the resulting graph $G_i^{f_i}$. This implies that for any f_i , in $G_i^{f_i}$ we delete all edges of F (where F is the union of edges in the bicliques). Hence, the maximum degree of $G_i^{f_i}$ is at most k^3 , and therefore it has degeneracy at most k^3 . Now using the independence covering step of the algorithm for degenerate graphs, we can finish the algorithm. The proof of Theorem 2 is obtained by carefully analyzing the reason for the failure of a greedy algorithm.

Our next result is an affirmative answer to Question 2.

► **Theorem 3.** *For any fixed $i, j \in \mathbb{N}$, there is an FPT algorithm that given a graph G and a positive integer k , decides if there is Grundy coloring of G using at least k colors.*

For our algorithm, we use a reinterpretation of the problem which is based on the existence of a *small witness*. Gyarfas et al. [22], and Zaker [38] independently showed that a given instance (G, k) of GRUNDY COLORING is a yes-instance if and only if there is a vertex subset W of size at most 2^{k-1} , such that $(G[W], k)$ is also a yes-instance of the problem. The existence of this small induced subgraph directly yield an XP algorithm for the problem [38]. Using characterizations of [22, 38] and basic Grundy coloring properties, we can reduce GRUNDY COLORING to finding a homomorphic image, satisfying some independence constraints, of some *specific labeled trees* (see Fig. 1, where different parts of it will be

■ **Figure 1** Illustration of a labelled homomorphism $\omega : V(T_4) \rightarrow V(G)$, where the graph is shown in part (i), T_4 with $V(T_4) = \{r_4, r_{4,3}, r_{4,2}, r_{4,1}, r_{4,3,2}, r_{4,3,1}, r_{4,2,1}\}$ is shown in part (ii), and a relation to Grundy coloring is illustrated in part (iii). Here, $\omega(r_4) = v_1, \omega(r_{4,3}) = v_6, \omega(r_{4,2}) = v_2, \omega(r_{4,1}) = v_3, \omega(r_{4,3,2}) = v_2, \omega(r_{4,3,1}) = v_3, \text{ and } \omega(r_{4,2,1}) = v_4$.

discussed, shortly). Let the pair (T, ℓ) denote a rooted tree T together with a labeling function $\ell : V(T) \rightarrow [k]$. Given (T, ℓ) and a graph G , a function $\omega : V(T) \rightarrow V(G)$ is a *labelled homomorphism* if: i) for each $\{u, v\} \in E(T)$, we have $\{\omega(u), \omega(v)\} \in E(G)$, and ii) for $u, v \in V(T)$, if $\ell(u) \neq \ell(v)$, then $\omega(u) \neq \omega(v)$. In particular, we will reduce the problem to the following.

CONSTRAINED LABEL TREE HOMOMORPHISM (CLTH) **Parameter:** $|V(T)|$

Input: A host graph G and $(T, \ell : V(T) \rightarrow [k])$, where T is a tree.

Question: Does there exist a labeled homomorphism $\omega : V(T) \rightarrow V(G)$ such that for any $z \in [k]$, $W_i = \{\omega(t) \mid t \in V(T) \text{ and } \ell(t) = i\}$ is an independent set in G ?

Now our goal is to identify ω (and thus the witness set W). The first step of our algorithm will be to use the color-coding technique of Alon-Yuster-Zwick [2] to ensure that the labeling requirement of the graph homomorphism ω is satisfied. To this end, we randomly color the vertices of G using k colors, where we would like the random coloring to ensure that for each $z \in [k]$, all the vertices in W_z are assigned the color z . Let X_1, X_2, \dots, X_k be the color classes in a coloring that achieves the above property. Our objective will be to find ω such that vertices of T that are labeled $z \in [k]$ are assigned to vertices in X_z .

Our next challenge is to find a homomorphism that additionally satisfies the independence condition. That is, vertices of the same label in T are assigned to an independent set in G . Note that the number of potential ω s that satisfy our requirements can be very huge; however, we will be able to carefully exploit $K_{i,j}$ -freeness to design a dynamic programming-based algorithm to identify one such ω (and thus the set W). Our approach here is inspired by dynamic programming in the design of FPT algorithms based on computations of “representative sets” [19,30]. However, this inspiration ends here, as to apply known methods we need to have an underlying family of sets that form a matroid. Unfortunately, we do not have any matroid structure to apply the known technique. Here, we exploit the fact that we have a specific labeled tree (T, ℓ) and a $K_{i,j}$ -free graph. Next we define the specific trees that we will be interested in (see Fig. 1, (ii)).

► **Definition 4.** For each $k \in \mathbb{N} \setminus \{0\}$, we (recursively) define a pair $(T_k, \ell_k : V(T_k) \rightarrow [k])$, called a k -Grundy tree, where T_k is a tree and ℓ_k is a *labelling* of $V(T_k)$, as follows :

1. $T_1 = (\{r_1\}, \emptyset)$ is a tree with exactly one vertex r_1 (which is also its root), and $\ell_1(r_1) = 1$.
2. Consider any $k \geq 2$, we (recursively) obtain T_k as follows. For each $z \in [k-1]$, let (T_z, ℓ_z) be the z -Grundy tree with root r_z . We assume that for distinct $z, z' \in [k-1]$, T_z and

$T_{z'}$ have no vertex in common, which we can ensure by renaming the vertices.¹ We set $V(T_k) = (\cup_{z \in [k-1]} V(T_z)) \cup \{r_k\}$ and $A(T_k) = (\cup_{z \in [k-1]} A(T_z)) \cup \{(r_k, r_z) \mid z \in [k-1]\}$. We set $\ell_k(r_k) = k$, and for each $z \in [k-1]$ and $t \in V(T_z)$, we set $\ell_k(t) = \ell_z(t)$. For $v \in V(T_k)$, $\ell_k(v)$ is the *label* of v in (T_k, ℓ_k) , and the elements in $[k]$ are *labels* of T_k .

Observe that the label of a vertex $t \in V(T)$ is the depth of the subtree rooted at t (the depth of a leaf is 1). In particular, the leaves are assigned the label 1, and when they are deleted, we get vertices with the label 2 as leaves, and so on. This allows us to do a bottom-up dynamic programming over T_k . Roughly speaking, for each $z \in [k]$, we solve the special labelled tree homomorphism from $\omega_z : V(T_z) \rightarrow X_1 \cup X_2 \dots \cup X_z$, where the root of T_z is mapped to a fixed vertex $v \in X_z$ as follows: instead of having all potential choices for ω_z (or $W_z = \{\omega_z(t) \mid t \in V(T_z)\}$), we find enough representatives, that will allow us to replace W_z by something that we have stored. It is a priori not clear that such representative sets of small size exist and furthermore, even if they exist, how to find them. The existence and computation of small representative sets in this setting is our main technical contribution for GRUNDY COLORING.

We heavily exploit the $K_{i,j}$ -freeness in our “representative set” computation. Very roughly stating, while we have computed required representatives for W_z , and wish to build such a representatives for W_{z+1} , by exploiting $K_{i,j}$ -freeness, we either find a small hitting set or a large sub-family of pair-wise disjoint sets. In the former case, we can split the family and focus on the subfamily containing a particular vertex from the hitting set and obtain a “representative” for it (and then take the union over such families). In the latter case, we show that we are very close to satisfying the required property, except for the sets containing vertices from an appropriately constructed small set S of vertices. The construction of this *small* set S is crucially based on the $K_{i,j}$ -freeness of the input graph. Once we have the set S , we can focus on sets containing a vertex from it and compute “representatives” for them.

Again, using standard hash functions, we can obtain a deterministic FPT algorithm for the problem by derandomizing the color coding based step [2, 31].

2 Preliminaries

Generic Notations. We denote the set of natural numbers by \mathbb{N} . For $n \in \mathbb{N}$, $[n]$ denotes the set $\{1, 2, \dots, n\}$. For a function $f : X \rightarrow Y$ and $y \in Y$, $f^{-1}(y) := \{x \in X \mid f(x) = y\}$.

For standard graph notations not explicitly stated here, we refer to the textbook of Diestel [13]. For a graph G , we denote its vertex and edge set by $V(G)$ and $E(G)$, respectively. Also, if the context is clear, we will use n and m to denote the numbers $|V(G)|$ and $|E(G)|$, respectively. The neighborhood of a vertex v in a graph G is the set of vertices that are adjacent to v in G , and we denote it by $N_G(v)$. The degree of a vertex v is the size of its neighborhood in G , and we denote it by $d_G(v)$. For a set of vertices $S \subseteq V(G)$, we define $N_G(S) = (\cup_{v \in S} N(v)) \setminus S$. When the graph is clear from the context, we drop the subscript G from the above notations. For $X \subseteq V(G)$, the induced subgraph of G on X , denoted by $G[X]$, is the graph with vertex set X and edge set $\{\{u, v\} \mid u, v \in X \ \& \ \{u, v\} \in E(G)\}$. Also, $G[V(G) \setminus X]$ is denoted by $G - X$. For $v \in V(G)$, we use $G - v$ to denote $G - \{v\}$ for ease of notation. For an edge subset $F \subseteq E(G)$, $G - F$ is the graph with vertex set $V(G)$ and edge set $E(G) \setminus F$. A bipartite graph $G = (A \uplus B, E)$ is called a *biclique* if every vertex in A

¹ For the sake of notational simplicity we will not explicitly write the renaming of vertices used to ensure pairwise vertex disjointness of the trees. This convention will be followed in the relevant section.

is adjacent to every vertex in B . We assume that A and B are both non-empty sets. For $d \in \mathbb{N}$, a graph is d -degenerate if each of its subgraphs has a vertex of degree at most d . For terminologies related to parameterized complexity, see the textbook of Cygan et al. [11].

3 FPT Algorithm for Partial Grundy Coloring

Consider a graph G and an integer $k \in \mathbb{N} \setminus \{0\}$. For a (not necessarily proper) coloring $\chi : V(G) \rightarrow [k]$, for simplicity, we sometimes write χ as the ordered tuple $(\chi^{-1}(1), \chi^{-1}(2), \dots, \chi^{-1}(k))$. Recall that a proper coloring of a graph is a coloring of its vertices so that for none of its edges, the two endpoints of it are of the same color. Also, a k -partial Grundy coloring of G is a proper coloring $c : V(G) \rightarrow [k]$, such that for each $i \in [k]$, there is a vertex $v \in V(G)$ with: (i) $c(v) = i$ and (ii) for every $j \in [i - 1]$, there is $u \in N_G(v)$ with $c(u) = j$.

We will begin with some definitions and results that will be useful in obtaining our main structural result (Theorem 2) and our FPT-algorithm (Theorem 1).

Observe that given a k -partial Grundy coloring of an induced subgraph \widehat{G} of a graph G , we can extend this coloring to a partial Grundy coloring of the whole graph G using at least k colors by greedily coloring the uncolored vertices of $G - V(\widehat{G})$. The following observation will be particularly useful when we work with a small “witness”.

► **Observation 5.** *Given a graph G , an induced subgraph \widehat{G} of G , and a partial Grundy coloring of \widehat{G} using k colors, we can find a partial Grundy coloring of G using at least k colors in linear time.*

Proof. Let $\widehat{c} : V(\widehat{G}) \rightarrow [k]$ be a partial Grundy coloring of \widehat{G} with exactly k colors. We construct a partial Grundy coloring $c : V(G) \rightarrow \mathbb{N}$ of G using at least k colors as follows. For each vertex $v \in V(\widehat{G})$, set $c(v) := \widehat{c}(v)$. Let $v_1, v_2, \dots, v_{n'}$ be an arbitrarily fixed order of vertices in $V(G) \setminus V(\widehat{G})$. Let $G_0 = \widehat{G}$, and for each $p \in [n']$, $G_p = G[V(\widehat{G}) \cup \{v_1, v_2, \dots, v_p\}]$. We iteratively create a partial Grundy coloring c_p of G_p using at least k colors (in increasing values of p) as follows. Note that $c_0 = \widehat{c}$ is already a partial Grundy coloring of G_0 that uses at least k colors. Consider $p \in [n'] \setminus \{0\}$, and assume that we have already computed a partial Grundy coloring $c_{p-1} : V(G_{p-1}) \rightarrow \mathbb{N}$ of G_{p-1} that uses $k' \geq k$ colors. For each $z \in [k']$, let $V_z = c_{p-1}^{-1}(z)$. For each $v \in V(G_{p-1})$, we set $c_p(v) := c_{p-1}(v)$. If the vertex v_p has a neighbor in each of the sets $V_1, V_2, \dots, V_{k'}$, i.e., if for each $z \in [k']$, $N_G(v_p) \cap V_z \neq \emptyset$, then set $c_p(v_p) := k' + 1$. Otherwise, let $z^* \in [k']$ be the smallest number such that $N_G(v_p) \cap V_{z^*} = \emptyset$, and set $c_p(v_p) := z^*$. Notice that by construction, c_p is a partial Grundy coloring of G_p using at least k colors. From the above discussions, $c_{n'}$ is a partial Grundy coloring of $G = G_{n'}$ using at least k colors. ◀

► **Definition 6.** Consider a graph G and an integer $k \in \mathbb{N} \setminus \{0\}$. A sequence of pairwise disjoint independent sets (Q_1, Q_2, \dots, Q_k) of G is a k -partial Grundy witness if the following holds. For any $i \in [k]$, there is $v \in Q_i$ such that for all $j \in [i - 1]$, $Q_j \cap N_G(v) \neq \emptyset$. The vertex v is called a *dominator* in Q_i .

► **Observation 7.** *Given a graph G and an integer k , let (Q_1, Q_2, \dots, Q_k) be a k -partial Grundy witness. Suppose Y_1, Y_2, \dots, Y_k are pairwise disjoint independent sets in G such that $Q_i \subseteq Y_i$, for all $i \in [k]$. Then (Y_1, Y_2, \dots, Y_k) is also a k -partial Grundy witness of G .*

A k -partial Grundy witness (X_1, X_2, \dots, X_k) is *small* if for each $i \in [k]$, $|X_i| \leq k - i + 1$. Next, we prove the existence of a small k -partial Grundy witness. This result is the same as the one obtained by Effantin et al. [15]; however, it is stated slightly differently for convenience.

► **Observation 8** (♠).² Let G be a graph and k be an integer, where G has a k -partial Grundy witness (Q_1, \dots, Q_k) . Then, there exists a k -partial Grundy witness (X_1, X_2, \dots, X_k) such that for each $i \in [k]$, $X_i \subseteq Q_i$ and $|X_i| \leq k - i + 1$.

The remainder of this section is organized as follows. In Section 3.1 we prove our key structural result (Theorem 2), and then obtain our algorithm in Section 3.2. (Readers who may want to read the algorithm directly, may skip Section 3.1.)

3.1 Degree Reduction: Proof of Theorem 2

The objective of this section is to prove Theorem 2. The proof of this theorem is based on the following lemma for bipartite graphs.

► **Lemma 9.** *There is a polynomial-time algorithm that, given a bipartite graph $G = (A \uplus B, E)$ and a positive integer k , does one of the following.*

- (i) *Correctly concludes that the partial Grundy coloring of G is at least k .*
- (ii) *Outputs at most $4k - 4$ bicliques A_1, \dots, A_ℓ in G such that for any $v \in V(G)$, degree of v in $G - F$ is at most k^2 , where F is the union of the edges in the above bicliques.*

We first give a proof of Theorem 2 based on the above lemma.

Proof of Theorem 2. Consider a graph G and a positive integer k . First, we run the first-fit greedy algorithm for proper coloring of the graph G for an arbitrarily fixed ordering (v_1, v_2, \dots, v_n) of $V(G)$. For each j , let C_j be the vertices colored j and k' be the largest integer such that $C_{k'} \neq \emptyset$. Note that $(C_1, \dots, C_{k'})$ is a proper coloring of G . Also, for any $j \in [k']$ and any vertex v in C_j , v has a neighbor in $C_{j'}$ for all $j' \in [j - 1]$. If $k' \geq k$, then $(C_1, \dots, C_{k'})$ is a partial Grundy coloring of G using at least k colors, and thus we can correctly report it.

Next, we assume that $k' < k$. Note that all the edges in G are between the color classes $C_1, \dots, C_{k'}$. Now for every distinct $i, j \in [k']$, where $i < j$, we apply Lemma 9 on $(H_{i,j} = (C_i \uplus C_j, E(C_i, C_j)), k)$, where $E(C_i, C_j)$ is the set of edges in G between the color classes C_i and C_j . Our algorithm will declare that G has a partial Grundy coloring using at least k colors if we get the output given in statement (i) in any of the $\binom{k'}{2}$ applications of Lemma 9. Otherwise, for every distinct $i, j \in [k']$, where $i < j$, let $A_{i,j,1}, \dots, A_{i,j,\ell_{i,j}}$ be the bicliques, we get as output by the algorithm in Lemma 9 on $(H_{i,j}, k)$. Note that $\ell_{i,j} \leq 4k - 4$. Now our algorithm will output the bicliques $\{A_{i,j,r} : 1 \leq i < j \leq k', r \in [\ell_{i,j}]\}$. As $k' < k$ for all $1 \leq i < j \leq k'$, the number of bicliques we output is at most $(4k - 4) \binom{k'}{2}$, that is, at most $2k^3$. Since any vertex in a color class C_r has neighbors in other color classes, for $r \in [k']$ and we applied Lemma 9 for every pair of color classes, the degree of v in $G - F$ is at most k^3 for any $v \in V(G)$, where F is the union of the edges in the above bicliques. This completes the proof of the theorem. ◀

We now focus on the proof of Lemma 9. Toward this, we give a polynomial time procedure that, given a bipartite graph $G = (L \uplus R, E)$ and a positive integer k , either concludes that the input graph has partial Grundy coloring using at least k colors or it outputs at most $2k - 2$ bicliques A_1, \dots, A_ℓ in G such that for any $v \in L$, $d_{G-F}(v) \leq k^2$, where F is the union of the edges in the above bicliques. That is, removal of the edges of these bicliques bounds the degree of each vertex in L by k^2 . We get the proof of Lemma 9 by applying this algorithm once for L and then for R .

² The proofs of the result marked with ♠ can be found in the full version of the paper on arXiv.

Overview of our algorithm. Let $\sigma = v_1, v_2, \dots, v_n$ be an ordering of the vertices in L in non-increasing order of their degree in G . The algorithm constructs *specific* color classes Q_1, Q_2, \dots, Q_r in this order so that $(C_1 = Q_r, C_2 = Q_{r-1}, \dots, C_r = Q_1)$ is an r -partial Grundy witness, where $|Q_j| \leq j$. Furthermore, we will construct sets $B_i, i \in [r]$, which will be used to construct the bicliques. Notice that if we obtain $r \geq k$, then we will be able to conclude that G has a partial Grundy coloring using at least k colors. Let $Q_1 = \{v_1\}$ and in our construction v_1 will be the dominator in Q_1 (and our construction needs to ensure this property; see Definition 6). Consider the construction of Q_2 . Let i be the smallest index in $\{2, 3, \dots, n\}$ for which there is a vertex $w \in N_G(v_1)$ such that v_i is not adjacent to w . Then, we set $Q_2 = \{v_i, w\}$, and designate v_i as the dominator in color class $C_{r-1} = Q_2$. Notice that all the vertices in $B_1 = \{v_2, \dots, v_{i-1}\}$ are adjacent to all the vertices in $N_G(v_1)$, and hence they together form a biclique (with bipartition B_1 and $N_G(v_1)$). This property will be extended in building each Q_j s and the required bicliques.

For the construction of Q_j , we consider *unprocessed vertices* (i.e., the vertices that do not belong to the previously constructed sets, i.e., to $Q_1 \cup B_1 \cup \dots \cup Q_{j-1} \cup B_{j-1}$) as follows. We would now like to choose an unprocessed vertex $v_{i'}$, so that we can make $v_{i'}$ the dominator of Q_j , and additionally, for each $j' \in [j-1]$, we can include a neighbor of the dominator from $Q_{j'}$ to the set Q_j . Note for us to do the above, we need to ensure that the vertices that we add to Q_j is an independent set in G , and all the vertices that we want to include in the set Q_j are outside $Q_1 \cup \dots \cup Q_{j-1}$. That is, among the unprocessed vertices, we choose the first vertex $v_{i'}$ with the following property: for each $j' \in [j-1]$, we have a neighbor $w_{j'}$ of the previously constructed dominator in $Q_{j'}$ such that $w_{j'} \notin Q_1 \cup \dots \cup Q_{j-1}$ and $(v_{i'}, w_{j'}) \notin E(G)$; we set $Q_j = \{v_{i'}, w_1, \dots, w_{j-1}\}$. We would like to mention that all the dominators we construct are from the bipartition L and hence $\{w_1, \dots, w_{j-1}\} \subseteq R$. This will imply that Q_j is an independent set.

Moreover, by the choice of $v_{i'}$ as the smallest vertex with the desired property, it follows that for any vertex v_r that appears before $v_{i'}$ in the order σ and $v_r \notin P = Q_1 \cup \dots \cup Q_{j-1}$, the vertex v_r is adjacent to all the vertices in $N(x_{j'}) \setminus P$, where $x_{j'}$ is the dominator in $Q_{j'}$, for some $j' \in [j-1]$. Then we add v_r to $B_{j'}$. Note that in the above process, we still maintain the biclique property, by explicitly ensuring that $B_{j'}$ and $N(x_{j'}) \setminus (Q_1 \cup \dots \cup Q_{j-1} \cup Q_j)$ forms a biclique.

Description of the algorithm. We give a pseudocode of our algorithm in Algorithm 1. First, the algorithm initializes the sets B_i and Q_i to be the empty set, for all $i \in [k]$ (see Algorithm 1). Let $\sigma = v_1, v_2, \dots, v_n$ be an ordering of the vertex set L in the non-increasing order of their degrees. Now, we want to construct the color classes Q_1, Q_2, \dots, Q_k , iteratively, such that $(C_1, C_2, \dots, C_k) = (Q_k, Q_{k-1}, \dots, Q_1)$ is a k -partial Grundy witness. At line 3, we initialize with $Q_1 := \{v_1\}$, $x_1 := v_1$, and fix the index $q = 2$. Here, Q_1 will be the color class C_k with dominator vertex x_1 . Now consider an iteration of the **while** loop. The algorithm checks if the set $L \setminus (\bigcup_{j \in [q-1]} (Q_j \cup B_j))$ is non-empty and executes the **while** loop. At this point we have constructed sets Q_1, \dots, Q_{q-1} such that $(Q_{q-1}, Q_{q-2}, \dots, Q_1)$ is a $(q-1)$ -partial Grundy witness such that each x_i is a dominator vertex in Q_i . Let v_r be the first unprocessed vertex in L and $P = \bigcup_{j \in [q-1]} Q_j$ by Lines 5 and 6. Now, we check if we can construct the current color class Q_q with vertex v_r as a dominator vertex, and for that, we need to add a neighbor w_j (which is not added to any $Q_{i'}$ before) for each already discovered dominator x_j such that w_j is non-adjacent to v_r . Now, if there exists some $j \in [q-1]$ such that each neighbor of x_j is a neighbor of v_r , then we will not be able to construct Q_q with vertex v_r in it. In that case, we choose such a value j and add v_r to B_j (See

5:10 Parameterized Saga of First-Fit and Last-Fit Coloring

22 |   |   | and  $S_j$  be the graph induced on  $N[x_j]$ , where  $P = \bigcup_{j \in [q-1]} Q_j$ .
23 |   | Output  $A_1, \dots, A_{q-1}$  and  $S_1, \dots, S_{q-1}$ 
24 end

```

Line 8). Here, notice that v_r is adjacent to all the vertices $N(x_j) \setminus P$. We will maintain this property for all the vertices added to B_j , i.e., B_j union $N(x_j) \setminus \bigcup_i Q_i$ forms a biclique. Now consider the case that the condition in the **if** statement in Line 7 is false. Then, we choose a vertex $w_j \in N(x_j) \setminus (P \cup N(v_r))$ for each $j \in [q-1]$, by line 11 and set the vertex v_r as the dominator for Q_q , that is, $Q_q := \{x_q\} \cup \{w_1, \dots, w_{q-1}\}$, at Line 13. Notice that Q_q is an independent set because there is no edge between x_1 and a vertex in $\{w_1, \dots, w_{q-1}\}$, and $\{w_1, \dots, w_{q-1}\}$ is a subset of R , the right part of the bipartition of G . We repeat the iteration until one of the **while** loop conditions at line 4 fails. Next, if $q \geq k + 1$, we conclude that G has a partial Grundy coloring using k colors by line 18, because (Q_{q-1}, \dots, Q_1) is a $(q-1)$ -partial Grundy witness, where $q-1 \geq k$. Otherwise, by line 20, let A_j be the graph induced on $B_j \cup (N(x_j) \setminus P)$ and S_j be the graph induced on $N[x_j]$, for each $j \in [q-1]$. Recall that A_j is a biclique. It is easy to see that S_j is a biclique, because G is a bipartite graph. At line 21, the algorithm outputs the set of graphs A_1, \dots, A_{q-1} and S_1, \dots, S_{q-1} .

The number of iterations of the **while** loop is at most n and each step in the algorithm takes polynomial time, the total running time of the algorithm is polynomial in the input size. Next, we prove the correctness of the algorithm.

► **Lemma 10.** *Algorithm 1 is correct.*

Proof. Let q^* be the value of q at the end of the algorithm. To prove the correctness of the algorithm, first, we prove the following claim.

■ **Figure 2** Here the vertex $v \in B_i$ in the biclique A_i (right side). The number of neighbors of v outside A_i (blue edges) cannot be more than $|P|$ as $d_G(v) \leq d_G(x_i) = |N_G(x_i)|$ and v has $|N(x) \setminus P|$ neighbours in the biclique A_i .

▷ **Claim 11.** The following statements are true.

- (i) For each $i \in [q^* - 1]$, Q_i is an independent set and $Q_i \neq \emptyset$.
- (ii) For each $i \in [q^* - 1]$ and $j \in [i - 1]$, $N(x_j) \cap Q_i \neq \emptyset$.
- (iii) For each $i \in [q^* - 1]$ and $v \in B_i$, v is adjacent to all the vertices in $N(x_i) \setminus (\bigcup_{j \in [q^* - 1]} Q_j)$ and $d_G(v) \leq d_G(x_i)$.

Proof. We prove the statements by induction on i . The base case is when $i = 1$. Clearly, $Q_1 = \{x_1\}$ and hence statement (i) is true. Statement (ii) is vacuously true. Next, we prove statement (iii). Notice that in any iteration of the **while** loop, in Step 8, we may add a vertex v_r to B_1 . If this happens, then we know that $N(x_1) \subseteq P \cup N(v_r)$, where P is a subset of $\bigcup_{j \in [q^* - 1]} Q_j$. That is, all the vertices in $N(x_1) \setminus P$ are adjacent to v_r . This implies that v_r is adjacent to all the vertices in $N(x_1) \setminus (\bigcup_{j \in [q^* - 1]} Q_j)$. Since x_1 is the vertex with the maximum degree, we have that $d_G(v_r) \leq d(x_1)$.

Next, for the induction step, we assume that the induction hypothesis is true for $i - 1$, and we will prove that the hypothesis is true for i . Consider the iteration h^* of the **while** loop when $q = i$ and Steps 11-14 is executed. Let v_r be the vertex mentioned in Step 5 during that iteration. The vertices w_1, \dots, w_{q-1} belongs to R (the right side of the bipartition of G) and hence $\{w_1, \dots, w_{q-1}\}$ is an independent set. Also, notice that each w_j does not belong to $N(v_r)$ (See Step 11). Hence, $Q_q := \{v_r\} \cup \{w_1, \dots, w_{q-1}\}$ is an independent set and $Q_q \neq \emptyset$. Thus, we proved statement (i). Again, notice that $w_j \in N(x_j)$ for all $j \in [q - 1]$ (See Step 11). Thus, statement (ii) follows. Next, we prove statement (iii), which is similar to the proof of it in the base case. Notice that in any iteration of the while loop (after the iteration h^*), in Step 8, we may add a vertex $v_{r'}$ to B_i . If this happens, then we know that $N(x_i) \subseteq P \cup N(v_{r'})$, where P is a subset of $\bigcup_{j \in [q-1]} Q_j$. That is, all the vertices in $N(x_i) \setminus P$ are adjacent to $v_{r'}$. This implies that $v_{r'}$ is adjacent to all the vertices in $N(x_i) \setminus (\bigcup_{j \in [q-1]} Q_j)$. Since $x_i \in Q_i$, considered in iteration h^* , $d_G(v_{r'}) \leq d_G(x_i)$ (See Step 5). This completes the proof of the claim. ◁

Now suppose $q^* \geq k + 1$. Then, by Statements (i) and (ii) in Claim 11, we get that (Q_k, \dots, Q_1) is a partial Grundy coloring of the graph induced on $\bigcup_{j \in [q^* - 1]} Q_j$. Thus, if the algorithm executes Step 18, then it is correct because of Observation 5.

Now suppose $q^* \leq k$. Then the algorithm executes Step 21 and outputs the sets $A_1, \dots, A_{q^* - 1}$ and $S_1, \dots, S_{q^* - 1}$. Statement (iii) in Claim 11 implies that each A_j is a biclique in G , where $j \in [q^* - 1]$. Also, note that S_j is a biclique in G as it is induced on the set $N[x_j]$, for each $j \in [q^* - 1]$. Let F be the union of the edges in the bicliques

5:12 Parameterized Saga of First-Fit and Last-Fit Coloring

A_1, \dots, A_{q^*-1} and S_1, \dots, S_{q^*-1} . Next, we prove that for any $v \in L$, $d_{G-F}(v) \leq k^2$. Let $X = \{x_1, \dots, x_{q^*-1}\}$. It is easy to see that $|Q_j| \leq k$ and $L \cap Q_j = \{x_j\} \subseteq X$, for all $j \in [q^* - 1]$ (See Steps 11-13). Hence, $|\bigcup_{j \in [q^*]} Q_j| \leq k^2$. Let v be an arbitrary vertex in L . Note that if $v \in X$, the degree of v in $G - F$ is zero (by the definition of S_j). Next, suppose that $v \in L \setminus X$. Since $L \subseteq \bigcup_{j \in [q^*-1]} (Q_j \cup B_j)$ (this is the condition for **while** loop to exit) and $L \cap Q_j \subseteq X$ for all $j \in [q^* - 1]$, v belongs to B_i for some $i \in [q^* - 1]$. By statement (iii) in Claim 11, v is adjacent to all the vertices in $N(x_i) \setminus (\bigcup_{j \in [q^*-1]} Q_j)$ and $d_G(v) \leq d_G(x_i)$. Recall that the biclique A_i is the graph with bipartition B_i and $N(x_i) \setminus (\bigcup_{j \in [q^*-1]} Q_j)$. Moreover $v \in B_i$ and $d_G(v) \leq d_G(x_i) = |N_G(x_i)|$. This implies that the number of neighbors of v that does not belong to A_i is at most $|\bigcup_{j \in [q^*-1]} Q_j|$, which is upper bounded by k^2 . Therefore, the degree of v in $G - F$ is at most k^2 . See Figure 2 for an illustration. This concludes the proof. \blacktriangleleft

3.2 FPT Algorithm for Partial Grundy Coloring

In this section, we design an FPT algorithm \mathcal{A} for PARTIAL GRUNDY COLORING when the input has a structure dictated the second item of Lemma 9. Then, we explain how to get an FPT algorithm for PARTIAL GRUNDY COLORING on general graphs using \mathcal{A} and Theorem 2. Moreover, our algorithm \mathcal{A} will provide a faster algorithm for PARTIAL GRUNDY COLORING on d -degenerate graphs, improving the result in [1]. Toward the first task, we define the following problem.

STRUCTURAL PARTIAL GRUNDY COLORING (SPGC)

Input: Positive integers $k, d, \ell \in \mathbb{N}$, a graph G , and ℓ bicliques A_1, \dots, A_ℓ in G such that $G - F$ is d -degenerate, where F is the union of the edges in the above bicliques.

Question: Decide if there is a partial Grundy coloring for G using at least k colors.

First, we design a randomized polynomial time algorithm \mathcal{A}_1 for SPGC with a success probability at least $(k(d+1))^{-2k^2-k} \cdot 2^{-\ell k}$. We increase the probability of success to a constant by running \mathcal{A}_1 multiple times. Finally, we explain the derandomization of our algorithm. Then we prove Theorem 1 using this algorithm and our structural result (Theorem 2). To design the algorithm \mathcal{A}_1 , we use the following result of Lokshtanov et al. [28].

► **Proposition 12** (Lemma 1.1. [28]). *There is a linear-time randomized algorithm that, given a d -degenerate graph H and an integer k , outputs an independent set Y such that for any independent set X in H with $|X| \leq k$, the probability that $X \subseteq Y$ is at least $\left(\binom{k(d+1)}{k} \cdot k(d+1)\right)^{-1}$.*

The algorithm \mathcal{A}_1 has the following steps.

1. Color all vertices in $V(G)$ uniformly and independently at random with colors from the set $[k]$. Let the obtained coloring be $\phi : V(G) \rightarrow [k]$, and $Z_i = \phi^{-1}(i)$, for each $i \in [k]$.
2. For each $i \in [\ell]$, let $A_i = (L_i \uplus R_i, E_i)$. For each $j \in [k]$ and $i \in [\ell]$, uniformly at randomly assign $P_{j,i} := L_i$ or $P_i := R_i$. That is, with probability $\frac{1}{2}$, $P_{j,i} := L_i$ and with probability $\frac{1}{2}$, $P_{j,i} := R_i$. Let $D_j = \bigcup_{i \in [\ell]} P_{j,i}$.
3. Now for each $j \in [k]$, we apply the algorithm in Proposition 12 for $(G[Z_j - D_j], k)$ to obtain an independent set Y_j .
4. If (Y_1, \dots, Y_k) is a k -partial Grundy witness of G , then output **Yes**, else, output **No**.

Since the algorithm in Proposition 12 runs in linear time, the algorithm \mathcal{A}_1 can be implemented to run in linear time because Z_1, \dots, Z_k is a partition of $V(G)$. Clearly, if the algorithm \mathcal{A}_1 outputs **Yes**, then G has a k -Partial Grundy witness and hence G has a partial Grundy coloring using at least k colors. We can prove that if G has a k -Partial Grundy witness the algorithm \mathcal{A}_1 outputs **Yes** with probability $(k(d+1))^{-2k^2-k} \cdot 2^{-\ell k}$.

Also, by running \mathcal{A}_1 , $3 \cdot (k(d+1))^{2k^2+k} 2^{\ell k}$ times and outputting **Yes** if at least one of the runs outputs a **Yes**, and outputs **No**, otherwise, we can boost the success probability to $2/3$, and thus obtain the following result.

► **Theorem 13.** *There is a randomized algorithm for SPGC running in time $\mathcal{O}((k(d+1))^{2k^2+k} \cdot 2^{\ell k} \cdot (m+n))$. In particular, if (G, k) is a no-instance then with probability 1 the algorithm outputs **No**; and if (G, k) is a yes-instance then with probability $2/3$ the algorithm outputs **Yes**.*

Theorem 2 and 13 imply the following theorem.

► **Theorem 14.** *There is a randomized algorithm for PARTIAL GRUNDY COLORING running in time $2^{\mathcal{O}(k^4)} n^{\mathcal{O}(1)}$. In particular, if (G, k) is a no-instance then with probability 1 the algorithm outputs **No**; and if (G, k) is a yes-instance then with probability $2/3$ the algorithm outputs **Yes**.*

Proof Sketch. First we run the algorithm mentioned in Theorem 2. If it concludes that G has a partial Grundy coloring with at least k colors, then we output **Yes**. Otherwise, we get at most $2k^3$ induced bicliques $A_1 \cdots, A_\ell$ in G such that the following holds. For any $v \in V(G)$, the degree of v in $G - F$ is at most k^3 , where F is the union of the edges in the above bicliques. That is the degeneracy of $G - F$ is at most k^3 . Then, we apply Theorem 13, and outputs accordingly. ◀

The derandomization of our algorithm can be found in the full version.

4 FPT Algorithm for Grundy Coloring on $K_{i,j}$ -free Graphs

This section aims to prove Theorem 3. Consider fixed $i, j \in \mathbb{N} \setminus \{0\}$, where $i \geq j$. Recall that a graph is $K_{i,j}$ -free if it does not contain a subgraph isomorphic to $K_{i,j}$. We call the special case of GRUNDY COLORING where the input graph is $K_{i,j}$ -free, $K_{i,j}$ -FREE GRUNDY COLORING. Let (G, k) be an instance of $K_{i,j}$ -FREE GRUNDY COLORING. We begin by intuitively explaining the flow of our algorithm.

Consider a Grundy coloring $c : V(G) \rightarrow [k']$ of G , where $k' \geq k$, and for each $z \in [k]$, $c^{-1}(z) \neq \emptyset$. Furthermore, for $z \in [k']$, let $C_z = c^{-1}(z)$. Let us focus on the first k color classes, and for $z \in [k]$, arbitrarily fix a vertex $v_z \in C_z$. (Note that v_z has a neighbor in $C_{z'}$, for each $z' \in [z-1]$.) We next intuitively describe construction, for each $z \in [k]$, a set W_z initialized to $\{v_z\}$ as follows. Basically, for each v_z , add an arbitrarily chosen neighbor of it in color class $C_{z'}$, for every $z' < z$. We do the above process exhaustively; whenever we add a vertex to a set W_z , we add an arbitrarily chosen neighbor of it from each color class $C_{z'}$ to $W_{z'}$, where $z' < z$. Then, let $W = \cup_{z \in [k]} W_z$; we will call such a set W a k -Grundy set for G and we will show that such a set of size at most 2^{k-1} exists (for yes instances). For $z \in [k]$, let $W_{\leq z} = \cup_{z' \in [z]} W_{z'}$ and $W_{> z} = \cup_{z' \in [k] \setminus [z]} W_{z'}$. Note that $c|_W$ is a k -Grundy coloring of $G[W]$. Also, we will show that G has a Grundy coloring using at least k colors if and only if some subgraph of G has a Grundy coloring using *exactly* k colors. We remark that the above result and the existence of W are the same as the results of Gyarfas et al. [22] and Zaker [38], although, for the sake of convenience, we state it here slightly differently. If we

■ **Figure 3** An illustration of a graph G that admits a 4-Grundy coloring (on the left) and a 4-Grundy-witness ω (on the right).

can identify all the vertices in W (or some other k -Grundy set), then we will be done. The first step of our algorithm will be to use the technique of color coding to randomly color the vertices of G using k colors so that, for each $z \in [k]$, $v \in W_z$ is colored z ; such a coloring will be a *nice coloring* and it will be denoted by χ .

The next step of our algorithm is inspired by the design of FPT algorithms based on computations of “representative sets” [19,30]. To this end, we will interpret W in a “tree-like” fashion. With this interpretation, in a bottom-up fashion, for each $z \in [k]$ and $v \in X_z$, we will compute a family $\mathcal{F}'_{z,v}$, so that, if $v \in W_z$, then there will be $W' \in \mathcal{F}'_{z,v}$ so that $W' \cup W_{>z}$ is also a k -Grundy set for G . We will now formalize the above steps.

Grundy Tree & Grundy Witness. We recall the Definition 4 from Section 1, and obtain some properties regarding it.

- **Observation 15 (♠).** For $k \in \mathbb{N} \setminus \{0\}$, for the k -Grundy tree (T_k, ℓ_k) , $|V(T_k)| = 2^{k-1}$.
- **Observation 16 (♠).** Consider $k \in \mathbb{N} \setminus \{0\}$ and the k -Grundy tree (T_k, ℓ_k) . We have $|\ell^{-1}(k)| = 1$ and for each $z \in [k-1]$, $|\ell^{-1}(z)| = 2^{k-z-1}$.

Next, we define the notion of k -Grundy witness in a graph G .

► **Definition 17.** Consider $k \in \mathbb{N} \setminus \{0\}$ and a graph G . A k -Grundy witness for G is a function $\omega : V(T_k) \rightarrow V(G)$, where (T_k, ℓ_k) is the k -Grundy tree, such that: 1) for each $z \in [k]$, $\{\omega(t) \mid t \in V(T_k) \text{ and } \ell_k(t) = z\}$ is an independent set in G , 2) for each $t, t' \in V(T_k)$, if $\ell_k(t) \neq \ell_k(t')$ then $\omega(t) \neq \omega(t')$, and 3) for each $(t, t') \in A(T_k)$, we have $\{\omega(t), \omega(t')\} \in E(G)$.

Recall that for $k \in \mathbb{N} \setminus \{0\}$, for the k -Grundy tree (T_k, ℓ_k) , T_k is the tree obtained by adding a root vertex r_k attached to the roots of (pairwise vertex disjoint) trees $T_{k-1}, T_{k-2}, \dots, T_1$, where for each $z \in [k-1]$, (T_z, ℓ_z) is the z -Grundy tree. We have the following observation.

► **Observation 18 (♠).** Consider $k \in \mathbb{N} \setminus \{0\}$, a graph G and a k -Grundy witness $\omega : V(T_k) \rightarrow V(G)$ for G . For each $z \in [k]$, $\omega|_{V(T_z)}$ is a z -Grundy witness for G .

The next observation is a partial Grundy counterpart of Observation 5.

► **Observation 19 (♠).** Consider a graph G , any induced subgraph \widehat{G} of it, and an integer $k \in \mathbb{N}$. If \widehat{G} has a Grundy coloring that uses exactly k colors, then G has a Grundy coloring that uses at least k colors.

In the following two lemmas, we show that the existence of a k -Grundy witness for a graph is equivalent to the graph admitting a Grundy coloring with at least k colors.

► **Lemma 20.** *For any $k \in \mathbb{N} \setminus \{0\}$ and a graph G , if G has a k -Grundy witness, then G has a Grundy coloring with at least k colors.*

Proof. Consider a graph G and any $k \in \mathbb{N} \setminus \{0\}$. For a k -Grundy witness $\omega : V(T_k) \rightarrow V(G)$ of G , let $\widehat{V}_\omega = \{\omega(t) \mid t \in V(T_k)\}$, and for each $z \in [k]$, let $\widehat{V}_{\omega,z} = \{\omega(t) \mid t \in V(T_k) \text{ and } \ell_k(t) = z\}$. Note that from item 2 of Definition 17, $\widehat{V}_{\omega,1}, \widehat{V}_{\omega,2}, \dots, \widehat{V}_{\omega,k}$ is a partition of \widehat{V}_ω , where none of the parts are empty. Let $c_\omega : \widehat{V}_\omega \rightarrow [k]$ be the function such that for each $z \in [k]$ and $v \in \widehat{V}_{\omega,z}$, we have $c_\omega(v) = z$.

For each $k \in \mathbb{N} \setminus \{0\}$ and a k -Grundy witness $\omega : V(T_k) \rightarrow V(G)$ of G , we will prove by induction (on k) that c_ω is Grundy coloring of $G[\widehat{V}_\omega]$ using k colors. The above statement, together with Observation 19, will give us the desired result.

The base case is $k = 1$, where T_1 has exactly one vertex, r_1 . For any 1-Grundy witness, ω of G , note that $c_\omega(\omega(r_1)) = 1$ is a Grundy coloring for $G[\{\omega(r_1)\}]$ using 1 color. Now for the induction hypothesis suppose that for some $\widehat{k} \in \mathbb{N} \setminus \{0, 1\}$, for each $0 < k < \widehat{k}$, the statement is true. Now we will prove the statement for $k = \widehat{k}$, and to this end, we consider a k -Grundy witness $\omega : V(T_k) \rightarrow [k]$, where r_k is the root of T_k . Recall that T_k is the tree obtained by adding a root vertex r_k attached to the roots of (pairwise vertex disjoint) trees $T_{k-1}, T_{k-2}, \dots, T_1$, where for each $z \in [k-1]$, (T_z, ℓ_z) is the z -Grundy tree, and T_z is rooted at r_z . Let $V' = \widehat{V}_\omega \setminus \widehat{V}_{\omega,k}$, and consider a vertex $v \in \widehat{V}_{\omega,z^*}$, where $z^* \in [k-1]$. We will argue that for each $z' \in [z^* - 1]$, $N_G(v) \cap \widehat{V}_{\omega,z'} \neq \emptyset$. Note that there must exist $z \in [k-1]$ and $t \in V(T_z)$ such that $\omega(t) = v$ and $\ell_z(v) = z^*$, and we arbitrarily choose one such z and t . Let $V_z = \{\omega(t) \mid t \in V(T_z)\}$. From Observation 18, $\omega_z = \omega|_{V(T_z)}$ is a z -Grundy witness for G . Thus, from our induction hypothesis, $c_{\omega_z} = c_\omega|_{V_z}$ is a Grundy coloring for $G[V_z]$. From the above we can conclude that for each $q' \in [z^* - 1]$, $N_G(v) \cap \widehat{V}_{\omega,q'} \neq \emptyset$. Now consider the vertex $\omega(r_k) = v_k^*$ and any $z \in [k-1]$. Note that $\ell_k(r_z) = z$ and from item 3 of Definition 17, we can obtain that $\{v_k^*, \omega(r_z)\} \in E(G)$. From the above discussions, we can obtain that c_ω is Grundy coloring of $G[\widehat{V}_\omega]$ using at least z colors. This concludes the proof. ◀

► **Lemma 21.** *For any $k \in \mathbb{N} \setminus \{0\}$ and a graph G , if G has a Grundy coloring with at least k colors, then G has a k -Grundy witness.*

Proof. Consider a Grundy coloring $c : V(G) \rightarrow [k']$ of G with $k' \geq k$ colors, and for each $q \in [k']$, let $C_q = c^{-1}(q)$. We construct a Grundy witness $\omega : V(T_k) \rightarrow V(G)$ by processing labels of T_k starting at k and iteratively proceeding to smaller labels as follows while maintaining the below invariants.

Pre-condition: When we begin processing a label $q \in [k-1]$, for each $t \in V(T_k)$ with $\ell_k(t) \geq q$, we have fixed the vertex $\omega(t)$.

Post-condition: After processing label $q \in [k]$, we have fixed, for each $t \in V(T_k)$ with $\ell_k(t) \geq q$, and $t' \in N_{T_k}[t]$, the vertex $\omega(t')$; and these are the only vertices in T_k for which the vertex in G assigned by ω is determined.

Note that the pre-condition is vacuously satisfied for $q = k$. Recall that T_k is the tree obtained by adding a root vertex r_k attached to the roots $r_{k-1}, r_{k-2}, \dots, r_1$ of (pairwise vertex disjoint) trees $T_{k-1}, T_{k-2}, \dots, T_1$, respectively, where for each $q \in [k-1]$, (T_q, ℓ_q) is a q -Grundy tree. Pick any vertex $v_k \in C_k$, and set $\omega(r_k) := v_k$ and for each $q \in [k-1]$, set $\omega(r_q) := w_q^k$, where w_q^k is an arbitrarily chosen neighbor of v_k from C_q (which exists as c is a Grundy coloring). After the above step, the post-condition is satisfied for $q = k$.

Now we (iteratively, in decreasing order) consider $q \in [k-1] \setminus \{1\}$. From the pre-condition for q , we have fixed, for each $t \in V(T_k)$ with $\ell_k(t) \geq q$, the vertex $\omega(t)$. Consider $t \in V(T_k)$ with $\ell_k(t) = q$ and let $v_t = \omega(t)$. Let \widehat{T}_q be the subtree of T_k rooted at t , and let

$\widehat{\ell}_q = \ell_k|_{V(\widehat{T}_q)}$. Notice that $(\widehat{T}_q, \widehat{\ell}_q)$ is a q -Grundy tree, where \widehat{T}_q is the tree obtained from by adding edge between t and the roots $\widehat{r}_{q-1}, \widehat{r}_{q-2}, \dots, \widehat{r}_1$ of $\widehat{T}_{q-1}, \widehat{T}_{q-2}, \dots, \widehat{T}_1$, respectively, where $(\widehat{T}_{q'}, \ell_k|_{V(\widehat{T}_{q'})})$ is a q' -Grundy tree, for each $q' \in [q-1]$. For each $q' \in [q]$, let $\widehat{w}_{q'}^q$ be an arbitrarily chosen vertex from $N_G(v) \cap C_{q'}$, and we set $\omega(\widehat{r}_{q'}) = \widehat{w}_{q'}^q$. Notice that after the above step, the post-condition is satisfied for q , and the pre-condition is satisfied for $q-1$.

After we are done processing each $q \in [k] \setminus \{1\}$, the post-condition for $q=2$ (and the pre-condition of $q=1$ implies that for each $t \in V(T_k)$, we have determined the vertex $\omega(t)$). Moreover, the construction of ω implies that all the three conditions in Definition 17 are satisfied. This concludes the proof. \blacktriangleleft

We next summarize the result we obtain from the above two lemmas.

► **Lemma 22.** *Consider any $k \in \mathbb{N} \setminus \{0\}$ and a graph G . The graph G has a k -Grundy witness if and only if G has a Grundy coloring with at least k colors.*

Color Coding of G . We will next use the above lemma to simplify our job in the following sense. Let $\omega : V(T_k) \rightarrow V(G)$ be a (fixed) k -Grundy witness of G (if it exists), where (T_k, k) is a k -Grundy tree. Let $\widehat{V}_\omega = \{\omega(t) \mid t \in V(T_k)\}$, and for each $q \in [k]$, let $\widehat{V}_{\omega,q} = \{\omega(t) \mid t \in V(T_k) \text{ and } \ell_k(t) = q\}$. Roughly speaking, our new objective will be to find the vertices in \widehat{V}_ω and say that $G[\widehat{V}_\omega]$ admits a Grundy coloring with at least k colors, using which we can conclude that G admits a Grundy coloring with at least k colors. We will use the technique of color coding introduced by Alon et al. [2], to color the vertices in \widehat{V}_ω “nicely” as follows. Color each vertex in G uniformly at random using a color from $[k]$, and let $\chi : V(G) \rightarrow [k]$ be this coloring. A *nice* coloring is the one where, for each $q \in [k]$, the coloring assigns the color q to all the vertices in $\widehat{V}_{\omega,q}$.

We will work with the assumption that χ is a nice coloring of G , and for each $q \in [k]$, let $X_q = \chi^{-1}(q)$. Our objective will be to look for a k -Grundy witness $\widehat{\omega} : V(T_k) \rightarrow V(G)$, where (T_k, k) is a k -Grundy tree, such that for each $q \in [k]$ and $t \in V(T_k)$ with $\ell_k(t) = q$, we have $\widehat{\omega}(t) \in X_q$. To this end, we will store a “Grundy representative family” for each vertex in a bottom-up fashion, starting from $q=1$. The definition of such a representative is inspired by the q -representative families [19, 30], although here we need a “vectorial” form of representation. To this end, we introduce the following notations and definitions.

Grundy Representative Sets. Recall we have the coloring χ of G with color classes $X_z = \chi^{-1}(z)$, for $z \in [k]$. A vertex subset $A \subseteq V(G)$ is χ -independent if for each $z \in [k]$, $A \cap X_z$ is an independent set in G . For $p \in \mathbb{N}$, a family of vertex subsets \mathcal{F} is a p -family if each set in \mathcal{F} has size at most p and each $A \in \mathcal{F}$ is χ -independent. We will only be working with vectors all of whose entries are from \mathbb{N} without explicitly stating it. For a vector $\vec{q} = (q_1, q_2, \dots, q_k)$, $\text{sum}(\vec{q})$ denotes the number $\sum_{z \in [k]} q_z$. For a vector $\vec{q} = (q_1, q_2, \dots, q_k)$ and $B \subseteq V(G)$, we say that the *size* of B is \vec{q} , written as $|B| = \vec{q}$, if for each $z \in [k]$, $|B \cap X_z| = q_z$. For vertex subsets A and B , A fits B if $A \cup B$ is χ -independent. For two vectors $\vec{q}_1 = (q_1^1, q_2^1, \dots, q_k^1)$ and $\vec{q}_2 = (q_1^2, q_2^2, \dots, q_k^2)$, and $\diamond \in \{\leq, \geq, >, <, =\}$, we write $\vec{q}_1 \diamond \vec{q}_2$ if for each $z \in [k]$, we have $q_z^1 \diamond q_z^2$. We next define the notion of \vec{q} -Grundy representation.

► **Definition 23.** Consider $p \in \mathbb{N}$, a vector $\vec{q} = (q_1, q_2, \dots, q_k)$, and a p -family \mathcal{F} of vertex subsets of G . For a sub-family $\mathcal{F}' \subseteq \mathcal{F}$, we say that \mathcal{F}' \vec{q} -Grundy represents \mathcal{F} , written as $\mathcal{F}' \subseteq_{\text{prep}}^{\vec{q}} \mathcal{F}$, if the following holds. For any set B of size \vec{q} , if there is $A \in \mathcal{F}$ that fits B , then there is $A' \in \mathcal{F}'$ that fits B . In the above, \mathcal{F}' is a \vec{q} -Grundy representative for \mathcal{F} .

Next, we obtain some properties regarding \vec{q} -Grundy representatives.

► **Observation 24** (♠). Consider $p \in \mathbb{N}$, a vector $\vec{q} = (q_1, q_2, \dots, q_k)$, and any two p -families \mathcal{F}_1 and \mathcal{F}_2 . If $\mathcal{F}'_1 \subseteq_{\vec{q}}^{\text{grep}} \mathcal{F}_1$ and $\mathcal{F}'_2 \subseteq_{\vec{q}}^{\text{grep}} \mathcal{F}_2$, then $\mathcal{F}'_1 \cup \mathcal{F}'_2 \subseteq_{\vec{q}}^{\text{grep}} \mathcal{F}_1 \cup \mathcal{F}_2$.

Consider $p \in \mathbb{N}$ and $v \in V(G)$. For a family \mathcal{F} over $V(G)$, $\mathcal{F} + v$ denotes the family $\{A \cup \{v\} \mid A \in \mathcal{F} \text{ and } A \cup \{v\} \text{ is } \chi\text{-independent}\}$. Similarly, $\mathcal{F} - v$ denotes the family $\{A \setminus \{v\} \mid A \in \mathcal{F}\}$. A p -family \mathcal{F} is a (p, v) -family if for each $A \in \mathcal{F}$, we have $v \in A$.

► **Observation 25** (♠). Consider $p \in \mathbb{N}$, a vector $\vec{q} = (q_1, q_2, \dots, q_k)$, a vertex $v \in V(G)$ and a (p, v) -family \mathcal{F} . Let \vec{h} be the vector obtained from \vec{q} by increasing its $\chi(v)$ th coordinate by 1. If $\mathcal{F}' \subseteq_{\vec{h}}^{\text{grep}} \mathcal{F} - v$ and $\mathcal{F}'' \subseteq_{\vec{q}}^{\text{grep}} \mathcal{F} - v$, then $(\mathcal{F}' + v) \cup (\mathcal{F}'' + v) \subseteq_{\vec{q}}^{\text{grep}} \mathcal{F}$.

For a p_1 -family \mathcal{F}_1 and a p_2 -family \mathcal{F}_2 , we define a $(p_1 + p_2)$ -family, $\mathcal{F}_1 \star \mathcal{F}_2 = \{A_1 \cup A_2 \mid A_1 \in \mathcal{F}_1, A_2 \in \mathcal{F}_2, \text{ and } A_1 \cup A_2 \text{ is } \chi\text{-independent}\}$. The following lemma will be helpful in obtaining a \vec{q} -representative for $\mathcal{F}_1 \star \mathcal{F}_2$.

► **Lemma 26**. Consider a p_1 -family \mathcal{F}_1 , a p_2 -family \mathcal{F}_2 , and a vector $\vec{q} = (q_1, q_2, \dots, q_k)$, where $\text{sum}(\vec{q}) + p_1 + p_2 \leq 2^{k-1}$. Let $\mathcal{F}'_1 \subseteq \mathcal{F}_1$ be a p_1 -family such that for every vector $\vec{q}'_1 \geq \vec{q}$ with $\text{sum}(\vec{q}'_1) \leq \text{sum}(\vec{q}) + p_2$, $\mathcal{F}'_1 \subseteq_{\vec{q}'_1}^{\text{grep}} \mathcal{F}_1$. Similarly, consider a p_2 -family $\mathcal{F}'_2 \subseteq \mathcal{F}_2$ such that for every vector $\vec{q}'_2 \geq \vec{q}$ with $\text{sum}(\vec{q}'_2) \leq \text{sum}(\vec{q}) + p_1$, $\mathcal{F}'_2 \subseteq_{\vec{q}'_2}^{\text{grep}} \mathcal{F}_2$. Then, $\mathcal{F}'_1 \star \mathcal{F}'_2 \subseteq_{\vec{q}}^{\text{grep}} \mathcal{F}_1 \star \mathcal{F}_2$.

Proof. Consider any $B \subseteq V(G)$ of size \vec{q} for which there is $A \in \mathcal{F}_1 \star \mathcal{F}_2$, such that A fits B . As $A \in \mathcal{F}_1 \star \mathcal{F}_2$, there must exist sets $A_1 \in \mathcal{F}_1, A_2 \in \mathcal{F}_2$, such that $A_1 \cup A_2 = A$.

Let $\vec{\delta}'_1 = (\delta'_1 = |(A_2 \cap X_z) \setminus B|)_{z \in [k]}$. Note that $|B \cup A_2| = \vec{q} + \vec{\delta}'_1$, A_1 fits $B \cup A_2$ and $\text{sum}(\vec{q}) + \text{sum}(\vec{\delta}'_1) \leq \text{sum}(\vec{q}) + p_2$. By the premise of the lemma, there exist $A'_1 \in \mathcal{F}'_1$ such that A'_1 fits $B \cup A_2$, as $\mathcal{F}'_1 \subseteq_{\vec{q} + \vec{\delta}'_1}^{\text{grep}} \mathcal{F}_1$. The above implies that A_2 fits $B \cup A'_1$, where $A'_1 \in \mathcal{F}'_1$. Let $\vec{\delta}'_2 = (\delta'_2 = |(A'_1 \cap X_z) \setminus B|)_{z \in [k]}$, and note that $|B \cup A'_1| = \vec{q} + \vec{\delta}'_2$, A_2 fits $B \cup A'_1$ and $\text{sum}(\vec{q}) + \text{sum}(\vec{\delta}'_2) \leq \text{sum}(\vec{q}) + p_1$. Again, as $\mathcal{F}'_2 \subseteq_{\vec{q} + \vec{\delta}'_2}^{\text{grep}} \mathcal{F}_2$, there exists $A'_2 \in \mathcal{F}'_2$ such that A'_2 fits $B \cup A'_1$. The above discussions imply that, $A'_1 \in \mathcal{F}'_1, A'_2 \in \mathcal{F}'_2$, and thus $A'_1 \cup A'_2 \in \mathcal{F}'_1 \star \mathcal{F}'_2$, where $A'_1 \cup A'_2$ fits B . This concludes the proof. ◀

Recall that G is a $K_{i,j}$ -free graph, where $i \geq j$. Consider any computable function $f(k)$. Let $\eta_{f(k)} := i \cdot f(k) \cdot k$; where we skip the subscript $f(k)$ when the context is clear. Also, for $p \in \mathbb{N}$, let $\alpha_p := 3 \cdot k \cdot (p\eta)^{i+1}$; again we skip the subscript p , when the context is clear. We next state the main lemma, which lies at the crux of our algorithm.

► **Lemma 27** (♠). Consider any computable function $f : \mathbb{N} \rightarrow \mathbb{N} \setminus \{0\}$. There is an algorithm that takes as input $k \in \mathbb{N} \setminus \{0\}$, $p \in \mathbb{N}$, a vector $\vec{q} = (q_1, q_2, \dots, q_k)$, and a p -family \mathcal{F} of vertex subsets of a $K_{i,j}$ -free graph G on n vertices with a coloring $\chi : V(G) \rightarrow [k]$, where $p + \text{sum}(\vec{q}) \leq f(k)$. In time bounded by $\mathcal{O}(\alpha^{2p + \text{sum}(\vec{q})} \cdot p \cdot |\mathcal{F}|)$ we can find $\mathcal{F}' \subseteq \mathcal{F}$ with at most $\alpha^{2p + \text{sum}(\vec{q})}$ sets such that $\mathcal{F}' \subseteq_{\vec{q}}^{\text{grep}} \mathcal{F}$.

In the remainder of this section, we prove Theorem 3, assuming the correctness of Lemma 27.

Some Useful Notations. For $z \in \mathbb{N} \setminus \{0\}$ and $z' \in [z]$, let $\gamma_{z,z'}$ be the number of vertices with label z' in the z -Grundy tree (T_z, ℓ_z) , i.e., $\gamma_{z,z'} = |\ell_z^{-1}(z')|$.

Let $\vec{q}^* = \vec{\gamma}_k := (\gamma_{k,1}, \gamma_{k,2}, \dots, \gamma_{k,k})$. We will define a vector $\vec{q}_z^* = (q_{z,1}^*, q_{z,2}^*, \dots, q_{z,k}^*)$, for every $z \in [k]$. Intuitively speaking, the z' th entry of \vec{q}_z^* will denote the number of vertices with label z' appearing in T_k after removing exactly one subtree rooted at a vertex with label

z . Formally, for each $z' \in \{z+1, z+2, \dots, k\}$, we have $q_{z,z'}^* = \gamma_{k,z'}$, and for each $z' \in [z]$, $q_{z,z'}^* = \gamma_{k,z'} - \gamma_{z,z'}$. For $z \in [k]$, we let $\vec{0}_z$ be the vector of dimension k where the z th entry is 1, and all the other entries are 0.

For a tree \widehat{T} rooted at r and $t \in V(\widehat{T})$, we let \widehat{T}^t be the subtree of \widehat{T} rooted at t , i.e., $V(\widehat{T}^t) = \{t' \in V(\widehat{T}) \mid t' = t, \text{ or } t' \text{ is a descendant of } t \text{ in } \widehat{T}\}$ and $\widehat{T}^t = \widehat{T}[V(\widehat{T}^t)]$.

For a set $W \subseteq V(G)$, we say that W is a k -Grundy set if there is a k -Grundy witness $\omega : V(T_k) \rightarrow W$ for G . Moreover, W is *minimal* if no proper subset $W' \subset W$ is a k -Grundy set for G . For a k -Grundy set W and a k -Grundy witness $\omega : V(T_k) \rightarrow W$ for G , for $t \in V(T_k)$, we let $W_{\text{sub},t} = \{\omega(t') \mid t' \in V(T_k^t)\}$ and $W_{\text{exc},t} = \{\omega(t') \mid t' \in V(T_k) \setminus V(T_k^t)\}$.

Recall that we have a graph G and a coloring $\chi : V(G) \rightarrow [k]$, where for $z \in [k]$, we have $X_z = \chi^{-1}(z)$. For $z \in [k]$ and $v \in V(G)$, we define $\mathcal{F}_{z,v} := \{W \subseteq \cup_{z' \in [z]} X_{z'} \mid v \in W, W \text{ is } \chi\text{-independent and } z \leq |W| \leq 2^{z-1}\}$.

Description of the Algorithm. The objective of our algorithm will be to compute, for each $z \in [k]$ and $v \in X_z$, a family $\mathcal{F}'_{z,v} \subseteq \mathcal{F}_{z,v}$; starting from $z = 1$ (and then iteratively, for other values of z in increasing order), satisfying the following constraints:

Size Constraint. $|\mathcal{F}'_{z,v}| \leq \alpha^{2^k+1}$.

Correctness Constraint. For any $z \in [k]$ and $v \in X_z$, the following holds:

1. Each $A \in \mathcal{F}'_{z,v}$ is a z -Grundy set in G .
2. Consider any minimal k -Grundy set W , such that $v \in W$ (if it exists). Furthermore, let $\omega : V(T_k) \rightarrow W$ be a k -Grundy witness for G . For any $t \in V(T_k)$ with $\omega(t) = v$, where $\vec{q}_t = |W_{\text{exc},t}|$, there is $W' \in \mathcal{F}'_{z,v} \subseteq \mathcal{F}_{z,v}$ such that $W_{\text{exc},t} \cup W'$ is a k -Grundy set in G , i.e., $\mathcal{F}'_{z,v} \subseteq_{\text{grep}}^{\vec{q}_t} \mathcal{F}_{z,v}$.

Base Case. We are in our base case when $z = 1$; note that $[2^0] = \{1\}$. For each $v \in X_1$, set $\mathcal{F}'_{1,v} := \mathcal{F}_{1,v} = \{\{v\}\}$. Note that $\mathcal{F}'_{1,v}$ satisfies both the size and the correctness constraints.

Recursive Formula. Consider $z \in [k] \setminus \{1\}$ and $v \in X_z$. We suppose that for each $z' \in [z-1]$ and $v' \in X_{z'}$, we have computed $\mathcal{F}'_{z',v'}$ that satisfies both the size and the correctness constraints.

For each $z' \in [z-1]$, we create a family $\mathcal{F}_{z,v,z'}$, initialized to \emptyset as follows. For each $u \in X_{z'} \cap N_G(v)$ and $W \in \mathcal{F}'_{z',u}$, if $W \cup \{v\}$ is χ -independent and $|W \cup \{v\}| \leq 2^{z-1}$, then add $W \cup \{v\}$ to $\mathcal{F}_{z,v,z'}$. Note that $|\mathcal{F}_{z,v,z'}| \leq n \cdot \alpha_p^{2^k+1}$, where $p = 2^{z'-1}$. Using Lemma 27, for each vector $\vec{q} \leq \vec{q}_z^*$, we compute $\mathcal{F}'_{z,v,z',\vec{q}} \subseteq_{\text{grep}}^{\vec{q}} \mathcal{F}_{z,v,z'}$, where $|\mathcal{F}'_{z,v,z',\vec{q}}| \leq \alpha^{2^k}$, and set $\mathcal{F}'_{z,v,z'} = \cup_{\vec{q} \leq \vec{q}_z} \mathcal{F}'_{z,v,z',\vec{q}}$. Note that $|\mathcal{F}'_{z,v,z'}| \leq 2^{(k-1)k} \cdot \alpha^{2^k} \leq \alpha^{2^k+1}$ and we can compute it in time bounded by $\mathcal{O}(\alpha^{2^k+1} \cdot 2^{k-1} \cdot |\mathcal{F}_{z,v,z'}|)$.

Next we will iteratively “combine and reduce” the families $\mathcal{F}'_{z,v,z'}$, for $z' \in [z]$, to obtain a family $\widehat{\mathcal{F}}_{z,v} \subseteq \mathcal{F}_{z,v}$ as follows. We set $\widehat{\mathcal{F}}_{z,v,1} := \mathcal{F}'_{z,v,1}$. Iteratively, (in increasing order), for each $z' \in [z-1] \setminus \{1\}$, we do the following:

1. Set $\widetilde{\mathcal{F}}_{z,v,z'} := \widehat{\mathcal{F}}_{z,v,z'-1} \star \mathcal{F}'_{z,v,z'}$.
2. Compute $\widehat{\mathcal{F}}_{z,v,z',\vec{q}} \subseteq_{\text{grep}}^{\vec{q}} \widetilde{\mathcal{F}}_{z,v,z'}$, for each $\vec{q} \leq \vec{q}_z^* = \vec{\gamma}_k - (\sum_{z' \in [z']} (\vec{\gamma}_k - \vec{q}_z^*)) - \vec{0}_z$, and set $\widehat{\mathcal{F}}_{z,v,z'} = \cup_{\vec{q} \leq \vec{q}_z^*} \widehat{\mathcal{F}}_{z,v,z',\vec{q}}$. Note that $|\widehat{\mathcal{F}}_{z,v,z'}| \leq \alpha^{2^k+1}$ and it can be computed in time bounded by $\mathcal{O}(\alpha^{2^k+1} \cdot 2^{k-1} \cdot |\widetilde{\mathcal{F}}_{z,v,z'}|)$.

We add each $A \in \widehat{\mathcal{F}}_{z,v,z'-1}$ to $\mathcal{F}'_{z,v}$, which is a z -Grundy set in G (note that since the size of each set is bounded by 2^{k-1} , we can easily do it in the allowed amount of time). In the following lemma, we show that $\mathcal{F}'_{z,v}$ satisfies the correctness constraints.

► **Lemma 28.** $\mathcal{F}'_{z,v}$ satisfies the correctness constraint.

Proof. Consider any $v \in X_z$ and a minimal k -Grundy set W , such that $v \in W$ (if it exists) and let $\omega : V(T_k) \rightarrow W$ be a k -Grundy witness for G . Next consider any $t \in V(T_k)$ with $\omega(t) = v$. We will argue that, there is $W' \in \mathcal{F}'_{z,v}$ such that $W_{\text{exc},t} \cup W'$ is a k -Grundy set in G . For each $z' \in [z-1]$, let $t_{z'}$ be the child of t in T_k with $\ell_k(t_{z'}) = z'$ and $v_{z'} = \omega(t_{z'})$. Note that for each $z' \in [z-1]$, $v_{z'} \in X_{z'}$. For each $z' \in [z-1]$, let $\widehat{A}_{z'} = \{\omega(t') \mid t' \in V(T_k^{t_{z'}})\}$, and note that $|\widehat{A}_{z'}| \leq 2^{z'-1}$. Now we iteratively take the union of the above sets as follows. For each $z' \in [z-1]$, let $A_{z'} = \bigcup_{z \in [z']} \widehat{A}_{z'}$. Now for each $z' \in [z-1]$, we construct a subset, $B_{z'}$ of W that contains $\omega(t')$, for each $t' \in V(T_k)$ that does not belong to the subtrees rooted at any of the vertices $t_1, t_2, \dots, t_{z'}$. Formally, for $z' \in [z-1]$, let $B_{z'} = \{\omega(t') \mid t' \in V(T_k) \setminus (\bigcup_{z'' \in [z']} V(T_k^{t_{z''}}))\}$. Furthermore, let $\vec{s}_{z'}$ be the size of $B_{z'}$. Notice that for each $z' \in [z-1]$, all of the following holds:

1. $\vec{s}_{z'} \leq \vec{q}_{z'}$,
2. $|A_{z'}| \leq \sum_{z \in [z']} 2^{\widehat{z}-1}$,
3. $|\widehat{A}_{z'}| \leq 2^{z'-1}$ and $\widehat{A}_{z'} \in \mathcal{F}'_{z',v_{z'}}$,
4. $A_{z'} \cup B_{z'} = W$, and thus, $A_{z'}$ fits $B_{z'}$.

We will now iteratively define sets $A'_1, A'_2, \dots, A'_{z-1}$ and functions $\omega_1, \omega_2, \dots, \omega_{z-1}$, and we will ensure that, for each $z' \in [z-1]$, we have: i) $\omega_{z'} : V(T_k) \rightarrow A'_{z'} \cup B_{z'}$ is a k -Grundy witness for G , ii) for each $z' \in [z-1]$ and $t' \in V(T_k) \setminus (\bigcup_{z'' \in [z']} V(T_k^{t_{z''}}))$, we have $\omega_{z'}(t') = \omega(t')$, iii) $A'_{z'} \in \widehat{\mathcal{F}}_{z,v,z'}$, and iv) for each $z'' \in [z']$, there is a minimal z'' -Grundy set $A'_{z',z''} \subseteq A'_{z'}$, where the unique vertex in $A'_{z',z''} \cap X_{z''}$ is a neighbor of v .

Recall that $z \geq 2$ and $\widehat{\mathcal{F}}_{z,v,1} = \mathcal{F}'_{z,v,1} \subseteq \mathcal{F}_{z,v,1}$. Also, we have $\widehat{A}_1 = A_1 = \{u'\}$, for some $u' \in N_G(v) \cap X_1$, and $A_1 \cup B_1 = W$ is a k -Grundy set. Thus, there must exist $A'_1 \in \mathcal{F}'_{z,v,1}$ such that $A'_1 \cup B_1$ is χ -independent. Moreover by the construction of $\mathcal{F}'_{z,v,1}$, $A'_1 = \{u\}$, for some $u \in N_G(v) \cap X_1$. Let $\omega_1 : V(T_k) \rightarrow A'_1 \cup B_1$ be the function such that for each $t' \in V(T_k) \setminus \{t_1\}$, we have $\omega_1(t') = \omega(t')$ and $\omega_1(t_1) = u$. As $A'_1 \cup B_1$ is χ -independent and $\{u, v\} \in E(G)$, we can obtain that ω_1 is a k -Grundy witness for G . Note that if $z = 2$, then by the above arguments, we have constructed the desired sets and functions, which is just the set A'_1 and the function ω_1 .

We now consider the case when $z' \geq 2$. Also, we assume that for some $\widehat{z} \in [z-2]$, for each $z' \in [\widehat{z}]$, we have constructed $A'_{z'}$ and $\omega_{z'}$ satisfying the desired condition. Now we prove the statement for $z' = \widehat{z} + 1$. Note that $A'_{z'-1} \cup B_{z'-1}$ is a k -Grundy set and $\omega_{z'-1} : V(T_k) \rightarrow A'_{z'-1} \cup B_{z'-1}$ is a k -Grundy witness for G , where $A'_{z'-1} \in \widehat{\mathcal{F}}_{z,v,z'}$. Note that $\widehat{A}_{z'} \subseteq B_{z'-1}$. Let $B'_{z'} = \{\omega_{z'-1}(t') \mid t' \in V(T_k) \setminus V(T_k^{t_{z'}})\}$. Note that $|B'_{z'}| \leq \vec{q}_{z'}$ and $\widehat{A}_{z'}$ fits $B'_{z'}$, and recall that $\widehat{A}_{z'} \in \mathcal{F}'_{z',v_{z'}}$. As $\mathcal{F}'_{z',v_{z'}} \subseteq_{\vec{q}} \mathcal{F}_{z',v_{z'}}$, for every $\vec{q} \leq \vec{q}_{z'}$, there must exist $\widetilde{A}_{z'} \in \mathcal{F}'_{z',v_{z'}}$, such that $\widetilde{A}_{z'}$ fits $B'_{z'}$. By the construction of $\mathcal{F}'_{z',v_{z'}}$, we have $v_{z'} \in \widetilde{A}_{z'}$ and $\widetilde{A}_{z'} \cup B'_{z'}$ is χ -independent, and also $v \in B'_{z'}$. From the above discussions we can conclude that $\widetilde{A}_{z'} \cup \{v\} \in \mathcal{F}_{z,v,z'}$. Moreover, as $A'_{z'-1} \in \widehat{\mathcal{F}}_{z,v,z'-1}$, $A'_{z'-1} \subseteq B'_{z'}$ and $\widetilde{A}_{z'} \cup B'_{z'}$ is χ -independent, we can obtain that $A'_{z'-1} \cup \widetilde{A}_{z'} \cup \{v\} \in \widehat{\mathcal{F}}_{z,v,z'-1} \star \mathcal{F}'_{z,v,z'} = \widehat{\mathcal{F}}_{z,v,z'}$. As $\widehat{\mathcal{F}}_{z,v,z'} \subseteq_{\vec{q}} \mathcal{F}_{z,v,z'}$, for every $\vec{q} \leq \vec{q}_{z'}^*$ and $|B_{z'}| \leq \vec{q}_{z'}^*$, there must exist $A'_{z'} \in \widehat{\mathcal{F}}_{z,v,z'}$ such that $A'_{z'} \cup B_{z'}$ is χ -independent.

As $A'_{z'} \in \widehat{\mathcal{F}}_{z,v,z'}$, there must exist $\widehat{C} \in \widehat{\mathcal{F}}_{z,v,z'-1}$ and $C' \cup \{v\} \in \mathcal{F}'_{z,v,z'}$, such that $A'_{z'} = \widehat{C} \cup C' \cup \{v\}$. By the correctness for $z'-1$, C' contains for each $z'' \in [z'-1]$, a minimal z'' -Grundy set $A'_{z'-1,z''} \subseteq A'_{z'-1}$, where the unique vertex in $A'_{z'-1,z''} \cap X_{z''}$ is a neighbor of v . Also by the construction of $\mathcal{F}'_{z,v,z'}$, C' contains a minimal z' -Grundy set C'' in G , where the unique vertex in $C'' \cap X_{z'}$ is a neighbor of v . From the above discussions, we can conclude that $A'_{z'} \cup B_{z'}$ is a k -Grundy set in G . \blacktriangleleft

Using the above algorithm, we can compute for each $z \in [k]$ and $v \in X_z$, a family $\mathcal{F}'_{z,v} \subseteq \mathcal{F}_{z,v}$ that satisfies the correctness and the size constraints, in time bounded by $\alpha^{\mathcal{O}(2^k+1)} \cdot n^{\mathcal{O}(1)}$. Note that G has a Grundy coloring using at least k colors if and only if for some $v \in X_k$, $\mathcal{F}'_{z,v} \neq \emptyset$. This implies a proof of Theorem 3.

Abstract

We investigate the structure of graphs of twin-width at most 1, and obtain the following results:

- Graphs of twin-width at most 1 are permutation graphs. In particular they have an intersection model and a linear structure.
- There is always a 1-contraction sequence closely following a given permutation diagram.
- Based on a recursive decomposition theorem, we obtain a simple algorithm running in linear time that produces a 1-contraction sequence of a graph, or guarantees that it has twin-width more than 1.
- We characterise distance-hereditary graphs based on their twin-width and deduce a linear time algorithm to compute optimal sequences on this class of graphs.

1 Introduction

Twin-width is a graph invariant introduced by Bonnet, Kim, Thomassé, and Watrigant [11] as a generalisation of a parameter on permutations introduced by Guillemot and Marx [21]. The main result of the seminal paper [11] is an FPT algorithm for FO model-checking on graphs of bounded twin-width, when given a *contraction sequence* certifying their width. Graphs of

bounded twin-width capture a wide variety of classes such as bounded rank-width and proper minor-closed classes, unifying many results on tractable FO model-checking. Furthermore, it gives an exact dichotomy between tractability and intractability of FO model-checking for hereditary classes of ordered structures [8] and of tournaments [19].

While these results are sufficient to consider twin-width an important graph parameter, we are still lacking an FPT algorithm for computing “good” contraction sequences, i.e. contraction sequences of width bounded by a function of the twin-width. Such an algorithm is required for FO model-checking to be FPT on bounded twin-width classes. Regarding exact algorithms for twin-width, it is known that computing twin-width is hard even for constant values: distinguishing graphs of twin-width 4 from graphs of twin-width 5 is NP-hard [5]. Still, a polynomial-time algorithm for recognizing graphs of twin-width 1 was given in [10], where the worst-case time complexity is not explicitly given but corresponds to a polynomial of degree 4 or 5 depending on implementation. Meanwhile, the hardness of recognizing twin-width 2 and 3 graphs remains open. Nevertheless, it is known that sparse graphs of twin-width 2 have bounded treewidth [7]. As for approximation, there is an algorithm to compute contraction sequences of approximate width for ordered structures [8]. It is still wide open whether there is an XP, let alone FPT, approximation algorithm in the general case. Regarding parameterized algorithms, some results are known with parameters that are still quite far from twin-width [3, 4]. Interestingly, the more general parameter flip-width introduced by Torunczyk [25] has an XP approximation algorithm but the status of FO model-checking for this parameter is unknown.

In this paper, we are interested in the structure of graphs of twin-width 1, and in the complexity of their recognition. Let us briefly recall the definition of k -contraction sequences, which are witnesses for twin-width at most k . Given a graph G , a contraction sequence of G starts with G , and consists in a sequence of identifications of pairs of vertices (contractions) recording “neighbourhood errors” as *red edges*, ending with a graph on a single vertex. Specifically, at each step, we create red edges from the contracted vertex to vertices that were not homogeneous to the pair. That is, vertices which were not both adjacent or non-adjacent to the pair. In particular, red edges remain red. Then, a k -contraction sequence is one where at each step the vertices have most k incident red edges.

Towards understanding graphs of twin-width one, it will be useful to look at the structure and behaviour of classes of graphs which are related. There is a rich literature on hereditary classes of graphs related to perfect graphs. It follows from the following observation and the strong perfect graph theorem [13] that twin-width 1 graphs are perfect graphs. It is then natural to wonder how they compare to other subclasses of perfect graphs.

► **Observation 1** (See [1, Lemma 2.3]). *Every cycle of length at least 5 has twin-width 2. This also implies that complements of cycles of length at least 5 have twin-width 2.*

A natural way of understanding classes of twin-width at most k is to interpret them as a generalization of cographs. Indeed, cographs are exactly the graphs which admit a sequence of twin identifications ending in a single vertex, that is, graphs of twin-width 0. Then, graphs of twin-width k correspond to relaxing the twin condition to allow for at most k “twin errors”.

We now compare twin-width 1 graphs with other generalisations of cographs. Cographs are the graphs of clique-width at most 2. In this direction, cographs are generalised by the class of distance-hereditary graphs which are themselves closely related to graphs of clique-width at most 3 [14]. Distance-hereditary (DH) graphs are not closed by complementation, and have a tree-like structure. They also have a characterisation by a sequential elimination of twins and pendant vertices. Cographs are permutation graphs, which is exactly the complementation-closed class of graphs whose edges can be transitively oriented [17]. Permutation graphs are

asteroidal triple-free (AT-free), as such, they are dominated by a path [15]. A caterpillar is an AT-free tree, the following result suggests a relation between AT-free graphs and twin-width 1.

► **Lemma 2** (Ahn, Hendrey, Kim, and Oum [2, Lemma 6.6]). *For a tree T , $\text{tw}(T) \leq 1$ if and only if T is a caterpillar.*

Cographs, distance-hereditary graphs, and permutation graphs can all be recognised in linear time. It is only natural to expect that the closely related class of twin-width 1 graphs can also be recognised efficiently.

Previous results on graphs of twin-width at most 1

The recognition algorithm for twin-width one given in [10] makes use of the relation between modules and twin-width, by observing that the twin-width of a graph can be determined by considering independently the subgraphs induced by modules (see Lemma 5). It is straightforward to deduce that the twin-width of a graph is the maximal twin-width over all prime nodes of its modular decomposition (defined in Section 2). Since this decomposition may be computed in linear time [24], one then only needs to recognise prime graphs of twin-width one. In their paper [10], the recognition is done by branching on valid sequences that have at most one red edge at any intermediate step of the sequence, after the observation that such sequences always exist. Furthermore, when the trigraph has a red edge, the only possible contractions in such a sequence involve at least one vertex of the red edge. Essentially, the complexity of their algorithm stems from the need to branch over all possible first contractions, to greedily simulate a contraction sequence for each possible first contraction, and the lack of an efficient way to detect eventual twins to be contracted at each step. In particular, a more explicit understanding of the structure of graphs of twin-width at most 1 seems to be required to avoid the enumeration of all pairs of possible first contractions.

Our results

We investigate the structure of graphs of twin-width at most 1, and uncover that it defines a relatively well-behaved hereditary class of graphs, which fits surprisingly well in the landscape of classical hereditary classes. Graphs of twin-width at most 1 were already known to have some form of linear structure, due to a bound on their linear rankwidth if they are prime (see Lemma 7 and [9]). We show that they are in fact contained in the class of permutation graphs, thus they admit an intersection model called “permutation diagram”, making it easier to reason on their structure. Furthermore, we show that there is a close relationship between permutation diagrams and 1-contraction sequences. We use these structural results to obtain a recursive decomposition theorem for prime graphs of twin-width at most 1. We then use it to devise a simple linear time algorithm to compute a 1-contraction sequence, or conclude that the graph has twin-width more than 1. The algorithm starts by computing a permutation diagram and a modular decomposition which can be done in time $O(n + m)$, where n is the number of vertices and m is the number of edges, and then it checks that the diagram respects the decomposition theorem in time $O(n)$.

Regarding the challenge of avoiding the enumeration of possible first contractions, we can significantly reduce the number of candidates by using the permutation diagram and related properties of contraction sequences. We consider a slightly different scheme to avoid this challenge. Instead of guessing the first contraction, we guess the vertex that will be contracted last. It turns out that, in well-behaved contraction sequences, such a vertex

holds a special position in permutation diagrams, reducing the number of candidates to 4. However, we do not exclude the possibility that the scheme of the previous algorithm can be implemented in linear time with some further arguments.

Interestingly, our structural analysis via the permutation diagrams allows us to avoid a characterisation by forbidden induced subgraphs. Moreover, we prove most structural tools inductively and in a unified way instead of proving the observations required for our algorithm separately.

In the full version, we also present some intermediate results on distance-hereditary graphs and split decompositions that turned out to be unnecessary for the recognition algorithm thanks to the use of permutation diagrams. We show that twin-width 1 trigraphs with a pendant red edge are distance-hereditary. We also show that distance-hereditary graphs have twin-width at most 2. Combining these results, we can compute an optimal contraction sequence for distance-hereditary graphs in linear time. We also obtain a simple inductive proof that all distance-hereditary AT-free graphs are permutation graphs, and a characterisation of the twin-width of a distance-hereditary graph by the structure of its split decomposition. This is a generalisation of the characterisation of twin-width 1 trees [2] mentioned above.

Distance-hereditary graphs are also related to the following infinite family of permutation graphs of twin-width 2: linking two obstructions to distance-hereditary graphs (domino, house, or gem) by a path of arbitrary length. In particular, this class of examples shows that a linear time algorithm for the recognition of twin-width 1 graphs cannot be deduced from the linear algorithm to find patterns in a permutation of Guillemot and Marx [21].

We also observe that bipartite graphs of twin-width 1 constitute a well-behaved subclass. Indeed, in their 1-contraction sequences, all trigraphs are bipartite. This is because there are no induced odd cycles of length more than 3, and triangles have at most one red edge from which we can deduce an original edge and complete it in a triangle of the starting graph (this is a particular case of Observation 14).

Perspectives

One may hope that understanding the structure of graphs of twin-width 1 well enough can guide a subsequent study of graphs of twin-width 2. We expect that this hereditary class can be characterised by a tree-like decomposition with a very constrained local structure. Our results also point toward the fact that split decompositions could be a convenient tool for the analysis of the structure of twin-width 2 graphs.

In another direction, one may wonder if it is possible to compute other values of the twin-width efficiently for permutation graphs. An FPT approximation algorithm is already known in this setting [11], although one may try to find tighter approximation bounds.

Organisation

We organise this paper as follows. In Section 2, we present some terminology and useful known results on twin-width, and on permutation graphs. In Section 3, we show that every graph of twin-width at most 1 is a permutation graph. In Section 4, we present a linear-time algorithm that recognises graphs of twin-width at most 1.

2 Preliminaries

In this paper, all graphs are finite and simple. For an integer i , we denote by $[i]$ the set of positive integers at most i . Note that if $i \leq 0$, then $[i]$ is an empty set. A subset $I \subseteq [i]$ is an *interval* of $[i]$ if there are integers $i_1, i_2 \in [i]$ such that $I = \{j : i_1 \leq j \leq i_2\}$.

Let G be a graph. We denote the complement graph by \overline{G} . For a vertex v of G , we denote by $N_G(v)$ the set of neighbours of v , and let $N_G[v] := N_G(v) \cup \{v\}$. Then, $\overline{N}_G(v) = V(G) \setminus N[v]$. For a set $X \subseteq V(G)$, let $N_G[X] := \bigcup_{v \in X} N_G[v]$ and let $N_G(X) := N_G[X] \setminus X$. Distinct vertices v and w of G are *twins in G* if $N_G(v) \setminus \{w\} = N_G(w) \setminus \{v\}$. For a set $X \subseteq V(G)$, we denote by $G[X]$ the subgraph of G induced by X . A *dominating set* of G is a set $D \subseteq V(G)$ such that $N_G[D] = V(G)$. A *dominating path* of G is a path whose vertex set is a dominating set of G . Three vertices form an *asteroidal triple* if each pair of vertices is connected by a path that does not dominate the third vertex. A graph is *asteroidal triple-free* (AT-free) if it contains no asteroidal triple. An *independent set* of a graph G is a set $I \subseteq V(G)$ such that G has no edge between two vertices in I .

A *module* of a graph G is a set $M \subseteq V(G)$ such that for every vertex $v \in V(G) \setminus M$, v is either adjacent to every vertex in M , or nonadjacent to every vertex in M . If M is not a module, we call *splitter* of M a vertex $v \in V(G) \setminus M$, that has both a neighbour and a non-neighbour in M . Note that M is a module exactly if it has no splitter. A module is *trivial* if it either has size at most 1, or is equal to $V(G)$. A graph is *prime with respect to modules*, or simply *prime*, if all of its modules are trivial. A *modular partition* of a graph G is a partition of $V(G)$ where each part is a module of G . For a modular partition $\mathcal{M} = (M_1, \dots, M_\ell)$ of a graph G , we denote by G/\mathcal{M} , the subgraph of G induced by a set containing exactly one vertex from each M_i . A module M is *strong* if it does not overlap with any other module, i.e. for every module M' , we have $M \subseteq M'$, or $M' \subseteq M$, or $M \cap M' = \emptyset$.

The *modular decomposition* of a graph G is a tree T corresponding to the recursive modular partition by the maximal strong modules. The leaves of the tree are vertices of G , and each internal node n has an associated quotient graph $Q(n)$ which encodes the adjacency relation between vertices of G introduced in subtrees below n . In particular, quotient graphs are induced subgraphs of G , and the modular decomposition of an induced subgraph of G can easily be deduced from the modular decomposition of G . There are three types of internal nodes: *series*, *parallel*, and *prime*, corresponding to cliques, independent sets and prime graphs (with respect to modules). Prime graphs are graphs whose modules are all trivial i.e. singletons and the complete vertex set. Series and parallel nodes are called *degenerate*, and two degenerate nodes of the same type may not be adjacent in T . The reason they are called degenerate is because any subset of vertices of a clique or an independent set is a module. Cographs are exactly the graphs whose modular decompositions have no prime nodes, their modular decomposition is usually called a cotree.

2.1 Permutation graphs

A graph G on n vertices is a *permutation graph* if there are two linear orderings $\sigma : V(G) \rightarrow [n]$ and $\tau : V(G) \rightarrow [n]$ such that two vertices u and v are adjacent in G if and only if $\{u, v\}$ is an inversion of $\sigma^{-1} \circ \tau$. We remark that $\sigma^{-1} \circ \tau$ and its inverse permutation $\tau^{-1} \circ \sigma$ have the same set of inversions. A *permutation diagram* of G with respect to σ and τ is a drawing of n line segments between two parallel lines ℓ_1 and ℓ_2 such that each of ℓ_1 and ℓ_2 has n distinct points, and for each $v \in V(G)$, there is a line segment between $\sigma(v)$ -th point of ℓ_1 and $\tau(v)$ -th point of ℓ_2 . Note that two vertices are adjacent in G if and only if their corresponding line segments intersect each other in the permutation diagram.

We denote by $G[\sigma, \tau]$ the graph on V where uv is an edge if and only if $\{u, v\}$ is an inversion of $\sigma^{-1} \circ \tau$. As pointed earlier, we have $G[\sigma, \tau] = G[\tau, \sigma]$. If $G = G[\sigma, \tau]$, we call (σ, τ) a *realiser* of G (as a permutation graph).

For σ an ordering of V , we define intervals of V as follows: for $\{i, i+1, \dots, j-1, j\}$ an interval of $[n]$, we have an interval of V for σ $\{\sigma^{-1}(i) = u, \dots, \sigma^{-1}(j) = v\}$ that we denote by $[u, v]_\sigma$. We extend the notation to open intervals similarly.

We say that $I \subseteq V$ is an *interval* of realiser (σ, τ) if it is an interval for σ or for τ . We also say that $u, v \in V(G_i)$ are *consecutive* for (σ, τ) if $\{u, v\}$ is an interval of (σ, τ) . Similarly, two intervals are *consecutive* if their union is an interval. We say that I is a *common interval* of realiser (σ, τ) if it is an interval for σ and for τ . A vertex v of G is *extremal* for realiser (σ, τ) (or equivalently the corresponding permutation diagram) if it is the first or last vertex of σ or τ .

It is known that for a prime permutation graph, its permutation diagram (or equivalently its realiser) is unique up to symmetry [18, 20]. More generally, the modular decomposition encodes all possible realisers. Furthermore, we have the following known observation which will be very convenient for our analysis.

► **Observation 3.** *If M is a common interval of a realiser of G , then M is a module of G . Conversely, if M is a strong module of G , then it is a common interval of all realisers.*

It will also be useful to note that extremal vertices of a prime permutation graph do not depend on the realiser. See [6, 12, 16, 22] for further details on this.

Moreover, for a permutation diagram of G with respect to linear orderings σ and τ of $V(G)$, if we reverse one of σ and τ , then we obtain a permutation diagram of \overline{G} . In other words, \overline{G} has a permutation diagram with respect to σ and $n+1-\tau$, or to $n+1-\sigma$ and τ .

Thus, a graph G is a permutation graph if and only if \overline{G} is a permutation graph.

2.2 Trigraphs and twin-width

A *trigraph* is a triple $H = (V(H), B(H), R(H))$ where $B(H)$ and $R(H)$ are disjoint sets of unordered pairs of $V(H)$. We denote by $E(H)$ the union of $B(H)$ and $R(H)$. The *edges* of H are the elements in $E(H)$. The *black edges* of H are the elements of $B(H)$, and the *red edges* of H are the elements of $R(H)$. We identify a graph $G = (V, E)$ with a trigraph (V, E, \emptyset) .

The *underlying graph* of a trigraph H is the graph $(V(H), E(H))$. We identify H with its underlying graph when we use standard graph-theoretic terms and notations. A *black neighbour* of v is a vertex u with $uv \in B(H)$ and a *red neighbour* of v is a vertex w with $vw \in R(H)$. The *red degree* of v is the number of red neighbours of v . For an integer d , a *d-trigraph* is a trigraph with maximum red degree at most d . For a set $X \subseteq V(H)$, we denote by $H - X$ the trigraph obtained from H by removing all vertices in X . If $X = \{v\}$, then we write $H - v$ for $H - X$.

For a trigraph H and distinct vertices u and w of H , we denote by $H/\{u, v\}$ the trigraph H' obtained from $H - \{u, v\}$ by adding a new vertex x such that for every vertex $y \in V(H) \setminus \{u, v\}$, the following hold:

- if y is a common black neighbour of u and v , then $xy \in B(H')$,
- if y is adjacent to none of u and v , then $xy \notin E(H')$, and
- otherwise, $xy \in R(H')$.

We say that H' is obtained by *contracting u and v* .

A *contraction sequence* of G is a sequence of trigraphs G_n, \dots, G_1 where $G_n = G$, G_1 as a single vertex, and G_{i-1} is obtained from G_i by contracting a pair of vertices. For an integer d , a contraction sequence G_n, \dots, G_1 is a *d -sequence* if for every $i \in [t]$, the maximum red-degree of G_i is at most d . The *twin-width* of G , denoted by $\text{tw}(G)$, is the minimum integer d such that there is a d -sequence of G .

The vertices of the trigraphs in the contraction sequence can be interpreted as a partition of $V(G)$, this leads to a very natural characterisation of red edges in a trigraph as pairs of part such that the relation between vertices in the two parts is not homogeneous (i.e. there is an edge and a non-edge).

We have the following observations from [11].

► **Observation 4** (Bonnet, Kim, Thomassé, and Watrigant [11]). *For a graph G , the twin-width of G is equal to that of \overline{G} , and every induced subgraph of G has twin-width at most $\text{tw}(G)$.*

► **Lemma 5** (Bonnet, Kim, Reinald, Thomassé, and Watrigant [10, Lemma 9]). *Let G be a graph and let $\mathcal{M} = (M_1, \dots, M_\ell)$ be a modular partition. Then*

$$\text{tw}(G) = \max \left\{ \text{tw}(G/\mathcal{M}), \max_{i \in [\ell]} \text{tw}(G[M_i]) \right\}.$$

We sketch the proof as this will be of importance throughout the paper.

Proof. A contraction in a module M does not create red edges incident to $V(G - M)$. Therefore, we can always first contract the induced subgraphs $G[M_i]$ in any order, and then contract G/\mathcal{M} once all subgraphs $G[M_i]$ have been contracted to single vertices. ◀

► **Corollary 6.** *The twin-width of a graph G is equal to the maximum twin-width of the quotient graphs of nodes of its modular decomposition.*

Proof. We may always contract leaf nodes of the modular decomposition via their optimal contraction sequence until the whole graph is reduced to a single vertex. This corresponds exactly to a recursive application of the above lemma with maximal strong modules. ◀

The above statements show that computing the twin-width of a graph reduces to the case of a prime graph. Thus, throughout this paper, we focus on prime graphs of twin-width at most 1. The following lemma on the structure of twin-width 1 graphs will be useful.

► **Lemma 7** (Bonnet, Kim, Reinald, Thomassé, and Watrigant [10, Lemma 31]). *Let G be a prime graph of twin-width 1 and let $G_n (= G), \dots, G_1$ be a 1-sequence of G . Then for every $i \in [n - 1] \setminus \{1\}$, the trigraph G_i has exactly one red edge.*

3 Permutation diagrams

In this section, we show that every graph of twin-width at most 1 is a permutation graph.

► **Theorem 8.** *Every graph of twin-width at most 1 is a permutation graph.*

It would be sufficient to prove that graphs of twin-width at most 1 are comparability graphs. Indeed, since twin-width is stable by complementation, this implies that graphs of twin-width at most 1 are also co-comparability graphs. We could then conclude because permutation graphs are exactly the graphs that are both comparability and co-comparability graphs [17]. To do this, one could make use of the following characterisation of comparability graphs via forbidden induced subgraphs given by Gallai [18] (see also [23]).

► **Theorem 9.** *A graph G is a comparability graph if and only if G does not contain any graph of Figure 3 as induced subgraph, and \overline{G} does not contain any graph of Figure 4 as induced subgraph.*

We instead present a constructive proof because it gives combinatorial insights on the relationship between contraction sequences and permutation diagrams that will be useful to find an efficient recognition algorithm. The trick is to decompose the graph by considering the contraction sequence backwards and to realise that vertices that are contracted together at some point in the contraction sequence should be consecutive or almost consecutive in a realiser.

The following recursive decomposition of twin-width 1 graphs is meant as a simple introduction to the technique. This decomposition will later be strengthened in Lemma 11 and Corollary 15. We abusively extend the terminology of universal vertex and isolated vertex to modules M such that replacing M by a single vertex makes it universal or isolated.

► **Lemma 10.** *The class \mathcal{G} of graphs of twin-width at most 1 satisfies the following recursive characterisation:*

$$\mathcal{G} = \left\{ G \mid \exists M \subset V(G), \begin{array}{l} G - M \in \mathcal{G}, G[M] \in \mathcal{G}, M \text{ is a module of } G, \\ M \text{ is universal or } M \text{ is isolated or} \\ G - M \text{ admits a 1-contraction sequence ending} \\ \text{with the (possibly red) edge } \{N(M), \overline{N}(M)\} \end{array} \right\}.$$

Proof. Consider a graph G such that there exists a module $M \subset V(G)$ such that $G - M \in \mathcal{G}$ and $G[M] \in \mathcal{G}$. If M is universal or isolated, $G - M$ is a module of G and, by Lemma 5, G is also a graph of \mathcal{G} . If $G - M$ admits a partial 1-contraction sequence π ending with edge $\{N(M), \overline{N}(M)\}$, then π is also a partial 1-contraction sequence of G , and can be extended to be 1-contraction sequence of G . Indeed, no red edge incident to M appears when applying π to G since pairs of contracted vertices are always either in $N(M)$ or $\overline{N}(M)$, we can then apply the 1-contraction sequence of M , and finally contract arbitrarily the resulting 3-vertex trigraph.

Conversely, consider a graph of \mathcal{G} . It admits a 1-contraction sequence with a 3-vertex trigraph G_3 . G_3 has at most one red edge ab (pick a, b arbitrarily in $V(G_3)$ if there is no red edge). We consider $v \in V(G_3) - \{a, b\}$. The set M of vertices of G that were contracted to form v is a module since there are no incident red edges in G_3 . $G - M \in \mathcal{G}$ and $G[M] \in \mathcal{G}$ since they are induced subgraphs of G . Let A and B be the sets of vertices that were contracted to form a and b , respectively. Since v has no red neighbour, it must be that $A \subseteq N(M)$ or $A \subseteq \overline{N}(M)$, similarly, $B \subseteq N(M)$ or $B \subseteq \overline{N}(M)$. We conclude that M is universal, isolated or $G - M$ admits a contraction sequence ending with the edge $\{N(M), \overline{N}(M)\}$. ◀

Given a permutation graph $G = (V, E)$ and $U \subseteq V$, we denote by $\sigma[U]$ and $\tau[U]$ the restrictions of σ and τ (re-numbered by $[[U]]$). They form a realiser of $G[U]$ as a permutation graph. We also use the notation $\sigma \cdot \tau$ to denote the concatenation of two orderings on disjoint domains (all elements of σ are before elements of τ , relative orders in σ and τ are preserved).

The following lemma implies Theorem 8.

► **Lemma 11.** *Let G be a graph of twin-width at most 1, and G_n, \dots, G_2, G_1 be a fixed 1-contraction sequence of G .*

Then G is a permutation graph admitting a realiser (σ, τ) satisfying the following.

- *For every $x \in V(G_i)$, $\{v \in V(G) \mid v \in x\}$ is an interval of (σ, τ) .*

- For every $x, y \in V(G_i)$, if $xy \in R(G_i)$, then $\{v \in V(G) \mid v \in (x \cup y)\}$ is an interval on one of the orderings $\pi \in \{\sigma, \tau\}$, and both $\{v \in V(G) \mid v \in x\}$ and $\{v \in V(G) \mid v \in y\}$ are intervals on the other ordering.

Proof. We proceed by induction on the number of vertices of the graph by leveraging the recursive characterization given in Lemma 10.

The statement is trivial for graphs on at most 3 vertices. We now consider a graph $G \in \mathcal{G}$ on more than 3 vertices and its contraction sequence $G_n, \dots, G_3, G_2, G_1$. Let M be the set of vertices of G that were contracted into a vertex of G_3 not incident to a red edge in G_3 , M is a module of G . Restricting the sequence G_n, \dots, G_1 to $G - M$ and $G[M]$, respectively, yields a 1-contraction sequence for each of them. By induction hypothesis applied with these sequences, we obtain realisers σ_1, τ_1 and σ_2, τ_2 of $G - M$ and $G[M]$, respectively. The following cases are illustrated in Figure 1. If M is universal (resp. isolated), $\sigma_1 \cdot \sigma_2, \tau_2 \cdot \tau_1$ (resp. $\sigma_1 \cdot \sigma_2, \tau_1 \cdot \tau_2$) is a realiser of G . Otherwise, the contraction sequence $G_n - M, \dots, G_3 - M$ is such that $V(G_3 - M) = \{N(M), \overline{N}(M)\}$. In particular, we know from the induction hypothesis that $B = N(M)$ and $A = \overline{N}(M)$ are intervals of either σ_1 or τ_1 , as they correspond to the sets of vertices contracted into the last two vertices on the sequence. Without loss of generality, we assume they are intervals of σ_1 . We can now produce the realiser $\sigma_1[B] \cdot \sigma_2 \cdot \sigma_1[A], \tau_2 \cdot \tau_1$. In all cases, the realiser satisfies the desired properties: it suffices to observe that by construction we do not contract vertices from $G - M$ with vertices from $G[M]$ until the last two contractions, so we must check only the last two contractions which are on trigraphs of order at most 3 hence the properties are satisfied. ◀

■ **Figure 1** The different cases of the induction constructing the realiser.

We now move on to show related properties that will be useful in further understanding permutation diagrams and their relation to contraction sequences.

In the particular case of a prime graph, we deduce the following two corollaries of Lemma 11.

- **Corollary 12.** In a prime graph G of twin-width 1, the first contraction must involve two vertices that are consecutive for one ordering, and with exactly one vertex between them for the other ordering.

Proof. In G_{n-1} , let x', z be the vertices incident to the red edge (there is a red edge because the graph is prime, see Lemma 7) with x' resulting of the contraction of vertices x and y of G . $X' = \{x, y\}$ is an interval for one ordering σ of the realiser. z must be a splitter of X' because it is incident to the red edge, this implies that z is between x and y in the ordering τ . ◀

Unfortunately, there can be linearly many such pairs. On the other hand, there are only 4 extremal vertices in a prime permutation graph. Hence, the following corollary is useful for obtaining a linear time recognition algorithm.

► **Corollary 13.** *In a prime graph of twin-width 1, for any 1-contraction sequence, the last vertex to become incident to the red edge is an extremal vertex of the realiser.*

Proof. Due to the graph being prime, the last vertex of G to become incident to the red edge is also a vertex of G_3 and is adjacent to exactly one other vertex of G_3 . The other two vertices of G_3 are connected because prime graphs are connected, hence G_3 is isomorphic to P_3 whose vertices are all extremal. In particular, the last vertex incident to the red edge is extremal. ◀

► **Observation 14.** *If G_n, \dots, G_1 are the trigraphs of a 1-contraction sequence of G , their underlying graphs form a chain for the induced subgraph relation, i.e. G_{i-1} is an induced subgraph of G_i for $i \in [2, n]$.*

Proof. We describe how to construct the induced subgraph of G by picking a representative in G for each vertex in G_i .

Consider a vertex v of G_i , either it has only black incident edges and we may pick any vertex of G that was contracted into v , or it has exactly one incident red edge vw , in which case we can pick the endpoints of some edge of G that is between the vertices contracted into v and the vertices contracted into w .

This construction picks only one vertex of G per vertex of G_i because the red degree is at most one meaning we do not pick more than once. ◀

This property only holds for 1-contraction sequences (e.g. contracting non-adjacent vertices of a matching creates a path on 3 vertices which is not an induced subgraph). It allows to view the contraction sequence as a sequence of vertex deletions. In particular, underlying graphs of the trigraphs of a 1-contraction sequence are also permutation graphs and one of their permutation diagrams is the induced permutation diagram obtained by seeing G_i as an induced subgraph of G . Observe that this diagram preserves the relative order of vertices that are not deleted. This will be important for our inductive reasoning since we can keep the same diagram while decomposing the graph. We denote by $\sigma[G_i]$ the ordering induced by G_i seen as an induced subgraph of G .

► **Corollary 15.** *Let G be a graph and G_n, \dots, G_1 a 1-contraction sequence of G . The realiser constructed from G_n, \dots, G_1 using Lemma 11 has the property that, for every $i > 1$, the vertices being contracted from G_i to G_{i-1} are consecutive for $(\sigma[G_i], \tau[G_i])$, and endpoints of red edges are consecutive for $(\sigma[G_i], \tau[G_i])$.*

Conversely, for any realiser (σ', τ') , there exists a 1-contraction sequence G_n, \dots, G_1 such that for every $i > 1$ the contracted vertices of G_i are consecutive in $(\sigma'[G_i], \tau'[G_i])$ and for any $xy \in R(G_i)$, x and y are consecutive in $(\sigma'[G_i], \tau'[G_i])$.

Proof. Suppose we contract $a, b \in V(G_i)$ into vertex $c \in V(G_{i-1})$. Let C be the set of vertices of G contracted into c , and A, B those contracted into a, b . By Lemma 11, A, B and C are all intervals of (σ, τ) . Since $C = A \cup B$, we may assume without loss of generality they

are all intervals of σ . Hence, a and b are consecutive for $\sigma[G_i]$. Similarly, the set of vertices of G contracted into a fixed red edge is an interval of (σ, τ) . Since the sets of vertices of G incident to the red edge are also intervals, this means the endpoints of the red edge in G_i are consecutive.

Now, consider any realiser (σ', τ') for graph G , and let us show the second part of the lemma by induction on the modular decomposition of G . The result holds trivially for leaves of the decomposition. Let us then consider an internal node q of the decomposition of G and consider the subgraphs H_1, \dots, H_k of G induced by the children of q . Now, since each H_i is a strong module of G , they each form a common interval of (σ', τ') by Observation 3. They also have twin-width 1, so our induction hypothesis along with Lemma 5 yields that we can contract each child fully by respecting the consecutivity properties on $(\sigma'[H_i], \tau'[H_i])$, and thus on (σ', τ') . Then, if q is a degenerate node, we can always find a pair of consecutive twins and contract them. Otherwise, q is prime, and as such it admits a unique realiser (up to symmetry), which is given by Lemma 11, for which the contraction sequence satisfies the desired properties by the first part of the lemma. ◀

4 Linear-time recognition algorithm

A realiser (σ, τ) , if it exists, can be found in linear time [24]. From the Corollaries 6, 12 and 15, we deduce that the algorithm of [10] can be implemented in time $O(n^2 + m)$. Indeed, for every prime node of the modular decomposition, it suffices to compute σ and τ for its quotient graph. At this point, we have restricted the set of possible first contractions to the set all pairs of consecutive vertices, and we may then simulate contraction sequences efficiently using the fact that new vertices to be contracted can be found in constant time, since they are consecutive. In order to obtain a linear time algorithm, we will instead guess the end of the sequence, and try to extend the sequence from its end, see Figure 2.

► **Lemma 16.** *Let G be a prime permutation graph of twin-width 1, which admits a 1-contraction sequence where an extremal vertex s is last to become incident to a red edge. Let also $G^1 = G[N(s)]$ and $G^2 = G[\overline{N}(s)]$.*

Then, there is a module M of G^i for some i that has a unique splitter $s' \in V(G^{3-i})$, such that $G[M \cup \{s'\}]$ admits a 1-contraction sequence where s' is the last vertex to be incident to the red edge, where:

- (i) *either M is a pair of consecutive twins in G^i and there are no prime nodes in the modular decompositions of G^1 and G^2 ,*
- (ii) *or M corresponds to the subtree rooted at a prime node p in the modular decomposition, and p is the unique prime node in the modular decompositions of G^1 and G^2 .*

Moreover, let $k = |V(G) - (M \cup \{s'\})|$, there is an ordering $\pi : [k] \rightarrow V(G) - (M \cup \{s'\})$ such that for all $i \in [k]$, $M \cup \{s'\} \cup \pi([i])$ forms an interval of σ and two intervals of τ for a realiser (σ, τ) where σ is the linear ordering for which s is extremal.

Proof. Let (σ, τ) be a realiser of G and s be an extremal vertex for σ which is the last vertex incident to the red edge in some 1-contraction sequence of G . Such a vertex exists due to Corollary 13. Let $G^1 = G[N(s)]$ and $G^2 = G[\overline{N}(s)]$ and observe that since G is prime, G^1 and G^2 are not empty. As s is extremal for σ , adjacent to $V(G^1)$ and non-adjacent to $V(G^2)$, $V(G^1)$ and $V(G^2)$ must be disjoint intervals of τ .

▷ **Claim 17.** In any contraction sequence as considered, we only contract pairs of vertices of G^1 or pairs of vertices of G^2 until we reach the 3-vertex trigraph.

Proof. Due to the assumption on s being the last vertex incident to a red edge, we cannot contract a vertex of G^1 with a vertex of G^2 , unless G^1 and G^2 both have been contracted to a single vertex, because they are split by s . \triangleleft

▷ **Claim 18.** For any non-trivial module M of G^i there is a splitter $s' \in V(G^{3-i})$. Furthermore, for any splitter $s' \in V(G^{3-i})$ of M there are a, b in M such that $\sigma(a) < \sigma(s') < \sigma(b)$.

Proof. Indeed, M cannot be a module of G , as G is a prime graph, so it must have a splitter s' in $G - V(G^i)$. Also note that s is not a splitter of M by definition of G^i . Furthermore, since s' is a splitter it must be adjacent to some $a \in M$ and non-adjacent to some $b \in M$. Since $V(G^1)$ and $V(G^2)$ are intervals of τ , we get that $\sigma(a) < \sigma(s') < \sigma(b)$ or $\sigma(a) < \sigma(s') < \sigma(b)$ by definition of the permutation diagram. \triangleleft

The following observation will allow to simplify the analysis.

► **Observation 19.** *If X induces a prime subgraph of H , and $t \in V(H) \setminus X$ is a splitter of X , then we can both extract a pair of vertices of X that are adjacent and split by t , and a pair of vertices of X that are non-adjacent and split by t .*

Proof. Consider the cut $C = (X \cap N(t), X - N(t))$ in $H[X]$, since $H[X]$ is prime both $H[X]$ and $\overline{H[X]}$ are connected, yielding both an edge and a non-edge across C . \blacktriangleleft

▷ **Claim 20.** There cannot be disjoint non-trivial strong modules in G^i .

Proof. We proceed by contradiction and consider M, M' two maximal disjoint non-trivial strong modules of G^i , without loss of generality $i = 1$. We first show that, in G , M and M' must have distinct splitters from $V(G^2)$, and then conclude that this contradicts the assumption that G has a 1-contraction sequence respecting Claim 17.

Using the fact that $V(G^1)$ and $V(G^2)$ are intervals of τ and the common interval characterisation of strong modules of G^1 given by Observation 3, we deduce that a splitter t , which necessarily belongs to $V(G^2)$, cannot split both M and M' . Indeed, we have $\sigma(M) < \sigma(M')$ or $\sigma(M') < \sigma(M)$, so if t is a splitter of M there exist $a, b \in M$ such that $\sigma(a) < \sigma(t) < \sigma(b)$ as seen in the previous claim. In particular, t is not a splitter of M' .

Now because M and M' are non-trivial modules of G^1 , they each have a splitter in G^2 . Let t and t' be such splitters. By maximality, M and M' correspond to subtrees rooted at siblings of the same node n in the modular decomposition of G^1 . Let us first consider the case when n is a prime node. In this case, Lemma 7 guarantees a red edge for $Q(n)$, and the two splitters t, t' forbid the existence of a contraction sequence with consecutivity properties as guaranteed by Lemma 11 and Corollary 15.

We may now assume that n is a degenerate node, and exhibit an induced subgraph H of G that does not admit a 1-contraction sequence respecting our assumptions. This will contradict the existence of such a sequence for the whole G , as its restriction to H would also be valid (as in Observation 4). The graph H consists of splitters t, t' , as well as two pairs of twins $a, b \in M$ and $a', b' \in M'$ distinguished by t, t' respectively. Then, vertices a, b, a', b' induce a cograph whose corresponding cotree is a complete binary tree of depth 2. In other words, (a, b) and (a', b') are present if and only if $\{a, b\}$ is adjacent to $\{a', b'\}$.

We first reduce M and M' so as to induce exactly the quotient graph of their corresponding node in the modular decomposition (recall that this is well defined because they are strong) by picking one vertex in each subtree below this node. We may ensure that t and t' still split this subset of vertices (e.g. by picking extremal vertices of the interval of σ corresponding to M and M' , recalling Observation 3).

Now we observe that if M (resp. M') has a degenerate root node, it is of the opposite type of the node n , and any pair of vertices of M (resp. M') that is split by t (resp. t') can be taken for our subgraph H . Otherwise, M (resp. M') has a prime root node, and we apply Observation 19 to obtain a pair of vertices that is split and has the required adjacency relation.

Let us now show that H does not admit a 1-contraction sequence satisfying our assumptions. Indeed, t and t' may only be contracted together, because they are the only vertices in $V(G^2)$ of our subgraph (Claim 17), but they are split by at least two vertices in $V(G^1)$. Now, any order of contractions on a, b, a', b' will create two red edges. More precisely, contracting a vertex from each nontrivial module creates two red edges, unless one module was already reduced to a single vertex, in which case it has a red edge to its splitter from $V(G^2)$. This will inevitably contradict Lemma 7. \triangleleft

\triangleright Claim 21. If G^i has a prime node p in its modular decomposition, the first red edge must appear in the module M corresponding to the subtree rooted at p . In this case, M has exactly one splitter s' from G^{3-i} and s' should not be incident to a red edge until M is contracted to a single vertex.

Proof. Let p be a prime node of the modular decomposition of G^i and M the module corresponding to the subtree rooted at p . Without loss of generality assume $i = 1$. We first make the observation that, since there cannot be two disjoint nontrivial strong modules in G^1 by Claim 20, and since prime graphs have at least 4 vertices, there are vertices introduced by node p .

We first consider the case when a red edge incident to a vertex of G^2 is created before we fully contract M . This red edge has to remain incident to a vertex of G^2 due to Claim 17. Contracting a vertex introduced in prime node p will create another red edge with both endpoints in G^1 , which is thus different and contradicts Lemma 7.

We now deal with the case where no red edge incident to a vertex of G^2 appears before we fully contract M . Assume the first red edge does not have both endpoints in M . Observe that the first contraction cannot be between vertices that are both not in M but have a different adjacency to it because M is a module on at least 4 vertices, and this would create a red edge to all of them. Observe also that if the first contraction had involved a vertex of M , there would also be a red edge with both endpoints in M . Indeed, on the one hand, if both contracted vertices were in M , red edges with both endpoints in G^i would have both endpoints in M because it is a module. On the other hand, M is also a strong module with a prime node at its root, so all of its vertices have a mixed adjacency to the rest of M , contrary to vertices outside M . We conclude that the first contraction is between two vertices outside of M , so the corresponding red edge has both endpoints outside of M . This has the following implications: both contracted vertices have an homogeneous adjacency to M , but they also have a unique splitter in G^1 , this implies we cannot contract the red edge before contracting the subgraph corresponding to p . Indeed, the two vertices incident to the red edge must have opposite adjacency relations with respect to M . Since contracting M will force the creation of a second red edge, this contradicts Lemma 7.

M is a non-trivial strong module of G^1 so it has at least one splitter in G^2 . From Lemma 7 and Claim 17, it follows that a red edge incident to this splitter cannot appear before M is contracted to a single vertex. Finally, only one red edge may appear when M is contracted to a single vertex meaning the splitter must be unique. \triangleleft

In particular, this shows that only one of G^1 and G^2 can have a prime node in their modular decomposition. We can moreover deduce that if there is a prime node in G^i , it must be unique. Indeed, a red edge has to appear in some M corresponding to the subtree of the

prime node that is deepest in the modular decomposition of G^i . At any step of the sequence, M contains a red edge, until it is a single vertex with a red edge towards its splitter. Then, vertices introduced in any higher prime node cannot be contracted on such red edges without producing an additional red edge, which contradicts Lemma 7.

We are now ready to define M . Consider the first red edge appearing between $X_1 \subseteq V(G^1)$ and $X_2 \subseteq V(G^2)$ in a 1-contraction sequence as considered, and assume without loss of generality that it stems from a contraction in G^1 . Then, X_2 can only consist in a single vertex s' due to Claim 17, Lemma 7, and the fact that this is the first red edge with an endpoint in both G^1 and G^2 . Then, X_1 is included in a module of G^1 which admits as unique splitter s' . In the case when there is no prime node, X_1 induces a cograph, so we may then take M to be any pair of consecutive twins $a, b \in X_1$, which are also consecutive twins in G^1 by Corollary 15, distinguished by s' (because G is prime and s' is the only splitter of X_1).

Otherwise, we can take M and s' as guaranteed by Claim 21 on G^1 and G^2 . The restriction of our contraction sequence to $G[M \cup s']$ yields a 1-contraction sequence in which s' becomes incident to a red edge last, as desired.

Having defined M , we are ready to show the following.

▷ **Claim 22.** There exists a 1-contraction sequence of G that starts by contracting only vertices of M until it is reduced to a single vertex. In particular, this creates a red edge towards s' at the last contraction.

Proof. We can extend the contraction sequence that contracts M first into a sequence contracting the smallest interval I of $\sigma[V(G^1)]$ containing X_1 because X_1 is not split by any splitter from G^2 other than s' , and it does not have disjoint non trivial strong modules. After contraction of M to a single vertex, the remaining vertices of I induce a cograph that is not split by any vertex of G^2 other than s' . We can then proceed with the rest of the contraction of G simply by contracting remaining vertices according to our initial contraction sequence. ◁

At this point, in both cases, we know M forms a common interval for $(\sigma[V(G^1)], \tau[V(G^1)])$, and that there is some 1-sequence for G that first contracts M and in which s is the last vertex to be incident to a red edge. We deduce that $M \cup \{s'\}$ satisfies the setting of Corollary 15, and any further contractions must be consecutive to M due to Corollary 15, ensuring the existence of π . ◀

The crucial observation now is that π can easily be computed greedily using the realiser.

► **Lemma 23.** *Given a permutation diagram of a prime permutation graph G and an extremal vertex s of G , we can produce in time linear in the number of vertices of G a 1-contraction sequence such that s is the last vertex of G to be incident to the red edge, or conclude that no such sequence exists.*

Proof. This is essentially an implementation of the result of Lemma 16, we reuse similar notations and provide an illustration in Figure 2. The algorithm works as follows.

We initialise indices at the endpoints of the intervals A and B of τ that are split by s , and at the endpoints of the interval $C = V(G) - \{s\}$ of σ . We add s to the global list Π and mark it as a splitter.

While there is one endpoint v of C that is also an endpoint of A or an endpoint of B , we add v to the global list Π and update indices describing A, B , and C in accordance to the removal of v . We call such a vertex v *doubly extremal*.

■ **Figure 2** An example of a twin-width 1 graph and its permutation diagram. Shown here is the decomposition of Lemma 23 starting from extremal vertex s_1 . The segments of splitters s_1, s_2, s_3 are represented in dashed blue, green and orange respectively. Then, intervals of the corresponding colour are the intervals A, B, C produced during the iteration in which the splitter is considered. A and B induce subgraphs G^i from Lemma 16. Then, segments of the same colour as a splitter correspond to doubly extremal vertices eliminated in the corresponding step.

If the intervals have become empty, return Π , otherwise, if either A or B contains a single vertex, we set s' to be this vertex and M to be the other interval, and apply the algorithm recursively to $G[M \cup \{s'\}]$ with s' as the last vertex incident to a red edge. Finally, if both A and B contain more than one vertex, we reject.

We can use marked vertices to deduce a contraction sequence: we iterate through Π , starting from the last vertices added. When reaching a marked vertex, we contract the red edge. Otherwise, we contract the current vertex to the vertex of the red edge with the same adjacency to the next marked vertex.

If the algorithm does not reject, let us show by induction on the recursive calls that the list Π , along with its marked vertices, describes a valid order of contractions for G . First, we clarify the starting red edge that we consider in the part of the contraction sequence built at this step of the recursion. In the case when we emptied A and B (so M and s' are not defined), take the last vertex in A and the last vertex in B as a starting red edge. We move to the case where M and s' are defined. Here, by induction hypothesis, the algorithm finds a 1-contraction sequence with s' as the last vertex incident to a red edge for $G[M \cup \{s'\}]$. This contraction sequence for $G[M \cup \{s'\}]$ gives a partial 1-contraction sequence for G (see Observation 4) yielding a red edge between M and s' , with all other vertices of G not contracted yet.

We now check that each vertex added to Π at this step can be contracted in the order described by Π . This is the case because the vertex does not split the vertices of A contracted before it, nor the vertices of B contracted before it. By contracting it to the vertex of the red edge with the same adjacency to s , we create no additional red edge. In particular, s is still not incident to a red edge. Once we contracted all vertices of A and B , the red edge can be safely contracted. Indeed, s is the unique splitter of $A \cup B$.

If the algorithm rejects, it contradicts the existence of π guaranteed by Lemma 16. Indeed, if for all i , the $M \cup \{s'\} \cup \pi([i])$ are intervals as claimed, it must be that for each i , $\pi(i)$ is extremal on $\sigma[M \cup \{s'\} \cup \pi([i])]$ and on $\tau[(M \cup \{s'\} \cup \pi([i])) \cap V(G^j)]$ for some $j \in \{1, 2\}$. In particular, all vertices that are not in $M \cup \{s'\}$ will become doubly extremal if π exists. Note that this is independent of the order in which they are contracted. Indeed, a vertex remains (doubly) extremal while we delete other vertices.

We conclude that G has twin-width more than 1. ◀

► **Theorem 24.** *We can decide in linear time if a given graph G has twin-width at most 1.*

Proof. We first compute a modular decomposition of G and realisers for the quotient graphs of prime nodes [24]¹, or conclude that G is not a permutation graph and therefore not a graph of twin-width 1. It is well-known that the total size of the quotient graphs of prime nodes is linear in the size of the original graph.

We then check all prime nodes with corresponding quotient graph H as follows:

Guess an extremal vertex s (out of at most 4) that can be the last vertex incident to the red edge in a 1-contraction sequence of H , and then apply the recursive algorithm of Lemma 23.

If all prime nodes have twin-width 1, we obtained a contraction sequence for all of them and they can be combined to form a contraction sequence of G using Corollary 6.

All of the above procedures can be implemented to run in linear time. ◀

Abstract

In the EDGE COLORING problem, we are given an undirected graph G with n vertices and m edges, and are tasked with finding the smallest positive integer k so that the edges of G can be assigned k colors in such a way that no two edges incident to the same vertex are assigned the same color. EDGE COLORING is a classic NP-hard problem, and so significant research has gone into designing fast *exponential-time* algorithms for solving EDGE COLORING and its variants exactly. Prior work showed that EDGE COLORING can be solved in $2^m \text{poly}(n)$ time and polynomial space, and in graphs with average degree d in $2^{(1-\varepsilon_d)m} \text{poly}(n)$ time and exponential space, where $\varepsilon_d = (1/d)^{\Theta(d^3)}$.

We present an algorithm that solves EDGE COLORING in $2^{m-3m/5} \text{poly}(n)$ time and polynomial space. Our result is the first algorithm for this problem which simultaneously runs in faster than $2^m \text{poly}(m)$ time and uses only polynomial space. In graphs of average degree d , our algorithm runs in $2^{(1-6/(5d))m} \text{poly}(n)$ time, which has far better dependence in d than previous results. We also consider a generalization of EDGE COLORING called LIST EDGE COLORING, where each edge e in the input graph comes with a list $L_e \subseteq \{1, \dots, k\}$ of colors, and we must determine whether we can assign each edge a color from its list so that no two edges incident to the same vertex receive the same color. We show that this problem can be solved in $2^{(1-6/(5k))m} \text{poly}(n)$ time and polynomial space. The previous best algorithm for LIST EDGE COLORING took $2^m \text{poly}(n)$ time and space.

Our algorithms are algebraic, and work by constructing a special polynomial P based off the input graph that contains a multilinear monomial (i.e., a monomial where every variable has degree at most one) if and only if the answer to the LIST EDGE COLORING problem on the input graph is YES. We then solve the problem by detecting multilinear monomials in P . Previous work also employed such monomial detection techniques to solve EDGE COLORING. We obtain faster algorithms both by carefully constructing our polynomial P , and by improving the runtimes for certain structured monomial detection problems using a technique we call partition sieving.

1 Introduction

Coloring graphs is a rich area of research in graph theory and computer science. Given a graph G , a *proper vertex coloring* of G is an assignment of colors to its nodes such that no two adjacent vertices receive the same color. In the VERTEX COLORING problem, we are given an undirected graph G on n vertices, and are tasked with computing the smallest positive

integer k such that G admits a proper vertex coloring using k colors. VERTEX COLORING is a classic combinatorial problem, NP-hard to solve even approximately [27]. An influential line of research has worked on designing faster and faster exponential-time algorithms for this problem [24, 17, 13, 8], culminating in an algorithm solving VERTEX COLORING in $O^*(2^n)$ time and space [11], where throughout we write $O^*(f(n))$ as shorthand for $f(n) \text{ poly}(n)$.

In this paper, we study exact algorithms for the closely related EDGE COLORING problem. Given a graph G , a *proper edge coloring* of G is an assignment of colors to its edges such that no two edges incident to a common vertex receive the same color. The smallest positive integer k such that G admits a proper edge coloring using k colors is the *chromatic index* of G , denoted by $\chi'(G)$. In the EDGE COLORING problem, we are given an undirected graph G on n vertices and m edges, and are tasked with computing $\chi'(G)$.

Let Δ denote the maximum degree of the input graph G . For each vertex v in G , a proper edge coloring of G must assign distinct colors to the edges incident to v . Thus $\chi'(G) \geq \Delta$. A classic result in graph theory known as Vizing's theorem proves that in fact $\chi'(G) \leq \Delta + 1$, so that the simple Δ lower bound is close to the truth. Moreover, a proper edge coloring of G using $(\Delta + 1)$ colors can be found in near-linear time [2]. Consequently, solving EDGE COLORING amounts to distinguishing between the cases $\chi'(G) = \Delta$ and $\chi'(G) = \Delta + 1$. Despite this powerful structural result, the EDGE COLORING problem is NP-hard just like VERTEX COLORING, even for graphs where all vertices have degree exactly $\Delta = 3$ [21].

In recent years, researchers have made major strides in our knowledge of algorithms for *approximate* variants of EDGE COLORING in the distributed [19, 5, 3] and dynamic settings [15, 14, 6]. In comparison, much less is known about the exponential-time complexity for solving the EDGE COLORING problem *exactly*.

A simple way to solve EDGE COLORING is by reduction to VERTEX COLORING. Given the input graph G , we can construct in polynomial time the *line graph* $L(G)$ whose nodes are edges of G , and whose nodes are adjacent if the corresponding edges in G are incident to a common vertex. By construction, the solution to VERTEX COLORING on $L(G)$ gives the solution to EDGE COLORING on G . If G has m edges and maximum degree Δ , then $L(G)$ has m vertices and maximum degree $(2\Delta - 1)$. Using the aforementioned $O^*(2^n)$ time and space algorithm for VERTEX COLORING, this immediately implies a $O^*(2^m)$ time and space algorithm for EDGE COLORING. In graphs with maximum degree Δ , VERTEX COLORING can be solved in $O^*(2^{(1-\varepsilon)n})$ time and space, where $\varepsilon = (1/2)^{\Theta(\Delta)}$ [9]. By applying the above reduction, EDGE COLORING can similarly be solved in $O^*(2^{(1-\varepsilon)m})$ time and space, for $\varepsilon = (1/2)^{\Theta(\Delta)}$.

Line graphs are much more structured objects than generic undirected graphs (for example, there are small patterns that line graphs cannot contain as induced subgraphs [4, Theorem 3]), so one might hope to solve EDGE COLORING faster without relying on a black-box reduction to VERTEX COLORING. Nonetheless, there is only one result from previous work which solves EDGE COLORING on general undirected graphs without using this reduction. Specifically, [10, Section 5.6] shows that EDGE COLORING can be solved in $O^*(2^m)$ time and polynomial space. In comparison, it remains open whether VERTEX COLORING can be solved in $O^*(2^n)$ time using only polynomial space.

In summary, algorithms from previous work can solve EDGE COLORING in

- $O^*(2^m)$ time using polynomial space, or in
- faster than $O^*(2^m)$ time in bounded degree graphs, using exponential space.

Given this state of affairs, it is natural to ask:

Can EDGE COLORING be solved in faster than $O^(2^m)$ time, using only polynomial space?*

We answer this question affirmatively by proving the following result.

► **Theorem 1.1.** *There is a randomized algorithm which solves EDGE COLORING with high probability and one-sided error in $O^*(2^{m-3n/5})$ time and polynomial space.*

If the input graph has average degree d , then $m = dn/2$, so Theorem 1.1 equivalently states that EDGE COLORING can be solved in $O^*(2^{(1-\varepsilon)m})$ time for $\varepsilon = \frac{6}{5d}$. In comparison, the current fastest algorithm for VERTEX COLORING on graphs with average degree d takes $O^*(2^{(1-\delta)n})$ time, where $\delta = (1/d)^{\Theta(d^3)}$ [18, Lemma 4.4 and Theorem 5.4]. Prior to our work, the fastest algorithm for EDGE COLORING in the special case of regular graphs (i.e., graphs where all vertices have the same degree) took $O^*(2^{m-n/2})$ time [10, Theorem 6]. The regularity assumption simplifies the EDGE COLORING problem significantly, as in this case the problem reduces to finding a collection of $(\Delta - 1)$ mutually disjoint perfect matchings, which together consist of only $(m - n/2)$ edges. Theorem 1.1 improves upon this runtime with an algorithm that succeeds on *all* undirected graphs, not just regular graphs.

In the case of regular graphs, we obtain improvements beyond Theorem 1.1 when the graphs have high degree. We say a graph is d -regular if all its nodes have degree d . Given a positive integer k , let

$$H_k = \sum_{j=1}^k \frac{1}{j} \tag{1}$$

denote the k^{th} Harmonic number. We prove the following result.

► **Theorem 1.2.** *For each integer $d \geq 6$, there is a randomized algorithm that solves EDGE COLORING with high probability and one-sided error on d -regular graphs in $O^*(2^{m-\alpha_d n})$ time and polynomial space, for $\alpha_d = 1 - H_{d+1}/(d+1)$.*

For example for $d = 6$, Theorem 1.2 shows that we can solve EDGE COLORING in 6-regular graphs in $O^*(2^{m-0.62n})$ time, slightly faster than the runtime presented in Theorem 1.1. The savings in the exponent are better for larger d , approaching a runtime of $O^*(2^{m-n})$ as the degree d grows since we have $\alpha_d = 1 - \Theta((\log d)/d)$.

We also consider a generalization of EDGE COLORING called LIST EDGE COLORING. In this problem, we are given an undirected graph G with m edges as before, together with a positive integer k and a list of possible colors $L_e \subseteq \{1, \dots, k\}$ for each edge e . We are tasked with determining whether G admits a proper edge coloring, which assigns each edge e a color from the list L_e . If we set $k = \Delta$ to be the maximum degree of G and set $L_e = \{1, \dots, k\}$ for each edge e , we recover the standard EDGE COLORING problem. Using more sophisticated arguments, we generalize Theorem 1.1 to the LIST EDGE COLORING problem.

► **Theorem 1.3.** *There is a randomized algorithm that solves LIST EDGE COLORING with high probability and one-sided error in $O^*(2^{m-3n/5})$ time and polynomial space.*

Prior to our work, no algorithm was known for LIST EDGE COLORING which simultaneously ran in faster than $O^*(2^m)$ time and used polynomial space.

1.1 Our Techniques

Our algorithms for EDGE COLORING and LIST EDGE COLORING are algebraic, and involve reducing these problems to certain *monomial detection* tasks, by now a common paradigm in graph algorithms. To achieve the $O^*(2^{m-3n/5})$ runtime and polynomial space bounds for these problems, we combine and improve techniques in polynomial sieving, matroid constructions, and enumeration using matrices.

7:4 Faster Edge Coloring by Partition Sieving

The main technical ingredient in our work builds off the *determinantal sieving* technique introduced in [16]. Given a homogeneous multivariate polynomial $P(X)$ of degree k and a linear matroid \mathcal{M} on X of rank k , this technique allows one to test in $O^*(2^k)$ time whether $P(X)$ contains a multilinear monomial (i.e., a monomial where each variable has degree at most one) that forms a basis in \mathcal{M} . We recall the formal definition of matroids in Section 2. For the purpose of this overview, a matroid \mathcal{M} is a family of subsets of variables of P satisfying certain properties, and a basis in \mathcal{M} is a set in this family whose size equals the rank k . In our applications, we construct P to enumerate certain structures in the input graph. Finding a multilinear monomial in P corresponds to identifying a particularly nice structure in the graph (e.g., a solution to the EDGE COLORING problem). Determinantal sieving is useful because one can pick \mathcal{M} in such a way that identifying a monomial in P that forms a basis in \mathcal{M} recovers extra information about the relevant structures in the graph.

We build off determinantal sieving and introduce the *partition sieving* method. This technique involves a *partition matroid* \mathcal{D} , which is a simple type of matroid defined using an underlying partition of the variable set of P . Given a partition matroid \mathcal{D} whose partition has p parts, and a polynomial P *compatible* with \mathcal{D} (“compatible” is a technical condition defined in Section 3 – intuitively, it requires that monomials in P have degrees respecting the partition defining \mathcal{D}), we can test whether P contains a multilinear monomial forming a basis in \mathcal{D} in $O^*(2^{k-p})$ time and polynomial space. This offers an exponential speed-up over determinantal sieving. To apply partition sieving, we need to carefully design both the polynomial P and the partition matroid \mathcal{D} to be compatible in our technical framework.

We design the polynomial P using the notion of the Pfaffian of a matrix. If A is a symbolic skew-symmetric adjacency matrix of G , then its Pfaffian $\text{Pf } A$ is a polynomial that enumerates the perfect matchings in G . The EDGE COLORING problem may be rephrased as asking whether the edge set of G can be partitioned into a collection of k matchings. One can design a polynomial that enumerates k matchings by computing a product of k Pfaffians of adjacency matrices. However, this simple construction does not meet the technical conditions we need to employ partition sieving. Instead we utilize the Ishikawa-Wakayama formula [22], a convolution identity for Pfaffians and determinants, to design a polynomial that enumerates matchings which satisfy certain degree constraints. Specifically, the formula lets us construct a polynomial P whose monomials correspond to k -tuples of matchings in G , where each vertex in G appears as an endpoint in exactly $\deg_G(v)$ of the matchings in the tuple.

We design the partition matroid \mathcal{D} in terms of a *dominating set* of the input graph. A subset of vertices D is a dominating set in G if every vertex in $V \setminus D$ is adjacent to a node in D . Given a dominating set D in G , we show that it is always possible to construct a partition matroid \mathcal{D} with $p = |V \setminus D|$ parts, compatible with our enumerating polynomial P (in our proofs, \mathcal{D} is actually only compatible with a polynomial obtained from P by the inclusion-exclusion principle, but we ignore that distinction in this overview). We achieve compatibility using the degree condition imposed on P , mentioned at the end of the previous paragraph. Partition sieving then lets us detect a multilinear monomial in P , and thus solve EDGE COLORING, in $O^*(2^{m-|V \setminus D|})$ time.

► **Lemma 1.4.** *There is a randomized algorithm that, given a graph G on n vertices and m edges and a dominating set D of G , solves EDGE COLORING on G with high probability and one-sided error in $O^*(2^{m-n+|D|})$ time and polynomial space.*

In other words, by finding smaller dominating sets in G , we can solve EDGE COLORING faster. In polynomial time, it is easy to construct a dominating set of size at most $n/2$ in any connected graph G with n vertices. Consequently, the partition sieving framework lets us solve EDGE COLORING in $O^*(2^{m-n/2})$ time. We obtain faster algorithms using the fact

that if a graph with $n \geq 8$ nodes has minimum degree two, then it contains a dominating set of size at most $2n/5$ [29]. We make this result effective, showing how to *find* such a dominating set in $O^*(2^{m-3n/5})$ time and polynomial space. When solving EDGE COLORING, it turns out one can assume without loss of generality that the graph has minimum degree two, and so this framework yields a $O^*(2^{m-3n/5})$ time algorithm for the problem. The situation is far more complex for LIST EDGE COLORING, where unit-degree vertices cannot be removed freely. For this problem, we construct a more complicated polynomial P , by enforcing additional matroid conditions in the Ishikawa-Wakayama formula. Intuitively, we identify a subgraph G_{new} of minimum degree two in G , and use P to determine whether G_{new} admits a list edge coloring which can be *extended* to all of G .

Organization

In Section 2 we review notation, basic assumptions, and useful facts about polynomials, matrices, and matroids. In Section 3 we introduce our partition sieving method for monomial detection. In Section 4 we present a generic algorithmic template for solving coloring problems using polynomials. In Section 5 we apply this framework to design our algorithms for EDGE COLORING and prove Theorems 1.1 and 1.2. We conclude in Section 6 with a summary of our work and some open problems. Our LIST EDGE COLORING algorithm and the proof of Theorem 1.3 is deferred to the full version of this paper.

2 Preliminaries

General Notation

Given a positive integer a , we let $[a] = \{1, \dots, a\}$ denote the set of the first a consecutive positive integers. Given a set S and positive integer k , we let $\binom{S}{k}$ denote the family of subsets of S of size k . Given a positive integer k , we let H_k denote the k^{th} Harmonic number, defined in Equation (1).

Graph Notation and Assumptions

Throughout, we consider graphs which are undirected. We let n and m denote the number of vertices and edges in the input graphs for the problems we study. We assume that the input graphs are connected, so that $m \geq n - 1$. This is without loss of generality, since when solving EDGE COLORING and LIST EDGE COLORING on disconnected graphs, it suffices to solve the problems separately on each connected component. Given a graph G and vertex v , we let $\deg_G(v)$ denote the number of neighbors of v (i.e., the degree of v in G). For the LIST EDGE COLORING problem where each edge is assigned a list of colors from a subset of $[k]$, we assume that $\deg_G(v) \leq k$ for all vertices v in G , since if some vertex v has degree greater than k , its incident edges must all be assigned distinct colors in a proper edge coloring, and the answer to the LIST EDGE COLORING problem is trivially no.

We let $\Pi(G)$ denote the set of perfect matchings of G – partitions of the vertex set of G into parts of size two, such that each part consists of two adjacent vertices.

Dominating Sets

A dominating set D in a graph G is a subset of vertices of G such that every vertex in G is either in D or adjacent to a node in D . We collect some useful results relating to finding small dominating sets in graphs.

7:6 Faster Edge Coloring by Partition Sieving

► **Lemma 2.1** (Simple Dominating Set). *There is a polynomial time algorithm which takes in a connected graph on n nodes and outputs a dominating set for the graph of size at most $n/2$.*

Lemma 2.1 is due to Ore [32], and we include a proof in the full version of this paper.

► **Lemma 2.2** (Dominating Sets in Dense Graphs [12, 29]). *If G has $n \geq 8$ nodes, and every vertex in G has degree at least two, then G has a dominating set of size at most $2n/5$.*

► **Lemma 2.3** (Dominating Sets in Regular Graphs [1, 33]). *Any d -regular graph on n vertices has a dominating set of size at most $(H_{d+1}/(d+1))n$.*

► **Lemma 2.4** (Dominating Set Algorithm). *Let G' be a graph obtained by starting with G , and repeatedly deleting vertices of degree one until no vertices of degree one remain. Suppose at most $n/5$ unit-degree vertices were deleted from G to produce G' . Then a minimum-size dominating set of G' can be found in $O^*(2^{m-3n/5})$ time and polynomial space.*

Lemma 2.4 is proved in the full version of this paper.

Finite Field Arithmetic

Throughout, we work with polynomials and matrices over a field $\mathbb{F} = \mathbb{F}_{2^\ell}$ of characteristic two, where $\ell = \text{poly}(n)$ is sufficiently large. Arithmetic operations over \mathbb{F} take $\text{poly}(n)$ time. All elements $a \in \mathbb{F}$ satisfy $a^{2^\ell} = a$. Consequently, given any element $a \in \mathbb{F}$, we can compute its unique square root as $a^{2^{\ell-1}}$ by repeated squaring in $\text{poly}(n)$ time.

Polynomials

Let $P(X)$ be a polynomial over a set of variables $X = \{x_1, \dots, x_n\}$. A monomial \mathbf{m} is a product $\mathbf{m} = x_1^{m_1} \cdots x_n^{m_n}$ for some nonnegative integers m_1, \dots, m_n . A monomial \mathbf{m} is *multilinear* if $m_i \leq 1$ for each $i \in [n]$. We say \mathbf{m} appears in the polynomial P if the coefficient of \mathbf{m} in P is nonzero. We define the *support* of \mathbf{m} to be the set of indices

$$\text{supp}(\mathbf{m}) = \{i \in [n] \mid m_i > 0\}$$

of variables which appear with positive degree in \mathbf{m} .

Similarly, we define the *odd support* of \mathbf{m} to be the set

$$\text{osupp}(\mathbf{m}) = \{i \in [n] \mid m_i \equiv 1 \pmod{2}\}$$

of indices of variables which appear with odd degree in \mathbf{m} . By definition, $\text{osupp}(\mathbf{m}) \subseteq \text{supp}(\mathbf{m})$ for all monomials \mathbf{m} .

The *degree* of a monomial $\mathbf{m} = x_1^{m_1} \cdots x_n^{m_n}$ is defined to be $\deg(\mathbf{m}) = m_1 + \cdots + m_n$. Given $S \subseteq [n]$, we define the degree of \mathbf{m} restricted to the variables indexed by S to be

$$\sum_{i \in S} m_i.$$

The *total degree* (or just *degree*) of P is defined to be

$$\deg P = \max_{\mathbf{m}} \deg(\mathbf{m})$$

where the maximum is taken over all monomials \mathbf{m} with nonzero coefficient in P . We say that a polynomial P is *homogeneous* if $\deg(\mathbf{m}) = \deg P$ for all monomials \mathbf{m} in P .

We recall the Lagrange Interpolation formula, which allows one to recover coefficients of a low degree univariate polynomial from a small number of evaluations of that polynomial.

► **Proposition 2.5** (Lagrange Interpolation). *Let $P(z)$ be a univariate polynomial of degree less than n . Suppose that $P(z_i) = p_i$ for distinct $z_1, \dots, z_n \in \mathbb{F}$. Then*

$$P(z) = \sum_{i \in [n]} p_i \prod_{j \in [n] \setminus \{i\}} \frac{z - z_j}{z_i - z_j}.$$

So given n evaluations of P at distinct points, we can compute all the coefficients of $P(z)$ in polynomial time.

We also record the following observation, proven for example in [30, Theorem 7.2], which shows that to test whether a low degree polynomial P is nonzero, it suffices to check whether a random evaluation of P over a sufficiently large field is nonzero.

► **Proposition 2.6** (Schwartz-Zippel Lemma). *Let P be a nonzero polynomial over a finite field \mathbb{F} of degree at most d . If each variable of P is assigned an independent, uniform random value from \mathbb{F} , then the corresponding evaluation of P is nonzero with probability $1 - d/|\mathbb{F}|$.*

Matrices

Given a matrix A and sets of rows I and columns J , we let $A[I, J]$ denote the submatrix of A restricted to rows in I and columns in J . We let $A[I, \cdot]$ denote the submatrix of A restricted to rows in I but using all columns, and $A[\cdot, J]$ denote the submatrix of A restricted to columns in J but using all rows. If the rows and column sets of A are identical, we write $A[S]$ as shorthand for $A[S, S]$. We let O denote the all-zeros matrix, whose dimensions will always be clear from context. We let A^\top denote the transpose of A . A matrix A is *symmetric* if $A = A^\top$, and *skew-symmetric* if it is symmetric and has zeros along its main diagonal (we employ this definition because we work over characteristic two).

If A is a square matrix, we let $\det A$ denote the determinant of A .

Given a set V , a perfect matching on V is a partition of V into sets of two elements each. We let $\Pi(V)$ denote the set of perfect matchings on V . Given a skew-symmetric matrix A with rows and columns indexed by a set V , we define the *Pfaffian* of A to be

$$\text{Pf } A = \sum_{M \in \Pi(V)} \prod_{\{u, v\} \in M} A[u, v]. \quad (2)$$

The standard definition for Pfaffians involves a sign term (see e.g., [31, Section 7.3.2]), which we ignore here because we work over a field of characteristic two. It is well known that for all skew-symmetric A , we have $\det A = (\text{Pf } A)^2$ (see e.g., [31, Proposition 7.3.3] for a proof). Consequently, the Pfaffian of matrix A over the field \mathbb{F}_{2^ℓ} can be computed in $\text{poly}(n, \ell) \leq \text{poly}(n)$ time by using the equation $\text{Pf } A = \sqrt{\det A} = (\det A)^{2^{\ell-1}}$.

We record the following useful facts for computation with Pfaffians and determinants.

► **Proposition 2.7** (Direct Sums). *For any skew-symmetric matrices A_1 and A_2 , we have*

$$\text{Pf} \begin{pmatrix} A_1 & O \\ O & A_2 \end{pmatrix} = (\text{Pf } A_1) (\text{Pf } A_2)$$

over a field of characteristic two.

Proposition 2.7 is proved in the full version of this paper.

► **Proposition 2.8** (Ishikawa-Wakayama Formula). *For a skew-symmetric $n \times n$ -matrix A and a $k \times n$ -matrix B with $k \leq n$, we have*

$$\text{Pf } BAB^\top = \sum_{S \in \binom{[n]}{k}} \det B[\cdot, S] \text{Pf } A[S].$$

7:8 Faster Edge Coloring by Partition Sieving

Proposition 2.8 is due to [22] (see [23, Section 4.3] for a recent alternate proof).

Matroids

A *matroid* is a pair $\mathcal{M} = (X, \mathcal{I})$, consisting of a *ground set* X and a collection \mathcal{I} of subsets of X called *independent sets*, satisfying the following axioms:

1. $\emptyset \in \mathcal{I}$.
2. If $B \in \mathcal{I}$ and $A \subset B$, then $A \in \mathcal{I}$.
3. For any $A, B \in \mathcal{I}$ with $|A| < |B|$, there exists an element $b \in B \setminus A$ such that $A \cup \{b\} \in \mathcal{I}$.

A maximal independent set in a matroid \mathcal{M} is called a *basis*. It is well known that all bases of \mathcal{M} have the same size r , which is referred to as the *rank* of \mathcal{M} . We say $S \subseteq V$ *spans* \mathcal{M} if S is a superset of a basis of \mathcal{M} . If there exists a matrix A with column set X such that for every $S \subseteq X$, the set S is independent in \mathcal{M} if and only if $A[:, S]$ has full rank, then we say that \mathcal{M} is a *linear matroid represented* by A . Provided we work over a large enough field of size $\text{poly}(|X|)$, it is known that if \mathcal{M} is linear, then it can be represented by a matrix whose number of rows equals the rank of \mathcal{M} (see e.g., [26] or [28, Section 3.7]).

Given matroids $\mathcal{M}_1, \dots, \mathcal{M}_k$ over disjoint ground sets X_1, \dots, X_k respectively, we define the direct sum

$$\mathcal{M} = \bigoplus_{i=1}^k \mathcal{M}_i$$

of these matroids to be the ground set $X = X_1 \sqcup \dots \sqcup X_k$ together with the family \mathcal{I} of subsets S of X with the property that $S \cap X_i$ is independent in \mathcal{M}_i for all $i \in [k]$. It is well known that \mathcal{M} is a matroid as well, whose rank is equal to the sum of the ranks of the \mathcal{M}_i .

The following result lets us represent direct sums of linear matroids [28, Section 3.4].

► **Proposition 2.9 (Matroid Sum).** *Given linear matroids $\mathcal{M}_1, \dots, \mathcal{M}_k$ represented by matrices A_1, \dots, A_k respectively, their direct sum is represented by the block-diagonal matrix*

$$A = \begin{pmatrix} A_1 & O & \dots & O \\ O & A_2 & \dots & O \\ \vdots & \vdots & \ddots & \vdots \\ O & O & \dots & A_k \end{pmatrix}.$$

In our EDGE COLORING algorithm, we make use of two simple types of matroids: uniform and partition matroids. Given a ground set X and a nonnegative integer r , the *uniform matroid* over X of rank r has as its independent sets all subsets of X of size at most r .

► **Proposition 2.10 (Uniform Matroid Representation [28, Section 3.5]).** *Given a set X , a nonnegative integer r , and a field \mathbb{F} with $|\mathbb{F}| > |X|$, we can construct an $r \times |X|$ matrix representing the uniform matroid over X of rank r in $\text{poly}(|X|)$ time.*

Given a set X partitioned $X = X_1 \sqcup \dots \sqcup X_k$ into parts X_i , and a list of nonnegative integer capacities c_1, \dots, c_k , the *partition matroid* \mathcal{M} over the ground set X for this partition and list of capacities has as its independent sets all subsets $S \subseteq X$ satisfying $|S \cap X_i| \leq c_i$ for all $i \in [k]$. Equivalently, \mathcal{M} is the direct sum of uniform matroids of rank c_i over X_i for all $i \in [k]$. By definition, \mathcal{M} has rank $r = (c_1 + \dots + c_k)$. By Propositions 2.9 and 2.10 we see that we can efficiently construct representations of partition matroids [28, Proposition 3.5].

► **Proposition 2.11 (Partition Matroid Representation).** *Given a partition matroid \mathcal{M} over X of rank r , and a field \mathbb{F} with $|\mathbb{F}| > |X|$, we can construct an $r \times |X|$ matrix representing \mathcal{M} in $\text{poly}(|X|)$ time.*

3 Polynomial Sieving

In this section, we develop faster algorithms for a certain monomial detection problem. This is our main technical result, which allows us to obtain faster algorithms for EDGE COLORING and LIST EDGE COLORING. We recall the following well-known sieving technique:

► **Proposition 3.1** (Inclusion-Exclusion). *Let $P(X)$ be a polynomial over a field of characteristic two, with variable set $X = \{x_1, \dots, x_n\}$. Fix $T \subseteq X$. Let $Q(X)$ be the polynomial consisting of all monomials (with corresponding coefficients) in P that are divisible by $\prod_{x \in T} x$. Then*

$$Q = \sum_{S \subseteq T} P_S$$

where P_S is the polynomial obtained from P by setting $x_i = 0$ for all $i \in S$.

See [35, Lemma 2] for a proof of Proposition 3.1.

Combining Propositions 2.5 and 3.1, we obtain the following result.

► **Lemma 3.2** (Coefficient Extraction). *Let $P(X)$ be a polynomial over a field of characteristic two, with variable set $X = \{x_1, \dots, x_n\}$. For $T \subseteq X$, let $Q(X \setminus T)$ be the coefficient of $\prod_{x \in T} x$ in $P(X)$, viewed as a polynomial over the variable set $X \setminus T$. Then we can evaluate $Q(X \setminus T)$ at a point as a linear combination of $2^{|T|}$ poly(n) evaluations of $P(X)$.*

Proof. Fix a subset $T \subseteq X$. Let F be the polynomial with variable set $X \cup \{z\}$ obtained by substituting each variable $x \in T$ with xz in P . Let $G(X)$ be the coefficient of $z^{|T|}$ in F . By definition of F , G is the polynomial obtained by taking the monomials in P whose degree restricted to T equals $|T|$. By Proposition 2.5, we can compute $G(X)$ at any point as a linear combination of poly(n) evaluations of P .

By definition, $Q(X \setminus T)$ is the polynomial obtained by taking monomials of $G(X)$ that are divisible by $\prod_{x \in T} x$, and then setting all variables in T equal to 1. So by Proposition 3.1 we can evaluate $Q(X \setminus T)$ as the sum of $2^{|T|}$ evaluations of G . Then by the conclusion of the previous paragraph, we get that we can evaluate $Q(X \setminus T)$ at any point as a linear combination of $2^{|T|}$ poly(n) evaluations of P as claimed. ◀

The inclusion-exclusion principle allows us to sieve for the multilinear term in a polynomial that is the product of all its variables. This was extended to the parameterized setting, where the goal is to sieve for multilinear terms of degree k in $O^*(2^k)$ time [7, 10, 36], and then further extended to multilinear monomial detection in the matroid setting [16].

► **Lemma 3.3** (Basis Sieving [16, Theorem 1.1]). *Let $P(X)$ be a homogeneous polynomial of degree k over a field \mathbb{F} of characteristic 2, and let $\mathcal{M} = (X, \mathcal{I})$ be a matroid on X of rank k , with a representation over \mathbb{F} given. Then there is a randomized algorithm running in $O^*(2^k)$ time and polynomial space, which determines with high probability if $P(X)$ contains a multilinear monomial \mathbf{m} such that $\text{supp}(\mathbf{m})$ is a basis of \mathcal{M} .*

Moreover, [16] introduced a variant of sieving that takes the odd support into account. This tool is key to our exponential speed-up for the EDGE COLORING problem.

► **Lemma 3.4** (Odd Sieving [16, Theorem 1.2]). *Let $P(X)$ be a polynomial of degree d over a field \mathbb{F} of characteristic 2, and let $\mathcal{M} = (X, \mathcal{I})$ be a matroid on X of rank k , represented by a $k \times n$ matrix over \mathbb{F} . Then using $O^*(d2^k)$ evaluations of $P(X)$ and polynomial space, we can determine if $P(X)$ contains a monomial \mathbf{m} such that $\text{osupp}(\mathbf{m})$ spans \mathcal{M} .*

7:10 Faster Edge Coloring by Partition Sieving

Let $P(X)$ be a homogeneous polynomial of degree d in variables $X = \{x_1, \dots, x_n\}$. Consider a partition $X = X_1 \sqcup \dots \sqcup X_p$ into parts X_i . Let $c_1, \dots, c_p \geq 0$ be integers with

$$c_1 + \dots + c_p = d.$$

Let \mathcal{M} be the partition matroid defined by the partition of X into the parts X_i and the capacities c_i for $i \in [p]$. We say $P(X)$ is *compatible* with \mathcal{M} if for every $i \in [p]$ and every monomial \mathbf{m} in P , the degree of \mathbf{m} restricted to X_i equals $c_i \geq 1$.

The following result gives an improvement over Lemma 3.3 for polynomials that are compatible with partition matroids.

► **Theorem 3.5 (Partition Sieving).** *Let $P(X)$ be a polynomial of degree d over a field \mathbb{F} of characteristic 2 with $|\mathbb{F}| > d$, and let $\mathcal{M} = (X, \mathcal{I})$ be a partition matroid on X of rank d with p partition classes. If P is compatible with \mathcal{M} , then there is a randomized algorithm which runs in $O^*(2^{d-p})$ time and polynomial space that determines with high probability if $P(X)$ contains a monomial \mathbf{m} such that $\text{supp}(\mathbf{m})$ is a basis of \mathcal{M} .*

Proof. Let $X = X_1 \sqcup \dots \sqcup X_p$ be the partition and c_1, \dots, c_p be the capacities defining the partition matroid \mathcal{M} . By assumption, $c_i \geq 1$ for all $i \in [p]$. Let \mathcal{M}' be the partition matroid over X defined by the same partition as \mathcal{M} , but with capacities $(c_i - 1)$ for $i \in [p]$. From this construction, \mathcal{M}' has rank $(d - p)$.

Our algorithm to determine whether $P(X)$ contains a monomial whose support spans \mathcal{M} works as follows. By Proposition 2.11, a linear representation of \mathcal{M} over \mathbb{F} can be computed in polynomial time. We run the odd sieving algorithm of Lemma 3.4 with P and \mathcal{M}' to determine in $O^*(2^{d-p})$ time whether P contains a monomial whose odd support spans \mathcal{M}' . We return YES if such a monomial exists, and return NO otherwise. We now prove that this algorithm is correct.

First, suppose that $P(X)$ has a monomial \mathbf{m} whose support $\text{supp}(\mathbf{m})$ is a basis of \mathcal{M} . By the compatibility condition, \mathbf{m} is multilinear, which implies that $\text{supp}(\mathbf{m}) = \text{osupp}(\mathbf{m})$. Since $\text{osupp}(\mathbf{m})$ is a basis of \mathcal{M} , and thus spans \mathcal{M} , it follows that $\text{osupp}(\mathbf{m})$ spans \mathcal{M}' .

Conversely, suppose $P(X)$ has a monomial \mathbf{m} such that $\text{osupp}(\mathbf{m})$ spans \mathcal{M}' . We claim that $\text{supp}(\mathbf{m})$ spans \mathcal{M} . Indeed, since $\text{osupp}(\mathbf{m})$ spans \mathcal{M}' , the set $\text{osupp}(\mathbf{m})$ contains at least $(c_i - 1)$ variables of X_i for each $i \in [p]$. Hence its superset $\text{supp}(\mathbf{m})$ contains at least $(c_i - 1)$ variables of each part X_i as well.

▷ **Claim 3.6.** The set $\text{supp}(\mathbf{m})$ contains exactly c_i variables of each part X_i .

Proof. Suppose to the contrary that $\text{supp}(\mathbf{m})$ does not contain c_j variables of X_j for some index $j \in [p]$. Then \mathbf{m} contains exactly $(c_j - 1)$ variables of X_j . Since P is compatible with \mathcal{M} , the monomial \mathbf{m} has degree exactly c_j when restricted to X_j . The only way this is possible is if $c_j \geq 2$, and \mathbf{m} has exactly $(c_j - 2)$ variables in X_j of degree one and a single variable in X_j with degree two. The variable of degree two does not show up in the odd support of \mathbf{m} , which implies that $\text{osupp}(\mathbf{m})$ has at most $(c_j - 2)$ elements, which contradicts the assumption that $\text{osupp}(\mathbf{m})$ spans \mathcal{M}' . ◁

By Claim 3.6, the set $\text{supp}(\mathbf{m})$ has exactly c_i variables from X_i for each $i \in [p]$. Since P is compatible with \mathcal{M} , this implies that \mathbf{m} has degree one in every variable in X . Hence $\text{supp}(\mathbf{m}) = \text{osupp}(\mathbf{m})$ spans \mathcal{M} , as claimed.

This shows that the algorithm is correct, and proves the desired result. ◀

4 Coloring Algorithm Template

Recall that in the LIST EDGE COLORING problem we are given a graph $G = (V, E)$, an integer $k \geq 1$, and lists $L_e \subseteq [k]$ of colors for every edge $e \in E$, and are tasked with determining if G contains an assignment of colors $c(e) \in L_e$ to each edge such that no two edges incident to the same vertex are assigned the same color. We call such an assignment a proper edge coloring of G with respect to the lists L_e , or just a proper list edge coloring if the L_e are clear from context.

For each $i \in [k]$, let $G_i = (V, E_i)$ be the subgraph of G , where we define $E_i \subseteq E$ to be the set of all edges e in the graph which have $i \in L_e$ available as a color. Let \mathcal{F} denote the collection of k -tuples (M_1, \dots, M_k) of matchings such that

1. for all $i \in [k]$, M_i is a matching in G_i , and
2. for all vertices $v \in V$, v appears as the endpoint of exactly $\deg_G(v)$ of the M_i matchings.

Observe that G admits a proper list edge coloring if and only if \mathcal{F} contains a tuple of edge-disjoint matchings. Indeed, suppose G admits a proper list edge coloring. For each $i \in [k]$, the set of edges assigned color i must be a matching $M_i \subseteq E_i$ in G . Moreover, every edge is assigned a color, so each vertex v appears as an endpoint in $\deg_G(v)$ of these matchings, hence the matchings form an edge-disjoint tuple in \mathcal{F} . Conversely, given an edge-disjoint tuple $(M_1, \dots, M_k) \in \mathcal{F}$, assigning the edges in M_i color i gives a color to every edge in G by condition 2 above, and thus yields a proper list edge coloring by condition 1.

The basic idea of our algorithmic template is to construct a polynomial P which enumerates a certain subfamily $\mathcal{C} \subseteq \mathcal{F}$. We then argue that P contains a multilinear monomial satisfying certain matroid constraints if and only if \mathcal{C} contains a tuple of edge-disjoint matchings. Using similar reasoning to the previous paragraph, this then lets us solve LIST EDGE COLORING by running monomial detection algorithms on P .

4.1 Enumerating Matchings

In this section, we design a polynomial P whose monomials enumerate tuples of matchings satisfying special conditions. To construct P , we first define certain polynomial matrices.

For each edge $e \in E$ we introduce a variable x_e , and for each pair $(e, i) \in E \times [k]$ we introduce a variable y_{ei} . Let X be the set of x_e variables and Y be the set of y_{ei} variables.

For each $i \in [k]$, define A_i to be the matrix with rows and columns indexed by V with

$$A_i[u, w] = A_i[w, u] = \begin{cases} x_e y_{ei} & \text{if } e = \{u, w\} \in E_i, \\ 0 & \text{otherwise.} \end{cases}$$

For each $i \in [k]$, define $V_i = \{v_i \mid v \in V\}$ to be a copy of V . Let

$$W = \bigsqcup_{i=1}^k V_i$$

be the union of these copies. Let A be the symmetric matrix with rows and columns indexed by W , defined by taking

$$A = \begin{pmatrix} A_1 & O & \dots & O \\ O & A_2 & \dots & O \\ \vdots & \vdots & \ddots & \vdots \\ O & O & \dots & A_k \end{pmatrix} \tag{3}$$

and identifying V_i as the row and column set indexing A_i .

7:12 Faster Edge Coloring by Partition Sieving

Note that A is $(kn) \times (kn)$, and over a field of characteristic two is skew-symmetric.

For each vertex $v \in V$, let $S_v = \{v_i \mid i \in [k]\}$ be the set of k copies of v .

For each vertex v , let \mathcal{M}_v be a linear matroid of rank $\deg_G(v)$ over S_v . These matroids will be specified later on, in our algorithms for EDGE COLORING and LIST EDGE COLORING. Let \mathcal{W} be the direct sum

$$\mathcal{W} = \bigoplus_{v \in V} \mathcal{M}_v \quad (4)$$

of these matroids.

By Proposition 2.7 the matroid \mathcal{W} is linear and has rank equal to the sum of the degrees of vertices in G , which is $2m$. Let B be a $2m \times |W|$ matrix representing \mathcal{W} .

Let \mathcal{C} be the collection of k -tuples of matchings (M_1, \dots, M_k) in G such that

1. all edges in M_i have lists containing the color i ,
2. every vertex v is incident to exactly $\deg_G(v)$ edges across the matchings M_i , and
3. for each vertex v , the set of copies v_i taken over all i such that v appears as an endpoint of an edge in M_i forms an independent set in \mathcal{M}_v .

We define the polynomial

$$P(X, Y) = \text{Pf } BAB^\top. \quad (5)$$

The next result shows that P enumerates tuples of matchings from \mathcal{C} .

► **Lemma 4.1** (Enumerating Matchings). *We have*

$$\text{Pf } BAB^\top = \sum_{(M_1, \dots, M_k) \in \mathcal{C}} c_{M_1, \dots, M_k} \left(\prod_{i \in [k]} \prod_{e \in M_i} y_{ei} \right) \left(\prod_{e \in M_1 \cup \dots \cup M_k} x_e \right),$$

where each $c_{M_1, \dots, M_k} \neq 0$ is a constant depending only on M_1, \dots, M_k .

Proof. Let $U \subseteq W$ be a subset of W of size $2m$. By Proposition 2.8, we have

$$\text{Pf } BAB^\top = \sum_{U \in \binom{W}{2m}} \det B[\cdot, U] \text{Pf } A[U]. \quad (6)$$

By Equation (3) and Proposition 2.7, for every subset $U \subseteq W$ of size $2m$ we have

$$\text{Pf } A[U] = \prod_{i \in [k]} \text{Pf } A_i[U \cap V_i].$$

Substituting the above equation into Equation (6) yields

$$\text{Pf } BAB^\top = \sum_{U \in \binom{W}{2m}} \det B[\cdot, U] \prod_{i \in [k]} \text{Pf } A_i[U \cap V_i].$$

Recall that given a graph H , we let $\Pi(H)$ denote the set of perfect matchings of H . By expanding out the definition of $\text{Pf } A_i[U \cap V_i]$ in the above equation, we see that

$$\text{Pf } BAB^\top = \sum_{U \in \binom{W}{2m}} \det B[\cdot, U] \prod_{i \in [k]} \sum_{M_i \in \Pi(G[U_i])} \prod_{e \in M_i} A_i[e],$$

where $U_i \subseteq V$ is defined as a copy of $U \cap V_i$, i.e., $U_i = \{v \mid v_i \in U \cap V_i\}$. By interchanging the order of the product and the summation, we see that the above is equivalent to summing over all collections (M_1, \dots, M_k) , where M_i is a matching in $G[U_i]$ for each $i \in [k]$:

$$\text{Pf } BAB^\top = \sum_{U \in \binom{W}{2m}} \det B[\cdot, U] \sum_{(M_1, \dots, M_k)} \prod_{i \in [k]} \prod_{e \in M_i} A_i[e].$$

Let $\vec{M} = (M_1, \dots, M_k)$ be a tuple such that the summand corresponding to \vec{M} in the above equation appears with nonzero coefficient in $\text{Pf } BAB^\top$. Since $A_i[e]$ is nonzero if and only if $i \in L_e$, the tuple \vec{M} meets condition 1 in the definition of \mathcal{C} . By the definition of B , we have $\det B[\cdot, U] \neq 0$ if and only if $U \cap S_v$ is independent in \mathcal{M}_v for every vertex $v \in V$. Thus \vec{M} meets condition 3 the definition of \mathcal{C} . Since \mathcal{M}_v has rank $\deg_G(v)$ for each vertex v , U has size $2m$, and the sum of degrees of vertices in G is $2m$, we see that the only way for $U \cap S_v$ to be independent in \mathcal{M}_v for all v is if in fact $|U \cap S_v| = \deg_G(v)$ always. So \vec{M} satisfies condition 2 from the definition of \mathcal{C} .

Thus, the nonzero terms in the above sum correspond precisely to tuples $\vec{M} \in \mathcal{C}$, which proves the desired result. \blacktriangleleft

4.2 Partition Sieving With Dominating Sets

In this section, we describe a generic way of going from a dominating set in G to a certain partition matroid \mathcal{D} . After defining this \mathcal{D} , we will apply Theorem 3.5 to P and \mathcal{D} to achieve a fast algorithm for detecting a multilinear monomial in P .

Recall that a *dominating set* of a graph G is a subset of vertices D such that every vertex in G is either in D or adjacent to a vertex in D .

Fix a dominating set $D \subseteq V$ of the input graph G . Let $V' = V \setminus D$. Let E' be the set of edges in G with one endpoint in D and one endpoint in V' , and $X' = \{x_e \mid e \in E'\}$ be the corresponding set of variables. For each $v \in V'$, let

$$\partial(v) = \{e \in E' \mid e \ni v\}$$

be the set of edges incident to v which connect v to a vertex in D . By definition, we have a partition

$$E' = \bigsqcup_{v \in V'} \partial(v).$$

Let \mathcal{D} be the partition matroid over E' with respect to the above partition, and with capacities $c_v = \deg_{E'}(v)$ for each $v \in V'$, where E' is viewed as a subgraph of G . Since D is a dominating set, every vertex $v \in V'$ is adjacent to some node in D , and thus the capacities $c_v \geq 1$ are all positive.

We now use this partition matroid to sieve over the polynomial P , defined in Equation (5).

► Lemma 4.2 (Accelerated Multilinear Monomial Detection). *There is a randomized algorithm that determines with high probability whether $P(X, Y)$ has a monomial divisible by $\prod_{e \in E} x_e$, running in $O^*(2^{m-|V'|})$ time and polynomial space.*

Proof. Let $Q(X', Y)$ be the coefficient of

$$\prod_{e \in E \setminus E'} x_e$$

in $P(X, Y)$. By definition, $P(X, Y)$ contains a monomial divisible by $\prod_{e \in E} x_e$ if and only if $Q(X', Y)$ contains a monomial divisible by $\prod_{e \in E'} x_e$.

7:14 Faster Edge Coloring by Partition Sieving

Let $R(Y)$ be the coefficient of $\prod_{e \in E'} x_e$ in Q , viewed as a polynomial with variable set Y . Note that the total degree of $R(Y)$ is $\text{poly}(n)$. Take a uniform random assignment over \mathbb{F} to the variables in Y . By Proposition 2.6, if R is nonzero, then it remains nonzero with high probability after this evaluation, provided we take $|\mathbb{F}| = \text{poly}(n)$ to be sufficiently large. For the rest of this proof, we work with polynomials P, Q, R after this random evaluation, so that P is a polynomial in X , Q is a polynomial in X' , and R is a field element.

By the discussion in the first paragraph of this proof, it suffices to check whether $Q(X')$ contains the monomial $\prod_{e \in E'} x_e$ in $O^*(2^{m-|V'|})$ time and polynomial space.

We observe the following helpful property of Q .

▷ **Claim 4.3.** The polynomial $Q(X')$ is compatible with the matroid \mathcal{D} .

Proof. Take an arbitrary monomial \mathbf{m} in Q . By definition, there is a corresponding monomial

$$\mathbf{m}' = \mathbf{m} \cdot \prod_{e \in E \setminus E'} x_e$$

in P . By Lemma 4.1, for every $v \in V$, \mathbf{m}' has degree exactly $\deg_G(v)$ when restricted to the variables x_e corresponding to edges e containing v . Consequently, for all $v \in V'$, \mathbf{m} has degree exactly

$$\deg_G(v) - |\{e \notin E' \mid e \ni v\}| = \deg_{E'}(v)$$

when restricted to variables x_e with $e \in \partial(v)$. Since this holds for arbitrary monomials \mathbf{m} in Q , the polynomial Q is compatible with the partition matroid \mathcal{D} as claimed. ◁

By Lemma 4.1, P , viewed as a polynomial in X , is homogeneous of degree $|E| = m$. Hence Q , viewed as a polynomial in X' , is homogeneous of degree $d = |E'|$. By Claim 4.3, Q is compatible with \mathcal{D} . Since \mathcal{D} is a partition matroid with positive capacities and $p = |V'|$ parts in its underlying partition, by Theorem 3.5 we can determine whether Q contains a monomial \mathbf{m} in the X' variables such that $\text{supp}(\mathbf{m})$ is a basis of \mathcal{D} using

$$O^*(d2^{d-p}) \leq O^*(2^{|E'| - |V'|}) \tag{7}$$

evaluations of Q . Since E' is the unique basis of \mathcal{D} , this means we can test whether $Q(X')$ contains the monomial $\prod_{e \in E'} x_e$ using $O^*(2^{|E'| - |V'|})$ evaluations of $Q(X')$.

By Lemma 3.2, $Q(X')$ can be evaluated at any point by computing a linear combination of $O^*(2^{m-|E'|})$ evaluations of $P(X)$. Combining this observation with Equation (7), we get that we can determine whether $Q(X')$ contains the monomial $\prod_{e \in E'} x_e$ by computing a linear combination of

$$O^*(2^{m-|E'|} \cdot 2^{|E'| - |V'|}) \leq O^*(2^{m-|V'|})$$

evaluations of $P(X, Y)$. Each evaluation of $P(X, Y) = \text{Pf } BAB^\top$ takes polynomial time, so the desired result follows. ◀

5 Edge Coloring Algorithm

In this section, we present our algorithm for **EDGE COLORING** and prove Theorems 1.1 and 1.2. Recall that in this problem, we are given an input graph G with n vertices, m edges, and maximum degree Δ . To solve the problem, it suffices to determine whether G admits a proper edge coloring using at most Δ colors (i.e., whether $\chi'(G) \leq \Delta$).

5.1 Removing Low Degree Vertices

► **Lemma 5.1** (Unit-Degree Deletion). *Let G be a graph with a vertex v of degree one. Let G' be the graph obtained by deleting v from G . Then $\chi'(G') \leq \Delta$ if and only if $\chi'(G) \leq \Delta$.*

Proof. If G admits a proper edge coloring with Δ colors, then this coloring is also a proper edge coloring for G' with Δ colors.

Conversely, suppose G' admits a proper edge coloring with Δ colors. Since $\deg_G(v) = 1$, there is a unique vertex w in G that v is adjacent to. Then

$$\deg_{G'}(w) \leq \deg_G(w) - 1 \leq \Delta - 1$$

because G has maximum degree Δ . So vertex w has edges using at most $(\Delta - 1)$ distinct colors incident to it. Taking the coloring of G' and assigning edge $\{v, w\}$ a color not used by the edges incident to w in G' recovers a proper edge coloring of G with at most Δ colors. ◀

5.2 Instantiating the Template

Recall the definitions from Section 4. We view the EDGE COLORING problem as a special case of LIST EDGE COLORING, where $k = \Delta$ and every edge e is assigned the list $L_e = [\Delta]$. For each vertex v , we set \mathcal{M}_v to be the uniform matroid over S_v of rank $\deg_G(v)$. Then by Equation (4), \mathcal{W} is the partition matroid over W defined by the partition

$$W = \bigsqcup_{v \in V} S_v$$

and the capacities $c_v = \deg_G(v)$ for parts S_v . By Proposition 2.11, we can construct the matrix B representing \mathcal{W} in polynomial time. In this case, condition 3 is identical to condition 2 in the definition of the collection \mathcal{C} .

► **Lemma 5.2** (Characterization by Polynomials). *We have $\chi'(G) \leq \Delta$ if and only if the polynomial $P(X, Y)$ has a monomial divisible by $\prod_{e \in E} x_e$.*

Proof. Suppose $P(X, Y) = \text{Pf } BAB^\top$ contains a monomial divisible by $\prod_{e \in E} x_e$. Since P is homogeneous of degree m in the X variables, by Lemma 4.1 this means there exists a Δ -tuple of *edge-disjoint* matchings $(M_1, \dots, M_\Delta) \in \mathcal{C}$, such that every edge of G appears in some matching M_i . Consequently, assigning the edges in M_i color i yields a proper edge coloring of G using at most Δ colors.

Conversely, suppose G has a proper edge coloring with Δ colors. Without loss of generality, let the set of colors used be $[\Delta]$. For each $i \in [\Delta]$, let M_i be the set of edges assigned color i . Since this is a proper edge coloring, each M_i is a matching in G . Since every edge is assigned a unique color, each vertex v has exactly $\deg_G(v)$ edges across the matchings M_i . Hence $(M_1, \dots, M_\Delta) \in \mathcal{C}$. Then by Lemma 4.1, P contains a monomial divisible by $\prod_{e \in E} x_e$. ◀

We can now prove Lemma 1.4 as a simple application of Lemma 5.2.

► **Lemma 1.4.** *There is a randomized algorithm that, given a graph G on n vertices and m edges and a dominating set D of G , solves EDGE COLORING on G with high probability and one-sided error in $O^*(2^{m-n+|D|})$ time and polynomial space.*

Proof. Let G have vertex set V and edge set E , and let $V' = V \setminus D$. By Lemma 5.2, we have $\chi'(G) \leq \Delta$ if and only if $P(X, Y)$ has a monomial divisible by $\prod_{e \in E} x_e$. By Lemma 4.2, we can determine whether such a monomial exists in

$$O^*(2^{m-|V'|}) \leq O^*(2^{m-n+|D|})$$

time and polynomial space, as desired. ◀

Having established Lemma 1.4, we are ready to present our EDGE COLORING algorithms.

► **Theorem 1.1.** *There is a randomized algorithm which solves EDGE COLORING with high probability and one-sided error in $O^*(2^{m-3n/5})$ time and polynomial space.*

Proof. To solve EDGE COLORING, it suffices to determine whether $\chi'(G) \leq \Delta$.

If G has a vertex of degree one, delete it. Keep performing such deletions, until we are left with a graph containing no vertices of degree one. By repeated application of Lemma 5.1, the resulting graph admits a proper edge coloring using Δ colors if and only if $\chi'(G) \leq \Delta$. If the resulting graph has constant size, we can determine this trivially. Each such deletion decreases the number of edges and vertices in the graph by one, and thus also decreases the value of $(m - 3n/5)$. Consequently, to show the desired result, we may assume without loss of generality that G has minimum degree two, and at least eight vertices.

Since G has minimum degree two and $n \geq 8$ nodes, by Lemma 2.2 the graph has a dominating set of size at most $2n/5$. By Lemma 2.4, we can then find a dominating set D in G with $|D| \leq 2n/5$ in $O^*(2^{m-3n/5})$ time and polynomial space. Hence by Lemma 1.4 we can solve EDGE COLORING on G in $O^*(2^{m-3n/5})$ time and polynomial space, as desired. ◀

► **Theorem 1.2.** *For each integer $d \geq 6$, there is a randomized algorithm that solves EDGE COLORING with high probability and one-sided error on d -regular graphs in $O^*(2^{m-\alpha_d n})$ time and polynomial space, for $\alpha_d = 1 - H_{d+1}/(d+1)$.*

Proof. Let G be the input graph. By exhaustive search over all subsets of vertices, we can find a minimum-size dominating set D of G in $O^*(2^n)$ time and polynomial space. Being d -regular, G has $m = dn/2 \geq 3n$ edges, so we find D in $O^*(2^{m-n}) \leq O^*(2^{m-\alpha_d n})$ time.

Since G is d -regular, by Lemma 2.3 we must have $|D| \leq n(H_{d+1}/(d+1))$. Then by Lemma 1.4 we can solve EDGE COLORING on G in

$$O^*(2^{m-n+|D|}) \leq O^*(2^{m-\alpha_d n})$$

time as claimed. ◀

6 Conclusion

In this paper, we presented the first algorithms for EDGE COLORING and LIST EDGE COLORING which run in faster than $O^*(2^m)$ time while using only polynomial space. Our algorithm is based off a *partition sieving* procedure that works over polynomials of degree d and partition matroids with p parts. We showed how to implement this sieving routine in $O^*(2^{d-p})$ time when the polynomial is in some sense compatible with the matroid, an improvement over the $O^*(2^d)$ runtime that arose in previous techniques.

Overall, we solve EDGE COLORING in faster than $O^*(2^m)$ time by

- Step 1** designing a polynomial P enumerating matchings meeting certain degree constraints,
- Step 2** finding a dominating set D of size at most $2n/5$ in the input graph, and
- Step 3** applying partition sieving with a partition matroid on $p = |D|$ parts.

Implementing **step 2** above was possible for EDGE COLORING because we could assume that the input graph had minimum degree two without loss of generality, and such graphs on $n \geq 8$ nodes always have dominating sets of size at most $2n/5$. For LIST EDGE COLORING we cannot make this assumption, but nonetheless implement a variant of **step 2** by identifying a subgraph with minimum degree two and using extension matroids to handle unit-degree vertices for free. For all sufficiently large n , it is also known that graphs on n nodes with minimum degree three have dominating sets of size at most $3n/8$ [34]. If degree-two vertices could somehow be “freely removed” from the input graph just like unit-degree vertices can,

one could use this bound on the dominating set to solve coloring problems faster. More general connections between the minimum degree of a graph and the minimum size of its dominating set have also been studied [20].

Understanding the precise time complexity of EDGE COLORING and its variants remains an interesting open research direction. Is EDGE COLORING solvable in $O^*(1.9999^m)$ time, or at least in $O^*(2^{m-n})$ time? Establishing any nontrivial lower bounds for EDGE COLORING would also be very interesting. The reductions from [21] imply that solving EDGE COLORING in graphs with maximum degree $\Delta = 3$ requires $2^{\Omega(n)}$ time, assuming the Exponential Time Hypothesis (ETH), a standard hypothesis from fine-grained complexity. Does ETH similarly imply a $2^{\Omega(m)}$ or even a $2^{\Omega(n \log n)}$ time lower bound for EDGE COLORING in dense graphs (this question was previously raised in [25, Open problem 4.25])?

Abstract

Propositional proof complexity deals with the lengths of polynomial-time verifiable proofs for Boolean tautologies. An abundance of proof systems is known, including algebraic and semialgebraic systems, which work with polynomial equations and inequalities, respectively. The most basic algebraic proof system is based on Hilbert’s Nullstellensatz [7]. Tropical (“min-plus”) arithmetic has many applications in various areas of mathematics. The operations are the real addition (as the tropical multiplication) and the minimum (as the tropical addition). Recently, [8, 17, 21] demonstrated a version of Nullstellensatz in the tropical setting.

In this paper we introduce (semi)algebraic proof systems that use min-plus arithmetic. For the dual-variable encoding of Boolean variables (two tropical variables x and \bar{x} per one Boolean variable x) and $\{0, 1\}$ -encoding of the truth values, we prove that a *static* (Nullstellensatz-based) tropical proof system polynomially simulates *daglike* resolution and also has short proofs for the propositional pigeon-hole principle. Its dynamic version strengthened by an additional derivation rule (a tropical analogue of resolution by linear inequality) is equivalent to the system **Res(LP)** (aka **R(LP)**), which derives nonnegative linear combinations of linear inequalities; this latter system is known to polynomially simulate Krajíček’s **Res(CP)** (aka **R(CP)**) with unary coefficients. Therefore, tropical proof systems give a finer hierarchy of proof systems below **Res(LP)** for which we still do not have exponential lower bounds. While the “driving force” in **Res(LP)** is resolution by linear inequalities, dynamic tropical systems are driven solely by the transitivity of the order, and static tropical proof systems are based on reasoning about differences between the input linear functions. For the truth values encoded by $\{0, \infty\}$, dynamic tropical proofs are equivalent to **Res(∞)**, which is a small-depth Frege system called also DNF resolution.

Finally, we provide a lower bound on the size of derivations of a much simplified tropical version of the BINARY VALUE PRINCIPLE in a static tropical proof system. Also, we establish the non-deducibility of the tropical resolution rule in this system and discuss axioms for Boolean logic that do not use dual variables. In this extended abstract, full proofs are omitted.

1 Introduction and Organization of this Extended Abstract

This paper introduces tropical proof systems, that is, proof systems that use min-plus arithmetic. To the best of our knowledge, these are the first tropical proof systems described in the literature though one of them is equivalent to a known proof system **Res**(LP) [19], which is a weakened version of **Res**(CP) (**R**(CP)) [23], these systems are working with disjunctions of inequalities. Thus our proof systems not only introduce a new paradigm, but also give a scale of proof systems between **Res**(CP) and resolution (this scale is visualised in Fig. 1).

In this extended abstract, we briefly recall the standard setup for propositional proof complexity and survey previous results concerning relevant proof systems (Sect. 2), recall tropical arithmetic (Sect. 3) and introduce tropical proof systems (Sect. 4), survey our results (Sect. 6), and discuss further directions (Sect. 7). Preliminary versions of full proofs can be found in the preprint [3].

2 General setup

2.1 Propositional proof complexity

A proof system for language L is¹ a deterministic polynomial-time algorithm V such that for every $x \in L$, there is a *proof* $\pi \in \{0, 1\}^*$ such that $V(x, \pi) = 1$, and for every $x \notin L$ and every candidate proof π , it holds that $V(x, \pi) = 0$. In this paper, we are interested in proofs for the language **UNSAT** of unsatisfiable Boolean formulas in conjunctive normal form (CNF) and, more broadly, in proofs for the language of unsolvable systems of linear equations (and even their disjunctions) with rational coefficients. Frequently (but not always) a proof of the unsatisfiability of a formula derives semantically implied statements from previously derived (or input) statements (in the case of a formula in CNF, the input statements are Boolean clauses). The existence of a proof system that has a polynomial-size proof for every $x \in L$ is equivalent to **NP** = **co-NP**, this equivalence of the classes is unlikely and proving or disproving it is far beyond the reach of the current methods.

Propositional proof complexity is a rapidly developing area where we typically prove four kinds of results:

- A superpolynomial lower bound on the size of the shortest proof for a certain (infinite) set of inputs $x_1, x_2 \dots \in L$ in some specific proof system.
- A polynomial *simulation* between two proof systems, that is, for every $x \in L$, one proof system has a proof of x that has the same or a smaller length (up to a polynomial factor) than the shortest proof of x in the other proof system.
- A polynomial upper bound on the proof size for a certain (infinite) set of inputs $x_1, x_2 \dots \in L$ in a specific proof system.
- A superpolynomial *separation* between proof systems, which is typically obtained by providing a set of inputs for which we can prove a polynomial size upper bound in one proof system and a superpolynomial size lower bound in another proof system.

When we have both a polynomial simulation and a superpolynomial separation between two specific systems, we say that one system is strictly stronger than the other one. Thus proof systems (for the same language) form a lattice² with respect to the partial non-strict order composed of the simulations; if one system is strictly stronger than the other one, then the

¹ This definition deviates from Cook and Reckhow's definition [11], but for our purpose they are equivalent.

² Note that we do not require the simulations to be computable in polynomial time (p-simulations) though in most cases the simulations are indeed efficient.

order is strict for these two systems. *Cook's (or Cook-Reckhow's) program* in the propositional proof complexity is the intention for proving superpolynomial lower bounds for stronger and stronger proof systems, thus developing new methods for proving superpolynomial lower bounds, which are the crux of computational complexity.

2.2 Previous proof complexity results relevant to this paper

The area essentially started with superpolynomial (and then exponential) lower bounds for various versions of the resolution proof system [31, 18, 32], where proofs proceed by deriving the resolvent $C \vee D$ of two already derived (or input) clauses $C \vee x$ and $D \vee \bar{x}$ until we derive the empty clause. We refer the reader to Krajíček's book [25] for a detailed overview of the area.

The previously known proof systems that are the most relevant to us are proof systems that work with linear inequalities.

The Cutting Plane (CP) proof system [12] uses the rounding rule and nonnegative linear combinations of inequalities

$$\frac{\sum_i ca_i x_i - d \geq 0}{\sum_i a_i x_i - \lceil d/c \rceil \geq 0} \quad (c, a_i, d \in \mathbb{Z}), \quad \frac{f_1 \geq 0 \quad f_2 \geq 0}{\alpha_1 f_1 + \alpha_2 f_2 \geq 0} \quad (\alpha_1, \alpha_2 > 0)$$

as its derivation steps (here f_1 and f_2 are the affine forms). The derivation starts from linear inequalities expressing Boolean clauses and from the axioms $x_i \geq 0$, $1 - x_i \geq 0$ for every variable x_i . It finishes with deriving the contradictory inequality $-1 \geq 0$. An exponential lower bound for CP was proved in [29].

Krajíček [23] generalized CP to a new system $\mathbf{R}(\mathbf{CP})$, also called $\mathbf{Res}(\mathbf{CP})$, by allowing to reason about disjunctions of *affine* inequalities (the disjunctions are interpreted as sets, trivially false constant inequalities are dropped out, and a disjunction can be weakened by adding new inequalities to it). The two rules above are generalized to

$$\frac{\sum_i ca_i x_i - d \geq 0 \vee \Gamma}{\sum_i a_i x_i - \lceil d/c \rceil \geq 0 \vee \Gamma} \quad (c, a_i, d \in \mathbb{Z}), \quad \frac{(f_1 \geq 0) \vee \Gamma \quad (f_2 \geq 0) \vee \Gamma}{(\alpha_1 f_1 + \alpha_2 f_2 \geq 0) \vee \Gamma} \quad (\alpha_1, \alpha_2 > 0). \quad (+\mathbf{RES})$$

Also the notion of the negation of an inequality is introduced through the rule

$$\frac{\emptyset}{f - 1 \geq 0 \vee -f \geq 0}.$$

The same idea has been used to define other proof systems (for example, $\mathbf{Res}(k)$ [24], $\mathbf{Res}(\mathbf{Lin})$ [30], $\mathbf{Res}(\oplus)$ [20]). In particular, Hirsch and Kojevnikov stripped $\mathbf{Res}(\mathbf{CP})$ of the negation and the rounding rule and defined the system $\mathbf{Res}(\mathbf{LP})$ that uses the splitting rule

$$\frac{\emptyset}{(x - 1 \geq 0) \vee (-x \geq 0)} \quad (x \text{ is a variable}).$$

No superpolynomial size lower bounds for $\mathbf{Res}(\mathbf{CP})$ or $\mathbf{Res}(\mathbf{LP})$ are known. Derivations can be daglike (as usual) or treelike (where we have to re-derive a statement again every time we use it). Beame et al. defined the Stabbing Planes proof system [6] that is equivalent to **treelike** $\mathbf{Res}(\mathbf{CP})$. While usually the coefficients of linear inequalities are written in *binary*, one can consider weaker proof systems when they are written in *unary*. In the unary coefficients setting, Fleming et al. have shown a quasipolynomial simulation of Stabbing Planes in CP (with binary coefficients) thus obtaining an exponential lower bound for it [14]. Very recently, Gläser and Pfetsch have shown an exponential bound for Stabbing Planes for the case of binary coefficients by providing a quasipolynomial monotone interpolation [15]. The daglike versions of $\mathbf{Res}(\mathbf{CP})$ and $\mathbf{Res}(\mathbf{LP})$ with unary coefficients are polynomially equivalent [19] and no superpolynomial lower bounds are known for them to the date.

3 Tropical arithmetic

Tropical (or min-plus) arithmetic involves operations $\min, +$ in place of $+, \times$ in classical arithmetic; we refer the interested reader to [27] for the introduction and survey of tropical arithmetic and in particular its history and the origin of the name “tropical”. Tropical arithmetic has several sources including algebraic geometry (valuations), mathematical physics, and optimization, and, respectively, numerous applications (some of them can be found in [27], also neural networks are a more recent application).

We consider a tropical semifield based on $\mathbb{Q} \cup \{+\infty\}$. Many of the results of this paper can be also formulated and proved using a similar semifield based on \mathbb{Q} .

Tropical operations. We consider the min-plus (or tropical) semifield defined by the set $\mathbb{Q}_\infty = \mathbb{Q} \cup \{+\infty\}$ endowed with two operations: the tropical addition \oplus and the tropical multiplication \odot defined in the following way:

$$a \oplus b = \min\{a, b\}, \quad a \odot b = a + b,$$

where \min and $+$ are the usual (traditional) arithmetic operations extended to work with the neutral element ∞ : namely, $a \oplus \infty = a$ and $a \odot \infty = \infty$. A tropical *power* n of a is defined as

$$a^{\odot 0} = 0, \quad a^{\odot n} = \underbrace{a \odot \dots \odot a}_{n \text{ copies}},$$

where n is a positive integer. Sometimes we use a bigger \bigoplus to facilitate reading.

Tropical polynomials.

► **Definition 1.** A tropical monomial is a tropical product of tropical powers of variables. For a vector of variables $\vec{x} = (x_1, \dots, x_n)$ and a vector of integers $I = (i_1, \dots, i_n)$ we introduce the notation

$$\vec{x}^I = x_1^{\odot i_1} \odot \dots \odot x_n^{\odot i_n}.$$

Then $\text{degtr}(\vec{x}^I) = i_1 + \dots + i_n$ is called the (total) (tropical) degree of this monomial.

Note that we never use the word “monomial” for a submonomial, that is, a subset of monomial (in other words, the monomial $x \odot y$ does *not* occur in $x \odot y^{\odot 2} \oplus x \odot y \odot z$).

In this paper, a (tropical, or min-plus) *term* $t = c \odot m$ is a tropical product of a tropical monomial m and a constant $c \in \mathbb{Q}_\infty$. One can treat a tropical term classically as a linear function $a + i_1 x_1 + \dots + i_n x_n$. By analogy with the traditional arithmetic (and its zero), a constant term is the only situation where the coefficient $c = \infty$ is meaningful (since $\infty \odot m = \infty$). We assume that if a term is non-constant, it has a finite coefficient. This is important when we say “monomial m occurs” somewhere: we mean that a term based on m occurs. The degree of a term is the degree of its monomial.

Note that when we work with constants, we use traditional operations and treat the constant as a whole, for example, $x \odot (10 - 2 + 1)$ is the same as $x \odot 9$.

► **Definition 2.** Let x_1, \dots, x_n be variables, and let \mathcal{I} be a finite set of their power vectors ($\mathcal{I} \subseteq \mathbb{N}_0^n$). A tropical polynomial is an element of $(\mathbb{Q}_\infty, \oplus, \odot)[x_1, \dots, x_n]$, that is, the tropical sum of a set of tropical terms $t_I(\vec{x}) = c_I \odot \vec{x}^I$ with distinct power vectors $I \in \mathcal{I}$:

$$f(\vec{x}) = \bigoplus_{I \in \mathcal{I}} t_I(\vec{x}).$$

If $\mathcal{I} = \emptyset$, we identify this polynomial with the constant polynomial ∞ .

In other words, tropical polynomials are members of the $(\mathbb{Q}_\infty, \oplus, \odot)$ -linear space spanned by the monomials (for example, $1 \oplus x^{\odot 2} \odot y \oplus 2 \odot x$ and ∞ are tropical polynomials). One can treat f as a concave piecewise linear function.

Tropical addition and multiplication are correctly defined on tropical polynomials as $\infty \odot m = \infty$ and $a \odot m \oplus b \odot m = \min\{a, b\} \odot m$ for any monomial m , and thus we never need more than one term per monomial.

Complexity of tropical polynomials. We usually write the coefficients and the exponents in binary, so the bit-size of x^{2^n} is polynomial (which is important when we estimate the size of a proof that uses tropical polynomials). The degree of a tropical polynomial f , denoted by $\text{degtr}(f)$, is the maximal degree of its terms. Let $\mu(f)$ be the number of terms in f (it is strictly positive).

Min-plus polynomials and inequalities. A *min-plus polynomial* is a pair of tropical polynomials $(f(\vec{x}), g(\vec{x}))$. The degree of a min-plus polynomial is the maximum of the degrees of f and g . A point $\vec{a} \in \mathcal{R}^n$ is a root of this polynomial if the following equality holds: $f(\vec{a}) = g(\vec{a})$. We can apply tropical operations component-wise to min-plus polynomials, thus min-plus polynomials can be summed using the tropical addition \oplus and can be tropically multiplied by a tropical monomial using tropical multiplication \odot , and these operations preserve the common roots of the involved polynomials. Thus, the closure of a set of min-plus polynomials under these operations is a (tropical) ideal. One of the central issues in tropical algebra is a criterion for the existence of common roots for systems of min-plus polynomials $\{(f_1, g_1), \dots, (f_k, g_k)\}$. In classical algebra such a criterion is provided by Hilbert’s Nullstellensatz (over an algebraically closed field). In tropical algebra a criterion of solvability has been formulated as a Min-Plus Nullstellensatz [8, 17, 21, 26], further extended in [1].

In this paper we will deal with a more convenient (albeit equivalent) framework of the problem of the existence of common roots for systems of min-plus polynomial inequalities $\{f_1 \leq g_1, \dots, f_k \leq g_k\}$. A *min-plus polynomial inequality* is a pair of tropical polynomials f, g that we write as $f \leq g$ or (f, g) . A point $\vec{a} \in \mathcal{R}^n$ is a root of min-plus inequality $f \leq g$ if $f(\vec{a}) \leq g(\vec{a})$. Note that \vec{a} is a root of $f \leq g$ iff it is a root of $(f \oplus g, f)$. In what follows, we abuse the notation by writing $f = g$ instead of the two inequalities $f \leq g$ and $g \leq f$.

Note that while one can consider solving min-plus equations and inequalities over \mathbb{Q} or over \mathbb{Q}_∞ , tropical polynomials will always have coefficients in \mathbb{Q}_∞ , in particular, ∞ is a tropical polynomial equivalent to “the empty tropical polynomial”.

An order on tropical polynomials. For tropical polynomials L and R , let $L \succeq R$ denote the component-wise \geq of the coefficients of the respective monomials in L and R .

Let $L \succ R$ denote the component-wise $>$ of the coefficients of the respective monomials in L and R , where R may also contain extra monomials not present in L .

Note that if $L \succ R$, then it is impossible for $R \leq L$ to have finite roots.

We define \preceq and \prec similarly. The following lemma is easy to see.

► **Lemma 3** (\succ inside \oplus, \odot). *Let $\Gamma, \Delta, \Gamma', \Delta'$ be tropical polynomials.*

1. *If $\Gamma \succ \Delta$ and $\Gamma' \succ \Delta'$, then $\Gamma \oplus \Gamma' \succ \Delta \oplus \Delta'$.*
2. *For a tropical term $t \neq \infty$, if $\Gamma \succ \Delta$, then $\Gamma \odot t \succ \Delta \odot t$.*

4 Tropical proof systems

Similarly to the already classical “algebraic” proof systems Nullstellensatz and Polynomial Calculus [7, 10] based on Hilbert’s Nullstellensatz, we introduce proof systems that rely on the Min-Plus Nullstellensatz. The most general static proof system MP-NS (Min-Plus Nullstellensatz, Definition 7) for the language of unsolvable linear inequalities requires a proof that is a contradictory algebraic combination of the input inequalities and trivial axioms $0 \leq 0$, $f \leq \infty$. That is, for a system of min-plus inequalities $f_i \leq g_i$, the proof is a contradictory inequality $\bigoplus_{j=1}^K p_j \leq \bigoplus_{j=1}^K q_j$ for some $K \geq 1$, where for each $1 \leq j \leq K$ we have $(p_j, q_j) = (t_j \odot f_{i_j}, t_j \odot g_{i_j})$ for some term t_j and some $1 \leq i_j \leq k$. The contradiction must follow immediately from the coefficients of the inequality; namely, for every monomial present in the left-hand side, its coefficient must be strictly greater than the coefficient of the same monomial in the right-hand side (also, for technical reasons the right-hand side must have a finite constant term).

For example, the system of inequalities $\{x \leq y, y \leq z, z + 1 \leq x, 2x \leq 0\}$, which is written tropically as $\{x \leq y, y \leq z, z \odot 1 \leq x, x^{\odot 2} \leq 0\}$, can be refuted by tropically multiplying its inequalities by $x \odot \frac{1}{3}$, $x \odot \frac{2}{3}$, x , and $\frac{1}{3}$, respectively. This results in

$$\underline{x^{\odot 2} \odot \frac{1}{3}} \oplus \underline{y \odot x \odot \frac{2}{3}} \oplus \underline{z \odot x \odot 1} \leq \underline{y \odot x \odot \frac{1}{3}} \oplus \underline{z \odot x \odot \frac{2}{3}} \oplus \underline{x^{\odot 2} \odot 0} \oplus \underline{\frac{1}{3}}.$$

One can see that the requirement on the coefficients is satisfied.

Similarly to algebraic proof systems, we introduce a dynamic version of MP-NS: Min-Plus Polynomial Calculus (MP-PC), see Definition 11. It derives the contradiction of the same sort step by step by tropically adding inequalities, tropically multiplying them by terms, and substituting inequalities into other inequalities.

We also consider the additional *tropical resolution* rule

$$\frac{t \oplus f \leq 0 \quad t' \oplus f \leq 0}{(t \odot t') \oplus f \leq 0}, \text{ where } t, t' \text{ are terms,} \quad (\odot\text{RES})$$

which is a counterpart of (+RES) in Res(LP) and Res(CP). When we add this rule to our systems, we mention this explicitly. While this rule is not needed for the completeness of our tropical proof systems, on the one hand, and is looking very natural, on the other hand, its elimination from the system may be expensive, as shown in Theorem 27.

The proof systems MP-NS and MP-PC can be transformed into proof systems for UNSAT using several possibilities to encode the truth values, Boolean variables and Boolean clauses. In the “default” setting, we encode the truth values by $\{0, 1\}$, introduce the dual variable \bar{x} for every variable x , and transform a clause into the corresponding linear inequality (which, in tropical terms, is $1 \leq m$ for a multilinear monomial m). These proof systems are called MP-NSR and MP-PCR; the diagram of connections between them and known systems is given in Figure 1. One can also considered different encodings (without dual variables or with values in $\{0, \infty\}$), the detailed treatment of these is delayed to the full version of the paper.

4.1 The basic static proof system, MP-NS

► **Definition 4.** Consider a system of min-plus polynomials $F = \{(f_1, g_1), \dots, (f_k, g_k)\}$. An algebraic combination of F is a min-plus polynomial (f, g) that can be represented as

$$(f, g) = \left(\bigoplus_{j=1}^K p_j, \bigoplus_{j=1}^K q_j \right), \quad (1)$$

for some $K \geq 1$, where for each $1 \leq j \leq K$ we have $(p_j, q_j) = (t_j \odot f_{i_j}, t_j \odot g_{i_j})$ for some term t_j and some $1 \leq i_j \leq k$. We will abuse the language by calling an “algebraic combination” both the min-plus polynomial (f, g) and the composition (1), that is, t_j ’s.

We call a system of min-plus polynomials *symmetric* if it always includes (f_i, g_i) together with (g_i, f_i) . The possibility of refuting min-plus systems of equations (and inequalities) using min-plus proofs is based on the following theorem.

► **Theorem 5** (Min-Plus Nullstellensatz, [17, Theorem 3.8] over \mathbb{Q}_∞ without the degree claim). *Consider a symmetric system of min-plus polynomial equations F as in Def. 4 in n variables.*

The system F has no roots over the tropical semifield \mathbb{Q}_∞ iff we can construct an algebraic min-plus combination

$$(f, g) = \left(\bigoplus_{j=1}^K p_j, \bigoplus_{j=1}^K q_j \right)$$

of F such that for each monomial m occurring in f , and also for the constant monomial even if it is infinite, its coefficient in f is greater than the coefficient of this monomial in g (in particular, m must be present in g).

It can be easily observed that one direction of the theorem is trivial: indeed, if there is an algebraic combination (f, g) satisfying the conditions of the theorem (recall also that in terms of integer operations, the “coefficient” is the additive constant in a standard arithmetic linear combination of variables), so the system F is unsatisfiable. The finite constant term in g saves us from the parasite all- ∞ solution.

It is easy to see that in the case of systems of inequalities (which correspond to not necessarily symmetric systems of min-plus polynomials), a similar result holds as a corollary.

► **Theorem 6.** *Consider a system of min-plus polynomial inequalities S in n variables over \mathbb{Q}_∞ . Let $F = S \cup \{(0, 0)\} \cup \{(g_i, \infty) \mid (f_i, g_i) \in S\}$.*

The system S has no roots over the tropical semifield \mathbb{Q} iff we can construct an algebraic min-plus combination

$$(f, g) = \left(\bigoplus_{j=1}^K p_j, \bigoplus_{j=1}^K q_j \right)$$

of F (in terms of Def. 4) such that for each monomial $m \neq \infty$ occurring in f , its coefficient is greater than the coefficient of this monomial in g (in particular, m must be present in g).

Over the semifield \mathbb{Q}_∞ we need an additional property: the constant term in g is finite.

► **Definition 7** (Min-Plus Nullstellensatz, MP-NS). *We will call a min-plus algebraic combination (that is, $(t_j)_{j=1}^K$ in terms Def. 4) satisfying the conditions of Theorem 6 (over \mathbb{Q}_∞ , unless otherwise stated) a Min-Plus Nullstellensatz (MP-NS) refutation of S .*

► **Note 8** (The $0 \leq c$ “axiom”). In Theorem 6 we have added the axioms $0 \leq 0$ and $g \leq \infty$ to MP-NS. Note that, for any constant $c \geq 0$, the inequality $0 \leq c$ can be easily derived as a tropical sum of $0 \leq \infty$ and $0 \leq 0$ tropically multiplied by c . In what follows we will use it without further notice both for MP-NS and for our dynamic proof system described later.

In fact, the “last line” of the proof (that is, (f, g) in terms of the theorem, after combining similar terms) can be thought of as a refutation itself: the composition of this algebraic combination can be easily reconstructed, and its complexity parameters are bounded by a

polynomial in the complexity of (f, g) . (In what follows, when we speak about the size of a rational number, we mean the size of its nominator plus the size of its denominator; for ∞ this is zero.)

► **Proposition 9** (MP-NS derivation reconstruction). *Given a system of min-plus inequalities (f_i, g_i) and given their algebraic combination as two polynomials (f, g) , we can find the terms t_j 's of this algebraic combination in polynomial time, their number is bounded by a polynomial in the number of monomials in the system and (f, g) , their coefficient size is bounded by a polynomial in the size of coefficients in the system and (f, g) . and their degree does not exceed the degree of monomials in f and g .*

► **Remark 10.** Now we say a few words about the complexity of constructing an MP-NS refutation given a system of min-plus equations, or more generally, inequalities (including strict ones). First, one can estimate a bound on the degree of a refutation (algebraic combination) with the help of [17, Theorem 3.8] in the case of min-plus equations, which was extended to the case of min-plus inequalities in Theorem 3.1 [1]. For a given bound on the degree, an algebraic combination can be treated as a system of min-plus **strict linear** inequalities (whose unknowns are the rational coefficients of an algebraic combination). Solvability of a system of min-plus linear inequalities (including strict ones) is reduced in [5] (within polynomial complexity) to solvability of a system of min-plus linear equations (with integer coefficients and thereby, integer unknowns).

One can apply to a system of min-plus linear equations one of the algorithms to solve it (see e.g., [9, 2, 16]). The complexity of each of these algorithms is polynomial in the number of unknowns and equations and in the absolute values of integer coefficients of the system. Observe that this complexity bound is not polynomial in the size of the input because the complexity depends on the absolute values of the coefficients rather than on their bit-sizes. It is a longstanding open problem whether a system of min-plus linear equations is solvable within polynomial complexity. However, this problem belongs to the class $\mathbf{NP} \cap \mathbf{co-NP}$ (see e.g., [2, 16]).

4.2 The basic dynamic proof system, MP-PC

We also consider a dynamic version of MP-NS called the Min-Plus Polynomial Calculus (MP-PC). It has some informal resemblance to Krajíček's original quantifier-free propositional LK(CP) proof system [23]: it uses both sides of a “sequent” while Res(CP) used only one because of the presence of an efficient negation, which we are missing. However, the “sequents” of our system contain tropical terms (affine functions) and not inequalities.

We will sometimes use equations to abbreviate pairs of two opposite inequalities.

► **Definition 11** (Min-Plus Polynomial Calculus, MP-PC). *Consider a system of min-plus polynomial inequalities $S = \{f_1 \leq g_1, \dots, f_m \leq g_m\}$ in n variables. A Min-Plus PC (MP-PC) refutation of F is a list of min-plus inequalities*

$$p_1 \leq q_1, \dots, p_K \leq q_K$$

such that

1. In the last inequality, for each monomial $m = x_1^{\odot j_1} \odot \dots \odot x_n^{\odot j_n}$ in p_K there is a matching monomial in q_K , and the coefficient in the monomial in p_K is greater than the corresponding coefficient in q_K . Moreover, the constant term in q_K must be present and must be finite.

► **Note 12** (0/1 variables in \mathbb{Q}_∞). Later on, in our systems dealing with $\{0, 1\}$ variables, all monomials become bounded from the above and thus the requirement on the constant term can be satisfied automatically.

2. Each inequality $p_i \leq q_i$ is obtained from the previously derived inequalities using the following rules.

Axioms:

$$\frac{\emptyset}{f_j \leq g_j}, \quad \text{where } 1 \leq j \leq m,$$

$$\frac{\emptyset}{0 \leq 0},$$

$$\frac{\emptyset}{p \leq \infty}, \quad \text{for any tropical polynomial } p. \quad (\text{WEAK})$$

Minimum. We can take a minimum of two previously derived inequalities:

$$\frac{p \leq q \quad p' \leq q'}{p \oplus p' \leq q \oplus q'}.$$

Tropical multiplication:

$$\frac{p \leq q}{p \odot t \leq q \odot t},$$

where t is a term.

Transitivity of the order:

$$\frac{p \leq h \quad h \leq r}{p \leq r}.$$

► **Note 13** (Substitutions). It is easy to see that by combining transitivity with other rules we can substitute inequalities into each other on the left or on the right, for example,

$$\frac{p \oplus h \leq q \quad r \leq h}{p \oplus r \leq q} \quad \frac{p \leq q \oplus h \quad h \leq r}{p \leq q \oplus r}.$$

and do it even inside monomials by multiplying the substitution by an appropriate term. In what follows, we refer to these derivations as **substitutions**.

► **Note 14** (Tropical product). Note that we can take the tropical product (\odot) of two inequalities by first multiplying one of them by the left-hand-side of the other one and then applying the transitivity rule. We will discuss the complexity issues of constructing tropical products of inequalities later.

► **Note 15** (Natural weakening). Note also that we can weaken inequalities by dropping a summand from the right-hand side or adding a summand to the left-hand side. This is simulated using the (WEAK) axiom with the minimum rule and substitution on the right.

► **Note 16** (Systems based on equations instead of inequalities). Similarly to Theorem 5, it is possible to talk about symmetric systems and thus min-plus equations, even in the context of dynamic proof systems. For example, one could define a refutation system for symmetric systems with the same rules except for the axiom (WEAK), and with an additional rule to swap an equation ($f = g \rightarrow g = f$). This apparently weaker proof system turns out to be polynomially equivalent to MP-PC for symmetric systems (see full version of this paper). As inequalities provide a more natural framework and allow to refute more unsolvable systems, we stick to using inequalities.

4.3 The tropical resolution rule

As usual, when we consider stronger systems that include additional rules, we denote them by “system+rule”, for example, MP-PC+(\odot RES).

In what follows f denotes any tropical monomial.

The following rule can be viewed as the generalization of the resolution-like rule (+RES) in Res(CP)-like systems (though we limit it very much) or as tropical multiplication of two inequalities, each one being in the tropical sum.

$$\frac{t \oplus f \leq 0 \quad t' \oplus f \leq 0}{(t \odot t') \oplus f \leq 0}, \text{ where } t, t' \text{ are terms.} \quad (\odot\text{RES})$$

While this rule is looking very natural, we do not know how to eliminate its use at a polynomial cost. Moreover, we will show later that its direct simulation in the static proof systems is impossible.

4.4 Encoding of Boolean logic: MP-NSR and MP-PCR systems

In this extended abstract we concentrate on the following encoding. We use 0 for **false** and 1 for **true** and introduce a “dual variable” for the negation of each variable. Note that we use $\neg\Phi$ as the Boolean negation of a Boolean formula Φ (without distinguishing Φ from $\neg\neg\Phi$) while keeping the notation \bar{x} for dual variables. Recall that we denote literals (which are variables or the negations of variables) by $\ell, \ell_1, \ell_2, \dots$ without further notice.

We thus obtain from (the systems for refuting conjunctions of min-plus inequalities) MP-NS and MP-PC the propositional proof systems MP-NSR and MP-PCR, respectively. In order to do that we translate a formula in CNF into a conjunction of tropical inequalities. Namely, we translate each clause into an inequality and also add additional inequalities (axioms) to ensure that variables are Boolean.

Boolean axioms. We include the axioms

$$\frac{\emptyset}{x \odot \bar{x} = 1} \quad (01/\odot) \qquad \frac{\emptyset}{x \oplus \bar{x} = 0} \quad (01/\oplus)$$

to ensure that x and \bar{x} are dual and in $\{0, 1\}$.

► **Note 17.** For any binary variable x we can derive from $(01/\oplus)$ in MP-PC that $0 \leq x$ and $x \leq 1$. The first inequality can be derived from $0 \leq x \oplus \bar{x}$ by simplification. The latter inequality can be derived in the following way: from $0 \leq \bar{x}$ we can derive $x \leq x \odot \bar{x}$, from which we can derive $x \leq 1$ using $x \odot \bar{x} \leq 1$.

Translations of Boolean clauses. We can encode a Boolean clause $\ell_1 \vee \ell_2 \vee \dots \vee \ell_k$ using the equation

$$\bar{\ell}_1 \oplus \bar{\ell}_2 \oplus \dots \oplus \bar{\ell}_k \leq 0. \quad (\text{D})$$

Note that clauses are encoded in Res(Lin) [30] in exactly the same way (the absence of the dual variables does not matter as re-encoding is done by a simple linear substitution).

However, there is another possibility to encode a clause, which is used in CP and similar proof systems:

$$1 \leq \ell_1 \odot \ell_2 \odot \dots \odot \ell_k. \quad (\text{I})$$

It is not difficult to see that in the case of MP-PCR these encodings are equivalent. A formal proof of this statement can be found in the full version of the paper.

5 Preliminary lemmas and the equivalence of encodings

Before we come to the main results, we state several technical lemmas about derivations in tropical systems.

► **Lemma 18** (tropical product, treelike, no axioms). *For $1 \leq i \leq k$, let A_i, B_i be tropical terms. Then there is a treelike MP-PC derivation of all the inequalities*

$$\bigodot_{i=1}^j A_i \leq \bigodot_{i=1}^j B_i, \text{ for } j \leq k,$$

from the inequalities $A_i \leq B_i$ (each used once).

The derivation contains $O(k)$ (not necessarily different) terms and the bit-size of every coefficient (respectively, the tropical exponent) in the derivation is upper bounded by $O(k \cdot b)$, where b is the maximum bit-size of a coefficient (respectively, a tropical exponent) in any of the A_i, B_i . In particular, the coefficients (resp., tropical exponents) in the derivation are sums of the original coefficients (resp., tropical exponents).

Proof. Start with $A_1 \leq B_1$. Tropically multiply it by A_2 and tropically multiply $A_2 \leq B_2$ by B_1 to conclude $A_1 \odot A_2 \leq B_1 \odot B_2$ by transitivity.

Continue in the same way for $j = 3, \dots, k$, multiplying $A_j \leq B_j$ by $\bigodot_{i=1}^{j-1} A_i$, multiplying the previously derived $\bigodot_{i=1}^{j-1} A_i \leq \bigodot_{i=1}^{j-1} B_i$ by B_j , and applying the transitivity rule. ◀

► **Lemma 19** (powers of axioms, treelike). *For a variable x and an integer $b > 0$, there are treelike MP-PCR derivations from the axioms of the following inequalities:*

$$x^{\odot b} \odot \bar{x}^{\odot b} \leq b, \tag{2}$$

$$b \leq x^{\odot b} \odot \bar{x}^{\odot b}, \tag{3}$$

$$x^{\odot b} \oplus \bar{x}^{\odot i} \leq 0 \text{ (as well as of the symmetrical inequality), for } 1 \leq i \leq b. \tag{4}$$

The tropical degree of these derivations is $O(b)$. The derivations of (2), (3) contain $O(b)$ (not necessarily distinct) terms, all the coefficients in them and constants are $\leq b$. The derivation of (4) contains $O(b^3)$ (not necessarily distinct) terms, all the coefficients in it are zeroes.

Proof. The inequalities (2) and (3) follow from Lemma 18.

To show (4) for $i = 1$, proceed by induction on b (starting with $b = 1$). Tropically multiply the axiom $x \oplus \bar{x} \leq 0$ by $x^{\odot(b-1)}$ and substitute $\bar{x} \leq \bar{x} \odot x^{\odot(b-1)}$ (which is $0 \leq x^{\odot(b-1)}$, provided by Lemma 18, multiplied by \bar{x}) into its left-hand side getting

$$x^{\odot b} \oplus \bar{x} \leq x^{\odot(b-1)}.$$

Tropically add \bar{x} to both sides and substitute the induction hypothesis for $b - 1$ on the right obtaining the desired inequality.

The inequality $x^{\odot b} \oplus \bar{x} \leq 0$ provided by the previous argument is the starting point for deriving (4), now by the induction on i (where $i = 1$ is the base). Take it and tropically multiply it by $\bar{x}^{\odot(i-1)}$ obtaining

$$x^{\odot b} \odot \bar{x}^{\odot(i-1)} \oplus \bar{x}^{\odot i} \leq \bar{x}^{\odot(i-1)}.$$

Tropically add $x^{\odot b}$ to both sides, substitute the induction hypothesis on the right. Substitute $x^{\odot b} \leq x^{\odot b} \odot \bar{x}^{\odot(i-1)}$ (which is $0 \leq \bar{x}^{\odot(i-1)}$, provided by Lemma 18, multiplied by $x^{\odot b}$) on the left. ◀

■ **Figure 1** Map of tropical systems with $\{0, 1\}$ dual encoding. An arrow $\Pi \rightarrow \Psi$ means polynomial simulation of Π by Ψ . Proof systems known to be not polynomially bounded are shown in green.

6 Our results and methods

6.1 Static systems: Already stronger than Resolution

Static tropical proofs with dual variables over $\{0, 1\}$ turn out to be surprisingly powerful. We start with a natural statement that static tropical proofs are equivalent to treelike proofs:

► **Theorem 20.** *MP-NS polynomially simulates treelike MP-PC.*

Proof Sketch. Simulating a treelike tropical proof is done by combining the steps of the proof in a single algebraic combination with *decreasing coefficients*. Namely, when we go down (towards the root) the proof tree, which becomes now the formula tree of the algebraic combination, we tropically multiply subformulas by small positive coefficients. A similar idea is demonstrated in more detail in the proof of the next Theorem 21. ◀

Note that when we convert a treelike proof into a formula, the tropical multiplication of a tropical polynomial p applies to the whole subtree deriving p , thus this strategy does not work for simulating daglike tropical proofs (if p is multiplied by different terms t_i , we need to repeat it as many times).

However, we show that MP-NSR polynomially simulates *daglike* resolution. While the simulation of the treelike tropical proof is technical but intuitively straightforward, the simulation of the Resolution proof system is trickier due to its daglike nature.

► **Theorem 21.** *MP-NSR polynomially simulates Resolution.*

Proof. We simulate a resolution proof by putting it into the static proof step by step. For a disjunction $A = \ell_1 \vee \dots \vee \ell_k$, define its translation $[A] = 0 \odot \ell_1 \odot \dots \odot \ell_k$ with the meaning that it is true iff $[A] > 0$. In particular, every initial clause A is translated into $1 \leq [A]$, as we expect in MP-NSR.

Translate a Resolution proof into an MP-NSR proof as follows. Let s be the number of steps in the Resolution proof. We can assume that steps can be of two kinds: a resolution step

$$\frac{A \vee x \quad A \vee \neg x}{A}, \quad (5)$$

and a weakening step

$$\frac{A}{A \vee \ell}, \tag{6}$$

where A is a clause, x is a variable, and ℓ is a literal.

We now compose our algebraic combination.

For every initial clause A , we take its translation $1 \leq [A]$:

$$1 \leq 0 \odot [A]. \tag{7}$$

At step $i = 1, 2, \dots, s$, we do the following. Let $c_i = i/(s + 1)$.

- For a resolution step, multiply the axiom $x \oplus \bar{x} \leq 0$ by $c_i \odot [A]$ obtaining

$$c_i \odot x \odot [A] \oplus c_i \odot \bar{x} \odot [A] \leq c_i \odot [A]. \tag{8}$$

Observe that $[A \vee v] = [A] \odot v$ for every variable v , so the terms in (8) are exactly the translation of (5) multiplied by c_i .

- For a weakening step, we would like to multiply $0 \leq [\ell]$ by $c_i \odot [A]$ obtaining

$$c_i \odot [A] \leq c_i \odot [A] \odot [\ell]. \tag{9}$$

Observe that the terms in (9) are exactly the translation of (6) multiplied by c_i .

Strictly speaking, $0 \leq [\ell]$ is not an axiom, while $0 \leq [\neg\ell] \oplus [\ell]$ is. Formally, we must multiply the latter (rather than the former) by $c_i \odot [A]$. However, this leaves only extra terms in the right-hand side compared to (9), which cannot harm our MP-NSR refutation.

Note that the last step's right-hand side is $c_s \odot [\emptyset]$, that is, $1 - 1/(s + 1)$.

Our algebraic combination is a tropical sum of all inequalities (7) (for all the initial clauses A), (8), and (9) (for all steps of the Resolution proof).

The constant terms of the combination are 1 in the left-hand side, from the initial clauses, and $1 - 1/(s + 1)$ in the right-hand side, from the last clause; $1 > 1 - 1/(s + 1)$.

Every other monomial in the left-hand side has its counterpart in the right-hand side, from the previous steps of the proof. The coefficient is smaller in the simulation of the previous steps and in the initial clauses (thus, on the right-hand side).

It is clear that the total number of terms appearing in the proof is bounded by a polynomial in s , the degree of every monomial is bounded by the width of the resolution proof, and the nominators and denominators of the rational coefficients are also bounded by a polynomial in s . ◀

We also show that MP-NSR has polynomial-size proofs for *the propositional pigeonhole principle*, thus it is strictly stronger than Resolution. We consider the following translation of the pigeonhole principle:

$$1 \leq \bigodot_{j=1}^n x_{ij} \text{ for } 1 \leq i \leq m,$$

$$1 \leq \bar{x}_{ij} \odot \bar{x}_{ij} \text{ for } 1 \leq i \leq m, 1 \leq j \leq n.$$

- ▶ **Theorem 22.** *For any $n > m$, PHP_n^m has polynomial-size MP-NSR refutations.*

Proof. For the refutation of the propositional pigeonhole principle, we construct a treelike MP-PCR proof and then convert it into a static proof. We use the overall strategy for a treelike CP proof [22, Proposition 19.5]. The main step of this proof is the inductive

8:14 Tropical Proof Systems: Between R(CP) and Resolution

derivation of long inequalities $\sum_i x_{ij} \leq 1$ stating that every hole contains at most one pigeon, from short inequalities $x_{ij} + x_{i'j} \leq 1$. In CP this is done using the rounding rule, however, in MP-NSR we do not have it. Instead, we consider the cases for the newly added pigeon using tropical tools. More precisely, we will prove the following lemma

► **Lemma** (short to long inequalities). *Let $v_1 \dots v_k, \bar{v}_1, \dots, \bar{v}_k$ be variables. Given the Boolean axioms and the set of inequalities $v_i \odot v_{i'} \leq 1$ for $1 \leq i < i' \leq k$, one can construct a treelike MP-PCR derivation of $\bigodot_{i=1}^k v_i \leq 1$, which contains $O(k^4)$ terms, has tropical degree $O(k)$, and its coefficients are zeroes and ones.*

Proof of Lemma. Denote $V_j = \bigodot_{i=1}^j v_i$. We proceed by the induction on the number of variables constructing a treelike MP-PCR derivation of $V_j \leq 1$.

The base ($j = 2$) is trivial. The induction step comes in three stages.

Stage 1. Take the induction hypothesis for $j - 1$ and tropically multiply it by v_j getting

$$V_j \leq 1 \odot v_j. \quad (10)$$

Stage 2. For $i = 1, \dots, j - 1$, construct also the following derivation: tropically multiply the initial inequality $v_i \odot v_j \leq 1$ by \bar{v}_j and substitute its left-hand side by the axiom $1 \leq v_j \odot \bar{v}_j$ multiplied by v_i . Multiply the result by (-1) obtaining $v_i \leq \bar{v}_j$. Apply Lemma 18 to multiply these inequalities for $i = 1, \dots, j - 1$:

$$\bigodot_{i=1}^{j-1} v_i \leq \bar{v}_j^{\odot(j-1)}.$$

Further multiply it by v_j and substitute $v_j \odot \bar{v}_j \leq 1$ multiplied by $\bar{v}_j^{\odot(j-2)}$ into it obtaining

$$V_j \leq 1 \odot \bar{v}_j^{\odot(j-2)}. \quad (11)$$

Stage 3. Take the tropical sum of (10) and (11) and substitute its right-hand side with $v_j \oplus \bar{v}_j^{j-2} \leq 0$ (due to Lemma 19) multiplied by 1 eventually obtaining $V_j \leq 1$. ◀

Given the lemma, we apply it to x_{1j}, \dots, x_{mj} for each $j = 1, \dots, n$ separately. Multiply the results to get

$$\bigodot_{j=1}^n \bigodot_{i=1}^m x_{ij} \leq n.$$

On the other hand, by multiplying the initial inequalities, we get

$$m \leq \bigodot_{i=1}^m \bigodot_{j=1}^n x_{ij}$$

After substitution of the first equation into the right-hand side of the second equation, we arrive at the contradiction $m \leq n$. ◀

This shows that MP-NSR is strictly stronger than resolution; however, its relation to CP remains open. This makes MP-NSR a nice frontier proof system, for which (as a proof system for unsatisfiable formulas in CNF) we do not know any superpolynomial lower bounds.

6.2 Dynamic systems: Going up to Res(LP)

We do not know whether MP-PCR simulates Res(LP). The additional (\odot RES) rule strengthening MP-PCR is needed for that. We prove the following equivalence.

► **Theorem 23.** *MP-PCR+(\odot RES) with $\{0, 1\}$ encoding is polynomially equivalent to Res(LP).*

Proof Sketch. We simulate a Res(LP) proof step by step. A line of a Res(LP) refutation of the form $f_1 \geq 0 \vee f_2 \geq 0 \vee \dots \vee f_k \geq 0$ is translated into the min-plus inequality

$$[-f_1] \oplus [-f_2] \oplus \dots \oplus [-f_k] \leq 0,$$

where for a linear inequality $f \geq 0$, its translation $[-f]$ is given by the natural tropical term semantically equivalent to $-f$. To simulate the “main” rule (+RES) deriving a nonnegative linear combination, we split its coefficients into bits, simulate linear combinations for this easy case, and then sum everything together using (\odot RES).

In the other direction, a min-plus inequality $f_1 \oplus f_2 \oplus \dots \oplus f_t \leq g_1 \oplus g_2 \oplus \dots \oplus g_k$ is translated into the disjunctions of inequalities, one for each $1 \leq j \leq k$:

$$\bigvee_{i=1}^t \{f_i\} \leq \{g_j\},$$

where $\{\cdot\}$ again defines the natural semantically equivalent translation of tropical terms into linear inequalities. One can prove that a dynamic tropical proof can always be finished by a constant inequality $1 \leq 0$ (this is done in the same vein as simulating treelike proofs by static proofs, but now dynamically). Therefore, we do not need to deal with a complicated last line of the tropical proof in our simulation by Res(LP). ◀

Systems over $\{0, \infty\}$. One can consider systems that encode **false** and **true** by $\{0, \infty\}$ instead of $\{0, 1\}$. The axioms (01/ \odot) and (01/ \oplus) are then replaced by

$$\frac{\emptyset}{x \odot \bar{x} = \infty} \quad (0\infty/\odot), \quad \frac{\emptyset}{x \oplus \bar{x} = 0} \quad (0\infty/\oplus)$$

to ensure that x and \bar{x} are dual and in $\{0, \infty\}$. With this encoding, MP-PCR becomes equivalent to a different proof system (additional rules are not needed in this setting):

► **Theorem 24.** *MP-PCR that uses $\{0, \infty\}$ encoding with dual variables is polynomially equivalent to Res(∞), the unbounded version of the Res(k) proof system [24].*

The proof is similar to the $\{0, 1\}$ case; the main difference is that for $\{0, \infty\}$ tropical operations are essentially conjunction and disjunction, so it remains to process accurately statements like $f = c$ for a term f and a constant $c \in \mathbb{Q} \cup \{\infty\}$, and prove the corresponding translations of MP-PCR rules in Res(∞). The other direction goes almost literally by translating clauses composed of DNFs into the corresponding min-plus inequalities over $\{0, \infty\}$.

6.3 Lower bounds

We prove the lower bound k on the size of refutations of a much simplified tropical version $x^{\odot k} = c$ (where $c \in \mathbb{Q} \setminus \mathbb{N}_0$) of the (generalized) BINARY VALUE PRINCIPLE [4, 28] in MP-NSR.

► **Theorem 25.** *The size of MP-NSR refutations of a tropical binomial $x^{\odot k} = c$ for $c \in \mathbb{Q}$ is greater than k .*

In particular, for $x^{\odot 2^n} = -1$ this is an exponential lower bound when the coefficients and the degrees of tropical proofs are represented in binary.

The proof adheres to the following ideology. The MP-NS refutations are based on comparing coefficients in left- and right-hand sides in algebraic combinations. Having this in mind, when talking about size in MP-NSR, we construct a directed graph on monomials occurring in a tropical algebraic combination. We do it in a way such that some specific function on the vertices of the graph related to the coefficients is strictly monotone along any arrow. To establish the lower bound on the size of refutations of $x^{\odot k} = c$ in MP-NSR we prove that any cycle in this graph should contain at least k arrows.

Proof. Consider a refutation

$$(f, g) := \bigoplus_{i,j} x^{\odot i} \odot \bar{x}^{\odot j} \odot (a_{i,j} \odot (x \oplus \bar{x}, 0) \oplus b_{i,j} \odot (0, x \oplus \bar{x}) \\ \oplus d_{i,j} \odot (x \odot \bar{x}, 1) \oplus e_{i,j} \odot (1, x \odot \bar{x}) \oplus u_{i,j} \odot (x^{\odot k}, c) \oplus v_{i,j} \odot (c, x^{\odot k})),$$

where $a_{i,j}, b_{i,j}, d_{i,j}, e_{i,j}, u_{i,j}, v_{i,j} \in \mathbb{Q}_{\infty}$ and $f \succ g$.

We construct a directed graph H (See Fig. 2) whose vertices are tropical monomials m appearing in g . We distinguish 7 cases regarding from which summand in the right-hand side of the refutation a monomial m emerges in g :

$$m = x^{\odot i} \odot \bar{x}^{\odot j}, \quad c(m) = a_{i,j}; \quad (12)$$

$$m = x^{\odot(i+1)} \odot \bar{x}^{\odot j}, \quad c(m) = b_{i,j}; \quad (13)$$

$$m = x^{\odot i} \odot \bar{x}^{\odot(j+1)}, \quad c(m) = b_{i,j}; \quad (14)$$

$$m = x^{\odot i} \odot \bar{x}^{\odot j}, \quad c(m) = d_{i,j} + 1; \quad (15)$$

$$m = x^{\odot(i+1)} \odot \bar{x}^{\odot(j+1)}, \quad c(m) = e_{i,j}; \quad (16)$$

$$m = x^{\odot i} \odot \bar{x}^{\odot j}, \quad c(m) = u_{i,j} + c; \quad (17)$$

$$m = x^{\odot(i+k)} \odot \bar{x}^{\odot j}, \quad c(m) = v_{i,j} \quad (18)$$

for suitable i, j . If several cases apply to the same monomial, we choose one of them in an arbitrary way.

Draw an arrow in H from m to

$$x \odot m = x^{\odot(i+1)} \odot \bar{x}^{\odot j} \text{ in case (12);} \quad (19)$$

$$x^{\odot i} \odot \bar{x}^{\odot j} \text{ in case (13);} \quad (20)$$

$$x^{\odot i} \odot \bar{x}^{\odot j} \text{ in case (14);} \quad (21)$$

$$x^{\odot(i+1)} \odot \bar{x}^{\odot(j+1)} \text{ in case (15);} \quad (22)$$

$$x^{\odot i} \odot \bar{x}^{\odot j} \text{ in case (16);} \quad (23)$$

$$x^{\odot(i+k)} \odot \bar{x}^{\odot j} \text{ in case (17);} \quad (24)$$

$$x^{\odot i} \odot \bar{x}^{\odot j} \text{ in case (18).} \quad (25)$$

■ **Figure 2** Possible arrows in a fragment of the graph H in Theorem 25 (not all arrows are present in a specific proof!). Coefficients decrease more than by the value shown on the arrows (according to (26)–(32)).

Since $f \succ g$, these arrows indeed correspond to strict inequalities on the coefficients:

$$c(x^{\odot(i+1)} \odot \bar{x}^{\odot j}) < c'(x^{\odot(i+1)} \odot \bar{x}^{\odot j}) \leq c(x^{\odot i} \odot \bar{x}^{\odot j}) \text{ in cases (12), (19);} \quad (26)$$

$$c(x^{\odot i} \odot \bar{x}^{\odot j}) < c'(x^{\odot i} \odot \bar{x}^{\odot j}) \leq c(x^{\odot(i+1)} \odot \bar{x}^{\odot j}) \text{ in cases (13), (20);} \quad (27)$$

$$c(x^{\odot i} \odot \bar{x}^{\odot j}) < c'(x^{\odot i} \odot \bar{x}^{\odot j}) \leq c(x^{\odot i} \odot \bar{x}^{\odot(j+1)}) \text{ in cases (14), (21);} \quad (28)$$

$$c(x^{\odot(i+1)} \odot \bar{x}^{\odot(j+1)}) < c'(x^{\odot(i+1)} \odot \bar{x}^{\odot(j+1)}) \leq c(x^{\odot i} \odot \bar{x}^{\odot j}) - 1 \quad (29)$$

in cases (15), (22);

$$c(x^{\odot i} \odot \bar{x}^{\odot j}) < c'(x^{\odot i} \odot \bar{x}^{\odot j}) \leq c(x^{\odot(i+1)} \odot \bar{x}^{\odot(j+1)}) + 1 \text{ in cases (16), (23);} \quad (30)$$

$$c(x^{\odot(i+k)} \odot \bar{x}^{\odot j}) < c'(x^{\odot(i+k)} \odot \bar{x}^{\odot j}) \leq c(x^{\odot i} \odot \bar{x}^{\odot j}) - c \text{ in cases (17), (24);} \quad (31)$$

$$c(x^{\odot i} \odot \bar{x}^{\odot j}) < c'(x^{\odot i} \odot \bar{x}^{\odot j}) \leq c(x^{\odot(i+k)} \odot \bar{x}^{\odot j}) + c \text{ in cases (18), (25).} \quad (32)$$

There exists a cycle Z in the graph H . To justify the required lower bound k when the numbers of arrows of types (24), (25) differ, note that the degree of x changes at most by one in all other types of arrows.

When they are equal, we observe that the number of arrows of type (23) in Z is greater than the number of arrows of type (22), because the coefficient at a tropical monomial increases (respectively, decreases) by 1 along an arrow of type (23) due to (16) (respectively, of type (22) due to (15)), while the coefficient does not change along arrows of types (19), (20), (21) due to (12), (13), (14), respectively. This leads to a contradiction since the tropical degree with respect to \bar{x} of a tropical monomial decreases (respectively, increases) by 1 along an arrow of type (23) (respectively, (22)), while this tropical degree does not increase along arrows of other types. ◀

6.4 Non-deducibility results

We also show two non-deducibility results. First we notice that one could encode Boolean logic without dual variables by replacing the axioms (01/·) and (01/⊕) by semantically equivalent

$$\frac{\emptyset}{x^{\odot 2} \oplus 1 = x} \quad (01/E)$$

We show that the inequality $0 \leq x$ is not derivable from (01/E) (thus showing the difference between two Boolean encodings). Formally, we prove the following theorem.

► **Theorem 26.** $\Gamma \oplus c \leq x \oplus \Delta$ is not derivable in MP-NS from (01/E) for any $c \in \mathbb{Q}_\infty$ and any $\Gamma \succ \Delta$.

After that we establish that the tropical resolution rule cannot be simulated directly in MP-PCR by providing an easy example of premises of these rules that cannot yield the conclusion through an algebraic combination with Boolean axioms (even with auxiliary polynomials remaining in the algebraic combination). More precisely, the next theorem states that there is no inference of the inequality $x^{\odot 2} \leq 0$ from the axioms in MP-NSR. Note that this demonstrates that one cannot infer the tropical resolution rule (\odot RES): namely, from $t \oplus f \leq 0$, $t' \oplus f \leq 0$ to infer $t \odot t' \oplus f \leq 0$, setting $t := t' := x$, $f := x^{\odot 2}$.

► **Theorem 27.** For any $\Gamma \succ \Delta$, there is no MP-NSR inference of $\Gamma \oplus x^{\odot 2} \leq 0 \oplus \Delta$ from the axioms of these systems.

This proof uses techniques similar to those of the size lower bounds. To prove non-derivability in MP-NSR, we again construct a directed graph on monomials occurring in a tropical algebraic combination, such that some specific function on the vertices of the graph related to the coefficients is strictly monotone along any arrow. Then we show the existence of a cycle in the graph, which leads to a contradiction.

7 Conclusion and Further Research

In this paper we introduced a new view of previously known proof systems by using tropical arithmetic. This view allowed us to isolate weaker fragments of Res(CP) (see Figure 1) so that we could hope for proving superpolynomial lower bounds on the proof size for them. The weakest of these fragments, static tropical proof systems, allow for different (and more elementary) methods of proving lower bounds. We provided several steps in this direction (though not for formulas in CNF). We view proving lower bounds for tropical proof systems as a promising direction.

The “knowledge border” for Boolean formulas in CNF lies between treelike Res(CP), where exponential lower bounds have been recently proved using quasipolynomial monotone interpolation [15], treelike Res(Lin) with semantic weakening, where exponential lower bounds are known for PHP [28], regular Res(\oplus), where exponential lower bounds for the binary pigeon-hole principle have been proved recently [13], on the one hand, and, on the other hand, Res(LP*) as well as Res(Lin) and Res(\oplus), where the question is so far open. In the non-CNF case, exponential lower bounds are known also for the Binary Value Principle in daglike Res(Lin) [28].

Tropical proof systems refine these borders. The static system MP-NSR lies between daglike Resolution and (through, for example, MP-PCR and Res(LP)) Res(CP). In the non-CNF case, we have shown an exponential lower bound on the refutations of a greatly simplified version of the Binary Value Principle in MP-NSR.

Several promising directions are (all questions concern $\{0, 1\}$ -variables encodings):

1. We were able to show the polynomial simulation of Res(LP) only after we added the rule (\odot RES) to MP-PCR.
 - a. It gives an additional hope to prove **lower bounds for MP-PCR** as it may be weaker than Res(LP).
 - b. Or maybe the two systems are polynomially equivalent even without this rule? (We only proved that it cannot be simulated directly in a rule-by-rule fashion.)

2. Fleming et al. [14] prove that CP quasipolynomially simulates `treelike Res(CP*)`. While `Res(CP*)` and `Res(LP*)` are polynomially equivalent, this is not necessarily true for their `treelike` versions. In fact, `treelike Res(LP)` has very limited ability to work with integer arithmetic at all, because it is unable to make rounding with big coefficients efficiently. Can we quasipolynomially simulate `treelike Res(LP)` in CP? Perhaps, we can quasipolynomially simulate MP-NSR in CP?
3. Relations between MP-NSR and CP are unclear, both for unary and binary coefficients, and even for `treelike` CP.
4. Relations between `treelike MP-PCR+(⊙RES)` and `treelike Res(LP)` are also unclear. Even polynomial simulation of MP-NSR in `treelike Res(LP)` does not seem to be trivial.

Abstract

We investigate semi-streaming algorithms for the Traveling Salesman Problem (TSP). Specifically, we focus on a variant known as the (1,2)-TSP, where the distances between any two vertices are either *one* or *two*. Our primary emphasis is on the closely related Maximum Path Cover Problem, which aims to find a collection of vertex-disjoint paths that covers the maximum number of edges in a graph. We propose an algorithm that, for any $\epsilon > 0$, achieves a $(\frac{2}{3} - \epsilon)$ -approximation of the maximum path cover size for an n -vertex graph, using $\text{poly}(\frac{1}{\epsilon})$ passes. This result improves upon the previous $\frac{1}{2}$ -approximation by Behnezhad et al. [3] in the semi-streaming model. Building on this result, we design a semi-streaming algorithm that constructs a tour for an instance of (1,2)-TSP with an approximation factor of $(\frac{4}{3} + \epsilon)$, improving upon the previous $\frac{3}{2}$ -approximation factor algorithm by Behnezhad et al. [3]¹.

Furthermore, we extend our approach to develop an approximation algorithm for the Maximum TSP (Max-TSP), where the goal is to find a Hamiltonian cycle with the maximum possible weight in a given weighted graph G . Our algorithm provides a $(\frac{7}{12} - \epsilon)$ -approximation for Max-TSP in $\text{poly}(\frac{1}{\epsilon})$ passes, improving on the previously known $(\frac{1}{2} - \epsilon)$ -approximation obtained via maximum weight matching in the semi-streaming model.

1 Introduction

The Traveling Salesman Problem (TSP) is a fundamental problem in combinatorial optimization. Given a graph $G = (V, E)$ with distances assigned to the edges, the objective is to find a Hamiltonian cycle with the lowest possible cost. The general form of TSP is known to be inapproximable unless $P = NP$ [22]. Consequently, research often focuses on specific types of

¹ Although Behnezhad et al. do not explicitly state that their algorithm works in the semi-streaming model, it is easy to verify.

distance functions, particularly the metric TSP, where distances satisfy the triangle inequality. Two notable metric versions of TSP are the graphic TSP, where distances correspond to the shortest path lengths in an unweighted graph, and (1,2)-TSP, a variant of TSP with distances restricted to either *one* or *two* [1, 4, 5, 6, 12, 14, 15, 17, 18, 19, 23, 24, 25].

Most research is conducted within the classic centralized model of computation. However, with the surge of large data sets in various real-world applications (as reviewed in [7]), there is a growing demand for algorithms capable of handling massive inputs. For very large graphs, classical algorithms are not only too slow but also suffer from excessive space complexity. When a graph's size exceeds the memory capacity of a single machine, algorithms that rely on random access to the data become impractical, necessitating alternative computational models. One such model that has gained significant attention recently is the graph stream model, introduced by Feigenbaum et al. [8, 9]. In this model, edges of the graph are not stored in memory but arrive sequentially in a stream, requiring processing in that order. The challenge is to design algorithms that use minimal space and ideally make only a small constant number of passes over the stream. A widely studied variant of this is the semi-streaming model. In the semi-streaming model, as outlined by Feigenbaum et al. [9], we consider a graph G with n vertices. The algorithm processes the graph's edges as they arrive in the stream and aims to compute results with minimal passes while using limited memory, constrained to $\tilde{O}(n) := O(n \cdot \text{polylog}(n))$.

It is straightforward to design a deterministic one-pass streaming algorithm to compute the cost of a Minimum Spanning Tree (MST) exactly, even in graph streams, which in turn immediately provides an $\tilde{O}(n)$ space algorithm to estimate TSP cost within a factor of 2. Thus, in the semi-streaming regime, the key challenge is to estimate TSP cost within a factor that is strictly better than 2. Recently, Chen, Khanna, and Tan [5] proposed a deterministic two-pass 1.96-approximation factor algorithm for metric TSP cost estimation in the semi-streaming model. For the case of (1,2)-TSP, using the approach of Behnezhad et al. [3], it is possible to provide a 1.5-approximation factor algorithm in the semi-streaming model. In [3], authors presented a sub-linear version of their algorithm; however, it is straightforward to implement their algorithm in the semi-streaming model.

In section 11 of [3], the authors showed a reduction from (1,2)-TSP to maximum matching and stated that achieving better approximation than 1.5 for (1,2)-TSP in the sub-linear model, solves an important open problem in sub-linear maximum matching. Considering the same reduction in semi-streaming model shows achieving non-trivial approximations for (1,2)-TSP in semi-streaming model is challenging. Since the maximum matching problem is studied in the semi-streaming model extensively, the following question naturally arises.

Question. What is the trade off between the approximation ratio and the number of passes for (1,2)-TSP in the semi-streaming model?

Maximum Path Cover. In an unweighted graph G , a subset of edges is called a *path cover* if it forms a union of vertex-disjoint paths. A maximum path cover (MPC²) in an unweighted graph is a path cover with the maximum number of edges (not paths) among all possible path covers in the graph. The problem of finding an MPC is known to be NP-complete. It is

² Throughout this paper we use this acronym for 'Maximum Path Cover'. Please note that we do **not** refer to the common abbreviation for 'Massively Parallel Computation'.

straightforward to see that a maximum matching provides a $1/2$ -approximation for MPC. Therefore, computing a maximal matching, which is a $1/2$ -approximation for maximum matching, yields a $1/4$ -approximate solution for MPC.

Behnezhad et al. [3] developed a $1/2$ -approximate MPC algorithm, which provides a 1.5 -approximate solution for $(1, 2)$ -TSP. Their algorithm can be implemented in one pass within the semi-streaming model using $\tilde{O}(n)$ space to return the cost, and in two passes if the approximate solution itself is required. Our primary contribution is an improvement in the approximation factor of their algorithm.

Result 1 (Formally as Theorem 8). For a given unweighted graph G , there is a semi-streaming algorithm that returns a $(\frac{2}{3} - \epsilon)$ -approximation of MPC in $\text{poly}(\frac{1}{\epsilon})$ passes.

(1, 2)-TSP. The classical problem $(1, 2)$ -TSP is well-studied and known to be NP-hard [15], and even APX-hard [20]. One can easily observe that in an instance of $(1, 2)$ -TSP, the optimal tour is almost the same as finding the MPC of the induced subgraph on edges with weight 1 and then joining their endpoints with edges with weight 2, except for a possible difference of 1 (in the case that there exists a Hamiltonian cycle all of whose edges have weight 1). A simple computation shows that if one can find a set of vertex-disjoint paths that is at least α times the optimal size ($\alpha \leq 1$), then one can also find a tour whose cost is no more than $(2 - \alpha)$ times the optimal cost for $(1, 2)$ -TSP. Thus, Result 1 implies the following result.

Result 2 (Formally as Theorem 10). For an instance of $(1, 2)$ -TSP, there is a semi-streaming algorithm that returns a $(\frac{4}{3} + \epsilon)$ -approximation of $(1, 2)$ -TSP in $\text{poly}(\frac{1}{\epsilon})$ passes.

In the second part of the paper, we examine Max-TSP in the semi-streaming model.

Max-TSP. For a given complete weighted graph G , the goal of Max-TSP is to find a Hamiltonian cycle such that the sum of the weights of the edges in this cycle is maximized.

It is evident that a maximum weighted matching provides a $\frac{1}{2}$ -approximation for the cost of Max-TSP. Consequently, the result of Huang and Saranurak [13], which computes a $(1 - \epsilon)$ -approximate maximum weight matching in the semi-streaming model, yields a $(\frac{1}{2} - \epsilon)$ -approximation for Max-TSP. In this paper, we improve this bound to $\frac{7}{12} - \epsilon$. Our result is as follows.

Result 3 (Formally as Theorem 16). For a given weighted graph G , there is a semi-streaming algorithm that returns a $(\frac{7}{12} - \epsilon)$ -approximation of Max-TSP in $\text{poly}(\frac{1}{\epsilon})$ passes.

To the best of our knowledge, this is the first non-trivial approximation algorithm for Max-TSP in the semi-streaming model.

Further related work

Our approach for computing MPC, $(1, 2)$ -TSP and Max-TSP mainly uses the subroutines for computing maximum matching in unweighted graphs and maximum weight matching in weighted graphs.

In the semi-streaming model, Fischer, Mitrovic and Uitto [10] gave a $(1 - \epsilon)$ -approximation for the maximum matching problem in $\text{poly}(1/\epsilon)$ passes. This result was an improvement over the $(1/\epsilon)^{O(1/\epsilon)}$ passes algorithm by McGregor [16].

For the maximum weight matching in the semi-streaming model, Paz and Schwartzman gave a simple deterministic single-pass $(1/2 - \epsilon)$ -approximation algorithm [21]. Gamlath, Kale, Mitrovic, and Svensson gave a $(1 - \epsilon)$ -approximation streaming algorithm that uses $O_\epsilon(1)$ passes and $O_\epsilon(n \cdot \text{poly}(\log n))$ memory. This was the first $(1 - \epsilon)$ -approximation streaming algorithm for weighted matching that uses a constant number of passes (only depending on ϵ) [11]. Also, Huang and Su in [13], gave a deterministic $(1 - \epsilon)$ -approximation for maximum weighted matching using $\text{poly}(1/\epsilon)$ passes in the semi-streaming model. When ϵ is smaller than a constant $O(1)$ but at least $1/\log^{o(1)} n$, their algorithm is more efficient than [11].

1.1 Notation

Let G be a simple graph. We denote the set of vertices and edges of G by $V(G)$ and $E(G)$ respectively. We also denote the maximum matching size in G by $\mu(G)$ and the size of the MPC in G by $\rho(G)$.

For a subset of edges $T \subseteq E(G)$, we denote G/T as the contraction of G on T , which is the graph derived by repeatedly removing edges of T (it is well-known that the order does not matter) from the graph and merging its endpoints to be a single node in the new graph. Note that after contraction the graph might have parallel edges, but this does not interfere with our algorithm. In the weighted case, if $w(e)$ is the weight of edge e , then we define $w(T)$ to be the sum of weights of the elements of T i.e. $\sum_{e \in T} w(e)$. Let $P = (u_1, u_2, \dots, u_k)$ be a path of length $k - 1$ ($u_i \in V$ for $1 \leq i \leq k$). We call u_1 and u_k *end points* of P and u_i for $2 \leq i \leq k - 1$ *middle points* of P .

2 Technical Overview and Our Contribution

We propose a simple algorithm that constructs a path cover with an approximation factor of almost $\frac{2}{3}$ for MPC. This new algorithm merely depends on basic operations and computing matching and approximate matching.

Our algorithm for MPC is as follows. Assume that $\text{MM}\epsilon$ is a $(1 - \epsilon)$ -approximation algorithm for computing maximum matching in an unweighted graph G . We use $\text{MM}\epsilon$ as a subroutine in our algorithm, which has two phases. In the first phase, we run $\text{MM}\epsilon$ to compute a $(1 - \epsilon)$ -approximate maximum matching, denoted by M_1 . In the next phase, we contract all edges in M_1 to obtain a new graph $G' = G/M_1$. Then, we compute a $(1 - \epsilon)$ -approximate maximum matching, denoted by M_2 , for G' using $\text{MM}\epsilon$. Finally, we return the edges of M_1 and M_2 as a path cover for G (see Algorithm 1).

We will show that the output of our algorithm is a collection of vertex-disjoint paths, i.e., a valid path cover (see Lemma 1).

The algorithm is simple, but proving that its approximation factor is $\frac{2}{3} - \epsilon$ is challenging. As a warm-up, it is straightforward to see that by computing a maximum matching in the first phase, we achieve a $\frac{1}{2}$ -approximate MPC. However, the challenge lies in the second phase, which helps to improve the approximation factor.

Now we explain the idea of our proof to find the approximation factor of Algorithm 1. For the matching M_1 in graph G , we provide a lower bound for $\mu(G/M_1)$. We show that if we consider a maximum path cover P^* and contract P^* on M_1 , the contracted graph becomes a particular graph in which we can find a lower bound on the size of its maximum

matching. Let M_2 be a maximum matching of G/M_1 , then this results in a lower bound for $|M_2|$. Finally, we exploit this lower bound for $|M_2|$ together with a lower bound for $|M_1|$, to come up with the approximation factor of Algorithm 1.

We explain how to implement this algorithm in the semi-streaming model, achieving an improved approximation factor for $(1, 2)$ -TSP within this model.

For the Max-TSP, we use a similar algorithm, except we compute maximum weight matching instead of maximum matching (see Algorithm 3). By computing the approximation factor of this algorithm, we provide a non-trivial approximation algorithm for Max-TSP in the semi-streaming model. Despite the extensive study of the weighted version of the maximum matching problem, Max-TSP has not been studied extensively in the literature within the semi-streaming model. One reason could be that it is not possible to extend the approaches for the unweighted version to the weighted version. Fortunately, we can extend our algorithm to the weighted version and improve the approximation factor of Max-TSP in the semi-streaming model. However, our method for analyzing the approximation factor of Algorithm 1 does not apply to the weighted version, so we present a different proof approach for computing the approximation factor of Algorithm 3.

3 Improved Approximation Factor Semi-Streaming Algorithm for MPC

In Algorithm 1, we presented our novel algorithm for MPC. This section provides an analysis of its approximation factor, followed by a detailed explanation of its streaming implementation.

■ **Algorithm 1** Approximating maximum path cover on a graph G .

-
- 1: Run MM_ϵ on G to find a matching M_1 .
 - 2: Contract G on M_1 to get a new graph $G' = G/M_1$.
 - 3: Run MM_ϵ on G' to find another matching M_2 .
 - 4: **return** $M_1 \cup M_2$.
-

We start by proving the correctness of this algorithm.

► **Lemma 1.** *If M_1 and M_2 are the matchings obtained in Algorithm 1, then $M_1 \cup M_2$ forms a path cover for G .*

Proof. We claim that $M_1 \cup M_2$ is a vertex-disjoint union of paths of length 1, 2 or 3. As a result, it is a path cover. Suppose $M_1 = \{u_1v_1, u_2v_2, \dots, u_kv_k\}$. Let us denote the vertices of G/M_1 by $\{(uv)_1, (uv)_2, \dots, (uv)_k, w_1, w_2, \dots, w_l\}$ where $(uv)_i$ represents the vertices u_i and v_i , merged in the contracted graph G/M_1 and w_j 's for $1 \leq j \leq l$ are the rest of the vertices. Let $xy \in M_2$ be an arbitrary edge. By symmetry between x and y , there are three cases as follows:

1. $x, y \in \{w_1, w_2, \dots, w_l\}$.
In this case, x and y are intact vertices after contraction, which means there are no edges in M_1 adjacent to x and y . Since $xy \in M_2$ and M_2 is a matching, there are no other edges in $M_1 \cup M_2$ adjacent to x and y in G . As a result, xy would be a path of length 1 in $M_1 \cup M_2$.
2. $x \in \{(uv)_1, (uv)_2, \dots, (uv)_k\}$ and $y \in \{w_1, w_2, \dots, w_l\}$.
In this case, $x = (uv)_i$ for some $1 \leq i \leq k$. As a result, xy would be u_iy or v_iy in G . By symmetry, assume that $xy = u_iy$ in G . Since M_1 is a matching, no other edges in M_1 are adjacent to u_i and v_i . No edge in M_1 is adjacent to y . Since M_2 is a matching, the only edge in M_2 adjacent to at least one of u_i, v_i and y in G is $xy = u_iy$. Finally, we can see that (v_i, u_i, y) is a path of length 2 in $M_1 \cup M_2$.

3. $x, y \in \{(uv)_1, (uv)_2, \dots, (uv)_k\}$.

In this case, let $x = (uv)_i$ and $y = (uv)_j$ and by symmetry, assume that xy is the edge connecting u_i to u_j in G . Since M_1 is a matching, the only edges in M_1 adjacent to at least one of u_i, u_j, v_i, v_j are $u_i v_i$ and $u_j v_j$. Since M_2 is a matching, the only edge in M_2 adjacent to at least one of u_i, u_j, v_i, v_j is $(uv)_i(uv)_j$. As a result, (v_i, u_i, u_j, v_j) would be a path of length 3 in $M_1 \cup M_2$.

So, $M_1 \cup M_2$ is a union of vertex-disjoint paths of length 1, 2 or 3. ◀

3.1 Analysis of the Approximation Factor of Algorithm 1

We start with a simple and basic lemmas that is crucial in our proof.

► **Lemma 2.** *Let G be an arbitrary graph. We have:*

$$\rho(G) \geq \mu(G) \geq \frac{1}{2}\rho(G).$$

Proof. Since every matching is a path cover, we have $\rho(G) \geq \mu(G)$. Also, given an MPC, we can select every other edge in this MPC to obtain a matching that contains at least half of its edges, which implies $\mu(G) \geq \frac{1}{2}\rho(G)$. ◀

► **Corollary 3.** *If M is a $(1 - \epsilon)$ -approximation of maximum matching in graph G , then*

$$|M| \geq \frac{1}{2}(1 - \epsilon)\rho(G).$$

We now present a lemma regarding the size of the maximum matching in a specific type of graph. This lemma may be of independent interest. In this paper we utilize this lemma on G/M_1 to derive a lower bound for $|M_2|$.

► **Lemma 4.** *Assume G is a graph without loops such that each vertex v of G has degree 1, 2, or 4. If $V_4(G)$ denotes the set of vertices of degree 4 in G , then we have*

$$\mu(G) \geq \frac{|E(G)| - |V_4(G)|}{3}.$$

Proof. The proof of this lemma is a bit long and technical. Here, we provide the proof sketch of the lemma due to page limit constraints and we refer the reader to the full version of the paper to see the complete proof.³ The main tools for the proof are induction and a charging scheme. The induction is on the number of edges between nodes of degree 2 or 4 in graph G denoted by $|E_{2,4}(G)|$.

In a high level, we provide some special local topological properties of the graph. If G does not satisfy at least one of the properties, then we do some delicate local changes on G to get G' such that $|E_{2,4}(G')| \leq |E_{2,4}(G)|$. Next, we improve a matching in G' to a matching for G with the desired size.

In the case that G satisfies all of the properties, we provide a charging scheme that takes some tokens for each edge in an arbitrary maximum matching and spread these tokens between incident edges, which proves the desired inequality. ◀

Using above lemma, we have the main lemma of this section as follows.

³ A full version of this extended abstract can be found at [2].

► **Lemma 5.** *If M is an arbitrary matching in a graph G , then*

$$\mu(G/M) \geq \frac{\rho(G) - |M|}{3}.$$

Proof. Assume P^* is a maximum path cover in G such that $P^* \cap M$ is maximal. We claim that every $e \in M \setminus P^*$ connects two middle points of P^* . The proof of this claim follows from a case by case argument. For the sake of contradiction, assume $e = uv \in M \setminus P^*$ does not connect two middle points of P^* . We have three cases for u and v as follows.

- None of u and v belong to P^* (case 1).
- Exactly one of them (say u) belongs to P^* . Then, u is an end point (case 2), or u is a middle point (case 3).
- Both u and v belong to P^* . Then, we have two sub cases.
 - u and v are on different paths. Then either they are both end points (case 4), or one is a middle point (say u) and the other one is an end point (case 5). Note that we have considered that both of u and v are not middle points at the same time.
 - u and v belong to the same path. Then, either they are both end points (case 6), or one is a middle point (say u) and the other one is an end point (case 7). Note that we have assumed both of them are not middle points at the same time.

Now, we explain each case in detail.

1. Neither u nor v belongs to \tilde{P} .
This case is impossible because $P^* + e$ is a path cover with a size larger than $|P^*|$, which is in contradiction with P^* being MPC (see Figure 1a).
2. u is an end point of a path in P^* and v is not contained in P^* .
Again, this case is impossible since $P^* + e$ is a path cover with a size larger than $|P^*|$, which is in contradiction with P^* being MPC (see Figure 1b).
3. u is a middle point of a path in P^* and v is not contained in P^* .
Let (p_1, p_2, \dots, p_k) be the path in P^* containing $u = p_i$. Replace P^* by $P^* - p_{i-1}p_i + e$ which is an MPC of G (see Figure 1c). Since $e \in M$, we have $p_{i-1}p_i \notin M$. Therefore, $|\tilde{P} \cap M|$ increments. This is in contradiction with $|P^* \cap M|$ being maximal.
4. u and v are end points of different paths in P^* .
In this case, let (p_1, p_2, \dots, p_k) and (q_1, q_2, \dots, q_l) be the paths in P^* containing $u = p_1$ and $v = q_1$, respectively. $P^* + e$ would be a path cover of size greater than $|P^*|$ which is in contradiction with P^* being MPC (see Figure 1d).
5. u and v are the middle and end points of different paths in P^* , respectively.
In this case, let (p_1, p_2, \dots, p_k) and (q_1, q_2, \dots, q_l) be the paths in P^* containing $u = p_i$ and $v = q_1$ respectively. Replace P^* by $P^* - p_{i-1}p_i + e$ which is an MPC of G (see Figure 1e). Since $e \in M$, we have $p_{i-1}p_i \notin M$. Therefore, $|P^* \cap M|$ increments. This is in contradiction with $|P^* \cap M|$ being maximal.
6. u and v are end points of the same path in P^* .
In this case, let (p_1, p_2, \dots, p_k) be the path in P^* containing $u = p_1$ and $v = p_k$. Replace P^* by $P^* - p_1p_2 + e$ which is an MPC of G (see Figure 1f). Since $e \in M$ we have $p_1p_2 \notin M$. Therefore, $|P^* \cap M|$ increments. This is in contradiction with $|P^* \cap M|$ being maximal.
7. u and v are the middle and end points of the same path in P^* , respectively.
In this case, let (p_1, p_2, \dots, p_k) be the path in P^* containing $u = p_i$ and $v = p_1$ (since $e \notin P^*$, we have $2 < i$). Replace P^* by $P^* - p_{i-1}p_i + e$ which is an MPC of G (see Figure 1g). Since $e \in M$, we have $p_{i-1}p_i \notin M$. Therefore, $|P^* \cap M|$ increments. This is in contradiction with $|P^* \cap M|$ being maximal.

Figure 1 Different possible cases for u and v .

Each case leads to a contradiction, implying that every $e \in M \setminus P^*$ connects two middle points of P^* .

Now, contraction of each $e \in M \setminus P^*$ makes a vertex of degree 4 in P^*/M . Contraction of each $e \in M \cap P^*$ makes a vertex of degree 2 and decrements the number of edges in P^* . As a result, P^*/M is a graph whose vertices' degrees are 1,2 or 4, $|E(P^*/M)| = |P^*| - |P^* \cap M|$ and $|V_4(P^*/M)| = |M \setminus P^*|$. Finally, using Lemma 4 for P^*/M we have

$$\mu(P^*/M) \geq \frac{|E(P^*/M)| - |V_4(P^*/M)|}{3} = \frac{|P^*| - |P^* \cap M| - |M \setminus P^*|}{3} = \frac{|P^*| - |M|}{3}.$$

Since P^*/M is a subgraph of G/M we have

$$\mu(G/M) \geq \mu(P^*/M) \geq \frac{|P^*| - |M|}{3} = \frac{\rho(G) - |M|}{3}. \quad \blacktriangleleft$$

Using the above results, we compute the approximation factor of Algorithm 1.

► **Theorem 6.** *The approximation factor of Algorithm 1 is $\frac{2}{3}(1 - \epsilon)$, i.e.,*

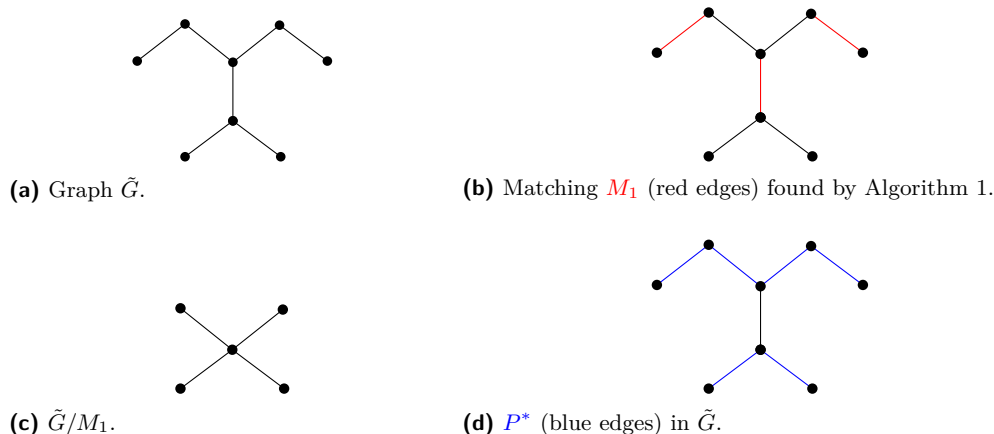

$$\rho(G) \geq |M_1 \cup M_2| \geq \frac{2}{3}(1 - \epsilon)\rho(G). \quad (1)$$

Proof. By Corollary 3 and, Lemma 5, we have

$$\begin{aligned} |M_1 \cup M_2| &= |M_1| + |M_2| \\ &\geq |M_1| + (1 - \epsilon)\mu(G/M_1) \\ &\geq |M_1| + \frac{1 - \epsilon}{3}(\rho(G) - |M_1|) \\ &\geq \frac{1 - \epsilon}{3}\rho(G) + \frac{2}{3}|M_1| \\ &\geq \frac{1 - \epsilon}{3}\rho(G) + \frac{1 - \epsilon}{3}\rho(G) = \frac{2}{3}(1 - \epsilon)\rho(G). \end{aligned}$$

Since $M_1 \cup M_2$ is a path cover, we have $\rho(G) \geq |M_1 \cup M_2|$. Hence, the approximation factor of Algorithm 1 is at least $\frac{2}{3}(1 - \epsilon)$. ◀

Now, we show that our analysis of the approximation factor of Algorithm 1 is tight. Consider the graph in Figure 2a and denote it by \tilde{G} . If we run Algorithm 1 on \tilde{G} , then the edges of M_1 could be the red edges shown in Figure 2b. After contracting \tilde{G} on M_1 , we have \tilde{G}/M_1 shown in Figure 2c. Finally, the second matching M_2 found by Algorithm 1 in \tilde{G}/M_1 contains at most one edge which implies $|M_1 \cup M_2| \leq 4$. On the other hand, maximum path cover P^* in \tilde{G} contains 6 edges shown in Figure 2d.

■ **Figure 2** An example of a graph \tilde{G} for which Algorithm 1 produces a path cover whose size is $\frac{2}{3}$ times the size of the MPC.

As a result, $\frac{|M_1 \cup M_2|}{|P^*|} \leq \frac{2}{3}$, so this example and Theorem 6 imply that the approximation factor of Algorithm 1 is $\frac{2}{3} - \epsilon$.

3.2 Implementation of Algorithm 1 in the Semi-Streaming Model

Now we explain how to implement Algorithm 1 in the semi-streaming model. We start with the following theorem by Fischer, Mitrovic and Uitto [10].

► **Theorem 7** (Theorem 1.1 in [10]). *Given a graph on n vertices, there is a deterministic $(1 - \epsilon)$ -approximation algorithm for maximum matching that runs in $\text{poly}(\frac{1}{\epsilon})$ passes in the semi-streaming model. Furthermore, the algorithm requires $n \cdot \text{poly}(\frac{1}{\epsilon})$ words of memory.*

To implement Algorithm 1 in the semi-streaming model, we proceed as follows: In the first phase, by applying Theorem 7, we compute a $(1 - \epsilon)$ -approximate matching for the graph G , denoted as M_1 . At the end of this phase, we have the edges of this matching. In the second phase, we again apply Theorem 7 to compute a matching for G/M_1 in the streaming model.

During the second phase, when we apply the algorithm of Theorem 7, while processing each edge (v_i, v_j) in the stream, we follow these rules: If $(v_i, v_j) \in M_1$, we ignore this edge. If $(v_i, v_j) \notin M_1$, but one of v_i or v_j is an endpoint of an edge in M_1 (e.g., $v_i, v_k \in M_1$), then since (v_i, v_j) is contracted, we consider v_i and v_j as a single vertex, v_{ij} . In this case, v_k is considered adjacent to the new vertex v_{ij} . Consequently, we can compute a $(1 - \epsilon)$ -approximation matching for G/M_1 in the next $\text{poly}(1/\epsilon)$ passes.

Thus, combining the results of Algorithm 1, Theorem 6, and Theorem 7, we have the main result of this section:

► **Theorem 8.** *Given an unweighted graph G on n vertices, there is a deterministic algorithm that returns a $(\frac{2}{3} - \epsilon)$ -approximate MPC in the semi-streaming model in $\text{poly}(\frac{1}{\epsilon})$ passes.*

4 (1, 2)-TSP

In this section, we present our algorithm for the (1, 2)-TSP, detailed in Algorithm 2, and analyze its approximation factor. We also provide an explanation of how to implement this algorithm in the semi-streaming model.

■ **Algorithm 2** Our algorithm for (1, 2)-TSP.

-
- 1: Let G_1 be the subgraph of G consisting of edges with weight 1.
 - 2: Run Algorithm 1 on G_1 to get a path cover \tilde{P} .
 - 3: Arbitrarily extend \tilde{P} to a Hamiltonian cycle \tilde{C} by adding edges between end points of \tilde{P} or/and existing vertices not in \tilde{P} .
 - 4: **return** \tilde{C} .
-

► **Theorem 9.** *The approximation factor of Algorithm 2 for (1, 2)-TSP is $\frac{4}{3} + \epsilon + \frac{1}{n}$.*

Proof. Let T^* be the optimal solution of (1,2)-TSP, ρ^* be the size of an MPC in G_1 , and n be the number of vertices of G . Since every Hamiltonian cycle contains n edges with weights 1 or 2, we have $n \leq T^* \leq 2n$. We also have $T^* = 2n - \rho^* - 1$ or $T^* = 2n - \rho^*$, where $T^* = 2n - \rho^* - 1$ occurs only when G contains a Hamiltonian cycle consisting solely of edges with weight 1.

Let $\tilde{\rho}$ be the size of the path cover obtained by Algorithm 1 in G_1 . The Hamiltonian cycle obtained by Algorithm 2 has a cost of at most $2(n - \tilde{\rho}) + \tilde{\rho} = 2n - \tilde{\rho}$. Let $\alpha \leq 1$ be the approximation factor of Algorithm 1, then we have $\alpha\rho^* \leq \tilde{\rho} \leq \rho^*$. As a result, $T^* \leq 2n - \rho^* \leq 2n - \tilde{\rho}$. We also have:

$$\begin{aligned}
 2n - \tilde{\rho} &\leq 2n - \alpha\rho^* = (2 - 2\alpha)n + \alpha(2n - \rho^* - 1) + \alpha \\
 &\leq (2 - 2\alpha)T^* + \alpha T^* + \alpha = (2 - \alpha)T^* + \alpha \\
 &\leq (2 - \alpha)T^* + 1 \\
 &\leq (2 - \alpha)T^* + \frac{T^*}{n} = \left(2 - \alpha + \frac{1}{n}\right)T^*. \tag{2}
 \end{aligned}$$

By Theorem 6, we have $\alpha \geq \frac{2}{3} - \epsilon$. Using Equation (2), we conclude that:

$$\begin{aligned}
 2n - \tilde{\rho} &\leq \left(2 - \alpha + \frac{1}{n}\right)T^* \\
 &\leq \left(2 - \left(\frac{2}{3} - \epsilon\right) + \frac{1}{n}\right)T^* = \left(\frac{4}{3} + \epsilon + \frac{1}{n}\right)T^*.
 \end{aligned}$$

Hence, $T^* \leq 2n - \tilde{\rho} \leq \left(\frac{4}{3} + \epsilon + \frac{1}{n}\right)T^*$. So, the approximation factor of our algorithm for (1,2)-TSP is $\frac{4}{3} + \epsilon + \frac{1}{n}$. ◀

4.1 Implementation of Algorithm 2 in the Semi-Streaming Model

For a given instance of (1, 2)-TSP in the streaming model, we compute an approximate MPC for the induced subgraph on the edges of weight 1 as explained in Theorem 8, then we add extra edges to connect these paths and vertices not in these paths arbitrarily to construct a Hamiltonian cycle, which gives us a $(\frac{4}{3} + \epsilon + \frac{1}{n})$ -approximate tour for (1, 2)-TSP. So, we have the main result of this section as follows.

► **Theorem 10.** *Given an instance of (1, 2)-TSP on n vertices, there is a deterministic algorithm that returns a $(\frac{4}{3} + \epsilon + \frac{1}{n})$ -approximate (1, 2)-TSP in the semi-streaming model in $O(\text{poly}(\frac{1}{\epsilon}))$ passes.*

5 Max-TSP

In this section, we introduce our algorithm for Max-TSP, which closely resembles our approach for MPC. The key difference is that, instead of using MM_ϵ , we employ a subroutine to compute an approximate maximum weight matching in a weighted graph.

Let MWM_ϵ be a subroutine for computing a $(1 - \epsilon)$ -approximate maximum weighted matching in a weighted graph G . First, we compute a matching M_1 for G using MWM_ϵ . Then, we contract the edges of M_1 to obtain another graph $G' = G/M_1$ and compute another matching, M_2 , for G' using MWM_ϵ again. We derive the union of the two weighted matchings, $M_1 \cup M_2$. Similar to Lemma 1, it is evident that $M_1 \cup M_2$ forms a union of vertex-disjoint paths in G . Finally, since the graph is complete, there can be only one vertex that is not in $M_1 \cup M_2$. In this case we connect this vertex to one of the paths in $M_1 \cup M_2$. Now, we add edges arbitrarily between the endpoints of the paths in $M_1 \cup M_2$ to obtain a Hamiltonian cycle C for G .

■ **Algorithm 3** Our algorithm for Max-TSP on a complete weighted graph G .

-
- 1: Run MWM_ϵ on G to find a matching M_1 .
 - 2: Contract G on M_1 to get a new graph $G' = G/M_1$.
 - 3: Run MWM_ϵ on G' to find another matching M_2 .
 - 4: Arbitrarily extend $M_1 \cup M_2$ to a Hamiltonian cycle C by adding edges between endpoints of $M_1 \cup M_2$ or/and existing vertices not in $M_1 \cup M_2$.
 - 5: **return** C .
-

Note that after contracting G on M_1 to obtain $G' = G/M_1$, this new graph might have parallel edges between vertices. Since we aim to find a maximum matching in G' , we can simply consider the edge with the largest weight for parallel edges and ignore the rest.

5.1 Analysis of the Approximation Factor of Algorithm 3

To analyze the approximation factor of Algorithm 3, we begin with a series of lemmas.

► **Lemma 11.** *Suppose C is a cycle of length k in a weighted graph G . Then, there exists a matching $M \subseteq C$ such that $w(M) \geq \frac{k-1}{2k}w(C)$.*

Proof. Assume that $e \in C$ is the edge with the minimum weight. Hence, $w(e) \leq w(C)/k$. Since $C - e$ is a path, there is a matching $M \subseteq C - e$ (which is also a subset of C) whose weight is at least $w(C - e)/2$. Finally,

$$w(M) \geq \frac{1}{2}w(C - e) = \frac{1}{2}(w(C) - w(e)) \geq \frac{1}{2} \left(w(C) - \frac{w(C)}{k} \right) = \frac{k-1}{2k}w(C). \quad \blacktriangleleft$$

► **Lemma 12.** *Suppose T is a path or a cycle in a weighted graph G . Then there exists a matching $M \subseteq T$ such that $w(M) \geq \frac{1}{3}w(T)$.*

Proof. We have two cases

- T is a path. Enumerate the edges of T from one end point to the other. The odd numbered edges form a matching called M_{odd} . The same applies for even numbered edges, which form a matching called M_{even} . Since $T = M_{\text{odd}} \cup M_{\text{even}}$, at least one of these two matchings has weight no less than $w(T)/2$.
- T is a cycle. If it is a cycle of length 2 (i.e. T consists of two parallel edges), then obviously we can pick the edge e with bigger weight that satisfies $w(e) \geq \frac{1}{2}w(T) \geq \frac{1}{3}w(T)$. If the length of T is at least 3, then using Lemma 11, we conclude that there is a matching $M \subseteq T$ such that $w(M) \geq \frac{k-1}{2k}w(T) \geq \frac{1}{3}w(T)$. ◀

Now, we provide a lemma similar to Lemma 5 which works for the weighted version.

► **Lemma 13.** *Suppose M is a matching in a weighted graph G and C^* is a maximum weight Hamiltonian cycle of G . Then,*

$$\mu(G/M) \geq \frac{w(C^*) - w(M)}{6} - \frac{1}{3n}w(C^*).$$

Proof. We contract C^* on M in two steps. First, we contract C^* on the edges in $C^* \cap M$. Next, we contract the resulting graph on $M' = M \setminus C^*$. After the first step, $C' = C^*/(C^* \cap M)$ is a cycle with weight $w(C^*) - w(C^* \cap M)$ (see Figure 3).

■ **Figure 3** C^* remains a path cover after contraction on $C^* \cap M$ (red edges).

Here M' is a matching that connects some vertices of C' together (see Figure 4a, Figure 4b and Figure 4c).

Assume that the length of C' is k . Using Lemma 11, there is a matching $M^* \subseteq C'$ whose weight is at least $\frac{k-1}{2k}w(C')$ (see Figure 4d). Since the matching M_1 contains at most half of the edges of C^* , we conclude that $k \geq n/2$. As a result,

$$\begin{aligned} w(M^*) &\geq \frac{k-1}{2k}w(C') \geq \frac{n-2}{2n}(w(C^*) - w(C^* \cap M)) \\ &\geq \frac{w(C^*) - w(C^* \cap M)}{2} - \frac{1}{n}w(C^*). \end{aligned} \tag{3}$$

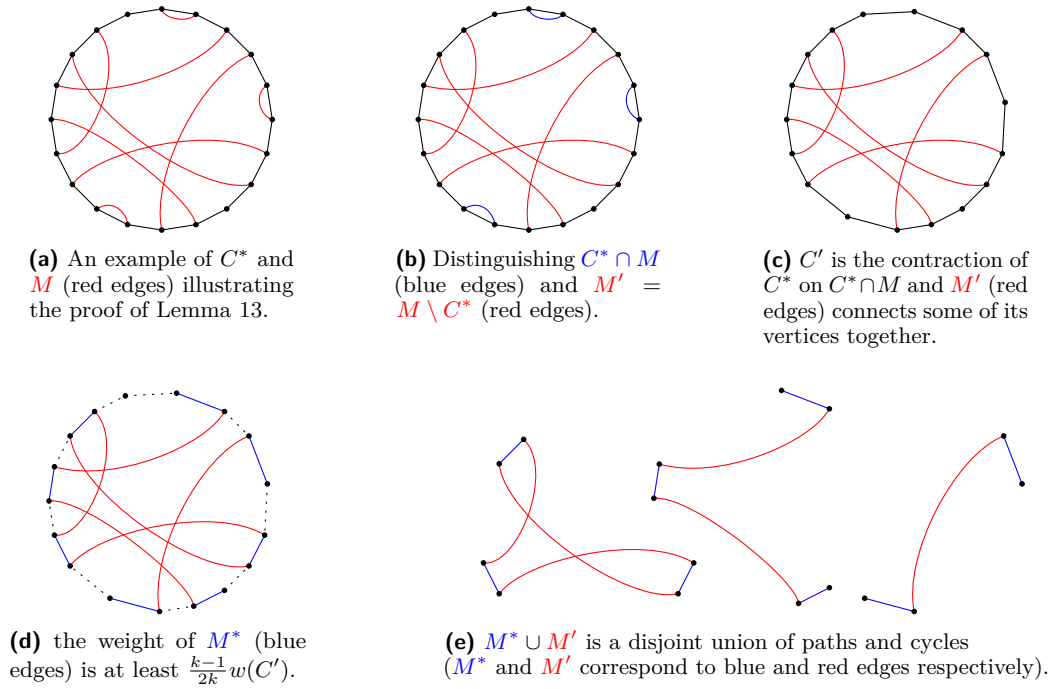

Since $M' \cap C' = \emptyset$, we conclude that $M' \cap M^* = \emptyset$. Because M^* and M' are matchings, it follows that $M^* \cup M'$ is a union of disjoint paths and cycles (see Figure 4e). As a result, after doing the second step of contraction, M^*/M' would also be a disjoint union of paths and cycles (whose number of edges is equal to $|M^*|$ since $M^* \cap M' = \emptyset$) in C'/M' . For instance, if $M^* \cup M'$ contains a cycle of length 4, then M^*/M' would contain a cycle of length 2 which contains parallel edges.

Now, consider each connected component of M^*/M' . This component is either a path or a cycle. Hence, by Lemma 12, We obtain a matching with a weight of at least one-third of the weight of the component.

Finally, since these components are vertex-disjoint, the union of obtained matching would be a matching whose weight is at least $w(M^*)/3$. Note that this matching is also a matching in G/M . Hence, using Equation (3), we have

$$\begin{aligned} \mu(G/M) &\geq \frac{w(M^*)}{3} \geq \frac{w(C^*) - w(C^* \cap M)}{6} - \frac{1}{3n}w(C^*) \\ &\geq \frac{w(C^*) - w(M)}{6} - \frac{1}{3n}w(C^*). \end{aligned} \quad \blacktriangleleft$$

So, we have the following theorem which is a lower bound for the approximation factor of Algorithm 3.

■ **Figure 4** An example of C^* and M illustrating the steps in the proof of Lemma 13.

► **Theorem 14.** *The approximation factor of Algorithm 3 is at least $(\frac{7}{12} - \frac{3}{4n})(1 - \epsilon)$.*

Proof. Let C^* be a maximum weight Hamiltonian cycle in G . By Lemma 11, there exists at least one matching $M \subseteq C^*$ whose weight is at least

$$\frac{n-1}{2n}w(C^*).$$

Since M_1 is a $(1 - \epsilon)$ -approximation of the maximum weighted matching in G we have

$$w(M_1) \geq \frac{(1 - \epsilon)(n-1)}{2n}w(C^*).$$

By using Lemma 13 for M_2 on G/M_1 , we have

$$\begin{aligned} w(M_1 \cup M_2) &= w(M_1) + w(M_2) \\ &\geq w(M_1) + (1 - \epsilon)\mu(G/M_1) \\ &\geq w(M_1) + \frac{1 - \epsilon}{6}(w(C^*) - w(M_1)) - \frac{1 - \epsilon}{3n}w(C^*) \\ &\geq (1 - \epsilon) \left(\frac{1}{6} - \frac{1}{3n} \right) w(C^*) + \frac{5}{6}w(M_1) \\ &\geq (1 - \epsilon) \left(\frac{1}{6} - \frac{1}{3n} \right) w(C^*) + \frac{5(1 - \epsilon)(n-1)}{12n}w(C^*) \\ &= \left(\frac{7}{12} - \frac{3}{4n} \right) (1 - \epsilon)w(C^*). \end{aligned}$$

Since the weight of the edges of G are nonnegative, we have

$$w(C) \geq w(M_1 \cup M_2) \geq \left(\frac{7}{12} - \frac{3}{4n} \right) (1 - \epsilon)w(C^*).$$

Finally, C is a Hamiltonian cycle which means $w(C^*) \geq w(C)$. Hence, the approximation factor of Algorithm 1 is at least $(\frac{7}{12} - \frac{3}{4n})(1 - \epsilon)$. ◀

5.2 Implementation of Algorithm 3 in the semi-streaming model

The implementation of Algorithm 3 in the semi-streaming model follows a similar approach as described in the previous section. Therefore, we omit a detailed explanation here. However, note that in this part, we should use a subroutine for computing a $(1 - \epsilon)$ -approximate maximum weight matching in the semi-streaming model. First, we recall the following theorem from [13]. We use the algorithm of this theorem as MWM_ϵ in our semi-streaming implementation of Algorithm 3.

► **Theorem 15** (Theorem 1.3 in [13]). *There exists a deterministic algorithm that returns a $(1 - \epsilon)$ -approximate maximum weight matching using $\text{poly}(\frac{1}{\epsilon})$ passes in the semi-streaming model. The algorithm requires $O(n \cdot \log W \cdot \text{poly}(\frac{1}{\epsilon}))$ words of memory where W is the maximum edge weight in the graph.*

Thus, Algorithm 3, Theorem 14, and Theorem 15 present the following theorem for Max-TSP in the semi-streaming model.

► **Theorem 16.** *Given an instance of Max-TSP on n vertices, there is an algorithm that returns a $(\frac{7}{12} - \frac{3}{4n})(1 - \epsilon)$ -approximate Max-TSP the semi-streaming model in $O(\text{poly}(\frac{1}{\epsilon}))$ passes. The algorithm requires $O(n \cdot \log W \cdot \text{poly}(\frac{1}{\epsilon}))$ words of memory where W is the maximum edge weight in the graph.*

6 Future Work

As a future work we propose the following algorithm that can help to improve the approximation factor for MPC in the semi-streaming model. The algorithm improves Algorithm 1 by iteratively finding new matchings and contracting the graph over these matchings. It is crucial to ensure that this process preserves the path cover property. Hence, during the k th iteration of our loop, we must remove all the edges in G that are incident to a middle point of any path (connected component) within $\cup_{i=1}^k M_i$. This is because $(\cup_{i=1}^k M_i) \cup M_{k+1}$ must remain a path cover, which means M_{k+1} cannot include any edge incident to a middle point of a path in $\cup_{i=1}^k M_i$. See Algorithm 4.

■ **Algorithm 4** Extension of Algorithm 1.

-
- 1: Run MM_ϵ (or MWM_ϵ for weighted version) on G to find a matching M_1 .
 - 2: Let $i = 1$.
 - 3: while $M_i \neq \emptyset$:
 - 4: Let $G^{(i)} = G$.
 - 5: Remove all $e \in E(G^{(i)}) \setminus (\cup_{k=0}^i M_k)$ from $E(G^{(i)})$ that are incident to at least one middle point of a path (connected component) in $\cup_{k=0}^i M_k$.
 - 6: Contract $G^{(i)}$ on $\cup_{k=0}^i M_k$.
 - 7: Run MM_ϵ (or MWM_ϵ for weighted version) on $G^{(i)}$ to find a matching M_{i+1} .
 - 8: $i = i + 1$
 - 9: **return** $\cup_{k=1}^i M_k$.
-

We leave the computation of the approximation factor of Algorithm 4 as a challenging open problem. Currently, we know that the approximation factor is at most $3/4$. Consider the graph in Figure 5a: the algorithm may select the red edges as M_1 . After contraction, it might select the red edge in Figure 5b as M_2 . In the next iteration, the graph becomes empty, as we must remove any edge incident to a middle point of $M_1 \cup M_2$. Thus, the algorithm terminates with a path of length 3. However, the MPC has 4 edges (see Figure 5c).

■ **Figure 5** An example of a graph where Algorithm 4 terminates after two iterations. The algorithm produces a $\frac{3}{4}$ -approximation of the Maximum Path Cover (MPC).

The main bottleneck to find the approximation ratio of Algorithm 4 is that after the second iteration, there might be a lot of edges that we have to remove from the contracted graph in order to make sure that the union of matchings remains a path cover. More precisely, while running line 5 of Algorithm 4, a bunch of edges that are contained in every maximum path cover might be removed. We are not aware of any argument how to bound the number of these edges. This prevents us to provide an argument like Lemma 5 and Lemma 13. Finding the exact approximation ratio of Algorithm 4 seems to require clever new ideas, already for three matchings.

Monotone Weak Distributive Laws over the Lifted Powerset Monad in Categories of Algebras

Quentin Aristote  

Université Paris Cité, CNRS, Inria, IRIF, F-75013, Paris, France

Abstract

In both the category of sets and the category of compact Hausdorff spaces, there is a monotone weak distributive law that combines two layers of non-determinism. Noticing the similarity between these two laws, we study whether the latter can be obtained automatically as a weak lifting of the former. This holds partially, but does not generalize to other categories of algebras. We then characterize when exactly monotone weak distributive laws over powerset monads in categories of algebras exist, on the one hand exhibiting a law combining probabilities and non-determinism in compact Hausdorff spaces and showing on the other hand that such laws do not exist in a lot of other cases.

2012 ACM Subject Classification Theory of computation → Categorical semantics

Keywords and phrases weak distributive law, weak extension, weak lifting, iterated distributive law, Yang-Baxter equation, powerset monad, Vietoris monad, Radon monad, Eilenberg-Moore category, regular category, relational extension

1 Introduction

In the study of the semantics of programming languages, and since the seminal work of Moggi [26], effectful computations are usually modeled with monads: an effectful function of type $X \multimap Y$ is interpreted as a function of type $X \rightarrow TY$, where the monadic structure on T allows for having identities and compositions of such effectful functions. When considering several effects at the same time, a natural question arises: given monads corresponding to two effects, is it possible to construct a monad that corresponds to the combination of these two effects? In particular, combining probabilities and non-determinism has been a very popular subject of study in the topological and (dually) domain-theoretic settings: see for instance the introduction of [21] for an extensive bibliography on the topic.

The most straightforward way to combine two monads S and T would be to compose their underlying functors, but unfortunately in general the resulting endofunctor ST may not carry the structure of a monad. For this to hold, a sufficient condition is the existence of a *distributive law* of T over S , i.e. a natural transformation $TS \Rightarrow ST$ satisfying four axioms involving the units and multiplications of the two monads [2]. Such a distributive law makes ST into a monad, and its data is equivalent to the data of a *lifting* of S to the Eilenberg-Moore category $\mathbf{EM}(T)$ of T -algebras or to the data of an *extension* of T to the Kleisli category $\mathbf{KI}(S)$ of free S -algebras.

Unfortunately, distributive laws turn out to be not so common: proving that some specific pairs of monads do not admit any distributive law between them has been the focus of several works [22, 29, 12], culminating in [31] where general techniques for proving the absence of distributive laws between monads on **Set**, so-called “no-go theorems”, are exhibited. Among the culprits are the powerset monad **P** and the probability distributions monad **D**: there is no distributive law $\mathbf{PP} \Rightarrow \mathbf{PP}$ nor $\mathbf{DP} \Rightarrow \mathbf{PD}$.

A next step in combining monads is thus to weaken the requirements asked for by distributive laws. In [3] a 2-categorical theory of such weakened distributive laws, where the axioms relating to the units of the monads are relaxed, is developed. This theory encompasses two orthogonal kinds of weakened laws, both called weak distributive laws: those of [28], extensively studied in [5, 6, 4], and those more recently put light on in [14] and given further instances of in [18, 19, 7]. This work focuses on the latter kind of laws: in the following a *weak distributive law* of \mathbf{T} over \mathbf{S} will thus be a natural transformation of type $\mathbf{TS} \Rightarrow \mathbf{ST}$ (again), where only three of the four axioms of distributive laws are required. Such a weak distributive law need not make \mathbf{ST} into a monad, but does so of a retract of it when the category is well-behaved. Weak laws $\mathbf{TS} \Rightarrow \mathbf{ST}$ are equivalent to *weak extensions* of \mathbf{T} to $\mathbf{KI}(\mathbf{S})$ – extensions of the semi-monad underlying \mathbf{T} , i.e. of its endofunctor and multiplication but not of its unit – or, when the category is well-behaved, *weak liftings* of \mathbf{S} to $\mathbf{EM}(\mathbf{T})$ – liftings of \mathbf{S} up to a retraction.

Weak extensions are a precious tool for building weak distributive laws, because *monotone extensions* to \mathbf{Rel} – the category of sets and relations, which also happens to be the category of free algebras of the powerset monad \mathbf{P} on \mathbf{Set} – admit a nice characterization: this makes it possible to find weak distributive laws without having to guess their formulæ anymore, and the monotonicity of the extension is a strong indicator that the resulting law will be semantically interesting. In the context of weak distributive laws, this strategy was first used by Garner [14], who exhibited a law $\mathbf{PP} \Rightarrow \mathbf{PP}$, but also a law $\mathbf{\beta P} \Rightarrow \mathbf{P\beta}$ combining the ultrafilter monad $\mathbf{\beta}$ and the powerset monad and whose corresponding weak lifting turned out to be the Vietoris monad \mathbf{V} of closed subsets on the category \mathbf{KHaus} of compact Hausdorff spaces (the algebras of $\mathbf{\beta}$ [24]). The same strategy was then used for instance in [18], where a law $\mathbf{DP} \Rightarrow \mathbf{PD}$, combining probabilities and non-determinism, is described.

In fact, most non-trivial weak distributive laws in the literature (trivial ones are described in [16, §2.2]) are laws of type $\mathbf{TP} \Rightarrow \mathbf{PT}$ built using this strategy. On the other hand, in [19] the goal was to find weak distributive laws in other categories than \mathbf{Set} , and it was reached as a law $\mathbf{VV} \Rightarrow \mathbf{VV}$, combining two layers of non-determinism in a continuous setting, was described. This last law was also built by constructing a monotone weak extension, and its formula is thus very close to that of the law $\mathbf{PP} \Rightarrow \mathbf{PP}$. In topological settings, non-determinism can also be combined with probabilities: weak distributive laws for this purpose are constructed by hand in a very recent pre-print [15].

The goal of the present work is to take over this program of finding non- \mathbf{Set} -based weak distributive laws: we focus here on categories of algebras, which fit in the general framework for monotone weak laws presented in [19]. In particular, we notice in Theorem 12 that the law $\mathbf{VV} \Rightarrow \mathbf{VV}$ is not only very similar to the law $\mathbf{PP} \Rightarrow \mathbf{PP}$, but is also actually some sort of weak lifting of it. We thus study whether there is a general framework for not only weakly lifting monads (as weak distributive laws do), but also weakly lifting weak distributive laws themselves: this framework should yield or simplify the construction of the law $\mathbf{VV} \Rightarrow \mathbf{VV}$, and hopefully generalize it to other categories of algebras, in particular $\mathbf{EM}(\mathbf{P})$ and $\mathbf{EM}(\mathbf{D})$ which have weakly lifted powerset monads thanks to the laws $\mathbf{PP} \Rightarrow \mathbf{PP}$ and $\mathbf{DP} \Rightarrow \mathbf{PD}$.

This question is largely related to the problem of composing weak distributive laws, which was investigated in [17] from the point of view of the Yang-Baxter equations – the usual tool for composing and lifting plain distributive laws [10]. We end up getting a general “no-go theorem” for monotone weak laws over weakly lifted powerset monads: in that sense this work is also close in spirit to [31], where general no-go theorems for (strict) distributive laws are given. While not restricted to monotone distributive laws, these theorems are unlikely to generalize to our setting because they are based on the correspondence between monads and algebraic theories, which is mostly restricted to \mathbf{Set} and does not have any obvious generalization to semi-monads – to which weak distributive laws are deeply related.

This article is organized as follows. In Section 2, we recall definitions and notations for and give examples of monads and weak distributive laws, and also recall the framework of [19] for monotone weak distributive laws in regular categories. This culminates in Theorem 12, where we notice that the law $\mathbf{VV} \Rightarrow \mathbf{VV}$ is some sort of weak lifting of the law $\mathbf{PP} \Rightarrow \mathbf{PP}$. The next two sections focus on lifting weak distributive laws: in Section 3 we study the approach of the Yang-Baxter equation, showing it indeed allows for weakly lifting weak laws but does not apply to the examples we consider; while in Section 4 we focus on the monotonicity of the laws, giving a simple characterization for the existence of monotone weak laws in categories of algebras and applying it to several examples. We conclude in Section 5.

Our main contributions are the following:

- we show that, while the law $\mathbf{VV} \Rightarrow \mathbf{VV}$ is a kind of weak lifting of the law $\mathbf{PP} \Rightarrow \mathbf{PP}$ (Theorem 18), this lifting does not come from a Yang-Baxter equation (Theorem 16), the usual approach to lifting laws: it is an instance of a general no-go theorem for Yang-Baxter equations involving the law $\mathbf{PP} \Rightarrow \mathbf{PP}$ (Theorem 15);
- we characterize the Kleisli category of the weak lifting \bar{S} of a monad S to the algebras of a monad T as the category of T -algebras and $\mathbf{KI}(S)$ -morphisms between them (Theorem 22);
- we give a characterization of the Kleisli categories of weakly lifted powerset monads as subcategories of relations (Theorem 29), in which a certain class of *decomposable morphisms* play a central role: it follows that monads must preserve these decomposable morphisms to have monotone weak distributive laws over weakly lifted powerset monads, and this is in fact a sufficient condition for monads that are themselves weak liftings (Theorem 37);
- concrete instances of this result are then easily derived: we recover independently the law combining probabilities and non-determinism in compact Hausdorff spaces and recently exhibited in [15] (Theorem 38), but we observe otherwise that monotone weak distributive laws over weakly lifted powerset monads in categories of algebras seem very rare (Table 1).

2 Preliminaries

In this section we first recall the theory of weak distributive laws from [14] and the tools that come along, especially the ones developed in [19]. The reader is assumed to be familiar with the basics of category theory, an introduction to which appearing for instance in [8].

2.1 Monads and (Weak) Distributive Laws

► **Definition 1** (monad). A monad on a category \mathcal{C} is the data (T, η^T, μ^T) , often abbreviated T , of an endofunctor $T: \mathcal{C} \rightarrow \mathcal{C}$ and natural transformations $\eta^T: \text{Id} \Rightarrow T$ and $\mu^T: TT \Rightarrow T$ satisfying the axioms $\mu^T \circ T\eta^T = \text{id} = \mu^T \circ \eta^T T$ and $\mu^T \circ T\mu^T = \mu^T \circ \mu^T T$.

► **Example 2** (monads). In this work we will be particularly concerned with the following monads on **Set**. Thereafter X and Y are sets, x is an element of X and $f: X \rightarrow Y$ is a function.

The powerset monad \mathbf{P} . $\mathbf{P}X = \{\text{subsets of } X\}$; for $e \subseteq X$, $(\mathbf{P}f)(e) = f[e] = \{f(x') \mid x' \in e\}$; $\eta_X^{\mathbf{P}}(x) = \{x\}$; for $E \subseteq \mathbf{P}X$, $\mu_X^{\mathbf{P}}(E) = \bigcup E$.

The probability distributions monad \mathbf{D} . $\mathbf{D}X$ is the set of finitely-supported probability distributions on X , i.e. functions $\varphi: X \rightarrow [0, 1]$ such that $\varphi^{-1}(0, 1]$ is finite and $\sum_{x \in X} \varphi(x) = 1$; $\mathbf{D}f$ is the pushforward along f given by $(\mathbf{D}f)(\varphi)(y) = \sum_{x \in f^{-1}(y)} \varphi(x)$ for $\varphi \in \mathbf{D}X$ and $y \in Y$; $\eta_X^{\mathbf{D}}(x)$ is the Dirac δ_x for $x \in X$, i.e. the probability distribution such that $\delta_x(x) = 1$; and $\mu^{\mathbf{D}}$ computes the mean of a distribution of distributions, so that for $\Phi \in \mathbf{D}\mathbf{D}X$, $\mu^{\mathbf{D}}(\Phi)(x) = \sum_{\varphi \in \mathbf{D}X} \Phi(\varphi) \cdot \varphi(x)$.

The ultrafilter monad β . βX is the set of maximal filters on X , where filters are sets $E \in \mathbf{PX}$ that are non-empty, up-closed (for inclusion), stable under finite intersections and do not contain the empty set; for an ultrafilter $E \in \beta X$, $(\beta f)(E) = \{e' \supseteq f[e] \mid e \in E\}$; $\eta_X^\beta(x)$ is the principal filter $\{e \in \mathbf{PX} \mid x \in e\}$; and, for $\mathfrak{E} \in \beta\beta X$, $\mu_X^\beta(\mathfrak{E}) = \bigcup \{\bigcap \mathfrak{e} \mid \mathfrak{e} \in \mathfrak{E}\}$.

We will also be concerned with a topological analogue of the powerset monad, defined on the category \mathbf{KHaus} of compact Hausdorff spaces and continuous functions. Thereafter X and Y are compact Hausdorff spaces, x is an element of X , and $f: X \rightarrow Y$ is a continuous function.

The Vietoris monad \mathbf{V} . $\mathbf{V}X$ is the space of closed subsets of X equipped with the topology for which a subbase is given by the sets $\square u = \{c \in \mathbf{V}X \mid c \subset u\}$ and $\diamond u = \{c \in \mathbf{V}X \mid c \cap u \neq \emptyset\}$ where u ranges among all open sets of X ; $(\mathbf{V}f)(c) = f[c] = \{f(x) \mid x \in c\}$ for $c \in \mathbf{V}X$; $\eta_X^\mathbf{V}(x) = \{x\}$; and $\mu_X^\mathbf{V}(C) = \bigcup C$ for $C \in \mathbf{V}\mathbf{V}X$.

We also write \mathbf{P}_* and \mathbf{V}_* for the non-empty powerset and Vietoris monads, respectively obtained by removing the empty set from $\mathbf{P}X$ and $\mathbf{V}X$.

Weak distributive laws are a certain type of natural transformations involving monads.

► **Definition 3** ((weak) distributive law [14, Definition 9]). *A monad \mathbf{T} weakly distributes over a monad \mathbf{S} when there is a weak distributive law of \mathbf{T} over \mathbf{S} , i.e. a natural transformation $\rho: \mathbf{T}\mathbf{S} \Rightarrow \mathbf{S}\mathbf{T}$ such that the Diagrams (η^+) , (μ^-) , and (μ^+) below commute. A (strict) distributive law is a weak distributive law that moreover has the diagram (η^-) below commute.*

$$\begin{array}{ccc}
 & \mathbf{S} & \\
 \eta^{\mathbf{T}\mathbf{S}} \swarrow & & \searrow \eta^{\mathbf{S}\mathbf{T}} \\
 \mathbf{T}\mathbf{S} & \xrightarrow{\rho} & \mathbf{S}\mathbf{T} \\
 & (\eta^-) &
 \end{array}
 \qquad
 \begin{array}{ccccc}
 \mathbf{T}\mathbf{T}\mathbf{S} & \xrightarrow{\mathbf{T}\rho} & \mathbf{T}\mathbf{S}\mathbf{T} & \xrightarrow{\rho^{\mathbf{T}}} & \mathbf{S}\mathbf{T}\mathbf{T} \\
 \mu^{\mathbf{T}\mathbf{S}} \downarrow & & (\mu^-) & & \downarrow \mathbf{S}\mu^{\mathbf{T}} \\
 \mathbf{T}\mathbf{S} & \xrightarrow{\rho} & \mathbf{S}\mathbf{T} & &
 \end{array}$$

$$\begin{array}{ccc}
 & \mathbf{T} & \\
 \mathbf{T}\eta^{\mathbf{S}} \swarrow & & \searrow \eta^{\mathbf{S}\mathbf{T}} \\
 \mathbf{T}\mathbf{S} & \xrightarrow{\rho} & \mathbf{S}\mathbf{T} \\
 & (\eta^+) &
 \end{array}
 \qquad
 \begin{array}{ccccc}
 \mathbf{T}\mathbf{S}\mathbf{S} & \xrightarrow{\rho^{\mathbf{S}}} & \mathbf{T}\mathbf{S}\mathbf{S} & \xrightarrow{\mathbf{S}\rho} & \mathbf{S}\mathbf{S}\mathbf{T} \\
 \mathbf{T}\mu^{\mathbf{S}} \downarrow & & (\mu^+) & & \downarrow \mu^{\mathbf{S}\mathbf{T}} \\
 \mathbf{T}\mathbf{S} & \xrightarrow{\rho} & \mathbf{S}\mathbf{T} & &
 \end{array}$$

If $\rho: \mathbf{T}\mathbf{S} \Rightarrow \mathbf{S}\mathbf{T}$ is a distributive law, $\mathbf{S}\mathbf{T}$, $\eta^{\mathbf{S}\mathbf{T}} = \eta^{\mathbf{S}}\eta^{\mathbf{T}}$ and $\mu^{\mathbf{S}\mathbf{T}} = \mu^{\mathbf{S}}\mu^{\mathbf{T}} \circ \mathbf{S}\rho$ form a monad [2]. If it is only a weak distributive law this is not the case anymore, because $\mu^{\mathbf{S}\mathbf{T}} \circ \eta^{\mathbf{S}\mathbf{T}}\mathbf{S}\mathbf{T}$ is not the identity anymore, only an idempotent (its composite with itself is itself). But suppose now it is a split idempotent, i.e. that there is a functor $\mathbf{S} \bullet \mathbf{T}$ and natural transformations $p: \mathbf{S}\mathbf{T} \Rightarrow \mathbf{S} \bullet \mathbf{T}$ and $i: \mathbf{S} \bullet \mathbf{T} \Rightarrow \mathbf{S}\mathbf{T}$ such that $p \circ i = \text{id}$ and $i \circ p = \mu^{\mathbf{S}\mathbf{T}} \circ \eta^{\mathbf{S}\mathbf{T}}\mathbf{S}\mathbf{T}$. Then $\mathbf{S} \bullet \mathbf{T}$ can be made into a monad [14] with unit $\eta^{\mathbf{S} \bullet \mathbf{T}} = p \circ \eta^{\mathbf{S}}\eta^{\mathbf{T}}$ and multiplication $\mu^{\mathbf{S} \bullet \mathbf{T}} = p \circ \mu^{\mathbf{S}}\mu^{\mathbf{T}} \circ \mathbf{S}\rho$: the monad $\mathbf{S} \bullet \mathbf{T}$ is called the *weak composite* of \mathbf{S} and \mathbf{T} .

► **Example 4** (weak distributive laws). In this work we will be particularly concerned with the following weak distributive laws:

- in \mathbf{Set} , the weak distributive law $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{P}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{P}$ given by Equation (1) below has for weak composite the monad $\mathbf{P} \bullet \mathbf{P}$ of sets of subsets closed under non-empty unions [14];
- in \mathbf{KHaus} , there is a weak distributive law $\lambda^{\mathbf{V}/\mathbf{V}}: \mathbf{V}\mathbf{V} \Rightarrow \mathbf{V}\mathbf{V}$ given by Equation (2) below [19];
- in \mathbf{Set} , the weak distributive law $\lambda^{\mathbf{D}/\mathbf{P}}: \mathbf{D}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{D}$ given by Equation (3) below has for weak composite the monad $\mathbf{P} \bullet \mathbf{D}$ of convex sets of finitely supported probability distributions [18].

$$\lambda_X^{\mathbf{P}/\mathbf{P}}(E) = \left\{ e' \in \mathbf{P}X \mid e' \subseteq \bigcup E \text{ and } \forall e \in E, e \cap e' \neq \emptyset \right\} \quad (1)$$

$$\lambda_X^{\mathbf{V}/\mathbf{V}}(C) = \left\{ c' \in \mathbf{V}X \mid c' \subseteq \bigcup C \text{ and } \forall c \in C, c \cap c' \neq \emptyset \right\} \quad (2)$$

$$\lambda_X^{\mathbf{D}/\mathbf{P}}(\Phi) = \left\{ (\mu_X^{\mathbf{D}} \circ \mathbf{D}f)(\Phi) \mid f: \mathbf{P}X \rightarrow \mathbf{D}X \text{ and } \forall e \in \mathbf{P}X, \Phi(e) \neq 0 \Rightarrow f(e) \in \mathbf{D}e \right\} \quad (3)$$

At this point two questions may come to the curious reader: how do we actually find these weak distributive laws – the formulas in Theorem 4 are not trivial – and how exactly is the monad structure on $\mathbf{S} \bullet \mathbf{T}$ constructed. These two questions will respectively be answered in the next two sections, which give two other equivalent presentations of weak distributive laws.

2.2 Regular Categories and Monotone (Weak) Extensions

Given a monad \mathbf{S} , one may form its *Kleisli category* $\mathbf{Kl}(\mathbf{S})$, which is intuitively the category of \mathbf{S} -effectful arrows of \mathbf{C} : its objects are those of \mathbf{C} , its arrows $X \dashrightarrow Y$ are those arrows $X \rightarrow \mathbf{S}Y$ in \mathbf{C} , the identity arrow $X \dashrightarrow X$ is given by $\eta_X^{\mathbf{S}}: X \rightarrow \mathbf{S}X$, and the composite of two arrows $f: X \dashrightarrow Y$ and $g: Y \dashrightarrow Z$ is given by the composition $X \xrightarrow{f} \mathbf{S}Y \xrightarrow{\mathbf{S}g} \mathbf{S}\mathbf{S}Z \xrightarrow{\mu_Z^{\mathbf{S}}} \mathbf{S}Z$ in \mathbf{C} . $\mathbf{Kl}(\mathbf{S})$ comes with an adjunction $\mathbf{F}_{\mathbf{S}}: \mathbf{C} \rightleftarrows \mathbf{Kl}(\mathbf{S}): \mathbf{U}_{\mathbf{S}}$, such that $\mathbf{U}_{\mathbf{S}}\mathbf{F}_{\mathbf{S}} = \mathbf{S}$: the left adjoint $\mathbf{F}_{\mathbf{S}}$ sends objects on themselves and an arrow $f: X \rightarrow Y$ to the *pure* effectful arrow $X \xrightarrow{f} Y \xrightarrow{\eta_Y^{\mathbf{S}}} \mathbf{S}Y$, and the right adjoint $\mathbf{U}_{\mathbf{S}}$ sends an object X on $\mathbf{S}X$ and an effectful arrow $f: X \rightarrow \mathbf{S}Y$ to the arrow $\mathbf{S}X \xrightarrow{\mathbf{S}f} \mathbf{S}\mathbf{S}Y \xrightarrow{\mu_Y^{\mathbf{S}}} \mathbf{S}Y$. The unit of the adjunction is $\eta^{\mathbf{S}}$ and its counit is the natural transformation $\varepsilon^{\mathbf{S}}: \mathbf{F}_{\mathbf{S}}\mathbf{U}_{\mathbf{S}} \Rightarrow \text{Id}$ (in $\mathbf{Kl}(\mathbf{S})$) with components the effectful arrows $\text{id}_{\mathbf{S}X}: \mathbf{S}X \rightarrow \mathbf{S}X$.

An endofunctor $\mathbf{T}: \mathbf{C} \rightarrow \mathbf{C}$ extends to $\mathbf{Kl}(\mathbf{S})$ if there is an endofunctor $\underline{\mathbf{T}}: \mathbf{Kl}(\mathbf{S}) \rightarrow \mathbf{Kl}(\mathbf{S})$ such that $\underline{\mathbf{T}}\mathbf{F}_{\mathbf{S}} = \mathbf{F}_{\mathbf{S}}\mathbf{T}$. If \mathbf{T} and \mathbf{T}' have extensions $\underline{\mathbf{T}}$ and $\underline{\mathbf{T}'}$, a natural transformation $\alpha: \mathbf{T} \Rightarrow \mathbf{T}'$ extends to $\mathbf{Kl}(\mathbf{S})$ if $\underline{\alpha}$, given by $\underline{\alpha}\mathbf{F}_{\mathbf{S}} = \mathbf{F}_{\mathbf{S}}\alpha$, is a natural transformation $\underline{\mathbf{T}} \Rightarrow \underline{\mathbf{T}'}$.

► **Definition 5** (extensions of monads). *Let \mathbf{S} be a monad on \mathbf{C} . A monad $(\mathbf{T}, \eta^{\mathbf{T}}, \mu^{\mathbf{T}})$ on \mathbf{C} weakly extends to $\mathbf{Kl}(\mathbf{S})$ when \mathbf{T} and $\mu^{\mathbf{T}}$ extend to $\mathbf{Kl}(\mathbf{S})$. It extends to $\mathbf{Kl}(\mathbf{S})$ when $\eta^{\mathbf{T}}$ also extends to $\mathbf{Kl}(\mathbf{S})$.*

Giving an extension of a monad \mathbf{T} to $\mathbf{Kl}(\mathbf{S})$ is equivalent to giving a distributive law $\rho: \mathbf{T}\mathbf{S} \Rightarrow \mathbf{S}\mathbf{T}$, just like giving a weak extension thereof is equivalent to giving a weak distributive law of the same type [14]: in both cases, the law ρ induces the extension which sends $f: X \rightarrow \mathbf{S}Y$ to $\mathbf{T}X \xrightarrow{\mathbf{T}f} \mathbf{T}\mathbf{S}Y \xrightarrow{\rho} \mathbf{S}\mathbf{T}Y$, and is computed from the extension as $\rho = \mathbf{U}_{\mathbf{S}}\underline{\mathbf{T}}\varepsilon^{\mathbf{S}}\mathbf{F}_{\mathbf{S}} \circ \eta^{\mathbf{S}}\mathbf{T}\mathbf{S}$. In particular Theorem 4 also yields examples of weak extensions.

Monotone extensions

If $\mathbf{Kl}(\mathbf{S})$ carries more structure than just that of a category then it is natural to ask that extensions of functors preserve this additional structure: intuitively, the more structure preserved, the more semantically canonical the resulting law should be. For instance, recall that $\mathbf{Kl}(\mathbf{P})$ is the category \mathbf{Rel} of sets and relations and that relations between two sets are ordered by inclusion. Laws arising from monotone extensions to \mathbf{Rel} are thus of particular interest.

► **Definition 6** (monotone (weak) distributive laws and extensions). *A (weak) distributive law $\mathbf{T}\mathbf{S} \Rightarrow \mathbf{S}\mathbf{T}$ and its (weak) extension $\underline{\mathbf{T}}$ to $\mathbf{Kl}(\mathbf{S})$ are called monotone when the sets of morphisms of $\mathbf{Kl}(\mathbf{S})$ admit a canonical order that is preserved by $\underline{\mathbf{T}}$.*

10:6 Monotone Weak Distributive Laws in Categories of Algebras

It turns out that such monotone extensions to relations can be defined and characterized in any *regular category*, as described in [19] and recalled now.

Let \mathbf{C} be a finitely complete category. The *kernel pair* of an arrow $f: X \rightarrow Y$ is the pullback $p_1, p_2: X \times_Y X \rightrightarrows X$ of the cospan $X \xrightarrow{f} Y \xleftarrow{f} X$. Assume \mathbf{C} has all the coequalizers of these kernel pairs: these coequalizers are called regular epimorphisms. \mathbf{C} is then called *regular* if these conditions are satisfied and if the regular epimorphisms are stable under pullbacks¹. Regular categories enjoy the fact that every arrow $f: X \rightarrow Y$ may be factored as a regular epimorphism (denoted with \twoheadrightarrow) followed by a monomorphism (denoted with \hookrightarrow), and this factorization is unique up to unique isomorphism – one should think of it as factoring an arrow through its image. **Set** is a canonical example of a regular category.

Regular categories are useful because they are categories where we can speak of relations: if \mathbf{C} is a regular category, a \mathbf{C} -relation between two objects X and Y is a subobject $r: R \hookrightarrow X \times Y$. Relations are preordered: $r: R \hookrightarrow X \times Y$ is smaller than $s: S \hookrightarrow X \times Y$, written $r \leq s$, when there is a monomorphism $m: R \hookrightarrow S$ such that $s \circ m = r$. One may form the category **Rel**(\mathbf{C}) with objects those of \mathbf{C} and arrows $X \rightsquigarrow Y$ the equivalence classes of relations between X and Y . The identity on X is the diagonal $\langle \text{id}_X, \text{id}_X \rangle: X \hookrightarrow X \times X$, and composition of relations $r = \langle r_X, r_Y \rangle: R \hookrightarrow X \times Y$ and $s = \langle s_Y, s_Z \rangle: S \hookrightarrow Y \times Z$, written $s \cdot r: X \rightsquigarrow Z$, is constructed as in Figure 1a: by considering the pullback $R \times_Y S \rightarrow R \times S$ of $R \xrightarrow{r_Y} Y \xleftarrow{s_Y} S$, and taking the monomorphism in the factorization of $R \times_Y S \rightarrow R \times S \xrightarrow{r_X \times s_Z} X \times Z$.

Figure 1 Diagrams involved in the definition of **Rel**(\mathbf{C}).

The graph functor $\mathbf{Graph}_{\mathbf{C}}: \mathbf{C} \rightarrow \mathbf{Rel}(\mathbf{C})$ sends objects to themselves and an arrow $f: X \rightarrow Y$ to the relation $\langle \text{id}_X, f \rangle: X \hookrightarrow X \times Y$. There is also a contravariant transpose functor $-\dagger: \mathbf{Rel}(\mathbf{C}) \rightarrow \mathbf{Rel}(\mathbf{C})$ that sends objects on themselves and a relation $\langle r_X, r_Y \rangle: R \hookrightarrow X \times Y$ to $\langle r_Y, r_X \rangle: R \hookrightarrow Y \times X$. All in all, a relation $\langle f, g \rangle: R \hookrightarrow X \times Y$ can also be written as the composite $\mathbf{Graph}_{\mathbf{C}}g \cdot (\mathbf{Graph}_{\mathbf{C}}f)^\dagger$: we will often omit **Graph** and write directly $g \cdot f^\dagger$.

If $\mathbf{KI}(\mathbf{S})$ is a wide² subcategory of **Rel**(\mathbf{C}) (with $\mathbf{Graph}_{\mathbf{C}}$ being the left adjoint in the Kleisli adjunction), an extension to $\mathbf{KI}(\mathbf{S})$ can be constructed by first finding a monotone extension to **Rel**(\mathbf{C}) and then restricting this extension to $\mathbf{KI}(\mathbf{S})$. This is a very useful technique because such monotone extensions to **Rel**(\mathbf{C}), called *relational extensions*, have a very nice characterization in terms of near pullbacks: a square is a near pullback when its limiting morphism into the corresponding pullback is a regular epimorphism – as in Figure 1b. A functor between regular categories is said to be *nearly cartesian* when it sends pullbacks

¹ a class of arrows is stable under pullbacks when for every pullback square $a \circ b = c \circ d$, if a is in the class then so is d
² a wide subcategory is a subcategory that contains all objects of the bigger category

on near pullbacks and preserves³ regular epimorphisms, or equivalently when it preserves near pullbacks, while a natural transformation $\alpha: F \Rightarrow G$ between nearly cartesian functors is *nearly cartesian* as well when its naturality squares $\alpha \circ Ff = Gf \circ \alpha$ are near pullbacks.

► **Theorem 7** ([19, Theorem 6]). *Let $F: C \rightarrow D$ be a functor between regular categories. F has a relational extension, i.e. an order-preserving functor $\mathbf{Rel}(F): \mathbf{Rel}(C) \rightarrow \mathbf{Rel}(D)$ such that $\mathbf{Rel}(F) \mathbf{Graph}_C = \mathbf{Graph}_D F$, if and only if F is nearly cartesian. In that case there is only one possible such $\mathbf{Rel}(F)$, given by $\mathbf{Rel}(F)(g \cdot f^\dagger) = (Fg) \cdot (Ff)^\dagger$.*

Let $F, G: C \rightrightarrows D$ be two such functors and $\alpha: F \Rightarrow G$ be a natural transformation between them. Then $\mathbf{Rel}(\alpha)$, given by $\mathbf{Rel}(\alpha) \mathbf{Graph}_D = \mathbf{Graph}_D \alpha$, is a natural transformation $\mathbf{Rel}(F) \Rightarrow \mathbf{Rel}(G)$, called the relational extension of α , if and only if α is nearly cartesian.

Just like we omit to write **Graph**, we will often omit to write the functor **Rel**, and instead write $F(g \cdot f^\dagger)$ for $\mathbf{Rel}(F)(g \cdot f^\dagger) = Fg \cdot (Ff)^\dagger$ and α for $\mathbf{Rel}(\alpha)$.

► **Example 8** (monotone extensions). **Set** is a regular category whose regular epimorphisms are the surjections and such that $\mathbf{Rel}(\mathbf{Set}) = \mathbf{Rel} \cong \mathbf{KI}(\mathbf{P})$. The endofunctors and the multiplications of the monads **P** and **D** are nearly cartesian, hence **P** and **D** have monotone weak extensions to $\mathbf{KI}(\mathbf{P})$: this is how the weak distributive laws $\mathbf{PP} \Rightarrow \mathbf{PP}$ and $\mathbf{DP} \Rightarrow \mathbf{PD}$ of Theorem 4 were constructed [14, 18]. **KHaus** is also a regular category: its regular epimorphisms are the surjective continuous functions and $\mathbf{Rel}(\mathbf{KHaus})$ is the category of compact Hausdorff spaces and closed relations, i.e. closed subsets of $X \times Y$, while $\mathbf{KI}(\mathbf{V})$ is the category of compact Hausdorff spaces and continuous relations, i.e. closed relations $r: X \leftrightarrow Y$ such that $r^{-1}[u]$ is open in X for every open u of Y . The endofunctor and multiplication of **V** are nearly cartesian hence they have a relational extension, which restricts to continuous relations: this yields a monotone weak extension of **V** to $\mathbf{KI}(\mathbf{V})$, and this is how the weak distributive law $\mathbf{VV} \Rightarrow \mathbf{VV}$ of Theorem 4 was constructed [19].

2.3 Weak Liftings

Let **T** be a monad over a category **C**. Its category of algebras $\mathbf{EM}(\mathbf{T})$ is the category whose objects are pairs (A, a) of a **C**-object A and a **C**-arrow $a: \mathbf{T}A \rightarrow A$, and whose arrows $(A, a) \rightarrow (B, b)$ are those **C**-arrows $A \rightarrow B$ such that $f \circ a = b \circ \mathbf{T}f$ – the identity morphism is the one with the identity as its underlying **C**-arrow, and composition of morphisms is done by composing the underlying **C**-arrows. Just like for $\mathbf{KI}(\mathbf{T})$, there is an adjunction $\mathbf{F}^\mathbf{T}: \mathbf{C} \rightleftarrows \mathbf{EM}(\mathbf{T}): \mathbf{U}^\mathbf{T}$ such that $\mathbf{U}^\mathbf{T} \mathbf{F}^\mathbf{T} = \mathbf{T}$: the left adjoint $\mathbf{F}^\mathbf{T}$ sends an algebra (A, a) to its carrier object A and a morphism $(A, a) \rightarrow (B, b)$ to the underlying arrow $A \rightarrow B$, while $\mathbf{U}^\mathbf{T}$ sends an object X to the free **T**-algebra on X , given by the pair $(\mathbf{T}X, \mu_X^\mathbf{T})$, and an arrow $f: X \rightarrow Y$ to the morphism $(\mathbf{T}X, \mu_X^\mathbf{T}) \rightarrow (\mathbf{T}Y, \mu_Y^\mathbf{T})$ with underlying **C**-arrow $\mathbf{T}f: \mathbf{T}X \rightarrow \mathbf{T}Y$. There is finally a natural transformation $\varepsilon^\mathbf{T}: \mathbf{F}^\mathbf{T} \mathbf{U}^\mathbf{T} \rightarrow \text{Id}$ (in $\mathbf{EM}(\mathbf{T})$) given by $\mathbf{U}^\mathbf{T} \varepsilon_{(A,a)}^\mathbf{T} = a: \mathbf{T}A \rightarrow A$.

► **Definition 9** (weak liftings [3, Definitions 4.1 and 4.2]). *A weak lifting of an endofunctor $S: C \rightarrow C$ to $\mathbf{EM}(\mathbf{T})$ is the data of an endofunctor $\bar{S}: \mathbf{EM}(\mathbf{T}) \rightarrow \mathbf{EM}(\mathbf{T})$ along with natural transformations $\pi_S^\mathbf{T}: \mathbf{S} \mathbf{U}^\mathbf{T} \Rightarrow \mathbf{U}^\mathbf{T} \bar{S}$ and $\iota_S^\mathbf{T}: \mathbf{U}^\mathbf{T} \bar{S} \Rightarrow \mathbf{S} \mathbf{U}^\mathbf{T}$ – also written π_S and ι_S when not ambiguous – such that $\pi_S^\mathbf{T} \circ \iota_S^\mathbf{T} = \text{id}$. The composite $\iota_S^\mathbf{T} \circ \pi_S^\mathbf{T}$ is then written $\kappa_S^\mathbf{T}$.*

³ throughout this work we will say that a functor preserves a class of diagrams whenever it sends any diagram in that class to a diagram in that class

10:8 Monotone Weak Distributive Laws in Categories of Algebras

Let $\alpha: \mathbb{S} \Rightarrow \mathbb{R}$ be a natural transformation between two \mathbb{C} -endofunctors with weak liftings $(\bar{\mathbb{S}}, \pi_{\bar{\mathbb{S}}}, \iota_{\bar{\mathbb{S}}})$ and $(\bar{\mathbb{R}}, \pi_{\bar{\mathbb{R}}}, \iota_{\bar{\mathbb{R}}})$. If a natural transformation $\bar{\alpha}: \bar{\mathbb{S}} \Rightarrow \bar{\mathbb{R}}$ has Diagram (π) , Diagram (ι) or both Diagrams (π) and (ι) below commute, it is respectively a weak π -, weak ι - or a weak lifting thereof.

$$\begin{array}{ccc} \mathbf{S}\mathbf{U}^{\mathbf{T}} & \xrightarrow{\pi_{\bar{\mathbb{S}}}^{\mathbf{T}}} & \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}} \\ \alpha\mathbf{U}^{\mathbf{T}}\downarrow & (\pi) & \downarrow\mathbf{U}^{\mathbf{T}}\bar{\alpha} \\ \mathbf{R}\mathbf{U}^{\mathbf{T}} & \xrightarrow{\pi_{\bar{\mathbb{R}}}^{\mathbf{T}}} & \mathbf{U}^{\mathbf{T}}\bar{\mathbb{R}} \end{array} \quad \begin{array}{ccc} \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}} & \xrightarrow{\iota_{\bar{\mathbb{S}}}^{\mathbf{T}}} & \mathbf{S}\mathbf{U}^{\mathbf{T}} \\ \mathbf{U}^{\mathbf{T}}\bar{\alpha}\downarrow & (\iota) & \downarrow\alpha\mathbf{U}^{\mathbf{T}} \\ \mathbf{U}^{\mathbf{T}}\bar{\mathbb{R}} & \xrightarrow{\iota_{\bar{\mathbb{R}}}^{\mathbf{T}}} & \mathbf{R}\mathbf{U}^{\mathbf{T}} \end{array}$$

As discussed in [3], weak π - and weak ι -liftings are necessarily unique and given by $\mathbf{U}^{\mathbf{T}}\bar{\alpha} = \pi_{\bar{\mathbb{R}}}^{\mathbf{T}} \circ \alpha \circ \iota_{\bar{\mathbb{S}}}^{\mathbf{T}}$ if they exist. Their existence is moreover fully characterized:

► **Theorem 10** ([3, Proposition 4.3 and Theorem 4.4]). *Suppose idempotents split in \mathbb{C} . Then idempotents also split in $\mathbf{EM}(\mathbb{T})$, and having a weak lifting of $\mathbb{S}: \mathbb{C} \rightarrow \mathbb{C}$ to $\mathbf{EM}(\mathbb{T})$ is equivalent to having a law $\rho: \mathbb{T}\mathbb{S} \Rightarrow \mathbb{S}\mathbb{T}$ that has Diagram (μ^+) commute.*

Fix now liftings $\bar{\mathbb{S}}$ and $\bar{\mathbb{R}}$ of \mathbb{S} and \mathbb{R} given by laws $\rho: \mathbb{T}\mathbb{S} \Rightarrow \mathbb{S}\mathbb{T}$ and $\sigma: \mathbb{T}\mathbb{R} \Rightarrow \mathbb{R}\mathbb{T}$. Then, $\alpha: \mathbb{S} \Rightarrow \mathbb{R}$ respectively has a weak π -, weak ι - or weak lifting if and only if it makes Diagram (7), Diagram (8) or both Diagrams (7) and (8) below commute. The latter case holds equivalently if and only if $\sigma \circ \mathbb{T}\alpha = \alpha\mathbb{T} \circ \rho$.

$$\begin{array}{ccc} \mathbb{T}\mathbb{S} & \xrightarrow{\rho} & \mathbb{S}\mathbb{T} \\ \mathbb{T}\eta^{\mathbb{T}}\mathbb{S}\downarrow & (\gamma) & \downarrow\alpha\mathbb{T} \\ \mathbb{T}\mathbb{T}\mathbb{S} & \xrightarrow{\mathbb{T}\rho} \mathbb{T}\mathbb{S}\mathbb{T} \xrightarrow{\mathbb{T}\alpha\mathbb{T}} \mathbb{T}\mathbb{R}\mathbb{T} \xrightarrow{\sigma\mathbb{T}} \mathbb{R}\mathbb{T}\mathbb{T} \xrightarrow{\mathbb{R}\mu^{\mathbb{T}}} & \mathbb{R}\mathbb{T} \\ \eta^{\mathbb{T}}\mathbb{T}\mathbb{S}\uparrow & (\delta) & \uparrow\sigma \\ \mathbb{T}\mathbb{S} & \xrightarrow{\mathbb{T}\alpha} & \mathbb{T}\mathbb{R} \end{array}$$

This correspondence is moreover compositional: the composition of the weak (resp. weak π -, weak ι -) liftings of two functors is a weak (resp. weak π -, weak ι -) lifting of their composite.

In [14], Garner instantiates Theorem 10 to give another presentation of weak distributive laws: if idempotents split in \mathbb{C} , a weak distributive law $\mathbb{T}\mathbb{S} \Rightarrow \mathbb{S}\mathbb{T}$ is equivalently given by a weak lifting of $(\mathbb{S}, \eta^{\mathbb{S}}, \mu^{\mathbb{S}})$ to $\mathbf{EM}(\mathbb{T})$, i.e. by weak liftings of \mathbb{S} , $\eta^{\mathbb{S}}$ and $\mu^{\mathbb{S}}$, respectively coming from Diagrams (μ^-) , (η^+) , and (μ^+) . That these two natural transformations weakly lift respectively means that Diagrams $(\pi \circ \eta)$ and $(\iota \circ \eta)$ and Diagrams $(\pi \circ \mu)$ and $(\iota \circ \mu)$ below commute. When Diagram (η^-) also commutes, ρ is a (strict) distributive law and this weak lifting is a (strict) lifting: $\pi_{\bar{\mathbb{S}}}$ and $\iota_{\bar{\mathbb{S}}}$ are both the identity.

$$\begin{array}{ccc} & \mathbf{U}^{\mathbf{T}} & \\ \eta^{\mathbb{S}}\mathbf{U}^{\mathbf{T}} \swarrow & & \searrow \mathbf{U}^{\mathbf{T}}\eta^{\bar{\mathbb{S}}} \\ \mathbf{S}\mathbf{U}^{\mathbf{T}} & \xrightarrow{\pi_{\bar{\mathbb{S}}}^{\mathbf{T}}} & \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}} \end{array} \quad \begin{array}{ccc} \mathbf{S}\mathbf{S}\mathbf{U}^{\mathbf{T}} & \xrightarrow{S\pi_{\bar{\mathbb{S}}}^{\mathbf{T}}} & \mathbf{S}\mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}} \xrightarrow{\pi_{\bar{\mathbb{S}}}^{\mathbf{T}}\bar{\mathbb{S}}} & \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}}\bar{\mathbb{S}} \\ \mu^{\mathbb{S}}\mathbf{U}^{\mathbf{T}}\downarrow & (\pi \circ \mu) & \downarrow\mathbf{U}^{\mathbf{T}}\mu^{\bar{\mathbb{S}}} \\ \mathbf{S}\mathbf{U}^{\mathbf{T}} & \xrightarrow{\pi_{\bar{\mathbb{S}}}^{\mathbf{T}}} & \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}} \end{array}$$

$$\begin{array}{ccc} & \mathbf{U}^{\mathbf{T}} & \\ \mathbf{U}^{\mathbf{T}}\eta^{\bar{\mathbb{S}}} \swarrow & & \searrow \eta^{\mathbb{S}}\mathbf{U}^{\mathbf{T}} \\ \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}} & \xrightarrow{\iota_{\bar{\mathbb{S}}}^{\mathbf{T}}} & \mathbf{S}\mathbf{U}^{\mathbf{T}} \end{array} \quad \begin{array}{ccc} \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}}\bar{\mathbb{S}} & \xrightarrow{\iota_{\bar{\mathbb{S}}}^{\mathbf{T}}\bar{\mathbb{S}}} & \mathbf{S}\mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}} \xrightarrow{S\iota_{\bar{\mathbb{S}}}^{\mathbf{T}}} & \mathbf{S}\mathbf{S}\mathbf{U}^{\mathbf{T}} \\ \mathbf{U}^{\mathbf{T}}\mu^{\bar{\mathbb{S}}}\downarrow & (\iota \circ \mu) & \downarrow\mu^{\mathbb{S}}\mathbf{U}^{\mathbf{T}} \\ \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}} & \xrightarrow{\iota_{\bar{\mathbb{S}}}^{\mathbf{T}}} & \mathbf{S}\mathbf{U}^{\mathbf{T}} \end{array}$$

The weak composite monad $\mathbf{S} \bullet \mathbf{T}$ corresponding to a weak distributive law $\mathbb{T}\mathbb{S} \Rightarrow \mathbb{S}\mathbb{T}$ can be retrieved from the weak lifting of \mathbb{S} to $\mathbf{EM}(\mathbb{T})$ by setting $\mathbf{S} \bullet \mathbf{T} = \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}}\mathbf{F}^{\mathbf{T}}$, $\eta^{\mathbf{S} \bullet \mathbf{T}} = \mathbf{U}^{\mathbf{T}}\eta^{\bar{\mathbb{S}}}\mathbf{F}^{\mathbf{T}} \circ \eta^{\mathbf{T}}$ and $\mu^{\mathbf{S} \bullet \mathbf{T}} = \mathbf{U}^{\mathbf{T}}\mu^{\bar{\mathbb{S}}}\mathbf{F}^{\mathbf{T}} \circ \mathbf{U}^{\mathbf{T}}\bar{\mathbb{S}}\varepsilon^{\mathbf{T}}\bar{\mathbb{S}}\mathbf{F}^{\mathbf{T}}$. $\kappa_{\bar{\mathbb{S}}}^{\mathbf{T}}\mathbf{F}^{\mathbf{T}}$ is moreover the idempotent $\mu^{\mathbf{S}\mathbf{T}} \circ \eta^{\mathbf{S}\mathbf{T}}\mathbf{S}\mathbf{T}: \mathbf{S}\mathbf{T} \Rightarrow \mathbf{S}\mathbf{T}$, and its splitting is thus given by $\pi_{\bar{\mathbb{S}}}^{\mathbf{T}}\mathbf{F}^{\mathbf{T}}: \mathbf{S}\mathbf{T} \Rightarrow \mathbf{S} \bullet \mathbf{T}$ and $\iota_{\bar{\mathbb{S}}}^{\mathbf{T}}\mathbf{F}^{\mathbf{T}}: \mathbf{S} \bullet \mathbf{T} \Rightarrow \mathbf{S}\mathbf{T}$.

► **Example 11** (weak liftings). All idempotents split in **Set** (they factor through their image). The algebras of **P** are the *complete join-semilattices* (we write $\mathbf{EM}(\mathbf{P}) \cong \mathbf{JSL}$): the weak lifting corresponding to the law $\mathbf{PP} \Rightarrow \mathbf{PP}$ is the monad of *subsets closed under non-empty joins* [19]. The algebras of **D** are the *barycentric algebras*, also called *convex spaces* (we write $\mathbf{EM}(\mathbf{D}) \cong \mathbf{Conv}$): the weak lifting corresponding to the law $\mathbf{DP} \Rightarrow \mathbf{PD}$ is the monad of *convex-closed subsets* [18]. Finally, there is also a weak distributive law $\mathbf{\beta P} \Rightarrow \mathbf{P\beta}$. Assuming the axiom of choice, the algebras of **\beta** are the compact Hausdorff spaces [24] (we write $\mathbf{EM}(\mathbf{\beta}) \cong \mathbf{KHaus}$): the corresponding weak lifting is the Vietoris monad **V**. In that case $\pi_{\mathbf{P}}$ computes the topological closure of a subset, while $\iota_{\mathbf{P}}$ embeds the set of closed sets into the set of all subsets.

3 Weakly Lifting Weak Distributive Laws

With Theorem 11 and the fact that **V** is a weak lifting of **P** to **KHaus** in mind, we may now notice that not only are the two laws $\mathbf{PP} \Rightarrow \mathbf{PP}$ (1) and $\mathbf{VV} \Rightarrow \mathbf{VV}$ (2) very similar, but the second one seems to be some kind of weak lifting to $\mathbf{KHaus} \cong \mathbf{EM}(\mathbf{\beta})$ of the first one:

► **Lemma 12.** $\mathbf{U}^{\beta} \lambda^{\mathbf{V}/\mathbf{V}} = \pi_{\mathbf{P}} \mathbf{V} \circ \mathbf{P} \pi_{\mathbf{P}} \circ \lambda^{\mathbf{P}/\mathbf{P}} \mathbf{U}^{\beta} \circ \mathbf{P} \iota_{\mathbf{P}} \circ \iota_{\mathbf{P}} \mathbf{V}$.

Proof. Recall from [14] that, if X is a compact Hausdorff space that we see as a **\beta**-algebra, the X -component of $\pi_{\mathbf{P}}$ is the function $\mathbf{P}X \rightarrow \mathbf{V}X$ that takes a subset of a compact Hausdorff space and outputs its closure, while the X -component of $\iota_{\mathbf{P}}$ is the function $\mathbf{V}X \rightarrow \mathbf{P}X$ that embeds closed subsets in the set of all subsets. Hence for C a closed set of closed sets,

$$\begin{aligned} \left(\mathbf{P} \pi_{\mathbf{P}} \circ \lambda^{\mathbf{P}/\mathbf{P}} \mathbf{U}^{\beta} \circ \mathbf{P} \iota_{\mathbf{P}} \circ \iota_{\mathbf{P}} \mathbf{V} \right)_X (C) &= \left\{ \bar{e} \mid e \subseteq \bigcup C \text{ and } \forall c \in C, c \cap e \neq \emptyset \right\} \\ &= \left\{ c \in \mathbf{V}X \mid c \subseteq \bigcup C \text{ and } \forall c' \in C, c \cap c' \neq \emptyset \right\} \\ &= \left(\iota_{\mathbf{P}} \mathbf{V} \circ \mathbf{U}^{\beta} \lambda^{\mathbf{V}/\mathbf{V}} \right)_X (C) \end{aligned}$$

(where \bar{e} denotes the closure of e). Indeed if $e \subseteq \bigcup C$ then $\bar{e} \subseteq \bigcup C$ because $\bigcup C = \mu^{\mathbf{V}}(C)$ is closed, and if $e \cap c \neq \emptyset$ then $\bar{e} \cap c \neq \emptyset$.

Because $\pi_{\mathbf{P}} \circ \iota_{\mathbf{P}} = \text{id}$, $\mathbf{U}^{\beta} \lambda^{\mathbf{V}/\mathbf{V}} = \pi_{\mathbf{P}} \mathbf{V} \circ \mathbf{P} \pi_{\mathbf{P}} \circ \lambda^{\mathbf{P}/\mathbf{P}} \mathbf{U}^{\beta} \circ \mathbf{P} \iota_{\mathbf{P}} \circ \iota_{\mathbf{P}} \mathbf{V}$. ◀

Is this just a coincidence, or is this an instance of Theorem 10? And in the latter case, can the weak distributivity of $\lambda^{\mathbf{V}/\mathbf{V}}$ be automatically derived from that of $\lambda^{\mathbf{P}/\mathbf{P}}$, and does this law $\mathbf{PP} \Rightarrow \mathbf{PP}$ also weakly lift to laws on other categories of algebras where the powerset monad weakly lifts, say $\mathbf{EM}(\mathbf{P})$ and $\mathbf{EM}(\mathbf{D})$?

In this section we thus consider three monads $(\mathbf{T}, \eta^{\mathbf{T}}, \mu^{\mathbf{T}})$, $(\mathbf{S}, \eta^{\mathbf{S}}, \mu^{\mathbf{S}})$ and $(\mathbf{R}, \eta^{\mathbf{R}}, \mu^{\mathbf{R}})$ on a category \mathbf{C} , and three weak distributive laws $\rho: \mathbf{TS} \Rightarrow \mathbf{ST}$, $\sigma: \mathbf{TR} \Rightarrow \mathbf{RT}$ and $\tau: \mathbf{SR} \Rightarrow \mathbf{RS}$ (a mnemonic for which is which is that ρ does not involve \mathbf{R} , σ does not involve \mathbf{S} and τ does not involve \mathbf{T}). We assume that idempotents split in \mathbf{C} , so that the corresponding weak composite and weak liftings all exist.

3.1 The Yang-Baxter Equation for Weak Distributive Laws

The standard way to lift (strict) distributive laws is to use the so-called Yang-Baxter equation. The Yang-Baxter equation for the three laws ρ , σ and τ holds when diagram (YB) below commutes.

$$\begin{array}{ccccc} & & \mathbf{TRS} & \xrightarrow{\sigma^{\mathbf{S}}} & \mathbf{RTS} & & \\ & \nearrow^{\mathbf{T}\tau} & & & & \searrow^{\mathbf{R}\rho} & \\ \mathbf{TSR} & & & & & & \mathbf{RST} \\ & \searrow_{\rho^{\mathbf{R}}} & & & & \nearrow_{\tau^{\mathbf{T}}} & \\ & & \mathbf{STR} & \xrightarrow{\sigma^{\mathbf{S}}} & \mathbf{SRT} & & \end{array} \quad \text{(YB)}$$

10:10 Monotone Weak Distributive Laws in Categories of Algebras

If these laws are strict distributive laws, then it is well-known since [10] that the Yang-Baxter equation is enough to show that $R\rho \circ \sigma S: TRS \Rightarrow RST$ is a distributive law of T over RS , and that the distributive law $\tau: SR \Rightarrow RS$ lifts to a distributive law $\bar{\tau}: \bar{S}\bar{R} \Rightarrow \bar{R}\bar{S}$ in $\mathbf{EM}(T)$. The composition of weak distributive laws using the Yang-Baxter equation was investigated in [17]. A notable result is the following:

► **Proposition 13** ([17, Theorem 4.3]). *If the weak distributive laws $\rho: TS \Rightarrow ST$, $\sigma: TR \Rightarrow RT$ and $\tau: SR \Rightarrow RS$ have Diagram (YB) commute, then $\pi_{\bar{R}}^S \mathbf{F}^S T \circ R\rho \circ \sigma S \circ T \iota_{\bar{R}}^S \mathbf{F}^S$ is a weak distributive law $T(R \bullet S) \Rightarrow (R \bullet S)T$.*

The Yang-Baxter equation thus allows for weakly lifting $R \bullet S$ to $\mathbf{EM}(T)$. More importantly for our purpose, we show it also allows for weakly lifting the weak distributive law $SR \Rightarrow RS$:

► **Theorem 14.** *Weak distributive laws $\rho: TS \Rightarrow ST$, $\sigma: TR \Rightarrow RT$ and $\tau: SR \Rightarrow RS$ satisfy the Yang-Baxter equation if and only if $\tau: SR \Rightarrow RS$ weakly lifts to $\mathbf{EM}(T)$, i.e. if there is a natural transformation $\bar{\tau}: \bar{S}\bar{R} \Rightarrow \bar{R}\bar{S}$ such that Diagrams (14) and (15) commute.*

If this holds, $\bar{\tau}$ is a weak distributive law, and the weak composite $\bar{R} \bullet \bar{S}$ and the weak lifting $\overline{R \bullet S}$ (recall that $R \bullet S$ weakly lifts to $\mathbf{EM}(T)$ by Theorem 13) can be chosen to be equal (as monads).

$$\begin{array}{ccc}
 \text{SRU}^T \xrightarrow{S\pi_R} \text{SU}^T\bar{R} \xrightarrow{\pi_S\bar{R}} \text{U}^T\bar{S}\bar{R} & & \text{U}^T\bar{S}\bar{R} \xrightarrow{\iota_S\bar{R}} \text{SU}^T\bar{R} \xrightarrow{S\iota_R} \text{SRU}^T \\
 \tau\text{U}^T \downarrow & (14) & \downarrow \text{U}^T\bar{\tau} \\
 \text{RSU}^T \xrightarrow{R\pi_S} \text{RU}^T\bar{S} \xrightarrow{\pi_R\bar{S}} \text{U}^T\bar{R}\bar{S} & & \text{U}^T\bar{R}\bar{S} \xrightarrow{\iota_R\bar{S}} \text{RU}^T\bar{S} \xrightarrow{R\iota_S} \text{RSU}^T \\
 & & \downarrow \tau\text{U}^T
 \end{array}$$

When Theorem 14 holds it immediately follows that $\text{U}\bar{\tau} = \pi_{\bar{R}}\bar{S} \circ R\pi_S \circ \tau\text{U}^T \circ S\iota_R \circ \iota_S\bar{R}$, which is exactly the result we got in Theorem 12 for $\bar{\tau} = \lambda^{\mathbf{V}/\mathbf{V}}: \mathbf{V}\mathbf{V} \Rightarrow \mathbf{V}\mathbf{V}$ and $\tau = \lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{P}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{P}$. It would thus be a reasonable conjecture that $\lambda^{\mathbf{B}/\mathbf{P}}: \mathbf{B}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{B}$, $\lambda^{\mathbf{B}/\mathbf{P}}: \mathbf{B}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{B}$ and $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{P}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{P}$ satisfy the Yang-Baxter equation, from which we would immediately retrieve the weak distributivity of $\lambda^{\mathbf{V}/\mathbf{V}}: \mathbf{V}\mathbf{V} \Rightarrow \mathbf{V}\mathbf{V}$ but also learn that the weak composite $\mathbf{V} \bullet \mathbf{V}$ is a weak lifting of $\mathbf{P} \bullet \mathbf{P}$. Unfortunately, the Yang-Baxter equation does not hold in that case. A rather simple way to see this is to notice that $\lambda^{\mathbf{V}/\mathbf{V}}$ does not make Diagram (15) commute, i.e. it is not a ι -lifting of $\lambda^{\mathbf{P}/\mathbf{P}}$. More generally, we show the following no-go theorem for weak ι -liftings:

► **Proposition 15.** *Let $\lambda^{\mathbf{T}/\mathbf{P}}: \mathbf{T}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{T}$ be a weak distributive law with corresponding weak lifting $\bar{\mathbf{P}}$, and write $\bar{\mathbf{P}}\bar{\mathbf{P}}A = (\mathbf{P}\iota_{\bar{\mathbf{P}}} \circ \iota_{\bar{\mathbf{P}}}\mathbf{P}) \left[\text{U}^T\bar{\mathbf{P}}\bar{\mathbf{P}}(A, a) \right]$ when (A, a) is a T -algebra. If there is an (A, a) such that $\{A\} \in \bar{\mathbf{P}}\bar{\mathbf{P}}A$ and $\mathbf{P}_*A \notin \bar{\mathbf{P}}\bar{\mathbf{P}}A$, then $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{P}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{P}$ does not have a weak ι -lifting to $\mathbf{EM}(T)$.*

► **Corollary 16.** *There is no weak ι -lifting (let alone weak liftings) of $\lambda^{\mathbf{P}/\mathbf{P}}$ to \mathbf{KHaus} , \mathbf{JSL} or \mathbf{Conv} .*

Proof sketch.

1. Given a compact Hausdorff space given as a \mathbf{B} -algebra (A, a) , $\bar{\mathbf{P}}\bar{\mathbf{P}}A$ is the set of all closed sets (in the Vietoris topology) of closed sets of (A, a) . $\{A\}$ is such a closed set of closed sets (all singletons and the whole set are always closed in a compact Hausdorff space) but \mathbf{P}_*A is not in general because it contains all non-empty sets, in particular non-closed sets if there are any (which is the case for the unit interval, for instance). ◀

► **Remark 17.** It is not hard to show that the Yang-Baxter equation holding for $\rho: \mathbf{TS} \Rightarrow \mathbf{ST}$, $\sigma: \mathbf{TR} \Rightarrow \mathbf{RT}$ and $\tau: \mathbf{SR} \Rightarrow \mathbf{RS}$ is also equivalent to $\rho: \mathbf{TS} \Rightarrow \mathbf{ST}$ having an extension $\underline{\rho}: \underline{\mathbf{TS}} \Rightarrow \underline{\mathbf{ST}}$ to $\mathbf{KI}(\mathbf{R})$. In the case of $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{\beta P} \Rightarrow \mathbf{P\beta}$, $\underline{\lambda}$ is in fact a lax monad on \mathbf{Rel} whose algebras are the topological spaces [1]. Unfortunately, we have just shown that the Yang-Baxter equation does not hold for $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{\beta P} \Rightarrow \mathbf{P\beta}$, $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{PP} \Rightarrow \mathbf{PP}$ and $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{PP} \Rightarrow \mathbf{PP}$, and so do not get a way to weakly lift $\underline{\mathbf{P}}$ to topological spaces for free.

Theorem 14 does have some concrete instances: in [17], Goy gives a substantial number of examples of triples of weak distributive laws for which the Yang-Baxter equation holds, although these examples all involve at least one strictly distributive law out of the three.

3.2 The π -Yang-Baxter Equation

We still do not have an explanation for why $\lambda^{\mathbf{V}/\mathbf{V}}$ looks so much like $\lambda^{\mathbf{P}/\mathbf{P}}$. But $\lambda^{\mathbf{V}/\mathbf{V}}$ being a weak lifting of $\lambda^{\mathbf{P}/\mathbf{P}}$ is not a necessary condition for retrieving Theorem 12: in fact, $\lambda^{\mathbf{V}/\mathbf{V}}$ being only a weak ι - or π -lifting of $\lambda^{\mathbf{P}/\mathbf{P}}$ would be enough. We saw in Theorem 16 that the weak ι -lifting hypothesis was a dead-end: how about $\lambda^{\mathbf{V}/\mathbf{V}}$ being a weak π -lifting of $\lambda^{\mathbf{P}/\mathbf{P}}$? This turns out to be true, although the proof is of course more involved than that of the weaker Theorem 12.

► **Lemma 18.** $\lambda^{\mathbf{V}/\mathbf{V}}: \mathbf{VV} \Rightarrow \mathbf{VV}$ is a weak π -lifting of $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{PP} \Rightarrow \mathbf{PP}$.

Theorem 14 adapts to weak π -liftings, hence we immediately retrieve as a consequence of Theorem 18 that $\lambda^{\mathbf{V}/\mathbf{V}}: \mathbf{VV} \Rightarrow \mathbf{VV}$ is a weak distributive law.

► **Proposition 19.** Weak distributive laws $\rho: \mathbf{TS} \Rightarrow \mathbf{ST}$, $\sigma: \mathbf{TR} \Rightarrow \mathbf{RT}$ and $\tau: \mathbf{SR} \Rightarrow \mathbf{RS}$ satisfy the π -Yang-Baxter equation, given by Diagram (π -YB), if and only if $\tau: \mathbf{SR} \Rightarrow \mathbf{RS}$ weakly π -lifts to $\mathbf{EM}(\mathbf{T})$, i.e. if there is a natural transformation $\bar{\tau}: \bar{\mathbf{SR}} \Rightarrow \bar{\mathbf{RS}}$ such that Diagram (14) commutes.

If this holds, $\bar{\tau}$ is a weak distributive law.

$$\begin{array}{ccccc}
 \mathbf{TSR} & \xrightarrow{\mathbf{T}\tau} & \mathbf{TRS} & \xrightarrow{\sigma\mathbf{S}} & \mathbf{RTS} & \xrightarrow{\mathbf{R}\rho} & \mathbf{RST} \\
 \rho\mathbf{R} \downarrow & & & & & & \uparrow \mathbf{RS}\mu^{\mathbf{T}} \\
 \mathbf{STR} & & (\pi\text{-YB}) & & \mathbf{RSTT} & & \\
 \mathbf{S}\sigma \downarrow & & & & \uparrow \mathbf{R}\rho\mathbf{T} & & \\
 \mathbf{SRT} & \xrightarrow{\tau\mathbf{T}} & \mathbf{RST} & \xrightarrow{\eta^{\mathbf{T}}\mathbf{RST}} & \mathbf{TRST} & \xrightarrow{\sigma\mathbf{ST}} & \mathbf{RTST}
 \end{array}$$

We also retrieve that $\lambda^{\mathbf{V}/\mathbf{V}}$ is a monotone weak distributive law:

► **Proposition 20.** Consider a monotone weak distributive law $\lambda^{\mathbf{S}/\mathbf{P}}: \mathbf{SP} \Rightarrow \mathbf{PS}$ in \mathbf{Set} that has a weak π -lifting to $\mathbf{EM}(\mathbf{T})$. If the components of $\kappa_{\mathbf{P}}: \mathbf{PU}^{\mathbf{T}} \Rightarrow \mathbf{PU}^{\mathbf{T}}$ are monotone functions (they preserve inclusion of subsets) then $\bar{\lambda}^{\mathbf{S}/\mathbf{P}}: \bar{\mathbf{SP}} \Rightarrow \bar{\mathbf{PS}}$ is also a monotone weak distributive law.

Of course the point of Theorems 19 and 20 is that they make it easier to exhibit weak distributive laws in categories of algebras. Still, working with Diagram (π -YB) may be quite tedious, as it involves up to four composed layers of functors. In fact in Theorem 18 we did not use this π -Yang-Baxter equation at all, instead we directly proved that $\lambda^{\mathbf{V}/\mathbf{V}}$ was a weak π -lifting because we were already able to take for granted that its components were morphisms of $\mathbf{\beta}$ -algebras, i.e. continuous functions. Another problem with Theorem 19 is

10:12 Monotone Weak Distributive Laws in Categories of Algebras

that even if we manage to disprove its prerequisites for some examples, we only get that there is no weak π -lifting of the weak distributive law, but we do not learn anything about other possible meaningful weak distributive laws in the category of algebras.

For all of these reasons we do not try to apply Theorem 19 to weakly π -lift $\lambda^{\mathbf{P}/\mathbf{P}}: \mathbf{PP} \Rightarrow \mathbf{PP}$ to $\mathbf{EM}(\mathbf{P})$ and $\mathbf{EM}(\mathbf{D})$, and immediately turn towards another approach in Section 4 instead: we try to weakly lift the conditions for the existence of monotone weak distributive laws (described in Section 2.2). This is a reasonable strategy because monotone laws are easier to reason about (all non-trivial weak distributive laws described in the literature are monotone) and are closer to being fully characterized, meaning we should hopefully be able to prove no-go theorems for monotone weak distributive laws. In fact we will prove that there is no such law $\mathbf{PP} \Rightarrow \mathbf{PP}$ in $\mathbf{EM}(\mathbf{P})$ or $\mathbf{EM}(\mathbf{D})$, so that by Theorem 20 $\lambda^{\mathbf{P}/\mathbf{P}}$ cannot weakly π -lift to $\mathbf{EM}(\mathbf{P})$ nor to $\mathbf{EM}(\mathbf{D})$.

4 Weakly Lifting Monotone Weak Distributive Laws

Let \mathbf{T} be a monad on a regular category \mathbf{C} . It is folklore that, under mild conditions, $\mathbf{EM}(\mathbf{T})$ is regular as well. For instance on **Set**, all finitary monads, and even all monads if the axiom of choice is assumed to be true, have regular categories of algebras [9, Theorems 3.5.4 and 4.3.5]. Here we will assume that \mathbf{T} is a nearly cartesian functor, but the following result also holds for monads that preserve reflexive coequalizers.

► **Theorem 21** (categories of algebras are regular). *Let $(\mathbf{T}, \eta^{\mathbf{T}}, \mu^{\mathbf{T}})$ be a monad on a regular category \mathbf{C} such that \mathbf{T} is nearly cartesian. Then $\mathbf{EM}(\mathbf{T})$ is regular and $\mathbf{U}^{\mathbf{T}}$ creates finite limits and near pullbacks (a square is a near pullback in $\mathbf{EM}(\mathbf{T})$ if and only if its image by $\mathbf{U}^{\mathbf{T}}$ is so in \mathbf{C}).*

Consider weak distributive laws $\rho: \mathbf{TS} \Rightarrow \mathbf{ST}$, $\sigma: \mathbf{TR} \Rightarrow \mathbf{RT}$ and $\tau: \mathbf{SR} \Rightarrow \mathbf{RS}$ on \mathbf{C} . Note that because \mathbf{C} is a regular category, idempotents split in \mathbf{C} by way of the factorization into regular epimorphisms followed by monomorphisms: in particular, all the weak composites and weak liftings corresponding to these weak distributive laws exist. When $\tau: \mathbf{SR} \Rightarrow \mathbf{RS}$ is a monotone weak distributive law thanks to the framework of [19], it is now natural to ask when there is also a monotone weak distributive law $\bar{\mathbf{S}}\bar{\mathbf{R}} \Rightarrow \bar{\mathbf{R}}\bar{\mathbf{S}}$ in $\mathbf{EM}(\mathbf{T})$ arising in the same way: it is for instance the case for $\mathbf{T} = \mathbf{\beta}$ and $\mathbf{S} = \mathbf{R} = \mathbf{P}$.

To apply the framework for monotone weak distributive laws of [19] to monads $\bar{\mathbf{S}}$ and $\bar{\mathbf{R}}$, we need to characterize $\mathbf{KI}(\bar{\mathbf{R}})$ as a subcategory of relations – we do this in Section 4.1 – and then prove that $\bar{\mathbf{S}}$ and $\mu^{\bar{\mathbf{S}}}$ are nearly cartesian and investigate when the extension of $\bar{\mathbf{S}}$ to $\mathbf{Rel}(\mathbf{EM}(\mathbf{T}))$ restricts to $\mathbf{KI}(\bar{\mathbf{R}})$ – we do this in Section 4.2. We finally apply our results in Section 4.3.

Because we strive to be as general as possible, in the following the assumptions that we use vary from result to result. In the propositions and theorems we thus recall every time all the assumptions that are necessary.

4.1 Kleisli Categories of Weakly Lifted Monads

Let us forget about regular categories and internal relations for an instant and first describe the Kleisli categories of a weakly lifted monad $\bar{\mathbf{R}}$ in terms of the Kleisli category of \mathbf{R} itself.

► **Proposition 22.** *Let $\sigma: \mathbf{TR} \Rightarrow \mathbf{RT}$ be a weak distributive law in a category \mathbf{C} where idempotents split, so that \mathbf{R} has a weak lifting $\bar{\mathbf{R}}$ to $\mathbf{EM}(\mathbf{T})$ and \mathbf{T} a weak extension $\underline{\mathbf{T}}$ to $\mathbf{KI}(\mathbf{R})$. Then $\mathbf{KI}(\bar{\mathbf{R}})$ -arrows $(A, a) \dashrightarrow (B, b)$ are in one-to-one correspondence with $\mathbf{KI}(\mathbf{R})$ -arrows $f: A \dashrightarrow B$ such that $f \circ \mathbf{F}_{\mathbf{R}}a = \mathbf{F}_{\mathbf{R}}b \circ \underline{\mathbf{T}}f$.*

Assume now that the framework of [19] applies: $\mathbf{KI}(\mathbf{R})$ is a wide subcategory of $\mathbf{Rel}(\mathbf{C})$ (and the left adjoint coincides with the graph functor $\mathbf{Graph}_{\mathbf{C}}: \mathbf{C} \rightarrow \mathbf{Rel}(\mathbf{C})$), \mathbb{T} and $\mu^{\mathbb{T}}$ are nearly cartesian and the weak extension of $(\mathbb{T}, \eta^{\mathbb{T}}, \mu^{\mathbb{T}})$ to $\mathbf{KI}(\mathbf{R})$ is the restriction of the relational extension of \mathbb{T} and $\mu^{\mathbb{T}}$ to $\mathbf{Rel}(\mathbf{C})$.

By Theorems 7 and 21, $\mathbf{U}^{\mathbb{T}}$ has a relational extension $\mathbf{Rel}(\mathbf{U}^{\mathbb{T}}): \mathbf{Rel}(\mathbf{EM}(\mathbb{T})) \rightarrow \mathbf{Rel}(\mathbf{C})$, and by Theorem 22 $\mathbf{KI}(\overline{\mathbf{R}})$ -morphisms $(A, a) \rightarrow (B, b)$ correspond to \mathbf{C} -relations $\psi: A \rightsquigarrow B$ that are in $\mathbf{KI}(\mathbf{R})$ and such that $\psi \cdot a = b \cdot \mathbb{T}\psi$. $\mathbf{KI}(\overline{\mathbf{R}})$ is thus itself a wide subcategory of $\mathbf{Rel}(\mathbf{EM}(\mathbb{T}))$:

► **Lemma 23.** *When the endofunctor \mathbb{T} is nearly cartesian, a \mathbf{C} -relation $\psi: A \rightsquigarrow B$ is the image of an $\mathbf{EM}(\mathbb{T})$ -relation $(A, a) \rightsquigarrow (B, b)$ by the faithful functor $\mathbf{Rel}(\mathbf{U}^{\mathbb{T}}): \mathbf{Rel}(\mathbf{EM}(\mathbb{T})) \rightarrow \mathbf{Rel}(\mathbf{C})$ if and only if $\psi \cdot a \geq b \cdot \mathbb{T}\psi$.*

We now describe in more concrete terms which $\mathbf{EM}(\mathbb{T})$ -relations are arrows in $\mathbf{KI}(\overline{\mathbf{P}})$. Decomposable \mathbb{T} -algebra morphisms play a central role in this description:

► **Definition 24** (decomposable morphisms of algebra). *Let \mathbb{T} be a monad on a category \mathbf{C} such that $\mathbf{EM}(\mathbb{T})$ is regular. A \mathbb{T} -algebra morphism $f: X \rightarrow Y$ is called decomposable when the square $f \circ \varepsilon_X^{\mathbb{T}} = \varepsilon_Y^{\mathbb{T}} \circ \mathbf{F}^{\mathbb{T}} \mathbf{U}^{\mathbb{T}} f$ is a near pullback.*

Given a jointly monic span $\langle \psi_X, \psi_Y \rangle$ in $\mathbf{EM}(\mathbb{T})$, the corresponding relation $\psi = \psi_Y \cdot \psi_X^{\dagger}$ is called decomposable when ψ_X is so.

Before looking at examples, let us give two lemmas that will make working with decomposability of morphisms and relations easier.

► **Lemma 25.** *If $\mathbf{U}^{\mathbb{T}}$ creates near pullbacks, a \mathbb{T} -morphism $f: (A, a) \rightarrow (B, b)$ is decomposable if and only if $\mathbf{U}^{\mathbb{T}} f \circ a = b \circ \mathbf{TU}^{\mathbb{T}} f$ is a near pullback in \mathbf{C} . In particular if \mathbb{T} is a monad on \mathbf{Set} , this holds if and only if for every $x \in A$ and $u \in \mathbf{T}B$ such that $f(x) = b(u)$, there is some $t \in \mathbf{T}A$ such that $(\mathbf{T}f)(t) = u$ and $a(t) = x$.*

► **Lemma 26.** *Suppose $\mathbf{U}^{\mathbb{T}}$ creates and \mathbb{T} preserves regular epimorphisms. If $g = h \circ e$ is decomposable and e is a regular epimorphism, then h is decomposable as well. In particular, if $f: R \rightarrow X$ is decomposable then for any $g: R \rightarrow Y$, $g \cdot f^{\dagger}$ is a decomposable relation.*

Decomposable morphisms have been studied in [11, Definition 3.1.1] in the setting of *monoidal topology*. There, these morphisms are called *open* as they generalize open maps between compact Hausdorff spaces, as the next example shows. We prefer the term “decomposable” here as we focus on other examples that feel more algebraic than topological:

► **Example 27** (decomposable morphisms and relations in categories of algebras over \mathbf{Set}). In $\mathbf{EM}(\beta) \cong \mathbf{KHaus}$, a continuous map is decomposable if and only if it is open (it preserves open sets), and decomposable relations are the continuous ones, i.e. those relations $\psi: X \rightsquigarrow Y$ such that $\psi^{-1}[u]$ is open in X for every open subset u of Y .

In $\mathbf{EM}(\mathbf{P}) \cong \mathbf{JSL}$, $\psi: X \rightsquigarrow Y$ is decomposable if and only if for every family $(x_i)_{i \in I}$ of elements of X and every $y \in Y$ such that $(\bigvee_{i \in I} x_i, y) \in \psi$, there is a family $(y_i)_{i \in I}$ of elements of Y such that $(x_i, y_i) \in \psi$ for all $i \in I$ and $\bigvee_{i \in I} y_i = y$.

In $\mathbf{EM}(\mathbf{D}) \cong \mathbf{Conv}$, $\psi: X \rightsquigarrow Y$ is decomposable if and only if for every $x \in X$, every *disintegration* of x as a barycenter $x = \sum_{i=1}^n \lambda_i x_i$ and every $y \in Y$ such that $(x, y) \in \psi$, y disintegrates as a barycenter $y = \sum_{i=1}^n \lambda_i y_i$ such that $(x_i, y_i) \in \psi$ for all $i \in I$.

A more general example of decomposable morphism is the following:

► **Lemma 28.** *When \mathbf{U}^T creates near pullbacks, μ^T is nearly cartesian if and only if every free algebra morphism $\mathbf{F}^T f: (\mathbf{T}X, \mu_X^T) \rightarrow (\mathbf{T}Y, \mu_Y^T)$ with $f: X \rightarrow Y$ is decomposable.*

We are now able to state the main result of this section. We first state it in full generality (Theorem 29), but in practice we will be especially concerned with the case $\mathbf{R} = \mathbf{P}$ on $\mathbf{C} = \mathbf{Set}$ (Theorem 30).

► **Theorem 29.** *Let $(\mathbf{T}, \eta^T, \mu^T)$ be a monad on a regular category \mathbf{C} . When the endofunctor \mathbf{T} is nearly cartesian, an $\mathbf{EM}(\mathbf{T})$ -relation $\psi: (A, a) \rightsquigarrow (B, b)$ is decomposable if and only if $\mathbf{U}^T \psi \cdot a = b \cdot \mathbf{T}\mathbf{U}^T \psi$. If μ^T is also nearly cartesian and $\mathbf{Rel}(\mathbf{T})$ restricts to $\mathbf{KI}(\mathbf{R}) \hookrightarrow \mathbf{Rel}(\mathbf{C})$ for some monad \mathbf{R} on \mathbf{C} , then the Kleisli category $\mathbf{KI}(\bar{\mathbf{R}})$ of the corresponding weakly lifted monad $\bar{\mathbf{R}}$ on $\mathbf{EM}(\mathbf{T})$ has for arrows $(A, a) \twoheadrightarrow (B, b)$ the decomposable relations $\psi: (A, a) \rightsquigarrow (B, b)$ in $\mathbf{EM}(\mathbf{T})$ such that $\mathbf{U}^T \psi$ is in $\mathbf{KI}(\mathbf{R})$.*

► **Corollary 30.** *If \mathbf{T} has a monotone weak distributive law over \mathbf{P} in \mathbf{Set} , the Kleisli category of the lifted powerset monad \mathbf{P} on $\mathbf{EM}(\mathbf{T})$ is the category of \mathbf{T} -algebras and decomposable relations between them.*

► **Remark 31** (subobject classifiers in categories of algebras). Recall that an elementary topos is a regular category such that the **Graph** functor has a right adjoint [13, §1.911]; the corresponding monad is called the powerset monad. If \mathbf{C} is an elementary topos with powerset monad \mathbf{P} , and if \mathbf{T} is a monad on \mathbf{C} such that the endofunctor \mathbf{T} and the natural transformation μ^T are nearly cartesian, then by Theorem 29 $\mathbf{EM}(\mathbf{T})$ is an elementary topos as soon as every \mathbf{T} -algebra morphism is decomposable. We retrieve for instance that the categories of group actions (algebras for monads $G \times -$ where G is a group) are toposes, because the corresponding morphisms of algebras are easily shown to all be decomposable.

This is not a necessary condition for a category of algebras to be an elementary topos: it is well known that categories of monoid actions (algebras for monads $M \times -$ where M is a monoid) are toposes, but there are equivariant morphisms that are not decomposable.

If $\mathbf{EM}(\mathbf{T})$ is an elementary topos as in Theorem 31, $\bar{\mathbf{P}}1$ classifies subobjects in the sense that subobjects $X \hookrightarrow Y$ are in one-to-one correspondence with morphisms $Y \rightarrow \bar{\mathbf{P}}1$, where 1 is the terminal object [13, §1.912].

This can be generalized when Theorem 29 holds as follows: $\bar{\mathbf{R}}1$ classifies decomposition-closed subobjects, in the sense that decomposable monomorphisms $X \hookrightarrow Y$ are in one-to-one correspondence with morphisms $Y \rightarrow \bar{\mathbf{R}}1$ (the correspondence comes from the adjunction $\mathbf{KI}(\bar{\mathbf{R}})(Y, 1) \cong \mathbf{EM}(\mathbf{T})(Y, \bar{\mathbf{R}}1)$). For instance, the Vietoris monad on $\mathbf{KHaus} \cong \mathbf{EM}(\beta)$ classifies clopen subsets of compact Hausdorff spaces, the non-empty-join-closed powerset monad on $\mathbf{JSL} \cong \mathbf{EM}(\mathbf{P})$ classifies downwards-closed subsets of join-semilattices, and the convex-closed powerset monad on $\mathbf{Conv} \cong \mathbf{EM}(\mathbf{D})$ classifies *walls*, i.e. subsets E such that if $x \in E$ and $\sum_{i=1}^n x_i = x$, $x_i \in E$ as well for all $1 \leq i \leq n$ (walls appear for instance in the structure theorem for convex algebras, which state that every convex algebra is a subalgebra of the *Plonka sum* of its walls [27, Theorem 4.5]).

4.2 Monotone Extensions to Kleisli Categories of Weakly Lifted Monads

In Section 4.1 we assumed \mathbf{T} had a monotone weak distributive law over \mathbf{R} coming from a relational extension of \mathbf{T} and μ^T , and described the Kleisli category of the corresponding weakly lifted monad $\bar{\mathbf{R}}$. Suppose now there is another monad \mathbf{S} that weakly lifts to $\mathbf{EM}(\mathbf{T})$ and that also has a monotone weak distributive law over \mathbf{R} coming from a relational extension of \mathbf{S} and μ^S . When do we also get a monotone weak distributive law of $\bar{\mathbf{S}}$ over $\bar{\mathbf{R}}$ coming from a relational extension of $\bar{\mathbf{S}}$ and $\mu^{\bar{\mathbf{S}}}$?

For the relational extension to exist, we need \bar{S} and $\mu^{\bar{S}}$ to be nearly cartesian. This always holds:

► **Lemma 32.** *Let C be a regular category where idempotents split, and suppose T is nearly cartesian. If $F: C \rightarrow C$ is nearly cartesian and weakly lifts to $\mathbf{EM}(T)$, then its weak lifting is nearly cartesian. If $\alpha: F \Rightarrow G$ between two such functors is nearly cartesian and weakly lifts to $\mathbf{EM}(T)$, then its weak lifting is nearly cartesian as well.*

\bar{S} thus has a relational extension $\mathbf{Rel}(\bar{S})$. By adapting Theorem 7, we can not only characterize when relational extensions restrict to $\mathbf{Kl}(\bar{R})$, but when any endofunctor or natural transformation has a monotone extension to $\mathbf{Kl}(\bar{R})$. We can even state this characterization more generally, without necessarily speaking of decomposable morphisms: we do this now.

► **Definition 33.** *Let Γ be a wide subcategory of a regular category C such that, in C ,*

- Γ -arrows are stable under pullbacks (in C);
- if $f \circ e$ is a Γ -arrow and e is a regular epimorphism (in C), f is a Γ -arrow.

Then we define $C \cdot \Gamma^\dagger$ to be the wide subcategory of $\mathbf{Rel}(C)$ whose arrows are the C -relations $\psi: X \rightsquigarrow Y$ given by jointly monic spans $\langle \psi_X, \psi_Y \rangle$ such that ψ_X is a Γ -arrow, and we write $\mathbf{Graph}_\Gamma: C \rightarrow C \cdot \Gamma^\dagger$ for the restriction of $\mathbf{Graph}_C: C \rightarrow \mathbf{Rel}(C)$ to $C \cdot \Gamma^\dagger$.

We also define a $\Gamma^\dagger \cdot C$ -square to be a square $a \circ b = c \circ d$ such that a or c is a Γ -arrow.

► **Definition 34.** *Let C and D be two regular categories with respective wide subcategories Γ and Δ as in Theorem 33. Let F be a functor $C \rightarrow D$. A (Γ, Δ) -relational extension of F is a functor $\underline{F}_{\Gamma, \Delta}: C \cdot \Gamma^\dagger \rightarrow D \cdot \Delta^\dagger$ such that $\underline{F}_{\Gamma, \Delta} \mathbf{Graph}_\Gamma = \mathbf{Graph}_\Delta \underline{F}_{\Gamma, \Delta}$. If $\alpha: F \Rightarrow G$ is a natural transformation between functors $C \rightarrow D$ with (Γ, Δ) -relational extensions $\underline{F}_{\Gamma, \Delta}$ and $\underline{G}_{\Gamma, \Delta}$, a (Γ, Δ) -relational extension is a (necessarily unique) natural transformation $\underline{\alpha}_{\Gamma, \Delta}: \underline{F}_{\Gamma, \Delta} \Rightarrow \underline{G}_{\Gamma, \Delta}$ such that $\underline{\alpha}_{\Gamma, \Delta} \mathbf{Graph}_\Gamma = \mathbf{Graph}_\Delta \underline{\alpha}_{\Gamma, \Delta}$.*

► **Theorem 35.** *Let C, D, Γ, Δ and $F: C \rightarrow D$ be as in Theorem 34. F has a monotone (Γ, Δ) -relational extension if and only if the following two conditions hold:*

- F restricts to a functor $\Gamma \rightarrow \Delta$;
- F sends near pullback $\Gamma^\dagger \cdot C$ -squares on near pullback (necessarily $\Delta^\dagger \cdot D$ -) squares (this is always true when F is nearly cartesian).

Such a monotone (Γ, Δ) -relational extension, if it exists, is necessarily unique and given by $\underline{F}_{\Gamma, \Delta}(g \cdot f)^\dagger = Fg \cdot (Ff)^\dagger$.

Let $\alpha: F \Rightarrow G$ be a natural transformation between two functors $C \rightarrow D$ having such monotone (Γ, Δ) -relational extensions. α has a (necessarily unique) (Γ, Δ) -relational extension if and only if it has near pullbacks for its naturality squares along Γ -morphisms (this is always true when α is nearly cartesian).

A first corollary, while not especially ground-breaking, is the following:

► **Corollary 36.** *In \mathbf{Set} , a monad (T, η^T, μ^T) whose endofunctor and multiplication are nearly cartesian also has a (necessarily unique) monotone weak distributive law over the monad \mathbf{P}_* of non-empty subsets, and has one over the monad \mathbf{P}_f of finite subsets if and only if T preserves functions with finite pre-images of elements.*

We could more generally characterize the existence of monotone weak distributive laws over these powerset monads for any monad on \mathbf{Set} . Still, Theorem 36 is already enough to prove that \mathbf{P} has monotone weak distributive laws over \mathbf{P}_f and \mathbf{P}_* , that \mathbf{D} has a monotone weak distributive law over \mathbf{P}_* but not over \mathbf{P}_f , and that \mathbf{b} has a monotone weak distributive law over \mathbf{P}_* . A more impactful corollary – we will apply it repeatedly in Section 4.3 – is the following:

► **Corollary 37.** *Let T be a monad on \mathbf{Set} equipped with a monotone weak distributive law $TP \Rightarrow PT$, and let S be a monad on $\mathbf{EM}(T)$. If there is a monotone weak distributive law $S\bar{P} \Rightarrow \bar{P}S$, S preserves decomposable T -algebra morphisms. Moreover if S is itself the weak lifting of a monad on \mathbf{Set} that has a monotone weak distributive law over \mathbf{P} , then the previous condition is not only necessary, but also sufficient.*

4.3 Monotone Weak Distributive Laws in Categories of Algebras

A first use of Theorem 37 is retrieving the monotone weak distributive law $\mathbf{V}\mathbf{V} \Rightarrow \mathbf{V}\mathbf{V}$: once \mathbf{V} and $\mu^{\mathbf{V}}$ are shown to be nearly cartesian, we only need to prove that decomposable morphisms are the open maps (Theorem 27) instead of proving that $\mathbf{KI}(\mathbf{V})$ -arrows are the continuous relations, and that \mathbf{V} preserves open maps, which is technically much simpler than proving that $\underline{\mathbf{V}}$ preserves continuous relations, as originally done in [19, Proposition 20]. We are also able to answer quite easily Goy's [16, Conjecture 7.31] on the weak distributivity of the Radon monad – the monad of Radon probability measures on a compact Hausdorff space – over the Vietoris monad:

► **Theorem 38.** *The Radon monad \mathbf{R} does not have a monotone weak distributive law over the Vietoris monad \mathbf{V} , but it has (a unique) one over the non-empty Vietoris monad \mathbf{V}_* .*

Let us stress the importance of this new weak distributive law: the question of how to combine probability and non-determinism has been the topic of numerous works (again, see the introduction of [21]), and this law provides an answer in \mathbf{KHaus} that is derived from a generic construction and thus comes with generic tools, e.g. generalized determinization and up-to techniques [18, 16]. In a very recent pre-print [15], Goubault-Larrecq also constructs this law $\mathbf{R}\mathbf{V}_* \Rightarrow \mathbf{V}_*\mathbf{R}$ as an instance of weak distributive laws between monads of continuous valuations and non-deterministic choice in more general categories of topological spaces: our result is more restricted, but we derive the law from generic categorical principles instead of building it by hand, exhibit its canonicity (it comes from a relational extension), and show why the non-empty version of the Vietoris monad is needed.

A second use of Theorem 37 is in proving the absence of monotone weak distributive laws. In Section 3 we were able to prove that the law $\mathbf{P}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{P}$ does not weakly lift to $\mathbf{EM}(\mathbf{P})$ nor $\mathbf{EM}(\mathbf{D})$, but we were not able to say anything about the existence of other monotone weak distributive laws $\bar{\mathbf{P}}\mathbf{P} \Rightarrow \mathbf{P}\bar{\mathbf{P}}$. Now, thanks to the framework developed above and in particular Theorem 37, we are able to prove that such laws cannot exist. We start with $\mathbf{EM}(\mathbf{P})$:

► **Example 39.** In $\mathbf{EM}(\mathbf{P}) \cong \mathbf{JSL}$, let $\bar{\mathbf{P}}$ be the monad of subsets closed under non-empty joins: the join of a family $(E_i)_{i \in I}$ of non-empty-joins-closed subsets of X is the non-empty-joins-closed subset $\{\bigvee_{i \in I} x_i \mid x_i \in E_i\}$. Let $f: 4 \rightarrow 2$ (where $2 = \{0, 1\}$ and $4 = \{0, 1, 2, 3\}$) be the function given by $f(0) = f(2) = 0$ and $f(1) = f(3) = 1$. Then $\mathbf{F}^{\mathbf{P}}f$ is decomposable (by Theorem 28), but $\bar{\mathbf{P}}\mathbf{F}^{\mathbf{P}}f$ is not. Indeed, let $A \in \bar{\mathbf{P}}\mathbf{F}^{\mathbf{P}}4$ and $B, B_1, B_2 \in \mathbf{P}\mathbf{F}^{\mathbf{P}}2$ be as depicted in Figure 2a (page 17): $(\bar{\mathbf{P}}\mathbf{F}^{\mathbf{P}}f)(A) = B = B_1 \vee B_2$ but there are no $A_1, A_2 \in \bar{\mathbf{P}}\mathbf{F}^{\mathbf{P}}4$ such that $A = A_1 \vee A_2$ and $(\bar{\mathbf{P}}\mathbf{F}^{\mathbf{P}}f)(A_1) = B_1$ as well as $(\bar{\mathbf{P}}\mathbf{F}^{\mathbf{P}}f)(A_2) = B_2$.

Proof. Suppose indeed there are such A_1 and A_2 . Then $A_1, A_2 \subseteq A$ and thus $\{0, 1, 2, 3\} \in A_1 \cup A_2$ ($\{0, 1, 2, 3\}$ is join-irreducible in A). This would imply $\{0, 1\} \in B_1 \cup B_2$, which does not hold. ◀

$\overline{\mathbf{P}}$ does not preserve decomposable \mathbf{P} -algebra morphisms, and thus there is no monotone weak distributive law $\overline{\mathbf{P}\mathbf{P}} \Rightarrow \overline{\mathbf{P}\mathbf{P}}$. In fact because the counter-example decomposable morphism is surjective and has finite pre-images, this also proves that there are no monotone weak distributive laws $\mathbf{P}\mathbf{P}_* \Rightarrow \mathbf{P}_*\mathbf{P}$ or $\mathbf{P}\mathbf{P}_f \Rightarrow \mathbf{P}_f\mathbf{P}$ in $\mathbf{EM}(\mathbf{P})$.

Because there is a morphism of monads $\mathbf{D} \Rightarrow \mathbf{P}$ (that sends a probability distribution to its support), there is a functor $\mathbf{EM}(\mathbf{P}) \rightarrow \mathbf{EM}(\mathbf{D})$ which allows us to transfer Theorem 39 to $\mathbf{EM}(\mathbf{D})$: there are no monotone weak distributive laws $\mathbf{P}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{P}$ or $\mathbf{P}\mathbf{P}_* \Rightarrow \mathbf{P}_*\mathbf{P}$ in $\mathbf{EM}(\mathbf{D})$. But this argument is not entirely satisfying, as the resulting example is that of a morphism of convex algebras with a very unnatural structure, namely that of complete join-semilattices: one could imagine restricting to a full subcategory of $\mathbf{EM}(\mathbf{D})$ that does not contain these semilattices, and perhaps $\overline{\mathbf{P}}$ would preserve decomposable morphisms there. As shown by the following example, due to Harald Woracek and Ana Sokolova (private communication), this cannot be the case as soon as free convex algebras come in the picture.

► **Example 40** ([30]). In $\mathbf{EM}(\mathbf{D}) \cong \mathbf{Conv}$, let $\overline{\mathbf{P}}$ be the monad of convex subsets: a convex combination of some convex subsets of X is the convex set of the corresponding convex combinations of their points (in X). Let $f: \{A, B, C\} \rightarrow \{B, C\}$ be the function given by $f(A) = f(B) = B$ and $f(C) = C$. Then $\mathbf{F}^{\mathbf{D}}f$ is decomposable (by Theorem 28) but $\overline{\mathbf{P}}\mathbf{F}^{\mathbf{D}}f$ is not. Indeed, depicting $\mathbf{F}^{\mathbf{D}}\{A, B, C\}$ as the triangle depicted in Figure 2b (page 17), $\mathbf{F}^{\mathbf{D}}\{B, C\}$ is the line segment $[BC]$ and $\mathbf{F}^{\mathbf{D}}f$ is the vertical projection. Now $\frac{1}{2}\{B\} + \frac{1}{2}\{FC\} = [DE] = (\overline{\mathbf{P}}\mathbf{F}^{\mathbf{D}}f)([GD])$, but $[GD]$ itself cannot be disintegrated as the mean of two convex subsets of ABC , one above B and the other above $[FC]$.

Proof. If such a disintegration existed, then the convex subset above B would contain both B (because $D \in [DG]$) and A (because $G \in [DG]$), hence would be $[AB]$. The subset above $[FC]$ would contain at least one point, and hence the mean of these two subsets would have to contain a non-trivial vertical line segment, which is not the case of $[DG]$. ◀

Using similar arguments, we are able to prove the existence or absence of monotone weak distributive laws over lifted powerset monads in several categories of algebras: these results are gathered in Table 1. All the negative results in this table come from the non-preservation of decomposable morphisms, and thus the absence of monotone extensions of the endofunctors themselves. The topmost row indicates in which category we work. A monad in the second topmost row has a monotone weak distributive law over a monad in the left column if the corresponding cell is filled with \checkmark , otherwise it is filled with \times . In **Set**, $\overline{\mathbf{P}}$ and $\overline{\mathbf{P}}_*$ are the

■ **Figure 2** Counterexamples to preservation of decomposability.

	Set						KHaus		JSL	Conv	Mon				CMon			
	L	M	D	P	β	M_S	V	R	\bar{P}	\bar{P}	\bar{M}	\bar{D}	\bar{P}	\bar{M}_S	\bar{M}	\bar{D}	\bar{P}	
\bar{P}	✓	✓	✓	✓	✓	✓	✓	✗	✗	✗	✗	✗	✗	✗	✗	✗	✗	✗
\bar{P}_*	✓	✓	✓	✓	✓	✓	✓	✓	✗	✗	✗	✗	✗	✗	✗	✗	✗	✗

usual powerset monads \mathbf{P} and \mathbf{P}_* . \mathbf{L} is the monad of lists, \mathbf{M} that of multisets and \mathbf{M}_S that of modules for a semiring S satisfying the conditions of [7, Theorem 3.1]. $\mathbf{Mon} \cong \mathbf{EM}(\mathbf{L})$ is the category of monoids and $\mathbf{CMon} \cong \mathbf{EM}(\mathbf{M})$ that of commutative monoids. Linear theories distribute over commutative monads [25], hence \mathbf{L} and \mathbf{M} distribute over \mathbf{M} , \mathbf{P} , \mathbf{D} and \mathbf{M}_S when S is commutative, and so these four monads have liftings (in particular weak liftings) to \mathbf{Mon} and \mathbf{CMon} .

5 Conclusion

Noticing the similarity between the laws $\mathbf{V}\mathbf{V} \Rightarrow \mathbf{V}\mathbf{V}$ and $\mathbf{P}\mathbf{P} \Rightarrow \mathbf{P}\mathbf{P}$, we developed the theory for weakly lifting weak distributive laws and showed that it only applied partially in this case. We then focused on the monotonicity of the laws, and gave full characterizations of monotone weak distributive laws over weakly lifted powerset monads in categories of algebras by characterizing the Kleisli categories of the latter, a key notion appearing then being that of decomposable morphisms. We finally applied this result to exhibit a new law $\mathbf{R}\mathbf{V}_* \Rightarrow \mathbf{V}_*\mathbf{R}$ for combining probability and non-determinism in \mathbf{KHaus} , but also to show that in general these monotone weak distributive laws seem to be quite rare.

We leave for further work the development of a full 2-categorical theory for iterating weak distributive laws (in the vein of [10, 4]), which would complete Section 3 but would likely be scarce in new examples. With monotone laws over powerset-like monads fully characterized, another natural question is now whether this can be done in other settings, e.g. in \mathbf{Pos} -regular categories [23] or over other monads: the multiset monad for instance is a good candidate as its Kleisli category can also be described through spans. Finally, the author believes it would be interesting to transpose the results of Section 4 in the setting of monoidal topology [20], where categories of algebras for nearly cartesian monads generalize the category of compact Hausdorff spaces in a formal sense: perhaps for instance the weakly lifted powerset monads we study are a generalization of the Vietoris monads of topological spaces.

Generalized Inner Product Estimation with Limited Quantum Communication

Srinivasan Arunachalam

Abstract

In this work, we consider the fundamental task of distributed inner product estimation when allowed limited communication. Suppose Alice and Bob are given k copies of an unknown n -qubit quantum state $|\psi\rangle, |\phi\rangle$ respectively, are allowed to send q qubits to one another, and the task is to estimate $|\langle\psi|\phi\rangle|^2$ up to constant additive error. We show that $k = \Theta(\sqrt{2^{n-q}})$ copies are essentially necessary and sufficient for this task (extending the work of Anshu, Landau and Liu (STOC'22) who considered the case when $q = 0$). Additionally, we also consider the task when the goal of the players is to estimate $|\langle\psi|M|\phi\rangle|^2$, for arbitrary Hermitian M . For this task we show that certain norms on M determine the sample complexity of estimating $|\langle\psi|M|\phi\rangle|^2$ when using only classical communication.

1 Introduction

The construction of quantum networks is a major goal in quantum information science [22, 27, 24, 15]. These networks are envisioned to consist of disjoint quantum processing nodes with quantum communication interlinks, likely implemented through photonics. While the nodes may consist of the same type of qubit, this is not a requirement, and work has gone into designing heterogeneous networks where the nodes have different physical compositions [19]. With this in mind it is of interest to develop distributed protocols in a platform-independent framework.

In this paper we consider a natural *distributed* variant of the inner product estimation problem: suppose there are two spatially separated parties Alice and Bob who are each given copies of an unknown d -dimensional quantum state $|\psi\rangle$ and $|\phi\rangle$ respectively and their goal is to compute $|\langle\psi|M|\phi\rangle|^2$ for some Hermitian operator M . We will be interested in the difficulty of this task depending on how much entanglement Alice and Bob share. The core motivation for our setup is that distributing entanglement between nodes in a network is not a free resource and adds time and difficulty to a protocol. Thus, it is useful to minimize the amount of entanglement required. Similar concerns arise in various papers on distributed quantum computing [28, 18, 1].

We call this the *generalized distributed inner product estimation* problem (GIPE). The setting of $M = \mathbb{I}$ in GIPE (which we refer to as *distributed inner product estimation* DIPE) is one of the important steps in cross-platform verification proposed in [16] where the goal is to test if two quantum computers (say built on different platforms) are preparing the same quantum state; a fundamental problem for near-term devices. A natural constraint in these papers is how the quantum computers communicate with one another and in these works they

consider either only classical communication or limited quantum communication (the latter being the focus of our work). Apart from verification, on a theoretical level, understanding the complexity of a question, as fundamental as inner product estimation, in a distributed manner is a natural question.

The seminal work of Buhrman, Cleve, Watrous and Wolf [9] on *quantum fingerprinting* introduced the so-called *swap test*. This subroutine takes as input one copy of unknown quantum states $|\psi\rangle$ and $|\phi\rangle$ and outputs a bit whose bias equals $|\langle\psi|\phi\rangle|^2$; allowing us to estimate the *inner product* between two unknown quantum states without knowing anything about the states themselves. This subroutine has found applications in several areas in quantum computing from complexity theory, learning theory, entanglement theory, to optimization. Although so widely used, there still remain some open fundamental questions about estimating inner products, which is the topic of this work.

There are two techniques to solve GIPE under different settings: (i) If allowed quantum communication, then Alice can send a few copies of the d -dimensional quantum state over to Bob, then Bob could perform a variant of the swap test to estimate $|\langle\psi|M|\phi\rangle|^2$; (ii) if allowed only classical communication, i.e., Alice and Bob only send classical messages, then a recent work of Anshu et al. [3] showed that $\Theta(\sqrt{d})$ copies of $|\psi\rangle, |\phi\rangle$ are necessary and sufficient in order to estimate $|\langle\psi|\phi\rangle|^2$. This setting is often referred to as *local operations and classical communication* (LOCC) and has received a lot of attention in quantum information theory [13, 7, 17]. Although (ii) is surprising in that, the sample complexity is quadratically better than full-state tomography, the exponential (since we typically work with $d = 2^n$, where n is the number of qubits) nature of the complexity seems rather large in practice. Their work raises two natural questions, which will be the focus here:

1. With the advent of near-term quantum devices, sending the full-quantum state (as in the protocol (i) above) might be hard, but it is plausible that one could send a *few* qubits of quantum message. If this were possible, then what is the complexity of DIPE when allowed q -qubit messages?
2. The work of Anshu et al. [3] showed how to solve GIPE when $M = \mathbb{I}$, but other natural properties of quantum states are captured by letting M be an arbitrary operator, for example, predicting few-body properties, such as two-point correlation functions, entanglement entropy of small subsystems, expectation values of observables, projector onto a subspace or perhaps a Pauli string, then M may be different than \mathbb{I} . In this case, understanding the complexity of GIPE for arbitrary M is relevant.

These questions were explicitly raised by Anshu et al. [3] (and as open question 21 in [2]) and in this work we answer both.

1.1 Results

Our first result considers the setup where Alice and Bob may communicate a few qubits in an interactive protocol but not necessarily enough to teleport copies of their states. For simplicity assume that Alice and Bob each have n -qubit states and can transmit in total q qubits of communication. As we mentioned above, the sample complexity when $q = 0$ was shown to be $\sqrt{2^n}$ by [3] and when $q = n$, the sample complexity is $O(1)$. Is there some saving in sample complexity when allowed q qubits of communication? Our first result shows a smooth interpolation between both these settings.

► **Theorem 1 (Informal).** *Suppose Alice and Bob are given k copies of n -qubit states $|\psi\rangle$ and $|\phi\rangle$ respectively. They can communicate $\Theta(q)$ qubits along with performing LOCC. Then it is necessary and sufficient for them to obtain*

$$k = \Theta\left(2^{(n-q)/2}\right),$$

*copies of their states to estimate $|\langle\phi|\psi\rangle|^2$ up to constant accuracy with high probability.*¹

The upper bound $k = \mathcal{O}\left(2^{(n-q)/2}\right)$ shows that quantum communication may help. However, to reach sub-exponential scaling, a large amount of quantum communication is necessary i.e., unless $q = n - \text{polylog}(n)$, our lower bound is still exponential in n . Informally, entanglement helps, but not too much.

Our next result concerns the sample complexity, under LOCC, of GIPE, i.e., for arbitrary Hermitian operators M . A natural possibility when estimating $|\langle\psi|M|\phi\rangle|^2$ is that, perhaps Alice and Bob only need to confirm that their states have a large overlap in one of several smaller subspaces “within M ”. Then, it is conceivable that this task would be much easier than full inner product estimation (i.e., when $M = \mathbb{I}$). We show that this is indeed the case! Let M_ε be M restricted to subspaces with eigenvalue of magnitude at least $\varepsilon/2$. We prove the following near-optimal results for general GIPE.

► **Theorem 2 (Informal).** *For every M with $\|M\| \leq 1$ and $\varepsilon > 0$, to estimate $|\langle\phi|M|\psi\rangle|^2$ to error ε , it is sufficient to obtain*

$$k = \mathcal{O}(\max\{1/\varepsilon^2, \|M_\varepsilon\|_2/\varepsilon\})$$

copies of $|\psi\rangle, |\phi\rangle$ and

$$k = \Omega(\max\{1/\varepsilon^2, \|M_\varepsilon\|_2/\sqrt{\varepsilon}\})$$

copies are necessary.

Interestingly, this implies that M having both positive and negative eigenvalues may not render estimation harder than definite operators. Take Pauli strings as an example, an important set of operators in quantum information. These have eigenspaces of eigenvalues ± 1 each of dimension 2^{n-1} . Then, in evaluating $|\langle\phi|M|\psi\rangle|^2$ there may be cancellations between components of the states lying in eigenspaces of different signs. However, our results show that estimating such an M is no harder than estimating \mathbb{I} , which is positive definite and basis independent. While our upper and lower bounds do not exactly match, this is partially due to choice of presentation. The lower bound we prove is actually $\Omega(\|M_\varepsilon\|_1/\varepsilon\sqrt{d_\varepsilon})$, where d_ε is the dimension of the support of M_ε . Converting 1 to 2 norm yields the lower bound as presented above. However, in some cases this more precise bound is tight. Take, for example, M a projector onto a subspace or a Pauli string. Then, we obtain the lower bound $\Omega(\|M_\varepsilon\|_2/\varepsilon)$, *exactly* matching the upper bound.

Proof sketch. In [3], they prove their lower bound using a very interesting connection to quantum cloning: in particular, they show that if one could solve a decision-version of DIPE, then one could have cloned the states “well-enough”. One of the main challenges in proving our lower bound was that the cloning-based lower bounds do not work when

¹ We will state the constants in this theorem more clearly when proving this theorem.

allowed even few qubits of communication in the cloning channel (which is the setting in which we would like lower bounds). Instead, here we showed that one could use the notion of *robustness of entanglement*, a concept from entanglement theory and split a protocol with a quantum channel into a sum of LOCC protocols. Proving this is a small technical lemma which we combine with the lower bound of [3] to obtain our overall lower bound of $\sqrt{2^{n-q}}$. In order to prove our upper bound, we use ideas from the celebrated Johnson-Lindenstrauss lemma. Our main idea is to perform projections onto random subspaces, i.e., Alice and Bob pick random subspaces and project their states onto these subspaces, maintaining the inner product between their states with high probability. Further, this protocol is completely agnostic to the states they started with. Now holding smaller-dimensional projections of their states, they can use classical communication to detect when their subspace-projections have collisions, use their shared quantum channel and perform SWAP tests to estimate the inner product within the subspace. With some analysis, we are able to show that the overall sample complexity for this scales as $\sqrt{2^{n-q}}$ as well, matching our lower bound.

For estimating bilinear forms, our protocol is fairly similar to the one in [3] except that we need to deal with some technicalities due to the Hermitian operator M . The key observation we first make is that $|\langle \phi | M | \psi \rangle|^2$ and $|\langle \phi | M_\varepsilon | \psi \rangle|^2$ can only differ by at most $\varepsilon/2$. So it suffices for Alice and Bob to restrict themselves to the support of M_ε . Then, they can simultaneously measure the magnitude of the components of their states in this subspace as well as the weighted inner product of said components. The calculations here are similar to the one in [3] wherein one needs to compute the mean variance of the estimator, but a little bit more technical in order to bound all the terms in terms of $\|M_\varepsilon\|_2$. The lower bound follows from realizing that M_ε when restricted to its support, is not too far off from identity and then we can invoke the lower bounds for inner product estimation can be applied. We remark that the lower bound here is much more subtle than the one in [3] since one needs to project onto the eigenspaces of M carefully in order to get the optimal dependence on $\|M_\varepsilon\|_2$.

1.2 Related works and open questions

Like we mentioned earlier, our work answers two open questions raised by Anshu et al. [3]. There have been a few more papers since their work: Hinsche et al. [21] look at specific instantiations of DIPE (when the protocol used by Alice and Bob are Pauli sampling and the quantum states are structured) and prove some positive and negative results to this end. Chen et al. [10] extend the work of [3] by proving better bounds for non-trace-preserving quantum channels, Chen et al. [11] also looked at quantum property testing in the LOCC model.

Distinguishability under LOCC has a rich history in the quantum information literature. Bennett, et al. demonstrated that there exist product bases which are easily distinguished, but are indistinguishable under LOCC [7]. Enough entanglement renders this task easy as the two parties can simply teleport states. Subsequent works showed that much less entanglement may suffice for this task [14, 29]. Unlike our framework, these papers concerned themselves with measurements of a single copy and further identifying states from some known ensemble, rather than learning some property.

A natural open question. A tantalizing open question left open by [3] and also this work is the analogue of DIPE in the mixed case setting. Here the goal is as follows: Alice has copies of ρ , Bob has copies of σ and they engage in LOCC. They need to distinguish if $\rho = \sigma$ or $\|\rho - \sigma\|_{tr} \geq \varepsilon$, promised one of them is the case. Using the bounds obtained in [3], we have an upper bound of $O(d^2/\varepsilon^4 + d^{1.5}/\varepsilon^2)$. As for lower bounds, [5] showed that if Alice also had copies of σ (instead of Bob having them), then one can solve this property testing task using

$\mathcal{O}(d/\varepsilon^2)$ copies (this procedure requires a highly-entangling operation between copies of ρ and σ). Furthermore, if we restricted the measurements to be single-copy measurements and if we fix $\sigma = \mathbb{I}/d$, then $\Omega(d^{3/2})$ copies are necessary [12]. Despite several attempts in making progress on this question, we have not been able to obtain a lower bound better than $\Omega(d)$ and believe that the sample complexity of mixed state DIPE should be $\mathcal{O}(d)$. We leave this as an open question.

2 Preliminaries

2.1 Quantum States and Measurements

Pure quantum states are unit vectors in \mathbb{C}^d . A qubit is a state in \mathbb{C}^2 and n -qubits is a state in $(\mathbb{C}^2)^{\otimes n} \cong \mathbb{C}^{2^n}$. Mixed states, also known as density matrices, ρ , are positive semi-definite operators on \mathbb{C}^d with unit trace. Pure states correspond to rank 1 mixed states and we will routinely use the notation $|\psi\rangle$ to refer to the density matrix corresponding to a pure state $|\psi\rangle$. Measurements of quantum systems are described by positive operator valued measures (POVMs), ensembles of positive semi-definite operators $\{M_i\}_i$ such that $\sum_i M_i = \mathbb{I}$. The probability of observing an outcome i is given by $\text{Tr}[M_i\rho]$. By $\|M\|$ we denote the operator norm of an operator.

In quantum computation states are manipulated via unitary evolution. That is, $|\psi\rangle$ is mapped to $U|\psi\rangle$ for some unitary U . An important unitary we will make repeated usage of is the SWAP gate on a bipartite state. This has the action $\text{SWAP}|\psi\rangle \otimes |\phi\rangle = |\phi\rangle \otimes |\psi\rangle$.

Operators on two Hilbert spaces \mathcal{H}_A and \mathcal{H}_B lie in the tensor product space $\mathcal{B}(\mathcal{H}_A \otimes \mathcal{H}_B)$. A positive semi-definite operator M acting on these tensor product space is said to be separable if it admits a decomposition $M = \sum_i A_i \otimes B_i$, where each A_i and B_i are positive semi-definite. We will be interested in separable POVMs, where each aspect M_i is separable. These are measurements that cannot create entanglement between distributed parties. However, such measurements may still go beyond those achievable with classical communication. With this in mind, one can define local operations and classical communication (LOCC) [13]. This can roughly be defined as all protocols where Alice performs some measurement in her lab, communicates the result to Bob, who then performs a measurement in his lab and communicates the result to Alice and so on. However, the set of LOCC measurements is mathematically unwieldy and it is generally easier to prove results regarding separable measurements. An e -bit is a standard resource of entanglement in quantum information. This is a shared two qubit resource state $|\Phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$. With n e -bits and classical communication, two distributed parties can teleport an n qubit state [23].

2.2 Subroutines

We will make repeated reference to the SWAP test, which can be used to estimate the overlap between two states $|\psi\rangle$ and $|\phi\rangle$ [6, 9].

► **Definition 3 (SWAP test).** *Given two mixed states ρ and σ and an ancilla qubit initialized in the state $|0\rangle_E$, the SWAP test performs the unitary $(H_E \otimes \mathbb{I}_{AB})(|0\rangle\langle 0| \otimes \mathbb{I}_{AB} + |1\rangle\langle 1| \otimes \text{SWAP}_{AB})(H_E \otimes \mathbb{I}_{AB})$ and measures the ancilla in the computation basis. The measurement probabilities are given by*

$$p(0) = \frac{1 + \text{Tr}[\rho\sigma]}{2}, \quad p(1) = \frac{1 - \text{Tr}[\rho\sigma]}{2}.$$

11:6 Generalized Inner Product Estimation with Limited Quantum Communication

Via standard amplification arguments, $\mathcal{O}(1/\varepsilon^2)$ trials are sufficient to estimate $\text{Tr}[\psi\phi]$ to error ε . Using block-encodings, this can be extended to estimating $|\langle\phi|M|\psi\rangle|^2$ for an arbitrary hermitian M such that $\|M\| \leq 1$. Again, standard amplification arguments show that $\mathcal{O}(1/\varepsilon^2)$ trials suffices to estimate $|\langle\phi|M|\psi\rangle|^2$. We will also use the standard POVM on the symmetric subspace. The symmetric group S_k has a natural action on the state space of $(\mathbb{C}^d)^{\otimes k}$ given by

$$\pi \bigotimes_{i=1}^k |\psi_i\rangle = \bigotimes_{i=1}^k |\psi_{\pi^{-1}(i)}\rangle \quad \forall \pi \in S_k . \quad (1)$$

► **Definition 4** (Symmetric Subspace). *The k -copy symmetric subspace of a vector space $V \cong \mathbb{C}^d$, is given by*

$$\vee^k \mathbb{C}^d = \left\{ |\psi\rangle \in (\mathbb{C}^d)^{\otimes k} \mid \pi |\psi\rangle = |\psi\rangle \forall \pi \in S_k \right\} .$$

The symmetric subspace has a natural spanning set given by $\left\{ |\phi\rangle^{\otimes k} \mid |\phi\rangle \in \mathbb{C}^d \right\}$ [20]. Due to $\vee^k \mathbb{C}^d$ being an irreducible representation of the unitary group (under the action $U^{\otimes k}$), we can define a uniform POVM on the symmetric subspace, which is known as the standard POVM.

► **Definition 5** (Standard POVM on $\vee^k \mathbb{C}^d$). *The standard POVM on $\vee^k \mathbb{C}^d$ is the continuous POVM with elements*

$$\left\{ \binom{d+k-1}{k} |\varphi\rangle\langle\varphi|^{\otimes k} d\varphi \mid |\varphi\rangle \in \mathbb{C}^d \right\} . \quad (2)$$

We require one last fact about the symmetric subspace:

► **Fact 6** (Haar moments). *If $|\psi\rangle$ is drawn from the Haar measure on \mathbb{C}^d , then*

$$\mathbb{E}_\psi[|\psi\rangle] = \frac{\mathbb{I}}{d} , \quad \mathbb{E}_\psi[|\psi\rangle\langle\psi|^{\otimes 2}] = \frac{1}{d(d+1)} (\mathbb{I} + \text{SWAP}) . \quad (3)$$

3 Estimating Inner Product

In this section we consider the following task: Alice and Bob each have copies of unknown d -dimensional states $|\phi\rangle$ and $|\psi\rangle$. They may use any amount of classical communication and some restricted quantum communication. Their goal is to estimate $|\langle\phi|\psi\rangle|^2$ using as few samples of $|\psi\rangle$ and $|\phi\rangle$ as possible. Here we will assume the desired measurement precision is some constant.

► **Theorem 7.** *Suppose Alice and Bob share a q -qubit entangled state, can perform measurements on k copies of their respective d -dimensional states $|\psi\rangle$ and $|\phi\rangle$ respectively and engage in unbounded classical communication. If they are able to estimate $|\langle\psi|\phi\rangle|^2$ to accuracy ε with high probability, then $\Omega(\max\{1/\varepsilon^2, \sqrt{d/q}/\varepsilon\})$ are necessary.*

► **Theorem 8.** *Suppose Alice and Bob share a $10q$ -qubit entangled state, can perform measurements on k copies of their respective d -dimensional states $|\psi\rangle$ and $|\phi\rangle$ respectively and engage in unbounded classical communication. It suffices to obtain $k = O(\sqrt{d/q}/\varepsilon^2)$ copies, in order to estimate $|\langle\psi|\phi\rangle|^2$ to accuracy ε with high probability.*

We remark that there is a constant-factor difference in the amount of entanglement bounds in the upper and lower bound. This largely seems to stem from the sample complexity still being greater than 1 even when $q = n$: say that Alice is able to transmit her state exactly and Bob does the swap test. Even then, in order to compute the inner product $|\langle\psi|\phi\rangle|^2$ to error 0.1, they need to repeat the swap test constantly many times. Our lower bound for this setting would imply a constant lower bound as well (matching the upper bound, but not “exactly” since it would be a constant-factor off). Regardless, our lower bound can be understood as saying that entanglement does not help for inner product estimation unless the shared entanglement dimension scales with d .

3.1 Lower bound in main theorem

To obtain a lower bound we consider the decision problem constructed in [3] (which is called the DIPE, *distributed inner product estimation* problem). Alice and Bob are promised to be in one of the following two scenarios. Their version restricts Alice and Bob to LOCC protocols. However, here we allow them to share some resource state σ as well.

- **Definition 9** (Distributed Inner Product Estimation, Decision Version). *Alice and Bob each have access to k copies of the states $|\phi\rangle$ and $|\psi\rangle$ in \mathbb{C}^d respectively and are asked to decide, using LOCC and perhaps a resource state σ , which of the following two scenarios they are in:*
- **YES:** $|\phi\rangle = |\psi\rangle$ and they are Haar random
 - **NO:** $|\phi\rangle, |\psi\rangle$ are Haar random.

Say that Alice and Bob are able to transmit a r dimensional quantum message. Because of quantum teleportation, this communication channel is equivalent, under LOCC, to sharing a r -dimensional maximally entangled state. Going forward, we let $\sigma = \frac{1}{r} \sum_{i,j=1}^r |ii\rangle\langle jj|$ be the state Alice and Bob share.

We also introduce a measure of entanglement called the *robustness of entanglement*.

- **Definition 10** (Robustness of entanglement [26]). *Any quantum state $\sigma \in \mathcal{B}(\mathcal{H}_A \otimes \mathcal{H}_B)$ can be decomposed as $\sigma = (1+s)\sigma^+ - s\sigma^-$, where σ^+ and σ^- are both separable states and $s \in \mathbb{R}_{\geq 0}$. The minimum value of s over all such decompositions is called the robustness of entanglement. We denote this minimum value by $E(\sigma)$.*

In particular, we will use the following lemma.

- **Lemma 11** ([26]). *If σ is a pure bipartite state, then the robustness of entanglement is $E(\sigma) = (\sum_i \lambda_i)^2 - 1$, where $\{\lambda_i\}_i$ are the Schmidt coefficients.*

Thus, the robustness of entanglement of σ is $E(\sigma) = r - 1$ (since all of its Schmidt coefficients are $1/\sqrt{r}$). In [3] they show the following result:

- **Theorem 12** ([3]). *Let M be a separable measurement, then*

$$|\mathbb{E}_{\phi,\psi} [M \cdot \text{Tr}[\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k})]]| \leq e^{k^2/d} - 1. \quad (4)$$

With this we now prove our main theorem lower bound.

Proof of lower bound of Thm 7. Say that there exists a separable protocol \mathcal{A} that uses k copies of the states $|\phi\rangle$ and $|\psi\rangle$ and the resource state σ and returns an estimate of $|\langle\psi|\phi\rangle|^2$ to accuracy ε with probability at least $3/4$. Because of anti-concentration of the Haar measure, Alice and Bob will be able to use this protocol to solve problem 9 with high probability. Let $B([\phi], \varepsilon)$ be the ball of radius $\varepsilon \leq \pi/2$ around $[\phi]$ in $\mathbb{C}\mathbb{P}(d)$ with respect to the Fubini-Study

metric, which we will denote as $d([\phi, \psi]) = \arccos |\langle \psi | \phi \rangle|$. Then, it is known that, under the uniform distribution, the volume of $B([\phi], \varepsilon)$ for $\varepsilon \leq \pi/2$ is given by $\sin^{2d-2} \varepsilon$ [8]. If $|\langle \psi | \phi \rangle|^2 > \varepsilon$, then $d([\psi, \phi]) \leq \arccos \sqrt{\varepsilon}$ (and $\arccos \sqrt{\varepsilon} \leq \pi/2$ for $\varepsilon \in [0, 1]$). Thus, for constant ε it follows that $|\langle \phi | \psi \rangle|^2 \leq \varepsilon$ with exponentially (in d) high probability in case two of 9. Thus, if Alice and Bob use the protocol \mathcal{A} , they will solve problem 9 with probability at least $2/3$ as well. This implies that there is some separable POVM $\{M, \mathbb{I} - M\}$ such that

$$1/3 \leq |\mathbb{E}_{\phi, \psi} \text{Tr}[M(\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k}) \otimes \sigma)]|. \quad (5)$$

We now show that the RHS of the inequality above can be upper bounded by $(1 + 2E(\sigma))(e^{k^2/d} - 1)$. To see this, split σ into $\sigma = (1 + E(\sigma))\sigma^+ - E(\sigma)\sigma^-$, where σ^+ and σ^- are both separable states. Then, it follows that

$$\begin{aligned} \text{Tr}[M(\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k}) \otimes \sigma)] &= (1 + E(\sigma))\text{Tr}[M(\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k}) \otimes \sigma^+)] \\ &\quad + E(\sigma)\text{Tr}[M(\phi^{\otimes k} \otimes (\psi^{\otimes k} - \phi^{\otimes k}) \otimes \sigma^-)]. \end{aligned} \quad (6)$$

Note that the sign of σ^- has been absorbed into the trace in the second term above. Now, because σ^\pm are separable, each term above could be replaced by a separable measurement on $\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k})$ without any reference state. To see this, decompose σ^+ into $\sigma^+ = \sum_i p_i \rho_i^A \otimes \rho_i^B$. Using spectral decompositions $\rho_i^A = \sum_k \lambda_{i,k} |u_{i,k}\rangle \langle u_{i,k}|$ and $\rho_i^B = \sum_k \nu_{i,k} |v_{i,k}\rangle \langle v_{i,k}|$, we arrive at

$$\text{Tr}[M(\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k}) \otimes \sigma^+)] \quad (7)$$

$$= \sum_i p_i \sum_{j,k} \lambda_{i,k} \nu_{i,j} \text{Tr}[M(\phi^{\otimes k} \otimes \psi^{\otimes k} \otimes |u_{i,j}\rangle \langle u_{i,j}| \otimes |v_{i,k}\rangle \langle v_{i,k}|)]. \quad (8)$$

As a separable measurement, we have $M = \sum_t A_t \otimes B_t$. Now define a new measurement

$$M' := \sum_t \sum_i p_i \left(\sum_j \lambda_{i,j} A_t^{i,j,j} \right) \otimes \left(\sum_k \nu_{i,k} B_t^{i,k,k} \right), \quad (9)$$

where $A_t = \sum_{j,j'} A_t^{i,j,j'} \otimes |u_{i,j}\rangle \langle u_{i,j'}|$ and $B_t = \sum_{k,k'} B_t^{i,k,k'} \otimes |v_{i,k}\rangle \langle v_{i,k'}|$. As a sum of positive operators, this is positive. As a convex combination of operators majorized by \mathbb{I} , this is also majorized by \mathbb{I} . It then follows that M' is a separable POVM. From Thm 12 it then follows that

$$\begin{aligned} |\mathbb{E}_{\phi, \psi} [\text{Tr}[M(\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k}) \otimes \sigma^+)]]| &= |\mathbb{E}_{\phi, \psi} [\text{Tr}[M'(\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k}) \otimes \sigma^+)]]| \\ &\leq e^{k^2/d} - 1. \end{aligned} \quad (10)$$

The same proof shows that

$$|\mathbb{E}_{\phi, \psi} [\text{Tr}[M(\phi^{\otimes k} \otimes (\psi^{\otimes k} - \phi^{\otimes k}) \otimes \sigma^-)]]| \leq e^{k^2/d} - 1. \quad (11)$$

Thus, we have that

$$|\mathbb{E}_{\phi, \psi} [\text{Tr}[M(\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k}) \otimes \sigma)]]| \leq (1 + 2E(\sigma))(e^{k^2/d} - 1). \quad (12)$$

Putting the above along with our lower bound in Eq.(5) shows

$$1/3 \leq |\mathbb{E}_{\phi, \psi} \text{Tr}[M(\phi^{\otimes k} \otimes (\phi^{\otimes k} - \psi^{\otimes k}) \otimes \sigma)]| \leq (1 + 2E(\sigma))(e^{k^2/d} - 1). \quad (13)$$

Rearranging, this implies that

$$k = \Omega\left(\sqrt{\frac{d}{\log E(\sigma)}}\right). \quad (14)$$

So, if Alice and Bob share q Bell pairs, then $E(\sigma) = 2^q - 1$ and we get the desired lower bound.

Using techniques similar to [3, Section 5.3], wherein they showed how to use standard concentration techniques to reduce the decision version of DIPE (for which we have a $\Omega(\sqrt{d/q})$ lower bound) to prove a lower bound for estimating the inner product between $|\phi\rangle$ and $|\psi\rangle$ with a factor of $1/\varepsilon$. In particular, they prove that if there exists a protocol that solves the ε -version of inner product estimation then it can be used to solve DIPE with high probability. Then, the lower bound on DIPE follows from their reduction. \blacktriangleleft

3.2 Upper bound in main theorem

We now give a protocol which achieves the promised sample complexity of Thm 8. At a high level, the protocol works by randomly projecting $|\phi\rangle$ and $|\psi\rangle$ into small-dimensional subspaces. Since such a projection maintains the inner product between two states with high probability, Alice can simply send Bob these smaller dimensional states and Bob can perform a swap test. The reader may notice that this assumes that Alice can transmit an arbitrary state in a q -dimensional subspace of a d -dimensional space. This, however, does not lead to any issues since Alice *knows* the subspace the state lies in. Then, any maximally entangled state on a q -dimensional subspace can be converted to a maximally entangled state on the desired subspace via a unitary transformation. From there, Alice and Bob simply perform a teleportation protocol.

► **Theorem 13.** *Let $q = \Omega(\log d)$. Using $k = \mathcal{O}(\sqrt{d/q})$ copies of $|\psi\rangle$ and $|\phi\rangle$, there is a protocol that uses $\Theta(1)$ r -dimensional quantum messages, single copy measurements, and returns $|\langle\psi|\phi\rangle|^2$ up to constant error with high probability*

Proof. Let $\psi = |\psi\rangle\langle\psi|$ and $\phi = |\phi\rangle\langle\phi|$. Fix some unitary U . For convenience of notation we will assume that r divides d (working with qubits, if Alice and Bob may communicate $\log(r)$ qubits then this holds). Divide the d -dimensional Hilbert space into d/r subspaces each of dimension r . Let this decomposition be given by a collection of orthogonal projectors $\{P_i\}_{i=1}^{d/r}$. Alice and Bob perform the protocol in Figure 1.

Our theorem will follow by repeating the protocol above constantly many times, each time by sending a r -dimensional quantum message. To see the correctness, we will require the following fact.

► **Fact 14** ([25, Fact 2]). *Let $1 \leq q \leq d$. Let $v \in \mathbb{C}^d$ be a unit vector and P_i be an arbitrary projector onto a r -dimensional subspace. Let U be drawn from the unitary Haar measure. Then,*

$$\Pr_U \left[\|P_i U v\|_2 \notin (1 \pm \Delta) \sqrt{\frac{r}{d}} \right] \leq 4 \exp \left\{ -\frac{\Delta^2 r}{16} \right\}, \quad (15)$$

By linearity this extends to arbitrary vectors in \mathbb{C}^d , as the following corollary demonstrates.

► **Corollary 15.** *Let $1 \leq r \leq d$. Let $u \in \mathbb{C}^d$ be any vector and P_i an arbitrary projector onto a r -dimensional subspace. Let U be drawn from the unitary Haar measure. Then,*

$$\Pr_U \left[\|P_i U u\|_2 \notin (1 \pm \Delta) \sqrt{\frac{r}{d}} \|u\|_2 \right] \leq 4 \exp \left\{ -\frac{\Delta^2 r}{16} \right\}, \quad (16)$$

11:10 Generalized Inner Product Estimation with Limited Quantum Communication

Input: Alice gets $|\psi\rangle^{\otimes k}$, Bob gets $|\phi\rangle^{\otimes k}$

Output: ε -approximation of $|\langle\psi|\phi\rangle|^2$

1. Using shared randomness, Alice and Bob sample a unitary U from Haar measure.
2. Alice and Bob apply the POVM $\{UP_iU^\dagger\}_{i=1}^{\lceil d/r \rceil}$ on each of the k copies and record which copies were projected onto which subspaces.
3. Using a two-way classical communication they determine which copies lie now in the same subspaces. Alice sends Bob a constant number of such projected states which can be paired with a post-projection state of Bob's. Say the number of such pairs is m .
4. Bob performs a SWAP test between the post-projected pairs of states lying in the same subspaces. We say a SWAP test succeeds if Bob measures $|0\rangle$ on the ancilla register. Let the number of successes be s .
5. Bob declares the inner product between $|\psi\rangle$ and $|\phi\rangle$ to be $2s/m - 1$.

■ **Figure 1** Protocol to estimate inner product using shared entanglement.

Proof. This follows readily from Fact 14 via linearity. Apply Fact 14 to $\frac{u}{\|u\|_2}$ while multiplying both $\|P_iUu/\|u\|_2\|_2$ and $(1 \pm \Delta)\sqrt{\frac{r}{d}}$ by $\|u\|_2$. ◀

For a fixed unitary U , let $|\psi'_i\rangle = \frac{P_iU|\psi\rangle}{|P_iU|\psi|}$ and $|\phi'_i\rangle = \frac{P_iU|\phi\rangle}{|P_iU|\phi|}$ be the normalized projections of $|\psi\rangle$ and $|\phi\rangle$ into the subspace given by P_i . We will now show that, with high probability over the choice of U , $|\langle\psi'_i|\phi'_i\rangle|^2 \approx |\langle\psi|\phi\rangle|^2$.

► **Lemma 16.** *Let $\Delta > 0$. Then,*

$$\Pr_U \left[\left| |\langle\phi'_i|\psi'_i\rangle|^2 - |\langle\psi|\phi\rangle|^2 \right| \leq 16\Delta \text{ for every } i \in [d/r] \right] \geq 1 - O(d/r \cdot \exp(-\Delta^2 r/16)). \quad (17)$$

Proof. Using Fact 14, with probability at least $1 - 16 \exp\{-\frac{\Delta^2 r}{16}\}$, the following four conditions hold

$$\|P_iU|\psi\rangle\|_2, \|P_iU|\phi\rangle\|_2 \in (1 \pm \Delta)\sqrt{\frac{r}{d}}, \quad (18)$$

$$\|P_iU(|\psi\rangle - |\phi\rangle)\|_2 \in (1 \pm \Delta)\sqrt{\frac{r}{d}}\|\psi - \phi\|_2, \quad (19)$$

$$\|P_iU(|\psi\rangle - i|\phi\rangle)\|_2 \in (1 \pm \Delta)\sqrt{\frac{r}{d}}\|\psi - i\phi\|_2. \quad (20)$$

We now follow steps similar to those of [25, Theorem 1] to obtain

$$|\langle\phi_i|\psi_i\rangle - \langle\psi|\phi\rangle| \leq 8\Delta. \quad (21)$$

Let $x, y \in \mathbb{C}$ be such that $|x - y| \leq \Delta$. Then,

$$|x|^2 - |y|^2 = (|x| - |y|)(|x| + |y|) \leq \Delta(|x| + |y|). \quad (22)$$

In our case, this implies that

$$|\langle\phi_i|\psi_i\rangle|^2 \in |\langle\psi|\phi\rangle|^2 \pm 16\Delta. \quad (23)$$

Taking a union bound over all d/r subspaces completes the proof. ◀

Now, after receiving m pairs of post-projected states, Bob then performs m many SWAP tests. A SWAP test on the pair $|\psi'_i\rangle$ and $|\phi'_i\rangle$ succeeds with probability $\frac{1}{2} + \frac{1}{2}|\langle\phi'_i|\psi'_i\rangle|^2 \in \frac{1}{2} + \frac{1}{2}|\langle\phi|\psi\rangle| \pm 8\Delta$. The expected value of the sample average s/m then satisfies

$$\left| \mathbb{E} \left[\frac{s}{m} \right] - \frac{1}{2} - \frac{1}{2}|\langle\psi|\phi\rangle|^2 \right| \leq 8\Delta, \quad (24)$$

which implies $2\mathbb{E} \left[\frac{s}{m} \right] - 1 \in |\langle\phi|\psi\rangle|^2 \pm 16\Delta$, and by a Hoeffding bound, we get

$$2 \left| \frac{s}{m} - \mathbb{E} \left[\frac{s}{m} \right] \right| \leq \delta, \quad (25)$$

with probability at least $1 - 2\exp(-2m\delta^2)$. In this case, the total error of the estimator is at most $16\Delta + \delta$. For constant error, $m = O(1)$ suffices.

It remains to determine k needs to be to obtain $m = O(1)$ projected pairs with high probability. To this end, let $E_{a,b}$ be an indicator variable for if Alice's a th projection falls into the same subspace as Bob's b th projection. The expected number of collisions is given by

$$\sum_{a,b} \mathbb{E}[E_{a,b}] = k^2 \sum_i \text{Tr}[P_i U \psi U^\dagger] \text{Tr}[P_i U \phi U^\dagger] \geq k^2 (1 - \Delta)^4 \frac{r}{d}, \quad (26)$$

where the inequality follows from $\|P_i U |\psi\rangle\|, \|P_i U |\phi\rangle\| \geq (1 - \Delta)\sqrt{\frac{r}{d}}$. By a Hoeffding bound, it suffices to take $k = \Omega(\sqrt{d/r})$ to obtain a collision with high probability. As we only require a constant number of pairs, this can simply be repeated a constant number of times to obtain a constant number of collisions with high probability. Thus, the protocol succeeds for $k = \Omega(\sqrt{d/r})$. It remains to pick Δ and δ such that the claims go through: we require that $\frac{d}{r} \exp(-\Delta^2 r/16) = O(1)$, which can be achieved by letting $\Delta = O(1)$ and $r = \Omega(\log d)$. ◀

4 Generalized Distributed Inner Product Estimation

Now we turn to bilinear forms $f : \mathbb{C}^d \otimes \mathbb{C}^d \rightarrow \mathbb{C}$. Any such form can be expressed as $f(u, v) = u^\dagger M v$ for a matrix M . Here we will assume that M is Hermitian, which implies that $f(u, v) = \overline{f(v, u)}$. Without loss of generality we will assume M to be normalized such that $\|M\| = 1$. Due to the unphysical nature of global phases, $f(|\psi\rangle, |\phi\rangle)$ is less meaningful than $|f(|\psi\rangle, |\phi\rangle)|^2$ and we concern ourselves entirely with this value instead. Of course, the special case of $M = \mathbb{I}$ corresponds to inner product estimation. Fixing such an M , let P_ε be a projector which annihilates all eigenspaces of M of eigenvalue less than $\varepsilon/2$. We define d_ε to be the dimension of the support of P_ε . Now define $M_\varepsilon = P_\varepsilon M P_\varepsilon$. The intuition behind this is that we can drop eigenspaces with small weights in estimating $|\langle\phi|M|\psi\rangle|^2$. The following lemma formalizes this.

► **Lemma 17.** *Let M be a Hermitian operator and $M_\varepsilon = P_\varepsilon M P_\varepsilon$, then*

$$\left| |\langle\phi|M|\psi\rangle|^2 - |\langle\phi|M_\varepsilon|\psi\rangle|^2 \right| \leq \varepsilon/2. \quad (27)$$

Proof.

$$|\text{Tr}[M\psi M\phi] - \text{Tr}[M_\varepsilon\psi M_\varepsilon\phi]| = |\text{Tr}[\psi(M\phi M - M_\varepsilon\phi M_\varepsilon)]| \quad (28)$$

$$= |\text{vec}(\psi)^\dagger (M \otimes M - M_\varepsilon \otimes M_\varepsilon)^T \text{vec}(\phi)| \quad (29)$$

$$\leq \|M \otimes M - M_\varepsilon \otimes M_\varepsilon\| \leq \varepsilon/2, \quad (30)$$

where the second line uses the linear map $\text{vec} : \mathcal{B}(\mathcal{H}) \rightarrow \mathcal{H} \otimes \mathcal{H}$ defined by $\text{vec}(|i\rangle\langle j|) = |i\rangle \otimes |j\rangle$ and the identity $\text{vec}(AXB) = (A \otimes B)^T \text{vec}(X)$. ◀

Input: An operator M . Alice gets $|\psi\rangle^{\otimes k}$, Bob gets copies of $|\phi\rangle^{\otimes k}$.

Output: An ε -approximation of $\langle\psi|M|\phi\rangle^2$.

1. Alice and Bob each perform the two-outcome measurement $\{P_\varepsilon, \mathbb{I} - P_\varepsilon\}$ on each of the k copies of their respective states and obtain s_a and s_b copies of the states projected into one of the two subspace. If $s_a = 0$ or $s_b = 0$ then Alice and Bob simply output 0.
2. Alice and Bob independently perform the standard POVM in the symmetric subspace on the support of M_ε , obtaining the classical outcomes $|u\rangle$ and $|v\rangle$.
3. Alice communicates $|u\rangle$ and s_a to Bob who outputs

$$w := \frac{(d_\varepsilon + s_a)(d_\varepsilon + s_b)}{k^2} |\langle u|M_\varepsilon|v\rangle|^2 - \frac{\text{Tr}[M^2]}{k^2}. \quad (31)$$

■ **Figure 2** Protocol to estimate $|\langle\phi|M_\varepsilon|\psi\rangle|^2$ using only LOCC.

Using this lemma, if Alice and Bob can estimate $|\langle\phi|M_\varepsilon|\psi\rangle|^2$ up to precision $\varepsilon/2$, that directly implies an ε -approximation to the quantity $|\langle\phi|M|\psi\rangle|^2$. For the remainder of this section, we will be primarily focused on upper and lower bounds for estimating $|\langle\phi|M_\varepsilon|\psi\rangle|^2$.

With this notation, in this section our main result will be the following theorem, proving close-to-optimal upper and lower bounds for estimating bilinear forms on $|\psi\rangle, |\phi\rangle$.

► **Theorem 18.** *For every M with $\|M\| \leq 1$, with only LOCC, it is sufficient to obtain*

$$k = O(\max\{1/\varepsilon^2, \|M_\varepsilon\|_2/\varepsilon\})$$

copies of $|\psi\rangle, |\phi\rangle$ to estimate $|\langle\phi|M|\psi\rangle|^2$ to error ε with high prob. and it necessary to obtain

$$k = \Omega(\max\{1/\varepsilon^2, \|M_\varepsilon\|_2/\sqrt{\varepsilon}\})$$

copies to produce an ε -approximation to $|\langle\phi|M|\psi\rangle|^2$.

4.1 Upper Bound

In Figure 2 we outline a protocol that estimates $|\langle\phi|M_\varepsilon|\psi\rangle|^2$. Recall that the standard POVM on the symmetric subspace, def 5, has continuous aspects $\left\{ \binom{d+k-1}{k} \varphi^{\otimes k} \mid |\varphi\rangle \in \mathbb{C}^d \right\}$. This can be extended to $\vee^k W$ for arbitrary subspaces $W \subseteq \mathbb{C}^d$:

$$\left\{ \binom{\dim W + k - 1}{k} \varphi^{\otimes k} \mid |\varphi\rangle \in W \right\}. \quad (32)$$

The second step of the protocol of Figure 2 has Alice and Bob implementing this POVM for $\text{Im}P_\varepsilon \subseteq \mathbb{C}^d$. Since they may not have k copies after the projection step, this is a POVM on $\vee^{s_a} \text{Im}P_\varepsilon$ and $\vee^{s_b} \text{Im}P_\varepsilon$, respectively. First note that if $P_\varepsilon|\psi\rangle = 0$ or $P_\varepsilon|\phi\rangle = 0$ then they always output 0, which must be a good estimate in this case. Thus, we assume that $|\psi_\varepsilon\rangle = P_\varepsilon|\psi\rangle / \|P_\varepsilon|\psi\rangle\|$ and $|\phi_\varepsilon\rangle = P_\varepsilon|\phi\rangle / \|P_\varepsilon|\phi\rangle\|$ both exist. The technical lemmas that we prove are the mean and variance of our estimators, whose proofs we defer to the full version [4].

► **Lemma 19.** *The expected value of the estimator w given in Figure 2 is*

$$\mathbb{E}[w] = |\langle\phi|M_\varepsilon|\psi\rangle|^2 + \frac{\text{Tr}[M_\varepsilon^2\phi_\varepsilon]}{k} \text{Tr}[P_\varepsilon\psi] + \frac{\text{Tr}[M_\varepsilon^2\psi_\varepsilon]}{k} \text{Tr}[P_\varepsilon\phi]. \quad (33)$$

► **Lemma 20.** *The variance of the estimator of Figure 2 is upper bounded by*

$$\text{Var}(w) = \mathcal{O}\left(\frac{1}{k} + \frac{\|M_\varepsilon\|_2^2}{k^2} + \frac{\|M_\varepsilon\|^4}{k^4}\right). \quad (34)$$

Our estimator is biased, but the bias is at most $2/k$. Taking

$$k = \Omega\left(\max\left\{\frac{1}{\varepsilon^2}, \frac{\|M_\varepsilon\|_2^2}{\varepsilon}\right\}\right),$$

ensures that both the variance and bias are small enough that Alice and Bob's estimate is within $\varepsilon/2$ of $|\langle\phi|M_\varepsilon|\psi\rangle|^2$ and thus within ε of $|\langle\phi|M|\psi\rangle|^2$ (with high probability).

4.2 Lower Bound

We now prove the claimed lower bounds in Theorem 18. The first, $\Omega(1/\varepsilon^2)$ follows from lemma 13 in [3]. We restate their argument here slightly adapted to our setup.

► **Lemma 21.** *Say there is an algorithm acting on $\rho^{\otimes k} \otimes \sigma^{\otimes k}$ that outputs an estimate of $\text{Tr}[M\rho M\sigma]$ to accuracy ε with high probability. Then, $k = \Omega(1/\varepsilon^2)$.*

Proof. Let $|0\rangle$ be such that $M|0\rangle = \pm 1$, which exists for since $\|M\| = 1$ and the unit sphere is compact. Let $|1\rangle$ be an eigenvector of M orthogonal to $|0\rangle$. Consider the states

$$|\psi_0\rangle = \sqrt{\frac{1}{2} - \varepsilon}|0\rangle + \sqrt{\frac{1}{2} + \varepsilon}|1\rangle, \quad |\psi_1\rangle = \sqrt{\frac{1}{2} + \varepsilon}|0\rangle + \sqrt{\frac{1}{2} - \varepsilon}|1\rangle. \quad (35)$$

Now, say that Alice is given k copies of $|\psi_0\rangle$ or $|\psi_1\rangle$ and Bob is given k copies of $|0\rangle$. We have that

$$|\langle\psi_0|M|0\rangle|^2 = \frac{1}{2} - \varepsilon, \quad |\langle\psi_1|M|0\rangle|^2 = \frac{1}{2} + \varepsilon. \quad (36)$$

Thus, if Alice and Bob can estimate $|\langle\psi|M|\phi\rangle|^2$ to accuracy ε , they can distinguish between these two states. However, the fidelity between these states is given by

$$F(\psi_0^{\otimes k}, \psi_1^{\otimes k}) = (1 - 4\varepsilon^2)^k \geq 1 - 4k\varepsilon^2, \quad (37)$$

which implies that $k = \Omega(1/\varepsilon^2)$. ◀

Before proving the second lower bound, we give some intuition. Say that $M \geq 0$. If $|\psi\rangle$ and $|\phi\rangle$ are drawn independently from the Haar measure, then

$$\mathbb{E}[\text{Tr}[M\psi M\phi]] = \text{Tr}[M^2]/d^2. \quad (38)$$

If they are identical, that is $\psi = \phi$ always, then instead the expected value is

$$\mathbb{E}[\text{Tr}[M\psi M\psi]] = \frac{1}{d(d-1)} (\text{Tr}[M^2] + \text{Tr}[M]^2). \quad (39)$$

The difference between these two is roughly $\text{Tr}[M^2]/d^2$. Thus, if Alice and Bob are able to estimate $|\langle\psi|M|\phi\rangle|^2$ to this order, then they can solve DIPE (that we defined as Problem 9). However, $\text{Tr}[M^2]/d^2$ may be quite small. Restricted to the support of M_ε , we instead have that $\varepsilon^2/4 \leq \text{Tr}[M_\varepsilon^2]/d_\varepsilon^2 \leq 1$. We will show that if Alice and Bob can estimate $|\langle\phi|M_\varepsilon|\psi\rangle|^2$, then they can solve the following decision problem, which is known to require $k = \Omega(\sqrt{\dim \mathcal{H}}/\varepsilon)$ samples [3] (when $\varepsilon \leq 0.01$).

11:14 Generalized Inner Product Estimation with Limited Quantum Communication

► **Definition 22** (Inner product estimation, ε decision version). *Let $\varepsilon > 0$. Alice and Bob are given k copies each of pure states $|\psi\rangle, |\phi\rangle \in \mathcal{H}$, for some finite dimensional Hilbert space \mathcal{H} . They are asked to decide, using LOCC, which of the following two scenarios they are in:*

■ **YES instance:**

$$|\psi\rangle = \sqrt{1 - \varepsilon}e^{i\theta} |0\rangle + \sqrt{\varepsilon} |\chi\rangle, \quad |\phi\rangle = \sqrt{1 - \varepsilon}e^{i\theta'} |0\rangle + \sqrt{\varepsilon} |\chi\rangle, \quad (40)$$

where $|\chi\rangle$ is drawn from the Haar measure on the orthogonal complement of $|0\rangle$ and θ and θ' are independently and uniformly drawn from $[0, 2\pi)$.

■ **NO instance:**

$$|\psi\rangle = \sqrt{1 - \varepsilon}e^{i\theta} |0\rangle + \sqrt{\varepsilon} |\chi\rangle, \quad |\phi\rangle = \sqrt{1 - \varepsilon}e^{i\theta'} |0\rangle + \sqrt{\varepsilon} |\varphi\rangle, \quad (41)$$

where $|\chi\rangle$ and $|\varphi\rangle$ are drawn independently from the Haar measure on the orthogonal complement of $|0\rangle$ and θ and θ' are independently and uniformly drawn from $[0, 2\pi)$.

We will require the two following technical lemmas in proving the lower bound. Here Lipschitz constants are taken to be with respect to the Euclidean norm $\|\cdot\|_2$.

► **Fact 23** (Levy's Lemma). *If $f : \mathbb{S}^d \rightarrow \mathbb{R}$ is λ -Lipschitz, then*

$$\Pr_u[|f(u) - \mathbb{E}[f(u)]| \geq t] \leq 2e^{-\frac{dt^2}{2\lambda^2}}, \quad (42)$$

where u is drawn from the Haar measure on \mathbb{S}^d .

► **Lemma 24.** *Let $c < 1$ be a sufficiently small constant. Say there is a protocol acting on $\rho^{\otimes k} \otimes \sigma^{\otimes k}$ via LOCC that outputs an estimate of $\text{Tr}[M\rho M\sigma]$ to accuracy $c\varepsilon$ with high probability. Then, $k = \Omega(\|M_\varepsilon\|_1/\varepsilon\sqrt{d_\varepsilon})$.*

Proof. Let $M|0\rangle = |0\rangle$ be stabilized by M . Such a vector exists by considering either M or $-M$, and we choose the appropriate sign without loss of generality. Let $W = \{|\psi\rangle \in \mathbb{C}^d \mid \langle 0|\psi\rangle = 0\} \cap \text{Im}P_\varepsilon$ and $\tilde{M}_\varepsilon = M_\varepsilon|_W$. Without loss of generality we assume that \tilde{M}_ε is a (semi)definite matrix. Indeed, let $\tilde{M}_\varepsilon = \tilde{M}_\varepsilon^+ - \tilde{M}_\varepsilon^-$ then $\|\tilde{M}_\varepsilon\|_2^2 = \|\tilde{M}_\varepsilon^+\|_2^2 + \|\tilde{M}_\varepsilon^-\|_2^2$. Of course, this means that $\|\tilde{M}_\varepsilon^+\|_2 \geq \|\tilde{M}_\varepsilon\|_2/\sqrt{2}$ or $\|\tilde{M}_\varepsilon^-\|_2 \geq \|\tilde{M}_\varepsilon\|_2/\sqrt{2}$. Thus, we restrict ourselves further and consider the subspace, again labeled by W , in the support of the operator with a larger norm.

We will now show that estimating $|\langle \phi|M|\psi\rangle|^2$ suffices to solve problem 22 with high probability where $\mathcal{H} = \mathbb{C}|0\rangle \oplus W$. Let $\tilde{d} := \dim W$. Set the precision parameter in problem 22 to be $\delta := \varepsilon\tilde{d}/200\text{Tr}[\tilde{M}_\varepsilon]$ and define $\vartheta := \theta - \theta'$. Since $\text{Tr}[\tilde{M}_\varepsilon] \geq \varepsilon\tilde{d}/2$, $\delta \leq 0.01$ as required. Let f be Alice and Bob's estimate of $|\langle \phi|M|\psi\rangle|^2$, and say that it is within $c \cdot \varepsilon$ of the true value with probability at least 0.99. Then, if f lies in the range $[(1 - \delta)^2 - 3c \cdot \varepsilon, (1 - \delta)^2 + c \cdot \varepsilon]$, they REJECT. Otherwise, they ACCEPT. We split the proof into the two cases.

YES instance: in this case

$$|\langle \phi|M|\psi\rangle|^2 = (1 - \delta)^2 + \delta^2\text{Tr}[M\chi]^2 + 2\delta(1 - \delta)\cos\vartheta\text{Tr}[M\chi]. \quad (43)$$

Thus,

$$\Pr[f \in [(1 - \delta)^2 - \frac{\delta}{8}, (1 - \delta)^2 + x]] \quad (44)$$

$$\leq \Pr[\delta^2\text{Tr}[M\chi]^2 + 2\delta(1 - \delta)\cos\vartheta\text{Tr}[M\chi] \in [-\frac{\delta}{8} - c\varepsilon, \frac{\delta}{8} + c\varepsilon]] + 0.01. \quad (45)$$

$\text{Tr}[M\chi]$ is 2-Lipschitz:

$$|\langle\psi|M|\psi\rangle - \langle\phi|M|\phi\rangle| = |(\langle\psi| - \langle\phi|)M|\psi\rangle - \langle\phi|M(|\phi\rangle - |\psi\rangle)| \quad (46)$$

$$\leq |(\langle\psi| - \langle\phi|)M|\psi\rangle| + |\langle\phi|M(|\phi\rangle - |\psi\rangle)| \quad (47)$$

$$\leq 2\| |\psi\rangle - |\phi\rangle \|, \quad (48)$$

where the final inequality follows from $\|M\| = 1$ and Cauchy-Schwarz. Then, using fact 23, it holds that

$$\Pr \left[|\text{Tr}[M\chi] - \mathbb{E}_\chi[\text{Tr}[M\chi]]| \leq \frac{7}{\sqrt{\tilde{d}}} \right] > 0.99. \quad (49)$$

We now have that $\frac{7}{\sqrt{\tilde{d}}} \leq \frac{\text{Tr}[\tilde{M}_\varepsilon]}{4\tilde{d}}$, since $28/\sqrt{\tilde{d}} \leq \varepsilon$. But notice that if $\varepsilon = o(1/\sqrt{\tilde{d}})$, then the lower bound $k = \Omega(1/\varepsilon^2) = \Omega(d)$ dominates since $\|M_\varepsilon\|_2/\sqrt{\varepsilon} \leq \sqrt{\tilde{d}}/\sqrt{\varepsilon} = o(1/\varepsilon^2)$. The above bounds imply that we can take $\text{Tr}[M\chi]^2 \leq 25\text{Tr}[\tilde{M}_\varepsilon]^2/16\tilde{d}^2$. We are then interested in the probability

$$\Pr \left[2\delta(1-\delta)\frac{3\text{Tr}[\tilde{M}_\varepsilon]}{4\tilde{d}} \cos \vartheta \in \left[-\frac{\delta}{8} - c\varepsilon - \delta^2\frac{25\text{Tr}[\tilde{M}_\varepsilon]^2}{16\tilde{d}^2}, \frac{\delta}{8} + c\varepsilon - \delta^2\frac{\text{Tr}[\tilde{M}_\varepsilon]^2}{\tilde{d}^2} \right] \right]. \quad (50)$$

Now, by construction $\delta \leq 0.01$ and thus $2(1-\delta) \geq 99/50$. It follows that

$$2\delta(1-\delta)\frac{3\text{Tr}[\tilde{M}_\varepsilon]}{4\tilde{d}} \geq \frac{297}{40000}\varepsilon. \quad (51)$$

Then, the above probability is upper bounded by

$$\Pr \left[\cos \vartheta \in \left[-\frac{1}{2} - \frac{25\varepsilon}{4752}, \frac{1}{2} + \frac{\varepsilon}{297} \right] \right] \leq \Pr [\cos \vartheta \in [-0.51, 0.51]] \leq 0.34. \quad (52)$$

In total, they accept in the YES case with probability at least 0.66.

NO instance: in this case

$$|\langle\varphi|M|\chi\rangle|^2 = (1-\delta)^2 + \delta^2\text{Tr}[M\varphi M\chi] + 2\delta(1-\delta)\text{Re}(e^{i\vartheta}\langle\varphi|M|\chi\rangle). \quad (53)$$

By symmetry, $\mathbb{E}[\text{Re}(e^{i\vartheta}\langle\varphi|M|\chi\rangle)] = 0$. Now, fixing $|\varphi\rangle$, $|\langle\varphi|M|\chi\rangle|$ is 1-Lipschitz in $|\chi\rangle$. This implies that $|\langle\varphi|M|\chi\rangle| \leq 8/\sqrt{\tilde{d}}$ with probability at least 0.999. This then implies that $\text{Tr}[M\varphi M\chi] \leq 84/\tilde{d}$. Then, we have that

$$|\langle\varphi|M|\chi\rangle|^2 - (1-\delta)^2 \leq \frac{\delta}{\sqrt{\tilde{d}}} \left(\frac{84}{\sqrt{\tilde{d}}} + 16 \right). \quad (54)$$

Further, $\delta/\sqrt{\tilde{d}} \leq 1/100\sqrt{\tilde{d}}$. We assume that $84/\sqrt{\tilde{d}} < 1$ (as otherwise the lower bound is constant anyways) and obtain

$$|\langle\varphi|M|\chi\rangle|^2 - (1-\delta)^2 \leq \frac{17}{100\sqrt{\tilde{d}}}. \quad (55)$$

We require that this is less than $c\varepsilon/3$. This requires that $\varepsilon = \Omega(1/\sqrt{\tilde{d}})$, but, as previously stated, we assume this as otherwise the other lower bound dominates. The total probability for this instance to be rejected is then at least 0.9.

Thus, Alice and Bob are able to solve problem 22 with high probability. Then, it must be that $k = \Omega(\sqrt{\tilde{d}}/\delta) = \Omega(\text{Tr}[\tilde{M}_\varepsilon]/\varepsilon\sqrt{\tilde{d}})$. ◀

► **Corollary 25.** *Let $c < 1$ be a sufficiently small constant. Say there is a protocol acting on $\rho^{\otimes k} \otimes \sigma^{\otimes k}$ via LOCC that outputs an estimate of $\text{Tr}[M\rho M\sigma]$ to accuracy $c\varepsilon$ with high probability. Then, $k = \Omega(\|M_\varepsilon\|_2/\sqrt{\varepsilon})$.*

Proof. Lemma 24 yields a lower bound of $k = \Omega(\text{Tr}[\tilde{M}_\varepsilon]/\varepsilon\sqrt{\tilde{d}})$. Using $\text{Tr}[\tilde{M}_\varepsilon] \geq \|\tilde{M}_\varepsilon\|_2^2$ and $\|\tilde{M}_\varepsilon\|_2 \geq \sqrt{\varepsilon\tilde{d}/2}$, we arrive at our claimed lower bound of $k = \Omega(\|M_\varepsilon\|_2/\sqrt{\varepsilon})$. ◀

Abstract

We study the property of H -freeness in graphs with known bounded average degree, i.e. the property of a graph not containing some graph H as a subgraph. H -freeness is one of the fundamental graph properties that has been studied in the property testing framework.

Levi [10] showed that triangle-freeness is testable in graphs of bounded *arboricity*, which is a superset of e.g. planar graphs or graphs of bounded degree. Complementing this result is a recent preprint [7] by Eden *et al.* which shows that, for every $r \geq 4$, C_r -freeness is not testable in graphs of bounded arboricity.

We proceed in this line of research by using the r -admissibility measure that originates from the field of structural sparse graph theory. Graphs of bounded 1-admissibility are identical to graphs of bounded arboricity, while graphs of bounded degree, planar graphs, graphs of bounded genus, and even graphs excluding a fixed graph as a (topological) minor have bounded r -admissibility for any value of r [12].

In this work we show that H -freeness is testable in graphs with bounded 2-admissibility for all graphs H of diameter 2. Furthermore, we show the testability of C_4 -freeness in bounded 2-admissible graphs directly (with better query complexity) and extend this result to C_5 -freeness. Using our techniques it is also possible to show that C_6 -freeness and C_7 -freeness are testable in graphs with bounded 3-admissibility. The formal proofs will appear in the journal version of this paper.

These positive results are supplemented with a lower bound showing that, for every $r \geq 4$, C_r -freeness is not testable for graphs of bounded $(\lfloor r/2 \rfloor - 1)$ -admissibility. This lower bound will appear in the journal version of this paper. This implies that, for every $r > 0$, there exists a graph H of diameter $r + 1$, such that H -freeness is not testable on graphs with bounded r -admissibility. These results lead us to the conjecture that, for every $r > 4$, and $t \leq 2r + 1$, C_t -freeness is testable in graphs of bounded r -admissibility, and for every $r > 2$, H -freeness for graphs H of diameter r is testable in graphs with bounded r -admissibility.

1 Introduction

A *graph property* is a class of graphs closed under isomorphisms. A property-tester for a property P is a probabilistic algorithm that receives as input the size of a graph G , a distance parameter $\epsilon > 0$ (among potentially other parameters), and oracle access to the graph G . The algorithm accepts with probability at least $2/3$ any input from P and rejects with probability at least $2/3$ an input that it is ϵ -far from the property P . The term “ ϵ -far” is a notion of distance that depends on the exact problem setting and discuss it further

below. The complexity measure of a property-tester is a function that bounds above the total number of queries to the oracle the algorithm uses, as a function of the input parameters ϵ , size of the graph and any other input parameters provided. A property is *testable* if it has a property-tester whose query complexity is independent of the size of the input graph.

We study here the property of H -freeness, where H is a fixed known graph, i.e. the property of graphs that do not have a subgraph isomorphic to H , which is one of the fundamental graph properties that has been studied in the property testing framework. H -freeness was studied in the dense, sparse and general graph models. In the dense model it was shown implicitly in [1] that H -freeness is testable, for a more explicit result see [2]. Goldreich and Ron [8], showed that H -freeness is testable in the bounded degree graph model. In an effort to move towards larger sparse¹ graph classes, Czumaj *et al.* [4] showed that H -freeness is testable in sparse graphs when H is a tree. This result is most likely tight for sparse graphs as Alon *et al.* [3] showed that triangle-freeness is not testable in sparse graphs.

While this settles the question for the most general notion of sparse graphs, the question is still open for a plethora of sparse graph subclasses which are more structured. Possibly the most famous among them is the class of planar graphs. Czumaj *et al.* [5] showed that H -freeness is testable for this class. Proceeding in this line of research, and moving to a much larger class of sparse graphs, Levi [10] showed that triangle-freeness is testable in graphs of bounded *arboricity*, which is a superset of the family of planar graphs. In Eden *et al.* [7] it is shown that, for every $r \geq 4$, C_r -freeness is not testable in graphs of bounded arboricity. Specifically, it is shown that, in graphs of bounded arboricity, the query complexity of C_4 -freeness and C_5 -freeness is $\tilde{\Theta}(n^{1/4})$, the query complexity of C_6 -freeness is $\tilde{O}(n^{1/2})$, and for every $k \geq 6$, the query complexity of C_k -freeness is $O(n^{1-1/\lfloor k/2 \rfloor})$ and $\Omega(n^{1/3})$. These results also leave open the question of which sparse classes – somewhere between bounded arboricity and planar graphs – and which values of r is C_r -freeness testable.

In order to identify a suitable notion of sparseness, we draw inspiration from the field of structural sparse graph theory and propose the r -admissibility measure of graphs as a parameter that governs the testability of H -freeness. 2-admissibility was originally defined in [9], where it was simply referred to as admissibility. The more general notion of r -admissibility² for natural values of r was first defined in [6]. Strictly speaking, r -admissibility is a family of measures where r governs how “deep” into the graph we look. We remark that, graph classes with bounded 1-admissibility are equivalent to graphs with bounded arboricity (both measures lie within a constant factor of each other). Many well-known sparse classes, like planar graphs, graphs of bounded genus, graphs excluding a fixed (topological) minor and graphs of bounded degree have bounded r -admissibility [12, 14, 6] meaning that the r -admissibility of any member of such a class can be bounded by a function which only depends on r and the class itself.

We show that C_4 -freeness is testable in graphs with bounded 2-admissibility, and that H -freeness, for every H of diameter 2, is also testable in graphs with bounded 2-admissibility and in particular C_5 -freeness is testable in graphs with bounded 2-admissibility. Using our techniques it is possible to show that C_6 and C_7 are testable in graphs with bounded 3-admissibility. This result will appear in the journal version of this paper that will also contain a lower bound which shows that, for every $r \geq 4$, C_r -freeness is not testable in

¹ Here sparse should be understood as having a linear number of edges or equivalently bounded average degree

² If you are interested in a more formal definition in this stage, we suggest that you proceed to Section 3, and read up to Proposition 3 before you proceed here.

graphs of bounded $(\lfloor r/2 \rfloor - 1)$ -admissibility. This implies that for every $r > 0$, there exists a graph H of diameter $r + 1$ such that H -freeness is not testable on graphs with bounded r -admissibility. The above leads us to conjecture that, for every $r \in \mathcal{N}$ and $t \leq 2r + 1$, C_t -freeness is testable in graphs with bounded r -admissibility and furthermore for every $r > 2$, H -freeness, for H of diameter r , is testable in graphs with bounded r -admissibility.

Techniques

All the lower bounds use Yao’s Minimax Principle [13] and the construction of suitable input instances. The graph constructions used for the lower bounds, unsurprisingly, are very similar to the ones used in [7] to prove a lower bound on testing C_4 -freeness in bounded arboricity graphs. We chose to provide our lower bounds here and not refer to [7], to demonstrate how they apply to testing C_r -freeness of graphs of bounded $\lfloor r/2 \rfloor - 1$ -admissibility, for natural values of r . This is not covered in [7]. In addition, the graphs provided in the proof also demonstrate that, for every natural value of r and large enough n , there are bounded r -admissibility graphs with n vertices some of which have degree $\Omega(\sqrt{n})$. It should be noted that these graphs are also “far” from being planar.

All upper bounds are based on the same algorithm and can be seen as a variation of the “standard” BFS (breadth first search) based testers for the bounded degree graph model. Many examples of “standard” BFS testers can be found in [8]. In such testers, initially a small subset of the vertices of the graph is selected uniformly at random (u.a.r.) and then a fixed depth BFS is performed (using oracle queries) from every vertex in the selected set. The tester presented here (Algorithm 1) differs from the “standard” testers at the BFS stage as follows: While the “standard” testers queries proceeds with the BFS by querying all neighbours of a vertex v , Algorithm 1 randomly selects size at most $\min\{\alpha, \deg_G(v)\}$ subset of $[\deg_G(v)]$, where α is a parameter provided to the algorithm and $\deg_G v$ is the degree of the vertex v in the input graph G , and queries the identity of the i th neighbour of the vertex, for every i in the selected set. We note Algorithm 1 behaves like the “standard” BFS based tester if the input graph has maximum degree α .

Algorithm 1 has a one-sided error, i.e. it only rejects if it detects an H -subgraph (a subgraph that is isomorphic to H), therefore, to prove its correctness, it is sufficient to show that, given oracle access to a bounded admissibility graph that is ϵ -far from being H -free, Algorithm 1 rejects with high probability.

H-subgraph

To prove the required rejection probability we show the following. Given an input graph G with bounded admissibility, we can remove edges from the graph in a process we refer to as *trimming* to obtain a new auxiliary graph \tilde{G} . We relate this graph \tilde{G} to G in two ways: first we show that if G is far from H -freeness, then so is \tilde{G} . Then we show that if there exists an H -subgraph in \tilde{G} , then this subgraph includes a vertex with low degree, such that if Algorithm 1 starts its search from this vertex in G (not in \tilde{G}), then with high probability it will discover an H -subgraph (though not necessarily the one we just referred to). The “high probability” is proved to be sufficiently large by using the properties of the graph \tilde{G} . Note that the construction of \tilde{G} is only a tool for this proof, it is not actually constructed by the testing algorithm.

Finally, we show that when \tilde{G} is far from being H -free, then there are many such low degree vertices in G . This implies that with sufficiently high probability Algorithm 1 initially selects such a vertex.

2 Preliminaries

$\mathcal{N}, \mathcal{R}, [k]$ We use \mathcal{N} for the set of integer numbers, \mathcal{R} for the set of real numbers, \mathcal{R}^+ for the set of positive real numbers. For an integer k , we use $[k]$ as a shorthand for the set $\{1, 2, \dots, k\}$. In this paper, all graphs are simple. For a graph G we use $V(G)$ and $E(G)$ to refer to its vertex- and edge-set, respectively. For a vertex $u \in V(G)$ we use the notation $N_G(u)$ to denote the set of all of u 's neighbours in G . We omit the subscript, when clear for context. The diameter of a graph is the maximum of the distance between u and v over all pairs of vertices u and v in $V(G)$.

Heavy We use the notation $\text{Heavy}_\alpha(G)$, where $\alpha \in \mathcal{N}$ to denote the set of vertices in $V(G)$ that have degree larger than α . We write Heavy_α when G is clear from context. In some places we will use the notation without initially stating the value of α , in those cases α is calculated further down when its concrete value is required.

xPy For sequences of vertices x_1, x_2, \dots, x_ℓ , in particular paths, we use notations like x_1Px_ℓ , x_1 or x_1P or Px_ℓ to indicate subpaths P that are part of the larger path. For example, the notation uPv for a path u, a, b, c, v would mean that P is the subpath a, b, c , whereas uP in the same context would mean that P is the subpaths a, b, c, v . All the paths in this paper are simple. Though paths here are undirected, we often treat them as directed by specifying a start and end vertex.

Property testing

We work only with properties of (p, r) -admissible graphs, which we formally define in the next section. At this stage it is enough to know that both p and r take integer values that are strictly positive and that a (p, r) -admissible graph of n vertices can have at most pn edges.

graph property, far, close A *graph property* (or simply *property* in this paper) is a class of graphs closed under isomorphism and we say that a graph has the property if it is contained in this class. The distance of a graph G from a property of (p, r) -admissible graphs is the minimum number of edges that must be removed/added to G in order to arrive at a (p, r) -admissible graph with the property. We say a graph is ϵ -far from a property of (p, r) -admissible graph, if the graph's distance to the property is at least ϵpn (an ϵ portion of the maximum number of edges possible in (p, r) -admissible graphs) and otherwise we say that it is ϵ -close to the property.

Property tester A property tester is a randomised algorithm that receives oracle access to a graph as part of its input. An oracle can answer the following queries for vertices $u, v \in V(G)$:

- the degree $\deg(v)$ of a vertex v (degree query),
- the i th neighbour of v in G (neighbour query),
- whether $\{u, v\}$ is an edge in G (adjacency query).

By combining these queries it can in particular reveal the whole neighbourhood of a vertex v using $1 + \deg(v)$ queries. The oracle returns the special symbol " \perp " when asked out of range neighbour queries, e.g. when asked to return the 10th neighbour of a vertex with less than 10 neighbours.

Formally, a *property tester* for a property P of (p, r) -admissible graphs, is a randomized algorithm \mathcal{A} that receives as input parameters $n \in \mathcal{N}$, $p, r \in [n]$, $\epsilon > 0$ and oracle access to a (p, r) -admissible graph G with n vertices. If the graph G is ϵ -far from P , then \mathcal{A} rejects with probability at least $2/3$. If the graph G is in P , then \mathcal{A} accepts with probability 1 (if the tester is *one-sided*) or with probability at least $2/3$ (if the tester is *two-sided*). The

complexity measure of a property tester is a function depending on n, p, r , and ϵ which bounds the maximum number of queries the tester makes on an input graph with those parameters.

In this paper, we study the property of (p, r) -admissible graphs that are H -free. That is, graphs that are (p, r) -admissible and do not have any H -subgraph (a subgraph isomorphic to H). In some cases, H may be a specific graph, for example, H may be a C_i (cycle of length i), for some $i \geq 3$ and we then refer to the problem as C_i -freeness.

In further sections, we use the term *knowledge graph* to refer to the graph that includes all the vertices, edges and anti-edges (learned from negative answers to neighbour queries) that the algorithm discovered via queries.

H-free,
H-subgraph

Knowledge graph

3 Graph degeneracy and admissibility, related notations and necessary lemmas

An *ordered graph* is a pair $\mathbb{G} = (G, \leq)$ where G is a graph and \leq is a total order relation on $V(G)$. We write $\leq_{\mathbb{G}}$ to denote the ordering of \mathbb{G} and extend this notation to derive relations $<_{\mathbb{G}}, >_{\mathbb{G}}, \geq_{\mathbb{G}}$. For simplicity we will call \mathbb{G} an *ordering of G* and we write $\pi(G)$ for the set of all possible orderings of G .

\mathbb{G} , *ordered graph,*
 $\pi(G)$

We use the same notations for graphs and ordered graphs, additionally we write $N_{\mathbb{G}}^-(u) := \{v \in N(u) \mid v <_{\mathbb{G}} u\}$ for the *before neighbourhood* and $N_{\mathbb{G}}^+(u) := \{v \in N(u) \mid v >_{\mathbb{G}} u\}$ for the *after neighbourhood* of a vertex $u \in \mathbb{G}$. We omit the graphs in the subscripts if clear from the context. We further use $\deg_{\mathbb{G}}^-(u) := |N_{\mathbb{G}}^-(u)|$ and $\deg_{\mathbb{G}}^+(u) := |N_{\mathbb{G}}^+(u)|$, as well as $\Delta^-(\mathbb{G}) := \max_{u \in \mathbb{G}} \deg_{\mathbb{G}}^-(u)$ and $\Delta^+(\mathbb{G}) := \max_{u \in \mathbb{G}} \deg_{\mathbb{G}}^+(u)$. We omit subscripts if clear from the context.

before and after
neighbourhood,
 $N_{\mathbb{G}}^-(u), N_{\mathbb{G}}^+(u),$
 $\Delta_{\mathbb{G}}^+(u), \Delta^-(\mathbb{G})$

► **Definition 1 (Degeneracy).** A graph G is γ -degenerate if there exists an ordering \mathbb{G} (a degeneracy ordering) such that $\Delta^-(\mathbb{G}) \leq \gamma$.

Degeneracy

In particular, for every vertex v in a γ -degenerate graph G and every degeneracy ordering \mathbb{G} of the graph it holds that $\deg_{\mathbb{G}}^-(v) \leq \gamma$. Consequently, the number of edges in a γ -degenerate graph is bounded by γn . A degeneracy ordering of a graph can be computed in time $O(n+m)$ and $O(\gamma n)$ for γ -degenerate graphs [11].

Admissibility

■ **Figure 1** On the left, the green highlighted edges form an example of a maximal 2-admissible path packing of size 2 that is rooted at the blue vertex in position 5. On the right, the yellow highlighted edges form an example of a maximal 3-admissible path packing of size 3 that is rooted at the blue vertex in position 5. In both packings the only vertex common to all the paths is their root. Also in both packing every path’s end vertex is smaller than the root and all the path’s internal vertices are all larger than the root.

Let $\mathbb{G} = (G, \leq)$ and $v \in V(G)$. A path vPx is r -admissible in \mathbb{G} if its length $\|vPx\| \leq r$, $x <_{\mathbb{G}} v$ and $\min P >_{\mathbb{G}} v$. That is, the path goes from v to x using only vertices w such that $w >_{\mathbb{G}} v$ and x satisfies $v >_{\mathbb{G}} x$.

r-admissible path

12:6 Results on H -Freeness Testing in Graphs of Bounded r -Admissibility

Target For every integer $i > 0$ we let $\text{Target}_{\mathbb{G}}^i(v)$ be the set of all vertices $u \in V(G)$ such that $u <_{\mathbb{G}} v$ and u is reachable from v via an r -admissible path vPu of length exactly i . We omit the subscript \mathbb{G} when it is clear from context.

(r, \mathbb{G}) -admissible path packing An r -admissible path packing is a collection of paths $\{vP_i x_i\}_i$ with joint root v and the additional properties that every path $vP_i x_i$ is r -admissible and the subpaths $P_i x_i$ are all pairwise vertex-disjoint (cf. Figure 1). In particular, all endpoints $\{x_i\}_i$ are distinct. We write $\text{pp}_{\mathbb{G}}^r(v)$ to denote maximum size of any r -admissible path packing rooted at v .

► **Definition 2** (Admissibility). *The r -admissibility of an ordered graph \mathbb{G} , denoted $\text{adm}_r(\mathbb{G})$ and the admissibility of an unordered graph G , denoted $\text{adm}_r(G)$ are³*

$$\text{adm}_r(\mathbb{G}) := \max_{v \in \mathbb{G}} \text{pp}_{\mathbb{G}}^r(v) \quad \text{and} \quad \text{adm}_r(G) := \min_{\mathbb{G} \in \pi(G)} \text{adm}_r(\mathbb{G}).$$

Admissibility ordering If \mathbb{G} is an ordering of G such that $\text{adm}_r(\mathbb{G}) = \text{adm}_r(G)$, then we call \mathbb{G} an *admissibility ordering* of G . The 1-admissibility of a graph coincides with its degeneracy and therefore such orderings are easily computable in linear time. For $r \geq 2$ an optimal ordering can also be computed in linear time in n , albeit the machinery required is much more complicated, see [6].

(p, r) -admissible, adm_r -bounded We say that a graph G is (p, r) -admissible if $\text{adm}_r(G) = p$. Note that, by definition, if a graph G is (p, r) -admissible it is also (p, r') -admissible for all $r' \leq r$. We call a graph class adm_r -bounded if all of its members are (p, r) -admissible for some finite value p .

The following is a well-known result in the field of sparse graphs, we replicate it here using our notation for completeness:

► **Proposition 3.** *Let r and p be natural numbers, and $\mathbb{G} = (G, \leq)$ such that $\text{adm}_r(G) = p$, then for every $v \in V(G)$, and $h \in [r]$ it holds that $|\text{Target}_{\mathbb{G}}^h(v)| \leq p(p-1)^{h-1}$ and in particular $|N_{\mathbb{G}}^-(v)| \leq p$.*

Proof. Let v be an arbitrary vertex in $V(G)$, and $h \in [r]$. Note first that, by construction, $N_{\mathbb{G}}^-(v) = \text{Target}_{\mathbb{G}}^1(v)$, and hence we only need to prove the bound on $|\text{Target}_{\mathbb{G}}^h(v)|$.

For every $u \in \text{Target}_{\mathbb{G}}^h(v)$, let $vP_u u$ be an r -admissible path of length h ; such a path exists by the definition of $\text{Target}_{\mathbb{G}}^h(v)$. Let W be a subgraph of G defined as follows: $V(W)$ includes exactly the vertex v , all the vertices in $\text{Target}_{\mathbb{G}}^h(v)$ and all the vertices in P_u , for every $u \in \text{Target}_{\mathbb{G}}^h(v)$; and $E(W)$ includes every edge of G participating in a path $vP_u u$ for some $u \in \text{Target}_{\mathbb{G}}^h(v)$.

By construction, the set of vertices $\text{Target}_{\mathbb{G}}^h(v)$ is independent in W and for every $w \in \text{Target}_{\mathbb{G}}^h(v)$, $\deg_W(w) = 1$. Also by construction, the distance in W of v from any vertex in $\text{Target}_{\mathbb{G}}^h(v)$ is at most h . Hence, we can find a rooted tree T in W with the following properties: v is the root of T , the set $\text{Target}_{\mathbb{G}}^h(v)$ is the set of leaves of T and the depth of T is at most h .

We next show that the degree of every vertex in the tree is at most p . This implies that indeed $|\text{Target}_{\mathbb{G}}^h(v)| \leq p(p-1)^{h-1}$ and in particular $|N_{\mathbb{G}}^-(v)| \leq p$.

Let p_v be the degree of v in W . Since T is a tree, there are at most p_v edge disjoint paths from v to the leaves of T (the vertices in $\text{Target}_{\mathbb{G}}^h(v)$). These paths have length at most h , they share only the vertex v , and they correspond to r -admissible paths of \mathbb{G} . The last part holds since $u >_{\mathbb{G}} v$, for every internal vertex u (non-leaf or root vertex) of T and,

³ Note that some authors choose to define the admissibility as $1 + \max_{v \in \mathbb{G}} \text{pp}_{\mathbb{G}}^r(v)$ as this matches with some other, related measures.

for every $w \in \text{Target}_{\mathbb{G}}^h(v)$ (the leaves of T), it holds that $w <_{\mathbb{G}} v$. Therefore, these paths are an r -admissible packing of \mathbb{G} , and hence their number $p_v \leq p$, and in particular the degree of v in T is at most p .

We now show that this applies also to every internal vertex y of T . We notice that it also holds that $w <_{\mathbb{G}} y$, for every $w \in \text{Target}_{\mathbb{G}}^h(v) \cup \{v\}$. However, it is not necessarily the case that $u <_{\mathbb{G}} y$ when u is an internal vertex of T . This is resolved by noticing that for any $x \in \text{Target}_{\mathbb{G}}^h(v)$ and path yPx in T , if P has a vertex that is smaller than y , then instead of taking the path yPx , we take its shortest subpath $yP'x'$ such that $x' <_{\mathbb{G}} y$. Now, the same reasoning we used for v implies that the degree of y in T is at most p . ◀

4 Upper bounds strategy and the testing algorithm

In this section we present Algorithm 1 which is used for all upper bounds presented. Algorithm 1 receives as an input a graph H , a set of parameters including the parameter p and oracle access to a graph G . We note that for each upper bound shown in this paper, the parameters provided to Algorithm 1, in addition to p , are dependent on the graph H .

■ **Algorithm 1** The PBFS.

 Accept

Algorithm 1 can be seen as a variation of the “standard” BFS (breadth first search) based testers for properties of bounded degree graphs. In such testers, initially a small subset of the graph’s vertices is randomly selected and then a fixed depth BFS is performed (using oracle queries) from every vertex in the selected set.

Algorithm 1 differs from the “standard” testers, at the BFS stage: In the “standard” tester the search is expanded to all neighbours of a discovered vertex (until the fixed depth is reached). In contrast, Algorithm 1 only queries a subset of neighbours, specifically for

12:8 Results on H -Freeness Testing in Graphs of Bounded r -Admissibility

a vertex v it randomly selects a size at most $\min\{\deg(v), \lceil \alpha \rceil\}$ subset $X \subseteq [\deg_G(v)]$ and then it queries the identity of every i th neighbour for $i \in X$. We call this type of search *PBFS* *pseudo-BFS* and refer to it with the acronym *PBFS*.

► **Lemma 4.** *On input $n \in \mathcal{N}$, $p \in [n]$, $\alpha, \tau \in \mathbb{R}$, $\epsilon > 0$, fixed graph H , the query complexity of Algorithm 1 is $O((\alpha/(\epsilon p))\alpha^\tau)$.*

Proof. The proof follows directly from the algorithm. ◀

Upper bound strategy

Algorithm 1 has a one-sided error, i.e. it only rejects if it discovers an H -subgraph. That is, once Algorithm 1 finished its last query, its knowledge graph has an H -subgraph). Therefore, to prove its correctness, it is sufficient to show that, with high constant probability, it rejects a bounded admissibility graph that is ϵ -far from being H -free.

To prove the required rejection probability we proceed as follows: given an input graph G with bounded admissibility, a new graph \tilde{G} is constructed by initially setting $\tilde{G} = G$, and then removing edges from \tilde{G} , in a process we refer to as *trimming*. We call \tilde{G} the auxiliary graph.

We relate the auxiliary graph \tilde{G} to G in two ways: first we show that if G is far from H -freeness, then so is \tilde{G} . Then we show that if there exists an H -subgraph in \tilde{G} , then this subgraph includes a vertex with low degree, such that assuming Algorithm 1 starts its search from this vertex in G (not in \tilde{G}), then with high probability it will discover an H -subgraph of G (though not necessarily the one we just referred to). The “high probability” is proved to be sufficiently large by using the properties of the graph \tilde{G} . Finally, we show that when \tilde{G} is far from being H -free, then there are many such low degree vertices in G . This implies that with sufficiently high probability Algorithm 1 initially selects such a vertex in the sample set S_0 .

The “trimming” process is problem dependent. The simplest case is for C_4 -freeness in adm_2 -bounded graphs and we provide some intuition here before the full formal treatment in the next section. Suppose that $v \in \text{Heavy}_\alpha$ and $u \in \text{Target}_\mathbb{C}^2(v)$. Suppose also that the set X of their common neighbours, not including those in Heavy_α , is small relative to the degree of v in G . In the trimming process we then remove all edges that are incident to v as well as some vertex in X . We can then show that (i) we did not remove too many edges and (ii) if u and v participate in a C_4 -subgraph (a subgraph isomorphic to a C_4) in \tilde{G} , then a large enough portion of the neighbours of v , are also neighbours of u and are not in Heavy_α . Therefore, if v is encountered in the first iteration of the external loop of Algorithm 1 (guaranteed to happen if S_0 has a neighbour of v that is not in Heavy_α), then with high probability the knowledge graph will include two edges vw_1 and vw_2 , where w_1 and w_2 are not in Heavy_α and are common neighbours of both u and v . Since the PBFS continues with these common neighbour and they are both not in Heavy_α , the edges uw_1 and uw_2 will also appear in the knowledge graph. Thus, the knowledge graph contains a C_4 -subgraph. Similar – but more involved – ideas work for H -freeness, when H has diameter 2 and for C_6 -freeness and C_7 -freeness.

It is important to note that proving the above properties (i) and (ii) hold relies on the graph G being adm_r -bounded (for some problem-dependent value of r), and we make extensive use of Proposition 3.

5 Testing C_4 -freeness in adm_2 -bounded graphs

In this section we fix some $\epsilon > 0$, an integer $p > 0$, $\alpha = 32p^2/\epsilon$. The input graph G is $(p, 2)$ -admissible and we let \mathbb{G} be an ordering of G with $\text{adm}_2(\mathbb{G}) = p$.

Trimming. In the trimming procedure we construct \tilde{G} from G . We begin with $\tilde{G} = G$ and then remove edges from $E(\tilde{G})$ as follows:

1. For every $v \in \text{Heavy}_\alpha(G)$, and $u \in N^-(v)$, the edge uv is removed from $E(\tilde{G})$.
2. For every $v \in V(G)$ and $u \in \text{Target}_{\mathbb{G}}^2(v)$, if $|N_{\tilde{G}}(u) \cap N_{\tilde{G}}(v)| \leq \deg_G(v)/(\alpha/2)$, then for every $w \in N_{\tilde{G}}(u) \cap N_{\tilde{G}}(v)$, the edge vw is removed from $E(\tilde{G})$.
3. The previous step is repeated until it does not result in the removal of any edges from $E(\tilde{G})$.

We first show that this trimming procedure preserves farness:

► **Lemma 5.** *If G is ϵ -far from being C_4 -free, then \tilde{G} is $\epsilon/2$ -far from being C_4 -free.*

Proof. Initially $E(\tilde{G}) = E(G)$ and then edges are removed from $E(\tilde{G})$ in Steps 1 and 2 of the trimming. We next show that, in Step 1 of the trimming, at most $\epsilon|E(G)|/4$ edges are removed from $E(\tilde{G})$, and that the same applies to Step 2 of the trimming. This implies the lemma.

In Step 1 of the trimming, for every $v \in \text{Heavy}_\alpha(G)$ we remove $|N_{\tilde{G}}^-(v)|$ edges. Thus, the total number of edges removed in this step is at most $\sum_{v \in \text{Heavy}_\alpha(G)} |N_{\tilde{G}}^-(v)|$. By Proposition 3, for every $u \in V(G)$, it holds that $|N_{\tilde{G}}^-(u)| \leq p$. Hence, the preceding sum is at most $\sum_{v \in \text{Heavy}_\alpha(G)} p = p \cdot |\text{Heavy}_\alpha(G)|$ and

$$p \cdot |\text{Heavy}_\alpha(G)| = \frac{p \cdot |\text{Heavy}_\alpha(G)|}{|E(G)|} |E(G)| \leq \frac{p \cdot |\text{Heavy}_\alpha(G)|}{\alpha |\text{Heavy}_\alpha(G)|/2} |E(G)| = \frac{2p}{\alpha} |E(G)| < \frac{\epsilon pn}{4},$$

where the first inequality follows since $|E(G)| \geq \alpha |\text{Heavy}_\alpha(G)|/2$ (the sum of degrees is twice the number of edges), and the last equality holds because $\alpha = 32p^2/\epsilon$.

In Step 2 of the trimming, for every $v \in V(G)$ and $u \in \text{Target}_{\mathbb{G}}^2(v)$ at most $\deg_G(v)/(\alpha/2)$ edges are removed. Thus, in this step, at most $\sum_{v \in V(G)} \sum_{u \in \text{Target}_{\mathbb{G}}^2(v)} \deg_G(v)/(\alpha/2)$ edges are removed. By Proposition 3, for every $u \in V(G)$, it holds that $|\text{Target}_{\mathbb{G}}^2(u)| < p^2$. Hence, the preceding sum is strictly less than $\sum_{v \in V(G)} p^2 \deg_G(v)/(\alpha/2) = (\epsilon/8) \sum_{v \in V(G)} \deg_G(v) \leq \epsilon pn/4$, where the first equality follows because $\alpha = 32p^2/\epsilon$. ◀

► **Lemma 6.** *Every C_4 -subgraph C of \tilde{G} that has more than one vertex from $\text{Heavy}_\alpha(G)$, has exactly two vertices w_1 and w_2 from $\text{Heavy}_\alpha(G)$, all the other two vertices of C are neighbours of both w_1 and w_2 and, there exists $i \in \{1, 2\}$, such that $|N_G(w_1) \cap N_G(w_2)| \geq \deg_G(w_i)/(\alpha/2)$.*

Proof. Let C be a C_4 -subgraph of \tilde{G} such that $|V(C) \cap \text{Heavy}_\alpha(G)| > 1$ and w_1 and w_2 be two vertices in $V(C) \cap \text{Heavy}_\alpha(G)$. Assume without loss of generality that $w_1 >_{\mathbb{G}} w_2$, and otherwise rename the vertices accordingly.

According to Step 1 of the trimming, $w_1 w_2 \notin E(\tilde{G})$ and hence w_1 and w_2 are not adjacent in C . By the same reasoning w_1 and w_2 are the only vertices of $\text{Heavy}_\alpha(G)$ in $V(C)$. We conclude that C consists of the two vertices w_1 and w_2 in $\text{Heavy}_\alpha(G)$ and two vertices that are not in $\text{Heavy}_\alpha(G)$ and are neighbours of both w_1 and w_2 .

Let $v \in V(C) \setminus \text{Heavy}_\alpha(G)$ and $Y = N_{\tilde{G}}(w_1) \cap N_{\tilde{G}}(w_2)$. By the same reasoning as before we may conclude that $v >_{\mathbb{G}} w_1$. Thus, as $w_1 >_{\mathbb{G}} w_2$, $w_2 \in \text{Target}_{\mathbb{G}}^2(w_1)$. Consequently, by Step 1 of the trimming, $|Y| > \deg_G(w_1)/(\alpha/2)$, since otherwise $Y = \emptyset$ in contradiction to $v \in Y$

12:10 Results on H -Freeness Testing in Graphs of Bounded r -Admissibility

(because v is adjacent to both w_1 and w_2). As \tilde{G} is a subgraph of G and $Y \cap \text{Heavy}_\alpha(G) = \emptyset$ (because of Step 1 of the trimming), we can conclude that also in the graph G it holds that $|(N_G(w_1) \cap N_G(w_2)) \setminus \text{Heavy}_\alpha(G)| > \deg_G(w_1)/(\alpha/2)$. ◀

The next two lemmas show that if the set S_0 selected by Algorithm 1 contains specific types of vertices from $V(G) \setminus \text{Heavy}_\alpha(G)$, then it rejects with sufficient probability to prove the main Theorem of this section.

► **Lemma 7.** *Suppose that Algorithm 1 is executed with oracle access to G and parameters p , $H = C_4$, $\alpha = 32p^2/\epsilon$, $\tau = 3$ and let S_0 be the set selected by the algorithm in the first step. Assume there exists a vertex $v \in S_0 \setminus \text{Heavy}_\alpha(G)$ such that v is in a C_4 -subgraph C of \tilde{G} and C satisfies $|V(C) \cap \text{Heavy}_\alpha(G)| \leq 1$. Then Algorithm 1 rejects with probability 1.*

Proof. Let v be as in the statement of the lemma. Since C is a C_4 -subgraph that includes, together with v , three vertices from $V(C) \setminus \text{Heavy}_\alpha(G)$ in G , it follows that C includes a path P of length 2 that consists of v and two other vertices from $V(C) \setminus \text{Heavy}_\alpha(G)$.

Now, as Algorithm 1 will execute a PBFS of depth 3 (we set $\tau = 3$) it is guaranteed that the knowledge graph constructed by Algorithm 1 will include *all* vertices of P and *all* edges incident to these vertices. In particular, the knowledge graph eventually has C as a subgraph with probability 1 and the claim follows. ◀

► **Lemma 8.** *Suppose that Algorithm 1 is executed with oracle access to G and parameters, p , $H = C_4$, $\alpha = 32p^2/\epsilon$, $\tau = 3$. Let S_0 be the set selected by the algorithm in the first step. Assume there exists a vertex $v \in S_0 \setminus \text{Heavy}_\alpha(G)$ such that v is in a C_4 -subgraph C of \tilde{G} and C satisfies $|V(C) \cap \text{Heavy}_\alpha(G)| \geq 2$. Then Algorithm 1 rejects with probability at least $5/6$.*

Proof. Let v be as in the statement of the lemma. By Lemma 6, C has exactly two vertices w_1 and w_2 from $\text{Heavy}_\alpha(G)$, the other two vertices of C are neighbours of both w_1 and w_2 and are not in $\text{Heavy}_\alpha(G)$. Since $\deg_G(v) < \alpha$, Algorithm 1 queries all of v 's edges, in the first iteration of the PBFS. Thus after the first iteration of the PBFS the knowledge graph already contains the edges vw_1 and vw_2 .

We show next that with with probability at least $5/6$ Algorithm 1 queries a neighbour $u \neq v$ of w_1 that is not in $\text{Heavy}_\alpha(G)$ and is also a neighbour of w_2 , so after the second iteration of the PBFS the knowledge graph also contains the edge uw_1 . We note that this implies the lemma, because in the third iteration of the PBFS (this is the last iteration, since $\tau = 3$) Algorithm 1 will discover all the edges incident to u , since $\deg_G(u) \leq \alpha$, and in particular it will discover the edge uw_2 , which implies that after the end of the PBFS from v the knowledge graph will contain a C_4 -subgraph and hence Algorithm 1 will reject.

Let $Y = (N_G(w_1) \cap N_G(w_2)) \setminus \text{Heavy}_\alpha(G)$. According to Lemma 6, there exists $i \in \{1, 2\}$ such that $|Y| \geq \deg_G(w_i)/(\alpha/2)$. Without loss of generality assume that $i = 1$ and otherwise rename w_1 and w_2 accordingly. Since $\deg_G(w_1) \geq \alpha$, we can conclude that $|Y| \geq 2$ and hence we can assume that at least $1/2$ of the vertices in Y are not v . Thus, $|Y \setminus \{v\}| \geq \deg_G(w_1)/(2\alpha/2)$. Algorithm 1 selects a vertex from $N(w_1)$ independently and u.a.r. 2α times and hence the probability that none of them are from $|Y \setminus \{v\}|$ is at most $(1 - 1/\alpha)^{2\alpha} < e^{-2} < 1/6$. So with probability at least $5/6$ Algorithm 1 finds a vertex u in $Y \setminus \{v\}$ and the claim follows. ◀

► **Theorem 9.** *Suppose that Algorithm 1 is executed with oracle access to G and parameters, p , $H = C_4$, $\alpha = 32p^2/\epsilon$, $\tau = 3$, then (i) if G is C_4 -free, then Algorithm 1 accepts with probability 1; and (ii) if G is ϵ -far from being C_4 -free, then Algorithm 1 rejects with probability at least $2/3$. Algorithm 1 uses at most $O(p^7/\epsilon^5)$ queries.*

Proof. The query complexity of the algorithm follows from Lemma 4 and the values of α and τ .

If G is C_4 -free, then the knowledge graph constructed by Algorithm 1 will not have a C_4 -subgraph and hence Algorithm 1 accepts with probability 1. So assume in the sequel that G is ϵ -far from C_4 -freeness.

Let U be the set of all vertices in $V(G) \setminus \text{Heavy}_\alpha(G)$ that participate in a C_4 -subgraph of \tilde{G} . Since the degree of all vertices in $V(G) \setminus \text{Heavy}_\alpha(G)$ is less than α , if we remove every edge that is incident to a vertex from U , then the total number of edges we removed is bounded above by $\alpha|U|$ and the resulting graph does not have a C_4 -subgraph. Now, by Lemma 5, \tilde{G} is $\epsilon/2$ -far from C_4 -freeness it must be the case that $\alpha|U| \geq \epsilon np/2$. Consequently, $|U| \geq \epsilon np/(2\alpha)$.

Algorithm 1 selects $\lceil 4\alpha/(\epsilon p) \rceil$ vertices u.a.r. for the set S_0 . The probability that none of them are from U is at most $(1 - \epsilon p/(2\alpha))^{\lceil 4\alpha/(\epsilon p) \rceil} < e^{-2} < 1/6$. So with probability at least $5/6$, the set S_0 includes a vertex $v \in V(G) \setminus \text{Heavy}_\alpha(G)$ that participates in a C_4 -subgraph of \tilde{G} .

Let C be a C_4 -subgraph of \tilde{G} that includes a vertex $v \in V(G) \setminus \text{Heavy}_\alpha(G)$. One of two cases applies to C : Either (a) C includes at most one vertex from $\text{Heavy}_\alpha(G)$ or (b) C includes more than one vertex from $\text{Heavy}_\alpha(G)$. We now show that given $v \in S_0$, with probability at least $5/6$, the knowledge graph of Algorithm 1 eventually has a C_4 -subgraph. By using the union bound we can conclude that Algorithm 1 rejects with probability at least $2/3$.

According to Lemma 7, if case (a) occurs, then Algorithm 1 rejects with probability 1. According to Lemma 8, if case (b) occurs, then Algorithm 1 rejects with probability at least $5/6$. We conclude that Algorithm 1 rejects with probability at least $(5/6)^2 > 2/3$, as claimed. \blacktriangleleft

6 Testing H -freeness in adm_2 -bounded graphs when H has diameter 2

In this section we fix $\epsilon > 0$, $p \in \mathcal{N}$, $\alpha = 3|V(H)|\lceil \epsilon^{-1}2^{2|V(H)|+4p^2 \log p} \rceil$. As before, G is an arbitrary $(p, 2)$ -admissible graph and \mathbb{G} is an ordering of G with $\text{adm}_2(\mathbb{G}) = p$. Finally, H is an arbitrary diameter 2 graph.

The trimming process in this section depends on the structure of H and requires an extra construct (**H**). Let us first provide some intuition why this is required.

Suppose that \tilde{H} is an H -subgraph of \tilde{G} and h is the largest vertex in $V(\tilde{H}) \setminus \text{Heavy}_\alpha(G)$. We show below that the number of vertices like h in \tilde{G} is large enough to ensure that with high enough probability one of them will be in the set S_0 selected by Algorithm 1.

Ideally, in \tilde{H} , every vertex $u \in V(\tilde{H})$, is reachable from h via vertices not from $\text{Heavy}_\alpha(G)$. This is an ideal case, because of the following. The depth of the PBFs used is $|V(H)|$. Thus, as the PBFs queries all the neighbours of vertices $V(\tilde{H}) \setminus \text{Heavy}_\alpha(G)$, all these vertices will be discovered and also all edges incident to them. This means that the algorithm discovers all the edges of \tilde{H} except those that are incident on two vertices from $V(\tilde{H}) \cap \text{Heavy}_\alpha(G)$. The trimming we use ensures that there are no edges between heavy vertices, so in particular, this latter case cannot occur and Algorithm 1 will discover \tilde{H} .

If we do not find ourselves in the ideal case, \tilde{H} has a separator \tilde{K} that consists only of vertices from $\text{Heavy}_\alpha(G)$. By similar reasoning to the ideal case, if h is included in the set S_0 that Algorithm 1 selects, it discovers all the vertices in \tilde{H} that can be reached from h via vertices in $V(\tilde{H}) \setminus \text{Heavy}_\alpha(G)$, this includes all the vertices of \tilde{K} . Let us denote the subgraph found so far by \tilde{H}_1 . The algorithm now still needs to find the remaining vertices of \tilde{H} that are “behind” the separator, let us call denote this subgraph by \tilde{H}_2 .

12:12 Results on H -Freeness Testing in Graphs of Bounded r -Admissibility

The problem here is that the vertices \tilde{K} of on the boundary between \tilde{H}_1 and \tilde{H}_2 have a high degree, therefore the probability to discover \tilde{H}_2 may be arbitrarily small. We therefore design a trimming process that will ensure that there are many “useful” \tilde{H}_2 -subgraphs \tilde{H}'_2 isomorphic to \tilde{H}_2 in \tilde{G} that can serve to complete \tilde{H}_1 into a graph isomorphic to H . Specifically, a subgraph \tilde{H}'_2 is useful if $\tilde{K} \subset V(\tilde{H}'_2)$ and there exists an isomorphism from \tilde{H}'_2 to \tilde{H}_2 which maps every vertex of \tilde{K} to itself.

Let Q' be a maximum family of vertex disjoint useful \tilde{H}_2 -subgraphs with respect to the fixed graph \tilde{H}_1 . If Q' is small then we can remove them all simply by removing all edges between members of Q' and \tilde{K} . If this is not possible, Q' must be sufficiently large and the PBFS can discover one of its members with sufficiently high probability.

The above is a simplification, since \tilde{H} might disconnect into more than two components when removing the separator \tilde{K} . In this case we also need to ensure that the members of Q' are sufficiently disjoint.

Finally, in the preceding discussion we fixed a single \tilde{H} with separator \tilde{K} , however \tilde{H} is of course not known in advance. We therefore enumerate all possible sets $K \subset H$ that can take the role of \tilde{K} (not that, by Proposition 3, we only need to look at sets of size $< p^2$). Since K consists only of heavy vertices and our trimming removes edges between heavy vertices, we can further assume K to be independent.

Kernel, \mathbf{H} ► **Definition 10 (Kernel and \mathbf{H}).** A kernel K of the graph H is an independent subset of $V(H)$ of size less than p^2 for which H has two subgraphs H_1 and H_2 such that

1. both H_1 and H_2 are induced and connected,
2. $V(H_1) \cap V(H_2) = K$,
3. $V(H_1) \cup V(H_2) = V(H)$,
4. every edge of H that is incident to a vertex from $V(H_1)$ and $V(H_2)$, is incident to an edge from K (K is a vertex separator in H),
5. the induced subgraph of H_1 on the vertices $V(H_1) \setminus K$ is connected.

We define \mathbf{H} to be the family of ordered pairs (H_2, K) over all kernels K of H .

► **Definition 11 (Sibling subgraphs).** Let L be a subset of $V(\tilde{G})$, and R_1 and R_2 be two subgraphs of \tilde{G} , both including the set of vertices L . We say that R_1 and R_2 are siblings if $V(R_1) \cap V(R_2) = L$ and there exists an isomorphism ϕ from R_1 to R_2 , such that, for every $\ell \in L$, $\phi(\ell) = \ell$.

We say a set of graphs is a set of sibling graphs by L , if every pair of graphs in the set are siblings by L .

Trimming **Trimming.** In the trimming procedure we construct \tilde{G} from G . We begin with $G = \tilde{G}$ and then remove edges from $E(\tilde{G})$ as follows:

1. For every $v \in \text{Heavy}_\alpha(G)$, and $u \in N^-(v)$, the edge uv is removed from $E(\tilde{G})$.
2. For every $v \in \text{Heavy}_\alpha(G)$, $(H_2, K) \in \mathbf{H}$ and size $|K|$ subset $M \subseteq \text{Target}_{\mathbb{G}}^2(v)$, if a maximum set of vertex disjoint H_2 -subgraphs of \tilde{G} that are siblings by M , and are isomorphic to H_2 so that the vertices of M are mapped to the vertices of K , has size at most $2|V(H)| \deg_G(v)/\alpha$, then, for every vertex w in a subgraph of this set, we remove every edge incident to w and a vertex in $\text{Target}_{\mathbb{G}}^2(v)$.
3. The previous steps are repeated until it does not result in the removal of any edges from $E(\tilde{G})$.

► **Proposition 12.** For every $v \in \text{Heavy}_\alpha(G)$, $(H_2, K) \in \mathbf{H}$ and size $|K|$ subset $M \subseteq \text{Target}_{\mathbb{G}}^2(v)$, if in some execution of Step 2, for a maximum family of vertex disjoint H_2 -subgraphs that are siblings by M , and are isomorphic to H_2 so that the vertices of M are

mapped to the vertices of K , the following holds: for every vertex w in a subgraph of this set, we remove every edge incident to w and a vertex in $\text{Target}_{\mathbb{G}}^2(v)$, then after the specific execution of Step 2, there does not exist any H_2 -subgraph that is a sibling by M of a subgraph in the maximum family.

Proof. Recall that H has diameter 2, so if it has a separator K , then all the vertices of H that are not in the separator must be adjacent to some vertex in the separator. Therefore in Step 2, when for every w in a subgraph of the set all edges between w and $\text{Target}_{\mathbb{G}}^2(v)$ are removed, we have that every such vertex w cannot participate in any subgraph like the one in the set. Hence, as the family is of maximum size the proposition follows. ◀

► **Lemma 13.** *If G is ϵ -far from being H -free, then \tilde{G} is $\epsilon/2$ -far from being H -free.*

Proof. Note that initially $E(\tilde{G}) = E(G)$ and then edges are removed from $E(\tilde{G})$ in Steps (1) and (2) of the trimming. Given that the value of α here is larger than the value used in Section 5, and that Step 1 of the trimming here is the same as Step 1 in Section 5, by the same considerations as in Lemma 5, at most $\epsilon pn/4$ edges are removed from $E(\tilde{G})$, at Step 1 of the trimming. So, to complete the proof, we only need to show that in Step 1 of the trimming also at most $\epsilon pn/4$ edges are removed from $E(\tilde{G})$.

According to Step 2 of the trimming, the total number of edges removed from $E(\tilde{G})$, for every vertex in $\text{Heavy}_{\alpha}(G)$, is bounded above by the product of the following values:

- $|\mathbf{H}|$, and
- $(p^2)!$, which is an upper bound on the number of options to choose (while considering order) a size $|K|$ subset of $\text{Target}_{\mathbb{G}}^2(v)$ (where, for every $v \in V(G)$, by Proposition 3, $|\text{Target}_{\mathbb{G}}^2(v)| < p^2$), and
- $2|V(H)| \deg_G(v)/\alpha$, the threshold for edge removal for number of subgraphs in a maximum set of sibling subgraphs, and
- $p^2|V(H)|$, the number of edges incident to a vertex from $\text{Target}_{\mathbb{G}}^2(v)$ and vertices in a subgraph of a maximum set of sibling subgraphs.

The size of \mathbf{H} is the number of subsets $V(H)$ with size less than p^2 . Hence, $|\mathbf{H}| < 2^{|V(H)|}$. So, the total number of edges removed from $E(\tilde{G})$ is at most

$$\sum_{v \in \text{Heavy}_{\alpha}(G)} 2^{|V(H)|} \cdot (p^2)! \cdot (2|V(H)| \deg_G(v)/\alpha) \cdot p^2|V(H)| < \frac{\epsilon}{8} \sum_{v \in \text{Heavy}_{\alpha}(G)} \deg_G(v) \leq \frac{\epsilon pn}{4},$$

where the first equality follows because $\alpha = 3|V(H)| \lceil \epsilon^{-1} 2^{2|V(H)| + 4p^2 \log p} \rceil$. ◀

► **Proposition 14.** *Let \tilde{H} be a H -subgraph of \tilde{G} . $\text{Heavy}_{\alpha}(G)$ is an independent set in \tilde{G} , the largest vertex in \tilde{H} is not in $\text{Heavy}_{\alpha}(G)$ and if \tilde{H} has a separator $U \subseteq \text{Heavy}_{\alpha}(G)$, then $U = \text{Heavy}_{\alpha}(G) \cap V(\tilde{H})$ and U is the only separator in \tilde{H} consisting of only vertices from $\text{Heavy}_{\alpha}(G)$.*

Proof. According to Step 1 of the trimming, for every $v \in \text{Heavy}_{\alpha}(G)$, if $vu \in E(\tilde{G})$, then $u >_{\mathbb{G}} v$. Thus, as one vertex is greater than the other for every pair of vertices in $\text{Heavy}_{\alpha}(G)$ there cannot be an edge in \tilde{G} that is incident to both. Therefore, $\text{Heavy}_{\alpha}(G)$ is an independent set. By the same reasoning, the largest vertex in an H -subgraph of \tilde{G} is not in $\text{Heavy}_{\alpha}(G)$, since it is adjacent to vertices smaller than it (H is connected, because it has diameter 2).

Finally, for the last part the claim, in the proof of Proposition 12, we noticed that for every separator of H , every vertex of H that is not in the separator must be adjacent to some vertex in the separator. The same applies to \tilde{H} . So, if a separator of \tilde{H} is a subset

12:14 Results on H -Freeness Testing in Graphs of Bounded r -Admissibility

of $\text{Heavy}_\alpha(G)$, then every vertex that is adjacent to some vertex in the separator is not in $\text{Heavy}_\alpha(G)$ and in particular all the vertices of \tilde{H} that are not in the separator. This also implies that U is the only separator in \tilde{H} consisting of only vertices from $\text{Heavy}_\alpha(G)$. ◀

► **Lemma 15.** *Let \tilde{H} be an H -subgraph of \tilde{G} and $U = V(\tilde{H}) \cap \text{Heavy}_\alpha(G)$ and suppose that U is a separator of \tilde{H} , then $|U| < p^2$.*

Proof. Let v be the largest vertex in U . Since H is of diameter 2, it has a common neighbour with every vertex in U . By Step 1, v does not have any neighbours smaller than it and hence together with the previous we can conclude that $U \setminus \{v\} \subseteq \text{Target}_{\mathbb{G}}^2(u)$. By Proposition 3, $\text{Target}_{\mathbb{G}}^2(u) \leq p(p-1)$ and the lemma follows. ◀

► **Theorem 16.** *If Algorithm 1 is executed with oracle access to G and parameters, p , H , $\alpha = 3|V(H)|\lceil \epsilon^{-1}2^{2|V(H)|+4p^2 \log p} \rceil$, $\tau = |H|$, then (i) if G is H -free, then Algorithm 1 accepts with probability 1; and (ii) if G is ϵ -far from being H -free, then Algorithm 1 rejects with probability at least $2/3$. Algorithm 1 uses at most $O(2^{(|V(H)|+1)(2|V(H)|+4p^2 \log p)})$ queries.*

Proof. The query complexity of the algorithm follows from Lemma 4 and the values of α and τ .

If G is H -free, then knowledge graph of Algorithm 1, will never have an H -subgraph and hence, Algorithm 1 accepts with probability 1. So, from here on in this proof, assume that G , is ϵ -far from H -freeness.

Let U be the set of all vertices in $V(G)$ that are the largest vertices in a H -subgraph of \tilde{G} . By Proposition 14, $U \cap \text{Heavy}_\alpha(G) = \emptyset$ and therefore, by the same reasoning as in Theorem 9, it holds that $|U| > \epsilon np / (2\alpha)$ and, with probability at least $5/6$ that $S_0 \cap U \neq \emptyset$. So, assume that v is a vertex in S_0 that is the largest vertex in a H -subgraph \tilde{H} of \tilde{G} .

One of two cases applies to \tilde{H} : (a) every vertex $u \in V(\tilde{H})$, is reachable from v via the vertices in $V(\tilde{H}) \setminus \text{Heavy}_\alpha(G)$, and (b) there exists a set M such that $M = V(\tilde{H}) \cap \text{Heavy}_\alpha(G)$ that is a separator of \tilde{H} .

If case (a) applies, then as we already described previously in this section, with probability 1, the knowledge graph of Algorithm 1 will eventually have an H -subgraph. Thus, Algorithm 1 will reject with probability 1. So, from here on we assume that case (b) applies.

So, assume that \tilde{H} has a separator M consisting only of vertices from $\text{Heavy}_\alpha(G)$ (by Proposition 14, this separator includes all the vertices of $\text{Heavy}_\alpha(G) \cap V(\tilde{H})$). Since $v \notin \text{Heavy}_\alpha(G)$, the diameter of H is 2 and $\text{Heavy}_\alpha(G)$ is an independent set, for every vertex in M , v is either its neighbour or shares a neighbour x with it, where $x \notin \text{Heavy}_\alpha(G)$. This ensures that, with probability 1, after two steps of the PBFS all the vertices in M are discovered. By similar consideration to the previous case, with probability 1, all vertices reachable from v via vertices not in $\text{Heavy}_\alpha(G)$ are added to the knowledge graph. For every one these vertices that is not in $\text{Heavy}_\alpha(G)$ also all the edges incident on them are also in the knowledge graph. This implies that all the edges between the vertices of M and the vertices added to the knowledge graph as described are also in the knowledge graph.

It remains to show that with sufficiently high probability, the edges required to complete the above to H -subgraph are included in the knowledge graph. Let ℓ be the largest vertex in M . Let \tilde{H}' be an induced subgraph of \tilde{H} that includes all the vertices of M and all other vertices of \tilde{H} that are separated from v by M . By Step 2, of the trimming we are guaranteed that there exists a family \mathcal{Q} , of size greater than $2|V(H)| \deg_G(v) / \alpha$, that consists of vertex disjoint subgraphs of \tilde{G} , where every graph in the family is either \tilde{H}' or its sibling by M .

Let be the graph \tilde{H}^* induced by \tilde{H}' on $V(\tilde{H}') \setminus M$ If we were guaranteed that \tilde{H}^* is connected, then we would only need to show that with high probability Algorithm 1 will discover an edge incident to ℓ and a vertex x of this subgraph (or similar subgraph of one of

its siblings in M , that does not share any vertices with the part of the H -subgraph already discovered). This holds because, every vertex in \tilde{H}^* is not in $\text{Heavy}_\alpha(G)$, and there are enough steps of the PBFS so that the PBFS reaches all the vertices in \tilde{H}^* and discovers all the edges adjacent to them (the PBFS has $|V(H)|$ steps, and the vertices on a shortest path from ℓ to x are not in \tilde{H}^*), thus the PBFS will discover all the vertices of \tilde{H}^* and the edges incident on them.

However, the above guarantee does not hold. So \tilde{H}^* may contain almost $|V(H)|$ connected components. Regardless, if for every one of these connected components, the knowledge graph has it as a subgraph or has its isomorphic equivalent in one of the subgraphs in \mathcal{Q} , and if none of the isomorphic equivalent shares a vertex with other vertices of \tilde{H}' in the knowledge graph, the knowledge graph has an H -subgraph.

For each connected component, there are at least $3|V(H)| \deg_G(\ell)/\alpha \geq 3|V(H)|\alpha/\alpha = 3|V(H)|$ vertex disjoint copies (where the inequality follows because $\ell \in \text{Heavy}_\alpha(G)$). So, at least two thirds of the copies of such connected component do not include any other vertices from \tilde{H} .

The probability of not discovering one such component is $(1 - 4|V(H)|/(3\alpha))^{2\alpha} \leq e^{-|V(H)|/6} < (6|V(H)|)^{-1}$. By the union bound, with probability at least $5/6$, the knowledge graph has all the subgraphs required so that it has a H -subgraph. Thus, the proof is complete. \blacktriangleleft

7 Testing C_6 and C_7 -freeness in adm_3 -bounded graphs

The proof of the following theorem will appear in the journal version of this paper.

► **Theorem 17** (\star). *If Algorithm 1 is executed with oracle access to G and parameters, $H = C_7$, $\alpha = \lceil 2^{12}p^4/\epsilon \rceil$, $\tau = 7$, then (i) if G is C_7 -free, then Algorithm 1 accepts with probability 1; and (ii) if G is ϵ -far from being C_7 -free, then Algorithm 1 rejects with probability at least $2/3$. Algorithm 1 uses at most $O(p^{27}/\epsilon^8)$ queries.*

8 Lower bounds for testing C_r -freeness for $r \geq 4$

The proof of the following theorem will appear in the journal version of this paper.

► **Theorem 18** (\star). *For every integer $r \geq 4$ and sufficiently large integer n , every two-sided Property-Tester for the C_r -freeness, has query complexity $\Omega(n^{1/4})$, on $(2\lfloor r/2 \rfloor - 1)$ input graphs of size n .*

Abstract

Hyperbolic random graphs inherit many properties that are present in real-world networks. The hyperbolic geometry imposes a scale-free network with a strong clustering coefficient. Other properties like a giant component, the small world phenomena and others follow. This motivates the design of simple algorithms for hyperbolic random graphs.

In this paper we consider threshold hyperbolic random graphs (HRGs). Greedy heuristics are commonly used in practice as they deliver a good approximations to the optimal solution even though their theoretical analysis would suggest otherwise. A typical example for HRGs are degeneracy-based greedy algorithms [Bläsius, Fischbeck; Transactions of Algorithms '24]. In an attempt to bridge this theory-practice gap we characterise the parameter of degeneracy yielding a simple approximation algorithm for colouring HRGs. The approximation ratio of our algorithm ranges from $(2/\sqrt{3})$ to $4/3$ depending on the power-law exponent of the model. We complement our findings for the degeneracy with new insights on the clique number of hyperbolic random graphs. We show that degeneracy and clique number are substantially different and derive an improved upper bound on the clique number. Additionally, we show that the core of HRGs does not constitute the largest clique.

Lastly we demonstrate that the degeneracy of the closely related standard model of geometric inhomogeneous random graphs behaves inherently different compared to the one of hyperbolic random graphs.

1 Introduction

Many real-world networks have a heterogeneous degree distribution, close to a power-law, as well as a constant clustering coefficient. The *hyperbolic random graph* model (HRG) introduced by Krioukov et. al. [29] combines both properties [19], which has led to considerable interest

in recent years. Various aspects of HRGs have been studied, including clique size [8, 9, 16], treewidth [10], minimum vertex cover size [4, 5], and diameter [17, 24, 33]. A hyperbolic random graph is a graph embedded in the hyperbolic plane where pairs of vertices have an edge if they are close according to the hyperbolic distance. It is generated by randomly throwing n vertices on a disk of radius R (dependent on n). Since hyperbolic space grows exponentially, most vertices are of small degree and located close to the boundary of the disk, while few vertices have large degree and lie close to the centre. This distribution of vertices leads to the power-law degree distribution of HRGs.

In this paper, we study the vertex colouring problem on HRGs, along with the related concepts of clique number and degeneracy. The k -colouring problem asks to colour the vertices of a graph with k colours, while assigning different colours to adjacent vertices. The *chromatic number* $\chi(G)$ is the minimum number of colours needed to colour a graph in such a way. For $k \geq 3$ the problem is one of the original NP-hard problems [13, 21]. On general graphs, even loosely approximating the chromatic number is particularly hard [36].

The answer to the colouring problem is closely related to the clique number $\omega(G)$ and the degeneracy of a graph. The *clique number* is the number of vertices of the largest clique of the graph and it serves as a natural lower bound to the chromatic number. The *degeneracy* $\kappa(G)$ is the minimum integer k' for which there exists an ordering of the vertex set of G , $V = (v_1, v_2, \dots, v_n)$, such that for every index $i \in [n - 1]$, v_i has at most k' neighbours with greater index. Any graph G can be *easily* coloured with $\kappa(G) + 1$ colours by iterating through the vertices in reverse order and simply colouring a vertex with a colour not used by any of its higher ranked neighbours.

We aim to study these structural parameters that are not only fundamental to the model but also in general for algorithm design in various models of computation [2, 12, 18]. The most prominent large clique in an HRG is formed by the vertices in the graph's core [8]. Simply put, the core emerges among polynomially many vertices of distance at most $R/2$ from the centre of the disk, which due to the triangle inequality form a clique. We denote the size of this clique by $\sigma(G)$. At this point one may wonder whether the core forms the largest clique of the graph, a statement that we disprove in Proposition 16. Nevertheless we show that the largest clique can at most be small constant factor larger than the core.

► **Theorem** (Simplified version of Theorem 20). *There exists a constant $\delta > 0$ such that for any threshold HRG G , $\sigma(G) + 1 \leq \omega(G) \leq \sqrt{4/3 - \delta} \cdot \sigma(G)$ holds w.e.h.p.¹*

This upper bound improves on prior work [8], which showed that there exists some constant $c > 1$ such that $\omega(G) \leq c \cdot \sigma(G)$ holds w.e.h.p., but without providing any upper bound on c .

We can now see that the core and clique are not the same. Nonetheless, (i) this theorem shows that the largest clique size and the core size are closely related, and (ii) the core of HRGs is a very well understood object, whereas the largest clique is not. Thus the natural approach to bound the degeneracy is to use the core. We show the following theorem.

► **Theorem** (Simplified version of Theorem 9). *There exist constants $\delta_1, \delta_2 > 0$ such that for any threshold HRG G , $(1 + \delta_1) \cdot \sigma(G) \leq \kappa(G) \leq (4/3 - \delta_2) \cdot \sigma(G)$ holds w.e.h.p.*

The main surprise of this theorem is that the degeneracy is bounded away from the coresize by a constant factor. As the chromatic number is lower bounded by the core size, the upper bound on the degeneracy in this theorem implies a simple algorithm colouring with at most

¹ An event holds *with extremely high probability* (w.e.h.p.), if for every $c > 1$, there exists an n_0 such that for every $n \geq n_0$ the event holds with probability at least $1 - n^{-c}$.

$(4/3 - \delta_2)\chi(G)$ colours. The approximation guarantee of this algorithm ranges from $2/\sqrt{3}$ to $4/3$ depending on further model parameters, see Section 2 and Theorem 11 for details. In any case, this improves on the previously best approximation ratio of 2 [7, Lemma 7]. The algorithm iteratively removes vertices of degree at most $(4/3 - \delta_2)\sigma(G) - 1$ and then colours them in the reverse order. The next thing one would hope is to be able colour the graph with $\omega(G)$ colours using the same process. In [3], the authors conducted experiments where they were iteratively removing the vertex with the smallest degree of the graph, up to vertices with residual degree equal to $\omega(G)$. In their findings, this process did not remove every vertex, implying $\omega(G) < \kappa(G)$ for their generated graphs. We substantiate their findings by providing a rigorous proof demonstrating that the clique number is, in fact, a constant factor smaller than the degeneracy.

► **Theorem** (Simplified version of Theorem 13). *There exists a constant $\varepsilon > 0$ such that for any threshold HRG G , $\omega(G) \leq (1 - \varepsilon) \cdot \kappa(G)$ holds w.e.h.p.*

Our final contribution is to study the degeneracy of *geometric inhomogeneous random graphs* (GIRGs) [23], a sibling to HRGs. The GIRGs also combine heterogeneity and high clustering. For most properties GIRGs and HRGs exhibit the same behaviour. Perhaps the first paper to find a difference between them is [9], where the authors show that the minimum number of maximal cliques in the two models differ. We show a significant discrepancy for the degeneracy of GIRGs compared to that of HRGs, see Figure 1 and Corollary 24.

Outline. See Figure 1 for a table with our results, as well as a plot comparing the bounds of our theorems for various model parameters. In Section 1.1 we provide a detailed discussion of our results and techniques. Section 3 contains bounds on the degeneracy of HRGs (Theorem 9). In Section 4, we show the gap between clique number and degeneracy (Theorem 13), as well as bounds on the clique number (Theorem 20). Finally, Section 5 contains results about the degeneracy of GIRGs. Statements where proofs or details are omitted due to space constraints can be found in the full version [1].

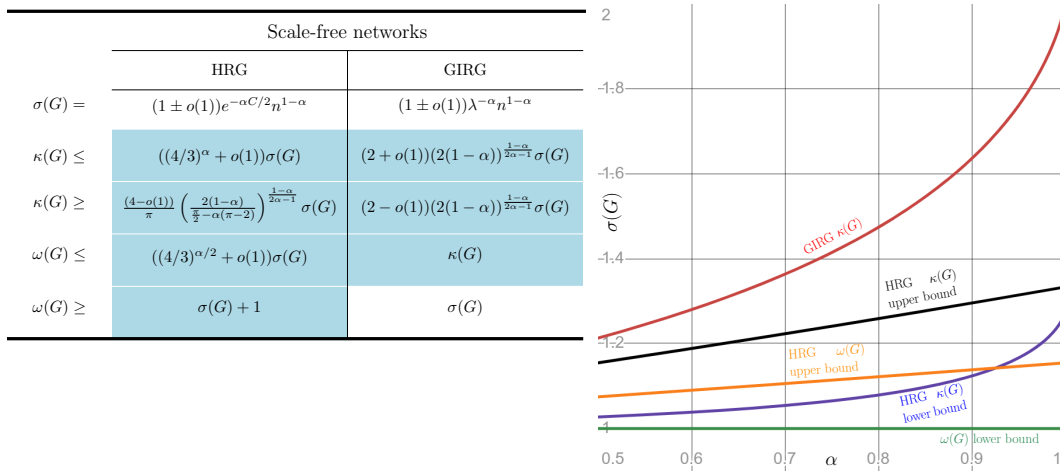

1.1 Discussion of our Results and Techniques

HRGs have a power-law degree distribution [19, 34], that is, the probability that a vertex has degree k is given by $\sim k^{-(2\alpha+1)}$. The model parameter $\alpha \in (1/2, 1)$ controls the power-law exponent and all our results, particularly the size of the aforementioned constant factor gap depends on the choice of α . For the ease of presentation this overview largely omits this dependence, but the summary of our results in Figure 1 plots it in detail.

Upper bound on degeneracy (Theorem 9). One consequence of generating a graph in hyperbolic space is that vertices tend to have fewer neighbours with increasing radius, i.e., the expected number of neighbours of a vertex decreases with the distance from the centre of the hyperbolic disc. This produces the power-law degree distribution that is valuable in modelling real-world networks. It also leads to a simple approach for upper bounding degeneracy: instead of removing vertices ordered by (increasing) degree, we remove them by (decreasing) radius. If k is such that each vertex has at most k neighbours of smaller radius, then k is an upper bound on the degeneracy.

The notion governing this approach is the *inner-neighbourhood* of a vertex, see Figure 2. The inner-neighbourhood of a vertex u with radius r , denoted $\Gamma(u)$, is the set of vertices of distance at most R from u , i.e., they are neighbours of u , and with radius at most r , i.e., they are closer to the centre of the disc than u . The size $|\Gamma(u)|$ of the inner-neighbourhood

13:4 Hyperbolic Random Graphs: Clique Number and Degeneracy

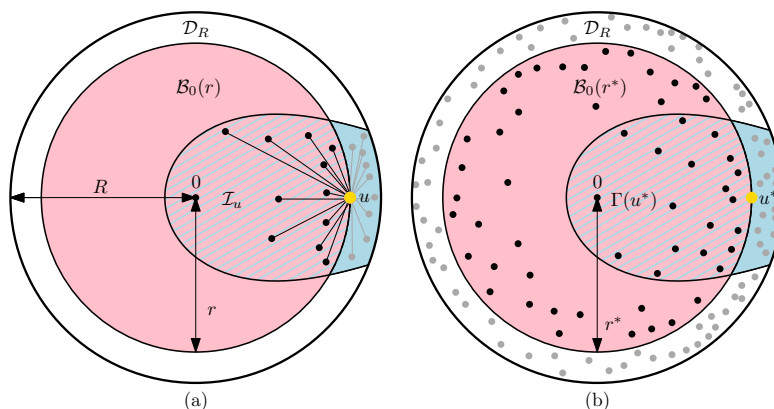

■ **Figure 1** Results on the degeneracy $\kappa(G)$ and the size of the largest clique $\omega(G)$ in hyperbolic random graphs (HRG) and geometric inhomogeneous random graphs (GIRG). The bounds hold w.e.h.p. and are stated in comparison to the core size $\sigma(G)$. Each curve represents the multiplicative factor in front of $\sigma(G)$ for $\kappa(G)$ and $\omega(G)$ (y-axis) depending on the parameter $\alpha \in (1/2, 1)$ (x-axis). Prior work is listed with white background, whereas our results are listed with blue background.

is called the *inner-degree* of u . The expected value of $|\Gamma(u)|$ scales with the area of u 's *inner-ball* $\mathcal{I}(r) = \mathcal{B}_u(r) \cap \mathcal{B}_0(r)$. More precisely, $\mathbb{E}[|\Gamma(u)|] = (n-1) \cdot \mu(\mathcal{I}(r))$. See Figure 2 a for a visual representation. The vertex of largest inner-degree is denoted u^* ; the choice of u^* and the value of $|\Gamma(u^*)|$ depend on the random distribution of the vertices.

If vertices are removed from outside to inside, then each vertex at the time of its removal will have degree less or equal to the inner-degree of u^* . To bound the degeneracy, we derive a probabilistic upper bound for $|\Gamma(u^*)|$. We do this by finding the radius that maximises $\mu(\mathcal{I}(r))$, which upper bounds $\mathbb{E}[|\Gamma(u)|]$ (for every vertex u). Since $|\Gamma(u)|$ is concentrated we can apply a Chernoff and a union bound to obtain a high probability upper bound for $|\Gamma(u^*)|$. Despite the simplicity of the inner-neighbourhood, we elaborate on this key concept as it is not only crucial to our upper bound on degeneracy but also for most of our other results discussed later on.

Lower bound on degeneracy (Theorem 9). In Lemma 6 we show that the maximum inner-degree also produces a lower bound on the degeneracy $\kappa(G)$, in the sense that $\kappa(G) \geq (1 - o(1))|\Gamma(u^*)|$ w.e.h.p. This yields asymptotically tight bounds on $\kappa(G)$. We prove the lower bound of $\kappa(G)$ by considering the subgraph G' induced by the vertices that have smaller radius than u^* (see Figure 2 b). Note that G' contains vertices that are not neighbours of u^* . We show that every vertex u in G' has, w.e.h.p., at least $(1 - o(1))|\Gamma(u^*)|$ neighbours in G' ; this statement uses the choice of u^* and is not true if u was an arbitrary vertex. Now, in any ordering of the vertices of G' , the first vertex has at least $(1 - o(1))|\Gamma(u^*)|$ neighbours of greater index, implying $(1 - o(1))|\Gamma(u^*)| \leq \kappa(G') \leq \kappa(G)$. While this provides a lower bound that asymptotically matches our upper bound, a lower order gap remains.

Gap between clique number and degeneracy (Theorem 13). The most immediate lower bound for degeneracy is the clique number [2], because in every ordering of the vertices of G , the vertex of the clique with the lowest index has at least $\omega(G) - 1$ neighbours of

■ **Figure 2** Illustration of the inner-neighbourhood. (a) The pink area is the ball $\mathcal{B}_0(r)$. The hatched area $\mathcal{I}_u = \mathcal{B}_u(R) \cap \mathcal{B}_0(r)$ is the inner-ball of u . The vertices $V \cap \mathcal{I}_u$ form the inner-neighbourhood $\Gamma(u)$. (b) Sketch of proof of Lemma 6. Vertex u^* is the vertex with the largest inner-degree. Each vertex $v \in U = V \cap \mathcal{B}_0(r^*)$ has at least nearly as many neighbours within $\mathcal{B}_0(r^*)$ as $|\Gamma(u^*)|$ (w.e.h.p.).

higher index. We prove that the lower bounds on the degeneracy that are derived from the clique number are strictly worse than the bounds discussed above obtained via analysing the inner-degree. Our approach to show this is the following: we take an arbitrary clique K and the vertex u with the largest radius in K . Let G'' be the subgraph induced by $\Gamma(u)$. Next, we partition G'' into three sets of vertices, each containing at least a constant fraction of the vertices of G'' w.e.h.p. See Figure 3 b for an illustration of this partition. Lastly, we use purely geometric arguments to show that K cannot contain vertices from all three sets. The gap then follows as the left out set contains a constant fraction of u 's inner neighbourhood. This gap between $\omega(G)$ and $\kappa(G)$ makes approaches for computing the clique number via degeneracy, like that of Walteros and Buchanan [35], unsuitable for HRGs.

Clique number and the core (Theorem 20). The upper bound on the clique number is proven via a geometric approach. Let u, v, w be any three vertices. If the vertices are far apart they cannot be contained in a clique. Otherwise their pairwise distance is at most R . Using the hyperbolic version of Jung's theorem [20, 14, 15] implies that they are contained in a ball \mathcal{B} of small radius and we show that \mathcal{B} also has a small area. Hence the expected number of vertices in \mathcal{B} is small as well. As this expectation is well concentrated whenever the area is significantly large, this bound holds with extremely high probability when introducing lower order deviations from the expectation. Via a union bound over all possible $\binom{n}{3}$ triples of vertices we rule out that any clique contained in such a covering ball is large. The main claim now follows because any clique has to be contained in one of these coverings balls. The question of whether $\omega(G)/\sigma(G) \rightarrow 1$ as $n \rightarrow \infty$ remains open.

2 Preliminaries

Hyperbolic Random Graphs. We follow the formalisation of hyperbolic random graphs introduced in [34], which is known as the *native representation*. We denote by $\mathbb{H}^2 = [0, \infty) \times [0, 2\pi)$ the hyperbolic plane in the polar coordinate system, where a point $x \in \mathbb{H}^2$ is parametrised by a radius $r(x)$ and an angle $\varphi(x)$. We equip \mathbb{H}^2 with a metric $d_h(x, y)$ characterised by

13:6 Hyperbolic Random Graphs: Clique Number and Degeneracy

$$\cosh(d_h(x, y)) = \cosh(r(x)) \cosh(r(y)) - \sinh(r(y)) \sinh(r(x)) \cos(\varphi(x) - \varphi(y)). \quad (1)$$

This metric is what gives \mathbb{H}^2 a hyperbolic geometry, of curvature -1, as opposed to the Euclidean metric. We equip \mathbb{H}^2 with the topology induced by d_h .

The geometric space of most importance in this work is the bounded disk in \mathbb{H}^2 defined by $\mathcal{D}_R = [0, R] \times [0, 2\pi)$, where $R = 2 \log(n) + C$ with $C \in \Theta(1)$. We refer to point $(0, 0)$ as the *centre of this disk*. The space \mathcal{D}_R inherits the topology of \mathbb{H}^2 , and from now on we shall only consider subsets of this space – thus, for example, a ball around a point $x \in \mathcal{D}_R$ is defined by the set $\mathcal{B}_x(\varepsilon) = \{y \in \mathcal{D}_R : d_h(x, y) \leq \varepsilon\} \subseteq \mathcal{D}_R$.

We now introduce a probability measure μ on \mathcal{D}_R , which is parametrised by the model parameter $\alpha \in (1/2, 1)$, and was first defined by Papadopoulos et. al. [34]. For measurable $\mathcal{S} \subseteq \mathcal{D}_R$, define

$$\mu(\mathcal{S}) = \int_{\mathcal{S}} \rho(x) dx, \quad \rho(x) = \frac{\alpha \sinh(\alpha x)}{2\pi(\cosh(\alpha R) - 1)},$$

where ρ is the density of μ with respect to the Lebesgue measure on \mathcal{D}_R . This measure differs from the uniform probability measure on \mathcal{D}_R in that it puts more mass at the centre of the disk; both measures coincide at $\alpha = 1$. The benefit of μ lies in the properties it induces in our central object of study, the hyperbolic random graph.

Threshold hyperbolic random graph (HRG). A (*threshold*) *hyperbolic random graph* or *HRG* is a pair $G = (V, E)$ defined by the following procedure. First, n vertices are sampled independently at random in \mathcal{D}_R according to μ . Then any two vertices $u, v \in V$ are connected by an edge if and only if their distance $d_h(u, v)$ is at most R . We write $G \sim \mathcal{G}(n, \alpha, C)$ to denote a graph generated in this way. A vertex $u \in V$ is identified by its point coordinates in \mathbb{H}^2 and we write $V \cap \mathcal{A}$ to denote the set of vertices that are located in an area $\mathcal{A} \subseteq \mathcal{D}_R$.

The use of μ to distribute vertices in \mathcal{D}_R has the effect of giving G a power-law degree distribution, as was shown in [19, 34]. It is sometimes convenient to characterise connection of vertices in terms of their *angular distance*, and to that end we define

$$\theta_R(r_1, r_2) = \arccos\left(\frac{\cosh(r_1) \cosh(r_2) - \cosh(R)}{\sinh(r_1) \sinh(r_2)}\right),$$

which per (1) yields the following observation.

► **Observation 1.** *Two vertices u and v are connected if and only if their angular distance is less than $\theta_R(r(u), r(v))$.*

We also make use of the following expression of the distribution of the radius of a vertex u .

$$\mathbb{P}(r(u) \leq r) = \mu(\mathcal{B}_0(r)) = \int_0^r \int_{-\pi}^{\pi} \rho(x) d\theta dx = \frac{\cosh(\alpha r) - 1}{\cosh(\alpha R) - 1} = (1 - o(1))e^{-\alpha(R-r)} \quad (2)$$

We briefly note that a variant of HRGs exists in which vertices are not connected purely according to whether their distance is below a threshold, but rather with probability $p(u, v) = (1 + \exp(\frac{1}{2T}(d_h(u, v) - R)))^{-1}$ determined by both distance and a “temperature” parameter T (see e.g. [30, §3.1]).

Degeneracy, clique number, chromatic number and core. For a graph $G = (V, E)$, the *degeneracy* $\kappa(G)$ is the minimum integer k for which there exists an ordering of the vertex set of G , $V = (v_1, v_2, \dots, v_n)$, such that for every index $i \in [n - 1]$, v_i has at most k neighbours with greater index. The *clique number* $\omega(G)$ is the size of the largest clique of G . The *chromatic number* $\chi(G)$ is the smallest number of colours required so that a conflict-free vertex colouring is possible for G . The *core* of a hyperbolic random graph is the set of vertices with radius at most $R/2$ and we denote its size by $\sigma(G)$. Since for any points $u, v \in \mathcal{B}_0(R/2)$ the distance is at most $d_h(u, v) \leq R$, the core forms a clique. Finally, since the core is a clique, any vertex of a clique needs a different colour in a conflict-free colouring, and $\chi(G) \leq \kappa(G) + 1$ (see e.g. [31, Lemma 4]), we have the following chain of inequalities.

► **Observation 2.** *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then,*

$$\sigma(G) \leq \omega(G) \leq \chi(G) \leq \kappa(G) + 1.$$

Concentration bounds. We use the following Chernoff bounds [32, Theorem 4.4].

► **Theorem 3 (Chernoff bound).** *For $i \in [k]$, let $X_i \in \{0, 1\}$ be independent random variables and $X = \sum_i X_i$. Then for $\varepsilon \in (0, 1)$,*

$$\mathbb{P}(X \geq (1 + \varepsilon)\mathbb{E}[X]) \leq e^{-\varepsilon^2 \cdot \mathbb{E}[X]/3} \text{ and } \mathbb{P}(X \leq (1 - \varepsilon)\mathbb{E}[X]) \leq e^{-\varepsilon^2 \cdot \mathbb{E}[X]/2}.$$

3 Degeneracy of Hyperbolic Random Graphs

A tool we make use of several times is the *inner-ball* of a point $x \in \mathcal{D}_R$, defined by $\mathcal{I}_x = \mathcal{B}_x(R) \cap \mathcal{B}_0(r(x))$. The inner-ball of a vertex is the inner-ball of the point using the vertex' coordinates. The *inner-neighbourhood* of a vertex u is the set of vertices (excluding u) contained in its inner-ball, that is, the neighbours of u that have a smaller radius than u (see Figure 2 a), and is denoted $\Gamma(u)$.

We upper bound the degeneracy $\kappa(G)$ via the inner-neighbourhood by using the following informal process. Consider a graph G and order its vertices (v_1, v_2, \dots, v_n) by decreasing radius, so $r(v_i) \geq r(v_{i+1})$, and iteratively remove vertices from G one-by-one, from lower to higher index. Note that the set of neighbours of v_i that have greater index than i coincide with $\Gamma(v_i)$. This implies that the degree of each vertex v_i at the time of its removal is $|\Gamma(v_i)|$. Let u^* be the vertex v_k that maximises $|\Gamma(v_k)|$. As the largest degree of a vertex at the time of its removal is given by $|\Gamma(u^*)|$, we get the following upper bound for the degeneracy.

► **Observation 4.** *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG and let u^* be the vertex of G with the largest inner-degree in G . Then $\kappa(G) \leq |\Gamma(u^*)|$.*

We will now show that the largest inner-degree does not only yield an immediate upper bound on the degeneracy, but also a lower bound. Informally, this lower bound follows from the following argument. Order the vertices of the graph in descending order of their radius, that is, (v_1, v_2, \dots, v_n) such that $r(v_i) \geq r(v_{i+1})$. For $i \in [n]$, let $G_i = G \setminus \{v_1, v_2, \dots, v_i\}$. Let v_k be the node with the maximum inner neighbourhood in G . We show (with a probabilistic guarantee) that the graph G_k has minimum degree $(1 - o(1))|\Gamma(v_k)|$. Before we make this formal, we introduce a slightly modified version of [19, Lemma 3.3], that implies the following: the closer a vertex is to the origin, the more neighbours it has in expectation. This can be derived via the fact that the angle $\theta_R(r, x)$ is monotonically decreasing in x .

► **Corollary 5.** *Let $r, s, t \in [0, R)$ with $s < t$. Then $\mu(\mathcal{B}_s(R) \cap \mathcal{B}_0(r)) \geq \mu(\mathcal{B}_t(R) \cap \mathcal{B}_0(r))$.*

13:8 Hyperbolic Random Graphs: Clique Number and Degeneracy

Corollary 5 tells us that any vertex with radius at most r has in expectation at least as many neighbours up to radius r , as the expected inner-degree of a vertex with radius exactly r . In order to derive a high-probability bound on $|\Gamma(u^*)|$ it now suffices to show concentration around the expectation of all considered neighbourhoods.

Since the size of every clique K is upper bounded by the inner-degree of the vertex in $u \in K$ that has the largest radius, $\omega(G)$ is a lower bound for the maximum inner-degree. We can now lower bound the degeneracy $\kappa(G)$ based on the largest inner-degree. Note that, in contrast to the upper bound of Observation 4, the lower bound is not deterministic.

► **Lemma 6.** *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then $\kappa(G) \geq (1 - o(1))|\Gamma(u^*)|$ w.e.h.p.*

Proof. For any subgraph $H \subseteq G$, it is clear that $\kappa(G) \geq \min_{v \in V(H)} \deg_H(v)$, where $\deg_H(v) = \sum_{w \in V \setminus \{v\}} \mathbb{1}\{\{v, w\} \in E(H)\}$. We let H be the (random) subgraph of G created by restricting G to vertices that land in $\mathcal{B}_0(r)$, that is, that have radius at most r , and keeping the same edges. Then for any $v \in V$,

$$\begin{aligned} \mathbb{E}[\deg_H(v) | r(v)] &= \sum_{w \in V \setminus \{v\}} \mathbb{P}(w \in \mathcal{B}_0(r) \cap \mathcal{B}_{r(v)}(R) | r(v)) \mathbb{1}\{r(v) \leq r\} \\ &= (n-1)\mu(\mathcal{B}_0(r) \cap \mathcal{B}_{r(v)}(R)) \mathbb{1}\{r(v) \leq r\} \\ &\geq (n-1)\mu(\mathcal{B}_0(r) \cap \mathcal{B}_r(R)) \mathbb{1}\{r(v) \leq r\}. \end{aligned} \quad (\text{Corollary 5})$$

We write $\gamma := (n-1)\mu(\mathcal{B}_0(r) \cap \mathcal{B}_r(R))$. Since $\deg_H(v)$ is a sum of Bernoulli random variables that are all independent under $\mathbb{P}(\cdot | r(v))$, a Chernoff bound (Theorem 3) gives

$$\begin{aligned} \mathbb{P}\left(\min_{v \in V(H)} \deg_H(v) < (1-\varepsilon)\gamma\right) &= \mathbb{P}\left(\bigcup_{v \in V} \{\deg_H(v) < (1-\varepsilon)\gamma, r(v) \leq r\}\right) \\ &\leq n\mathbb{P}(\deg_H(v) < (1-\varepsilon)\gamma, r(v) \leq r) \quad (\text{Union bound}) \\ &= n\mathbb{E}[\mathbb{P}(\deg_H(v) < (1-\varepsilon)\gamma | r(v)) \mathbb{1}\{r(v) \leq r\}] \quad (\text{Tower rule}) \\ &\leq n\mathbb{E}\left[e^{-\varepsilon^2 \mathbb{E}[\deg_H(v) | r(v)]/2} \mathbb{1}\{r(v) \leq r\}\right] \quad (\text{Chernoff bound}) \\ &\leq ne^{-\gamma\varepsilon^2/2} \mathbb{P}(r(v) \leq r) \leq ne^{-\gamma\varepsilon^2/2}. \end{aligned}$$

Taking r to be the argmax of γ yields $\gamma(r) \geq \mathbb{E}[\Gamma(u^*)]$. By Observation 2 and applying (2) at $R/2$ we have that $\gamma(r) \geq \mathbb{E}[\Gamma(u^*)] \geq \mathbb{E}[\sigma(G)] \in n^{\Omega(1)}$. Thus, choosing $\varepsilon = 1/\log(n)$, we obtain for any constant c as long as n is large enough

$$\mathbb{P}(\kappa(G) < (1-\varepsilon)|\Gamma(u^*)|) \leq \mathbb{P}(\kappa(G) < (1-\varepsilon)\gamma(r)) \leq ne^{-\gamma(r)\varepsilon^2/2} \leq ne^{-n^{\Omega(1)}/\log(n)} \leq n^{1-c},$$

that is, $\kappa(G) \geq (1 - o(1))|\Gamma(u^*)|$ w.e.h.p. ◀

In the rest of this section we derive bounds for the largest inner-degree on HRGs that hold w.e.h.p. which, by Observation 4 and Lemma 6, translate into results for the degeneracy. Since a vertex v belongs to the inner-neighbourhood of a vertex u , if and only if it resides in the inner-ball of u , we can use the measure of an inner-ball \mathcal{I}_u to bound the maximum inner-degree of a graph. Moreover, the measure of the inner-ball is invariant under rotation around the origin, which is why we write $\mu(\mathcal{I}(r))$ instead of $\mu(\mathcal{I}_u)$ for $r = r(u)$. We sum up our results for the area of the inner-ball in the following technical lemma.

► **Lemma 7** (Volume of the inner-ball). *Let $\Delta \in \Theta(1)$ and let $u \in \mathcal{D}_R$ with radius $r = R/2 + \Delta$. Then, depending on Δ , there exist constants γ, η , such that*

$$\begin{aligned} \mu(\mathcal{I}(r)) &\geq (1 + \Theta(e^{-\alpha R})) \frac{\alpha e^{-\alpha r}}{(\alpha - 1/2)} \left(\frac{2}{\pi} e^{\frac{1}{2}(2\alpha-1)(2r-R)} - \left(\frac{2}{\pi} - \frac{(\alpha - 1/2)}{\alpha} \right) \right) \quad \text{and} \\ \mu(\mathcal{I}(r)) &\leq (1 + \Theta(e^{-\alpha R})) \frac{\alpha e^{-\alpha r}}{\alpha - 1/2} \left(\gamma e^{\frac{1}{2}(2\alpha-1)(2r-R)} - \eta \right), \end{aligned}$$

where

$$\gamma, \eta = \begin{cases} 1, \frac{1}{2\alpha} & \text{for } \Delta \geq 0, \\ \frac{4}{3\sqrt{3}}, \frac{1}{2\alpha} - \left(1 - \frac{4}{3\sqrt{3}}\right) \left(\frac{4}{3}\right)^{(\alpha-1/2)} & \text{for } \Delta \geq \log(\sqrt{4/3}), \\ \frac{1}{\sqrt{2}}, \frac{1}{2\alpha} - \left(1 - \frac{4}{3\sqrt{3}}\right) \left(\frac{4}{3}\right)^{(\alpha-1/2)} - \left(\frac{4}{3\sqrt{3}} - \frac{1}{\sqrt{2}}\right) 2^{(\alpha-1/2)} & \text{for } \Delta \geq \log(\sqrt{2}), \\ \frac{2}{3}, \frac{1}{2\alpha} - \left(1 - \frac{4}{3\sqrt{3}}\right) \left(\frac{4}{3}\right)^{(\alpha-1/2)} - \left(\frac{4}{3\sqrt{3}} - \frac{1}{\sqrt{2}}\right) 2^{(\alpha-1/2)} - \left(\frac{1}{\sqrt{2}} - \frac{2}{3}\right) 2^{(2\alpha-1)} & \text{for } \Delta \geq \log(2). \end{cases}$$

► **Lemma 8.** *Let r^* be the radial coordinate of the point in \mathcal{D}_R that maximises the measure of the inner-ball. Then $r^* = R/2 + \log\left(\frac{\alpha\eta}{\gamma(1-\alpha)}\right)/(2\alpha - 1)$.*

Proof. Using the expression of $\mu(\mathcal{I}(r))$ in Lemma 7,

$$\frac{d}{dr} \mu(\mathcal{I}(r)) = (1 + \Theta(e^{-\alpha R})) \left(\frac{\eta \alpha^2 e^{-\alpha r}}{\alpha - 1/2} - \frac{\gamma \alpha e^{-\alpha r}}{\alpha - 1/2} \left((1 - \alpha) e^{\frac{1}{2}(2\alpha-1)(2r-R)} \right) \right).$$

Setting this equal to 0 and solving for r yields $r^* = R/2 + \log\left(\frac{\alpha\eta}{\gamma(1-\alpha)}\right)/(2\alpha - 1)$. ◀

We use Lemma 7 to upper and lower bound the degeneracy. The lower bound tells us that there exists a constant $\delta_\alpha > 0$ such that $\kappa(G) \geq (1 + \delta_\alpha)\sigma(G)$ w.e.h.p. The constant δ_α is increasing with increasing $1/2 < \alpha < 1$, see Figure 1.

► **Theorem 9** (Bounds on the degeneracy). *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then w.e.h.p. its degeneracy $\kappa(G)$ satisfies*

$$\frac{(4 - o(1))}{\pi} \left(\frac{2(1 - \alpha)}{\frac{\pi}{2} - \alpha(\pi - 2)} \right)^{\frac{1-\alpha}{2\alpha-1}} \sigma(G) \leq \kappa(G) \leq ((4/3)^\alpha + o(1))\sigma(G).$$

Proof sketch. The upper bound is obtained by using r^* as stated in Lemma 8 for the upper bound of the inner-ball with $(n - 1)\mu(\mathcal{I}(r^*))$, and using a Chernoff bound along with a union bound which gives an upper bound for $|\Gamma(u^*)|$ w.e.h.p. Observation 4 then yields the upper bound for the degeneracy. For the lower bound, we first show that there exists a vertex with a radius \tilde{r} close in value to r^* w.e.h.p. Then $(1 - o(1))(n - 1)\mu(\mathcal{I}(\tilde{r}))$ lower bounds $|\Gamma(u^*)|$ w.e.h.p. This gives a lower bound for the degeneracy, due to Lemma 6. ◀

Applying Observation 2 and Theorem 9, the following is immediate.

► **Corollary 10** (Bounds on the chromatic number). *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then w.e.h.p. its chromatic number is $\sigma(G) \leq \chi(G) \leq ((4/3)^\alpha + o(1))\sigma(G)$.*

Our structural results directly produce algorithmic applications. The small gap between degeneracy and core translates into an efficient approximation algorithm to colour a HRG.

► **Theorem 11.** *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then an approximate vertex colouring of G can be computed in time $\mathcal{O}(n)$ with approximation ratio $((4/3)^\alpha + o(1))$ w.e.h.p.*

Proof sketch. Using a *smallest-last* vertex ordering [31] the number of colours required is upper-bounded by $\kappa(G)$. Computing the smallest-last vertex ordering, and then using the ordering to colour the graph, both takes linear as the giant component is sparse w.e.h.p. by [25, Corollary 17]. The approximation ratio is achieved by comparing the lower bound of the chromatic number in Corollary 10 to the upper bound of the degeneracy in Theorem 9. ◀

4 Clique Number of Hyperbolic Random Graphs

Recall that for any graph G , the clique number $\omega(G)$, chromatic number $\chi(G)$, and degeneracy $\kappa(G)$ are related via the inequalities $\omega(G) \leq \chi(G) \leq \kappa(G)+1$. For this reason we are interested in the relationship between clique number and degeneracy for hyperbolic random graphs. In Section 4.1 we show that the two differ and that for HRGs, the degeneracy is strictly larger than the clique number by a constant multiplicative constant. In Section 4.2 we give new insights about where in the hyperbolic disk the largest clique is formed. We then conclude the section by providing a new upper bound for the clique number in Section 4.3 that states a leading constant in front of the size of the core, and that is increasing in α .

4.1 The gap between Clique Number and Degeneracy

Because of the centralising effect of hyperbolic geometry, one might hope to show that the clique contained in the core of the disk is the largest, and that $\omega(G) = (1 - o(1))\kappa(G)$. This would achieve two things on HRGs: first, it would imply a tight bound for the chromatic number $\chi(G)$, sandwiching it between clique number and degeneracy. Moreover, it would also imply a linear time $(1 + o(1))$ -approximation algorithm for the two NP-complete problems clique number and chromatic number using a smallest-last vertex ordering (see [31]).

In this section we disprove these claims. We show that there exists a constant gap between clique number and degeneracy; this is the content of Theorem 13. Before embarking on the details of the proof, we first sketch its idea. For any clique K , its size is bounded by the inner-degree $|\Gamma(u)|$, where u is the vertex with largest radius among the vertices of K . For $r(u) \leq R/2 + o(1)$ and $r(u) \in R/2 + \omega(1)$, $|\Gamma(u)|$ is already smaller by a multiplicative constant than the lower bound for the degeneracy given in Theorem 9. What remains is to extend the result to $r(u) \in R/2 + \Theta(1)$, which requires more intricate arguments and is addressed in the following lemma.

► **Lemma 12.** *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG, let $\Delta \in \Theta(1)$ and let K be any clique where $u \in K$ is the vertex with largest radius $r_K = R/2 + \Delta$. Then w.e.h.p. there exists a constant $\varepsilon \in (0, 1)$ such that $|K| \leq (1 - \varepsilon)|\Gamma(u)|$.*

Proof. Let G' be the inner-neighbourhood of u , i.e., the induced subgraph $G' = G[\Gamma(u)]$. Then $K \subseteq V(G')$, and thus $\omega(G') \geq |K|$. We show that $\omega(G') < (1 - \varepsilon)|\Gamma(u)|$ w.e.h.p.

We accomplish this by proving that there exists a colouring for G' with $(1 - \varepsilon)|V(G')| = (1 - \varepsilon)|\Gamma(u)|$ many colours. This implies an upper bound for the chromatic number $\chi(G')$, which also serves as an upper bound for $\omega(G')$. We do this by partitioning the inner-neighbourhood \mathcal{I}_u into three disjoint sub-regions $\mathcal{S}_0 \cup \mathcal{S}_1 \cup \mathcal{S}_2$ such that no vertex in \mathcal{S}_1 is adjacent to any vertex in \mathcal{S}_2 . Thus, \mathcal{S}_0 separates \mathcal{S}_1 from \mathcal{S}_2 and we can colour the set of vertices $V \cap \mathcal{S}_1$ with the same colours as $V \cap \mathcal{S}_2$. Thus if $\min\{|V \cap \mathcal{S}_1|, |V \cap \mathcal{S}_2|\} \geq \varepsilon|\Gamma(u)|$ w.e.h.p., our desired statement will be proven.

To find such a separator \mathcal{S}_0 , we follow the lines drawn by Bläsius et. al. [10] where *hypercycles* for hyperbolic random graphs were introduced (see Figure 3 a). A hypercycle \mathcal{H}_φ (of radius $R/2$) is defined as follows: let a_φ denote the line whose points have angle φ

■ **Figure 3** Illustration of a separator. (a) The line a_φ partitions disk \mathcal{D}_R into two halfdisks \mathcal{D}_1 (blue) and \mathcal{D}_2 (pink). The hypercycle \mathcal{H}_φ (hatched area) is defined by the line a_φ . Points located in different halfdisks and outside the hatched area have distance at least R . (b) The separator (hatched area) separates the inner-neighbourhood (grey area) of a vertex u of radius r_K into three sub-areas \mathcal{S}_0 , \mathcal{S}_1 and \mathcal{S}_2 . Any vertex located in \mathcal{S}_1 has no edge to a vertex in \mathcal{S}_2 .

and $\varphi + \pi$. Then $\mathcal{H}_\varphi := \{u \in \mathcal{D}_R : d_h(u, a_\varphi) \leq R/2\}$, i.e. the set of points with distance at most $R/2$ to line a_φ . Consider the point $u = (r_K, \varphi)$ and let $\mathcal{S}_0 := \mathcal{I}_u \cap \mathcal{H}_\varphi$. To define \mathcal{S}_1 and \mathcal{S}_2 separate \mathcal{D}_R into the two disjoint *halfdisks* $\mathcal{D}_1 = \{x \in \mathcal{D}_R : \varphi(x) - \varphi \leq \pi\}$ and $\mathcal{D}_2 = \{x \in \mathcal{D}_R : \varphi(x) - \varphi \geq \pi\}$ (see Figure 3 a). Then we define $\mathcal{S}_1 := (\mathcal{I}_u \cap \mathcal{D}_1) \setminus \mathcal{H}_\varphi$ and symmetrically $\mathcal{S}_2 := (\mathcal{I}_u \cap \mathcal{D}_2) \setminus \mathcal{H}_\varphi$.

We observe that any point $w \in \mathcal{S}_1$ has distance at least R to any point $v \in \mathcal{S}_2$. This can be shown for example by observing that the geodesic between w and v must pass through some point $x \in a_\varphi$, and so $d_h(w, v) = d_h(w, x) + d_h(x, v) \geq d_h(w, a_\varphi) + d_h(a_\varphi, v) > R$. This ensures our objective of separating the two regions via \mathcal{S}_0 .

Next, we show that there exists a constant $\varepsilon > 0$ small enough, such that $\mu(\mathcal{S}_1) = \mu(\mathcal{S}_2) \geq \varepsilon n^{-\alpha}$ (a sketch of the idea is given in Figure 3 b). Setting $\phi(x) = \max(0, \theta_R(r_K, x) - \theta_R(x, x)/2)$ we derive by symmetry

$$\mu(\mathcal{S}_1) = \mu(\mathcal{S}_2) = \int_{R/2}^r \int_0^{\phi(x)} \rho(x) d\phi dx = \int_{R/2}^{R/2+\Delta} \phi(x) \rho(x) dx.$$

Now we choose another constant $\Delta' < \Delta$ that fulfills $2\theta_R(R/2 + \Delta, R/2 + \Delta') - \theta_R(R/2 + \Delta', R/2 + \Delta') =: c \in \Theta(1)$. This is possible because $\Delta \in \Omega(1)$. By our choice of Δ' we then obtain

$$\begin{aligned} \mu(\mathcal{S}_1) &\geq \int_{R/2+\Delta'}^{R/2+\Delta} \phi(x) \rho(x) dx = \int_{R/2+\Delta'}^{R/2+\Delta} \left(\theta_R(R/2 + \Delta, x) - \frac{\theta_R(x, x)}{2} \right) \rho(x) dx \\ &\geq c \int_{R/2+\Delta'}^{R/2+\Delta} \rho(x) dx = \frac{c(\cosh(\alpha(R/2 + \Delta)) - \cosh(\alpha(R/2 + \Delta')))}{\cosh(\alpha R) - 1} \in \Omega(n^{-\alpha}), \end{aligned}$$

where the last line follows since $\theta_R(\cdot, \cdot)$ is monotonically decreasing and since $\rho(x) = \frac{\alpha \sinh(\alpha x)}{\cosh(\alpha R) - 1}$, $|\Delta - \Delta'| > 0$ and $R = 2 \log(n) + C$. Therefore $\mu(\mathcal{S}_1) \in \Omega(\mathbb{E}[\|\Gamma(u)\|] / n)$ w.e.h.p., since

$$\liminf_{n \rightarrow \infty} \frac{n\mu(\mathcal{S}_1)}{\mathbb{E}[\|\Gamma(u)\|]} = \liminf_{n \rightarrow \infty} \frac{\mu(\mathcal{S}_1)}{n^{-\alpha}} \frac{n^{1-\alpha}}{\mathbb{E}[\|\Gamma(u)\|]} > 0,$$

13:12 Hyperbolic Random Graphs: Clique Number and Degeneracy

where $\mathbb{E}[|\Gamma(u)|] \leq n\mu(\mathcal{B}_0(R/2 + \Delta)) \in \mathcal{O}(n^{1-\alpha})$ by Equation (2), because $\Delta \in \mathcal{O}(1)$. Thus there exists some $\varepsilon > 0$ for which, for n large enough,

$$\mathbb{E}[|V \cap \mathcal{S}_2|] = \mathbb{E}[|V \cap \mathcal{S}_1|] = n\mu(\mathcal{S}_1) \geq (1 - 1/\log(n))^{-2}\varepsilon\mathbb{E}[|\Gamma(u)|];$$

since $|V \cap \mathcal{S}_1| \leq |\Gamma(u)|$ a.s. and is strictly smaller with positive probability, then $\varepsilon < 1$.

Using a Chernoff bound for both $|V \cap \mathcal{S}_1|$ and $|V \cap \mathcal{S}_2|$, we obtain that neither random variable is smaller than $(1 - 1/\log(n))\mathbb{E}[|V \cap \mathcal{S}_1|] \geq (1 - 1/\log(n))^{-1}\varepsilon\mathbb{E}[|\Gamma(u)|]$ w.e.h.p. On the other hand, another application of a Chernoff bound reveals $|\Gamma(u)| \leq (1 + 1/\log(n))\mathbb{E}[|\Gamma(u)|]$ w.e.h.p., since for $r(u) \in R/2 + \Theta(1)$ we have $\mathbb{E}[|\Gamma(u)|] \in \Theta(n^{(1-\alpha)})$ using Lemma 7. A union bound then shows that w.e.h.p., $\min\{|V \cap \mathcal{S}_1|, |V \cap \mathcal{S}_2|\} \geq \frac{\varepsilon\mathbb{E}[|\Gamma(u)|]}{1 - 1/\log(n)} \geq \varepsilon|\Gamma(u)|$. As argued above, a naïve colouring that colours the vertices of \mathcal{S}_1 and \mathcal{S}_2 with the same set of colours yields the upper bound. \blacktriangleleft

► **Theorem 13 (Clique-degeneracy-gap).** *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then w.e.h.p. there exists a constant $\varepsilon \in (0, 1)$ such that $\kappa(G)/\omega(G) > 1 + \varepsilon$.*

Proof. Let K be the largest clique of G , and let u be the vertex of K with maximal radius $r_K := r(u)$. We assume the following cases for r_K which cover all possibilities:

Case 1 [$r_K \in R/2 + \omega(1)$]: Observe that $K \subseteq V \cap \mathcal{I}(r_K)$. Hence, $|K| \leq |V \cap \mathcal{I}(r_K)|$ and

$$\mu(\mathcal{I}(r_K)) \leq (1 + \Theta(e^{-\alpha R})) \frac{\alpha e^{-\alpha r_K}}{\alpha - 1/2} \left(\gamma e^{\frac{1}{2}(2\alpha-1)(2r_K-R)} - \eta \right) \in \Theta(1)n^{-\alpha}e^{-(1-\alpha)\omega(1)},$$

by Lemma 7 since γ and η are both constants. Taking the expectation and using a Chernoff bound we have $|K| \in o(n^{1-\alpha})$ w.e.h.p. Recall that $\kappa(G) > (1 + \delta)e^{-\alpha C/2}n^{1-\alpha}$ w.e.h.p. by Theorem 9. It follows $\kappa(G)/|K| \in \omega(1)$ w.e.h.p.

Case 2 [$r_K \leq R/2 + o(1)$]: Observe that the size of any clique $K \subseteq V \cap \mathcal{B}_0(r)$ is upper bounded by $X = |V \cap \mathcal{B}_0(r)|$. By Equation (2) we have $\mu(\mathcal{B}_0(r_K)) \leq (1 + o(1))n^{-\alpha}e^{-\alpha C/2}$. Hence, we get $\mathbb{E}[X] \leq (1 + o(1))n^{1-\alpha}e^{-\alpha C/2}$. Since X is a binomial random variable we can apply a Chernoff bound, which yields $|K| \leq X \leq (1 + o(1))n^{1-\alpha}e^{-\alpha C/2}$ w.e.h.p. Taking $\varepsilon = \delta/(1 + \delta)$ with δ as in Theorem 9, we have

$$\frac{|K|}{1 - \varepsilon} \leq (1 + o(1))(1 + \delta)n^{1-\alpha}e^{-\alpha C/2} < (1 + o(1))\kappa(G) \text{ w.e.h.p.}$$

Case 3 [$r_K \in R/2 + \Theta(1)$]: Let $\xi \in o(1)$. Using Lemmas 6 and 12, we get w.e.h.p. that

$$\omega(G) = |K| \leq \frac{1 - \varepsilon}{1 - \xi} |\Gamma(u)| \leq \frac{1 - \varepsilon}{1 - \xi} |\Gamma(u^*)| \leq (1 - \varepsilon)\kappa(G),$$

for an adequate choice of ξ . \blacktriangleleft

► **Corollary 14.** *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then there exists a constant $\varepsilon \in (0, 1)$ such that w.e.h.p., $\omega(G) \leq (4(1 - \varepsilon)/3)^\alpha \sigma(G)$.*

Proof. This follows from Theorems 9 and 13. \blacktriangleleft

4.2 Cliques larger than the Core

In this section, we show that there exist a super-constant number of unique cliques that contain the core, but are strictly larger than it. The overall argument goes as follows. We consider a set of vertices with radial coordinates slightly outside the core. We show that any vertex of this set has a constant probability to be adjacent to all vertices belonging to the core, and thus induces a clique that is larger than the core itself. To this end, the following lemma concerned about points close to the core proves useful.

■ **Figure 4** Sketch of the proof idea for Proposition 16. (a) Illustration of the set of points \mathcal{A} (blue) of width ξ slightly outside of the core (pink). The intersection with a sector of angle ψ and the band \mathcal{A} forms a box \mathcal{A}_i that contains a vertex w.e.h.p. The number of non-intersecting boxes is $k = 2\pi/\psi \in \omega(\log(n))$. (b) A vertex u located on the boundary of the area \mathcal{A} . The hatched area \mathcal{F}_u with angle at most ϕ is the corresponding forbidden area of u . Any point in \mathcal{F}_u has distance at least R to u . An adequate choice for the width ξ yields that this area is empty with constant probability.

► **Lemma 15.** *Let $k \in \mathbb{N} \setminus \{0\}$ and $\xi_k = \log(1 + \frac{\log^k(n)}{n^{1-\alpha}}) \in o(1)$. Consider two points with radial coordinates $r = R/2 + \xi_k$ and $x = R/2$. Then $\theta_R(r, x) \geq \pi - 2\sqrt{\log^k(n)n^{\alpha-1}}$.*

Lemma 15 lower bounds the angle distance such that two points have distance at most R .

► **Proposition 16.** *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then w.e.h.p. there exist $\omega(\log(n))$ cliques that are larger than $\sigma(G)$.*

Proof. For the proof we consider the Poissonized version of the HRG model (see e.g. [26, 27]). The upshot of this model is that it allows us to analyse disjoint areas in the hyperbolic disk independently. Since the final result holds w.e.h.p. this directly carries over to the uniform model w.e.h.p. ([22, Lemma 3.9]). We start by defining an area \mathcal{A} close to the core. Let $\xi = \log(1 + \frac{\log^3(n)}{n^{1-\alpha}}) \in o(1)$ and consider a band of points $\mathcal{A} := \mathcal{B}_0(R/2 + \xi) \setminus \mathcal{B}_0(R/2)$. We see via $R = 2 \log(n) + C$ that

$$\begin{aligned}
 \mu(\mathcal{A}) &= \int_{R/2}^{R/2+\xi} \frac{\sinh(\alpha x)}{\cosh(\alpha R) - 1} = \frac{\cosh(\alpha(R/2 + \xi)) - \cosh(\alpha R/2)}{\cosh(\alpha R) - 1} \\
 &= (1 + \Theta(e^{-\alpha R}))(e^{-\alpha(R/2-\xi)} - e^{-\alpha R/2}) \\
 &= (1 + \Theta(e^{-\alpha R}))(n^{-\alpha} e^{-\alpha C/2} (1 + \log^3(n)n^{\alpha-1}) - n^{-\alpha} e^{-\alpha C/2}) \\
 &= (1 + \Theta(e^{-\alpha R}))(e^{-\alpha C/2} \log^3(n)n^{-1}) \in \Theta(\log^3(n)/n). \tag{3}
 \end{aligned}$$

Let $A = V \cap \mathcal{A}$. Then $\mathbb{E}[|A|] \in \Theta(\log^3(n))$. We further partition the band \mathcal{A} into $k = \lceil \log^{3/2}(n) \rceil$ sectors $\mathcal{A}_1, \dots, \mathcal{A}_k$, each of equal size (see Figure 4 a), and $A_i = V \cap \mathcal{A}_i$. Since $\mathbb{E}[|A|] \in \Theta(\log^3(n))$ and $k = \log^{3/2}(n)$, we have for any $i \in [k]$ that $\mathbb{E}[|A_i|] = \frac{\mathbb{E}[|A|]}{k} \in \omega(\log(n))$. Since we are in the Poissonized model we get $\mathbb{P}(|A_i| = 0) = e^{-\mathbb{E}[|A_i|]} \in n^{-\omega(1)}$. Subsequently, a union bound yields that there is no sector \mathcal{A}_i that is empty w.e.h.p.

In the second step, we show that for any vertex $u \in A$, the probability that there exists a vertex in its *forbidden area* $\mathcal{F}_u := \{x \in \mathcal{B}_0(R/2) : d_h(u, x) > R\}$ (see Figure 4 b) is strictly less than 1. Since $r(u) \leq R/2 + \xi$, we have that $u \in A$ has distance at most R (and thus, an

13:14 Hyperbolic Random Graphs: Clique Number and Degeneracy

edge) to any vertex in the area $\mathcal{B}_0(R/2 - \xi)$. Hence, we have $\mathcal{F}_u \subset \mathcal{B}_0(R/2) \setminus \mathcal{B}_0(R/2 - \xi)$. Now, for $R/2 \geq x \geq R/2 - \xi$ we seek to find the angle size $\phi = 2(\pi - \theta_R(r(u), x))$ in order to upper bound $\mu(\mathcal{F}_u)$. Since $\theta_R(r, x)$ is monotonically decreasing in x we have $\phi \leq 2(\pi - \theta_R(R/2 + \xi, R/2))$ and we obtain

$$\begin{aligned} \mu(\mathcal{F}_u) &= \int_{R/2-\xi}^{R/2} \int_0^\phi \rho(x) \, d\phi \, dx \leq 2(\pi - \theta_R(R/2 + \xi, R/2)) \int_{R/2}^{R/2+\xi} \rho(x) \, dx \\ &\leq 2(\pi - \theta_R(R/2 + \xi, R/2))\mu(\mathcal{A}), \end{aligned}$$

where we used $\int_{R/2-\xi}^{R/2} \rho(x) \, dx \leq \int_{R/2}^{R/2+\xi} \rho(x) \, dx = \mu(\mathcal{A})$. By our choice of $\xi = \log(1 + \log^3(n)n^{\alpha-1}) \in o(1)$, we can apply Lemma 15 and obtain $\theta_R(R/2 + \xi, R/2) \geq \pi - 2\sqrt{\frac{\log^3(n)}{n^{1-\alpha}}}$. In Equation (3) we established that $\mu(\mathcal{A}) \in \Theta(\log^3(n)/n)$. Combining the two leads to $\mu(\mathcal{F}_u) \in \mathcal{O}\left(\sqrt{\log^9(n)n^{\alpha-3}}\right)$.

Notice that for $\alpha \in (1/2, 1)$, the measure of the forbidden area of a vertex $u \in A$ is $\mu(\mathcal{F}_u) \in o(1/n)$. Hence, writing $F = V \cap \mathcal{F}_u$, we get $\mathbb{E}[|F|] \in o(1)$, i.e., the expected number of vertices in \mathcal{F}_u is vanishing. Applying Markov's inequality then gives us $\mathbb{P}(|F| \geq 1) \in o(1)$. Thus $p := \mathbb{P}(|F| < 1) \in \Omega(1)$, so the forbidden area is empty with constant probability.

We now establish our third and final desired property. Namely, we construct a subset $U \subset A$, consisting of vertices whose forbidden areas are empty and disjoint and for which $\mathbb{E}[|U|] \in \omega(\log(n))$.

Recall that we partitioned \mathcal{A} into $k = \log^{3/2}(n) \in \omega(\log(n))$ sectors. Let X_i be the indicator that there exists a vertex $u \in \mathcal{A}_i$ whose forbidden area \mathcal{F}_u is empty. Then $X = \sum_{i=1}^{\lfloor k/2 \rfloor} X_{2i}$ is a loose lower bound on the number of sectors with this property. By linearity of expectation, p constant and $k = \log^{3/2}(n)$ we then obtain

$$\mathbb{E}[X] \geq \mathbb{E}\left[\sum_{i=1}^{\lfloor k/2 \rfloor} X_{2i}\right] \geq p \cdot \Theta(1) \log^{3/2}(n) \in \omega(\log(n)).$$

We proceed by showing independence among the random variables X_i and X_j for $|j - i| > 1$. To this end, observe that the angle ψ (see Figure 4 b) spanned by any sector \mathcal{A}_i is $\psi = 2\pi/k \geq \left\lfloor 2\pi \log^{-3/2}(n) \right\rfloor$. In contrast, we recall $\phi \leq 2(\pi - \theta_R(R/2 + \xi, R/2)) \leq 4\sqrt{\log^3(n)n^{\alpha-1}}$. Since $\sqrt{\log^3(n)n^{\alpha-1}} \in o(\log^{-3/2}(n))$ we conclude $\phi \in o(\psi)$. This implies that the forbidden areas \mathcal{F}_u and \mathcal{F}_v of any $u \in \mathcal{A}_i, v \in \mathcal{A}_j$ are disjoint. Thus X_i and X_j are independent.

To wrap things up, recall that in the first step we established that each sector \mathcal{A}_i contains a vertex w.e.h.p. Moreover, since the X_i are independent, we have by a Chernoff bound that $X \in \omega(\log(n))$ w.e.h.p. Though these two events are not independent, we can apply the union bound to their complements to obtain that w.e.h.p. $\omega(\log(n))$ vertices outside of $\mathcal{B}_0(R/2)$ are adjacent to all vertices in $\mathcal{B}_0(R/2)$, which finishes the proof. \blacktriangleleft

4.3 Upper Bound on the Clique Number

Recall that two vertices u, v are adjacent if and only if $d_h(u, v) \leq R$ and that we call the clique formed in $\mathcal{B}_0(R/2)$ the core whose size is $\sigma(G) = (1 - o(1))e^{-\alpha C/2}n^{1-\alpha}$ w.e.h.p. The core size is a lower bound for the clique number $\omega(G)$. We have established that the largest clique is smaller than the degeneracy w.e.h.p. (Theorem 13), and in this section we further investigate an upper bound for $\omega(G)$. We note that the upper bound we derive in this section implies Theorem 13 for α large enough (see Figure 1). However, for smaller α , the upper bound for $\omega(G)$ is larger than the lower bound (Theorem 9) for $\kappa(G)$ in the HRG model, and thus does not directly imply Theorem 13 for these values for α .

Before going into details, we lay out our proof strategy. We aim to bound the region where a clique can be located. Since vertices are adjacent if and only if their (hyperbolic) distance is at most R , this can be done by characterising a shape that covers any hyperbolic region of diameter R . A classic result by Jung [20] answers the question of how large the radius of a ball in Euclidean space needs to be at most, so that its interior can contain an entire set of points of fixed diameter. The hyperbolic version of this result was discovered by Dekster [14, 15] nearly a century later. He extended Jung's result to (among other geometries) hyperbolic space and we apply it as follows: we identify $\mathcal{O}(n^3)$ many balls where one of these balls contains the clique of largest size $\omega(G)$. This clique (and all the other identified cliques) needs to be located in a ball $B_x(r)$ with radius r large enough. We use the hyperbolic variant of Jung's theorem to upper bound r which, in turn, allows us to upper bound the area of this ball. This yields an upper bound for the amount of vertices one such ball $B_x(r)$ could contain w.e.h.p., leading to an upper bound for $\omega(G)$. Since we only need to consider at most $\mathcal{O}(n^3)$ balls, a union bound is sufficient to derive the same bound for the worst case. We work with the following version of Jung's theorem for hyperbolic geometry.

► **Theorem 17.** [14, Theorem 2] *Let $\mathcal{K} \subset \mathbb{H}^d$ be compact and suppose that for any $y, z \in \mathcal{K}$, $d_h(y, z) \leq D$. Then there exists $x \in \mathbb{H}^d$ such that $\mathcal{K} \subseteq \mathcal{B}_x(r)$ for r satisfying*

$$D \geq 2 \sinh^{-1} \left(\sqrt{\frac{d+1}{2d}} \sinh(r) \right).$$

In the hyperbolic plane \mathbb{H}^2 , this simplifies to the following.

► **Corollary 18.** *Let $\mathcal{K} \subset \mathbb{H}^2$ be compact and suppose that for any $y, z \in \mathcal{K}$, $d_h(y, z) \leq R$. Then there exists $x \in \mathbb{H}^2$ such that $\mathcal{K} \subseteq \mathcal{B}_x(r)$ for r satisfying $r \leq R/2 + \log(2/\sqrt{3})$.*

Proof. Using that $d = 2$, we directly get from Theorem 17 for diameter R that $\frac{R}{2} \geq \sinh^{-1}(\sqrt{3/4} \sinh(r))$. Rearranging and using for $x \in \mathbb{R}$ that $\sinh(x) = \frac{1}{2}e^x(1 - e^{-2x})$ yields

$$R/2 - r \geq \log(\sqrt{3/4}) + \log \left(\frac{(1 - e^{-2r})}{(1 - e^{-R})} \right).$$

Solving for r and using that $r \geq R/2 \geq \log(n) + C/2$ in conjunction with recalling that $C \in \Theta(1)$, it follows that $r \leq R/2 + \log(2/\sqrt{3})$. ◀

Our next observation follows from the definition of μ , and formalises the intuition that μ puts more mass at the centre of the disk.

► **Observation 19.** *Let $0 < r \leq R$ and $u, v \in \mathcal{D}_R$ with $r(u) \geq r(v)$. Then $\mu(\mathcal{B}_u(r)) \leq \mu(\mathcal{B}_v(r))$.*

Recall that $\sigma(G)$ denotes the core size $|V \cap \mathcal{B}_0(R/2)|$ which is a lower bound for the clique number $\omega(G)$ (see Observation 2), and that $\sigma(G) = (1 - o(1))e^{-\alpha C/2}n^{1-\alpha}$ w.e.h.p. We state our upper bound relative to this lower bound.

► **Theorem 20** (Clique upper bound). *Let $G \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG with $\alpha \in (1/2, 1)$. Then w.e.h.p.*

$$\omega(G) \leq \left((4/3)^{\alpha/2} + o(1) \right) \sigma(G).$$

13:16 Hyperbolic Random Graphs: Clique Number and Degeneracy

Proof. Consider any triplet of vertices $u, v, w \in V$ with pairwise distance at most R , so that they are pairwise adjacent. Since u, v, w are a.s. in general position, there is a unique ball $\mathcal{B}_x(r)$ such that u, v, w lie on the boundary $\partial\mathcal{B}_x(r)$. By Corollary 18, $r \leq R/2 + \log(\sqrt{4/3})$ since $\max(d_h(u, v), d_h(v, w), d_h(u, w)) \leq R$. Over all possible triplets $u, v, w \in V$ this gives us a set B of at most $\binom{n}{3}$ closed balls. Any clique must be contained in one of these balls, and therefore so is the largest clique. Thus upper bounding the number of vertices for each individual ball $\mathcal{B} \in B$ yields an upper bound on the size of the largest clique.

We now upper bound the expected number of vertices in one ball B . To this end we fix a ball $\mathcal{B} = \mathcal{B}_x(r) \in B$ and let $Y_{\mathcal{B}}$ be the random variable counting the number of vertices in \mathcal{B} . The balls in B are identically (though clearly not independently) distributed. Since vertices are thrown independently according to μ , we have that $Y_{\mathcal{B}} - 3 \sim \text{Bin}(n - 3, \mu(\mathcal{B}))$, and so

$$\begin{aligned} \mathbb{E}[Y_{\mathcal{B}}] &= 3 + (n - 3)\mu(\mathcal{B}) \leq 3 + (n - 3)\mu(\mathcal{B}_0(r)) && \text{(Observation 19)} \\ &\leq 3 + (n - 3)\mu(\mathcal{B}_0(R/2 + \log(2/\sqrt{3}))) && \text{(Corollary 18)} \\ &\leq ((2/\sqrt{3})^\alpha + o(1))e^{-\alpha C/2}n^{1-\alpha}. && \text{(Equation (2))} \end{aligned}$$

Thus $((4/3)^{\alpha/2} + o(1))\sigma(G) \geq (1 + 1/\log(n))\mathbb{E}[Y_{\mathcal{B}}]$ w.e.h.p. This is relevant to the bound in the theorem statement because it implies that

$$\begin{aligned} \mathbb{P}\left(\omega(G) > ((4/3)^{\alpha/2} + o(1))\sigma(G)\right) &\leq \mathbb{P}\left(\max_{\mathcal{B} \in B} Y_{\mathcal{B}} > ((4/3)^{\alpha/2} + o(1))\sigma(G)\right) \\ &\leq \mathbb{P}\left(\max_{\mathcal{B} \in B} Y_{\mathcal{B}} > (1 + 1/\log(n))\mathbb{E}[Y_{\mathcal{B}}]\right) + n^{-c} \end{aligned}$$

for arbitrary c . Thus to finish the proof we need to show concentration, which via a union bound over all triplets u, v, w will yield the result. To show concentration we apply a Chernoff bound Theorem 3. Using $\varepsilon = (1/\log(n))$ we obtain

$$\mathbb{P}(Y_{\mathcal{B}} > (1 + 1/\log(n))\mathbb{E}[Y_{\mathcal{B}}]) \leq e^{-\mathbb{E}[Y_{\mathcal{B}}]/(3(1/\log(n))^2)} \leq e^{-\Theta(1)(n^{1-\alpha})/\log^2(n)} \leq n^{-c}$$

for any choice of c , since for $\alpha < 1$, $\Theta(1)(n^{1-\alpha}) \in n^{\Theta(1)}$ and $\liminf_{n \rightarrow \infty} \frac{n^{\Theta(1)}}{\log^2(n)} \in \omega(\log(n))$. Finally, to show that this holds w.e.h.p. for all balls in B , we use that $|B| \leq \binom{n}{3} < n^3$, so that

$$\begin{aligned} \mathbb{P}\left(\max_{\mathcal{B} \in B} Y_{\mathcal{B}} \geq (1 + 1/\log(n))\mathbb{E}[Y_{\mathcal{B}}]\right) &\leq \sum_{\mathcal{B} \in B} \mathbb{P}(Y_{\mathcal{B}} \geq (1 + 1/\log(n))\mathbb{E}[Y_{\mathcal{B}}]) \\ &\leq n^3 \mathbb{P}(Y_{\mathcal{B}} \geq (1 + 1/\log(n))\mathbb{E}[Y_{\mathcal{B}}]) \leq n^{-c+3}. \quad \blacktriangleleft \end{aligned}$$

A further refinement of the ‘‘clique covering’’ argument of Theorem 20 should be possible. Any clique has by definition a diameter of at most R , and so the shape in \mathbb{H}^2 of diameter R with maximal area would provide an improved upper bound via a similar covering argument. It is not clear what a tight bound would be, and $\omega(G) \leq (1 + o(1))\sigma(G)$ may be possible.

5 Geometric Inhomogeneous Random Graphs

Geometric Inhomogeneous Random Graphs or *GIRGs* were introduced in [11] as an alternative model to HRGs that capture many of the same properties, in particular the power-law degree distribution. In their most general form, GIRGs strictly generalise HRGs, but they are more often studied in a slightly restricted form; comparisons are made in [6, 28]. In this restricted form, called the *standard* GIRG model by [16], any HRG G can be coupled with two GIRGs H_1 and H_2 such that $H_1 \subseteq G \subseteq H_2$, where \subseteq denotes graph inclusion.

Because of this relationship, GIRGs are used as proxies for HRGs in some theoretical and experimental works. This is partly done because GIRGs are (by design) far more tractable than HRGs. It is therefore valuable to understand differences between the two models. In [6] experimental evidence was given to suggest that the “sandwiching” of an HRG by two standard GIRGs is not tight. In Corollary 24 we provide a theoretical result demonstrating a difference between the two models.

► **Definition 21** (Standard GIRG model). *Let $\beta \in (2, 3)$, $\lambda \in \Theta(1)$, and $n \in \mathbb{N}$. A geometric inhomogeneous random graph $G \sim \mathcal{G}(n, \beta, \lambda)$ is a random graph with vertex set $V = \{v_1, \dots, v_n\}$ satisfying the following properties.*

1. *Every $u \in V$ is equipped with a random tuple (w_u, x_u) , where weight $w_u \in [1, \infty)$ has density $f(y) = (\beta - 1)y^{-\beta}$ and coordinate x_u is drawn uniformly at random from $[0, 1]$;*
2. *Any pair of vertices $u, v \in V$ are connected if and only if $\min\{|x_u - x_v|, 1 - |x_u - x_v|\} \leq t(u, v)$, where $t(u, v) = \frac{1}{2} \left(\frac{\lambda w_u w_v}{n} \right)$.*

One way of thinking of a GIRG is that vertices are being thrown uniformly at random onto the 1-dimensional torus \mathbb{T}^1 , and connected according to whether their distance is below their threshold $t(u, v)$. The weights are drawn according to a Pareto distribution. Analogously to HRGs, for a vertex u of a GIRG we define the inner-degree of u to be $|\Gamma(u)| = |\{v \in V \mid u \text{ and } v \text{ are connected and } w_v \geq w_u\}|$. The proofs of Observation 4 and Lemma 6 can be adapted to the GIRG model to characterise the degeneracy via the largest inner-degree.

► **Corollary 22.** *Let $G \sim \mathcal{G}(n, 2\alpha + 1, \lambda)$ be a standard GIRG. Consider the vertex u^* with the largest inner-degree in G . Then w.e.h.p. $\kappa(G) = (1 - o(1))|\Gamma(u^*)|$.*

Corollary 22 allows us to state a tight bound for the degeneracy in comparison to the core of the GIRG, which is defined to contain all vertices of weight $\hat{w} \geq \sqrt{n/\lambda}$, and has size $\sigma(G) = (1 \pm o(1))\lambda^{-\alpha}n^{1-\alpha}$ w.e.h.p. This is analogous to the core of an HRG, which is the clique formed by vertices of radius at most $R/2$, regardless of their angular coordinates.

► **Theorem 23.** *Let $G \sim \mathcal{G}(n, 2\alpha + 1, \lambda)$ be a threshold GIRG. The degeneracy is w.e.h.p.*

$$\kappa(G) = (2 \pm o(1))(2(1 - \alpha))^{(1-\alpha)/(2\alpha-1)}\sigma(G).$$

Proof. We bound the maximal inner-degree $|\Gamma(u^*)|$; the statement then follows from Corollary 22. Notice that, independent of the geometric distance, a vertex with weight w is adjacent to any vertex with weight w' if $w' \geq \frac{n}{w\lambda}$ since $t(w, w') = \frac{\lambda w w'}{2n} \geq \frac{\lambda w \frac{n}{w\lambda}}{2n} = \frac{1}{2}$ which is the maximal distance between two points in the unit torus. Thus, using $\beta = 2\alpha + 1$, the probability that a vertex v is in the inner-neighbourhood of a vertex u with weight w is

$$\begin{aligned} \mathbb{P}(v \in \Gamma(u)) &= \mathbb{P}(\{\{u, v\} \in E\} \cap \{W_v \geq w\}) \\ &= \mathbb{P}\left(W_v \geq \frac{n}{w\lambda}\right) + 2 \int_w^{\frac{n}{w\lambda}} t(y, w) 2\alpha y^{-(2\alpha+1)} dy && (t(w, n/w\lambda) = 1/2) \\ &= \left(\frac{n}{w\lambda}\right)^{-2\alpha} + \frac{2\alpha\lambda w}{n} \int_w^{\frac{n}{w\lambda}} y^{-2\alpha} dy && (\text{Pareto and threshold}) \\ &= \left(\frac{n}{w\lambda}\right)^{-2\alpha} + \frac{2\alpha\lambda w}{n(2\alpha-1)} \left(w^{1-2\alpha} - \left(\frac{n}{w\lambda}\right)^{1-2\alpha}\right) && \left(\int y^{-2\alpha} dy = \left[\frac{y^{1-2\alpha}}{1-2\alpha}\right]\right) \\ &= \left(\frac{n}{w\lambda}\right)^{-2\alpha} + \frac{\alpha}{\alpha-1/2} \left(\frac{\lambda w^{2(1-\alpha)}}{n} - \left(\frac{n}{w\lambda}\right)^{-2\alpha}\right). && (4) \end{aligned}$$

13:18 Hyperbolic Random Graphs: Clique Number and Degeneracy

Next, we calculate the value w^* , which maximises the expected inner-degree. To this end, we consider the probability measure of the inner-neighbourhood, take its derivative with respect to w and set it equal to 0. Differentiating yields

$$\frac{d}{dw} \mathbb{P}(v \in \Gamma(u)) = \frac{2(nw)^{-(2\alpha+1)}(1-\alpha)\alpha(n^{2\alpha}w^2\lambda - nw^{4\alpha}\lambda^{2\alpha})}{2\alpha-1},$$

and solving for the maximum reveals $w^* = (2(1-\alpha))^{\frac{1}{4\alpha-2}} \sqrt{\frac{n}{\lambda}} \in \Theta(\sqrt{n})$.

We plug in w^* for the weight of u denoted by u^* into $\mathbb{P}(v \cap \Gamma(u^*))$ and get by (4) that

$$\mathbb{P}(v \in \Gamma(u^*)) = 2(2(1-\alpha))^{(1-\alpha)/(2\alpha-1)}(n\lambda)^{-\alpha}.$$

Recalling that $\sigma(G) = (1 \pm o(1))\lambda^{-\alpha}n^{1-\alpha}$ w.e.h.p., the upper bound now follows from the expectation of $|\Gamma(u^*)|$ and applying a Chernoff bound in conjunction with a union bound. The lower bound is established by showing that there exists a vertex within the range of weights $\tilde{w} = [w^*(1+n^{\alpha-1}\log^2(n))^{-1/(2\alpha)}, w^*]$ w.e.h.p. and lower bound the inner-degree of such vertex. Using the Pareto distribution and $w^* \in \Theta(\sqrt{n})$, we calculate the probability for a vertex u to belong to the range of weights \tilde{w} . We obtain

$$\begin{aligned} \mathbb{P}(W_u \in \tilde{w}) &= \mathbb{P}\left(w^*(1+n^{\alpha-1}\log^2(n))^{-1/(2\alpha)} \leq W_u \leq w^*\right) && \text{(Range of } \tilde{w}\text{)} \\ &= \mathbb{P}(W_u \leq w^*) - \mathbb{P}\left(W_u \leq w^*(1+n^{\alpha-1}\log^2(n))^{-1/(2\alpha)}\right) \\ &= 1 - (w^*)^{-2\alpha} - (1 - (w^*(1+n^{\alpha-1}\log^2(n))^{-1/(2\alpha)})^{-2\alpha}) && \text{(Pareto)} \\ &= (w^*(1+n^{\alpha-1}\log^2(n))^{-1/(2\alpha)})^{-2\alpha} - (w^*)^{-2\alpha} \\ &= (w^*)^{-2\alpha}n^{\alpha-1}\log^2(n) \\ &= \Theta(1)\frac{\log^2(n)}{n}. && (w^* \in \Theta(\sqrt{n})) \end{aligned}$$

By this we have $\mathbb{E}[|V \cap \tilde{w}|] \in \omega(\log(n))$. Using a Chernoff bound there exists a vertex within the desired weight range \tilde{w} w.e.h.p. To conclude the proof we lower bound the inner-degree of a vertex \tilde{u} included in the weight range \tilde{w} . Note that $\tilde{w} = (1-o(1))w^* = (2-o(1)(1-\alpha))^{\frac{1}{4\alpha-2}}\sqrt{\frac{n}{\lambda}}$. We then have via Equation (4)

$$\mathbb{E}[|\Gamma(\tilde{u})|] = (n-1)\mathbb{P}(v \cap \Gamma(\tilde{u})) \geq (2-o(1))(2(1-\alpha))^{(1-\alpha)/(2\alpha-1)}\lambda^{-\alpha}n^{1-\alpha}.$$

A final application of a Chernoff bound then ensures the concentration to finish the proof. ◀

Comparing the lower bound of the degeneracy for GIRGs given in Theorem 23 to the upper bound of a HRG we obtained in Theorem 9 we draw the conclusion that the degeneracy-to-core ratio between the two models is fundamentally different.

► **Corollary 24** (GIRG-HRG degeneracy difference). *Fix an $\alpha \in (1/2, 1)$. Let $G \sim \mathcal{G}(n, 2\alpha+1, \lambda)$ be a standard GIRG and $H \sim \mathcal{G}(n, \alpha, C)$ be a threshold HRG. Then w.e.h.p.*

$$\left| \frac{\kappa(G)}{\sigma(G)} - \frac{\kappa(H)}{\sigma(H)} \right| \in \Theta(1).$$

6 Conclusion

We have shown that the clique number, degeneracy, and chromatic number of HRGs are asymptotically (with small differences in the leading O -notation constants) as large as the core, though the clique number and degeneracy differ significantly. Our upper bound on

the degeneracy provides a constant factor approximation algorithm for the graph colouring problem. The approximation ratio ranges from $2/\sqrt{3}$ to $4/3$ and depends on the model parameter α . This raises several open questions and future research directions.

- Is the chromatic number bounded away from the degeneracy, the clique number, or both?
- Can HRGs be coloured optimally in polynomial time or is it NP-complete?
- What are the asymptotics of $\omega(G)/\sigma(G)$? Is the clique number a constant factor larger than the core and has similar behaviour as the degeneracy?

There are further directions of research such as determining other differences between HRGs and GIRGs or designing colouring algorithms for HRGs in various models of computation.

Abstract

Let G be a weighted graph embedded in a metric space (M, d_M) . The vertices of G correspond to the points in M , with the weight of each edge uv being the distance $d_M(u, v)$ between their respective points in M . The dilation (or stretch) of G is defined as the minimum factor t such that, for any pair of vertices u, v , the distance between u and v – represented by the weight of a shortest u, v -path – is at most $t \cdot d_M(u, v)$. We study DILATION t -AUGMENTATION, where the objective is, given a metric M , a graph G , and numerical values k and t , to determine whether G can be transformed into a graph with dilation t by adding at most k edges.

Our primary focus is on the scenario where the metric M is the shortest path metric of an unweighted graph Γ . Even in this specific case, DILATION t -AUGMENTATION remains computationally challenging. In particular, the problem is W[2]-hard parameterized by k when Γ is a complete graph, already for $t = 2$. Our main contribution lies in providing new insights into the impact of combinations of various parameters on the computational complexity of the problem. We establish the following.

- The parameterized dichotomy of the problem with respect to dilation t , when the graph G is sparse: Parameterized by k , the problem is FPT for graphs excluding a biclique $K_{d,d}$ as a subgraph for $t \leq 2$ and the problem is W[1]-hard for $t \geq 3$ even if G is a forest consisting of disjoint stars.
- The problem is FPT parameterized by the combined parameter $k + t + \Delta$, where Δ is the maximum degree of the graph G or Γ .

1 Introduction

Consider a finite metric space $\mathcal{M} = (V, d_M)$, and let G be a sparse weighted graph with vertices corresponding to the points in V . The weights assigned to the edges of G represent the distances in \mathcal{M} between their end-points. That is, the graph $G = (V, E)$ is embedded in a metric space $\mathcal{M} = (V, d_M)$. The graph G is called a t -spanner if, for every pair of vertices $u, v \in V$, the distance between them in G is at most $t \cdot d_M(u, v)$. The concept of spanners, introduced by Peleg and Schäffer [19], has evolved into a fundamental tool in various domains, including algorithms, distributed computing, networking, data structures and metric geometry, as highlighted in [18]. The minimum number t for which G is a t -spanner defines the *stretch* or *dilation* of G .

In their book [18, p.474, Problem 9], Narasimhan and Smid presented the problem of enhancing the dilation of a spanner by adding at most k edges: Develop an efficient algorithm to identify the $k > 1$ edges that minimize (or approximately minimize) the stretch factor of the resulting geometric graph. Formally, the problem is defined as follows.

DILATION t -AUGMENTATION

Input: A graph $G = (V, E)$ embedded in a metric space $\mathcal{M} = (V, d_M)$ and an integer k .

Question: Does there exist a set of k edges $S \subseteq V \times V$ such that the dilation of $G' = (V, E \cup S)$ is at most t ?

The case where $k = 1$, was investigated by Farshi, Giannopoulos, Gudmundsson [8], Luo, Wulff-Nilsen [17], and Wulff-Nilsen [20]. However, for the more general scenario where $k > 1$, the problem becomes significantly more challenging and poorly understood. Giannopoulos et al. [12] and Gudmundsson and Smid [13] demonstrated that obtaining the best dilation spanner by adding k edges to an empty graph is already NP-hard. Gudmundsson and Wong [14] proposed an algorithm that in $\mathcal{O}(n^3 \log n)$ time, identifies k edges whose addition to G results in a graph with a stretch factor within $\mathcal{O}(k)$ of the minimum stretch factor. Related problems have also been studied in geometric settings, e.g., Aronov et al. [1], who showed that, given a set S of n points in \mathbb{R}^2 , and an integer $0 \leq k < n$, we can construct a *geometric graph* with vertex set S , at most $n - 1 + k$ edges, maximum degree five, and dilation $\mathcal{O}(n/(k + 1))$ in time $\mathcal{O}(n \log n)$.

We approach the DILATION t -AUGMENTATION problem from the perspective of Multivariate (Parameterized) Complexity – another popular paradigm to deal with intractable problems [4, 6, 10]. The two most natural parameters associated with the problem are the size of the solution k (the size of the augmented set) and the stretch factor t . We are looking for an algorithm with running time $f(k) \cdot n^{\mathcal{O}(1)}$ or $g(k, t) \cdot n^{\mathcal{O}(1)}$. Here, $n = |V(G)|$. These algorithms are called fixed-parameter tractable (FPT) algorithms. There is also an accompanying theory of W -hardness that allows us to show that problems do not admit FPT algorithms (see [4, 6, 10] for further details). The problem of finding a t -spanner for a given graph is considered from the perspective of parameterized complexity in [15, 16]. Observe that, DILATION t -AUGMENTATION admits an algorithm with running time $n^{\mathcal{O}(k)}$ – try all possible subsets of size k of $V \times V$ as S . Thus, this naturally leads to the following.

■ **Figure 1** An instance of DILATION 2-AUGMENTATION with $k = 2$. The edges of the solution S are shown in dashed red. The edge weights in G are derived from the corresponding shortest path in Γ .

Does DILATION t -AUGMENTATION admit an FPT algorithm?

A simple result shows that, in its full generality, the problem is $W[2]$ -hard. In fact, consider $\mathcal{M} = (V, d_M)$ derived from an unweighted clique K on n vertices. That is, the vertices of the metric correspond to the vertices of K , and $d_M(u, v)$ is the length of shortest path between u and v in K , which is 1. Then, for $t = 2$, DILATION 2-AUGMENTATION corresponds to adding edges to G so that the diameter of the augmented graph becomes 2 (see Figure 1 for an illustration). This is the well-known DIAMETER 2-AUGMENTATION problem which is known to be $W[2]$ -hard [11]. Thus, we do not expect that DILATION t -AUGMENTATION to admit an algorithm with running time $g(k) \cdot n^{\mathcal{O}(t)}$. This simple hardness result motivates the following set of questions:

- For which metrics \mathcal{M} , does DILATION t -AUGMENTATION admit an FPT algorithm?
- For which family of input graphs \mathcal{G} , does DILATION t -AUGMENTATION admit an FPT algorithm?
- For which pairs of family of input graphs and metric, $(\mathcal{G}, \mathcal{M})$, does DILATION t -AUGMENTATION admit an FPT algorithm?

In this article, we specifically concentrate on the fundamental and non-trivial scenario where the metric \mathcal{M} corresponds to the shortest-path metric of an unweighted graph. Our contribution represents a substantial addition to the limited body of literature that addresses the challenging problem of DILATION t -AUGMENTATION.

1.1 Our Model, Results, and Methods

Throughout this paper, we deal with the shortest-path metric derived from an unweighted graph, unless otherwise mentioned.¹ For an edge weighted graph H , let $d_H(u, v)$ denote the *weighted shortest path distance* in the graph H between two vertices u and v . Additionally, we use $\text{hop}_H(u, v)$ to denote the length of the shortest path between u and v when we forget the edge weights. In other words, this denotes the length of the shortest path in H when all edges receive weight 1. We will use d_H and hop_H *only when H is edge weighted*; otherwise, both d_H and hop_H represent the same thing. Throughout the article, the metric \mathcal{M} will be derived from an undirected unweighted graph $\Gamma = (V, E)$. That is, the vertices of the metric correspond to the vertices of Γ , and $d_M(u, v)$ is assigned the shortest path distance in Γ , between u and v . Observe that $d_M(u, v) = d_{\Gamma}(u, v) = \text{hop}_{\Gamma}(u, v)$. We will use (G, Γ, k) as an

¹ Any metric can be derived from an edge weighted graph. Thus, our assumption represents a simplification.

instance of DILATION t -AUGMENTATION problem. Since \mathcal{M} is derived from Γ , for ease of notation, we use $d_\Gamma(u, v)$ instead of $d_M(u, v)$. Furthermore, recall that G is embedded in the metric space \mathcal{M} derived from Γ . That is, G is an edge-weighted graph, where the weights assigned to the edges of G represent the distances in Γ between their end-points. That is, $w(u, v) = d_\Gamma(u, v)$ and $d_G(u, v)$ denote the *weighted shortest path distance* in G .

The starting point of our research is the result of Peleg and Schäffer [19] that DILATION t -AUGMENTATION is NP-hard for $t = 2$, where G is an empty graph and the metric \mathcal{M} is derived from an undirected graph Γ . So, a natural question is whether this special subcase is FPT. Starting with this question, we trace the boundaries of the DILATION t -AUGMENTATION problem by instantiating different graph families to which Γ can belong or by instantiating different graph families to which G can belong. Our results consist of the following.

1. Our main algorithmic result is an FPT algorithm for DILATION 2-AUGMENTATION when G belongs to the family of $\mathcal{K}_{d,d}$ -free graphs. Recall that a graph G is $\mathcal{K}_{d,d}$ -free if it does not contain a complete bipartite graph with d vertices, each on both sides of the bipartition, as a subgraph. However, there is no restriction on Γ .

We complement this result by showing that this result cannot be extended for $t = 3$. Indeed, we show that when G is a disjoint union of a star and an independent set, and Γ is an arbitrary graph, then DILATION 3-AUGMENTATION is W[1]-hard. In a slight converse we also show that DILATION 3-AUGMENTATION is W[2]-hard when Γ is a star, and G is an arbitrary graph. On the other hand, in a generalization of the latter setting when Γ is a tree, we show that DILATION 2-AUGMENTATION is polynomial-time solvable.

2. Observe that for the families of stars we cannot bound the maximum degree of each graph uniformly. We show that if G (resp. Γ) belongs to the family of graphs with a maximum degree at most d and Γ (resp. G) is an arbitrary graph, then DILATION t -AUGMENTATION admits an algorithm FPT with running time $f(k, t, d) \cdot n^{\mathcal{O}(1)}$.

We complement this result by showing that this result cannot be extended for the weighted metric. That is, when G belongs to the family of graphs of maximum degree 3 and the graph Γ is edge-weighted, then the problem becomes intractable. In fact, the edges of Γ get weights from the two-size set $\{1, w\}$. We show that DILATION $(2 + \epsilon)$ -AUGMENTATION is W[1]-hard in this case.

It is important to note that the family of $\mathcal{K}_{d,d}$ -free graphs includes trees, planar graphs, graphs that exclude a fixed graph H as a minor, graphs of bounded expansion, nowhere dense graphs, and graphs of bounded degeneracy.² We refer to Table 1 for a quick reference of all the results shown in this article. Our algorithmic results are based on the structural interaction between Γ and G . We start by defining the notion of conflict pairs (a pair (u, v) in G such that $d_G(u, v) > t \cdot d_\Gamma(u, v)$) and show that to resolve these pairs it suffices to focus on those pairs that are adjacent in Γ (that is, $(u, v) \in E(\Gamma)$). We call them adjacent conflicts. Resolving adjacent conflict pairs is the key to our results, both algorithms and hardness.

Our main result regarding DILATION 2-AUGMENTATION when G is $\mathcal{K}_{d,d}$ -free is given in Section 3. Our algorithm can be broadly divided into three separate phases. First, in Section 3.1 we define the notion of a *conflict graph* and bound the size of the minimum vertex cover in this graph using the restrictions imposed on the solution for DILATION t -AUGMENTATION in the special case of $t = 2$. Then, in Section 3.2, we analyze the interplay

² For a formal definition of many of these graph classes, we refer to standard texts on graph theory, e.g., Diestel [5].

■ **Table 1** Complexity of the DILATION t -AUGMENTATION for different G , metric, parameters and t .

G	Metric (Γ)	Parameter(s)	t	Complexity
$\mathcal{K}_{d,d}$ -free	General	$k + d$	2	FPT (Section 3)
Star forest	General	k	3	W[1]-hard (Section 5.1)
General	Star	k	3	W[1]-hard (Section 5.2)
General	Tree	k	2	P (♠)
General	Bounded degree	$k + t + \Delta$	t	FPT (Section 4.1)
Bounded degree	General	$k + t + \Delta$	t	FPT (Section 4.2)
Subcubic	$(1, w)$ -weighted	k	$2 + \epsilon$	W[1]-hard (♠)
Edgeless	General	k	2	NP-hard (♠)
General	Clique	k	2	W[2]-hard (♠)

between the bounded-size vertex cover, along with the structural properties of G due to the fact that it is $\mathcal{K}_{d,d}$ -free, and use it to design a recursive algorithm that tries to guess a certain kind of edges that must belong to any solution in a YES-instance. At the leaves of this recursive procedure, we can upper bound the total number of vertices involved in conflicts. Nevertheless, we cannot get rid of all other vertices since they may be crucial for certain shortest paths. Finally, in Section 3.3 we bound the size of the instance by carefully eliminating a subset of conflict-free vertices, at which point we can enumerate all possible solutions. For the other two algorithmic results, we obtain a small set of V that contains all the end-points of edges of the solution. The hardness results are shown via parameter preserving reductions from known W-hard problems, using classical gadget constructions. The details of the results/statements marked with ♠ can be found in the full version of the paper [2].

Notations. Let $[n]$ be the set of integers $\{1, \dots, n\}$. For any graph G , we denote the set of vertices of G by $V(G)$ and the set of edges by $E(G)$. We denote the set of non-edges by $\overline{E}(G)$, that is, $\overline{E}(G) = \binom{V(G)}{2} \setminus E(G)$, where $\binom{V(G)}{2}$ is the set of all unordered pairs of distinct vertices in $V(G)$. For notational convenience, even though our edges/non-edges are undirected, we use the notation (a, b) instead of $\{a, b\}$ – note that due to this convention, $(a, b) = (b, a)$. A graph $G = (V, E)$ is said to be a *star*, if there exists a vertex $c \in V(G)$ such that $E = \{(u, c) : u \in V(G) \setminus \{c\}\}$. In this case, we say that c is the *center* of the star. Vertices of $V(G) \setminus \{c\}$ (if any) are said to be the *leaves* of the star. If every connected component of a graph G is a star, then we say that G is a *star forest*.

For a graph $G = (V, E)$ and a subset S of edges in $\overline{E}(G)$, we use the notation $G + S$ to mean the graph $G' = (V, E \cup S)$. For a graph G , a path is a sequence of distinct vertices $v_1 \dots v_\ell$ such that $(v_i, v_{i+1}) \in E(G)$ for $i \in [\ell - 1]$ and this path is denoted by $\langle v_1, \dots, v_\ell \rangle$. For an undirected unweighted graph H , we use $\text{hop}_H(u, v)$ to denote the length of the shortest path between u and v . For a graph H , a vertex v and an integer ℓ , $N_H^\ell(v)$ denotes all vertices w such that $\text{hop}_H(v, w) \leq \ell$. Similarly, for a graph H , a vertex subset W and an integer ℓ , $N_H^\ell(W) = \cup_{w \in W} N_H^\ell(w)$.

2 Conflict versus Adjacent Conflicts

Let (G, Γ, k) be an instance of DILATION t -AUGMENTATION problem. Two vertices u and v in G are in t -conflict if $d_G(u, v) > t \cdot d_\Gamma(u, v)$. Furthermore, two vertices are said to be in *adjacent t -conflict* with each other, if u and v are in conflict and u and v are adjacent in Γ . We say that a graph G is (*adjacent*) t -conflict-free if there is no pair of vertices (u, v) such that u and v are in (*adjacent*) t -conflict. Throughout the discussion, the value of t will be clear from the context, so we use the terms *conflict/conflict-free* instead of *t -conflict/ t -conflict-free*. The following lemma shows the relationship between conflict-free and adjacent conflict-free.

► **Lemma 1** (♠). *For any set of edges S , $G + S$ is conflict-free iff $G + S$ is adjacent conflict-free.*

For our problem, we add edges to G to make it conflict-free. Lemma 1 shows that for this purpose it is sufficient to focus *only* on adjacent conflicts. Thus, from now on, we only focus on adjacent conflicts. Unless explicitly mentioned otherwise, by *conflict*, we mean adjacent conflict. Nevertheless, we may use *adjacent conflict* at some places to emphasize the adjacent-ness of the conflict.

The next result formalizes the fact that the distances in G are lower bounded by the distances in Γ . The proof follows from definition, and hence omitted.

► **Observation 2.** *Let $G = (V, E)$ be a graph embedded in a metric space derived from the undirected graph Γ . Then for any pair of vertices x and y we have $d_\Gamma(x, y) \leq d_G(x, y)$.*

Let (G, Γ, k) be a YES-instance of DILATION t -AUGMENTATION and S be an (unknown) minimal solution. The set S is also called dilation t -augmentation set. We use V_S to denote the set of end-points of the edges in S . Let V_c denote the set of all vertices in G that are in conflict with some other vertex. In the next two sections, V_c and V_S will be used repeatedly.

3 Dilation 2-Augmentation for $\mathcal{K}_{d,d}$ -free Graphs

Let (G, Γ, k) be an instance of DILATION 2-AUGMENTATION. In this section, we consider the case where G belongs to the family of $\mathcal{K}_{d,d}$ -free graphs. Recall that a graph G is $\mathcal{K}_{d,d}$ -free if it does not contain a complete bipartite graph with d vertices each on both sides of the bipartition. However, there is no restriction on Γ .

3.1 Conflict Graph and Vertex Cover

We first define a *conflict graph* \mathbb{C} on the set of vertices $V(G)$, which captures all adjacent conflicts. We place an edge between two vertices u and v in \mathbb{C} if and only if u and v are in adjacent conflict with each other. Note that V_c (the set of vertices present in adjacent conflicts) is exactly the set of vertices with degree at least one in \mathbb{C} . The next result shows that every edge in $E(\mathbb{C})$ intersects some edge of a dilation 2-augmentation set S .

► **Lemma 3** (♠). *Let (G, Γ, k) be a YES-instance of DILATION 2-AUGMENTATION and let S be a minimal solution to the given instance. In addition, let \mathbb{C} be the corresponding conflict graph. Then, for any edge $(u, v) \in E(\mathbb{C})$, $|\{u, v\} \cap V_S| \geq 1$.*

Lemma 3 allows us to bound the size of a minimum vertex cover (set of vertices that intersects all the edges) of \mathbb{C} . To do so, we propose the next reduction rule and prove its correctness (or safety).

► **Reduction Rule 1.** *If the size of a maximum matching in \mathbb{C} is more than $2k$, return NO.*

► **Lemma 4** (♠). *Reduction Rule 1 is safe.*

First, we use a polynomial-time algorithm (e.g., [7]) to find the maximum matching M in \mathbb{C} and apply Reduction Rule 1. Notice that if the reduction rule 1 is not applicable, then $|M| \leq 2k$, which implies that it has a vertex cover of size at most $4k$ – in particular, we can take the set of end-points of the edges of in M to be such a vertex cover, call it R .

Let $I = V \setminus R$. Note that I induces an independent set in \mathbb{C} , but not necessarily in G . Next, we bound the degree of each vertex in R in \mathbb{C} . This will imply that the number of conflict pairs is bounded.

The set R is at most of size $4k$. For our algorithm at this stage, we “guess the edges of S that have both end-points in R ”. This results in an equivalent annotated instance, which is now formalized. We first define an “annotated” instance of the problem. An example of the annotated version of the problem is given by the tuple (G', Γ, k', R') , where we also provide a vertex cover R' of the corresponding conflict graph, which is used mainly for book keeping purposes. The task is still to find a dilation 2-augmentation set S of size at most k' . Here, we are not allowed to add an edge to a solution that does not have an end-point outside R .

Let \overline{E}_R be the set of non-edges in $G[R]$. For every subset $\emptyset \subseteq E_j \subseteq \overline{E}_R$ of size at most k , we create an instance \mathcal{I}_j of the annotated problem, as follows: $\mathcal{I}_j := (G_j, \Gamma, k_j, R)$ where $G_j = G + E_j$ and $k_j = k - |E_j|$. The following lemma is immediate.

► **Lemma 5.** *(G, Γ, k) is a YES-instance if and only if one of the instances in $\{(G_j, \Gamma, k_j, R) : \forall \emptyset \subseteq E_j \subseteq \overline{E}_R \text{ s.t. } k_j \leq k\}$ is a YES-instance.*

From now on, we assume that we have an annotated instance of DILATION 2-AUGMENTATION. That is, (G, Γ, k, R) is an instance of DILATION 2-AUGMENTATION and we are seeking a dilation 2-augmentation set S such that for any edge (x, y) in S , $|\{x, y\} \cap R| \leq 1$. That is, every edge added must contain at least one end-point that does not belong to R .

3.2 Bounding the Size of the V_c in Annotated Instances

We now describe how to solve the annotated version of the problem. As a first step, we give a recursive algorithm such that at the end we obtain instances such that the size of V_c gets upper-bounded by a function of k and d alone. To this end, and to make it easier to understand, we adapt the following technical definition of [3] in the context of our problem.

► **Definition 6** ([3]). *A decreasing FPT-Turing-reduction is an FPT algorithm which, given an annotated instance (G, Γ, k, R) , produces $\ell = g(k, d)$ annotated instances $(G_1, \Gamma, k_1, R_1), \dots, (G_\ell, \Gamma, k_\ell, R_\ell)$, such that: (1) (G, Γ, k, R) is a YES-instance iff one of the annotated instances in $\{(G_i, \Gamma, k_j, R_i) : 1 \leq j \leq \ell\}$ is a YES-instance, and (2) $k_j \leq k - 1$ for every $j \in [\ell]$.*

We now give a sequence of FPT Turing reductions to solve the problem. At a high level, we will iterate over the vertices in R that have high degrees in \mathbb{C} , and at each step we will add at least one vertex from I to R , and at least one new edge to G . Thus, in each step, the budget k reduces by at least one. At least one of the resulting instances will correspond to a “correct” set of choices. Note that initially the size of R is at most $4k$; however during the sequence of Turing FPT reductions, the size of R may increase. Nevertheless, we will maintain the invariant that $|R|$ remains bounded by $5k$.

14:8 Multivariate Exploration of Metric Dilation

Let us define an auxiliary function f that is useful for defining some parameters in the upcoming steps. This function is defined as follows.

$$f(i) = \begin{cases} d & \text{if } i = d \\ d \cdot k + k^2 + k & \text{if } i = d - 1 \\ d \cdot k^{d-i} + k^{d-i+1} + \left(2 \cdot \sum_{j=2}^{d-i} k^j\right) + k & \text{if } 0 \leq i \leq d - 2 \end{cases}$$

It is easy to verify that f satisfies the following property.

► **Proposition 7.** *For any $1 \leq i \leq d$, $f(i-1) = (f(i) + k) \cdot k + k$.*

Thus, if each vertex of R has at most $f(0)$ many neighbours in I in \mathbb{C} , then eventually $|V_{\mathbb{C}}|$ gets bounded by $5k \cdot f(0)$. We then move to the final step described below after Corollary 16.

Now we are in the situation where there is a vertex in R with at least $f(0) + 1$ neighbors in I in \mathbb{C} . Let v be such a vertex in R . Let $U = \{u_1, u_2, \dots, u_{\kappa}\} \subseteq I \cap N_{\mathbb{C}}(v)$ be the set of neighbours of v in I , where $\kappa > f(0)$.

► **Reduction Rule 2.** *If there is no vertex $w \in I$ such that $|U \cap N_G(w)| > f(1)$ then we return NO.*

► **Lemma 8.** *Reduction Rule 2 is safe.*

Proof. Assume that for every vertex $w \in I$, we have $|U \cap N_G(w)| \leq f(1)$. Then, we will show that we cannot resolve all conflicts involving v . Suppose (G, Γ, k, R) is a YES-instance of DILATION 2-AUGMENTATION and S be a minimal solution of size at most k . Since each (v, u_i) is an adjacent conflict, we have $d_{G+S}(v, u_i) \leq 2$. This implies $\text{hop}_{G+S}(v, u_i) \leq 2$. Therefore, the edge of S that resolves the conflict (v, u_i) must be adjacent to v or u_i or both. Fix an edge $(v, w) \in S$. Since S is a solution to the annotated instance of the vertex $w \in I$, the number of paths of hop 2 in $G + S$ starting at v , using (v, w) and ending at a vertex in U is upper-bounded by $|U \cap N_G(w)| + |S| \leq f(1) + k$. Therefore, the total number of conflicts that can be resolved by edges of the form (v, w) is at most $(f(1) + k)|Z|$. Here, $Z \subseteq S$ contains edges of the form (v, w) . Let us now focus on the conflicts that are resolved by edges of the form (w, u_i) , $u_i \in U$. This implies that we have paths of the form $\langle v, w, u_i \rangle$ such that $(v, w) \in E(G)$ and $(w, u_i) \in S$. The number of paths of this kind is upper bounded by $|S| - |Z|$. This implies that the total number of conflicts in which v participates, and can be resolved by S , is bounded by $(f(1) + k)|Z| + |S| - |Z| \leq f(1) \cdot k + k^2 + k = f(0)$. ◀

Now, if Reduction Rule 2 is not applicable, then there must be a vertex $w \in I$ such that w has at least $f(1)$ neighbors in U . We use w to identify a small set of edges that must intersect every solution S of size at most k .

► **Lemma 9.** *There exists a polynomial-time algorithm to find a set $W_v = \{w_1, w_2, \dots, w_{\delta}\}$ such that (1) $\delta < d$, and (2) If we have a YES-instance, then any solution S of size at most k satisfies that $S \cap \{(v, w_i) : i \in [\delta]\} \neq \emptyset$.*

Proof. By our definition of \mathbb{C} , the vertex v is in adjacent conflict with each vertex in U . First, by Reduction Rule 2 and Lemma 8, we know that for a YES-instance there exists a vertex $w \in I$ such that $|U \cap N_G(w)| > d \cdot k^d$. We let this vertex to be w_1 . Now either $(v, w_1) \in S$, and then we are done. Else we are in the case when $(v, w_1) \notin S$. Let us define $W_1 := \{w_1\}$.

Suppose we have inductively found a set $W_{i-1} = \{w_1, \dots, w_{i-1}\}$ for some $i \geq 2$. Further, inductively assume that $U_{i-1} := \bigcap_{j \in [i-1]} U \cap N_G(w_j)$ is such that $|U_{i-1}| > f(i-1)$. See Figure 3.2 for an illustration. We prove the following crucial claim which lets us obtain the next vertex in the sequence. Its proof is along the same lines as Lemma 8.

■ **Figure 2** Illustration of arguments used in Lemma 9.

▷ **Claim 10.** Suppose (G, Γ, k, R) is a YES-instance of DILATION 2-AUGMENTATION and S be a solution of size at most k . If $S \cap \{(v, w_j) : j \in [i - 1]\} = \emptyset$. Then there exists a vertex $w_i \in I \setminus W_{i-1}$ such that w_i has more than $f(i)$ neighbours in G , from U_{i-1} .

Proof. Assume that for every vertex $w \in I \setminus W_{i-1}$, we have $|U_{i-1} \cap N_G(w)| \leq f(i)$. Then, we will show that we cannot resolve all conflicts involving v with the vertices from U_{i-1} . Suppose (G, Γ, k, R) is a YES-instance of DILATION 2-AUGMENTATION and S is a solution of size at most k such that $S \cap \{(v, w_j) : j \in [i - 1]\} = \emptyset$. Now we have that for each $u \in U_{i-1}$, (v, u) is an adjacent conflict but $d_{G+S}(v, u) \leq 2$. This implies $\text{hop}_{G+S}(v, u) \leq 2$. Therefore, the edge of S that resolves the conflict (v, u) must be adjacent to v or u or both. Fix an edge $(v, w) \in S$. Since S is a solution to the annotated instance of the vertex $w \in I$, and $w \notin W_{i-1}$ (by assumption), the number of paths of hop 2 in $G + S$ starting at v , using (v, w) and ending at a vertex in U_{i-1} is upper-bounded by $|U_{i-1} \cap N_G(w)| + |S| \leq f(i) + k$. Therefore, the total number of conflicts (v, u) where $u \in U_{i-1}$ that can be resolved by edges of the form (v, w) where $w \notin W_{i-1}$ is at most $(f(i) + k) \cdot |Z| \leq (f(i) + k) \cdot k$. Here, $Z \subseteq S$ contains edges of the form (v, w) . Let us now focus on the conflicts that are resolved by edges of the form (w, u) , $u \in U_{i-1}$. This implies that we have paths of the form $\langle v, w, u \rangle$ such that $(v, w) \in E(G)$ and $(w, u) \in S$. The number of paths of this kind is upper bounded by $|S| - |Z| \leq k$. This implies that the total number of conflicts (v, u) where $u \in U_{i-1}$, and can be resolved by S , is bounded by $(f(i) + k) \cdot k + k = f(i - 1)$, by Proposition 7. Recall that, by induction, $|U_{i-1}| > f(i - 1)$. This contradicts that S is a solution, and the claim follows. ◁

Thus, if we find a vertex w_i satisfying the requirements as mentioned in Claim 10, we define $W_i = W_{i-1} \cup \{w_i\}$ and proceed to the next iteration. Otherwise, if we cannot find w_i , then we stop and output the current set W_{i-1} as the set W_v as required by the lemma. In this case, by Claim 10, we know that, if we have a YES-instance, then $S \cap \{(v, w_j) : j \in [i - 1]\} \neq \emptyset$.

Suppose the iterative procedure goes on for δ iterations, i.e., $W_v = W_\delta = \{w_1, w_2, \dots, w_\delta\}$. Observe that if $\delta \geq d$ then the vertex set $\{w_1, w_2, \dots, w_d\}$ and $\bigcap_{j \in [\delta]} (U \cap N_G(w_j))$ induce a $\mathcal{K}_{d,d}$ in G which contradicts the fact that G is $\mathcal{K}_{d,d}$ -free. Thus, $\delta < d$, and (1) holds. ◀

We use the algorithm in Lemma 9 to find the set W_v of size $\delta < d$ as claimed. We know that, if we have a YES-instance, then any minimal solution S contains at least one edge of the form (v, w_i) , $i \in [\delta]$. The following reduction rule essentially tries to guess the set $W' \subseteq W_v$ for which such edges belong to the solution, and add those vertices to the vertex cover R . Further, due to our invariant, when we add W' to R , we also need to guess the edges between W' and the vertices already in R . The following reduction rule is a Turing reduction from the annotated version of the problem to itself – we prove later that it is a valid decreasing Turing FPT reduction step.

14:10 Multivariate Exploration of Metric Dilation

► **Reduction Rule 3.** Let $v \in R$ be any vertex such that $\deg_{\mathbb{C}}(v) \geq f(0) + 1$. For every non-empty subset $W' \subseteq W_v$, and for any subset

$$\overline{E}_x \subseteq \left\{ (p, q) \in \overline{E}(G) : p \in W', q \in W' \cup (R \setminus \{v\}) \right\}$$

of non-edges in G , we create the following instances. (G_j, Γ, k_j, R') where $G_j = G + (\{(v, w_a) | w_a \in W'\} \cup \overline{E}_x)$, $k_j = k - |W'| - |\overline{E}_x|$ and $R' = R \cup W'$.

► **Lemma 11.** Reduction Rule 3 is a valid decreasing FPT-Turing-reduction.

Proof. First, note that $|W_v| \leq d$, which implies that the number of subsets $W' \subseteq W$ is at most 2^d . Then, for each fixed subset W' of size δ , there are at most $2^{\mathcal{O}(k \log d)}$ many subset \overline{E}_x . So in total the number of instances we created is bounded by $2^{\mathcal{O}(d+k \log d)}$. Now we show the safeness of the Reduction Rule 3.

▷ **Claim 12.** (G, Γ, k, R) is a YES-instance if and only if one of the instances in $\{(G_j, \Gamma, k_j, R')\}$ is a YES-instance.

Proof. The backward direction is trivial. In the forward direction, assume that (G, Γ, k, R) is a YES-instance and S is a minimal solution. Due to the Lemma 9 the solution S must satisfy the condition that $S \cap \{(v, w_i) : i \in [\delta]\} \neq \emptyset$. Let $S' := S \cap \{(v, w_i) : i \in [\delta]\}$, $W'' := V_{S'} \setminus \{v\}$, and $S'' := S \cap \{(w, r) : w \in W'', r \in R \cup W''\}$. Clearly $W'' \subseteq W_v$ and $S'' \subseteq \{(p, q) \in \overline{E}(G) : \text{either } p, q \in W' \text{ or } p \in W', q \in R \setminus \{v\}\}$. Now considering $S'' = \overline{E}_x$, $G_j = G + S' + S''$, $k_j = k - |S'| - |S''|$, and $R' = R \cup W''$, we have that (G_j, Γ, k_j, R') is a YES-instance. ◁

As W' is a non-empty subset of W_v so $k_j \leq k - |W'| \leq k - 1$. So in each created instance, the value of the parameter decreases by at least one. Hence the lemma follows. ◀

Next we formalize an observation that follows from the definition of FPT-Turing-reduction.

► **Observation 13.** Starting from an annotated instance (G, Γ, k, R) , let (G_j, Γ, k_j, R_j) be one of the instances produced by Reduction Rule 3. Then, $|R_j| \leq |R| + (k - k_j)$. In particular, this implies that the size of $|R'|$ in any of the instances produced by a sequence of decreasing Turing FPT reductions, remains bounded by $5k$.

We keep applying Reduction Rule 3 until each vertex in R has at most $f(0)$ neighbors in I in the graph \mathbb{C} . In each step, we maintain the invariant that we have included all possible solution edges within R in G and reduced k appropriately. Observe that when Reduction Rule 3 is not applicable, the total number of vertices in the conflict is at most $\mathcal{O}(k \cdot f(0))$.

Let (G, Γ, k, R) be an annotated instance of DILATION 2-AUGMENTATION. Find a dilation 2-augmentation set S such that $|\{x, y\} \cap R| \leq 1$. That is, every edge added must contain at least one end-point that does not belong to R . In addition, $|R| \leq 5k$ and $|V_c| = \mathcal{O}(k \cdot f(0))$, where $f(0) = d \cdot k^d + k^{d+1} + \left(2 \cdot \sum_{j=2}^d k^j\right) + k$.

3.3 Solving Annotated Instances with bounded V_c

In the rest of the section, we describe how to solve an annotated instance $\mathcal{I} = (G, \Gamma, k, R)$ when the size of V_c is bounded by some function of k and d . Note that although $|V_c| \leq h(k, d)$, we cannot completely forget about the vertices outside V_c – since some conflicts may be resolved by using edges incident to vertices outside V_c . We will argue that we do not need to keep all such vertices, but it suffices to keep one representative from each “equivalence class”, which we formalize below. Note that in this last step, we do not need the vertex cover R .

Let $O = V(G) \setminus V_c$ denote the vertices *outside* V_c . For each $A, B \subseteq V_c$ with $A \cap B = \emptyset$, let $O(A, B)$ denote the set of vertices $v \in O$ satisfying the following two properties:

1. Set of vertices $u \in V_c$ such that $d_G(u, v) = 1$ is *exactly* equal to A , and
 2. Set of vertices $w \in V_c$ such that $(v, w) \notin E(G)$, but $d_\Gamma(v, w) = 1$ is *exactly* equal to B .
- We have the following observation.

- **Observation 14.** 1. $\mathcal{P} = \{O(A, B) : A, B \subseteq V_c, A \cap B = \emptyset\}$ forms a partition of O .
2. $|\mathcal{P}|$ is bounded by $3^{|V_c|} \leq g(k, d)$ for some computable function g .

For each $O(A, B) \in \mathcal{P}$ such that $O(A, B) \neq \emptyset$, we mark an arbitrary vertex $v(A, B) \in O(A, B)$. Let $U \subseteq O$ denote the set of unmarked vertices. In the following reduction rule, we eliminate all the vertices of U from G and Γ , and then prove that it is correct.

- **Reduction Rule 4.** Given the annotated instance $\mathcal{I}_1 = (G, \Gamma, k, R)$, produce the annotated instance $\mathcal{I}_2 = (G', \Gamma', k, R)$, where $\Gamma' = \Gamma - U$ and $G' = G - U$.

- **Lemma 15.** Reduction Rule 4 is safe.

Proof. We argue that \mathcal{I}_1 is a YES-instance if and only if \mathcal{I}_2 is a YES-instance. The reverse direction is trivial, since any solution for \mathcal{I}_s is also a solution for \mathcal{I}_1 (recall that the vertices of U are not involved in any conflict). So we show the forward direction.

Let $S \subseteq \overline{E}(G)$ be a minimal solution of size k with the set of end-points being V_S . From this solution, we define another solution S' as follows. Consider any $u \in U \cap V_S$, and let $S(u) = \{(u, w) \in S\}$, and let $N(u) = \{w : (u, w) \in S(u)\}$. First, note that $N(u) \subseteq V_c$ – suppose not, i.e., there exists some $w \in N(u)$ but $w \notin V_c$, then (u, w) cannot be part of a path of hop length 2 between two vertices in V_c , which contradicts the minimality of S . Now, suppose u belongs to the set $O(A, B) \in \mathcal{O}$, then $O(A, B) \neq \emptyset$, which implies that some $v(A, B) \in V(G) \setminus U = V(\Gamma) \setminus U$. We define another set $S' := S \setminus S(u) \cup \{(v(A, B), w) : w \in S(u)\}$. Note that $|S| = |S'|$. We prove that S' is also a solution.

Consider any path $\langle x, u, y \rangle$ in $G + S$, such that $d_\Gamma(x, u) = d_\Gamma(u, y) = 1$. There are three cases: (i) $(x, u) \in E(G)$ and $(u, y) \in S$. In this case, note that $(x, v(A, B)) \in E(G')$ with $d_{G'}(x, v(A, B)) = d_G(x, v(A, B)) = 1$, and $d_\Gamma(u, y) = d_\Gamma(v(A, B), y) = 1$. Further, $(v(A, B), y) \in S'$. (ii) $(x, u) \in S$ and $(u, y) \in E(G)$ is symmetric. (iii) $(x, y), (y, u) \in S$. In this case, $d_\Gamma(v(A, B), x) = d_\Gamma(u, x) = 1$, and $d_\Gamma(v(A, B), y) = d_\Gamma(u, y) = 1$. Thus, in all three cases, $\langle x, v(A, B), y \rangle$ path exists in $G + S'$, or in other words, the replaced edges incident to $v(A, B)$ can resolve the same set of conflicts as the edges of $S(u)$. By iterating over the vertices of $V_S \cap U$ and modifying the solution in this way, we obtain a solution S'' containing entirely the edges within $E(\Gamma')$. This completes the forward direction. ◀

- **Corollary 16.** The number of vertices in the reduced annotated instance (G', Γ', k, R) is bounded by some $g(k, d)$.

Thus, there are at most $\binom{g(k, d)}{2k} = \binom{2^{\mathcal{O}(h(k, d))}}{2k} = 2^{\mathcal{O}(k \cdot h(k, d))}$ possibilities for the end-points of the solution edges. For each such subset, we can guess the actual set of at most k edges in time $k^{\mathcal{O}(k)}$. Thus, the total number of possibilities is bounded by $f(k, d)$ for some computable function f . We finish the discussion with the following theorem, and its immediate corollary.

- **Theorem 17.** DILATION 2-AUGMENTATION can be solved in time $f(k, d) \cdot n^{\mathcal{O}(1)}$ when G is a $\mathcal{K}_{d,d}$ -free graph for any $d \in \mathbb{N}$.

- **Corollary 18.** DILATION 2-AUGMENTATION can be solved in time $f(k) \cdot n^{\mathcal{O}(1)}$ when G is a forest, planar graph, bounded-treewidth graph, an H -minor free graph for some fixed H , a nowhere dense graph, or bounded degeneracy graph.

4 DILATION t -AUGMENTATION for Bounded Degree Graphs is FPT

In this section either G is of bounded degree or Γ is of bounded degree. Observe that a $\mathcal{K}_{d,d}$ -free graph generalizes bounded-degree graphs, and thus the result when G is of bounded degree may appear to be subsumed by those presented in Section 3. However, the result presented here works for any value of t , but the result in Section 3 only worked for $t = 2$.

In either case, we will use the following easy lemma to bound the number of vertices in a ball of radius ℓ around a vertex subset of small size.

► **Observation 19.** *Let H be a graph with maximum degree Δ . For any subset of vertices $U \subseteq V(H)$, $|N_H^\ell(U)| \leq |U| \cdot \sum_{i=0}^{\ell} \Delta^i \leq |U| \cdot \Delta^{\ell+1}$.*

4.1 Γ is of Bounded Degree

Let (G, Γ, k) be an instance of DILATION t -AUGMENTATION. In this subsection, we consider the case where Γ belongs to the family of graphs of maximum degree at most Δ . However, there is no restriction on G . That is, G is an arbitrary undirected graph. The idea of the proof is to identify a subset of vertices of Γ of size at most $f(k, \Delta, t)$ such that V_S belongs to balls of radius t around them. Once the set is identified, the algorithm tries all potential solutions of size at most k and returns YES, if either leads to the desired solution. The hypothetical solution S is of size at most k , and hence from Observation 19 we have $|N_\Gamma^t(V_S)| \leq 2k \cdot \Delta^{t+1}$. First, we show that the vertices of V_S are in distance t from the vertices of V_c in Γ .

► **Lemma 20 (♠).** *Let (G, Γ, k) be a YES-instance of DILATION t -AUGMENTATION. Then, $V_S \subseteq N_\Gamma^t(V_c)$.*

Observe that we cannot upper bound the size of $N_\Gamma^t(V_c)$, as the size of V_c may not be bounded by any function of t, k and Δ . Next, we show a kind of converse of Lemma 20 showing that, in fact, V_c is contained inside the balls of radius t around V_S in Γ . The proof is identical to Lemma 20 and is presented separately for clarity.

► **Lemma 21 (♠).** *Let (G, Γ, k) be a YES-instance of DILATION t -AUGMENTATION. Then, $V_c \subseteq N_\Gamma^t(V_S)$.*

Lemma 21, along with Observation 19 implies that in a YES-instance, the size of V_c is bounded by $2k \cdot \Delta^{t+1}$. Thus, if $|V_c| > 2k \cdot \Delta^{t+1}$, we say NO. Now assume that $|V_c| \leq 2k \cdot \Delta^{t+1}$. Next, via Lemma 20, we have that $V_S \subseteq N_\Gamma^t(V_c) =: Q$, say. Again, by Observation 19, $|Q| \leq |V_c| \cdot \Delta^{t+1} \leq 2k \cdot \Delta^{2t+2}$. We know we have to add at most k edges between the vertices in Q to resolve all the conflicts. Since the size of Q is bounded by a function of k, Δ , and t , this leads to the following theorem.

► **Theorem 22.** *DILATION t -AUGMENTATION can be solved in time $2^{\mathcal{O}(k \log k)} \cdot \Delta^{\mathcal{O}(kt)} \cdot n^{\mathcal{O}(1)}$, where Δ denotes the maximum degree of the graph Γ .*

4.2 G is of Bounded Degree

Let (G, Γ, k) be an instance of DILATION t -AUGMENTATION. In this subsection, we consider the case where G belongs to the family of graphs of maximum degree at most Δ . However, there is no restriction on Γ . The proof strategy in this section is similar to that used for Theorem 22. As before, the idea is to identify a subset of vertices of G of maximum size $f(k, \Delta, t)$ such that V_S belongs to balls of radius t^2 around them.

■ **Figure 3** Path in $G + S$ is shown in red (solid lines), path in Γ is shown in green (dashed) and path in G is shown in blue (dashed-dotted).

► **Lemma 23** (♠). *Let (G, Γ, k) be a YES-instance of DILATION t -AUGMENTATION. Then, $V_c \subseteq N_G^t(V_S)$.*

As $|V_S| \leq 2k$, the next observation follows from Observation 19.

► **Observation 24.** $|N_G^t(V_S)| \leq 2k \cdot \Delta^{t+1}$.

Lemma 23 and Observation 24 together yield the following reduction rule that yields an upper bound on the size of the conflict set V_c .

► **Reduction Rule 5.** *If $|V_c| > 2k \cdot \Delta^{t+1}$, return NO.*

To identify the vertices in V_S , we show that they lie in the balls of radius t^2 around V_c in G .

► **Lemma 25.** *Let (G, Γ, k) be a YES-instance of DILATION t -AUGMENTATION and S be a hypothetical minimal solution. Then, $V_S \subseteq N_G^{t^2}(V_c)$.*

Proof. Let $a \in V_S$ and (a, b) be an edge in S containing a . Due to the minimality of S , for every edge $e = (a, b)$ in S , there exist at least two vertices s_1 and s_2 such that (i) s_1 and s_2 are in conflict (again, adjacent conflict) with each other in G , and (ii) $e = (a, b)$ appears in a shortest path P of length at most t between s_1 and s_2 in $G + S$. Note that a and b may not be in conflict. We show that there exists a vertex $w \in V_c$ such that w is at most t^2 hop distance from the vertex a in G (that is, $\text{hop}_G(w, a) \leq t^2$). Let P' be the subpath of length $\tau \leq t$ between s_1 and a (see Figure 3). Since $G + S$ is also a graph embedded in a metric space derived from the undirected graph Γ , by Observation 2 we have $d_\Gamma(s_1, a) \leq d_{G+S}(s_1, a) = \tau \leq t$.

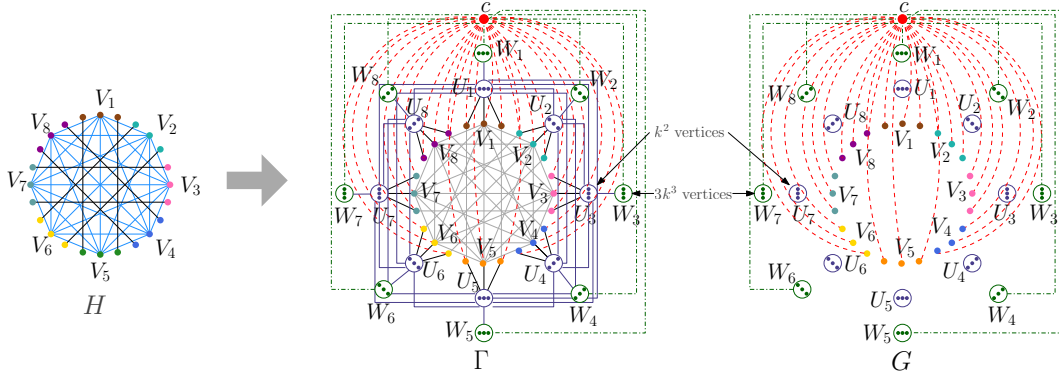

Let $Q = \langle s_1 = a_1, a_2, \dots, a_{\tau+1} = a \rangle$ be a path between s_1 and a in Γ of length $d_\Gamma(s_1, a) \leq t$. Let $j \in [\tau + 1]$ be the largest index such that $a_j \in V_c$. Since $s_1 \in V_c$, an index j always exists. Observe that for all $j \leq i \leq \tau$, a_i and a_{i+1} are *not in conflict* and a_i and a_{i+1} are *adjacent* in Γ . Therefore, there exists a path R_i between a_i and a_{i+1} , $j \leq i \leq \tau$, in G of maximum length t . Thus, by concatenating the paths $R_j \bullet R_{j+1} \bullet \dots \bullet R_\tau$, we get a walk with a weighted length at most t^2 between a_j and a in G . This implies that there is a path between a_j and a in G of length t^2 . That is, $d_G(a_j, a) \leq t^2$. Since all the edge weights in G are at least 1, we have $\text{hop}_G(a_j, a) \leq t^2$. This implies $a \in N_G^{t^2}(a_j) \subseteq N_G^{t^2}(V_c)$. ◀

From Lemma 25 and Reduction Rule 5, and Observation 19, we get the following.

► **Lemma 26.** *Let (G, Γ, k) be a YES-instance of DILATION t -AUGMENTATION. Then, $|N_G^{t^2}(V_c)| \leq 2k \cdot \Delta^{t+1} \cdot \Delta^{t^2+1}$.*

We have to add at most k edges between the vertices in $N_G^{t^2}(V_c)$ to resolve all the conflicts. Since the size of $N_G^{t^2}(V_c)$ is bounded by $f(k, t, \Delta)$, this leads to the following theorem.

► **Theorem 27.** *DILATION t -AUGMENTATION can be solved in time $2^{\mathcal{O}(k \log k)} \cdot \Delta^{\mathcal{O}(kt^2)} \cdot n^{\mathcal{O}(1)}$, where Δ denotes the maximum degree of the graph G .*

■ **Figure 4** Hardness for $t = 3$ when G is a disjoint union of a star, and a set of isolated vertices.

5 Dilation 3-Augmentation For Forest and Stars

In this section, we focus on DILATION 3-AUGMENTATION when G is a forest (Section 5.1), or when Γ is a star (Section 5.2). We show that DILATION 3-AUGMENTATION is W -hard in both cases. In contrast to this, we know that DILATION 2-AUGMENTATION is FPT when G is a forest, due to Theorem 17.

5.1 $W[1]$ -hardness of DILATION 3-AUGMENTATION when G is Forest

We sketch a polynomial-time parameter preserving reduction from the MULTICOLORED CLIQUE problem – which is known to be $W[1]$ -hard [9] – to an instance of DILATION 3-AUGMENTATION when G is a disjoint union of a star and an independent set. The input of MULTICOLORED CLIQUE consists of a graph H , an integer k , and a partition $\mathcal{V} = (V_1, V_2, \dots, V_k)$ of the vertices of H ; our aim is to decide if there is a clique of size k containing exactly one vertex from each set $V_i, i \in [k]$. We denote this instance by (H, k, \mathcal{V}) . We can assume that for each $i \in [k]$, V_i is an independent set. From an instance (H, k, \mathcal{V}) of MULTICOLORED CLIQUE for $k \geq 2$, we construct an instance (G, Γ, k') of DILATION 3-AUGMENTATION with the following way (see Figure 4).

- For every set $V_i, i \in [k]$, we introduce a set U_i of k^2 vertices and a set W_i of $3k^3$ vertices.
- Construction of the graph Γ :
 1. The vertex set in Γ consists of vertex set $H_G \cup \{U_1 \cup \dots \cup U_k\} \cup \{W_1 \cup \dots \cup W_k\} \cup \{c\}$ where $H_G = V(H)$.
 2. The edge set of Γ is defined by $E(\Gamma) = E_H \cup E_U \cup E_W \cup E_c$; here $E_H = E(H)$, $E_U = \{(v, u) | v \in V_i, u \in U_i, i \in [k]\} \cup \{(v, u) | v \in U_i, u \in U_j, i, j \in [k], i \neq j\}$, $E_W = \{(u, w) | u \in U_i, w \in W_i, i \in [k]\}$ and $E_c = \{(c, v) | v \in H_G \cup W_1 \cup \dots \cup W_k\}$.
- The graph G consists of the vertex set $V(\Gamma)$ and the edge set E_c .
- We set $k' = \binom{k}{2} + k^3$.

It is easy to see that in the constructed instance (G, Γ, k') the graph G is indeed a disjoint union of a star and independent set. Also, the construction can be performed in time polynomial in $|V(H)|$ and k . Towards the correctness of our reduction, we prove the following.

► **Lemma 28.** *(H, k, \mathcal{V}) is a YES-instance of MULTICOLORED CLIQUE if and only if (G, Γ, k') is a YES-instance of DILATION 3-AUGMENTATION.*

Proof. (\Rightarrow) In the forward direction, suppose that there is a multicolored clique Q in H . Let the set of vertices in Q be $V_Q = \{v_1, \dots, v_k\}$ where $v_i \in V_i$ and the edgeset of Q be E_Q . Consider the set of edges $E^{VU} = \{(v_i, u) | i \in [k], u \in U_i\}$. Observe that $|E_Q| = \binom{k}{2}$ and $|E^{VU}| = k \cdot k^2$ as $|U_i| = k^2$ for each $i \in [k]$. Next, we show that the dilation of $G + (E_Q \cup E^{VU})$ is at most 3. Notice that all the edges incident to c in Γ are also present in G . Hence c is not involved in any adjacent conflicts. Now we consider all other pairs of adjacent vertices in Γ , say a and b , and show that there exists a path between them of length at most 3 in $G + (E_Q \cup E^{VU})$. This suffices our proof due to Lemma 1. We argue with the following cases.

Case (i): $a \in V_i$ and $b \in V_j$. There is a length 2 path between them in G itself which is precisely $\langle a, c, b \rangle$.

Case (ii): $a \in V_i$ and $b \in U_i$. If $a = v_i$ then a and b are adjacent in $G + E^{VU}$. Otherwise, there is a length 3 path between them in $G + E^{VU}$ which is precisely $\langle a, c, v_i, b \rangle$.

Case (iii): $a \in U_i$ and $b \in U_j$. If $i \neq j$, we use two edges from $E_Q \cup E^{VU}$. The vertices a and b are connected by a length 3 path $\langle a, v_i, v_j, b \rangle$ in $G + (E_Q \cup E^{VU})$. Suppose that $i = j$. Then $\langle a, v_i, b \rangle$ is a path in $G + (E_Q \cup E^{VU})$ of length 2.

Case (iv): $a \in U_i$ and $b \in W_i$. In this case, we use an edge from E^{VU} . The vertices a and b are connected by a length 3 path $\langle a, v_i, c, b \rangle$ in $G + E^{VU}$.

(\Leftarrow) In the backward direction, let E_X be a solution to the instance (G, Γ, k') of DILATION 3-AUGMENTATION, that means dilation of $G + E_X$ is at most 3. We start with the following claim.

\triangleright **Claim 29.** For each $i \in [k]$ and every $u \in U_i$, the set E_X contains an edge (u, v) for $v \notin \bigcup_{j=1}^k U_j$.

Proof. The proof is by contradiction. Suppose that there are $i \in [k]$ and $u \in U_i$ such that for every $(u, v) \in E_X$, $v \in \bigcup_{j=1}^k U_j$. Because $|E_X| \leq k' = \binom{k}{2} + k^3$ and $|W_i| = 3k^3$, we have that $|W_i| - 2|E_X| \geq 1$ and, therefore, there is $w \in W_i$ such that w is not incident to any edge of E_X . Thus, any shortest (u, w) -path in $G + E_X$ contains the edge (w, c) and an edge (u, v) for some $v \in \bigcup_{j=1}^k U_j$. However, the distance between c and v in Γ is 2. This implies that the length of any (u, w) -path in $G + E_X$ is at least 4. Because u and w are adjacent in Γ , this contradicts that the dilation of $G + E_X$ is at most 3 and proves the claim. \triangleleft

Due to the above claim, summing over all $i \in [k]$, we have that the set E_X contains at least $k \cdot k^2 = k^3$ edges incident to the vertices of $\bigcup_{i=1}^k U_i$ whose second end-points are outside $\bigcup_{i=1}^k U_i$. Because $|E_X| \leq \binom{k}{2} + k^3$, we have that for each $i \in [k]$, there are at least $k^2 - 2\binom{k}{2} \geq k \geq 2$ vertices of U_i that are adjacent to exactly one edge of E_X . For $i \in [k]$, we denote by $U'_i \subseteq U_i$ the set of vertices incident to unique edges of E_X . We make the following observation.

\triangleright **Claim 30.** For each $i \in [k]$, there is $u \in U'_i$ such that u is incident to a single edge $(u, v) \in E_X$ such that $(u, v) \in E(\Gamma)$.

Proof. Consider arbitrary $u \in U'_i$. This vertex has a unique neighbor v in $G + E_X$ where $v \notin \bigcup_{j=1}^k U_j$ by Claim 29. If $(u, v) \in E(\Gamma)$, the claim holds. Suppose that $(u, v) \notin E(\Gamma)$. Recall that $|U'_i| \geq 2$. Thus, there is $u' \in U'_i$ distinct from u . In the same way as above, u' has a unique neighbor v' in $G + E_X$ where $v' \notin \bigcup_{j=1}^k U_j$. Then any (u, u') -path in $H + E_X$ contains the edges (u, v) and (u', v') . Since $(u, u') \in E(\Gamma)$ and the dilation of $G + E_X$ is at most 3, we have that the length of (u', v) is one. Therefore, $(u', v) \in E(\Gamma)$. This concludes the proof. \triangleleft

14:16 Multivariate Exploration of Metric Dilation

Using Claim 30, for every $i \in [k]$, we denote by u_i the vertex of U'_i that is incident to a single edge of $E_X \cap E(\Gamma)$ and we use v_i to denote the second end-point of the edge.

▷ **Claim 31.** $\{v_1, \dots, v_k\}$ is a clique of H .

Proof. First, we show that $v_i \in V_i$ for each $i \in [k]$. Consider $i \in [k]$. Note that by Claims 29 and 30 and the construction of Γ , either $v_i \in W_i$ or $v_i \in V_i$. Suppose that $v_i \in W_i$ and consider u_j for $j \in [k]$ distinct from i . We have that $(u_i, u_j) \in E(\Gamma)$. Therefore, $G + E_X$ should have a (u_i, u_j) -path of length at most 3. Any (u_i, u_j) -path contains the edges (u_i, v_i) and (u_j, v_j) . Thus, a shortest (u_i, u_j) -path should contain $(v_i, v_j) \in E(\Gamma)$. However, since $v_i \in W_i$ and $v_j \in V_j \cup W_j$, we have no such an edge by the construction of Γ . This contradiction proves that $v_i \in V_i$.

Finally, we show that for all distinct $i, j \in [k]$, v_i and v_j are adjacent in H . For this, we again observe that $G + E_X$ should have a (u_i, u_j) -path of length at most 3 that includes (u_i, v_i) and (u_j, v_j) . This implies that $(v_i, v_j) \in E(\Gamma)$. Because $v_i \in V_i$ and $v_j \in V_j$, we have that (v_i, v_j) is in E_X and is an edge of H . This proves the claim. ◁

Claim 31 completes the proof of the lemma. ◀

Hence, we have the following theorem.

► **Theorem 32.** DILATION 3-AUGMENTATION is $W[1]$ -hard parameterized by k when G is star forest.

5.2 $W[1]$ -hardness of DILATION 3-AUGMENTATION when Γ is Star

We present a parameter preserving reduction from the DOMINATING SET problem.

Let (H, k) be an instance of DOMINATING SET. We create the instance (G, Γ, k) of the DILATION 3-AUGMENTATION problem as follows. Graphs Γ and G are defined over the vertex sets $V(H) \cup \{c\}$, where c is a new vertex distinct from the vertices of $V(H)$. Γ is a star with center c and leaves $V(H)$. That is, $E(\Gamma) = \{(c, v) : v \in V(H)\}$. Note that in the shortest path metric defined by Γ , $d_\Gamma(u, v) = 2$ for any $u, v \in V(H)$. We let $E(G) = E(H)$, which implies that G is a disjoint union of H and the singleton vertex c . Note that the weight of each edge in G is 2. The proof of equivalence can be found in the full version.

► **Observation 33 (♠).** (H, k) is an YES-instance of DOMINATING SET if and only if (G, Γ, k) is an YES-instance of DILATION 3-AUGMENTATION.

Hence we have the following theorem.

► **Theorem 34.** DILATION 3-AUGMENTATION is $W[2]$ -hard parameterized by k even when Γ is star.

6 Conclusion

In this article, we introduced DILATION t -AUGMENTATION and explored its multivariate complexity of the problem by restricting either the graph class to which Γ could belong or the graph class to which G could belong. Other special graph classes that one could consider include geometric intersection graphs such as interval graphs, unit-disk graphs, disk-graphs, or, more generally, string graphs. In an alternate direction, we can consider the problem in its full generality. However, as we saw, the problem in its full generality cannot admit FPT algorithm. So, a next natural question that stems from our work is exploring these problems from the perspective of FPT-approximation.

Abstract

Algorithmic meta-theorems state that problems definable in a fixed logic can be solved efficiently on structures with certain properties. An example is Courcelle’s Theorem, which states that all problems expressible in monadic second-order logic can be solved efficiently on structures of small treewidth. Such theorems are usually proven by algorithms for the model-checking problem of the logic, which is often complex and rarely leads to highly efficient solutions. Alternatively, we can solve the model-checking problem by grounding the given logic to propositional logic, for which dedicated solvers are available. Such encodings will, however, usually not preserve the input’s treewidth.

This paper investigates whether all problems definable in monadic second-order logic can efficiently be encoded into SAT such that the input’s treewidth bounds the treewidth of the resulting formula. We answer this in the affirmative and, hence, provide an alternative proof of Courcelle’s Theorem. Our technique can naturally be extended: There are treewidth-aware reductions from the optimization version of Courcelle’s Theorem to MAXSAT and from the counting version of the theorem to #SAT. By using encodings to SAT, we obtain, ignoring polynomial factors, the same running time for the model-checking problem as we would with dedicated algorithms. Another immediate consequence is a treewidth-preserving reduction from the model-checking problem of monadic second-order logic to integer linear programming (ILP). We complement our upper bounds with new lower bounds based on ETH; and we show that the block size of the input’s formula and the treewidth of the input’s structure are tightly linked.

Finally, we present various side results needed to prove the main theorems: A treewidth-preserving cardinality constraints, treewidth-preserving encodings from CNFs into DNFs, and a treewidth-aware quantifier elimination scheme for QBF implying a treewidth-preserving reduction from QSAT to SAT. We also present a reduction from projected model counting to #SAT that increases the treewidth by at most a factor of $2^{k+3.59}$, yielding a algorithm for projected model counting that beats the currently best running time of $2^{2^{k+4}} \cdot \text{poly}(|\psi|)$.

1 Introduction

Many tools from the automated reasoning quiver can be implemented efficiently if a graphical representation of the given formula with good structural properties is given. The textbook example is the *satisfiability problem* (SAT), which can be solved in time $O(2^k \text{poly}(|\psi|))$ on formulas ψ whose *primal graph* G_ψ has *treewidth* k . (The primal graph contains a vertex for every variable of the formula and connects them if they appear together in a clause. Its treewidth intuitively measures how close it is to being a tree.) The result extends to the *maximum satisfiability problem* (MAXSAT), in which the clauses of the formula have weights and the goal is to minimize the weights of falsified clauses, and to the *model counting problem* (#SAT), in which the goal is to compute the *number* of satisfying assignments. In this article, we will use the notation $\text{tower}(h, t)$ to describe a tower of twos of height h with t at the top, and $\text{tower}^*(h, t)$ as shorthand to hide polynomial factors, e.g., $O(2^k \text{poly}(|\psi|)) = \text{tower}^*(1, k)$:

► **Fact 1** (folklore, see for instance [1, 4, 5, 14, 24, 29, 30]). *One can solve SAT, MAXSAT, and #SAT in time $\text{tower}^*(1, k)$ if a width- k tree decomposition is given.*

It is worth to take some time to inspect the details of Fact 1. The hidden polynomial factor is not the subject of this paper (as indicated by the notation), but can be made as small as $O(|\varphi|)$ [10, 26]. Our focus will be the value on top of the tower, which in Fact 1 is simply “ k ”. Under the *exponential-time hypothesis* (ETH), this is best possible.

The natural extension of the satisfiability problem to higher logic is the validity problem of fully *quantified Boolean formulas* (QSAT). While it is well-known that QSAT is fixed-parameter tractable (i.e., it is in FPT) with respect to treewidth [11], the dependencies on the treewidth is less sharp than in Fact 1. The height of the tower depends on the *quantifier alternation* $\text{qa}(\psi)$ of the formula, while the top value has the form $O(k + \log k + \log \log k + \dots)$ due to the management of nested tables in the involved dynamic program.

► **Fact 2** ([11, 10]). *One can solve QSAT in time $\text{tower}^*(\text{qa}(\psi) + 1, O(k))$ if a width- k tree decomposition is given.*

In contrast to Fact 1, there is a big-oh on top of the tower in Fact 2. The higher order version of the model counting problem is the *projected model counting problem* (PMC), in which we need to count the number of models that are not identical on a given set of variables.

► **Fact 3** ([15]). *One can solve PMC in time $\text{tower}^*(2, k + 4)$ if a width- k tree decomposition is given.*

The fine art of automated reasoning is *descriptive complexity*, which studies the complexity of problems in terms of the complexity of a description of these problems; independent of any abstract machine model [21, 25]. A prominent example is *Courcelle’s Theorem* that states that the problems that can be expressed in *monadic second-order logic* can be solved efficiently on instances of bounded treewidth [12]. Differently phrased, the theorem states that the *model-checking problem* for MSO logic (MC(MSO)) is fixed-parameter tractable (the parameter is the size of the formula and the treewidth of the structure):

► **Fact 4** ([12]). *One can solve MC(MSO) in time $\text{tower}^*(\text{qa}(\varphi) + 1, O(k + |\varphi|))$ if a width- k tree decomposition is given.*

For instance, the 3-coloring problem (Can we color the vertices of a graph with three colors such that adjacent vertices obtain different colors?) can be described by the sentence:

$$\begin{aligned} \varphi_{\text{3col}} = & \exists R \exists G \exists B \forall x \forall y. (Rx \vee Gx \vee Bx) \\ & \wedge Exy \rightarrow \neg((Rx \wedge Ry) \vee (Gx \wedge Gy) \vee (Bx \wedge By)). \end{aligned}$$

The sentence can be read aloud as: There are three colors red, blue, and green ($\exists R \exists G \exists B$) such that for all vertices x and y ($\forall x \forall y$) we have that (i) each vertex has at least one color ($Rx \vee Gx \vee Bx$), and (ii), if x and y are connected by an edge (Exy) then they do not have the same color ($\neg((Rx \wedge Ry) \vee (Gx \wedge Gy) \vee (Bx \wedge By))$). The model-checking problem $\text{MC}(\text{MSO})$ obtains as input a relational structure \mathcal{S} (say a graph like \mathfrak{G}_1 or \mathfrak{G}_2) and an MSO sentence φ (as the one from above) and asks whether \mathcal{S} is a model of φ , denoted by $\mathcal{S} \models \varphi$. In our example we have $\mathfrak{G}_1 \models \varphi_{3\text{col}}$ and $\mathfrak{G}_2 \not\models \varphi_{3\text{col}}$. Using Fact 4, we can conclude from $\varphi_{3\text{col}}$ that the 3-coloring problem parameterized by the treewidth lies in FPT.

Instead of utilizing Fact 4, another reasonable approach is to *ground* the MSO sentence to a propositional formula and to then apply Fact 1. Formally, this means to reduce the model checking problem $\text{MC}(\text{MSO})$ to SAT, i.e., given a relational structure \mathcal{S} and an MSO sentence φ , we need to produce, in polynomial time, a propositional formula ψ such that $\mathcal{S} \models \varphi$ iff $\psi \in \text{SAT}$. The naïve way of doing so is by generating an indicator variable X_u for every set variable X and every element u in the universe of \mathcal{S} . Then we replace every first-order \exists -quantifier by a “big-or” and \forall -quantifier by a “big-and”:

$$\psi_{3\text{col}} = \bigwedge_{u \in V(G)} \bigwedge_{v \in V(G)} \overbrace{\left(\underbrace{Rx \vee Gx \vee Bx}_{\text{propositional variables}} \right) \wedge \bigwedge_{\{u,v\} \in E(G)} \overbrace{\left(\underbrace{\neg((R_u \wedge R_v) \vee (G_u \wedge G_v) \vee (B_u \wedge B_v))}_{\text{propositional variables}} \right)}^{Exy \rightarrow}}$$

The emerging question now is whether an automated translation such as the one we just sketched preserves treewidth in the following sense: Given a relational structure \mathcal{S} of treewidth $\text{tw}(\mathcal{S})$ and an MSO sentence φ , can we mechanically derive a propositional formula ψ with $\mathcal{S} \models \varphi$ iff $\psi \in \text{SAT}$ and $\text{tw}(\psi) \leq f(\text{tw}(\mathcal{S}))$ for some function computable $f: \mathbb{N} \rightarrow \mathbb{N}$? Consider for instance the following graph shown on the left (it is “almost a tree” and has treewidth 2) and the *primal graph* of $\psi_{3\text{col}}$ obtained using the just sketched transformation on the right. In this example, the tree-like structure is preserved, as the treewidth gets increased by a factor of 3 and is at most 6:

We recap this finding as the following observation: The automated grounding process from $\text{MC}(\text{MSO})$ to SAT *implies* a reduction from the 3-coloring problem parameterized by the input’s treewidth to SAT. We can, thus, derive that the 3-coloring problem can be solved in time $\text{tower}^*(1, 3k)$ using Fact 1 – without actually utilizing Courcelle’s Theorem!

For a second example consider the optimization and counting version of the dominating set problem: Given a graph G , the task is either to find a minimum-size set $S \subseteq V(G)$ of vertices such that every vertex is in S or adjacent to vertex in S , or to count the number of such sets. Optimization and counting problems can be modeled in descriptive complexity by “moving” an existential second-order quantifier (“guessing” the solution) out of the sentence and making it a free variable. The task is either to find a set of minimum size such that the given structure together with this set is a model of the formula, or to count the number of such sets. For instance, the following formula describes that X is a dominating set:

$$\varphi_{\text{ds}}(X) = \forall x \exists y \cdot Xx \vee (Exy \wedge Xy).$$

We will also say that the formula *Fagin-defines* the property that X is a dominating set. The problem $\#FD(MSO)$ asks, given a relational structure \mathcal{S} and an MSO formula with a free-set variable X , how many subsets S of the universe of \mathcal{S} satisfy $\mathcal{S} \models \varphi(S)$. The optimization problem $FD(MSO)$ gets as additional input an integer t and asks whether there is such a S with $|S| \leq t$. The reduction from $MC(MSO)$ to SAT can be extended to a reduction from $FD(MSO)$ to MAXSAT and from $\#FD(MSO)$ to PMC. In order to ground $FD(MSO)$, we add new indicator variables X_u for the free-variable X and every element u of \mathcal{S} (as we did for the second-order quantifiers). For $FD(MSO)$, we additionally add a soft clause $(\neg X_u)$ for each of these variables – implying that we seek a model that minimizes $|X|$. We may now again ask: If we mechanically ground $\varphi_{ds}(X)$ on a structure of bounded treewidth to a propositional formula ψ_{ds} , what can we say about the treewidth of ψ_{ds} ? Unfortunately, not so much. Even if the input has treewidth 1, the primal graph of ψ_{ds} may become a clique (of treewidth n):

It follows that we *cannot* derive an fpt-algorithm for the dominating set problem or its counting version by reasoning about ψ_{ds} , while we can conclude the fact from φ_{ds} using appropriate versions of Courcelle’s Theorem. To summarize, we can naturally describe model-checking, optimization, and counting problems using monadic second-order logic. Using Courcelle’s Theorem, we can solve all of these problems in fpt-time on structures of bounded treewidth. Alternatively, we may ground the MSO formulas to propositional logic and solve the problems using Fact 1. The produced encodings sometimes preserve the input’s structure (as for 3-coloring) and, thus, themselves serve as proof that the problems lie in FPT. However, the input’s structure can also get eradicated, as we observed for the dominating set problem. The present paper is concerned with the question whether there is a unifying grounding procedure that maps Fagin-defined MSO properties to propositional logic while preserving the input’s treewidth.

Contribution I: Faster Structure-guided Reasoning. Before we develop a unifying, structure-aware grounding process from the model-checking problem of monadic second order logic to propositional logic, we first improve both of the underlying results. In particular, we remove the logarithmic dependencies on k in top of the tower of Fact 2 and, thus, provide the first major improvement on QBF upper bounds with respect to treewidth since 20 years:

► **Theorem 1** (QBF Theorem). *One can solve QSAT in time $\text{tower}^*(\text{qa}(\psi) + 1, k + 3.92)$ if a width- k tree decomposition is given.*

This bound matches the ETH lower bound for QSAT:

► **Fact 5** ([16]). *Unless ETH fails, QSAT cannot be solved in time $\text{tower}^*(\text{qa}(\psi) + 1, o(\text{tw}(\psi)))$.*

We will prove Theorem 1 fully in the spirit of an automated reasoning paper by an encoding into SAT. In particular, we will not need any pre-requirements other than Fact 1. With a similar encoding scheme, we will also slightly improve on Fact 3:

► **Theorem 2** (PMC Theorem). *One can solve PMC in time $\text{tower}^*(2, k + 3.59)$ if a width- k tree decomposition is given.*

► **Fact 6** ([15]). *Unless ETH fails, PMC cannot be solved in time $\text{tower}^*(2, o(\text{tw}(\psi)))$.*

Contribution II: A SAT Version of Courcelle’s Theorem. We answer the main question of the introduction in the affirmative and provide a unifying, structure-aware encoding scheme from properties Fagin-defined with monadic second-order logic to variants of SAT:

► **Theorem 3** (A SAT Version of Courcelle’s Theorem). *Assuming that the MSO formulas on the left side are in prenex normal form and that a width- k tree decomposition is given, there are encodings from ...*

1. $\text{MC}(\text{MSO})$ to SAT of size $\text{tower}^*(\text{qa}(\varphi), (k+9)|\varphi| + 3.92)$;
2. $\text{FD}(\text{MSO})$ to MAXSAT of size $\text{tower}^*(\text{qa}(\varphi) + 1, (k+9)|\varphi| + 3.92)$;
3. $\#\text{FD}(\text{MSO})$ to $\#\text{SAT}$ of size $\text{tower}^*(\text{qa}(\varphi) + 1, (k+9)|\varphi| + 3.92)$.

All encodings of size $\text{tower}^(s, t)$ have a treewidth of $\text{tower}(s, t)$ and can be computed in linear time with respect to their size.*

In conjunction with Fact 1, the theorem implies Courcelle’s Theorem with sharp bounds on the values on top of the tower:

► **Corollary 4.** *One can solve $\text{MC}(\text{MSO})$ in time $\text{tower}^*(\text{qa}(\varphi) + 1, (k+9)|\varphi| + 3.92)$, and $\text{FD}(\text{MSO})$ and $\#\text{FD}(\text{MSO})$ in time $\text{tower}^*(\text{qa}(\varphi) + 2, (k+9)|\varphi| + 3.92)$ if a width- k tree decomposition is given.*

Since the reduction [27] from SAT to integer linear programming (ILP) is treewidth-preserving and results in an instance of bounded domain, another consequence of Theorem 3 is an “ILP Version of Courcelle’s Theorem” via the dynamic program for ILP [22].

Contribution III: ETH Lower Bounds for the Encoding Size. Given that we can encode MSO definable properties into SAT while preserving the input’s treewidth, we may ask next whether we can improve on the *size* of the encodings. While it is well-known that incarnations of Courcelle’s Theorem have to depend on the input’s treewidth and the formula’s size in a non-elementary way [3] (and hence, the encodings have to be huge at some point as well), these insights do not give us precise bounds on achievable encoding sizes.

► **Theorem 5** (ETH Lower Bound). *Under ETH, there is no SAT encoding for $\text{MC}(\text{MSO})$ of size $\text{tower}^*(\text{qa}(\varphi) - 2, o(\text{tw}(\mathcal{S})))$ that can be computed in this time.*

We can make the lower bound a bit more precise in the following sense: The value at the top of the tower actually does not just depend on the treewidth $\text{tw}(\mathcal{S})$, but on the product of the treewidth and the *block size* $\text{bs}(\varphi)$ of the sentence φ . The block size of a formula is the maximum number of consecutive quantifiers of the same type.

► **Theorem 6** (Trade-off Theorem). *Under ETH, there is no SAT encoding for $\text{MC}(\text{MSO})$ of size $\text{tower}^*(\text{qa}(\varphi) - 2, o(\text{tw}(\mathcal{S}) \text{bs}(\varphi)))$ that can be computed within this time.*

1.1 Related Work

The concept of treewidth was discovered multiple times. The name was coined in the work by Robertson and Seymour [28], while the concept was studied by Arnborg and Proskurowski [2] under the name partial k -trees simultaneously. However, treewidth was discovered even earlier by Bertelè and Brioschi [6], and independently by Halin [19]. Courcelle’s Theorem was proven in a series of articles by Bruno Courcelle [12], see also the textbook by Courcelle and Engelfriet for a detailed introduction [13]. The expressive power of monadic second-order logic was studied before, prominently by Büchi who showed that MSO over strings characterizes the regular languages [9]. Related to our treewidth-aware reduction from $\text{MC}(\text{MSO})$ to SAT is the work by Gottlob, Pichler, and Wei, who solve $\text{MC}(\text{MSO})$ using monadic Datalog [18]; and the work of Bliem, Pichler, and Woltran, who solve it using ASP [8].

1.2 Structure of this Article

We provide preliminaries in the next section, prove Theorem 1 and 2 in Section 3, and establish a SAT version of Courcelle’s Theorem in Section 4. The technical details of the latter can be found in the technical report version of this article. We extend the result to Fagin-definable properties in Section 5 and provide corresponding ETH lower bounds in Section 6. We conclude and provide pointers for further research in the last section, which also contains an overview table of this article’s results. Due to lack of space, most proofs are only available in the technical report and are replaced by a proof sketch within the main text. The corresponding positions are clearly marked with a “▼”.

2 Preliminaries: Background in Logic and Structural Graph Theory

We use the notation of Knuth [23] and consider *propositional formulas* in conjunctive normal form (CNFs) like $\psi = (x_1 \vee \neg x_2 \vee \neg x_3) \wedge (\neg x_1 \vee x_4 \vee \neg x_5) \wedge (x_2) \wedge (x_6)$ as *set of sets* $\{\{x_1, \neg x_2, \neg x_3\}, \{\neg x_1, x_4, \neg x_5\}, \{x_2\}, \{x_6\}\}$. We denote the sets of variables, literals, and clauses of ψ as $\text{vars}(\psi)$, $\text{lits}(\psi)$, and $\text{clauses}(\psi)$. A (*partial*) *assignment* is a subset $\beta \subseteq \text{lits}(\psi)$ such that $|\{x, \neg x\} \cap \beta| \leq 1$ for all $x \in \text{vars}(\psi)$, that is, a set of literals that does not contain both polarities of any variable. We use $\beta \sqsubseteq \text{vars}(\psi)$ to denote partial assignments. The formula *conditioned under a partial assignment* β is denoted by $\psi|\beta$ and obtained by removing all clauses from ψ that contain a literal $l \in \beta$ and by removing all literals l' with $\neg l' \in \beta$ from the remaining clauses. An assignment is *satisfying* for a CNF ψ if $\psi|\beta = \emptyset$, and it is *contradicting* if $\emptyset \in \psi|\beta$. A DNF is a disjunction of conjunctions, i.e., a set of terms. We use the same notations as for CNFs, however, in $\psi|\beta$ we delete terms that contain a literal that appears negated in β and remove the literals in β from the remaining terms. Hence, β is *satisfying* if $\emptyset \in \psi|\beta$, and *contradicting* if $\psi|\beta = \emptyset$.

The *model counting problem* asks to compute the number of satisfying assignments of a CNF and is denoted by #SAT. In *projected model counting* (PMC) we count the number of models that are not identical on a given set of variables. In the *maximum satisfiability problem* (MAXSAT) we partition the clauses of ψ into a set $\text{hard}(\psi)$ of *hard clauses* and a set $\text{soft}(\psi)$ of weighted *soft clauses*, i.e., every clause $C \in \text{soft}(\psi)$ comes with a *weight* $w(C) \in \mathbb{Q}$. The formula is then called a WCNF and the goal is to find under all assignments $\beta \sqsubseteq \text{vars}(\psi)$ with $\text{hard}(\psi)|\beta = \emptyset$ the one that maximizes $\sum_{C \in \text{soft}(\psi), \{C\}|\beta = \emptyset} w(C)$. In a fully *quantified Boolean formula* (a QBF, also called a *second-order propositional sentence*) all variables are bounded by existential or universal quantifiers. Throughout the paper we assume that QBFs are in prenex normal form, meaning that all quantifiers appear in the front of a quantifier-free formula called the *matrix*. As is customary, we assume that the matrix is a CNF if the last (i.e., most inner) quantifier is existential, and a DNF otherwise. A QBF is *valid* if it evaluates to true (see Chapter 29–31 in [7]). Define QSAT to be the problem of deciding whether a given QBF is valid.

2.1 Descriptive Complexity

A *vocabulary* is a finite set $\tau = \{R_1^{a_1}, R_2^{a_2}, \dots, R_\ell^{a_\ell}\}$ of relational symbols R_i of arity a_i . A (finite, relational) τ -*structure* \mathcal{S} is a tuple $(U(\mathcal{S}), R_1^{\mathcal{S}}, R_2^{\mathcal{S}}, \dots, R_\ell^{\mathcal{S}})$ with *universe* $U(\mathcal{S})$ and *interpretations* $R_i^{\mathcal{S}} \subseteq U(\mathcal{S})^{a_i}$. The *size* of \mathcal{S} is $|\mathcal{S}| = |U(\mathcal{S})| + \sum_{i=1}^{\ell} a_i \cdot |R_i^{\mathcal{S}}|$. We denote the *set of all τ -structures* by $\text{STRUC}[\tau]$ – e.g., $\text{STRUC}[\{E^2\}]$ is the set of directed graphs.

Let τ be a vocabulary and x_0, x_1, x_2, \dots be an infinite repertoire of first-order variables. The *first-order language* $\mathcal{L}(\tau)$ is inductively defined, where the *atomic formulas* are the strings $x_i = x_j$ and $R_i(x_1, \dots, x_{a_i})$ for relational symbols $R_i \in \tau$. If $\alpha, \beta \in \mathcal{L}(\tau)$ then so are

$\neg(\alpha)$, $(\alpha \wedge \beta)$, and $\exists x_i(\alpha)$. A variable that appears next to \exists is called *quantified* and *free* otherwise. We denote a formula $\varphi \in \mathcal{L}(\tau)$ with $\varphi(x_{i_1}, \dots, x_{i_q})$ if x_{i_1}, \dots, x_{i_q} are precisely the free variables in φ . A formula without free variables is called a *sentence*. As customary, we extend the language of first-order logic by the usual abbreviations, e.g., $\alpha \rightarrow \beta \equiv \neg\alpha \vee \beta$ and $\forall x_i(\alpha) \equiv \neg\exists x_i(\neg\alpha)$. To increase readability, we will use other lowercase Latin letters for variables and drop unnecessary braces by using the usual operator precedence instead. Furthermore, we use the *dot notation* in which we place a “.” instead of an opening brace and silently close it at the latest syntactically correct position. A τ -structure \mathcal{S} is a *model* of a sentence $\varphi \in \mathcal{L}(\tau)$, denoted by $\mathcal{S} \models \varphi$, if it evaluates to true under the semantics of quantified propositional logic while interpreting equality and relational symbols as specified by the structure. For instance, $\varphi_{\text{undir}} = \forall x \forall y \cdot Exy \rightarrow Eyx$ over $\tau = \{E^2\}$ describes the set of undirected graphs, and we have $\text{undir} \models \varphi_{\text{undir}}$ and $\text{dir} \not\models \varphi_{\text{undir}}$.

We obtain the language of *second-order logic* by allowing quantification over relational variables of arbitrary arity, which we will denote by uppercase Latin letters. A relational variable is said to be *monadic* if its arity is one. A *monadic second-order* formula is one in which all quantified relational variables are monadic. The set of all such formulas is denoted by MSO. The *model checking problem* for a vocabulary τ is the set $\text{MC}_\tau(\text{MSO})$ that contains all pairs (\mathcal{S}, φ) of τ -structures \mathcal{S} and MSO sentences φ with $\mathcal{S} \models \varphi$. Whenever τ is not relevant (meaning that a result holds for all fixed τ), we will refer to the problem as $\text{MC}(\text{MSO})$. We note that in the literature there is often a distinction between MSO_1 - and MSO_2 -logic, which describes the way the input is encoded [20]. Since we allow arbitrary relations, we do not have to make this distinction.

2.2 Treewidth and Tree Decompositions

While we consider graphs G as relational structures \mathcal{G} as discussed in the previous section, we also use common graph-theoretic terminology and denote with $V(G) = U(\mathcal{G})$ and $E(G) = E^{\mathcal{G}}$ the vertex and edge set of G . Unless stated otherwise, graphs in this paper are *undirected* and we use the natural set notations and write, for instance, $\{v, w\} \in E(G)$. The *degree* of a vertex is the number of its neighbors. A *tree decomposition* of G is a pair (T, χ) in which T is a tree (a connected graph without cycles) and $\chi: V(T) \rightarrow 2^{V(G)}$ a function with the following two properties:

1. for every $v \in V(G)$ the set $\{x \mid v \in \chi(x)\}$ is non-empty and connected in T ;
2. for every $\{u, v\} \in E(G)$ there is at least one node $x \in V(T)$ with $\{u, v\} \subseteq \chi(x)$.

The *width* of a tree decomposition is the maximum size of its bags minus one, i.e., $\text{width}(T, \chi) = \max_{x \in V(T)} |\chi(x)| - 1$. The *treewidth* $\text{tw}(G)$ of a graph G is the minimum width any tree decomposition of G must have. We do not require additional properties of tree decompositions, but we assume that T is rooted at a $\text{root}(T) \in V(T)$ and, thus, that nodes $t \in V(T)$ may have a $\text{parent}(t) \in V(T)$ and $\text{children}(t) \subseteq V(T)$. Without loss of generality, we may also assume $|\text{children}(t)| \leq 2$.

► **Example 7.** The treewidth of the Big Dipper constellation (as graph shown on the left) is at most two, as proven by the tree decomposition on the right:

2.3 Treewidth of Propositional Formulas and Relational Structures

The definition of treewidth can be lifted to other objects by associating a graph to them. The most common graph for CNFs (or DNFs) ψ is the *primal graph* G_ψ , which is the graph on vertex set $V(G_\psi) = \text{vars}(\psi)$ that connects two vertices by an edge if the corresponding variables appear together in a clause. We then define $\text{tw}(\psi) := \text{tw}(G_\psi)$ and refer to a tree decomposition of G_ψ as one of ψ . Note that other graphical representations lead to other definitions of the treewidth of propositional formulas. A comprehensive listing can be found in the *Handbook of Satisfiability* [7, Chapter 17]. A *labeled tree decomposition* (T, χ, λ) extends a tree decomposition with a mapping $\lambda: V(T) \rightarrow 2^\psi$ (i.e., a mapping from the nodes of T to a subset of the clauses (or terms) of ψ) such that for every clause (or term) C there is exactly one $t \in V(T)$ with $C \in \lambda(t)$ that contains all variables appearing in C . It is easy to transform a tree decomposition (T, χ) into a labeled one (T, χ, λ) by traversing the tree once's and by duplicating some bags. Hence, we will assume throughout this article that all tree decompositions are labeled.

A similar approach can be used to define tree decompositions of arbitrary structures: The *primal graph* $G_\mathcal{S}$ of a structure \mathcal{S} , in this context also called the *Gaifman graph*, has as vertex set the universe of \mathcal{S} , i.e., $V(G_\mathcal{S}) = U(\mathcal{S})$, and contains an edge $\{u, v\} \in E(G_\mathcal{S})$ iff u and v appear together in some tuple of \mathcal{S} . As before, we define $\text{tw}(\mathcal{S}) := \text{tw}(G_\mathcal{S})$. One can alternatively define the concept of tree decompositions directly over relational structures, which leads to the same definition [17].

3 New Upper Bounds for Second-Order Propositional Logic

Central to our reductions are treewidth-preserving encodings from QSAT to SAT and from PMC to #SAT. These encoding establishes new proofs of Chen's Theorem [11] and the theorem by Fichte et al. [15], and improve the dependencies on k in the tower of Fact 2 and 3.

3.1 Treewidth-Aware Encodings from QSAT to SAT

We use a quantifier elimination scheme that eliminates the most-inner quantifier block at the cost of introducing $O(2^k|\varphi|)$ new variables while increasing the treewidth by a factor of $12 \cdot 2^k$. Let first $\varphi = Q_1 S_1 \dots \forall_\ell S_\ell \cdot \psi$ be the given QBF, in which ψ is a DNF. Let further (T, χ, λ) be the given labeled width- k tree decomposition of φ . We describe an encoding into a QBF, in which the last quantifier block $Q_\ell S_\ell$ gets replaced by new variables in $S_{\ell-1}$.

We have to encode the fact that for an assignment on $\bigcup_{i=1}^{\ell-1} S_i$ all assignments to S_ℓ satisfy ψ , i.e., at least *one* term in ψ . For that end, we introduce auxiliary variables for every term $d \in \text{terms}(\psi)$ and any partial assignment α of the variables in S_ℓ that also appear in the bag that contains d . More precisely, let $\lambda^{-1}(d)$ be the node in $V(T)$ with $d \in \lambda(t)$ and let $\alpha \sqsubseteq \chi(\lambda^{-1}(d)) \cap S_\ell$ be an assignment of the variables of the bag that are quantified by Q_ℓ . We introduce the variable sat_d^α that indicates that this assignment satisfies d :

$$\bigwedge_{d \in \text{terms}(\psi)} \bigwedge_{\alpha \sqsubseteq \chi(\lambda^{-1}(d)) \cap S_\ell} \left[\text{sat}_d^\alpha \leftrightarrow \bigwedge_{x \in \text{lits}(\{d\}|\alpha)} x \right], \quad // \alpha \text{ may satisfy } d \quad (1)$$

$$\bigwedge_{d \in \text{terms}(\psi)} \bigwedge_{\alpha \sqsubseteq \chi(\lambda^{-1}(d)) \cap S_\ell} \left[\neg \text{sat}_d^\alpha \right]. \quad // \alpha \text{ falsifies } d \quad (2)$$

We have to track whether ψ can be satisfied by a local assignment α . For every $t \in V(T)$ and every $\alpha \sqsubseteq \chi(t) \cap S_\ell$ we introduce a variable $\text{sat}_{\leq t}^\alpha$ that indicates that α can be extended to a satisfying assignment for the subtree rooted at t . Furthermore, we create variables

$sat_{<t,t'}^\alpha$ for $t' \in \text{children}(t)$ that propagate the information about satisfiability along the tree decomposition. That is, $sat_{<t,t'}^\alpha$ is set to true if there is an assignment $\beta \sqsubseteq \chi(t') \cap S_\ell$ that can be extended to a satisfying assignment and that is compatible with α :

// Either there is a term satisfying the bag or we can propagate:

$$\bigwedge_{t \in V(T)} \bigwedge_{\alpha \sqsubseteq \chi(t) \cap S_\ell} \left[sat_{\leq t}^\alpha \leftrightarrow \bigvee_{d \in \lambda(t)} sat_d^\alpha \vee \bigvee_{t' \in \text{children}(t)} sat_{<t,t'}^\alpha \right], \quad (3)$$

// Propagate satisfiability:

$$\bigwedge_{t \in V(T)} \bigwedge_{\alpha \sqsubseteq \chi(t) \cap S_\ell} \bigwedge_{t' \in \text{children}(t)} \left[sat_{<t,t'}^\alpha \leftrightarrow \bigwedge_{\substack{\beta \sqsubseteq \chi(t') \cap S_\ell \\ \beta \cap \text{lits}(\chi(t)) = \alpha \cap \text{lits}(\chi(t'))}} sat_{\leq t'}^\beta \right]. \quad (4)$$

Finally, since $Q_\ell = \forall$, we need to ensure that for all possible assignments of S_ℓ there is at least one term that gets satisfied. Since satisfiability gets propagated to the root of the tree decomposition by the aforementioned constraint, we can enforce this property with:

$$\bigwedge_{\alpha \sqsubseteq \chi(\text{root}(T)) \cap S_\ell} sat_{\leq \text{root}(T)}^\alpha. \quad (5)$$

The following lemma observes the correctness of the construction, and the subsequent lemma handles the case $Q_\ell = \exists$.

► **Lemma 8** (▼). *There is an algorithm that, given a QBF $\varphi = Q_1 S_1 \dots \exists_{\ell-1} S_{\ell-1} \forall_\ell S_\ell \cdot \psi$ and a width- k tree decomposition of G_φ , outputs in time $O^*(2^k)$ a QBF $\varphi' = Q_1 S_1 \dots \exists_{\ell-1} S'_{\ell-1} \cdot \psi'$ and a width- $(12 \cdot 2^k)$ tree decomposition of $G_{\varphi'}$ such that φ is valid iff φ' is valid.*

► **Lemma 9** (▼). *There is an algorithm that, given a QBF $\varphi = Q_1 S_1 \dots \forall_{\ell-1} S_{\ell-1} \exists_\ell S_\ell \cdot \psi$ and a width- k tree decomposition of G_φ , outputs in time $O^*(2^k)$ a QBF $\varphi' = Q_1 S_1 \dots \forall_{\ell-1} S'_{\ell-1} \cdot \psi'$ and a width- $(12 \cdot 2^k)$ tree decomposition of $G_{\varphi'}$ such that φ is valid iff φ' is valid.*

Sketch of Proof. The case $Q_\ell = \exists$ (in which ψ is a CNF) works similarly: The result follows by negating the inverse, where the roles of CNF and DNF are switched, and universal and existential quantification are switched as well. ◀

Proof of Theorem 1. The theorem follows by exhaustively applying Lemma 8 and Lemma 9 until a CNF is reached. The price for removing one alternation are $O(2^k |\varphi|)$ new variables and an increase of the treewidth by a factor of $12 \cdot 2^k$. Hence, after removing one quantifier block we have a treewidth of $12 \cdot 2^k \leq 2^{k+\log 12}$, after two we have $12 \cdot 2^{k+\log 12} \leq 2^{k+\log 12+\log 12}$, after three we then have $2^{2^{k+\log 12+\log 12+\log 12}}$; and so on. We can bound all the intermediate “+ log 12” by adding a “+1” on top of the tower, leading to a bound on the treewidth of $\text{tower}(\text{qa}(\varphi), k + \log 12 + 1) \leq \text{tower}(\text{qa}(\varphi), k + 4.59)$. In fact, we can bound the top of the tower even tighter by observing $\log 12 \leq 3.59$ and guessing 3.92 as a fix point. Inserting yields $3.59 + 2^{3.59+k} \leq 2^{3.92+k}$ and $2^{3.92+2^{3.59+k}} \leq 2^{3.92+k}$. Consequently, we can bound the treewidth of the encoding by $\text{tower}(\text{qa}(\varphi), k+3.92)$ and the size by $\text{tower}^*(\text{qa}(\varphi), k+3.92)$. ◀

3.2 Treewidth-Aware Encodings from PMC to #SAT

Recall that the input for PMC is a CNF ψ and a set $X \subseteq \text{vars}(\psi)$. The task is to count the assignments $\alpha \sqsubseteq X$ that can be extended to models $\alpha^* \sqsubseteq \text{vars}(\psi)$ of ψ . We can also think of a formula $\psi(X) = \exists Y \cdot \psi'(X, Y)$ with free variables X and existential quantified variables Y

(ψ' is quantifier-free), for which we want to count the assignments to X that make the formula satisfiable. The idea is to rewrite $\psi(X) = \exists Y. \psi'(X, Y) \equiv \exists X \exists Y. \psi'(X, Y)$, and to use a similar encoding as in the proof of Lemma 9 to remove the second quantifier.

In detail, we add a variable sat_c^α for every clause $c \in \text{clauses}(\psi)$ and every assignment of the corresponding bag $\alpha \sqsubseteq \chi(\lambda^{-1}(c)) \cap Y$. The semantic of this variable is that the clause c is satisfiable under the partial assignment α . We further add the propagation variables $sat_{\leq t}^\alpha$ and $sat_{< t, t'}$ for all $t \in V(T)$, $t' \in \text{children}(t)$, and $\alpha \sqsubseteq \chi(\lambda^{-1}(c)) \cap Y$. The former indicates that the assignment α can be extended to a satisfying assignment of the subtree rooted at t ; the later propagates partial solutions from children to parents within the tree decomposition:

// α may satisfy c :

$$\bigwedge_{c \in \text{clauses}(\psi)} \bigwedge_{\alpha \sqsubseteq \chi(\lambda^{-1}(c)) \cap Y} \left[sat_c^\alpha \leftrightarrow \bigvee_{\ell \in \text{lits}(\{c\}|\alpha)} \ell \right], \quad (1)$$

// α satisfies c :

$$\bigwedge_{c \in \text{clauses}(\psi)} \bigwedge_{\alpha \sqsubseteq \chi(\lambda^{-1}(c)) \cap Y} \left[sat_c^\alpha \right]. \quad (2)$$

// Either there is a clause satisfying the bag or we can propagate:

$$\bigwedge_{t \in V(T)} \bigwedge_{\alpha \sqsubseteq \chi(t) \cap Y} \left[sat_{\leq t}^\alpha \leftrightarrow \bigwedge_{c \in \lambda(t)} sat_c^\alpha \wedge \bigwedge_{t' \in \text{children}(t)} sat_{< t, t'}^\alpha \right], \quad (3)$$

// Propagate satisfiability:

$$\bigwedge_{t \in V(T)} \bigwedge_{\alpha \sqsubseteq \chi(t) \cap Y} \bigwedge_{t' \in \text{children}(t)} \left[sat_{< t, t'}^\alpha \leftrightarrow \bigwedge_{\substack{\beta \sqsubseteq \chi(t') \cap Y \\ \beta \cap \text{lits}(\chi(t)) = \alpha \cap \text{lits}(\chi(t'))}} sat_{\leq t'}^\beta \right]. \quad (4)$$

Observe that the constraints (1)–(4) contain no variable from Y (we removed them by locally speaking about α) and, furthermore, constraints (1), (3), and (4) are pure propagations, which leave no degree of freedom on the auxiliary variables. Hence, models of these constraint only have freedom in the variables in X within constraint (2). We are left with the task to count only models that actually satisfy the input formula, which we achieve with:

$$\bigvee_{\alpha \sqsubseteq \chi(\text{root}(T)) \cap Y} sat_{\leq \text{root}(T)}^\alpha. \quad (5)$$

► **Lemma 10 (▼).** *There is an algorithm that, given a CNF ψ , a set $X \subseteq \text{vars}(\psi)$, and a width- k tree decomposition of G_ψ , outputs in time $O^*(2^k)$ a CNF ψ' and a width- $(12 \cdot 2^k)$ tree decomposition of $G_{\psi'}$ such that the projected model count of ψ on X equals $\#(\psi')$.*

Proof of Theorem 2. By applying Fact 1 to the formula generated by Lemma 10 we obtain an algorithm for PMC with running time $\text{tower}^*(2, k + 3.59)$. ◀

4 A SAT Version of Courcelle's Theorem

We demonstrate the power of treewidth-aware encodings by providing an alternative proof of Courcelle's theorem. We prove the main part of Theorem 3 in the following form:

► **Lemma 11.** *There is an algorithm that, given a relational structure \mathcal{S} , a width- k tree decomposition of \mathcal{S} , and an MSO sentence φ in prenex normal form, produces in time $\text{tower}^*(\text{qa}(\varphi), (k+9)|\varphi| + 3.92)$ a propositional formula ψ and tree decomposition of G_ψ of width $\text{tower}(\text{qa}(\varphi), (k+9)|\varphi| + 3.92)$ such that $\mathcal{S} \models \varphi \Leftrightarrow \psi \in \text{SAT}$.*

The lemma assumes that the sentence is in prenex normal form with a quantifier-free part ψ in CNF, i.e., $\varphi \equiv Q_1 S_1 \dots Q_{q-1} S_{q-1} Q_q s_q \dots Q_\ell s_\ell \cdot \bigwedge_{i=1}^p \psi_i$ with $Q_i \in \{\exists, \forall\}$ and S_i (s_i) being second-order (first-order) variables. The requirement that the second-order quantifiers appear before the first-order ones is for sake of presentation, the encoding works as is if the quantifiers are mixed. The main part of the proof is a treewidth-aware encoding from MC(MSO) into QSAT; which is then translated to SAT using Theorem 1.

4.1 Auxiliary Encodings

Let ψ be a propositional formula and $X \subseteq \text{lits}(\psi)$ be an arbitrary set of literals. A *cardinality constraint* $\text{card}_{\bowtie c}(X)$ with $\bowtie \in \{\leq, =, \geq\}$ ensures that $\{ \text{at most, exactly, at least} \} c$ literals of X get assigned to true. Classic encodings of cardinality constraints increase the treewidth of ψ by quite a lot. For instance, the naive encoding for $\text{card}_{\leq 1}(X) \equiv \bigwedge_{u,v \in X; u \neq v} (\neg u \vee \neg v)$ completes X into a clique. We encode a cardinality constraint without increasing the treewidth by distributing a *sequential unary counter*:

► **Lemma 12** (▼). *For every $c \geq 0$ we can, given a CNF ψ , a set $X \subseteq \text{lits}(\psi)$, and a width- k tree decomposition of ψ , encode $\text{card}_{\bowtie c}(X)$ such that $\text{tw}(\psi \wedge \text{card}_{\bowtie c}(X)) \leq k + 3c + 3$.*

Sketch of Proof. We add $c + 1$ variables to every bag t of the tree decomposition, which count the number of literals set to true in the subtree rooted at t . The semantics of the sequential counter encoding [31] is then implemented along the edges of the decomposition. To cover the new constraints, we can add the auxiliary variables of the (at most two) children of t to the bag of t as well, resulting in an overall increase of the treewidth by $3c + 3$. ◀

The second auxiliary encoding is a treewidth-preserving conversion from CNFs to DNFs.

► **Lemma 13.** *There is a polynomial-time algorithm that, given a CNF ψ and a width- k tree decomposition of G_ψ , produce a DNF ψ' and a width- $(k+4)$ tree decomposition of $G_{\psi'}$ such that for any $\alpha \sqsubseteq \text{vars}(\psi)$, $\psi|\alpha = \emptyset$ iff $\psi'|\alpha$ is a tautology ($\neg(\psi'|\alpha)$ is unsatisfiable).*

Sketch of Proof. For every clause C we add a variable f_C that is true iff C is satisfied. Satisfiability is encoded along the tree by variables $f_{\leq t}$ indicating that ψ is satisfied in the subtree rooted at t via $\bigvee_{t \in V(T)} \neg \left[f_{\leq t} \leftrightarrow \bigwedge_{C \in \lambda(t)} f_C \wedge \bigwedge_{t' \in \text{children}(t)} f_{\leq t'} \right]$. ◀

4.2 Indicator Variables for the Quantifiers

To prove Lemma 11 we construct a QBF for a given MSO sentence φ , structure \mathcal{S} , and tree decomposition of \mathcal{S} . We first define the primary variables of ψ , i.e., the prefix of ψ (primary here refers to the fact that we will also need some auxiliary variables later). For every second-order quantifier $\exists X$ or $\forall X$ we introduce, as we did in the introduction, an indicator variable X_u for every element $u \in U(\mathcal{S})$ with the semantic that X_u is true iff $u \in X$. These variables are either existentially or universally quantified, depending on the second-order quantifier. If there are multiple quantifiers (say $\exists X \forall Y$), the order in which the variables are quantified is the same as the order of the second-order quantifiers. For first-order quantifiers $\exists x$ or $\forall x$ we do the same construction, i.e., we add variables x_u for all $u \in U(\mathcal{S})$ with the semantics that x_u is true iff x was assigned to u . Of course, of these variables we have to set *exactly one* to true, which we enforce by adding $\text{card}_{=1}(\{x_u \mid u \in U(\mathcal{S})\})$ using Lemma 12.

4.3 Evaluation of Atoms

The last ingredient of our QBF encoding is the evaluation of the atoms in the MSO sentence φ . An atom is Rx_1, \dots, x_a for a relational symbol R from the vocabulary of arity a , containment in a second-order variable Xu , equality $x = y$, and the negation of the aforementioned. For every atom ι that appears in φ we introduce variables p_t^ι and $p_{\leq t}^\iota$ for all $t \in V(T)$ that indicate that ι is true in bag t or somewhere in the subtree rooted at t , respectively. Note that the same atom can occur multiple times in φ , for instance in

$$\forall x \forall y \exists z . (x = y \rightarrow x = z) \vee (x = y \rightarrow y = z)$$

there are two atoms $x = y$. However, since φ is in prenex normal form (and, thus, variables cannot be rebound), these always evaluate in exactly the same way. Hence, it is sufficient to consider the *set of atoms*, which we denote by $\text{atoms}(\varphi)$. We can propagate information about the atoms along the tree decomposition with:

$$\bigwedge_{t \in V(T)} \bigwedge_{\iota \in \text{atoms}(\varphi)} \left[p_{\leq t}^\iota \leftrightarrow (p_t^\iota \vee \bigvee_{t' \in \text{children}(t)} p_{\leq t'}^\iota) \right].$$

This encoding introduces two variables per atom ι per bag t (namely p_t^ι and $p_{\leq t}^\iota$), which increases the treewidth by at most $2 \cdot |\text{atoms}(\varphi)|$. To synchronize with the two children t' and t'' , we add $p_{\leq t'}^\iota$ and $p_{\leq t''}^\iota$ to $\chi(t)$, yielding a total treewidth of at most $4 \cdot |\text{atoms}(\varphi)|$.

An easy atom to evaluate is $x = y$, since if x and y are equal (i.e., they both got assigned to the same element $u \in U(\mathcal{S})$), we can conclude this fact within a bag that contains u :

$$\bigwedge_{t \in V(T)} \left[p_t^{x=y} \leftrightarrow \bigvee_{u \in \chi(t)} (x_u \wedge y_u) \right].$$

For every $u \in U(\mathcal{S})$ and every quantifier $\exists x$ (or $\forall x$), we add the propositional variable x_u to all bags containing u . We increase the treewidth by at most the quantifier rank and, in return, cover constraints as the above trivially. Similarly, if there is a second-order variable X and a first-order variable x , the atom Xx can be evaluated locally in every bag:

$$\bigwedge_{t \in V(T)} \left[p_t^{Xx} \leftrightarrow \bigvee_{u \in \chi(t)} (X_u \wedge x_u) \right].$$

We have to evaluate atoms corresponding to relational symbols R of the vocabulary. For each such symbol of arity a we encode:

$$\bigwedge_{t \in V(T)} \left[p_t^{R(x_1, x_2, \dots, x_a)} \leftrightarrow \bigvee_{\substack{u_1, \dots, u_a \in \chi(t) \\ (u_1, \dots, u_a) \in R^{\mathcal{S}}}} ((x_1)_{u_1} \wedge (x_2)_{u_2} \wedge \dots \wedge (x_a)_{u_a}) \right].$$

Here “ $R(x_1, x_2, \dots, x_a)$ ” is an atom in which R is a relational symbol and x_1, x_2, \dots, x_a are quantified first-order variables. In the inner “big-or” we consider all u_1, \dots, u_a in $\chi(t)$, i.e., elements $u_1, \dots, u_a \in U(\mathcal{S})$ that are in the relation $(u_1, \dots, u_a) \in R^{\mathcal{S}}$. Then “ $(x_i)_{u_i}$ ” is a variable that describes that x_i gets assigned to u_i . Note that all tuples in $R^{\mathcal{S}}$ appear together in at least one bag of the tree decomposition and, hence, there is at least one bag t for which $p_t^{R(x_1, x_2, \dots, x_a)}$ can be evaluated to true. The propagation ensures that, for every $\iota \in \text{atoms}(\varphi)$, the variable $p_{\leq \text{root}(T)}^\iota$ will be true iff ι is true. Since the quantifier-free part of φ is a CNF $\bigwedge_{j=1}^p \psi_j$, we can encode it by replacing every occurrence of ι in ψ_j with $p_{\leq \text{root}(T)}^\iota$.

4.4 The Full Encoding in one Figure

For the readers convenience, we compiled the encoding into Figure 1. Combining the insights of the last sections proves Lemma 11, but if the inner-most quantifier is universal, existentially projecting the encoding variables would produce a QBF with one more block. This can, however, be circumvent using Lemma 13. We formally prove that “combining the insights” indeed leads to a sound proof of Lemma 11 in the technical report.

Cardinality Propagation

$$c_{\leq t}^x \leftrightarrow \bigvee_{u \in \chi(t) \setminus \chi(\text{parent}(t))} x_u \vee \bigvee_{t' \in \text{children}(t)} c_{\leq t'}^x \quad \text{for every } t \text{ in } T, x \in \{s_q, \dots, s_\ell\} \quad (1)$$

At-Least-One Constraint

$$c_{\leq \text{root}(T)}^x \quad \text{for every } x \in \{s_q, \dots, s_\ell\} \quad (2)$$

At-Most-One Constraint

$$\neg x_u \vee \neg x_{u'} \quad \text{for every } t \text{ in } T, u, u' \in \chi(t), u \neq u', x \in \{s_q, \dots, s_\ell\} \quad (3)$$

$$\neg x_u \vee \neg c_{\leq t'}^x \quad \text{for every } t \text{ in } T, t' \in \text{children}(t), u \in \chi(t) \setminus \chi(\text{parent}(t)), x \in \{s_q, \dots, s_\ell\} \quad (4)$$

$$\neg c_{\leq t'}^x \vee \neg c_{\leq t''}^x \quad \text{for every } t \text{ in } T, t', t'' \in \text{children}(t), t' \neq t'', x \in \{s_q, \dots, s_\ell\} \quad (5)$$

Proofs of MSO Atoms

$$p_t^{x=y} \leftrightarrow \bigvee_{u \in \chi(t)} (x_u \wedge y_u) \quad \text{for every } t \text{ in } T, x, y \in \{s_q, \dots, s_\ell\}, (x=y) \in \text{atoms}(\varphi) \quad (6)$$

$$p_t^{X(x)} \leftrightarrow \bigvee_{u \in \chi(t)} (X_u \wedge x_u) \quad \text{for every } t \text{ in } T, X \in \{S_1, \dots, S_{q-1}\}, x \in \{s_q, \dots, s_\ell\}, X(x) \in \text{atoms}(\varphi) \quad (7)$$

$$p_t^{R(x_1, \dots, x_a)} \leftrightarrow \bigvee_{\substack{u_1, \dots, u_a \in \chi(t) \\ (u_1, \dots, u_a) \in R^S}} ((x_1)_{u_1} \wedge \dots \wedge (x_a)_{u_a}) \quad \text{for every } t \text{ in } T, \{x_1, \dots, x_a\} \subseteq \{s_q, \dots, s_\ell\}, \\ R \in \mathcal{S}, R(x_1, \dots, x_r) \in \text{atoms}(\varphi) \quad (8)$$

$$p_{\leq t}^\iota \leftrightarrow p_t^\iota \vee \bigvee_{t' \in \text{children}(t)} p_{\leq t'}^\iota \quad \text{for every } t \text{ in } T, \iota \in \text{atoms}(\varphi) \quad (9)$$

Deriving MSO Atoms requires Proof

$$\iota \leftrightarrow p_{\leq \text{root}(T)}^\iota \quad \text{for every } t \text{ in } T, \iota \in \text{atoms}(\varphi) \quad (10)$$

Verify MSO Formula

$$\psi \quad (11)$$

■ **Figure 1** The reduction $\mathcal{R}_{\text{MSO} \rightarrow \text{QSAT}}(\varphi, \mathcal{S}, \mathcal{T})$ that takes as input an MSO formula in prenex normal form $\varphi = Q_1 S_1 \dots Q_{q-1} S_{q-1} Q_q s_q \dots Q_\ell s_\ell \cdot \psi$ and a structure \mathcal{S} with a TD $\mathcal{T} = (T, \chi)$ of \mathcal{S} of width k . It obtains a QBF $\varphi' = Q_1 S'_1 \dots Q_\ell S'_\ell \exists E' \cdot \psi'$, where ψ' is the conjunction of Equations (1)–(11), $S'_i = \{(S_i)_u \mid u \in U(\mathcal{S})\}$ and $E' = \text{vars}(\psi') \setminus (\bigcup_{i=1}^\ell S'_i)$. Formula ψ' can be easily converted into CNF of width linear in k (for constant-size MSO formulas φ).

5 Fagin Definability via Automated Reasoning

In this section we prove the remaining two items of Theorem 3, i.e., a treewidth-aware encoding of the optimization version of Courcelle’s Theorem to MAXSAT; and a #SAT encoding of the counting version of the theorem. The general approach is as follows: We obtain a MSO formula

$\varphi(X)$ with a free set variable X as input (rather than a MSO sentence as in Lemma 11). The objective of the model-checking problems adds requirements to this variable (for $\text{FD}(\text{MSO})$ we seek a $S \subseteq U(\mathcal{S})$ of minimum size such that $\mathcal{S} \models \varphi(S)$; for $\#\text{FD}(\text{MSO})$ we want to count the number of sets $S \subseteq U(\mathcal{S})$ with $\mathcal{S} \models \varphi(S)$). The “trick” is to rewrite $\varphi(X) = \xi$ as $\varphi' = \exists X \xi$ and apply Lemma 11 to φ' in order to obtain a propositional formula ψ . Observe that the quantifier alternation of φ' may be one larger than the one of φ .

► **Lemma 14** (▼). *There is an algorithm that, given a structure \mathcal{S} with weights $w_i: U(\mathcal{S}) \rightarrow \mathbb{Q}$ for $i \in \{1, \dots, \ell\}$, a width- k tree decomposition of \mathcal{S} , and an MSO formula $\varphi(X_1, \dots, X_\ell)$ in prenex normal form, produces in time $\text{tower}^*(\text{qa}(\varphi) + 1, (k + 9)|\varphi| + 3.92)$ a WCNF ψ and a tree decomposition of width $\text{tower}(\text{qa}(\varphi) + 1, (k + 9)|\varphi| + 3.92)$ of G_ψ such that the maximum weight of any model of ψ equals the maximum value of $\sum_{i=1}^{\ell} \sum_{s \in S_i} w_i(s)$ under $S_1, \dots, S_\ell \subseteq U(\mathcal{S})$ with $\mathcal{S} \models \varphi(S_1, \dots, S_\ell)$.*

Sketch of Proof. Consider $\psi \wedge \bigwedge_{u \in U(\mathcal{S})} (\neg X_u)$ such that the clauses in ψ are *hard* and the added clauses are *soft*. A model maximizing the soft clauses will minimize the number of X_u variables set to true, i.e., corresponds to a minimum-size set S with $\mathcal{S} \models \varphi(S)$. ◀

► **Lemma 15** (▼). *There is an algorithm that, given a relational structure \mathcal{S} , a width- k tree decomposition of \mathcal{S} , and an MSO formula $\varphi(X_1, \dots, X_\ell)$ in prenex normal form, produces in time $\text{tower}^*(\text{qa}(\varphi) + 1, (k + 9)|\varphi| + 3.92)$ a CNF ψ and a tree decomposition of width $\text{tower}(\text{qa}(\varphi) + 1, (k + 9)|\varphi| + 3.92)$ of G_ψ such that the number of models of ψ equals the number of sets $S_1, \dots, S_\ell \subseteq U(\mathcal{S})$ with $\mathcal{S} \models \varphi(S_1, \dots, S_\ell)$.*

Sketch of Proof. We need to compute the number of models of ψ projected to the X_u variables. In other words, it is sufficient to solve the *projected model counting problem* on the instance generated with Lemma 11 using Lemma 10. ◀

6 Lower Bounds for the Encoding Size of Model Checking Problems

We companion our SAT encodings for $\text{MC}(\text{MSO})$ with lower bounds on the achievable encoding size under ETH. The first lower bound (Theorem 5) is obtained by an encoding from QSAT into $\text{MC}(\text{MSO})$ that implies that SAT encodings of $\text{MC}(\text{MSO})$ lead to faster QSAT algorithms.

► **Lemma 16** (▼). *There is a polynomial-time algorithm that, given a QSAT sentence ψ , outputs a structure \mathcal{S} and an MSO sentence φ with $\text{tw}(\mathcal{S}) \leq \text{tw}(\psi) + 1$ and $\text{qa}(\varphi) \leq \text{qa}(\psi) + 2$ such that $\mathcal{S} \models \varphi$ iff ψ evaluates to true.*

Sketch of Proof. The structure \mathcal{S} is the *incidence graph* of ψ (the graph containing a node for every variable and every clause that connects variables to the clauses containing them) with some additional labels. The sentence φ uses $\text{qa}(\psi)$ second-order quantifier to guess the assignment of ψ , and one additional $\forall x \exists y$ -block to evaluate it. ◀

Proof of Theorem 5. Combine Lemma 16 with Fact 5. ◀

6.1 An Encoding for Compressing Treewidth

For QSAT one can “move” complexity from the quantifier rank of the formula to its treewidth and *vice versa* [16]. By Lemma 16, this means that any reduction from QSAT to $\text{MC}(\text{MSO})$ may produce an instance with small treewidth or quantifier alternation while increasing the other. We show that one can also decrease the treewidth by increasing the *block size*.

► **Lemma 17 (▼).** *For every $c > 0$ there is a polynomial-time algorithm that, on input of a CNF ψ and a width- k tree decomposition of G_ψ , outputs a constant-size MSO sentence φ with $\text{qa}(\varphi) = 2$ and $\text{bs}(\varphi) = c$, and a structure \mathcal{S} with $\text{tw}(\mathcal{S}) \leq \lceil \frac{k+1}{c} \rceil$ such that $\psi \in \text{SAT} \Leftrightarrow \mathcal{S} \models \varphi$.*

Sketch of Proof. The idea of the proof is to (i) encode the input’s formula as an incidence graph over which we reason with an MSO sentence; we then (ii) replace this structure by its tree decomposition with additional “sync edges”; and finally we (iii) contract vertices in the tree decomposition to lower the treewidth, while we encode statements like $x \in S$ (for a set variable S) by defining new set variables S_1, \dots, S_c and by interpreting $y \in S_i$ as “the i th vertex contracted to y is in S ”. ◀

Proof of Theorem 6. We obtain the Trade-off Theorem by combining the proof strategy of Lemma 17 with the reduction from QSAT to MC(MSO) of Lemma 16. The result is a polynomial-time algorithm for every $c > 0$ that, on input of a QBF ψ and a width- k tree decomposition of G_ψ , outputs a constant-size MSO sentence φ with $\text{qa}(\varphi) \leq \text{qa}(\psi) + 2$ and $\text{bs}(\varphi) = c$, and a structure \mathcal{S} with $\text{tw}(\mathcal{S}) \leq \lceil \frac{k+1}{c} \rceil$ such that ψ is valid iff $\mathcal{S} \models \varphi$. ◀

It is out of the scope of this article, but worth mentioning, that the proofs of Lemma 17 and Theorem 6 can be generalized to the following finite-model theoretic result:

► **Proposition 18.** *For every $c > 0$ there is a polynomial-time algorithm that, given a relational structure \mathcal{S} , a width- k tree decomposition of \mathcal{S} , and an MSO sentence φ , outputs a structure \mathcal{S}' and a sentence φ' such that:*

1. $\mathcal{S} \models \varphi \iff \mathcal{S}' \models \varphi'$;
2. $\text{tw}(\mathcal{S}') \leq \lceil \frac{k+1}{c} \rceil$;
3. $\text{bs}(\varphi') \leq c \cdot \text{bs}(\varphi)$.

7 Conclusion and Further Research

We studied *structure-guided automated reasoning*, where we utilize the input’s structure in propositional encodings. The scientific question we asked was whether we can encode every MSO definable problem on structures of bounded treewidth into SAT formulas of bounded treewidth. We proved this in the affirmative, implying an alternative proof of Courcelle’s Theorem. The most valuable aspects are, in our opinion, the simplicity of the proof (it is “just” an encoding into propositional logic) and the potential advantages in practice for formulas of small quantifier alternation (SAT solvers are known to perform well on instances of small treewidth, even if they do not actively apply techniques such as dynamic programming). Another advantage is the surprisingly simple generalization to the optimization and counting version of Courcelle’s Theorem – we can directly “plug in” MAXSAT or #SAT and obtain the corresponding results. As a byproduct, we also obtain new proofs showing (purely as encodings into propositional logic) that QSAT parameterized by the input’s treewidth plus quantifier alternation is fixed-parameter tractable (improving a complex dynamic program with nested tables) and that PMC parameterized by treewidth is fixed-parameter tractable (improving a multi-pass dynamic program). Table 1 provides an overview of the encodings presented within this article.

Our encodings are exponentially smaller than the best known running time for MC(MSO), i.e., when we solve the instances using Fact 1, we obtain the same runtime. We complemented this finding with new ETH-based lower bounds. Further research will be concerned with closing the remaining gap in the height of the tower between the lower and upper bounds. We show in an upcoming paper that the terms “ $\text{qa}(\varphi)$ ” in Theorem 3 and “ $\text{qa}(\varphi) - 2$ ” in

■ **Table 1** We summarize the encodings presented within this article. An encoding maps *from* one problem *to* another. The third and fourth columns define the treewidth and size of the encoding, whereby we assume that $c > 0$ is a constant, a width- k tree decomposition is given, ψ is a propositional formula, and φ is a fixed MSO formula.

<i>Encoding...</i>				
<i>From</i>	<i>To</i>	<i>Treewidth</i>	<i>Size</i>	<i>Reference</i>
QSAT	SAT	$\text{tower}(\text{qa}(\psi), k + 3.92)$	$\text{tower}^*(\text{qa}(\psi), k + 3.92)$	Theorem 1
PMC	#SAT	$\text{tower}(1, k + 3.59)$	$\text{tower}^*(1, k + 3.59)$	Theorem 2
$\text{card}_{\geq c}(X)$	SAT	$k + 3c + 3$	$O(c \psi)$	Lemma 12
CNF	DNF	$k + 4$	$O(\psi)$	Lemma 13
MC(MSO)	SAT	$\text{tower}(\text{qa}(\varphi), (9k + 9) \varphi + 3.92)$	$\text{tower}^*(\text{qa}(\varphi), (9k + 9) \varphi + 3.92)$	Lemma 11
FD(MSO)	MAXSAT	$\text{tower}(\text{qa}(\varphi) + 1, (9k + 9) \varphi + 3.92)$	$\text{tower}^*(\text{qa}(\varphi) + 1, (9k + 9) \varphi + 3.92)$	Lemma 14
#FD(MSO)	#SAT	$\text{tower}(\text{qa}(\varphi) + 1, (9k + 9) \varphi + 3.92)$	$\text{tower}^*(\text{qa}(\varphi) + 1, (9k + 9) \varphi + 3.92)$	Lemma 15
SAT	MC(MSO)	$\lceil \frac{k+1}{c} \rceil$	$O(k \psi)$	Lemma 17
QSAT	MC(MSO)	$\lceil \frac{k+1}{c} \rceil$	$O(k \psi)$	Theorem 6

Theorem 5 can be replaced by “ $\text{qa}_2(\varphi)$ ” on *guarded* formulas, i.e., formulas in which there are only two first-order quantifiers that are only allowed to quantify edges. Here, $\text{qa}_2(\varphi)$ refers to the quantifier alternation of the second-order quantifiers only. Hence, on such guarded formulas (e.g., on all examples in the introduction), the bounds are tight. Another task that remains for further research is to evaluate the encodings in practice. This would also be interesting for the auxiliary encodings, e.g., can a treewidth-aware cardinality constraint compete with classical cardinality constraint?

Abstract

We prove that the spanning trees of any outerplanar triangulation G can be listed so that any two consecutive spanning trees differ in an exchange of two edges that share an end vertex. For outerplanar graphs G with faces of arbitrary lengths (not necessarily 3) we establish a similar result, with the condition that the two exchanged edges share an end vertex or lie on a common face. These listings of spanning trees are obtained from a simple greedy algorithm that can be implemented efficiently, i.e., in time $\mathcal{O}(n \log n)$ per generated spanning tree, where n is the number of vertices of G . Furthermore, the listings correspond to Hamilton paths on the 0/1-polytope that is obtained as the convex hull of the characteristic vectors of all spanning trees of G .

Acknowledgements We thank both reviewers of this paper for a number of very helpful suggestions that improved the writing.

1 Introduction

For a given graph G , let $\mathcal{T}(G)$ denote the set of all spanning trees of G . Two spanning trees of G differ in an *edge exchange* if the symmetric difference of their edge sets is a 2-element set, i.e., each of the two spanning trees is obtained from the other one by removing one edge and adding another. The *flip graph* $\mathcal{F}(G)$ has the set $\mathcal{T}(G)$ as vertex set, and an edge between any two spanning trees that differ in an edge exchange; see Figure 1. It is well-known that $\mathcal{F}(G)$ is the skeleton of the 0/1-polytope that is obtained as the convex hull of all characteristic vectors $\chi(T)$ of spanning trees $T \in \mathcal{T}(G)$ (see [25, Thm. 40.6]). Specifically, if the edge set of G is $\{1, \dots, m\}$, then for all $e \in \{1, \dots, m\}$ the characteristic vector $\chi(T)$ has a 1-bit at position e if the edge e belongs to T , and a 0-bit at position e otherwise.

We are interested in computing Hamilton paths or cycles in the flip graph $\mathcal{F}(G)$, i.e., we aim to list all spanning trees of G such that any two consecutive spanning trees differ in an edge exchange. Such a listing of combinatorial objects subject to some small-change condition is generally referred to as a *Gray code* [24, 19]. A Gray code is called *cyclic* if the first and last object also differ in the small-change condition, i.e., this corresponds to a Hamilton cycle in the flip graph.

Cummins [8] first proved that $\mathcal{F}(G)$ admits a Hamilton cycle for any graph G . He showed more generally that for any prescribed edge of $\mathcal{F}(G)$, there is a Hamilton cycle containing this edge. Similar results were obtained by Shank [26], Kamae [11], and Kishi and Kajitani [13].

■ **Figure 1** The spanning tree flip graph $\mathcal{F}(G)$ for the “diamond” graph G on the left, with a Hamilton cycle highlighted. For each spanning tree, the set of edges is shown above, and the characteristic vector is shown below. Edges of $\mathcal{F}(G)$ are labelled by the two edges of G being exchanged.

Harary and Holzmam [10] proved more generally that the base exchange flip graph of any matroid has a Hamilton cycle. They showed this in the stronger sense that any edge of this flip graph can be prescribed to be contained in the cycle, and to be avoided by another cycle. Furthermore, Naddef and Pulleyblank [20, 21] proved that the skeleton of any 0/1-polytope either admits a Hamilton path between any two prescribed end vertices, or it is a hypercube, in which case it admits a Hamilton path between any two end vertices of opposite parity.

Algorithmically, a Hamilton path in $\mathcal{F}(G)$ can be computed in time $\mathcal{O}(1)$ on average per generated tree using Smith’s algorithm [30] (this is Algorithm S in [14, Sec. 7.2.1.6]); see Figure 2 (a). Given these strong Hamiltonicity properties of the graph $\mathcal{F}(G)$, there has recently been interest to strengthen them by restricting the allowed edge exchanges.

1.1 The pivot-exchange property

We introduce some more notation. For a graph G , we write $V(G)$ and $E(G)$ for set of vertices and edges of G , respectively. For a subgraph $H \subseteq G$ and edges $e \in E(H)$ and $f \in E(G) \setminus E(H)$, we write $H - e$ and $H + f$ for the graphs obtained from H by removing and adding the edges e and f , respectively. We will think of a subgraph H as a subset of edges from $E(G)$, so the operations $H - e$ and $H + f$ remove and add an element from the set, respectively. Formally, an *edge exchange* for a spanning tree $T \in \mathcal{T}(G)$ is a pair $\{e, f\}$ of edges such that $e \in E(T)$ and $f \in E(G) \setminus E(T)$ with $T - e + f = T \Delta \{e, f\} \in \mathcal{T}(G)$.

(b) Cameron, Grubb, Sawada [CGS24]

(c) Merino, Mütze, Williams [MMW22]

■ **Figure 2** Three different edge exchange Gray codes for listing the 21 spanning trees of the fan graph F_5 . In each spanning tree, the edge removed to reach the next tree is highlighted (prefixed by $-$ in (c)), and the non-edge being added is dashed (prefixed by $+$ in (c)). In (b) and (c), the common end vertex of each pivot-exchange operation is highlighted, and in (c), the common face of each face-exchange operation is highlighted. The right-hand side of (c) shows the characteristic vectors of each spanning tree.

Cameron, Grubb, and Sawada [3] introduced the stronger notion of a *pivot-exchange*, which is an exchange $\{e, f\}$ with the additional property that e and f have a common end vertex. For example, in the graph G shown in Figure 1, all exchanges except $\{1, 5\}$ and $\{2, 4\}$ are pivot-exchanges. They raised the following problem.

► **Problem 1.** *Does every graph G admit a pivot-exchange Gray code of its spanning trees?*

16:4 Listing Spanning Trees of Outerplanar Graphs

Additionally, they asked if such a listing can be computed using a greedy strategy, and possibly by an efficient algorithm. Problem 1 is a special case of a more general question raised by Knuth in Vol. 4A of his seminal series “The Art of Computer Programming” [14], stated as problem 102 in Section 7.2.1.6 with a difficulty rating of 46/50: ¹

► **Problem 2.** *Does every directed graph admit an edge exchange Gray code of its oriented spanning trees, also known as arborescences, i.e., spanning trees in which all arcs are oriented away from a fixed root vertex r ?*

Note that for any exchange $\{e, f\}$ in this directed setting, in order to preserve the arborescence property, the arcs e and f must point to the same vertex, i.e., it must be a pivot-exchange. Furthermore, a positive answer to Problem 2 would imply an affirmative answer to Problem 1: Indeed, given an undirected graph G , construct the directed graph G^{\leftrightarrow} by replacing each undirected edge of G by two oppositely oriented arcs, and pick an arbitrary vertex as root r . Listing the oriented spanning trees of G^{\leftrightarrow} by arc exchanges produces every spanning tree of G exactly once, namely in the orientation forced by the choice of r .

1.2 Fan graphs

■ **Figure 3** The fan graphs F_n .

As a first step towards Problem 1, Cameron, Grubb, and Sawada [3] provided a pivot-exchange Gray code for listing the spanning trees of *fan graphs* F_n , which are obtained by joining an extra vertex to all vertices of a path on $n - 1$ vertices; see Figure 3.

► **Theorem 3** ([3, Thm. 4]). *For any $n \geq 3$, there is a pivot-exchange Gray code for the spanning trees of F_n .*

The output of their algorithm for the case $n = 5$ is shown in Figure 2 (b). The algorithm uses a greedy strategy that prioritizes exchanges based on vertex labels.

1.3 A simple greedy algorithm

Merino, Mütze and Williams [17] discovered a simple greedy algorithm for listing the spanning trees of a graph G by (arbitrary) edge exchanges. The algorithm operates based on a total ordering of the edges of G , which is captured by labeling the edges by integers. Specifically, if m denotes the number of edges of G , then an *edge labeling* is a bijection $\ell : E(G) \rightarrow \{1, \dots, m\}$. For an edge $e \in E(G)$, we refer to $\ell(e)$ as the *label* of the edge e . In the following examples, we will often identify edges by their labels. In particular, edge exchanges $\{e, f\}$ will be denoted by the pairs of labels $\{\ell(e), \ell(f)\}$. We will also use the abbreviation $[m] := \{1, \dots, m\}$.

The output of Algorithm G when applied to the fan graph F_5 is shown in Figure 2 (c), using the edge labeling displayed on the left. To illustrate the greedy rule in step G2, when reaching the sixth spanning tree $T_6 = \{1, 2, 5, 6\}$, there are seven possible edge exchanges to

¹ A flawed attempt at settling this problem was published in [5] (see [22]).

■ **Algorithm G** Greedy edge exchanges.

This algorithm greedily generates the spanning trees of a graph G with m edges via edge exchanges, using an edge labeling $\ell : E(G) \rightarrow [m]$ and an initial spanning tree $\tilde{T} \in \mathcal{T}(G)$.

- G1. [Initialize] Visit the initial spanning tree \tilde{T} .
- G2. [Exchange] Perform an edge exchange in the current spanning tree that minimizes the larger of the two edge labels in the exchange and that yields an unvisited spanning tree from $\mathcal{T}(G)$. If no such exchange exists, then terminate. Otherwise visit this new spanning tree and repeat G2.

obtain another spanning tree in $\mathcal{T}(F_5)$, namely $\{1, 3\}, \{2, 3\}, \{1, 4\}, \{2, 4\}, \{4, 5\}, \{5, 7\}$ and $\{6, 7\}$; see Figure 4. Only $\{1, 4\}, \{2, 4\}, \{5, 7\}$ and $\{6, 7\}$ give an unvisited spanning tree, and among those, $\{1, 4\}$ and $\{2, 4\}$, minimize the larger label, which is 4. In this case, the exchange $\{2, 4\}$ is applied, but $\{1, 4\}$ would be a valid alternative for the algorithm.

■ **Figure 4** Illustration of the sixth iteration of Algorithm G in the run shown in Figure 2 (c).

In general, in step G2 there may be several edge exchanges

$$\{e_1, f\}, \{e_2, f\}, \dots, \{e_t, f\} \text{ with } \ell(e_1) < \ell(e_2) < \dots < \ell(e_t) < \ell(f), \tag{1}$$

applicable to the current spanning tree to give an unvisited spanning tree, which all have $\ell(f)$ as the larger label, differing only in the smaller label $\ell(e_i), i \in [t]$. We refer to such a situation as a *tie*. A *tie-breaking rule* is a procedure that determines which exchange to apply in case of a tie.

By definition of the step G2, Algorithm G only selects edge exchanges that result in a previously unvisited spanning tree of G , i.e., the produced listing of spanning trees will not contain repetitions. However, it could be that the algorithm terminates before having visited the entire set $\mathcal{T}(G)$, a situation that is ruled out by the next theorem.

► **Theorem 4** ([17, Thm. 10]). *For any graph G , for any edge labeling of G , for any initial spanning tree $\tilde{T} \in \mathcal{T}(G)$, and for any tie-breaking rule, Algorithm G yields a genlex listing of all spanning trees of G .*

A listing of bitstrings is called *genlex* if all strings with the same suffix appear consecutively. In particular, all strings ending with 0 appear before all strings ending with 1, or vice versa. A genlex listing of bitstrings is also sometimes referred to as suffix-partitioned in the literature. Note that genlex order generalizes colexicographic order. In the context of spanning trees, the *genlex* property refers to the corresponding characteristic vectors $\chi(T)$ of spanning

trees $T \in \mathcal{T}(G)$; see the right-hand side of Figure 2 (c). In other words, all spanning trees not containing the highest-labeled edge appear before all spanning trees containing this edge, or vice versa, and this property is true recursively within the blocks.

As evidenced by this theorem, the greedy Algorithm G is very powerful and versatile. In fact, the algorithm can be generalized for listing the bases of any matroid by base exchanges, and even more generally, for traversing a Hamilton path on the skeleton of any 0/1-polytope [16].

1.4 The face-exchange property

The paper [17] also introduced another closeness condition for edge exchanges, which is well-defined only for plane graphs. Specifically, a *face-exchange* between two spanning trees of a plane graph is an exchange of two edges that lie on a common face. If an edge exchange is both a pivot-exchange *and* face-exchange, then we refer to it as a *pivot \wedge face-exchange*. A weaker requirement is that it is a pivot-exchange *or* a face-exchange, and then we refer to it as a *pivot \vee face-exchange*. These notions give rise to the following question.

► **Problem 5.** *Does every plane graph G admit a pivot \wedge face-exchange or a pivot \vee face-exchange Gray code of its spanning trees?*

Pivot- and face-exchanges are connected through the well-known concept of the dual graph; see Figure 5 (a). For a plane graph G , we write $F(G)$ for the set of faces of G . The *dual graph* G' is the plane graph obtained from G as follows: For every face $\alpha \in F(G)$, the dual graph G' has a vertex $\alpha' \in V(G')$, and for every edge e of G between faces α and β of G , the dual graph G' has the edge $e' = (\alpha', \beta')$. For every vertex $v \in V(G)$, we write $v' \in F(G')$ for the corresponding face of G' dual to it. For a spanning tree $T \in \mathcal{T}(G)$, the *dual spanning tree* $T' \in \mathcal{T}(G')$ has the dual edge $e' \in E(T')$ for every non-edge $e \in E(G) \setminus E(T)$ and a dual non-edge $e' \notin E(T')$ for every edge $e \in E(T)$; see Figure 5 (b). Observe that a pivot-exchange $\{e, f\}$ in T is a face-exchange $\{e', f'\}$ in the dual spanning tree T' ; see Figure 5 (c). Symmetrically, a face-exchange $\{e, f\}$ in T is a pivot-exchange $\{e', f'\}$ in T' .

■ **Figure 5** Connection between pivot- and face-exchanges via the dual spanning tree.

Merino, Mütze and Williams [17] strengthened Theorem 3, by showing that for a suitable edge labeling of the fan graph F_n and a suitable tie-breaking rule, Algorithm G yields a pivot \wedge face-exchange Gray code. Specifically, the edges of F_n are labeled from *left-to-right*, as shown in Figure 2 (c), and ties are broken according to the *closest* tie-breaking rule, which in case of a tie as in (1) selects the exchange $\{e_t, f\}$, i.e., the exchange that maximizes the smaller of the edge labels $\ell(e_t)$ (equivalently, the one for which the smaller label is closest to the larger label $\ell(f)$).

■ **Figure 6** (a) Pivot-exchange Gray code for the spanning trees of the outerplane triangulation G . (b) Pivot \vee face-exchange Gray code for the spanning trees of the outerplane graph G' , which has the four marked face-exchanges $\{1, 7\}$, and the rest pivot-exchanges. Both listings were computed by Algorithm G, and the spanning trees are represented by their characteristic vectors, with 1-bits and 0-bits drawn as black and white squares, respectively. The initial spanning tree is highlighted in both graphs.

► **Theorem 6.** *For any $n \geq 3$, for the left-to-right labeling of the edges of F_n , for any initial spanning tree $\tilde{T} \in \mathcal{T}(F_n)$, and for the closest tie-breaking rule, Algorithm G yields a genlex pivot \wedge face-exchange Gray code for the spanning trees of F_n .*

In fact, the Gray code from Theorem 3 also has the stronger pivot \wedge face-exchange property.

1.5 Our results

In this work, we solve Problems 1 and 5 for certain families of plane graphs that generalize fan graphs, thus generalizing Theorems 3 and 6.

An *outerplane* graph is a plane graph in which all vertices are incident to the outer face. An outerplane graph is a *triangulation* if all of its faces, except possibly the outer face, are triangles. Note that fan graphs are a very special case of outerplane triangulations.

► **Theorem 7.** *For any outerplane triangulation G , there is an edge labeling of G , so that for any initial spanning tree $\tilde{T} \in \mathcal{T}(G)$, there is a tie-breaking rule for which Algorithm G yields a genlex pivot-exchange Gray code for the spanning trees of G .*

► **Theorem 8.** *For any outerplane graph G , there is an edge labeling of G , so that for any initial spanning tree $\tilde{T} \in \mathcal{T}(G)$, there is a tie-breaking rule for which Algorithm G yields a genlex pivot\face-exchange Gray code for the spanning trees of G .*

These theorems directly yield efficient algorithms. Specifically, using the techniques described in [16, Sec. 7.2+Cor. 32], Algorithm G can be implemented to output each spanning tree in time $\mathcal{O}(n \log n)$, where n is the number of vertices of G . The required space for the algorithm is $\mathcal{O}(n)$. In particular, this implementation is *history-free* in the sense that no previously computed spanning trees apart from the current spanning tree need to be stored, plus some simple data structures for bookkeeping.

Two examples of Gray code listings of spanning trees obtained from these theorems are shown in Figure 6.

► **Corollary 9.** *Any outerplane triangulation admits a genlex pivot-exchange Gray code of its spanning trees. Any outerplane graph admits a genlex pivot\face-exchange Gray code of its spanning trees.*

The *weak dual* graph of a plane graph G , denoted G^- is the graph obtained from the dual graph G' by removing the vertex corresponding to the outer face of G ; see Figure 7 (a).

■ **Figure 7** Illustration of (a) weak dual graph; (b) 2-connected outerplane triangulation and its weak dual tree; (c) 2-connected outerplane triangulation whose weak dual tree is a path.

Note that G is a 2-connected outerplane graph if and only if the weak dual G^- is a tree; see Figure 7 (b). Also note that G^- is a path if and only if G is 2-connected and all but at most two sides of every inner face are incident with the outer face; see Figure 7 (c). In particular, for a triangulation G , we have that G^- is a path if and only if G is 2-connected and at least one side of every triangle touches the outer face. This is true in particular for fan graphs F_n .

We show that fan graphs, and more generally outerplane triangulations for which the weak dual is a path, are exactly the outerplane graphs that have the maximum number of spanning trees for a fixed number of edges. Moreover, the counts are the Fibonacci numbers, defined as $f_0 := 0$, $f_1 := 1$ and

$$f_{m+1} := f_m + f_{m-1} \tag{2}$$

for all $m \geq 1$. We write $t(G) := |\mathcal{T}(G)|$ for the number of spanning trees of G .

► **Theorem 10.** *For any outerplane graph G with m edges we have $t(G) \leq f_{m+1}$, with equality if and only if G is a triangulation such that G^- is a path.*

The identity $t(G) = f_{m+1}$ when G is a triangulation for which G^- is a path was already noticed by Slater [29, Prop. 1].

► **Remark 11.** We remark that Problems 1, 2 and 5 are perfectly valid also for multigraphs, i.e., graphs that may have parallel edges and/or loops (though loops are irrelevant in the context of spanning trees). In fact, Theorems 4, 7 and 8, and hence Corollary 9, also hold in this more general setting. An “outerplane triangulation” in this case has all inner faces of lengths at most 3, instead of exactly 3. The time and space bounds stated after Theorem 8 change to $\mathcal{O}(m \log n)$ and $\mathcal{O}(m)$, respectively, where m is the number of edges of the multigraph. However, for simplicity we do our proofs in the setting of simple graphs, where no parallel edges nor loops are allowed. Nonetheless, our proof of Theorem 10 will actually use multigraphs.

► **Remark 12.** The listings of spanning trees produced by Algorithm G are in general not Hamilton cycles in $\mathcal{F}(G)$, but only Hamilton paths, i.e., the first and last spanning tree in general do not differ in an edge exchange. This remark applies to all the Gray codes mentioned in Theorems 4, 6, 7, and 8, and in Corollary 9. For some graphs, some edge labelings, and some initial spanning trees, however, the Gray codes are cyclic, such as the one mentioned in Theorem 6 for the L-shaped initial spanning tree shown in Figure 2 (c), which ends with the mirrored L.

1.6 Related work

There has been an extensive amount of work [23, 9, 15, 12, 27, 28] on efficiently generating the set $\mathcal{T}(G)$ of all spanning trees of G , *without* the requirement that any two consecutive trees differ in an edge exchange, i.e., the computed listings are *not* Hamilton paths or cycles in the flip graph $\mathcal{F}(G)$. The algorithms in the last three of the aforementioned papers achieve this in time $\mathcal{O}(1)$ on average per generated tree. See the survey [4] for a comparison of the different algorithms.

If instead of listing all spanning trees of G , we want to count them, then this can be achieved by Kirchhoff’s Matrix-Tree Theorem, which reduces the problem to computing a determinant, which can be done efficiently. This problem is closely connected to finding the so-called *most vital edge* of G , which is the edge contained in the most spanning trees from $\mathcal{T}(G)$. Random sampling [1, 2] and ranking/unranking [6, 7] of spanning trees have also been considered.

1.7 Outline of this paper

In Section 2 we prove Theorems 7 and 8. In Section 3 we prove Theorem 10. We conclude with some open questions in Section 4, and there we also report on some experimental evidence.

2 Proof of Theorems 7 and 8

For the proofs of Theorems 7 and 8, we will assume w.l.o.g. that the outerplane graph G is 2-connected. If G is not 2-connected, then all the arguments presented in the following apply to each of its blocks, and the spanning trees of G are obtained by combining the spanning trees in each block in all possible ways, and pivot- or face-exchanges remain valid within the blocks.

We first describe the labeling of edges of a 2-connected outerplane graph G that we use in order to run Algorithm G on the graph G . We then establish two important properties of these labelings (Lemmas 13 and 14) that are crucial to show that whenever an arbitrary edge exchange becomes applicable in step G2 of Algorithm G, then ties can be broken to instead use a pivot- or face-exchange (Lemma 15).

2.1 The edge labeling

To define the edge labeling, we need another definition. Let v be the vertex of G' corresponding to the outer face of G , and let d be the degree of v . The *split dual* graph, denoted G^* , is obtained from G' by splitting v into d many degree-1 vertices, one adjacent to each neighbor of v ; see Figure 8 (a).

Note that the weak dual graph G^- is a tree if and only if the split dual graph G^* is a tree; see Figures 7 (b) and 8 (b). Furthermore, G^- is a path if and only if G^* is a caterpillar, i.e., a tree in which all vertices are in distance ≤ 1 from a central path; see Figures 7 (c) and 8 (c).

■ **Figure 8** Illustration of (a) split dual graph; (b) 2-connected outerplane triangulation and its split dual tree; (c) 2-connected outerplane triangulation whose split dual tree is a caterpillar (cf. Figure 7).

Let G be a 2-connected outerplane graph with m edges. We consider the split dual tree G^* , we pick a leaf r of this tree as root, and we orient all of its edges away from r , giving an oriented tree \vec{G}^* , referred to as *oriented split dual*. We label the edges of \vec{G}^* in a depth-first-search manner with integers $1, \dots, m$, starting at the root r and processing subtrees in counterclockwise (ccw) order; see Figure 9. The labeling of the edges of \vec{G}^* induces a labeling of the corresponding dual edges of G with integers from $[m]$. We refer to this labeling of the edges of G as *dual-tree labeling*. Note that there is freedom in the choice of the root in the tree G^* , and different choices yield different oriented split dual trees \vec{G}^* and hence different edge labelings of the same graph G . Note that the left-to-right labeling of the fan graph $G = F_n$ shown in Figure 2 (c) is one particular dual-tree labeling.

■ **Figure 9** Illustration of the dual-tree labeling procedure.

2.2 Proofs of theorems

Throughout this section, we let G be a 2-connected outerplane graph with m edges, \vec{G}^* an oriented split dual tree, and $\ell : E(G) \rightarrow [m]$ the corresponding dual-tree labeling of the edges of G . Before proving Theorems 7 and 8, we first derive two properties of the edge labelings defined in the previous section, stated in Lemmas 13 and 14 below.

The following definitions are illustrated in Figure 10. We denote a face α of G of length t by the sequence of edges (e_1, \dots, e_t) bounding this face in ccw order, starting with the edge e_1 whose dual edge in \vec{G}^* is oriented towards α' (all other edges of \vec{G}^* are oriented away from α'). For a face $\alpha = (e_1, \dots, e_t)$ and an index $i \in [t]$, the (α, e_i) -lobe L_{α, e_i} is the set of edges of G that are dual to the edges in the maximal subtree of G^* that contains the edge e'_i , but none of the other edges e'_j , $j \in [t] \setminus \{i\}$.

■ **Figure 10** Illustration of lobes.

► **Lemma 13.** *For any face $\alpha = (e_1, \dots, e_t)$ of G , we have $\ell(e_1) < \ell(e_2) < \dots < \ell(e_t)$. Furthermore, for any $i \in \{2, \dots, t\}$ and $f \in L_{\alpha, e_i} \setminus \{e_i\}$ we have $\ell(e_i) < \ell(f)$, and $\ell(f) < \ell(e_{i+1})$ if $i < t$.*

Proof. This is an immediate consequence of the labeling procedure which processes subtrees in the oriented split dual in ccw order and in a depth-first-search manner. Specifically, for all $i \in \{2, \dots, t\}$, all edges of $L_{\alpha, e_i} \setminus \{e_i\}$ are labeled directly after e_i , and directly before e_{i+1} if $i < t$. ◀

16:12 Listing Spanning Trees of Outerplanar Graphs

For a vertex v of G , the *incidence list* E_v is the sequence of edges incident to v in clockwise order around v , starting and ending with the two edges that bound the outer face; see Figure 11. We say that an edge e incident with v is a *cw-edge* or *ccw-edge*, respectively, according to the clockwise or counterclockwise orientation of the dual edge e' in $\overrightarrow{G^*}$ around v .

► **Lemma 14.** *For any vertex v , let $E_v =: (e_1, \dots, e_t)$ be its incidence list. Then there is an index $i \in \{0, \dots, t\}$ such that e_1, \dots, e_i are ccw-edges, e_{i+1}, \dots, e_t are cw-edges, and we have $\ell(e_i) < \ell(e_{i-1}) < \dots < \ell(e_1) < \ell(e_{i+1}) < \ell(e_{i+2}) < \dots < \ell(e_t)$. In particular, for any cw-edge e_j and any $i \in [j - 1]$ we have $\ell(e_i) < \ell(e_j)$.*

■ **Figure 11** Illustration of Lemma 14.

Proof. For any sequence of edges $P = (a_1, \dots, a_t)$ that form a path in the oriented tree $\overrightarrow{G^*}$, there is an index $i \in \{0, \dots, t\}$ such that a_1, \dots, a_i are oriented towards the start vertex of P and a_{i+1}, \dots, a_t are oriented towards the end vertex of P . The special cases $i = 0$ and $i = t$ mean that the path is oriented conformly, towards the end or start vertex, respectively.

The sequence of dual edges $P := (e'_1, \dots, e'_t)$ is a path in $\overrightarrow{G^*}$ to which the aforementioned observation applies. For $j \in \{1, \dots, t - 1\}$, let f_j be the face of G bounded by e_j and e_{j+1} . Furthermore, we denote the outer face of G by $f_0 = f_t$. Note that e'_j is oriented towards f'_{j-1} in $\overrightarrow{G^*}$ for $j = 1, \dots, i$, i.e., these are all ccw-edges w.r.t. v . Furthermore, e'_j is oriented towards f'_j in $\overrightarrow{G^*}$ for $j = i + 1, \dots, t$, i.e., these are all cw-edges w.r.t. v .

Applying Lemma 13 to the faces f_j , $j = 1, \dots, i - 1$ and $j = i + 1, \dots, t - 1$, yields $\ell(e_i) < \ell(e_{i-1}) < \dots < \ell(e_1)$ and $\ell(e_{i+1}) < \ell(e_{i+2}) < \dots < \ell(e_t)$, respectively. Furthermore, applying Lemma 13 to L_{f_i, e_i} and $L_{f_i, e_{i+1}}$ proves that $\ell(e_1) < \ell(e_{i+1})$. Combining these inequalities proves the lemma. ◀

► **Lemma 15.** *Let $T \in \mathcal{T}(G)$ and let $\{e, f\}$ with $\ell(e) < \ell(f)$ be an edge exchange for T . Then there is a pivot\face-exchange $\{d, f\}$ with $\ell(d) < \ell(f)$. Furthermore, if G is a triangulation, then $\{d, f\}$ is a pivot-exchange.*

Proof. We let $\alpha = (e_1, \dots, e_t)$ be the face incident with f in G for which the dual edge f' in $\overrightarrow{G^*}$ is oriented away from α' . As $\ell(f) > \ell(e) \geq 1$ we have $\ell(f) > 1$, and consequently α is not the outer face, but an inner face. We have $f = e_i$ for some $i \in \{2, \dots, t\}$. The graph $T \cup \{e, f\}$ contains exactly one cycle C , which contains both edges e and f . As $\ell(e) < \ell(f)$, Lemma 13 implies that $e \notin L_{\alpha, f}$, and as $e \in C$, we obtain that C contains edges from every lobe L_{α, e_i} for all $i \in [t]$, and furthermore $e \in L_{\alpha, e_j}$ for some $j \in \{1, \dots, i - 1\}$.

We now distinguish the cases whether $f \in T$ or $f \notin T$, i.e., whether the exchange $\{e, f\}$ adds the edge e and removes f , or removes e and adds f , respectively. These two cases are illustrated in Figure 12 (a) and (b), respectively.

Figure 12 Illustration of the two cases in the proof of Lemma 15.

Case (a). $f \in T$. Note that $\{d, f\}$ with $d := e_j$ is a valid face-exchange for T , and we have $\ell(d) < \ell(f)$ by Lemma 13. Furthermore, if G is a triangulation, then we have $t = 3$ and consequently $f = e_i$ and $d = e_j$ share an end vertex, so the exchange $\{d, f\}$ is a pivot-exchange.

Case (b). $f \notin T$. Let d be the edge of C incident with f in the lobe $L_{\alpha, e_{i-1}}$. Note that $\{d, f\}$ is a valid pivot-exchange for T . If $i > 2$, then we have $\ell(d) < \ell(f)$ by Lemma 13. If $i = 2$, then let v be the common end vertex of $e_1 = e_j$ and $e_2 = e_i$, and consider the incidence list E_v of v . The edge e_1 is a cw-edge and d comes before it (or is equal to e_1) on the list E_v , and so Lemma 14 yields $\ell(d) \leq \ell(e_1)$. By Lemma 13 we have $\ell(e_1) < \ell(f)$ and therefore $\ell(d) < \ell(f)$. ◀

We are now in position to prove Theorems 7 and 8.

Proof of Theorems 7 and 8. By Lemma 15, whenever Algorithm G considers an edge exchange $\{e, f\}$ with $\ell(e) < \ell(f)$, there is a pivot-face-exchange $\{d, f\}$ with $\ell(d) < \ell(f)$. By Theorem 4, the listing of spanning trees produced by Algorithm G has the genlex property, which implies that if $T \triangle \{e, f\}$ is unvisited, then $T \triangle \{d, f\}$ is also unvisited. It follows that there is a tie-breaking rule for Algorithm G to only ever use pivot-face-exchanges.

Furthermore, if G is a triangulation, then by Lemma 15 the alternative exchange $\{d, f\}$ is a pivot-exchange, so there is a tie-breaking rule for Algorithm G to only ever use pivot-exchanges. ◀

3 Proof of Theorem 10

We prove Theorem 10 in the more general setting of multigraphs (recall Remark 11), i.e., from now on we allow multiple edges between pairs of vertices. Two edges between the same pair of vertices are sometimes referred to as *parallel* edges. Loops may be present, but are never contained in a spanning tree and hence irrelevant for us. However, the distinction of parallel edges is important. For example, the plane graph formed by two vertices connected by m parallel edges has m different spanning trees, each containing exactly one of the m edges.

16:14 Listing Spanning Trees of Outerplanar Graphs

All notions introduced in Section 1 are valid in the more general context of multigraphs. The only exception is the definition of an *outerplane triangulation*, which we change from “face length 3” to “face length ≤ 3 ”. A length-2 face comes from two parallel edges, and is called a *digon*.

In addition to edge removal and edge addition, we now also introduce the operation of *edge contraction*. Given a graph G and an edge $e \in E(G)$, we write G/e for the graph obtained from G by contracting the edge e . Note that even if G is a simple graph, G/e may still contain parallel edges, and if G has parallel edges, then G/e may contain loops (which can be ignored when counting spanning trees). The number of spanning trees $t(G)$ of a graph G obeys the well-known recursive relation

$$t(G) = t(G - e) + t(G/e), \quad (3)$$

valid for any (non-loop) edge $e \in E(G)$ (see [18]).

We need the following auxiliary lemma about Fibonacci numbers.

► **Lemma 16.** *For any two integers $i, j \geq 1$, we have $f_i \cdot f_j \leq f_{i+j-1}$, with equality if and only if $i = 1$ or $j = 1$.*

Proof. If $i = 1$ or $j = 1$, then one can check directly that the claimed equality holds.

Now assume that $i, j \geq 2$. We prove that $f_i \cdot f_j < f_{i+j-1}$ by induction on $i + j$. In the base case $i + j = 4$ we have $i = j = 2$ and therefore $f_i = f_j = f_2 = 1$ and $f_{i+j-1} = f_3 = 2$, so the claim is true. For the induction step we distinguish the cases $j \in \{2, 3\}$ and $j > 3$. If $j = 2$ we have $f_i \cdot f_j = f_i < f_{i+1} = f_{i+j-1}$ (recall that $i \geq 2$). If $j = 3$ we have $f_i \cdot f_j = 2f_i < f_i + f_{i+1} = f_{i+2} = f_{i+j-1}$. It remains to consider the case $j > 3$. We have

$$f_i \cdot f_j = f_i \cdot (f_{j-2} + f_{j-1}) = f_i \cdot f_{j-2} + f_i \cdot f_{j-1} < f_{i+j-3} + f_{i+j-2} = f_{i+j-1},$$

where the strict inequality in the third step holds by induction, using that $j - 2 > 1$. ◀

Theorem 10 is an immediate consequence of the following more general statement for multigraphs.

► **Theorem 17.** *For any outerplane (multi)graph G with m edges we have $t(G) \leq f_{m+1}$, with equality if and only if G is a triangulation such that G^- is a path and all digons are incident with the outer face.*

Note that digons incident with the outer face correspond to degree 1 vertices in the dual graph G^- , so if G^- is a path, then there are at most two such digons corresponding to end vertices of the path.

Theorem 17 is illustrated in Figure 13.

Proof. We argue by induction on m . The induction basis $m = 0$ is trivial. For the induction step we assume that $m \geq 1$.

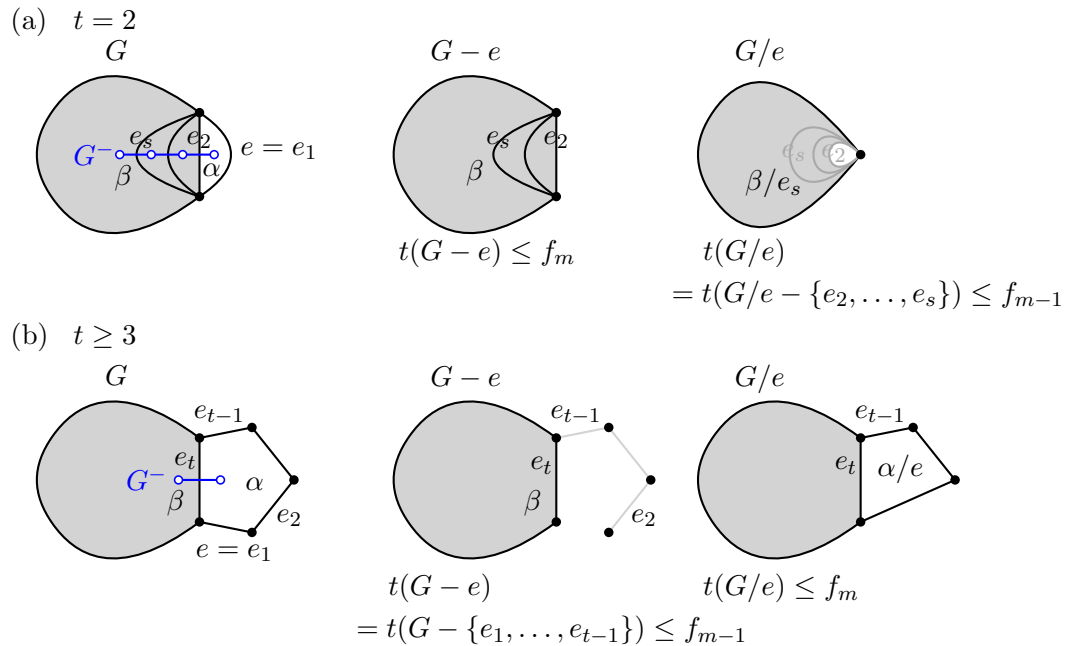

If G is not 2-connected, then it has at least two blocks A and B with $a \geq 1$ and $b \geq 1$ edges, respectively, where $a + b = m$. We have $t(G) = t(A) \cdot t(B)$ and therefore $t(G) \leq f_{a+1} \cdot f_{b+1} < f_{a+b+1} = f_{m+1}$, where the strict inequality follows from Lemma 16.

It remains to consider the case that G is 2-connected. If G is a single edge, then $t(G) = 1 = f_2$. If G has only one inner face, then it is a cycle and we have $t(G) = m \leq f_{m+1}$, and this inequality is tight for $m \in \{2, 3\}$ and strict for $m \geq 4$. The same estimates hold if all inner faces of G are digons, i.e., G has 2 vertices and all m edges are parallel to each other. For the rest of the proof we assume that G has at least two faces, not all of which

■ **Figure 13** Sequence of outerplane graphs that maximize the number of spanning trees, with the corresponding counts, the Fibonacci numbers. They are all triangulations for which G^- is a path, and they either have no digons (red) or one digon incident with the outer face (blue). For each graph, deleting or contracting the bold edge yields the two preceding graphs.

are digons. This implies in particular that $m \geq 4$. We consider a face α of G for which the dual vertex α' has degree at most 1 in G^- . We denote the sequence of edges bounding α by e_1, \dots, e_t in clockwise order, ending with the edge e_t that has a dual edge in G^- . We distinguish two cases, namely whether α is a digon ($t = 2$) or not ($t \geq 3$), and we bound the number of spanning trees using (3) with respect to the edge $e := e_1$, i.e., the first edge of the face α . These two cases are illustrated in Figure 14 (a) and (b), respectively.

■ **Figure 14** Illustration of the proof of Theorem 17.

Case (a). $t = 2$. $G - e$ has $m - 1$ edges, and therefore

$$t(G - e) \leq f_m \tag{4}$$

by induction. Let $s \geq 2$ be the number of edges that are parallel to e_1 (including e_1 and e_2), and denote them by e_1, e_2, \dots, e_s in ccw order around the corresponding common end vertex; see Figure 14 (a). Furthermore, we let β be the face incident with e_s but not e_{s-1} . In the graph G/e , the edges e_2, \dots, e_s are loops, and we can therefore remove all of them, so we have

16:16 Listing Spanning Trees of Outerplanar Graphs

$$t(G/e) = t(G/e - \{e_2, \dots, e_s\}) \leq f_{m-1} \quad (5)$$

by induction. Combining (2), (3), (4), and (5) proves that $t(G) \leq f_{m+1}$, as claimed. Furthermore, this inequality is tight if and only if (4) and (5) are tight, which happens if and only if the conditions stated in the theorem hold for $G - e$ and G/e , which happens if and only if $s = 2$ and β is a triangle that is incident with the outer face, if and only if the conditions stated in the theorem hold for G .

Case (b). $t \geq 3$. Let β be the face incident with e_t but not e_1 . G/e has $m - 1$ edges, and therefore

$$t(G/e) \leq f_m \quad (6)$$

by induction. In the graph $G - e$, the edges e_2, \dots, e_{t-1} are present in every spanning tree, so we have

$$t(G - e) = t(G - \{e_1, \dots, e_{t-1}\}) \leq f_{m-1} \quad (7)$$

by induction. Combining (2), (3), (6) and (7) proves that $t(G) \leq f_{m+1}$, as claimed. Furthermore, this inequality is tight if and only if (6) and (7) are tight, which happens if and only if the conditions stated in the theorem hold for G/e and $G - e$, which happens if and only if $t = 3$ and β is a triangle that is incident with the outer face, if and only if the conditions stated in the theorem hold for G . ◀

4 Open problems

Problems 1 and 5 remain open for general graphs, i.e., for graphs not covered by Theorems 7 and 8 (recall Remark 11). Also, Knuth's more general Problem 2 for directed graphs remains very much open.

Concerning Problem 1, we checked experimentally that all 2-connected graphs on up to 6 vertices admit a pivot-exchange Gray code for their spanning trees, and these Gray codes are all cyclic. Regarding Problem 2, we checked that all directed graphs on up to 5 vertices (oppositely oriented arcs are allowed) whose underlying undirected graph is 2-connected admit an edge exchange Gray code for their arborescences, for any choice of fixed root. In some cases those flip graphs admit no Hamilton cycle, but only a Hamilton path (see [22]), so not all of these Gray codes are cyclic. Regarding Problem 5, we checked that all outerplane graphs on up to 6 vertices admit a cyclic pivot ^ face-exchange Gray code for their spanning trees.

Furthermore, Knuth [14] asked in Exercise 101 in Section 7.2.1.6 whether the complete graph K_n admits a “nice” Gray code listing of its spanning trees. One interpretation of this question, in the spirit of Problem 1, could be: Is there a pivot-exchange Gray code for the spanning trees of K_n ? Alternatively, is there a Gray code listing that provides a more fine-grained explanation of Cayley's formula n^{n-2} for the number of spanning trees? Similar questions can be asked for the complete bipartite graph $K_{n,n}$.

Does Theorem 10 hold without the outerplane requirement for m sufficiently large? The only complete graphs K_n that violate the bound $t(K_n) \leq f_{\binom{n}{2}+1}$ arise for $n = 4, 5, 6$.

Abstract

We examine the possibility of approximating MAXIMUM VERTEX-DISJOINT SHORTEST PATHS. In this problem, the input is an edge-weighted (directed or undirected) n -vertex graph G along with k terminal pairs $(s_1, t_1), (s_2, t_2), \dots, (s_k, t_k)$. The task is to connect as many terminal pairs as possible by pairwise vertex-disjoint paths such that each path is a shortest path between the respective terminals. Our work is anchored in the recent breakthrough by Locht [SODA '21], which demonstrates the polynomial-time solvability of the problem for a fixed value of k .

Lochet's result implies the existence of a polynomial-time ck -approximation for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS, where $c \leq 1$ is a constant. (One can guess $1/c$ terminal pairs to connect in $k^{O(1/c)}$ time and then utilize Locht's algorithm to compute the solution in $n^{f(1/c)}$ time.) Our first result suggests that this approximation algorithm is, in a sense, the best we can hope for. More precisely, assuming the gap-ETH, we exclude the existence of an $o(k)$ -approximation within $f(k) \cdot \text{poly}(n)$ time for any function f that only depends on k .

Our second result demonstrates the infeasibility of achieving an approximation ratio of $m^{1/2-\epsilon}$ in polynomial time, unless $P = NP$. It is not difficult to show that a greedy algorithm selecting a path with the minimum number of arcs results in a $\lceil \sqrt{\ell} \rceil$ -approximation, where ℓ is the number of edges in all the paths of an optimal solution. Since $\ell \leq n$, this underscores the tightness of the $m^{1/2-\epsilon}$ -inapproximability bound.

Additionally, we establish that MAXIMUM VERTEX-DISJOINT SHORTEST PATHS is fixed-parameter tractable when parameterized by ℓ but does not admit a polynomial kernel. Our hardness results hold for undirected graphs with unit weights, while our positive results extend to scenarios where the input graph is directed and features arbitrary (non-negative) edge weights.

1 Introduction

We study a variant of the well-known problem VERTEX-DISJOINT PATHS. In the latter, the input comprises a (directed or undirected) graph G and k terminal pairs. The task is to identify whether pairwise vertex-disjoint paths can connect all terminals. VERTEX-DISJOINT PATHS has long been established as NP-complete [21] and has played a pivotal role in the graph-minor project by Robertson and Seymour [29].

Eilam-Tzoref [14] introduced a variant of VERTEX-DISJOINT PATHS where all paths in the solution must be *shortest* paths between the respective terminals. The parameterized complexity of this variant, known as VERTEX-DISJOINT SHORTEST PATHS, was recently

resolved [25] and subsequently the running time improved [3]: The problem, parameterized by k , is W[1]-hard and in XP (that is, polynomial-time solvable for constant k) for undirected graphs. On directed graphs, the problem is NP-hard already for $k = 2$ if zero-weight edges are allowed [16]. The problem is solvable in polynomial time for $k = 2$ for positive edge weights [4]. It is NP-hard when k is part of the input and the complexity for constant $k > 2$ remains open.

The optimization variant of VERTEX-DISJOINT SHORTEST PATHS, where not necessarily all terminal pairs need to be connected, but at least p of them, is referred to as MAXIMUM VERTEX-DISJOINT SHORTEST PATHS.

MAXIMUM VERTEX-DISJOINT SHORTEST PATHS

Input: A graph $G = (V, E)$, an edge-length function $w: E \rightarrow \mathbb{Q}_{\geq 0}$, terminal pairs $(s_1, t_1), (s_2, t_2), \dots, (s_k, t_k)$ where $s_i \neq t_i$ for $i \in [k]$, and an integer p .

Question: Is there a set $S \subseteq [k]$ with $|S| \geq p$ such that there is a collection $\mathcal{C} = \{P_i\}_{i \in S}$ of pairwise vertex-disjoint paths such that for each $i \in S$, path P_i is a shortest path from s_i to t_i ?

A few remarks are in order. In the literature concerning VERTEX-DISJOINT PATHS and its variants, one usually distinguishes between vertex-disjoint and internally vertex-disjoint paths. In the latter, two paths in a solution might share common endpoints while in the former, all paths must be completely vertex disjoint – including the two ends. We focus on the variant where paths must be completely vertex-disjoint, but most of our results also hold for internally vertex-disjoint paths.

Note that VERTEX-DISJOINT SHORTEST PATHS is a special case of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS with $p = k$. For the maximization version, we are not given p as input but are instead asked to find a set S that is as large as possible. Slightly abusing notation, we do not distinguish between these two variants and refer to both as MAXIMUM VERTEX-DISJOINT SHORTEST PATHS.

While parameterization by k yields strong hardness bounds (both in terms of parameterized complexity and, as we will show later, approximation), another natural parameterization would be the sum of path lengths in a solution. We initiate the study of a related parameter ℓ , the minimum number of edges in an optimal solution (assuming the instance is a yes-instance, otherwise, we define $\ell = n$). If we confine all edge weights to be positive integers, then ℓ serves as a lower bound for the sum of path lengths. Since our hardness results apply to unweighted graphs, studying ℓ instead of the sum of path lengths does not weaken the negative results and ℓ proves to be very useful for approximation and parameterized algorithms. Note that the sum of path lengths is not a suitable parameter as dividing all edge weights by $m \cdot w_{\max}$ (where w_{\max} is the maximum weight of any edge in the input) yields an equivalent instance where the sum of path lengths in the solution is at most one.

For the parameterized complexity of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS, we note that the results for VERTEX-DISJOINT SHORTEST PATHS [3, 25] for the parameterization by k directly translate for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS parameterized by p . The problem is W[1]-hard as a generalization of VERTEX-DISJOINT SHORTEST PATHS, and to obtain an XP algorithm, it is sufficient to observe that in $n^{O(p)}$ time we can guess a set $S \subseteq [k]$ of size p and apply the XP algorithm for VERTEX-DISJOINT SHORTEST PATHS for the selected set of terminal pairs.

Before the recent work of Chitnis, Thomas, and Wirth [8], little was known about approximation algorithms for the MAXIMUM VERTEX-DISJOINT SHORTEST PATHS problem. Chitnis, Thomas, and Wirth demonstrated that no $(2 - \varepsilon)$ -approximation could be achieved in time $f(k) \cdot n^{o(k)}$ assuming the gap-ETH.

■ **Table 1** Overview of our results. New results are bold. All hardness results hold for unweighted and undirected graphs, while all new algorithmic results hold even for directed graphs with arbitrary non-negative edge weights.

Parameter	Exact	Approximation
no	NP-complete	no $m^{1/2-\varepsilon}$-approximation in poly(n) time
k	XP and W[1]-hard	no $o(k)$-approximation in $f(k) \cdot \text{poly}(n)$ time
ℓ	FPT and no poly kernel	$\lceil \sqrt{\ell} \rceil$ -approximation

For the related MAXIMUM VERTEX-DISJOINT PATHS, where the task is to connect the maximum number of terminal pairs by disjoint but not necessarily shortest paths, $O(\sqrt{n})$ -approximation algorithms are due to Kleinberg [23] and Kolliopoulos and Stein [24]. The best known lower bounds for this variant are $2^{\Omega(\sqrt{\log n})}$ and $n^{\Omega(1/(\log \log n)^2)}$. The first lower bound holds even if the input graph is an unweighted planar graph, while the second holds even if the input graph is an unweighted grid graph [9, 10]. For these two special cases, there are approximation algorithms achieving ratios $\tilde{O}(n^{9/19})$ and $\tilde{O}(n^{1/4})$, respectively [9, 10].

When requiring the solution paths to be edge-disjoint rather than vertex-disjoint, it is known that even computing a $m^{1/2-\varepsilon}$ -approximation is NP-hard in the directed setting [18]. There have also been some studies on relaxing the notion so that each edge appears in at most $c > 1$ of the solution paths. The integer c is called the congestion and the currently best known approximation algorithm achieves a $\text{poly}(\log n)$ -approximation with $c = 2$ [11].

Our results. We show that computing a $m^{1/2-\varepsilon}$ -approximation for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS is NP-hard for any $\varepsilon > 0$ (Theorem 3). Moreover in terms of FPT-approximations, we demonstrate in Theorem 1 that any $k^{o(1)}$ -approximation in time $f(k) \cdot \text{poly}(n)$ implies $\text{FPT} = \text{W}[1]$ and that it is impossible to achieve an $o(k)$ -approximation in time $f(k) \cdot \text{poly}(n)$ unless the gap-ETH fails. This significantly improves the current state of approximation results for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS in two ways. First, we use the weaker assumption $\text{FPT} \neq \text{W}[1]$ instead of the gap-ETH. Second, our theorem excludes approximation factors polynomial in the input size, rather than only constant factors larger than 2 as shown by Chitnis et al. [8].

We complement the first lower bound by showing that a simple greedy strategy for MAXIMUM VERTEX-DISJOINT PATHS achieves a $\lceil \sqrt{\ell} \rceil$ -approximation also for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS (Theorem 4). In Theorems 5 and 7, we show that MAXIMUM VERTEX-DISJOINT SHORTEST PATHS is fixed-parameter tractable when parameterized by ℓ , but it does not admit a polynomial kernel. We mention that our hardness results hold for undirected graphs with unit weights, and all our positive results hold even for directed and edge-weighted input graphs. We summarize our results in Table 1.

2 Preliminaries

For a positive integer x , we denote by $[x] = \{1, 2, \dots, x\}$ the set of all positive integers at most x . We denote by $G = (V, E)$ a graph and by n and m the number of vertices and edges in G , respectively. A graph G is said to be k -partite if V can be partitioned into k disjoint sets V_1, V_2, \dots, V_k such that each set V_i induces an independent set, that is, there is no edge $\{u, v\} \in E$ with $\{u, v\} \subseteq V_i$ for some $i \in [k]$. The *degree* of a vertex v is the number of edges in E that contain v as an endpoint and the *maximum degree* of a graph is the highest degree of any vertex in the graph.

A *path* in a graph G is a sequence $(v_0, v_1, \dots, v_\ell)$ of distinct vertices such that each pair (v_{i-1}, v_i) is connected by an edge in G . The first and last vertex v_0 and v_ℓ are called the *ends* of P . We also say that P is a path *from* v_0 *to* v_ℓ or a v_0 - v_ℓ -path. The length of a path is the sum of its edge lengths or simply the number ℓ of edges if the graph is unweighted. For two vertices v, w , we denote the length of a shortest v - w -path in G by $\text{dist}_G(v, w)$ or $\text{dist}(v, w)$ if the graph G is clear from the context.

We assume the reader to be familiar with the big-O notation and basic concepts in computational complexity like NP-completeness and reductions. We refer to the textbook by Garey and Johnson [17] for an introduction.

For a detailed introduction to parameterized complexity and kernelization, we refer the reader to the text books by Cygan et al. [12] and Fomin et al. [15]. A *parameterized problem* P is a language containing pairs (I, ρ) where I is an instance of an (unparameterized) problem and ρ is an integer called the *parameter*. In this paper, the parameter will usually be either the number k of terminal pairs or the minimum number ℓ of edges in a solution (a maximum collection of vertex-disjoint shortest paths between terminal pairs). A parameterized problem P is *fixed-parameter tractable* if there exists an algorithm solving any instance (I, ρ) of P in $f(\rho) \cdot \text{poly}(|I|)$ time, where f is some computable function only depending on ρ . To show that a problem is presumably not fixed-parameter tractable, one usually shows that the problem is hard for a complexity class known as $W[1]$. The class XP contains all parameterized problems which can be solved in $|I|^{f(\rho)}$ time, that is, in polynomial time if ρ is constant. A parameterized problem is said to admit a *polynomial kernel*, if there is a polynomial-time algorithm that given an instance (I, ρ) computes an equivalent instance (I', ρ') (called the *kernel*) such that $|I'| + \rho'$ are upper-bounded by a polynomial in ρ . It is known that any parameterized problem admitting a polynomial kernel is fixed-parameter tractable and each fixed-parameter tractable problem is contained in XP .

An α -approximation algorithm for a maximization problem is a polynomial-time algorithm that for any input returns a solution of size at least OPT/α where OPT is the size of an optimal solution. A parameterized α -approximation algorithm also returns a solution of size at least OPT/α , but its running time is allowed to be $f(\rho) \cdot \text{poly}(n)$, where ρ is the parameter and f is some computable function only depending on ρ . In this work, we always consider (unparameterized) approximation algorithms unless we specifically state a parameterized running time.

To exclude an α -approximation for an optimization problem, one can use the framework of *approximation-preserving reductions*. A strict approximation-preserving reduction is a pair of algorithms – called the *reduction algorithm* and the *solution-lifting algorithm* – that both run in polynomial time and satisfy the following. The reduction algorithm takes as input an instance I of a problem L and produces an instance I' of a problem L' . The solution-lifting algorithm takes any solution S' of I' and transforms it into a solution S of I such that if S' is an α -approximation for I' for some $\alpha \geq 1$, then S is an α -approximation for I . If a strict approximation-preserving reduction from L to L' exists and L is hard to approximate within some value β , then L' is also hard to approximate within β .

The *exponential time hypothesis (ETH)* introduced by Impagliazzo and Paturi [20] states that there is some $\varepsilon > 0$ such that each (unparameterized) algorithm solving 3-SAT takes at least $2^{\varepsilon n + o(n)}$ time, where n is the number of variables in the input instance. A stronger conjecture called the *gap-ETH* was independently introduced by Dinur [13] and Manurangsi and Raghavendra [27]. It states that there exist $\varepsilon, \delta > 0$ such that any $(1 - \varepsilon)$ -approximation algorithm for MAX 3-SAT¹ takes at least $2^{\delta n + o(n)}$ time.

¹ MAX 3-SAT is a generalization of 3-SAT where the question is not whether the input formula is satisfiable

3 Approximation

In this section, we show that MAXIMUM VERTEX-DISJOINT SHORTEST PATHS admits no $o(k)$ -approximation in $f(k) \cdot \text{poly}(n)$ time unless the gap-ETH fails and no $m^{1/2-\varepsilon}$ -approximation in polynomial time unless $P = NP$. We complement the latter result by developing a $\lceil \sqrt{\ell} \rceil$ -approximation algorithm that runs in polynomial time. We start with a reduction based on a previous reduction by Bentert et al. [3] and make it approximation-preserving.² Moreover, our result is tight in the sense that a k -approximation can be computed in polynomial time by simply connecting any terminal pair by a shortest path. A ck -approximation for any constant $c \leq 1$ can also be computed in polynomial time by guessing $\frac{1}{c}$ terminal pairs to connect and then using the XP-time algorithm by Bentert et al. [3] to find a solution. Note that since c is a constant, the XP-time algorithm for $\frac{1}{c}$ terminal pairs runs in polynomial time.

► **Theorem 1.** *Unless $FPT = W[1]$, MAXIMUM VERTEX-DISJOINT SHORTEST PATHS cannot be $k^{o(1)}$ -approximated in $f(k) \cdot \text{poly}(n)$ time, and assuming the gap-ETH, it cannot be $o(k)$ -approximated in $f(k) \cdot \text{poly}(n)$ time. All of these results hold even for subcubic graphs with terminals of degree one.*

Proof. We present a strict approximation-preserving reduction from MULTICOLORED CLIQUE to MAXIMUM VERTEX-DISJOINT SHORTEST PATHS such that the maximum degree is three and each terminal vertex has degree one. Moreover, the maximum number OPT of vertex-disjoint shortest paths between terminal pairs will be equal to the largest clique in the original instance. The theorem then follows from the fact that a $f(k) \cdot \text{poly}(n)$ -time $k^{o(1)}$ -approximation for CLIQUE would imply that $FPT = W[1]$ [7, 22], a $f(k) \cdot \text{poly}(n)$ -time $o(k)$ -approximation for CLIQUE refutes the gap-ETH [6], and that the textbook reduction from CLIQUE to MULTICOLORED CLIQUE only increases the number of vertices by a quadratic factor and does not change the size of a largest clique in the graph [12].

The reduction is depicted in Figure 1 and works as follows. Let $G = (V, E)$ be a k -partite graph (or equivalently a graph colored with k colors where all vertices of any color form an independent set) with ν vertices of each color. Let $V_i = \{v_1^i, v_2^i, \dots, v_\nu^i\}$ be the set of vertices of color $i \in [k]$ in G . We start with a terminal pair (s_i, t_i) for each color i and a pair of (non-terminal) vertices (s_j^i, t_j^i) for each vertex $v_j^i \in V_i$. Next for each color i , we add a binary tree of height $\lceil \log(\nu) \rceil$ where the vertices s_j^i are the leaves for all $v_j^i \in V_i$. We make s_i adjacent to the root of the binary tree. Analogously, we add a binary tree of the same height with leaves t_j^i and make t_i adjacent to the root. Next, we add a crossing gadget for each pair of vertices (v_j^i, v_b^a) with $i < a$. If $\{v_j^i, v_b^a\} \in E$, then the gadget consists of four vertices $u_{j,b}^{i,a}, v_{j,b}^{i,a}, x_{j,b}^{i,a}$, and $y_{j,b}^{i,a}$ and edges $\{u_{j,b}^{i,a}, v_{j,b}^{i,a}\}$ and $\{x_{j,b}^{i,a}, y_{j,b}^{i,a}\}$. If $\{v_j^i, v_b^a\} \notin E$, then the gadget consists of only two vertices $u_{j,b}^{i,a}$ and $v_{j,b}^{i,a}$ and the edge $\{u_{j,b}^{i,a}, v_{j,b}^{i,a}\}$. For the sake of notational convenience, we will in the latter case also denote $u_{j,b}^{i,a}$ by $x_{j,b}^{i,a}$ and $v_{j,b}^{i,a}$ by $y_{j,b}^{i,a}$. To complete the construction, we connect the different gadgets as follows. First, we connect via paths of length two $v_{j,b}^{i,a}$ and $u_{j,b+1}^{i,a}$ for all $b < \nu$ and $y_{j,b}^{i,a}$ and $x_{j-1,b}^{i,a}$ for all $j > 1$. Second, we connect via paths of length two the vertices $v_{j,\nu}^{i,a}$ to $u_{j,1}^{i,a+1}$ for all $j \in [\nu]$ and all $a < k$

but rather how many clauses can be satisfied simultaneously.

² We mention in passing that essentially the same modification to the reduction by Bentert et al. has been found by Akmal et al. [1] in independent research. While we use the modification to show stronger inapproximability bounds, they use it to show stronger fine-grained hardness results with respect to the minimum degree of a polynomial-time algorithm for constant k .

■ **Figure 1** An illustration of the reduction from MULTICOLORED CLIQUE to MAXIMUM VERTEX-DISJOINT SHORTEST PATHS.

Top right: Example instance for MULTICOLORED CLIQUE with $k = 4$ colors and $n = 4$ vertices per color. A multicolored clique is highlighted (by thick edges).

Bottom left: The constructed instance with the four shortest paths corresponding to the vertices of the clique highlighted. Note that these paths are pairwise disjoint. The dotted edges (incident to s_i and t_i vertices) indicate binary trees (where all leaves have distance $\lceil \log(\nu) \rceil$ from the root). Red edges indicate paths of length 2ν and blue edges indicate paths of length 2.

and $y_{1,b}^{i,a}$ to $x_{\nu,b}^{i+1,a}$ for all $b \in [\nu]$ and all $i < a - 1$. Third, we connect also via paths of length two $y_{1,b}^{i,i+1}$ to $u_{b,1}^{i+1,i+2}$ for all $i < k - 1$ and all $b \in [\nu]$. Next, we connect via paths of length 2ν each vertex s_j^i to $x_{\nu,j}^{1,i}$ for each $i > 1$ and $j \in [\nu]$. Similarly, $v_{j,\nu}^{i,k}$ is connected to t_j^i via paths of length 2ν . Finally, we connect s_j^1 with $u_{j,1}^{1,2}$ for all $j \in [\nu]$ and $y_{1,j}^{k-2,k-1}$ with t_j^k for all $j \in [\nu]$. This concludes the construction.

We next prove that all shortest s_i - t_i -paths are of the form

$$s_i - s_i^j - x_{\nu,j}^{1,i} - y_{1,j}^{i-1,i} - u_{j,1}^{i,i+1} - v_{j,\nu}^{i,k} - t_i^j - t_i \quad (1)$$

for some $j \in [\nu]$ and where the s_1 - t_1 -paths go directly from s_1^j to $u_{j,1}^{1,2}$ and the s_k - t_k -paths go directly from $y_{1,j}^{k-1,k}$ to t_j^k . We say that the respective path is the j^{th} canonical path for color i .

To show the above claim, first note that the distance from s_i to any vertex s_i^j is the same value $x = \lceil \log(\nu) \rceil + 1$ for all pairs of indices i and j . Moreover, the same holds for t_i and t_i^j , each s_i - t_i -path contains at least one vertex s_i^j and one vertex $t_i^{j'}$ for some $j, j' \in [\nu]$, and all paths of the form in Equation (1) are of length $y = 2x + 4\nu + 3(k-1)\nu - 2$. We first show that each s_i - t_i -path of length at most y contains an edge of the form $y_{1,b}^{i,i+1}$ to $u_{b,1}^{i+1,i+2}$. Consider the graph where all of these edges are removed. Note that due to the

grid-like structure, the distance between s_i and $x_{j,b}^{i',a}$ for any values $i' \leq i \leq a, j$, and b is at least $x + 2\nu + 3(i' - 1)\nu + 3(\nu - j)$ if $i = a$ and at least $x + 2\nu + 3(i' - 1)\nu + 3(a - i)\nu + 3(\nu - j) + 3b$ if $i < a$.³ Hence, all shortest s_i - t_i -paths use an edge of the form $y_{1,b}^{i,i+1}$ to $u_{b,1}^{i+1,i+2}$ and the shortest path from s_i^j to some vertex $y_{1,b}^{i,i+1}$ is to the vertex $y_{1,j}^{i,i+1}$. Note that the other endpoint of the specified edge is $u_{j,1}^{i,i+1}$ and the shortest path to t_i now goes via t_i^j for analogous reasons. Thus, all shortest s_i - t_i -paths have the form (1).

We next prove that any set of p disjoint shortest paths between terminal pairs (s_i, t_i) in the constructed graph has a one-to-one correspondence to a multicolored clique of size p for any p . For the first direction, assume that there is a set P of disjoint shortest paths between p terminal pairs. Let $S \subseteq [k]$ be the set of indices such that the paths in P connect s_i and t_i for each $i \in S$. Moreover, let j_i be the index such that the shortest s_i - t_i -path in P is the j_i^{th} canonical path for i for each $i \in S$. Now consider the set $K = \{v_{j_i}^i \mid i \in S\}$ of vertices in G . Clearly K contains at most one vertex of each color and is of size p as S is of size p . It remains to show that K induces a clique in G . To this end, consider any two vertices $v_{j_i}^i, v_{j_{i'}}^{i'} \in K$. We assume without loss of generality that $i < i'$. By assumption, the j_i^{th} canonical path for i and the $j_{i'}^{\text{th}}$ canonical path for i' are disjoint. This implies that $u_{j_i, j_{i'}}^{i, i'} \neq x_{j_i, j_{i'}}^{i, i'}$ as the j_i^{th} canonical path for i contains the former and the $j_{i'}^{\text{th}}$ canonical path for i' contains the latter. By construction, this means that $\{v_{j_i}^i, v_{j_{i'}}^{i'}\} \in E$. Since the two vertices were chosen arbitrarily, it follows that all vertices in K are pairwise adjacent, that is, K induces a multicolored clique of size p .

For the other direction assume that there is a multicolored clique $C = \{v_{j_1}^{i_1}, v_{j_2}^{i_2}, \dots, v_{j_p}^{i_p}\}$ of size p in G . We will show that the j_q^{th} canonical path for i_q is vertex-disjoint from the j_r^{th} canonical path for i_r for all $q \neq r \in [p]$. Let q, r be two arbitrary distinct indices in $[p]$ and let without loss of generality be $q < r$. Note that the two mentioned paths can only overlap in vertices $u_{j_q, j_r}^{i_q, i_r}, v_{j_q, j_r}^{i_q, i_r}, x_{j_q, j_r}^{i_q, i_r}$, or $y_{j_q, j_r}^{i_q, i_r}$ and that the j_q^{th} canonical path for i_q only contains vertices $u_{j_q, j_r}^{i_q, i_r}$ and $v_{j_q, j_r}^{i_q, i_r}$ and the j_r^{th} canonical path for i_r only contains $x_{j_q, j_r}^{i_q, i_r}$ and $y_{j_q, j_r}^{i_q, i_r}$. Moreover, since by assumption $v_{j_q}^{i_q}$ and $v_{j_r}^{i_r}$ are adjacent, it holds by construction that $u_{j_q, j_r}^{i_q, i_r}, v_{j_q, j_r}^{i_q, i_r}, x_{j_q, j_r}^{i_q, i_r}$, and $y_{j_q, j_r}^{i_q, i_r}$ are four distinct vertices. Thus, we found vertex disjoint paths between p distinct terminal pairs. This concludes the proof of correctness.

To finish the proof, observe that the constructed instance has maximum degree three, all terminal vertices have degree one, and the construction can be computed in polynomial time. \blacktriangleleft

We mention in passing that in graphs of maximum degree three with terminal vertices of degree one, two paths are vertex disjoint if and only if they are edge disjoint. Hence, Theorem 1 also holds for MAXIMUM EDGE-DISJOINT SHORTEST PATHS, the edge-disjoint version of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS.

► **Corollary 2.** *Unless $FPT = W[1]$, MAXIMUM EDGE-DISJOINT SHORTEST PATHS cannot be $k^{o(1)}$ -approximated in $f(k) \cdot \text{poly}(n)$ time, and assuming the gap-ETH, it cannot be $o(k)$ -approximated in $f(k) \cdot \text{poly}(n)$ time. All of these results hold even for subcubic graphs with terminals of degree one.*

³ We mention that there are some pairs of vertices $x_{j_1, b_1}^{i_1, a_1}$ and $x_{j_2, b_2}^{i_2, a_2}$, where the distance between the two is less than $3(|i_1 - i_2| + |a_1 - a_2|)\nu + 3(|j_1 - j_2| + |b_1 - b_2|)$. An example is the pair $(x_{1,1}^{1,2} = u_{1,1}^{1,2}, x_{2,2}^{1,2})$ in Figure 1 with a distance of 4. However, in all examples it holds that $i_1\nu - j_1 \neq i_2\nu - j_2$ and $a_1\nu + b_1 \neq a_2\nu + b_2$ such that the left side is either smaller in both inequalities or larger in both inequalities. Hence, these pairs cannot be used as shortcuts as they move “down and left” instead of towards “down and right” in Figure 1.

■ **Figure 2** An illustration of the reduction from CLIQUE to MAXIMUM VERTEX-DISJOINT SHORTEST PATHS.

Left side: Example instance for CLIQUE with a highlighted solution (by thick edges).

Right side: The constructed instance with the four shortest paths corresponding to the solution on the left side highlighted. Note that each shortest s_i - t_i -path uses exactly two of the diagonal edges.

We continue with an unparameterized lower bound by establishing that computing a $m^{\frac{1}{2}-\varepsilon}$ -approximation is NP-hard. We mention that the reduction is quite similar to the reduction in the proof for Theorem 1.

► **Theorem 3.** *Computing a $m^{1/2-\varepsilon}$ -approximation for any $\varepsilon > 0$ for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS is NP-hard.*

Proof. It is known that computing a $n^{1-\varepsilon}$ -approximation for CLIQUE is NP-hard [19, 30]. We present an approximation-preserving reduction from CLIQUE to MAXIMUM VERTEX-DISJOINT SHORTEST PATHS based on Theorem 1. We use basically the same reduction as in Theorem 1 but we start from an instance of CLIQUE and have a separate terminal pair for each vertex in the graph. Moreover, we do not require the binary trees pending from the terminal vertices and neither do we require long induced paths (red edges in Figure 1). These are instead paths with one internal vertex. An illustration of the modified reduction is given in Figure 2. Note that the number of vertices and edges in the graph is at most $3N^2$, where N is the number of vertices in the instance of CLIQUE. Moreover, for each terminal pair (s_i, t_i) , there is exactly one shortest s_i - t_i -path (the path that moves horizontally in Figure 2 until it reaches the main diagonal, then uses exactly two edges on the diagonal, and finally moves vertically to t_i).

We next prove that for any p , there is a one-to-one correspondence between a set of p disjoint shortest paths between terminal pairs (s_i, t_i) in the constructed graph and a clique of size p in the input graph. For the first direction, assume that there is a set P of disjoint shortest paths between p terminal pairs. Let $S \subseteq [k]$ be the set of indices such that the paths in P connect s_i and t_i for each $i \in S$. Now consider the set $K = \{v_i \mid i \in S\}$ of vertices in G . Clearly K contains p vertices. It remains to show that K induces a clique in G . To this end, consider any two vertices $v_i, v_j \in K$. We assume without loss of generality that $i < j$. By assumption, the unique shortest s_i - t_i -path and the unique shortest s_j - t_j -path are vertex-disjoint. By the description of the shortest paths between terminal pairs and the fact that s_i is higher than s_j and t_i is to the left of t_j , it holds that the two considered paths both visit the region that is to the right of s_j and above t_i . This implies that two edges must be crossing at this position, that is, there are four vertices in the described region and not

only two. By construction, this means that $\{v_i, v_j\} \in E$. Since the two vertices were chosen arbitrarily, it follows that all vertices in K are pairwise adjacent, that is, K induces a clique of size p in the input graph.

For the other direction assume that there is a clique $C = \{v_{i_1}, v_{i_2}, \dots, v_{i_p}\}$ of size p in the input graph. We will show that the unique shortest s_{i_q} - t_{i_q} -path is vertex-disjoint from the unique shortest s_{i_r} - t_{i_r} -path for all $q \neq r \in [p]$. Let q, r be two arbitrary distinct indices in $[p]$ and let without loss of generality be $q < r$. Note that the two mentioned paths can only overlap in the region that is to the right of s_{i_r} and above t_{i_q} . Moreover, since by assumption v_{i_q} and v_{i_r} are adjacent, it holds by construction that there are four distinct vertices in the described region and the two described paths are indeed vertex-disjoint. Thus, we found vertex disjoint paths between p distinct terminal pairs.

We conclude by analyzing the approximation ratio. Note that we technically did not prove a strict reduction for the factor $m^{1-\varepsilon}$ as the number of vertices in the original instance and the number of edges in the constructed instance are not identical. Still, the number m of edges in the constructed instance is at most $3N^2$, where N is the number of vertices in the original instance of CLIQUE. Hence, any $m^{1/2-\varepsilon}$ -approximation for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS corresponds to a $(3N^2)^{1/2-\varepsilon} = N^{1-\varepsilon'}$ -approximation for CLIQUE for some $0 < \varepsilon' < 2\varepsilon$ and therefore computing a $m^{1/2-\varepsilon}$ -approximation for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS is NP-hard. ◀

Note that the maximum degree of the constructed instance is again three and all terminal vertices are of degree one. Thus, Theorem 3 also holds for the edge disjoint version of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS. However in this case, a very similar result was already known before. Guruswami et al. [18] showed that computing a $m^{1/2-\varepsilon}$ -approximation is NP-hard for a related problem called LENGTH BOUNDED EDGE-DISJOINT PATHS. Their reduction immediately implies the same hardness for MAXIMUM EDGE-DISJOINT SHORTEST PATHS. To the best of our knowledge, the best known unparameterized approximation lower bound for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS was the $2 - \varepsilon$ lower bound due to Chitnis et al. [8] and we are not aware of any lower bound for MAXIMUM VERTEX-DISJOINT PATHS.

We next show that this result is tight, that is, we show how to compute a \sqrt{n} -approximation for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS in polynomial time. We also show that the same algorithm achieves a $\lceil \sqrt{\ell} \rceil$ -approximation. Note that we can always assume that $\ell \leq n$ as a set of vertex-disjoint paths is a forest and the number of edges in a forest is less than its number of vertices. We mention that this algorithm is basically identical to the best known (unparameterized) approximation algorithm for MAXIMUM DISJOINT PATHS [23, 24].

► **Theorem 4.** *There is a polynomial-time algorithm for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS on directed and weighted graphs that achieves an approximation factor of $\min\{\sqrt{n}, \lceil \sqrt{\ell} \rceil\}$.*

Proof. Let OPT be a maximum subset of terminal pairs that can be connected by shortest pairwise vertex-disjoint paths and let j be the index of a terminal pair (s_j, t_j) such that a shortest (s_j, t_j) -path contains a minimum number of arcs. We can compute the index j as well as a shortest s_j - t_j -path with a minimum number of arcs by running a folklore modification of Dijkstra's algorithm from each terminal vertex s_i .⁴ Let ℓ_j be the number of arcs in the

⁴ The standard Dijkstra's algorithm is modified by assigning to each vertex a pair of labels: the distance

found path. Our algorithm iteratively picks the shortest s_j - t_j -path using ℓ_j arcs, removes all involved vertices from the graph, recomputes the distance between all terminal pairs, removes all terminal pairs whose distance increased, updates the index j , and recomputes ℓ_j . We distinguish whether $\ell_j + 1 \leq \min(\sqrt{n}, \lceil \sqrt{\ell} \rceil)$ or not.

While $\ell_j + 1 \leq \min(\sqrt{n}, \lceil \sqrt{\ell} \rceil)$, note that we removed at most $\ell_j + 1$ terminal pairs in OPT. Hence, if $\ell_j + 1 \leq \min(\sqrt{n}, \lceil \sqrt{\ell} \rceil)$ holds at every stage, then we connected at least $|\text{OPT}| / \min(\sqrt{n}, \lceil \sqrt{\ell} \rceil)$ terminal pairs, that is, we found a $\min(\sqrt{n}, \lceil \sqrt{\ell} \rceil)$ -approximation.

So assume that at some point $\ell_j > \min(\sqrt{n}, \lceil \sqrt{\ell} \rceil)$ and let x be the number of terminal pairs that we already connected by disjoint shortest paths. By the argument above, we have removed at most $x \cdot \min(\sqrt{n}, \lceil \sqrt{\ell} \rceil)$ terminal pairs from OPT thus far. We now make a case distinction whether or not $\sqrt{n} \leq \lceil \sqrt{\ell} \rceil$. If $\ell_j + 1 > \lceil \sqrt{\ell} \rceil \geq \sqrt{n}$, then we note that all remaining paths in OPT contain at least \sqrt{n} vertices each and since the paths are vertex-disjoint, there can be at most \sqrt{n} paths left in OPT. Hence, we can infer that $|\text{OPT}| \leq (x + 1) \cdot \sqrt{n}$. Consequently, even though we might remove all remaining terminal pairs in OPT by connecting s_j and t_j , this is still a \sqrt{n} -approximation (and a $\lceil \sqrt{\ell} \rceil$ -approximation as we assumed $\lceil \sqrt{\ell} \rceil \geq \sqrt{n}$).

If $\ell_j + 1 > \sqrt{n} \geq \lceil \sqrt{\ell} \rceil$, then we note that all remaining paths in OPT contain at least $\ell_j > \lceil \sqrt{\ell} \rceil - 1$ edges each. Moreover, since ℓ_j and $\lceil \sqrt{\ell} \rceil$ are integers, each path contains at least $\lceil \sqrt{\ell} \rceil$ edges each. Since all paths in OPT contain by definition at most ℓ edges combined, the number of paths in OPT is at most $\ell / \lceil \sqrt{\ell} \rceil \leq \lceil \sqrt{\ell} \rceil$. Hence, we can infer in that case that $|\text{OPT}| \leq (x + 1) \cdot \lceil \sqrt{\ell} \rceil$. Again, even if we remove all remaining terminal pairs in OPT by connecting s_j and t_j , this is still a $\lceil \sqrt{\ell} \rceil$ -approximation (and a \sqrt{n} -approximation as we assumed $\sqrt{n} \geq \lceil \sqrt{\ell} \rceil$). This concludes the proof. ◀

4 Exact Algorithms

In this section, we show that MAXIMUM VERTEX-DISJOINT SHORTEST PATHS is fixed-parameter tractable when parameterized by ℓ , but it does not admit a polynomial kernel. The proof for the first result uses the technique of *color coding* of Alon, Yuster, and Zwick [2]. Imagine we are searching for some structure of size k in a graph. The idea of color coding is to color the vertices (or edges) of the input graph with a set of k colors and then only search for colorful solutions, that is, structures in which all vertices have distinct colors. Of course, this might not yield an optimal solution, but by trying enough different random colorings, one can often get a constant error probability in $f(k) \cdot \text{poly}(n)$ time. Using the standard tool of (n, k) -perfect hash families, these types of algorithms can be derandomized without significant overhead in the running time.

► **Theorem 5.** *MAXIMUM VERTEX-DISJOINT SHORTEST PATHS on weighted and directed graphs can be solved in $2^{O(\ell)} \text{poly}(n)$ time.*

Proof. Let $(G, w, (s_1, t_1), \dots, (s_k, t_k), p)$ be an instance of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS. First, we guess the value of ℓ by starting with $\ell = p$ and increasing the value of ℓ by one whenever we cannot find a solution with at least p shortest paths and at most ℓ edges. We start with $\ell = p$ as any set of p disjoint paths contains at least ℓ edges. Notice that the total number of vertices in a (potential) solution with p paths is at most $\ell + p$. We use the color-coding technique of Alon, Yuster, and Zwick [2]. We color the

from the terminal and the number of arcs in the corresponding path; then the pairs of labels are compared lexicographically.

vertices of G uniformly at random using $p + \ell$ colors (the set of colors is $[\ell + p]$) and observe that the probability that all the vertices in the paths in a solution have distinct colors is at least $\frac{(p+\ell)!}{(p+\ell)^{(p+\ell)}} \geq e^{-(p+\ell)}$. We say that a solution to the considered instance is *colorful* if distinct paths in the solution have no vertices of the same color. Note that we do not require that the vertices within a path in the solution are colored by distinct/equal colors. The crucial observations are that any colorful solution is a solution and the probability of the existence of a colorful solution for a yes-instance of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS is at least $e^{-(p+\ell)}$ as any solution in which all vertices receive distinct colors is a colorful solution.

We use dynamic programming over subsets of colors to find a colorful solution. More precisely, we find the minimum number of arcs in a collection $\mathcal{C} = \{P_i\}_{i \in S}$ of p pairwise vertex-disjoint paths for some $S \subseteq [k]$ satisfying the conditions: (i) for each $i \in S$, the path P_i is a shortest path from s_i to t_i and (ii) there are no vertices of distinct paths of the same color.

For a subset $X \subseteq [p + \ell]$ of colors and a positive integer $r \leq p$, we denote by $f[X, r]$ the minimum total number of arcs in r shortest paths connecting distinct terminal pairs such that the paths contains only vertices of colors in X and there are no vertices of distinct paths of the same color. We set $f[X, r] = \infty$ if such a collection of r paths does not exist.

To compute f , if $r = 1$, then let $W \subseteq V$ be the subset of vertices colored by the colors in X . We use Dijkstra's algorithm to find the set $I \subseteq [k]$ of all indices $i \in [k]$ such that the lengths of the shortest s_i - t_i -paths in G and $G[W]$ are the same. If $I = \emptyset$, then we set $f[X, 1] = \infty$. Assume that this is not the case. Then, we use the variant of Dijkstra's algorithm mentioned in Theorem 4 to find the index $i \in I$ and a shortest s_i - t_i -path P in $G[W]$ with a minimum number of arcs. Finally, we set $f[X, 1]$ to be equal to the number of arcs in P .

For $r \geq 2$, we compute $f[X, r]$ for each $X \subseteq [p + \ell]$ using the recurrence relation

$$f[X, r] = \min_{Y \subset X} \{f[X \setminus Y, r - 1] + f[Y, 1]\}. \quad (2)$$

The correctness of computing the values of $f[X, 1]$ follows from the description and the correctness of recurrence (2) follows from the condition that distinct paths should not have vertices of the same color.

We compute the values $f[X, r]$ in order of increasing $r \in [p]$. Since computing $f[Y, 1]$ for a given set Y of colors can be done in polynomial time, we can compute all values in overall $3^{p+\ell} \text{poly}(n)$ time. Once all values $f[X, r]$ are computed, we observe that a colorful solution exists if and only if $f[S, p] \leq \ell$.

If there is a colorful solution, then we conclude that $(G, w, (s_1, t_1), \dots, (s_k, t_k), p)$ is a yes-instance of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS. Otherwise, we discard the considered coloring and try another random coloring and iterate. If we fail to find a solution after executing $N = \lceil e^{p+\ell} \rceil$ iterations, we obtain that the probability that $(G, w, (s_1, t_1), \dots, (s_k, t_k), p)$ is a yes-instance is at most $(1 - \frac{1}{e^{p+\ell}})^{e^{p+\ell}} \leq e^{-1}$. Thus, we return that $(G, w, (s_1, t_1), \dots, (s_k, t_k), p)$ is a no-instance with the error probability upper bounded by $e^{-1} < 1$. Since the running time in each iteration is $3^{p+\ell} \text{poly}(n)$ and $p \leq \ell$, the total running time is in $2^{O(\ell)} \text{poly}(n)$. Note that we do the color coding and dynamic programming for each value between p and the actual value ℓ . However, this only adds an additional factor of $\ell \leq n$ which disappears in the $\text{poly}(n)$.

The above algorithm can be derandomized using the results of Naor, Schulman, and Srinivasan [28] by replacing random colorings by perfect hash families. We refer to the textbook by Cygan et al. [12] for details on this common technique. ◀

17:12 Tight Approximation and Kernelization Bounds for Vertex-Disjoint Shortest Paths

The FPT result of Theorem 5 immediately raises the question about the existence of a polynomial kernel. To show that a parameterized problem P does presumably not admit a polynomial kernel, one can use the framework of *cross-compositions*. Given an NP-hard problem L , a polynomial equivalence relation R on the instances of L is an equivalence relation such that (i) one can decide for any two instances in polynomial time whether they belong to the same equivalence class, and (ii) for any finite set S of instances, R partitions the set into at most $\max_{I \in S} \text{poly}(|I|)$ equivalence classes. Given an NP-hard problem L , a parameterized problem P , and a polynomial equivalence relation R on the instances of L , an OR-cross-composition of L into P (with respect to R) is an algorithm that takes q instances I_1, I_2, \dots, I_q of L belonging to the same equivalence class of R and constructs in $\text{poly}(\sum_{i=1}^q |I_i|)$ time an instance (I, ρ) of P such that (i) ρ is polynomially upper-bounded by $\max_{i \in [q]} |I_i| + \log(q)$, and (ii) (I, ρ) is a yes-instance of P if and only if at least one of the instances I_i is a yes-instance of L . If a parameterized problem admits an OR-cross-composition, then it does not admit a polynomial kernel unless $\text{NP} \subseteq \text{coNP}/\text{poly}$ [5].

In order to exclude a polynomial kernel, we first show that a special case of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS remains NP-hard. We call this special case LAYERED VERTEX-DISJOINT SHORTEST PATHS and it is the special case of VERTEX-DISJOINT SHORTEST PATHS where all edges have weight 1 and the input graph is layered, that is, there is a partition of the vertices into (disjoint) sets $V_1, V_2, \dots, V_\lambda$ such that all edges $\{u, v\}$ are between two consecutive layers, that is $u \in V_i$ and $v \in V_{i+1}$ or $u \in V_{i+1}$ and $v \in V_i$ for some $i \in [\lambda - 1]$. Moreover, each terminal pair (s_i, t_i) satisfies that $s_i \in V_1$, $t_i \in V_\lambda$, and each shortest path between the two terminals is *monotone*, that is, it contains exactly one vertex of each layer. LAYERED VERTEX-DISJOINT SHORTEST PATHS is formally defined as follows.

LAYERED VERTEX-DISJOINT SHORTEST PATHS

Input: A λ -layered graph $G = (V, E)$ with a λ -partition $\{V_1, V_2, \dots, V_\lambda\}$ of the vertex set, terminal pairs $(s_1, t_1), (s_2, t_2), \dots, (s_k, t_k)$ with $s_i \in V_1$, $t_i \in V_\lambda$, and $\text{dist}(s_i, t_i) = \lambda - 1$ for all $i \in [k]$.

Question: Is there a collection $\mathcal{C} = \{P_i\}_{i \in [k]}$ of pairwise vertex-disjoint paths such that P_i is an s_i - t_i -path of length $\lambda - 1$ for all $i \in [k]$?

It is quite straight-forward to prove that LAYERED VERTEX-DISJOINT SHORTEST PATHS is NP-complete.

► **Proposition 6.** *LAYERED VERTEX-DISJOINT SHORTEST PATHS is NP-complete.*

Proof. We focus on the NP-hardness as LAYERED VERTEX-DISJOINT SHORTEST PATHS is a special case of VERTEX-DISJOINT SHORTEST PATHS and therefore clearly in NP. We reduce from 3-SAT. The main part of the reduction is a selection gadget. The gadget consists of a set U of $n + 1$ vertices u_0, u_1, \dots, u_n and between each pair of consecutive vertices u_{i-1}, u_i , there are two paths with m internal vertices each. Let the set of vertices be $V_i = \{v_1^i, v_2^i, \dots, v_m^i\}$ and $W_i = \{w_1^i, w_2^i, \dots, w_m^i\}$. The set of edges in the selection gadget is

$$E = \{\{u_{i-1}, v_1^i\}, \{u_{i-1}, w_1^i\}, \{v_m^i, u_i\}, \{w_m^i, u_i\} \mid i \in [n]\} \\ \cup \{\{v_j^i, v_{j+1}^i\}, \{w_j^i, w_{j+1}^i\} \mid i \in [n] \wedge j \in [m-1]\}.$$

The constructed instance will have $m + 1$ terminal pairs and is depicted in Figure 3. We set $s_{m+1} = u_0$ and $t_{m+1} = u_n$ and we will ensure that any shortest s_{m+1} - t_{m+1} -path contains all vertices in U and for each $i \in [n]$ either all vertices in V_i or all vertices in W_i . These

■ **Figure 3** An example of the construction in the proof of Proposition 6 for the input formula $(x_1 \vee x_2 \vee \bar{x}_3) \wedge (x_1 \vee \bar{x}_2 \vee x_3)$.

choices will correspond to setting the i^{th} variable to either true or false. Additionally, we have a terminal pair (s_j, t_j) for each clause C_j . There are (up to) three disjoint paths between s_j and t_j , each of which is of length $n \cdot (m + 1)$. These paths correspond to which literal in the clause satisfies it. For each of these paths, let x_i be the variable corresponding to the path. If x_i appears positively in C_j , then we identify the $(i - 1)(m + 1) + j + 1^{\text{st}}$ vertex in the path with w_j^i and if x_i appears negatively, then we identify the vertex with v_j^i . Note that the constructed instance is $(m + 1)n$ -layered and that once any monotone path starting in s_{m+1} leaves the selection gadget, it cannot end in t_{m+1} as any vertex outside the selection gadget has degree at most two and at the end of these paths are only terminals t_1, t_2, \dots, t_m .

Since the construction runs in polynomial time, we focus on the proof of correctness. If the input formula is satisfiable, then we connect all terminal pairs as follows. Let β be a satisfying assignment. The terminal pair (s_{m+1}, t_{m+1}) is connected by a path containing all vertices in U and for each $i \in [n]$, if β assigns the i^{th} variable to true, then the path contains all vertices in V_i and otherwise all vertices in W_i . For each clause C_j , let x_{i_j} be variable in C_j which β uses to satisfy C_j (if multiple such variables exist, we choose an arbitrary one). By construction, there is a path associated with x_{i_j} that connects s_j and t_j and only uses one vertex in W_i if x_{i_j} appears positively in C_j and a vertex in V_i , otherwise. Since each vertex in V_i and W_i is only associated with at most one such path, we can connect all terminal pairs. For the other direction assume that all $m + 1$ terminal pairs can be connected by disjoint shortest paths. As argued above, the s_{m+1} - t_{m+1} -path stays in the selection gadget. We define a truth assignment by assigning the i^{th} variable to true if and only if the s_{m+1} - t_{m+1} -path contains the vertices in V_i . For each clause C_j , we look at the neighbor of s_j in the solution. This vertex belongs to a path of degree-two vertices that at some point joins the selection gadget. By construction, the vertex where this happens is not used by the s_{m+1} - t_{m+1} -path, which guarantees that C_j is satisfied by the corresponding variable. Since all clauses are satisfied by the same assignment, the formula is satisfiable and this concludes the proof. ◀

With the NP-hardness of LAYERED VERTEX-DISJOINT SHORTEST PATHS at hand, we can now show that it does not admit a polynomial kernel when parameterized by ℓ by providing an OR-cross-composition from its unparameterized version to the version parameterized by ℓ .

■ **Figure 4** The construction to merge two instances of LAYERED VERTEX-DISJOINT SHORTEST PATHS into one equivalent instance. The dotted edges can be read as regular edges for $k = 4$ and indicate where additional vertices and edges have to be added for more terminal pairs. Note that the height of a vertex in the drawing does not indicate its layer as dotted edges distort the picture.

► **Theorem 7.** *LAYERED VERTEX-DISJOINT SHORTEST PATHS* parameterized by $\ell = k \cdot (\lambda - 1)$ does not admit a polynomial kernel unless $NP \subseteq coNP/poly$.

Proof. We present an OR-cross-composition from LAYERED VERTEX-DISJOINT SHORTEST PATHS into LAYERED VERTEX-DISJOINT SHORTEST PATHS parameterized by ℓ . To this end, assume we are given t instances of LAYERED VERTEX-DISJOINT SHORTEST PATHS all of which have the same number λ of layers and the same number k of terminal pairs. Moreover, we assume that t is some power of two. Note that we can pad the instance with at most t trivial no-instances to reach an equivalent instance in which the number of instances is a power of two and the size of all instances combined has at most doubled.

The main ingredient for our proof is a construction to merge two instances into one. The construction is depicted in Figure 4. We first prove that the constructed instance is a yes-instance if and only if at least one of the original instances was a yes-instance. Afterwards, we will show how to use this construction to get an OR-cross-composition for all t instances.

To show that the construction works correctly, first assume that one of the two original instances is a yes-instance. Since both cases are completely symmetrical, assume that there are shortest disjoint paths between all terminal pairs (s_a^i, t_a^i) for all $a \in [k]$ in G_i . Then, we can connect all terminal pairs (s_b, t_b) by using the unique shortest paths between s_b and s_b^i and between t_b^i and t_b for all $b \in [k]$ together with the solution paths inside G_i . Now assume that there is a solution in the constructed instance, that is, there are pairwise vertex-disjoint shortest paths between all terminal pairs (s_b, t_b) for all $b \in [k]$. First assume that the s_1 - t_1 -path passes through G_i . Then, this path uses the unique shortest path from t_1^i to t_1 . Note that this path blocks all paths between t_b^j and vertices in G_j for all $b \neq 1$. Thus, all paths have to pass through the graph G_i . Note that the only possible way to route vertex-disjoint paths from all s -terminals to all s^i terminals and from all t^i -terminals to all t -terminals is to connect s_a to s_a^i and t_a^i to t_a for all $a \in [k]$. This implies that there is a solution that contains vertex-disjoint shortest paths between s_a^i and t_a^i in G_i for all $a \in [k]$, that is, at least one of the two original instances is a yes-instance. The case where the s_1 - t_1 -path passes

through G_j is analogous since the only monotone path from s_1 to a vertex in G_j is the unique shortest s_1 - s_1^j -path and this path blocks all monotone paths from s_a to vertices in G_i for all $a \neq 1$.

Note that the constructed graph is layered and that the number of layers is $\lambda + 2k$. Moreover, the size of the new instance is in $O(|G_i| + |G_j| + k^2)$. To complete the reduction, we iteratively half the number of instances by partitioning all instances into arbitrary pairs and merge the two instances in a pair into one instance. After $\log t$ iterations, we are left with a single instance which is a yes-instance if and only if at least one of the t original instances is a yes-instance. The size of the instance is in $O(\sum_{i \in [t]} |G_i| + t \cdot k^2)$ which is clearly polynomial in $\sum_{i \in [t]} |G_i|$ as each instance contains at least k vertices. Moreover, the parameter ℓ in the constructed instance is $k \cdot (\lambda - 1) + 2k \log t$, which is polynomial in $|G_i| + \log t$ for each graph G_i as G_i contains at least one vertex in each of the λ layers and at least k terminal vertices. Thus, all requirements of an OR-cross-composition are met and this concludes the proof. \blacktriangleleft

Note that since LAYERED VERTEX-DISJOINT SHORTEST PATHS is a special case of VERTEX-DISJOINT SHORTEST PATHS (and therefore of MAXIMUM VERTEX-DISJOINT SHORTEST PATHS), Theorem 7 also excludes polynomial kernels for these problems parameterized by ℓ .

► **Corollary 8.** *VERTEX-DISJOINT SHORTEST PATHS and MAXIMUM VERTEX-DISJOINT SHORTEST PATHS parameterized by ℓ do not admit polynomial kernels unless $NP \subseteq coNP/poly$.*

5 Conclusion

In this paper, we studied MAXIMUM VERTEX-DISJOINT SHORTEST PATHS. We show that there is no $m^{1/2-\epsilon}$ -approximation in polynomial time unless $P = NP$. Moreover, if $FPT \neq W[1]$ or assuming the stronger gap-ETH, we show that there are no non-trivial approximations for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS in $f(k) \cdot \text{poly}(n)$ time. When parameterized by ℓ , there is a simple $\lceil \sqrt{\ell} \rceil$ -approximation in polynomial time that matches the $m^{1/2-\epsilon}$ lower bound as $\ell \leq \min(n, m)$. Finally, we showed that MAXIMUM VERTEX-DISJOINT SHORTEST PATHS is fixed-parameter tractable when parameterized by ℓ , but it does not admit a polynomial kernel.

A way to combine approximation algorithms and the theory of (polynomial) kernels are *lossy kernels* [26]. Since the exact definition is quite technical and not relevant for this work, we only give an intuitive description. An α -approximate kernel or lossy kernel for an optimization problem is a pair of algorithms that run in polynomial time which are called *pre-processing algorithm* and *solution-lifting algorithm*. The pre-processing algorithm takes as input an instance (I, ρ) of a parameterized problem P and outputs an instance (I', ρ') of P such that $|I'| + \rho' \leq g(\rho)$ for some computable function g . The solution-lifting algorithm takes any solution S of (I', ρ') and transforms it into a solution S^* of (I, ρ) such that if S is a γ -approximation for (I', ρ') for some $\gamma \geq 1$, then S^* is an $\gamma \cdot \alpha$ -approximation for (I, ρ) . If the size of the kernel is $g(\rho)$ and if g is constant or a polynomial, then we call it a constant-size or polynomial-size α -approximate kernel, respectively. It is known that a (decidable) parameterized problem admits a constant-size approximate α -kernel if and only if the unparameterized problem associated with P can be α -approximated (in polynomial time) [26]. Moreover, any (decidable) parameterized problem admits an α -approximate kernel (of arbitrary size) if and only if the problem can be α -approximated in $f(\rho) \cdot \text{poly}(|I|)$ time.

In terms of lossy kernelization, our results imply that there are no non-trivial lossy kernels for the parameter k . For the parameter ℓ , Theorem 4 implies a constant-size lossy kernel for $\alpha \in \Omega(\sqrt{\ell})$ and Theorem 5 implies an $f(\ell)$ -size lossy kernels for any $\alpha \geq 1$. This leaves the following gap which we pose as an open problems.

► **Open Problem 1.** *Are there any poly(ℓ)-size lossy kernels for MAXIMUM VERTEX-DISJOINT SHORTEST PATHS with $\alpha \in o(\sqrt{\ell})$ (or even constant α)?*

Online Disjoint Set Covers: Randomization Is Not Necessary

Abstract

In the online disjoint set covers problem, the edges of a hypergraph are revealed online, and the goal is to partition them into a maximum number of disjoint set covers. That is, n nodes of a hypergraph are given at the beginning, and then a sequence of hyperedges (subsets of $[n]$) is presented to an algorithm. For each hyperedge, an online algorithm must assign a color (an integer). Once an input terminates, the gain of the algorithm is the number of colors that correspond to valid set covers (i.e., the union of hyperedges that have that color contains all n nodes).

We present a deterministic online algorithm that is $O(\log^2 n)$ -competitive, exponentially improving on the previous bound of $O(n)$ and matching the performance of the best randomized algorithm by Emek et al. [ESA 2019].

For color selection, our algorithm uses a novel potential function, which can be seen as an online counterpart of the derandomization method of conditional probabilities and pessimistic estimators. There are only a few cases where derandomization has been successfully used in the field of online algorithms. In contrast to previous approaches, our result extends to the following new challenges: (i) the potential function derandomizes not only the Chernoff bound, but also the coupon collector's problem, (ii) the value of OPT of the maximization problem is not bounded a priori, and (iii) we do not produce a fractional solution first, but work directly on the input.

1 Introduction

In this paper, we study online algorithms for maximizing the number of set covers of a set of nodes. We focus on a hypergraph (set system) $G = (V, E)$ that has $n = |V|$ nodes and where each hyperedge $S \in E$ is a subset of nodes from V . A subset $E' \subseteq E$ is called *set cover* if $\bigcup_{S \in E'} S = V$, i.e., every node is covered by at least one hyperedge of E' . In the *disjoint set covers* (DSC) problem [15, 12, 20], the goal is to partition the set of hyperedges E into *maximum number* of mutually disjoint subsets $E = E_1 \uplus E_2 \uplus \dots \uplus E_k$, where each E_j is a set cover. Note that E is a multi-set, i.e., it can contain multiple copies of the same hyperedge.

The problem has been studied in a theoretical setting, but as we discuss later, it also finds applications in sensor networks [12] or assignment tasks [20].

Coloring Perspective. When constructing a solution to the DSC problem, it is convenient to think in terms of coloring hyperedges.¹ Each color then corresponds to a subset of hyperedges that have that color, and the color is *fully used* if the hyperedges colored with it form a set cover. The problem then becomes equivalent to coloring hyperedges, so that the number of fully used colors is maximized.

Online Variant. In this paper, we focus on the *online* variant of the DSC problem, where the set V is given in advance, but the hyperedges of E arrive in an online fashion. Once a hyperedge $S \in E$ arrives, it must be colored immediately and irrevocably. Again, the goal is to maximize the number of fully used colors. The performance of an online algorithm is measured by the competitive ratio, i.e., the ratio of the number of fully used colors produced by the optimal *offline* algorithm OPT to that of an online algorithm ALG .

Our Contribution. We present a deterministic online $O(\log^2 n)$ -competitive algorithm DET for the DSC problem, which exponentially improves on the $O(n)$ -competitive algorithm by Emek et al. [14] and matches the performance of their randomized algorithm [14]. We discuss the challenges and technical contribution in more detail in Subsection 1.3.

1.1 Offline Scenario: Previous Results

The disjoint set covers problem is a fundamental NP-complete problem [12] that can be approximated within a factor of $(1 + o(1)) \cdot \ln |V|$ [20] and cannot be approximated within a factor of $(1 - \varepsilon) \cdot \ln |V|$ for $\varepsilon > 0$ unless $\text{NP} \subseteq \text{DTIME}(n^{\log \log n})$ [15].²

OPT vs. Min-degree. We use $\text{OPT}(E)$ to denote the maximum number of disjoint set covers of a hypergraph $G = (V, E)$. This value is also called *cover-decomposition number* [6]. We denote the minimum degree of the hypergraph $G = (V, E)$ as $\delta(E) \triangleq \min_{i \in V} |S \in E : i \in S|$. Note that trivially $\text{OPT}(E) \leq \delta(E)$. While this bound may not be tight (cf. Subsection 1.4), $\delta(E)$ serves as a natural benchmark for approximation and online algorithms.

Random Coloring and its Straightforward Derandomization. An $O(\log n)$ -approximation algorithm for the *offline* DSC problem [21] can be obtained by coloring each hyperedge with a color chosen uniformly at random from the palette of $\Theta(\delta(E)/\log n)$ colors. To analyze this approach, we focus on a single node $i \in V$. We say that node i *gathers* color r if i is contained in a hyperedge colored with r . Since node i is contained in at least $\delta(E)$ hyperedges, and there are $\Theta(\delta(E)/\log n)$ available colors, i gathers all palette colors with high probability. By the union bound, this property holds for all nodes, i.e., all $\Theta(\delta(E)/\log n)$ colors are fully used by an algorithm (also with high probability). Since $\text{OPT}(E) \leq \delta(E)$, the approximation ratio of $O(\log n)$ follows.

The hyperedges can be processed in a fixed order, and the random choice of a color can be replaced by the deterministic one by a simple application of the method of conditional probabilities [21, 3].

¹ The DSC problem should not be confused with the hyperedge coloring problem, which requires that the hyperedges of the same color be disjoint.

² The authors of [15] call this problem *set cover packing* or *one-sided domatic problem*.

1.2 Online Scenario: Previous Results

In the online case, an algorithm first learns the set of nodes V , and then the edges of E are revealed sequentially. For notational convenience, we use E to denote both the set and a sequence of hyperedges (the input). We use $\text{ALG}(E)$ to denote the number of fully used colors in the solution of an online algorithm ALG .

It is important to note that no parameter of the hypergraph other than the number of nodes is known a priori. In particular, an online algorithm does not know the value of $\delta(E)$ in advance.

Competitive Ratio. We say that ALG is (*non-strictly*) c -competitive if there exists $\beta \geq 0$ such that

$$\text{ALG}(E) \geq \text{OPT}(E) / c - \beta. \quad (1)$$

While β can be a function of n , it cannot depend on the input sequence E . If (1) holds with $\beta = 0$, the algorithm is *strictly* c -competitive.

For randomized algorithms, we replace $\text{ALG}(E)$ with its expected value taken over the random choices of the algorithm.

Randomized Algorithms. The current best randomized algorithm was given by Emek et al. [14]; it achieves the (strict) competitive ratio of $O(\log^2 n)$. The general idea of their algorithm is as follows. To color a hyperedge S , their algorithm first computes the minimum degree δ^* of a node from S . By a combinatorial argument, they show that they can temporarily assume that $\delta(E) = O(n \cdot \delta^*)$. Their algorithm then chooses ℓ uniformly at random from the set $\{\delta^*, 2\delta^*, 4\delta^*, \dots, 2^{\log n} \cdot \delta^*\}$; with probability $\Omega(1/\log n)$ such ℓ is a 2-approximation of $\delta(E)$. Finally, to color S , it chooses a color uniformly at random from the palette of $\Theta(\ell/\log^2 n)$ colors, using the arguments similar to those in the offline case.

We refrain from discussing it further here, as we present a variant of their algorithm, called RAND , in Subsection 2.1 (along with a description of the differences from their algorithm).

The best lower bound for the (strict and non-strict) competitive ratio of a randomized algorithm is $\Omega(\log n / \log \log n)$ [14]; it improves on an earlier bound of $\Omega(\sqrt{\log n})$ by Pananjady et al. [20].

Deterministic Algorithms. The deterministic case is well understood if we restrict our attention to *strict* competitive ratios. In such a case the lower bound is $\Omega(n)$ [20]. The asymptotically matching upper bound $O(n)$ is achieved by a simple greedy algorithm [14].

On the other hand, the current best lower bound for the non-strict deterministic competitive ratio is $\Omega(\log n / \log \log n)$ [14].³ The $O(n)$ upper bound of [14] clearly holds also in the non-strict setting, but no better algorithm has been known so far.

Lack of General Derandomization Tools. Unlike approximation algorithms, derandomization is extremely rare in online algorithms.⁴ To understand the difficulty, consider the standard (offline) method of conditional probabilities [3] applied to the offline DSC problem:

³ This discrepancy in achievable strict and non-strict competitive ratios is quite common for many maximization problems: the non-strict competitive ratio allows the algorithm to have zero gain on very short sequences, thus avoiding initial choices that would be bad in the long run.

⁴ Many online problems (e.g., caching [23, 1] or metrical task systems [7, 8, 9]) exhibit a provable exponential discrepancy between the performance of the best randomized and deterministic algorithms. For many other problems, the best known deterministic algorithms are quite different (and more complex) than randomized ones.

■ **Table 1** Previous and new bounds on the strict and non-strict competitive ratios for the online DSC problem, for randomized and deterministic algorithms.

	Upper bound	Lower bound
randomized strict and non-strict	$O(\log^2 n)$ [14]	$\Omega(\log n / \log \log n)$ [14]
deterministic strict	$O(n)$ [14]	$\Omega(n)$ [20]
deterministic non-strict	$O(n)$ [14] $O(\log^2 n)$ (Theorem 5)	$\Omega(\log n / \log \log n)$ [14]

the resulting algorithm considers all the random choices (color assignments) it could make for a given hyperedge S , and computes the probability that future random choices, *conditioned on the current one*, will lead to the desired solution. Choosing the color that maximizes this probability ensures that the probability of reaching the desired solution does not decrease as subsequent hyperedges are processed. In some cases, exact computations are not possible, but the algorithm can instead estimate this probability by computing a so-called *pessimistic estimator* [22]. This is not feasible in the online setting, since an algorithm does not know the future hyperedges, and thus cannot even estimate these probabilities.⁵

1.3 Our Technical Contribution

In this paper, we present a deterministic online polynomial-time algorithm DET that is $O(\log^2 n)$ -competitive, which exponentially improves the previous bound of $O(n)$. This resolves an open question posed by the authors of [14] who asked whether the method of conditional expectations could be used to derandomize their algorithm.

Our bound is obtained for the non-strict competitive ratio: as we discussed in the previous subsection, this is unavoidable for the DSC problem. Our result requires a relatively small ($1/4$) additive term β in the definition of the competitive ratio (1).

We begin by constructing a *randomized* solution RAND. It will be a variation of the approach by Emek et al. [14]; we present it in Subsection 2.1. As RAND is closely related to the previous randomized algorithm, it is quite plausible that it achieves the same competitive ratio of $O(\log^2 n)$. However, our analysis does not support this conjecture. Instead, we use RAND as a stepping stone to our deterministic algorithm in the following way.

- We define a particular random event, denoted \mathcal{T}_E , of RAND executed on instance E .
- We show that for each execution of RAND satisfying \mathcal{T}_E , it holds that $\text{RAND}(E) \geq \Omega(1/\log^2 n) \cdot \text{OPT}(E) - 1/4$.

We will provide the exact definition of the event \mathcal{T}_E in Subsection 2.2. For now, we just note that \mathcal{T}_E is a property that certifies that, *at each step t* , we can relate the number of colors gathered so far by each node i to its current degree.

While a relaxed version of the property \mathcal{T}_E (requiring that the relation between the gathered colors and the current degree *only at the end of the input*) follows quite easily with a constant probability, it seems that \mathcal{T}_E itself is quite strong and does not hold with a reasonable probability. However, this is not an obstacle to creating a deterministic solution, as we show in the following claim.

⁵ As observed by Pananjady et al. [20], however, these probabilities can be estimated if an online algorithm knows the final min-degree $\delta(E)$ in advance, which would lead to an $O(\log n)$ -competitive algorithm for this semi-offline scenario.

- It is possible to replace the random choices of RAND by deterministic ones (in an online manner), so that \mathcal{T}_E always holds.

This will immediately imply the competitive ratio of the resulting deterministic algorithm.

Our approach is based on a novel potential function that guides the choice of colors. As we discuss later in Subsection 2.2, our approach can be seen as an online-computable counterpart of the method of conditional probabilities that simultaneously controls the derandomization of the Chernoff bound and the coupon collector's problem.

1.4 Related Work

Applications of the DSC problem include allocating servers to users in file systems and users to tasks in crowd-sourcing platforms [20].

Another application arises in a sensor network, where each node corresponds to a monitoring target and each hyperedge corresponds to a sensor that can monitor a set of targets. At any given time, all targets must be monitored. A possible battery-saving strategy is to partition the sensors into disjoint groups (each group covering all targets) and activate only one group at a time, while the other sensors remain in a low-power mode [12].

When the assumption that each sensor can only participate in a single group is dropped, this leads to more general sensor coverage problems. The goal is then to maximize the lifetime of the network of sensors while maintaining the coverage of all targets. The offline variants of this problem have been studied both in general graphs [4, 13, 21] and in geometric settings [11, 16].

Another line of work studied the relationship between the minimum degree $\delta(E)$ and the cover-decomposition number $\text{OPT}(E)$. As pointed out in Subsection 1.1, $\delta(E)/\text{OPT}(E) \geq 1$. This ratio is constant if G is a graph [17], and it is at most $O(\log n)$ for every hypergraph; the latter bound is asymptotically tight [6]. Interestingly enough, all the known papers on the DSC problem (including ours) relate the number of disjoint set covers to $\delta(E)$. It is an open question whether our estimate of the competitive ratio is tight: it could possibly be improved by relating the gain of an algorithm directly to $\text{OPT}(E)$ instead of $\delta(E)$.

1.5 Preliminaries

An input to our problem is a gradually revealed hypergraph $G = (V, E)$. V consists of n nodes numbered from 1 to n , i.e., $V = [n]$. The set E of hyperedges is presented one by one: in a step t , an algorithm learns $S_t \in E$, where $S_t \subseteq [n]$, and has to color it. We say that node i *gathers* color r if i is contained in a hyperedge colored with r . We say that a color r is *fully used* if all nodes have gathered it. The objective of an algorithm is to maximize the number of fully used colors.

At any point in time, the *degree* of a node j , denoted $\text{deg}(j)$, is the current number of hyperedges containing j . Let $\delta(E) = \min_{i \in [n]} |\{S_t \in E : v_i \in S_t\}|$, i.e., $\delta(E)$ is the minimum degree of G at the end of the input E . Clearly, $\text{OPT}(E) \leq \delta(E)$. It is important to note that $\delta(E)$ is not known in advance to an online algorithm.

```

2 Our Algorithm

2.1 Definition of RAND

We start with some notions, defined for each integer $k \geq 0$:

$$h \triangleq \lceil \log n \rceil, \quad q_k \triangleq \left\lceil \left(1 - \frac{1}{2n}\right) \cdot 2^k \right\rceil, \quad R_k \triangleq \{2^k, \dots, 2^{k+1} - 1\}.$$

Note that $|R_k| = 2^k$.

For each node i independently, RAND maintains its *phase* $p(i)$, initially set to 0. We use $C_{i,k}$ to denote the set of colors from the palette R_k that node i has gathered so far. A phase k for node i ends when it has gathered q_k colors from palette R_k . In such a case, node i increments its phase number $p(i)$ at the end of the step.

We now describe the behavior of RAND in a single step, when a hyperedge S appears. Let $p_S = \min_{i \in S} p(i)$, where $p(i)$ is the phase of node i before S appears. RAND first chooses a random integer k^* uniformly from the set $\{p_S, p_S + 1, \dots, p_S + h - 1\}$. Second, RAND chooses a color r uniformly at random from the set R_{k^*} and colors S with it; in effect all nodes in S gather color r .

The pseudocode of RAND is given in Algorithm 1.

Comparison with the Previous Randomized Algorithm. RAND is closely related to the randomized algorithm by Emek et al. [14]. The main difference is that the phases of the nodes in their algorithm are of fixed lengths, being powers of 2.⁶ They use probabilistic arguments to argue that with high probability each node gathers q_k colors in a phase of length $\Theta(2^k \cdot \log^2 n)$. Instead, we treat the number of colors gathered in a phase as a hard constraint (we require that each node gathers q_k of them), and instead the phase lengths of the nodes become random variables. As it turns out, this subtle difference allows us to derandomize the algorithm.

⁶ The pseudocode of their algorithm does not use phases, but with some fiddling with constants, it can be transformed into one that does.

Another small difference concerns the color selection. While RAND chooses the color uniformly at random from the set R_{k^*} , the algorithm of [14] would choose it from the set $\uplus_{j=0}^{k^*} R_j$. This difference affects only the constant factors of the analysis.

Gain of RAND. As mentioned earlier, the gain of RAND is directly ensured by the algorithm definition *provided* that each node has completed some number of phases.

Note that q_k is slightly less than $|R_k| = 2^k$; this gives a better bound on the the expected phase lengths, while still ensuring that if all nodes completed phase ℓ , they gathered at least $2^{\ell-1}$ common colors.

► **Lemma 1.** *If every node has completed phase ℓ , then $RAND(E) \geq 2^{\ell-1}$.*

Proof. In phase ℓ , each node gathers at least q_ℓ colors from the palette R_ℓ , i.e., all colors from R_ℓ except at most $|R_\ell| - q_\ell \leq 2^\ell / (2n)$ colors. Thus, all nodes share at least $|R_\ell| - n \cdot (2^\ell / (2n)) = 2^{\ell-1}$ common colors from R_ℓ , i.e., RAND fully uses at least $2^{\ell-1}$ colors. ◀

Note that we could sum the above bound over all phases completed by all nodes, but this would not change the asymptotic gain.

The above lemma points us to the goal: to show that for an input E with a sufficiently large $\delta(E)$, each node completes an appropriately large number of phases. In Subsection 2.3, we show that if $\delta(E) = \Omega(2^\ell \cdot \log^2 n)$, then each node completes ℓ phases, *provided* a certain random event \mathcal{T}_E occurs.

2.2 Constructing the Potential: Insights and Definitions

In the field of online algorithms, the derandomization has been successfully conveyed several times by replacing the method of conditional probabilities by an *online-computable potential function* that guides the choice of the deterministic algorithm [2, 5, 10, 18].

This method is based on the following framework. First, introduce ℓ random expressions $\{Z_i\}_{i=1}^\ell$ to be controlled. Second, define a potential function $\Phi = \sum_{i=1}^\ell \exp(Z_i)$. Third, show that the random actions of an algorithm at each step decrease $\exp(Z_i)$ (for each i) in expectation, which implies that Φ decreases as well. (By the probabilistic method, this implies the existence of a *deterministic action* of an algorithm in a step that does not increase Φ .) Finally, by the non-negativity of the exponential function, $\exp(Z_i)$ is bounded by the initial value Φ^0 of the potential (in each step), which shows that Z_i can always be bounded by $\ln(\Phi^0)$. This process can be seen as a derandomization of the Chernoff bound / high probability argument.

In order to apply this very general framework, we must overcome several technical difficulties, which we explain below. Except for the definition of Φ (and related definitions of w_{ik} , c_{ik} , d_k and Z_i), the discussion in this section is informal and will not be used in formal proofs later.

Variables to be Controlled. The first step is to identify the variables to control. Natural choices are the node degrees and the number of colors gathered so far by each node.

For this purpose, we define $c_{ik} = |C_{ik}|$ for each node i and each phase $k \geq 0$.

We also introduce counters w_{ik} , which are initially set to zero. Recall that whenever a new hyperedge S containing node i arrives, RAND computes $p_S = \min_{i \in S} p(i)$. For each node $i \in S$ such that $p(i) \leq p_S + h - 1$, we increment the counter $w_{i,p(i)}$. Note that these $w_{i,p(i)}$ variables are incremented exactly for nodes i for which there is a non-zero probability of increasing their set of colors $C_{i,p(i)}$ (as then a random integer k^* chosen by RAND has a non-zero chance of being equal to $p(i)$).

By the definition of w_{ik} , at each step $\sum_{k \geq 0} w_{ik} \leq \deg(i)$. While these quantities are not necessarily equal, we will treat $\sum_{k \geq 0} w_{ik}$ as a good proxy for $\deg(i)$ and deal with the discrepancy between these two quantities later.

Linking the Variables. Now we want to introduce an expression that links $\sum_{k \geq 0} w_{ik}$ (the proxy for degree) with $\sum_{k \geq 0} c_{ik}$ (the number of colors gathered) for a node i . A simple difference of these two terms does not make sense: the expected growth of c_{ik} varies over time, since it is easier to gather new colors when c_{ik} is small. This effect has been studied in the context of the coupon collector's problem [19]. To overcome this issue, we introduce the following function, defined for each integer $k \geq 0$:

$$d_k(m) \triangleq h \cdot \sum_{j=1}^m \frac{2^k}{2^k - j + 1} \quad (\text{defined for each } m \leq 2^k)$$

Note that in a process of choosing random colors from palette R_k of 2^k colors, the expected number of steps till m different colors are gathered is $d_k(m)/h$.

Now we focus on a single node i in phase $p(i)$. We consider a sequence of hyperedges S containing node i , neglecting those hyperedges S for which $p(i) \geq p_S + h$. That is, all considered hyperedges increment the counter $w_{i,p(i)}$. Then, the value of $d_k(c_{i,p(i)})$ corresponds to the expected number of such hyperedges needed to gather $c_{i,p(i)}$ colors from the palette $R_{p(i)}$. We can thus use the expression $\sum_{k \geq 0} (w_{ik} - 2 \cdot d_k(c_{ik}))$ to measure the progress of node i : small values of this expression indicate that it is gathering colors quite fast, while large values indicate that it is falling behind. Note that since $c_{ik} \leq q_k \leq 2^k$, the value of $d_k(c_{ik})$ is always well defined.

We note that the previous applications of the potential function method [2, 5, 10, 18] did not require such transformations of variables: in their case, the potential function was used to guide deterministic *rounding*: the function Φ directly compared the cost (or gain) of a deterministic algorithm with that of an online fractional solution. Instead, our solution operates directly on the input, without the need to generate a fractional solution first.

Scaling. Using the random choices of RAND, we can argue that in expectation the value of $Z_i^* \triangleq \sum_{k \geq 0} (w_{ik} - 2 \cdot d_k(c_{ik}))$ is decreasing in time. However, to argue that $\exp(Z_i^*)$ is also decreasing in expectation, we would have to ensure that Z_i^* is upper-bounded by a small constant (and use the fact that $\exp(x)$ can be approximated by a linear function for small x).

In the previous papers [2, 5, 10, 18], this property was achieved by scaling down Z^* by the value of OPT. An algorithm was then either given an upper bound on OPT (in the case of the throughput maximization of the virtual circuit routing [10]) or OPT was estimated by standard doubling techniques (in the case of the cost minimization for set cover variants [2, 5, 18]). In the latter case, the algorithm was restarted each time the estimate on OPT was doubled. Unfortunately, the DSC problem (which is an unbounded-gain maximization problem) does not fall into any of the above categories, and the doubling approach does not seem to work here.

Instead, we replace the scaling with a weighted average. That is, for each node i , we define

$$Z_i \triangleq \sum_{k \geq 0} \frac{w_{ik} - 2 \cdot d_k(c_{ik})}{4h \cdot 2^k}$$

and the potential as

$$\Phi \triangleq \sum_{i \in [n]} \exp(Z_i).$$

Note that all counters and variables defined above are random variables; they depend on particular random choices of RAND. We use $p^t(i)$, $\deg^t(i)$, w_{ik}^t , c_{ik}^t , Z_i^t and Φ^t to denote the values of the corresponding variables at the end of step t of the algorithm (after RAND has processed the hyperedge presented in step t). The value of $t = 0$ corresponds to the state of these variables at the beginning of the algorithm; note that $p^0(i) = \deg^0(i) = w_{ik}^0 = c_{ik}^0 = Z_i^0 = 0$ for all i and k . Therefore,

$$\Phi^0 = n. \tag{2}$$

Random event \mathcal{T}_E . For an input instance E consisting of T steps, we define a random event \mathcal{T}_E that occurs if $\Phi^t \leq n$ for each step $t \in \{0, \dots, T\}$ of RAND execution on input E .

2.3 Relating Potential to Algorithm Performance

We begin by presenting the usefulness of the event \mathcal{T}_E . We emphasize that the following lemma holds for all executions of RAND in which the event \mathcal{T}_E occurs. Its proof is deferred to Section 3.

► **Lemma 2.** *Fix a sequence E such that $\delta(E) > 24h \cdot \ln(4e \cdot n) \cdot 2^\ell$ for some integer $\ell \geq 0$. If \mathcal{T}_E occurs, then each node has completed its phase ℓ .*

Using the lemma above, we can relate the gain of RAND on an arbitrary input E to that of OPT, if only \mathcal{T}_E occurs.

► **Lemma 3.** *Fix a sequence E . If \mathcal{T}_E occurs, then $\text{RAND}(E) \geq \text{OPT}(E)/(96h \cdot \ln(4e \cdot n)) - 1/4$.*

Proof. Let $r \triangleq 24h \cdot \ln(4e \cdot n)$. We consider two cases.

- First, we assume that $\delta(E) > r$. Then we can find an integer $\ell \geq 0$ such that $r \cdot 2^\ell < \delta(E) \leq r \cdot 2^{\ell+1}$. By Lemma 2, each node then completes its phase ℓ , and so by Lemma 1, $\text{RAND}(E) \geq 2^{\ell-1} \geq \delta(E)/(4r)$.
- Second, we assume that $\delta(E) \leq r$. Trivially, $\text{RAND}(E) \geq 0 \geq (\delta(E) - r)/(4r)$.

In both cases, $\text{RAND}(E) \geq (\delta(E) - r)/(4r) \geq \text{OPT}(E)/(4r) - 1/4$. ◀

2.4 Derandomization of RAND

To analyze the evolution of Φ , we note that Φ^t (and also other variables w_{ik}^t , c_{ik}^t or Z_i^t) depends only on the random choices of RAND till step t (inclusively). Moreover, $\{\Phi^t\}_{t \geq 0}$ is a supermartingale with respect to the random choices of RAND in consecutive steps. Specifically, the following lemma holds; its proof is deferred to Section 4.

► **Lemma 4.** *Fix a step t and an outcome of random choices till step $t - 1$ inclusively. (In particular, this will fix the value of Φ^{t-1} .) Then, $\mathbb{E}[\Phi^t] \leq \Phi^{t-1}$, where the expectation is taken exclusively over random choices of RAND in step t .*

The above lemma states that the value of Φ is non-increasing in expectation. In fact, an inductive application of this lemma shows that $\mathbb{E}[\Phi^t] \leq \Phi^0 = n$. However, this does not imply that \mathcal{T}_E occurs with a reasonable probability, especially when the input length is large.⁷

⁷ By Markov's inequality, for a chosen step t , $\Phi^t \leq 2n$ holds with probability at least $1/2$. While such a relaxed bound on Φ^t would be sufficient for our needs, in our proof, we need such a bound to hold for all steps t simultaneously.

18:10 Online Disjoint Set Covers: Randomization Is Not Necessary

However, using Lemma 4, we can easily derandomize RAND using the method of conditional probabilities using potential Φ as an online-computable counterpart of a pessimistic estimator. To do this, we proceed iteratively, ensuring at each step t that $\Phi^t \leq n$. This is trivial at the beginning, since $\Phi^0 = n$ by (2).

Suppose we have already fixed the random choices of RAND till step $t - 1$ inclusively and have $\Phi^{t-1} \leq n$. Consider a hyperedge S presented in step t . Note that all other variables indexed by $t - 1$, such as $p^{t-1}(i)$, are also fixed. Then Lemma 4 states that $\mathbb{E}[\Phi^t] \leq \Phi^{t-1} \leq n$. That is, the random choice of a color at step t guarantees that $\mathbb{E}[\Phi^t] \leq n$. This choice is made from a finite and well-defined set of colors $\mathcal{R} \triangleq \biguplus_{p_S \leq k \leq p_S + h - 1} R_k$, where $p_S = \min_{i \in S} p^{t-1}(i)$.

By the probabilistic method, at each step t , there exists a *deterministic* choice of a color from \mathcal{R} that ensures that $\Phi^t \leq n$. The resulting algorithm is called DET. (If more than one color leads to $\Phi^t \leq n$, DET chooses any of them.) Since $|\mathcal{R}|$ is bounded by a polynomial of n and $|E|$, DET can be implemented in polynomial time by simply checking all possible colors of \mathcal{R} .

► **Theorem 5.** *DET is $O(\log^2 n)$ -competitive for the DSC problem.*

Proof. As described above, DET guarantees that $\Phi^t \leq n$ for each step $t \in \{0, \dots, T\}$, i.e., \mathcal{T}_E occurs. Note that Lemma 3 lower-bounds the gain of RAND in every execution conditioned on \mathcal{T}_E , and DET can be seen as such an execution. Therefore, the bound of Lemma 3 can be applied, yielding

$$\text{DET}(E) \geq \frac{\text{OPT}(E)}{96 \cdot h \cdot \ln(4e \cdot n)} - \frac{1}{4},$$

i.e., the competitive ratio of DET is at most $96 \cdot h \cdot \ln(4e \cdot n) = O(\log^2 n)$.

Note that, by the lower bounds of [20, 14], an additive term (in our case equal to $1/4$) is inevitable for obtaining a sub-linear competitive ratio. ◀

3 Bounding Number of Phases

In this section, we fix an input sequence E consisting of T steps. Our goal is to estimate the number of phases of nodes in the execution of RAND, conditioned on the random event \mathcal{T}_E , i.e., to prove Lemma 2. To this end, we consider a node i , assume that it has completed ℓ phases, and show an upper bound on the final degree of i as a function of ℓ .

Bounding Variables w Using Potential. Recall that in some steps where the degree of a node i grows, the counter $w_{i,p(i)}$ is incremented. Thus, our first goal is to upper-bound values of these counters at the end of the execution of RAND.

Below, $H(m)$ denotes the m -th harmonic number. The following technical claim is proved in Appendix A.

▷ **Claim 6.** For each $k \geq 0$ it holds that $H(2^k) - H(2^k - q_k) \leq \ln(4e \cdot n)$.

► **Lemma 7.** Fix a step $t \leq T$, a node i and a phase $k \geq 0$. Then, $d_k(c_{ik}^t) \leq h \cdot \ln(4e \cdot n) \cdot 2^k$.

Proof. Note that at all times, $c_{ik}^t \leq q_k$. Using the definition of d_k ,

$$\begin{aligned} d_k(c_{ik}^t) &\leq d_k(q_k) = h \cdot \sum_{j=1}^{q_k} \frac{2^k}{2^k - j + 1} \\ &= h \cdot (H(2^k) - H(2^k - q_k)) \cdot 2^k \\ &\leq h \cdot \ln(4e \cdot n) \cdot 2^k. \end{aligned} \quad \text{(by Claim 6)} \quad \blacktriangleleft$$

► **Lemma 8.** *Fix a node i and a phase $\ell \geq 0$. If the event \mathcal{T}_E occurs, then $\sum_{k=0}^{\ell} w_{ik}^T \leq 8h \cdot \ln(4e \cdot n) \cdot 2^\ell$.*

Proof. Fix the last step $t \leq T$ in which $\sum_{k=0}^{\ell} w_{ik}$ increases. By the choice of t , we have $w_{ik}^t = c_{ik}^t = 0$ for every phase $k > \ell$.

Since \mathcal{T}_E occurs, $n \geq \Phi^t = \sum_{j \in [n]} \exp(Z_j^t)$. Due to the non-negativity and monotonicity of the exponential function, $Z_i^t \leq \ln n$. Using the definition of Z_i^t , we get

$$\begin{aligned} \ln n \geq Z_i^t &= \sum_{k \geq 0} \frac{w_{ik}^t - 2 \cdot d_k(c_{ik}^t)}{4h \cdot 2^k} \\ &= \sum_{k=0}^{\ell} \frac{w_{ik}^t - 2 \cdot d_k(c_{ik}^t)}{4h \cdot 2^k} \\ &\geq \frac{1}{4h \cdot 2^\ell} \cdot \left(\sum_{k=0}^{\ell} w_{ik}^t - 2 \cdot \sum_{k=0}^{\ell} h \cdot \ln(4e \cdot n) \cdot 2^k \right). \quad (\text{by Lemma 7}) \end{aligned}$$

Hence, again by the choice of t ,

$$\sum_{k=0}^{\ell} w_{ik}^T = \sum_{k=0}^{\ell} w_{ik}^t \leq 4h \cdot 2^\ell \cdot \ln n + 4h \cdot \ln(4e \cdot n) \cdot 2^\ell < 8h \cdot \ln(4e \cdot n) \cdot 2^\ell. \quad \blacktriangleleft$$

Bounding Node Degrees. Recall that whenever a new hyperedge S containing node i arrives, $p_S = \min_{i \in S} p(i)$ is determined. Then, for each node $i \in S$, if $p(i) \leq p_S + h - 1$, the counter $w_{i,p(i)}$ is incremented. If $p(i) \geq p_S + h$, the degree of i grows, but $w_{i,p(i)}$ is not incremented. To estimate the degree of i , we therefore introduce the counters s_{ik} , which are incremented in the latter case. That is, for each node $i \in S$, we always have $\sum_{k \geq 0} (w_{ik} + s_{ik}) = \deg(i)$.

The growth of the variables s_{ik} is not controlled by the potential, but they grow only for nodes whose degree is very high compared to the current minimum degree. By constructing an appropriate charging argument, we can link their growth to the growth of other variables w_{ik} .

► **Lemma 9.** *Fix a step $t \leq T$, a node i , and a phase $\ell \geq 0$. Then, $s_{i\ell}^t \leq \sum_{j \in [n]} \sum_{r=0}^{\ell-h} w_{jr}^t$.*

Proof. We fix node i , phase $\ell \geq 0$, and show the lemma by induction on t . The inductive basis is trivial, as $s_{i\ell}^0 = 0 = \sum_{j \in [n]} \sum_{r=0}^{\ell-h} w_{jr}^0$.

Now suppose that the lemma statement holds for step $t - 1$. We look at how both sides of the inequality change as we increase the step superscripts from $t - 1$ to t , and argue that the increase of the right hand side is at least as large as the increase of the left hand side. If $s_{i\ell}$ does not change, the inductive claim follows trivially. Otherwise, $s_{i\ell}$ is incremented by 1. This happens only if $\ell = p(i)$, $i \in S$, and $\ell \geq p_S + h$. By the definition of p_S , this means that there exists at least one node $j^* \in S$ such that $p(j^*) = p_S$, and the corresponding counter w_{j^*,p_S} is also incremented. This means that the right hand side of the lemma inequality is incremented by at least $\sum_{j \in [n]} \sum_{r=0}^{\ell-h} (w_{jr}^t - w_{jr}^{t-1}) \geq w_{j^*,p_S}^t - w_{j^*,p_S}^{t-1} = 1$, and the inductive claim follows. \blacktriangleleft

► **Lemma 10.** *Fix a node i and a phase $\ell \geq 0$. If the event \mathcal{T}_E occurs, then $\sum_{k=0}^{\ell} s_{ik}^T \leq 16h \cdot \ln(4e \cdot n) \cdot 2^\ell$.*

18:12 Online Disjoint Set Covers: Randomization Is Not Necessary

Proof. By Lemma 9,

$$\begin{aligned} s_{ik}^T &\leq \sum_{j \in [n]} \sum_{r=0}^{k-h} w_{jr}^T \leq n \cdot 8h \cdot \ln(4e \cdot n) \cdot 2^{k-h} && \text{(by Lemma 8)} \\ &\leq 8h \cdot \ln(4e \cdot n) \cdot 2^k. && \text{(as } h = \lceil \log n \rceil) \end{aligned}$$

Hence, $\sum_{k=0}^{\ell} s_{ik}^T < 16h \cdot \ln(4e \cdot n) \cdot 2^{\ell}$. \blacktriangleleft

Finally, we can show Lemma 2, restated below.

► **Lemma 2.** *Fix a sequence E such that $\delta(E) > 24h \cdot \ln(4e \cdot n) \cdot 2^{\ell}$ for some integer $\ell \geq 0$. If \mathcal{T}_E occurs, then each node has completed its phase ℓ .*

Proof. Suppose for a contradiction that there exists a node i for which $p(i) \leq \ell$ at the end of the input. Then,

$$\delta(E) \leq \deg^T(i) = \sum_{k \geq 0} (w_{ik}^T + s_{ik}^T) = \sum_{k=0}^{\ell} (w_{ik}^T + s_{ik}^T) \leq 24h \cdot \ln(4e \cdot n) \cdot 2^{\ell},$$

where the last inequality follows by Lemma 8 and Lemma 10. This would contradict the assumption of the lemma. \blacktriangleleft

4 Controlling the Potential

In this section, we show that $\{\Phi^t\}_{t \geq 0}$ is a supermartingale with respect to the choices of RAND made in corresponding steps, i.e., we prove Lemma 4.

Throughout this section, we focus on a single step t , in which RAND processes a hyperedge S . Recall that RAND first chooses a random integer k^* uniformly from the set $\{p_S, p_S + 1, \dots, p_S + h - 1\}$. Second, conditioned on the first choice, it chooses a random color uniformly from the set R_{k^*} .

By the definition of our variables, for each node i and each integer $k \geq 0$, it holds that $w_{ik}^t - w_{ik}^{t-1} \in \{0, 1\}$ and $c_{ik}^t - c_{ik}^{t-1} \in \{0, 1\}$.

► **Lemma 11.** *Fix a node $i \in S$ and let $p = p^{t-1}(i)$. If $p \leq p_S + h - 1$, then $c_{ip}^t = c_{ip}^{t-1} + 1$ with probability $(2^p - c_{ip}^{t-1})/(h \cdot 2^p)$.*

Proof. By the definition of p_S , we have $p \geq p_S$. Combining this with the lemma assumption, we get $p \in \{p_S, \dots, p_S + h - 1\}$.

Note that $c_{ip}^t = c_{ip}^{t-1} + 1$ when node i gathers a new color from R_p , and $c_{ip}^t = c_{ip}^{t-1}$ otherwise. For a node i to gather a new color from R_p , first the integer k^* chosen randomly from the set $\{p_S, \dots, p_S + h - 1\}$ must be equal to p , which happens with probability $1/h$. Second, conditioned on the former event, a color chosen randomly from the palette R_p must be different from all c_{ip}^{t-1} colors from R_p gathered so far by node i , which happens with probability $(|R_p| - c_{ip}^{t-1})/|R_p| = (2^p - c_{ip}^{t-1})/2^p$. Hence, the probability of gathering a new color is $(2^p - c_{ip}^{t-1})/(h \cdot 2^p)$. \blacktriangleleft

We emphasize that the relations involving random variables in the following lemma (e.g., the statements such as $Z_i^t \leq Z_i^{t-1}$) hold for all random choices made by RAND.

► **Lemma 12.** Fix a node i . Let $p = p^{t-1}(i)$. Then, either $Z_i^t \leq Z_i^{t-1}$ or

$$Z_i^t \leq Z_i^{t-1} + \frac{1}{4h \cdot 2^p} + \begin{cases} -1/(2h \cdot 2^p \cdot \alpha) & \text{with probability } \alpha, \\ 0 & \text{otherwise.} \end{cases}$$

where $\alpha = (2^p - c_{ip}^{t-1})/(h \cdot 2^p)$. The probability is computed exclusively with respect to random choices of RAND in step t .

Proof. For brevity, for an integer $k \geq 0$, we define

$$\begin{aligned} \Delta w_{ik} &= w_{ik}^t - w_{ik}^{t-1}, \\ \Delta d_k(c_{ik}) &= d_k(c_{ik}^t) - d_k(c_{ik}^{t-1}). \end{aligned}$$

As $c_{ik}^t \geq c_{ik}^{t-1}$ and d_k is a non-decreasing function, we have $\Delta d_k(c_{ik}) \geq 0$.

Let S be the hyperedge presented in step t . By the definition of the variables w_{ik} (cf. Subsection 2.2), we have

$$\Delta w_{ik} = \begin{cases} 1 & \text{if } i \in S \text{ and } k = p \text{ and } p \leq p_S + h - 1, \\ 0 & \text{otherwise.} \end{cases}$$

Now we consider two cases.

■ It holds that $i \notin S$ or $p \geq p_S + h$. Then,

$$Z_i^t - Z_i^{t-1} = \sum_{k \geq 0} \frac{\Delta w_{ik} - 2 \cdot \Delta d_k(c_{ik})}{4h \cdot 2^k} \leq \sum_{k \geq 0} \frac{\Delta w_{ik}}{4h \cdot 2^k} = 0.$$

■ It holds that $i \in S$ and $p \geq p_S + h - 1$. Then, $\Delta w_{ip} = 1$ and $\Delta w_{ik} = 0$ for $k \neq p$. Therefore,

$$\begin{aligned} Z_i^t - Z_i^{t-1} &= \sum_{k \geq 0} \frac{\Delta w_{ik} - 2 \cdot \Delta d_k(c_{ik})}{4h \cdot 2^k} \\ &= \frac{\Delta w_{ip} - 2 \cdot \Delta d_p(c_{ip})}{4h \cdot 2^p} + \sum_{k \neq p} \frac{\Delta w_{ik} - 2 \cdot \Delta d_k(c_{ik})}{4h \cdot 2^k} \\ &\leq \frac{1}{4h \cdot 2^p} - \frac{\Delta d_p(c_{ip})}{2h \cdot 2^p}. \end{aligned}$$

To complete the proof, it now suffices to argue that $\Delta d_p(c_{ip}^t) = 1/\alpha$ with probability α and 0 with the remaining probability. This follows immediately by Lemma 11: With probability α we have $c_{ip}^t = c_{ip}^{t-1} + 1$, and hence $\Delta d_p(c_{ip}) = d_p(c_{ip}^t) - d_p(c_{ip}^{t-1}) = h \cdot 2^p / (2^p - c_{ip}^t + 1) = h \cdot 2^p / (2^p - c_{ip}^{t-1}) = 1/\alpha$. With the remaining probability $c_{ip}^t = c_{ip}^{t-1}$ and thus $\Delta d_p(c_{ip}) = 0$. ◀

For the final lemma, we need the following technical bound (proven in Appendix A). This can be seen as a reverse Jensen's type inequality.

▷ **Claim 13.** Fix $\varepsilon \in [0, 1]$, $\alpha \in [\varepsilon, 1]$ and a real x . Let X be a random variable such that

$$X = \begin{cases} x - \varepsilon/\alpha & \text{with probability } \alpha, \\ x & \text{otherwise.} \end{cases}$$

Then, $\mathbb{E}[e^{-X}] \leq e^{x-\varepsilon/2}$.

Finally, we can prove Lemma 4, restated below.

► **Lemma 4.** *Fix a step t and an outcome of random choices till step $t - 1$ inclusively. (In particular, this will fix the value of Φ^{t-1} .) Then, $\mathbb{E}[\Phi^t] \leq \Phi^{t-1}$, where the expectation is taken exclusively over random choices of RAND in step t .*

Proof. Fix a node i . We will show that

$$\mathbb{E}[\exp(Z_i^t)] \leq \exp(Z_i^{t-1}). \quad (3)$$

The lemma then follows by summing the above inequality over all nodes.

If $Z_i^t \leq Z_i^{t-1}$, (3) follows trivially. Otherwise, Lemma 12 implies that

$$Z_i^t \leq Z_i^{t-1} + \frac{1}{4h \cdot 2^p} + \begin{cases} -1/(2h \cdot 2^p \cdot \alpha) & \text{with probability } \alpha, \\ 0 & \text{otherwise.} \end{cases}$$

where $p = p^{t-1}(i)$ and $\alpha = (2^p - c_{ip}^{t-1})/(h \cdot 2^p)$. As the random choices are fixed until step $t - 1$, the variables Z_i^{t-1} , p and α are no longer random variables, but real numbers.

Note that $c_{ip}^{t-1} \leq q_p - 1 \leq 2^p - 1$ as otherwise phase p of node i would have ended in an earlier step. Hence, $\alpha = (2^p - c_{ip}^{t-1})/(h \cdot 2^p) \geq 1/(2h \cdot 2^p)$.

Thus, $x = Z_i^{t-1} + 1/(4h \cdot 2^p)$, $\varepsilon = 1/(2h \cdot 2^p)$, and α satisfy the conditions of Claim 13. (In particular, $\varepsilon \leq \alpha \leq 1$.) This claim now yields

$$\mathbb{E}[\exp(Z_i^t)] \leq \exp\left(Z_i^{t-1} + \frac{1}{4h \cdot 2^p} - \frac{1}{2} \cdot \frac{1}{2h \cdot 2^p}\right) = \exp(Z_i^{t-1}),$$

which concludes the proof of (3), and thus also the lemma. ◀

5 Conclusions

In this paper, we have constructed a deterministic $O(\log^2 n)$ -competitive algorithm for the disjoint set covers (DSC) problem. Closing the remaining logarithmic gap between the current upper and lower bounds is an interesting open problem that seems to require a new algorithm that goes beyond the phase-based approach.

We have developed new derandomization techniques that extend the existing potential function methods. We hope that these extensions will be useful for derandomizing other online randomized algorithms, and eventually for providing a coherent online derandomization toolbox.

A Proofs of Technical Claims

▷ Claim 6. For each $k \geq 0$ it holds that $H(2^k) - H(2^k - q_k) \leq \ln(4e \cdot n)$.

Proof. Assume first that $2^k < 4n$. As $H(m) \leq 1 + \ln m = \ln(e \cdot m)$ for each m , we get $H(2^k) - H(2^k - q_k) < H(4n) \leq \ln(4e \cdot n)$ and the lemma follows.

Hence, in the following, we assume that $2^k \geq 4n$, obtaining

$$\begin{aligned} 2^k - q_k &= 2^k - \lceil (1 - 1/(2n)) \cdot 2^k \rceil && \text{(by the definition of } q_k) \\ &\geq 2^k - (1 - 1/(2n)) \cdot 2^k - 1 \\ &= 2^k/(2n) - 1 \\ &\geq 2^k/(4n). && \text{(as } 2^k \geq 4n) \end{aligned}$$

As $q_k \leq 2^k$, we can use the relation $H(m) \geq \ln m$ holding for every $m \geq 0$, obtaining

$$H(2^k) - H(2^k - q_k) \leq \ln(e \cdot 2^k) - \ln(2^k - q_k) \leq \ln(e \cdot 2^k) - \ln(2^k/(4n)) = \ln(4e \cdot n). \quad \triangleleft$$

▷ Claim 13. Fix $\varepsilon \in [0, 1]$, $\alpha \in [\varepsilon, 1]$ and a real x . Let X be a random variable such that

$$X = \begin{cases} x - \varepsilon/\alpha & \text{with probability } \alpha, \\ x & \text{otherwise.} \end{cases}$$

Then, $\mathbb{E}[e^X] \leq e^{x - \varepsilon/2}$.

Proof. Using $\alpha \geq \varepsilon$, we obtain

$$(1 + \varepsilon/\alpha) \cdot (1 - \varepsilon/(2\alpha)) = 1 + \varepsilon/(2\alpha) - \varepsilon^2/(2\alpha^2) \geq 1. \quad (4)$$

Next, we use the relation $e^{-y} \leq (1 + y)^{-1}$ (holding for every $y > -1$) and (4) to argue that

$$\exp(-\varepsilon/\alpha) \leq (1 + \varepsilon/\alpha)^{-1} \leq 1 - \varepsilon/(2\alpha). \quad (5)$$

Finally, this gives

$$\begin{aligned} \mathbb{E}[e^X] &= \alpha \cdot \exp(x - \varepsilon/\alpha) + (1 - \alpha) \cdot \exp(x) \\ &= e^x \cdot (\alpha \cdot \exp(-\varepsilon/\alpha) + 1 - \alpha) \\ &\leq e^x \cdot (\alpha - \varepsilon/2 + 1 - \alpha) && \text{(by (5))} \\ &\leq e^{x - \varepsilon/2}. && \text{(as } 1 - \varepsilon/2 \leq e^{-\varepsilon/2} \text{ for each } \varepsilon) \quad \triangleleft \end{aligned}$$

The Complexity of Learning LTL, CTL and ATL Formulas

Abstract

We consider the problem of learning temporal logic formulas from examples of system behavior. Learning temporal properties has crystallized as an effective means to explain complex temporal behaviors. Several efficient algorithms have been designed for learning temporal formulas. However, the theoretical understanding of the complexity of the learning decision problems remains largely unexplored. To address this, we study the complexity of the passive learning problems of three prominent temporal logics, Linear Temporal Logic (LTL), Computation Tree Logic (CTL) and Alternating-time Temporal Logic (ATL) and several of their fragments. We show that learning formulas with unbounded occurrences of binary operators is NP-complete for all of these logics. On the other hand, when investigating the complexity of learning formulas with bounded occurrences of binary operators, we exhibit discrepancies between the complexity of learning LTL, CTL and ATL formulas (with a varying number of agents).

1 Introduction

Temporal logics are the de-facto standard for expressing temporal properties for software and cyber-physical systems. Originally introduced in the context of program verification [33, 15], temporal logics are now well-established in numerous areas, including reinforcement learning [40, 25, 10], motion planning [17, 12], process mining [13], and countless others. The popularity of temporal logics can be attributed to their unique blend of mathematical rigor and resemblance to natural language.

Until recently, formulating properties in temporal logics has been a manual task, requiring human intuition and expertise [6, 39]. To circumvent this step, in the past ten years, there have been numerous works to automatically learn (i.e., generate) properties in temporal logic. Among them, a substantial number of works [29, 11, 35, 26, 41] target Linear Temporal Logic (LTL) [33]. There is now a growing interest in learning formulas [16, 34, 9] in Computation Tree Logic (CTL) [15] and Alternating-time Temporal Logic (ATL) [1] due to their ability to express branching-time properties, including for multi-agent systems.

■ **Table 1** The complexity results for learning LTL, CTL and ATL formulas. The notation ATL^k refers to ATL-formulas with k agents. $\mathbf{U}^t \subseteq \{\neg, \mathbf{X}, \mathbf{F}, \mathbf{G}\}$ refers to the set of unary temporal operators.

	Unbounded use of binary operators	Bounded use of binary operators		
		$\mathbf{X} \in \mathbf{U}^t$	$\mathbf{X} \notin \mathbf{U}^t$	
			$\{\mathbf{F}, \mathbf{G}\} \subseteq \mathbf{U}^t$	$\mathbf{U}^t = \{\mathbf{F}\}, \{\mathbf{G}\}$
LTL	NP-c	L		
CTL		NP-c	NL-c	
ATL^2		NP-c		P-c
ATL^k		NP-c		

While existing approaches for learning temporal properties demonstrate impressive empirical performance, detailed comparisons of computational complexity across different temporal logics remain underexplored. Most related works focus on LTL, either in the verification domain [18, 27] or the database domain [19, 24]. These studies primarily report complexity results, often highlighting NP-completeness for learning LTL-formulas and their fragments. In contrast, the computational complexity of learning CTL- and ATL-formulas has not yet been thoroughly examined.

In this work, we extend the study of learning temporal properties to include CTL- and ATL-formulas. Additionally, we broaden existing results for LTL to cover a more comprehensive set of operators, specifically addressing all binary operators (temporal or not).

To elaborate on our contributions, let us precisely describe the problem that we consider, the *passive learning* problem for temporal logic [29, 11]. Its decision version asks the following question: given two sets \mathcal{P} , \mathcal{N} of positive and negative examples of a system’s behavior and a size bound B , does there exist a “separating” formula of size at most B , which is satisfied by the positive examples and violated by the negative ones.

Our instantiation of the above problem depends on the considered logic, following related literature [29, 34, 9]: LTL-formulas express linear-time properties, CTL-formulas express branching-time properties, and ATL-formulas express properties on multi-agent systems. Accordingly, the input examples for learning LTL, CTL and ATL are linear structures (or equivalently infinite words), Kripke structures and concurrent game structures, respectively. We refer to Section 2 for formal definitions and other prerequisites.

We summarize our contributions in Table 1. Our first result, illustrated in the left column, shows that allowing formulas with unrestricted use of at least one binary operator makes the corresponding learning decision problem NP-complete for all considered logics. Some of these NP-hardness results are (closely) inspired by [27], involving reductions from the hitting set problem – one of Karp’s 21 NP-complete problem; some others require novel proof techniques, e.g. one involves a reduction from an NP-complete modulo-2 calculus problem. We describe the outline of the proofs in Section 3.

All of the above NP-hardness proofs rely on separating formulas with linearly many (in the size of the input) occurrences of binary operators. Thus, in the search of expressive temporal logic fragments with lower complexities, we focus on formulas with a bounded occurrences of binary logical operators such as \wedge (and), \vee (or), etc. and no binary temporal operators such as \mathbf{U} (until), \mathbf{R} (release), etc. This choice of formulas is motivated by the fact that such formulas can still express interesting properties (e.g., GR(1) [32] formulas, mode-target formulas [4], etc.) and are used in several practical applications (see Section 4.1 for details). We explore several fragments with different unary temporal operators, \mathbf{X} (next),

F (eventually) and **G** (globally), and present the results in the rightmost column of Table 1. We notice that, in this case, the complexity of the learning problems varies considerably between different logics and unary operators. Importantly, we exhibit fragments where the learning problem is below NP. We prove the three NP-hardness results using a reduction from the hitting set problem; we give key insights on all of these results in Section 4.

All details can be found in the extended version [8].

Related Works. The most closely related works are [18] and [27], which operate within a similar framework to ours. Both works consider learning problems in several fragments of LTL, especially involving boolean operators such as \vee and \wedge , and temporal operators such as **X**, **F** and **G** and prove their NP-completeness. We extend part of their work by categorizing fragments based on the arity of the operators and studying which type of operators contribute to the hardness. Moreover, there are several differences in the parameters considered for the learning problem. The most important one is the following: the above works consider the size upper bound B to be in binary, while we assume B given in unary. Although, in complexity problems, integers are most often assumed to be written in binary, we believe that considering size bound in unary is justified since one may want to not only decide the existence of a formula but also effectively output one, which will require to explicitly write it. The other differences with the setting of the above works are mostly due to the fact that we do not only consider LTL learning, but CTL and ATL learning as well. A thorough discussion of these differences can be found in the extended version of this paper [8].

In the past, complexity analysis of passive learning has been studied for formalisms other than temporal logics. For instance, [21] and [2] proved NP-completeness of the passive learning problems of deterministic finite automata (DFAs) and regular expressions (REs).

When it comes to temporal logics, most related works focus on developing efficient algorithms for learning temporal logic formulas. Among these, the emphasis has predominantly been on learning LTL (or its significant fragments), which has been discussed in detail in a recent survey summarizing various learning techniques [30]. Broadly, the techniques can be categorized into three main types: constraint solving [29, 11, 37, 20, 22], enumerative search [35, 41], and neuro-symbolic techniques [26, 42].

For learning CTL, some approaches rely on handcrafted templates [14, 43] for simple enumerative search, while others employ constraint-solving methods to learn formulas with arbitrary structures [34]. The constraint-solving methods are extended to learn ATL-formulas as well [9]. There are also works on learning other logics such as Signal Temporal Logic [7, 28], Metric Temporal Logic [36], Past LTL [3], Property Specification Language [38], etc.

2 Preliminaries and Definitions

We let \mathbb{N} denote the set of all integers and \mathbb{N}_1 denote the set of all positive integers. For all $i \leq j \in \mathbb{N}$, we let $[i, \dots, j] \subseteq \mathbb{N}$ denote the set of integers $\{i, i+1, \dots, j\}$.

Given any non-empty set Q , we let Q^* , Q^+ and Q^ω denote the sets of finite, non-empty finite and infinite sequences of elements in Q , respectively. For all $\rho \in Q^+$, we denote by $|\rho| \in \mathbb{N}$ the number of elements of ρ . For all $\bullet \in \{+, \omega\}$, $\rho \in Q^\bullet$ and $i \in \mathbb{N}_1$, if ρ has at least i elements, we let: $\rho[i] \in Q$ denote the i -th element in ρ , in particular $\rho[1] \in Q$ is the first element of ρ ; $\rho[:i] \in Q^+$ denotes the non-empty finite sequence $\rho_1 \cdots \rho_i \in Q^+$; $\rho[i:] \in Q^\bullet$ denotes the non-empty sequence $\rho_i \cdot \rho_{i+1} \cdots \in Q^\bullet$, in particular we have $\rho[1:] = \rho$.

For the remainder of this section, we fix a non-empty set of propositions Prop .

2.1 Structures

Usually, ATL-formulas are interpreted on concurrent game structures, i.e. games where, at each state, the concurrent actions of several agents have an impact on the next state reached. A special kind of concurrent game structures are turn-based game structures, where each state belongs to a specific agent who decides what the next state is. Here, we introduce only this special kind of games mainly due to a lack of space, but also because all of our hardness results, presented in Table 1, hold even when only considering turn-based game structures.

► **Definition 1.** A turn-based game structure (TGS for short) $T = \langle Q, I, \text{Succ}, \text{Ag}, \alpha, \text{Prop}, \pi \rangle$ is a tuple where: Q is a finite set of states; $I \subseteq Q$ is the set of initial states; $\text{Succ} : Q \rightarrow 2^Q \setminus \emptyset$ maps each state to its set of successors; $\text{Ag} \subseteq \mathbb{N}$ denotes the set of agents; $\alpha : Q \rightarrow \text{Ag}$ maps each state to the agent owning it; and $\pi : Q \mapsto 2^{\text{Prop}}$ maps each state $q \in Q$ to the set of propositions that hold in q . A state q is said to be self-looping if $q \in \text{Succ}(q)$. A structure is self-looping if all of its states are self-looping.

For all coalitions of agents $A \subseteq \text{Ag}$, a strategy s_A for the coalition A is a function $s_A : Q^+ \rightarrow Q$ such that, for all $\rho = \rho_1 \cdots \rho_n \in Q^+$, if $\alpha(\rho_n) \in A$, then $s_A(\rho) \in \text{Succ}(\rho_n)$. We denote by S_A the set of strategies for the coalition A . Then, from any state $q \in Q$, we define the set $\text{Out}(q, s_A)$ of infinite paths compatible with the strategy s_A from q : $\text{Out}(q, s_A) := \{\rho \in Q \cdot Q^\omega \mid \forall i \in \mathbb{N}_1 : \alpha(\rho[i]) \in A \implies \rho[i+1] = s_A(\rho[:i])\}$.

Finally, the size $|T|$ of the turn-based structure T is equal to: $|T| = |Q| + |\text{Ag}| + |\text{Prop}|$.

Unless otherwise stated, a turn-based structure T will always refer to the tuple $T = \langle Q, I, \text{Succ}, A, \alpha, \text{Prop}, \pi \rangle$.

There are also special kinds of turn-based structures of interest for us, introduced below.

► **Definition 2.** A Kripke structure is a turn-based structure with only one agent. A linear structure is a Kripke structure such that: $|I| = 1$, and for all $q \in Q$, we have $|\text{Succ}(q)| = 1$. Finally, a turn-based structure is size-1 if $|Q| = 1$.

Unless otherwise stated, a Kripke structure K will always refer to a tuple $\langle Q, I, \text{Succ}, \text{Prop}, \pi \rangle^1$.

We have introduced the notion of linear structures as we are going to interpret LTL-formulas on them. In the literature, they are usually interpreted on ultimately periodic words. However, both models are equivalent and can be encoded into each other straightforwardly.

2.2 ATL, CTL and LTL formulas

The LTL, CTL and ATL-formulas that we consider throughout this paper use the following temporal operators: **X** (neXt), **F** (Future), **G** (Globally), **U** (Until), **R** (Release), **W** (Weak until), **M** (Mighty release). We group these operators into the sets of unary and binary operators: $\text{Op}_{\text{Un}} := \{\neg, \mathbf{X}, \mathbf{F}, \mathbf{G}\}$ and $\text{Op}_{\text{Bin}}^{\text{tp}} := \{\mathbf{U}, \mathbf{R}, \mathbf{W}, \mathbf{M}\}$. We also let $\text{Op}_{\text{Bin}}^{\text{lg}}$ be the set of all logical binary operators, i.e. classical logical operators, along with their negations: $\text{Op}_{\text{Bin}}^{\text{lg}} := \{\vee, \wedge, \implies, \Leftarrow, \Leftrightarrow, \neg\vee, \neg\wedge, \neg\implies, \neg\Leftarrow, \neg\Leftrightarrow\}$ (we have $|\text{Op}_{\text{Bin}}^{\text{lg}}| = 10$).

To define ATL-formulas, we consider two types of formulas: state formulas – where strategic operators occur, denoted with the Greek letter ϕ – and path formulas – where temporal operators occur, denoted with the Greek letter ψ . Consider some $\text{U}^t \subseteq \text{Op}_{\text{Un}}$, $\text{B}^t \subseteq \text{Op}_{\text{Bin}}^{\text{tp}}$, and $\text{B}^l \subseteq \text{Op}_{\text{Bin}}^{\text{lg}}$. For all $k \in \mathbb{N}_1$, we denote by $\text{ATL}^k(\text{Prop}, \text{U}^t, \text{B}^t, \text{B}^l)$ the set of ATL^k -state formulas defined by the grammar:

$$\phi ::= p \mid \neg\phi \mid \phi * \phi \mid \langle\langle A \rangle\rangle\psi \qquad \psi ::= *_1\phi \mid \phi *_2\phi$$

¹ In Kripke structures, there is only one agent, thus Ag and α are irrelevant.

where ϕ is a state-formula, ψ is a path formula, $p \in \text{Prop}$, $* \in \mathbf{B}^l$, $A \subseteq [1, \dots, k]$ is a subset of agents, $*_1 \in \mathbf{U}^t \setminus \{\neg\}$, and $*_2 \in \mathbf{B}^t$. We denote by ATL^k the set of all ATL^k -state formulas ϕ . Note that CTL-formulas are $\text{ATL}^1(\text{Prop}, \mathbf{U}^t, \mathbf{B}^t, \mathbf{B}^l)$ -formulas. Hence, there are only two possible strategic operator: $\langle\langle \emptyset \rangle\rangle$, usually denoted \forall , and $\langle\langle \{1\} \rangle\rangle$ usually denoted \exists . We define LTL-formulas as ATL^1 -formulas using only the quantifier \exists . Since LTL-formulas are interpreted on linear structures, where each state has exactly one successor, the strategic operators used have no impact on the satisfaction of the formula. For readability, we will depict LTL-formulas without the \exists quantifier.

The set of sub-formulas $\text{SubF}(\phi)$ of a formula ϕ is then defined inductively as follows: $\text{SubF}(\phi) := \{\phi\} \cup S$ where $S := \emptyset$ if $\phi = p \in \text{Prop}$, $S := \text{SubF}(\phi')$ if $\phi \in \{\neg\phi', \langle\langle A \rangle\rangle *_1 \phi'\}$ and $S := \text{SubF}(\phi_1) \cup \text{SubF}(\phi_2)$ if $\phi \in \{\phi_1 * \phi_2, \langle\langle A \rangle\rangle(\phi_1 *_2 \phi_2)\}$. The size $|\phi|$ of a formula is then defined as its number of sub-formulas: $|\phi| := |\text{SubF}(\phi)|$. We also denote by $|\phi|_{\text{bin}}$ the number of sub-formulas of ϕ using a binary operator, $|\phi|_{\text{bin}} := |\text{SubBin}(\phi)|$ with: $\text{SubBin}(\phi) := \{\phi_1 * \phi_2 \in \text{SubF}(\phi) \mid \phi_1, \phi_2 \in \text{SubF}(\phi), * \in \text{Op}_{\text{Bin}}^{\text{tp}} \cup \text{Op}_{\text{Bin}}^{\text{lg}}\}$.

We interpret ATL-formulas over TGS using the standard definitions [1]. That is, given a state q and a state formula ϕ , the fact q satisfies ϕ , denoted $q \models \phi$, is defined inductively:

$$\begin{aligned} q \models p & \quad \text{iff } p \in \pi(q) & q \models \phi_1 * \phi_2 & \quad \text{iff } (q \models \phi_1) * (q \models \phi_2) = \text{True} \\ q \models \neg\phi & \quad \text{iff } q \not\models \phi & q \models \langle\langle A \rangle\rangle\psi & \quad \text{iff } \exists s_A \in \mathbf{S}_A, \forall \pi \in \text{Out}(q, s), \pi \models \psi \end{aligned}$$

where $* \in \text{Op}_{\text{Bin}}^{\text{lg}}$ is a binary operator seen as a boolean function $* : \mathbb{B} \times \mathbb{B} \rightarrow \mathbb{B}$ with $\mathbb{B} := \{\text{True}, \text{False}\}$. Furthermore, given a path $\pi \in Q^\omega$ and a path formula ψ , the fact that ψ holds for the path π , also denoted $\pi \models \psi$, is defined inductively as follows:

$$\begin{aligned} \pi \models \mathbf{X}\phi & \quad \text{iff } \pi[2:] \models \phi; & \pi \models \phi_1 \mathbf{U}\phi_2 & \quad \text{iff } \exists i \in \mathbb{N}_1, \pi[i:] \models \phi_2 \text{ and} \\ \pi \models \mathbf{F}\phi & \quad \text{iff } \exists i \in \mathbb{N}_1, \pi[i:] \models \phi; & & \quad \forall 1 \leq j \leq i-1, \pi[j:] \models \phi_1 \\ \pi \models \mathbf{G}\phi & \quad \text{iff } \forall i \in \mathbb{N}_1, \pi[i:] \models \phi & \pi \models \phi_1 \mathbf{R}\phi_2 & \quad \text{iff } \pi \models \neg(\neg\phi_1 \mathbf{U}\neg\phi_2) \\ \pi \models \phi_1 \mathbf{W}\phi_2 & \quad \text{iff } \pi \models (\phi_1 \mathbf{U}\phi_2) \vee \mathbf{G}\phi_1 & \pi \models \phi_1 \mathbf{M}\phi_2 & \quad \text{iff } \pi \models (\phi_1 \mathbf{R}\phi_2) \wedge \mathbf{F}\phi_1 \end{aligned}$$

An ATL-formula ϕ accepts a TGS T , denoted by $T \models \phi$, if $q \models \phi$ for all initial states $q \in I$, otherwise it rejects it. Given two formulas ϕ, ϕ' , we write $\phi \implies \phi'$ if, for all TGS T , if $T \models \phi$, then $T \models \phi'$. We write $\phi \equiv \phi'$ when $\phi \implies \phi'$ and $\phi' \implies \phi$.

2.3 Learning decision problem

We define the LTL, CTL and ATL learning problems below, where models for LTL, CTL, and ATL are linear structures, Kripke structures and turn-based game structures, respectively.

► **Definition 3.** Let $\text{TL} \in \{\text{LTL}, \text{CTL}, \text{ATL}^k \mid k \in \mathbb{N}_1\}$ and consider some sets of operators $\mathbf{U}^t \subseteq \text{Op}_{\text{Un}}$, $\mathbf{B}^t \subseteq \text{Op}_{\text{Bin}}^{\text{tp}}$ and $\mathbf{B}^l \subseteq \text{Op}_{\text{Bin}}^{\text{lg}}$. For all $n \in \mathbb{N} \cup \{\infty\}$, we denote by $\text{TL}_{\text{Learn}}(\mathbf{U}^t, \mathbf{B}^t, \mathbf{B}^l, n)$ the decision problem:

- *Input:* $(\text{Prop}, \mathcal{P}, \mathcal{N}, B)$ where Prop is a set of propositions, \mathcal{P}, \mathcal{N} are two finite sets of models for TL, and $B \in \mathbb{N}$.
- *Output:* yes if and only if there exists a TL-formula $\varphi \in \text{TL}(\text{Prop}, \mathbf{U}^t, \mathbf{B}^t, \mathbf{B}^l)$ such that $|\varphi| \leq B$, $|\varphi|_{\text{bin}} \leq n$, and φ is separating, i.e. such that : for all $X \in \mathcal{P}$ (resp. $X \in \mathcal{N}$), we have $X \models \varphi$ (resp. $X \not\models \varphi$).

The size of the input is equal to $|\text{Prop}| + |\mathcal{P}| + |\mathcal{N}| + B$ (i.e. B is written in unary).

As the model checking problems for LTL, CTL, ATL are in P [1], it follows that the learning problems for all these logics are in NP, with a straightforward guess-and-check subroutine.

► **Proposition 4.** For all $U^t \subseteq \text{Op}_{U^n}$, $B^t \subseteq \text{Op}_{\text{Bin}}^{\text{tp}}$, $B^l \subseteq \text{Op}_{\text{Bin}}^{\text{lg}}$, $n \in \mathbb{N} \cup \{\infty\}$, and $\text{TL} \in \{\text{LTL}, \text{CTL}, \text{ATL}^k \mid k \in \mathbb{N}_1\}$, the decision problem $\text{TLearn}(U^t, B^t, B^l, n)$ is in NP.

2.4 Hitting set problem

We recall below the NP-complete problem from which we will establish almost all of our (NP-hardness) reductions.

- **Definition 5 (Hitting set problem).** We denote by *Hit* the following decision problem:
- *Input:* a triple (l, C, k) where $l \in \mathbb{N}_1$, $C = C_1, \dots, C_n$ are non-empty subsets of $[1, \dots, l]$
 - *Output:* yes iff there is a subset $H \subseteq [1, \dots, l]$ of size at most k such that, we have $H \cap C_i \neq \emptyset$ for all $1 \leq i \leq n$. In such a case, the set H is called a hitting set.

In the following, if (l, C, k) is an instance of the hitting set problem, then C refers to C_1, \dots, C_n for some $n \in \mathbb{N}_1$.

3 Learning with unbounded use of binary operators

First, we consider the case of learning a formula with arbitrarily many occurrences of binary operators. The main result of this section is stated in Theorem 6 below.

► **Theorem 6.** Let $B^t \subseteq \text{Op}_{\text{Bin}}^{\text{tp}}$ and $B^l \subseteq \text{Op}_{\text{Bin}}^{\text{lg}}$ such that $B^t \cup B^l \neq \emptyset$. Then, for all $U^t \subseteq \text{Op}_{U^n}$, the decision problem $\text{LTL}_{\text{Learn}}(U^t, B^t, B^l, \infty)$ is NP-hard.

In the passive learning setting that we consider, the size of the formulas is crucial due to the upper bound B . Therefore, although it is possible to express e.g. disjunctions with conjunctions and negations, since doing so affects the size of the formulas involved, if we have proved that a learning problem is NP-hard with the operators \vee, \neg , it does not imply a priori that it is also NP-hard with the operator \wedge . Hence, for the sake of completeness, we consider all those fourteen binary operators (ten logical, four temporal), although it seems that some of these binary operators (like \vee or \wedge) make much more sense to consider than others (like \Leftrightarrow or $\neg \Leftrightarrow$). Since these operators behave differently, we cannot do a single reduction working for all these operators at once. However, we do partition these operators in different groups and exhibit a reduction per group of operators.

Most of the reductions use only size-1 structures, that are (almost) entirely defined by the subset of propositions labeling their only state. In addition, most of the reductions are done from the hitting set problem. In that case, how we extract a hitting set from a (small enough) separating formula relies only on the variables that need to occur in a formula separating the positive and negative structures, regardless of the operators involved.

We start with the operators $\vee, \Rightarrow, \Leftarrow$, i.e. we assume that $B^l \cap \{\vee, \Rightarrow, \Leftarrow\} \neq \emptyset$. The reduction for this case is actually a straightforward adaptation of the proof of [27, Theorem 2]. We describe it here. Given an instance (l, C, k) of the hitting set problem, we let $\text{Prop} := \{a_j, b_j \mid 1 \leq j \leq l\}$. Furthermore, for all subsets $T \subseteq [1, \dots, l]$, we let $\mathcal{L}(T)$ denote a size-1 (linear) structure whose only state is labeled by the set $\{a_j, b_{j'} \mid j \in T, j' \notin T\}$. Then, we let $\text{In}^{\vee, \Rightarrow, \Leftarrow} := (\text{Prop}, \mathcal{P}, \mathcal{N}, B)$ for $\mathcal{P} := \{\mathcal{L}(C_i) \mid 1 \leq i \leq n\}$, $\mathcal{N} := \{\mathcal{L}(\emptyset)\}$, and $B := 2k - 1$. Let us illustrate this reduction on a simple example. Assume that $l = 4$, $C = (\{1, 2, 3\}, \{2, 4\}, \{1, 4\})$, and $k = 2$. Then, the sets labeling the only state of the positive structures are $\{a_1, a_2, a_3, b_4\}$, $\{b_1, a_2, b_3, a_4\}$, and $\{a_1, b_2, b_3, a_4\}$ while the set labeling the only state of the negative structure is $\{b_1, b_2, b_3, b_4\}$. Furthermore, $B = 3$. Then, $H := \{1, 4\}$ is the a hitting set with $|H| \leq 2$, while $\varphi_{\vee} := a_1 \vee a_4$, $\varphi_{\Rightarrow} := b_1 \Rightarrow a_4$, and $\varphi_{\Leftarrow} := a_1 \Leftarrow b_4$ are all separating formulas with $|\varphi_{\vee}| = |\varphi_{\Rightarrow}| = |\varphi_{\Leftarrow}| \leq 3$.

We claim that (l, C, k) is a positive instance of **Hit** iff $\text{In}^{\vee, \Rightarrow, \Leftarrow}$ is a positive instance of $\text{LTL}_{\text{Learn}}(\mathbf{U}^t, \mathbf{B}^t, \mathbf{B}^l, \infty)$. Indeed, given a hitting set $H = \{i_1, \dots, i_r\}$ with $r \leq k$, one can check that the LTL-formula $\varphi_{\vee} := \bigvee_{1 \leq x \leq r} a_{i_x}$ of size $2r - 1 \leq B$ accepts \mathcal{P} and rejects \mathcal{N} . Note that, the LTL-formulas $\varphi_{\Rightarrow} := b_{j_1} \Rightarrow (b_{j_2} \Rightarrow (\dots \Rightarrow a_{j_r}))$ and $\varphi_{\Leftarrow} := ((a_{j_1} \Leftarrow b_{j_2}) \Leftarrow \dots) \Leftarrow b_{j_r}$ of size $2r + 1 \leq B$ also accept \mathcal{P} and reject \mathcal{N} . On the other hand, consider an LTL-formula φ of size at most B that accepts \mathcal{P} and rejects \mathcal{N} . We let $H := \{1 \leq j \leq l \mid a_j \text{ or } b_j \text{ occurs in } \varphi\}$. Since $|\varphi| \leq B$, we have $|H| \leq k$. Furthermore, consider any $1 \leq i \leq n$. Let us consider the set S_i (resp. S) labeling the only state of the structure $\mathcal{L}(C_i)$ (resp. $\mathcal{L}(\emptyset)$). We have $\Delta(S_i, S) := S_i \setminus S \cup S \setminus S_i = \{a_j, b_j \mid j \in C_i\}$. One can then show (rather straightforwardly, by induction on LTL-formulas) that, since φ accepts $\mathcal{L}(C_i)$ and rejects $\mathcal{L}(\emptyset)$, at least one variable in $\Delta(S_i, S)$ occurs in φ . That is, $C_i \cap H \neq \emptyset$ and H is a hitting set of size at most k .

In fact, the reduction for the operators $\wedge, \neg \Rightarrow, \neg \Leftarrow$ is obtained from the above one by reversing the positive and negative sets (the arguments are almost identical).

We then handle the operators $\neg \vee, \neg \wedge$. The above reductions cannot be used since, when the operator $\neg \wedge$ (or the operator $\neg \vee$) is used successively, the formula obtained is semantically equivalent to an alternation of conjunctions and disjunctions. For instance, consider six variables $r_1, r_2, r_3, r_4, x_1, x_2$ to use in a single LTL-formula using only the $\neg \wedge$ operator, e.g.: $\varphi := r_1 \neg \wedge (x_1 \neg \wedge (r_2 \neg \wedge (x_2 \neg \wedge (r_3 \neg \wedge r_4))))$. It is semantically equivalent to: $\varphi \equiv \neg r_1 \vee (x_1 \wedge (\neg r_2 \vee (x_2 \wedge (\neg r_3 \vee \neg r_4))))$. This is in sharp contrast with the above-formulas $\varphi_{\vee}, \varphi_{\Leftarrow}$ and φ_{\Rightarrow} . To circumvent this difficulty, we change the reduction by adding propositions labeling the only state of all the positive size-1 linear structures (but not the only state of all the negative ones). We can then place these propositions where x_2 and x_4 were in the above formula. That way, we semantically obtain a disjunction on relevant variables r_1, r_2, r_3, r_4 . The obtained reduction is slightly more subtle than the previous ones.

Before considering the last two logical operators $\Leftrightarrow, \neg \Leftrightarrow$, we handle the temporal operators **W, M**. The two previous reductions only use size-1 structures. On such structures, the temporal operators **W, M** are actually equivalent to \vee and \wedge respectively. Hence, the reductions for \vee and \wedge can also be used as is for the operators **W** and **M** respectively.

We then handle the final two logical operators $\Leftrightarrow, \neg \Leftrightarrow$. These operators are unlike the other operators. Let us give an intuition of how the learning problems with these operators behave. Consider an LTL-formula φ using only the operators \neg, \Rightarrow and $\neg \Leftrightarrow$ and a size-1 structure \mathcal{L} . Let S denote the set of propositions labeling the only state of \mathcal{L} . We let $\text{Neg}(\varphi)$ denote the number of occurrences of the operators $\neg, \neg \Leftrightarrow$ in φ . We also let $\text{NbOc}_{\bar{S}}(\varphi)$ denote the number of occurrences of the propositions not in S in φ . Then, one can realize that $\mathcal{L} \models \varphi$ if and only if $\text{Neg}(\varphi)$ and $\text{NbOc}_{\bar{S}}(\varphi)$ have the same parity. This simple observation suggests that the learning problem with the operators $\Leftrightarrow, \neg \Leftrightarrow$ is linked to modulo-2 calculus. The reduction for these operators is established from an NP-complete problem dealing with modulo-2 calculus, known as the Coset Weight problem [5].

Finally, we handle the temporal operators **U** and **R**. On size-1 structures, for all LTL-formulas φ_1, φ_2 , we have the following equivalences: $\varphi_1 \mathbf{U} \varphi_2 \equiv \varphi_1 \mathbf{R} \varphi_2 \equiv \varphi_2$. That is, contrary to the temporal operators **W** and **M**, on size-1 structures, **U** and **R** are equivalent to unary operators. Hence, the reduction that we consider does not involve only size-1 structures. It is once again established from the hitting set problem, though the construction and the correctness proof are more involved than for the above cases.

On top of that, for all sets of operators, ATL learning is at least as hard as CTL learning, which is itself at least as hard as LTL learning. Thus, from Theorem 6, we obtain that CTL and ATL learning with unbounded use of binary operators are NP-hard. This justifies the leftmost column of Table 1.

4 Learning with a bounded amount of binary operators

Since, with unbounded use of binary operators, all the learning problems are NP-hard, we focus on learning formulas where the number of occurrences of binary operators is bounded. Note that the bound n parameterizes the decision problem itself, and therefore is independent of the input. For simplicity, we restrict ourselves to formulas that do not use at all binary temporal operators. Before we dive into the details of our results as summarized in the rightmost column of Table 1, let us first argue why this fragment is interesting to focus on.

4.1 Expressivity

The passive learning problem that we consider in this paper bounds the size of the formulas considered. This is because we want a separating formula not to overfit the input (i.e. not to simply describe the positive and negative models). However, another benefit is that the smaller the formulas, the more understandable they are for users. Similarly, using too many binary operators could make the formulas hard to grasp, regardless of their size.

In addition, there are examples of interesting specifications that can be expressed with a bounded amount of binary operators. We give three examples below with LTL-formulas.

Consider first so-called “mode-target” formulas of the shape $\bigwedge_j (\mathbf{F G} M_j \Rightarrow \bigvee_i \mathbf{F G} T_{i,j})$, where all $M_j, T_{i,j}$ are propositions. These types of formulas were introduced in [4] and exhibit two interesting features: the corresponding LTL-synthesis problem is tractable, and these formulas express an interesting property, which can be summarized as follows: if a model eventually settles in a mode M_j , then it should eventually settle in one of the target $T_{i,j}$. Interestingly, when the number of different modes and targets that a system can have is fixed, then the number of binary operators sufficient to express such specification is also bounded.

Similarly, there are also interesting specifications related to “generalized reactivity” (from [32] for LTL-formulas). Such specifications are of the shape $\bigwedge_i \mathbf{G F} \psi_i \Rightarrow \bigwedge_i \mathbf{G F} \psi'_i$, where all formulas ψ_i and ψ'_i do not feature at all temporal operators. As such, up to introducing additional propositions, these could be expressible with few binary operators. These formulas can be read as an implication between assumptions and guarantees. As above, when the number of assumptions and guarantees is bounded, then the number of binary operators sufficient to express such formulas also is.

Finally, one of the popular LTL learning tools, Scarlet [35], relies on a fragment of LTL, directed LTL and its dual, which uses unary temporal operators and binary logical operators only. In these fragments, formulas of a fixed length (a search parameter they define) can use several of $\mathbf{F G}$ and \mathbf{X} operators while using only bounded occurrences of \wedge and \vee operators.

4.2 Abstract recipes

The six decision problems captured in the rightmost column of Table 1 are of two kinds: three are NP-complete, while three others are below NP. In fact, the proofs of all three results of the same kind will follow the same abstract recipes. We present them below.

Recipe for the membership-below-NP proofs. Let TL denote either LTL formulas, or CTL formulas without the operator \mathbf{X} , or ATL^2 formulas with only one unary operator \mathbf{F} or \mathbf{G} (i.e. one of the three logical fragment for which the corresponding decision problem is below NP). Then, we follow the two steps below:

- A) First, we show that given the set of propositions Prop and the bound B , there is a set of relevant TL-formulas $\text{RelForm}(\text{Prop}, B)$ such that: 1) For all TL(Prop)-formulas ϕ of size at most B , there is a formula $\phi' \in \text{RelForm}(\text{Prop}, B)$ such that $\phi \equiv \phi'$; and 2) the size of $\text{RelForm}(\text{Prop}, B)$ is polynomial in $|\text{Prop}|$ and B .

- B) Second, we show that for all TL-formulas $\phi \in \text{RelForm}(\text{Prop}, B)$, deciding if ϕ satisfies a TL-model M can be done, depending on $|\text{Prop}|, B, |M|$, within the resources allowed, i.e. logarithmic space for the LTL case, non-deterministic logarithmic space for the CTL case, and polynomial time for the ATL² case.

Due to a lack of space, in this paper we will only present these two steps in the context of formulas that do not use any binary operator. Since the occurrences of binary operators is bounded in any case, the arguments are essentially the same for the general case. For instance, for the first step, from the result established for formulas without binary operators, we can straightforwardly deduce the result for all formulas, by induction on the bound n . That way, we obtain that $|\text{RelForm}(\text{Prop}, B)|$ could be exponential in the bound n , but this does not have an impact complexity-wise, since n is fixed.

Recipe for the NP-hardness proofs. The formulas that we consider only use a bounded amount of binary operators. Thus, contrary to the NP-hardness reductions of Section 3, here, our NP-hardness proofs do not rely on binary operators. In fact, these binary operators make it harder to argue about how the permitted unary operators interact. For this reason, our proof of NP-hardness is decomposed into two steps. We first exhibit reductions for the learning problems without binary operators. Then, from these reductions, we devise reductions for the learning problems with bounded occurrences of binary operators. We present in details the former reductions in this paper and give intuition behind the later reductions below.

Let $n \in \mathbb{N}$ and $*$ $\in \text{Op}_{\text{Bin}}^{\text{lg}}$ be a binary (non-temporal) operator. We consider n propositions $\{p_1, \dots, p_n\}$ and we define multiple size-1 structures using the propositions $\{p_1, \dots, p_n\}$ forming two sets $\mathcal{A}_{n,*}$ and $\mathcal{B}_{n,*}$. The idea is that to distinguish these two sets, a separating formula will necessarily feature all the propositions $\{p_1, \dots, p_n\}$. In fact, from a positive and a negative sets of structures \mathcal{P} and \mathcal{N} on the set of proposition $\{p\}$ ² (which is the only proposition that unary formulas can use in our reductions), we can show the following: if a formula of size at most $B + 2n$, with at most n occurrences of binary operators, separates both \mathcal{P} and \mathcal{N} , and $\mathcal{A}_{n,*}$ and $\mathcal{B}_{n,*}$, then there is a unary formula of size at most B that separates \mathcal{P} and \mathcal{N} .³ That way, a reduction for the learning problem without binary operators can be translated (in logspace) into a reduction for the learning with bounded occurrences of binary operators. Note that the arguments presented in this paragraph are not straightforward to formally state and prove (this is handled in Theorem “Proving NP-hardness without binary operators is sufficient” in the extended version [8]).

Let us now consider how we handle the reduction without binary operators. From an instance (l, C, k) of the hitting problem, we proceed as follows. We define a sample of structures (and a bound B) such that all separating formulas have a specific shape, and there is a bijection between subsets $H \subseteq [1, \dots, l]$ and formulas $\varphi(l, H)$ of that specific shape. This correspondence allows us to extract a hitting set. More specifically, we follow the abstract recipe below:

- (a) We define the bound B and positive and negative structures that “eliminate” certain operators or pattern of operators from any potential separating formula. This way we ensure that any separating formula will be of the form $\varphi(l, H)$, for some $H \subseteq [1, \dots, l]$.
- (b) We define a negative structure satisfied by a formula $\varphi(l, H)$ if and only if $|H| \geq k + 1$.
- (c) For all $1 \leq i \leq n$, we define a positive structure that a formula $\varphi(l, H)$ accepts if and only if $H \cap C_i \neq \emptyset$.

² In fact, for technical reason, in [8], we use two propositions $\{p, \bar{p}\}$.

³ Actually, we can also show the converse (which is important for us to prove that the reduction is correct).

19:10 Learning LTL, CTL and ATL Formulas

By construction, the instance of the learning decision problem that we obtain is a positive instance if and only if the hitting set instance (l, C, k) also is. Furthermore, note that in all three cases, this reduction can be computed in logspace.

4.3 LTL learning

We start with LTL learning. We have the proposition below.

► **Proposition 7.** *For all sets of unary operators $U^t \subseteq \text{Op}_{U_n}$, sets of binary (non-temporal) operators $B^l \subseteq \text{Op}_{B_{in}}^{lg}$, and $n \in \mathbb{N}$, the decision problem $\text{LTL}_{\text{Learn}}(U^t, \emptyset, B^l, n)$ is in L.*

We present Steps A and B of Section 4.2 in the case $n = 0$. Toward Step A, we have the equivalences below (see e.g. [27, Prop. 8]), which imply the corollary that follows.

► **Observation 8.** *For all LTL-formulas φ and $k \in \mathbb{N}$, we have: 1) $\mathbf{F} \mathbf{X}^k \varphi \equiv \mathbf{X}^k \mathbf{F} \varphi$, $\mathbf{G} \mathbf{X}^k \varphi \equiv \mathbf{X}^k \mathbf{G} \varphi$; 2) $\mathbf{F} \mathbf{F} \varphi \equiv \mathbf{F} \varphi$, $\mathbf{G} \mathbf{G} \varphi \equiv \mathbf{G} \varphi$; 3) $\mathbf{F} \mathbf{G} \mathbf{F} \varphi \equiv \mathbf{G} \mathbf{F} \varphi$, $\mathbf{G} \mathbf{F} \mathbf{G} \varphi \equiv \mathbf{F} \mathbf{G} \varphi$.*

► **Corollary 9.** *Consider a set of propositions Prop . We let $\text{Lit}(\text{Prop}) := \{x, \neg x \mid x \in \text{Prop}\}$ and $\text{LTL}_{U_n}(\text{Prop}) := \{\mathbf{X}^k x, \mathbf{X}^k \mathbf{F} x, \mathbf{X}^k \mathbf{G} x, \mathbf{X}^k \mathbf{F} \mathbf{G} x, \mathbf{X}^k \mathbf{G} \mathbf{F} x \mid k \in \mathbb{N}, x \in \text{Lit}(\text{Prop})\}$.*

Then, for any LTL-formula $\varphi \in \text{LTL}(\text{Prop}, \text{Op}_{U_n}, \emptyset, B^l, 0)$, there is an LTL-formula $\varphi' \in \text{LTL}_{U_n}(\text{Prop}) \cap \text{LTL}(\text{Prop}, \text{Op}_{U_n}, \emptyset, B^l, 0)$ such that $\varphi \equiv \varphi'$ and $|\varphi'| \leq |\varphi|$.

Proof sketch. With the equivalences 1) from Observation 8, we can push the \mathbf{X} operators in φ at the beginning of the formula. The equivalences 2) and 3) from Observation 8 ensure that it is possible to have at most two nested \mathbf{F}, \mathbf{G} operators in the resulting formula φ' . ◀

The set of relevant formulas $\text{RelForm}(\text{Prop}, B)$ is then obtained directly from the set of formulas $\text{LTL}_{U_n}(\text{Prop})$. Note that however, how it is obtained depends on the exact operators in U^t . For instance, if $\mathbf{G} \notin U^t$ while $\neg, \mathbf{F} \in U^t$, we should replace the occurrences of \mathbf{G} in formulas in $\text{RelForm}(\text{Prop}, B)$ by $\neg \mathbf{F} \neg$. Nonetheless, in any case, we obtain a set $\text{RelForm}(\text{Prop}, B)$ of relevant formulas whose number of elements is linear in $|\text{Prop}| \cdot B$. This concludes the arguments for Step A. As for Step B, one can realize that since there are at most two nested \mathbf{F}, \mathbf{G} operators in formulas in $\text{RelForm}(\text{Prop}, B)$, then checking that they hold on a linear structure can be done in logarithmic space (because it suffices to have a constant number of pointers browsing the structure).

4.4 CTL learning

Consider now the more involved case of CTL learning. As can be seen in Table 1, we distinguish two cases: with and without the operator \mathbf{X} .

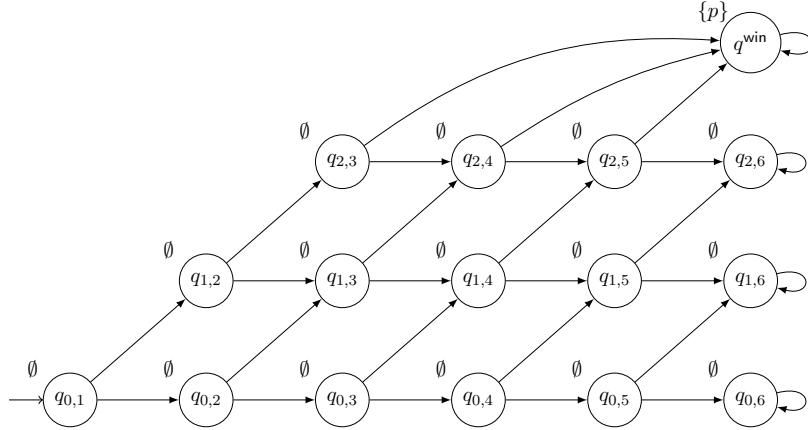

Assume that $\mathbf{X} \in U^t$. The goal is to show the theorem below.

► **Theorem 10.** *For all sets $U^t \subseteq \text{Op}_{U_n}$, $B^l \subseteq \text{Op}_{B_{in}}^{lg}$, and bound $n \in \mathbb{N}$, if $\mathbf{X} \in U^t$, then the decision problem $\text{CTL}_{\text{Learn}}(U^t, \emptyset, B^l, n)$ is NP-hard.*

As stated in Section 4.2, we argue the theorem in the case $n = 0$. Recall that in that case we consider a single proposition $\{p\}$. Consider an instance (l, C, k) of the hitting set problem Hit. We follow the three Steps a, b, and c. Toward Step a, we define Kripke structures that prevent the use of the operators $\mathbf{F}, \mathbf{G}, \neg$. To do so, we let $B := l + 1$ and for two sets $S_1, S_2 \subseteq \{p\}$, we consider the Kripke structure K_{l, S_1, S_2} that is depicted in Figure 1. These structures satisfy the lemma below.

■ **Figure 1** The structure K_{l,S_1,S_2} where $S_1 \subseteq \{p\}$ (resp. $S_2 \subseteq \{p\}$) labels q_{l+1} (resp. q_{l+2}).

■ **Figure 2** The Kripke structure $K_{\exists > 2}^5$.

► **Lemma 11.** *A formula $\phi \in \text{CTL}(\{p\}, \text{U}^t, \emptyset, \text{B}^l, 0)$ of size at most $l + 1$ accepting $K_{l,\{p\},\emptyset}$ and rejecting $K_{l,\emptyset,\{p\}}$ and $K_{l,\emptyset,\emptyset}$ cannot use the operators $\mathbf{F}, \mathbf{G}, \neg$.*

Proof sketch. Consider an equivalent CTL-formula ϕ' with $|\phi'| \leq |\phi|$ where negations, if any, occur right before the proposition p . Then, if ϕ' uses the operator \mathbf{G} , it cannot distinguish the structures $K_{l,\{p\},\emptyset}$ and $K_{l,\emptyset,\emptyset}$. Otherwise, if it uses the operator \mathbf{F} , it cannot distinguish the structures $K_{l,\{p\},\emptyset}$ and $K_{l,\emptyset,\{p\}}$. Otherwise, since $K_{l,\{p\},\emptyset}, K_{l,\emptyset,\{p\}}$, and $K_{l,\emptyset,\emptyset}$ coincide on the first l states, ϕ' has to use at least l operators \mathbf{X} . Since $|\phi'| \leq l + 1$, it cannot use a negation. Thus ϕ' does not use $\mathbf{F}, \mathbf{G}, \neg$, and neither does ϕ . ◀

In fact, a CTL-formula $\phi \in \text{CTL}(\{p\}, \text{U}^t, \emptyset, \text{B}^l, 0)$ of size at most $l + 1$ accepting $K_{l,\{p\},\emptyset}$ and rejecting $K_{l,\emptyset,\{p\}}, K_{l,\emptyset,\emptyset}$ necessarily uses exactly l operators \mathbf{X} followed by the proposition p . Such a formula is therefore entirely defined by the \mathbf{X} operators before which it uses the \exists quantifier. This suggests the definition below of the CTL-formula $\phi(l, H)$ induced by a subset $H \subseteq [1, \dots, l]$.

► **Definition 12.** *For all $H \subseteq [1, \dots, l]$, we let $\phi(l, H) \in \text{CTL}(\{p\}, \text{U}^t, \emptyset, \text{B}^l, 0)$ denote the CTL-formula defined by $\phi(l, H) := Q_1 \mathbf{X} \dots Q_l \mathbf{X} p$ where, for all $1 \leq i \leq l$, we have $Q_i \in \{\exists, \forall\}$ and $Q_i = \exists$ if and only if $i \in H$.*

For $1 \leq i \leq l + 1$, we let $\phi_i(l, H) := Q_i \mathbf{X} \dots Q_l \mathbf{X} p$ (with $\phi_{l+1}(l, H) := p$).

Let us now turn toward Step b. We define a structure $K_{\exists > k}^l$ with $k + 2$ different levels, where: the single starting state $q_{0,1}$ is at the bottommost level; the proposition p only labels the state q^{win} at the topmost level; and every state of the bottom $k + 1$ levels has a successor at the same level and one level higher. That way, going from $q_{0,1}$ to q^{win} is equivalent to leveling up $k + 1$ times. Furthermore, the top most level can be reached in at most l . An example is depicted in Figure 2. This structure satisfies the lemma below.

► **Lemma 13.** *For all $H \subseteq [1, \dots, l]$, we have $K_{\exists > k}^l \models \phi(l, H)$ if and only if $|H| > k$.*

■ **Figure 3** The Kripke structure $K_{5, \{2,5\}}$.

Consider now Step c. For $C \subseteq [1, \dots, l]$, we define the Kripke structure $K(l, C)$ with $\{q_1, \dots, q_l, q_{l+1}, q^{\text{win}}\}$ as set of states where q^{win} is the only state labeled with p ; and for all $1 \leq j \leq l$, q_j branches to q_{j+1} and, if (and only if) $j \in C$, q_j also branches to q^{win} , as exemplified in Figure 3. Such structures satisfy the lemma below.

► **Lemma 14.** *For all $C, H \subseteq [1, \dots, l]$, we have $K_{(l,C)} \models \phi(l, H)$ if and only if $C \cap H \neq \emptyset$.*

Proof sketch. We can show by induction on $l + 1 \geq j \geq 1$ the property $\mathcal{P}(j)$: $q_j \models \phi_j(l, H)$ if and only if $H \cap [j, \dots, l] \cap C \neq \emptyset$. The lemma is then given by $\mathcal{P}(1)$. ◀

We can finally define the reduction that we consider. We let $\text{In}^{\text{CTL}} := (\{p\}, \mathcal{P}, \mathcal{N}, B)$, with $B := l + 1$, $\mathcal{P} := \{K_{l, \{p\}, \emptyset}, K_i \mid 1 \leq i \leq n\}$ and $\mathcal{N} := \{K_{l, \emptyset, \emptyset}, K_{l, \emptyset, \{p\}}, K_{\exists > k}^l\}$, be an input of the decision problem $\text{CTL}_{\text{Learn}}(\text{U}^t, \emptyset, \text{B}^l, 0)$. By Lemmas 11, 13, 14, In^{CTL} is a positive instance of the decision problem $\text{CTL}_{\text{Learn}}(\text{U}^t, \emptyset, \text{B}^l, 0)$ if and only if (l, C, k) is a positive instance of the decision problem Hit. Theorem 10 follows (in the case $n = 0$).

Assume that $X \notin \text{U}^t$. In that case, the CTL learning problem is now in NL.

► **Theorem 15.** *For all sets of operators $\text{U}^t \subseteq \{\mathbf{F}, \mathbf{G}, \neg\}$, $\text{B}^l \subseteq \text{Op}_{\text{Bin}}^{\text{lg}}$, and bounds $n \in \mathbb{N}$, the decision problem $\text{CTL}_{\text{Learn}}(\text{U}^t, \emptyset, \text{B}^l, n)$ is in NL.*

Toward Step A, a crucial observation is that using the operators \mathbf{F} or \mathbf{G} twice in a row is useless. This is stated in the lemma below in the context of ATL-formula because this lemma will be used again in the next subsection.

► **Lemma 16.** *Let $I \subseteq J \subseteq \mathbb{N}$, and ϕ be an ATL-formula. We have:*

$$\langle\langle J \rangle\rangle \mathbf{F} \phi \equiv \langle\langle I \rangle\rangle \mathbf{F} \langle\langle J \rangle\rangle \mathbf{F} \phi \equiv \langle\langle J \rangle\rangle \mathbf{F} \langle\langle I \rangle\rangle \mathbf{F} \phi \quad \langle\langle I \rangle\rangle \mathbf{G} \phi \equiv \langle\langle I \rangle\rangle \mathbf{G} \langle\langle J \rangle\rangle \mathbf{G} \phi \equiv \langle\langle J \rangle\rangle \mathbf{G} \langle\langle I \rangle\rangle \mathbf{G} \phi$$

Proof sketch. We argue the result for \mathbf{F} , the case of \mathbf{G} is dual. We have $\langle\langle J \rangle\rangle \mathbf{F} \phi \implies \langle\langle I \rangle\rangle \mathbf{F} \langle\langle J \rangle\rangle \mathbf{F} \phi$ by definition of \mathbf{F} . Furthermore, if a state q satisfies $\langle\langle I \rangle\rangle \mathbf{F} \langle\langle J \rangle\rangle \mathbf{F} \phi$ then there is a strategy s_I for the coalition I such that eventually a state satisfying $\langle\langle J \rangle\rangle \mathbf{F} \phi$ is surely reached. For all such states q , we consider a strategy s_J^q for the coalition J ensuring to eventually visit a state satisfying ϕ . Then, consider a strategy s'_J for the coalition J that mimics s_I (which is possible since $I \subseteq J$) until a state q satisfying $\langle\langle J \rangle\rangle \mathbf{F} \phi$ is reached, and then switches to the strategy s_J^q . That strategy ensures eventually reaching a state satisfying ϕ . Therefore, $\langle\langle I \rangle\rangle \mathbf{F} \langle\langle J \rangle\rangle \mathbf{F} \phi \implies \langle\langle J \rangle\rangle \mathbf{F} \phi$. This is similar for $\langle\langle J \rangle\rangle \mathbf{F} \langle\langle I \rangle\rangle \mathbf{F} \phi$. ◀

From this, we can actually deduce (this is not direct) that there is a bound $M \in \mathbb{N}$ such that, for any set of propositions Prop and for all $\text{U}^t \subseteq \{\mathbf{F}, \mathbf{G}, \neg\}$, given any $\text{CTL}(\text{Prop}, \text{U}^t, \emptyset, \text{B}^l, 0)$ -formula ϕ , there is an equivalent $\text{CTL}(\text{Prop}, \text{U}^t, \emptyset, \text{B}^l, 0)$ -formula ϕ' , with $|\phi'| \leq M$. Thus, the number of CTL-formulas to consider is linear in $|\text{Prop}|$. As for Step B, consider any such formula ϕ . Since the number of quantifiers it uses is bounded by M and $\text{NL} = \text{coNL}$, we deduce that checking that it satisfies a Kripke structure can be done in NL.

■ **Figure 4** The turn-based structure $T_{4:1,2}$. ■ **Figure 5** On the left T_p , on the right $T_{no 2 G}$.

Proof of NL-hardness. In Table 1, we do not state only that CTL learning without the operator \mathbf{X} is in NL, but also that it is NL-hard. Proving this result is actually straightforward. We exhibit a reduction from the problem of reachability in a graph (which is NL-complete [23]). Given an input (\mathcal{G}, s, t) of that problem, with \mathcal{G} a graph, s the source state and t the target state, we define a positive Kripke structure K that is obtained from \mathcal{G} by making s its only initial state, and t the only state labeled by the proposition p . Additionally, we consider $B := 2$ as the bound, and with an additional structure, we ensure that if there is a separating formula, then the formula $\phi := \exists \mathbf{F} p$ is separating.

4.5 ATL learning

We have seen that CTL learning with the operator \mathbf{X} is NP-hard, which implies that it is also the case for ATL learning. Here, we consider the case of ATL learning without the operator \mathbf{X} . First, let us informally explain why the NP-hardness reduction that we have described above for CTL cannot possibly work without the operator \mathbf{X} . A central aspect of the proof of Lemma 14 is to be able to associate a specific operator in a prospective formula with a specific state in a Kripke structure. That is intrinsically not possible with the operator \mathbf{F} since this operator looks at arbitrarily distant horizons. At least, this is true with CTL-formulas interpreted on Kripke structures. However, with ATL-formulas interpreted on turn-based structures, it is possible to “block the horizon” of \mathbf{F} operators. Indeed, consider the structure of Figure 4, where blue lozenge-shaped states are Agent-1 states, and red square-shaped states are Agent-2’s. Here, one can see that $q_2^{1,2} \not\models \langle\langle 1 \rangle\rangle \mathbf{F} p$ because Agent 2 can enforce to loop on the Agent-2 state $q_1^{1,2}$ and not see the state q^{win} , labeled by p .

These kinds of turn-based games will be extensively used in the following. In all generality, there are defined as follows: given a pair of agents $i \neq j$ and $l \in \mathbb{N}$, in the turn-based structure $T_{l:i,j}$, there are $l + 1$ self-looping states, alternatively belonging to Agents i and j , that can get closer and closer to the self-looping sink q^{win} , the only state labeled by p . In fact, such structures are linked to alternating-formulas, defined below.

► **Definition 17.** An ATL-formula is positive if it does not use any negation. For a pair of agents $i \neq j$ and $l \in \mathbb{N}$, a positive ATL-formula ϕ is (i, j) -free if it does not use an operator $\langle\langle A \rangle\rangle \mathbf{F}$ with $i, j \in A$. It is (i, j, l) -alternating if it is (i, j) -free and if there are at least l alternating occurrences of operators $\langle\langle A_i \rangle\rangle \mathbf{F}$ with $i \in A_i$ and $\langle\langle A_j \rangle\rangle \mathbf{F}$ with $j \in A_j$.

► **Lemma 18.** Consider two agents $i \neq j$, $l \in \mathbb{N}$, and a positive ATL-formula ϕ that is (i, j) -free. The formula ϕ accepts the structure $T_{l:i,j}$ if and only if it is (i, j, l) -alternating.

ATL² learning with $\{\mathbf{F}, \mathbf{G}\} \subseteq \mathbf{U}^t$. Here, all the turn-based structures that we consider use the set of agents $\text{Ag} = \{1, 2\}$. The goal is to show the theorem below.

► **Theorem 19.** For all sets $\mathbf{U}^t \subseteq \text{Op}_{\mathbf{U}^t}$, $\mathbf{B}^l \subseteq \text{Op}_{\mathbf{B}^l}^{\text{lg}}$, and bound $n \in \mathbb{N}$, if $\{\mathbf{F}, \mathbf{G}\} \subseteq \mathbf{U}^t$ and $\mathbf{X} \notin \mathbf{U}^t$, then the decision problem $\text{ATL}_{\text{Learn}}^2(\mathbf{U}^t, \emptyset, \mathbf{B}^l, n)$ is NP-hard.

■ **Figure 6** The structure $T_{no\ 1\ G \geq 2}$.

■ **Figure 7** The structure $T_{2, \{1\}, 2}$.

In the following, to ease the notations, the strategic operators $\langle\langle\emptyset\rangle\rangle$, $\langle\langle\{1\}\rangle\rangle$, $\langle\langle\{2\}\rangle\rangle$, $\langle\langle\{1, 2\}\rangle\rangle$ will simply be denoted \emptyset , 1, 2 and 1, 2 respectively. Consider an instance (l, C, k) of the hitting set problem. We follow the recipe of Subsection 4.2. Here, we want separating formulas to be promising, i.e. to only use the operators $1\mathbf{F}$, $2\mathbf{F}$ and $1\mathbf{G}$. To this end, all the structures we use are self-looping, thus making the operators $\emptyset\mathbf{F}$ and $1, 2\mathbf{G}$ useless.

► **Lemma 20.** *For all ATL-formulas ϕ and self-looping states q , we have: $q \models \phi$ if and only if $q \models \emptyset\mathbf{F}\phi$ if and only if $q \models 1, 2\mathbf{G}\phi$*

Proof. Since q is self-looping the coalition of agents $\{1, 2\}$ has a strategy s such that $\text{Out}(q, s) = \{q^\omega\}$. The lemma follows from the definition of the operators \mathbf{F} and \mathbf{G} . ◀

We also consider the two structures $T_p, T_{no\ 2\mathbf{G}}$, of Figure 5 satisfying the lemma below.

► **Lemma 21.** *For all ATL-formulas $\phi \in \text{ATL}(\{p\}, \mathbf{U}^t, \emptyset, \mathbf{B}^1, 0)$ accepting $T_p, T_{no\ 2\mathbf{G}}$ and rejecting $T_{2l+1;1,2}$, there is a promising formula $\phi' \in \text{ATL}(\{p\}, \mathbf{U}^t, \emptyset, \mathbf{B}^1, 0)$ with $|\phi'| \leq |\phi|$ that is equivalent to ϕ on self-looping structures.*

Proof sketch. Consider an ATL-formula ϕ' equivalent to ϕ with $|\phi'| \leq |\phi|$ and with at most one negation occurring before the proposition p . Since ϕ' accepts T_p , it follows that it is positive. By Lemma 20, we can remove the operators $1, 2\mathbf{G}$ and $\emptyset\mathbf{F}$ from ϕ' . Furthermore: ϕ' cannot use $\emptyset\mathbf{G}, 2\mathbf{G}$, since it accepts $T_{no\ 2\mathbf{G}}$, and it cannot use $1, 2\mathbf{F}$ since it rejects $T_{2l+1;1,2}$. It is therefore promising. ◀

We will also consider $T_{2l;1,2}$ as a positive structure, thus allowing us to focus on $(1, 2, 2l)$ -alternating formulas (recall Lemma 18). Then, we want to associate to a subset $H \subseteq [1, \dots, l]$ a promising $(1, 2, 2l)$ -alternating ATL-formula. To get an intuition, let us consider the turn-based structure $T_{no\ 1\mathbf{G} \geq t}$ for $t = 2$ of Figure 6. This structure $T_{no\ 1\mathbf{G} \geq t}$ is analogous to the structure $T_{2t;1,2}$ except that all Agent-2 states have an additional successor: the state q^{lose} that does not satisfy any positive formula. Back to the structure of Figure 6, because Agent 2 owns the states q_3^G, q_1^G , these states do not accept any positive ATL-formula of the shape $1\mathbf{G}\phi$. Therefore, for all $q \in \{q_4^G, q_2^G\}$ and positive ATL-formulas ϕ , we have $q \models 1\mathbf{F}1\mathbf{G}2\mathbf{F}\phi$ if and only if $q \models \phi$. This actually implies that a $(1, 2, 2l)$ -alternating formula ϕ accepts

$T_{\text{no } 1\mathbf{G} \geq 2}$ if and only if the sequence of operators $1\mathbf{F}2\mathbf{F}$ (without $1\mathbf{G}$ in between) occurs at least twice in ϕ (to go from $q_4^{\mathbf{G}}$ to $q_2^{\mathbf{G}}$ and then from $q_2^{\mathbf{G}}$ to q^{win}). In fact, we consider formulas that only use $1\mathbf{G}$ operators after $1\mathbf{F}$ and before $2\mathbf{F}$, as defined below. Such formulas satisfy the lemma that follows.

► **Definition 22.** For all $H \subseteq [1, \dots, l]$, we let $\phi(l, H, 2) \in \text{ATL}^2(\{p\}, \mathbf{U}^t, \emptyset, \mathbf{B}^l, 0)$ denote the ATL-formula defined by: $\phi(l, H, 2) := 1\mathbf{F}Q_12\mathbf{F} \cdots 1\mathbf{F}Q_l2\mathbf{F}p$ where, for all $1 \leq i \leq l$, we have $Q_i \in \{\epsilon, 1\mathbf{G}\}$ and $Q_i = 1\mathbf{G}$ iff $i \notin H$.

For all $1 \leq i \leq l+1$, we let $\phi_i(l, H, 2) := 1\mathbf{F}Q_i2\mathbf{F} \cdots 1\mathbf{F}Q_l2\mathbf{F}p$ (with $\phi_{l+1}(l, H, 2) := p$).

► **Lemma 23.** A promising $(1, 2, 2l)$ -alternating formula ϕ with $|\phi| \leq 3l + 1 - k$ rejects $T_{\text{no } 1\mathbf{G} \geq k+1}$ if and only if $\phi = \phi(l, H, 2)$ for some $H \subseteq [1, \dots, l]$ such that $|H| = k$.

Proof sketch. Since ϕ is $(1, 2, 2l)$ -alternating, it uses at least l operators $1\mathbf{F}$ and $2\mathbf{F}$. Thus, it can use at most $l - k$ operators $1\mathbf{G}$. In addition, ϕ accepts $T_{\text{no } 1\mathbf{G} \geq k+1}$ iff there are at least $k + 1$ occurrences of the sequence $1\mathbf{F}2\mathbf{F}$ in ϕ . Thus, ϕ uses each $l - k$ remaining operators $1\mathbf{G}$ between a different pair of successive $1\mathbf{F}, 2\mathbf{F}$ iff it rejects $T_{\text{no } 1\mathbf{G} \geq k+1}$. ◀

With $T_p, T_{\text{no } 2\mathbf{G}}, T_{2l:1,2}$ as positive structures and $T_{2l+1:1,2}, T_{\text{no } 1\mathbf{G} \geq k+1}$ as negative structures, we have achieved both Steps a and b. Let us turn to Step c. For all $C \subseteq [1, \dots, l]$, we define a turn-based structure $T_{l,C,2}$. An example is depicted in Figure 7 for $l = 2$. The structure $T_{l,C,2}$ features a sequence of states $q_1^1, q_1^2, \dots, q_l^1, q_l^2$ alternating between Agent-1 and Agent-2 states ending in a self-looping sink q^{lose} not labeled by p . However, the Agent-1 states q_i^1 for which $i \in C$ have a “testing state” q_i^{Test} as successor. That state is self-looping, and may branch to the self-looping sink q^{lose} or to the structure $T_{2(l-i):1,2}$. That state is such that $q_i^{\text{Test}} \models Q_i 2\mathbf{F} \phi_{i+1}(l, H, 2)$ iff $Q_i = \epsilon$ (iff $i \in H$). Furthermore, note that it is useless to “wait” at the state q_i^1 before branching to q_i^{Test} . Indeed, if for instance $Q_i = 1\mathbf{G}$ but $Q_{i+1} = \epsilon$, then it may seem that $q_i^{\text{Test}} \models \varphi'$, for $\varphi' := Q_{i+1}2\mathbf{F} \phi_{i+2}(l, H, 2)$ and therefore $q_i^1 \models \phi_i(l, H, 2) = 1\mathbf{F}Q_i2\mathbf{F}1\mathbf{F}\varphi'$. However, it is not the case because we do not have $q_i^{\text{Test}} \models \varphi'$, since $\phi_{i+2}(l, H, 2)$ is not $(1, 2, 2(l-i))$ -alternating, and thus it does not satisfy the structure $T_{2(l-i):1,2}$. Overall, we have the lemma below.

► **Lemma 24.** For all $C, H \subseteq [1, \dots, l]$, we have $T_{(l,C)} \models \phi(l, H, 2)$ if and only if $C \cap H = \emptyset$.

We have achieved Step c. Then, we let $\text{In}^{\text{ATL}^2} := (\{p\}, \mathcal{P}, \mathcal{N}, B)$ be an input of the decision problem $\text{ATL}_{\text{Learn}}^2(\mathbf{U}^t, \emptyset, \mathbf{B}^l, 0)$ where $\mathcal{P} := \{T_p, T_{\text{no } 2\mathbf{G}}, T_{2l:1,2}, T_{(l,C_i,2)} \mid 1 \leq i \leq n\}$, $\mathcal{N} := \{T_{2l+1:1,2}, T_{\text{no } 1\mathbf{G} \geq k+1}\}$, and $B := 3l + 1 - k$. By Lemmas 21, 23 and 24, In^{ATL^2} is a positive instance of $\text{ATL}_{\text{Learn}}^2(\mathbf{U}^t, \emptyset, \mathbf{B}^l, 0)$ iff (l, C, k) is a positive instance of Hit.

ATL² learning with $\mathbf{U}^t = \{\mathbf{F}\}$ or $\mathbf{U}^t = \{\mathbf{G}\}$. The ATL² learning problem is now in P.

► **Theorem 25.** For all sets of operators $\mathbf{U}^t \in \{\{\mathbf{F}\}, \{\mathbf{G}\}\}$, $\mathbf{B}^l \subseteq \text{Op}_{\text{Bin}}^{\text{lg}}$, and bounds $n \in \mathbb{N}$, the decision problem $\text{ATL}_{\text{Learn}}^2(\mathbf{U}^t, \emptyset, \mathbf{B}^l, n)$ is in P.

We focus on the case $\mathbf{U}^t = \{\mathbf{F}\}$, the other is analogous. Towards Step A, consider a formula $\phi \in \text{ATL}^2(\text{Prop}, \{\mathbf{F}\}, \emptyset, \mathbf{B}^l, 0)$ and the only proposition $p \in \text{Prop}$ occurring in ϕ . By Lemma 16, we can make the following observations: 1) If the operator $1, 2\mathbf{F}$ occurs in ϕ , then $\phi \equiv 1, 2\mathbf{F}p$; 2) Otherwise, if the only operator occurring in ϕ is $\emptyset\mathbf{F}$ then $\phi \equiv \emptyset\mathbf{F}p$; 3) Otherwise, ϕ is equivalent to a formula ϕ' alternating between the operators $1\mathbf{F}$ and $2\mathbf{F}$, with $|\phi'| \leq |\phi|$. These observations suggest the definition below, which satisfies the lemma that follows.

► **Definition 26.** For a set of propositions Prop , we define the set $\text{ATL}_{\mathbf{F}}^2(\text{Prop}) := \{\text{Qt} \cdot p \mid p \in \text{Prop}, \text{Qt} \in \text{Quant}_{\text{Alt}}^{\mathbf{F}}\}$ where $\text{Quant}_{\text{Alt}}^{\mathbf{F}} := \{\epsilon, \emptyset \mathbf{F}, 1, 2 \mathbf{F}, (1 \mathbf{F} \cdot 2 \mathbf{F})^*, (1 \mathbf{F} \cdot 2 \mathbf{F})^* \cdot 1 \mathbf{F}, (2 \mathbf{F} \cdot 1 \mathbf{F})^*, (2 \mathbf{F} \cdot 1 \mathbf{F})^* \cdot 2 \mathbf{F}\}$.

► **Lemma 27.** For a set of propositions Prop , and $\phi \in \text{ATL}^2(\text{Prop}, \{\mathbf{F}\}, \emptyset, \mathbf{B}^1, 0)$, there is an ATL-formula $\phi' \in \text{ATL}_{\mathbf{F}}^2(\text{Prop})$ such that $\phi \equiv \phi'$ and $|\phi'| \leq |\phi|$.

This concludes Step A since the number of formulas of size at most B in $\text{ATL}_{\mathbf{F}}^2(\text{Prop})$ is polynomial in B and $|\text{Prop}|$. As for Step B, in this case it is trivial since checking that an ATL-formula satisfies a structure can always be done in polynomial time.

Proof of P-hardness. In Table 1, we additionally state only that ATL^2 learning with $\mathbf{U}^t \in \{\{\mathbf{F}\}, \{\mathbf{G}\}\}$ is P-hard. The proof of this fact is actually very similar to the proof that CTL learning without the operator \mathbf{X} is NL-hard, except that the reduction is made from the problem of reachability in a turn-based game (which is P-complete [31]).

ATL³ learning with $\mathbf{U}^t \in \{\{\mathbf{F}\}, \{\mathbf{G}\}\}$. Let us consider ATL learning with one more agent, i.e. ATL^3 learning, still with $\mathbf{U}^t \in \{\{\mathbf{F}\}, \{\mathbf{G}\}\}$. The turn-based structures that we consider now use the set of agents $\text{Ag} = \{1, 2, 3\}$. The goal is to show the theorem below.

► **Theorem 28.** For all sets $\mathbf{U}^t \in \{\{\mathbf{F}\}, \{\mathbf{G}\}\}$, $\mathbf{B}^1 \subseteq \text{Op}_{\text{Bin}}^{\text{lg}}$, and bound $n \in \mathbb{N}$, the decision problem $\text{ATL}_{\text{Learn}}^3(\mathbf{U}^t, \emptyset, \mathbf{B}^1, n)$ is NP-hard.

We focus on the case $\mathbf{U}^t = \{\mathbf{F}\}$ (the case $\mathbf{U}^t = \{\mathbf{G}\}$ is analogous since the operators \mathbf{F} and \mathbf{G} have a dual behavior). Once again, let us consider an instance (l, C, k) of the problem Hit. We start right away by defining the ATL^3 -formula associated to a subset $H \subseteq [1, \dots, l]$.

► **Definition 29.** For $H \subseteq [1, \dots, l]$, we let $\phi(l, H, 3)$ denote the ATL^3 -formula defined by $\phi(l, H, 3) := 1 \mathbf{F} \langle \langle A_1 \rangle \rangle \mathbf{F} \cdots 1 \mathbf{F} \langle \langle A_l \rangle \rangle \mathbf{F} p$ where, for all $1 \leq i \leq l$, we have $A_i \in \{\{2\}, \{2, 3\}\}$ and $A_i = \{2, 3\} \mathbf{F}$ if and only if $i \in H$.

For $1 \leq i \leq l + 1$, we let $\phi_i(l, H, 3) := 1 \mathbf{F} \langle \langle A_i \rangle \rangle \mathbf{F} \cdots 1 \mathbf{F} \langle \langle A_l \rangle \rangle \mathbf{F} p$ (with $\phi_{l+1}(l, H, 3) = p$).

Toward Step a, we define $T_{2l+1:1,2}, T_{2(k+1):1,3}$ as negative structures, thus ensuring that a separating formula does not use an operator $\langle \langle A \rangle \rangle \mathbf{F}$ with $1, 2 \in A$, or $1, 3 \in A$. We also define $T_{2l:1,2}$ as a positive structure with the bound $B := 2l + 1$. That way, a separating formula is necessarily $(1, 2, 2l)$ -alternating and only uses the operators $1 \mathbf{F}, 2 \mathbf{F}$, and $2, 3 \mathbf{F}$.

► **Lemma 30.** If a formula $\phi \in \text{ATL}^3(\{\{p\}, \{\mathbf{F}\}, \emptyset, \mathbf{B}^1, n)$ with $|\phi| \leq 2l + 1$ accepts $T_{2l:1,2}$ and rejects $T_{2l+1:1,2}, T_{2(k+1):1,3}$, then there is some $H \subseteq [1, \dots, l]$ such that $\phi = \phi(l, H, 3)$.

Note that, if $|H| \geq k + 1$, then $\phi(l, H, 3)$ is $(1, 3, 2(k + 1))$ -alternating. Therefore, since $T_{2(k+1):1,3}$ is a negative structure, if $\phi(l, H, 3)$ is separating, then $|H| \leq k$, i.e. we have also achieved Step b. Let us now turn to Step c. For all $C \subseteq [1, \dots, l]$, we define the structure $T_{l,C,3}$. An example is given in Figure 8 with $l = 3$. This structure $T_{l,C,3}$ features a sequence of states $q_1^1, q_1^2, \dots, q_l^1, q_l^2$ alternating between Agent-1 and Agent-2 states ending in a self-looping sink q^{lose} . However, the Agent-1 states q_i^1 for which $i \in C$ have an Agent-3 “testing state” q_i^{test} as successor. That state is self-looping and also branches to the structure $T_{(l-i):1,2}$. Note that, given $r \geq i + 1$, the sub-formula $\phi_r(l, H, 3)$ is $(1, 2, l - r + 1)$ -alternating, and therefore satisfies the structure $T_{(l-i):1,2}$, iff $r = i + 1$. Thus, since q_i^{test} is an Agent-3 state, $q_i^{\text{test}} \models \langle \langle A_i \rangle \rangle \mathbf{F} \phi_{i+1}(l, H, 3)$ iff $3 \in A_i$ iff $i \in H$. Thus, we have the following lemma.

► **Lemma 31.** For all $C, H \subseteq [1, \dots, l]$, we have $T_{(l,C,3)} \models \phi(l, H, 3)$ if and only if $C \cap H \neq \emptyset$.

■ **Figure 8** The turn-based structure $T_{3,\{2\},3}$.

This concludes Step c. Overall, we let $\text{In}^{\text{ATL}^{(3),\mathbf{F}}} := (\{p\}, \mathcal{P}, \mathcal{N}, B)$ be an input of the decision problem $\text{ATL}_{\text{Learn}}^3(\{\mathbf{F}\}, \emptyset, \mathbf{B}^1, 0)$ where $\mathcal{P} := \{T_{2l:1,2}, T_{(l,C_i,3)} \mid 1 \leq i \leq n\}$, $\mathcal{N} := \{T_{2l+1:1,2}, T_{2(k+1):1,3}\}$, and $B := 2l + 1$. We have that $\text{In}^{\text{ATL}^{(3),\mathbf{F}}}$ is a positive instance of $\text{ATL}_{\text{Learn}}^3(\{\mathbf{F}\}, \emptyset, \mathbf{B}^1, 0)$ if and only if (l, C, k) is a positive instance of Hit.

5 Future Work

Within our setting, we have covered many cases, as can be seen in Table 1. That is why the complete version of this work [8] is already quite long. However, there are still some cases that we have not tackled. First, there is the case of ATL^2 learning with $\mathbf{U}^t \in \{\{\mathbf{F}, \neg\}, \{\mathbf{G}, \neg\}\}$. We believe that it behaves like the case $\mathbf{F}, \mathbf{G} \in \mathbf{U}^t$, but the proofs would entail many additional technical details, since replacing \mathbf{F} with $\neg \mathbf{G} \neg$ increases the size of the formulas.

More importantly, when considering a bounded amount of binary operators, we have not allowed binary temporal operators ($\mathbf{U}, \mathbf{R}, \mathbf{W}, \mathbf{M}$). Doing so would enhance the expressivity of the fragment that we consider, and we conjecture that we would obtain the same result as in this paper, with proofs that should be only moderately more involved.

On a more high level perspective, in this paper we have focused solely on solving exactly the learning problems and although we have found some relevant tractable cases, many are untractable. A promising research direction would be to look for tractable approximation algorithms, similarly to what is done in [27].

Abstract

The Krohn-Rhodes decomposition theorem is a pivotal result in automata theory. It introduces the concept of *cascade product*, where two semiautomata, that is, automata devoid of initial and final states, are combined in a feed-forward fashion. The theorem states that any semiautomaton can be decomposed into a sequence of permutation-reset semiautomata. For the counter-free case, this decomposition consists entirely of reset components with two states each. This decomposition has significantly impacted recent research in various areas of computer science, including the identification of a class of transformer encoders equivalent to star-free languages and the conversion of Linear Temporal Logic formulas into past-only expressions (pastification).

The paper revisits the cascade product in the context of *reset automata*, thus considering each component of the cascade as a language acceptor. First, we give regular expression counterparts of cascades of reset automata. We then establish several expressiveness results, identifying hierarchies of languages based on the restriction of the height (number of components) of the cascade or of the number of states in each level. We also show that any cascade of reset automata can be transformed, with a quadratic increase in height, into a cascade that only includes two-state components. Finally, we show that some fundamental operations on cascades, like intersection, union, negation, and concatenation with a symbol to the left, can be directly and efficiently computed by adding a two-state component.

1 Introduction

The Krohn-Rhodes decomposition theorem is a fundamental result both in automata theory and in semigroup algebra [12]. It relies on the concept of *cascade product* of two semiautomata, i.e., automata devoid of initial and final states, and thus, ultimately, edge-labeled graphs.

In this setup, the first semiautomaton operates on an alphabet Σ , while the second one reads symbols belonging to the Cartesian product of Σ and the set of states of the first semiautomaton. The key feature of the cascade product, which extends the notion of direct product, is that the second semiautomaton transitions from state s to state s' by reading the pair (σ, q) if and only if the input symbol is σ and the first semiautomaton is in state q .

The Krohn-Rhodes theorem states that any semiautomaton can be decomposed into a *cascade* (i.e., a sequence of cascade products) of *permutation-reset semiautomata*.¹ In such semiautomata, each symbol of the alphabet induces a function on the set of states that is either a *permutation*, i.e., a bijective function, or a *reset*, that is, there is a specific state to which all other states are mapped into when reading that symbol. Crucially, if the semiautomaton is *counter-free*, that is, it does not contain non-trivial cycles [18], the Krohn-Rhodes theorem guarantees the existence of a decomposition that consists of *reset automata* only, i.e., automata where all symbols induce reset functions (as described above) or the identity function.

The Krohn-Rhodes theorem, in particular the decomposition of counter-free automata into reset automata, had a significant impact on some meaningful problems of current research in computer science. A notable example comes from Angluin et al. [1], who employ the Krohn-Rhodes decomposition theorem to prove that Linear Temporal Logic (LTL [19]) is equivalent to transformer encoders with hard attention and strict future masking (see also [13]). Specifically, they show how reset semiautomata can be encoded in **B-RASP**, a minimal programming language that compiles into transformers. Similarly, studies such as [21, 10, 11] utilized this theorem to analyze the sample complexity of cascades and the expressiveness of Recurrent Neural Networks without circular dependencies. Another example is provided by Maler [14, 15], who used the decomposition theorem to transform any formula of LTL, interpreted over finite words, into an equivalent formula using only past operators (see also [20]), a problem now known as *pastification* [2].

In this paper, we revisit the cascade product in the *reset automata* setting, i.e., language acceptors whose underlying semiautomaton is a reset. We address various expressiveness issues for cascade products by themselves and in relation to regular expressions. These results represent a necessary step towards a more efficient exploitation of Krohn-Rhodes decomposition in pastification, with the ultimate goal of lowering its current, triply exponential upper bound, which is far away from the known, singly exponential lower bound.

The paper consists of three main parts. In the first part, we address the question: given a cascade of reset automata, which is its corresponding regular expression? We begin by focusing on cascades of height 1, proving that the language corresponding to a reset automaton over the alphabet Σ is always of the form $J \cup (\Sigma^* \cdot R \cdot I^*)$, for some $I, R \subseteq \Sigma$, such that $I \cap R = \emptyset$ and either $J = I^*$ or $J = \emptyset$. Then, we extend the analysis to cascades of reset automata of arbitrary height. As a first step, we show that the last level can always be transformed into a two-state automaton, and then, by exploiting such a result, we derive the regular expression corresponding to a generic cascade of reset automata.

In the second part, we build on the previously obtained results and establish several expressiveness results about cascades of reset automata. We structure the analysis into three types of cascades:

- (i) short cascades (whose height is bounded by 2),
- (ii) narrow cascades (where each component has two states, but there is not a height limitation), and
- (iii) general cascades (with no limitations on the height or on the number of states per level).

¹ Formally, the decomposition is guaranteed to preserve a homomorphism from the cascade to the initial semiautomaton.

As for short cascades, we prove that any language \mathcal{L} over an alphabet Σ of cardinality k that is definable by a reset cascade of height 2 can also be defined by one where the first component has at most $k + 1$ states. Additionally, we show that increasing the number of states in the first component results in a strict increase in expressiveness: there exists a family of languages which are definable by a two-reset cascade whose first component has n states, but are not definable if the first component is restricted to $n - 1$ states. Similarly, for narrow cascades, we show that increasing the height results in an increase in expressiveness. These two results – the increase in the number of states in the first component for short cascades and the increase in height for narrow cascades – lead to two hierarchies (with infinitely many levels) of languages that are not definable at previous levels. Finally, we show that any general cascade can be transformed into one whose components have all 2 states, with an increase in height of at most a quadratic factor (relative to the height of the original cascade).

In the last part, we deal with closure properties of the languages recognized by reset cascades, and show that some fundamental operations can be computed in an efficient way. More precisely, we prove that the operations of intersection, union, negation, and concatenation with Σ to the left (“next operation”) all require the addition of one component with 2 states only.

The paper is structured as follows. Related work is discussed in Section 2. In Section 3, we provide some background knowledge. In Section 4, we introduce the cascades of reset automata, we state some basic results about them, and we provide a characterization of the languages that they recognize in terms of regular expressions. In Section 5, we present some expressiveness results for short, narrow, and general cascades of reset automata. Section 6 focus on closure properties and the efficient computation of some basic operations. Finally, Section 7 provides an assessment of the work done, and it outlines some directions for future research.

2 Related Work

The Krohn-Rhodes theorem and the cascade product turn out to be quite useful in understanding the structure and the expressiveness of finite-state systems, in particular in the context of automata and neural networks, and their connection to logic. Various recent contributions have leveraged this foundational theory to explore the expressiveness, modularity, and learning potential of automata in such a context.

A pivotal contribution in this area is the work by Maler on the cascade decomposition of semiautomata [14, 15]. It revisits the Eilenberg’s variant of the Krohn-Rhodes theorem [6] and offers a constructive proof that any semiautomaton can be decomposed into a cascade of elementary (permutation and reset) semiautomata. The paper introduces the *holonomy tree* as a data structure to represent cascade decompositions and an algorithm to build such a tree. Crucially, the algorithm carefully maps the permutations of the obtained cascade product to non-trivial cycles of the starting semiautomaton: this guarantees that, whenever the starting semiautomaton is counter-free, that is, devoid of non-trivial cycles, the generated cascade decomposition only consists of reset components. An exponential bound on the size of the cascade decomposition in terms of the size of the starting semiautomaton is given. This algorithm can be used to actually translate counter-free automata to temporal logic. More precisely, Maler shows how to translate any cascade product of reset semiautomata into a pure past LTL formula, that is, a formula featuring only past temporal modalities.

Together with the transformation of the future fragment of LTL, interpreted over finite words, into counter-free automata, this leads to a triply exponential upper bound to the problem of transforming pure-future LTL over finite words into pure-past LTL (pastification problem). Equivalently, in the case of LTL interpreted over infinite words, Maler shows how to use the proposed algorithm to normalize every LTL formula by mapping it into one belonging to the *Reactivity* class [16], at a cost of a triply exponential blowup. For both problems, that is, pastification and normalization, the best known lower bounds are singly exponential [3, 17].

The Krohn-Rhodes theorem has also been applied to analyze the complexity of semigroups, as shown in [9]. This study examines semigroups of upper triangular matrices over finite fields and establishes that the Krohn-Rhodes complexity of these semigroups corresponds to $n - 1$, where n is the matrix dimension. These results underline the deep connection between the algebraic structure of semigroups and their matrix representations, providing a measure of how intricate the cascade product representation needs to be for such semigroups.

In [8], the Krohn-Rhodes theorem is used to characterize piecewise testable and commutative languages. The authors define biased reset semiautomata, where the current state changes at most once, and characterize cascades $\mathcal{A} \circ \mathcal{B}$, where \mathcal{B} is a biased reset semiautomaton. Theorem 4.12 in Section 4 can be seen as a simplification and a generalization (to cascades of unbounded height) of such a characterization. Finally, the authors propose the notion of scope of a cascade, which is used to analyze the dot-depth of star-free languages.

In [21], Ronca builds on the Krohn-Rhodes theorem, proposing automata cascades as a structured and modular framework to describe complex systems. The resulting framework allows automata to be decomposed into components with specific functionalities, enabling fine-grained control of their expressiveness. By focusing on component-based decomposition, the study demonstrates that the sample complexity of learning automata cascades is linear in the number of components and their individual complexities, up to logarithmic factors. This contrasts with traditional state-centric perspectives, where sample complexity scales with the number of states, often limiting the feasibility of learning large systems. The relationships between the cascade product and neural networks are investigated in [10]. Recurrent Neural Cascades (RNCs) are a class of networks with acyclic connections, which naturally align with the cascade product of automata. By exploiting the Krohn-Rhodes theorem, the authors prove that RNCs capture star-free regular languages.

The Krohn-Rhodes theorem also underpins the exploration of transformer models in [13]. While transformers lack recurrence, the paper demonstrates that their layered architecture can simulate the cascade decomposition of finite automata. Leveraging Krohn-Rhodes theory, the authors show that shallow transformers can hierarchically approximate automata computations, enabling polynomial-sized and constant-depth shortcuts for specific automata.

In [1], Angluin et al. draws direct parallels between the expressive power of masked hard-attention transformers and star-free regular languages. These models, constrained by strict future masking, are shown to be equivalent to LTL and counter-free automata – both closely tied to the Krohn-Rhodes cascade framework. The study underscores how the structured limitations of these transformers, akin to a cascade decomposition, yield expressive yet computationally efficient models.

Together, these contributions extend the applicability of the Krohn-Rhodes theory to neural networks, transformers, and beyond, demonstrating the versatility of the cascade framework as a powerful principle in computation.

3 Background

A *semiautomaton* \mathcal{A} is a tuple (Σ, Q, δ) such that:

- (i) Σ is a (finite) alphabet;
- (ii) Q is a set of states;
- (iii) $\delta : Q \times \Sigma \rightarrow Q$ is a transition function.

An *automaton* $\mathcal{A} = (\Sigma, Q, \delta, q_0, F)$ is a semiautomaton extended with an initial state $q_0 \in Q$ and a set $F \subseteq Q$ of final states. With δ^* we denote the Kleene's closure of δ . We say that \mathcal{A} is *two-state* iff $|Q| = 2$.

Given an automaton $\mathcal{A} = (\Sigma, Q, \delta, q_0, F)$ and a (finite) word $\sigma := \langle \sigma_0, \dots, \sigma_n \rangle \in \Sigma^*$, the *run* $\tau \in Q^+$ induced by σ is a sequence $\langle q_0, q_1, \dots, q_{n+1} \rangle$ such that $\delta(q_i, \sigma_i) = q_{i+1}$, for all $0 \leq i \leq n$. We say that τ is *accepting* iff $q_{n+1} \in F$. A word $\sigma \in \Sigma^*$ is *accepted* by \mathcal{A} iff the run induced by σ is accepting. We define the *language of* \mathcal{A} , denoted by $\mathcal{L}(\mathcal{A})$, as the set of accepted words. Given a state $q \in Q$, let $\mathcal{L}_q(\mathcal{A})$ be the set of words inducing a run $\tau := \langle q_0, \dots, q_m \rangle$ with $q_m = q$. The classic *direct product* of automata is defined as follows.

► **Definition 3.1** (Direct product of automata). *Let $\mathcal{A} = (\Sigma, Q, \delta, q_0, F)$ and $\mathcal{A}' = (\Sigma, Q', \delta', q'_0, F')$ be two automata. The direct product of \mathcal{A} and \mathcal{A}' , denoted by $\mathcal{A} \times \mathcal{A}'$, is the automaton $(\Sigma, Q \times Q', \delta'', (q_0, q'_0), F \times F')$ such that, for all $(q, q') \in Q \times Q'$ and for all $a \in \Sigma$, it holds that $\delta''((q, q'), a) = (\delta(q, a), \delta'(q', a))$.*

The cascade product of semiautomata is defined as follows.

► **Definition 3.2** (Cascade Product of semiautomata [15, 22]). *Let Σ be a finite alphabet and let $\mathcal{A} = (\Sigma, Q, \delta)$ and $\mathcal{A}' = (\Sigma \times Q, Q', \delta')$ be two semiautomata over the alphabets Σ and $\Sigma \times Q$, respectively. We define the cascade product between \mathcal{A} and \mathcal{A}' , denoted with $\mathcal{A} \circ \mathcal{A}'$, as the semiautomaton $(\Sigma, Q \times Q', \delta'')$ such that, for all $(q, q') \in Q \times Q'$ and for all $a \in \Sigma$:*

$$\delta''((q, q'), a) = (\delta(q, a), \delta'(q', (a, q)))$$

We will often simply use “*cascade*” for “*cascade product*”.

It is worth noticing that the cascade product of semiautomata is a generalization of the classic direct product: the latter can be recovered by imposing the alphabet of the second semiautomaton to be Σ (i.e., the alphabet of the first one) instead of $\Sigma \times Q$.

The cascade product is an *associative* operation, meaning that $(\mathcal{A} \circ \mathcal{A}') \circ \mathcal{A}''$ is the same semiautomaton as $\mathcal{A} \circ (\mathcal{A}' \circ \mathcal{A}'')$. We define the *height* of the product $\mathcal{A}_1 \circ \dots \circ \mathcal{A}_n$ as n .

We now introduce two classes of semiautomata, *reset* and *permutation*, depending on the form of their transitions. We first define the notion of *function induced by a symbol*.

► **Definition 3.3** (Function induced by a symbol). *Let $\mathcal{A} = (\Sigma, Q, \delta)$ be a semiautomaton. For each symbol $a \in \Sigma$, we define the function induced by a in \mathcal{A} , denoted by $\tau_a^{\mathcal{A}}$ (or simply τ_a when \mathcal{A} is clear from the context), as the transformation $\tau_a : Q \rightarrow Q$ such that, for all $q \in Q$, it holds $\tau_a(q) = q'$ iff $\delta(q, a) = q'$.*

Reset and permutation functions are defined as follows.

► **Definition 3.4** (Reset and permutation functions). *Let $\tau : Q \rightarrow Q$. We say that τ is a reset function iff there exists $q' \in Q$ such that $\tau(q) = q'$, for all $q \in Q$. In this case, we say that τ is a reset on q' . If $\tau : Q \rightarrow Q$ is a bijection, then it is called a permutation.*

On the basis of the functions induced by the symbols of their alphabet, we define the following classes of semiautomata.

► **Definition 3.5** (Classes of semiautomata). Let $\mathcal{A} = (\Sigma, Q, \delta)$ be a semiautomaton. We say that \mathcal{A} is:

- a permutation-reset semiautomaton iff, for each $a \in \Sigma$, τ_a is either a permutation or a reset.
- a permutation semiautomaton iff, for each $a \in \Sigma$, τ_a is a permutation;
- a reset semiautomaton iff, for each $a \in \Sigma$, τ_a is either the identity function or a reset function;
- a pure-reset semiautomaton iff, for each $a \in \Sigma$, τ_a is a reset function.

We now introduce counter-free semiautomata [18]. Let $\sigma \in \Sigma^*$. From now on, we denote by $(\sigma)^i$ the word generated by concatenating i times the word σ to itself. A word $\sigma \in \Sigma^*$, with $\sigma \neq \varepsilon$, defines a *nontrivial cycle* in a semiautomaton $\mathcal{A} = (\Sigma, Q, \delta)$ if there exists a state $q \in Q$ such that:

- (i) $\delta^*(q, \sigma) \neq q$
- (ii) $\delta^*(q, (\sigma)^i) = q$, for some $i > 1$.

We say that a semiautomaton \mathcal{A} is *counter-free* if there are no words that define a nontrivial cycle. Counter-free automata recognize exactly the set of languages definable by *star-free* regular expressions, i.e., expressions devoid of Kleene's star. We denote this set by \mathcal{SF} .

A fundamental result in the field is the Krohn-Rhodes Cascade Decomposition Theorem. The theorem's initial formulation was expressed in the context of semigroups [12], and its automata-theoretic counterpart [14] can be articulated as follows.

► **Theorem 3.6** (The Krohn-Rhodes Cascade Decomposition Theorem [12, 14]). For each semiautomaton $\mathcal{A} = (\Sigma, Q, \delta)$, there exists a cascade product of semiautomata $\mathcal{C} := \mathcal{A}_1 \circ \mathcal{A}_2 \circ \dots \circ \mathcal{A}_n$ such that:

- (i) \mathcal{A}_i is a permutation-reset semiautomaton, for each $1 \leq i \leq n$;
- (ii) there is an homomorphism² from \mathcal{C} to \mathcal{A} ;
- (iii) if \mathcal{A} is counter-free, then \mathcal{A}_i is a two-state reset semiautomaton, for each $1 \leq i \leq n$.

4 Cascades of automata

In this section, we begin our study of the languages recognized by cascades of automata. We start by formally defining them and stating some basic properties. Then, we focus on cascades of reset automata, and provide a characterization of the languages they recognize in terms of regular expressions.

4.1 Definitions and basic properties

To begin with, we generalize the notion of cascade product of semiautomata (Definition 3.2) to automata.

► **Definition 4.1** (Cascade product of automata). Let Σ be a finite alphabet and let $\mathcal{A} = (\Sigma, Q, \delta, q_0, F)$ and $\mathcal{A}' = (\Sigma \times Q, Q', \delta', q'_0, F')$ be two automata over the alphabets Σ and $\Sigma \times Q$, respectively. We define the cascade product of \mathcal{A} and \mathcal{A}' , denoted by $\mathcal{A} \circ \mathcal{A}'$, as the automaton $(\Sigma, Q \times Q', \delta'', (q_0, q'_0), F \times F')$ where δ'' is defined as in Definition 3.2.

We say that a language \mathcal{L} is *definable* by a cascade \mathcal{C} iff $\mathcal{L} = \mathcal{L}(\mathcal{C})$. Figure 1 shows the cascade product of two reset automata defining the language $a \cdot \Sigma^*$.

² We refer to [12, 14] for a formal definition of homomorphism between semiautomata.

■ **Figure 1** The reset automaton \mathcal{A}_1 with set of states $Q = \{q_0, q_1\}$ over the alphabet $\Sigma = \{a, b\}$ (left). The reset automaton \mathcal{A}_2 over the alphabet $\Sigma \times Q$ (middle). The cascade product $\mathcal{A}_1 \circ \mathcal{A}_2$ over the alphabet Σ that recognizes the languages $a \cdot \Sigma^*$ (right).

In the following, we will use the term cascade to refer both to the component automata and to the resulting automaton.

We now show how to compute the language recognized by a cascade of automata on the basis of the languages recognized by its components. Let Σ_1 and Σ_2 be two alphabets. Let $\sigma^1 = \sigma_1^1 \dots \sigma_n^1 \in (\Sigma_1)^n$ and $\sigma^2 = \sigma_1^2 \dots \sigma_n^2 \in (\Sigma_2)^n$ be two words of length n . We define $\text{aug}(\sigma^1, \sigma^2) \in (\Sigma_1 \times \Sigma_2)^n$ as the word $(\sigma_1^1, \sigma_1^2) \dots (\sigma_n^1, \sigma_n^2)$.

▶ **Definition 4.2** (Language of \mathcal{B} at a state s over \mathcal{A}). Let $\mathcal{A} = \langle \Sigma, Q, \delta_A, q_0, F_A \rangle$ and $\mathcal{B} = \langle \Sigma \times Q, S, \delta_B, s_0, F_B \rangle$ be two automata. The language of \mathcal{B} at state $s \in S$ over \mathcal{A} , denoted by $\mathcal{L}_s(\mathcal{B})[\mathcal{A}]$, is defined as follows: the empty word only belongs to $\mathcal{L}_{s_0}(\mathcal{B})[\mathcal{A}]$; a word $\sigma = \sigma_1 \dots \sigma_k$, with $k \geq 1$, belongs to $\mathcal{L}_s(\mathcal{B})[\mathcal{A}]$ if

- (i) $\sigma_1 \dots \sigma_{k-1}$ induces a run $\tau = \langle q_0, q_1, \dots, q_{k-1} \rangle$ on \mathcal{A} ; and
- (ii) $\text{aug}(\sigma, \tau) \in \mathcal{L}_s(\mathcal{B})$.

The language of a cascade can be computed from those of its components as follows. Let $\mathcal{C} = \mathcal{A} \circ \mathcal{B}$ be a cascade. The words forcing \mathcal{C} to reach a state (q, s) are exactly those words such that:

- (i) they force \mathcal{A} to reach state q ; and
- (ii) they force \mathcal{B} to reach state s , when augmented with the run of \mathcal{A} .

▶ **Proposition 4.3** (Language of a cascade in terms of its components). Let $\mathcal{A} = \langle \Sigma, Q, \delta_A, q_0, F_A \rangle$ and $\mathcal{B} = \langle \Sigma \times Q, S, \delta_B, s_0, F_B \rangle$ be two automata. It holds that:

1. $\mathcal{L}_{(q,s)}(\mathcal{A} \circ \mathcal{B}) = \mathcal{L}_q(\mathcal{A}) \cap \mathcal{L}_s(\mathcal{B})[\mathcal{A}]$, for all states $q \in Q$ and $s \in S$;
2. $\mathcal{L}(\mathcal{A} \circ \mathcal{B}) = \bigcup_{(q,s) \in F} \mathcal{L}_{(q,s)}(\mathcal{A} \circ \mathcal{B})$.

We now show that, as it happens with semiautomata, the direct product of automata is just a special case of the cascade product. To this end, we first define the notion of augmentation of an automaton.

▶ **Definition 4.4** (Augmentation). Let $\mathcal{A} = \langle \Sigma, Q, \delta, q_0, F \rangle$ and $\mathcal{A}' = \langle \Sigma', Q', \delta', q'_0, F' \rangle$ be two automata such that either $\Sigma' = \Sigma$ or $\Sigma' = \Sigma \times S$, for an arbitrary finite set S . We define the augmentation of \mathcal{A}' relative to \mathcal{A} , denoted by $\text{aug}(\mathcal{A}, \mathcal{A}')$, as the automaton $(\Sigma'', Q', \delta'', q'_0, F')$ such that:

- if $\Sigma' = \Sigma$, then $\Sigma'' := \Sigma \times Q$ and for all $q \in Q'$ and all $a \in \Sigma$, $\delta''(q, (a, *)) = \delta'(q, a)$;
- if $\Sigma' = \Sigma \times S$, then $\Sigma'' := \Sigma \times Q \times S$ and, for all $q \in Q'$ and for all $(a, s) \in \Sigma \times S$, it holds that $\delta''(q, (a, *, s)) = \delta'(q, (a, s))$.

Given a cascade $\mathcal{C} = \mathcal{A}'_1 \circ \dots \circ \mathcal{A}'_n$ over Σ , we define the augmentation of \mathcal{C} relative to \mathcal{A} , denoted by $\text{aug}(\mathcal{A}, \mathcal{C})$, as the cascade $\text{aug}(\mathcal{A}, \mathcal{A}'_1) \circ \dots \circ \text{aug}(\mathcal{A}, \mathcal{A}'_n)$.

The notion of augmentation can be generalized to a pair of cascades \mathcal{C} and \mathcal{C}' by treating \mathcal{C} as a single automaton: from now on, when we will refer to the cascade product of \mathcal{C} and \mathcal{C}' , we will interpret it as the cascade product of the automaton \mathcal{A} generated by \mathcal{C} and \mathcal{C}' .

The next proposition shows that direct product can be simulated by means of augmentation and cascade product.

► **Proposition 4.5** (Direct product by means of cascade product). *Let $\mathcal{A} = \langle \Sigma, Q, \delta, q_0, F \rangle$ be an automaton and let \mathcal{C} be a cascade over Σ . It holds that $\mathcal{A} \circ \text{aug}(\mathcal{A}, \mathcal{C}) = \mathcal{A} \times \mathcal{C}$.*

Furthermore, augmenting an automaton does not affect its property of being *reset* (or *permutation*), as stated by the following Proposition 4.6.

► **Proposition 4.6.** *Let Σ be a finite alphabet and let \mathcal{A} be an automaton over Σ or $\Sigma \times S$, for an arbitrary finite set S . If \mathcal{A} is a reset (resp., permutation) automaton, then, for any automaton \mathcal{A}' over Σ , $\text{aug}(\mathcal{A}', \mathcal{A})$ is a reset (resp., permutation) automaton.*

It follows that, in particular, if \mathcal{C} is a cascade of reset (resp., permutation) automata, then $\text{aug}(\mathcal{A}, \mathcal{C})$ is a cascade of reset (resp., permutation) automata. From Propositions 4.5 and 4.6, it follows directly that, given two cascades \mathcal{C} and \mathcal{C}' of height m and n of reset (resp., permutation) automata, there exists a cascade of height $m + n$ of reset (resp., permutation) automata for $\mathcal{L}(\mathcal{C}) \cap \mathcal{L}(\mathcal{C}')$. In Section 6, we will show how to compute other basic operations on cascades of resets.

4.2 Languages of cascades of resets

In this part, we characterize the language recognized by a cascade of reset automata in terms of regular expressions. We begin with the case of cascades of height 1 and then we move to cascades of unbounded height.

4.2.1 Cascades of height 1

The study of which regular expressions characterize height-1 cascades of resets coincides with the study of the languages recognized by *reset automata*. The following theorem gives a characterization of reset automata in terms of regular expressions.

► **Theorem 4.7** (The languages of reset automata). *Let Σ be a finite alphabet. A language $\mathcal{L} \subseteq \Sigma^*$ is recognized by a reset automaton if and only if $\mathcal{L} = J \cup (\Sigma^* \cdot R \cdot I^*)$ for some $I, R \subseteq \Sigma$ such that $I \cap R = \emptyset$ and either $J = I^*$ or $J = \emptyset$.*

Intuitively, an automaton reading a symbol that induces a reset function on a final state is forced to end up in that state, regardless of which state it was in before. Furthermore, it remains in that state if all subsequent symbols induce identity functions. In the case of words containing multiple resets on a final state, only the last of these symbols matters, resulting in words of the form $\Sigma^* \cdot R \cdot I^*$. The case of $J = I^*$ arises when the initial state is also final. In this scenario, to accept a word, the automaton does not need to read a symbol that induces a reset on a final state (since it is already there), but only needs to stay in the initial state.

A by-product of Theorem 4.7 is that any reset automaton is equivalent to one with two states, only one of which is final. The rationale is as follows:

- (i) the symbols in R induce a reset on the single final state;
- (ii) the symbols in I act as identities; and
- (iii) the symbols neither in R nor in I induce resets on the single non-final state.

■ **Figure 2** The reset automaton corresponding to a language of the form $J \cup (\Sigma^* \cdot R \cdot I^*)$ in the case $J = \emptyset$ (on the left) and in the case $J = I^*$ (on the right).

Moreover, the initial state is also the final state if and only if $J = I^*$. A graphical account is given in Figure 2.

► **Proposition 4.8.** *For every reset automaton, there exists an equivalent one with two states, exactly one of which is final.*

Theorem 4.7 allows us to establish a first connection between *Linear Temporal Logic on finite traces* (LTLf [5]) formulas and equivalent reset cascades. As highlighted in the introduction, the languages expressible in LTLf are exactly the star-free languages, that is, those languages that can be represented by regular expressions that do not use the Kleene star, or equivalently, by languages whose minimal automaton is counter-free [18]. By Krohn-Rhodes' theorem (Theorem 3.6), it follows that the languages definable in LTLf are precisely those expressible through cascades of resets. Given the relevance of reset cascade decomposition in problems such as *pastification* [2, 4] and *normalization* [7] of temporal logic formulas, it is crucial to understand which LTLf formulas can be expressed with cascades of a specific height. The following result shows that even simple formulas like p (the proposition letter “p” holds at the initial time point) or $p \cup q$ (there is a future point where “q” holds, and until then, “p” remains true) cannot be expressed with cascades of resets of height 1. In fact, the languages they recognize³ are respectively $\vec{p} \cdot \Sigma^*$ and $(\vec{p})^* \cdot \vec{q} \cdot \Sigma^*$, which are not of the form $J \cup (\Sigma^* \cdot R \cdot I^*)$, for any choice of R , I , and J . However, the formula $\text{F}p$ (there exists a point in the future where “p” holds) can be expressed with reset cascades of height 1, as its language is of the form $J \cup (\Sigma^* \cdot R \cdot I^*)$, choosing $R := \vec{p}$, $I := \Sigma \setminus \vec{p}$, and $J = \emptyset$.

► **Corollary 4.9.** *The languages defined by the LTLf formulas p and $p \cup q$ are not definable with height-1 cascades of resets.*

4.2.2 Cascades of unbounded-height

In this section we derive regular expressions for cascades of arbitrary height. As a first step, we show that a cascade of height h of reset automata, say $\mathcal{A}_1 \circ \dots \circ \mathcal{A}_h$, can be transformed into an equivalent cascade of the same height, still consisting of reset automata, where the last automaton (\mathcal{A}_h) has exactly two states, one of which is the only accepting state. This result forms the basis for Theorem 4.12, which provides the characterization of cascades of arbitrary height.

► **Lemma 4.10.** *Let \mathcal{A} be an automaton with set of states Q over the alphabet Σ , and let \mathcal{B} be a reset automaton over the alphabet $\Sigma \times Q$. There exists a 2-states reset automaton \mathcal{B}' , with exactly one final state, such that $\mathcal{L}(\mathcal{A} \circ \mathcal{B}) = \mathcal{L}(\mathcal{A} \circ \mathcal{B}')$.*

³ Here, assuming a set of atomic propositions $\mathcal{AP} := \{p, q, r, \dots\}$, the languages of formulas over \mathcal{AP} are defined over the alphabet $\Sigma := 2^{\mathcal{AP}}$. Moreover, given any $p \in \mathcal{AP}$, we indicate with \vec{p} all the letters $a \in \Sigma$ such that $p \in a$.

20:10 On Cascades of Reset Automata

The proof of Lemma 4.10 heavily relies on the characterization of cascades of height 1. More precisely, since \mathcal{B} is a reset automaton over the alphabet $\Sigma \times Q$, by Proposition 4.8, there exists an equivalent reset automaton with two states (one of which is the only accepting state) over the same alphabet. Since \mathcal{B} is at the bottom of the cascade, the language of the cascade $\mathcal{A} \circ \mathcal{B}'$ is the same as the language of $\mathcal{A} \circ \mathcal{B}$. This is because there are no other automata below \mathcal{B} in the cascade that can exploit information about \mathcal{B} 's current state. As a matter of fact, in Section 5, we will prove that this is no longer true when applying the same procedure to \mathcal{A} : there exist languages definable by a cascade $\mathcal{A} \circ \mathcal{B}$, where \mathcal{A} has 3 states and \mathcal{B} has 2 states, that cannot be expressed if the number of states of \mathcal{A} is limited to 2.

Let us now introduce the notion of *filtered automaton*, which is obtained from a given automaton by removing (filtering) certain outgoing transitions and possibly changing its initial state.

► **Definition 4.11** (Filtered Automaton). *Let $\mathcal{A} = \langle Q, \Sigma, q_0, \delta, F \rangle$ be an automaton. A filter is pair (q, H) , where $q \in Q$ and $H \subseteq \Sigma \times Q$. The partial automaton \mathcal{A} , filtered by (q, H) , denoted as $\mathcal{A} \downarrow_H^q$, is the automaton $(Q, \Sigma, q, \delta', F)$ where $\delta'(q', \sigma) := \delta(q', \sigma)$ if $(\sigma, q') \in H$, or is undefined otherwise.*

Before formally stating Theorem 4.12, that characterizes the languages of cascades of unbounded-height, we give an intuitive account of it. Let $\mathcal{A} \circ \mathcal{B}$ be a cascade, with \mathcal{A} an automaton and \mathcal{B} a reset automaton, where, w.l.o.g. (Lemma 4.10), \mathcal{B} has only two states and exactly one final state. Any word accepted by $\mathcal{A} \circ \mathcal{B}$ must drive both \mathcal{A} and \mathcal{B} to an accepting state. Its language can be captured by analyzing the symbols inducing a reset function that leads to a final state of \mathcal{B} , and the symbols inducing identities in \mathcal{B} . The words in the language of $\mathcal{A} \circ \mathcal{B}$ are precisely those consisting of

- (i) a *prefix* that, for any symbol (σ, q) inducing a reset on a final state of \mathcal{B} , drives automaton \mathcal{A} to state q ;
- (ii) followed by the symbol $\sigma \in \Sigma$ (let q_σ be the state reached by \mathcal{A} after reading it);
- (iii) a *suffix* that forces \mathcal{B} to remain in its accepting state through its identity functions I_B , and forces \mathcal{A} to reach a final state starting from q_σ .

In addition, \mathcal{A} cannot transition from state q' when reading a symbol σ' if the pair (σ', q') does not belong to \mathcal{B} 's identity functions, as this would cause \mathcal{B} to leave its accepting state. Therefore, the suffix corresponds to the language of automaton \mathcal{A} , filtered by $(\delta_A(q, \sigma), I_B)$. This is formally expressed by the following theorem.

► **Theorem 4.12** (Languages of cascades of unbounded-height). *Let $\mathcal{A} = \langle \Sigma, Q = \{q_0, \dots, q_n\}, \delta_A, q_0, F_A \rangle$ be an automaton and let $\mathcal{B} = \langle \Sigma \times Q, \{s_0, s_1\}, \delta, s_0, \{s_f\} \rangle$, with $s_f \in \{s_0, s_1\}$, be a two-state reset automaton with one final state. It holds that:*

$$\mathcal{L}(\mathcal{A} \circ \mathcal{B}) = M \cup \bigcup_{(\sigma, q) \in R_{s_f}} \mathcal{L}_q(\mathcal{A}) \cdot \sigma \cdot \mathcal{L}(\mathcal{A} \downarrow_{I_B}^{\delta_A(q, \sigma)})$$

where R_{s_f} is the set of symbols in $\Sigma \times Q$ that induce a reset function on state s_f , and $M := \mathcal{L}(\mathcal{A} \downarrow_{I_B}^{q_0})$ if $s_0 = s_f$ or $M := \emptyset$ otherwise.

Figure 3 gives an example of application of Theorem 4.12 to a cascade over the alphabet $\Sigma := \{a, b\}$ of two reset automata, \mathcal{A} (on the left) and \mathcal{B} (on the center), with two states each, recognizing the language $b^* \cdot a^+$. Using Theorem 4.12, we have that $\mathcal{L}(\mathcal{A} \circ \mathcal{B}) = \mathcal{L}_{q_0}(\mathcal{A}) \cdot a \cdot \mathcal{L}(\mathcal{A} \downarrow_{I_B}^{q_1})$, where $\mathcal{A} \downarrow_{I_B}^{q_1}$ is the automaton obtained from \mathcal{A} filtered by the identities $I_B = \{(a, q_1), (b, q_0)\}$ of automaton \mathcal{B} . Since $\mathcal{L}_{q_0}(\mathcal{A}) = b^*$ and $\mathcal{L}(\mathcal{A} \downarrow_{I_B}^{q_1}) = a^*$, we obtain $\mathcal{L}(\mathcal{A} \circ \mathcal{B}) = b^* \cdot a^+$. The following is a corollary of Theorem 4.12 in the case in which \mathcal{B} is a pure-reset automaton.

Figure 3 On the left and on the center, the reset automata \mathcal{A} and \mathcal{B} , respectively, for the cascade $\mathcal{A} \circ \mathcal{B}$ recognizing the language $b^* \cdot a^+$. On the right, the automaton $\mathcal{A} \downarrow_{I_B}^{s_1}$, where $I_B = \{(a, q_1), (b, q_0)\}$ are the identities of automaton \mathcal{B} .

► **Corollary 4.13.** *Let $\mathcal{A} = \langle \Sigma, \{q_0, \dots, q_n\}, \delta_A, q_0, F_A \rangle$ be an automaton and let $\mathcal{B} = \langle \Sigma \times Q, \{s_0, s_1\}, \delta, s_0, \{s_f\} \rangle$ be a two-state pure-reset automaton with one final state. It holds that*

$$\mathcal{L}(\mathcal{A} \circ \mathcal{B}) = M \cup \bigcup_{\substack{(\sigma, q) \in R_{s_f} \\ \delta_A(q, \sigma) \in F_A}} \mathcal{L}_q(\mathcal{A}) \cdot \sigma$$

where $M := \epsilon$ if $s_0 = s_f$ and $q_0 \in F_A$, or $M := \emptyset$ otherwise.

It is worth noticing that the regular expressions in Theorem 4.12 and Corollary 4.13 refer to states of the cascade under consideration. This is a major difference with the characterization of reset cascades of height 1 (Theorem 4.7). In order to prove some undefinability results in the next section, we provide a characterization of the languages recognized by cascades of two-states resets of height 2 where the second component is pure-reset, based on regular expressions that do not refer to states of the cascade.

► **Lemma 4.14.** *Let $\mathcal{L} \subseteq \Sigma^*$ be a language. \mathcal{L} is definable by a cascade of height 2 in which the second component is pure-reset if and only if $\mathcal{L} = M \cup \bigcup_{i=1}^n K_i \cdot \sigma_i$ for some M, n, σ_i and K_i such that:*

- (i) M is either ϕ or ϵ ;
- (ii) $0 \leq n \leq 2 \cdot |\Sigma|$;
- (iii) for all $i = 1 \dots n$ it holds $\sigma_i \in \Sigma$;
- (iv) there exists a language L recognizable by a two-state reset automaton such that for all $i = 1 \dots n$, either K_i is L or K_i is $\bar{L} = \Sigma^* \setminus L$.

Notice that the Lemma above can be easily extended to the case in which the first automaton in the cascade has k states, for some $k \geq 2$. This is done by relaxing (iv) and imposing that K_i can be chosen between k languages K_1, \dots, K_k such that $\{K_1, \dots, K_k\}$ is a partition of Σ^* and each K_i is definable by a cascade of resets of height 1. Constraint (ii) is also relaxed to $0 \leq n \leq k \cdot |\Sigma|$.

We will use Theorem 4.12, Corollary 4.13, and Lemma 4.14 in the next section to prove undefinability results of certain languages by cascades of a given height and with a specified number of states at each level.

5 Expressiveness results

In this section, we analyze the expressive power of various types of reset automaton cascades. We begin by defining several language classes, and subsequently structure our analysis into *short cascades* (where the height is constrained to at most two), *narrow cascades* (where the height is unbounded but each component contains two states), and *general cascades* (with no restrictions on either the height or the number of states).

■ **Figure 4** Summary of (some of) the results in Section 5.

► **Definition 5.1** (Classes \mathcal{R} and \mathcal{RPR}). Let $h \in \mathbb{N}^{>0}$ and let $k_1, \dots, k_h \in \mathbb{N}^{>1}$. We denote by $\mathcal{R}(k_1, \dots, k_h)$ the class of languages definable by a cascade $\mathcal{A}_1 \circ \dots \circ \mathcal{A}_h$ of reset automata such that \mathcal{A}_i has k_i states, for each $1 \leq i \leq h$. We denote by $\mathcal{RPR}(k_1, \dots, k_h)$ the subclass of $\mathcal{R}(k_1, \dots, k_h)$ where the last automaton (\mathcal{A}_h) is required to be pure-reset. For $h > 0$ and $k > 1$, we define $\mathcal{R}_k^h := \bigcup_{2 \leq k_1, \dots, k_h \leq k} \mathcal{R}(k_1, \dots, k_h)$ as the set of languages definable by a cascade of height h , where each component has at most k states. We define $\mathcal{R} := \bigcup_{h > 0, k > 1} \mathcal{R}_k^h$ as the set of languages definable by any cascade of reset automata. The classes \mathcal{RPR}_k^h and \mathcal{RPR} are defined analogously.

Figure 4 provides an overview of (some of) the results presented in this section. Specifically, it illustrates that increasing the cascade height and increasing the number of states at the first level lead to two distinct language hierarchies.

5.1 Short Cascades

We begin by considering *short* cascades, i.e. cascades of reset automata of height 2. As a first step, we start by comparing the classes $\mathcal{R}(2), \mathcal{RPR}(2, 2)$ and $\mathcal{R}(2, 2)$, and then we focus on $\mathcal{RPR}(k, 2)$ and $\mathcal{R}(k, 2)$ for every $k > 2$.

We already know that with a single pure-reset automaton we can recognize the set of all words ending with a certain symbol of the alphabet (this follows from Theorem 4.7 in the special case in which $I = \emptyset$). As an example, it holds that $\Sigma^*a \in \mathcal{RPR}(2)$. Now, if we introduce an additional pure-reset layer, we can effectively recognize the set of words ending with a *two-character suffix*. However, we also demonstrate that this is impossible using a single reset automaton.

► **Lemma 5.2.** Let $L = \Sigma^*aa$. It holds that:

- (i) $L \in \mathcal{RPR}(2, 2)$;
- (ii) $L \notin \mathcal{R}(2)$.

Lemma 5.2 shows that increasing the height of a cascade, even of height 1 and even with a pure-reset automaton, results into a gain of expressive power.

In the upcoming lemma, we demonstrate that, at the same height, prohibiting identities in the final layer results in a loss of expressive power. To illustrate this, let us consider the language $a \cdot \Sigma^*$. As shown in Figure 1, this language can be defined using a cascade of two reset

■ **Figure 5** On the left, the reset automaton \mathcal{A} and on the right the reset automaton \mathcal{B} such that, for $\Sigma = \{a, b, c\}$, the cascade $C := \mathcal{A} \circ \mathcal{B}$ accepts the language $\Sigma^* (\Sigma^2 \setminus \{aa, bb, cc\}) \cup \{b, c\}$, which precisely corresponds to the language L_3 described in Lemma 5.4. When viewed as a single automaton, C is also the minimal automaton for the language L_3 .

automata, with the last one specifically containing identities. Building upon Lemma 4.14, we further demonstrate that achieving the same language recognition is not possible when prohibiting identities in the final layer, no matter of the number of states of the first automaton.

- **Lemma 5.3.** *Let Σ be an alphabet with at least two symbols, let $L = a\Sigma^*$. It holds that:*
- (i) $L \in \mathcal{R}(2, 2)$;
 - (ii) $L \notin \mathcal{RPR}(k, 2)$, for every $k \geq 2$.

In Lemma 4.10, we have shown that the final component of a cascade can always be restricted to two states. A natural question arises: *Can the first component also be limited to just two states?* The answer is negative, as illustrated by the following example. Consider an alphabet of three symbols and the language L consisting of all words that end with two distinct symbols (e.g. $cb \in L$ but $aa \notin L$). As demonstrated in Figure 5, this language can be recognized by a cascade of two reset automata where the first component has three states. However, we will prove that it cannot be recognized if the first component has only two states. Intuitively, the first component’s role is to remember the second-to-last symbol, but with an alphabet of three symbols and only two states, this task becomes impossible. The following *Width-Hierarchy Lemma* formalizes this intuition, demonstrating the existence of an infinite hierarchy of languages that can be defined using cascades of two resets where the first component contains k states, but cannot be defined when the first component is restricted to $k - 1$ states.

- **Lemma 5.4 (Width-Hierarchy Lemma).** *For each $k > 2$, let $\Sigma = \{\sigma_0, \dots, \sigma_{k-1}\}$. Let $L_k = \Sigma^* (\Sigma^2 \setminus \bigcup_{0 \leq i < k} \sigma_i \sigma_i) \cup (\Sigma \setminus \sigma_0)$, it holds that:*
- (i) $L_k \in \mathcal{RPR}(k, 2)$;
 - (ii) $L_k \notin \mathcal{R}(k - 1, 2)$.

The following corollary (depicted in Figure 4) follows from Lemmas 5.2–5.4.

- **Corollary 5.5.** *It holds that:*
- $\emptyset \subsetneq \mathcal{R}(2) \subsetneq \mathcal{RPR}(2, 2) \subsetneq \mathcal{R}(2, 2)$;
 - $\mathcal{RPR}(3, 2) \not\subseteq \mathcal{R}(2, 2)$ and $\mathcal{R}(2, 2) \not\subseteq \mathcal{RPR}(3, 2)$.

Additionally, we prove that for a fixed alphabet Σ of cardinality k , any language over Σ expressible by a cascade of height 2 can also be expressed by a cascade of height 2 where the first component has at most $k + 1$ states. The intuition behind this is that, due to

■ **Figure 6** The cascade $C := \mathcal{A} \circ \mathcal{B}$ accepts the language $L'_3 := \Sigma^* (\Sigma^2 \setminus \{aa, bb, cc\})$. When treated as a single automaton, C consists of 8 states, in contrast to the minimal automaton for L'_3 , which has only 7 states.

the restriction of transitions to resets or identities, only a finite number of states can be reached from the initial state. This is formalized in the next lemma, which also establishes the optimality of the bound on the number of states of the first component.

► **Lemma 5.6.** *Let Σ be a finite alphabet with size $|\Sigma| = k$. Let L be a language such that $L \subseteq \Sigma^*$. For every $m \in \mathbb{N}^{>0}$, if $L \in \mathcal{R}(m, 2)$, then $L \in \mathcal{R}(k + 1, 2)$. Furthermore, there exists a language $L'_k \subseteq \Sigma^*$ such that $L'_k \in \mathcal{R}(k + 1, 2)$ but $L'_k \notin \mathcal{R}(k, 2)$.*

The language L'_k used to prove the optimality of the bound in Lemma 5.6 is defined as $\Sigma^* (\Sigma^2 \setminus \bigcup_{0 \leq i < k} \sigma_i \sigma_i)$. As an example, Figure 6 shows the case of L'_3 .

5.2 Narrow Cascades

Thus far, our discussion has centered around cascades composed of one or two components. Now, we shift our focus to *narrow cascades*, i.e. cascades of greater height but in which each component is restricted to have two states (i.e. \mathcal{R}_2^h). Just as we have seen that some languages cannot be expressed by cascades of height 1, we will demonstrate that for any given height, there exists a language that cannot be captured at that height, provided the components of the cascade are restricted to two states. We call this the *Height-Hierarchy Lemma*, and is a counterpart of the Width-Hierarchy Lemma (Lemma 5.4) focused on the height of cascades. It is based on the following family of languages: for each $h \geq 2$, we consider the language $L_h = \Sigma^{h-2} a \Sigma^*$, that is all words that contain symbol “a” precisely at position $h - 1$. The Height-Hierarchy Lemma below proves that, for any $h \geq 2$, the language L_h is *not* definable by cascades of two states reset automata of height less than h .

► **Lemma 5.7 (Height-Hierarchy Lemma).** *For each $h \geq 2$, let $L_h = \Sigma^{h-2} a \Sigma^*$. It holds that:*

- (i) $L_h \in \mathcal{R}_2^h$;
- (ii) $L_h \notin \mathcal{R}_2^{h-1}$.

■ **Figure 7** Switch automaton.

We briefly explain the intuition behind Lemma 5.7. Regarding point (i) $L_h \in \mathcal{R}_2^h$, the construction of the two-state reset cascade proceeds as follows. The base case corresponds to Figure 1, while the inductive step for height h involves the use of the two-state reset automaton \mathcal{A}_{switch} (illustrated in Figure 7) in cascade with the augmentation of the cascade for the case $h - 1$. Intuitively, \mathcal{A}_{switch} recognizes all words containing at least one symbol. Using in cascade $h - 2$ copies of \mathcal{A}_{switch} together with the cascade in Figure 1, corresponds exactly to the language $\Sigma^{h-2}a\Sigma^*$. In Figure 8, we provide an example of the construction for the case $h = 3$.

The proof that $L_h \notin \mathcal{R}_2^{h-1}$ is more involved and proceeds by induction on h . For the base case ($h = 2$), we have $L_2 = a\Sigma^*$. This case is verified by Lemma 5.3. For the inductive step, assume that the statement holds for every $i \leq h$. We need to prove that it also holds for $i = h + 1$. Suppose, by contradiction, that $L_{h+1} \in \mathcal{R}_2^h$. By definition, this would imply the existence of a cascade $C = \mathcal{A}_1 \circ \dots \circ \mathcal{A}_h$ of two-state reset automata such that $\mathcal{L}(C) = L_{h+1} = \Sigma^{h-1}a\Sigma^*$. However, starting from C , the proof shows how to construct a new cascade $C' = \mathcal{B}_1 \circ \dots \circ \mathcal{B}_{h-1}$ of two-state reset automata such that $\mathcal{L}(C') = \Sigma^{h-2}a\Sigma^* = L_h$. The existence of C' contradicts the inductive hypothesis, which states that $L_h \notin \mathcal{R}_2^{h-1}$. Therefore, the assumption that $L_{h+1} \in \mathcal{R}_2^h$ must be false, and the cascade C cannot exist.

5.3 General Cascades

In this subsection, we examine cascades of reset automata without imposing restrictions on the number of states in each component or on the total number of components. In the previous part, Lemma 5.6 demonstrates that, for cascade of two resets over the alphabet Σ , the maximum expressiveness is achieved when the first component has $|\Sigma| + 1$ states. Here, we extend this result to cascades of unbounded height in the *Width-Collapse Lemma*, that provides lower bounds on the number of states in each component, for which adding states at certain levels does not affect expressiveness.

► **Lemma 5.8** (Width-Collapse Lemma). *Let Σ be a finite alphabet with $|\Sigma| = k \geq 2$. Let $L \subseteq \Sigma^*$ be a language. For any positive integers h and k_1, \dots, k_h , if $L \in \mathcal{R}(k_1, \dots, k_h, 2)$, then $L \in \mathcal{R}(f(1), \dots, f(h), 2)$, where $f(i) = \frac{k^{i+1}-1}{k-1}$.*

We now demonstrate how to transform *general cascades* into narrow cascades. Specifically, we show how any cascade of reset automata (of height h and with k_i states at level i , for each $i \in \{1, \dots, h\}$) can be transformed into an equivalent *narrow cascade* (i.e. made of two-state resets), at the cost of increasing its height at most by a factor of $2 + \sum_{i=1}^{h-1} \lceil \log_2(k_i) \rceil$. This result is based on two key points:

1. Given a general cascade, we can always append a pure-reset automaton at the end without altering its language;
2. the *Narrowing Lemma*, which we prove below, demonstrates that any cascade of reset automata, whose final component is pure-reset and containing a component \mathcal{A}_j with k_j states (and $k_j > 2$), can be transformed into a new cascade where \mathcal{A}_j is replaced by two new automata, with 2 and $\lceil \frac{k_j}{2} \rceil$ states each.

20:16 On Cascades of Reset Automata

■ **Figure 8** A cascade $C_3 = \mathcal{A}_1 \circ \mathcal{A}_2 \circ \mathcal{A}_3$ that recognizes the language $\Sigma a \Sigma^*$. The first two components enforce that any accepted word contains at least two symbols, as $\mathcal{L}(\mathcal{A}_1 \circ \mathcal{A}_2) = \Sigma \Sigma \Sigma^*$.

Instrumental to the Narrowing Lemma, the following result demonstrates that, given a general cascade whose last component is a pure-reset automaton, we can modify this last component to make all the states of the preceding components final, without altering the recognized language.

► **Lemma 5.9.** *Consider a cascade $\mathcal{A} \circ \mathcal{B}$ of automata, where \mathcal{B} is a two-state pure-reset automaton. Let \mathcal{A}' be the automaton obtained from \mathcal{A} by making all states final. Then, there exists a two-state pure-reset automaton \mathcal{B}' such that $\mathcal{L}(\mathcal{A} \circ \mathcal{B}) = \mathcal{L}(\mathcal{A}' \circ \mathcal{B}')$.*

The Narrowing Lemma is stated as follows.

► **Lemma 5.10 (Narrowing Lemma).** *Let $C = \mathcal{A}_1 \circ \dots \circ \mathcal{A}_h$ be a cascade where \mathcal{A}_i is a reset automaton with k_i states for each $1 \leq i \leq h-1$, and \mathcal{A}_h is a pure-reset automaton. Let j be an index such that $1 \leq j \leq h-1$. Then, there exists a cascade C' of reset automata*

$$C' = \mathcal{A}'_1 \circ \dots \circ \mathcal{A}'_{j-1} \circ \mathcal{B}_1 \circ \mathcal{B}_2 \circ \mathcal{A}'_{j+1} \circ \dots \circ \mathcal{A}'_h$$

such that:

- (i) each \mathcal{A}'_i has k_i states for $i \neq j$;
- (ii) if \mathcal{A}_i is pure-reset (resp., reset), then also \mathcal{A}'_i is pure-reset (resp., reset), for $i \neq j$;
- (iii) \mathcal{B}_1 has 2 states and \mathcal{B}_2 has $\lceil \frac{k_j}{2} \rceil$ states; and
- (iv) $\mathcal{L}(C) = \mathcal{L}(C')$.

By iteratively applying the Narrowing Lemma to every component with more than two states, we obtain a procedure that, given a cascade of reset automata, produces an equivalent cascade where all components are two-state reset automata. Moreover, it is worth noticing that:

- (i) by Lemma 4.10, *w.l.o.g.* the last component of any cascades of reset (or pure-resets) has two states, and therefore the Narrowing Lemma does not need to be applied at the last level;
- (ii) if the final component of a cascade is not a pure-reset, a new pure-reset level can always be added without affecting the language of the cascade.

This leads to the following inclusions.

► **Corollary 5.11.** *For each positive h, k_1, \dots, k_h it holds that*

1. $\mathcal{RPR}(k_1, \dots, k_h) \subseteq \mathcal{RPR}_2^{H+1}$
 2. $\mathcal{R}(k_1, \dots, k_h) \subseteq \mathcal{R}_2^{H+2}$
- where $H = \lceil \log_2 k_1 \rceil + \dots + \lceil \log_2 k_{h-1} \rceil$.

Combining Lemma 5.8 and Corollary 5.11, we conclude that if a language L is recognized by a cascade of resets of height h , it can also be recognized by a cascade of height $\Theta(h^2)$ composed entirely of two-state resets.

► **Corollary 5.12.** *Let Σ be an alphabet such that $|\Sigma| = k \geq 2$ and let $L \subseteq \Sigma^*$ be a language. If L admits a cascade of reset automata of height h , then $L \in \mathcal{R}_2^H$ where $H \in \Theta(h^2)$. If $k = 2$, then $H = \frac{h^2+h+2}{2}$.*

Exploiting the bound for the case $|\Sigma| = 2$, we can prove undefinability of certain languages by *general cascades*, i.e. without any bound on their height nor on the number of states of its component. As an example, by Lemma 5.7, we know that the language $L = \Sigma^6 a \Sigma^*$ over the alphabet $\Sigma = \{a, b\}$ does not belong to the class \mathcal{R}_2^7 . If L could be recognized by a cascade of height $h = 3$, then it would also be recognized by a two-state cascade of height $H = \frac{h^2+h+2}{2} = 7$, leading to the following conclusion: with $\Sigma = \{a, b\}$, the language $\Sigma^6 a \Sigma^*$ does not admit any cascade of resets of height 3.

Building upon this reasoning, we can formulate the Generalized Height-Hierarchy Lemma. Unlike the original Height-Hierarchy Lemma, which focuses solely on two-state cascades, the generalized version addresses the undefinability of cascades in a broader context, encompassing general cascades.

► **Lemma 5.13 (Generalized Height-Hierarchy Lemma).** *Let h be a positive integer, and define $H = \frac{h^2+h+2}{2} + 1$. Consider the language $L_H \subseteq \Sigma^*$, where $L_H = \Sigma^{H-2} a \Sigma^*$ and Σ is a two-symbol alphabet. The language L_H cannot be recognized by any cascade of reset automata of height h , but it holds that $L_H \in \mathcal{R}_2^H$.*

6 Efficient closure properties of cascades of reset automata

In this section, we present an efficient method for computing specific closure properties of reset cascades. For instance, for the case in which the operation \otimes is binary, given two cascades of resets \mathcal{C} and \mathcal{C}' (made of only two-states components), we show how it is possible to compute a cascade of two-states resets that recognizes $\mathcal{L}(\mathcal{C}) \otimes \mathcal{L}(\mathcal{C}')$ by adding *at most one* two-state reset automaton (that, in this context, we call *brick*). We show this for the following operations:

- (i) intersection;
- (ii) complementation;
- (iii) union; and
- (iv) left-concatenation of Σ , i.e. given a language \mathcal{L} to compute $\Sigma \cdot \mathcal{L}$.⁴

Proposition 4.5 already shows that *intersection* can be implemented efficiently for cascades of resets: given two reset cascades \mathcal{C} and \mathcal{C}' (with m and n two-states components, respectively), there exists a cascade for $\mathcal{L}(\mathcal{C}) \cap \mathcal{L}(\mathcal{C}')$ with $m + n$ two-state resets.

Before showing the construction for the remaining operations, we give the following key definitions. We define the *finalized version* of an automaton \mathcal{A} , denoted with $\text{finv}(\mathcal{A})$, as the automaton obtained from \mathcal{A} by setting all its states as final. The definition naturally extends to cascades: the finalized version of \mathcal{C} , denoted with $\text{finv}(\mathcal{C})$, is defined as $\text{finv}(\mathcal{A}_1) \circ \dots \circ \text{finv}(\mathcal{A}_n)$. Clearly, if \mathcal{C} is a cascade of reset automata, $\text{finv}(\mathcal{C})$ is still a cascade of reset automata. We define the *reachability set* of an automaton relative to a set of states as follows.

► **Definition 6.1 (Reachability Set).** *Let $\mathcal{A} = \langle \Sigma, Q, \delta, q_0, F \rangle$ be an automaton. Let $P \subseteq Q$ be a set of states. The reachability set of \mathcal{A} with respect to P , denoted with $\text{RS}(\mathcal{A}, P)$, is the set $\{(\sigma, q) \in (\Sigma \times Q) : \delta(q, \sigma) \in P\}$. We denote with $\overline{\text{RS}(\mathcal{A}, P)}$ the set $(\Sigma \times Q) \setminus \text{RS}(\mathcal{A}, P)$. We write $\text{RS}(\mathcal{A})$ to refer to $\text{RS}(\mathcal{A}, F)$.*

⁴ It is worth noticing that this operation corresponds to compute the closure under the LTL *next* modality.

■ **Figure 9** The *negation brick* $\text{negb}(\mathcal{A})$ in the two cases: (a) $\epsilon \in \mathcal{L}(\mathcal{A})$ (b) $\epsilon \notin \mathcal{L}(\mathcal{A})$.

We now show how to efficiently compute the remaining closure properties.

Complementation

To compute complementation, we introduce the *negation brick*, whose structure is illustrated in Figure 9 and is formally defined here below.

► **Definition 6.2** (Negation brick). *Let $\mathcal{A} = \langle \Sigma, Q, \delta, q_0, F \rangle$ be an automaton. The negation brick for \mathcal{A} , denoted with $\text{negb}(\mathcal{A})$, is the two-state pure-reset automaton $\langle \Sigma \times Q, \{n_0, n_1\}, \delta, n_0, \{n_f\} \rangle$ such that:*

- (i) *the final state n_f is n_1 if and only if $\epsilon \in \mathcal{L}(\mathcal{A})$;*
- (ii) *the function τ induced by symbols in $\text{RS}(\mathcal{A})$ maps all states in the non-final state, i.e. $\tau : \{n_0, n_1\} \mapsto \{n_0, n_1\} \setminus \{n_f\}$;*
- (iii) *the function τ' induced by symbols in $\overline{\text{RS}(\mathcal{A})}$ maps all states in the final one, i.e. $\tau' : \{n_0, n_1\} \mapsto \{n_f\}$.*

The intuition is that the negation brick, when appended to the end of a cascade \mathcal{C} , reaches its final state if and only if the underlying cascade \mathcal{C} is not in a final state. Consequently, by setting all the states of \mathcal{C} as final, we obtain a cascade that recognizes the complement of $\mathcal{L}(\mathcal{C})$, as proved by the following lemma.

► **Lemma 6.3.** *Let \mathcal{C} be a cascade of automata. The cascade $\mathcal{C}' := \text{finv}(\mathcal{C}) \circ \text{negb}(\mathcal{C})$ recognizes the language $\overline{\mathcal{L}(\mathcal{C})}$. Moreover, if \mathcal{C} is a cascade of reset automata, then so is \mathcal{C}' .*

Interestingly, if the cascade terminates with a pure-reset layer \mathcal{A} , this automaton can itself serve the function of the negation brick, without the need of an additional component.

► **Lemma 6.4.** *Let $\mathcal{C} = \mathcal{A}_1 \circ \dots \circ \mathcal{A}_n$ be a cascade of automata such that \mathcal{A}_n is a pure-reset automaton. There exists a cascade $\mathcal{C}' = \mathcal{A}'_1 \circ \dots \circ \mathcal{A}'_n$ such that:*

- (i) $\mathcal{L}(\mathcal{C}') = \overline{\mathcal{L}(\mathcal{C})}$;
- (ii) *each automaton \mathcal{A}'_i has the same number of states as \mathcal{A}_i ;*
- (iii) *if \mathcal{A}_i is a reset (resp., pure-reset), then \mathcal{A}'_i is also a reset (resp., pure-reset).*

Union

Given two cascades \mathcal{C} and \mathcal{C}' of height m and n , respectively, since $\mathcal{L}(\mathcal{C}) \cup \mathcal{L}(\mathcal{C}') = \overline{\overline{\mathcal{L}(\mathcal{C})} \cap \overline{\mathcal{L}(\mathcal{C}')}}$, it is possible to build cascade for $\mathcal{L}(\mathcal{C}) \cup \mathcal{L}(\mathcal{C}')$ of height $m + n + 3$, using the previously discussed constructions. In this section, we present a more efficient construction that introduces only one additional component, referred to as the *union brick*, resulting in a cascade for $\mathcal{L}(\mathcal{C}) \cup \mathcal{L}(\mathcal{C}')$ of height $n + m + 1$.

► **Definition 6.5** (Union brick). *Let $\mathcal{A} = \langle \Sigma, Q_A, \delta_A, q_{0A}, F_A \rangle$ and $\mathcal{B} = \langle \Sigma, Q_B, \delta_B, q_{0B}, F_B \rangle$ be two automata. Let $U \subseteq Q_A \times Q_B$ the set of states $\{(q_A, q_B) : q_A \in F_A \vee q_B \in F_B\}$. Let $\mathcal{C} = \mathcal{A} \circ \text{aug}(\mathcal{A}, \mathcal{B})$. The union brick of \mathcal{A} and \mathcal{B} , denoted with $\text{unionb}(\mathcal{A}, \mathcal{B})$, is the two-state pure-reset automaton $\langle \Sigma \times Q, \{u_0, u_1\}, \delta, u_0, \{u_f\} \rangle$ such that:*

- (i) the final state u_f is u_0 if and only if $\epsilon \in \mathcal{L}(\mathcal{A}) \cup \mathcal{L}(\mathcal{B})$;
- (ii) the function τ induced by symbols in $\text{RS}(\mathcal{C}, U)$ maps all states in the final one, i.e. $\tau : \{n_0, n_1\} \mapsto \{n_f\}$;
- (iii) the function τ' induced by symbols in $\overline{\text{RS}(\mathcal{C}, U)}$ maps all states in the non-final state, i.e. $\tau : \{n_0, n_1\} \mapsto \{n_0, n_1\} \setminus \{n_f\}$.

Similarly to the case of complementation, when appended to the end of a cascade $\mathcal{C} \circ \text{aug}(\mathcal{C}, \mathcal{C}')$, the union brick reaches its final state if and only if either \mathcal{C} is in a final state or $\text{aug}(\mathcal{C}, \mathcal{C}')$ is in a final state. This leads to the following lemma.

► **Lemma 6.6.** *Let \mathcal{C} and \mathcal{C}' be two cascade of automata. The cascade $\mathcal{C}'' := \text{finv}(\mathcal{C} \circ \text{aug}(\mathcal{C}, \mathcal{C}')) \circ \text{unionb}(\mathcal{C}, \mathcal{C}')$ recognizes the language $\mathcal{L}(\mathcal{C}) \cup \mathcal{L}(\mathcal{C}')$. Moreover, if \mathcal{C} and \mathcal{C}' are cascades of reset automata, then so is \mathcal{C}'' .*

Also in this case, if one of the two automata corresponds to a cascade terminating with a pure-reset component \mathcal{A} , the union can be performed without the need for additional layers: the automaton \mathcal{A} effectively serves as the union brick.

Left-concatenation of Σ

Given a cascade \mathcal{C} , we demonstrate how to construct a cascade that recognizes the language $\Sigma \cdot \mathcal{L}(\mathcal{C})$, adding only one brick and guaranteeing that the property of being a reset cascade is preserved. As a by-product of this construction, we obtain that, given a cascade of resets of height h equivalent to an LTL formula ϕ (interpreted over finite words), it is possible to construct a cascades of resets for $\text{X}(\phi)$ of height $h + 1$, where X is the *next* modality of LTL.

We first define the *next version* of an automaton. The next version of an automaton \mathcal{A} , denoted as $\text{nextv}(\mathcal{A})$, is defined considering the Cartesian product between the alphabet of \mathcal{A} and the set $\{\text{off}, \text{on}\}$. Intuitively, if \mathcal{A} transitions from q to q' with a symbols σ , so does $\text{nextv}(\mathcal{A})$ with the symbol (σ, on) . On the contrary, all symbols (σ, off) force $\text{nextv}(\mathcal{A})$ to transition to the initial state. The formal definition of $\text{nextv}(\mathcal{A})$ is given here below.

► **Definition 6.7** (Next version of an automaton). *Let $\mathcal{A} = \langle \Sigma', Q, \delta, q_0, F \rangle$ be an automaton such that either $\Sigma' = \Sigma$ or $\Sigma' = \Sigma \times S$, for an arbitrary finite set S . We define the next version of \mathcal{A} , denoted as $\text{nextv}(\mathcal{A})$, as the automaton $(\Sigma'', Q, \delta', q_0, F)$ such that:*

- if $\Sigma' = \Sigma$, then $\Sigma'' := \Sigma \times \{\text{off}, \text{on}\}$ and, for all $q \in Q$ and for all $a \in \Sigma$, it holds: $\delta'(q, (a, \text{on})) = \delta(q, a)$ and $\delta'(q, (*, \text{off})) = q_0$.
- if $\Sigma' = \Sigma \times S$, then $\Sigma'' := \Sigma \times \{\text{off}, \text{on}\} \times S$ and, for all $q \in Q$ and for all $(a, s) \in \Sigma \times S$, it holds that: $\delta'(q, (a, \text{on}, s)) = \delta(q, (a, s))$ and $\delta'(q, (*, \text{off}, *)) = q_0$.

Given a cascade $\mathcal{C} = \mathcal{A}_1 \circ \dots \circ \mathcal{A}_n$ over Σ , we define the next version of \mathcal{C} , denoted with $\text{nextv}(\mathcal{C})$, as the cascade $\text{nextv}(\mathcal{A}_1) \circ \dots \circ \text{nextv}(\mathcal{A}_n)$ over $\Sigma \times \{\text{off}, \text{on}\}$.

Figure 10 shows the next versions of the automata in Figure 1. Crucially, computing the next version of an automaton does not alter its property of being a reset automaton.

► **Lemma 6.8.** *Let Σ be a finite alphabet and let \mathcal{A} be an automaton over Σ or over $\Sigma \times S$ for an arbitrary finite set S . If \mathcal{A} is reset automaton, then also $\text{nextv}(\mathcal{A})$ is a reset automaton.*

Now, given any cascade \mathcal{C} , to capture the language $\Sigma \cdot \mathcal{L}(\mathcal{C})$, it suffices to consider the automaton $\mathcal{A}_{\text{switch}}$ (depicted in Figure 7) with the next version of \mathcal{C} . In fact, considering that initially both $\mathcal{A}_{\text{switch}}$ and $\text{nextv}(\mathcal{C})$ are in their initial states (which, for $\mathcal{A}_{\text{switch}}$, is state off), reading the first input symbol σ forces:

■ **Figure 10** The next version of the two automata in the cascade of Figure 1.

- (i) \mathcal{A}_{switch} to transition to state on; and
- (ii) $nextv(\mathcal{C})$ to remain in its initial state, because the symbol it reads is (σ, off) .

After the first symbol and for all the rest of the input word, \mathcal{A}_{switch} remains in state on, while $nextv(\mathcal{C})$ operates like \mathcal{C} because it reads symbols of the form (σ', on) . As shown by the following lemma, this captures exactly $\Sigma \cdot \mathcal{L}(\mathcal{C})$.

► **Lemma 6.9.** *Let \mathcal{C} be a cascade of automata. The cascade $\mathcal{C}' := \mathcal{A}_{switch} \circ nextv(\mathcal{C})$ recognizes the language $\Sigma \cdot \mathcal{L}(\mathcal{C})$. Moreover, if \mathcal{C} is a cascade of reset automata, then so is \mathcal{C}' .*

From Lemma 5.7, it follows the optimality of the construction outlined in Lemma 6.9.

7 Conclusions and Future Work

In this paper, we investigated some fundamental properties of cascades of reset automata. Unlike the approach commonly followed in the literature, where the cascade product is restricted to semi-automata, we focused on the case of automata. This allowed us to study the properties of the recognized languages. As an initial step, we showed how to compute regular expressions equivalent to a cascade. Then, on the basis of such a transformation, we established some meaningful expressiveness results, in particular lower bounds to the height and to the minimum number of states per level of a cascade of resets for specific families of languages. Finally, we showed how to compute the closure of reset cascades under certain basic operations by adding at most one brick to the end of the cascade.

As for the future developments of the work, finding an efficient construction for the closure of reset cascades under the concatenation operation is undoubtedly a crucial direction. This would enable the design of an efficient approach to handling the *eventually* and *until* operators of LTL, providing, together with the results given in the last section of the paper, an efficient decomposition into reset cascades for full LTL. This would improve the triply-exponential upper bound to such a decomposition achieved by Maler’s algorithm [4, 15]. Last but not least, giving analogous expressiveness and closure results for permutation automata appears to be another promising avenue for further investigation.

Abstract

Subshifts are sets of colorings of \mathbb{Z}^d defined by families of forbidden patterns. Given a subshift and a finite pattern, its extender set is the set of admissible completions of this pattern. It has been conjectured that the behavior of extender sets, and in particular their growth called *extender entropy* [10], could provide a way to separate the classes of sofic and effective subshifts. We prove here that both classes have the same possible extender entropies: exactly the Π_3 real numbers of $[0, +\infty)$.

1 Introduction

In dimension $d \in \mathbb{N}$, subshifts are sets of colorings of \mathbb{Z}^d where a family of patterns, *i.e.* colorings of finite portions of \mathbb{Z}^d , have been forbidden. They were originally introduced to discretize continuous dynamical systems [19]. One of the main families of subshifts that has been studied is the class of *subshifts of finite type* (SFTs), which can be defined with a finite family of forbidden patterns. This class has independently been introduced under the formalism of Wang tiles [25] in dimension 2 in order to study fragments of second order logic.

In dimension 1, *sofic subshifts* [26], which are obtained as letter-to-letter projections of SFTs, are studied mainly through their defining graphs. In dimension 2 and higher, SFTs (and thus sofic subshifts) can embed arbitrary Turing machine computations; as such, the main tool in the study of subshifts becomes computability theory. This led to the introduction of a new class of subshifts, the *effective subshifts*, which can be defined by computably enumerable families of forbidden patterns [13].

An important question in symbolic dynamics is thus to find criteria separating sofic from effective subshifts [15, 22, 12, 3]. In dimension 1, a subshift is sofic if it can be defined by a regular language of forbidden patterns: the Myhill–Nerode theorem states that these are exactly the languages that have finitely many Nerode congruence classes. In dimension 2 and higher, no such clear characterization exists. Indeed, many effective subshifts have been

proved to be sofic, such as substitutive subshifts [20], or effective subshifts on $\{0, 1\}$ whose densities of symbols 1 are sublinear [6]; it even turns out that sofic subshifts of dimension $d + 1$ capture all the behaviors of effective shifts of dimension d [13, 8, 2].

All the methods used to prove some cases of non-soficity that are known by the authors revolve around a counting argument: only a linear amount of information may cross the border of an $n \times n$ square pattern (see for example [1, Proposition 9.4.5]). The most recent argument in this vein uses resource-bounded Kolmogorov complexity [7].

One formalization of this counting argument relies on *extender sets* of patterns [15], which can be considered as a higher-dimensional generalization of Nerode congruence classes: the extender set of a pattern p is the set of all configurations with a p -shaped hole that may extend p . For SFTs, the extender set of a given pattern is entirely determined by its boundary, which implies that the number of extender sets of an SFT cannot grow too quickly. For subshifts in dimension 1, [21, Lemma 3.4] proves the analog of Myhill-Nerode theorem: a subshift is sofic if and only if its number of extender sets of every size is bounded. In dimension 2 and higher, only sufficient conditions are known: for example, a subshift whose number of extender sets for patterns of size n^d is bounded by n must be sofic [21].

The study of the growth rate of the number of extender sets can be done asymptotically through the notion of the *extender entropy*, which is defined in a similar way to the classical notion of topological entropy [17]. Extender entropies in fact relate to the to notion of follower entropies [4], but are more robust in the sense that, despite it not being decreasing under factor map applications, the extender entropy of a subshift is still a conjugacy invariant.

In this paper, we achieve characterizations of the possible extender entropies in terms of computability, in the same vein as recent results on conjugacy invariants of subshifts [14, 18].

► **Theorem A.** *The set of extender entropies of \mathbb{Z} effective subshifts is exactly $\Pi_3 \cap [0, +\infty)$.*

► **Theorem B.** *The set of extender entropies of \mathbb{Z}^2 sofic subshifts is exactly $\Pi_3 \cap [0, +\infty)$.*

These results generalize to dimension $d \geq 2$ by Claim 8 and Corollary 12. While sofic subshifts were conjectured in [15] to have extender entropy zero, this was later disproved (see for example [7]); in fact, our characterization shows that the possible values are dense in $[0, +\infty)$. This also proves that extender entropies do not separate sofic from effective shifts.

	\mathbb{Z}	$\mathbb{Z}^d, d \geq 2$
SFT	{0} (Folklore: see Proposition 6)	
Sofic	{0} ([9, Theorem 1.1])	Π_3 (Theorem B)
Effective	Π_3 (Theorem A)	
Computable (\mathbb{Z} effective, \mathbb{Z}^d sofic)	Π_2 (Theorem 27)	
Sofic and minimal	{0} (Corollary 29)	
Effective and minimal	Π_1 (Corollary 30)	
Effective and 1-Mixing/Block-Gluing	Π_3 (Proposition 32)	Π_3 (Proposition 34)

■ **Figure 1** Sets of possible extender entropies for various classes of subshifts.

Finally, we also study extender entropies of subshifts constrained by some dynamical assumptions, such as minimality or mixingness. What is known by the authors at this stage can be summed up by the table Figure 1.

2 Definitions

2.1 Subshifts

Let \mathcal{A} denote a finite set of symbols and $d \in \mathbb{N}$ the dimension. A *configuration* is a coloring $x \in \mathcal{A}^{\mathbb{Z}^d}$, and the color of x at position $p \in \mathbb{Z}^d$ is denoted by x_p . A (d -dimensional) *pattern* over \mathcal{A} is a coloring $w \in \mathcal{A}^P$ for some set $P \subseteq \mathbb{Z}^d$ called its *support*¹. For any pattern w over \mathcal{A} of support P , we say that w *appears* in a configuration x (and we denote $w \sqsubseteq x$) if there exists $p_0 \in \mathbb{Z}^d$ such that $w_p = x_{p+p_0}$ for all $p \in P$.

The *shift functions* $(\sigma^t)_{t \in \mathbb{Z}^d}$ act on configurations as $(\sigma^t(x))_p = x_{p+t}$. For $t \in \mathbb{Z}^d$, a configuration x is *t-periodic* if $\sigma^t(x) = x$. We sometimes consider patterns or configuration by their restriction: for $S \subseteq \mathbb{Z}^d$ either finite or infinite, and $x \in \mathcal{A}^{\mathbb{Z}^d}$ a configuration (resp. w a pattern), we denote by $x|_S$ (resp. $w|_S$) the coloring of \mathcal{A}^S it induces on S .

► **Definition 1** (Subshift). *For any family of finite patterns \mathcal{F} , we define*

$$X_{\mathcal{F}} = \left\{ x \in \mathcal{A}^{\mathbb{Z}^d} \mid \forall w \in \mathcal{F}, w \not\sqsubseteq x \right\}$$

A set $X \subseteq \mathcal{A}^{\mathbb{Z}^d}$ is called a subshift if it is equal to some $X_{\mathcal{F}}$.

Given a subshift X and a finite support $P \subseteq \mathbb{Z}^d$, we define $\mathcal{L}_P(X)$ as the set of patterns w of support P that appear in the configurations of X . Such patterns are said to be *globally admissible* in X . We define the *language* of X as $\mathcal{L}(X) = \bigcup_{P \subseteq \mathbb{Z}^d \text{ finite}} \mathcal{L}_P(X)$. Slightly abusing notations, we denote $\mathcal{L}_n(X) = \mathcal{L}_{\llbracket 0, n-1 \rrbracket^d}(X)$ for $n \in \mathbb{N}$.

For $X \subseteq \mathcal{A}^{\mathbb{Z}^d}$ and $Y \subseteq \mathcal{B}^{\mathbb{Z}^d}$ two subshifts, $\varphi: X \rightarrow Y$ is a *factor map* if there exists some $N \subseteq \mathbb{Z}^d$ and $f: \mathcal{A}^N \rightarrow \mathcal{B}$ such that $\varphi(x)_p = f(x|_{p+N})$: then Y is a *factor* of X . X and Y are *conjugate* if there exists a bijective factor map $\varphi: X \rightarrow Y$ (called a conjugacy). Any object associated with subshifts that is preserved by conjugacy is a *conjugacy invariant*.

Subshifts can be classified as follows: a subshift is *of finite type* (SFT) if it is equal to $X_{\mathcal{F}}$ for some finite family \mathcal{F} of forbidden patterns; a subshift X is *effective* if it is equal to $X_{\mathcal{F}}$ for some computably enumerable family \mathcal{F} of forbidden patterns; and a subshift is *sofic* if it is a factor of some SFT, called its *SFT cover*. SFTs are sofic by definition, and sofic subshifts are effective.

Reciprocally, for a \mathbb{Z}^d subshift $X \subseteq \mathcal{A}^{\mathbb{Z}^d}$, define the following *lifts*:

- *the periodic lift* $X^\uparrow = \{x^\uparrow \in \mathcal{A}^{\mathbb{Z}^{d+1}} \mid x \in X\}$, where $(x^\uparrow)|_{\mathbb{Z}^d \times \{i\}} = x$ for all $i \in \mathbb{Z}$;
- *the free lift* $X^\uparrow = \{y \in \mathcal{A}^{\mathbb{Z}^{d+1}} \mid \forall i \in \mathbb{Z}, y_{\mathbb{Z}^d \times \{i\}} \in X\}$.

If X is sofic (resp. effective), then both X^\uparrow and X^\uparrow are also sofic (resp. effective) since they can be defined by the same forbidden patterns. On the other hand:

► **Theorem 2** ([13], [2, Theorem 3.1], [8, Theorem 10]). *If X is an effective \mathbb{Z}^d subshift, then X^\uparrow is a sofic \mathbb{Z}^{d+1} subshift.*

Finally, most of our constructions will involve the notion of *layers*: for a subshift of a cartesian product $X \subseteq \prod_{i \in I} L_i$, the layers of X are the projections of X onto each of the L_i , which are often named for convenience. For $J \subseteq I$, we will denote by $\pi_{L_{j_1} \times L_{j_2} \times \dots}: \prod_{i \in I} L_i \mapsto \prod_{j \in J} L_j$ the cartesian projection.

¹ It is sometimes convenient to consider patterns up to the translation of their support. Usually, context will make it clear whether patterns are truly equal, or only up to a \mathbb{Z}^d translation.

2.2 Pattern Complexity and Extender Sets

The traditional notion of complexity is called *pattern complexity* and is defined by $N_X(n) = \mathcal{L}_n(X)$. The exponential growth rate of $|N_X(n)|$ is the *topological entropy*:

$$h(X) = \lim_{n \rightarrow +\infty} \frac{\log |N_X(n)|}{n^d}.$$

In this article, we focus on another notion of complexity based on extender sets:

► **Definition 3** (Extender set). *For $X \subseteq \mathcal{A}^{\mathbb{Z}^d}$ a d -dimensional subshift, $P \subseteq \mathbb{Z}^d$ and $w \in \mathcal{A}^P$ a pattern of support P , the extender set of w is the set*

$$E_X(w) = \{x \in \mathcal{A}^{\mathbb{Z}^d \setminus P} \mid x \sqcup w \in X\},$$

where $(x \sqcup w)_p = w_p$ if $p \in P$ and $(x \sqcup w)_p = x_p$ otherwise.

In other words, $E_X(w)$ is the set of all possible valid “completions” of the pattern w in X . For example, for two patterns with the same support w, w' , we have $E_X(w) \subseteq E_X(w')$ if and only if the pattern w can be replaced by w' every time it appears in any configuration of X .

In the case of \mathbb{Z} subshifts, extender sets are similar to the more classical notions of *follower* (resp. *predecessor*) *sets*, which are the set of right-infinite (resp. left-infinite) words that complete a finite given pattern (see for example [9]). Parallels can also be drawn with Nerode congruence classes.

For X a \mathbb{Z}^d subshift, denote $E_X(n) = \{E_X(w) \mid w \in \mathcal{L}_n(X)\}$ its set of extender sets. The *extender set sequence* $(|E_X(n)|)_{n \in \mathbb{N}}$ and its growth rate² are defined in [9]:

► **Definition 4** ([10, Definition 2.17]). *For a \mathbb{Z}^d subshift X , its extender entropy is*

$$h_E(X) = \lim_{n \rightarrow +\infty} \frac{\log |E_X(n)|}{n^d}.$$

This limit is well-defined by the multivariate subadditive lemma (see [5, Theorem 1]). In particular, $h_E(X) = \inf_{n \rightarrow +\infty} \frac{\log |E_X(n)|}{n^d}$, and $h_E(X)$ could actually be computed along any sequence of hyperrectangles that eventually fills \mathbb{Z}^d .

Examples

1. Let us consider $X = \mathcal{A}^{\mathbb{Z}^d}$ some full-shift in dimension d . Then X has maximal topological entropy, but $h_E(X) = 0$: indeed, for any two patterns $w, w' \in \mathcal{L}_n(X)$, we have $E_X(w) = E_X(w') = \{\mathcal{A}^{\mathbb{Z}^d \setminus \llbracket 0, n-1 \rrbracket^d}\}$; which implies that $|E_X(n)| = 1$ for every $n \in \mathbb{N}$.
2. Let us consider X a (strongly) periodic subshift: there exist $p_1, \dots, p_d \in \mathbb{N}$ such that, for every $x \in X$ and $i \leq d$, we have $\sigma^{p_i \cdot e_i}(x) = x$. Then X has zero topological entropy, and we also have $h_E(X) = 0$. Indeed, for $n \geq \max p_i$ and $w \in \mathcal{L}_n(X)$, w is the only pattern w' such that $E_X(w') = E_X(w)$; so that $|E_X(n)| = |\mathcal{L}_n(X)| \leq p \mathcal{A}^p$ for $p = \prod_i p_i$.

Some Properties

► **Theorem 5** (From [10] on \mathbb{Z} subshifts). *On \mathbb{Z}^d subshifts:*

- h_E is a conjugacy invariant.
- h_E is not necessarily decreasing under factor map.

² The authors define it for \mathbb{Z} subshifts, but the definition makes sense for higher dimensional shifts.

- h_E is additive under product (i.e. for X, Y two subshifts, $h_E(X \times Y) = h_E(X) + h_E(Y)$).
- h_E is upper bounded by h (i.e. for X a subshift, $h_E(X) \leq h(X)$).

For SFTs, the following proposition is folklore:

► **Proposition 6** ([15, Section 2]). *Let X be a d -dimensional SFT. Then $h_E(X) = 0$.*

Sketch of proof. In an SFT defined by adjacency constraints, the extender set of a pattern $w \in \mathcal{A}^{\llbracket 0, n-1 \rrbracket^d}$ is determined by its border; and there are at most $2^{O(n^{d-1})}$ such borders. ◀

By an analog of the Myhill-Nerode theorem, \mathbb{Z} sofic subshifts have extender entropy zero:

► **Proposition 7** ([21, Lemma 3.4]). *Let X be a 1-dimensional subshift. Then X is sofic if and only if $(|E_n(X)|)_{n \in \mathbb{N}}$ is uniformly bounded.*

2.3 Computability Notions

2.3.1 Arithmetical Hierarchy

The *arithmetical hierarchy* [24, Chapter 4] stratifies formulas of first-order arithmetic over \mathbb{N} by the number of their alternating unbounded quantifiers: for $n \in \mathbb{N}$, define

$$\begin{aligned} \Pi_n^0 &= \{\forall k_1, \exists k_2, \forall k_3, \dots \phi(k_1, \dots, k_n) \mid \phi \text{ only contains bounded quantifiers}\} \\ \Sigma_n^0 &= \{\exists k_1, \forall k_2, \exists k_3, \dots \phi(k_1, \dots, k_n) \mid \phi \text{ only contains bounded quantifiers}\}. \end{aligned}$$

A decision problem is said to be in Π_n^0 (resp. Σ_n^0) if its set of solutions $S \subseteq \mathbb{N}$ is described by a Π_n^0 (resp. Σ_n^0) formula: in other words, $\Pi_0^0 = \Sigma_0^0$ corresponds to the set of computable decision problems; Σ_1^0 is the set of computably enumerable decision problems, etc. . .

2.3.2 Arithmetical Hierarchy of Real Numbers

The *arithmetical hierarchy of real numbers* [27] stratifies real numbers depending on the difficulty of computably approximating them: for $n \geq 0$, define

$$\begin{aligned} \Sigma_n &= \{x \in \mathbb{R} \mid \{r \in \mathbb{Q} \mid r \leq x\} \text{ is a } \Sigma_n^0 \text{ set}\} \\ \Pi_n &= \{x \in \mathbb{R} \mid \{r \in \mathbb{Q} \mid r \geq x\} \text{ is a } \Sigma_n^0 \text{ set}\} = \{x \in \mathbb{R} \mid \{r \in \mathbb{Q} \mid r \leq x\} \text{ is a } \Pi_n^0 \text{ set}\}. \end{aligned}$$

In particular, $\Sigma_0 = \Pi_0$ is the set of computable real numbers, *i.e.* numbers that can be computably approximated up to arbitrary precision; Π_1 real numbers are also called right-computable, since they can be computably approximated from above; etc. . .

Alternatively, this hierarchy is also defined by the number of alternating limit operations needed to obtain a real number from the computable ones [27]. In other words, for $n \geq 1$:

$$\begin{aligned} \Sigma_n &= \left\{ \sup_{k_1 \in \mathbb{N}} \inf_{k_2 \in \mathbb{N}} \sup_{k_3 \in \mathbb{N}} \dots \beta_{k_1, \dots, k_n} \mid (\beta_{k_1, \dots, k_n})_{k_1, \dots, k_n \in \mathbb{N}} \in \mathbb{Q}^{\mathbb{N}^n} \text{ is computable} \right\} \\ \Pi_n &= \left\{ \inf_{k_1 \in \mathbb{N}} \sup_{k_2 \in \mathbb{N}} \inf_{k_3 \in \mathbb{N}} \dots \beta_{k_1, \dots, k_n} \mid (\beta_{k_1, \dots, k_n})_{k_1, \dots, k_n \in \mathbb{N}} \in \mathbb{Q}^{\mathbb{N}^n} \text{ is computable} \right\} \end{aligned}$$

3 Elementary Constructions on Extender Sets

The free lift

We use this construction to generalize results on \mathbb{Z} or \mathbb{Z}^2 subshifts to higher dimensions:

▷ **Claim 8.** For a subshift $X \subseteq \mathcal{A}^{\mathbb{Z}^d}$, $h_E(X) = h_E(X^\uparrow)$.

Proof. Consider $X^\uparrow \subseteq \mathcal{A}^{\mathbb{Z}^{d+1}}$. Since each d -dimensional hyperplane of \mathbb{Z}^{d+1} contains an independent configuration, we have $|E_{X^\uparrow}(n)| = |E_X(n)|^n$ and $h_E(X^\uparrow) = h_E(X)$. ◀

The (semi)-mirror construction

▷ Claim 9. Let Y be any \mathbb{Z}^2 sofic subshift over an alphabet \mathcal{A} . There exists a \mathbb{Z}^2 sofic subshift Y_{mirror} such that $h_E(Y_{\text{mirror}}) = h(Y)$ ($= h(Y_{\text{mirror}})$).

A first idea to create one extender set per pattern of Y is the *mirror construction*: add a line of some special symbol $*$ to separate two half-planes; the upper half-plane contains a half-configuration of Y , while the lower half-plane contains its reflection by the line of $*$. As any two patterns of Y have distinct reflections, they generate different extender sets: this results in a subshift Y' verifying $h_E(Y') = h(Y)$. Unfortunately, Y' is not always sofic, see for example [1, Proposition 57].

(a) The (classical) mirror shift. (b) The semi-mirror shift.

■ **Figure 2** Example configurations of the mirror and semi-mirror subshifts.

To solve this non-soficness issue, the *semi-mirror with large discrepancy* from [7, Example 5''] reflects a single symbol instead of the whole upper-plane:

Sketch of proof. For $\mathcal{A}' = \mathcal{A} \cup \{\square, *\}$, define Y_{mirror} over the alphabet \mathcal{A}' as follows:

- Symbols $*$ must be aligned in a row, and there is at most one such row per configuration.
- If a row of $*$ appears in a configuration x , then the lower half-plane contains at most one non- \square position; and the upper half-plane must appear in a configuration of Y .
- If $x_{i,j} = *$ and $x_{i,j-k} \in \mathcal{A}$ for some $i \in \mathbb{Z}, j \in \mathbb{Z}, k \in \mathbb{N}$, then $x_{i,j+k} = x_{i,j-k}$. In other words, the only symbol of \mathcal{A} in the lower half-plane must be the mirror of the same symbol in the upper half-plane, as reflected by the horizontal row of $*$ symbols.

Then Y_{mirror} is sofic and $h_E(Y_{\text{mirror}}) = h(Y)$. Indeed, any two distinct patterns of Y must appear in Y_{mirror} and have distinct extender sets, since they can have different reflections. ◀

This construction shows that there exist subshifts with arbitrarily large extender entropy; and since every Π_1 real number is the topological entropy of some (SFT, thus) sofic subshift [14], every Π_1 number can be realized as the extender entropy of some sofic subshift. In particular, this further disproves the conjecture from [15] mentioned in the introduction.

4 Decision Problems on Extender Sets

4.1 Inclusion of Extender Sets

Let us consider the following decision problem:

EXTENDER-INCLUSION	
Input:	An effective subshift $X \subseteq \mathcal{A}^{\mathbb{Z}^d}$, and $u, v \in \mathcal{L}(X)$,
Output:	Whether $E_X(u) \subseteq E_X(v)$.

► **Proposition 10.** *EXTENDER-INCLUSION is a Π_2^0 -complete problem.*

Proof of inclusion. As $E_X(u) \subseteq E_X(v)$ if and only if $\forall B \in \mathcal{A}^*, u \sqsubseteq B \implies (B \notin \mathcal{L}(X) \vee ((B \setminus u) \sqcup v) \in \mathcal{L}(X))$, we obtain inclusions: indeed, for X effective, deciding whether a pattern w belongs in $\mathcal{L}(X)$ is a Π_1^0 problem. ◀

Proof of Π_2^0 -hardness for \mathbb{Z} subshifts. We reduce the following known Π_2^0 problem³:

DET-REC-STATE	
Input:	A deterministic Turing Machine M , and a state q ,
Output:	Is q visited infinitely often by M during its run on the empty input?

Let (M, q) be an instance of this DET-REC-STATE. We construct an effective subshift X over the alphabet $\{0, 1, \square\}$ as follows:

- Symbols 0 and 1 cannot appear together in a configuration. The symbol 1 can only appear at most once in a configuration.
 - If two symbols 0 appear in a configuration at distance, say, $n > 0$, then the whole configuration is n -periodic; and if M enters q at least n' times, then we impose $n > n'$.
- As the rules above forbid an enumerable set of patterns, X is an effective subshift.

Finally, $E_X(0) \subseteq E_X(1)$ if and only if M enters q infinitely many times. Indeed, the symbol 0 can be extended either by semi-infinite lines of symbols \square , which also extend the symbol 1 ; or by configurations containing n -periodic symbols 0, which do *not* extend the symbol 1 because of the first rule. However, by the second rule, this n -periodic configuration exists if and only if M visits q less than n times. ◀

4.2 Computing the Number of Extender Sets

Let us determine the computational complexity of the problem “ $k \leq |E_X(n)|$ ”, when given a subshift X , some size n and some k . It is equivalent to the following:

$$\bigvee_{v_1, \dots, v_k \in \mathcal{L}_n(X)} \bigwedge_{1 \leq i < j \leq k} E_X(v_i) \neq E_X(v_j).$$

Since $v_i \in \mathcal{L}_n(X)$ is a $\Pi_1^0 \subseteq \Sigma_2^0$ problem and that the class of Σ_2^0 problems is stable by finite disjunctions and conjunctions, we conclude from Proposition 10 that:

► **Lemma 11.** *For an effective subshift X , “ $k \leq |E_X(n)|$ ” is a Σ_2^0 problem.*

4.3 Upper Computational Bounds on Extender Entropies

► **Corollary 12.** *For X an effective subshift, $h_E(X) \in \Pi_3$.*

Proof. Given X and n , the set $\{k \leq |E_X(n)|\}$ is a Σ_2^0 set if X is effective by Lemma 11. This implies that $\frac{\log |E_X(n)|}{n^d}$ is Σ_2 ; and since $h_E(X) = \inf_n \frac{\log |E_X(n)|}{n^d}$, we obtain $h_E(X) \in \Pi_3$ as the infimum of Σ_2 real numbers. ◀

5 Π_3 Extender Entropies for \mathbb{Z} Effective Subshifts

Let us focus on one-dimensional subshifts for the time being.

► **Theorem A.** *The set of extender entropies of \mathbb{Z} effective subshifts is exactly $\Pi_3 \cap [0, +\infty)$.*

³ It is equivalent to INF (does a given machine halt on infinitely many inputs?). See [24, Theorem 4.3.2].

In order to construct a subshift Z_α with $h_E(Z_\alpha) = \alpha$, we would like to have $|E_{Z_\alpha}(n)| \simeq 2^{\alpha n}$. To do so, we could create one extender set per pattern, and $2^{\alpha n}$ patterns of size n (as the semi-mirror in Section 3); however, since effective subshifts have Π_1 entropies, this would not realize the whole class of Π_3 numbers.

Yet, realizing the right number of patterns is the main idea behind the proof that follows: we just do not blindly create one extender set per pattern, but only separate extender sets when some conditions are met.

5.1 Preliminary: Encoding Integers With Configurations $\langle i \rangle_k$

Before we begin our construction, we fix a way to encode integers in configurations: to encode the integer $i \in \mathbb{N}$, we use configurations where a symbol $*$ is i -periodic, and the rest is blank.

More formally, consider the alphabet $\mathcal{A}_* = \{*, \sqcup\}$. Denote by $\langle i \rangle_{k_1}$ the i -periodic configuration $\langle i \rangle_{k_1} = \sigma^{k_1}(\dots \sqcup \underbrace{* \sqcup \dots \sqcup *}_{i+1 \text{ symbols}} \sqcup \dots \sqcup * \sqcup \dots)$ properly defined as $(\langle i \rangle_{k_1})_p = *$ if and only if $p = k_1 \bmod i$. A configuration $\langle i \rangle_{k_1}$ is said to *encode* the integer $i \in \mathbb{N}$. Considering the subshift all the configurations $\langle i \rangle_{k_1}$ for $i \in \mathbb{N}$ and $k_1 \leq i$ generate, we denote:

$$X_* = \bigcup_{i \in \mathbb{N}} \{ \langle i \rangle_{k_1} \in \mathcal{A}_*^{\mathbb{Z}} \mid k_1 \leq i \} \cup \langle \infty \rangle$$

where $\langle \infty \rangle = \{x \in \mathcal{A}_*^{\mathbb{Z}} \mid |x|_* \leq 1\}$ is the set of configurations having at most one symbol $*$. The configurations of $\langle \infty \rangle$ are said to be *degenerate*, and they appear when taking the closure of all $\langle i \rangle_{k_1}$.

5.2 Preliminary: Toeplitz Density in Periodic Configurations

Our construction will also need to build configurations with a controlled density of symbols, *i.e.* configurations on $\{0, 1\}$ where the number of symbols 1 in large patterns converges to some value: for some fixed α , we want to build configurations $x \in \{0, 1\}^{\mathbb{Z}}$ such that $\lim_{n \rightarrow +\infty} \frac{1}{n} \cdot |x|_{\llbracket [0, n-1] \rrbracket} = \alpha$. Several explicit constructions of such configurations and subshifts exist. We choose to work with *Toeplitz sequences*.

Toeplitz density words

Consider the ruler sequence $T = 12131214\dots$ defined by $T_n = \max\{m \in \mathbb{N} : 2^m \mid 2n\}$ (see OEIS A001511). For a given binary sequence $u = (u_n)_{n \in \mathbb{N}} \in \{0, 1\}^{\mathbb{N}}$, we consider its Toeplitzification $T(u) \in \{0, 1\}^{\mathbb{N}}$ defined as $T(u)_n = u_{T_n}$ for $n \in \mathbb{N}$.

In particular, for $\beta \in [0, 1]$ a real number and $(\beta_n)_{n \in \mathbb{N}}$ its proper binary expansion, we consider the word $T(\beta) = (\beta_{T_n})_{n \in \mathbb{N}} = \beta_1 \beta_2 \beta_1 \beta_3 \beta_1 \beta_2 \dots$. Denoting by $|w|_1$ the numbers of letters 1 in a binary word $w \in \{0, 1\}^*$ and by $|w|$ its length, we have:

▷ **Claim 13.** For $\beta \in [0, 1]$ and $w \sqsubseteq T(\beta)$ a factor of $T(\beta)$, we have $|w|_1 = \beta \cdot |w| + O(1)$.

Toeplitz density in periodic configurations

For our specific construction, let $\alpha \in [0, 1]$ and $i \in \mathbb{N}$, and consider the subshift $T_{\leq \alpha, i}$ composed of i -periodic configurations made of truncated Toeplitz words:

$$T_{\leq \alpha, i} = \{x \in \{0, 1\}^{\mathbb{Z}} \mid \exists \beta \leq \alpha, \exists k_1 \in \llbracket [0, i-1] \rrbracket, \forall p \in \mathbb{Z}, x_p = T(\beta)_{(p+k_1 \bmod i)}\}$$

We denote $T(\beta, i)_{k_1} \in \{0, 1\}^{\mathbb{Z}}$ the configuration defined by $(T(\beta, i)_{k_1})_p = T(\beta)_{(p+k_1 \bmod i)}$ for $p \in \mathbb{Z}$. Notice that, for any $\alpha \in [0, 1]$, $i \in \mathbb{N}$ and $n \in \mathbb{N}$, there are $|\mathcal{L}_n(T_{\leq \alpha, i})| = 2^{\log(\min(i, n)) + O(1)} \cdot O(\min(i, n))$ factors of length n in $T_{\leq \alpha, i}$.

▷ **Claim 14.** Let $\alpha \in [0, 1] \cap \Pi_1$. Then $T_{\leq \alpha, i}$ is an SFT, and a family of forbidden patterns realizing $T_{\leq \alpha, i}$ can be computably enumerated from α .

Proof. Consider $\alpha \in \Pi_1$: the set $\{r \in \mathbb{Q} \mid r > \alpha\}$ is computably enumerable. Thus, the following family \mathcal{F} of forbidden patterns that realizes $T_{\leq \alpha, i}$ is recursively enumerable: forbid finite pattern that are either not i -periodic, or do not respect the structure of the ruler sequence in an i -period; and inside an i -period, forbid patterns $r_{T_1} r_{T_2} r_{T_1} \dots \in \{0, 1\}^i$ that encode the finite expansion of a rational $r = \sum_{k=1}^{\log i} r_k 2^{-k}$ if r is such that $r > \alpha$. ◁

5.3 Construction: the Effective \mathbb{Z} Subshift Z_α

Let us now begin the construction to prove Theorem A. Let $\alpha \in \Pi_3$ be a positive real number, $\alpha = \inf_i \sup_j \alpha_{i,j}$ for some computable sequence $(\alpha_{i,j})$ of Π_1 real numbers. We can assume $\alpha \leq 1$ since extender entropy is additive under cartesian products, and using [27, Lemma 3.1] we can assume that $(\alpha_{i,j})_{i,j \in \mathbb{N}^2}$ satisfies some monotonicity properties: for all i , $(\alpha_{i,j})_{j \in \mathbb{N}}$ is weakly increasing towards some α_i ; and the sequence $(\alpha_i)_{i \in \mathbb{N}}$ is weakly decreasing towards α .

Auxiliary subshift Z'_α

We create an auxiliary subshift Z'_α on the following three layers:

1. *First layer L_1 :* We take $L_1 = X_*$ to encode integers $i \in \mathbb{N}$. Intuitively, i will denote which Σ_2 number α_i is approximated in the configuration.
2. *Second layer L_2 :* We also set $L_2 = X_*$ to encode integers $j \in \mathbb{N}$, $j \geq i$. Intuitively, j will denote which Π_1 number $\alpha_{i,j}$ is approximated in the configuration.
3. *Density layer L_d :* We define the density layer as $L_d = \{0, 1\}^{\mathbb{Z}}$. Whenever the first two layers are non-degenerate, this layer will be restricted to densities $\lesssim \alpha_{i,j}$. Since the real numbers $\alpha_{i,j}$ are Π_1 , the subshifts $T_{\leq \alpha_{i,j}, i}$ are effective from the numbers $\alpha_{i,j}$.

such that Z'_α is defined as:

$$Z'_\alpha = \left\{ (z^{(1)}, z^{(2)}, z^{(d)}) \in L_1 \times L_2 \times L_d \mid z^{(2)} \in \langle \infty \rangle \right\} \\ \cup \bigcup_{i \in \mathbb{N}} \bigcup_{j \geq i} \left\{ (z^{(1)}, z^{(2)}, z^{(d)}) \in L_1 \times L_2 \times L_d \mid \exists k_1, k_2 \in \mathbb{N}, \right. \\ \left. z^{(1)} = \langle i \rangle_{k_1}, z^{(2)} = \langle j \rangle_{k_2} \text{ and } \exists \beta \leq \alpha_{i,j}, z^{(d)} = T(\beta, i)_{k_1} \right\}$$

■ **Figure 3** A proper configuration: L_d contains a Toeplitz encoding of $\overline{.1010}^2 = \frac{5}{8}$. $z = (\langle 15 \rangle_{11}, \langle 18 \rangle_1, T(\frac{5}{8}, 15)_{10})$. The vertical red line indicates the origin.

▷ **Claim 15.** The \mathbb{Z} subshift Z'_α is an effective subshift.

Proof. Since the subshift X_* is effective, the conditions on the first two layers L_1 and L_2 are straightforward to enforce. Furthermore, since the $\alpha_{i,j}$ are Π_1 real numbers enumerated by a single machine, by Claim 14 we can obtain Z'_α as follows: a pattern $w = (w^{(1)}, w^{(2)}, w^{(d)}) \in \mathcal{L}(X_*) \times \mathcal{L}(X_*) \times \{0, 1\}^n$ is forbidden whenever both $w^{(1)}$ and $w^{(2)}$ contain at least two symbols $*$ (so that $w^{(1)}$ encodes an integer $i \in \mathbb{N}$, $w^{(2)}$ encodes an integer $j \geq i$) and $w^{(d)}$ contains a pattern forbidden in $T_{\leq \alpha_{i,j}, i}$. ◁

21:10 Computability of Extender Sets in Multidimensional Subshifts

A configuration $z = (\langle i \rangle_{k_1}, \langle j \rangle_{k_2}, T(\beta, i)_{k_1}) \in Z'_\alpha$ is said to be *proper*. A configuration $z = (z^{(1)}, z^{(2)}, \cdot) \in Z'_\alpha$ with $z^{(2)} \in \langle \infty \rangle$ is said to be *degenerate*. Thus, we separate patterns into two categories: whenever $w \in \mathcal{L}(Z'_\alpha)$ only appears in degenerate configurations, we call it a *degenerate pattern*; if w can appear in a proper configuration, we call it a *proper pattern*.

On the one hand, degenerate patterns of Z'_α do not contribute much to the number of extender sets, despite being exponentially many:

▷ **Claim 16.** Let $n \in \mathbb{N}$, and consider $D_E(n) = \{E_{Z'_\alpha}(w) \mid w \in \mathcal{L}_n(Z'_\alpha) \text{ degenerate}\}$, the set of extender sets of degenerate patterns of size n . Then $|D_E(n)| = O(n^3)$.

Proof. Let $u, v \in \mathcal{L}_n(Z'_\alpha)$ be two degenerate patterns. Whenever $u^{(1)} = v^{(1)}$ and $u^{(2)} = v^{(2)}$, we have $E_{Z'_\alpha}(u) = E_{Z'_\alpha}(v)$ because the density layer of such patterns can be anything. Since at most a single symbol $*$ can appear on the second layer of degenerate patterns, by counting possibilities for their first layers we obtain $|D_E(n)| = O(n^3)$. ◁

On the other hand, all proper patterns of Z'_α belong to distinct extender sets:

▷ **Claim 17.** Let $u, v \in \mathcal{L}_n(Z'_\alpha)$ be two distinct proper patterns. Then $E_{Z'_\alpha}(u) \neq E_{Z'_\alpha}(v)$.

Proof. Let $u \in \mathcal{L}_n(Z'_\alpha)$ be a proper pattern. It can be extended into a whole proper configuration $z = (\langle i \rangle_{k_1}, \langle j \rangle_{k_2}, z^{(d)}) \in Z'_\alpha$ such that $z|_{\llbracket 0, n-1 \rrbracket} = u$. By definition, z is periodic of period $i \cdot j$: thus, $z|_{\llbracket 0, n-1 \rrbracket}$ is entirely determined by $z|_{\llbracket n, i \cdot j + n - 1 \rrbracket}$, and $z|_{\mathbb{Z} \setminus \llbracket 0, n-1 \rrbracket}$ can only extend the pattern u itself. ◁

However, there are only polynomially many distinct proper patterns of a given size in Z'_α . The next section will nevertheless create a subshift Z_α with the correct (exponential) amount of proper patterns, thanks to the following remark:

▷ **Claim 18.**

- For an integer $i \in \mathbb{N}$ and a proper configuration $z \in Z'_\alpha$ such that $z^{(1)} = \langle i \rangle_{k_1}$, an i -period of the density layer $z^{(d)}$ contains at most $\alpha_i \cdot i + O(1)$ symbols 1.
- For integers $n \in \mathbb{N}$ and $i \geq n$, and a proper configuration $z \in Z'_\alpha$ such that $z^{(1)} = \langle i \rangle_{k_1}$, a factor of length n of the density layer $z^{(d)}$ contains at most $\alpha_n \cdot n + O(1)$ symbols 1.

Proof. This follows from Claim 13 and the monotonicity of the sequence $(\alpha_{i,j})_{i,j \in \mathbb{N}^2}$. ◁

Free bits in the subshift Z_α

To create the desired exponential number of extender sets, we create the subshift Z_α by adding *free bits* on top of the symbols 1 of the density layer. Informally, if there were $\beta \cdot i + O(1)$ symbols 1 in an i -period of the density layer in Z'_α , adding free bits on top of the symbols 1 creates $2^{\beta \cdot i + O(1)}$ patterns in Z_α . Thus, we add a fourth layer to Z'_α :

4. *Free layer L_f* : We define the free layer as $L_f = \{\sqcup, 0, 1\}^{\mathbb{Z}}$. Given the synchronizing map $\pi_{\text{sync}}: \{\sqcup, 0, 1\} \rightarrow \{0, 1\}$ defined as $\pi_{\text{sync}}(0) = \pi_{\text{sync}}(1) = 1$ and $\pi_{\text{sync}}(\sqcup) = 0$, we say that two configurations $z^{(d)} \in L_d$ and $z^{(f)} \in L_f$ are *synchronized* if $\pi_{\text{sync}}(z^{(f)}) = z^{(d)}$.

and we define Z_α as:

$$Z_\alpha = \left\{ (z^{(1)}, z^{(2)}, z^{(d)}, z^{(f)}) \in L_1 \times L_2 \times L_d \times L_f \mid z^{(1)} \in \langle \infty \rangle \text{ or } z^{(2)} \in \langle \infty \rangle \right\} \\ \cup \bigcup_{i \in \mathbb{N}} \bigcup_{j \geq i} \left\{ (z^{(1)}, z^{(2)}, z^{(d)}, z^{(f)}) \in L_1 \times L_2 \times L_d \times L_f \mid \exists k_1, k_2 \in \mathbb{N}, \right. \\ \left. z^{(1)} = \langle i \rangle_{k_1}, z^{(2)} = \langle j \rangle_{k_2}, \pi_{\text{sync}}(z^{(f)}) = z^{(d)}, \right. \\ \left. \exists \beta \leq \alpha_{i,j}, z^{(d)} = T(\beta, i)_{k_1} \text{ and } z^{(f)} \text{ is } i\text{-periodic} \right\}.$$

▷ Claim 19. The \mathbb{Z} subshift Z_α is effective.

Proof. In addition to the forbidden patterns of Z'_α , forbid patterns $w = (w^{(1)}, w^{(2)}, w^{(d)}, w^{(f)})$ for which $w^{(1)}$ and $w^{(2)}$ both contain two symbols $*$ (in which case, denote by i the distance between two symbols $*$ in $w^{(1)}$), but $w^{(f)}$ is either not synchronized with $w^{(d)}$ or not i -periodic. ◁

We extend the terminology from Z'_α to Z_α and call *proper* the configurations of Z_α that encode integers $i \in \mathbb{N}$ and $j \geq i$ on their first two layers, and *degenerate* those who do not. Similarly, a pattern is *proper* if it can be extended into a proper configuration, and *degenerate* if it only extends into degenerate configurations.

Since the free layer is required to be i -periodic only in proper configurations, Claims 16 and 17 both extend from Z'_α to Z_α by the very same arguments:

▷ Claim 20.

- For $n \in \mathbb{N}$, consider $D_E(n) = \{E_{Z_\alpha}(w) \mid w \in \mathcal{L}_n(Z_\alpha) \text{ degenerate}\}$. Then $D_E(n) = O(n^2)$.
- Let $u, v \in \mathcal{L}_n(Z_\alpha)$ be two distinct proper patterns. Then $E_{Z_\alpha}(u) \neq E_{Z_\alpha}(v)$.

► **Lemma 21.** Let $P(n) = \{w \in \mathcal{L}_n(Z_\alpha) \mid w \text{ is proper}\}$. Then

$$2^{n \cdot \alpha_n + O(1)} \leq P(n) \leq \text{poly}(n) \cdot \sum_{i=1}^n 2^{\alpha_i \cdot i + O(1)}.$$

Proof: lower bound. Consider the patterns $w' = (\langle n \rangle_0, \langle j \rangle_0, T(\alpha_{n,j}, n)_0) \upharpoonright_{[0, n-1]}$ in Z'_α for $j \geq n$: the number of symbols 1 in the density layer $w'^{(d)}$ of such w' is $\alpha_{n,j} \cdot n + O(1)$ by Claim 13. Since $\alpha_{n,j} \rightarrow \alpha_n$, by taking $j \geq n$ large enough we obtain a proper pattern $w' \in \mathcal{L}_n(Z'_\alpha)$ such that its density layer $w'^{(d)}$ contains $\alpha_n \cdot n + O(1)$ symbols 1.

Thus, we obtain $2^{\alpha_n \cdot n + O(1)}$ proper patterns $w \in \mathcal{L}_n(Z_\alpha)$ such that $\pi_{L_1 \times L_2 \times L_d}(w) = w'$ (since each symbol 1 in $w^{(d)}$ leads to two distinct patterns in the free layer L_f). ◀

Proof: upper bound. To overestimate the number of proper patterns $|P(n)|$, we consider the restrictions $w' = z' \upharpoonright_{[0, n-1]}$ for z' ranging in the proper configurations of Z'_α (consider all values of $\langle i \rangle_{k_1}, \langle j \rangle_{k_2}$ and of n -factors in $y^{(d)}$), and bound the number of symbols 1 in each case: by Claim 18,

- If $i \leq n$, an i -period of the density layer $w'^{(d)}$ contains less than $\alpha_i \cdot i + O(1)$ symbols 1.
- For $i > n$, $w'^{(d)}$ contains less than $\alpha_n \cdot n + O(1)$ symbols 1.

Since each symbol 1 in an i -period of the density layer results in two distinct patterns in the free layer, and there are less than $O(i^2)$ possibilities for such periods, we obtain:

$$\begin{aligned} P(n) &\leq \sum_{i=1}^n \sum_{k_1=0}^{i-1} \sum_{j=1}^n \sum_{k_2=0}^{j-1} O(i^2) \cdot 2^{\alpha_i \cdot i + O(1)} + \sum_{k_1=0}^n \sum_{k_2=0}^n O(n^2) \cdot 2^{\alpha_n \cdot n + O(1)} \\ &\leq \text{poly}(n) \cdot \sum_{i=1}^n 2^{\alpha_i \cdot i + O(1)}. \end{aligned} \quad \blacktriangleleft$$

Combining Lemma 21 with Claim 20, we obtain by taking the limit over $\alpha_n \rightarrow \alpha$ that $h_E(Z_\alpha) = \alpha$, which concludes the proof.

6 Π_3 Extender Entropies for \mathbb{Z}^2 Sofic Subshifts

We now want to extend Theorem A to multidimensional sofic shifts: an idea could be to replace i -periodic words on \mathbb{Z} in the previous construction with (i, i) -periodic squares on \mathbb{Z}^2 . Unfortunately, such a subshift cannot be sofic⁴.

Yet, making configurations *periodic* is not necessary to ensure that two proper patterns u and v have distinct extender sets: it is enough to have a configuration that *witnesses* the difference between u and v (by extending one but not the other). This was already illustrated in the semi-mirror shift (see Section 3): instead of mirroring the whole half-plane (which is not sofic), non-deterministically reflecting a single bit from the upper to the lower half-plane is actually enough, since each bit can be reflected individually in some configuration. In this section, we use this idea to prove (see Figure 4):

(a) Whole (i, i) -periodic squares of free bits. (b) A single (i, i) -periodic free bit.

■ **Figure 4** The periodized area is highlighted in color ■ and hatched. To make the figure readable, symbols for free bits are $\{\square, \blacksquare\}$ instead of $\{b, b'\}$.

► **Theorem B.** *The set of extender entropies of \mathbb{Z}^2 sofic subshifts is exactly $\Pi_3 \cap [0, +\infty)$.*

6.1 Preliminary: Marking Offsets With Configurations $[2i]_{m_1, m_2}$

In our construction, we will need to mark some positions $(m_1 + i\mathbb{Z}, m_2 + i\mathbb{Z})$. To do so, we consider the alphabet $A_m = \{\square, \blacksquare\}$. Denote by $[2i]_{m_1, m_2}$ the $(2i, 2i)$ -periodic configuration formally defined as $([2i]_{m_1, m_2})_p = \blacksquare$ if and only if $p = (m_1, m_2) \bmod (2i, 2i)$. We say that a symbol \blacksquare is a *marker*.

For a configuration $x = [2i]_{m_1, m_2}$ with $(m_1, m_2) \in \llbracket 0, 2i - 1 \rrbracket^2$, we say that a position $p \in \mathbb{Z}^2$ is *marked* if $p \in (m_1 + i\mathbb{Z}, m_2 + i\mathbb{Z})$. This lattice has unit cells of size $i \times i$ instead of $2i \times 2i$: this is voluntary. In particular, some marked positions $p \in \mathbb{Z}^2$ satisfy $x_p = \square$.

Considering the subshift generated by all the configurations $[i]_{m_1, m_2}$, we define:

$$\mathcal{G} = \bigcup_{i \in \mathbb{N}} \{[i]_{m_1, m_2} \mid (m_1, m_2) \in \llbracket 0, i - 1 \rrbracket^2\} \cup [\infty]$$

where $[\infty] = \{x \in A_m^{\mathbb{Z}^2} \mid |x|_{\blacksquare} \leq 1\}$ is the set of configurations having at most one marker symbol \blacksquare : these are the configurations that appear when taking the closure of all $[i]_{m_1, m_2}$.

⁴ The argument proving that the classical mirror subshift cannot be sofic still applies here: there would be $2^{O(i^2)}$ distinct $i \times i$ patterns, but only $2^{O(i)}$ borders in the SFT cover.

6.2 Construction: the Sofic \mathbb{Z}^2 Subshift Y_α

Let us now begin a construction to prove Theorem B. We use the notations introduced in the proof of Theorem A: we fix $\alpha \in [0, 1] \cap \Pi_3$ such that $\alpha = \inf_i \sup_j \alpha_{i,j}$ for $\alpha_{i,j}$ a computable sequence of Π_1 real numbers (we assume the same monotonicity properties). We define a subshift Y_α on the following five layers:

- *Lifted layers:* We define the first three layers of Y_α as $L_1^\uparrow \times L_2^\uparrow \times L_d^\uparrow$, where L_1, L_2 and L_d are the three layers of the subshift Z'_α defined in the proof of Theorem A.
- *Marker layer L_m :* We define $L_m = \mathcal{G}$ to mark positions $p \in (m_1 + i\mathbb{Z}, m_2 + i\mathbb{Z})$.
- *Free layer L_f :* We also define the free layer by $L_f = \{\sqcup, 0, 1\}^{\mathbb{Z}^2}$.

and we define Y_α as (see Figure 5 for an illustration):

$$Y_\alpha = \left\{ (y^{(1)\uparrow}, y^{(2)\uparrow}, y^{(d)\uparrow}, y^{(m)}, y^{(f)}) \in L_1^\uparrow \times \langle \infty \rangle^\uparrow \times L_d^\uparrow \times L_m \times L_f \mid \right. \\ \left. \forall i \in \mathbb{N}, (\exists k_1 \in \mathbb{N}, y^{(1)} = \langle i \rangle_{k_1} \iff \exists m_1, m_2 \in \mathbb{N}, y^{(m)} = [2i]_{m_1, m_2}) \right\} \\ \cup \bigcup_{i \in \mathbb{N}} \bigcup_{j \geq i} \left\{ (y^{(1)\uparrow}, y^{(2)\uparrow}, y^{(d)\uparrow}, y^{(m)}, y^{(f)}) \in L_1^\uparrow \times L_2^\uparrow \times L_d^\uparrow \times L_m \times L_f \mid \exists k_1, m_1, m_2, k_2 \in \mathbb{N}, \right. \\ \left. y^{(1)} = \langle i \rangle_{k_1}, y^{(m)} = [2i]_{m_1, m_2}, y^{(2)} = \langle j \rangle_{k_2}, \pi_{\text{sync}}(y^{(f)}) = y^{(d)\uparrow}, \right. \\ \left. \exists \beta \leq \alpha_{i,j}, y^{(d)} = T(\beta, i)_{k_1} \text{ and } y^{(f)}|_{(m_1+i\mathbb{Z}) \times (m_2+i\mathbb{Z})} \text{ is constant} \right\}.$$

■ **Figure 5** Projection of a proper configuration on $L_1^\uparrow \times L_m \times L_f$. The symbols $*$ are on L_1^\uparrow , the symbols \blacksquare on L_m the symbols 1 on L_f . All the other bits of L_f (not drawn here) are free.

Extending the terminology from Z_α to Y_α , we call *proper* the configurations of Y_α that encode integers $i \in \mathbb{N}$ and $j \geq i$ on their first two layers, and *degenerate* those which do not. Additionally we say that a pattern is *proper* if it can be extended into a proper configuration, and *degenerate* otherwise. We say that two proper patterns $u, v \in \mathcal{L}_n(Y_\alpha)$ are *similar* if they are equal on their first four layers (i.e. $\pi_{L_1^\uparrow \times L_2^\uparrow \times L_d^\uparrow \times L_m}(u) = \pi_{L_1^\uparrow \times L_2^\uparrow \times L_d^\uparrow \times L_m}(v)$).

▷ **Claim 22.** Two similar proper patterns $u, v \in \mathcal{L}_n(Y_\alpha)$ have distinct extender sets if and only if there exists a proper configuration y that extends u and that *marks* a position $p \in \llbracket 0, n-1 \rrbracket^2$ such that $u_p^{(f)} \neq v_p^{(f)}$.

We would very much like an analog of Claim 20: unfortunately, not all proper patterns generate distinct extender sets. Indeed, by the previous claim, similar proper patterns generate distinct extender sets only when the positions at which they differ can be *marked* by an extending configuration (this depends on the relative position of an $n \times n$ window covering the four quadrants of a $2i \times 2i$ square, etc...). Yet, we do not need precise considerations to count the number of extender sets, and simply prove the following bounds:

► **Lemma 23.** *Let $P_E(n) = \{E_{Y_\alpha}(w) \in \mathcal{L}_n(Y_\alpha) \mid w \text{ is proper}\}$. Then*

$$2^{\alpha_n \cdot n^2 + O(n)} \leq P_E(n) \leq \text{poly}(n) \cdot \sum_{i=0}^n 2^{\alpha_i \cdot i^2 + O(i)}.$$

Proof: lower bound. For $j \geq n$, consider the set $J_j = \{(y \in Y_\alpha \mid y^{(1)} = \langle n \rangle_0, y^{(2)} = \langle j \rangle_0, y^{(d)} = T(\alpha_{n,j}, n))\}$. The number of symbols 1 in an $(n \times n)$ -period in the density layer of such configurations is $\alpha_{n,j} \cdot n^2 + O(n)$ by Claim 13. Since $\alpha_{n,j} \rightarrow \alpha_n$, by taking $j \geq n$ large enough we obtain a set $J = J_j$ of proper configurations y whose density layer $y^{(d)}$ contains $\alpha_n \cdot n^2 + O(n)$ symbols 1 in an $(n \times n)$ -period.

Considering the free layer of such patterns, there are at least $2^{\alpha_n \cdot n^2 + O(n)}$ distinct patterns in the finite set $W = \{y|_{\llbracket 0, n-1 \rrbracket^2} \mid y \in J_j \text{ and } y^{(m)}|_{\llbracket 0, n-1 \rrbracket^2} = \square^{\llbracket 0, n-1 \rrbracket^2}\}$, and we claim that they all generate distinct extender sets. Indeed, for any two distinct patterns $u, v \in W$, there exists a position $p \in \llbracket 0, n-1 \rrbracket^2$ such that $u_p^{(f)} \neq v_p^{(f)}$; and there exists a configuration $y \in J_j$ that extends u with $y^{(m)} = [2n]_{p+(n,n)}$: in particular, y marks the position p .⁵ By Claim 22, we obtain $E_{Y_\alpha}(u) \neq E_{Y_\alpha}(v)$. This proves that $P_E(n) \geq 2^{\alpha_n \cdot n^2 + O(n)}$. ◀

Proof: upper bound. We proceed as with the \mathbb{Z} effective subshift Z_α : to bound the cardinality of $P_E(n)$, we consider the restrictions $w = y|_{\llbracket 0, n-1 \rrbracket^2}$ for y ranging in the proper configurations of Y_α (for all values of $\langle i \rangle_{k_1}$, $\langle j \rangle_{k_2}$, $T(\beta, i)$ and $[2i]_{m_1, m_2}$), and count free layers by Claim 18:

- If $i \leq n$, an $i \times i$ square of the density layer $w^{(d)}$ contains less than $\alpha_i \cdot i^2 + O(i)$ symbols 1.
- If $i > n$, the density layer $w^{(d)}$ contains less than $\alpha_n \cdot n^2 + O(n)$ symbols 1.

Finally, when summing over all these cases, we overestimate the number of extender sets generated by the free layer by assuming that each position $p \in \llbracket 0, i-1 \rrbracket^2$ containing a symbol 1 on the density layer can be marked by a proper configuration y extending the pattern (while only a subset of such positions can be marked):

$$\begin{aligned} P_E(n) &\leq \sum_{i=1}^n \sum_{k_1=0}^{i-1} \sum_{j=1}^n \sum_{k_2=0}^{j-1} O(i^4) \cdot 2^{\alpha_i \cdot i^2 + O(i)} + \sum_{k_1=0}^n \sum_{k_2=0}^n O(n^4) \cdot 2^{\alpha_n \cdot n^2 + O(n)} \\ &\leq \text{poly}(n) \cdot \sum_{i=1}^n 2^{\alpha_i \cdot i^2 + O(i)}. \end{aligned} \quad \blacktriangleleft$$

By taking the limit $\alpha = \lim_n \alpha_n$, we obtain that $h_E(Y_\alpha) = \alpha$. Thus, we are left to prove:

► **Claim 24.** The subshift Y_α is a sofic subshift.

This proof is very standard and unsurprising, yet is included for the sake of exhaustiveness.

Sketch of proof. First, we introduce a grid subshift. Let us denote by Y_{grid} the subshift on the alphabet $\{+, -, | \}$ defined as the closure of all the square grid configurations (see Figure 6a). It is a sofic subshift: by enforcing the continuity of black lines between adjacent positions, we obtain an irregular grid; to obtain a regular square grid, we make each cross $+$ send diagonals in the SFT cover (since diagonals can only go through a cross, the grid becomes regular).

Let us now synchronize Y_{grid} with L_1^\uparrow : we define $Y_{\text{grid}^*} \subseteq L_1^\uparrow \times Y_{\text{grid}}$ the set of configurations $(x^{(1)\uparrow}, x^{(g)})$ such that $x^{(g)}$ has mesh $i \times i$ if and only if $x^{(1)}$ encodes some $i \in \mathbb{N}$ (see Figure 6b).

⁵ Markers were chosen to be $(2i, 2i)$ -periodic for this reason: we need to be able to mark a position $p \in \llbracket 0, i-1 \rrbracket^2$ in a configuration without seeing a marker in the square $\llbracket 0, i-1 \rrbracket^2$.

(a) A square grid configuration of mesh $i \times i$.

(b) Vertical blue columns of symbols $*$ are i -periodic, the square grid has mesh $i \times i$.

■ **Figure 6** Two configurations using grids.

▷ **Claim 25.** $Y_{\text{grid}*}$ is a \mathbb{Z}^2 sofic subshift.

Sketch of proof. Using areas of colors in the SFT cover, ensure that exactly one black vertical line in Y_{grid} can appear between two vertical lines of symbols $*$ in L_1^\uparrow . ◁

Let us now prove that Y_α is a \mathbb{Z}^2 sofic subshift. Intuitively, it follows from Theorem 2: Y_α is a “decorated version” of Z_α^\uparrow . The most tricky step is in the periodicity condition: periodicity of a free bit in $L^{(f)}$ should only be enforced whenever both layers $y^{(1)}$ and $y^{(2)}$ do not belong in $\langle \infty \rangle^\uparrow$, *i.e.* whenever they both actually encode some integers $i \in \mathbb{N}$ and $j \in \mathbb{N}$.

To proceed, we slightly alter the \mathbb{Z} subshift Z'_α to define a new subshift Z''_α : it contains an additional layer L_p (the *proper* layer) that can take two values (either $\mathfrak{p}^\mathbb{Z}$ or $\mathfrak{d}^\mathbb{Z}$), and is forced to be $\mathfrak{p}^\mathbb{Z}$ whenever both the first and second layer do encode integers:

$$Z''_\alpha = \left\{ (z^{(1)}, z^{(2)}, z^{(d)}, z^{(p)}) \in L_1 \times L_2 \times L_d \times \{\mathfrak{p}^\mathbb{Z}, \mathfrak{d}^\mathbb{Z}\} \mid z^{(2)} \in \langle \infty \rangle^\uparrow \right\} \\ \cup \bigcup_{i \in \mathbb{N}} \bigcup_{j \geq i} \left\{ (z^{(1)}, z^{(2)}, z^{(d)}, z^{(p)}) \in L_1 \times L_2 \times L_d \times \{\mathfrak{p}^\mathbb{Z}\} \mid \exists k_1, k_2 \in \mathbb{N}, \right. \\ \left. z^{(1)} = \langle i \rangle_{k_1}, z^{(2)} = \langle j \rangle_{k_2} \text{ and } \exists \beta \leq \alpha_{i,j}, z^{(d)} = T(\beta, i)_{k_1} \right\}.$$

By a slight alteration of Claim 15, the subshift Z''_α is effective whenever α is a Π_3 real number. By Theorem 2, the \mathbb{Z}^2 subshift Z''_α^\uparrow is thus sofic. Then, we use the proper layer to enforce periodicity of a free bit in $L^{(f)}$ only whenever $y^{(p)} = \mathfrak{p}^{\mathbb{Z}^2}$, and define Y'_α as:

$$Y'_\alpha = \left\{ (y^{(1)\uparrow}, y^{(2)\uparrow}, y^{(d)\uparrow}, y^{(p)\uparrow}, y^{(g)}, y^{(f)}) \in Z''_\alpha^\uparrow \times Y_{\text{grid}} \times \{\sqcup, 0, 1\}^{\mathbb{Z}^2} \mid \right. \\ \left. (y^{(1)\uparrow}, y^{(g)}) \in Y_{\text{grid}*}, \quad \pi_{\text{sync}}(y^{(f)}) = y^{(d)\uparrow}, \right. \\ \left. \exists b \in \{\sqcup, 0, 1\}, \forall p \in \mathbb{Z}^2, y^{(p)} = \mathfrak{p}^\mathbb{Z} \wedge y_p^{(g)} = \vdash \implies y_p^{(f)} = b \right\}$$

▷ **Claim 26.** Y'_α is a \mathbb{Z}^2 sofic subshift.

Sketch of proof. By the previous paragraph, the first four layers are sofic; and by Claim 25, the synchronization $Y_{\text{grid}*}$ of L_1^\uparrow and Y_{grid} is sofic. To make a free bit periodic, one can carry a unique symbol $b_{\text{grid}} \in \{\sqcup, 0, 1\}$ along the black lines of Y_{grid} in an SFT cover, and enforce the following: on positions at which a cross symbol \vdash appears on the grid layer $y^{(g)}$, and a symbol \mathfrak{p} appears on the proper layer $y^{(p)\uparrow}$, the free bit in $y^{(f)}$ is then made equal to the symbol b_{grid} . ◁

21:16 Computability of Extender Sets in Multidimensional Subshifts

We can now prove that Y_α is sofic. Indeed, fix an SFT cover of Y'_α in which we color cross symbols \dagger into two colors alternatingly: let us say, red and blue. On each horizontal and vertical line of the grid layer Y_{grid} , crosses are now alternating between red and blue. We claim that we obtain the subshift Y_α by projecting this SFT cover as follows:

- Erase the proper layer.
 - Projection of the grid layer: red crosses become \blacksquare , and all other symbols become \square .
- Indeed, projecting the grid layer as mentioned creates the marker layer L_m . The only condition that remains to be checked is the (i, i) -periodicity condition on a free bit.

Notice that in Y'_α , both cases $y^{(p)\dagger} = \mathbf{p}^{\mathbb{Z}^2}$ and $y^{(p)\dagger} = \mathbf{d}^{\mathbb{Z}^2}$ are possible whenever $y^{(1)} \in \langle \infty \rangle$ or $y^{(2)} \in \langle \infty \rangle$, so that erasing the proper layer in the projection merges the two cases together and removes the periodicity enforced a free bit of $y^{(f)}$; while whenever $y^{(1)} = \langle i \rangle_{k_1}$ and $y^{(2)} = \langle j \rangle_{k_2}$, only the case $y^{(p)} = \mathbf{p}^{\mathbb{Z}^2}$ is allowed: so that, when projecting, the periodicity condition is still enforced. \triangleleft

7 Realizing Extender Entropies: Computable Subshifts

A subshift X is said to be *computable* if its language $\mathcal{L}(X)$ is decidable. Following the proofs from Section 4, one proves that extender entropies of computable subshifts are Π_2 real numbers. We prove the converse inclusion and obtain:

► **Theorem 27.** *The set of extender entropies of computable \mathbb{Z} effective subshifts (resp. computable \mathbb{Z}^2 sofic subshifts) is exactly $\Pi_2 \cap [0, +\infty)$.*

Sketch of proof. We slightly alter our previous constructions. The subshift Z'_α constructed in Theorem A might not be computable whenever $\alpha \in \Pi_3$, since, given some $i, j \in \mathbb{N}$ and some factor of $T(\beta, i)$, it might be undecidable to know whether $\beta \leq \alpha_{i,j}$ when $\alpha_{i,j} \in \Pi_1$.

Yet, when taking $\alpha = \inf_i \alpha_i = \inf_i \sup_j \alpha_{i,j} \in \Pi_2$ for $(\alpha_{i,j})$ a computable sequence, the previous problem becomes decidable; thus, the subshift Z'_α is computable. Both proofs, on \mathbb{Z} and \mathbb{Z}^2 , then go through without any other modification. \blacktriangleleft

8 Extender Sets of Minimal Subshifts

Minimality is a general dynamical notion; in our context, a subshift is *minimal* if it contains no nonempty proper subshift. Extender sets are much easier in minimal subshifts and do not even depend on the computability of the language:

► **Proposition 28.** *Let X be a minimal subshift over \mathbb{Z}^d . Then for any $n > 0$ and any patterns $u, v \in \mathcal{L}_n(X)$, $E_X(u) \subseteq E_X(v) \iff u = v$.*

Proof. Let $u, v \in \mathcal{L}_n(X)$ and suppose that $E_X(u) \subseteq E_X(v)$. Then any appearance of u in a configuration can be replaced by v : by iterating the process while ordering patterns lexicographically (see [23, Lemma 2.2] for the complete argument), we obtain by compactness a configuration of X in which u does not appear, which contradicts minimality. \blacktriangleleft

This implies that $h_E(X) = h(X)$ if X is minimal. Since minimal sofic subshifts have zero entropy (folklore, see [11, Proposition 6.1]), and minimal effective subshifts have arbitrary Π_1 entropy (consider [16, Theorem 4.77] with computable sequences $(k_n)_{n \in \mathbb{N}}$), we obtain:

- **Corollary 29.** *The extender entropy of a minimal \mathbb{Z}^d sofic subshift is always 0.*
- **Corollary 30.** *The set of extender entropies of minimal \mathbb{Z}^d effective subshifts is exactly $\Pi_1 \cap [0, +\infty)$.*

9 Extender Sets of Subshifts With Mixing Properties

9.1 Mixing \mathbb{Z} Subshifts

Mixingness is another dynamical notion. In the context of \mathbb{Z} subshifts, mixingness intuitively implies that for any pair of admissible words, there exists a configuration containing both of them at arbitrary positions, provided they are sufficiently far apart:

► **Definition 31** (Mixing subshift). *A \mathbb{Z} subshift X is mixing if*

$$\forall n > 0, \exists N > 0, \forall u, v \in \mathcal{L}_n(X), \forall k \geq N, \exists w \in \mathcal{L}_k(X), uwv \in \mathcal{L}(X).$$

We say that X is $f(n)$ -mixing for some function f if N can be taken equal to $f(n)$ in the previous definition. When f is constant $f(n) = N$, we simply write that X is N -mixing.

One could expect that strong mixing conditions would restrict the behaviors of extender sets: indeed, all the examples we mentioned so far either have strong mixing properties (the full shift, \mathbb{Z} SFTs. . .) and zero extender entropy, or have positive extender entropy but are far from mixing (periodicity, reflected positions, . . .). However, we show in this section that even very restrictive mixing properties do not imply anything on extender entropies.

► **Proposition 32.** *Let X be a one-dimensional subshift. There exists a 1-mixing subshift $X_\#$ with $h_E(X) = h_E(X_\#)$. (Furthermore, if X was effective, then $X_\#$ can be taken effective.)*

Proof. Let $X \subseteq \mathcal{A}^{\mathbb{Z}}$ be a subshift, and $\alpha = h_E(X)$. Denote $\mathcal{F} = \mathcal{A}^* \setminus \mathcal{L}(X)$. Let us define a subshift $X_\#$ over the alphabet $\mathcal{A} \sqcup \{\#\}$ (assuming that $\#$ is a free symbol not in \mathcal{A}) by the same family of forbidden patterns \mathcal{F} : configurations of $X_\#$ are composed of (possibly infinite) words of $\mathcal{L}(X)$ separated by the *safe symbol* $\#$. Then $X_\#$ is 1-mixing, as for any $u, v \in \mathcal{L}(Y)$, we have $u\#v \in \mathcal{L}(Y)$.

We are left with proving that $h_E(X_\#) = h_E(X)$. First, we need to introduce the notion of *follower* and *predecessor sets*: in X , the *follower* and *predecessor sets* are respectively defined as $F_X(w) = \{x \in \mathcal{A}^{\mathbb{N}} \mid wx \sqsubseteq X\}$ and $P_X(w) = \{x \in \mathcal{A}^{-\mathbb{N}} \mid xw \sqsubseteq X\}$. In other words, the follower set (resp. predecessor set) of some word w correspond to the set of right-infinite (resp. left-infinite) sequences x such that ux (resp. xw) appears in some configuration of X .

Let $n \geq 0$. We prove that:

$$|E_X(n)| \leq |E_{X_\#}(n)| \leq |E_X(n)| + \sum_{i+j < n} |P_X(i)||F_X(j)|$$

Lower bound. The lower bound holds simply because if x extends a pattern $w \in \mathcal{L}(X)$ but not $w' \in \mathcal{L}(X)$, then x also belongs in $X_\#$ and still extends w but not w' in $X_\#$, so that $E_{X_\#}(w) \neq E_{X_\#}(w')$. \triangleleft

Upper bound. For the rightmost inequality, we need to distinguish some cases according to whether a pattern contains a $\#$ or not.

■ Let $w \in \mathcal{L}_n(X_\#)$ that does not contain a symbol $\#$. Then

$$E_{X_\#}(w) = E_X(w) \cup \bigcup_{l, r \in \mathcal{A}^* \mid lwr \in \mathcal{L}(X)} \{(x\#l, r\#x') \mid x, x' \text{ admissible in } X_\#\}$$

So, for $w, w' \in \mathcal{L}_n(X_\#)$. So, for $w, w' \in \mathcal{L}_n(X_\#)$ that do not contain a symbol $\#$, we have $E_{X_\#}(w) = E_{X_\#}(w')$ if and only if $E_X(w) = E_X(w')$.

- Let $w \in \mathcal{L}_n(X_\#)$ containing at least a symbol $\#$, and let $i \leq j$ be the first and last positions in w at which a symbol $\#$ appear. Let $l, r \in \mathcal{A}^*$ be respectively $w_{\llbracket 0, i-1 \rrbracket}$ and $w_{\llbracket j+1, n-1 \rrbracket}$. Since $\#$ is a safe symbol, $E_{X_\#}(w)$ is entirely determined by $(P_X(l), F_X(r))$:

$$E_{X_\#}(w) = (P_X(l) \times F_X(r)) \cup \bigcup_{\substack{l', r' \in \mathcal{A}^* \\ l' \cdot l, r \cdot r' \in \mathcal{L}(X)}} \{(y \# l', r' \# y') \mid y, y' \text{ admissible in } X_\#\}.$$

Doing a disjunction on these two cases, and over the pairs $i + j < n$ in the second case (and abusing notations again by denoting $P_X(i) = \{P_X(w) \mid w \in \mathcal{L}_i(X)\}$ and $F_X(j) = \{F_X(w) \mid w \in \mathcal{L}_j(X)\}$) we obtain:

$$|E_{X_\#}(n)| \leq |E_X(n)| + \sum_{i+j < n} |P_X(i)| |F_X(j)| \quad \triangleleft$$

As $|P_X(n)| \leq |E_X(n)|$ and $|F_X(n)| \leq |E_X(n)|$, and that $|E_X(n)| = 2^{\alpha n + o(n)}$, we obtain $2^{\alpha n + o(n)} \leq |E_{X_\#}(n)| \leq \text{poly}(n) \cdot 2^{\alpha n + o(n)}$, and conclude that $h_E(X_\#) = \alpha$. \blacktriangleleft

9.2 Block-gluing \mathbb{Z}^d Subshifts

There exists various mixing notions in higher dimension. We formulate our results for *block-gluing* subshifts:

► **Definition 33.** Let $X \subseteq \mathcal{A}^{\mathbb{Z}^d}$ be a subshift, and $f: \mathbb{N} \rightarrow \mathbb{N}$ be a (weakly) increasing function. We say that X is f -block-gluing if

$$\forall p, q \in \mathcal{L}_n(X), \forall k \geq n + f(n), \forall u \in \mathbb{Z}^d, \|u\|_\infty \geq k \implies (p \cup \sigma^u(q)) \in \mathcal{L}(X)$$

Said differently, X is f -block-gluing if any two square patterns of size n can appear at any position as long as they are placed with a gap of size at least $f(n)$ between them. As with Definition 31, we will simply write N -block-gluing for constant gluing distance ($f: n \rightarrow N$).

► **Proposition 34.** For any $\alpha \in \Pi_3 \cap [0, +\infty)$, there exists an effective and 1-block-gluing \mathbb{Z}^d subshift $Z_{\alpha, \#}$ such that $h_E(Z_{\alpha, \#}) = \alpha$.

Proof. Notice that the free lift of a 1-block-gluing \mathbb{Z}^d subshift to \mathbb{Z}^{d+1} is also 1-block-gluing. By Claim 8, the free lift preserves the extender entropy: thus, we reduce to the one-dimensional case. We conclude by combining the previous Proposition 32 with Theorem A. \blacktriangleleft

Abstract

We show that given a graph G we can CMSO-transduce its modular decomposition, its split decomposition and its bi-join decomposition. This improves results by Courcelle [Logical Methods in Computer Science, 2006] who gave such transductions using order-invariant MSO, a strictly more expressive logic than CMSO. Our methods more generally yield C_2 MSO-transductions of the canonical decomposition of weakly-partitive set systems and weakly-bipartitive systems of bipartitions.

1 Introduction

A decomposition of a graph, especially a tree-like decomposition, is a result of recursive separations of a graph and is extremely useful for investigating combinatorial properties such as colourability, and for algorithm design. Such a decomposition also plays a fundamental role when one wants to understand the relationship between logic and a graph class. Different notions of the complexity of a separation motivate different ways to decompose, such as tree-decomposition, branch-decomposition, rank-decomposition and carving-decomposition. Furthermore, some important graph classes can be defined through the tree-like decomposition they admit; cographs with cotrees and distance-hereditary graphs with split decompositions being prominent examples.

For a logic L , an L -transduction is a non-deterministic map from a class of relational structures to a new class of relational structures using L -formulas. Transducing a tree-like decomposition is of particular interest. Notably, transducing a decomposition of a graph implies that any property that is definable using a decomposition, is also definable on graphs that admit such a decomposition. Moreover, tree-like decompositions can be

often represented by labelled trees, for which the equivalence of recognisability by a tree automaton and definability in CMSO is well known [8]. Hence, it is an interesting question to consider what kind of graph decompositions can be transduced using L-transductions for some extension L of MSO.

In a series of papers [8, 9, 10, 12], Courcelle investigated the relationship between the graph properties that can be defined in an extension of MSO and the graph properties that can be recognized by a tree automaton. In particular, for graphs of bounded treewidth, Courcelle’s theorem states that any property that is definable in the logic MSO with modulo counting predicate, denoted CMSO, can be recognized by a tree automaton [8]. Combining this result with the linear time algorithm for computing tree-decompositions [1], yields that CMSO model-checking can be done in linear time on graphs of bounded treewidth. The converse statement – whether recognisability by a tree automaton implies definability in CMSO on graphs of bounded treewidth – was conjectured by Courcelle in [8] and finally settled by Bojańczyk and Pilipczuk [4]. The key step to obtain this result is obtaining a tree-decomposition of a graph via an MSO-transduction, a strategy which was initially proposed in [9] and is now standard.

The obvious next question is whether an analogous result can be proved for graphs of bounded clique-width and for more general combinatorial objects, most notably, matroids representable over a fixed finite field and of bounded branch-width. Due to the above-mentioned strategy, the key challenge is to produce corresponding tree-like decompositions by MSO-transduction. It is known that clique-width decompositions can be MSO-transduced for graphs of bounded linear clique-width [3]. However, it is unknown if clique-width decompositions can be MSO-transduced in general. In fact, this question remains open even for distance-hereditary graphs, which are precisely graphs of rank-width 1 (thus, of constant clique-width).

Besides tree-decompositions, the problem of transducing cotrees, and in general hierarchical decompositions such as modular decompositions and split decompositions were considered in the literature [10, 11, 12, 14]. In [10], Courcelle provides transductions using order-invariant MSO for cographs and modular decompositions of graphs of bounded modular width. Order-invariant MSO allows the use of a linear order of the set of vertices and is more expressive than CMSO [20]. The applicability of these transductions was later generalized using the framework of weakly-partitive set systems¹ to obtain order-invariant MSO-transductions of modular and split decompositions [12]. It was left as an open question whether one can get rid of the order (see for instance [13] where an overview of the result on hierarchical decompositions was given).

1.1 Our results

In this paper, we consider decompositions given by separations that do not overlap with any other separations of the same type. We view separations of a given kind as a “set system”. A set system consists of a set U , the universe, and a set \mathcal{S} of subsets of U . Two sets overlap if they have non-empty intersection but neither of them is contained in the other. If no two elements in a set system (U, \mathcal{S}) overlap, i.e. the set system is *laminar*, then the subset relation in (U, \mathcal{S}) can be described by a rooted tree T , called the *laminar tree* of (U, \mathcal{S}) . For any set system (U, \mathcal{S}) we can look at the subset of strong sets, i.e., sets that

¹ Weakly-partitive set systems are set systems enjoying some nice closure properties, which were then used to show that some set systems allow canonical tree representations, see for instance the thesis by Montgolfier and Rao [17, 24].

do not overlap with any other set, and the laminar tree T they induce. Additionally, we consider systems of bipartitions \mathcal{B} of a universe U . Two bipartitions of U overlap if neither side of one of the bipartition is contained in either side of the other bipartition. In case (U, \mathcal{B}) has no overlapping bipartitions, then (U, \mathcal{B}) can be described by an undirected tree, also called *laminar tree*, in which bipartitions correspond to edge cuts. We can define the concept of strong bipartitions equivalently and consider the laminar tree induced by the strong bipartitions in (U, \mathcal{B}) .

Given a graph G we can consider the set system $(V(G), \mathcal{M})$ where \mathcal{M} is the set of all modules in G , or the system of bipartition $(V(G), \mathcal{S})$ where \mathcal{S} contains all splits in G , or the system of bipartitions $(V(G), \mathcal{B})$ where \mathcal{B} contains all bi-joins in G . We obtain the modular decomposition/cotree/split decomposition/bi-join decomposition by equipping the laminar tree of the suitable set system/system of bipartitions with some additional structure. The additional structure allows us to recover the graph from the respective decomposition.

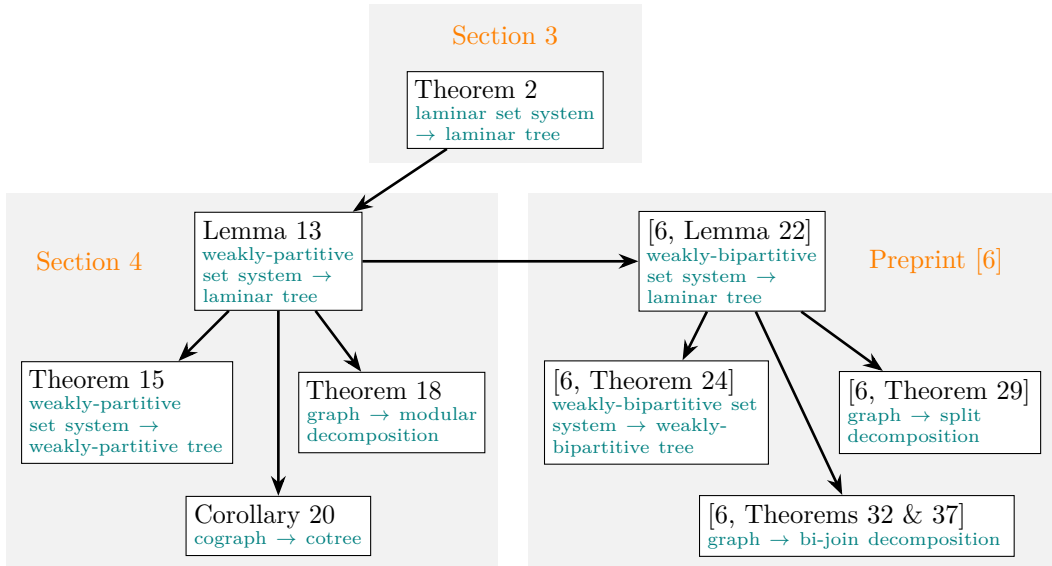

Abstractly, the set systems/systems of bipartitions mentioned are instances of *weakly-partitive set systems/weakly-bipartitive systems of bipartitions*. Roughly speaking, if a set system (U, \mathcal{S}) is well behaved, i.e. (U, \mathcal{S}) is weakly-partitive (definition in Section 2), then there is a labelling λ of T and a partial order $<$ of its nodes such that (U, \mathcal{S}) is completely described by $(T, \lambda, <)$ [7, 24]. A similar statement holds for systems of bipartitions [17].

We show the following, wherein each item λ is a suitable labelling of the nodes of the laminar tree T , $<$ is a partial ordering of its nodes, and F is an additional edge relation defined only on pairs of siblings in T . A visualization how results depend on each other is given in Figure 1. Due to space constraints, some proofs are omitted, but they are available in the extended preprint [6].

► **Theorem 1.** *There are non-deterministic C_2 MSO-transductions τ_1, \dots, τ_7 such that:*

1. *For any laminar set system (U, \mathcal{S}) , $\tau_1(U, \mathcal{S})$ is non-empty and every output in $\tau_1(U, \mathcal{S})$ is a laminar tree T of (U, \mathcal{S}) (Theorem 2);*
2. *For any graph G , $\tau_2(G)$ is non-empty and every output in $\tau_2(G)$ is a modular decomposition (T, F) of G (Theorem 18);*
3. *For any cograph G , $\tau_3(G)$ is non-empty and every output in $\tau_3(G)$ is a cotree (T, λ) of G (Corollary 20);*
4. *For any graph G , $\tau_4(G)$ is non-empty and every output in $\tau_4(G)$ is a split decomposition (T, F) of G [6, Theorem 29];*
5. *For any graph G , $\tau_5(G)$ is non-empty and every output in $\tau_5(G)$ is a bi-join decomposition (T, F) of G [6, Theorems 32 & 37];*
6. *For any weakly-partitive set system (U, \mathcal{S}) , $\tau_6(U, \mathcal{S})$ is non-empty and every output in $\tau_6(U, \mathcal{S})$ is a weakly-partitive tree $(T, \lambda, <)$ of (U, \mathcal{S}) (Theorem 15);*
7. *For any weakly-bipartitive set system (U, \mathcal{B}) , $\tau_7(U, \mathcal{B})$ is non-empty and every output in $\tau_7(U, \mathcal{B})$ is a weakly-bipartitive tree $(T, \lambda, <)$ of (U, \mathcal{B}) [6, Theorem 24].*

The key step in obtaining these transductions is to transduce the laminar tree T of a set system (U, \mathcal{S}) , namely Theorem 2. The crux here is to find a suitable representative of each node of T amongst the elements of U and a non-deterministic coloring which allows the assignment of representatives to nodes by means of a C_2 MSO-formula. It should be mentioned that a similar result is claimed in the preprint [2], where a proof sketch designing a C_3 MSO-transduction is described. Once the laminar tree is obtained, the additional relations for each decomposition can be obtained using a deterministic MSO-transduction. Notice that for each of these transductions, there exists an inverse deterministic MSO-transduction, namely a transduction that from the tree-like decomposition outputs the original structure.

■ **Figure 1** Overview of the various transductions in the paper. An arrow from x to y indicates that result x is used in the proof of result y .

1.2 Organization

The paper is organized as follows. In Section 2 we introduce terminology and notation needed. In Section 3 we prove Theorem 2. In Section 4 we provide the proof of Theorems 15 and 18 and obtain Corollary 20.

2 Preliminaries

2.1 Graphs, trees, set systems

Graphs. We use standard terminology of graph theory, and we fix some notations. Given a *directed graph* G , its sets of *vertices* and *edges* are denoted by $V(G)$ and $E(G)$, respectively. We denote by uv an edge $(u, v) \in E(G)$. An undirected graph is no more than a directed graph for which $E(G)$ is symmetric (*i.e.*, $uv \in E(G) \iff vu \in E(G)$). The notions of *paths*, *connected components*, *etc.* are defined as usual. Given a subset Z of $V(G)$, we denote by $G[Z]$ the sub-graph of G induced by Z .

Trees. A *tree* is a connected undirected graph without cycles. In the context of trees, we use a slightly different terminology than for graphs. In particular, vertices are called *nodes*, nodes of degree at most 1 are called *leaves*, and nodes of degree greater than 1 are called *inner*. The set of leaves is denoted $L(T)$; thus the set of inner nodes is $V(T) \setminus L(T)$. For a node t of a tree T and a neighbor s of t , we denote by T_s^t the connected component of $T - t$ containing s . We sometimes consider *rooted trees*, namely trees with a distinguished node, called the *root*. Rooted trees enjoy a natural orientation of their edges toward the root, which induces the usual notions of *parent*, *child*, *sibling*, *ancestor* and *descendant*. Hence, we represent a rooted tree by a set of nodes with an ancestor/descendant relationship (instead of specifying the root). We use the convention that every node is one of its own ancestors and descendants. We refer to ancestors (resp. descendants) of a node that are not the node itself as *proper ancestors* (resp. *proper descendants*). For a node t of a rooted tree T , we denote by T_t the subtree of T rooted in t (*i.e.*, the restriction of T to the set of descendants of t).

Set systems and laminar trees. A *set system* is a pair (U, \mathcal{S}) where U is a finite set, called the *universe*, and \mathcal{S} is a family of subsets of U where $\emptyset \notin \mathcal{S}$, $U \in \mathcal{S}$, and $\{a\} \in \mathcal{S}$ for every $a \in U$.² Two sets X and Y *overlap* if they are neither disjoint nor related by containment. A set system (U, \mathcal{S}) is said to be *laminar* (aka *overlap-free*) when no two sets from \mathcal{S} overlap. By extension, a set family \mathcal{S} is *laminar* if $(\bigcup \mathcal{S}, \mathcal{S})$ is a laminar set system (note this also requires that $\emptyset \notin \mathcal{S}$, $\bigcup \mathcal{S} \in \mathcal{S}$, and $\{a\} \in \mathcal{S}$ for every $a \in \bigcup \mathcal{S}$).

A laminar family \mathcal{S} of subsets of U naturally defines a rooted tree where the nodes are the sets from \mathcal{S} , the root is U , and the ancestor relation corresponds to set inclusion. We call this rooted tree the *laminar tree of U induced by \mathcal{S}* (or *laminar tree of (U, \mathcal{S})*). In this rooted tree, the leaves are the singletons $\{x\}$ for $x \in U$, which we identify with the elements themselves. That is to say, $L(T) = U$. Laminar trees have the property that each inner node has at least two children. Observe also that the size of a laminar tree is linearly bounded in the size of the universe.

2.2 Logic and transductions

We use *relational structures* to model both graphs and the various tree-like decompositions used in this paper. In order to concisely model set systems we use the more general notion of *extended relational structures*, namely *relational structure* extended with set predicate names. Such structures also naturally arise as outputs of *MSO-transductions* defined below.

Define an (*extended*) *vocabulary* to be a set of symbols, each being either a *relation* name R with associated arity $\text{ar}(R) \in \mathbb{N}$, or a *set predicate* name P with associated arity $\text{ar}(P) \in \mathbb{N}$. Set predicate names are aimed to describe relations between sets, *e.g.*, one may have a unary set predicate for selecting finite sets of even size, or a binary set predicate for selecting pairs of disjoint sets. We use capital R or names starting with a lowercase letter (*e.g.*, *edge*, *ancestor*, *t-edge*) for relation names, and capital P or uppercase names (*e.g.*, *SET*, *C₂*) for set predicate names. To refer to an arbitrary symbol of undetermined kind, we use capital Q . A *relational vocabulary* is an extended vocabulary in which every symbol is a relation name.

Let Σ be a vocabulary. An *extended relational structure over Σ* (Σ -*structure*) is a structure $\mathbb{A} = \langle U_{\mathbb{A}}, (Q_{\mathbb{A}})_{Q \in \Sigma} \rangle$ consisting on the one hand of a set $U_{\mathbb{A}}$ called *universe*, and on the other hand, for each symbol Q in Σ , an *interpretation $Q_{\mathbb{A}}$ of Q* , which is a relation of arity $\text{ar}(Q)$ either over the universe if Q is a relation name, or over the family of subsets of the universe if Q is a set predicate name. When Σ is not extended, \mathbb{A} is simply a *relational structure*.

Given a Σ -structure \mathbb{A} and, for some vocabulary Γ , a Γ -structure \mathbb{B} , we write $\mathbb{A} \sqsubseteq \mathbb{B}$ if $\Sigma \subseteq \Gamma$, $U_{\mathbb{A}} \subseteq U_{\mathbb{B}}$ and for each symbol Q in Σ , $Q_{\mathbb{A}} = Q_{\mathbb{B}}$.³ We write $\mathbb{A} \sqcup \mathbb{B}$ to denote the $(\Sigma \cup \Gamma)$ -structure consisting of the universe $U_{\mathbb{A}} \cup U_{\mathbb{B}}$ and, for each symbol $Q \in \Sigma \cup \Gamma$, the interpretation $Q_{\mathbb{A} \sqcup \mathbb{B}}$ which is $Q_{\mathbb{A}}$, $Q_{\mathbb{B}}$, or $Q_{\mathbb{A}} \cup Q_{\mathbb{B}}$ according to whether Q belongs to $\Sigma \setminus \Gamma$, to $\Gamma \setminus \Sigma$, or to $\Sigma \cap \Gamma$.⁴

To describe properties of (extended) relational structures, we use *monadic second order logic* (MSO) and refer for instance to [15, 19, 22, 25] for the definition of MSO on extended relational structures such as matroids or set systems in general. This logic allows quantification

² Though these restrictions on \mathcal{S} are not usual for set systems, it is convenient for our contribution and it does not significantly impact the generality of set systems: every family \mathcal{F} of subsets of U can be associated with a set system (U, \mathcal{S}) where $\mathcal{S} = (\mathcal{F} \setminus \{\emptyset\}) \cup \{U\} \cup \{\{a\} \mid a \in U\}$.

³ We require equality here (in particular only elements or subsets of $U_{\mathbb{A}}$ are related in $Q_{\mathbb{B}}$). This differs from classical notions of inclusions of relational structures which typically require equality only on the restriction of the universe to $U_{\mathbb{A}}$, *i.e.*, $Q_{\mathbb{A}} = Q_{\mathbb{B}/U_{\mathbb{A}}}$, *e.g.*, in order to correspond to induced graphs.

⁴ We do not require \mathbb{A} and \mathbb{B} to be disjoint structures whence we may have $\mathbb{A} \not\sqsubseteq \mathbb{A} \sqcup \mathbb{B}$.

both over single elements of the universe and over subsets of the universe. We also use *counting* MSO (CMSO), which is the extension of MSO with, for every positive integer p , a unary set predicate C_p that checks whether the size of a subset is divisible by p or not. We only use C_2 . As usual, lowercase variables indicate first-order-quantified variables, while uppercase variables indicate monadic-quantified variables. For a formula ϕ , we write, e.g., $\phi(x, y, X)$ to indicate that the variables x , y , and X belong to the set of *free variables of ϕ* , namely, the set of variables occurring in ϕ that are not bound to a quantifier within ϕ . A *sentence* is a formula without free variables.

We now fix some (extended) vocabularies that we will use.

Graphs. To model both graphs, unrooted trees, and directed graphs, we use the relational vocabulary $\{\text{edge}\}$ where edge is a relation name of arity 2. A (directed) graph $G = (V, E)$ is modeled as the $\{\text{edge}\}$ -structure \mathbb{G} with universe $U_{\mathbb{G}} = V$ and interpretation $\text{edge}_{\mathbb{G}} = E$. In particular if G is undirected, then $\text{edge}_{\mathbb{G}}$ is symmetric.

Rooted trees. We use the relational vocabulary $\{\text{ancestor}\}$ to model rooted trees where ancestor is a relation name of arity 2. A rooted tree T is modeled as the $\{\text{ancestor}\}$ -structure \mathbb{T} with universe $U_{\mathbb{T}} = V(T)$ and the interpretation $\text{ancestor}_{\mathbb{T}}$ being the set of pairs (u, v) such that u is an ancestor of v in T . It is routine to define FO-formulas over this vocabulary to express the binary relations *parent*, *child*, *proper ancestor*, (*proper*) *descendant*, as well as the unary relations *leaf* and *root*.

Set systems. To model set systems, we use the extended vocabulary $\{\text{SET}\}$ where SET is a set predicate name of arity 1. A set system $S = (U, \mathcal{S})$ is thus naturally modeled as the $\{\text{SET}\}$ -structure \mathbb{S} with universe $U_{\mathbb{S}} = U$ and interpretation $\text{SET}_{\mathbb{S}} = \mathcal{S}$.

Transductions

Let Σ and Γ be two extended vocabularies. A Σ -to- Γ *transduction* is a set τ of pairs formed by a Σ -structure, call the *input*, and a Γ -structure, called the *output*. We write $\mathbb{B} \in \tau(\mathbb{A})$ when $(\mathbb{A}, \mathbb{B}) \in \tau$. When for every pair $(\mathbb{A}, \mathbb{B}) \in \tau$ we have $\mathbb{A} \sqsubseteq \mathbb{B}$, we call τ an *overlay transduction*. Some transductions can be defined by means of MSO- or C_2 MSO-formulas. This leads to the notion of MSO- and C_2 MSO-*transductions*. Following the presentation of [3], for L denoting MSO or C_2 MSO, define an L -*transduction* to be a transduction obtained by composing a finite number of *atomic L-transductions* of the following kinds.

Filtering. An overlay transduction specified by an L -sentence ϕ over the input vocabulary Σ , which discards the inputs that do not satisfy ϕ and keeps the other unchanged. Hence, it defines a partial function (actually, a partial identity) from Σ -structures to Σ -structures.

Universe restriction. A transduction specified by an L -formula ϕ over the input vocabulary Σ , with one free first-order variable, which restricts the universe to those elements that satisfy ϕ . The output vocabulary is Σ and the interpretation of every relation (resp. every predicate) in the output structure is defined as the restriction of its interpretation in the input structure to those tuples of elements satisfying ϕ (resp. tuples of sets of elements that satisfy ϕ). This defines a total function from Σ -structures to Σ -structures.

Interpretation. A transduction specified by a family $(\phi_Q)_{Q \in \Gamma}$ over the input vocabulary Σ where Γ is the output vocabulary and each ϕ_Q has $\text{ar}(Q)$ free variables which are first-order if Q is a relation name and monadic if it is a set predicate name. The transduction outputs the Γ -structure that has the same universe as the input structure and in which each relation or predicate Q is interpreted as those set of tuples that satisfy ϕ_Q . This defines a total function from Σ -structures to Γ -structures.

Copying. An overlay transduction parametrized by a positive integer k that adds k copies of each element to the universe. The output vocabulary consists in the input vocabulary Σ extended with k binary relational symbols $(\text{copy}_i)_{i \in [k]}$ interpreted as pairs of elements (x, y)

saying that “ y is the i -th copy of x ”. The interpretation of the relations (resp. predicates) of the input structure are preserved, on original elements. This defines a total function from Σ -structures to Γ -structures, where $\Gamma = \Sigma \cup \{\text{copy}_i \mid i \in [k]\}$.

Colouring. An overlay transduction that adds a new unary relation $\text{color} \notin \Sigma$ to the structure. Any possible interpretation yields an output; indeed the interpretation is chosen non-deterministically. The interpretation of the relations (resp. predicates) of the input structure are preserved. Hence, it defines a total (non-functional) relation from Σ -structures to Γ -structures where $\Gamma = \Sigma \cup \{\text{color}\}$ (providing $\text{color} \notin \Sigma$).

We say an L-transduction is *deterministic* if it does not use colouring, it is *non-deterministic* otherwise. By definition, deterministic L-transductions define functions.

3 Transducing the laminar-tree

In this section, we present an overlay C_2 MSO-transduction that takes as input a laminar set system and outputs the laminar tree it induces.

► **Theorem 2.** *Let Σ be an extended vocabulary, including a unary set predicate name SET and not including the binary relational symbol ancestor. There exists a non-deterministic C_2 MSO-transduction τ such that, for each laminar set system (U, \mathcal{S}) represented as the {SET}-structure \mathbb{S} and inducing the laminar tree T with $L(T) = U$, and for each Σ -structure \mathbb{A} with $\mathbb{S} \sqsubseteq \mathbb{A}$, $\tau(\mathbb{A})$ is non-empty and every output in $\tau(\mathbb{A})$ is equal to some {ancestor}-structure \mathbb{T} representing T .*

Since the sets from \mathcal{S} are precisely the sets of leaves of the subtrees of T , there is an MSO-transduction which is the inverse of the above C_2 MSO-transduction; that is to say, given an {ancestor}-structure \mathbb{T} representing the laminar tree, it outputs the original set system \mathcal{S} . Namely,

1. An interpretation $\Phi_{\text{SET}}(S)$ that is true for a set S when there exists an element a such that an element x is in S if and only if a is an ancestor of x .
2. The filtering $\phi(x)$ keeping leaves only.

We prove Theorem 2 in Section 3.2, using the key tools developed in Section 3.1, that allow us to represent each inner node of T with a pair of leaves from its subtree, while keeping the number of inner nodes represented by a given leaf bounded.

3.1 Inner node representatives

In this section, the root of any rooted tree is always an inner node (unless the tree is a unique node). We fix a rooted tree T , in which every inner node has at least two children (a necessary assumption that is satisfied by laminar trees), and we let V denote the set of its nodes ($V = V(T)$) and $L \subseteq V$ denote the subset of its leaves ($L = L(T)$).

Let $S \subseteq V \setminus L$, and let (π, σ) be a pair of injective mappings from S to L . We say that the pair (π, σ) *identifies* S if for each $s \in S$, s is the least common ancestor of $\pi(s)$ and $\sigma(s)$. For $s \in S$ and $x \in V$, we say that x is *s-requested in* (π, σ) if x lies on the path from $\pi(s)$ to $\sigma(s)$ (namely, on either of the paths from $\pi(s)$ to s and from $\sigma(s)$ to s). We say that x is *requested in* (π, σ) if it is s -requested for some s . The pair (π, σ) has *unique request* if every node x of T is requested at most once in (π, σ) , *i.e.*, there exists at most one $s \in S$ such that x is s -requested in (π, σ) . Note that if (π, σ) has unique request then the paths from $\pi(s)$ to $\sigma(s)$ are pairwise disjoint for all the $s \in S$. We now state a few basic observations.

► **Remark 3.** Let (π, σ) identifying some subset S of $V \setminus L$.

1. The reversed pair (σ, π) also identifies S and has unique request whenever (π, σ) does.
2. If $S' \subset S$, then $(\pi|_{S'}, \sigma|_{S'})$ identifies S' , and has unique request if (π, σ) does.
3. For each $s \in S$, s is s -requested in (π, σ) .
4. If (σ, π) has unique request, then $\pi(S)$ and $\sigma(S)$ are disjoint subsets of L .

► **Lemma 4.** *Let (π, σ) identifying some subset S of $V \setminus L$ with unique request. Then for each $a \in \pi(S)$ the node $\pi^{-1}(a)$ is the least ancestor of a which belongs to S .*

Proof. Let $a \in \pi(S)$ and let $s = \pi^{-1}(a)$. By definition, s is an ancestor of a which belongs to S . Let y be the least ancestor of a that is contained in S . As s is an ancestor of a belonging to S , y must be a descendant of s . Hence, y is s -requested in (π, σ) . Additionally, by Item 3 of Remark 3, y is y -requested in (π, σ) . Since (π, σ) has unique request, $y = s$. Thus, s is the least ancestor of a which belongs to S . ◀

Notice that, by Item 1 of Remark 3, a similar result holds for each $b \in \sigma(S)$. It follows that the sets $\pi(S)$ and $\sigma(S)$ characterize (π, σ) .

► **Lemma 5.** *Let $S \subseteq V \setminus L$, and (π, σ) and (π', σ') be two pairs of injections from S to L identifying S with unique request. If $\pi(S) = \pi'(S)$ and $\sigma(S) = \sigma'(S)$ then $\pi = \pi'$ and $\sigma = \sigma'$.*

Proof. Let $s \in S$, $a = \pi(s)$, and $s' = \pi'^{-1}(a)$. Both s and s' are the least ancestor of a which belongs to S , hence $s = s'$ and $\pi'(s) = a$. Thus $\pi = \pi'$. By Item 1 of Remark 3, we also obtain that $\sigma = \sigma'$. ◀

Let A and B be two disjoint subsets of L . We call such a pair (A, B) a *bi-colouring*. We say that (A, B) *identifies* S if there exists a pair (π, σ) identifying S with unique request such that $\pi(S) = A$ and $\sigma(S) = B$. By the previous lemma, for a fixed set $S \subseteq V \setminus L$ the pair (π, σ) identifying S is unique when it exists. We will also prove that S is actually uniquely determined from (A, B) . Before that, we state the following technical lemma.

► **Lemma 6.** *Let (A, B) identify some subset S of $V \setminus L$ through a pair (π, σ) of injections having unique request. Then, for each inner node x , exactly one of the three following cases holds:*

1. $x \notin S$, x is not requested in (π, σ) , and for each child c of x , $|A \cap V(T_c)| = |B \cap V(T_c)|$;
2. $x \notin S$, x is requested in (π, σ) , and there exists one leaf $z \in (A \cup B) \cap V(T_x)$ such that, for each child c of x , $|(A \setminus \{z\}) \cap V(T_c)| = |(B \setminus \{z\}) \cap V(T_c)|$;
3. $x \in S$, x is requested in (π, σ) , and there exists two leaves $a \in A \cap V(T_x)$ and $b \in B \cap V(T_x)$ such that, for each child c of x , $|(A \setminus \{a\}) \cap V(T_c)| = |(B \setminus \{b\}) \cap V(T_c)|$ and $\{a, b\} \not\subseteq V(T_c)$.

Proof. Let x be an inner node. We consider the set $S' = S \setminus (V(T_x) \setminus \{x\})$ of all nodes which are not proper descendants of x and the restrictions π' and σ' of, respectively, π and σ to S' . By Item 2 of Remark 3 (π', σ') identify S' with unique request. We denote $A' = \pi'(S')$ and $B' = \sigma'(S')$, thus (A', B') identify S' . Let $A'_x = A' \cap V(T_x)$ and $B'_x = B' \cap V(T_x)$ be the sets of representatives contained in T_x of nodes in S' . Let a be an element of A'_x . The element $s_a = \pi^{-1}(a)$ is an ancestor of x because it is an ancestor of $a \in V(T_x)$ and belongs to S' whence not to $V(T_x) \setminus \{x\}$. Therefore, x is s_a -requested. As (π', σ') has unique request, there exists at most one element in A'_x . Similarly, B'_x has size at most 1. Moreover, $A'_x \cap B'_x = \emptyset$ by Item 4 of Remark 3. We thus we have three cases:

Case $A'_x \cup B'_x = \emptyset$. Then there is no $s \in S'$ such that $\pi(s) \in V(T_x)$ or $\sigma(s) \in V(T_x)$. Hence, x is not requested in (π, σ) , in particular, $x \notin S$.

Let c be a child of x . If $|A \cap V(T_c)| \neq |B \cap V(T_c)|$, then there exists $a \in (A \cup B) \cap V(T_c)$ such that, assuming without loss of generality that $a \in A$ and denoting $s_a = \pi^{-1}(a)$, $\sigma(s_a) \notin V(T_c)$. Hence, s_a is a proper ancestor of c , thus, equivalently, an ancestor of x , implying that x is s_a -requested in (π, σ) . This contradicts the above argument. So, $|A \cap V(T_c)| = |B \cap V(T_c)|$ for each child c of x .

Case $A'_x \cup B'_x = \{a\}$. Assume, without loss of generality, that $a \in A$, and denote $s_a = \pi^{-1}(a)$ and $b = \sigma(s_a)$. We have that s_a is a proper ancestor of x , since it is the least common ancestor of $a \in V(T_x)$ and $b \notin V(T_x)$. Thus, x is s_a -requested and $s_a \neq x$ so $x \notin S$.

Let c be a child of x . If $|A \cap V(T_c)| \neq |B \cap V(T_c)|$, then it means that there exists $z \in (A \cup B) \cap V(T_c)$, such that either $z \in A$ and $s_z = \pi^{-1}(z) \notin V(T_c)$, or $z \in B$ and $s_z = \sigma^{-1}(z) \notin V(T_c)$. In both cases, s_z is a proper ancestor of c , whence an ancestor of x . Thus, x is s_z -requested in (π, σ) . However, x is s_a -requested in (π, σ) which has unique request, hence $s_z = s_a$. If $z \in B$, it follows that $z = b$, which contradicts the fact $b \notin V(T_x)$. Hence, $z \in A$ and thus, $z = \pi(s_a) = a$. Therefore, $|(A \setminus \{a\}) \cap V(T_c)| = |B \cap V(T_c)|$ for each child c of x .

Case $A'_x = \{a\}$ and $B'_x = \{b\}$. Let $s_a = \pi^{-1}(a)$ and $s_b = \sigma^{-1}(b)$. The node x is s_a -requested and s_b -requested in (π, σ) , so, by the unique request property, $s_a = s_b$. Since s_a is the least common ancestor of a and b , it belongs to $V(T_x)$ whence $s_a = x$ implying $x \in X$. Let c be a child of x . If $|A \cap V(T_c)| \neq |B \cap V(T_c)|$, then there exists $z \in (A \cup B) \cap V(T_c)$ such that either $z \in A$ and $s_z = \pi^{-1}(z) \notin V(T_c)$, or $z \in B$ and $s_z = \sigma^{-1}(z) \notin V(T_c)$. In both cases, s_z is a proper ancestor of c , whence an ancestor of x , and thus x is s_z -requested in (π, σ) . However, x is x -requested in (π, σ) which has unique request, hence $s_z = x$ and thus $z \in \{a, b\}$. Therefore, $|(A \setminus \{a\}) \cap V(T_c)| = |(B \setminus \{b\}) \cap V(T_c)|$ for each child c of x . Because the least common ancestor of a and b is x , there is no child c of x containing both a and b as leaves, *i.e.*, $\{a, b\} \not\subseteq V(T_c)$.

This concludes the proof of the statement. \blacktriangleleft

It follows that for each bi-colouring (A, B) , there exists at most one set S of inner nodes identified by (A, B) .

► Lemma 7. *Let (A, B) be two disjoint subsets of L and let S and S' be two subsets of $V \setminus L$. If (A, B) identify both S and S' , then $S = S'$.*

Proof. We proceed by contradiction and thus assume $S \neq S'$. Let $s \in S \setminus S'$. By Lemma 6, the number of children c of s for which the set $(A \cup B) \cap V(T_c)$ has odd size is 2 since $s \in S$, while it should also be less than 2 since $s \notin S'$. A contradiction. \blacktriangleleft

When (A, B) identifies a set S , we call *A-representative* (resp. *B-representative*) of $s \in S$ the leaf $\pi(s) \in A$ (resp. $\sigma(s) \in B$), where (π, σ) witnessing that (A, B) identifies S . An example of bi-colouring identifying a subset of inner nodes is given in Figure 2.

Not every set of inner nodes has a bi-colouring identifying it. To ensure that such a pair exists, we consider *thin sets of inner nodes*. While thin sets always have bi-colourings identifying them, it is also guaranteed that the set of inner nodes can be partitioned into only 4 thin sets. A subset $X \subseteq V \setminus L$ is *thin* when, for each $x \in X$ not being the root, on the one hand, the parent p_x of x does not belong to X , and on the other hand, x admits at least one sibling (including possible leaves) that does not belong to X . Having a thin set X allows to find branches avoiding it.

■ **Figure 2** Illustration of a bi-colouring (A, B) identifying some set $S \subseteq V \setminus L$ in a binary tree T . Leaves from A are coloured blue, leaves from B are coloured red, and inner nodes from S are marked purple. Furthermore, the two paths connecting an inner node $s \in S$ to its A - and B -representatives are coloured blue and red, respectively.

► **Lemma 8.** *Let $X \subseteq V \setminus L$ and $s \in V \setminus X$. If X is thin, then there exists a leaf $t \in V(T_s)$ such that the path from t to s avoids X (i.e., none of the nodes along this path belong to X).*

Proof. If T_s has height 0, then s is a leaf and taking $t = s$ trivially gives the expected path. Otherwise, s is an inner node and, because X is thin, s has at least one child c_s not belonging to X . By induction, there is a path from some leaf $t \in V(T_{c_s})$ to c_s avoiding X and, since $s \notin X$, this path could be extended into a path from t to s avoiding X . ◀

The previous lemma allows to identify every thin set.

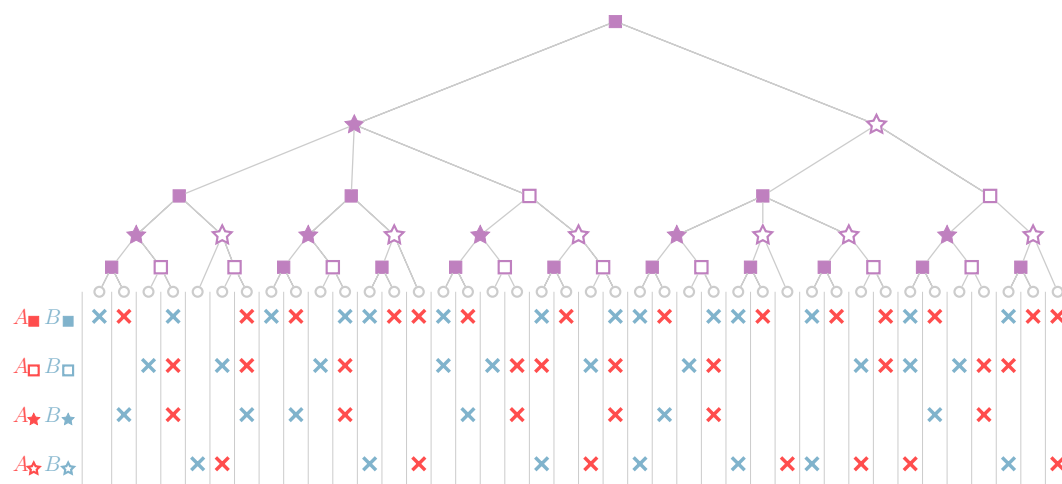

► **Lemma 9.** *If X is a thin set, then there exists a pair (π, σ) of injections from X to L that has unique request and that identifies X .*

Proof. We proceed by induction on the size of X . If $X = \emptyset$, the result is trivial. Let $n \in \mathbb{N}$ and suppose that for every thin set of size n there exists a pair of injections identifying it with unique request. Let X be a thin set of size $n + 1$, and let $s \in X$ be of minimal depth. Clearly, $X \setminus \{s\}$ is thin and thus there exists, by induction, a pair (π, σ) of injections from $X \setminus \{s\}$ to L identifying $X \setminus \{s\}$ with unique request. Since X is thin and $s \in X$, we can find two distinct children c_a and c_b of s not belonging to X .⁵ Then, by Lemma 8, there exists a leaf $a \in V(T_{c_a})$ (resp. a leaf $b \in V(T_{c_b})$) such that the path from a to c_a (resp. from b to c_b) avoids X . In particular, for each node y along these paths, since y has no ancestor that belongs to X but s , y is not requested in (π, σ) . Hence, extending π (resp. σ) in such a way that, besides mapping each $x \in X \setminus \{s\}$ to $\pi(x)$ (resp. to $\sigma(x)$), it maps s to a (resp. to b), we obtain a pair $(\hat{\pi}, \hat{\sigma})$ of injections from X to L that identifies X with unique request. ◀

A family $F = (A_1, B_1), \dots, (A_n, B_n)$ of bi-colourings *identifies* a set $S \subseteq V \setminus L$, if there exists a partition (S_1, \dots, S_n) of S such that, for each $i \in [n]$, (A_i, B_i) identifies S_i . Whenever $S = V \setminus L$ we say that F *identifies* T . A collection of subsets of $V \setminus L$ is *thin* if each of its subsets is thin. We now show that there exists a thin 4-partition.

► **Lemma 10.** *There exists a thin 4-partition of $V \setminus L$.*

⁵ Remember that every inner node of T has at least two children (including possible leaves).

■ **Figure 3** Illustration of a partition of the inner nodes into 4 thin sets indicated by different shapes/fillings. The four colourings identifying each thin set are indicated in the table below the leaves.

Proof. We build such a thin 4-partition as follows. First, consider the partition (D_e, D_o) of $V \setminus L$ in which D_e (resp. $D_o = V \setminus (D_e \cup L)$) is the set of all inner nodes of even (resp. odd) depth. Second, arbitrarily fix one child c_x of x for each inner node x , and consider the set $C = \{c_x \mid x \in V \setminus L\} \setminus L$, inducing a partition (C, \bar{C}) of $V \setminus L$ where $\bar{C} = V \setminus (L \cup C)$. By refining these two bi-partitions, we obtain a 4-partition which is thin by construction.⁵ ◀

Hence, four bi-colourings are enough to identify T . For an example see Figure 3.

► **Corollary 11.** *There exists a family of four bi-colourings identifying T .*

Proof. The result immediately follows from Lemmas 9 and 10. ◀

3.2 The transduction

The goal of this section is to prove Theorem 2, that is, to design a C_2 MSO-transduction that produces the laminar tree induced by an input laminar set system. We fix a laminar set system (U, \mathcal{S}) , represented by a $\{\text{SET}\}$ -structure \mathbb{S} . Before proving the theorem, we make the following basic observation. On \mathbb{S} , we can define two MSO-formulas $\text{desc}(X, Y)$ and $\text{child}(X, Y)$ expressing that in the laminar tree induced by \mathcal{S} , X and Y are nodes and X is a descendant or a child of Y , respectively:

$$\begin{aligned} \text{desc}(X, Y) &:= \text{SET}(X) \wedge \text{SET}(Y) \wedge X \subseteq Y; \\ \text{child}(X, Y) &:= \text{desc}(X, Y) \wedge X \neq Y \wedge \forall Z \left((\text{desc}(Z, Y) \wedge Z \neq Y) \rightarrow \text{desc}(Z, X) \right). \end{aligned}$$

The key point of our construction consists in defining a C_2 MSO-formula $\text{repr}_{A,B}(a, X)$ which, assuming a bi-colouring (A, B) of the universe modeled as disjoint unary relations and identifying a subset S of inner nodes of T , is satisfied exactly when $X \in S$ and a is its A -representative.

► **Lemma 12.** *Let (A, B) be a bi-colouring of $L(T)$ identifying a subset S of inner nodes of T . There exists a C_2 MSO-formula $\text{repr}_{A,B}(a, X)$ that is satisfied exactly when X is an inner node of T that belongs to S and is A -represented by a .*

22:12 CMSO-Transducing Tree-Like Graph Decompositions

Proof. First, we define a formula $\phi_{A,B}(X)$ that, under the above assumption, is satisfied exactly when X belongs to S . According to Lemma 6, this happens if and only if X is a node of T (i.e., $\text{SET}(X)$ is satisfied) and there exists $a \in X \cap A$ and $b \in X \cap B$ such that for each child Z of X , $\{a, b\} \not\subseteq Z$ and the set $(Z \setminus \{a, b\}) \cap (A \cup B)$ has even size. This property is easily expressed in $C_2\text{MSO}$, using the MSO-formula $\text{child}(X, Y)$ defined previously, as well as the predicate SET :

$$\phi_{A,B}(X) := \text{SET}(X) \wedge \exists a \exists b \left[a \in (X \cap A) \wedge b \in (X \cap B) \wedge \forall Z \left(\text{child}(Z, X) \rightarrow \left(\{a, b\} \not\subseteq Z \wedge C_2((Z \setminus \{a, b\}) \cap (A \cup B)) \right) \right) \right].$$

Now, we can easily define $\text{repr}_{A,B}(a, X)$ based on Lemma 4:

$$\text{repr}_{A,B}(a, X) := \phi_{A,B}(X) \wedge a \in (X \cap A) \wedge \forall Z \subsetneq X \left(a \in Z \rightarrow \neg \phi_{A,B}(Z) \right).$$

This concludes the proof. ◀

We are now ready to prove the theorem.

Proof of Theorem 2. The $C_2\text{MSO}$ -transduction is obtained by composing the following atomic $C_2\text{MSO}$ -transductions. The transduction makes use of the formulas $\text{repr}_{A,B}(a, X)$ given by Lemma 12.

1. Guess a family of four bi-colourings $(A_i, B_i)_{i \in [4]}$ identifying T (which exists by Corollary 11).
2. Copy the input graph four times, thus introducing four binary relations $(\text{copy}_i)_{i \in [4]}$ where $\text{copy}_i(x, y)$ indicates that x is the i -th copy of the original element y .
3. Filter the universe keeping only the original elements as well as the i -th copy of each vertex a for which there exists X such that $\text{repr}_{A_i, B_i}(a, X)$.
4. Define the relation $\text{ancestor}(x, y)$ so that it is satisfied exactly when there exist x', X, i , and Y such that, on the one hand $\text{desc}(Y, X)$ and $\text{copy}_i(x, x') \wedge \text{repr}_{A_i, B_i}(x', X)$, and, on the other hand, either y is an original element and $Y = \{y\}$, or there exists y' and j such that $\text{copy}_j(y, y') \wedge \text{repr}_{A_j, B_j}(y', Y)$. ◀

4 Transducing modular decompositions

The set of modules of a directed graph is a specific example of a particular type of set system, a “weakly-partitive set system” (and a “partitive set system” in the case of an undirected graph). In this section, we first give a general $C_2\text{MSO}$ -transduction to obtain the canonical tree-like decomposition of a weakly-partitive set system from the set system itself. We then show how to obtain the modular decomposition of a graph via a $C_2\text{MSO}$ -transduction as an application.

4.1 Transducing weakly-partitive trees

A set system (U, \mathcal{S}) is *weakly-partitive* if for every two overlapping sets $X, Y \in \mathcal{S}$, the sets $X \cup Y$, $X \cap Y$, $X \setminus Y$, and $Y \setminus X$ belong to \mathcal{S} . It is *partitive* if, moreover, for every two overlapping sets $X, Y \in \mathcal{S}$, their symmetric difference, denoted $X \triangle Y$, also belongs to \mathcal{S} . By extension, a set family \mathcal{S} is called *weakly-partitive* or *partitive* whenever $(\bigcup \mathcal{S}, \mathcal{S})$ is a set system which is weakly-partitive or partitive, respectively (note these also requires that $\emptyset \notin \mathcal{S}$, $\bigcup \mathcal{S} \in \mathcal{S}$, and $\{a\} \in \mathcal{S}$ for every $a \in \bigcup \mathcal{S}$).

A member of a set system (U, \mathcal{S}) is said to be *strong* if it does not overlap any other set from \mathcal{S} . The sub-family $\mathcal{S}_!$ of strong sets of \mathcal{S} is thus laminar by definition. Hence, it induces a laminar tree T . By extension, we say that T is *induced by the set system* (U, \mathcal{S}) (or simply by \mathcal{S}). The next result extends Theorem 2, by showing that T can be C_2 MSO-transduced from \mathcal{S} .

► **Lemma 13.** *Let Σ be an extended vocabulary, including a set unary predicate name SET and not including the binary relational symbol ancestor. There exists a non-deterministic C_2 MSO-transduction τ such that, for each set system (U, \mathcal{S}) represented as the {SET}-structure \mathbb{S} and inducing the laminar tree T with $L(T) = U$, and for each Σ -structure \mathbb{A} with $\mathbb{S} \sqsubseteq \mathbb{A}$, $\tau(\mathbb{A})$ is non-empty and every output in $\tau(\mathbb{A})$ is equal to some {ancestor}-structure \mathbb{T} representing T .*

Proof. On the {SET}-structure \mathbb{S} , it is routine to define an MSO-formula $\phi_{\text{SET!}}(Z)$ that identifies those subsets $Z \subseteq U$ that are strong members of \mathcal{S} :

$$\phi_{\text{SET!}}(Z) := \text{SET}(Z) \wedge \forall X \left((\text{SET}(X) \wedge X \cap Z \neq \emptyset) \rightarrow (X \subseteq Z \vee Z \subseteq X) \right).$$

Hence, we can design an MSO-interpretation that outputs the $\Sigma \cup \{\text{SET!}\}$ -structure corresponding to \mathbb{A} equipped with the set unary predicate SET! that selects strong members of \mathcal{S} . Thus, up to renaming the predicates SET! and SET, by Theorem 2, we can produce, through a C_2 MSO-transduction, the $\Sigma \cup \{\text{ancestor}\}$ -structure $\mathbb{A} \sqcup \mathbb{T}$ where \mathbb{T} is the tree-structure modeling the laminar tree T induced by $\mathcal{S}_!$ with $L(T) = U$ (once the output obtained, the interpretation drops the set predicate SET! which is no longer needed). ◀

Clearly, the laminar tree T of a weakly-partitive set system (U, \mathcal{S}) does not characterize (U, \mathcal{S}) . However, as shown by the below theorem, a labeling of its inner nodes and a controlled partial ordering of its nodes are sufficient to characterize all the sets of \mathcal{S} . For Z a set equipped with a partial order $<$ and X a subset of Z , we say that X is a *<-interval* whenever $<$ defines a total order on X and for every $a, b \in X$ and every $c \in Z$, $a < c < b$ implies $c \in X$.

► **Theorem 14** ([7, 24]). *Let \mathcal{S} be a weakly-partitive family, $\mathcal{S}_!$ be its subfamily of strong sets, and T be the laminar tree it induces. There exists a total labeling function λ from the set $V(T) \setminus L(T)$ of inner nodes of T to the set {degenerate, prime, linear}, and, for each inner node $t \in \lambda^{-1}(\text{linear})$, a linear ordering $<_t$ of its children, such that every inner node having exactly two children is labeled by degenerate and the following two conditions are satisfied:*

- for each $X \in \mathcal{S} \setminus \mathcal{S}_!$, there exists $t \in V(T)$ and a subset \mathcal{C} of children of t such that $X = \bigcup_{c \in \mathcal{C}} L(T_c)$ and either $\lambda(t) = \text{linear}$ and \mathcal{C} is a $<_t$ -interval, or $\lambda(t) = \text{degenerate}$;
- conversely, for each inner node t and each non-empty subset \mathcal{C} of children of t , if either $\lambda(t) = \text{linear}$ and \mathcal{C} is a $<_t$ -interval, or $\lambda(t) = \text{degenerate}$, then $\bigcup_{c \in \mathcal{C}} L(T_c) \in \mathcal{S}$.

Furthermore, T and λ are uniquely determined from \mathcal{S} , and, for each inner node t of T labeled by linear, only two orders $<_t$ are possible, one being the inverse of the other (indeed, inverting an order $<$ does preserve the property of being a $<$ -interval). Hence, every weakly-partitive family \mathcal{S} is characterized by a labeled and partially-ordered tree $(T, \lambda, <)$ where T is the laminar tree induced by the subfamily $\mathcal{S}_!$ of strong sets of \mathcal{S} , $\lambda : V(T) \setminus L(T) \rightarrow \{\text{degenerate, prime, linear}\}$ is the labeling function, and $<$ is the partial order $\bigcup_{t \in \lambda^{-1}(\text{linear})} <_t$ over $V(T)$. As, up-to inverting some of the $<_t$ orders, $(T, \lambda, <)$ is unique, we abusively call it *the weakly-partitive tree induced by \mathcal{S}* . Conversely, a weakly-partitive tree characterizes the unique weakly-partitive set system which induced it.

We naturally model a weakly-partitive tree $(T, \lambda, <)$ of a partitive set system (U, \mathcal{S}) by the {ancestor, degenerate, betweenness}-structure \mathbb{T} of universe $U_{\mathbb{T}} = V(T)$ such that $\langle V(T), \text{ancestor}_{\mathbb{T}} \rangle \sqsubseteq \mathbb{T}$ models T with $L(T) = U$, $\text{degenerate}_{\mathbb{T}}$ is a unary relation which selects

the inner nodes of T of label degenerate, *i.e.*, $\text{degenerate}_{\mathbb{T}} = \lambda^{-1}(\text{degenerate})$, and $\text{betweeness}_{\mathbb{T}}$ is a ternary relation selecting triples (x, y, z) satisfying $x < y < z$ or $z < y < x$. (Although it is possible, through a non-deterministic MSO-transduction, to define $<$ from $\text{betweeness}_{\mathbb{T}}$, the use of $\text{betweeness}_{\mathbb{T}}$ rather than $<_{\mathbb{T}}$ ensures unicity of the output weakly-partitive tree.) The inner nodes of T that are labeled by **linear** can be recovered through an MSO-formula as those inner nodes whose children are related by **betweeness**. The inner nodes labeled by **prime** can be recovered through an MSO-formula as those inner nodes that are labeled neither by **degenerate** nor by **linear**. Using Theorem 14, it is routine to design an MSO-transduction which takes as input a weakly-partitive tree and outputs the weakly-partitive set system which induced it. The inverse C_2 MSO-transduction is the purpose of the next result. The proof is omitted due to space constraints.

► **Theorem 15.** *There exists a non-deterministic C_2 MSO-transduction τ such that, for every weakly-partitive set system (U, \mathcal{S}) represented as the $\{\text{SET}\}$ -structure \mathbb{S} and inducing the weakly-partitive tree $(T, \lambda, <)$ represented as the $\{\text{ancestor, degenerate, betweeness}\}$ -structure \mathbb{T} , we have $\mathbb{T} \in \tau(\mathbb{S})$ and every output in $\tau(\mathbb{S})$ is a weakly-partitive tree of (U, \mathcal{S}) .*

If \mathcal{S} is partitive then the weakly-partitive tree it induces enjoys a simple form, and is truly unique. Indeed, the label **linear** and, thus, the partial order $<$, are not needed.

► **Theorem 16** ([7]). *Let \mathcal{S} be a weakly-partitive family and $(T, \lambda, <)$ be the weakly-partitive tree it induces. If \mathcal{S} is partitive, then $\lambda^{-1}(\text{linear}) = \emptyset$ and $<$ is empty.*

Hence, in case of a partitive set systems (U, \mathcal{S}) , we can consider the simpler object (T, λ) , called *the partitive tree induced by \mathcal{S}* (or *the partitive tree of (U, \mathcal{S})*) in which λ maps $V(T) \setminus L(T)$ to $\{\text{degenerate, prime}\}$. As a direct consequence of Theorems 15 and 16, we can produce, through a C_2 MSO-transduction, the partitive tree induced by a partitive set system and naturally modeled by an $\{\text{ancestor, degenerate}\}$ -structure.

► **Corollary 17.** *There exists a non-deterministic C_2 MSO-transduction τ such that, for each partitive set system (U, \mathcal{S}) represented as the $\{\text{SET}\}$ -structure \mathbb{S} and inducing the partitive tree (T, λ) represented as the $\{\text{ancestor, degenerate}\}$ -structure \mathbb{T} , we have $\mathbb{T} \in \tau(\mathbb{S})$ and every output in $\tau(\mathbb{S})$ is a partitive tree of (U, \mathcal{S}) .*

4.2 Application to modular decomposition

Let G be a directed graph and let $M \subseteq V(G)$. We say that M is a *module* (of G) if for every $u \notin M$ and every $v, w \in M$, $uv \in E(G) \iff uw \in E(G)$ and $vu \in E(G) \iff wu \in E(G)$. Clearly, the empty set, $V(G)$, and all the singletons $\{x\}$ for $x \in V(G)$ are modules; they are called *the trivial modules* of G . We say a non-empty module M is *maximal* if it is not properly contained in any non-trivial module. Let M and M' be two disjoint non-empty modules of G . Considering the edges that go from M to M' , namely edges from the set $(M \times M') \cap E(G)$, we have two possibilities: either it is empty, or it is equal to $M \times M'$. We write $M \not\rightarrow M'$ in the former case and $M \rightarrow M'$ in the latter. (It is of course possible to have both $M \rightarrow M'$ and $M' \rightarrow M$.) A *modular partition* of G is a partition $\mathcal{P} = \{M_1, \dots, M_\ell\}$ of $V(G)$ such that every M_i is a non-empty module. A modular partition $\mathcal{P} = \{M_1, \dots, M_\ell\}$ is called *maximal* if it is non-trivial and every M_i is strong and maximal. Note that every graph has exactly one maximal modular partition.

A *modular decomposition* of G is a rooted tree T in which the leaves are the vertices of G , and for each inner node $t \in T$, t has at least two children and the set $L(T_t)$ is a module of G . In a modular decomposition T of G , for each inner node $t \in V(T)$ with children c_1, \dots, c_r ,

the family $\mathcal{P}_t = \{L(T_{c_1}), \dots, L(T_{c_r})\}$ is a modular partition of $G[V(T_t)]$. When each such partition is maximal, the decomposition is unique and it is called *the maximal modular decomposition* of G . The maximal modular decomposition T of G alone is not sufficient to characterize G . However, enriching T with, for each inner node t with children c_1, \dots, c_j , the information of which pair of modules $(L(T_{c_i}), L(T_{c_j}))$ is such that $L(T_{c_i}) \rightarrow L(T_{c_j})$, yields a unique canonical representation of G . Formally, the *enriched modular decomposition* of G is the pair (T, F) where T is the maximal modular decomposition of G (with $L(T) = V(G)$) and $F \subset V(T) \times V(T)$ is a binary relation, that relates a pair (s, t) of nodes of T , denoted $st \in F$, exactly when s and t are siblings and $L(T_s) \rightarrow L(T_t)$. The elements of F are called *m-edges*.

It should be mentioned that the family of all non-empty modules of G is known to be weakly-partitive (or even partitive when G is undirected). In particular, the maximal modular decomposition T of G is the laminar tree induced by the family of strong modules. Hence Theorem 15 could be used to produce a partially-ordered and labeled tree which displays all the modules of G . However, this weakly-partitive tree is not sufficient for being able to recover the graph G from it. We now prove how to obtain the enriched modular decomposition of G through a C_2 MSO-transduction.

To model enriched modular decompositions as relational structures we use the relational vocabulary $\{\text{ancestor}, \text{m-edge}\}$ where *ancestor* and *m-edge* are two binary relation names. An enriched modular decomposition (T, F) of a graph G is modeled by the $\{\text{ancestor}, \text{m-edge}\}$ -structure \mathbb{M} with universe $U_{\mathbb{M}} = V(T)$, $\text{ancestor}_{\mathbb{M}}$ being the set of pairs (s, t) for which s is an ancestor of t in T , and $\text{m-edge}_{\mathbb{M}}$ being the set of all pairs (s, t) such that $st \in F$ (in particular, s and t are siblings in T). We use Lemma 13 in order to transduce the maximal modular decomposition of a graph.

► **Theorem 18.** *There exists a non-deterministic C_2 MSO-transduction τ such that for every directed graph G represented as the $\{\text{edge}\}$ -structure \mathbb{G} , $\tau(\mathbb{G})$ is non-empty and every output in $\tau(\mathbb{G})$ is equal to some $\{\text{ancestor}, \text{m-edge}\}$ -structure \mathbb{M} representing the enriched modular decomposition (T, F) of G .*

Proof. Let G be a graph represented by the $\{\text{edge}\}$ -structure \mathbb{G} . Several objects are associated to G , and each of them can be described by a structure:

- let \mathcal{M} be the family of non-empty modules of G and let \mathbb{S} be the $\{\text{SET}\}$ -structure modeling the weakly-partitive set system $(V(G), \mathcal{M})$ with $U_{\mathbb{S}} = V(G)$;
- let T be the laminar tree induced by the weakly-partitive family \mathcal{M} and let \mathbb{T} be the $\{\text{ancestor}\}$ -structure modeling it with $U_{\mathbb{T}} = V(T)$ and $L(T) = V(G) \subset U_{\mathbb{T}}$;
- let F be the m-edge relation, namely the subset of $V(T) \times V(T)$ such that (T, F) is the maximal modular decomposition of G , and let \mathbb{M} be the $\{\text{ancestor}, \text{m-edge}\}$ -structure modeling it with $\mathbb{T} \sqsubset \mathbb{M}$ and $U_{\mathbb{T}} = U_{\mathbb{M}}$.

Our C_2 MSO-transduction is obtained by composing the three following transductions:

- τ_1 : an MSO-interpretation which outputs the $\{\text{edge}, \text{SET}\}$ -structure $\mathbb{G} \sqcup \mathbb{S}$ from \mathbb{G} ;
- τ_2 : the non-deterministic C_2 MSO-transduction given by Lemma 13 which produces the $\{\text{edge}, \text{SET}, \text{ancestor}\}$ -structure $\mathbb{G} \sqcup \mathbb{S} \sqcup \mathbb{T}$ from $\mathbb{G} \sqcup \mathbb{S}$;
- τ_3 : an MSO-interpretation which outputs the $\{\text{ancestor}, \text{m-edge}\}$ -structure \mathbb{M} from $\mathbb{G} \sqcup \mathbb{S} \sqcup \mathbb{T}$.

In order to define τ_1 it is sufficient to observe that there exists an MSO-formula $\phi_{\text{SET}}(Z)$ with one monadic free-variable, which is satisfied exactly when Z is a non-empty module of G . Then, since τ_2 is given by Lemma 13, it only remains to define τ_3 . Given an inner node t , we can select, within MSO, the set $L(T_t)$ of leaves of the subtree rooted in t . We

thus assume a function `leafset`, with one first-order free-variable which returns the set of leaves of the subtree rooted at the given node. Equipped with this function, we can define the MSO-formula $\phi_{\text{m-edge}}$ which selects pairs (s, r) of siblings such that $sr \in F$. Remember that this happen exactly when there exist $u \in L(T_s)$ and $v \in L(T_r)$ such that $uv \in E(G)$. Hence, $\phi_{\text{m-edge}}$ could be defined as:

$$\phi_{\text{m-edge}}(s, r) := s \neq r \wedge \exists t (\text{parent}(t, s) \wedge \text{parent}(t, r)) \wedge \exists x \exists y (x \in \text{leafset}(s) \wedge y \in \text{leafset}(r) \wedge \text{edge}(x, y)).$$

Once defined, the MSO-interpretation τ_3 simply drops all non-necessary relations and predicates (namely `edge` and `SET`) and keeps only the ancestor and `m-edge` relations. ◀

Notice that it is routine to design a deterministic MSO-transduction which, given an $\{\text{ancestor}, \text{m-edge}\}$ -structure \mathbb{M} representing an enriched modular decomposition of some directed graph G , produces the $\{\text{edge}\}$ -structure \mathbb{G} representing G .

Cographs

Let G be a graph, (T, F) be its modular decomposition, and $(T, \lambda, <)$ be the weakly-partitive tree induced by the (weakly-partitive) family of its modules. Let t be an inner node of T , let \mathcal{C} be its set of children, and let C be the graph $(V(T) \setminus L(T), F)[\mathcal{C}]$ induced by F on the set of children of t . It can be checked that, if $\lambda(t) = \text{degenerate}$ then C is either a clique or an independant, and if $\lambda(t) = \text{linear}$ then C is a *tournament consistent with $<_t$* (i.e., for every $x, y \in \mathcal{C}$, xy is an edge of C if and only if $x <_t y$) or with the inverse of $<_t$. In the former case, we can refine the `degenerate` label into `series` and `parallel` labels, thus expressing that C is a clique or an independant, respectively. In the latter case, up-to reversing $<_t$, we can ensure that C is a tournament consistent with $<_t$. This yields a refined weakly-partitive tree $(T, \gamma, <)$, where γ maps inner nodes to $\{\text{series}, \text{parallel}, \text{prime}, \text{linear}\}$ and $<$ is the order $\bigcup_{t \in \gamma^{-1}(\text{linear})} <_t$ which ensures that tournaments are consistent with the corresponding $<_t$. Notice that this labeled and partially-ordered tree is now uniquely determined from G . Moreover, edges from F that connect children of a node not labeled by `prime` can be recovered from the so-refined weakly-partitive tree. In particular, if no nodes of T is labeled by `prime`, (T, F) and thus G is fully characterized by $(T, \gamma, <)$. Graphs for which this property holds are known as *directed cographs*, and can be described by the refined weakly-partitive tree, called *cotree*, explained above and formalized in the following statement.

► **Theorem 19.** *Let G be a directed cograph and let T be the laminar tree induced by the family of its strong modules. There exists a unique total labeling λ from the set $V(T) \setminus L(T)$ of inner nodes of T to the set $\{\text{series}, \text{parallel}, \text{linear}\}$ of labels, and, for each inner node $t \in \lambda^{-1}(\text{linear})$, a unique linear ordering $<_t$ of its children, such that every inner node having exactly two children is labeled `series` or `parallel`, and the following condition is satisfied:*

- *for every two leaves x and y of T , denoting by t their least common ancestor, xy is an edge of G if and only if either t is labeled by `linear` and $x <_t y$, or t is labeled by `series`.*

We naturally model cotrees as $\{\text{ancestor}, \text{series}, \varepsilon\text{-ord}\}$ -structures as follow. A cotree $(T, \gamma, <)$ is modeled by \mathbb{C} where $U_{\mathbb{C}} = V(T)$, $\text{series}_{\mathbb{C}} = \gamma^{-1}(\text{series})$, and $\varepsilon\text{-ord}_{\mathbb{C}} = \{(x, y) \mid x < y\}$. The nodes that are labeled by `linear` could be recovered as those inner nodes whose children are related by $\varepsilon\text{-ord}$, while the nodes that are labeled by `parallel` could be recovered as those inner nodes which are labeled neither by `series` nor by `linear`. Based on Theorem 19 and as a consequence of Theorem 18, we can design a C_2MSO -transduction which produces the cotree of a cograph G from G .

► **Corollary 20.** *There exists a non-deterministic C_2 MISO-transduction τ such that, for each cograph G modeled by the $\{\text{edge}\}$ -structure \mathbb{G} , $\tau(\mathbb{G})$ is non-empty and every output in $\tau(\mathbb{G})$ is equal to some $\{\text{ancestor, series, } \varepsilon\text{-ord}\}$ -structure \mathbb{C} representing the cotree $(T, \gamma, <)$ of G .*

5 Conclusion

We provide transductions for obtaining tree-like graph decompositions such as modular decompositions, cotrees, split decompositions and bi-join decompositions from a graph using CMSO. This improves upon results of Courcelle [10, 12] who gave such transductions for ordered graphs. In a more general settings, we also obtain CMSO-transductions outputting weakly-partitive and weakly-bipartitive trees of weakly-partitive and weakly-bipartitive systems (Items 6 and 7 of Theorem 1). It is worth mentioning that the latter transduction can be also used to CMSO-transduce canonical decompositions of other structures such as Tutte’s decomposition of matroids or generally split-decompositions of submodular functions [16] or modular decompositions of 2-structures [18] or of hypergraphs [21]. As shown by the application given in [12] for transducing Whitney’s isomorphism class of a graph, a line of research is to more investigate which structures can be CMSO-transduced from a graph or a set system by using the transductions from Theorem 1. Also, naturally, the question arises whether counting is necessary or whether MSO is sufficient to transduce such decompositions. Furthermore, our results include that transducing rank decompositions for graphs of rank-width 1 is possible using CMSO. But it is not known whether rank-decompositions can be transduced in general using some suitable extension of MSO. Nevertheless, a corollary of our results is that CMSO-transducing rank-decompositions can be now reduced to consider CMSO-transducing rank-decompositions of prime graphs wrt either modular decomposition or split-decomposition as if a graph has rank-width at least 2, then its rank-width is equal to the rank-width of its prime induced graphs wrt either modular or split decomposition. Thus, our results imply that, for any fixed k , there is a CMSO-transduction that computes a clique-decomposition of small width for any graph belonging to a graph class whose prime graphs have sizes bounded by k or prime graphs have linear clique-width bounded by k , e.g., many H -free graphs have small prime graphs or have small linear clique-width (see for instance [5] or [23] for prominent such examples).

How to Play the Accordion: Uniformity and the (Non-)Conservativity of the Linear Approximation of the λ -Calculus

Abstract

Twenty years after its introduction by Ehrhard and Regnier, differentiation in λ -calculus and in linear logic is now a celebrated tool. In particular, it allows to write the Taylor formula in various λ -calculi, hence providing a theory of linear approximations for these calculi. In the standard λ -calculus, this linear approximation is expressed by results stating that the (possibly) infinitary β -reduction of λ -terms is simulated by the reduction of their Taylor expansion: in terms of rewriting systems, the resource reduction (operating on Taylor approximants) is an extension of the β -reduction.

In this paper, we address the converse property, conservativity: are there reductions of the Taylor approximants that do not arise from an actual β -reduction of the approximated term? We show that if we restrict the setting to finite terms and β -reduction sequences, then the linear approximation is conservative. However, as soon as one allows infinitary reduction sequences this property is broken. We design a counter-example, the Accordion. Then we show how restricting the reduction of the Taylor approximants allows to build a conservative extension of the β -reduction preserving good simulation properties. This restriction relies on uniformity, a property that was already at the core of Ehrhard and Regnier's pioneering work.

1 Introduction

The traditional approach to program approximation in a functional setting consists in describing the total information that a (potentially non-terminating) program can produce by the supremum of the finite pieces of information it can produce in finite time. This

continuous approximation is tightly related to the Scott semantics of λ -calculi [29]: the Böhm tree of a term (or equivalently its semantics) is the limit of the approximants produced by hereditary head reduction [21, 32, 3].

More recently, Ehrhard and Regnier introduced the differential λ -calculus and differential linear logic [16, 17], following ideas rooted in the semantics of linear logic [20, 13, 14]. This suggested the renewed approach of *linear* approximation of functional programs. In this setting, a program (i.e. a λ -term) is approximated by multilinear (or “polynomial”) programs, obtained by iterated differentiation at zero. Using this differential formalism, the Taylor formula yields a weighted sum $\mathcal{T}(M)$ of all multilinear approximants of a λ -term M , producing the same total information as M , *via* normalization. More precisely, Ehrhard and Regnier’s “commutation” theorem [19, 18] ensure that the normal form of the Taylor expansion of M is the Taylor expansion of the Böhm tree of M :

$$\text{nf}(\mathcal{T}(M)) = \mathcal{T}(\text{BT}(M)) \tag{1}$$

(and a Böhm tree is uniquely determined by its Taylor expansion). This approach subsumes the previous one [2]. In addition, it allows for characterising quantitative properties of programs (e.g. complexity [11]), which is a key benefit of linearity. This approximation technique has been fruitfully applied to many languages, richer than the plain λ -calculus: nondeterministic [31], probabilistic [10], extensional [5], call-by-value [23], and call-by-push-value [15, 9] calculi, as well as for Parigot’s $\lambda\mu$ -calculus [1]. The interplay of the operational and Taylor approximations also suggests a broader notion of a approximation of a computation process [26, 12].

Another benefit of linear approximation is that it can approximate not only β -normalisation (the information ultimately produced by a program) but β -reduction (the “information flow” along program execution). In particular, Equation (1) can be refined into

$$M \longrightarrow_{\beta}^* N \Rightarrow \mathcal{T}(M) \longrightarrow_{\text{r}} \mathcal{T}(N), \tag{2}$$

where $\longrightarrow_{\text{r}}$ denotes the so-called “resource” reduction acting linearly on approximants. As highlighted by our previous work [8, 7], this can even be extended to

$$M \longrightarrow_{\beta}^{\infty} N \Rightarrow \mathcal{T}(M) \longrightarrow_{\text{r}} \mathcal{T}(N) \tag{3}$$

if one extends the λ -calculus with infinite λ -terms and an infinitary closure of the β -reduction, which is a way to encompass infinite computations and their limits [22].

This paper is interested in the converse of Equations (2) and (3): is the linear approximation of the λ -calculus conservative? In other terms, we ask whether every resource reduction from $\mathcal{T}(M)$ to $\mathcal{T}(N)$ corresponds to a β -reduction sequence from M to N .

We show that the finite β -reduction of finite λ -terms is conservatively approximated (Section 3), but we are able to design a counter-example to conservativity (the Accordion **A**) as soon as we want to approximate infinitary β -reductions (Section 4). However, we introduce a *uniform* linear approximation allowing for the same good properties as the standard one, while enjoying conservativity (Section 5).

2 Preliminaries

In this section, we briefly recall the linear approximation of the λ -calculus, following its refined presentation in [7]. We first recall the definition of the λ -calculus, as well as its “001” infinitary extension: this is the version of the infinitary λ -calculus that fits the formalism

of both continuous and linear approximations as they are usually presented (Section 2.1). Then we present the resource λ -calculus, i.e. a linear variant of the λ -calculus (there are no duplications or erasures of subterms during the reduction) enjoying strong confluence and normalisation properties (Section 2.2). Finally, the linear approximation relies on the Taylor expansion, that maps a λ -term to a sum of resource terms, in a way such that the reduction of λ -terms is simulated by the reduction of the resource approximants (Section 2.3).

2.1 Finite and infinitary λ -calculi

We give a brief presentation of the 001-infinitary λ -calculus. A more detailed exposition and a general account of infinitary λ -calculi can be found in [7, 4]. From now on, we fix a countable set \mathcal{V} of variables.

► **Definition 1.** *The set Λ of (finite) λ -terms is the set \mathcal{X} defined by the inductive rules:*

$$\frac{x \in \mathcal{V}}{x \in \mathcal{X}} \text{ (}\mathcal{V}\text{)} \quad \frac{x \in \mathcal{V} \quad M \in \mathcal{X}}{\lambda x.M \in \mathcal{X}} \text{ (}\lambda\text{)} \quad \frac{M \in \mathcal{X} \quad N \in \mathcal{X}}{(M)N \in \mathcal{X}} \text{ (}\@)\text{)}$$

The set Λ^{001} of **001-infinitary λ -terms** is the set \mathcal{X} defined by the rules (\mathcal{V}) , (λ) , and:

$$\frac{M \in \mathcal{X} \quad \triangleright N \in \mathcal{X}}{(M)N \in \mathcal{X}} \text{ (}\@^{001}\text{)} \quad \frac{N \in \mathcal{X}}{\triangleright N \in \mathcal{X}} \text{ (}\triangleright\text{)}$$

where the rule (\triangleright) is treated coinductively: infinite derivations are allowed provided each infinite branch crosses infinitely often this coinductive rule.

This means that Λ^{001} contains the infinitary λ -terms whose syntax tree contains only infinite branches entering infinitely often the argument side of an application.

Notice that we use Krivine's notation for applications [25], i.e. we parenthesise functions instead of arguments. We abbreviate the application of a term to successive arguments $(\dots((M)N_1)\dots)N_k$ as $(M)N_1 \dots N_k$, which is obtained by nesting applications on the left: this allows to use parentheses more sparingly, which will be a great relief later on. By contrast, $(M_1)(M_2)\dots(M_k)N$ is obtained by nesting applications on the right. A typical example of a term in Λ^{001} is $(x)^\omega := (x)(x)(x)\dots$. Observe also that there is an immediate inclusion $\Lambda \subseteq \Lambda^{001}$. On the contrary, neither $\lambda x_0.\lambda x_1.\lambda x_2.\dots$ nor $((\dots)x_2)x_1)x_0$ are allowed in Λ^{001} .

In practice we only consider infinitary terms having finitely many free variables, which allows us to consider them up to α -equivalence (i.e. renaming of bound variables) – as one usually does when dealing with λ -terms, and as we will do implicitly in all this paper. This enables us to define capture-avoiding substitution in the usual way, and we denote by $M[N/x]$ the term obtained by substituting N to x in M . We refer to [6] for a more careful and detailed presentation. These sets come equipped with the following dynamics.

► **Definition 2.** *The relation $\longrightarrow_\beta \subset \Lambda^{001} \times \Lambda^{001}$ of β -reduction is defined by the rules:*

$$\frac{}{(\lambda x.M)N \longrightarrow_\beta M[N/x]} \text{ (}\beta\text{)} \quad \frac{P \longrightarrow_\beta P'}{\lambda x.P \longrightarrow_\beta \lambda x.P'} \text{ (}\lambda_\beta\text{)}$$

$$\frac{P \longrightarrow_\beta P'}{(P)Q \longrightarrow_\beta (P')Q} \text{ (}\@l_\beta\text{)} \quad \frac{Q \longrightarrow_\beta Q'}{(P)Q \longrightarrow_\beta (P)Q'} \text{ (}\@r_\beta\text{)}$$

► **Definition 3.** The relation $\longrightarrow_{\beta}^{001} \subset \Lambda^{001} \times \Lambda^{001}$ of **001-infinitary β -reduction** is defined by the rules:

$$\frac{M \longrightarrow_{\beta}^* x}{M \longrightarrow_{\beta}^{001} x} (\mathcal{V}_{\beta}^{001}) \quad \frac{M \longrightarrow_{\beta}^* \lambda x.P \quad P \longrightarrow_{\beta}^{001} P'}{M \longrightarrow_{\beta}^{001} \lambda x.P'} (\lambda_{\beta}^{001})$$

$$\frac{M \longrightarrow_{\beta}^* (P)Q \quad P \longrightarrow_{\beta}^{001} P' \quad \triangleright Q \longrightarrow_{\beta}^{001} Q'}{M \longrightarrow_{\beta}^{001} (P')Q'} (\@_{\beta}^{001}) \quad \frac{Q \longrightarrow_{\beta}^{001} Q'}{\triangleright Q \longrightarrow_{\beta}^{001} Q'} (\triangleright)$$

where $\longrightarrow_{\beta}^*$ denotes the reflexive-transitive closure of \longrightarrow_{β} .

Infinitary β -reduction can be understood as allowing an infinite number of β -reduction steps, as long as the β -redexes are fired inside increasingly nested arguments of applications. This is formalised in the following result:

► **Theorem 4 (stratification).** Given $M, N \in \Lambda^{001}$, there is a reduction $M \longrightarrow_{\beta}^{001} N$ iff there exists a sequence of terms $(M_d) \in (\Lambda^{001})^{\mathbb{N}}$ such that for all $d \in \mathbb{N}$,

$$M = M_0 \longrightarrow_{\beta \geq 0}^* M_1 \longrightarrow_{\beta \geq 1}^* M_2 \longrightarrow_{\beta \geq 2}^* \dots \longrightarrow_{\beta \geq d-1}^* M_d \longrightarrow_{\beta \geq d}^{001} N,$$

where $\longrightarrow_{\beta \geq d}^*$ and $\longrightarrow_{\beta \geq d}^{001}$ denote β -reductions occurring inside (at least) d nested arguments of applications. Formally, **β -reduction at minimum depth d** is defined by:

$$\frac{M \longrightarrow_{\beta} M'}{M \longrightarrow_{\beta \geq 0} M'} (\mathcal{V}_{\beta \geq 0}) \quad \frac{P \longrightarrow_{\beta \geq d+1} P'}{\lambda x.P \longrightarrow_{\beta \geq d+1} \lambda x.P'} (\lambda_{\beta \geq d+1})$$

$$\frac{P \longrightarrow_{\beta \geq d+1} P'}{(P)Q \longrightarrow_{\beta \geq d+1} (P')Q} (\@l_{\beta \geq d+1}) \quad \frac{Q \longrightarrow_{\beta \geq d} Q'}{(P)Q \longrightarrow_{\beta \geq d+1} (P)Q'} (\@r_{\beta \geq d+1})$$

and **001-infinitary β -reduction at minimum depth d** is defined by:

$$\frac{M \longrightarrow_{\beta}^{001} M'}{M \longrightarrow_{\beta \geq 0}^{001} M'} (\mathcal{V}_{\beta \geq 0}^{001}) \quad \frac{}{x \longrightarrow_{\beta \geq d+1}^{001} x} (\mathcal{V}_{\beta \geq d+1}^{001})$$

$$\frac{P \longrightarrow_{\beta \geq d+1}^{001} P'}{\lambda x.P \longrightarrow_{\beta \geq d+1}^{001} \lambda x.P'} (\lambda_{\beta \geq d+1}^{001}) \quad \frac{P \longrightarrow_{\beta \geq d+1}^{001} P' \quad Q \longrightarrow_{\beta \geq d}^{001} Q'}{(P)Q \longrightarrow_{\beta \geq d+1}^{001} (P')Q} (\@_{\beta \geq d+1}^{001}).$$

A typical (and even motivating) example of an infinitary β -reduction involves the fix-point combinator $Y := \lambda f.(\lambda x.(f)(x)x)\lambda x.(f)(x)x$. It consists in the reduction $(Y)M \longrightarrow_{\beta}^{001} (M)^{\omega}$ corresponding to the sequence $(Y)M \longrightarrow_{\beta \geq 0}^* (M)(Y)M \longrightarrow_{\beta \geq 1}^* (M)(M)(Y)M \longrightarrow_{\beta \geq 2}^* \dots$. On the contrary, the infinite reduction sequence $\Omega \longrightarrow_{\beta} \Omega \longrightarrow_{\beta} \Omega \longrightarrow_{\beta} \dots$, where $\Omega := (\lambda x.(x)x)\lambda x.(x)x$, does not give rise to a 001-infinitary reduction because the redexes are fired at top-level all the way. On the other hand, each finite reduction sequence $\Omega \longrightarrow_{\beta}^* \Omega$ induces a reduction $\Omega \longrightarrow_{\beta}^{001} \Omega$, but only because $\longrightarrow_{\beta}^{001}$ contains $\longrightarrow_{\beta}^*$ (see [8], Lemma 2.13).

2.2 The resource λ -calculus

The resource λ -calculus is the target language of the linear approximation of the λ -calculus. We recall its construction, and we refer to [31, 7] for more details. The main intuition behind this calculus is that arguments become *finite multisets*, and that $(\lambda x.s)[t_1, \dots, t_n]$ will reduce to a term obtained by substituting *linearly* one t_i for each occurrence of x in s . The different matchings of the t_i 's and the occurrences of x are superposed by a sum operator; if a wrong number of t_i 's is provided, the term collapses to the empty sum.

Given a set \mathcal{X} , we denote by $!\mathcal{X}$ the set of finite multisets of elements of \mathcal{X} . A multiset is denoted by $\bar{x} = [x_1, \dots, x_n]$, with its elements in an arbitrary order. Multiset union is denoted multiplicatively, by $\bar{x} \cdot \bar{y}$. Accordingly, the empty multiset is denoted by 1. We may also write $[x_1^{k_1}, \dots, x_m^{k_m}]$ to indicate multiplicities: this is the same as $[x_1]^{k_1} \cdot \dots \cdot [x_m]^{k_m}$.

► **Definition 5.** The set Λ_r of **resource terms** is defined by the rules:

$$\frac{x \in \mathcal{V}}{x \in \Lambda_r} (\mathcal{V}) \quad \frac{x \in \mathcal{V} \quad s \in \Lambda_r}{\lambda x.s \in \Lambda_r} (\lambda) \quad \frac{s \in \Lambda_r \quad \bar{t} \in !\Lambda_r}{(s)\bar{t} \in \Lambda_r} (@!)$$

and is implicitly quotiented by α -equivalence. Multisets in $!\Lambda_r$ are called **resource monomials**. To denote indistinctly Λ_r or $!\Lambda_r$, we write $(!)\Lambda_r$.

Given a semiring \mathbb{S} and a set \mathcal{X} , we denote by $\mathbb{S}^{\mathcal{X}}$ the set of possibly infinite linear combinations of elements of \mathcal{X} with coefficients in \mathbb{S} , considered as formal weighted sums. Given a sum $\mathbf{S} \in \mathbb{S}^{\mathcal{X}}$, its support $|\mathbf{S}|$ is the set of all elements of \mathcal{X} bearing a non-null coefficient. We also denote by $\mathbb{S}^{(\mathcal{X})}$ the sub-semimodule of $\mathbb{S}^{\mathcal{X}}$ of all sums having a finite support.

We use the following syntactic sugar. The empty sum $\sum_{x \in \mathcal{X}} 0 \cdot x$ is denoted by 0. The one-element sum $\sum_{x \in \mathcal{X}} \delta_{x,y} \cdot x$ is assimilated to y , yielding an inclusion $\mathcal{X} \subseteq \mathbb{S}^{\mathcal{X}}$. Sums can be summed, i.e. $\sum_{x \in \mathcal{X}} a_x \cdot x + \sum_{x \in \mathcal{X}} b_x \cdot x = \sum_{x \in \mathcal{X}} (a_x + b_x) \cdot x$. It is also convenient to extend by linearity all the constructors of the calculus to sums of resource terms, i.e.

$$\begin{aligned} \lambda x. \left(\sum_{i \in I} a_i \cdot s_i \right) &:= \sum_{i \in I} a_i \cdot \lambda x.s_i, \\ \left(\sum_{i \in I} a_i \cdot s_i \right) \sum_{j \in J} b_j \cdot \bar{t}_j &:= \sum_{i \in I} \sum_{j \in J} a_i b_j \cdot (s_i)\bar{t}_j, \\ \left[\sum_{i \in I} a_i \cdot s_i \right] \cdot \sum_{j \in J} b_j \cdot \bar{t} &:= \sum_{i \in I} \sum_{j \in J} a_i b_j \cdot [s_i] \cdot \bar{t}_j. \end{aligned} \quad (4)$$

► **Definition 6.** For all $u \in (!)\Lambda_r$, $\bar{t} = [t_1, \dots, t_n] \in !\Lambda_r$ and $x \in \mathcal{V}$, the **multilinear substitution** of x by \bar{t} in u is the finite sum $s\langle \bar{t}/x \rangle \in \mathbb{N}^{(!)\Lambda_r}$ defined by

$$s\langle \bar{t}/x \rangle := \begin{cases} \sum_{\sigma \in \mathfrak{S}(n)} u[t_{\sigma(1)}/x_1, \dots, t_{\sigma(n)}/x_n] & \text{if } x \text{ occurs } n \text{ times in } u \\ 0 & \text{otherwise} \end{cases}$$

where x_1, \dots, x_n is an arbitrary enumeration of the occurrences of x in u , and $u[t_{\sigma(1)}/x_1, \dots]$ denotes the result of the (capture-avoiding) substitution of each x_i by the corresponding $t_{\sigma(i)}$.

► **Definition 7.** The relation $\longrightarrow_r \subset \mathbb{N}^{(!)\Lambda_r} \times \mathbb{N}^{(!)\Lambda_r}$ of **resource β -reduction** is defined using the auxiliary relation $\longrightarrow_r \subset (!)\Lambda_r \times \mathbb{N}^{(!)\Lambda_r}$ generated by the rules

$$\frac{}{(\lambda x.s)\bar{t} \longrightarrow_r s\langle \bar{t}/x \rangle} (\beta_r) \quad \frac{s \longrightarrow_r S'}{\lambda x.s \longrightarrow_r \lambda x.S'} (\lambda_r) \quad \frac{s \longrightarrow_r S'}{(s)\bar{t} \longrightarrow_r (S')\bar{t}} (@l_r)$$

$$\frac{\bar{t} \longrightarrow_r \bar{T}'}{(s)\bar{t} \longrightarrow_r (s)\bar{T}'} (@r_r) \quad \frac{s \longrightarrow_r S'}{[s] \cdot \bar{t} \longrightarrow_r [S'] \cdot \bar{t}} (!_r)$$

as well as the **lifting rule**

$$\frac{u_1 \longrightarrow_r U'_1 \quad \forall i \geq 2, u_i \overset{?}{\longrightarrow}_r U'_i}{\sum_{i=1}^n u_i \longrightarrow_r \sum_{i=1}^n U'_i} (\Sigma_r)$$

where $\overset{?}{\longrightarrow}_r$ is the reflexive closure of \longrightarrow_r .

From now on, we fix a semiring \mathbb{S} . We consider \mathbb{N} as a subset of \mathbb{S} through the map $n \mapsto 1 + \dots + 1$ (notice however that it might not be an injection), and we suppose that \mathbb{S} “has fractions”, i.e. for all non-null $n \in \mathbb{N}$ there is some $\frac{1}{n} \in \mathbb{S}$ such that $n \times \frac{1}{n} = 1$. This is the case of the semirings \mathbb{Q}_+ and \mathbb{R}_+ of non-negative rational (resp. real) numbers, but also of the semiring \mathbb{B} of boolean values (equipped with the logical “or” and “and” operations).

► **Definition 8.** *Given a set \mathcal{X} and a semiring \mathbb{S} , a family of sums $(\mathbf{S}_i)_{i \in I} \in (\mathbb{S}^{\mathcal{X}})^I$ is **summable** when each $x \in \mathcal{X}$ bears a non-null coefficient in finitely many of the \mathbf{S}_i . If this is the case then $\sum_{i \in I} \mathbf{S}_i$ is a well-defined sum.*

► **Definition 9.** *The relation $\longrightarrow_r \subset \mathbb{S}^{(!)\Lambda_r} \times \mathbb{S}^{(!)\Lambda_r}$ of **pointwise resource reduction** is defined by saying that there is a reduction $\mathbf{U} \longrightarrow_r \mathbf{V}$ whenever there are summable families $(u_i)_{i \in I} \in ((!)\Lambda_r)^I$ and $(V_i)_{i \in I} \in (\mathbb{N}^{(!)\Lambda_r})^I$ such that*

$$\mathbf{U} = \sum_{i \in I} a_i \cdot u_i, \quad \mathbf{V} = \sum_{i \in I} a_i \cdot V_i \quad \text{and} \quad \forall i \in I, u_i \longrightarrow_r^* V_i.$$

Notice that whereas \longrightarrow_r reduces finite sums with integer coefficients, \longrightarrow_r reduces arbitrary sums with arbitrary coefficients.

2.3 Linear approximation and the conservativity problems

We recall the definition of the Taylor expansion of λ -terms, and the approximation theorems it enjoys. Again, a detailed presentation can be found in [31], and in [7] for the adaption to infinitary λ -calculi. In the latter setting, we shall start with the following unusual definition.

► **Definition 10.** *The **Taylor expansion** is the map $\mathcal{T} : \Lambda^{001} \rightarrow \mathbb{S}^{\Lambda_r}$ defined by*

$$\mathcal{T}(M) := \sum_{s \in \Lambda_r} \mathcal{T}(M, s) \cdot s,$$

where the coefficient $\mathcal{T}(M, s)$ is defined by induction on $s \in \Lambda_r$ as follows:

$$\begin{aligned} \mathcal{T}(x, x) &:= 1 \\ \mathcal{T}(\lambda x.P, \lambda x.s) &:= \mathcal{T}(P, s) \\ \mathcal{T}\left((P)Q, (s)[t_1^{k_1}, \dots, t_m^{k_m}]\right) &:= \mathcal{T}(P, s) \times \prod_{i=1}^m \frac{\mathcal{T}(Q, t_i)^{k_i}}{k_i!}, \quad \text{the } t_i \text{'s being pairwise distinct} \\ \mathcal{T}(M, s) &:= 0 \quad \text{in all other cases.} \end{aligned}$$

Let us stress a crucial observation: whenever $s \in |\mathcal{T}(M)|$, the value of $\mathcal{T}(M, s)$ does not depend on M , hence $\mathcal{T}(M)$ is uniquely determined by its support [19].

Using the notation from Equation (4), we obtain the following description of the Taylor expansion. This is usually how the definition is presented for finite λ -terms, but since it is not a valid coinductive definition we had to provide Definition 10 in the infinitary setting.

► **Lemma 11** ([7], Corollary 4.7). *For all variables $x \in \mathcal{V}$ and terms $P, Q \in \Lambda^{001}$,*

$$\mathcal{T}(x) = x \quad \mathcal{T}(\lambda x.P) = \lambda x.\mathcal{T}(P) \quad \mathcal{T}((P)Q) = (\mathcal{T}(P))\mathcal{T}(Q)^\dagger,$$

where the operation of **promotion** is defined for all $\mathbf{S} \in \mathbb{S}^{\Lambda_r}$ by $\mathbf{S}^\dagger := \sum_{n \in \mathbb{N}} \frac{1}{n!} \cdot [\mathbf{S}]^n$.

We defined a map \mathcal{T} taking λ -terms to weighted sums of approximants. This induces an approximation of the λ -calculus, thanks to the following theorems expressing the fact that the reduction of the approximants can simulate the reduction of the approximated term.

► **Theorem 12** ([31], Lemma 7.6). *For $M, N \in \Lambda$, if $M \longrightarrow_\beta^* N$ then $\mathcal{T}(M) \longrightarrow_r \mathcal{T}(N)$.*

► **Theorem 13** ([7], Theorem 4.56). *For $M, N \in \Lambda^{001}$, if $M \longrightarrow_\beta^{001} N$ then $\mathcal{T}(M) \longrightarrow_r \mathcal{T}(N)$.*

In particular, the latter theorem encompasses the ‘‘Commutation theorem’’ [19, 18], which is usually presented as the cornerstone of the linear approximation of the λ -calculus: the normal form of $\mathcal{T}(M)$ is equal to the Taylor expansion of the Böhm tree of M (which is a notion of infinitary β -normal form of M), i.e. normalisation commutes with approximation¹.

► **Definition 14.** *Let (A, \longrightarrow_A) and (B, \longrightarrow_B) be two reduction systems. The latter is an **extension** of the former if:*

1. *there is an injection $i : A \hookrightarrow B$,*
2. *\longrightarrow_A **simulates** \longrightarrow_B through i , i.e. $\forall a, a' \in A$, if $a \longrightarrow_A a'$ then $i(a) \longrightarrow_B i(a')$.*

*This extension is said to be **conservative**² if $\forall a, a' \in A$, if $i(a) \longrightarrow_B i(a')$ then $a \longrightarrow_A a'$.*

Theorems 12 and 13 can be reformulated using this definition, thanks to the fact that $\mathcal{T} : \Lambda^{001} \rightarrow \mathbb{S}^{\Lambda_r}$ is injective [8, Lemma 5.18]:

- Theorem 12 tells that $(\mathbb{S}^{\Lambda_r}, \longrightarrow_r)$ simulates $(\Lambda, \longrightarrow_\beta^*)$,
- Theorem 13 tells that $(\mathbb{S}^{\Lambda_r}, \longrightarrow_r)$ simulates $(\Lambda^{001}, \longrightarrow_\beta^{001})$,

which leads us to the problems we tackle in this paper.

▷ Problem 15. Is $(\mathbb{S}^{\Lambda_r}, \longrightarrow_r)$ conservative wrt. $(\Lambda, \longrightarrow_\beta^*)$?

▷ Problem 16. Is $(\mathbb{S}^{\Lambda_r}, \longrightarrow_r)$ conservative wrt. $(\Lambda^{001}, \longrightarrow_\beta^{001})$?

3 Conservativity wrt. the finite λ -calculus

In this first section, we give a positive answer to Problem 15:

► **Theorem 17** (conservativity). *For all $M, N \in \Lambda$, if $\mathcal{T}(M) \longrightarrow_r \mathcal{T}(N)$ then $M \longrightarrow_\beta^* N$.*

We adapt a proof technique by Kerinec and the second author [24], who used it to prove that the algebraic λ -calculus is a conservative extension of the usual λ -calculus. Their proof relies on a relation \vdash , called ‘‘mashup’’ of β -reductions, relating λ -terms (from the ‘‘small world’’) to their algebraic reducts (in the ‘‘big world’’). In our setting, $M \vdash s$ when s is an approximant of a reduct of M .

► **Definition 18.** *The **mashup** relation $\vdash \subset \Lambda \times \Lambda_r$ is defined by the following rules:*

$$\frac{M \longrightarrow_\beta^* x}{M \vdash x} \quad \frac{M \longrightarrow_\beta^* \lambda x.P \quad P \vdash s}{M \vdash \lambda x.s}$$

$$\frac{M \longrightarrow_\beta^* (P)Q \quad P \vdash s \quad Q \vdash \bar{t}}{M \vdash (s)\bar{t}} \quad \frac{M \vdash t_1 \quad \dots \quad M \vdash t_n}{M \vdash [t_1, \dots, t_n]}$$

It is extended to $\Lambda \times \mathbb{S}^{\Lambda_r}$ by the following rule:

$$\frac{\forall i \in I, M \vdash s_i}{M \vdash \sum_{i \in I} a_i \cdot s_i}$$

for any index set I and coefficients $a_i \in \mathbb{S}$ such that the sum exists.

¹ To be rigorous, Theorem 13 must first be extended to a variant of the β -reduction called $\beta\perp$ -reduction. We remain allusive here, and refer to [8, 7] for more details.

² Notice that our definition varies from the one chosen by the *Terese* [30, § 1.3.21], where the conservativity of \longrightarrow_B wrt. \longrightarrow_A is defined as a property of the conversions $=_A$ and $=_B$ they generate. We prefer to distinguish between a conservative extension of a reduction (‘‘in the small world, the big reduction reduces the same people to the same people’’) and a conservative extension of the corresponding conversion.

23:8 How to Play the Accordion

► **Lemma 19.** For all $M \in \Lambda$, $M \vdash \mathcal{T}(M)$.

Proof. Take any $s \in |\mathcal{T}(M)|$. By an immediate induction on s , $M \vdash s$ follows from the rules of Definition 18 (where all the assumptions \rightarrow_{β}^* are just taken to be equalities). ◀

► **Lemma 20.** For all $M, N \in \Lambda$ and $\mathbf{S} \in \mathbb{S}^{\Lambda_r}$, if $M \rightarrow_{\beta}^* N$ and $N \vdash \mathbf{S}$ then $M \vdash \mathbf{S}$.

Proof. Take any $s \in |\mathbf{S}|$, then $N \vdash s$. By an immediate induction on s , $M \vdash s$ follows from the rules of Definition 18 (where the assumptions $M \rightarrow_{\beta}^* \dots$ follow from the corresponding $M \rightarrow_{\beta}^* N \rightarrow_{\beta}^* \dots$). ◀

► **Lemma 21.** For all $M, N \in \Lambda$, $x \in \mathcal{V}$, $s \in \Lambda_r$ and $\bar{t} \in !\Lambda_r$, if $M \vdash s$ and $N \vdash \bar{t}$ then $\forall s' \in |s(\bar{t}/x)|$, $M[N/x] \vdash s'$.

Proof. Assume M and N are given and show the following equivalent result by induction on s : if $M \vdash s$ then for all \bar{t} such that $N \vdash \bar{t}$ and for all $s' \in |s(\bar{t}/x)|$, $M[N/x] \vdash s'$. ◀

► **Lemma 22.** For all $M \in \Lambda$ and $\mathbf{S}, \mathbf{T} \in \mathbb{S}^{\Lambda_r}$, if $M \vdash \mathbf{S}$ and $\mathbf{S} \rightarrow_r \mathbf{T}$ then $M \vdash \mathbf{T}$.

Proof. Let us first show that for all $M \in \Lambda$ and $s \in \Lambda_r$ and $T \in \mathbb{N}^{(\Lambda_r)}$, if $M \vdash s \rightarrow_r T$ then $\forall t \in |T|$, $M \vdash t$. We do so by induction on $s \rightarrow_r T$. When $s = (\lambda x.u)\bar{v}$ is a redex, there exists a derivation:

$$\frac{M \rightarrow_{\beta}^* (P)Q \quad \frac{P \rightarrow_{\beta}^* \lambda x.P' \quad P' \vdash u}{P \vdash \lambda x.u} \quad Q \vdash \bar{v}}{M \vdash (\lambda x.u)\bar{v}}$$

By Lemma 21 with $P' \vdash u$, $Q \vdash \bar{v}$, for all $t \in |u(\bar{v}/x)|$, we obtain $P'[Q/x] \vdash t$. Finally, since $M \rightarrow_{\beta}^* (\lambda x.P')Q \rightarrow_{\beta} P'[Q/x]$, we conclude by Lemma 20. The other cases of the induction follow immediately by lifting to the context.

As a consequence, we can easily deduce the following steps:

- if $M \vdash s \rightarrow_r T$ then $M \vdash T$, for all $M \in \Lambda$, $s \in \Lambda_r$ and $T \in \mathbb{N}^{(\Lambda_r)}$,
- if $M \vdash S \rightarrow_r T$ then $M \vdash T$, for all $M \in \Lambda$ and $S, T \in \mathbb{N}^{(\Lambda_r)}$,
- if $M \vdash S \rightarrow_r^* T$ then $M \vdash T$, for all $M \in \Lambda$ and $S, T \in \mathbb{N}^{(\Lambda_r)}$,

which leads to the result. ◀

Before we state the last lemma of the proof, recall that there is a canonical injection $[-]_r : \Lambda \rightarrow \Lambda_r$ defined by:

$$[x]_r := x \quad [\lambda x.P]_r := \lambda x.[P]_r \quad [(P)Q]_r := ([P]_r) [[Q]_r]$$

and such that for all $N \in \Lambda$, $[N]_r \in |\mathcal{T}(N)|$.

► **Lemma 23.** For all $M, N \in \Lambda$, if $M \vdash \mathcal{T}(N)$ then $M \rightarrow_{\beta}^* N$.

Proof. If $M \vdash \mathcal{T}(N)$, then in particular $M \vdash [N]_r$. We proceed by induction on N :

- If $N = x$, then $M \vdash x$ so $M \rightarrow_{\beta}^* x$ by definition.
- If $N = \lambda x.P'$, then $M \vdash \lambda x.[P']_r$, i.e. there is a $P \in \Lambda$ such that $M \rightarrow_{\beta}^* \lambda x.P$ and $P \vdash [P']_r$. By induction, $P \rightarrow_{\beta}^* P'$, thus $M \rightarrow_{\beta}^* \lambda x.P' = N$.
- If $N = (P')Q'$, then $M \vdash ([P']_r) [[Q']_r]$ i.e. there are $P, Q \in \Lambda$ such that $M \rightarrow_{\beta}^* (P)Q$, $P \vdash [P']_r$ and $Q \vdash [[Q']_r]$. By induction, $P \rightarrow_{\beta}^* P'$ and $Q \rightarrow_{\beta}^* Q'$, thus $M \rightarrow_{\beta}^* (P')Q' = N$. ◀

Proof of Theorem 17. Suppose that $\mathcal{T}(M) \rightarrow_r \mathcal{T}(N)$. By Lemma 19 we obtain $M \vdash \mathcal{T}(M)$, hence by Lemma 22 $M \vdash \mathcal{T}(N)$. We can conclude with Lemma 23. ◀

4 Non-conservativity wrt. the infinitary λ -calculus

The previous theorem relied on the excellent properties of the Taylor expansion of finite λ -terms: a single (well-chosen) term $[M]_{\mathcal{r}} \in |\mathcal{T}(M)|$ is enough to characterise M , and a single (again, well-chosen) sequence of resource reducts of some $s \in |\mathcal{T}(M)|$ suffices to characterise any sequence $M \rightarrow_{\beta}^* N$. These properties are not true any more when considering more complicated settings, like the 001-infinitary λ -calculus. This does not only make the “mashup” proof technique fail, but also enables us to give a negative answer to Problem 16.

4.1 Failure of the “mashup” technique

Let us first describe where we hit an obstacle if we try to reproduce the proof we have given in the finite setting, which will make clearer the way we later build a counterexample.

First, it is not obvious what the mashup relation should be: we could just use the relation \vdash defined on $\Lambda^{001} \times \Lambda_{\mathcal{r}}$ by the same set of rules as in Definition 18, or define an infinitary mashup \vdash_{001} by the rules

$$\frac{M \rightarrow_{\beta}^{001} x}{M \vdash_{001} x} \quad \frac{M \rightarrow_{\beta}^{001} \lambda x.P \quad P \vdash_{001} s}{M \vdash_{001} \lambda x.s}$$

$$\frac{M \rightarrow_{\beta}^{001} (P)Q \quad P \vdash_{001} s \quad Q \vdash_{001} \bar{t}}{M \vdash_{001} (s)\bar{t}} \quad \frac{M \vdash_{001} t_1 \quad \dots \quad M \vdash_{001} t_n}{M \vdash_{001} [t_1, \dots, t_n]}$$

and extend it to $\mathbb{S}^{\Lambda_{\mathcal{r}}}$ accordingly. In fact, this happens to define the same relation.

► **Lemma 24.** *For all $M \in \Lambda^{001}$ and $s \in \Lambda_{\mathcal{r}}$, $M \vdash_{001} s$ iff $M \vdash s$.*

Proof. The inclusion $\vdash \subseteq \vdash_{001}$ is immediate. Let us show the converse. First, observe that the proof of Lemma 20 can be easily extended in order to show that for all $M, N \in \Lambda^{001}$ and $s \in \Lambda_{\mathcal{r}}$, if $M \rightarrow_{\beta}^{001} N \vdash_{001} s$ then $M \vdash_{001} s$. Then we proceed by induction on s .

- If $M \vdash_{001} x$, then $M \rightarrow_{\beta}^{001} x$, i.e. $M \rightarrow_{\beta}^* x$, and finally $M \vdash x$.
- If $M \vdash_{001} \lambda x.u$, then there is a derivation:

$$\frac{\frac{M \rightarrow_{\beta}^* \lambda x.P \quad P \rightarrow_{\beta}^{001} P'}{M \rightarrow_{\beta}^{001} \lambda x.P'} \quad P' \vdash_{001} u}{M \vdash_{001} \lambda x.u}}$$

Since $P \rightarrow_{\beta}^{001} P' \vdash_{001} u$, we have $P \vdash_{001} u$, and by induction on u we obtain $P \vdash u$. With $M \rightarrow_{\beta}^* \lambda x.P$, this yields $M \vdash \lambda x.u$.

- The case of $M \vdash_{001} (u)\bar{v}$ is similar. ◀

As a consequence, Lemmas 19–22 can be easily extended to $\rightarrow_{\beta}^{001}$ and \vdash_{001} . We have already explained how the proof of this can be done for Lemma 20; for the other ones, one just needs to observe that the proofs are all by induction on resource terms or on some inductively defined relation, hence replacing \rightarrow_{β}^* with $\rightarrow_{\beta}^{001}$ does not change anything (and neither does replacing \vdash with \vdash_{001} , thanks to Lemma 24).

The failure of the infinitary “mashup” proof occurs in the extension of Lemma 23. Indeed, this proof crucially relies on the existence of an injection $[-]_{\mathcal{r}} : \Lambda \rightarrow \Lambda_{\mathcal{r}}$, whereas for Λ^{001} there is only the counterpart $[-]_{\mathcal{r}, -} : \Lambda^{001} \times \mathbb{N} \rightarrow \Lambda_{\mathcal{r}}$ defined by

23:10 How to Play the Accordion

$$\begin{aligned} [x]_{r,d} &:= x & [(P)Q]_{r,0} &:= ([P]_{r,0}) 1 \\ [\lambda x.P]_{r,d} &:= \lambda x.[P]_{r,d} & [(P)Q]_{r,d+1} &:= ([P]_{r,d+1}) [[Q]_{r,d}]. \end{aligned}$$

Now, if we suppose that $M \vdash \mathcal{T}(N)$ and we want to show that $M \xrightarrow{\beta}^{001} N$, we cannot rely any more on the fact that $M \vdash [N]_r$, but only on the fact that $\forall d \in \mathbb{N}$, $M \vdash [N]_{r,d}$. This makes the induction fail. For instance, for the case where N is an abstraction $\lambda x.P'$, we obtain a d -indexed sequence of derivations

$$\frac{M \xrightarrow{\beta}^* \lambda x.P_d \quad P_d \vdash [P']_{r,d}}{M \vdash [N]_{r,d} = [\lambda x.P']_{r,d}}$$

but nothing tells us that the terms P_d and reductions $M \xrightarrow{\beta}^* \lambda x.P_d$ are coherent! This failure is what enables us to design a counterexample.

4.2 The Accordion

In this section, we define 001-infinitary λ -terms \mathbf{A} and $\bar{\mathbf{A}}$ and show that they form a counterexample not only to the 001-infinitary counterpart of Lemma 23, but also to the conservativity property in the infinitary setting.

► **Notation 25.** We denote as follows the usual representation of booleans, an “applicator” $\langle - \rangle$, and the Church encodings of integers and of the successor function:

$$\begin{aligned} \mathbf{T} &:= \lambda x.\lambda y.x & \mathbf{F} &:= \lambda x.\lambda y.y & \langle M \rangle &:= \lambda b.(b)M \\ \mathbf{n} &:= \lambda f.\lambda x.(f)^n x & \mathbf{Succ} &:= \lambda n.\lambda f.\lambda x.(n) f (f)x \end{aligned}$$

► **Definition 26.** The *Accordion* λ -term is defined as $\mathbf{A} := (\mathbf{P})\mathbf{0}$, where:

$$\mathbf{P} := (\mathbf{Y}) \lambda \phi.\lambda n. (\langle \mathbf{T} \rangle) ((n) \langle \mathbf{F} \rangle) \mathbf{Q}_{\phi,n} \quad \mathbf{Q}_{\phi,n} := (\mathbf{Y}) \lambda \psi.\lambda b. ((b) \langle \phi \rangle) (\mathbf{Succ}) n \psi.$$

We also define $\bar{\mathbf{A}} := (\langle \mathbf{T} \rangle) (\langle \mathbf{F} \rangle)^\omega$.

Let us show how this term behaves (and why we named it the Accordion). There exist terms \mathbf{P}'' (which is nothing but the first head reduct of \mathbf{P}) and \mathbf{Q}_n (for all $n \in \mathbb{N}$) such that the following reductions hold:

$$\begin{array}{cccccccc} \mathbf{A} & \xrightarrow{\beta}^* & \begin{array}{c} @ \\ / \quad \backslash \\ \mathbf{P}'' \quad \mathbf{0} \end{array} & \xrightarrow{\beta}^* & \begin{array}{c} @ \\ / \quad \backslash \\ \langle \mathbf{T} \rangle \quad \mathbf{Q}_0 \end{array} & \xrightarrow{\beta}^* & \begin{array}{c} @ \\ / \quad \backslash \\ \mathbf{P}'' \quad \mathbf{1} \end{array} & \xrightarrow{\beta}^* & \begin{array}{c} @ \\ / \quad \backslash \\ \langle \mathbf{T} \rangle \quad @ \\ \quad \quad \backslash \\ \quad \quad \langle \mathbf{F} \rangle \quad \mathbf{Q}_1 \end{array} & \xrightarrow{\beta}^* & \begin{array}{c} @ \\ / \quad \backslash \\ \mathbf{P}'' \quad \mathbf{n} \end{array} & \xrightarrow{\beta}^* & \begin{array}{c} @ \\ / \quad \backslash \\ \langle \mathbf{T} \rangle \quad @ \\ \quad \quad \backslash \\ \quad \quad \langle \mathbf{F} \rangle \quad @ \\ \quad \quad \quad \vdots \\ \quad \quad \quad @ \\ \quad \quad \quad \backslash \\ \quad \quad \quad \langle \mathbf{F} \rangle \quad \mathbf{Q}_n. \end{array} \end{array}$$

This means that:

1. for any $d \in \mathbb{N}$, \mathbf{A} reduces to terms \mathbf{A}_d that are similar to $\bar{\mathbf{A}}$ up to depth d (and, as a consequence, any finite approximant of $\bar{\mathbf{A}}$ is a reduct of approximants of \mathbf{A});
2. but this is not a valid infinitary reduction because we *need* to reduce a redex at depth 0 to obtain $\mathbf{A}_d \xrightarrow{\beta}^* \mathbf{A}_{d+1}$, thus the stratification property (Theorem 4) is violated: the depth of the reduced redexes does not tend to the infinity.

Our definition of \mathbf{A} and $\bar{\mathbf{A}}$ was entirely guided by this specification. More concretely:

- when fed with a Church integer argument \mathbf{n} , the term \mathbf{P}'' produces a term mimicking $\bar{\mathbf{A}}$ up to the n -th copy of $\langle \mathbf{F} \rangle$, the latter being applied to $\mathbf{Q}_n = \mathbf{Q}_{\mathbf{P}'', \mathbf{n}}$;
- the applicator $\langle - \rangle$ enforces a kind of call-by-value discipline, giving control to the argument (observe that $\langle \langle M \rangle \rangle N \rightarrow_{\beta} (N)M$);
- $\mathbf{Q}_{\mathbf{P}'', \mathbf{n}}$ eats up boolean arguments \mathbf{F} , until it is fed with a boolean \mathbf{T} (marking the root of the tree), at which point it restores \mathbf{P}'' , applied to the next Church integer.

In particular, this dynamics (\mathbf{A} is “stretched” and “compressed” over and over) justifies the name “Accordion”.

To be a counterexample to conservativity, \mathbf{A} actually has to satisfy a stronger property: *all reduction paths* starting from \mathbf{A} should have this “accordion” behaviour. A thorough analysis of the dynamics will allow us to establish this, and obtain:

► **Theorem 27.** (i) $\mathcal{T}(\mathbf{A}) \rightarrow_{\mathbf{r}} \mathcal{T}(\bar{\mathbf{A}})$, but (ii) there is no reduction $\mathbf{A} \rightarrow_{\beta}^{001} \bar{\mathbf{A}}$.

This theorem improves on the results from the first author’s PhD thesis [7, Theorem 5.12], where only the qualitative setting was treated (i.e. when $\mathbb{S} = \mathbb{B}$). Non-conservativity in the general case was presented as Conjecture 5.15, which is thereby solved.

4.3 Proof of the counterexample

In this (highly technical) section, we prove Theorem 27: a reader already satisfied with the above intuitions might prefer to skip it, and jump to Section 5. The key ingredient in the proof are the following well-known notions as well as the associated factorization property, due to Mitschke [28, cor. 5].

► **Definition 28.** A λ -term $M \in \Lambda^{001}$ has two possible *head forms*:

- either the form $\lambda x_1 \dots \lambda x_m. (y)M_1 \dots M_n$, called **head normal form (HNF)**,
- or the form $\lambda x_1 \dots \lambda x_m. (\lambda x. P)QM_1 \dots M_n$, where $(\lambda x. P)Q$ is called the **head redex**.

As a consequence, a β -reduction $M \rightarrow_{\beta} N$ reduces:

- either a head redex: it is a **head reduction**, denoted by $M \rightarrow_h N$,
- or any other redex: it is an **internal reduction**, denoted by $M \rightarrow_i N$.

► **Lemma 29** (head-internal decomposition). For all $M, N \in \Lambda$ such that $M \rightarrow_{\beta}^* N$, there exists an $M' \in \Lambda$ such that $M \rightarrow_h^* M' \rightarrow_i^* N$.

Let us also introduce some abbreviations³:

$$\begin{aligned} \mathbf{P}' &:= \lambda \phi. \lambda n. (\langle \mathbf{T} \rangle) (\langle n \rangle \langle \mathbf{F} \rangle) \mathbf{Q}_{\phi, n} & \mathbf{P}'' &:= (\lambda x. (\mathbf{P}') (x) x) \lambda x. (\mathbf{P}') (x) x & \mathbf{Q}_n &:= \mathbf{Q}_{\mathbf{P}'', (\text{Succ})^n 0} \\ \mathbf{Q}'_n &:= \lambda \psi. \lambda b. (\langle b \rangle \langle \mathbf{P}'' \rangle) (\text{Succ})^{n+1} 0 \psi & \mathbf{Q}''_n &:= (\lambda x. (\mathbf{Q}'_n) (x) x) \lambda x. (\mathbf{Q}'_n) (x) x. \end{aligned}$$

Using these definitions, Figure 1 describes the head reduction path starting from \mathbf{A} .

Proof of Theorem 27, item (i). For all $d \in \mathbb{N}$, we define:

- $\bar{\mathbf{A}}_d := (\langle \mathbf{T} \rangle) (\langle \mathbf{F} \rangle)^d \mathbf{Q}_n$. As a consequence of the reduction described in Figure 1, in particular its step 7, there are reductions $\mathbf{A} \rightarrow_{\beta}^* \bar{\mathbf{A}}_0 \rightarrow_{\beta}^* \bar{\mathbf{A}}_1 \rightarrow_{\beta}^* \bar{\mathbf{A}}_2 \rightarrow_{\beta}^* \dots$. By Theorem 12, we obtain

$$\mathcal{T}(\mathbf{A}) \rightarrow_{\mathbf{r}} \mathcal{T}(\bar{\mathbf{A}}_0) \rightarrow_{\mathbf{r}} \mathcal{T}(\bar{\mathbf{A}}_1) \rightarrow_{\mathbf{r}} \mathcal{T}(\bar{\mathbf{A}}_2) \rightarrow_{\mathbf{r}} \dots \quad (29)$$

³ Notice that the \mathbf{Q}_n we define here are slightly different from those in the example reduction described above, but they play the same role.

The first step is:		$\longrightarrow_h^* \left((Y)Q'_n \right) \underbrace{F \dots F}_n T$	(16)
$A = ((Y)P')0 \longrightarrow_h (P'')0$		$\longrightarrow_h (Q''_n) F \dots F T$	(17)
Then, for each $n \in \mathbb{N}$, we do the following head reduction steps:		$\longrightarrow_h ((Q'_n)Q''_n) F \dots F T$	(18)
$(P'')(Succ)^n 0$		$\longrightarrow_h (\lambda b. ((b)(P'')(Succ)^{n+1} 0) Q''_n) F \dots F T$	(19)
$\longrightarrow_h ((P')P'')(Succ)^n 0$	(5)	$\longrightarrow_h ((\lambda x. \lambda y. y)(P'')(Succ)^{n+1} 0) Q''_n \underbrace{F \dots F}_{n-1} T$	(20)
$\longrightarrow_h (\lambda n. ((T)) ((n)(F) Q_{P'',n}) (Succ)^n 0$	(6)	$\longrightarrow_h ((\lambda y. y)Q''_n) F \dots F T$	(21)
$\longrightarrow_h (T) (((Succ)^n 0) (F) Q_n$	(7)	$\longrightarrow_h (Q''_n) F \dots F T$	(22)
$\longrightarrow_h (Succ)^n 0 (F) Q_n T$	(8)		
$\longrightarrow_h (\lambda f. \lambda x. (((Succ)^{n-1} 0) f) (f)x) (F) Q_n T$	(9)		
$\longrightarrow_h (\lambda x. (((Succ)^{n-1} 0) (F) ((F)x) Q_n) T$	(10)	and by repeating steps (18) to (22):	
$\longrightarrow_h ((Succ)^{n-1} 0 (F) ((F)Q_n) T$	(11)	$\longrightarrow_h^* (Q''_n) T$	(23)
and by repeating steps (9) to (11):		$\longrightarrow_h ((Q'_n)Q''_n) T$	(24)
$\longrightarrow_h^* ((0)(F) ((F))^n Q_n) T$	(12)	$\longrightarrow_h (\lambda b. ((b)(P'')(Succ)^{n+1} 0) Q''_n) T$	(25)
$\longrightarrow_h ((\lambda x.x) ((F))^n Q_n) T$	(13)	$\longrightarrow_h ((\lambda x. \lambda y.x)(P'')(Succ)^{n+1} 0) Q''_n$	(26)
$\longrightarrow_h ((\lambda b.(b)F) ((F))^{n-1} Q_n) T$	(14)	$\longrightarrow_h (\lambda y.(P'')(Succ)^{n+1} 0) Q''_n$	(27)
$\longrightarrow_h (((F))^{n-1} Q_n) F T$	(15)	$\longrightarrow_h (P'')(Succ)^{n+1} 0$	(28)
and by repeating step (15):		which brings us back to step (5).	

■ **Figure 1** Exhaustive head reduction of the Accordion. We highlight the fired head redexes.

- $\mathcal{T}'_d(\bar{A}) := \mathcal{T}(((T))((F))^d \perp)$, where \perp is a constant such that $\mathcal{T}(\perp) := 0$ (this is just a trick to “cut” the Taylor expansion at some point), as well as

$$\begin{cases} \mathcal{T}_0(\bar{A}) := \mathcal{T}'_0(\bar{A}) \\ \mathcal{T}_{d+1}(\bar{A}) := \mathcal{T}'_{d+1}(\bar{A}) - \mathcal{T}'_d(\bar{A}) = \sum_{s \in |\mathcal{T}'_{d+1}(\bar{A})| \setminus |\mathcal{T}'_d(\bar{A})|} \mathcal{T}(s, \bar{A}) \cdot s. \end{cases}$$

By construction (using the observation that the coefficient of $s \in |\mathcal{T}(M)|$ does not depend on M), we obtain:

$$\mathcal{T}(\bar{A}_d) = \mathcal{T}_d(\bar{A}) + \mathbf{S}_d, \text{ for some } \mathbf{S}_d \text{ such that } |\mathcal{T}_d(\bar{A})| \cap |\mathbf{S}_d| = \emptyset \quad (30)$$

$$\mathcal{T}(\bar{A}) = \sum_{n \in \mathbb{N}} \mathcal{T}_d(\bar{A}) \quad (31)$$

Before we use this material to prove the theorem, we need to make the following crucial observation:

$$\forall s \in \mathcal{T}_d(\bar{A}), \forall k > 0, \nexists t \in \mathcal{T}_{d+k}(\bar{A}), s \longrightarrow_r^* t + T \quad (32)$$

for some $T \in \mathbb{N}^{(\Lambda_r)}$. This is due to the fact that terms in $\mathcal{T}(\bar{A})$ cannot see their (applicative) depth increase through resource reduction.

Now we start with Equation (29), having $\mathcal{T}(A) \longrightarrow_r \mathcal{T}(\bar{A}_0) \longrightarrow_r \mathcal{T}(\bar{A}_1)$. Thanks to Equation (30), this can be rewritten as $\mathcal{T}(A) \longrightarrow_r \mathcal{T}_0(\bar{A}) + \mathbf{S}_0 \longrightarrow_r \mathcal{T}_1(\bar{A}) + \mathbf{S}_1$. Equation (32) allows to say that only \mathbf{S}_0 contributes to $\mathcal{T}_1(\bar{A})$ in the second reduction. If we leave $\mathcal{T}_0(\bar{A})$ untouched and only reduce \mathbf{S}_0 , we obtain $\mathcal{T}_0(\bar{A}) + \mathbf{S}_0 \longrightarrow_r \mathcal{T}_0(\bar{A}) + \mathcal{T}_1(\bar{A}) + \mathbf{S}'_1$ for some \mathbf{S}'_1 that is part of \mathbf{S}_1 . If we keep applying Equations (30) and (32) and we iterate the process, we obtain:

$$\mathcal{T}(\mathbf{A}) \twoheadrightarrow_{\mathbf{r}} \mathcal{T}_0(\bar{\mathbf{A}}) + \mathbf{S}_0 \twoheadrightarrow_{\mathbf{r}} \mathcal{T}_0(\bar{\mathbf{A}}) + \mathcal{T}_1(\bar{\mathbf{A}}) + \mathbf{S}'_1 \twoheadrightarrow_{\mathbf{r}} \dots \twoheadrightarrow_{\mathbf{r}} \sum_{d=0}^N \mathcal{T}_d(\bar{\mathbf{A}}) + \mathbf{S}'_N \quad (33)$$

for all $N \in \mathbb{N}$. For each $s \in |\mathcal{T}(\mathbf{A})|$, this can be turned into⁴:

$$s \twoheadrightarrow_{\mathbf{r}}^* T_{s,0} + S_{s,0} \twoheadrightarrow_{\mathbf{r}}^* T_{s,0} + T_{s,1} + S_{s,1} \twoheadrightarrow_{\mathbf{r}}^* \dots \twoheadrightarrow_{\mathbf{r}}^* \sum_{d=0}^N T_{s,d} + S_{s,N} \quad (34)$$

for some $T_{s,d}, S_{s,d} \in \mathbb{N}^{(\Lambda_r)}$ satisfying $\mathcal{T}_d(\bar{\mathbf{A}}) = \sum_{s \in \Lambda_r} \mathcal{T}(s, \mathbf{A}) \cdot T_{s,d}$. In fact:

- There are only finitely many d 's such that $T_{s,d} \neq 0$ (this is due to the fact that a resource terms has only finitely many reducts [31, Lemma 3.13]).
- \mathbf{A} has no head normal form as demonstrated in Figure 1, which entails that $\mathcal{T}(\mathbf{A}) \twoheadrightarrow_{\mathbf{r}} 0$ [8, Theorem 5.6]. Since \mathbf{S}'_d only contains reducts of terms in $\mathcal{T}(\mathbf{A})$, this means that we can reduce $\mathbf{S}'_N \twoheadrightarrow_{\mathbf{r}}^* 0$.

As a consequence, $s \twoheadrightarrow_{\mathbf{r}}^* \sum_{d \in \mathbb{N}} T_{s,d}$ and we can conclude:

$$\mathcal{T}(\mathbf{A}) = \sum_{s \in \Lambda_r} \mathcal{T}(s, \mathbf{A}) \cdot s \twoheadrightarrow_{\mathbf{r}} \sum_{s \in \Lambda_r} \mathcal{T}(s, \mathbf{A}) \cdot \sum_{d \in \mathbb{N}} T_{s,d} = \sum_{d \in \mathbb{N}} \mathcal{T}_d(\bar{\mathbf{A}}) = \mathcal{T}(\bar{\mathbf{A}})$$

by Equation (31). ◀

Proof of Theorem 27, item (ii). We suppose that there is a reduction $\mathbf{A} \xrightarrow{\beta}^{001} \bar{\mathbf{A}}$ and we show that this leads to a contradiction. By Theorem 4 and Lemma 29, there exists respectively a sequence of terms $\mathbf{A}_d \in \Lambda$ and a term $\mathbf{A}'_0 \in \Lambda$ such that there are reductions

$$\mathbf{A} \xrightarrow{h}^* \mathbf{A}'_0 \xrightarrow{i}^* \mathbf{A}_1 \xrightarrow{\beta \geq 1}^* \mathbf{A}_d \xrightarrow{\beta \geq d}^{001} \bar{\mathbf{A}}.$$

\mathbf{A}'_0 and $\bar{\mathbf{A}}$ must have the same head form, i.e. there must be $M, N \in \Lambda$ such that $\mathbf{A}'_0 = (\lambda b.M)N$. The exhaustive description of the head reducts of \mathbf{A} detailed in Figure 1 allows to observe that this only happens in four cases (corresponding to steps 6, 7, 25 and 27 in Figure 1):

⁴ This inference might not be possible for an arbitrary reduction sequence, because the obtained reductions (34) occur in $\mathbb{N}^{(\Lambda_r)}$ (with integer coefficients only) while the original reductions (33) occur in \mathbb{S}^{Λ_r} (possibly with rational coefficients): if for some $s \in \mathbf{S}'_d$ the original reduction $\mathbf{S}'_d \twoheadrightarrow_{\mathbf{r}} \mathcal{T}_{d+1}(\bar{\mathbf{A}}) + \mathbf{S}'_{d+1}$ consists in doing $s = \frac{1}{3}s + \frac{2}{3}s \twoheadrightarrow_{\mathbf{r}} \frac{1}{3}S' + \frac{2}{3}S''$, we will not be able to retrieve a reduction $s \twoheadrightarrow_{\mathbf{r}}^* \dots$ of the desired shape.

But the reductions in \mathbb{S}^{Λ_r} we consider are not arbitrary: Equation (29) was obtained by simulating a sequence of β -reductions *via* Theorem 12, so that we can apply uniformity. With the notations to be introduced in Section 5, using Corollary 34 we obtain reductions $\mathbf{S}'_d \twoheadrightarrow_{\mathbf{r}}^* \mathcal{T}_{d+1}(\bar{\mathbf{A}}) + \mathbf{S}'_{d+1}$ instead of $\mathbf{S}'_d \twoheadrightarrow_{\mathbf{r}} \mathcal{T}_{d+1}(\bar{\mathbf{A}}) + \mathbf{S}'_{d+1}$. These reductions can only be derived as follows:

$$\frac{\sum_{s \in \Lambda_r} \mathcal{T}(s, \mathbf{A}) \cdot \underbrace{\sum_{i=1}^{n_{s,d}} s_{s,d,i}}_{\mathbf{S}_{s,d}} \xrightarrow{\mathbf{r}}^* \sum_{s \in \Lambda_r} \mathcal{T}(s, \mathbf{A}) \cdot \left(\underbrace{\sum_{i=1}^{n_{s,d}} T_{s,d+1,i}}_{\mathbf{T}_{s,d+1}} + \underbrace{\sum_{i=1}^{n_{s,d}} S_{s,d+1,i}}_{\mathbf{S}_{s,d+1}} \right)}{\sum_{s \in \Lambda_r} \mathcal{T}(s, \mathbf{A}) \cdot \sum_{i=1}^{n_{s,d}} s_{s,d,i} \xrightarrow{\mathbf{r}}^* \sum_{s \in \Lambda_r} \mathcal{T}(s, \mathbf{A}) \cdot \left(\sum_{i=1}^{n_{s,d}} T_{s,d+1,i} + \sum_{i=1}^{n_{s,d}} S_{s,d+1,i} \right)}$$

the premise of which allows to build a reduction $S_{s,d} \twoheadrightarrow_{\mathbf{r}}^* T_{s,d+1} + S_{s,d+1}$.

23:14 How to Play the Accordion

1. $A'_0 = (\lambda n. \langle T \rangle) ((n) \langle F \rangle) Q_{P'',n} (\text{Succ})^n 0$,
2. $A'_0 = \langle T \rangle (((\text{Succ})^n 0) \langle F \rangle) Q_n$,
3. $A'_0 = (\lambda b. ((b)(P''))(\text{Succ})^{n+1} 0) Q''_n T$,
4. $A'_0 = (\lambda y. (P'')) (\text{Succ})^{n+1} 0) Q''_n$,

for some $n \in \mathbb{N}$ (in the following, n denotes this specific integer appearing in A'_0). In particular, for one of these possible values of A'_0 there must be a reduction

$$A'_0 \longrightarrow_i^* A_{n+4} \longrightarrow_{\beta \geq n+4}^{001} \bar{A}.$$

Since A_{n+4} and \bar{A} are identical up to applicative depth $n+3$, we can write $A_{n+4} = \langle T \rangle (\langle F \rangle)^{n+1} M$ for some $M \in \Lambda$ such that $M \longrightarrow_{\beta}^{001} (\langle F \rangle)^\omega$ (we need to go up to depth $n+3$ since $\langle T \rangle$ and $\langle F \rangle$ are themselves of applicative depth 2). Finally, there must be a reduction

$$A'_0 \longrightarrow_i^* \langle T \rangle (\langle F \rangle)^{n+1} M.$$

For each of the possible cases for A'_0 , let us show that this is impossible. The easy cases are:

Case 1, step (6) Such a reduction would imply that $(\text{Succ})^n 0 \longrightarrow_{\beta}^* (\langle F \rangle)^{n+1} M$. However $(\text{Succ})^n 0 \longrightarrow_{\beta}^* n$, which is in β -normal form, while $(\langle F \rangle)^{n+1} M$ has no normal form. We conclude by confluence of the finite λ -calculus.

Case 3, step (25) Immediate because T is in normal form.

Case 4, step (27) Such a reduction would imply that $\lambda y. (P'') (\text{Succ})^{n+1} 0 \longrightarrow_{\beta}^* \langle T \rangle = \lambda y. (y) T$, and therefore that $(P'') (\text{Succ})^{n+1} 0$ has a HNF $(y) T$. This is impossible, as detailed in the exhaustive head reduction of A in Figure 1.

The remaining case concerns the reduct $\langle T \rangle (((\text{Succ})^n 0) \langle F \rangle) Q_n$. It is the only “non-degenerate” one, in the sense that it is where the accordion-like behaviour of A is illustrated: the sub-term $\langle T \rangle$ here is really “the same” as the one appearing at the root of \bar{A} but we need to reduce this sub-term at some point (i.e. to “compress” the Accordion). Thus there can be no 001-infinitary reduction towards \bar{A} . The formal proof of this case, i.e. of the impossibility of $(\text{Succ})^n 0 \langle F \rangle Q_n \longrightarrow_{\beta}^* (\langle F \rangle)^{n+1} M$, is given by Lemma 31 below. \blacktriangleleft

► **Lemma 30.** *For all $k \in \mathbb{N}$, $n \in \mathbb{N}$ and $M \in \Lambda$, there is no reduction*

$$\langle F \rangle^k Q_n \longrightarrow_{\beta}^* \langle F \rangle^{k+1} M.$$

Proof. We proceed by induction on k . First, take $k=0$ and suppose there is a reduction $Q_n \longrightarrow_{\beta}^* \langle F \rangle M$. By Lemma 29, there are $R, R' \in \Lambda$ such that

$$Q_n \longrightarrow_h^* (\lambda b. R) R' \longrightarrow_i^* \langle F \rangle M = (\lambda b. (b) F) M.$$

An exhaustive head reduction of Q_n gives the possible values of R and R' :

$$\begin{aligned} Q_n &= (Y) Q'_n \\ &\longrightarrow_h (\lambda x. (Q'_n)(x) x) \lambda x. (Q'_n)(x) x \\ &\longrightarrow_h (\lambda \psi. \lambda b. ((b)(P''))(\text{Succ})^{n+1} 0) \psi) Q''_n \\ &\longrightarrow_h \lambda b. ((b)(P''))(\text{Succ})^{n+1} 0) Q''_n, \end{aligned}$$

the last reduct being in HNF, which leaves only the first three possibilities. In any of those three cases, $R \longrightarrow_{\beta}^* (b) F$ (modulo renaming of b by α -conversion) is impossible by immediate arguments, so that $(\lambda b. R) R' \longrightarrow_i^* \langle F \rangle M$ cannot hold.

If $k \geq 1$, let us again suppose that there is a reduction $(\langle F \rangle)^k Q_n \rightarrow_{\beta}^* (\langle F \rangle)^{k+1} M$. Lemma 29 states that there are $R, R' \in \Lambda$ such that

$$(\langle F \rangle)^k Q_n \rightarrow_h^* (\lambda b. R) R' \rightarrow_i^* (\lambda b. (b)F) (\langle F \rangle)^k M.$$

An exhaustive head reduction of $(\langle F \rangle)^k Q_n$ gives the possible values of R and R' (we write only the reduction steps corresponding to the well-formed reducts – see the details in the detailed head reduction of \mathbf{A} , steps (15) and following):

$$\begin{aligned} (\langle F \rangle)^k Q_n &= (\lambda b. (b)F) (\langle F \rangle)^{k-1} Q_n \\ &\rightarrow_h^* (\lambda b. ((b)(P'')(\text{Succ})^{n+1} 0) Q_n'') F \\ &\rightarrow_h^* (\lambda y. y) Q_n'' \\ &\rightarrow_h Q_n'' \end{aligned}$$

In the first case, a reduction $(\lambda b. (b)F) (\langle F \rangle)^{k-1} Q_n \rightarrow_i^* (\lambda b. (b)F) (\langle F \rangle)^k M$ is impossible because it would imply that $(\langle F \rangle)^{k-1} Q_n \rightarrow_{\beta}^* (\langle F \rangle)^k M$, which is impossible by induction. The second and third cases are impossible by immediate arguments; the fourth case has already been explored (Q_n'' is exactly the term from the second line of the reduction of Q_n above). ◀

► **Lemma 31.** *For all $n \in \mathbb{N}$, $k \in [0, n]$ and $M \in \Lambda$, there is no reduction:*

$$(\text{Succ})^{n-k} 0 \langle F \rangle (\langle F \rangle)^k Q_n \rightarrow_{\beta}^* (\langle F \rangle)^{n+1} M.$$

Proof. We proceed by induction on $n - k$. The base case is $k = n$: if there is a reduction $(0) \langle F \rangle (\langle F \rangle)^n Q_n \rightarrow_{\beta}^* (\langle F \rangle)^{n+1} M$, then by Lemma 29 there are terms $R, R' \in \Lambda$ such that

$$(0) \langle F \rangle (\langle F \rangle)^n Q_n \rightarrow_h^* (\lambda b. R) R' \rightarrow_i^* (\lambda b. (b)F) (\langle F \rangle)^n M.$$

Observe that

$$(0) \langle F \rangle (\langle F \rangle)^n Q_n \rightarrow_h (\lambda x. x) (\langle F \rangle)^n Q_n \rightarrow_h (\langle F \rangle)^n Q_n$$

hence, because $\lambda x. x$ is in β -normal form and by Lemma 30, we reach a contradiction.

If $k < n$ and there is a reduction $(\text{Succ})^{n-k} 0 \langle F \rangle (\langle F \rangle)^k Q_n \rightarrow_{\beta}^* (\langle F \rangle)^{n+1} M$, then again by Lemma 29 there are terms $R, R' \in \Lambda$ such that

$$(\text{Succ})^{n-k} 0 \langle F \rangle (\langle F \rangle)^k Q_n \rightarrow_h^* (\lambda b. R) R' \rightarrow_i^* (\lambda b. (b)F) (\langle F \rangle)^n M.$$

Observe that

$$\begin{aligned} (\text{Succ})^{n-k} 0 \langle F \rangle (\langle F \rangle)^k Q_n &\rightarrow_h (\lambda f. \lambda x. (\text{Succ})^{n-k-1} 0 f(f)x) \langle F \rangle (\langle F \rangle)^k Q_n \\ &\rightarrow_h (\lambda x. (\text{Succ})^{n-k-1} 0 \langle F \rangle (\langle F \rangle)x) (\langle F \rangle)^k Q_n \\ &\rightarrow_h (\text{Succ})^{n-k-1} 0 \langle F \rangle (\langle F \rangle)^{k+1} Q_n \end{aligned}$$

The first reduct does not have the expected head form. In the second case, $(\lambda b. R) R' \rightarrow_i^* (\lambda b. (b)F) (\langle F \rangle)^n M$ would imply that $(\langle F \rangle)^k Q_n \rightarrow_{\beta}^* (\langle F \rangle)^n M$, which is impossible by Lemma 30 because $k < n$. In the third case, apply the induction hypothesis. ◀

5 The missing ingredient: Uniformity

The fact that the simulation of $\rightarrow_{\beta}^{001}$ by \rightarrow_r via the Taylor expansion is not conservative confirms that the pointwise reduction \rightarrow_r , even if needed in order to express the pointwise normal form of a sum through the resource reduction, weakens the dynamics of the β -reduction by allowing to reduce resource approximants along reductions paths that do not correspond to an actual reduction of the approximated term. As already underlined by Ehrhard and Regnier in their seminal work [19], *uniformity* is what gives the linear approximation all its robustness; this will also be the case for our study.

► **Definition 32.** *The relation $\circ \subset (!)\Lambda_r \times (!)\Lambda_r$ of **coherence** is defined by the rules:*

$$\frac{}{x \circ x} \quad \frac{s \circ s'}{\lambda x.s \circ \lambda x.s'} \quad \frac{s \circ s' \quad \bar{t} \circ \bar{t}'}{(s)\bar{t} \circ (s)\bar{t}'}$$

$$\frac{\forall i \in \{1, \dots, m\}, \forall j \in \{1, \dots, n\}, t_i \circ t'_j}{[t_1, \dots, t_m] \circ [t'_1, \dots, t'_n]} \quad (m, n \in \mathbb{N})$$

For $\mathbf{S}, \mathbf{T} \in \mathbb{S}^{(!)\Lambda_r}$, we write $\mathbf{S} \circ \mathbf{T}$ whenever $\forall s \in |\mathbf{S}|, \forall t \in |\mathbf{T}|, s \circ t$.

► **Definition 33.** *Given an index set I and a depth $d \in \mathbb{N}$, we define a relation $\curvearrowright_{r \geq d} \subset (!)\Lambda_r^I \times (\mathbb{N}^{(!)\Lambda_r})^I$ by the following rules:*

$$\frac{\forall i, j, s_i \circ s_j \quad \forall i, j, \bar{t}_i \circ \bar{t}_j}{((\lambda x.s_i)\bar{t}_i)_{i \in I} \curvearrowright_{r \geq 0} (s_i(\bar{t}_i/x))_{i \in I}} \quad \frac{(s_i)_{i \in I} \curvearrowright_{r \geq d} (S'_i)_{i \in I}}{(\lambda x.s_i)_{i \in I} \curvearrowright_{r \geq d} (\lambda x.S'_i)_{i \in I}}$$

$$\frac{(s_i)_{i \in I} \curvearrowright_{r \geq d} (S'_i)_{i \in I} \quad \forall i, j, \bar{t}_i \circ \bar{t}_j}{((s_i)\bar{t}_i)_{i \in I} \curvearrowright_{r \geq d} ((S'_i)\bar{t}_i)_{i \in I}} \quad \frac{(t_{i,j})_{\substack{i \in I \\ 1 \leq j \leq k_i}} \curvearrowright_{r \geq d} (T'_{i,j})_{\substack{i \in I \\ 1 \leq j \leq k_i}}}{([t_{i,1}, \dots, t_{i,k_i}])_{i \in I} \curvearrowright_{r \geq d} ([T'_{i,1}, \dots, T'_{i,k_i}])_{i \in I}}$$

$$\frac{\forall i, j, s_i \circ s_j \quad (\bar{t}_i)_{i \in I} \curvearrowright_{r \geq 0} (\bar{T}'_i)_{i \in I}}{((s_i)\bar{t}_i)_{i \in I} \curvearrowright_{r \geq 0} ((s_i)\bar{T}'_i)_{i \in I}} \quad \frac{\forall i, j, s_i \circ s_j \quad (\bar{t}_i)_{i \in I} \curvearrowright_{r \geq d} (\bar{T}'_i)_{i \in I}}{((s_i)\bar{t}_i)_{i \in I} \curvearrowright_{r \geq d+1} ((s_i)\bar{T}'_i)_{i \in I}}$$

The relation $\curvearrowright_{r \geq d} \subset \mathbb{S}^{(!)\Lambda_r} \times \mathbb{S}^{(!)\Lambda_r}$ of **uniform resource reduction at minimum depth d** is defined by

$$\frac{(u_i)_{i \in I} \curvearrowright_{r \geq d} (U'_i)_{i \in I}}{\sum_{i \in I} a_i u_i \curvearrowright_{r \geq d} \sum_{i \in I} a_i U'_i.}$$

We denote $\curvearrowright_{r \geq 0}$ and $\curvearrowright_{r \geq 0}$ simply by \curvearrowright_r and \curvearrowright_r , and call the latter **uniform resource reduction**.

The intuition behind \curvearrowright_r is that:

- it can only reduce “uniform” sums, i.e. sums containing resource terms that all have the same shape (formally, sums \mathbf{S} such that $\mathbf{S} \circ \mathbf{S}$),
- each reduction step of a sum is a “bundle” of resource reduction steps occurring at the same address in the elements of the sum (\curvearrowright_r is an inductive reformulation of Midez’ Γ -reduction [27]).

This allows to capture only the reductions of some $\mathcal{T}(M)$ that correspond to a β -reduction of M , as we will formally show. In fact, all the pointwise reductions \longrightarrow_r occurring in the proof of Theorem 12 are already instances of the particular case $\xrightarrow{*_r}$, hence the following reformulation.

► **Corollary 34** (of Theorem 12; [7], Lemma 4.50). *For all $M, N \in \Lambda$, if $M \longrightarrow_{\beta \geq d} N$ then $\mathcal{T}(M) \xrightarrow{*_r \geq d} \mathcal{T}(N)$.*

Let us show how this property can be used to build a conservative simulation of $\longrightarrow_{\beta}^{001}$. The simulating reduction needs to be:

- a restriction of \longrightarrow_r , because we want to eliminate the non-uniform reductions that cannot be turned into actual β -reductions,
- an extension of $\xrightarrow{*_r}$, because we want to be able to simulate not only finite, but also infinitary reductions.

The way we proceed is guided by the stratification property (Theorem 4).

► **Notation 35.** *The (applicative) **depth** of a resource term is the integer defined by*

$$\begin{aligned} \text{depth}(x) &:= 0 & \text{depth}((s)\bar{t}) &:= \max(\text{depth}(s), 1 + \text{depth}(\bar{t})) \\ \text{depth}(\lambda x.s) &:= \text{depth}(s) & \text{depth}([t_1, \dots, t_n]) &:= \max_{1 \leq i \leq n} \text{depth}(t_i). \end{aligned}$$

For all sum $\sum_{i \in I} a_i \cdot s_i \in \mathbb{S}^{\Lambda_r}$ and integer $d \in \mathbb{N}$, we write $\left(\sum_{i \in I} a_i \cdot s_i \right)_{< d} := \sum_{\substack{i \in I \\ \text{depth}(s_i) < d}} a_i \cdot s_i$.

► **Definition 36.** *The relation $\xrightarrow{*_r}^{\infty} \subset \mathbb{S}^{(!)\Lambda_r} \times \mathbb{S}^{(!)\Lambda_r}$ of **infinitary uniform resource reduction** is defined by writing $\mathbf{U} \xrightarrow{*_r}^{\infty} \mathbf{V}$ whenever there is a sequence $(\mathbf{U}_d)_{d \in \mathbb{N}}$ such that*

$$\mathbf{U}_0 = \mathbf{U} \quad \forall d \in \mathbb{N}, \mathbf{U}_d \xrightarrow{*_r \geq d} \mathbf{U}_{d+1} \quad \forall d \in \mathbb{N}, (\mathbf{U}_d)_{< d} = (\mathbf{V})_{< d}.$$

By design, $\xrightarrow{*_r}^{\infty}$ simulates the stratification of an infinitary β -reduction, hence the following property.

► **Corollary 37** (of Theorem 4 and Corollary 34). *For all $M, N \in \Lambda^{001}$, if $M \longrightarrow_{\beta}^{001} N$ then $\mathcal{T}(M) \xrightarrow{*_r}^{\infty} \mathcal{T}(N)$.*

Proof. We need to define a sequence $(\mathbf{U}_d)_{d \in \mathbb{N}}$ as in Definition 36. By stratification (Theorem 4), we obtain a sequence $(M_d)_{d \in \mathbb{N}}$ and we can define $\mathbf{U}_d := \mathcal{T}(M_d)$. The conclusion follows by Corollary 34 and by the fact that whenever $M \longrightarrow_{\beta \geq d}^{001} N$, then $(\mathcal{T}(M))_{< d} = (\mathcal{T}(N))_{< d}$. ◀

As announced, this simulation enjoys a converse conservativity property.

► **Theorem 38** (conservativity). *For $M, N \in \Lambda^{001}$, if $\mathcal{T}(M) \xrightarrow{*_r}^{\infty} \mathcal{T}(N)$ then $M \longrightarrow_{\beta}^{001} N$.*

The proof of the theorem goes as follows.

► **Lemma 39.** *For all $M, N \in \Lambda^{001}$ and $d \in \mathbb{N}$, if $\mathcal{T}(M) \xrightarrow{*_r \geq d} \mathcal{T}(N)$ then $M \longrightarrow_{\beta \geq d} N$.*

Proof. By an immediate induction on the reduction $(s)_{s \in |\mathcal{T}(M)|} \xrightarrow{*_r \geq d} (T_s)_{s \in |\mathcal{T}(M)|}$ induced by $\mathcal{T}(M) \xrightarrow{*_r \geq d} \mathcal{T}(N)$. ◀

► **Lemma 40.** *For all $M \in \Lambda^{001}$ and $\mathbf{S} \in \mathbb{S}^{\Lambda_r}$, if $\mathcal{T}(M) \xrightarrow{*_r} \mathbf{S}$ then there exists an $M' \in \Lambda^{001}$ such that $\mathbf{S} = \mathcal{T}(M')$.*

23:18 How to Play the Accordion

Proof. By an immediate induction on the reduction $(s)_{s \in |\mathcal{T}(M)|} \xrightarrow{r \geq d} (T_s)_{s \in |\mathcal{T}(M)|}$ induced by $\mathcal{T}(M) \xrightarrow{r \geq d} \mathbf{S}$. The base case relies on the same substitution lemma (Lemma 4.8 of [31]) as the proof of Theorem 12. ◀

► **Lemma 41.** Consider families $(u_i)_{i \in I} \in ((!) \Lambda_r)^I$ and $(V_i)_{i \in I} \in (\mathbb{N}^{(!) \Lambda_r})^I$ such that $(u_i)_{i \in I} \xrightarrow{r} (V_i)_{i \in I}$. For all $i, j \in I$, if $u_i = u_j$ then $V_i = V_j$.

Proof. By induction on $(u_i)_{i \in I} \xrightarrow{r} (V_i)_{i \in I}$. ◀

In particular, this lemma allows to change the index set I when writing a reduction $(u_i)_{i \in I} \xrightarrow{r} (V_i)_{i \in I}$, as soon as no u_i (and corresponding V_i) is erased or created – but duplications and erasures of duplicates are allowed.

► **Lemma 42.** For all $\mathbf{S}, \mathbf{T} \in \mathbb{S}^{\Lambda_r}$, if $\mathbf{S}^! \xrightarrow{r} \mathbf{T}^!$ then $\mathbf{S} \xrightarrow{r} \mathbf{T}$.

Proof. Suppose that $\mathbf{S}^! \xrightarrow{r} \mathbf{T}^!$. Thanks to Lemma 41, there is a derivation

$$\frac{\frac{\frac{(s_i)_{\substack{n \in \mathbb{N} \\ s_1, \dots, s_n \in |\mathbf{S}| \\ 1 \leq i \leq n}} \xrightarrow{r} (T_{s_i})_{\substack{n \in \mathbb{N} \\ s_1, \dots, s_n \in |\mathbf{S}| \\ 1 \leq i \leq n}}}{([s_1, \dots, s_n])_{\substack{n \in \mathbb{N} \\ s_1, \dots, s_n \in |\mathbf{S}|}} \xrightarrow{r} ([T_{s_1}, \dots, T_{s_n}])_{\substack{n \in \mathbb{N} \\ s_1, \dots, s_n \in |\mathbf{S}|}}}}{\sum_{n \in \mathbb{N}} \sum_{s_1, \dots, s_n \in |\mathbf{S}|} \underbrace{\frac{\prod_{i=1}^n a_{s_i}}{n!} \cdot [s_1, \dots, s_n]}_{\mathbf{S}^!} \xrightarrow{r} \sum_{n \in \mathbb{N}} \sum_{s_1, \dots, s_n \in |\mathbf{S}|} \underbrace{\frac{\prod_{i=1}^n a_{s_i}}{n!} \cdot [T_{s_1}, \dots, T_{s_n}]}_{\mathbf{T}^!}}$$

with $\mathbf{S} = \sum_{s \in |\mathbf{S}|} a_s \cdot s$. By Lemma 41 again, the hypothesis of the derivation is equivalent to $(s)_{s \in |\mathbf{S}|} \xrightarrow{r} (T_s)_{s \in |\mathbf{S}|}$, hence we can derive:

$$\frac{(s)_{s \in |\mathbf{S}|} \xrightarrow{r} (T_s)_{s \in |\mathbf{S}|}}{\mathbf{S} \xrightarrow{r} \sum_{s \in |\mathbf{S}|} a_s \cdot T_s.}$$

To see that $\mathbf{T} = \sum_{s \in |\mathbf{S}|} a_s \cdot T_s$, observe that

$$\begin{aligned} & \text{the coefficient of } t \text{ in } \mathbf{T} \\ &= \text{the coefficient of } [t] \text{ in } \mathbf{T}^! \\ &= \text{the coefficient of } [t] \text{ in } \sum_{n \in \mathbb{N}} \sum_{s_1, \dots, s_n \in |\mathbf{S}|} \frac{\prod_{i=1}^n a_{s_i}}{n!} \cdot [T_{s_1}, \dots, T_{s_n}] \\ &= \sum_{s \in |\mathbf{S}|} a_s \times \text{the coefficient of } t \text{ in } T_s \\ &= \text{the coefficient of } t \text{ in } \sum_{s \in |\mathbf{S}|} a_s \cdot T_s, \end{aligned}$$

which concludes the proof. ◀

Proof of theorem 38. Suppose that there is a sequence $(\mathbf{S}_d)_{d \in \mathbb{N}}$ such that

$$\mathbf{S}_0 = \mathcal{T}(M) \quad \forall d \in \mathbb{N}, \mathbf{S}_d \xrightarrow{r \geq d}^* \mathbf{S}_{d+1} \quad \forall d \in \mathbb{N}, (\mathbf{S}_d)_{< d} = (\mathcal{T}(N))_{< d}.$$

By Lemma 40 there is a sequence of terms $(M_d)_{d \in \mathbb{N}}$ such that $\forall d \in \mathbb{N}, \mathbf{S}_d = \mathcal{T}(M_d)$. We can take $M_0 = M$, and our hypotheses yield

$$\forall d \in \mathbb{N}, \mathcal{T}(M_d) \xrightarrow{r \geq d}^* \mathcal{T}(M_{d+1}) \tag{35}$$

$$\forall d \in \mathbb{N}, (\mathcal{T}(M_d))_{< d} = (\mathcal{T}(N))_{< d}. \tag{36}$$

For any sequence $(M_d)_{d \in \mathbb{N}}$ such that Equations (35) and (36) hold, we build a reduction $M_0 \rightarrow_{\beta}^{001} N$ by nested induction and coinduction on N .

- Case $N = x$. $(\mathcal{T}(M_1))_{<1} = (\mathcal{T}(N))_{<1} = x$ hence also $\mathcal{T}(M_1) = x$. As a consequence, $\mathcal{T}(M_0) \xrightarrow{r} x$ so by Lemma 39 $M_0 \xrightarrow{\beta}^* x$, which leads to the conclusion.
- Case $N = \lambda x.P'$. For all $d \geq 1$, $(\mathcal{T}(M_d))_{<d} = (\mathcal{T}(N))_{<d} = \lambda x.(\mathcal{T}(P'))_{<d}$ hence there is a term $P_d \in \Lambda^{001}$ such that $M_d = \lambda x.P_d$. We also define $P_0 := P_1$, so that $M_0 \xrightarrow{\beta}^* \lambda x.P_0$ by Equation (35) and Lemma 39.

The sequence $(P_d)_{d \in \mathbb{N}}$ satisfies Equations (35) and (36) wrt. P' , hence by induction we can build a reduction $P_0 \rightarrow_{\beta}^{001} P'$. We conclude with the rule (λ_{β}^{001}) from Definition 3.

- Case $N = (P')Q'$. For all $d \geq 1$, $(\mathcal{T}(M_d))_{<d} = (\mathcal{T}(N))_{<d} = ((\mathcal{T}(P'))_{<d})(\mathcal{T}(Q'))_{<d-1}$ hence there are terms $P_d, Q_d \in \Lambda^{001}$ such that $M_d = (P_d)Q_d$. We also define $P_0 := P_1$, so that $M_0 \xrightarrow{\beta}^* (P_0)Q_1$ by Equation (35) and Lemma 39.

By Equation (35), for all $d \geq 1$ there are reductions

$$\mathcal{T}(P_d) \xrightarrow{r \geq d}^* \mathcal{T}(P_{d+1}) \quad \text{and} \quad \mathcal{T}(Q_d)^! \xrightarrow{r \geq d-1}^* \mathcal{T}(Q_{d+1})^!.$$

From the first reduction we deduce that the sequence $(P_d)_{d \in \mathbb{N}}$ satisfies Equations (35) and (36) wrt. P' , hence by induction we can build a reduction $P_0 \rightarrow_{\beta}^{001} P'$. From the second reduction, by Lemma 42 we deduce that the sequence $(Q_{d+1})_{d \in \mathbb{N}}$ satisfies Equations (35) and (36) wrt. Q' : we apply rule $(@_{\beta}^{001})$ and proceed coinductively, through the guard (\triangleright) , to establish $Q_1 \rightarrow_{\beta}^{001} Q'$. ◀

In particular, observe that there is no reduction $\mathbf{A} \xrightarrow{r}^{\infty} \bar{\mathbf{A}}$: in the sequence of reductions given in Equation (29) in the proof of Theorem 27, item 1, all steps $\mathcal{T}(\mathbf{A}_d) \xrightarrow{r} \mathcal{T}(\mathbf{A}_{d+1})$ can be turned into $\mathcal{T}(\mathbf{A}_d) \xrightarrow{r}^* \mathcal{T}(\mathbf{A}_{d+1})$ (as explained in Footnote 4), but not into $\mathcal{T}(\mathbf{A}_d) \xrightarrow{r \geq d} \mathcal{T}(\mathbf{A}_{d+1})$ because there is always a reduction step occurring at depth 0.

We finally obtained a conservative approximation of the 001-infinitary λ -calculus. As a conclusive remark, let us mention that we did not take any \perp -reductions into account, though they are needed if one wants to simulate the reductions $M \rightarrow_{\beta \perp}^{001} \text{BT}(M)$ corresponding to Ehrhard and Regnier's commutation theorem. These reductions could be taken into account by adding the following rule:

$$\frac{\forall i, j, u_i \circ u_j \quad \forall i, u_i \xrightarrow{r}^* 0}{(u_i)_{i \in I} \xrightarrow{r \perp} (0)_{i \in I}}$$

to Definition 33. One would then be able to provide a conservative simulation of $\rightarrow_{\beta \perp}^{001}$ by $\xrightarrow{r \perp}^{\infty}$.

The question naturally arises whether this approach is transferrable to the richer λ -calculi already endowed with a linear approximation (as listed in the introduction). This remains unclear, since most of these settings are non-uniform, i.e. it is not true any more that $\mathcal{T}(M) \circ \mathcal{T}(M)$ in general. Investigating how existing techniques used to tame non-uniformity, e.g. in [31], can be exploited to address the conservativity problem in richer settings, remains an open line of research.

Abstract

Afek, Bremner-Barr, Kaplan, Cohen, and Merritt (PODC'01) in their seminal work on shortest path restorations demonstrated that after a single edge failure in a graph G , a *replacement shortest path* between any two vertices s and t , which avoids the failed edge, can be represented as the concatenation of two original shortest paths in G . They also showed that we cannot associate a canonical¹ shortest path between the vertex pairs in G that consistently allows for the replacement path (in the surviving graph) to be represented as a concatenation of these canonical paths. Recently, Bodwin and Parter (PODC'21) proposed a randomized tie-breaking scheme for selecting canonical paths for the “ordered” vertex pairs in graph G with the desired property of representing the replacement shortest path as a concatenation of canonical shortest-paths provided for ordered pairs.

An interesting open question is whether it is possible to provide a deterministic construction of canonical paths in an efficient manner. We address this question in our paper by presenting an $O(mn)$ time deterministic algorithm to compute a canonical path family $\mathcal{F} = \{P_{x,y}, Q_{x,y} \mid x, y \in V\}$ comprising of two paths per (unordered) vertex pair. Each replacement is either a PQ-path (of type $P_{x,y} \circ Q_{y,z}$), a QP-path, a QQ-path, or a PP-path. Our construction is fairly simple and is a straightforward application of independent spanning trees. We also present various applications of family \mathcal{F} in computing fault-tolerant structures.

1 Introduction

In their seminal work on shortest path restorations, Afek, Bremner-Barr, Kaplan, Cohen, and Merritt [1] studied the question of how the structure of shortest paths in a graph changes when edges fail. They showed that, after failure of any single edge in a graph, a replacement shortest path between any two vertices s and t avoiding a failed edge can be represented as the concatenation of two original shortest paths in the graph.

► **Theorem 1** (Afek et al. [1]). *For any vertices s, t and any failing edge e in G , a replacement shortest path between s and t in $G \setminus e$ is a concatenation of two original shortest paths in G , namely, $\pi(s, x)$ and $\pi(x, t)$, where vertex x is a function of s, t , and e .*

Various works in the past have employed the restoration path theory to develop efficient solutions for problems such as distance sensitivity oracles [2, 7, 8, 9], replacement paths [6, 5], fault-tolerant distance preservers [4, 5], routing schemes [5], among others.

¹ In Afek et al. (1991), the term “set of base paths” is used to refer to what is termed as “canonical paths” here.

An f -fault-tolerant distance preserver for a graph G is a sparse subgraph H such that, after failure of at most f edges, the distances between a pre-specified set of vertex pairs in the surviving part of H still match the corresponding distances in the surviving part of G . They are formally defined as follows.

► **Definition 2** (Fault Tolerant Distance Preservers). *For a graph $G = (V, E)$ and demand pairs P , a subgraph $H = (V, E_H \subseteq E)$ of G is an f -fault tolerant distance preserver (f -preserver) for P if for any subset F of E of size at most f , we have*

$$\text{dist}(s, t, G \setminus F) = \text{dist}(s, t, H \setminus F), \quad \text{for all } (s, t) \in P.$$

For a set $S \subseteq V$, we say that H is a **source-wise distance preserver** for S if $P = S \times V$; and a **subset distance preserver** for S if $P = S \times S$.

Parter and Peleg [15] showed that for any n -vertex unweighted undirected graph, there exists a 1-fault-tolerant $S \times V$ preserver with $O(|S|^{1/2}n^{3/2})$ edges. They also showed that this bound is existentially tight. Specifically, there exist n -vertex graphs and a set of sources S such that any $S \times V$ fault-tolerant preserver must have $\Omega(|S|^{1/2}n^{3/2})$ edges. Later, Parter [14] extended this result by providing an upper bound of $O(|S|^{1/3}n^{5/3})$ for dual fault-tolerant $S \times V$ preservers in undirected graphs. Gupta and Khan [11] extended this to directed graphs. For general f , Bodwin, Grandoni, Parter, and Williams [4] presented a construction of an f -fault-tolerant $S \times V$ preserver with $\tilde{O}(|S|^{1/2^f}fn^{2-1/2^f})$ edges.

For the problem of computing subset distance preservers, Bodwin, Choudhary, Parter and Shahar [3] presented a construction of 1-fault-tolerant $S \times S$ distance preserver with $\tilde{O}(|S|n)$ edges. Recently, Bodwin and Parter [5] extended this work to general f failures by providing a construction of $(f + 1)$ -fault-tolerant $S \times S$ preserver with $\tilde{O}(fn^{2-1/2^f}|S|^{1/2^f})$ edges, for any $f \geq 0$. These constructions for $S \times S$ preservers are obtained by employing the work of Afek, Bremler-Barr, Kaplan, Cohen, and Merritt [1] (see Theorem 1) on the structure of shortest paths in fault-prone graphs.

To exploit Theorem 1, Bodwin and Parter [5] introduced a tie-breaking scheme for selecting shortest paths in graph $G \setminus F$. Specifically, they used the Isolation lemma [13] to show that if each edge in G is assigned a random integer weight from the range $[1, n^{f+c+2}]$, then with probability $1 - 1/n^c$, for any pair of vertices s and t , and for any set F of edges, where $|F| \leq f$, exactly one of the shortest paths from s to t in $G \setminus F$ will be the unique shortest path in the modified edge weighted graph $G \setminus F$.

The main drawback of this tie-breaking scheme is that it is randomized and requires an additional $n^{O(f)}$ time to derandomize. This raises the following natural question:

Question: Is it possible to bypass randomness and have an efficient deterministic construction of the canonical path family?

We address this question by presenting a deterministic algorithm that runs in $O(mn)$ time to compute a canonical path family $\mathcal{F} = \{P_{x,y}, Q_{x,y} \mid x, y \in V\}$ comprising of two paths for each (unordered) vertex pair in G . We show that each replacement path in G can take the form of a PQ-path (of type $P_{x,y} \circ Q_{y,z}$), a QP-path, a QQ-path, or a PP-path. Our construction is not only straightforward but also represents a simple yet effective application of independent spanning trees [10].

We present in this paper an efficient construction of the family \mathcal{F} (see Theorem 10) and also explore various applications of these structures.

Sourcewise Distance Preservers

We introduce a stronger notion of fault-tolerant distance preserving subgraphs, which we call $(f, 1)$ -preservers.

► **Definition 3** ($(f, 1)$ -Preservers). *For a graph $G = (V, E)$ and a set of demand pairs P , a subgraph $H = (V, E_H \subseteq E)$ of G is an $(f, 1)$ -preserver if, for every pair $(s, t) \in P$, every set F of edges of size at most f , and every edge e in G that satisfies $\text{dist}(s, t, G \setminus F) = \text{dist}(s, t, G \setminus (F \cup e))$, we have*

$$\text{dist}(s, t, H \setminus (F \cup e)) = \text{dist}(s, t, G \setminus (F \cup e)).$$

Note that for any $f \geq 0$, an $(f + 1)$ -preserver is also an $(f, 1)$ -preserver. However, an f -preserver is not necessarily an $(f, 1)$ -preserver.

Our first contribution is a construction of $(f, 1)$ -preservers in polynomial time that matches the size of the current best construction of f -preservers given by Bodwin, Grandoni, Parter, and Williams [4].

► **Theorem 4.** *Let $f \geq 1$ be a positive integer. For any undirected, unweighted n -vertex graph $G = (V, E)$ with a set of source vertices $S \subseteq V$, we can compute a $(f, 1)$ -source-wise preserver for G with $\tilde{O}(fn^{2-1/2^f} |S|^{1/2^f})$ edges in $O(fmn)$ time.*

Further, for $f = 0$, we can compute a $(0, 1)$ -source-wise preserver for G with $O(|S|n)$ edges in $O(m + n)$ time.

Subset Distance Preservers

We provide the following relation between $(f, 1)$ -preservers and $(f + 1)$ -fault-tolerant subset distance preservers.

► **Theorem 5.** *In any undirected graph $G = (V, E)$, a source-wise $(f, 1)$ -preserver H with respect to a set S is an $(f + 1)$ -fault-tolerant subset distance preserver for pairs in $S \times S$.*

Combined with the construction of $(f, 1)$ -preservers, this gives us a deterministic algorithm to compute subset distance preservers in polynomial time.

► **Theorem 6.** *For any n -vertex graph $G = (V, E)$, a set of source vertices $S \subseteq V$, and a fixed non-negative integer f , there is an $(f + 1)$ -fault-tolerant distance preserver of G for pairs in $S \times S$ with $\tilde{O}((f + 1)n^{2-1/2^f} |S|^{1/2^f})$ edges which can be computed in $O(fmn)$ time when $f \geq 1$, and $O(|S|m)$ time when $f = 0$.*

Prior to our work, Bodwin et al. [5] gave construction for such preservers that takes $O(n^{2-1/2^f} |S|^{1/2^f})$ space and requires $O(mn)$ computation time in the randomized setting. However, the deterministic variant of their algorithm had a time complexity of $n^{O(f)}$, which is polynomial only for constant values of f . Our work improves upon this by providing a deterministic algorithm with a time complexity of $O((f + 1)mn)$, almost matching the efficiency of the randomized version of [5].

Fault-tolerant Distance Labeling Scheme

A distance labeling scheme is an assignment of bit-string labels to each node of G such that we can recover $\text{dist}(s, t, G)$ by looking at only the labels at s and t . An f -fault-tolerant distance labeling scheme allows us to compute the distances even when a set F of edges of size at most f fail.

While it is possible to store the entire graph within the labels, our objective is to find a labeling of subquadratic size. Bodwin et al. [5] gave an f -fault-tolerant distance labeling scheme that requires $O(n^{2-1/2^f} \log n)$ bits per vertex and can be computed in $O(mn)$ time in the randomized setting, and in $n^{O(f)}$ time deterministically. We offer an improvement to this by employing our $(f, 1)$ -preservers, which allows for the computation of the labels deterministically in polynomial time.

► **Theorem 7.** *For any fixed nonnegative integer $f \geq 0$, and n -vertex unweighted undirected graph, there is an $(f + 1)$ -fault-tolerant distance labeling scheme that assigns each vertex a label of $O((f + 1)n^{2-1/2^f} \log n)$ bits that can be computed in $O(fmn)$ time each when $f \geq 1$, and $O(m)$ time when $f = 0$.*

2 Preliminaries

Given a directed graph $G = (V, E)$ on $n = |V|$ vertices and $m = |E|$ edges, the following notations and definitions will be used throughout the paper. We omit the term G when graph is clear from context.

- $\text{dist}(x, y, G)$: Distance of node y from x in the graph G .
- $G \setminus F$: The graph obtained by removing the edges that lie in F from the graph G .
- $G \cup H$: The graph obtained by taking a union of the vertices and edges of G and H .
- $E(P)$: The edges lying in path P .
- $T[x, y]$: The path from vertex x to vertex y in tree T .
- $P[x, y]$: The subpath of path P lying between vertices x, y , assuming x precedes y on P .
- $\text{IN-EDGES}(v, G)$: The set of all edges incoming to v in G .
- (s, v) -cut-edge: An edge which lies on all (s, v) -paths and hence whose removal disconnects v from s .
- (s, v) -distance-cut edge: An edge that lies on all the (s, v) shortest paths and hence whose removal increases the distance from s to v .
- $\text{LASTE}(P)$: the last edge lying on the path P .

All graphs in this paper are undirected and unweighted, unless stated otherwise.

3 Fault Tolerant Preservers

3.1 Preservers for Source-wise setting

► **Theorem 8.** *Any undirected or directed graph $G = (V, E)$ with a positive integer $f \geq 1$ and a set $S \subseteq V$ of sources has a source-wise $(f, 1)$ -preserver H with $\tilde{O}(f|S|^{1/2^f} n^{2-1/2^f})$ edges, which can be computed in $O(fmn)$ time.*

We also improve the running time for $f = 0$.

► **Theorem 9.** *Any undirected or directed graph $G = (V, E)$ and a set $S \subseteq V$ of sources has a source-wise $(0, 1)$ -preserver H with $\tilde{O}(|S|n)$ edges which can be computed in $O(|S|m)$ time.*

We first establish the following theorem.

► **Theorem 10.** *Any directed/undirected graph $G = (V, E)$ with a destination vertex $t \in V$ can be processed in $O(m + n)$ time to implicitly compute, for each $s \in V$, a pair of (s, t) -shortest paths, denoted as $P_{s,t}$ and $Q_{s,t}$, which intersect solely at the (s, t) -distance-cut edges.*

Furthermore, if G is undirected then for any $s, t \in V$ and any $e \in E$, there exists a vertex $w \in V$ such that at least one of the four paths obtained by concatenating paths from the family $\{P_{s,w}, Q_{s,w}\} \times \{P_{w,t}, Q_{w,t}\}$ forms a replacement shortest path between s and t in $G \setminus e$.

In order to prove Theorem 10, we use the concept of independent trees. Given a directed graph G and a designated source r , a pair of trees T_1, T_2 rooted at r are said to be *independent trees*, if for each $v \neq r$, the paths from v to r in T_1 and T_2 intersect only at the (v, r) -cut-edges.

► **Theorem 11** (Georgiadis and Tarjan [10]). *Given a directed graph G and a designated source r , a pair of independent trees T_1, T_2 rooted at r are computable in $O(m + n)$ time.*

We are now ready to prove Theorem 10.

Proof of Theorem 10. We begin by proving the first claim. Consider a directed acyclic graph (DAG) $D = (V, E_D \subseteq E)$ containing only those edges $e = (x, y) \in E$ for which $\text{dist}(x, t, G) = \text{dist}(y, t, G) + 1$. Let T_1 and T_2 be a pair of independent trees rooted at t in D . Then, for any vertex $v \in V$, the paths from v to t in T_1 and T_2 intersect only at the (v, t) -cut edges in D . By Theorem 11, the time required to compute T_1 and T_2 is $O(m + n)$.

For each $s \in V$, we define $P_{s,t}$ and $Q_{s,t}$ to be the paths $T_1[s, t]$ and $T_2[s, t]$, respectively. Note that there is a one-to-one correspondence between (v, t) -cut edges in D and (v, t) -distance-cut edges in G . Therefore, $P_{s,t}$ and $Q_{s,t}$ are the shortest (s, t) -paths in G , and they intersect only at the edges whose failure increases the (s, t) -distance in G .

Next, we prove the second claim. By Theorem 1, for any pair $s, t \in V$ and any failing edge e , there exists a vertex w such that:

1. $\text{dist}(s, w, G \setminus e) = \text{dist}(s, w, G)$,
2. $\text{dist}(w, t, G \setminus e) = \text{dist}(w, t, G)$,
3. $\text{dist}(s, t, G \setminus e) = \text{dist}(s, w, G) + \text{dist}(w, t, G)$.

This implies that e is not a distance cut-edge for the pairs (s, w) and (w, t) . Therefore, at least one of the paths from $P_{s,w}, Q_{s,w}$ must avoid e , and similarly, at least one of the paths from $P_{w,t}, Q_{w,t}$ must avoid e .

Thus, we conclude that at least one of the four paths obtained by concatenating paths from the family $\{P_{s,w}, Q_{s,w}\} \times \{P_{w,t}, Q_{w,t}\}$ forms a replacement shortest path between s and t in $G \setminus e$. ◀

Proof of Theorem 9. For a source $s \in S$, let T_1^s and T_2^s be the independent trees constructed in the proof of Theorem 10. Then the graph $\bigcup_{s \in S} (T_1^s \cup T_2^s)$ is a $(0, 1)$ -preserver. The correctness is a corollary of the earlier proof. ◀

In order to compute H in Theorem 8 we associate a set E_t of edges incident to each node $t \in V$, so that the graph $H = \bigcup_{t \in V} E_t$ obtained by taking the union of edges lying in E_t is an $(f, 1)$ -preserver.

Our construction is inspired by FT-BFS algorithm of Bodwin et al. [4], and the running time matches the time taken by their construction of f -FT-BFS. Let S be the source set. For each $s \in S$, we compute a pair of (s, t) -shortest-paths, say $P_{s,t}$ and $Q_{s,t}$, using Theorem 10.

Now we set $L = \sqrt{8f|S|n \log n}$, and compute a uniformly random subset R of $V \setminus \{t\}$ of size L . Further, for $s \in S$, let

$$W_s = \{u \in V \mid 1 \leq \text{dist}(u, t, P_{s,t} \cup Q_{s,t}) \leq 8nf \log n / L\}.$$

Finally, with respect to $(\bigcup_{s \in S} W_s) \cup R$ as the source, we compute an $(f - 1, 1)$ -preserver for the graph $G_0 = (V, E \setminus \bigcup_{s \in S} (E(P_{s,t}) \cup E(Q_{s,t})))$ and designate E_t as the set of in-edges of t lying in this $(f - 1, 1)$ -preserver. To compute a $(0, 1)$ -preserver, we simply take E_t to be the last edges of $E(P_{s,t})$ and $E(Q_{s,t})$. This completes the description of our algorithm. For pseudocode see Algorithm 1.

■ **Algorithm 1** COMPUTE-INCIDENT-EDGES(G, S, t, f).

```

1 if  $f = 0$  then
2   | Return  $\{\text{LASTE}(P_{s,t}), \text{LASTE}(Q_{s,t}) \mid s \in S\}$ ;
3 end
4  $L \leftarrow \sqrt{8f|S|n \log n}$ ;
5  $R \leftarrow$  uniformly random subset of  $V \setminus \{t\}$  of size  $L$ ;
6 for  $s \in S$  do
7   |  $(P_{s,t}, Q_{s,t}) \leftarrow$  Pair of  $(s, t)$ -shortest-paths computed using Theorem 10;
8   |  $W_s \leftarrow \{u \in V \mid 1 \leq \text{dist}(u, t, P_{s,t} \cup Q_{s,t}) \leq 8nf \log n/L\}$ 
9 end
10  $G_0 \leftarrow (V, E \setminus \bigcup_{s \in S} E(P_{s,t}) \cup E(Q_{s,t}))$ ;
11 Return COMPUTE-INCIDENT-EDGES( $G_0, (\bigcup_{s \in S} W_s) \cup R, t, f - 1$ );
    
```

► **Lemma 12** (Correctness). *The graph $H = (V, \bigcup_{t \in V} E_t)$, where E_t are sets computed using Algorithm 1, is an $(f, 1)$ -preserver of G with respect to the source S .*

Proof. We prove the correctness using induction on the value of f . Consider a source node $s \in S$, a set F of failing edges of size t most f , and an edge $e \in E \setminus F$ satisfying $\text{dist}(s, t, G \setminus F) = \text{dist}(s, t, G \setminus F \cup e)$. For $f = 0$, note that $F = \emptyset$, and on the failure of e , at least one of $P_{s,t}$ or $Q_{s,t}$ must remain intact. Therefore, we focus on the case where $|F| \geq 1$.

Let $P_{s,t,F}$ and $Q_{s,t,F}$ denote an *arbitrary* pair of (s, t) -shortest paths in $G \setminus F$ intersecting only at (s, v) -distance-cut edges. Further, let x and y be respectively the last vertices in $P_{s,t,F}$ and $Q_{s,t,F}$ lying in the structure $\bigcup_{r \in S} (P_{r,t} \cup Q_{r,t}) \setminus t$, where, $P_{r,t}$ and $Q_{r,t}$ are (r, t) -shortest-paths computed using Theorem 10. Observe that we can assume $(P_{s,t} \cup Q_{s,t})$ contains at least one edge from the set F , as otherwise, it suffices to keep the last edges of $P_{s,t}$, $Q_{s,t}$ in the set E_t .

Next, we compute a vertex \bar{x} lying in $P_{s,t,F}$ as follows. If x lies in W_s , then simply set $\bar{x} = x$. If x does not lie in W_s , then $|P_{s,t,F}[x, t]| = \text{dist}(x, t, G \setminus F) \geq \text{dist}(x, t, G) > L$, implying that with a high probability R contains a vertex of path $P_{s,t,F}[x, t]$. So, in this case, \bar{x} is set as an arbitrary vertex of R lying in $P_{s,t,F}[x, t]$. In a similar manner, \bar{y} lying in $Q_{s,t,F}$ can be computed. It must be noted that the internal vertices of suffixes $P_{s,t,F}[\bar{x}, t]$ and $Q_{s,t,F}[\bar{y}, t]$ are disjoint from the structure $\bigcup_{r \in S} (P_{r,t} \cup Q_{r,t}) \setminus t$.

Observe that on the failure of e in the graph $G \setminus F$, at least one of the paths $P_{s,t,F}$ or $Q_{s,t,F}$ must be intact. Without loss of generality assume that $P_{s,t,F}$ does not contain e . Due to sub-structure property of shortest paths, we have $\text{dist}(\bar{x}, t, G \setminus F) = \text{dist}(\bar{x}, t, G \setminus (F \cup e))$. Thus, $P_{s,t,F}[s, \bar{x}]$ concatenated with an (x, t) -shortest-path in $G \setminus F$ that is disjoint from e gives us an (s, t) -shortest-path in $G \setminus F \cup e$. Such an (\bar{x}, t) -shortest-path lies in $\bigcup_{t \in V} E_t$ as it contains incoming edges of t in an $(f - 1, 1)$ preserver of $(V, E \setminus \bigcup_{r \in S} E(P_{r,t}) \cup E(Q_{r,t}))$ with respect to $\bar{x} \in (\bigcup_{s \in S} W_s) \cup R$. ◀

In order to bound the size of E_t , we establish a recurrence relation on the size of E_t in the following lemma.

► **Lemma 13.** *Let $\mathcal{M}(f, z)$ denote an upper bound on the in-degree of a vertex t in an $(f, 1)$ -preserver of an n -vertex graph with respect to a source set comprising z vertices. Then,*

$$\mathcal{M}(f, z) \leq \mathcal{M}(f - 1, 3\sqrt{8fzn \log n}) .$$

Proof. In Algorithm 1, the size of the set $|W_s|$ is at most $2(8nf \log n/L)$ by Theorem 10, and $|R|$ is exactly L by definition. Since $\sum_{s \in S} |W_s| = 2L$, we have $|(\bigcup_{s \in S} W_s) \cup R| \leq 3L$. By correctness of the algorithm, we get the required recurrence. ◀

► **Lemma 14** (Size Analysis). $\mathcal{M}(f, |S|) = \tilde{O}(f|S|^{1/2^f} n^{1-1/2^f})$, and therefore, the number of edges in the $(f, 1)$ -preserver is $\tilde{O}(f|S|^{1/2^f} n^{2-1/2^f})$.

Proof. Let $\alpha_f = 3\sqrt{8f \log n}$, and $|S|$ be z . By using $\alpha_f \geq \alpha_{f-1}$ and that $\mathcal{M}(f, x)$ is an increasing function in x , we can resolve the recurrence in Lemma 13 as follows,

$$\mathcal{M}(f, z) \leq \mathcal{M}(0, \alpha_f^{2^{-1/2^{f-1}}} z^{1/2^f} n^{1-1/2^f}).$$

By the algorithm's description $\mathcal{M}(0, z) \leq 2z$, therefore,

$$\mathcal{M}(f, z) \leq 2\alpha_f^{2^{-1/2^{f-1}}} z^{1/2^f} n^{1-1/2^f} \leq 2\alpha_f^2 z^{1/2^f} n^{1-1/2^f} = \tilde{O}(f|S|^{1/2^f} n^{1-1/2^f}). \quad \blacktriangleleft$$

► **Lemma 15** (Running Time). *Algorithm 1 can be made to run in $O(fmn)$ time.*

Proof. Rather than explicitly computing $(P_{s,t}, Q_{s,t})$ in the algorithm, we compute the two trees T_1, T_2 once using Theorem 10 in $O(m+n)$. We discard all edges from T_1 and T_2 which don't lie on an s - t path, $\cup_{s \in S} W_s$ can then be computed as $\{u \in V \mid 1 \leq \text{dist}(u, t, T_1 \cup T_2) \leq 8nf \log n/L\}$ which takes $O(n)$ time. In the final iteration, we simply compute a $(0, 1)$ -preserver which takes $O(m+n)$ time. We require $f+1$ iterations of this and run it for each node t , hence, the algorithm takes $O(fmn)$ time. \blacktriangleleft

3.2 Subset Distance Preservers

In this subsection, we will provide an efficient construction of subset distance preserver. In particular, we will prove the following result.

► **Theorem 16.** *Given an n -vertex graph $G = (V, E)$, a set of source vertices $S \subseteq V$, and a nonnegative integer f , there is an $(f+1)$ -fault-tolerant distance preserver of G for all pairs in $S \times S$ on $\tilde{O}((f+1)n^{2-1/2^f} |S|^{1/2^f})$ edges which can be computed in $O((f+1)mn)$ time.*

Further, the computation time can be reduced to $O(|S|m)$ when $f = 0$.

We make use of the shortest path restoration theory by Afek et al. [1] to first prove the following.

► **Lemma 17.** *For any undirected graph $G = (V, E)$ and any nonnegative integer f , a source-wise $(f, 1)$ -preserver H of G with respect to a source set S is an $(f+1)$ -fault-tolerant subset distance preserver for pairs in $S \times S$.*

Proof. Let (F, e) be a pair such that $F \subseteq E$, has at most f edges and e is an edge in $E \setminus F$. Applying Theorem 1 on $G \setminus F$, for any $s, t \in S$ and failing edge e there exists a vertex w such that, (i) $\text{dist}(s, w, G \setminus (F \cup e)) = \text{dist}(s, w, G \setminus F)$, (ii) $\text{dist}(w, t, G \setminus (F \cup e)) = \text{dist}(w, t, G \setminus F)$, and (iii) $\text{dist}(s, t, G \setminus (F \cup e)) = \text{dist}(s, w, G \setminus F) + \text{dist}(w, t, G \setminus F)$.

For any $s, t \in S$ and the corresponding node w , $\text{dist}(s, w, H \setminus (F \cup e)) = \text{dist}(s, w, G \setminus F)$ and $\text{dist}(w, t, H \setminus (F \cup e)) = \text{dist}(w, t, G \setminus F)$ by Definition 3, since H is an $(f, 1)$ -preserver with respect to source S . Therefore,

$$\begin{aligned} \text{dist}(s, t, H \setminus (F \cup e)) &\leq \text{dist}(s, w, H \setminus (F \cup e)) + \text{dist}(w, t, H \setminus (F \cup e)) \\ &= \text{dist}(s, w, G \setminus F) + \text{dist}(w, t, G \setminus F) \\ &= \text{dist}(s, t, G \setminus (F \cup e)). \end{aligned}$$

However, since H is a subgraph of G , $\text{dist}(s, t, H \setminus (F \cup e)) \geq \text{dist}(s, t, G \setminus (F \cup e))$ as well, which implies $\text{dist}(s, t, H \setminus (F \cup e)) = \text{dist}(s, t, G \setminus (F \cup e))$. \blacktriangleleft

As a corollary of Theorem 8, Theorem 9, and Lemma 17, we get the construction in Theorem 16.

4 Other Applications

4.1 Distance Labeling Schemes

In this section, we make use of our $(f, 1)$ -preserver to provide an alternate construction for distance labels of sub-quadratic size.

► **Theorem 18.** *For any fixed nonnegative integer $f \geq 0$, and n -vertex unweighted undirected graph, there is an $(f + 1)$ -fault-tolerant distance labeling scheme that assigns each vertex a label of $O((f + 1)n^{2-1/2^f} \log n)$ bits that can be computed in $O(fmn)$ time each when $f \geq 1$, and $O(m)$ time when $f = 0$.*

Proof. Let H_s be an $(f, 1)$ -preserver with respect to source $\{s\}$. At each node s , store H_s as the label. Since the number of edges in H_s is $O((f + 1)n^{2-1/2^f})$ and it takes $O(\log n)$ bits to describe an edge, each label takes $O((f + 1)n^{2-1/2^f} \log n)$ bits.

To compute $\text{dist}(s, t, G \setminus F)$ for any $|F| \leq f + 1$, we read the labels of s and t to determine H_s and H_t , then union them together to get $H_{st} = H_s \cup H_t$. We then simply find the distance in $H_{st} \setminus F$.

H_{st} is a $(f, 1)$ -preserver with respect to the source $\{s, t\}$. By Lemma 17, H_{st} is an $(f + 1)$ -fault-tolerant distance-preserver for pairs in $\{s, t\} \times \{s, t\}$. Thus, $\text{dist}(s, t, H_{st} \setminus F) = \text{dist}(s, t, G \setminus F)$ as desired. ◀

4.2 Subset Replacement Path Algorithm

In the Subset Replacement Path problem (SUBSET-RP), the input is a graph $G = (V, E)$ and a set of source vertices S , and for every pair of vertices $s, t \in S$ and failing edge $e \in E$, report $\text{dist}(s, t, G \setminus e)$.

We modify the algorithm by Bodwin et al. [5] to use our $(0, 1)$ -preserver from Theorem 9 to solve the SUBSET-RP problem.

► **Theorem 19.** *Given a graph $G = (V, E)$ and a set of source vertices S , we can solve the SUBSET-RP problem in $O(|S|m) + \tilde{O}(|S|^2n)$ time in the word-RAM model.*

To this end, we will make use of the following result whose proof we will omit as we only make a black box use of it.

► **Theorem 20** (Hershberger and Suri [12]). *When $|S| = 2$, there is an algorithm that solve SUBSET-RP(G, S) in time $\tilde{O}(m + n)$.*

We now propose Algorithm 2 to solve the general problem.

► **Algorithm 2** Algorithm for SUBSET-RP(G, S).

```

1 for  $s \in S$  do
2   | Compute  $H_s \leftarrow (0, 1)$ -preserver of  $G$  with source  $s$ .
3 end
4 for  $s, t \in S$  do
5   | Solve SUBSET-RP( $H_s \cup H_t, \{s, t\}$ ) using Theorem 20 to get the result for  $(s, t)$ .
6 end

```

► **Lemma 21** (Correctness). *Algorithm 2 solves the SUBSET-RP(G, S) problem.*

Proof. $H_s \cup H_t$ is a $(0, 1)$ -preserver with respect to the source set $\{s, t\}$. By Lemma 17, $H_s \cup H_t$ is a 1-fault-tolerant distance-preserver for pairs in $\{s, t\} \times \{s, t\}$. Thus for any edge e , $\text{dist}(s, t, (H_s \cup H_t) \setminus e) = \text{dist}(s, t, G \setminus e)$. Thus, applying Theorem 20 on $H_s \cup H_t$ correctly computes $\text{dist}(s, t, G \setminus e)$ for all edges e . ◀

► **Lemma 22 (Running Time).** *Algorithm 2 runs in $O(|S|m) + \tilde{O}(|S|^2n)$ time.*

Proof. By Theorem 10, we can compute H_s in $O(m + n)$ time. Since H_s has $O(n)$ size, $\text{SUBSET-RP}(H_s \cup H_t, \{s, t\})$ can be solved in $\tilde{O}(n)$ time by Theorem 20. Therefore, the total time taken is $O(|S|m) + \tilde{O}(|S|^2n)$. ◀

Abstract

The densest subgraph problem is a classic problem in combinatorial optimisation. Graphs with low maximum subgraph density are often called “uniformly sparse”, leading to algorithms parameterised by this density. However, in reality, the sparsity of a graph is not necessarily uniform. This calls for a formally well-defined, fine-grained notion of density.

Danisch, Chan, and Sozio propose a definition for *local density* that assigns to each vertex v a value $\rho^*(v)$. This local density is a generalisation of the maximum subgraph density of a graph. I.e., if $\rho(G)$ is the subgraph density of a finite graph G , then $\rho(G)$ equals the maximum local density $\rho^*(v)$ over vertices v in G . They present a Frank-Wolfe-based algorithm to approximate the local density of each vertex with no theoretical (asymptotic) guarantees.

We provide an extensive study of this local density measure. Just as with (global) maximum subgraph density, we show that there is a dual relation between the local out-degrees and the minimum out-degree orientations of the graph. We introduce the definition of the local out-degree $g^*(v)$ of a vertex v , and show it to be equal to the local density $\rho^*(v)$. We consider the local out-degree to be conceptually simpler, shorter to define, and easier to compute.

Using the local out-degree we show a previously unknown fact: that existing algorithms already dynamically approximate the local density for each vertex with polylogarithmic update time. Next, we provide the first distributed algorithms that compute the local density with provable guarantees: given any ε such that $\varepsilon^{-1} \in O(\text{poly } n)$, we show a deterministic distributed algorithm in the LOCAL model where, after $O(\varepsilon^{-2} \log^2 n)$ rounds, every vertex v outputs a $(1 + \varepsilon)$ -approximation of their local density $\rho^*(v)$. In CONGEST, we show a deterministic distributed algorithm that requires $\text{poly}(\log n, \varepsilon^{-1}) \cdot 2^{O(\sqrt{\log n})}$ rounds, which is sublinear in n .

As a corollary, we obtain the first deterministic algorithm running in a sublinear number of rounds for $(1 + \varepsilon)$ -approximate densest subgraph detection in the CONGEST model.

1 Introduction

Density or sparsity measures of graphs are widely studied and have many applications. Examples include the arboricity, the degeneracy, and the maximum subgraph density, all of which are asymptotically related within a factor of 2. Given a graph or subgraph H , its density, $\rho(H)$, is the average number of edges per vertex in H . The *maximum subgraph density* $\rho^{\max}(G)$ of a graph G is the maximum density $\rho(H)$ amongst all subgraphs $H \subseteq G$.

Computing maximum subgraph density has been studied both in the dynamic [10, 27], streaming [1, 4] and distributed [15, 28] setting. Often these measures are used to parameterise the sparsity of “uniformly sparse graphs” [2, 8, 25]. These measures are global measures in the sense that they measure the sparsity of the most dense part of the graph. In many cases the graph is not equally sparse (or dense) everywhere. Consider for example a lollipop graph: a large clique joined to a long path. The clique is a subgraph of high density, yet the vertices along the path sit in a part of the graph that is significantly less dense. Often, solutions for graph density related problems provide guarantees based on the most dense part of the graph. In some areas of computation more “local” solutions are desirable. Prior works of a global nature often completely disregard certain parts of the graphs, meaning that the output in sparser parts holds little to no information. We give three examples:

1) Many dynamic algorithms for estimating the subgraph density rely on modifying the solution locally. Algorithmic performance is expressed in terms of (global) graph sparsity, and thus fails to exploit the more fine-grained guarantee that local sparse areas yield.

2) In network analysis, one is often interested in determining dense subgraphs as these subgraphs can be interpreted, for instance, as communities within a social network. However, since many classical algorithms are tuned towards only detecting the densest subgraphs, these algorithms might fail to detect communities in sparser parts of the network [14, 26, 29].

3) Computing the maximum subgraph density is not very local, nor distributed. We consider the models LOCAL and CONGEST, and the lollipop graph. Here, almost instantly, the vertices of the clique realise they are part of a (very dense) clique. The vertices on the path may have to wait for diameter-many rounds before realising the maximum subgraph density of the graph. Distributed algorithms that wish to compute the *value* of the subgraph density are thus posed with a choice: either use $\Omega(D)$ rounds (where D is the diameter of the graph), or let every vertex output a value that is at most the maximum subgraph density.

1.1 Local density and results

We consider the definition of *local density* $\rho^*(v)$ by Danisch, Chan, and Sozio [14], defined at each node v of the graph (Definition 7). Our contributions can be split into four categories, which we present in four sections with corresponding titles.

A: Conceptual results for local density. Our primary contribution is an extensive overview of the theoretical properties of this local density measure. We show that, just as in the maximum-subgraph density problem, computing local density has a natural dual problem as we define the *local out-degree*. Consider a (fractional) orientation of the graph that is *locally fair*. i.e., for each directed edge (u, v) , the out-degree $g(u)$ is at most $g(v)$. We prove that for each vertex v , the out-degree of v has the same value over all locally fair orientations. We define this value $g^*(v)$ as the local out-degree of v . We prove that the local density of each vertex is the dual of its local out-degree and thereby $g^*(v) = \rho^*(v)$. This new definition for local out-degree is considerably shorter than the definition for local density. It allows us to show some previously unknown interesting properties of local density:

B: Results for dynamic algorithms. We prove that in an *approximately fair* orientation (a definition by Chekuri et al. [10]) the out-degree $g(v)$ of each vertex is a $(1 + \varepsilon)$ -approximation of $g^*(v) = \rho^*(v)$ (Theorem 12). This implies a previously unknown fact: that there exist dynamic polylogarithmic algorithms [10, 13, 12] where each vertex v maintains a $(1 + \varepsilon)$ -approximation of its local density $\rho^*(v)$ as by Danisch, Chan, and Sozio [14].

C: Results in LOCAL. We show that each node v can obtain a $(1 + \varepsilon)$ -approximation of $\rho^*(v)$ by surveying its $O(\varepsilon^{-2} \log^2 n)$ -hop neighbourhood. This induces a LOCAL algorithm where each vertex $v \in V$ computes a $(1 + \varepsilon)$ -approximation of $\rho^*(v)$ in $O(\varepsilon^{-2} \log^2 n)$ rounds.

Commentary on runtime: We observe that $\rho^{\max}(G)$ can be computed in LOCAL in $O(\varepsilon^{-1} \log n)$ rounds. In contrast, the stricter local density is computed in $O(\varepsilon^{-2} \log^2 n)$ rounds. This gap may be explained by considering the local density $\rho^*(v)$ for low-local-density vertices v in a graph that has high global density. The local density of v can be affected by a dense subgraph within a hop distance of $\Theta(\varepsilon^{-2} \log^2 n)$ (although it unclear if it can be affected *enough* to prohibit a $(1 + \varepsilon)$ -approximation of $\rho^*(v)$ in $o(\varepsilon^{-2} \log^2 n)$ time). The potential for a barrier of $O(\varepsilon^{-2} \log^2 n)$ rounds is also illustrated by existing dynamic algorithms [10, 28] that maintain η -fair orientations. In this scenario, these algorithms have a worst-case recourse of $\Omega(\varepsilon^{-2} \log^2 n)$. We consider it an interesting open problem to either improve our running time in LOCAL, or, show that $O(\varepsilon^{-2} \log^2 n)$ is tight.

D: Results in CONGEST. We show a significantly more involved algorithm in CONGEST, where after $O(\text{poly}\{\varepsilon^{-1}, \log n\} \cdot 2^{O(\sqrt{\log n})})$ rounds, each vertex v outputs a $(1 + \varepsilon)$ -approximation of $\rho^*(v)$. Since $\max_{v \in V} \rho^*(v) = \rho^{\max}(G)$, this is the first deterministic algorithm for $(1 + \varepsilon)$ -approximating of the global subgraph density $\rho^{\max}(G)$ in CONGEST, that runs in a number of rounds that is sublinear in the diameter of the graph.

In the main body, we focus on the value variant where we want each vertex v to output an approximation of $\rho^*(v)$. In the full version, we extend our analysis so that each vertex v can output a subgraph H with $v \in H$ where $\rho(H)$ approximates $\rho^*(v)$. See also Table 1.

■ **Table 1** Results in LOCAL (L) or CONGEST (C) where prior work for computing the global subgraph density is compared to our running time for the local subgraph density. D denotes the diameter. Orange running times are not deterministic and occur with high probability.

Model	Problem	Each v outputs ρ_v with	Rounds	Source

2 Preliminaries and related work

Let $G = (V, E)$ be an undirected weighted graph with n vertices and m edges. For any $v \in V$ and any integer k , we denote by $H_k(v)$ the k -hop neighborhood of v . For each edge $e \in E$ we denote by $g(e)$ the *weight* of e . Any edge with endpoints u, v may be denoted as \overline{uv} .

25:4 Local Density and Its Distributed Approximation

We can augment any weighted graph G with a (*fractional orientation*). An orientation \vec{G} assigns to each edge \overline{uv} two positive real values: $g(u \rightarrow v)$ and $g(v \rightarrow u)$ such that $g(\overline{uv}) = g(u \rightarrow v) + g(v \rightarrow u)$. These values may be interpreted as pointing a fraction of the edge \overline{uv} from u to v , and the other fraction from v to u . Given an orientation \vec{G} , we denote by $g(u) = \sum_{v \in V} g(u \rightarrow v)$ the *out-degree* of u (i.e., how much fractional edges point outwards from u in \vec{G}). Given these definitions, we can consider two graph measures of G : the maximum subgraph density and the minimum orientation of G .

Global graph measures. For any subgraph $H \subseteq G$, its *density* $\rho(H)$ is defined as $\rho(H) = \frac{1}{|V(H)|} \sum_{e \in E(H)} g(e)$. The *maximum subgraph density* $\rho^{\max}(G)$ is then the maximum over all $H \subseteq G$ of $\rho(H)$. A subgraph $H \subseteq G$ is *densest* whenever $\rho(H) = \rho^{\max}(G)$. For any orientation \vec{G} of G , its *maximum out-degree* $\Delta(\vec{G})$ is the maximum over all u of the out-degree $g(u)$. The *optimal out-degree* of G , denoted by $\Delta^{\min}(G)$, is subsequently the minimum over all \vec{G} of $\Delta(\vec{G})$. An orientation \vec{G} itself is *minimum* whenever $\Delta(\vec{G}) = \Delta^{\min}(G)$.

The density of G and the optimal out-degree are closely related. One way to illustrate this is through the following dual linear programs:

DS (Densest Subgraph)		FO (Fractional Orientation)
$\max \sum_{\overline{uv} \in E} g(\overline{uv}) \cdot y_{u,v}$	s.t.	$\min \rho$ s.t.
$x_u, x_v \geq y_{u,v} \quad \forall \overline{uv} \in E$		$g(u \rightarrow v) + g(v \rightarrow u) \geq g(\overline{uv}) \quad \forall \overline{uv} \in E$
$\sum_{v \in V} x_v \leq 1$		$\rho \geq \sum_{v \in V} g(u \rightarrow v) \quad \forall u \in V$
$x_v, y_{u,v} \geq 0 \quad \forall u, v \in V$		$g(u \rightarrow v), g(v \rightarrow u) \geq 0 \quad \forall u, v \in V$

Denote by R the optimal value of DS and by Δ the optimal value of FO. By duality, $R = \Delta$. Moreover, Charikar [9] relates these two linear programs to the densest subgraph problem:

► **Theorem 1** (Theorem 1 in [9]). *Let G be a unit weight graph. Denote by R the optimal solution of DS and by D the optimal solution of FO. Then $\rho^{\max}(G) = R = \Delta = \Delta^{\min}(G)$.*

We show that this can be generalised to when G is a weighted graph:

► **Lemma 2** (See the full version). *Let G be any weighted graph. Denote by R the optimal solution of DS and by D the optimal solution of FO. Then $\rho^{\max}(G) = R = D = \Delta^{\min}(G)$.*

2.1 Densest subgraph in dynamic algorithms

In a classical, non-distributed model of computation we can immediately formalise both the value variant of the (approximate) densest subgraph:

► **Problem 1.** *Given a graph G and an $\varepsilon > 0$, output $\rho' \in [(1+\varepsilon)^{-1}\rho^{\max}(G), (1+\varepsilon)\rho^{\max}(G)]$.*

Alternatively, in the Fractional Orientation (FO) problem the goal is to output a $(1 + \varepsilon)$ -approximation of $\Delta^{\min}(G)$. It turns out that FO is a more accessible problem to study. The LP formulations allow for a straightforward way to compute $\Delta^{\min}(G)$ and/or $\rho^{\max}(G)$. However, solving the LP requires information about the entire graph, and this information is expensive to collect. Sawlani and Wang [27] get around this difficulty by instead solving an approximate version of (FO). They work with a concept we call *local fairness*.

► **Definition 3.** Let \vec{G} be a fractional orientation of a graph G . We say that \vec{G} is locally fair whenever $g(u \rightarrow v) > 0$ implies $g(u) \leq g(v)$.

Chekuri et al. [10] extend this definition to η -fairness:

► **Definition 4.** Let \vec{G} be a fractional orientation of a graph G . We say that \vec{G} is η -fair (for $\eta > 0$) whenever $g(u \rightarrow v) > 0$ implies that $g(u) \leq (1 + \eta)g(v)$.

Related work in dynamic algorithms. Chekuri et al. [10] continue to focus on computing a $(1 + \varepsilon)$ -approximation of the Densest Subgraph problem. They show that, if G is a unit weight graph, there exists a $(1 + \varepsilon)$ -approximate solution to FO that is η -fair (for some smartly chosen η). They subsequently prove that an η -fair orientation allows you to find a $(1 + \varepsilon)$ -approximate densest subgraph. This allows them to dynamically maintain the value of the densest subgraph of G in $O(\varepsilon^{-6} \log^3 n \log \rho^{\max}(G))$ time per insertion or deletion of edges in G . By leveraging the η -fairness of the orientation, they can report a $(1 + \varepsilon)$ -approximate densest subgraph in time proportional to the size of the subgraph.

2.2 Approximate densest subgraph in LOCAL and CONGEST

We focus on the *value* variant of the problem, where each vertex outputs a value (as opposed to the *reporting* variant in the full version, where the goal is to report a densest subgraph).

► **Problem 2.** Given a graph G and an $\varepsilon > 0$, each vertex v outputs a value ρ_v and either:

- **Problem 2.1:** we require that $\forall v, \rho_v \in [(1 + \varepsilon)^{-1} \rho^{\max}(G), (1 + \varepsilon) \rho^{\max}(G)]$, or
- **Problem 2.2:** we require that $\max_v \rho_v \in [(1 + \varepsilon)^{-1} \rho^{\max}(G), (1 + \varepsilon) \rho^{\max}(G)]$.

Related work. Problem 2.1 has a trivial $\Omega(D)$ lower bound, obtained by constructing a lollipop graph (where D denotes the diameter). In LOCAL, it is trivial to solve Problem 2.1 in $\Theta(D)$ time. Problem 2.2 was studied by Ghaffari and Su [20] who present a randomised $(1 + \varepsilon)$ -approximation in LOCAL that uses $O(\varepsilon^{-3} \log^4 n)$ rounds. Fischer et al. [16] present a deterministic $(1 + \varepsilon)$ -approximation in LOCAL that uses $2^{O(\log^2(\varepsilon^{-1} \log n))}$ rounds. Ghaffari et al. [19] improve this to $O(\varepsilon^{-9} \log^{15} n)$ rounds. The work by Harris [24] improves this to $\tilde{O}(\varepsilon^{-6} \log^6 n)$ rounds. Su and Vu [28] present the state-of-the-art in this area. They prove that for any graph G , there exists a vertex v such that for the k -hop neighbourhood $H_k(v)$ (with $k \in O(\varepsilon^{-1} \log n)$) the density $\rho^{\max}(H_k)$ is a $(1 + \varepsilon)$ -approximation of $\rho^{\max}(G)$. This immediately leads to a trivial LOCAL algorithm: each vertex u collects its k -hop neighbourhood $H_k(u)$ in $O(\varepsilon^{-1} \log n)$ rounds, solves the LP of Densest Subgraph in its own node, and reports the value $\rho^{\max}(H_k(u))$.

In CONGEST, the state-of-the-art deterministic algorithm for Problem 2.1 and 2.2 is by Das Sarma et al. [15] who present a $(2 + \varepsilon)$ -approximation in $O(D \cdot \varepsilon^{-1} \log n)$ rounds. The best randomised work is by Su and Vu [28] who present a randomised algorithm for Problem 2.2 that runs in $O(\varepsilon^{-4} \log^4 n)$ rounds w.h.p. See also Table 1 for an overview.

2.3 Local density

Danisch, Chan, and Sozio [14] introduce a more local measure which they call the *local density*. Its lengthy definition assigns to each vertex v a value. We note for the reader that we almost immediately define our local out-degree (Definition 8), and only use local out-degree in proofs. Hence, the reader is not required to have a thorough understanding of the following:

► **Definition 5** (Definition 2.2 in [14]). Let $G = (V, E)$ be a weighted graph where an edge e has weight $g(e)$. Let $B \subseteq V$. For any $X \subseteq V - B$, we define the quotient edges $\hat{E}_B(X)$ as all edges in G with one endpoint in X , and the other endpoint in X or B . We define:

- for $X \subseteq V - B$, the quotient subgraph density $\hat{\rho}_B(X) := \frac{1}{|X|} \sum_{e \in \hat{E}_B(X)} g(e)$.
- the maximum quotient density $\hat{\rho}_B(G) := \max_{X \subseteq V - B} \hat{\rho}_B(X)$.

► **Definition 6** (Definition 2.3 in [14]). Given a weighted undirected graph $G = (V, E)$, we define the diminishing-dense decomposition \mathcal{B} of G as the sequence $B_0 \subset B_1 \dots \subset B_\ell = V$:

We define $B_0 = \emptyset$. For $i \geq 1$ if $B_{i-1} = V$ then $\ell := i$. Otherwise:

$$S_i := \arg \max_{X \subseteq V - B_{i-1}} \hat{\rho}_{B_{i-1}}(X), \text{ and } B_i := B_{i-1} \cup S_i.$$

► **Definition 7** (Definition 2.3 in [14]). Given a weighted undirected graph $G = (V, E)$ and a diminishing-dense decomposition \mathcal{B} , each vertex $v \in V$ has one integer i where $v \in S_i$. We define the local density $\rho^*(v) := \hat{\rho}_{B_{i-1}}(S_i)$.

The benefit of local measures. Problem 2's variants have drawbacks in a distributed model of computation. Problem 2.1 has an $\Omega(d)$ lower bound (making it trivial in LOCAL). Problem 2.2 allows some vertices to output nonsense. The definition of local density alleviates these issues, as we may define an algorithmic problem which we consider to be more natural:

► **Problem 3.** Given (G, ε) , each vertex v outputs $\rho_v \in [(1 + \varepsilon)^{-1} \rho^*(v), (1 + \varepsilon) \rho^*(v)]$.

Related work. Danisch, Chan, and Sozio [14] introduce the local density (Definition 7). Intuitively, they define a partition $V_1 \dots V_k$ of V . For each i , they consider the set $X_i = \bigcup_{j=1}^i V_j$. They then define the graph H_i as the vertex-induced subgraph of X_i where for each edge in G between a vertex in X_i and a vertex not in X_i , they add a self loop. They define the *quotient density* of V_i as the density of H_i . The local density $\rho^*(v)$ of a vertex v is the quotient density of V_i for $v \in V_i$. Danisch, Chan, and Sozio [14] then define a quadratic program \mathbf{FO}^2 . The domain of this program is the space of all orientations of the graph G . The cost function is the sum over all vertices u , of the out-degree squared. Consider an orientation \vec{G} of G that optimises the cost function. Danisch, Chan, and Sozio show that for each vertex v its out-degree $g(v)$ equals the local density $\rho^*(v)$. As a consequence, over all optimal solutions to \mathbf{FO}^2 , the out-degree of each vertex is unique. They provide a Frank-Wolfe based algorithm to solve the quadratic program with no theoretical guarantees.

Chekuri, Harb, and Quanrud [22] study computing the local density by solving the quadratic program. They show [22, Theorem 3.4] some interesting properties of \mathbf{FO}^2 . Specifically, they show that the uniqueness property by Danish, Chan and Sozio is a special case of Fujishige's result [18] from 1980. They additionally show that the algorithm GREEDY++ by Boob, Gao, Peng, Sawlani, Tsourakakis, Wang, and Wang [5] (when applied to this quadratic program) converges to an orientation where the out-degree of each vertex v is a $(1 + \varepsilon)$ -approximation of $\rho^*(v)$. Chekuri, Harb, and Quanrud [23] subsequently show that the more general SUPER-GREEDY++ algorithm by Chekuri, Quanrud and Torres [11] also converges to $(1 + \varepsilon)$ -approximation of each $\rho^*(v)$.

Borradaile, Migler, and Wilfong [7] observe that there is a correlation between the fairness of an orientation and local density. An *integral orientation* is any orientation of the graph where for each edge (u, v) , $g(u \rightarrow v) \in \{0, 1\}$. They consider an *egalitarian orientation* which is defined as an integral orientation where “the total available out-degree is shared among

the vertices as equally as allowed by the topology of the graph”. An egalitarian orientation, and other equivalent notions of “fair integral orientations”, are formally defined through an integer flow problem on the graph [6, 17, 30]. From section 2 in [6] it follows that an integral orientation is egalitarian if and only if $g(u \rightarrow v) = 1$ implies that $g(u) \leq g(v) + 1$.

Using an egalitarian orientation, they create a decomposition of the graph that they call a *density decomposition*. The density decomposition by Borradaile, Migler, and Wilfong [7] is not equal to the local density. The analysis of Kopelowitz, Krauthgamer, Porat, and Solomon shows that if \vec{G} is an egalitarian orientation then $\max_v g(v) \leq \rho(G) + O(\log n)$. Their decomposition, compared to the one used for the local density, can thus be viewed as one that is coarser but similar in spirit. It can thereby be argued that Borradaile, Migler, and Wilfong [7] are the first to show a connection between the local density and fair orientations of a graph. However, we note that the integrality of their orientation prevents exact (or $(1 + \varepsilon)$ -approximate) computations of the local density.

3 Results and organisation

Now we are ready to formally state our contributions. Our primary contribution is that we show a dual definition to local density, which we call the local out-degree:

► **Definition 8.** *Given a graph $G = (V, E)$, we define the local out-degree as:*

$$g^*(u) := \text{the out-degree } g(u) \text{ in any locally fair fractional orientation of } G.$$

It is not immediately clear that the local out-degree is well-defined. We prove (Theorem 9) that each vertex in G has the same out-degree across all locally fair orientations of G (and thus, the set of all locally fair orientations of G assigns to each vertex a real value). We believe that the local out-degree is conceptually simpler than the local density. Through this definition, we are able to show various algorithms to approximate the local density.

3.A Conceptual results for local density

We prove in Section 4 that these local definitions generalise the global definition of subgraph density and out-degree, as they exhibit the same dual behaviour. We show several previously unknown properties of the local density, which we consider to be of independent interest:

► **Theorem 9.** *For any weighted graph G , $\forall v \in V$, $g^*(v)$ is well-defined and equals $\rho^*(v)$.*

► **Corollary 10.** *Given a weighted graph G , $\rho^{\max}(G) = \Delta^{\min}(G) = \max_v g^*(v)$.*

► **Corollary 11.** *For any graph G , there exists a fractional orientation \vec{G} that is locally fair.*

3.B Results for dynamic algorithms

We show in Section 5 that η -fair orientations imply approximations for our local measures:

► **Theorem 12.** *Let G be a weighted graph and \vec{G} be an η -fair fractional orientation for $\eta \leq \frac{\varepsilon^2}{128 \cdot \log n}$. Then $\forall v \in V$: $(1 + \varepsilon)^{-1} \rho^*(v) \leq g(v) \leq (1 + \varepsilon) \rho^*(v)$.*

This immediately implies the following Corollary by applying [10]:

► **Corollary 13.** *There exists an algorithm [10] that can fractionally orient a dynamic unit-weight graph G with n vertices subject to edge insertions and deletions with deterministic worst-case $O(\varepsilon^{-6} \log^4 n)$ update time such that for all $v \in V$:*

$$g(v) \in [(1 + \varepsilon)^{-1} \rho^*(v), (1 + \varepsilon) \rho^*(v)].$$

3.C Results in LOCAL

The local density as a measure is not entirely local. However, we prove in Section 6 that far-away subgraphs affect the local density of a vertex v only marginally:

► **Theorem 14.** *Let G be a unit-weight graph. For any $\varepsilon > 0$ and vertex v , denote by $\rho^*(v)$ its local density and by $\rho_k^*(v)$ its local density in $H_k(v)$. Then $\rho_k^*(v) \in [(1+\varepsilon)^{-1}\rho^*(v), (1+\varepsilon)\rho^*(v)]$ for $k \in \Theta(\varepsilon^{-2} \log^2 n)$.*

This immediately implies a trivial algorithm for problem 2 in LOCAL (where each vertex v collects its k -hop neighbourhood $H_k(v)$ for $k \in \Theta(\varepsilon^{-2} \log^2 n)$ and then solves FO on $H_k(v)$):

► **Corollary 15.** *There exists an algorithm in LOCAL that given a unit graph G and $\varepsilon > 0$ computes in $O(\varepsilon^{-2} \log^2 n)$ rounds for all $v \in V$ a value $\rho_v \in [(1+\varepsilon)^{-1}\rho^*(v), (1+\varepsilon)\rho^*(v)]$.*

3.D Results in CONGEST

Finally in Section 7, we solve Problem 3 in CONGEST by computing an η -fair orientation. We use as a subroutine algorithm to compute *blocking flows* in an h -layered DAG [21]:

► **Theorem 16.** *Suppose one can compute a blocking flow in an n -node h -layered DAG in $\text{Blocking}(h, n)$ rounds. There exists an algorithm in CONGEST that given a unit-weight graph G and $\varepsilon > 0$ computes in $O(\varepsilon^{-3} \log^4 n \cdot (\varepsilon^{-2} \log^2 n + \text{Blocking}(\varepsilon^{-2} \log^2 n, n)))$ rounds an orientation \vec{G} such that for all $v \in V$: $g(v) \in [(1+\varepsilon)^{-1}\rho^*(v), (1+\varepsilon)\rho^*(v)]$.*

As a corollary, we obtain the first deterministic algorithm running in a sublinear number of rounds for $(1+\varepsilon)$ -approximate dense subgraph detection in the CONGEST model (Table 1).

4 Conceptual results for local density

Our primary contribution is the definition of local out-degree as a dual to local density.

► **Lemma 17.** *The local density is well-defined. That is, for any two locally fair orientations \vec{G} or \vec{G}' where a vertex u has out-degree $g(u)$ or $g'(u)$ respectively, $g(u) = g'(u)$.*

Proof. Suppose for the sake of contradiction that there exists two locally fair orientations (\vec{G}, \vec{G}') and a vertex $u \in V$ where $g(u) > g'(u)$. We define their *symmetric difference* graph S as a digraph where the vertices are V and there exists an edge \vec{ab} whenever $g(a \rightarrow b) > g'(a \rightarrow b)$. We may assume that S contains no directed cycles:

Indeed if S contains any directed cycle π we change \vec{G}' , where for all $\vec{ab} \in \pi$ we slightly increase $g'(a \rightarrow b)$ until S loses an edge. This operation does not change the out-degree of any vertex in \vec{G}' . So, we still have two locally fair orientations (\vec{G}, \vec{G}') with $g(u) > g'(u)$.

Since $g(u) > g'(u)$, the vertex u must have at least one out-edge in S and since S has no cycles, it follows that u must have some directed path π_v to a sink v in S . Since v is a sink in the symmetric difference graph it follows that $g(v) < g'(v)$.

However we now observe the following property of the path π_v :

- $\forall \vec{ab} \in \pi_v, g(a \rightarrow b) > g'(a \rightarrow b)$. Thus, $g(a \rightarrow b) > 0$ and so there exists a directed path from u to v in \vec{G} . Since \vec{G} is locally fair this implies that $g(u) \leq g(v)$.
- $\forall \vec{ab} \in \pi_v, g(a \rightarrow b) > g'(a \rightarrow b)$. Thus, $g'(a \rightarrow b) < g(ab)$ and so $g'(b \rightarrow a) > 0$. It follows that there exists a directed path from v to u in \vec{G}' . Local fairness implies $g'(v) \leq g'(u)$.

The 4 equations: $g(u) > g'(u)$, $g(v) < g'(v)$, $g(u) \leq g(v)$, and $g'(u) \geq g'(v)$ give a contradiction. ◀

Lemma 17 would imply that the local out-degree is well-defined, *if* the set of locally fair orientations is non-empty. Bera, Bhattacharya, Choudhari and Ghosh already aim to prove this in Section 4.1 of [3] (right above Equation 9). They claim that a locally fair orientation always exist by the following argument: They consider an arbitrary orientation \vec{G} that is not locally fair. They claim that for any pair (u, v) where $g(u) > g(v)$ and $g(u \rightarrow v) > 0$ it is possible to transfer some out-degree from $g(u)$ to $g(v)$. The existence of a locally fair orientation would follow, if it can be shown that this procedure converges to a locally fair orientation. Indeed, since the space of all orientations is a compact polytope, the limit of a converging sequence over this domain must lie within the space.

It is intuitive but not clear that this procedure indeed converges. Indeed, decreasing $g(u)$ and increasing $g(v)$ may cause some other edge (w, u) or (v, w) to start violating local fairness. One way to show convergence is to define a potential function and to show that such a transfer always decreases the potential. We define the potential function $\sum_{v \in V} g^2(v)$, thereby creating a quadratic program where the domain is the space of all orientations of G . We prove that any optimal solution to this quadratic program must be a locally fair orientation. Any quadratic function over a compact domain has an optimum and so the existence of a locally fair orientation follows.

► **Theorem 9.** *For any weighted graph G , $\forall v \in V$, $g^*(v)$ is well-defined and equals $\rho^*(v)$.*

Proof. We consider the following quadratic program \mathbf{FO}^2 from [14, Section 4] where we compute a fractional orientation of the graph G subject to a quadratic cost function:

$$\begin{array}{ll} \min \sum g(u)^2 & \text{s.t.} \\ g(u \rightarrow v) + g(v \rightarrow u) \geq g(\overline{uv}) & \forall \overline{uv} \in E \\ g(u) \geq \sum_{v \in V} g(u \rightarrow v) & \forall u \in V \\ g(u \rightarrow v), g(v \rightarrow u) \geq 0 & \forall u, v \in V \end{array}$$

Consider any optimal solution to the quadratic program. It must be that $g(u) = \sum_{v \in V} g(u \rightarrow v)$. Danisch, Chan, and Sozio [14, Corollary 4.4] prove that for any vertex u , the local density $\rho^*(u) = g(u)$.

We first note that any solution to the quadratic program is an orientation. Indeed, suppose for the sake of contradiction that there exists an edge $\overline{uv} \in E$ where $g(u \rightarrow v) + g(v \rightarrow u) > g(\overline{uv})$. We may now decrease either $g(u \rightarrow v)$ or $g(v \rightarrow u)$ to obtain another viable solution to the program. Consider decreasing $g(u \rightarrow v)$, then we may decrease $g(u)$ and maintain a viable and better solution to the program – a contradiction.

Secondly, we claim that the optimal solution to the quadratic program is a locally fair orientation. Suppose for the sake of contradiction that there exist u, v with $g(u) = g(v) + \delta'$ and $g(u \rightarrow v) = \delta$ for $\delta, \delta' > 0$. We can decrease $g(u \rightarrow v)$ to zero by increasing $g(v \rightarrow u)$ by $\Delta = \min\{\delta, \delta'\}$ and still maintain a solution to the program. This reduces the solution's value by $(g(u) - \Delta)^2 - (g(v) + \Delta)^2$. However, we now found a solution to the quadratic program with a lower value than the optimal solution – a contradiction.

Thus, the solution to \mathbf{FO}^2 gives a locally fair orientation \vec{G} where each vertex u has out-degree $g(u)$. The local density $g^*(u) = g(u)$ is by Lemma 17 well-defined. Danisch, Chan and Sozio [14, Corollary 4.4] show that $\rho^*(u) = g(u)$, which proves the theorem. ◀

Since the local density equals the local out-degree, we conclude from [14] that:

► **Corollary 10.** *Given a weighted graph G , $\rho^{\max}(G) = \Delta^{\min}(G) = \max_v g^*(v)$.*

25:10 Local Density and Its Distributed Approximation

Since a quadratic program over a convex domain always has a solution, we may also note the following interesting fact:

► **Corollary 11.** *For any graph G , there exists a fractional orientation \vec{G} that is locally fair.*

5 Results for dynamic algorithms

We use our definition of local out-degree to show that there already exist dynamic algorithms that approximate the local density of each vertex. Recall that an orientation \vec{G} is η -fair whenever for all $\overline{uv} \in E(\vec{G})$, $g(u \rightarrow v) > 0$ implies that $g(u) \leq (1 + \eta)g(v)$. We show that if we choose $\eta \leq \frac{\varepsilon^2}{128 \cdot \log n}$, then for any η -fair orientation, for all v , the out-degree $g(v)$ is a $(1 + \varepsilon)$ approximation of $g^*(v) = \rho^*(v)$. Moreover, we prove that the maximal local out-degree (i.e. $\max_{u \in V} g(u)$) is a $(1 + \varepsilon)$ approximation of $\Delta^{\min}(G) = \rho^{\max}(G)$; illustrating that approximating the local measures is a strictly more general problem. To this end, we prove the following helper lemma:

► **Lemma 18.** *Let $\eta \leq \frac{\varepsilon^2}{128 \cdot \log n}$ and $k \leq \log_{(1 + \frac{1}{16}\varepsilon)} n$. Then $(1 + \eta)^{-k} \geq (1 + 0.5\varepsilon)^{-1}$.*

Proof. Using $\log(1 + x) \geq x/2$ whenever $x < 1$, we obtain:

$$-\log_{1 + \frac{\varepsilon}{16}}(n) = -\frac{\log(n)}{\log 1 + \frac{\varepsilon}{16}} \geq -\frac{\log(n)}{\frac{\varepsilon}{32}} \geq -\frac{\varepsilon}{4} \cdot \frac{128 \log(n)}{\varepsilon^2}$$

$$(1 + \eta)^{-k} \geq \left(1 + \frac{\varepsilon^2}{128 \cdot c \cdot \log n}\right)^{-c \cdot \log_{1 + \frac{\varepsilon}{16}}(n)} \geq \left(1 + \frac{\varepsilon^2}{128 \cdot c \cdot \log n}\right)^{-\frac{\varepsilon}{4} \cdot \frac{128 \cdot c \cdot \log(n)}{\varepsilon^2}}$$

$$(1 + \eta)^{-k} \geq \text{EXP}\left[-\frac{\varepsilon}{4}\right] \geq \text{EXP}\left[-\log\left(1 + \frac{\varepsilon}{2}\right)\right] \geq \left(1 + \frac{\varepsilon}{2}\right)^{-1} \quad \blacktriangleleft$$

► **Theorem 12.** *Let G be a weighted graph and \vec{G} be an η -fair fractional orientation for $\eta \leq \frac{\varepsilon^2}{128 \cdot \log n}$. Then $\forall v \in V: (1 + \varepsilon)^{-1} \rho^*(v) \leq g(v) \leq (1 + \varepsilon) \rho^*(v)$.*

Proof. First, we show that for all vertices v , $g(v) \leq (1 + \varepsilon) \rho^*(v)$.

Suppose for the sake of contradiction that there exists a vertex u with $g(u) > (1 + \varepsilon) \rho^*(u)$. We fix $\rho^*(u) = g^*(u) = \gamma$ and work with γ throughout the remainder of this proof to show a contradiction. By Corollary 11, there exists at least one locally fair fractional orientation \vec{G}_x . By Corollary 10, every vertex v in this orientation has out-degree $g_x(v) = g^*(v) = \rho^*(v)$. And thus, the fractional orientation \vec{G}_x is not equal to \vec{G} .

Given \vec{G} and a locally fair fractional orientation \vec{G}_x , we do three steps:

- We partition the vertices of G to create two graphs G_1 and G_2 . The partition is based on the orientation \vec{G}_x as we set: $G^1 = G[v \in V \mid g_x(v) \leq \gamma]$ and by $G^2 = G[v \in V \mid g_x(v) > \gamma]$. For ease of notation, we write any edge with one endpoint $a \in V(G^1)$ and one endpoint $b \in V(G^2)$ as (a, b) and never as (b, a) .
- From G^1 , we create a family of nested subgraphs using \vec{G} . We define graphs $G_i^1 := G^1[v \in V(G^1) \mid g(v) \geq \frac{g(u)}{(1 + \eta)^i}]$. We denote by k the lowest integer such that $|V(G_{k+1}^1)| < (1 + \frac{\varepsilon}{16})|V(G_k^1)|$. We apply Lemma 18 to observe that $(1 + \eta)^{-k} \geq (1 + \varepsilon/2)^{-1}$.
- Finally, we use both orientations to create three claims that contradict one another.

The first claim. We denote by E_{\uparrow} the set of all edges $e = (a, b)$ with $a \in V(G_{k+1}^1)$ and $b \in V(G^2)$ and claim that:

$$\sum_{e \in E(G_{k+1}^1)} g(e) + \sum_{e \in E_{\uparrow}} g(e) \leq \sum_{v \in V(G_{k+1}^1)} g_x(v). \quad (1)$$

Indeed for $\overline{ab} \in E(G_{k+1}^1)$, both endpoints are in $V(G_{k+1})$. Because \vec{G}_x is locally fair, this implies that $g_x(a \rightarrow b) + g_x(b \rightarrow a) = g(\overline{ab})$. For all $\overline{ab} \in E_\uparrow$, $g_x(b) > \gamma \geq g_x(a)$ per definition of G^1 and G^2 . By local fairness, $g_x(a \rightarrow b) = g(\overline{ab})$ and the inequality follows.

The second claim. We secondly claim that:

$$\sum_{v \in V(G_k^1)} g(v) > \sum_{v \in V(G_{k+1}^1)} g_x(v). \quad (2)$$

This is because we can lower bound $\sum_{v \in V(G_k^1)} g(v)$ as follows:

$$\begin{aligned} \sum_{v \in V(G_k^1)} g(v) &\geq (1 + \eta)^{-k} \cdot g(u) \cdot |V(G_k^1)| > (1 + \eta)^{-k} \cdot g(u) \cdot |V(G_{k+1}^1)| \cdot (1 + \frac{\varepsilon}{16})^{-1} \\ &> (1 + \frac{\varepsilon}{2})^{-1} \cdot (1 + \varepsilon)\gamma \cdot |V(G_{k+1}^1)| \cdot (1 + \frac{\varepsilon}{16})^{-1} \geq \gamma \cdot |V(G_{k+1}^1)| \end{aligned}$$

The claim follows by noting that per definition of G^1 , for all $v \in V(G_{k+1}^1)$, $g_x(v) \leq \gamma$.

The third claim. Lastly, we claim that:

$$\sum_{v \in V(G_k^1)} g(v) \leq \sum_{e \in E(G_{k+1}^1)} g(e) + \sum_{e \in E_\uparrow} g(e) \quad (3)$$

Consider any $v \in V(G_k^1)$ and any vertex a with $g(v \rightarrow a) > 0$. Recall that \vec{G} is an η -fair orientation. Thus, if $a \in G^1$, then $\overline{va} \in E(G_{k+1}^1)$. If $a \in G^2$, then per definition $\overline{va} \in E_\uparrow$. Per definition of a fractional orientation $g(v \rightarrow a) \leq g(\overline{va})$ and so the claim follows.

A contradiction. Equation 1, 2 and 3 contradict each other. Thus, we have proven that for all vertices v , $g(v) \leq (1 + \varepsilon)\rho^*(v)$.

The full version finishes the proof by showing the other direction. ◀

If G is a unit-weight graph, Chekuri et al. [10] present a dynamic algorithm to maintain an η -fair orientation in a unit-weight graph with $\eta \in O(\varepsilon^{-2} \log n)$. Thus, by Theorem 12, we may now conclude that they approximate the local density (and/or the local out-degree):

► **Corollary 13.** *There exists an algorithm [10] that can fractionally orient a dynamic unit-weight graph G with n vertices subject to edge insertions and deletions with deterministic worst-case $O(\varepsilon^{-6} \log^4 n)$ update time such that for all $v \in V$:*

$$g(v) \in [(1 + \varepsilon)^{-1} \rho^*(v), (1 + \varepsilon) \rho^*(v)].$$

6 Results in LOCAL

We prove that the local out-degree of each $v \in V$ is (largely) determined by its local neighbourhood. As a result, we immediately get an algorithm to solve Problem 3 in LOCAL.

► **Theorem 14.** *Let G be a unit-weight graph. For any $\varepsilon > 0$ and vertex v , denote by $\rho^*(v)$ its local density and by $\rho_k^*(v)$ its local density in $H_k(v)$. Then $\rho_k^*(v) \in [(1 + \varepsilon)^{-1} \rho^*(v), (1 + \varepsilon) \rho^*(v)]$ for $k \in \Theta(\varepsilon^{-2} \log^2 n)$.*

Proof. To prove the theorem, we design a simple deletion-only algorithm to maintain an η -fair orientation. For $\eta = \frac{\varepsilon^2}{128 \log n}$, this algorithm has a recursive depth of $O(\varepsilon^{-2} \log^2 n)$.

■ **Algorithm 1** DECREASE($g(u \rightarrow v)$ by Δ – assuming that $\Delta \leq g(u \rightarrow v)$).

```

 $w^* \leftarrow \arg \max_{w \in V} \{g(w) \mid g(w \rightarrow u) > 0\}$ 
while  $\Delta > 0$  and  $g(w^*) > (1 + \eta)(g(u) - \Delta)$  do
    if  $\Delta > g(w^* \rightarrow u)$  then
        DECREASE( $g(w^* \rightarrow v)$  by  $g(w^* \rightarrow v)$ )
         $\Delta = \Delta - g(w^* \rightarrow u)$ 
    else
        DECREASE( $g(w^* \rightarrow v)$  by  $\Delta$ )
     $w^* \leftarrow \arg \max_{w \in V} \{g(w) \mid g(w \rightarrow u) > 0\}$ 
    
```

Specifically, we say that a directed edge \overline{uv} is bad whenever $g(u \rightarrow v) > 0$ and $g(u) > (1 + \eta)g(v)$. In an η -fair orientation no edge is bad. Whenever we delete an edge $\overline{x_1x_0}$, the out-degree $g(x_1)$ decreases by $g(x_1 \rightarrow x_0)$. For vertices x_2 with $g(x_2 \rightarrow x_1) > 0$, it may now be that $g(x_2) > (1 + \eta)g(x_1)$ (and thus the edge $\overline{x_2x_1}$ becomes bad). Note if there exists such a vertex x_2 , then it must hold for the vertex $x_2^* := \arg \max_{x_2 \in V} \{g(x_2) \mid g(x_2 \rightarrow x_1) > 0\}$. This leads to a recursive algorithm to decrease the out-degree of a vertex (Algorithm 1).

We claim that this algorithm as a recursive depth of $O(\log_{1+\eta} n)$. Indeed any sequence of recursive calls is a path in G . Denote the path belonging to the longest sequence of recursive calls by x_0, x_1, \dots, x_ℓ . Since Δ is always at most 1, it must hold for all i that: $g(x_i) > (1 + \eta)(g(x_{i-1}) - 1)$. Since a graph may have at most n^2 edges, $g(x_\ell) \leq n$ and it follows that the recursive depth is at most $\ell \in O(\log_{1+\eta} n)$. We now apply $\log(1 + x) \geq x/2$ and note that: $\ell \leq \frac{\log n}{\log(1+\eta)} \leq \frac{\log n}{\eta/2} \subseteq O(\frac{\log n}{64\varepsilon^2/\log n}) \subseteq O(\frac{\log^2 n}{\varepsilon^2})$.

Given this theoretical algorithm, we prove the lemma. Consider any fair orientation \vec{G} . Then by Theorem 9 for any vertex v , $g(v) = \rho^*(v)$. Choose some $k \in \Theta(\varepsilon^{-2} \log^2 n)$ sufficiently large and let $H_k(v)$ be the k -hop neighbourhood of v and E_k be all the edges in $H_{k+1}(v)$ that are not in H_k .

Choose $\eta = \frac{\varepsilon^2}{128 \log n}$. The orientation \vec{G} is per definition an η -fair orientation. We run on \vec{G} our deletion-only algorithm, deleting all edges in E_k . Since our algorithm has a recursive depth of $\ell < k$, we end up with an η -fair orientation of $H_k(v)$ where $g(v) = \rho^*(v)$. We apply Theorem 12 to conclude that $\rho^*(v) = g(v) \in [(1 + \varepsilon)^{-1} \rho_k^*(v), (1 + \varepsilon) \rho_k^*(v)]$ which concludes the theorem. ◀

► **Corollary 15.** *There exists an algorithm in LOCAL that given a unit graph G and $\varepsilon > 0$ computes in $O(\varepsilon^{-2} \log^2 n)$ rounds for all $v \in V$ a value $\rho_v \in [(1 + \varepsilon)^{-1} \rho^*(v), (1 + \varepsilon) \rho^*(v)]$.*

7 Results in CONGEST

We now describe an algorithm in CONGEST that for any unit-weight graph G , creates an η -fair orientation (with $\eta = \frac{\varepsilon^2}{128 \cdot \log n}$). Our algorithm uses as a subroutine a distributed algorithm to compute a *blocking flow* in an h -layered DAG in $O(\text{Blocking}(h, n))$ rounds.

► **Definition 19.** *An edge-capacitated DAG G is h -layered if the vertices can be embedded on a grid of height h , such that every directed edge \overline{uv} points downwards.*

► **Definition 20.** *For an edge-capacitated DAG G with sources S and terminals T , a flow f from S to T is blocking if every augmenting path of f contains at least one saturated edge.*

■ **Figure 1** Given a graph G , we arbitrarily orient G . This allows us to partition the vertices of G into levels L_1, \dots, L_6 based on their current out-degree. We say that an edge (u, v) is *violating* whenever $g(u \rightarrow v) > 0$, $u \in L_i$, $v \in L_j$ and $i > j + 1$. We show violating edges in red. Our algorithm iterates over an integer h from high to low, and tries to flip all violating edges from level L_h .

► **Lemma 21** (Lemma 7.2 and 9.1 in [21]). *There exists an algorithm which, given an n -node h -layer edge-capacitated DAG D with sources S and terminals T computes a blocking ST -flow in CONGEST in:*

- Blocking(h, n) = $\tilde{O}(h^4)$ rounds with high probability,
- Blocking(h, n) = $\tilde{O}(h^6 \cdot 2^{c\sqrt{\log n}})$ deterministic rounds for some constant c .

We compute an η -fair orientation by repeatedly constructing a DAG with $h \in O(\varepsilon^{-2} \log^2 n)$ and computing blocking flows. Theorem 12 implies in an η -fair orientation (for our choice of η) the out-degree of each vertex v is a $(1 + \varepsilon)$ -approximation $\rho^*(v)$.

The initialising step. Before we start our algorithm, we create a starting orientation where we set for every edge $e = \overline{uv}$, $g(u \rightarrow v) = \frac{1}{2}g(e)$ and $g(v \rightarrow u) = \frac{1}{2}g(e)$. This gives each vertex u some out-degree $g(u)$ which we partition:

► **Definition 22.** *Let each vertex u have out-degree $g(u)$. We define level i as:*

$$L_i := \left\{ u \in V \mid g(u) \in \left[\left(1 + \frac{\eta}{2}\right)^i, \left(1 + \frac{\eta}{2}\right)^{i+1} \right] \right\}.$$

A vertex $u \in L_i$ is at level i and ℓ' denotes the highest level that is not empty.

Whenever $g(u) = \left(1 + \frac{\eta}{2}\right)^i$, u may decide whether $u \in L_i$ or $u \in L_{i-1}$; whenever our algorithm increases $g(u)$ the vertex u defaults to the lowest possible level and vice versa.

► **Definition 23.** *Consider an edge \overline{uv} with $u \in L_i$ and $v \in L_j$. We say that:*

- (u, v) is an out-edge from u and an in-edge into v whenever $i > j$ and $g(u \rightarrow v) > 0$, and
- (u, v) is violating whenever $i > j + 1$ and $g(u \rightarrow v) > 0$

Note that the orientation is η -fair whenever there exist no violating edges.

► **Lemma 24.** *Let $\eta \leq \frac{\varepsilon^2}{128 \cdot \log n}$. For our orientation, let ℓ' be the highest level such that $L_{\ell'}$ is not empty then $\ell' \leq \varepsilon^{-2} \log^2 n$.*

Proof. The maximal out-degree of a vertex is n . Thus, $\ell' \leq \frac{\log n}{\log(1 + \frac{\eta}{2})}$. We now apply $\log(1 + x) \geq x/2$ and note that: $\ell' \leq \frac{\log n}{\log(1 + \frac{\eta}{2})} \leq \frac{\log n}{\eta/4} = \frac{\log n}{32\varepsilon^2/\log n} \leq \frac{\log^2 n}{\varepsilon^2}$. ◀

7.1 Algorithm overview

Denote $\ell = \lceil \varepsilon^{-2} \log^2 n \rceil$. Our algorithm runs on a “clock” denoted by $(h : m : s)$ where:

- Each HOUR h lasts $2\lceil \eta^{-1} \rceil + 2$ MINUTES,
- Each even MINUTE m lasts $4\lceil \log_{8/7} n \rceil + 2$ rounds,

25:14 Local Density and Its Distributed Approximation

- Each odd MINUTE m in HOUR h lasts $\ell - h + 1$ SECONDS,
- Each SECOND s lasts $\ell + \text{Blocking}(\ell, n)$ rounds.

Each vertex tracks the clock to know which actions of our algorithm it should execute (if any). Our clock is special, in the sense that hours tick downwards. Minutes and seconds tick upwards, starting from zero. Each vertex v in our graph keeps track of the current time, measured in the current HOUR h , MINUTE m and SECOND s . We maintain the following:

► **Invariant 1.** *During HOUR h , there are no violating out-edges from level k for all $k > h + 1$. At the start of each even MINUTE in HOUR h , there are no violating out-edges from level k for all $k > h$.*

This invariant implies that we compute an η -fair orientation when the clock reaches $(0 : 0 : 0)$. Going from HOUR h to HOUR $h - 1$ we maintain this invariant by flipping directed paths:

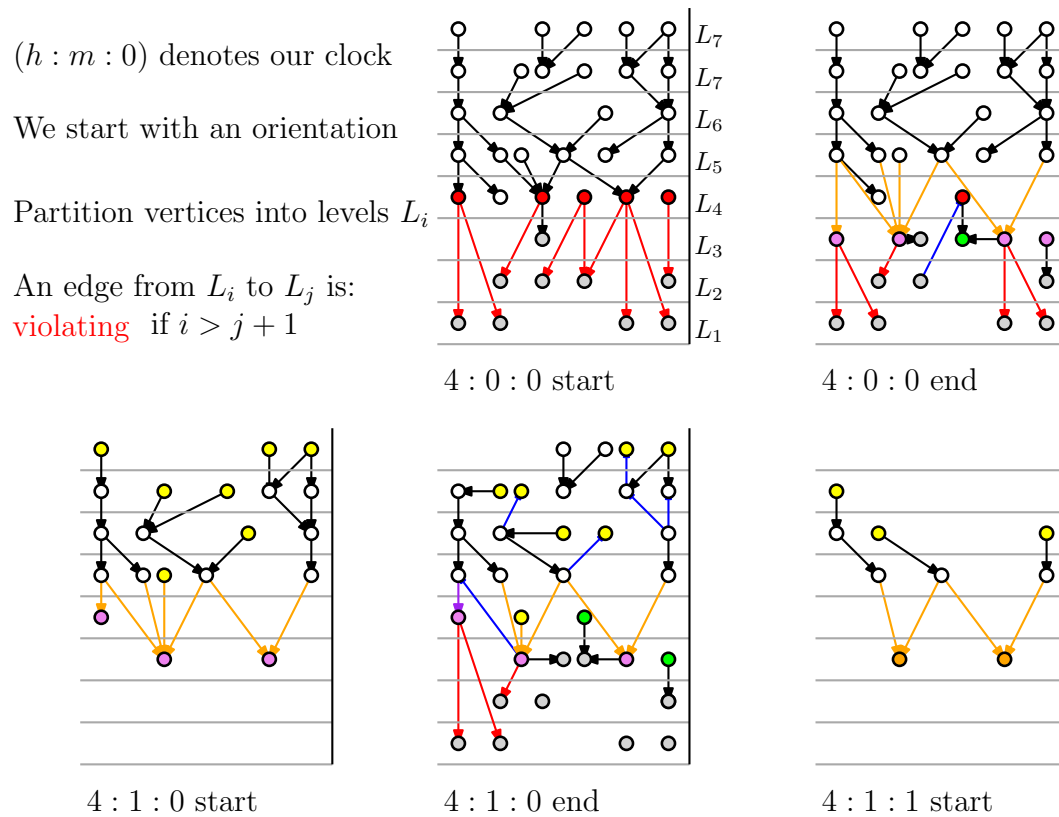

► **Definition 25.** *For any edge \overline{uv} with $g(u \rightarrow v) > 0$, we say that our algorithm is flipping \overline{uv} whenever it decreases $g(u \rightarrow v)$ (increasing $g(v \rightarrow u)$). Moreover, we say that \overline{uv} is flipped whenever our algorithm has decreased $g(u \rightarrow v)$ such that $g(u \rightarrow v) = 0$.*

Algorithm (see also Figure 2 and Algorithms 2 and 3 and 4 and 5). Each time frame has a purpose:

- Each HOUR h , the goal is to identify and “fix” all violating out-edges from vertices in L_h ; without introducing violating out-edges from vertices in a level L_k with $k > h$. We do this iteratively, using two different steps:
 - Each even MINUTE, we fix all violating out-edges from vertices in L_h , possibly creating violating out-edges from vertices in L_{h+1} to vertices in L_{h-1} .
 - Each odd MINUTE, we fix all violating out-edges from vertices in L_{h+1} to vertices in L_{h-1} . We do this in such a manner, that we create no new violating out-edges from vertices in L_k for $k > h$. However, we may create violating out-edges from level L_h .
- Each even MINUTE m' , we define the set $V_{m'} \subset L_h$ of vertices that have at least one violating out-edge. Over $4\lceil \log_{8/7} n \rceil + 2$ rounds, each $u \in V_{m'}$ flips violating out-edges \overline{uv} . Moreover:
 - The out-degree $g(u)$ is decreased such that u drops at most one level, and
 - The out-degree $g(v)$ such that v increases its level up to at most $h - 1$.

We prove that at the end of this MINUTE m' , there exist no more $u \in V_{m'}$ with a violating out-edge. Thus, for each vertex $u \in V_{m'}$, either u decreased one level, or all \overline{uv} that were violating now have that $g(u \rightarrow v) = 0$, or $v \in L_{h-1}$.
- In each odd MINUTE m , we inspect the vertices $T_m := \{u \in V_{m-1} \text{ that dropped a level}\}$. For each $u \in T_m$, for each edge \overline{wu} with $w \in L_{h+1}$ and $g(w \rightarrow u) > 0$ the edge (w, u) has become a violating in the previous MINUTE. We want to fix these edges, whilst guaranteeing that we create no violating in-edges from vertices in level $h + 2$ and above. We obtain this, by recording at the start of the MINUTE for every vertex u its level $l_m(u)$. We then invoke $\ell - h + 1$ SECONDS. Each SECOND s , we create a DAG D_s where the sinks are T_m . We increase for all $u \in T_m$ the out-degree $g(u)$ by flipping a directed path from a source in D_s to T_m . We construct our DAG in such a manner that this procedure does not create new violating in-edges, and that for all SECONDS s , D_{s+1} is a subgraph of D_s .
- At the start of SECOND s of each MINUTE m , we fix for every edge \overline{uv} the values $g_s(u \rightarrow v)$, and the levels $l_s(u)$ and $l_s(v)$ of u and v . We then define a graph $D_s = (V_s, E_s)$ as follows:
 - The edges E_s are all violating in-edges to vertices in T_m plus all \overline{uv} with: $l_s(u) = l_m(u) > h + 1$, $l_s(u) > l_s(v)$, and $g_s(u \rightarrow v) > 0$.
 - The vertices V_s include T_m plus all vertices in G with a directed path to T_m in E_s .

- The vertices $S_s \subset V_s$ are all sources in D_s (these are not in T_m). For each $v \in T_m$ we increase $g(v)$ by flipping a directed path from a vertex in S_s to v . We continue this until either $g(v) = (1 + \frac{\eta}{2})^{h+1}$, or, there exist no more edges $(u, v) \in E_s$ with $g(u \rightarrow v) > 0$. In both cases, v has no more violating in-edges. To find these directed paths, we create a flow problem on a graph D_s^* where the maximal path has length $\ell + 2$:
- For each $u \in S_s$, we define $\sigma(u) = g(u) - (1 + \frac{\eta}{2})^{l_m(u)-1}$ (the maximal amount we can decrease $g(u)$ such that it does not arrive in level $l_m(u) - 2$). We connect every $u \in S_s$ to a unique source s_u where the edge $\overline{s_u u}$ has capacity $\sigma(u)$.
- For each $v \in T_m$, we define $\delta(v) = (1 + \frac{\eta}{2})^{h+1} - g(v)$ (the maximal amount we can increase $g(v)$ such that it does not arrive in level $h + 1$). We connect every $v \in T_m$ to a unique sink t_v where the edge $\overline{v t_v}$ has capacity $\delta(v)$.
- Each other edge $\overline{uv} \in E_s$ has capacity $g(u \rightarrow v)$.

■ **Figure 2** $(4 : 0 : 0)$ – at the first MINUTE start in HOUR 4, we consider all violating out-edges \overline{uv} from level 4 (red). Per definition, these edges point to level 2 or lower.

$(4 : 0 : 0)$ – at the first MINUTE end, either u has dropped a level (pink), v increased their level to $h - 1$ (green) or the edge \overline{uv} is flipped (blue). We consider violating in-edges to pink vertices (orange)

$(4 : 1 : 0)$ – at the first SECOND start, we construct a DAG D_0 where the edges are the orange edges plus black edges. The vertex set are all u with a directed path to a pink vertex ($v \in T_1$). The yellow vertices are S_0 .

$(4 : 1 : 0)$ – at the first SECOND end, edges in the DAG may have flipped (blue), vertices in S_0 may have dropped a level or vertices in T_1 may have increased a level (making some edges no longer violating – purple).

$(4 : 1 : 1)$ – at the second SECOND start, we construct a DAG D_1 . Note that D_1 is a subgraph of D_0 .

7.2 Formal algorithm definition

We now formalise our algorithm top-down, starting with defining variables.

► **Definition 26.** *At the start of $(h, m', 0)$, where m' is even, we fix the set $V_{m'} := \{v \in L_h \mid v \text{ has at least one violating out-edge}\}$. At the start of $(h, m, 0)$ where m is odd, we fix:*

$$T_m := \{v \in V_{m-1} \mid v \text{ decreased by one level in the previous MINUTE and } v \text{ has at least one violating in-edge}\}.$$

Finally, we denote for any vertex u by $l_m(u)$ its level at the start of the MINUTE m .

► **Definition 27.** *At the start of $(h : m : s)$, where m is odd, we fix the following:*

- For any vertex u , we denote by $l_s(u)$ its level at the start of the SECOND.
- For any edge \overline{uv} denote by $g_s(u \rightarrow v)$ the out-degree from u to v at the start of the SECOND.
- We define the edge set E_s as all violating in-edges to vertices in T_m plus all \overline{uv} with: $l_s(u) = l_m(u) > h + 1$, $l_s(u) > l_s(v)$, and $g_s(u \rightarrow v) > 0$.
- V_s are all vertices with a directed path to a vertex in T_m .
- $D_s = (V_s, E_s)$ is a DAG where S_s are all the sources (per definition $S_s \cap T_m = \emptyset$).

► **Definition 28.** *At the start of (h, m, s) where m is odd, given T_m , S_s and D_s , we define the DAG D_s^* by connecting all $u \in S_s$ to a unique sink s_u and all $v \in T_m$ to a unique sink t_v .*

- For $u \in S_s$, the edge $\overline{s_u u}$ has capacity $\sigma(u) = g_s(u) - (1 + \frac{\eta}{2})^{l_m(u)-1}$.
- For $v \in T_m$, the edge $\overline{v t_v}$ has capacity $\delta(v) = (1 + \frac{\eta}{2})^{h+1} - g_s(v)$.
- Each other edge $\overline{uv} \in E_s$ has capacity $g_s(u \rightarrow v)$.

► **Observation 29.** *At the start of $(h : m : s)$ with m odd, if every vertex u is given $l_m(u)$, whether $u \in T_m$, and h , then we may compute all elements of Definitions 27 and 28 in ℓ rounds.*

■ **Algorithm 2** HOUR(h).

```

for  $m = 0$  to  $2\lceil\eta^{-1}\rceil + 2$  do
  if  $m$  is even then
    EVENMINUTE( $h, m$ )
  else
    ODDMINUTE( $h, m$ )
if  $h > 0$  then
  HOUR( $h - 1$ )

```

■ **Algorithm 5** SECOND(int h , int m , int s).

Compute the graph D_s in ℓ rounds.
 Compute the graph D_s^* by adding a shared source to S_s and a shared sink to T_m .
 $f = \text{COMPUTEBLOCKINGFLOW}(D_s^*)$
 Flip all edges in D_s with the corresponding flow in f .

7.3 Proving our algorithm's correctness

Per definition, our algorithm runs in $O(\eta^{-1} \log n \cdot \ell \cdot (\ell + \text{Blocking}(\ell, n))) = O(\varepsilon^{-3} \log^4 n \cdot (\varepsilon^{-2} \log^2 n + \text{Blocking}(\varepsilon^{-2} \log^2 n, n)))$ rounds. What remains is to show that we maintain Invariant 1, which implies that we compute an η -fair orientation.

We note that by the choice of our algorithm's variables, we have the following property:

► **Observation 30.** *For all times $(h : m : s)$ with m odd:*

- *Vertices at level $k > h$ only decrease their level and by at most one (because afterwards, $l_s(u) < l_m(u)$ and thus u has no out-edges in E_s),*
- *vertices at level $h - 1$ only increase their level (by at most 1), and*
- *vertices at level $k' < h - 1$ and level h do not change their level.*

We use this observation in the full version to show that we maintain Invariant 1 by induction. Trivially, Invariant 1 holds at the start of $(\ell : 0 : 0)$. We now assume that the invariant holds at $(h : 0 : 0)$, i.e. that there are no violating out-edges from level L_k with $k > h$. We prove that our algorithm ensures that at the start of $(h - 1 : 0 : 0)$ there are no violating out-edges from level L_k with $k \geq h$.

Moreover, we maintain the invariant that throughout HOUR $(h - 1)$ there are no violating out-edges from level $L_{k'}$ with $k' > h + 1$. We prove this in the following way:

- During $(h : m : s)$ for m even, our algorithm eliminates all violating edges going from L_h . We show that in each iteration, the number of violating edges from L_h drops by a factor $7/8$. The graph has at most n^2 edges. This implies that after the MINUTE, there are no more violating edges going from L_h . However, there may now be violating out-edges from vertices in L_{h+1} to vertices in $T_{m+1} \subseteq L_{h-1}$.
- During $(h : m : s)$ for m odd, our algorithm eliminates all violating edges going from L_{h+1} to T_m . We show that for all s , the DAG D_s is a subgraph of D_{s-1} where the height is one fewer. Since the height of D_s is at most $\ell - h + 1$, this implies that after the MINUTE m , the graph D_s is empty and there are no more violating in-edges to T_m .
- Each MINUTE, our algorithm alternates between having violating edges from L_h and L_{h+1} . We show that our algorithm can alternate at most η times before there are no violating edges from both L_h and L_{h+1} , which implies Invariant 1 at the start of $(h - 1 : 0 : 0)$.

Invariant 1 implies that we compute an η -fair orientation at time $(0 : 0 : 0)$, thus:

► **Theorem 16.** *Suppose one can compute a blocking flow in an n -node h -layered DAG in $\text{Blocking}(h, n)$ rounds. There exists an algorithm in CONGEST that given a unit-weight graph G and $\varepsilon > 0$ computes in $O(\varepsilon^{-3} \log^4 n \cdot (\varepsilon^{-2} \log^2 n + \text{Blocking}(\varepsilon^{-2} \log^2 n, n)))$ rounds an orientation \vec{G} such that for all $v \in V$: $g(v) \in [(1 + \varepsilon)^{-1} \rho^*(v), (1 + \varepsilon) \rho^*(v)]$.*

We plug in the runtime of $\text{Blocking}(h, n)$ of Lemma 21 by Haeupler, Hershkowitz, and Saranurak [21] to obtain the following runtime:

► **Corollary 31.** *There is an algorithm in CONGEST that given a unit-weight graph G and an $\varepsilon > 0$ computes an orientation \vec{G} such that $\forall v \in V$, the out-degree $g(v) \in [(1 + \varepsilon)^{-1}\rho^*(v), (1 + \varepsilon)\rho^*(v)]$ in:*

- $\tilde{O}(\varepsilon^{-11} \log^{12} n)$ rounds with high probability, or
- $\tilde{O}(\varepsilon^{-15} \log^{16} n \cdot 2^{O(\sqrt{\log n})})$ deterministic rounds.

Finally, we apply Corollary 10 which states that $\rho^{\max}(G) = \Delta^{\min}(G) = \max_v g^*(v)$ to conclude:

► **Corollary 32.** *There is a deterministic algorithm in CONGEST that given a unit-weight graph G and an $\varepsilon > 0$, that computes an orientation \vec{G} such that:*

$$\max_{v \in V} g(v) \in [(1 + \varepsilon)^{-1}\rho^{\max}(G), (1 + \varepsilon)\rho^{\max}(G)],$$

in a number of rounds that is sublinear in n .

This is the first deterministic sublinear algorithm that solves Problem 2.2.

Abstract

Proving formula depth lower bounds is a fundamental challenge in complexity theory, with the strongest known bound of $(3 - o(1)) \log n$ established by Håstad over 25 years ago. The Karchmer–Raz–Wigderson (KRW) conjecture offers a promising approach to advance these bounds and separate P from NC¹. It suggests that the depth complexity of a function composition $f \diamond g$ approximates the sum of the depth complexities of f and g .

The Karchmer–Wigderson (KW) relation framework translates formula depth into communication complexity, restating the KRW conjecture as $CC(KW_f \diamond KW_g) \approx CC(KW_f) + CC(KW_g)$. Prior work has confirmed the conjecture under various relaxations, often replacing one or both KW relations with the universal relation or constraining the communication game through strong composition.

In this paper, we examine the strong composition $KW_{\text{XOR}} \otimes KW_f$ of the parity function and a random Boolean function f . We prove that with probability $1 - o(1)$, any protocol solving this composition requires at least $n^{3-o(1)}$ leaves. This result establishes a depth lower bound of $(3 - o(1)) \log n$, matching Håstad’s bound, but is applicable to a broader class of inner functions, even when the outer function is simple. Though bounds for the strong composition do not translate directly to formula depth bounds, they usually help to analyze the standard composition (of the corresponding two functions) which is directly related to formula depth.

Our proof utilizes formal complexity measures. First, we apply Khrapchenko’s method to show that numerous instances of f remain unsolved after several communication steps. Subsequently, we transition to a different formal complexity measure to demonstrate that the remaining communication problem is at least as hard as $KW_{\text{OR}} \otimes KW_f$. This hybrid approach not only achieves the desired lower bound, but also introduces a novel technique for analyzing formula depth, potentially informing future research in complexity theory.

1 Introduction

Proving formula depth lower bounds is an important and difficult challenge in complexity theory: the strongest known lower bound $(3 - o(1)) \log n$ proved by Håstad [6] (following a line of works starting from Subbotovskaya [17, 9, 16]) remains unbeaten for more than 25 years already (in 2014, Tal [18] improved lower order terms in this lower bound). One of the most actively studied approaches to this problem is the one suggested by Karchmer, Raz, and Wigderson [11]. They conjectured that the naive approach of computing a composition of two functions is close to optimal. Namely, for two Boolean functions $f: \{0, 1\}^m \rightarrow \{0, 1\}$ and $g: \{0, 1\}^n \rightarrow \{0, 1\}$, define their composition $f \diamond g: \{0, 1\}^{m \times n} \rightarrow \{0, 1\}$ as a function that first applies g to every row of the input matrix and then applies f to the resulting

26:2 Strong Composition of XOR and a Random Function

column vector. The KRW conjecture then states that $D(f \diamond g)$ is close to $D(f) + D(g)$, where $D(\cdot)$ denotes the minimum depth of a de Morgan formula computing the given function. Karchmer, Raz, and Wigderson [11] proved that if the conjecture is true, then $P \not\subseteq NC^1$, that is, there are functions in P that cannot be computed in logarithmic parallel time.

A convenient way of studying the KRW conjecture is through the framework of Karchmer–Wigderson relation [12]. It not only allows one to apply the tools from communication complexity, but also suggests various important special cases of the conjecture. For a function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, the relation KW_f is defined as follows:

$$KW_f = \{(a, b, i) : a \in f^{-1}(1), b \in f^{-1}(0), i \in [n], a_i \neq b_i\}.$$

The communication complexity $CC(KW_f)$ of this relation is the minimum number of bits that Alice and Bob need to exchange to solve the following communication problem: Alice is given $a \in f^{-1}(1)$, Bob is given $b \in f^{-1}(0)$, and their goal is to find an index $i \in [n]$ such that $(a, b, i) \in KW_f$ (i.e., $a_i \neq b_i$). Karchmer and Wigderson [12] proved that, for any function f , the communication complexity of KW_f is equal to the depth complexity of f : $CC(KW_f) = D(f)$. Within this framework, the KRW conjecture is restated as follows: $CC(KW_f \diamond KW_g)$ is close to $CC(KW_f) + CC(KW_g)$ (where $KW_f \diamond KW_g$ is another name for $KW_{f \diamond g}$).

One natural way of relaxing the conjecture is to replace one or both of the two relations KW_f and KW_g by the universal relation, defined as follows:

$$U_n = \{(a, b, i) : a, b \in \{0, 1\}^n, a \neq b, i \in [n], a_i \neq b_i\}.$$

Using a universal relation instead of the Karchmer–Wigderson relation makes the corresponding communication game only harder, hence proving lower bounds for it is potentially easier and could lead to the resolution of the original conjecture. For this reason, such relaxations have been studied intensively.

Edmonds et al. [4] proved the KRW conjecture for the composition $U_m \diamond U_n$ of two universal relations using communication complexity methods. Håstad and Wigderson [7] improved it for a higher degree of composition using a different approach. Karchmer et al. [11] extended this result to monotone functions. Håstad [6] demonstrated the conjecture for the composition $f \diamond XOR_n$ of an arbitrary function $f: \{0, 1\}^m \rightarrow \{0, 1\}$ with the parity function XOR_n . This was later reaffirmed by Dinur and Meir [3] through a communication complexity approach. Further advancements were made by Gavinsky et al. [5] who established the conjecture for the composition $f \diamond U_n$ of any non-constant function $f: \{0, 1\}^m \rightarrow \{0, 1\}$ with the universal relation U_n . Mihajlin and Smal [15] proved the KRW conjecture for the composition of a universal relation with certain hard functions using XOR-composition. Subsequently, Wu [20] improved this result by extending it to the composition of a universal relation with a wider range of functions (though still not with the majority of them). de Rezende et al. [2] proved the conjecture in a semi-monotone setting for a wide range of functions g .

Another natural way of relaxing the initial conjecture is to constrain the communication game (instead of allowing for more inputs for the game). In the *strong composition* $KW_f \otimes KW_g$, Alice receives $X \in (f \diamond g)^{-1}(1)$ and Bob receives $Y \in (f \diamond g)^{-1}(0)$, and their objective is to identify a pair of indices (i, j) such that $X_{i,j} \neq Y_{i,j}$, similar to the regular composition. However, this time it must hold additionally that $g(X_i) \neq g(Y_i)$.

This way of relaxing the conjecture was considered in a number of previous papers and was formalized recently by Meir [14]. Håstad and Wigderson, in their proof of the lower bound for two universal relations, initially establish the result for what they call the extended

universal relation, a concept closely related to strong composition. Similarly, Karchmer et al. [11] demonstrate that, in the monotone setting, strong composition coincides with the standard composition. de Rezende et al. [2] utilized this notion, although without explicitly naming it. Meir [14] formalized the notion of strong composition in his proof of the relaxation of the KRW conjecture.

► **Theorem 1** (Meir, [14]). *There exists a constant $\gamma > 0.04$ such that for every non-constant function $f: \{0, 1\}^m \rightarrow \{0, 1\}$ and for all $n \in \mathbb{N}$, there exists a function $g: \{0, 1\}^n \rightarrow \{0, 1\}$ such that*

$$\text{CC}(\text{KW}_f \circledast \text{KW}_g) \geq \log \text{CC}(\text{KW}_f) - (1 - \gamma)m + n - O(\log(mn)).$$

1.1 Our Result

Håstad [6] proved the KRW conjecture for $\text{KW}_f \circledast \text{KW}_{\text{XOR}}$. However it is still an open question to prove the KRW conjecture for $\text{KW}_{\text{XOR}} \circledast \text{KW}_f$. In this paper, we study the strong composition $\text{KW}_{\text{XOR}_m} \circledast \text{KW}_f$ of the parity function XOR_m with a random function $f: \{0, 1\}^{\log m} \rightarrow \{0, 1\}$. Since Alice and Bob receive an input of size $m \log m$, we estimate the size of $\text{KW}_{\text{XOR}_m} \circledast \text{KW}_f$ in terms of $n = m \log m$. It is not difficult to see that the communication complexity of the corresponding game is at most $3 \log n$: KW_f can be solved in $\log m$ bits of communication, whereas KW_{XOR_m} can be solved in $2 \log m$ bits of communication, using the standard divide-and-conquer approach (Alice sends the parity of the first half, Bob then identifies the half in which the parity differs, thus, by utilizing 2 bits of communication, the input size is reduced by a factor of two). We prove that if the function f is well balanced and hard to approximate (which happens with probability $1 - o(1)$), then the bound $3 \log n$ is essentially optimal. Below, we state the result in terms of the protocol size (i.e., the number of leaves), rather than depth, since this gives a more general lower bound. In particular, it immediately implies a $(3 - o(1)) \log n$ depth lower bound.

► **Corollary 2.** *With probability $1 - o(1)$, for a random function $f: \{0, 1\}^{\log m} \rightarrow \{0, 1\}$, any protocol solving $\text{KW}_{\text{XOR}_m} \circledast \text{KW}_f$ has at least $n^{3-o(1)}$ leaves, where $n = m \log m$.*

In turn, this result follows from the following general lower bound, given in terms of $\mathbb{L}_{\frac{3}{4}}$ that stands for the smallest size of a formula that agrees with f on a $\frac{3}{4}$ fraction of inputs.

► **Theorem 3.** *For any 0.49-balanced function $f: \{0, 1\}^{\log m} \rightarrow \{0, 1\}$, any protocol solving $\text{KW}_{\text{XOR}_m} \circledast \text{KW}_f$ has at least $n^{2-o(1)} \cdot \mathbb{L}_{\frac{3}{4}}(f)$ leaves, where $n = m \log m$.*

In contrast to many results mentioned above and similarly to the bound by de Rezende et al. [2], our result works for a wide range of inner functions f , what brings us closer to resolving KRW, which makes a claim about the complexity of composing any pair of functions. Also, many of the previous techniques work well in the regime where the outer function is hard and give no strong lower bounds when the outer function is easy (as it is the case with the XOR function). For example, random restrictions (as one of the most successful methods for proving lower bounds) does not seem to give meaningful lower bounds for $\text{KW}_{\text{XOR}_m} \circledast \text{KW}_f$, as under a random restriction this composition turns into a XOR of a small number of variables which is easy to compute. The lower bound by Meir (see Theorem 1) also gives strong lower bounds in the regime where the outer function is hard (and only gives a trivial lower bound of the form $o(\log n)$ for the function that we study).

To prove the lower bound, we exploit formal complexity measures. As in [4, 15], we consider two stages of a protocol solving $\text{KW}_{\text{XOR}_m} \circledast \text{KW}_f$. During the first stage, we track the progress using the classical measure by Khrapchenko [13] and ensure that even after many steps of the

protocol, there are still many instances of f that need to be solved. At the second stage, we switch to another formal complexity measure and show that the remaining communication problem is, roughly, not easier than $\text{KW}_{\text{OR}} \otimes \text{KW}_f$. We believe that this proof technique is interesting on its own, since it is not only easy to show that Khrapchenko's measure cannot give superquadratic size lower bounds, but it is also known that natural generalizations of this measure are also unable to give stronger than quadratic lower bounds [8]. For more details on Khrapchenko's measure and its limitations, see Sections 2.1 and 2.5.

2 Notation, Known Facts, and Technical Lemmas

Throughout the paper, \log denotes the binary logarithm whereas \ln denotes the natural logarithm. By n we usually denote the size of the input. All asymptotic estimates are given under an implicit assumption that n goes to infinity. By $[n]$, we denote the set $\{1, 2, \dots, n\}$. By \mathbb{R}_+ we denote the set $\{x \in \mathbb{R} : x > 0\}$. We utilize the following asymptotic estimates for binomial coefficients. For any constant $0 < \alpha < 1$,

$$\Omega(n^{-1/2})2^{h(\alpha)n} \leq \binom{n}{\alpha n} \leq 2^{h(\alpha)n}, \quad (1)$$

where $h(x) = -x \log x - (1-x) \log(1-x)$ denotes the binary entropy function.

For a string $x \in \{0, 1\}^n$, its i -th bit of x is denoted by x_i . For a matrix $X \in \{0, 1\}^{m \times n}$, by X_i we denote the i -th row of X and by $X_{i,j}$ we denote the bit of X in the intersection of the i -th row and the j -th column.

2.1 Graphs

For a rooted tree, the *depth* of its node is the number of edges on the path from the node to the root; the depth of the tree is the maximum depth of its nodes.

Let $G(V, E)$ be a graph and $\emptyset \neq A \subseteq V$ be its nonempty subset of nodes. By $G[A]$, we denote a subgraph of G induced by A . By $\text{avgdeg}(G, A)$, we denote the average degree of A :

$$\text{avgdeg}(G, A) = \frac{1}{|A|} \sum_{v \in A} \deg(v). \quad (2)$$

For a bipartite graph $G(A \sqcup B, E)$ with nonempty parts, let

$$\psi(G) = \text{avgdeg}(G, A) \cdot \text{avgdeg}(G, B). \quad (3)$$

Clearly, $\psi(G) \leq |A| \cdot |B|$. The lemma below shows that this graph measure is subadditive.

► **Lemma 4.** *Let $G(A \sqcup B, E)$ be a bipartite graph and $A = A_L \sqcup A_R$ be a partition of A into two parts. Let $G_L = G[A_L \sqcup B]$ and $G_R = G[A_R \sqcup B]$. Then,*

$$\psi(G) \leq \psi(G_L) + \psi(G_R).$$

Proof. Let E_L and E_R be the set of edges of G_L and G_R , respectively. Clearly, $E = E_L \sqcup E_R$. Then,

$$\begin{aligned} \psi(G) \leq \psi(G_L) + \psi(G_R) &\iff \frac{|E|^2}{(|A_L| + |A_R|)|B|} \leq \frac{|E_L|^2}{|A_L||B|} + \frac{|E_R|^2}{|A_R||B|} \\ &\iff \frac{|E_L|^2 + |E_R|^2 + 2|E_L||E_R|}{|A_L| + |A_R|} \leq \frac{|E_L|^2}{|A_L|} + \frac{|E_R|^2}{|A_R|} \\ &\iff 2|E_L||E_R||A_L||A_R| \leq |E_R|^2|A_L|^2 + |E_L|^2|A_R|^2 \\ &\iff 0 \leq (|E_R||A_L| - |E_L||A_R|)^2. \quad \blacktriangleleft \end{aligned}$$

The next lemma shows that if G contains a node of small enough degree, then deleting it not only does not drop ψ , but also does not drop too much the average degree of the parts.

► **Lemma 5.** *Let a node $a \in A$ of a bipartite graph $G(A \sqcup B, E)$ satisfy $\deg(G, a) \leq \text{avgdeg}(G, A)/2$ and let $A' = A \setminus \{a\}$ and $G'(A' \sqcup B, E') = G[A \setminus \{a\} \sqcup B]$. Then,*

$$\psi(G') \geq \psi(G), \tag{4}$$

$$\text{avgdeg}(G', A') \geq \text{avgdeg}(G, A), \tag{5}$$

Proof. The inequality $\text{avgdeg}(G', A') \geq \text{avgdeg}(G, A)$ holds since A' results from A by removing a node of degree less than the average degree.

To prove the inequality (4), let $d = \deg(G, a)$. Then, $|E'| = |E| - d$ and

$$\begin{aligned} \psi(G') \geq \psi(G) &\iff \frac{(|E| - d)^2}{(|A| - 1)|B|} \geq \frac{|E|^2}{|A||B|} \\ &\iff \frac{|E|^2 - 2|E|d + d^2}{(|A| - 1)|B|} \geq \frac{|E|^2}{|A||B|} \\ &\iff \frac{|E| - 2d}{|A| - 1} \geq \frac{|E|}{|A|} \\ &\iff |E||A| - 2d|A| \geq |E|(|A| - 1) \\ &\iff d \leq \frac{|E|}{2|A|} = \frac{\text{avgdeg}(G, A)}{2}. \end{aligned} \quad \blacktriangleleft$$

2.2 Boolean Functions

By \mathbb{B}_n , we denote the set of all Boolean functions on n variables. For two disjoint sets $A, B \subseteq \{0, 1\}^n$, the set $A \times B$ is called a *combinatorial rectangle*, and it is called *full* if A and B form a partition of $\{0, 1\}^n$. Clearly, there is a bijection between \mathbb{B}_n and full combinatorial rectangles. For $f \in \mathbb{B}_n$, by $R_f = f^{-1}(1) \times f^{-1}(0)$, we denote the corresponding full rectangle. We say that a Boolean function f is *balanced* if $|f^{-1}(0)| = |f^{-1}(1)|$.

In this paper, it will prove convenient to apply a function $g \in \mathbb{B}_m$ not only to Boolean vectors $x \in \{0, 1\}^m$, but also to matrices $X \in \{0, 1\}^{n \times m}$:

$$g(X) = (g(X_1), \dots, g(X_n)),$$

i.e., $g(X) \in \{0, 1\}^n$ results by applying g to every row of X . This allows to define a composition in a natural way. For $f \in \mathbb{B}_m$ and $g \in \mathbb{B}_n$, their *composition* $f \diamond g: \{0, 1\}^{m \times n} \rightarrow \{0, 1\}$ treats the input as an $m \times n$ matrix and first applies g to all its rows and then applies f to the resulting column-vector:

$$f \diamond g(X) = f(g(X)) = f(g(X_1), \dots, g(X_m)).$$

For a set of matrices $\mathcal{X} \subseteq \{0, 1\}^{m \times n}$, by i -th projection $\text{proj}_i \mathcal{X}$, we denote the set of all i -th rows among the matrices of \mathcal{X} :

$$\text{proj}_i \mathcal{X} = \{X_i: X \in \mathcal{X}\} = \{t \in \{0, 1\}^n: \exists X \in \mathcal{X}: t = X_i\}. \tag{6}$$

In the proof of the main result, we will be dealing with Boolean matrices of dimension $n \times \log n$. Let $\mathcal{X} \subseteq \{0, 1\}^{n \times \log n}$ be a set of such matrices. We say that \mathcal{X} is α -*bounded* if $|\text{proj}_i \mathcal{X}| \leq \alpha n$, for all $i \in [n]$. The i -th projection of \mathcal{X} is called *sparse* if $|\text{proj}_i \mathcal{X}| < \frac{3}{8}n$, and *dense* otherwise. The following lemma shows that if $|\mathcal{X}|$ is large and \mathcal{X} is α -bounded,

26:6 Strong Composition of XOR and a Random Function

then the number of sparse projections of \mathcal{X} is low. Later on, we will be applying this lemma for \mathcal{X} which is almost 0.5-bounded and whose size gradually decreases to argue that the number of sparse projections cannot grow too fast.

► **Lemma 6.** *Let $k \in \mathbb{N}$ and $\alpha \in (\frac{3}{8}, \frac{1}{2}]$. If $\mathcal{X} \subseteq \{0, 1\}^{n \times \log n}$ is α -bounded and $|\mathcal{X}| \geq \alpha^n \frac{n^n}{2^k}$, then the number of sparse projections of \mathcal{X} does not exceed $k \log^{-1} \frac{8\alpha}{3}$.*

Proof. Let $\beta_i \in [0, 1]$ be such that $|\text{proj}_i \mathcal{X}| = \beta_i \alpha n$. The i -th projection is sparse if and only if $\beta_i < \frac{3}{8\alpha}$. Let t be the number of sparse projections and assume, without loss of generality, that the first t projections are sparse. Then,

$$\begin{aligned} \alpha^n \frac{n^n}{2^k} \leq |\mathcal{X}| &\leq \prod_{i=1}^n |\text{proj}_i \mathcal{X}| = (\alpha n)^n \prod_{i=1}^n \beta_i \iff \\ \frac{1}{2^k} &\leq \prod_{i=1}^n \beta_i = \prod_{i=1}^t \beta_i \cdot \prod_{i=t+1}^n \beta_i < \left(\frac{3}{8\alpha}\right)^t \implies k \log^{-1} \frac{8\alpha}{3} \geq t. \quad \blacktriangleleft \end{aligned}$$

2.3 Boolean Formulas

The computational model studied in this paper is *de Morgan formulas*: it is a binary tree whose leaves are labeled by variables x_1, \dots, x_n and their negations whereas internal nodes (called gates) are labeled by \vee and \wedge (binary disjunction and conjunction, respectively). Such a formula *computes* a Boolean function $f(x_1, \dots, x_n) \in \mathbb{B}_n$. We also say that a formula F *separates* a rectangle $A \times B$, if $f(a) = 1$ and $f(b) = 0$, for all $(a, b) \in A \times B$. This way, if a formula F computes a function f , then it separates R_f .

For a formula F , the *size* $L(F)$ is defined as the number of leaves in F . This extends to Boolean functions: for $f \in \mathbb{B}_n$, by $L(f)$ we denote the smallest size of a formula computing f . Similarly, the *depth* $D(F)$ is the depth of the tree whereas $D(f)$ is the smallest depth of a formula computing f .

By $L_{\frac{3}{4}}(f)$, we denote the smallest size of a formula F that agrees with f on a $\frac{3}{4}$ fraction of inputs, i.e.,

$$\Pr_{x \in \{0,1\}^n} [F(x) = f(x)] \geq \frac{3}{4}.$$

We say that F *approximates* f .

It is known that formulas can be balanced: $D(f) = \Theta(\log L(f))$ (see references in [10, Section 6.1]): this is proved by showing that, for any formula F , there exists an equivalent formula F' with $L(F') \leq L(F)^{O(1)}$ and $D(F') \leq O(\log L(F))$. The following theorem further refines this: by allowing a larger constant in the depth upper bound, one can control the size of the resulting balanced formula.

► **Theorem 7** ([1]). *For any $k \geq 2$ and any formula F , there exists an equivalent formula F' satisfying $D(F') \leq 3 \ln 2 \cdot k \cdot \log L(F)$ and $L(F') \leq L(F)^\gamma$, where $\gamma = 1 + \frac{1}{1 + \log(k-1)}$.*

Using a counting argument, one can show that, with probability $1 - o(1)$, for a random Boolean function $f \in \mathbb{B}_n$, $L(f) = \Omega(2^n / \log n)$. To prove this, one compares the number of small size formulas with the number of Boolean functions $|\mathbb{B}_n| = 2^{2^n}$, using the following estimate (see [10, Lemma 1.23]). It ensures that the number of formulas of size at most $\frac{2^n}{100 \log n}$ is $o(|\mathbb{B}_n|)$:

$$(17n)^{\frac{2^n}{100 \log n}} = 2^{\frac{\log(17n)}{100 \log n} 2^n}.$$

► **Lemma 8.** For all large enough l , the number of Boolean formulas over n variables with at most l leaves is at most

$$(17n)^l. \tag{7}$$

Proof. The number of binary trees with l leaves is at most 4^l . For each such tree, there are at most $(4n)^l$ ways to convert it into a de Morgan formula: there are $2n$ input literals for the leaves and two operations for each internal gate. Consequently, the total number of formulas with at most l leaves is at most

$$l \cdot 4^l \cdot (4n)^l = l \cdot 16^l \cdot n^l \leq (17n)^l,$$

which is true for $l \geq 71$. ◀

We say that $f \in \mathbb{B}_n$ is α -balanced if

$$\alpha \cdot 2^n \leq |f^{-1}(0)|, |f^{-1}(1)| \leq (1 - \alpha) \cdot 2^n$$

i.e., $||f^{-1}(0)| - |f^{-1}(1)|| \leq (1 - 2\alpha)2^n$.

► **Lemma 9.** For all sufficiently large n and any constant $\frac{3}{8} < \alpha < \frac{1}{2}$, a random function $f \in \mathbb{B}_n$ is α -balanced and $L_{\frac{3}{4}}(f) = \Omega(\frac{2^n}{\log n})$, with probability $1 - o(1)$.

Proof. For a formula over n variables, the number of Boolean functions it approximates is at most (by the estimate (1))

$$\sum_{d=3 \cdot 2^{n/4}}^{2^n} \binom{2^n}{d} = \sum_{d=0}^{2^n/4} \binom{2^n}{d} \leq 2^n \binom{2^n}{2^n/4} \leq 2^n \cdot 2^{h(1/4)2^n}.$$

Combining this with (7), we get that the number of functions approximated by formulas of size $\beta \frac{2^n}{\log n}$ is at most

$$(17n)^{\beta \frac{2^n}{\log n}} 2^n 2^{h(1/4)2^n} = 2^{2^n(\beta \frac{\log(17n)}{\log n} + h(1/4)) + n}.$$

For any constant $0 < \beta < 1 - h(1/4)$, this is a $o(1)$ fraction of \mathbb{B}_n .

Now, the probability that a random $f \in \mathbb{B}_n$ is not α -balanced (i.e., $||f^{-1}(0)| - |f^{-1}(1)|| > (1 - 2\alpha) \cdot 2^n$) is at most

$$\frac{1}{2^{2^n}} \cdot 2 \cdot \sum_{i=0}^{\alpha \cdot 2^n - 1} \binom{2^n}{i} \leq \frac{1}{2^{2^n}} \cdot 2 \cdot \alpha \cdot 2^n \cdot \binom{2^n}{\alpha \cdot 2^n} \leq 2^{2^n(h(\alpha) - 1) + n + 1} = o(1).$$

Thus, with probability $1 - o(1)$, a random $f \in \mathbb{B}_n$ is α -balanced and hard to approximate. ◀

2.4 Karchmer–Wigderson Games

Karchmer and Wigderson [12] came up with the following characterization of Boolean formulas. For a Boolean function $f \in \mathbb{B}_n$, the *Karchmer–Wigderson game* KW_f is the following communication problem. Alice is given $a \in f^{-1}(1)$, whereas Bob is given $b \in f^{-1}(0)$, and their goal is to find an index $i \in [n]$ such that $a_i \neq b_i$. A *communication protocol* for KW_f is a rooted binary tree whose leaves are labeled with indices from $[n]$ and each internal node v is labeled either by a function $A_v: f^{-1}(1) \rightarrow \{0, 1\}$ or by a function $B_v: f^{-1}(0) \rightarrow \{0, 1\}$. For any pair $(a, b) \in f^{-1}(1) \times f^{-1}(0)$, one can reach a leaf of the protocol by traversing

a path from the root to a leaf to determine to which of the two children to proceed from a node v , one computes either $A_v(a)$ or $B_v(b)$. We say that a protocol *solves* KW_f , if for any $(a, b) \in f^{-1}(1) \times f^{-1}(0)$, one reaches a leaf $i \in [n]$ such that $a_i \neq b_i$. Similarly to formulas, we say that a protocol separates a combinatorial rectangle $A \times B$, if it works correctly for all pairs $(a, b) \in A \times B$.

Karchmer and Wigderson showed that formulas computing f and protocols solving KW_f can be transformed (even mechanically) into one another. In particular, the smallest number of leaves in the protocol solving KW_f is equal to $L(f)$, whereas the smallest depth of a protocol (also known as the communication complexity of KW_f , denoted by $\text{CC}(\text{KW}_f)$) is nothing else but $D(f)$. By $L(A \times B)$ for a combinatorial rectangle $A \times B$, we denote the minimum number of leaves in a protocol separating A and B .

With each node of a protocol solving KW_f , one can associate a combinatorial rectangle in a natural way. The root of the protocol corresponds to R_f . For the two children of Alice's node v with a rectangle $A \times B$, one associates two rectangles $A_0 \times B$ and $A_1 \times B$, where $A_i = \{a \in A : A_v(a) = i\}$. This way, Alice splits the current rectangle horizontally. Similarly, when Bob speaks, he splits the current rectangle vertically. Each leaf of a protocol solving KW_f is associated with a *monochromatic* rectangle, i.e., a rectangle $A \times B$ such that there exists $i \in [n]$ for which $a_i \neq b_i$ for all $(a, b) \in A \times B$.

For functions $f \in \mathbb{B}_m$ and $g \in \mathbb{B}_n$, the *strong composition* of KW_f and KW_g , denoted as $\text{KW}_f \otimes \text{KW}_g$, is the following communication problem: Alice and Bob receive inputs $X \in (f \diamond g)^{-1}(1)$ and $Y \in (f \diamond g)^{-1}(0)$, respectively, and need to find indices (i, j) such that $X_{i,j} \neq Y_{i,j}$ and $g(X_i) \neq g(Y_j)$. We say that a protocol *strongly separates* sets $\mathcal{X} \subseteq (f \diamond g)^{-1}(1)$ and $\mathcal{Y} \subseteq (f \diamond g)^{-1}(0)$, if it solves the strong composition $\text{KW}_f \otimes \text{KW}_g$ on inputs $\mathcal{X} \times \mathcal{Y}$.

2.5 Formal Complexity Measures

For $f \in \mathbb{B}_n$, define a bipartite graph $G_f(f^{-1}(1) \sqcup f^{-1}(0), E_f)$ as follows:

$$E_f = \{\{u, v\} : u \in f^{-1}(1), v \in f^{-1}(0), d_H(u, v) = 1\},$$

where d_H is the Hamming distance. Khrapchenko [13] proved that, for any $f \in \mathbb{B}_n$, $\psi(G_f) \leq L(f)$ (recall (3) for the definition of $\psi(G)$). This immediately gives a lower bound $L(\text{XOR}_n) \geq n^2$. Note the two useful properties of $\psi(G_f)$: on the one hand, it is a lower bound to $L(f)$, on the other hand, it is much easier to estimate than $L(f)$.

Paterson [19, Section 8.8] noted that Khrapchenko's approach can be cast as follows. A function $\mu: \mathbb{B}_n \rightarrow \mathbb{R}_+$ is called a *formal complexity measure* if it satisfies the following two properties:

1. normalization: $\mu(x_i), \mu(\bar{x}_i) \leq 1$, for all $i \in [n]$,
 2. subadditivity: $\mu(f \vee g) \leq \mu(f) + \mu(g)$ and $\mu(f \wedge g) \leq \mu(f) + \mu(g)$, for all $f, g \in \mathbb{B}_n$.
- Note that Khrapchenko's measure can be defined in this notation as $\phi(f) = \psi(G_f)$. Its subadditivity is shown in Lemma 4, whereas the normalization property can be easily seen.

It is not difficult to see that L itself is a formal complexity measure. Moreover, it turns out that it is the largest formal complexity measure.

► **Lemma 10** (Lemma 8.1 in [19]). *For any formal complexity measure $\mu: \mathbb{B}_n \rightarrow \mathbb{R}$ and any $f \in \mathbb{B}_n$, $\mu(f) \leq L(f)$.*

3 Proof of the Main Result

In this section, we prove the main result of the paper.

► **Theorem 3.** *For any 0.49-balanced function $f: \{0, 1\}^{\log m} \rightarrow \{0, 1\}$, any protocol solving $\text{KW}_{\text{XOR}_m} \otimes \text{KW}_f$ has at least $n^{2-o(1)} \cdot \mathsf{L}_{\frac{3}{4}}(f)$ leaves, where $n = m \log m$.*

► **Corollary 2.** *With probability $1 - o(1)$, for a random function $f: \{0, 1\}^{\log m} \rightarrow \{0, 1\}$, any protocol solving $\text{KW}_{\text{XOR}_m} \otimes \text{KW}_f$ has at least $n^{3-o(1)}$ leaves, where $n = m \log m$.*

Proof. Lemma 9 guarantees that for a random function $f: \{0, 1\}^{\log m} \rightarrow \{0, 1\}$, f is 0.49-balanced and $\mathsf{L}_{\frac{3}{4}}(f) = \Omega(m / \log \log m)$ with probability $1 - o(1)$. Plugging this into Theorem 3 gives the required lower bound. ◀

3.1 Proof Overview

We start by proving a lower bound on the size of any protocol solving $\text{KW}_{\text{XOR}_m} \otimes \text{KW}_f$ and having a logarithmic depth. Then, using balancing techniques (see Theorem 7), we generalize the size lower bound to all protocols.

Fix a set $\mathcal{Z} \subseteq \{0, 1\}^{\log m}$ such that $|\mathcal{Z}| = 0.98m$ and f is balanced on \mathcal{Z} : $|\mathcal{X}_0| = |\mathcal{Y}_0| = 0.49m$, where $\mathcal{X}_0 = f^{-1}(1) \cap \mathcal{Z}$ and $\mathcal{Y}_0 = f^{-1}(0) \cap \mathcal{Z}$.

We prove a lower bound for any protocol that strongly separates $\text{KW}_{\text{XOR}_m} \otimes \text{KW}_f$ on inputs $\mathcal{X}_T \times \mathcal{Y}_T$ (which are defined later). To this end, we associate, with nodes of the protocol, a graph similar to G_{XOR_m} and use Khrapchenko’s measure to track the progress of the protocol. A node of the graph is associated with all inputs X having the same vector $f(X)$. The reasoning is that, in a natural scenario, the protocol will first solve XOR_m , followed by solving f , implying that the protocol does not need to distinguish between X and X' in the initial rounds, if $f(X) = f(X')$. We connect two graph nodes by an edge if their vectors differ in exactly one coordinate.

We aim to ensure that each edge in the graph has a large projection: for any two nodes connected by an edge, the elements of blocks associated with them cover a substantial number of inputs for the function f . There will be no small protocol capable of solving the problem within these two blocks since f is hard to approximate. This is the rationale behind ensuring that all edges in the graph have large projections on both sides. To achieve this, we enforce that each block that is associated with a node shrinks by at most a factor of two at each step of the protocol. This process ensures that a significant number of edges in the graph will maintain large projections on both sides.

Once the Khrapchenko measure becomes sufficiently small, we can assert that XOR_m is nearly solved, and the protocol, in a sense, must now solve an instance of $\text{OR}_d \otimes f$. Using the fact that solving each edge independently is hard, we conclude that solving an $\text{OR}_d \otimes f$ over these edges should be as difficult as approximately $d \cdot \mathsf{L}_{\frac{3}{4}}(f)$.

3.2 Proof

Throughout this section, we assume that m is large enough and $f \in \mathbb{B}_{\log m}$ is a fixed function that is 0.49-balanced. Fix sets $\mathcal{X}_0 \subseteq f^{-1}(1)$, $\mathcal{Y}_0 \subseteq f^{-1}(0)$ of size $0.49m$ and let

$$\mathcal{X}_T = \{X \in \{0, 1\}^{m \times \log m} : (\text{XOR}_m \diamond f)(X) = 1 \wedge X_i \in \mathcal{X}_0 \sqcup \mathcal{Y}_0, \forall i \in [m]\}, \quad (8)$$

$$\mathcal{Y}_T = \{Y \in \{0, 1\}^{m \times \log m} : (\text{XOR}_m \diamond f)(Y) = 0 \wedge Y_i \in \mathcal{X}_0 \sqcup \mathcal{Y}_0, \forall i \in [m]\}. \quad (9)$$

Let $\alpha > 0$ be a constant and P be a protocol that strongly separates $\mathcal{X}_T \times \mathcal{Y}_T$ and has depth at most $\alpha \log m$. Recall that each node S of P is associated with a rectangle $\mathcal{X}_S \times \mathcal{Y}_S$. We build a subtree D of P having the same root and associate a graph G_N to every node N of D . The graphs G_N are built inductively from the graphs associated with the parents of N

26:10 Strong Composition of XOR and a Random Function

as explained below, but all these graphs are subsets of the m -dimensional hypercube: the set of nodes of each such graph is a subset of $\{0, 1\}^m$ and for each edge $\{u, v\}$ it holds that $d_H(u, v) = 1$.

For the root T of the protocol P , the graph G_T is simply G_{XOR_m} (which is nothing else but the m -dimensional hypercube): its set of nodes is $\{0, 1\}^m$, two nodes are joined by an edge with label i if they differ in the i -th coordinate.

For any node v of the graph G_S , we associate the following set of inputs called *block*:

$$\mathcal{B}_S(v) = \{X \in \{0, 1\}^{m \times \log m} : X \in \mathcal{X}_S \sqcup \mathcal{Y}_S \text{ and } f(X) = v\}.$$

We say that an edge $\{u, v\}$ with label i of G_S is *heavy* if the projection of both $\mathcal{B}_S(u)$ and $\mathcal{B}_S(v)$ onto the i th coordinate is dense, i.e.,

$$|\text{proj}_i \mathcal{B}_S(u)|, |\text{proj}_i \mathcal{B}_S(v)| \geq \frac{3}{8}m,$$

and *light* otherwise.

Since the nodes of the graph G_S form a subset of $\{0, 1\}^m$, we can naturally divide them into two parts, as their blocks correspond to subsets of either \mathcal{X}_S or \mathcal{Y}_S .

$$A_S = \{v \in V(G_S) \mid \text{XOR}_m(v) = 1\}$$

$$B_S = \{v \in V(G_S) \mid \text{XOR}_m(v) = 0\}$$

For a graph G_S , we define $d_A(G_S)$ as the average degree of the part A_S and $d_B(G_S)$ as the average degree of the part B_S . We say that a graph G_S is *special* if

$$\min\{d_A(G_S), d_B(G_S)\} \leq 12\alpha \log^2 m.$$

We will construct the tree D inductively. For a node S in the tree D , we either stop the process if G_S is special, or construct the two children of S from the protocol P and their graphs. We continue building D on these two children inductively. Hence, all graphs corresponding to internal nodes of the tree D are not special, while all graphs associated with leaves of D are special.

► **Definition 11.** A graph G_S , associated with a node S in the tree D , is adjusted if all its edges are heavy and

$$\deg(v) > \frac{d_A(G_S)}{2}, \forall v \in A_S \quad \text{and} \quad \deg(v) > \frac{d_B(G_S)}{2}, \forall v \in B_S. \quad (10)$$

We will ensure that all graphs G_S for any node S in the tree D are adjusted.

► **Lemma 12.** For each node v of the graph G_T (associated with the root T of the protocol P),

1. the degree of v is m ;
2. $|\text{proj}_i \mathcal{B}_T(v)| = 0.49m$, for all $i \in [m]$;
3. $|\mathcal{B}_T(v)| = \frac{(0.98m)^m}{2^m}$.

Proof. Nodes of G_T are m -dimensional binary vectors, hence $\deg(v) = m$.

To prove the second property, recall that f is balanced on $\mathcal{X}_0 \sqcup \mathcal{Y}_0$. If $v_i = 1$ (or $v_i = 0$), for some $i \in [m]$, the i -th projection can take any value from \mathcal{X}_0 (\mathcal{Y}_0 , respectively). Hence, $|\text{proj}_i \mathcal{B}_T(v)| = 0.49m$.

Finally, to prove the third property, note the G_T has 2^m nodes and for each vertex v the size of the block $\mathcal{B}_T(v)$ is at most $(0.49m)^m$. Therefore, since each input from $\mathcal{X}_T \sqcup \mathcal{Y}_T$ belongs to exactly one block that is associated with a node from G_T and $|\mathcal{X}_T \sqcup \mathcal{Y}_T| = |\mathcal{X}_0 \sqcup \mathcal{Y}_0|^m = (0.98m)^m$, $|\mathcal{B}_T(v)| = \frac{(0.98m)^m}{2^m}$. ◀

Lemma 12 ensures that the graph G_T is adjusted and not special, thus the root T has two children. Using the function \mathcal{B} , we show how to construct an intermediate graph H_N for some child of a node S in the tree D and then we apply some cleanup procedures for the graph H_N to construct a graph G_N . Recall that each step of P partitions the set of either Alice's or Bob's inputs into two parts. Let G_S be a graph for some node S of the protocol P that is associated with a rectangle $\mathcal{X}_S \times \mathcal{Y}_S$ and assume, without loss of generality, that it is Alice's turn. Therefore, graph G_S is not special, otherwise we will stop the building process of the subtree of S . Let S_L be the left child of S in the protocol P and S_R be the right child. We add the same children of the node S in the tree D . Then, we put v from B_S into both H_{S_L} and H_{S_R} (since the block $\mathcal{B}_S(v)$ has not changed). For each node $v \in A_S$ we decide in which of the two graphs we will put it. The block $\mathcal{B}_S(v)$ is also split into two: $\mathcal{B}_{S_L}(v)$ and $\mathcal{B}_{S_R}(v)$, corresponding to the two ways of the protocol. We assign v to the left graph H_{S_L} if $2 \cdot |\mathcal{B}_{S_L}(v)| \geq |\mathcal{B}_S(v)|$, and to the right graph H_{S_R} if $2 \cdot |\mathcal{B}_{S_R}(v)| > |\mathcal{B}_S(v)|$. An edge $\{u, v\}$ from the edges of G_S goes to H_{S_L} if and only if both u and v are assigned to H_{S_L} . The same rule applies for edges in H_{S_R} . This approach ensures that the size of each block $\mathcal{B}_S(v)$ shrinks by at most a factor of two when transitioning from a parent to a child in the tree D . Then, the graphs G_{S_L} and G_{S_R} will be built using graphs H_{S_L} and H_{S_R} , respectively.

The idea of the structure of the graph G_S arises from Khrapchenko's graph, so we will use the same measure:

$$\psi(G_S) = d_A(G_S) \cdot d_B(G_S).$$

Lemma 4 states that ψ is subadditive.

After obtaining the graph H_C for a node C of the tree D , we make our first cleanup by deleting all light edges: let H'_C be a graph resulting from H_C by removing all its light edges. The next lemma shows that this does not drop the measure ψ too much.

► **Lemma 13.**

$$\psi(H'_C) \geq \psi(H_C) \left(1 - \frac{1}{\log m}\right).$$

Proof. Let S be the parent of C in D . Since S is not a leaf, we have that $\min\{d_A(G_S), d_B(G_S)\} > 12\alpha \log^2 m$ and the degree of every node in G_S is at least half of the average degree of its part. Without loss of generality, assume that inputs were deleted from \mathcal{X}_S , and therefore $d_A(H_C) \geq \frac{d_A(G_S)}{2} > 6\alpha \log^2 m$.

An edge $\{u, v\}$ can become light because of only one of its endpoints, because the blocks on the other side remain unchanged. From Lemma 12, we know that the initial size of each block is $(0.49m)^m$, and after each step of the protocol, the size of a block shrinks by at most a factor of two. Hence, for any node v , the size of its block $\mathcal{B}_S(v)$ is at least $\frac{(0.49m)^m}{2^{\alpha \log m}}$, because the protocol depth is bounded by $\alpha \log m$. Hence, we can bound the number of light edges incident to v by $3\alpha \log m$ using Lemma 6 (since $\log^{-1}(8 \cdot 0.49/3) < 3$). Therefore,

$$d_A(H'_C) \geq d_A(H_C) - 3\alpha \log m.$$

Now, consider $d_B(H'_C)$. Let E_C be the set of edges in H_C , whereas A_C and B_C be its parts of nodes. Then,

$$d_B(H'_C) \geq \frac{E_C - |A_C| \cdot 3\alpha \log m}{|B_C|} = d_B(H_C) - 3\alpha \log m \frac{|A_C|}{|B_C|}.$$

26:12 Strong Composition of XOR and a Random Function

Hence,

$$\begin{aligned}
\psi(H'_C) &= d_A(H'_C)d_B(H'_C) \geq (d_A(H_C) - 3\alpha \log m) \left(d_B(H_C) - 3\alpha \log m \frac{|A_C|}{|B_C|} \right) \\
&\geq \psi(H_C) - 3\alpha d_B(H_C) \log m - \frac{3\alpha |A_C| d_A(H_C) \log m}{|B_C|} \\
&= \psi(H_C) \left(1 - \frac{3\alpha \log m}{d_A(H_C)} - \frac{3\alpha |A_C| \log m}{|B_C|} \right) \\
&= \psi(H_C) \left(1 - \frac{6\alpha \log m}{d_A(H_C)} \right) \\
&> \psi(H_C) \left(1 - \frac{6\alpha \log m}{6\alpha \log^2 m} \right) = \psi(H_C) \left(1 - \frac{1}{\log m} \right). \quad \blacktriangleleft
\end{aligned}$$

The next lemma shows how to construct an adjusted graph G_C , from the intermediate graph H'_C .

► **Lemma 14.** *There exists a subgraph G_C of the graph H'_C such that G_C is adjusted and $\psi(G_C) \geq \psi(H_C) \left(1 - \frac{1}{\log m} \right)$.*

Proof. To get G_C , we keep removing nodes from H'_C until it satisfies (10). If (10) is violated, there exists, without loss of generality, a node $v \in A_C$ such that $\deg(v) \leq \frac{d_A(G_C)}{2}$. Let $G'_C = G_C \setminus \{v\}$. Lemma 5 guarantees that this does not decrease the measure. This process is clearly finite. ◀

This way, we construct the graph G_C for the node C . If C is not special, we continue expanding the subtree rooted at C . Recall also that, for each internal node S of the tree D , whose children are S_L and S_R , the following holds:

$$\psi(G_S) \leq \psi(H_{S_L}) + \psi(H_{S_R}).$$

Hence, combining it with Lemma 14 we have:

$$\psi(G_S) \left(1 - \frac{1}{\log m} \right) \leq \psi(G_{S_L}) + \psi(G_{S_R}). \quad (11)$$

On the other hand, if S is special, we will use the following two lemmas to argue that strongly separating $\mathcal{X}_S \times \mathcal{Y}_S$ is still difficult.

► **Lemma 15.** *Let S be a node of the tree D such that it has a node $v \in G_S$ having d adjacent edges. Then, any protocol that strongly separates \mathcal{X}_S and \mathcal{Y}_S has at least $\Omega \left(d \cdot L_{\frac{3}{4}}(f) \right)$ leaves.*

Proof. Consider the subgraph of G_S induced by v and its neighbors u_1, \dots, u_d connected to v . Denote by l_i the label of the edge $\{v, u_i\}$. Define a measure ξ on subrectangles of $\mathcal{X}_S \times \mathcal{Y}_S$:

$$\xi(\mathcal{X} \times \mathcal{Y}) = \sum_{i=1}^d L(\text{proj}_{l_i} \mathcal{B} \times \text{proj}_{l_i} \mathcal{B}_i),$$

where $\mathcal{X} \subseteq \mathcal{X}_S$, $\mathcal{Y} \subseteq \mathcal{Y}_S$, $\mathcal{B} = \mathcal{X} \cap \mathcal{B}_S(v)$ and $\mathcal{B}_i = \mathcal{Y} \cap \mathcal{B}_S(u_i)$, for all $i \in [d]$. By KW($A \times B$), for any $A \cap B = \emptyset$, we denote a Karchmer-Wigderson communication game where Alice gets $a \in A$, Bob gets $b \in B$, and they need to find $i: a_i \neq b_i$. We prove that any protocol strongly separating $\mathcal{X}_S \times \mathcal{Y}_S$ requires at least $\xi(\mathcal{X}_S \times \mathcal{Y}_S)$ leaves.

It is easy to see that ξ is subadditive, being a sum of subadditive measures: if $\mathcal{X} = \mathcal{X}' \sqcup \mathcal{X}''$, then $\xi(\mathcal{X} \times \mathcal{Y}) \leq \xi(\mathcal{X}' \times \mathcal{Y}) + \xi(\mathcal{X}'' \times \mathcal{Y})$ and the same applies when we split \mathcal{Y} . Namely, let $\mathcal{Y} = \mathcal{Y}' \sqcup \mathcal{Y}''$, $\mathcal{B}_i = \mathcal{Y}' \cap \mathcal{B}_S(u_i)$, and $\mathcal{B}_i'' = \mathcal{Y}'' \cap \mathcal{B}_S(u_i)$. Then,

$$\begin{aligned} \xi(\mathcal{X} \times \mathcal{Y}' \sqcup \mathcal{Y}'') &= \sum_{i=1}^d \mathsf{L}(\text{proj}_{l_i} \mathcal{B} \times \text{proj}_{l_i} \mathcal{B}'_i \sqcup \mathcal{B}''_i) \\ &\leq \sum_{i=1}^d \mathsf{L}(\text{proj}_{l_i} \mathcal{B} \times \text{proj}_{l_i} \mathcal{B}'_i) + \sum_{i=1}^d \mathsf{L}(\text{proj}_{l_i} \mathcal{B} \times \text{proj}_{l_i} \mathcal{B}''_i) \\ &= \xi(\mathcal{X} \times \mathcal{Y}') + \xi(\mathcal{X} \times \mathcal{Y}''). \end{aligned}$$

Consider a protocol P' strongly separating $\mathcal{X}_S \times \mathcal{Y}_S$ and its leaf L associated with a rectangle of inputs $\mathcal{X}'_L \times \mathcal{Y}'_L$. We show that $\xi(\mathcal{X}'_L \times \mathcal{Y}'_L) \leq 1$. Since L is a leaf, there exists i, j such that for each $X \in \mathcal{X}'_L$ and $Y \in \mathcal{Y}'_L$:

$$X_{i,j} \neq Y_{i,j} \quad \text{and} \quad f(X_i) \neq f(Y_i).$$

Let k be such that $\mathcal{B}_k \neq \emptyset$ (if all \mathcal{B}_t are empty, then $\xi = 0$). Then, $\mathcal{B}(u_t) = \emptyset$, for all $t \neq k$, as otherwise there would be no i such that $f(X_i) \neq f(Y_i)$ for all $(X, Y) \in \mathcal{X}'_L \times \mathcal{Y}'_L$, since u_k differs from v in the position l_k , and u_t differs from v in the position l_t and $l_k \neq l_t$. Thus, if $\xi(\mathcal{X}'_L \times \mathcal{Y}'_L) > 1$, then $\mathsf{L}(\text{proj}_{l_k} \mathcal{B} \times \text{proj}_{l_k} \mathcal{B}_k) > 1$, which contradicts to the existence of a pair (i, j) .

Thus, ξ is normal (has the value at most 1 for any leaf of any protocol that strongly separates $\mathcal{X}_S \times \mathcal{Y}_S$) and subadditive. Hence, its value for the whole protocol P' is a lower bound on the size of P' . Thus, it remains to estimate ξ for P' .

Since all d edges are heavy, we have:

$$|\text{proj}_{l_i} \mathcal{B}_S(v)| + |\text{proj}_{l_i} \mathcal{B}_S(u_i)| \geq \frac{3}{4}m, \quad \forall i \in [d].$$

Hence,

$$\mathsf{L}(\text{proj}_{l_i} \mathcal{B}_S(v) \times \text{proj}_{l_i} \mathcal{B}_S(u_i)) = \Omega\left(\mathsf{L}_{\frac{3}{4}}(f)\right),$$

for all $i \in [d]$. Summing over all $i \in [d]$, gives the desired lower bound. \blacktriangleleft

► **Lemma 16.** *For a special node S of the tree D , the number of leaves in any protocol strongly separating $\mathcal{X}_S \times \mathcal{Y}_S$ is*

$$\Omega\left(\frac{\psi(G_S) \cdot \mathsf{L}_{\frac{3}{4}}(f)}{\log^2 m}\right).$$

Proof. Assume, without loss of generality, that

$$d_A(G_S) \geq d_B(G_S) \quad \text{and} \quad d_B(G_S) \leq 12\alpha \log^2 m.$$

Applying Lemma 15 to a node of degree at least $d_A(G_S)$, we get that the number of leaves is at least

$$\Omega\left(d_A(G_S) \cdot \mathsf{L}_{\frac{3}{4}}(f)\right) = \Omega\left(\frac{\psi(G_S)}{d_B(G_S)} \cdot \mathsf{L}_{\frac{3}{4}}(f)\right) = \Omega\left(\frac{\psi(G_S) \cdot \mathsf{L}_{\frac{3}{4}}(f)}{\log^2 m}\right). \quad \blacktriangleleft$$

At this point, everything is ready to lower bound the size of any protocol of logarithmic depth.

26:14 Strong Composition of XOR and a Random Function

► **Theorem 17.** *The size of the protocol P (strongly separating $\mathcal{X}_T \times \mathcal{Y}_T$) is*

$$\Omega\left(\frac{m^2 \cdot \mathbb{L}_{\frac{3}{4}}(f)}{\log^2 m} \left(1 - \frac{1}{\log m}\right)^{\alpha \log m}\right).$$

Proof. Lemma 16 states that the number of leaves needed to resolve any leaf S of the tree D is $\Omega\left(\psi(G_S) \cdot \mathbb{L}_{\frac{3}{4}}(f) / \log^2 m\right)$. Let \mathcal{S} be the set of all leaves of the tree D . Using estimate (11), we have:

$$\psi(G_T) \cdot \left(1 - \frac{1}{\log m}\right)^{\alpha \log m} \leq \sum_{S \in \mathcal{S}} \psi(G_S).$$

Since $\psi(G_T) = m^2$ (by Lemma 12), Then, the number of leaves in P is

$$\Omega\left(\sum_{S \in \mathcal{S}} \frac{\psi(G_S) \cdot \mathbb{L}_{\frac{3}{4}}(f)}{\log^2 m}\right) \geq \Omega\left(\frac{m^2 \cdot \mathbb{L}_{\frac{3}{4}}(f)}{\log^2 m} \left(1 - \frac{1}{\log m}\right)^{\alpha \log m}\right). \quad \blacktriangleleft$$

Recall that α is a constant. Assuming $m \geq 4$, we have $\log m \geq 2$, and thus $1 - \frac{1}{\log m} \geq e^{-\frac{2}{\log m}}$. Then,

$$\frac{m^2 \cdot \mathbb{L}_{\frac{3}{4}}(f)}{\log^2 m} \left(1 - \frac{1}{\log m}\right)^{\alpha \log m} \geq \frac{m^2 \cdot \mathbb{L}_{\frac{3}{4}}(f)}{\log^2 m} e^{-\frac{2}{\log m} \cdot \alpha \log m} \geq m^{2-\varepsilon} \cdot \mathbb{L}_{\frac{3}{4}}(f),$$

for any constant $\varepsilon > 0$ when m is sufficiently large. Hence, the number of leaves needed for a protocol P is $m^{2-o(1)} \cdot \mathbb{L}_{\frac{3}{4}}(f)$.

Finally, we get rid of the assumption that the depth of P is logarithmic and prove the main result.

Proof of Theorem 3. Let P be a protocol with $m^{2-\varepsilon} \cdot \mathbb{L}_{\frac{3}{4}}(f)$ leaves, for some $\varepsilon > 0$, solving $\text{KW}_{\text{XOR}_m} \otimes \text{KW}_f$. We transform it into a protocol P' with $(m^{(2-\varepsilon)} \cdot \mathbb{L}_{\frac{3}{4}})^\gamma$ leaves and depth bounded by $3(3-\varepsilon)k \ln 2 \cdot \log m$, by applying Theorem 7, where $\gamma = 1 + \frac{1}{1+\log(k-1)}$. (Theorem 7 is stated in terms of formulas, but it is not difficult to see that it works also for protocols for strong composition.)

Since $\varepsilon > 0$ and $\lim_{k \rightarrow \infty} \gamma = 1$, there exist k and $\varepsilon' > 0$ such that

$$\left(m^{2-\varepsilon} \cdot \mathbb{L}_{\frac{3}{4}}(f)\right)^\gamma \leq m^{2-\varepsilon'} \cdot \mathbb{L}_{\frac{3}{4}}(f),$$

since $\mathbb{L}_{\frac{3}{4}}(m) \leq m$. Hence, protocol P' has logarithmic depth and at most $m^{2-\varepsilon'} \cdot \mathbb{L}_{\frac{3}{4}}(f)$ leaves, which contradicts Theorem 17. Therefore, P has $\Omega\left(m^{2-o(1)} \cdot \mathbb{L}_{\frac{3}{4}}(f)\right) = \Omega\left(m^{2-o(1)} \cdot \mathbb{L}_{\frac{3}{4}}(f)\right)$ leaves. ◀

Local Equivalence of Stabilizer States: A Graphical Characterisation

Abstract

Stabilizer states form a ubiquitous family of quantum states that can be graphically represented through the graph state formalism. A fundamental property of graph states is that applying a local complementation – a well-known and extensively studied graph transformation – results in a graph that represents the same entanglement as the original. In other words, the corresponding graph states are LU-equivalent. This property served as the cornerstone for capturing non-trivial quantum properties in a simple graphical manner, in the study of quantum entanglement but also for developing protocols and models based on graph states and stabilizer states, such as measurement-based quantum computing, secret sharing, error correction, entanglement distribution... However, local complementation fails short to fully characterise entanglement: there exist pairs of graph states that are LU-equivalent but cannot be transformed one into the other using local complementations. Only few is known about the equivalence of graph states beyond local complementation. We introduce a generalisation of local complementation which graphically characterises the LU-equivalence of graph states. We use this characterisation to show the existence of a strict infinite hierarchy of equivalences of graph states. Our approach is based on minimal local sets, which are subsets of vertices that are known to cover any graph, and to be invariant under local complementation and even LU-equivalence. We use these structures to provide a type to each vertex of a graph, leading to a natural standard form in which the LU-equivalence can be exhibited and captured by means of generalised local complementation.

1 Introduction

Stabilizer states, and in particular graph states, form a versatile family of entangled quantum states, which allow for easy and compact representations. They are used as entangled resource states in various quantum information applications, like measurement-based computation [29, 30, 5], error corrections [35, 34, 10, 33], quantum communication network routing [19, 26, 4, 7], and quantum secret sharing [25, 17], to cite a few. In all these applications, stabilizer states are used as multi-partite entangled resources, it is thus crucial to understand when two such states have the same entanglement. According to standard quantum information theory, two quantum states have the same entanglement if they can be transformed into each

other using only local operations, where “local” refers to operations that can be applied to at most one qubit at a time. Indeed, intuitively, such local operations can only decrease the strength of the entanglement of a quantum state, thus if a state can be transformed into another and back to the original one using only local operations, the two states do have the same entanglement. Concretely, the most general case is the so-called SLOCC-equivalence (stochastic local operations and classical communications) that encompass the use of local unitaries and measurements. In the particular case of stabilizer states, it is enough to consider *LU-equivalence* (local unitaries), as two stabilizer states are SLOCC-equivalent iff there exists $U = U_1 \otimes \dots \otimes U_n$ that transforms one state into the other, where each U_i is a 1-qubit unitary transformation [21]. Therefore, in this paper, we refer to LU-equivalence when stating that two stabilizer states possess the same entanglement.

Stabilizer states can be graphically represented through the graph state formalism, which consists in representing quantum states using graphs where each vertex corresponds to a qubit. Graph states form actually a sub-family of stabilizer states but any stabilizer state can be transformed into a graph state using local Clifford unitaries in a straightforward way [21], as a consequence it is sufficient to consider graph states when dealing with entanglement equivalence of stabilizer states. Notice that understanding the entanglement structure of graph states and how it can be characterised in a graphical way is the most fascinating fundamental question of the graph state formalism [21, 13, 14, 18, 23, 36, 37, 11].

An interesting combinatorial property of entanglement has been proved in [21]: LU-equivalent graph states have the same cut-rank function¹. However, there exist pairs of graph states that have the same cut-rank function but which are not LU-equivalent: a counterexample involves two isomorphic Petersen graphs [16, 21].

A fundamental property of the graph state formalism is that a *local complementation* – a graph transformation that consists in complementing the neighbourhood of a given vertex – preserves entanglement: if a graph can be transformed into another by means of local complementations then the two corresponding graph states are LU-equivalent. More precisely the corresponding graph states are LC-equivalent (local Clifford). Van den Nest [13] proved that two graph states are LC-equivalent if and only if the corresponding graphs are related by a sequence of local complementations. LC-equivalence and LU-equivalence of graph states were conjectured to coincide [24], as they coincide for several families of graph states [14, 38]. However, a counterexample of order 27 has been discovered using computer assisted methods [23]. Since then, the existence of a graphical characterisation of LU-equivalence has remained an open question. Furthermore, families of graph states for which LC-equivalence and LU-equivalence coincide have been a subject of interest [33, 37].

Contributions. We introduce the *r-local complementation*, a graphical transformation parametrised by a positive integer r , which coincides with the usual local complementation when $r = 1$. We show that an r -local complementation can be performed on the corresponding graph states by means of local unitaries in $LC_r = \langle H, Z(\pi/2^r) \rangle$, the group generated by the local Clifford group augmented with the $Z(\pi/2^r)$ gate. We additionally show that, conversely, for any fixed r , the LC_r -equivalence of graph states is captured by r -local complementations: if two graph states are LC_r -equivalent, then there is a sequence made of (usual) local complementations and at most one r -local complementation, that transforms one graph into the other. In particular, the known examples of graph states that are LU-equivalent but not

¹ The cut-rank function over a graph $G = (V, E)$ is the function that maps a set $A \subseteq V$ to the rank (in \mathbb{F}_2) of the cut-matrix $\Gamma_A = ((\Gamma_A)_{ab} : a \in A, b \in V \setminus A)$ where $\Gamma_{ab} = 1$ if and only if $(a, b) \in E$.

LC-equivalent [23, 36], are actually LC₂-equivalent, thus they are captured graphically by the 2-local complementation. This leads to the natural question of the existence of pairs of graph states that are LC₃-equivalent but not LC₂-equivalent, and so on. To answer this question, we show that the r -local complementations form a strict hierarchy: for any positive r there exist pairs of LC _{$r+1$} -equivalent graph states that are not LC _{r} -equivalent. Finally, we show that any LU-equivalent graph states are LC _{r} -equivalent for some r , even if there exist some local unitaries, like $R_Z(\pi/3)$, that are not contained in LC _{r} , for any r . In other words, two graph states are LU-equivalent if and only if the corresponding graphs can be transformed into each other by a sequence of generalised local complementations, leading to a full graphical description of LU-equivalence for graph states. As an application, we prove a conjecture on a family of graph states for which LU-equivalence and LC-equivalence coincide.

Related work. Other graphical extensions of local complementation have been introduced in particular for weighted hypergraph states [36], a wider family of quantum states. The connection between generalised local complementation and local complementation of weighted hypergraph states is discussed in section 3. In [18, 39], the authors proved that when considering LU-equivalence of stabilizer states it suffices to consider semi-Clifford unitaries². Symmetries of stabilizers and graph states have been explored in [15], where a characterisation of local operations that have graph states as fixed points, is provided; the characterisation of the LU-equivalence of graph states was however left as an open question.

Structure of the paper. In Section 2, we recall some definitions and notations and provide a handful of tools to manipulate graph states. In Section 3, we define the generalisation of the local complementation and we show that r -local complementations can be implemented on the corresponding graph states by means of local unitaries in LC _{r} . Section 4 is dedicated to the converse result: the graphs corresponding to any pair of LC _{r} -equivalent graph states can be transformed into each other by means of r -local complementations. To do so, we show that any graph can be put in a standard form by means of (usual) local complementations. This standard form is based on the so-called minimal local sets, which are subsets of vertices known to be invariant under LU-equivalence. As any graph can be covered by minimal local sets, we associate to any vertex of a graph a type on which is based the standard form. We then prove that if two graph states in standard form are LC _{r} -equivalent, there exists an r -local complementation transforming one graph into the other. We also prove that if two graph states on n qubits are LU-equivalent they are LC _{$n/2$} -equivalent. Finally, in Section 5, we introduce a family of variants of Kneser graphs, and show, using our graphical characterisation of LC _{r} -equivalence, that for any $r > 1$ there exists pairs of graph states that are LC _{r} -equivalent but not LC _{$r-1$} -equivalent.

2 Preliminaries

Let us first give some notations and basic definitions. A graph³ G is a pair (V, E) , where V is a finite set of vertices, and E is a set of unordered pairs of distinct vertices called edges. We assume the set of vertices to be totally ordered and use the notation $V = \{u_1, \dots, u_n\}$ s.t. $u_i \prec u_j$ iff $i < j$. The number $n = |V|$ of vertices is called the order of the graph and

² A unitary U is semi-Clifford if there exists a Pauli operator $P \in X, Y, Z$ such that UPU^\dagger is also a Pauli operator.

³ We only consider simple (no selfloop) undirected graphs.

$|G| := |E|$ its size. We use the notation $u \sim_G v$ when the vertices u and v are connected in G , i.e. $(u, v) \in E$. Given a vertex u , $N_G(u) = \{v \in V \mid (u, v) \in E\}$ is the neighbourhood of u . The odd and the common neighbourhoods are two natural generalisations of the notion of neighbourhoods to sets of vertices: for any $D \subseteq V$, $Odd_G(D) = \Delta_{u \in D} N_G(u) = \{v \in V \mid |N_G(v) \cap D| = 1 \pmod{2}\}$ is the odd neighbourhood of D , where Δ denotes the symmetric difference on vertices. Informally, $Odd_G(D)$ is the set of vertices that are the neighbours of an odd number of vertices in D . The common neighbourhood of D is denoted $\Lambda_G^D = \bigcap_{u \in D} N_G(u) = \{v \in V \mid \forall u \in D, v \in N_G(u)\}$. A local complementation with respect to a given vertex u consists in complementing the subgraph induced by the neighbourhood of u , leading to the graph $G \star u = G \Delta K_{N_G(u)}$ where Δ denotes the symmetric difference on edges and K_A is the complete graph on the vertices of A . Local complementation is an involution, i.e. $G \star u \star u = G$. A pivoting with respect to two connected vertices u and v is the operation that maps G to $G \wedge uv := G \star u \star v \star u$. Notice that pivoting is symmetric ($G \wedge uv = G \wedge vu$) and is an involution ($G \wedge uv \wedge uv = G$). With a slight abuse of notation we identify multisets of vertices with their multiplicity function $V \rightarrow \mathbb{N}$.⁴ A (multi)set S of vertices is independent if there is no two vertices of S that are connected.

Graph states form a standard family of quantum states that can be represented using graphs (Ref. [20] is an excellent introduction to graph states). Given a graph G of order n , the corresponding **graph state** $|G\rangle$ is the n -qubit state:

$$|G\rangle = \frac{1}{\sqrt{2^n}} \sum_{x \in \{0,1\}^n} (-1)^{|G[x]|} |x\rangle$$

where $G[x]$ denotes the subgraph of G induced by $\{u_i \mid x_i = 1\} \subseteq V$.

The i^{th} qubit of $|G\rangle$ can be associated with the vertex u_i of G , so, with a slight abuse of notation, we refer to V as the set of qubits of $|G\rangle$. Given a 1-qubit operation R , like $X : |a\rangle \mapsto |1-a\rangle$ or $Z : |a\rangle \mapsto (-1)^a |a\rangle$, and a subset $D \subseteq V$ of qubits, $R_D := \bigotimes_{u \in D} R_u$ is the local operation which consists in applying R on each qubit of D .

The graph state $|G\rangle$ is the unique quantum state (up to a global phase) that, for every vertex $u \in V$, is a fixed point of the Pauli operator $X_u Z_{N_G(u)}$. More generally, $|G\rangle$ is an eigenvector of any Pauli operator $X_D Z_{Odd(D)}$ with $D \subseteq V$:

► Proposition 1. *Let $G = (V, E)$ be a graph. The corresponding graph state $|G\rangle$ is a fixed point of $\mathcal{P}_D^G = (-1)^{|G[D]|} X_D Z_{Odd(D)}$ for any $D \subseteq V$, where $|G[D]|$ is the number of edges of the subgraph of G induced by D .*

The proof of Proposition 1 can be found in the full version of this paper [9]. The fact that a graph state can be defined as the common eigenvector of Pauli operators witnesses that graph states form a subfamily of stabilizer states⁵. Conversely, any stabilizer state can be turned into a graph state by means of local Clifford unitaries⁶ in a straightforward way (see for instance [13]). Thus we will focus in the rest of this paper on graph states.

The action of measuring, in the standard basis, a qubit of a graph state leads, roughly speaking, to the graph state where the corresponding vertex has been removed. A diagonal measurement can also be used to remove a vertex when this vertex is isolated:

⁴ Hence we also identify sets of vertices with their indicator functions $V \rightarrow \{0, 1\}$.

⁵ A n -qubit state is a stabilizer state if it is the fixpoint of n independent commuting Pauli operators (or equivalently 2^n distinct commuting Pauli operators).

⁶ Local Clifford unitaries are tensor products of single-qubit Clifford gates, which map the Pauli group to itself under conjugation. Formally, a single-qubit gate U is Clifford if for any $P \in \mathcal{P} := \{\pm 1, \pm i\} \times \{I, X, Y, Z\}$, $UPU^\dagger \in \mathcal{P}$.

► **Proposition 2.** For any graph G and any vertex u , $\langle 0|_u |G\rangle = \frac{1}{\sqrt{2}}|G \setminus u\rangle$. Moreover, if u is an isolated vertex (i.e. $N_G(u) = \emptyset$), then $\langle +|_u |G\rangle = |G \setminus u\rangle$ where $\langle +| = \frac{\langle 0| + \langle 1|}{\sqrt{2}}$.

► **Remark 3.** A standard basis measurement consists in applying either $\langle 0|$ or $\langle 1|$ which correspond the classical outcomes 0 and 1 respectively. Whereas the action in the 0 case is directly described in Proposition 2, the action in the 1 case can be recovered thanks to Proposition 1: $\langle 1|_u |G\rangle = \langle 0|_u X_u |G\rangle = \langle 0|_u Z_{N_G(u)} |G\rangle = \frac{1}{\sqrt{2}}Z_{N_G(u)} |G \setminus u\rangle$. Thus it also corresponds to a vertex deletion up to some Z corrections on the neighbourhood of the measured qubit.

We are interested in the action of 1-qubit unitaries on graph states, in particular Hadamard $H : |a\rangle \mapsto \frac{|0\rangle + (-1)^a |1\rangle}{\sqrt{2}}$, and Z - and X -rotations respectively defined as follows:

$$Z(\alpha) := e^{i\frac{\alpha}{2}} \left(\cos\left(\frac{\alpha}{2}\right) I - i \sin\left(\frac{\alpha}{2}\right) Z \right) \quad X(\alpha) := HZ(\alpha)H = e^{i\frac{\alpha}{2}} \left(\cos\left(\frac{\alpha}{2}\right) I - i \sin\left(\frac{\alpha}{2}\right) X \right)$$

In particular, local complementations can be implemented by $\pi/2$ X - and Z -rotations:

► **Proposition 4** ([13]). For any graph $G = (V, E)$ and any $u \in V$, $|G \star u\rangle = L_u^G |G\rangle$ where $L_u^G := X_u(\frac{\pi}{2}) \otimes_{v \in N_G(u)} Z_v(-\frac{\pi}{2})$.

Similarly, pivoting can be implemented by means of Hadamard transformations (up to Pauli transformations):

► **Proposition 5** ([27, 12]). For any graph $G = (V, E)$ and any $(u, v) \in E$, $|G \wedge uv\rangle = H_u H_v Z_{\Lambda_G^{\{u,v\}}} |G\rangle$

Beyond $\frac{\pi}{2}$ rotations, notice that any local unitary can be implemented using Hadamard and Z -rotations with arbitrary angles. We consider for any $r \in \mathbb{N}$ the set LC_r of local unitaries generated by H and $Z(\frac{\pi}{2r})$. In particular LC_1 is the set of local Clifford operators, moreover, for any r , $LC_r \subseteq LC_{r+1}$. Notice that there exist local unitaries, e.g. $Z(\frac{\pi}{3})$, that are not contained in LC_r for any r . We say that two states are LU-equivalent, denoted $|\psi\rangle =_{LU} |\psi'\rangle$ when there exists a local unitary transformation U such that $|\psi\rangle = U|\psi'\rangle$. Similarly two states are LC_r -equivalent, denoted $|\psi\rangle =_{LC_r} |\psi'\rangle$ when there exists a local unitary $U \in LC_r$ s.t. $|\psi\rangle = U|\psi'\rangle$.

It is well-known that two graph states $|G\rangle$ and $|G'\rangle$ are LC_1 -equivalent if and only if there exists a sequence of local complementations that transforms G into G' [13]. We slightly refine this result showing that there exists a reasonably small sequence of local complementation transforming G into G' , that corresponds to a particular Clifford operator:

► **Proposition 6.** If $|G_2\rangle = C|G_1\rangle$ where C is a local Clifford operator up to a global phase, then there exists a sequence of (possibly repeating) vertices a_1, \dots, a_m such that $G_2 = G_1 \star a_1 \star a_2 \star \dots \star a_m$ with $m \leq \lfloor 3n/2 \rfloor$, and the local Clifford operator that implements these local complementations is C up to a Pauli operator.

The proof of Proposition 6 can be found in the full version of this paper [9]

► **Remark 7.** The induced Clifford operator is of the form $\mathcal{P}_D^G C$ for some subset D of vertices. As $X_u Z_{N_G(u)} = (L_u^G)^2$, there exists a sequence at most $\lfloor 7n/2 \rfloor$ local complementations that transforms G_1 into G_2 and induces exactly the local Clifford operator C .

Whereas it has been originally conjectured that if two graphs states are LU-equivalent then there exists a sequence of local complementations transforming one in another [24], a couple of counter examples of pairs of LC_2 - but not LC_1 -equivalent graph states have been pointed out [23, 36]. To further understand the action of local unitaries on graph states, we thus introduce in the next section a generalisation of local complementation to graphically capture the equivalence of graph states that are LU- but not LC_1 -equivalent.

■ **Figure 1** Example of non LU-equivalent graph states. With the notations of Section 5, the graph on the left is a $C_{4,3}$ graph, and the one on the right is a $C'_{4,3}$ graph. Notice that applying a local complementation on the upper part of the bipartition ($S = \{a, b, c, d\}$) leaves the graphs invariant as each pair of vertices on the other part (e.g. (e, f)), has two common neighbours in S . However a 2-local complementation over S is not valid in both graphs as S is not 2-incident. See Section 4.1 for a proof that these graph states are not LU-equivalent.

3 Generalising Local Complementation

3.1 Local complementation over independent sets

As a first step towards a generalisation of local complementation, we introduce a natural shortcut $G \star S := G \star a_1 \dots \star a_k$ to denote the graph obtained after a series of local complementations when $S = \{a_1, \dots, a_k\}$ is an independent set in G . The independence condition is important as local complementations do not commute in general when applied on connected vertices.

Notice that the action of a local complementation over S can be described directly as toggling edges which have an odd number of common neighbours in S :

$$u \sim_{G \star S} v \Leftrightarrow (u \sim_G v \oplus |S \cap N_G(u) \cap N_G(v)| = 1 \pmod 2) \tag{1}$$

3.2 Towards a 2-local complementation

We introduce 2-local complementations as a refinement of *idempotent* local complementations, i.e. when $G \star S = G$. According to Equation (1), an idempotent local complementation occurs when each pair (u, v) of vertices has an even number of common neighbours in S , one can then consider a new graph transformation which consists in toggling an edge (u, v) when its number of common neighbours in S is equal to 2 modulo 4. However, such an action may not be implementable using local operations in the graph state formalism (see Figure 1). To guarantee an implementation by means of local unitary transformations on the corresponding graph states, we add the condition, called 2-incident, that any set of at most three vertices has an even number of common neighbours in S .

For instance in the following example, a 2-local complementation over $\{a, b\}$ performs the following transformation:

■ **Figure 2** Illustration on a 2-local complementation on the multiset $S = \{a, a, b, c\}$. S is 2-incident: indeed $S \bullet \Lambda_G^{\{d,e,f\}} = 2$, which is a multiple of $2^{2-1-0} = 2$. Similarly, $S \bullet \Lambda_G^{\{d,e\}} = S \bullet \Lambda_G^{\{d,f\}} = 2$ and $S \bullet \Lambda_G^{\{e,f\}} = 4$. Edges de and df are toggled as $S \bullet \Lambda_G^{\{d,e\}} = S \bullet \Lambda_G^{\{d,f\}} = 2 \pmod 4$, but not edge ef as $S \bullet \Lambda_G^{\{e,f\}} = 0 \pmod 4$.

In the LHS graph G , $S = \{a, b\}$ is an independent set. Moreover, a 1-local complementation over S is idempotent: $G \star S = G$, as a and b are twins. S is also 2-incident as any pairs and triplets of vertices have an even number of neighbours in S . Thus, a 2-local complementation over S is valid and consists in toggling the edges (c, d) , (c, e) , and (d, e) as each of them has a number of common neighbours in S equal to $2 \pmod 4$.

We also consider the case where S is actually a multiset, like in Figure 2 where a 2-local complementation over the multiset $\{a, a, b, c\}$ is performed. When S is a multiset, the number of common neighbours in S should be counted with their multiplicity.

Notice that when a 2-local complementation is invariant one can similarly refine the 2-local complementation into a 3-local complementation, leading to the general definition of generalised local complementation provided in the next section.

3.3 Defining generalised local complementation

We introduce a generalisation of local complementation, that we call r -local complementation for any positive integer r . This generalised local complementation denoted $G \star^r S$ is parametrised by a (multi)set S , that has to be independent and also r -incident, which is the following counting condition on the number of common neighbours in S of any set that does not intersect $\text{supp}(S)$, the support of S :

► **Definition 8** (r -Incidence). *Given a graph G , a multiset S of vertices is r -incident, if for any $k \in [0, r)$, and any $K \subseteq V \setminus \text{supp}(S)$ of size $k + 2$, $S \bullet \Lambda_G^K$ is a multiple of $2^{r-k-\delta(k)}$, where δ is the Kronecker delta⁷ and $S \bullet \Lambda_G^K$ is the number of vertices of S , counted with their multiplicity, that are neighbours to all vertices of K .⁸*

► **Definition 9** (r -Local Complementation). *Given a graph G and an r -incident independent multiset S , let $G \star^r S$ be the graph defined as*

$$u \sim_{G \star^r S} v \Leftrightarrow (u \sim_G v \oplus S \bullet \Lambda_G^{u,v} = 2^{r-1} \pmod{2^r})$$

A detailed example of a 2-local complementation is given in Figure 2.

We will also use r -local complementation parametrised with a set (rather than a multiset), in this case $S \bullet \Lambda_G^K = |S \cap \Lambda_G^K|$, and $S \bullet \Lambda_G^{u,v} = |S \cap N_G(u) \cap N_G(v)|$. Note that we recover the vanilla local complementation when $r = 1$.

⁷ $\delta(x) \in \{0, 1\}$ and $\delta(x) = 1 \Leftrightarrow x = 0$.

⁸ \bullet is the scalar product: $A \bullet B = \sum_{u \in V} A(u).B(u)$, so $S \bullet \Lambda_G^K = \sum_{u \in \Lambda_G^K} S(u)$.

We say that $G \star^r S$ is valid when S is an r -incident independent multiset in G . Moreover, generalising the notion of local equivalence on graphs, we say that two graphs G, G' are r -locally equivalent when there exists a sequence of r -local complementations transforming G into G' . In the case of the usual local complementation, we simply say that the graphs are locally equivalent.

Generalised local complementations satisfy a few basic properties (proven in the full version of this paper [9]), in particular, it is easy to double check that they are self inverse: $(G \star^r S) \star^r S = G$. Moreover, r -local complementations can be related to $(r + 1)$ and $(r - 1)$ -local complementations:

- **Proposition 10.** *If $G \star^r S$ is valid then:*
 - $G \star^{r+1} (2S)$ is valid and induces the same transformation: $G \star^{r+1} (2S) = G \star^r S$, where $2S$ is the multiset obtained from S by doubling the multiplicity of each vertex,
 - $G \star^{r-1} S$ is valid (when $r > 1$) and $G \star^{r-1} S = G$.

It implies in particular that two r -locally equivalent graphs are $(r + 1)$ -locally equivalent. An r -local complementation over S preserves the neighbourhood of the vertices in $\text{supp}(S)$:

- **Proposition 11.** *If $G \star^r S$ is valid, then for any $u \in \text{supp}(S)$, $N_{G \star^r S}(u) = N_G(u)$.*

Notice that r -local complementations can be composed:

- **Proposition 12.** *If $G \star^r S_1$ and $G \star^r S_2$ are valid and the disjoint union⁹ $S_1 \sqcup S_2$ is independent in G , then $G \star^r (S_1 \sqcup S_2) = (G \star^r S_1) \star^r S_2$.*

Finally, it is easy to see that the multiplicity in S can be upperbounded by 2^r : if $G \star^r S$ is valid, then $G \star^r S = G \star^r S'$, where, for any vertex u , $S'(u) = S(u) \bmod 2^r$.

3.4 Local Clifford operators and local complementation

It is well known that local complementations can be implemented on graph states by means of local Clifford operations [21, 20], we extend this result to r -local complementations that can be implemented using $\frac{\pi}{2^r}$ X- and Z-rotations:

- **Proposition 13.** *Given a graph $G = (V, E)$ and a r -incident independent multiset S of vertices,*

$$|G \star^r S\rangle = \bigotimes_{u \in V} X \left(\frac{S(u)\pi}{2^r} \right) \bigotimes_{v \in V} Z \left(-\frac{\pi}{2^r} \sum_{u \in N_G(v)} S(u) \right) |G\rangle$$

The proof of Proposition 13 can be found in the full version of this paper [9].

- **Remark 14.** The graph state formalism has been extended in various ways, notably through the introduction of *hypergraph states* [31] and even *weighted hypergraph states* [36]. Notice that the formalism of weighted hypergraph states provides a way to decompose a generalised local complementation over a multiset S of size k into k elementary transformations on weighted hypergraph states. Indeed, as shown in Proposition 13, a generalised local complementation can be implemented by means of k X-rotations (along with some Z-rotations), moreover the action of each X-rotation on weighted hypergraph states has been described in [36]. However, in such a decomposition, the intermediate weighted hypergraph states are not necessarily graph states.

⁹ for any vertex u , $(S_1 \sqcup S_2)(u) = S_1(u) + S_2(u)$.

In the next section, we prove the converse result: if a local unitary operation in LC_r transforms a graph state $|G\rangle$ into a graph state $|G'\rangle$ then there exists a sequence of r -local complementations transforming G into G' . More so, we show that r -local complementation actually captures completely the LU-equivalence of graph states. To prove these results, we make use of graphical tools, namely the so-called minimal local sets and a standard form for graphs.

4 Graphical characterisation of the action of local unitaries

4.1 Minimal local sets and Types

To characterise the action of local unitaries on graph states, we rely on properties that are invariant under local unitaries. A local set [22, 8] is one of them.

► **Definition 15.** *Given $G = (V, E)$, a local set L is a non-empty subset of V of the form $L = D \cup \text{Odd}_G(D)$ for some $D \subseteq V$ called a generator.*

Local sets of G are precisely the supports of the Pauli operators $\mathcal{P}_D^G = (-1)^{|G[D]|} X_D Z_{\text{Odd}(D)}$, with D a non-empty subset of qubits, that stabilises $|G\rangle$. Local sets are invariant under local complementation - hence their name: if L is a local set in a graph G , so is in $G \star u$, but possibly with a distinct generator [22]. Local sets are the same for graphs that have the same cut-rank function [8], thus graphs corresponding to LU-equivalent graph states have the same local sets.

A *minimal local set* is a local set that is minimal by inclusion. Minimal local sets have either 1 or 3 generators, and in the latter case, the minimal local sets are of even size. This was proved originally in the stabilizer formalism in [14], but an alternative graph-theoretic proof can be found in [8].

► **Proposition 16.** *Given a minimal local set L , only two cases can occur:*

- L has exactly one generator,
- L has exactly three (distinct) generators, of the form D_0 , D_1 , and $D_0 \Delta D_1$. This can only occur when $|L|$ is even.

In the first case, the minimal local set L is said to be of dimension 1; in the second, of dimension 2. The dimension of a minimal local set depends only on the cut-rank function, thus it is invariant by LU-equivalence. Just like (minimal) local sets, the dimension can be a useful tool to prove that two graph states are not LU-equivalent. For example, the two graphs of Figure 1 have the same minimal local sets, but they do not have the same dimension. Indeed, $\{a, b, c, h\}$ is a minimal local set of dimension 2 in the first graph, while it is a minimal local set of dimension 1 in the second one, proving that the two graph states are not LU-equivalent.

Minimal local sets provide crucial informations on local unitaries acting on graph states: it is known that if a local unitary U transforms $|G\rangle$ into $|G'\rangle$ and L is a minimal local set of dimension 2, then for any $v \in L$, U_v must be a Clifford operator [14]. Minimal local sets of dimension 1 are more permissive but also provide some constraints on U :

► **Lemma 17.** *Given two graphs G , G' and a local unitary U such that $|G\rangle = U|G'\rangle$, if L is a 1-dimensional minimal local set with generators respectively D in G and D' in G' , then*

$$\mathcal{P}_D^G U = U \mathcal{P}_{D'}^{G'}$$

27:10 Local Equivalence of Stabilizer States: A Graphical Characterisation

Proof. Following [14, 39], we consider the density matrix ρ_G^L (resp. $\rho_{G'}^L$) obtained by tracing out the qubits outside L . According to [20, 21]: $\rho_G^L = \frac{1}{2}(I + \mathcal{P}_D^G)$ and $\rho_{G'}^L = \frac{1}{2}(I + \mathcal{P}_{D'}^{G'})$. As $\rho_G^L = U\rho_{G'}^L U^\dagger$, we get $I + \mathcal{P}_D^G = I + U\mathcal{P}_{D'}^{G'}U^\dagger$, hence $\mathcal{P}_D^G U = U\mathcal{P}_{D'}^{G'}$. ◀

So, intuitively, every minimal local set L induces some constraints on a local unitary transformation U acting on the corresponding graph state, more precisely on the qubits of U that are in L . It has been recently shown that minimal local sets cover every vertex of a graph [8], which unlocks the use of minimal local sets in characterizing local unitaries acting on graph states, as it guarantees that minimal local sets impose constraints on every qubit of the local unitary:

► **Theorem 18** ([8]). *Each vertex of any graph is contained in at least one minimal local set.*

We abstract away the set of minimal local sets, which can be exponentially many in a graph (see [8]), as a simple labelling of the vertices that we call a *type*.

► **Definition 19.** *Given a graph G , a vertex u is of type*

- X if for any generator D of a minimal local set containing u , $u \in D \setminus \text{Odd}(D)$,
- Y if for any generator D of a minimal local set containing u , $u \in D \cap \text{Odd}(D)$,
- Z if for any generator D of a minimal local set containing u , $u \in \text{Odd}(D) \setminus D$,
- \perp otherwise.

The names X , Y and Z are chosen to match the Pauli operator at vertex u in \mathcal{P}_D^G . Notice that a vertex involved in a minimal local set of dimension 2 is necessarily of type \perp ¹⁰. We define $V_X^G \subseteq V$ (resp. V_Y^G, V_Z^G, V_\perp^G) as the set of vertices of type X (resp. Y, Z, \perp) in G . V_X^G, V_Y^G, V_Z^G and V_\perp^G form a partition of V : indeed, thanks to Theorem 18, every vertex has a type.

We show in the following a few properties of the vertex types. First notice that vertices of type Z represent at most half the vertices of a graph:

► **Lemma 20.** *For any graph G of order n , $|V_Z^G| \leq \lfloor n/2 \rfloor$.*

Proof. V_Z^G contains no minimal local set. Indeed, as the generator of a local set is non-empty, at least one vertex of a given minimal local set L is not of type Z . Conversely, any subset of the vertices of size $\lfloor n/2 \rfloor + 1$ contains at least one minimal local set [8]. ◀

Two LU-equivalent graph states share the same vertices of type \perp .

► **Lemma 21.** *Given two LU-equivalent graph states $|G_1\rangle$ and $|G_2\rangle$, $V_\perp^{G_1} = V_\perp^{G_2}$.*

Proof. Let U be a local unitary s.t. $|G_1\rangle = U|G_2\rangle$, and let $v \in V$ a vertex of type \perp in G_1 . If v is in a minimal local set of dimension 2 in G_1 , so is in G_2 as the dimension of minimal local sets is invariant under LU-equivalence. Otherwise, there exist two distinct minimal local sets L, L' , generated respectively by D_1 and by D'_1 in G_1 such that $\mathcal{P}_{D_1}^{G_1}$ and $\mathcal{P}_{D'_1}^{G_1}$ do not commute on qubit v .¹¹ Let D_2 (resp. D'_2) be the generator of L (resp. L') in G_2 . According to Lemma 17, $\mathcal{P}_{D_1}^{G_1} = U\mathcal{P}_{D_2}^{G_2}U^\dagger$ and $\mathcal{P}_{D'_1}^{G_1} = U\mathcal{P}_{D'_2}^{G_2}U^\dagger$, as a consequence, $\mathcal{P}_{D_2}^{G_2}$ and $\mathcal{P}_{D'_2}^{G_2}$ do not commute on qubit v , so v must be of type \perp in G_2 . ◀

¹⁰ If a vertex v has the same type with respect to two distinct generators D, D' of a minimal local set L , then v would not be in the local set generated by $D\Delta D'$ which contradicts the minimality of L .

¹¹ $V = \bigotimes_u V_u$ commutes with $W = \bigotimes_u W_u$ on qubit u_0 if V_{u_0} and W_{u_0} commute.

A vertex having the same type in two LU-equivalent graph states implies strong constraints on the local unitaries that relate the two corresponding graph states.

► **Lemma 22.** *If $|G_1\rangle =_{LU} |G_2\rangle$ i.e. $|G_2\rangle = U|G_1\rangle$, then $U = e^{i\phi} \bigotimes_{u \in V} U_u$ where:*

- U_u is a Clifford operator if u is of type \perp in both G_1 and G_2 ,
- $U_u = X(\theta_u)Z^{b_u}$ if u is of type X in both G_1 and G_2 ,
- $U_u = Z(\theta_u)X^{b_u}$ if u is of type Z in both G_1 and G_2 .

with $b_u \in \{0, 1\}$. Additionally, if $|G_1\rangle$ and $|G_2\rangle$ are LC_r -equivalent, there exists such a unitary U where every angle satisfies $\theta_u = 0 \pmod{\pi/2^r}$.

Proof. The first case, when u is of type \perp , is a variant of the minimal support condition [13] and was proved in [28] for the particular case of minimal local sets of dimension 2. If u is of type X , let L be a minimal local set such that $u \in L$. According to Lemma 17, $U_u X U_u^\dagger = e^{i\phi} X$. $U_u|+\rangle$ and $U_u|-\rangle$ are eigenvectors of $U_u X U_u^\dagger$ of eigenvalues respectively 1 and -1, implying $U_u X U_u^\dagger = \pm X$. If $U_u X U_u^\dagger = X$, then $U_u = e^{i\phi} X(\theta)$. If $U_u X U_u^\dagger = -X$, define $U' := U_u Z$. $U' X U'^\dagger = X$, so $U' = e^{i\phi} X(\theta)$, thus $U_u = e^{i\phi} X(\theta) Z$. The proof is similar when u is of type Z . If $|G_1\rangle$ and $|G_2\rangle$ are LC_r -equivalent, there exists $|G_2\rangle = U|G_1\rangle$ where $U = e^{i\phi} \bigotimes_{u \in V} U_u$, and each U_u is in LC_r . ◀

To fully characterise the unitaries that relate two graph states using Lemma 22, the type of every vertex needs to be the same. This is not the case in general, even for locally equivalent graphs¹². Thus, we introduce a standard form on graphs, such that two graphs in standard form corresponding to LU-equivalent graph states have the same types.

4.2 Standard Form

We define a standard form of graphs up to local complementation. A graph in standard form satisfies the following properties: all vertices are of type X , Z or \perp ; all the neighbours of a vertex of type X are of type Z (so in particular the vertices of type X form an independent set); and any vertex of type X is smaller than its neighbours according to the underlying total order \prec of the vertices. In other words:

► **Definition 23.** *A graph G is in said in standard form if*

- $V_Y^G = \emptyset$,
- $\forall u \in V_X^G$, any neighbour v of u is of type Z and satisfies $u \prec v$.

Note that standard form is not unique in general, in the sense that a class of local equivalence of graphs may contain several graphs in standard form. For example, any graph with only vertices of type \perp is in standard form, along with its entire orbit generated by local complementation. Conversely, each class of local equivalence contains at least a graph in standard form.

► **Proposition 24.** *For any graph G , there exists a locally equivalent G' in standard form.*

The proof of Proposition 24 is an algorithm that puts a graph in standard form by means of local complementation and can be found in the full version of this paper [9]. Standard form implies a similar structure in terms of types assuming LU-equivalence.

¹²A simple example involves the complete graph K_3 on 3 vertices and the line graph L_3 on three vertices. K_3 and L_3 are related by a single local complementation, however every vertex of K_3 is of type Y , while L_3 contains one vertex of type Z and two vertices of type X .

27:12 Local Equivalence of Stabilizer States: A Graphical Characterisation

► **Proposition 25.** *If G_1 and G_2 are both in standard form and $|G_1\rangle =_{LU} |G_2\rangle$, each vertex has the same type in G_1 and G_2 , and any vertex u of type X satisfies $N_{G_1}(u) = N_{G_2}(u)$.*

The proof of Proposition 25 can be found in the full version of this paper [9].

4.3 Graphical characterisation of local equivalence

Thanks to the standard form, one can accommodate the types of two LU-equivalent graph states, to simplify the local unitaries mapping one to the other:

► **Lemma 26.** *If G_1 and G_2 are both in standard form and $|G_1\rangle =_{LU} |G_2\rangle$, there exists G'_1 locally equivalent to G_1 in standard form such that $|G_2\rangle = \bigotimes_{u \in V_X^{G_1}} X(\alpha_u) \bigotimes_{v \in V_Z^{G_1}} Z(\beta_v) |G'_1\rangle$.*

The proof of Lemma 26 can be found in the full version of this paper [9]. Note that if $|G_1\rangle$ and $|G_2\rangle$ are LC_r -equivalent, we can choose the angles such that $\alpha_u, \beta_v = 0 \pmod{\pi/2^r}$. Additionally, G_1 and G'_1 are related by local complementation only on vertices of type \perp . They are strong constraints relating the angles of the X- and Z-rotations acting on different qubits:

- **Lemma 27.** *Given G_1, G_2 in standard form, if $|G_2\rangle = \bigotimes_{u \in V_X^{G_1}} X(\alpha_u) \bigotimes_{v \in V_Z^{G_1}} Z(\beta_v) |G_1\rangle$,*
- $\forall v \in V_Z^{G_1}, \beta_v = -\sum_{u \in N_{G_1}(v) \cap V_X^{G_1}} \alpha_u \pmod{2\pi}$,
- $\forall k \in \mathbb{N}, \forall K \subseteq V_Z^{G_1}$ of size $k+2$, $\sum_{u \in \Lambda_{G_1}^K \cap V_X^{G_1}} \alpha_u = 0 \pmod{\frac{\pi}{2^{k+\delta(k)}}}$.

The proof of Lemma 27 can be found in the full version of this paper [9]. The constraints coincide with r -incidence, so, when angles are multiples of $\pi/2^r$, this unitary transformation implements a r -local complementation.

► **Lemma 28.** *Given G_1, G_2 in standard form, if $|G_2\rangle = \bigotimes_{u \in V_X^{G_1}} X(\alpha_u) \bigotimes_{v \in V_Z^{G_1}} Z(\beta_v) |G_1\rangle$ and $\forall u \in V_X^{G_1}, \alpha_u = 0 \pmod{\pi/2^r}$, then $\bigotimes_{u \in V_X^{G_1}} X(\alpha_u) \bigotimes_{v \in V_Z^{G_1}} Z(\beta_v)$ implements an r -local complementation over the vertices of $V_X^{G_1}$.*

Proof. Let us construct an r -incident independent multiset S such that $G_2 = G_1 \star^r S$. We define S on the vertices of $V_X^{G_1}$ such that $\forall u \in V_X^{G_1}, \alpha_u = \frac{S(u)\pi}{2^r} \pmod{2\pi}$ with $S(u) \in [1, 2^r)$. Note that $\sum_{u \in \Lambda_{G_1}^K \cap V_X^{G_1}} \alpha_u = \frac{\pi}{2^r} S \bullet \Lambda_G^K$. Hence, by Lemma 27, For any $k \in [0, r)$, and any $K \subseteq V \setminus S$ of size $k+2$, $S \bullet \Lambda_G^K$ is a multiple of $2^{r-k-\delta(k)}$ meaning that S is r -incident. Also, by Lemma 27, $\beta_v = -\frac{\pi}{2^r} \sum_{u \in N_{G_1}(v)} S(u) \pmod{2\pi}$. Thus, $\bigotimes_{u \in V_X^{G_1}} X(\alpha_u) \bigotimes_{v \in V_Z^{G_1}} Z(\beta_v)$ implements an r -local complementation on S . ◀

We can now easily relate LC_r -equivalence to r -local complementations for graphs in standard form:

► **Lemma 29.** *If G_1 and G_2 are both in standard form and $|G_1\rangle =_{LC_r} |G_2\rangle$, then G_1 and G_2 are related by a sequence of local complementations on the vertices of type \perp along with a single r -local complementation over the vertices of type X .*

► **Remark 30.** The sequence of local complementations commutes with the r -local complementation, as vertices of type X and vertices of type \perp do not share edges by definition of the standard form.

Proof. By Lemma 26, there exists G'_1 locally equivalent to G_1 in standard form such that $|G_2\rangle = \bigotimes_{u \in V_X} X(\alpha_u) \bigotimes_{v \in V_Z} Z(\beta_v) |G'_1\rangle$ where V_X (resp. V_Z) denotes the set of vertices of type X (resp. Z) in G'_1 and G_2 , and $\forall u \in V$ of type X or Z, $\alpha_u, \beta_u = 0 \pmod{\pi/2^r}$. By Lemma 28, $\bigotimes_{u \in V_X} X(\alpha_u) \bigotimes_{v \in V_Z} Z(\beta_v)$ implements an r -local complementation over the vertices of type X. ◀

Notice in particular that when there is no vertex of type \perp , a single r -local complementation is required.

► **Corollary 31.** *If two \perp -free r -locally equivalent graphs G_1 and G_2 are both in standard form, they are related by a single r -local complementation on the vertices of type X.*

We are ready to prove that r -local equivalence coincides with LC_r -equivalence.

► **Theorem 32.** *The following properties are equivalent:*

1. $|G_1\rangle$ and $|G_2\rangle$ are LC_r -equivalent.
2. G_1 and G_2 are r -locally equivalent.
3. G_1 and G_2 are related by a sequence of local complementations along with a single r -local complementation.

Proof. We proceed by cyclic proof. (2 \Rightarrow 1): Follows from Proposition 13. (3 \Rightarrow 2): A local complementation is, in particular, an r -local complementation. (1 \Rightarrow 3): Follows from Proposition 24 along with Lemma 29. ◀

More than just LC_r -equivalence, r -local complementations can actually characterise the LU-equivalence of graph states.

► **Theorem 33.** *If $|G_1\rangle$ and $|G_2\rangle$ are LU-equivalent then G_1 and G_2 are $(\lfloor n/2 \rfloor - 1)$ -locally equivalent, where n is the order of the graphs.*

The proof of Theorem 33 can be found in the full version of this paper [9]. Remarkably, this result implies that for graph states, LU-equivalence reduces to equivalence up to operators in $\bigcup_{r \in \mathbb{N}} LC_r$, and even – as it has been hinted in [18] – to operators of the form $C_1 \bigotimes_{u \in V} Z(\alpha_u) C_2$ where C_1, C_2 are local Clifford operators and the angles are multiples of $\pi/2^r$ for some integer r . Notice that these local operators are actually those of the well-known Clifford hierarchy (see for example [1]).

4.4 Graph states whose class of LC and LU-equivalence coincide

Since the LU-LC conjecture was disproven in [38], classes of graph states whose class of LC_1 - and LU-equivalence coincide has been a subject of interest. We say that $LU \Leftrightarrow LC$ holds for a graph G if $|G\rangle =_{LU} |G'\rangle \Leftrightarrow |G\rangle =_{LC_1} |G'\rangle$ for any graph G' . It is known that $LU \Leftrightarrow LC$ holds for a graph G if either one of the following is true: **(1)** G is of order at most 8 [20, 6]; **(2)** G is a complete graph [14]; **(3)** every vertex of G is of type \perp (this is referred as the *minimal support condition*) [14]; **(4)** the graph obtained by removing all leaves (i.e. vertices of degree 1) vertices of G has only vertices of type \perp [38]; **(5)** G has no cycle of length 3 or 4 [38]; **(6)** the stabilizer of $|G\rangle$ has rank less than 6 [23]. A review of these necessary conditions, especially for **(6)**, can be found in [37]. Our results imply a new criterion for $LU \Leftrightarrow LC$ based on the standard form introduced in the last section. This criterion is actually a sufficient and necessary condition, meaning it can be used to prove both that $LU \Leftrightarrow LC$ holds for some graph, or the converse.

► **Proposition 34.** *Given a graph G , the following are equivalent:*

- $LU \Leftrightarrow LC$ holds for G .
- For **some** graph locally equivalent to G that is in standard form, any r -local complementation over the vertices of type X can be implemented by local complementations.
- For **any** graph locally equivalent to G that is in standard form, any r -local complementation over the vertices of type X can be implemented by local complementations.

The proof of Proposition 34 can be found in the full version of this paper [9]. Checking that r -local complementations can be implemented by local complementations is not easy in general, nonetheless it is convenient in many cases, for example when there is few vertices of type X or that they have low degree. Namely, this criterion is stronger than the minimal support condition, as graphs with only vertices of \perp have no vertex of type X . Furthermore, it has been left as an open question in [37] whether $LU \Leftrightarrow LC$ holds for some instances of repeater graph states. We use our new criterion to easily prove that this is the case. For this purpose, we prove that $LU \Leftrightarrow LC$ holds for a broader class of graph.

► **Proposition 35.** *$LU \Leftrightarrow LC$ holds for graphs where each vertex is either a leaf i.e. a vertex of degree 1, or is connected to a leaf.*

Proof. It is easy to prove (see the full version of this paper [9]) that such a graph G is in standard form (for some particular ordering of the vertices) and that the vertices of type X are exactly the leaves. Thus, any r -local complementation over the vertices of type X has no effect on G . According to Proposition 34, this implies that $LU \Leftrightarrow LC$ holds for G . ◀

Such graphs include some instances of *repeater graph states* [2]. A *complete-graph-based repeater graph state* is a graph state whose corresponding graph of order $2n$ is composed of a complete graph of order n , along with n leaves appended to each vertex. A *biclique-graph-based repeater graph state* is a graph state whose corresponding graph of order $4n$ is composed of a symmetric biclique (i.e. a symmetric bipartite complete graph) graph of order $2n$, along with $2n$ leaves appended to each vertex. Complete-graph-based repeater graph states are the all-photonic repeaters introduced in [3]. Biclique-graph-based repeater graph states are a variant introduced in [32] which is more efficient in terms of number of edges. It was left as an open question in [37] whether $LU \Leftrightarrow LC$ holds for complete-graph-based or biclique-graph-based repeater graph states (although it was proved for some variants). These graph states satisfy the condition of Proposition 35, hence we can answer this question by the positive:

► **Corollary 36.** *$LU \Leftrightarrow LC$ holds for complete-graph-based repeater graph states and biclique-graph-based repeater graph states.*

5 A hierarchy of generalised local equivalences

Two r -locally equivalent graphs are also $(r+1)$ -locally equivalent. This can be seen graphically as a direct consequence of Proposition 10, or using graph states through Theorem 32, as two LC_r -equivalent states are obviously LC_{r+1} -equivalent. The known counter examples to the LU - LC conjecture introduced in [23, 36] are actually LC_2 -equivalent graph states that are not LC_1 -equivalent, thus the corresponding graphs are 2-locally equivalent but not 1-locally equivalent. There was however no known examples of graph states that are LC_3 -equivalent but not LC_2 -equivalent, and more generally no known examples of graph states that are LC_r -equivalent but not LC_{r-1} -equivalent for $r > 2$. We introduce such examples in this section, by showing that for any r there exist pairs of graphs that are $(r+1)$ -locally equivalent

but not r -locally equivalent leading to an infinite hierarchy of generalised local equivalences. Our proof is constructive: for any r we exhibit pairs of graphs that are $(r + 1)$ -locally equivalent but not r -locally equivalent.

We introduce a family of bipartite graphs $C_{t,k}$ parametrized by two integers t and k . This family is a variant of the (bipartite) Kneser graphs and uniform subset graphs. The graph $C_{t,k}$ is bipartite: the first independent set of vertices corresponds to the integers from 1 to t , and the second independent set is composed of all the subsets of $[1, t]$ of size k . There is an edge between an integer $u \in [1, t]$ and a subset $A \subseteq [1, t]$ of size k if and only if $u \in A$:

► **Definition 37.** For any $k \geq 1$ and $t \geq k$ two integers, let $C_{t,k} = (V, E)$ be a bipartite graph defined as: $V = [1, t] \cup \binom{[1,t]}{k}$ and $E = \{(u, A) \in [1, t] \times \binom{[1,t]}{k} \mid u \in A\}$.

We introduce a second family of graphs $C'_{t,k}$, defined similarly to $C_{t,k}$, the independent set $[1, t]$ being replaced by a clique:

► **Definition 38.** For any $k \geq 1$ and $t \geq k$ two integers, let $C'_{t,k} = (V, E)$ be a graph defined as: $V = [1, t] \cup \binom{[1,t]}{k}$ and $E = \{(u, A) \in [1, t] \times \binom{[1,t]}{k} \mid u \in A\} \cup \{(u, v) \in [1, t] \times [1, t] \mid u \neq v\}$.

■ **Figure 3** (Left) The graph $C_{4,2}$. (Right) The graph $C'_{4,2}$.

Examples of such graphs with parameters $t = 4$ and $k = 2$ are given in Figure 3. For any odd $k \geq 3$, $t \geq k + 2$, $C_{t,k}$ and $C'_{t,k}$ are in standard form for any ordering such that, for any $u \in \binom{[1,t]}{k}$ and for any $v \in [1, t]$, $u \prec v$. More precisely the vertices in $\binom{[1,t]}{k}$ are of type X and the vertices in $[1, t]$ are of type Z. The proof can be found in the full version of this paper [9].

The following proposition gives a sufficient condition on t and k for the r -local equivalence of $C_{t,k}$ and $C'_{t,k}$.

► **Proposition 39.** For any $t \geq k \geq 1$, $C_{t,k}$ and $C'_{t,k}$ are r -locally equivalent if

$$\binom{t-2}{k-2} = 2^{r-1} \pmod{2^r} \quad \text{and} \quad \forall i \in [1, r-1], \quad \binom{t-i-2}{k-i-2} = 0 \pmod{2^{r-i}}$$

Proof. $C_{t,k}$ and $C'_{t,k}$ are related by a r -local complementation on the set $\binom{[1,t]}{k}$ (which can be seen as the multiset where each vertex of $\binom{[1,t]}{k}$ appears once). Let $K \subseteq [1, t]$ of size $k' + 2$. $\binom{[1,t]}{k} \bullet \Lambda_G^K = \left| \left\{ x \in \binom{[1,t]}{k} \mid K \subseteq x \right\} \right| = \binom{t-k'-2}{k-k'-2}$ is a multiple of $2^{r-k'-\delta(k')}$ by hypothesis. Thus, $\binom{[1,t]}{k}$ is r -incident. Besides, for any $u, v \in [1, t]$, $\binom{[1,t]}{k} \bullet \Lambda_G^{u,v} = \binom{t-2}{k-2} = 2^{r-1} \pmod{2^r}$ by hypothesis. Thus, $C_{t,k} \star^r \binom{[1,t]}{k} = C'_{t,k}$. ◀

The following proposition provides a sufficient condition on t and k for the non r -local equivalence of $C_{t,k}$ and $C'_{t,k}$.

► **Proposition 40.** For any odd $k \geq 3$, $t \geq k + 2$, $C_{t,k}$ and $C'_{t,k}$ are not r -locally equivalent if $\binom{t}{2}$ is odd and $\binom{k}{2} = 0 \pmod{2^r}$.

Proof. Let us suppose by contradiction that $C_{t,k}$ and $C'_{t,k}$ are r -locally equivalent. By Corollary 31, they are related by a single r -local complementation on the vertices in $\binom{[1,t]}{k}$. Let S be the multiset in $\binom{[1,t]}{k}$ such that $C_{t,k} \star^r S = C'_{t,k}$. For each $u, v \in [1, t]$, $S \bullet \Lambda_{C_{t,k}}^{u,v} = \sum_{x \in \Lambda_{C_{t,k}}^{u,v}} S(x) = 2^{r-1} \pmod{2^r}$. Summing over all pairs $u, v \in [1, t]$, and, as by hypothesis $\binom{t}{2}$ is odd, $\sum_{u,v \in [1,t]} S \bullet \Lambda_{C_{t,k}}^{u,v} = \binom{k}{2} \sum_{x \in \binom{[1,t]}{k}} S(x) = \binom{t}{2} 2^{r-1} \pmod{2^r} = 2^{r-1} \pmod{2^r}$. The first part of the equation is true because $\sum_{u,v \in [1,t]} S \bullet \Lambda_{C_{t,k}}^{u,v} = \sum_{u,v \in [1,t]} \sum_{x \in \Lambda_{C_{t,k}}^{u,v}} S(x) = \sum_{x \in \binom{[1,t]}{k}} \sum_{u,v \in x} S(x)$. This leads to a contradiction as $\binom{k}{2} = 0 \pmod{2^r}$ by hypothesis. ◀

It remains to find, for any r , parameters t and k such that the corresponding graphs are r -locally equivalent but not $(r-1)$ -locally equivalent. Fortunately, such parameters exist.

► **Theorem 41.** *For any $r \geq 2$, $C_{t,k}$ and $C'_{t,k}$ are r -locally equivalent but not $(r-1)$ -locally equivalent when $k = 2^r + 1$ and $t = 2^r + 2^{\lceil \log_2(r) \rceil + 1} - 1$. Thus, $|C_{t,k}\rangle$ and $|C'_{t,k}\rangle$ are LC_r -equivalent but not LC_{r-1} -equivalent.*

The proof of Theorem 41 can be found in the full version of this paper [9].

► **Remark 42.** For the case $r = 2$, we obtain the pair $(C_{7,5}, C'_{7,5})$, which is the 28-vertex counter-example to the LU-LC conjecture from [36]. In particular, this translates to an example of a pair of graph states that are LC_2 -equivalent but not LC_1 -equivalent.

Thus, while Ji et al. proved that there exist pairs of graph states that are LU-equivalent but not LC_1 -equivalent [23], we showed a finer result – the existence of a infinite strict hierarchy of graph states equivalence between LC_1 - and LU-equivalence. There exist LC_2 -equivalent graph states that are not LC_1 -equivalent, LC_3 -equivalent graph states that are not LC_2 -equivalent... On the other end, for any integer r , there exist LU-equivalent graph states that are not LC_r -equivalent.

6 Conclusion

In this paper, we have introduced of a graphical characterisation of LU-equivalence for graph states, and consequently for stabilizer states. To achieve this, we have introduced a generalisation of the local complementation, and leveraged the structures of minimal local sets in graphs. A key outcome of this characterisation is the establishment of a strict hierarchy of equivalences for graph states, which significantly advances our understanding of the gap between the LC- and LU-equivalence. Thanks to this graphical characterisation, we have also proven a conjecture regarding families of graphs states where LC- and LU-equivalence coincide.

This graphical characterisation has additional potential applications, such as the search of minimal examples of graph states that are LU-equivalent but not LC-equivalent. The smallest known examples are of order 27, and it is known there is no counter example of order less than 8. More generally one can wonder whether there are smaller examples of graphs that are LC_r equivalent but not LC_{r-1} as the ones we have introduced are of order exponential en r . In terms of complexity, determining whether two graph states are LC-equivalent can be done in polynomial time. The graphical characterization of LU-equivalence also offers new avenues for exploring the complexity of the LU-equivalence problem, as allows one to study this computational problem from a purely graphical standpoint.

Abstract

A central result by Marx [ToC '10] constructs k -vertex graphs H of maximum degree 3 such that $n^{o(k/\log k)}$ time algorithms for detecting colorful H -subgraphs would refute the Exponential-Time Hypothesis (ETH). This result is widely used to obtain almost-tight conditional lower bounds for parameterized problems under ETH.

Our first contribution is a new and fully self-contained proof of this result that further simplifies a recent work by Karthik et al. [SOSA 2024]. In our proof, we introduce a novel graph parameter of independent interest, the linkage capacity $\gamma(H)$, and show that detecting colorful H -subgraphs in time $n^{o(\gamma(H))}$ refutes ETH. Then, we use a simple construction of communication networks credited to Beneš to obtain k -vertex graphs of maximum degree 3 and linkage capacity $\Omega(k/\log k)$, avoiding arguments involving expander graphs, which were required in previous papers. We also show that every graph H of treewidth t has linkage capacity $\Omega(t/\log t)$, thus recovering a stronger result shown by Marx [ToC '10] with a simplified proof.

Additionally, we obtain new tight lower bounds on the complexity of subgraph detection for certain types of patterns by analyzing their linkage capacity: We prove that almost all k -vertex graphs of polynomial average degree $\Omega(k^\beta)$ for $\beta > 0$ have linkage capacity $\Theta(k)$, which implies tight lower bounds for finding such patterns H . As an application of these results, we also obtain tight lower bounds for counting small induced subgraphs having a fixed property Φ , improving bounds from, e.g., [Roth et al., FOCS 2020].

1 Introduction

Over the past two decades, it has been shown that complexity assumptions about *exponential-time* problems imply far-reaching lower bounds for *polynomial-time* [13, 67, 68] and *parameterized* [26, 56] problems. Among the first such results, it was shown that the Exponential-Time Hypothesis (ETH) about the Boolean satisfiability problem SAT implies an $n^{\Omega(k)}$ -time lower bound for the seemingly unrelated parameterized problem CLIQUE of detecting k -cliques in n -vertex graphs [16, 17]. This lower bound solidifies the status of CLIQUE as a canonical hard problem in parameterized complexity.

Ideally, when reducing CLIQUE to some target problem, we would like to transfer the $n^{\Omega(k)}$ -time lower bound under ETH to the target problem. However, reductions from CLIQUE often require k gadgets to encode the vertices of a k -clique and $\Theta(k^2)$ additional gadgets to verify the edges between all pairs of encoded vertices. As each gadget typically increases the parameter by at least a constant amount, instances for CLIQUE are transformed into target instances with a parameter value of $\Theta(k^2)$ (see, e.g., [26, Section 13.6.3]). This in turn means that only $n^{o(\sqrt{\ell})}$ -time algorithms can be ruled out for a target problem with parameter ℓ .

Tighter lower bounds could be obtained if we could reduce from a subgraph problem similar to CLIQUE, but involving k -vertex patterns H with only $O(k)$ rather than $\Theta(k^2)$ edges. More specifically, for a fixed graph H , let COLSUB(H) be the problem of detecting H -subgraph copies in graphs G with vertex-colors from $V(H)$ such that every $v \in V(H)$ is mapped to a vertex of color v in G . (This problem can equivalently be interpreted as a *constraint satisfaction problem* with variables x_v for $v \in V(H)$ and arity-2 relations R_e for $e \in E(H)$. The domain of x_v is the set of v -colored vertices in G .) Many known parameterized reductions from CLIQUE can be modified to use COLSUB(H) as the reduction source, and a seminal result by Marx [59, Corollary 6.1] shows that COLSUB(H) is indeed hard under ETH for graphs H of maximum degree 3, albeit not with an entirely tight lower bound:

► **Theorem 1.1** ([50, 59]). *Assuming ETH, there exists a universal constant $\alpha > 0$ and an infinite sequence of graphs H_1, H_2, \dots such that, for all $k \in \mathbb{N}$, the graph H_k has k vertices and maximum degree 3, and COLSUB(H) does not admit an $O(n^{\alpha \cdot k / \log k})$ -time algorithm.*

This theorem has become a standard tool to prove almost-tight lower bounds along the lines of the above reduction scheme, and it has been applied to numerous parameterized problems from a diverse range of areas [1, 5, 8, 9, 10, 11, 12, 14, 18, 19, 20, 21, 22, 23, 25, 28, 34, 35, 36, 39, 42, 45, 49, 52, 57, 60, 62, 64].¹

1.1 Main Concept: Linkage Capacity

In this paper, we provide a new perspective on the seminal Theorem 1.1, which allows us to prove new results and to obtain a significantly simpler proof, even compared to a recent simplified version [50]. Our new perspective hinges upon a new graph parameter, the *linkage capacity* $\gamma(H)$ of a graph H . Roughly speaking, this parameter measures how well vertices of H can be connected by vertex-disjoint paths on specified endpoint pairs.

¹ Theorem 1.1 is actually a corollary of a more general result proved by Marx [59]: Assuming ETH, there exists a universal constant $\alpha > 0$ such that, for every fixed graph H with treewidth t , the problem COLSUB(H) cannot be solved in time $O(n^{\alpha \cdot t})$. We defer the discussion of this more general result to Section 1.3. For most of the applications cited above, the corollary stated in Theorem 1.1 suffices.

Known Lower Bound for Cliques

To explain our ideas, let us first sketch the classical $n^{\Omega(k)}$ -time lower bound for CLIQUE under ETH (see, e.g., [26, Theorem 14.21]). The proof is as follows: It is known that, assuming ETH, the 3-COLORING problem in n -vertex graphs G with maximum degree 4 cannot be solved in $2^{o(n)}$ time. If G can be transformed into an equivalent instance X of CLIQUE with approximately $3^{n/k}$ vertices, then an $n^{o(k)}$ -time algorithm for CLIQUE would imply a $2^{o(n)}$ -time algorithm for the 3-COLORING problem, contradicting ETH.

To transform G into X , the vertex set $V(G)$ is divided equitably into blocks V_1, \dots, V_k . The vertices of X correspond to the 3-colorings of these blocks, and two vertices in X are connected by an edge if their colorings are compatible, meaning they come from different blocks and together form a proper coloring. This way, the k -cliques K in this “compatibility graph” X correspond bijectively to valid 3-colorings of G : Indeed, the vertices of K provide a valid coloring for each block, and the presence of edges between all $u, v \in V(K)$ in X ensures that the union of these partial colorings is a valid coloring of the entire graph G .

From Cliques to General Subgraphs

To show hardness of COLSUB(H) with general k -vertex patterns H , we adapt the lower bound for CLIQUE. First, consider the favorable scenario that the vertices of an input graph G for 3-COLORING can be split equitably into blocks V_1, \dots, V_k , corresponding to the k vertices of H , such that the edges of G “respect” H : Every edge of G is contained within one block or between blocks V_i and V_j with $ij \in E(H)$. In this scenario, not all pairs of partial 3-colorings need to be checked for compatibility. Indeed, it suffices to check this only between blocks V_i and V_j with $ij \in E(H)$, since no other edges could lead to an incompatibility.

In general however, we cannot assume that an n -vertex graph G of maximum degree 4 can be split equitably such that its edges respect H . To address this, we “re-route” the edges in G along paths on new vertices (that are placed in the old blocks) and edges that *do* respect H . While this eventually yields a graph G' in which all edges indeed respect H , it may be possible that most edges are routed on paths of length $\Omega(k)$, thus increasing the block size from n/k back to n . Even if routing via short paths is possible, it may be possible that a few blocks are hit disproportionately often, leading to the same problem. Both issues would render a fast algorithm for COLSUB(H) useless for the purpose of obtaining a (too) fast algorithm for 3-COLORING.

Linkage Capacity

The crucial observation is that many patterns H enable a simultaneous “batch-rerouting” of batches with $\Omega(k)$ edges in G ; adding all paths for any such a batch to G increases each block size only by 1. Moreover, as also observed in [50, Theorem 4.2], it is sufficient to consider batches that are matchings, since G has maximum degree 4 and thus admits a 5-edge-coloring, i.e., a partition of its edges into 5 matchings.

The *linkage capacity* $\gamma(H)$ allows us to precisely quantify how well H supports batch-rerouting of matchings by vertex-disjoint paths. To define it, first let the *blowup* $H \otimes J_t$ for $t \in \mathbb{N}$ be H with every vertex copied to t clones that form a clique; this is essentially the maximal graph with block size t whose edges respect H . See also Figure 1. Second, call a set X in a graph H' *matching-linked* if, for every matching M with vertex-set X , there exist disjoint u - v -paths in H' realizing the edges $uv \in M$. Then the linkage capacity $\gamma(H)$ of a graph H is the largest $c > 0$ such that $H \otimes J_t$ contains a matching-linked set X of size $\lfloor ct \rfloor$; this is finite, and we even have $\gamma(H) \leq k$, since $|X| \leq |V(H \otimes J_t)| = kt$.

Following the reduction sketch from 3-COLORING given above, and using large matching-linked sets in blowups $H \otimes J_t$ to accommodate the vertices of a 3-COLORING instance G , we establish a conditional lower bound on the complexity of COLSUB(H) based on $\gamma(H)$. For later use, we also prove a lower bound for the counting version #COLSUB(H) under the counting exponential-time hypothesis #ETH.

► **Theorem 1.2.** *Assuming ETH, there exists a universal constant $\alpha > 0$ such that no fixed graph H admits an $O(n^{\alpha \cdot \gamma(H)})$ -time algorithm for COLSUB(H). The same holds for #COLSUB(H) under #ETH.*

It remains to determine when H has large linkage capacity. For example, if H itself admits a large matching-linked set, then this translates to its blowups, thus establishing large $\gamma(H)$. This is however only a sufficient criterion, even though most of our lower bounds are based on it. As we investigate in Section 6, the linkage capacity is related to certain fractional multicommodity flow problems whose relevance in the context of lower bounds for COLSUB(H) under ETH was already identified before [50, 59]. Linkage capacity however is a much more elementary and more applicable concept. In particular, the restriction to matchings allows us to connect it to known results on routing with specified terminal pairs in order to obtain lower bounds on $\gamma(H)$. This in turn allows us to prove new results under ETH without much technical effort.

1.2 Applications of Linkage Capacity

With Theorem 1.2 in hand, we show lower bounds on the complexity of the colorful H -subgraph problem via the linkage capacity $\gamma(H)$. For this, we enlist the help of communication network theory [54, 6], random graph theory [15], linear programming [37, 55], and classical results on connectivity via vertex-disjoint paths from graph theory [58, 66].

A Fully Self-Contained Proof of Theorem 1.1

Our first application of Theorem 1.2 is a significantly simplified and self-contained² proof of the seminal Theorem 1.1. The original proof of this theorem by Marx [59] uses highly nontrivial arguments regarding multicommodity flows as a black box [37]. Even a very recent simplification [50] still requires the construction of expander graphs and routing algorithms for such graphs, both of which are highly nontrivial [2, 55].

By approaching the problem through linkage capacity, we observe that expansion is *not* required to obtain Theorem 1.1. Instead, we can rely on a very simple construction of telecommunication networks, credited to a 1964 paper by Beneš [6], then employed at Bell Labs: A *Beneš network* contains $s = 2^\ell$ input and output vertices, and $k = O(s \log s)$ vertices in total. For every pairing of inputs to outputs, the network guarantees private data streams (i.e., vertex-disjoint paths) connecting each input to its specified output. Both the network construction and routing therein are elementary divide-and-conquer arguments that feature in undergraduate introduction courses to discrete mathematics [54]. A minuscule augmentation of this construction gives us k -vertex graphs of maximum degree 4 and linkage capacity $\Omega(k/\log k)$. Combined with Theorem 1.2, this gives a novel proof of Theorem 1.1.

² We give a self-contained proof starting from the known result that, under ETH, the 3-COLORING problem requires $2^{\Omega(n)}$ time on 4-regular graphs with n vertices. This can be shown easily from ETH together with the sparsification lemma.

We recently found that graphs with large matching-linked sets have been used in communication and extension complexity: A paper by Göös, Jain, and Watson [41, Section 3.3] briefly mentions “bounded-degree butterfly graphs” from an unpublished manuscript on pebble games by Nordström [61, Proposition 5.2] as an alternative to expanders; this alternative construction turns out to be precisely that of Beneš.

Tight Lower Bounds for Dense Graphs

Alon and Marx [4, Theorem 1.4] argue that the logarithmic slack in Theorem 1.1 cannot be overcome by current approaches – including ours. This holds even for patterns H of constant *average* rather than *maximum* degree. More modestly, one can ask for “just slightly” dense k -vertex patterns H such that $\text{COLSUB}(H)$ requires $n^{\Omega(k)}$ time under ETH.

Indeed, Alon and Marx [4, Theorem 1.5(2)] showed that, for every $\delta > 0$, certain specifically constructed patterns S with average degree $O(k^\delta)$ enjoy strong embeddability properties that entail $n^{\Omega(k)}$ -time lower bounds on the colorful S -subgraph problem [4, Theorem 1.8]. For some problems of interest however, e.g., for counting induced k -vertex patterns [24, 32, 64], one can only reduce from the colorful H -subgraph problem for *some* (say, adversarially chosen) dense pattern H , which may not necessarily be a graph S constructed by Alon and Marx. This imposes a bottleneck towards tight lower bounds for such problems.

One partial remedy lies in using large clique minors (see, e.g., [27, 64]). Kostochka [53] showed that *every* graph H of average degree d contains a K_q -minor with $q = \Omega(d/\sqrt{\log d})$. Given a K_q -minor in H , a straightforward reduction yields an $n^{\Omega(q)}$ -time lower bound on the colorful H -subgraph problem under ETH. This implies that *every* pattern H of linear average degree $\Omega(k)$ requires an exponent of $\Omega(k/\sqrt{\log k})$ for the colorful H -subgraph problem (see, e.g., [27, Corollary 2.1]). While this improves upon the lower bound from Theorem 1.1, a slack of $\Omega(\sqrt{\log k})$ remains.

Using linkage capacity, we eliminate this slack and obtain a tight lower bound for dense patterns: Combining two textbook results [30], we show that every pattern H of average degree d has linkage capacity $\Omega(d)$.³ Theorem 1.2 then immediately yields:

► **Theorem 1.3.** *Assuming ETH, there exists a universal constant $\alpha > 0$ such that no fixed graph H with average degree d admits an $O(n^{\alpha \cdot d})$ -time algorithm for $\text{COLSUB}(H)$. The same holds for $\#\text{COLSUB}(H)$ under $\#\text{ETH}$.*

This theorem covers the “worst case”, i.e., patterns H of fixed average degree d that are adversarially chosen so as to minimize $\gamma(H)$. In particular, for linear average degree, an $n^{\Omega(k)}$ bound under ETH follows. This implies new tight lower bounds for very general classes of induced pattern counting problems [24, 64] (see Section 7 for details).

In the “average case”, much lower density turns out to be sufficient for an $n^{\Omega(k)}$ bound. Indeed, known results on routing in random graphs [15] imply directly that *almost all* k -vertex graphs H with average degree $d \in \Omega(k^\beta)$ for constant $\beta > 0$ have linkage capacity $\Theta(k)$. Observe that the average degree is that of the specifically constructed patterns S by Alon and Marx [4]; we show that not only specific patterns, but *almost all* patterns of polynomial average degree have an $n^{\Omega(k)}$ bound for $\text{COLSUB}(H)$.

³ This lower bound is asymptotically tight, since worst-case examples like $K_{d,s-d}$ have linkage capacity at most $2d + 1$. Indeed, a linked set of $2d + 2$ vertices would imply a linkage with $d + 1$ paths in $K_{d,s-d}$. This would in particular imply a matching with $d + 1$ edges, which clearly does not exist in $K_{d,s-d}$.

More generally, we show that the linkage capacity of the Erdős-Rényi random graph $\mathcal{G}(k, p)$ for non-degenerate probabilities p is $\Omega(k/\rho)$, where $\rho = \log(k)/\log(kp)$ is the typical distance between vertices in $\mathcal{G}(k, p)$ [7, 51]. We obtain the following general lower bound:

► **Theorem 1.4.** *Assuming ETH, there exists a universal constant $\alpha > 0$ such that for every constant $\epsilon > 0$ and every $p \geq (1 + \epsilon) \log k/k$, the following holds: With high probability, for an Erdős-Rényi random graph $H \sim \mathcal{G}(k, p)$, the problem COLSUB(H) does not admit an $O(n^{\alpha k/p})$ -time algorithm. Here, $\rho = \log(k)/\log(kp)$ is the typical distance in $G(k, p)$. The same holds for #COLSUB(H) under #ETH.*

Note that ρ is the logarithm of k in the base of the average degree kp ; this captures the time needed to concurrently explore all k vertices in a process that branches into kp random vertices from each vertex. It is intuitively clear that the linkage capacity should be at most $O(k/\rho)$: Almost all vertex pairs u, v in a random graph require u - v -paths of length ρ , so we cannot connect more than k/ρ vertex pairs without exhausting k vertices. The bound from [15] shows that, with high probability, $\Omega(k/\rho)$ vertex pairs *can* be connected.

1.3 Linkage Capacity and Treewidth

Theorems 1.3 and 1.4 are based on lower bounds on the linkage capacity of graphs H in terms of the density of H . We show that the linkage capacity can also be lower-bounded as a function of the *treewidth* of H . As already indicated above, Theorem 1.1 is actually a corollary of a much more general theorem on large-treewidth graphs shown by Marx [59]: Assuming ETH, he proved the existence of a universal constant $\alpha > 0$ such that no fixed graph H with treewidth t admits an $O(n^{\alpha t/\log t})$ -time algorithm for COLSUB(H). To obtain Theorem 1.1 from this general theorem, it suffices to choose a k -vertex expander graph H of maximum degree 3, since such graphs are known to have treewidth $\Omega(k)$.

We recover this theorem by showing that the linkage capacity of a graph H is lower-bounded by its treewidth, up to the “same” logarithmic factor that is missing in the original result by Marx [59]. That is, we show the lower bound $\gamma(H) = \Omega(t/\log t)$ for every graph H of treewidth t . In this proof, we use the same approximate min-cut/max-flow theorem for multicommodity flows [37, 55] that also appears in [59] as black box. Together with Theorem 1.2, this indeed recovers the more general theorem of Marx [59] (also for the counting version #COLSUB(H)) with a more transparent proof. Complementing the lower bound, we use a simple argument about balanced separations in low-treewidth graphs to show an upper bound of $\gamma(H) = O(t)$. We stress that both bounds are asymptotically tight. In particular, it can be shown that k -vertex expander graphs H of maximum degree 3 have linkage capacity $\gamma(H) = \Theta(k/\log k)$ and treewidth $\Theta(k)$.

It is a major open question in parameterized complexity whether the logarithmic loss in Marx’s lower bound [59] can be avoided for all graphs H . Indeed, the following conjecture seems to be known (e.g., communicated to us by Daniel Lokshtanov), although we are not aware of an explicit reference.

► **Conjecture 1.5 (You Cannot Beat Treewidth).** *Assuming ETH, there exists a universal constant $\alpha > 0$ such that no fixed graph H with treewidth t admits an $O(n^{\alpha t})$ -time algorithm for COLSUB(H).*

We note that even removing the $1/\log k$ factor from Theorem 1.1 would constitute a significant breakthrough. Alon and Marx [4] showed that current approaches cannot be used to achieve this; this is also true for our techniques. Still, with Theorems 1.3 and 1.4, we extend the scope where tight bounds for COLSUB(H) are known.

2 Preliminaries

We write $\mathbb{N} = \{1, 2, 3, \dots\}$ for the natural numbers. For $n \in \mathbb{N}$, we write $[n] := \{1, 2, \dots, n\}$. All logarithms are natural unless specified otherwise.

2.1 Basic Definitions

We use standard graph notation [30]. Graphs are finite and undirected, and we write uv for edges between u and v . A *path* from u to v is a sequence $P = (u = w_0, w_1, \dots, w_\ell = v)$ of distinct vertices such that consecutive vertices are adjacent. Slightly abusing notation, we also interpret P as a path from v to u . For a graph G and $X \subseteq V(G)$, we write $G[X]$ for the subgraph induced by X and $G - X := G[V(G) \setminus X]$ for the result of deleting X from G .

A *colored graph* is a triple $G = (V, E, c)$ where $c: V(G) \rightarrow C$ is a not necessarily proper *coloring* of the vertices. We say G is *canonically colored* if c is the identity mapping and we write G^{can} for the canonically colored version of G .

Given a “pattern” graph H and “host” graph G , we write $\#\text{Sub}(H \rightarrow G)$ for the number of subgraphs of G that are isomorphic to H . If H and G are colored, only subgraphs preserving the coloring are counted. For a fixed graph H , the problem $\#\text{COLSUB}(H)$ takes as input a colored graph $G = (V, E, c)$ with $c: V(G) \rightarrow V(H)$, and asks to compute $\#\text{Sub}(H^{\text{can}} \rightarrow G)$, while its decision version $\text{COLSUB}(H)$ asks whether $\#\text{Sub}(H^{\text{can}} \rightarrow G) \geq 1$.

To analyze the complexity of $\text{COLSUB}(H)$, we rely on several tools.

► **Definition 2.1** (Blowup). *Given a graph H and an integer $t \geq 1$, the blowup graph $H \otimes J_t$ contains the vertices $v^{(i)}$ for all $v \in V(H)$ and $i \in [t]$, and edges*

$$\{u^{(i)}v^{(j)} \mid uv \in E(H), i, j \in [t]\} \cup \{u^{(i)}u^{(j)} \mid u \in V(H), i \neq j \in [t]\}.$$

► **Remark 2.2.** Marx [59] uses the notation $H^{(t)}$ instead of $H \otimes J_t$. We choose $H \otimes J_t$ since there is no exponential increase in size, but we are rather taking a tensor product of H and the $(t \times t)$ all-ones matrix (usually denoted by J_t) and then turn cloned vertices into cliques.

A *multigraph* M is a graph that allows parallel edges with the same endpoints, but no self-loops. The *degree* $\deg_M(v)$ of a vertex $v \in V(M)$ is the number of edges incident to v , taking multiplicities into account. The *average degree* of M is $d(M) := 2|E(M)|/|V(M)|$.

A *matching* in M is set $M' \subseteq E(M)$ of pairwise vertex-disjoint edges. Slightly abusing notation, we regularly interpret M' again as a graph with edge set M' and vertices for all endpoints in M' . A *q -edge coloring* of M is a partition of $E(M)$ into q matchings. The *edge-chromatic number* of M , denoted by $\chi'(M)$, is the minimum number q such that M admits a q -edge coloring. A theorem by Shannon [65] provides an upper bound on the edge-chromatic number in terms of the maximum degree, though a looser bound with factor 2 can be achieved by a straightforward greedy algorithm.

► **Theorem 2.3** ([65]). *Every multigraph M of maximum degree d has $\chi'(M) \leq \lfloor \frac{3}{2}d \rfloor$.*

2.2 Linkages

Our hardness proofs for $\text{COLSUB}(H)$ crucially rely on linkages in graphs.

► **Definition 2.4** (Linkage and congestion). *Given a graph H and a multigraph M with vertex set $X \subseteq V(H)$, an M -linkage in H is a collection of paths $Q = (P_{uv})_{uv \in E(M)}$ such that P_{uv} has endpoints u and v . For $r \in \mathbb{N}$, we say that Q is r -congested if, for all $w \in V(H)$, at most r paths $P_{uv} \in Q$ contain w . If $r = 1$, we call Q an uncongested M -linkage.*

■ **Figure 1** (a) The grid graph \mathbb{E}_6 . Thick paths depict a 2-congested M -linkage, where $M = \{v_1v_4, v_2v_5, v_3v_6\}$ is a matching on the diagonal vertices. (b) The blowup graph $\mathbb{E}_6 \otimes J_2$, and an ungested M -linkage obtained from the 2-congested M -linkage in \mathbb{E}_6 .

Observe that, if Q is an ungested M -linkage, then M is necessarily a matching. We note that we commonly work with ungested M -linkages. More precisely, we usually require ungested M -linkages in blowups of graphs H . Towards this end, it is often convenient to “project” M back to the base graph H . Let H be a graph and let M be a multigraph with $V(M) \subseteq V(H \otimes J_q)$. We define the H -projection of M to be the multigraph $\pi(M)$ with vertex set $V(\pi(M)) := \{v \mid v^{(i)} \in V(M)\}$ and edge multiset $E(\pi(M)) := \{\{vw \mid v^{(i)}w^{(j)} \in E(M), v \neq w\}\}$.

► **Lemma 2.5.** *Let H be a graph and let $q \in \mathbb{N}$. Also let M be a matching with $V(M) \subseteq V(H \otimes J_q)$. If there is a q -congested $\pi(M)$ -linkage in H , then there is an ungested M -linkage in $H \otimes J_{2q}$.*

Note that a blowup of order $2q$ rather than q is needed. This is needed since we do not allow self-loops in the projection, i.e., the projection of M ignores edges contained in the same block $\{v^{(i)} \mid i \in [q]\}$. For technical reasons, we decide to handle those edges separately at the cost of losing a factor of two.

Proof. Let Q be a q -congested $\pi(M)$ -linkage in H . We obtain an ungested M -linkage Q' in $H \otimes J_{2q}$ as follows. For a vertex $w \in V(H)$, let P_1, \dots, P_t (if any exists) be all paths in Q that contain w as an internal vertex. We have $t \leq q$ by definition. We replace w in P_i with the vertex $w^{(q+i)}$ from the blowup graph $H \otimes J_{2q}$. Also, all endpoints of the paths are replaced in the natural way, i.e., if P has endpoints u and v , and uv is the “projection” of $u^{(i)}v^{(j)}$ in M , then P gets endpoints $u^{(i)}$ and $v^{(j)}$. Finally, for each edge $v^{(i)}v^{(j)} \in E(M)$, we add the path $(v^{(i)}, v^{(j)})$ to Q' . By the definition of the blowup graph, the resulting collection Q' is an ungested M -linkage in $H \otimes J_{2q}$. ◀

The following example illustrates the notion of linkages and the interplay between congestion and blowups; see Figure 1.

► **Example 2.6 (Grid graph).** Write \mathbb{E}_ℓ for the grid graph on vertex set $[\ell] \times [\ell]$. For every matching M on the set of diagonal vertices $v_i = (i, i)$ for $i \in [\ell]$, we observe that \mathbb{E}_ℓ contains a 2-congested M -linkage $Q(M) = \{P_{uv}\}_{uv \in M}$. This 2-congested linkage induces an ungested M -linkage in $\mathbb{E}_\ell \otimes J_2$ via Lemma 2.5. See also Figure 1.

More specifically, given an edge from $u = (a, a)$ to $v = (b, b)$ for $a < b$, we define P_{uv} as the concatenation of the path P_{uv}^{\rightarrow} on vertices $u = (a, a), \dots, (b, a)$ and the path P_{uv}^{\uparrow} on vertices $(b, a), \dots, (b, b) = v$. The paths P_{uv}^{\rightarrow} for $uv \in M$ are vertex-disjoint (as distinct paths have distinct y -coordinates), and so are the paths P_{uv}^{\uparrow} for $uv \in M$ (having distinct x -coordinates), so $Q(M)$ is indeed a 2-congested M -linkage.

3 Lower Bounds from Linkage Capacity

The Exponential-Time Hypothesis ETH [43] postulates the existence of a constant $\alpha > 0$ such that no $O(2^{\alpha n})$ time algorithm can decide, on input a 3-CNF formula φ with n variables, whether φ admits a satisfying assignment. Its *a priori* weaker counting version #ETH postulates the same lower bound for *counting* the satisfying assignments of φ [29]. For both hypotheses, the sparsification lemma [44, 29] rules out such algorithms even under the additional condition that every variable in φ appears in at most C clauses, for some constant $C \in \mathbb{N}$. By a standard reduction, lower bounds follow for the problem 3-COLORING of deciding whether an input graph G admits a proper vertex-coloring with 3 colors where no adjacent vertices receive the same color; see for example [56, Theorem 3.2].

► **Theorem 3.1.** *Assuming ETH, there is a constant $\beta > 0$ such that 3-COLORING cannot be solved in time $O(2^{\beta n})$ for n -vertex input graphs G of maximum degree 4. The same holds for #3-COLORING under #ETH.*

This theorem is the foundation for the lower bounds shown in this paper.

3.1 Instances That Fit into Blowups

It is useful for us to generalize 3-COLORING slightly, by allowing edges to either enforce equality or disequality of their endpoint colors. Since “equality edges” can be contracted without changing the number of valid assignments, we obtain an immediate way to simulate edges in a 3-COLORING instance by paths.

► **Definition 3.2.** *Given a graph $G = (V, E)$ with a partition $E = E_{=} \cup E_{\neq}$, a proper 3-assignment is a function $a : V \rightarrow [3]$ such that $a(u) = a(v)$ for all $uv \in E_{=}$, while $a(u) \neq a(v)$ for all $uv \in E_{\neq}$. The problem 3-ASSIGNMENT asks to determine the existence of a proper assignment on input $(G, E_{=}, E_{\neq})$, while #3-ASSIGNMENT asks to count them.*

It is possible to convert instances G for 3-ASSIGNMENT into instances X for COLSUB(H). Moreover, if G fits into a moderately small blowup of H , then X is only of moderately exponential size. This can be shown by a simple “split-and-list” reduction that follows the sketch given in the introduction for CLIQUE.

► **Lemma 3.3.** *Let H be a fixed k -vertex graph with canonical vertex-coloring. Given a subgraph G of $H \otimes J_t$ for $t \in \mathbb{N}$, a colored graph X on $k \cdot 3^t$ vertices can be computed in $9^t \cdot \text{poly}(k, t)$ time such that $\#\text{Sub}(H \rightarrow X)$ equals the number of proper 3-assignments in G .*

Proof. Suppose $V(H) = [k]$ and consider the partition of $V(G)$ into $V_w = \{w^{(1)}, \dots, w^{(t)}\}$ for $w \in [k]$. Define X_w for $w \in [k]$ as the set of all proper 3-assignments to $G[V_w]$.

For $w, w' \in [k]$, we call two 3-assignments $a \in X_w$ and $a' \in X_{w'}$ *compatible* if their union is a proper 3-assignment of $G[V_w \cup V_{w'}]$. Let us define

$$A_X := \{(a_1, \dots, a_k) \in X_1 \times \dots \times X_k \mid \forall ww' \in E(H) : a_w \text{ and } a_{w'} \text{ are compatible}\}$$

$$A_G := \{a : V(G) \rightarrow [3] \mid a \text{ is proper 3-assignment of } G\}$$

28:10 Can You Link Up With Treewidth?

We observe that the map $a \mapsto (a_1, \dots, a_k)$ from A_G to A_X , where a_w is the restriction of a to V_w , is a bijection. Indeed, in the image of $a \in A_G$ under this map, a_w and $a_{w'}$ are compatible for all $w, w' \in E(H)$. Conversely, given $(a_1, \dots, a_k) \in A_X$, recall that every edge $uv \in E(G)$ satisfies $u \in V_w$ and $v \in V_{w'}$ for some $w, w' \in [k]$ with (a) $w = w'$, or (b) $ww' \in E(H)$. In case (a), since a_w is proper, the endpoints of uv receive a proper assignment under a . In case (b), because the union of a_w and $a_{w'}$ is a proper 3-assignment of $G[V_w \cup V_{w'}]$, the endpoints of uv receive a proper assignment under a . Thus $a \in A_G$.

Finally, the graph X is defined on vertices $\bigcup_{w \in [k]} X_w$, where each vertex in X_w is colored by $w \in [k]$. An edge is present between $a \in X_w$ and $b \in X_{w'}$ if and only if $ww' \in E(H)$ and a and b are compatible. The (colored) subgraphs S of X isomorphic to H correspond to tuples in A_X . Indeed, $V(S)$ corresponds to a tuple $(a_1, \dots, a_k) \in X_1 \times \dots \times X_k$, and the presence of edges of H in S implies that a_w and $a_{w'}$ are compatible for $ww' \in E(H)$. Since $|X_w| \leq 3^t$ for all $w \in [k]$, the graph X can be computed by brute-force in $9^t \cdot \text{poly}(k, t)$ time. ◀

3.2 The Linkage Capacity of a Graph

First, we need to define a term for vertex sets X in graphs that can be paired up arbitrarily via paths in H . This resembles Diestel's [30] notion of *linkedness*, see Section 5.1, which however requires this property for the entire graph H .

► **Definition 3.4** (Matching-linked set). *Given a graph H , we say that $X \subseteq V(H)$ is matching-linked if H contains an uncongested M -linkage for every matching M on vertex set X .*

► **Remark 3.5.** We stress that the condition in the definition is crucially required even if the edges of M are *not* contained in $E(H)$: Only the *endpoints* of M need to be contained in X .

A simple edge-coloring argument, also used in Lemma 3.11, shows that large matching-linked sets X in blowups $H \otimes J_t$ suffice to embed graphs G of maximum degree Δ into $H \otimes J_{2\Delta \cdot t}$. Thus, large matching-linked sets X in blowups of H are a useful “resource” attainable from H that allows us to use Lemma 3.3.

Not all such sets X however need to originate from matching-linked sets in H itself. Consider a set X in H that *just* fails to be matching-linked, as in Example 2.6, in the sense that X still admits M -linkages of congestion 2 in H . Such M -linkages then induce uncongested M -linkages in $H \otimes J_2$. As our goal is to embed a 3-COLORING instance G into a moderately large blowup of H , such a constant-factor loss would be acceptable. This flexibility is captured by the *linkage capacity*, which measures the maximum size of matching-linked sets in blowups of H relative to the blowup order.

► **Definition 3.6** (Linkage capacity). *The linkage capacity $\gamma(H)$ is the supremum over $c > 0$ such that $H \otimes J_t$ contains a matching-linked set X with $|X| = \lfloor ct \rfloor$ for all large enough $t \in \mathbb{N}$.*

Every graph H trivially satisfies $1 \leq \gamma(H) \leq |V(H)|$. We show below that large matching-linked sets in H lift into blowups, establishing high linkage capacity $\gamma(H)$ – but as mentioned above, even a matching-linked set in a small blowup of H suffices.

► **Lemma 3.7.** *Let H be a graph and suppose $H \otimes J_q$ for $q \in \mathbb{N}$ contains a matching-linked set X . Then $\gamma(H) \geq \frac{1}{3} \cdot |X|/q$.*

Proof. The proof rests on the following claim.

▷ **Claim 3.8.** Let H' be a graph and suppose $X' \subseteq V(H')$ is a matching-linked set. Then $X'_t := \{v^{(i)} \mid v \in X', 1 \leq i \leq t/3\}$ is matching-linked in $H' \otimes J_t$ for every $t \in \mathbb{N}$.

Proof. Let M be a matching on X'_t and let $M' := \pi(M)$ be the H' -projection of M . Observe that M' has maximum degree at most $t/3$, so $\chi'(M') \leq t/2$ by Theorem 2.3. Hence, the multigraph M can be partitioned into $r \leq t/2$ matchings M_1, \dots, M_r on X' . Since X' is a matching-linked set, for every M_i , there is an uncongested M_i -linkage Q_i in H' . So $Q := \bigcup_{i \in [r]} Q_i$ is a r -congested M' -linkage in H' , and there is an uncongested M -linkage in $H' \otimes J_t$ by Lemma 2.5. \triangleleft

Let $c < \frac{1}{3} \cdot |X|/q$. Then there is $t_0 \in \mathbb{N}$ and $c' < \frac{1}{3} \cdot |X|$ such that

$$c' \cdot \lfloor t/q \rfloor \geq c \cdot t \tag{1}$$

for all $t \geq t_0$. Also, there is some $\ell_0 \in \mathbb{N}$ such that

$$|X| \cdot \lfloor \ell/3 \rfloor \geq \lfloor c'\ell \rfloor \tag{2}$$

for all $\ell \geq \ell_0$. Now let $t \geq \max(t_0, \ell_0 \cdot q)$ and let $\ell := \lfloor t/q \rfloor \geq \ell_0$ and consider the graph $H' := H \otimes J_q$. By Claim 3.8 the graph $H' \otimes J_\ell$ contains a matching-linked set X'_ℓ with

$$|X'_\ell| \geq |X| \cdot \lfloor \ell/3 \rfloor \stackrel{(1)}{\geq} \lfloor c'\ell \rfloor \stackrel{(2)}{\geq} \lfloor ct \rfloor.$$

Since $(H \otimes J_q) \otimes J_\ell$ is a subgraph of $H \otimes J_t$, we conclude that $H \otimes J_t$ contains a matching-linked set of size $\lfloor ct \rfloor$, thus proving the lemma. \blacktriangleleft

As a concrete example, let us use Example 2.6 to bound the linkage capacity of grids.

► **Lemma 3.9.** *For the ℓ -by- ℓ grid graph \boxplus_ℓ , we have $\gamma(\boxplus_\ell) \geq \ell/6$.*

Proof. Suppose $V(\boxplus_\ell) = [\ell]^2$. By Example 2.6, the set $X := \{(i, i)^{(1)} \mid i \in [\ell]\}$ is matching-linked in the blowup $\boxplus_\ell \otimes J_2$. The lemma follows by invoking Lemma 3.7. \blacktriangleleft

3.3 Fitting Instances into Blowups via Linkage Capacity

Having introduced linkage capacity and its key properties, we now use it to embed graphs G into blowups $H \otimes J_t$ with $t = O(n/\gamma(H))$. If we can show that $\gamma(H)$ is large, then ETH implies strong lower bounds for COLSUB(H) via Theorem 3.1 and Lemma 3.3.

A minor constructivity issue arises: Some techniques for lower-bounding $\gamma(H)$ do not necessarily yield efficient algorithms for finding linkages in blowups of H . Thus, it could *a priori* be possible for G to embed into $H \otimes J_t$, yet we cannot efficiently find an embedding. This concern is resolved by known algorithms for graphs of bounded neighborhood diversity [40, Theorem 3.7] (a self-contained argument is given in the full version):

► **Theorem 3.10.** *Let $f(k) = 3^{k^2+2}$. Given a k -vertex graph H and $t \geq 2$ as input, a matching-linked set X of maximum size in $H \otimes J_t$ can be found in $O(t^{f(k)})$ time. Given additionally a matching-linked set X in $H \otimes J_t$ and a matching M with vertex set X , an M -linkage in $H \otimes J_t$ can be found in $O(t^{f(k)})$ time.*

We can now turn to our main lemma. In the following, given graphs G and G' without loops or multi-edges, a G -linkage $Q = (P_{uv})_{uv \in E(G)}$ in G' is a *topological G -minor model* in G' if paths P_{uv} and $P_{u'v'}$ for $uv, u'v' \in E(G)$ in Q intersect only at endpoints. In particular, such intersections can occur only if uv and $u'v'$ share a common vertex. We refer to the subgraph of G' induced by Q as the *image* of Q .

■ **Figure 2** (a) A graph G that fails to be embedded into the blowup $\boxplus_3 \otimes J_2$ due to the colored edges, which are partitioned into three matchings. (b) An embedding of G into $\boxplus_3 \otimes J_3$ as a topological minor, where each colored edge gets routed via new vertices from the blowup.

▶ **Lemma 3.11.** *Let H be a fixed k -vertex graph and let $f(k) = 3k^{k+2}$. Then there is an $O(n^{f(k)})$ time algorithm that, given an instance G for 3-COLORING with n vertices and maximum degree 4, outputs an instance for 3-ASSIGNMENT with graph G' such that*

1. G' is the image of a topological G -minor in $H \otimes J_t$ for $t = 8\lceil n/\gamma(H) \rceil$, and
2. the proper 3-colorings of G correspond bijectively to the proper 3-assignments of G' .

Proof. Let $t' := \lceil n/\gamma(H) \cdot 15/14 \rceil$. Then $7t' \leq t$ whenever $t' \geq 14$. Definition 3.6 implies that, if t' is large enough then $H \otimes J_{t'}$ contains a matching-linked set X of size n .⁴ In $O(n^{f(k)})$ time, Theorem 3.10 finds such a set X . Fix $V(G) = X$ in the following.

The straightforward greedy algorithm yields a 7-edge-coloring $E(G) = M_1 \cup \dots \cup M_7$ in time $O(n)$. As X is matching-linked, the graph $H \otimes J_{t'}$ contains an uncongested M_i -linkage Q_i for every individual $i \in [7]$. Each linkage can be found $O(n^{f(k)})$ time via Theorem 3.10. These linkages together induce a topological G -minor model in $H \otimes J_{7t'}$ (see Figure 2): Consider $V(H \otimes J_{7t'})$ to be partitioned into 7 layers such that layer $i \in [7]$ contains the vertices $v^{(j)}$ with $v \in V(H)$ and $j \in (t' - 1)i + [t']$. By placing non-endpoint vertices from the linkages Q_1, \dots, Q_7 into different layers and keeping all endpoints in the first layer, we obtain a topological G -minor model Q in $H \otimes J_{7t'}$. Let us write G' for the image of Q .

We finalize the construction of the 3-ASSIGNMENT instance by specifying a partition of $E(G')$ into E_+ and E_- : For each path P_{uv} in Q , place one arbitrary edge into E_+ and all other edges into E_- . Then the proper 3-assignments to G' correspond to the proper 3-colorings of G , since contracting all equality edges in G' (which does not change the number of 3-assignments) yields an isomorphic copy of G on disequality edges. ◀

Combining the above, the proof of Theorem 1.2 is complete.

Proof of Theorem 1.2. By Theorem 3.1, ETH implies a constant $\beta > 0$ such that no $O(2^{\beta \cdot n})$ -time algorithm solves 3-COLORING on n -vertex graphs G of maximum degree 4. We set $\alpha = \beta/26$ and derive a contradiction from an $O(s^{\alpha \cdot \gamma})$ -time algorithm for COLSUB(H) on s -vertex input graphs, where H is any fixed graph with $\gamma = \gamma(H)$. Moreover, we only need to consider the case where $\gamma \geq 26/\beta$, because otherwise the theorem is trivial.

⁴ If t' is not large enough, then n is bounded by a function of H . We can then compute the number q of 3-colorings of G in constant time and output a dummy instance G' with q proper 3-assignments.

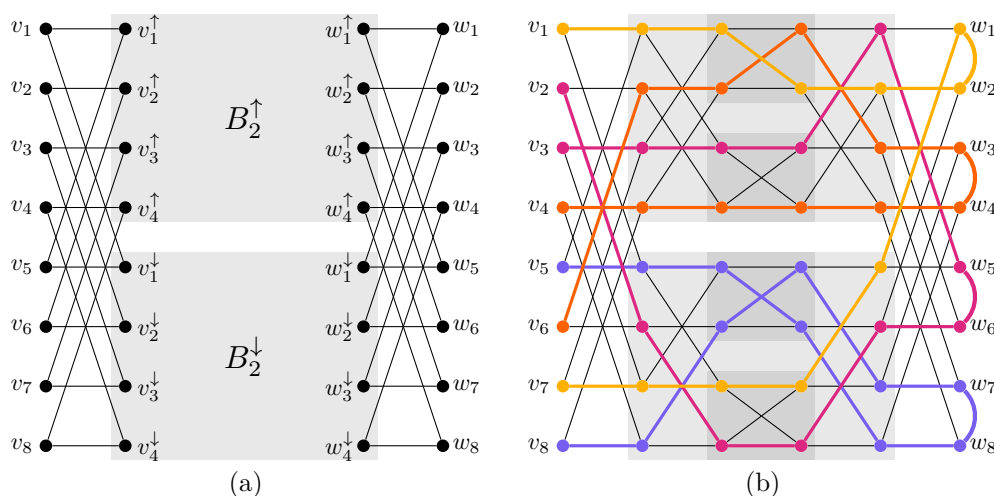

Figure 3 (a) Recursive construction of Beneš network B_3 with 8 inputs and 8 outputs from two copies of B_2 . (b) The augmented Beneš network \check{B}_3 is obtained by adding a matching to the outputs of B_3 , shown as curved edges. Thick paths indicate an M -linkage in \check{B}_3 for the matching $M = \{v_1v_7, v_2v_3, v_4v_6, v_5v_8\}$ on the input vertices.

In the following, let G be an instance for 3-COLORING of maximum degree 4. In time $O(n^{f(k)})$, Lemma 3.11 computes from G an equivalent instance for 3-ASSIGNMENT with a graph $G' \subseteq H \otimes J_t$ for $t = 8\lceil n/\gamma \rceil$. In time $9^t \cdot \text{poly}(k, t)$, Lemma 3.3 then yields a graph X with $|V(X)| \leq k \cdot 3^t$ such that 3-assignments in G' correspond to colorful H -copies in X . The overall running time to construct X is

$$O(n^{f(k)}) + 9^{8\lceil n/\gamma \rceil} \cdot \text{poly}(k, t) = O(2^{26n/\gamma}) = O(2^{\beta \cdot n}). \tag{3}$$

In the last step, we use the aforementioned assumption $\gamma \geq 26/\beta$. Then use the assumed $O(s^{\beta/26 \cdot \gamma})$ -time algorithm for COLSUB(H) on s -vertex input graphs. Its running time on the graph X constructed before, with $s \leq k \cdot 3^t$ vertices, is

$$O((k \cdot 3^t)^{\beta/26 \cdot \gamma}) = O(3^{8\lceil n/\gamma \rceil \cdot \beta/26 \cdot \gamma}) = O(3^{\beta/2 \cdot n}) = O(2^{\beta \cdot n}). \tag{4}$$

Combining Equations (3) and (4), we conclude that both constructing X and solving COLSUB(H) on X can be achieved in overall time $O(2^{\beta \cdot n})$. This contradicts Theorem 3.1. The proof for the counting version is analogous. \blacktriangleleft

4 Switching Networks

In this section, we consider a construction by Beneš [6] that yields k -vertex graphs with degree 4 and a linkage capacity of $\Omega(k/\log k)$. In particular, this allows us to complete the fully self-contained proof of Theorem 1.1.

The Beneš network B_ℓ for $\ell \in \mathbb{N}$ has 2^ℓ distinguished input and output vertices. In our terms, for every matching M between the inputs and outputs, the network B_ℓ admits an uncongested M -linkage. By “short-circuiting” the outputs, we obtain an *augmented Beneš network* \check{B}_ℓ , which allows routing paths from inputs back to inputs. In our terms, the inputs form a matching-linked set, since every matching M on the inputs admits an uncongested M -linkage in \check{B}_ℓ .

■ **Algorithm 1** Construct plain Beneš networks.

```

procedure BENES( $\ell$ ) returns  $B_\ell$  with  $s = 2^\ell$  in-/outputs
    if  $\ell = 1$  then return  $K_{2,2}$  with in-/outputs  $v_i, w_i$  for  $i \in [2]$ 
    else
         $B^\uparrow \leftarrow$  BENES( $\ell - 1$ ) with in-/outputs  $v_i^\uparrow, w_i^\uparrow$  for  $i \in [s/2]$ 
         $B^\downarrow \leftarrow$  BENES( $\ell - 1$ ) with in-/outputs  $v_i^\downarrow, w_i^\downarrow$  for  $i \in [s/2]$ 
         $B \leftarrow$  vertex-disjoint union of  $B^\uparrow$  and  $B^\downarrow$ 
        for  $i \in [s/2]$  do add to  $B$ 
            all four edges between  $\{v_i, v_{i+s/2}\}$  and  $\{v_i^\uparrow, v_i^\downarrow\}$ ,
            all four edges between  $\{w_i, w_{i+s/2}\}$  and  $\{w_i^\uparrow, w_i^\downarrow\}$ 
        return  $B$  with in-/outputs  $v_i, w_i$  for  $i \in [s]$ 
    
```

► **Definition 4.1** (Beneš networks). *The plain Beneš network B_ℓ for $\ell \in \mathbb{N}$ is the graph with distinguished inputs v_i and outputs w_i , for $i \in [s]$ with $s = 2^\ell$, returned by BENES(ℓ) in Algorithm 1. The augmented Beneš network \check{B}_ℓ is obtained from B_ℓ by adding an edge between outputs w_{2i-1} and w_{2i} , for each $i \in [s/2]$.*

A visualization can be found in Figure 3. Both B_ℓ and \check{B}_ℓ clearly have maximum degree 4. Let $T(s)$ for $s = 2^\ell$ count the vertices in the s -input Beneš network B_ℓ or \check{B}_ℓ . By construction, we have $T(s) = 2 \cdot T(s/2) + 2s$, and thus $T(s) = 2s \log_2 s$. Beneš networks are designed to admit uncongested linkages between the inputs and outputs [6]:

► **Theorem 4.2.** *For $\ell \in \mathbb{N}$, the set V of inputs in \check{B}_ℓ is matching-linked, with $|V| = s = 2^\ell$. Moreover, given as input $\ell \in \mathbb{N}$ and a matching M on V , an uncongested M -linkage in \check{B}_ℓ can be computed in $O(s \log s)$ time.*

With Lemma 3.7, we obtain:

► **Corollary 4.3.** *For $s = 2^\ell$, we have $\gamma(\check{B}_\ell) \geq s/3$.*

By combining Theorem 1.2 and Corollary 4.3, we can give an elementary proof of Theorem 1.1 (in a slightly modified form; see Remark 4.5).

► **Theorem 4.4.** *Assuming ETH, there exists a universal constant $\alpha > 0$ and an infinite sequence of graphs H_1, H_2, \dots such that, for all $k \in \mathbb{N}$, the graph H_k has k vertices and maximum degree 4, and COLSUB(H_k) does not admit an $O(n^{\alpha \cdot k / \log k})$ -time algorithm.*

Proof. For every $k \in \mathbb{N}$, pick $\ell \in \mathbb{N}$ maximal such that $|V(\check{B}_\ell)| \leq k$. Let H_k be obtained from \check{B}_ℓ by adding isolated vertices until the number of vertices is k . Since $|V(\check{B}_\ell)| = 2^{\ell+1}\ell$, we conclude that $2^{\ell+1}\ell \leq k < 2^{\ell+2}(\ell + 1)$ which implies that $k / \log_2 k < 2^{\ell+2}$. So

$$\gamma(H_k) \geq \gamma(\check{B}_\ell) \geq 2^\ell / 3 > \frac{1}{12} \cdot k / \log_2 k$$

by Corollary 4.3. Now the theorem follows from Theorem 1.2. ◀

► **Remark 4.5.** Observe that Theorem 1.1 provides a sequence of graphs of maximum degree 3 whereas Theorem 4.4 “only” guarantees maximum degree 4. However, the augmented Beneš networks \check{B}_ℓ can easily be modified to have maximum degree 3 by replacing each vertex with an edge, so \bowtie becomes $\bowtie \leftarrow$, and all other relevant properties remain the same.

For readers familiar with expander graphs, let us also remark that the Beneš network B_ℓ with $s = 2^\ell$ does *not* have constant expansion, as witnessed by its “upper half” U that contains the vertices of $B_{\ell-1}^+$ and all inputs and outputs with indices $i \in [s/2]$: We have $|U| = s \log_2 s$, but the $2s$ neighbors of U are all contained in the first two and last two columns of B_ℓ . This also holds for the augmented \check{B}_ℓ .

Universality of augmented Beneš networks

As an independent point of interest, let us remark that blowups of Beneš networks are universal for bounded-degree graphs with respect to topological minor containment: Mimicking the proof of Lemma 3.11, every n -vertex graph of maximum degree Δ can be found as a topological minor in the 2Δ -blowup of an augmented Beneš network with n inputs.

For comparison, every graph that contains every n -vertex graph of maximum degree Δ as a *subgraph* must necessarily have $\Omega(n^{2-2/\Delta})$ edges [3]. Under the more relaxed notion of universality via topological minor containment, Beneš networks show that universal graphs with only $O(\Delta^2 \cdot n \log n)$ vertices and edges are achievable.

► **Theorem 4.6.** *For every $n, \ell \in \mathbb{N}$, every graph G of maximum degree Δ and $n \leq 2^\ell$ vertices is a topological minor of $\check{B}_\ell \otimes J_{2\Delta-1}$. Moreover, on input G , a topological G -minor model in $\check{B}_\ell \otimes J_{2\Delta-1}$ can be computed in polynomial time.*

Proof. By Theorem 4.2, the inputs in \check{B}_ℓ form a matching-linked set X of size $s = 2^\ell \geq n$. We view $V(G) \subseteq X$ and decompose $E(G)$ into $2\Delta - 1$ matchings via the greedy edge-coloring algorithm. For each matching M , we use Theorem 4.2 to find an M -linkage Q in \check{B}_ℓ and place the internal vertices of Q in a private layer of $\check{B}_\ell \otimes J_{2\Delta-1}$, as in the proof of Lemma 3.11. The union of the linkages constructed this way is a topological G -minor model in $\check{B}_\ell \otimes J_{2\Delta-1}$. ◀

5 Patterns of Superlinear Density

We turn our attention to dense patterns, i.e., k -vertex patterns H of average degree $d(H) \in \omega(1)$. Unlike the sparse setting discussed earlier, a linkage capacity of $\Theta(k)$ is achievable in the dense case, which implies tight lower bounds for $\text{COLSUB}(H)$ under ETH.

5.1 Worst Case

We show that, for every graph H , the average degree $d(H) = 2|E(H)|/|V(H)|$ is a lower bound on the linkage capacity of H , up to a constant factor. First, we use Mader’s Theorem [58, Corollary 1] to extract a highly connected subgraph from H . A graph H is ℓ -connected if $|V(H)| > \ell$ and $H - X$ is connected for every set $X \subseteq V(H)$ with $|X| < \ell$.

► **Theorem 5.1** (see [30, Theorem 1.4.3]). *Every graph H with $d(H) \geq 4\ell$ contains a $(\ell + 1)$ -connected subgraph H' with $d(H') > d(H) - 2\ell$.*

Second, within the scope of this subsection only, we say that a graph H is ℓ -globally linked if $|V(H)| \geq 2\ell$ and each set $X \subseteq V(H)$ of size at most 2ℓ is matching-linked in H . (In graph theory, this notion is usually just called ℓ -linked – see, e.g., [30]. In our paper, we refer to it as ℓ -globally linked to distinguish it from our previous definitions of linkedness.) This definition implies in particular that H contains a matching-linked set X with $|X| \geq 2\ell$. Thomas and Wollan [66, Corollary 1.2] show that high connectivity implies high global linkedness.

► **Theorem 5.2** (see [30, Theorem 3.5.3]). *Let H be a graph and $\ell \in \mathbb{N}$. If H is 2ℓ -connected and $d(H) \geq 16\ell$, then H is ℓ -globally linked.*

28:16 Can You Link Up With Treewidth?

Together, these two theorems imply a lower bound on the linkage capacity that is linear in the average degree.

► **Lemma 5.3.** *For every graph H , we have $\gamma(H) \geq d(H)/48$.*

Proof. Theorem 5.1 yields a $\lceil d(H)/4 \rceil$ -connected subgraph H' of H with $d(H') > d(H)/2$. Theorem 5.2 shows that H' is $\lceil d(H)/32 \rceil$ -globally linked and thus contains a matching-linked set X of size at least $d(H)/16$. Then Lemma 3.7 shows that $\gamma(H) \geq \gamma(H') \geq d(H)/48$, where the first inequality uses that H' is subgraph of H . ◀

Now, Theorem 1.3 follows from Theorem 1.2 and Lemma 5.3.

5.2 Average Case

To show the hardness in the average case, we consider the linkage capacity of the Erdős-Rényi random graph. Let $\mathcal{G}(k, p)$ denote the distribution over k -vertex graphs where each edge is included independently with probability p . We need the following theorem adapted from [15], where “with high probability” refers to a probability tending to 1 for $k \rightarrow \infty$.

► **Theorem 5.4.** *Let $\varepsilon > 0$ be a constant. For all $p \geq (1 + \varepsilon) \log(k)/k$ the following holds: With high probability, for a random graph $H \sim \mathcal{G}(k, p)$, every matching M on $V(H)$ can be partitioned into $r = O(\log k / \log kp)$ matchings M_1, \dots, M_r such that H contains an uncongested M_i -linkage for all $i \in [r]$.*

The original theorem statement and proof in [15, Corollary 1.1] are concerned with the fixed-sized random graph model $G(k, m)$, and only deals with even k . But on the other hand, they give a stronger statement concerning the algorithmic efficiency of finding the desired partition, that it can be obtained with high probability by a random partition. A proof of the version stated here can be found in the full version.

The last theorem can be used to find large matching-linked sets inside a proper blowup of a random graph, which implies a high linkage capacity by Lemma 3.7.

► **Lemma 5.5.** *Let $\varepsilon > 0$ be a constant. For all $p \geq (1 + \varepsilon) \log(k)/k$, the linkage capacity of $H \sim \mathcal{G}(k, p)$ is at least $\Omega\left(\frac{k \log(kp)}{\log k}\right)$ with high probability.*

Proof. Let r be the bound specified in Theorem 5.4 and consider the blowup graph $H \otimes J_{2r}$. Let $X := \{v^{(1)} \mid v \in V(H)\}$. We show that X is matching-linked in $H \otimes J_{2r}$ with high probability, and the lemma then follows using Lemma 3.7.

Let M' be a matching on X . By the definition of X , its H -projection, $M := \pi(M')$, is also a matching on $V(H)$. We invoke Theorem 5.4 on the graph H with respect to the matching M to obtain a partition M_1, \dots, M_r , such that, for all $i \in [r]$ there is an uncongested M_i -linkage Q_i in H . Then $Q = \bigcup_{i \in [r]} Q_i$ is an r -congested M -linkage in H . So there is an uncongested M' -linkage in $H \otimes J_{2r}$ by Lemma 2.5. ◀

Now, Theorem 1.4 follows from Theorem 1.2 and Lemma 5.5.

6 Large-Treewidth Patterns and Concurrent Flows

In this section, we relate the linkage capacity of a graph to its treewidth. Towards this end, we first connect the linkage capacity to certain (fractional) multicommodity flows, and afterward rely on existing connections between such flows and treewidth [59, Section 3.1].

More specifically, given a graph H and $W \subseteq V(H)$, we consider the following multicommodity flow problem. For every pair $(u, v) \in W^2$, there is a distinct commodity uv that can be sent in arbitrary fractional amounts along different paths from u to v in H . The goal is to determine whether all pairs (u, v) can concurrently send an ϵ amount of uv to each other, while the total flow through every vertex $w \in V(H)$ is at most some globally fixed capacity C . Formally, this is captured by the following LP:

► **Definition 6.1.** *Let H be a graph. For $u, v \in V(H)$, write $\mathcal{P}_H(uv)$ for the set of paths from u to v in H ; the set $\mathcal{P}_H(uv)$ for $u = v$ contains only the path (u) . Given $W \subseteq V(H)$, the concurrent flow LP (for H and W) with vertex capacity $C > 0$ asks to*

$$\begin{aligned} & \text{maximize } \epsilon \\ & \text{subject to} \quad \sum_{p \in \mathcal{P}_H(uv)} x_p \geq \epsilon \quad \forall u, v \in W \\ & \quad \sum_{u, v \in W} \sum_{p \in \mathcal{P}_H(uv): w \in p} x_p \leq C \quad \forall w \in V(G) \\ & \quad x_p \geq 0 \quad \forall u, v \in W, p \in \mathcal{P}_H(uv). \end{aligned}$$

We write $\epsilon(H, W)$ to denote the optimal LP value for capacity $C = 1$.

While an optimal solution for $C = 1$ may assign fractional values to the variables x_p , every solution can be scaled to an integral solution, increasing the required capacity and the optimal LP value by the same factor. This integral solution then induces a congested model of the multigraph $K_{t,(q)}$ in H , where $t := |W|$ and $q \in \mathbb{N}$ is suitably chosen, and $K_{t,(q)}$ has t vertices and contains each possible (undirected) edge with multiplicity q .

► **Lemma 6.2.** *Let H be a graph and $W \subseteq V(H)$ be a set of size t . Then there is some $D \in \mathbb{N}$ such that $q := D \cdot \epsilon(H, W)$ is an integer and H contains a D -congested $K_{t,(q)}$ -linkage, where we set $V(K_{t,(q)}) = W$.*

Proof. Let D be the common denominator of the values for all x_p in a (rational) optimal solution of the concurrent flow LP for H and W with capacity $C = 1$. Then the LP with capacity D has an integral solution of value $q := D \cdot \epsilon(H, W)$. Now, consider the multiset Q which, for every distinct $u, v \in W$, contains every path $p \in \mathcal{P}_H(uv)$ with multiplicity x_p . Then Q is a D -congested $K_{t,(q)}$ -linkage where $V(K_{t,(q)}) = W$. ◀

Using this congested $K_{t,(q)}$ -linkage, we can establish lower bounds on the linkage capacity of H . Here, the following lemma is useful, since it allows us to route arbitrary multigraphs of bounded degree via short paths in this $K_{t,(q)}$.

► **Lemma 6.3.** *Let $q \in \mathbb{N}$ and let M be a multigraph with $V(M) = [t]$ and maximum degree at most qt . Then there is an M -linkage $Q = (P_{uv})_{uv \in E(M)}$ in K_t such that every edge $e \in E(K_t)$ appears in at most $18q$ paths in Q .*

We can conclude that a large value of the concurrent flow LP implies large linkage capacity.

► **Theorem 6.4.** *Let H be a graph and $W \subseteq V(H)$. Then $\gamma(H) \geq \epsilon(H, W) \cdot |W|^2/108$.*

Proof. Let $D \in \mathbb{N}$ be the integer obtained from Lemma 6.2 and set $D' := 18 \cdot D$. Let $q := D \cdot \epsilon(H, W)$ which, by Lemma 6.2, is an integer. Observe that $\epsilon(H, W) \leq 1/|W|$, so $D \geq q \cdot |W|$. Finally, let $s := q \cdot |W|$.

28:18 Can You Link Up With Treewidth?

Consider the graph $H \otimes J_{2D'}$ and let $X := \{w^{(i)} \mid w \in W, i \in [s]\}$. We show that X is matching-linked in $H \otimes J_{2D'}$. Let M be a matching on X . Let $\widehat{M} := \pi(M)$ be the H -projection of M . Observe that $\deg_{\widehat{M}}(w) \leq s = q \cdot |W|$ for all $w \in W$.

Lemma 6.3 finds an \widehat{M} -linkage $Q = (P_{uv})_{uv \in E(\widehat{M})}$ in $K_{t,(q)}$ (where $V(K_{t,(q)}) = W$) such that every edge of $K_{t,(q)}$ appears in at most 18 of those paths. Moreover, by Lemma 6.2, the graph H contains a D -congested $K_{t,(q)}$ -linkage $Q' = (P'_{uv})_{uv \in E(K_{t,(q)})}$. We construct a D' -congested \widehat{M} -linkage $\widehat{Q} = (\widehat{P}_{uv})_{uv \in E(\widehat{M})}$ in H as follows. For every $uv \in E(\widehat{M})$ we obtain \widehat{P}_{uv} from P_{uv} by substituting P'_e for every edge e appearing on P_{uv} . Clearly, \widehat{Q} is D' -congested since $D' = 18 \cdot D$. So there is an uncongested M -linkage in $H \otimes J_{2D'}$ by Lemma 2.5.

Overall, we get that X is matching-linked in $H \otimes J_{2D'}$. So

$$\gamma(G) \geq \frac{1}{3} \cdot \frac{|X|}{2 \cdot D'} = \frac{1}{3} \cdot \frac{s \cdot |W|}{36 \cdot D} = \frac{1}{108} \cdot \frac{q \cdot |W|^2}{D} = \frac{1}{108} \cdot \varepsilon(H, W) \cdot |W|^2$$

by Lemma 3.7. ◀

To bound the linkage capacity by the treewidth, we combine Theorem 6.4 with the following lemma that is (implicitly) shown by Marx [59].

► **Lemma 6.5** ([59]). *Let H be a graph of treewidth t . Then there is a set $W \subseteq V(H)$ such that $|W| = t$ and $\varepsilon(H, W) = \Omega(1/(t \log t))$.*

The basic idea to prove the lemma is to consider a set $W \subseteq V(H)$ of size t that does not admit balanced separators; large treewidth guarantees such a set (see [59, Lemma 3.2]). Then, using results from [37, 55], we obtain a bound on the optimal value of the dual LP, which gives $\varepsilon(H, W) = \Omega(1/(t \log t))$ (see [59, Proof of Lemma 3.6]).

► **Corollary 6.6.** *Let H be a graph of treewidth t . Then $\gamma(H) = \Omega(t/\log t)$.*

In particular, combining Theorem 1.2 and Corollary 6.6 allows us to recover the complexity lower bounds on $\text{COLSUB}(H)$ proved in [59].

We note without a proof that the bound in Corollary 6.6 is asymptotically optimal, since k -vertex 3-regular expander graphs have treewidth $\Theta(k)$ and linkage capacity $\Theta(k/\log k)$ (see also [4]). We complement Corollary 6.6 with the following upper bound on the linkage capacity.

► **Lemma 6.7.** *Let H be a graph of treewidth t . Then $\gamma(H) \leq 3(t+1)$.*

Proof. We first observe that $\text{tw}(H \otimes J_q) \leq q(t+1) - 1$ for every $q \in \mathbb{N}$. Indeed, given a tree decomposition (T, β) of H , we can obtain a tree decomposition for $H \otimes J_q$ by adding all copies of $v \in V(H)$ to all bags containing v .

Now, suppose towards a contradiction that $\gamma(H) > 3(t+1)$. Then there is some $q \in \mathbb{N}$ such that $H \otimes J_q$ contains a matching-linked set $X \subseteq V(H \otimes J_q)$ such that $|X| = 3q(t+1) + 3$. By [26, Lemma 7.20] there is a *balanced separation* for X , i.e., there are sets $A, B \subseteq V(H \otimes J_q)$ such that (1) $A \cup B = V(H \otimes J_q)$, (2) $|A \cap B| \leq q(t+1)$, (3) there is no edge between $A \setminus B$ and $B \setminus A$, and (4) $|X \cap A| \leq \frac{2}{3}|X|$ and $|X \cap B| \leq \frac{2}{3}|X|$. Hence, $|X \setminus A| \geq \frac{1}{3}|X| = q(t+1) + 1$ and $|X \setminus B| \geq \frac{1}{3}|X| = q(t+1) + 1$. Observe that the two sets $X \setminus A$ and $X \setminus B$ are disjoint (since $A \cup B = V(H \otimes J_q)$). So there is a matching M on the vertex set X (but not necessarily in $H \otimes J_q$) containing $q(t+1) + 1$ edges $M' \subseteq M$ with one endpoint in $X \setminus A$ and the other in $X \setminus B$. Now consider an uncongested M -linkage in $H \otimes J_q$ (which exists since X is matching-linked). Then every edge $e \in M'$ is realized by a path that needs to visit a vertex from $A \cap B$. However, this is a contradiction since $|M'| = q(t+1) + 1$ and $|A \cap B| \leq q(t+1)$. ◀

The upper bound is also asymptotically optimal by Lemma 3.9.

7 Implications for Counting Small Induced Subgraphs

We conclude with an application of our lower bounds for the complexity of counting induced k -vertex subgraphs. A k -vertex graph invariant Φ is an isomorphism-invariant map from k -vertex graphs H to the real numbers. We consider Φ to be fixed and wish to sum $\Phi(G[X])$ over all k -vertex subsets X of an input graph G to count, e.g., the planar or Hamiltonian induced k -vertex subgraphs of G . Formally, for a k -vertex graph invariant Φ , the problem $\#\text{INDSUB}(\Phi)$ takes as input a graph G , and asks to compute

$$\#\text{IndSub}(\Phi \rightarrow G) := \sum_{X \subseteq V(G)} \Phi(G[X]).$$

This problem was first studied in its parameterized version (where k is part of the input) by Jerrum and Meeks [46, 47, 48] and received significant attention in recent years [23, 24, 31, 32, 33, 38, 63, 64].

To determine the complexity of $\#\text{INDSUB}(\Phi)$, recent works usually analyze the *alternating enumerator* to build a generic reduction from $\#\text{COLSUB}(H)$. Formally, the *alternating enumerator* of a graph invariant Φ on a graph H is defined as⁵

$$\widehat{\Phi}(H) = (-1)^{|E(H)|} \sum_{S \subseteq E(H)} (-1)^{|S|} \Phi(H[S]),$$

where $H[S]$ has vertex set $V(H)$ and edge set S . Now, suppose H is a k -vertex graph with $\widehat{\Phi}(H) \neq 0$. Then the problem $\#\text{COLSUB}(H)$ can be reduced to $\#\text{INDSUB}(\Phi)$ in polynomial time (see, e.g., [24]). Hence, we also obtain new lower bounds for $\#\text{INDSUB}(\Phi)$ assuming $\widehat{\Phi}(H) \neq 0$ for suitable graphs H . In particular, we obtain the following result via Theorem 1.3, which improves over the corresponding lower bound in [24, Theorem 3.2(a)] (see also [31] and [32, Lemma 2.2]).

► **Theorem 7.1.** *There is a universal constant $\alpha_{\text{IND}} > 0$ and an integer $N_0 \geq 1$ such that for all numbers $k, \ell \geq 1$, the following holds: If Φ is a k -vertex graph invariant and there exists a graph H with $\widehat{\Phi}(H) \neq 0$ and $E(H) \geq k \cdot \ell \geq N_0$, then $\#\text{INDSUB}(\Phi)$ cannot be solved in time $O(n^{\alpha_{\text{IND}} \cdot \ell})$ unless ETH fails.*

As pointed out in Section 1.2, the weaker version, which only rules out an exponent of $\alpha_{\text{IND}} \cdot \ell / \sqrt{\log \ell}$, has been used to derive various lower bounds for specific types of invariants in [24, 32, 64]. All these lower bounds are improved by our new results. Let us give one concrete example, which improves over [24, Corollary 5.1]. For a k -vertex graph invariant Φ , we write $\text{supp}(\Phi)$ for the set of all graphs H with $V(H) = [k]$ and $\Phi(H) \neq 0$.

► **Corollary 7.2.** *For every $0 < \varepsilon < 1$ there are $N_0, \delta > 0$ such that the following holds. Let $k \geq N_0$ and let Φ be a k -vertex graph invariant with $1 \leq |\text{supp}(\Phi)| \leq (2 - \varepsilon)^{\binom{k}{2}}$. Then no algorithm solves $\#\text{INDSUB}(\Phi)$ in time $O(n^{\delta \cdot k})$ unless ETH fails.*

We stress that the exponent in the lower bound of Corollary 7.2 is asymptotically optimal.

For the other implications of Theorem 7.1, we refer the reader to the latest arXiv version of [24]. Indeed, following the first publication of this work, the latest version of [24] contains updated lower bounds for $\#\text{INDSUB}(\Phi)$ based on Theorem 7.1. However, let us stress that these improved lower bounds should (at least in part) be attributed to this work.

⁵ The precise formula is not relevant here, but we still give it for completeness.

Abstract

This work considers the problem of the noisy binary search in a sorted array. The noise is modeled by a parameter p that dictates that a comparison can be incorrect with probability p , independently of other queries. We state two types of upper bounds on the number of queries: the worst-case and expected query complexity scenarios. The bounds improve the ones known to date, i.e., our algorithms require fewer queries. Additionally, they have simpler statements, and work for the full range of parameters. All query complexities for the expected query scenarios are tight up to lower order terms. For the problem where the target prior is uniform over all possible inputs, we provide an algorithm with expected complexity upperbounded by $(\log_2 n + \log_2 \delta^{-1} + 3)/I(p)$, where n is the domain size, $0 \leq p < 1/2$ is the noise ratio, and $\delta > 0$ is the failure probability, and $I(p)$ is the information gain function. As a side-effect, we close some correctness issues regarding previous work. Also, en route, we obtain new and improved query complexities for the search generalized to arbitrary graphs. This paper continues and improves the lines of research of Burnashev–Zigangirov [Prob. Per. Informatsii, 1974], Ben-Or and Hassidim [FOCS 2008], Gu and Xu [STOC 2023], and Emamjomeh-Zadeh et al. [STOC 2016], Dereniowski et al. [SOSA@SODA 2019].

1 Introduction

1.1 Problem statement

An adaptive search problem for a general *search domain* \mathcal{S} and an arbitrary *adversary* can be formulated as follows. The goal is to design an adaptive algorithm, also referred to as a *strategy*, that finds a *target* initially unknown to the algorithm. Adaptivity means that the subsequent actions of the algorithm depend on the answers already received. The process is divided into *steps*: in each step the algorithm performs a *query* and receives an *answer*. Each query-reply pair provides new information to the algorithm: it learns that some part of the search space $S \subseteq \mathcal{S}$ does not contain the target while its complement does. From both

theoretical and practical viewpoints, it is of interest to develop error-resilient algorithms for such a search process. This can be modeled, for example, by the presence of a probabilistic noise: each reply can be erroneous with some fixed probability $0 < p < \frac{1}{2}$, independently. The performance of a strategy is measured by the number of performed queries.

In this work, we focus on searching with probabilistic noise in two particular types of search domains. The first is a sorted array (which, in the absence of noise, would lead to the classical binary search problem). Formally, for a linear order $v_1 < \dots < v_n$ with an unknown position of the target $v^* = v_j$, each query selects an element v_i , and the algorithm learns from the reply whether $v^* < v_i$ or $v^* \geq v_i$.

The second search domain we consider is a simple, undirected graph. More precisely, for an input graph G and an unknown target vertex v^* , each query selects some vertex v . The answer either states that v is the target or provides a neighbor u of v , that lies on a shortest path from v to v^* .

Searching through a graph can be viewed as a certain generalization of the former setting, as searching a linear order resembles searching a graph that is a path. However, it is important to note that the two models are not directly comparable, as in a graph search on a path there are three possible replies to a query, whereas in a search through an array, the answers are binary.

1.2 Overview of our results

To complete the search process, we need to learn roughly $\log_2 n$ bits of information (the identifier of the target). We can extract approximately $I(p) = 1 - H(p)$ bits of information from each reply, where $H(p) = -p \log_2 p - (1-p) \log_2 (1-p)$ is the binary entropy function. Therefore we expect the optimal algorithm to use around $\frac{\log_2 n}{I(p)}$ queries. In an idealized scenario where there always exists a query that perfectly bisects the search space, regardless of the answer, one could achieve this bound. However, perfect bisection is typically not possible due to the discrete nature of the search space, which causes algorithms to lose some lower-order terms.

Our results are summarized in Table 1. We use the following naming convention: if we are interested in the worst-case analysis of the query complexity, we refer to it as the *worst case* setting throughout the paper. Conversely, if we analyze the expected number of queries made by an algorithm, we call this the *expected query complexity* setting. We note that in each setting the process is randomized due to answers of the adversary. Additionally, some of our algorithms use random bits as well.

The binary search algorithms referenced in the theorems below are detailed in Section 3: Algorithms 16 and 13 correspond to Theorems 1 and 3, respectively. Interestingly, both algorithms are essentially the same and differ only by the stopping condition.

► **Theorem 1.** *For any noise parameter $0 < p < \frac{1}{2}$ and a confidence threshold $0 < \delta < 1$, there exists a binary search algorithm that after the **expected** number of*

$$\frac{1}{I(p)} (\log_2 n + \log_2 \delta^{-1} + 3)$$

queries finds the target in any linear order correctly with probability at least $1 - \delta$, given that the target position is chosen uniformly at random.

Using a previously known reduction from adversarial target placement to the uniformly random choice of a target ([3], see Lemma 10), we automatically obtain the following result for the adversarial version of the problem.

► **Corollary 2.** For any noise parameter $0 < p < \frac{1}{2}$ and a confidence threshold $0 < \delta < 1$, there exists a binary search algorithm that after the **expected** number of

$$\frac{1}{I(p)} (\log_2 n + \mathcal{O}(\log \delta^{-1}))$$

queries finds the target in any linear order correctly with probability at least $1 - \delta$.

► **Theorem 3.** For any noise parameter $0 < p < \frac{1}{2}$ and a confidence threshold $0 < \delta < 1$, there exists a binary search algorithm for any linear order that after

$$\frac{1}{I(p)} \left(\log_2 n + \mathcal{O}(\sqrt{\log n \log \delta^{-1}}) + \mathcal{O}(\log \delta^{-1}) \right)$$

queries returns the target correctly with probability at least $1 - \delta$.

For graph searching we obtain two analogous results (detailed in Section 4): Algorithms 23 and 25 correspond to Theorems 5 and 4, respectively.

► **Theorem 4.** For an arbitrary connected graph G , a noise parameter $0 < p < \frac{1}{2}$ and a confidence threshold $0 < \delta < 1$, there exists an graph searching algorithm that after the **expected** number of at most

$$\frac{1}{I(p)} (\log_2 n + \mathcal{O}(\log \log n) + \mathcal{O}(\log \delta^{-1}))$$

queries returns the target correctly with probability at least $1 - \delta$.

► **Theorem 5.** For an arbitrary connected graph G , a noise parameter $0 < p < \frac{1}{2}$ and a confidence threshold $0 < \delta < 1$, there exists an graph searching algorithm that after

$$\frac{1}{I(p)} \left(\log_2 n + \mathcal{O}(\sqrt{\log n \log \delta^{-1}}) + \mathcal{O}(\log \delta^{-1}) \right)$$

queries returns the target correctly with probability at least $1 - \delta$.

■ **Table 1** The summary of the results.

Setting	Binary search	Graph search
Worst case query complexity:	$\frac{1}{I(p)} \left(\log_2 n + \mathcal{O}(\sqrt{\log n \log \delta^{-1}}) + \mathcal{O}(\log \delta^{-1}) \right)$ (Thm. 3)	$\frac{1}{I(p)} \left(\log_2 n + \mathcal{O}(\log \log n) + \mathcal{O}(\log \delta^{-1}) \right)$ (Thm. 5)
Expected query complexity:	$\frac{1}{I(p)} (\log_2 n + \mathcal{O}(\log \delta^{-1}))$ (Cor. 2)	$\frac{1}{I(p)} (\log_2 n + \mathcal{O}(\log \log n) + \mathcal{O}(\log \delta^{-1}))$ (Thm. 4)

1.3 Comparison with previous works

1.3.1 Upper bounds for noisy binary search

Table 2 provides an overview of the known algorithms for noisy binary search that have complexity close to the optimal $\frac{\log_2 n}{I(p)}$. We provide a detailed comparison with our results below.

- Burnashev and Zigangirov [7] studied this problem from an information-theoretic perspective as early as 1974¹, in a setting where the location of the target element is chosen uniformly at random. We highlight that their query complexity is worse than ours by an additive term of $\log_2 \frac{1-p}{p}$, which tends to infinity when $p \rightarrow 0$. This behavior is rather unnatural, since when $p = 0$, the noise disappears, and the problem reduces to standard binary search.
- Feige et al. [15], in their seminal work, considered several problems in the noisy setting and, in particular, developed an asymptotically optimal algorithm for noisy binary search (with an adversarially placed target). However, their method intrinsically incurs a non-optimal constant in front of $\frac{\log_2 n}{I(p)}$.
- Later, Ben-Or and Hassidim [3], likely unaware of [7], developed algorithms with an expected query complexity of $\frac{1}{I(p)}(\mathcal{O}(\log n) + \mathcal{O}(\log \log n) + \mathcal{O}(\log \delta^{-1}))$. However, we claim that their proofs contain two *serious issues*.

Firstly, in the proof of Lemma 2.6 in [3], they consider all the queries made by the algorithm throughout its execution and sort them by their positions. Then, the number of ' $<$ ' answers in a fixed interval of positions is claimed to follow a binomial distribution. Notice, however, that while the answers to the particular queries are independent random variables, the *positions* of the queries depend on the answers to the previous queries, and the act of forgetting the order introduces correlation. To further illustrate this point, we note the rightmost query in their algorithm is guaranteed to have a ' $<$ ' answer, because a ' \geq ' answer would have changed the weights maintained by the algorithm, causing the next query to be asked further to the right, which contradicts the assumption that this query is the rightmost.

Secondly, the final expected number of steps is bounded by the ratio of total information needed to identify the target and the expected information gain per step (without any additional comments). However, the expected value does not work in this manner directly – to make this approach effective, one needs to employ additional probabilistic tools. Our paper uses Wald's identity for this purpose, see [19] for an example of the usage of martingales and the Optional Stopping Theorem. Moreover, the choice of a particular probabilistic theorem and the way this tool is handled may incur additional lower-order terms, making it unclear what the final complexity would be.

1.3.2 Reductions in complexity for expected length setting

Ben-Or and Hassidim in their work [3] showed a general technique that can transform any of the aforementioned algorithms (regardless if they are in the worst case or expected complexity setting) into an algorithm with the expected query complexity that is better by roughly a multiplicative factor of $(1 - \delta)$ at the cost of additive lower order term of order $\frac{\mathcal{O}(\log \log n)}{I(p)}$. Very recently Gu and Xu [19] showed how to improve that reduction in order to obtain a better constant in front of $\log \delta^{-1}$. They plug in our algorithm for noisy binary search (Corollary 2) as a black-box in order to get the $(1 + o(1))((1 - \delta)(\frac{\log_2 n}{I(p)} + \frac{\mathcal{O}(\log \log n)}{I(p)}) + \frac{\log_2 1/\delta}{(1-2p) \log \frac{1-p}{p}})$ expected query complexity.

¹ Curiously, it appears that until recently, this work has been largely unknown to the algorithmic community, despite the fact that the paper in question has over 100 citations. There is no mention of [7] in the well-known survey by Pelc [27], nor in the subsequent works that we reference. We suspect that the main reason for this oversight is that, until very recently, the work was only available in Russian. For the English translation of the algorithm and the proof, see [34].

1.3.3 Upper bounds for noisy graph search

Known algorithms for noisy graph search are summarized in Table 3. The problem for arbitrary graphs was first considered by Emamjomeh-Zadeh et al.[14]. Later on Dereniowski et al. [11] simplified that algorithm and obtained an improved dependence on $\log \delta^{-1}$. We make another progress in that direction: we further simplify the algorithms and the analysis while simultaneously improving the dependence on $\log \delta^{-1}$ even further.

Expected	$\frac{1}{I(p)}(\log_2 n + \mathcal{O}(\log \log n) + \mathcal{O}(\log \delta^{-1}))$	This work, Thm. 4.
Worst case	$\frac{1}{I(p)}(\log_2 n + o(\log n) + \mathcal{O}(\log^2 \delta^{-1}))$	Emamjomeh-Zadeh et al., 2016 [14]
	$\frac{1}{I(p)}(\log_2 n + \mathcal{O}(\sqrt{\log n \log \delta^{-1}} \cdot \log \frac{\log n}{\log \delta^{-1}}) + \mathcal{O}(\log \delta^{-1}))$	Dereniowski et al., 2019 [11]
	$\frac{1}{I(p)}(\log_2 n + \mathcal{O}(\sqrt{\log n \log \delta^{-1}}) + \mathcal{O}(\log \delta^{-1}))$	This work, Thm. 5.

1.3.4 Lower bounds

For the expected complexity of noisy binary search, Ben-Or and Hassidim [3] established the first lower bound of $(1 - \delta) \frac{\log_2 n - 10}{I(p)}$. Recently Gu and Xu [19] improved the lower bound to $(1 - o(1))((1 - \delta) \frac{\log_2 n}{I(p)} + \frac{\log_2 \frac{1}{\delta}}{(1-2p) \log \frac{1-p}{p}})$. However it works only for constant noise parameter p . They leave the question of improving the lower bound for an arbitrary p as an open problem.

Very recently, Gretta and Price [18] obtained a lower bound for the worst case setting of a more general problem (known as *Noisy Binary Search with Monotonic Probabilities*, which was introduced for the first time by [22]). For the worst case noisy binary search, their work implies a lower bound of the natural $\frac{\log_2 n}{I(p)}$. We note that we are not aware of any lower bounds for the lower order terms dependent on n in any of the considered settings.

1.4 Overview of the techniques

The core building block of our algorithms is Multiplicative Weights Update technique (MWU). This method has been employed in the past for noisy binary search and related problems [3, 5, 11, 22, 28]. The general outline of the method is as follows: we maintain weights that denote the "likelihood" of particular elements being the target and multiplicatively update them according to the answers to subsequent queries. After a certain number of steps, the algorithm returns the element with the highest weight, as it is the element we deem most likely to be the target.

The typical problem with this approach is that, at some point, we may encounter a situation where there is no good element to query, meaning that no query divides the search space close to the bisection. This usually occurs when a particular element becomes heavy, and subsequently querying this element yields less and less information. Previous works tried to different ways to resolve this issue, e.g. by ensuring that a good approximation of the target has been found and calling the algorithm recursively [3], introducing a phase with majority voting [14], etc.

We take a different approach by using a specifically tailored measure of progress of our algorithms, which differs from those used in previous works. For binary search, we define this measure as the total weight minus the weight of the target element. In the context of graph searching, the measure is slightly different – we use the total weight minus the weight of the heaviest vertex. This contrasts with the approach taken in prior studies, such as in [11], where the total weight itself was utilized. It is important to note that, in the case of graph search, the identity of the heaviest vertex may change throughout the search process, and at times, it may not even be the target vertex. However, our analysis guarantees the target will become the heaviest vertex by the end of the search, within the desired probability threshold.

This subtle change proves to be powerful and plays a vital role in all our proofs. We believe this is the key idea that enabled us to overcome the obstacles that the authors of the previous works might have faced.

Furthermore, in the case of binary search, when selecting which vertex to query, we employ a technique similar to that of [7]. Specifically, whenever we identify two elements that are closest to bisecting the search space, we randomly choose one of them with appropriate probability. Our analysis demonstrates that this effectively simulates the ideal subdivision of the search space and ensures the desired progress of our algorithm.

1.5 Other related work

There are many variants of the interactive query games, depending on the structure of queries and the way erroneous replies occur. The study of such games was initiated by Rényi [29] and Ulam [31]. A substantial amount of literature deals with a fixed number of errors for arbitrary membership queries or comparison queries; here we refer the reader to surveys [10, 27]. Among the most successful tools for tackling binary search with errors, is the idea of a volume [4, 28], which exploits the combinatorial structure of a possible distribution of errors. A natural approach of analyzing decision trees has been also successfully applied,

see e.g. [15]. See [5, 14] for examples of partitioning strategies into stages, where in each stage the majority of elements is eliminated and only few “problematic” ones remain. For a different reformulation (and asymptotically optimal results) of the noisy search see [22].

Although the adversarial and noisy models are most widely studied, some other ones are also considered. As an example, we mention the (linearly) bounded error model in which it is guaranteed that the number of errors is a r -fraction, $r < \frac{1}{2}$, of (any initial prefix of) the number of queries, see e.g. [1, 5, 12]. Interestingly, it might be the case that different models are so strongly related that a good bound for one of them provides also tight bounds for the other ones, see e.g. [11]. We refer the reader to distributional search where an arbitrary target distribution is known to the algorithm a priori [8, 9, 30]. A closely related theory of coding schemes for noisy communication is out of scope of this paper and we only point to some recent works [6, 16, 17, 20, 25].

The first steps towards generalizing binary search to graph-theoretic setting are works on searching in partially ordered data [2, 23, 24]. Specifically for the node search that we consider in this work, the first results are due to Onak and Parys for trees [26], where an optimal linear-time algorithm for error-less case was given.

2 Preliminaries

Whenever we refer to a *search space*, we mean either an (undirected and unweighted) graph or a linear order. Consequently, by an *element* of a search space, we refer to a vertex or an integer, respectively. In the following, let n denote the size of the search space, i.e., either the number of vertices in a graph or the number of integers in a linear order.

Throughout the search process, the strategies will maintain the weights $\omega(v)$ for the elements v of a search space V . For any $0 \leq c \leq 1$, v is *c-heavy* if $\omega(v)/\omega(V) \geq c$, where for any subset $U \subseteq V$ we write $\omega(U) = \sum_{u \in U} \omega(u)$. $\frac{1}{2}$ -heavy elements play a special role and we call them *heavy* for brevity. The weight of an element v at the end of step t is denoted by $\omega_t(v)$, with $\omega_0(v)$ being the initial value. The initial values are set uniformly by putting $\omega_0(v) = 1$ for each v in our algorithms.

Noisy binary search definition and model specifics

In the *noisy binary search* problem, we operate on a linear order $v_1 < \dots < v_n$. We are given an element v^* and the values $p \in [0, \frac{1}{2})$, $\delta \in (0, 1)$ as input. We are promised that there exists some $i \in [n]$ such that $v^* = v_i$. We call v^* the *target* element. We can learn about the search space by asking if $v^* < v_j$ for any $j \in [n]$, and receiving an answer that is correct with probability $1 - p$, independently for each query. The goal is to design an algorithm that finds the $i \in [n]$ such that $v^* = v_i$, and returns this index correctly with probability at least $1 - \delta$. We strive to minimize the number of queries performed in the process.

We adopt the following naming convention for query results. When we ask if $v^* \stackrel{?}{<} v_i$ and receive an affirmative answer (i.e., v^* is less than v_i), we call it a *yes-answer*. If the reply indicates v^* is greater than or equal to v_i (i.e., a negative answer), we call it a *no-answer*. An element v_j of a search space is considered *compatible* with the reply to a query $v^* \stackrel{?}{<} v_i$ if and only if:

- For a yes-answer (indicating $v^* < v_i$), $j < i$.
- For a no-answer (indicating $v^* \geq v_i$), $j \geq i$.

Noisy graph searching definition and model specifics

In the *noisy graph searching* problem we are given an unweighted, undirected, simple graph G and the values $p \in [0, \frac{1}{2}), \delta \in (0, 1)$. We know that one vertex v^* of G is marked as the *target*, but we don't know which one is it.

We can query the vertices of G , upon querying a vertex q we get one of two possible answers:

- $v^* = q$, i.e. the queried vertex is the target. We call it a *yes-answer*.
- $v^* \neq q$, but some neighbor u of q lies on a shortest path from q to v^* . We call it a *no-answer*. If there are multiple such neighbors (and hence shortest paths), then we can get an arbitrary one as an answer.

In fact, we assume for simplicity that each reply is given as a single vertex u . If $u = q$, then we interpret it as a yes-answer. If $u \neq q$, then u is a neighbor of q that lies on a shortest path from q to v^* . Again, we are interested in the noisy setting, therefore every reply is correct independently with probability $1 - p$. Observe that if the answer is *incorrect* then it can come in different flavors:

- if $q = v^*$, then an incorrect answer is any neighbor u of q ,
- if $q \neq v^*$, then an incorrect answer may be either q or any neighbor of q that does not lie on a shortest path from q to v^* .

Clearly, in both cases there might be several possible vertices that constitute an incorrect answer. Here we assume the strongest possible model where every time the choice among possible incorrect replies is made adversarially and independently for each query. The goal is, similarly as in noisy binary search, to design an algorithm that finds a target correctly with probability at least $1 - \delta$ and minimizes the number of queries. In fact, in this work we operate in a slightly weaker model of replies (as compared to [11, 13, 14, 26]) in which an algorithm receives less information in some cases. This is done in somewhat artificial way for purely technical reasons, i.e., to simplify several arguments during analysis. The only change to the model we have just described happens when we query a vertex that is heavy at the moment and a *no-answer* has been received. More specifically, if a *heavy* q is queried and a *no-answer* is given, the algorithm reads this reply as: the *target is not* q (ignoring the direction the target might be). Observe that this only makes our algorithms stronger, since they operate in a weaker replies model and any algorithmic guarantees for the above model carry over to the generic noisy graph search model.

Similarly to the case of noisy binary search, we say that a vertex v is *compatible* with the reply to the query q if and only if:

- $v = q$ in case of a yes-answer.
- The neighbor u given as a no-answer lies on a shortest path from q to v and q was not heavy.
- $v \neq q$ in case of a no-answer when q was heavy.

Common mathematical tools and definitions

We adopt the notation from [11] and denote $\varepsilon = \frac{1}{2} - p$ and $\Gamma = \frac{1-p}{p}$. These quantities appear frequently throughout the proofs, and this notation helps to make the presentation more concise.

The *information function*, denoted by $I(p)$, appears in all our running times. It is defined as follows $I(p) = 1 - H(p) = 1 + p \log_2 p + (1-p) \log_2 (1-p)$. In the analysis of our algorithms we frequently use the following quantitative fact about $I(p)$ and $\log_2 \Gamma$.

► **Proposition 6.** We have $I(p) = \Omega(\varepsilon^2)$ and $(\log_2 \Gamma)^2 p(1-p) = \mathcal{O}(\varepsilon^2)$.

Proof. We first observe that by Taylor's series expansion (which can be derived using elementary calculus, see e.g. [32]):

$$I(p) = \frac{1}{2 \ln 2} \sum_{n=1}^{\infty} \frac{(2\varepsilon)^{2n}}{n(2n-1)} \geq \frac{4\varepsilon^2}{2 \ln 2}.$$

To show the second bound we compute

$$\begin{aligned} p(1-p)(\log_2 \Gamma) &= (1/2 - \varepsilon)(1/2 + \varepsilon) \left(\log_2 \frac{1+2\varepsilon}{1-2\varepsilon} \right)^2 \\ &= (1 - 4\varepsilon^2) (\tanh^{-1} 2\varepsilon)^2 \frac{1}{(\ln 2)^2} \leq \frac{4}{(\ln 2)^2} \varepsilon^2 \end{aligned}$$

where the last step follows by observing that under the substitution $\varepsilon = 1/2 \cdot \tanh \gamma$ it reduces to $\gamma^2 \leq \sinh^2 \gamma$ and that inequality follows immediately from the Taylor expansion of $\sinh^2 \gamma$. ◀

Let $(X_m)_{m \in \mathbb{N}}$ be a sequence of i.i.d random variables. We say that a random variable T is a *stopping time* (with respect to $(X_m)_{m \in \mathbb{N}}$) if $\mathbb{1}_{\{T \leq m\}}$ is a function of X_1, X_2, \dots, X_m for every m .

We will use the following version of the Wald's identity.

► **Proposition 7 (Wald's Identity [33]).** Let $(X_m)_{m \in \mathbb{N}}$ be i.i.d with finite mean, and T be a stopping time with $\mathbb{E}[T] < \infty$. Then $\mathbb{E}[X_1 + \dots + X_T] = \mathbb{E}[X_1] \mathbb{E}[T]$.

Let us also recall a basic version of a Hoeffding bound, which we use in our calculations of query complexities in the worst case setting.

Multiplicative Weights Update Method

The core building block of our strategies for both binary and graph search is a standard Multiplicative Weights Update (MWU) technique. Below we formally define the version of MWU that we use in our algorithms (Algorithm 8).

► **Algorithm 8.** (MWU updates.)

In a step $t + 1$, for each element v of the search space do:

if v is compatible with the answer, then $\omega_{t+1}(v) \leftarrow \omega_t(v) \cdot 2(1-p)$,
if v is not compatible with the answer, then $\omega_{t+1}(v) \leftarrow \omega_t(v) \cdot 2p$.

Directly from the statement of our MWU method we obtain the following bound on the weight of the target. This bound applies to both binary and graph search, as the analysis is based solely on the number of erroneous replies and the fact that the target is always compatible with a correct answer.

► **Lemma 9.** If v^* is the target, then after τ queries, with probability at least $1 - \delta$ it holds

$$\omega_\tau(v^*) \geq \Gamma^{-\sqrt{2p(1-p)\tau \ln \delta^{-1}}} 2^{I(p)\tau}.$$

Proof. After τ queries with at most ℓ erroneous replies, the weight of the target satisfies:

$$\omega_\tau(v^*) \geq (2p)^\ell (2(1-p))^{\tau-\ell} = \Gamma^{p\tau-\ell} 2^{I(p)\tau}.$$

Denote $a = \sqrt{2p(1-p)\tau \ln \delta^{-1}}$. Then by Chernoff-Hoeffding bound [21], with probability at most δ there is $\ell - p\tau \geq a$. Thus, after τ queries, with probability at least $1 - \delta$ the weight of the target satisfies $\omega_\tau(v^*) \geq \Gamma^{-a} 2^{I(p)\tau}$. ◀

29:10 Noisy (Binary) Searching: Simple, Fast and Correct

Uniform prior for binary search

One can assume that the distribution of the target element in noisy binary search is *a priori* uniform by using a shifting trick described by Ben-Or and Hassidim [3]. We formally state it as a lemma below.

► **Lemma 10** (c.f. [3]). *Assume that the target element in noisy binary search problem was chosen adversarially. One can reduce that problem to the setting where the target element is chosen uniformly at random using $\mathcal{O}(\frac{\log \delta^{-1}}{I(p)})$ queries.*

3 Binary Search Algorithm

Each query performs the MWU updates using Algorithm 8. The element to be queried is selected as follows: let k be such that $\sum_{i=1}^{k-1} \omega(v_i) \leq \omega(V)/2$ and $\sum_{i=1}^k \omega(v_i) \geq \omega(V)/2$. Since the queries v_k and v_{k+1} are the closest possible to equi-division of the total weight, the algorithm chooses one of those with appropriate probability (cf. Algorithm 11.)

► **Algorithm 11.** (Query selection procedure.)

In step τ : let k be such that $\sum_{i=1}^{k-1} \omega_\tau(v_i) \leq \frac{\omega_\tau(V)}{2} \leq \sum_{i=1}^k \omega_\tau(v_i)$.

Then, query v_k with probability $\frac{1}{2\omega_\tau(v_k)}(\sum_{i=1}^k \omega_\tau(v_i) - \sum_{i=k+1}^n \omega_\tau(v_i))$, and otherwise query v_{k+1} .

In order to turn Algorithm 11 into a particular strategy, we will provide a stopping condition for each model. We start by determining the expected weight preservation during the search.

► **Lemma 12.** $\mathbb{E}[\omega_{\tau+1}(V \setminus \{v^*\}) \mid \omega_\tau(V \setminus \{v^*\})] \leq \omega_\tau(V \setminus \{v^*\})$.

Proof. We consider three cases, and show that this bound holds in each of those independently. Denote $A = \sum_{i=1}^{k-1} \omega_\tau(v_i)$, $B = \omega_\tau(v_k)$ and $C = \sum_{i=k+1}^n \omega_\tau(v_i)$. Denote the probability of querying v_k as $\alpha = \frac{A+B-C}{2B}$, and the probability of querying v_{k+1} as $\beta = \frac{C+B-A}{2B}$.

Case 1: $v^* = v_k$.

$$\begin{aligned} \mathbb{E}[\omega_{\tau+1}(V \setminus \{v^*\}) \mid \omega_\tau(V \setminus \{v^*\})] &= \alpha[2p^2C + 2(1-p)^2C + 2p(1-p)A + 2p(1-p)A] \\ &\quad + \beta[2p^2A + 2(1-p)^2A + 2p(1-p)C + 2p(1-p)C] \\ &= \alpha[(1+4\varepsilon^2)C + (1-4\varepsilon^2)A] + \beta[(1+4\varepsilon^2)A + (1-4\varepsilon^2)C]. \end{aligned}$$

Using the definition of α and β , we obtain

$$\begin{aligned} \mathbb{E}[\omega_{\tau+1}(V \setminus \{v^*\}) \mid \omega_\tau(V \setminus \{v^*\})] &= -4\varepsilon^2 \frac{(A-C)^2}{B} + (A+C) \\ &= -4\varepsilon^2 \frac{(A-C)^2}{B} + \omega_\tau(V \setminus \{v^*\}). \end{aligned}$$

Case 2: $v^* < v_k$. In this case,

$$\begin{aligned} \mathbb{E}[\omega_{\tau+1}(V \setminus \{v^*\}) \mid \omega_\tau(V \setminus \{v^*\})] &= (2p^2 + 2(1-p)^2)(A - \omega_\tau(v^*)) \\ &\quad + [\alpha 4p(1-p) + \beta(2p^2 + 2(1-p)^2)]B + 4p(1-p)C. \end{aligned}$$

Denote $p_1 = p^2 + (1-p)^2$ and $p_2 = 2p(1-p)$. Observe $p_1 + p_2 = 1$ and $p_1 \geq \frac{1}{2} \geq p_2$. Then,

$$\begin{aligned} \mathbb{E}[\omega_{\tau+1}(V \setminus \{v^*\}) \mid \omega_\tau(V \setminus \{v^*\})] &= 2p_1A + (C + B - A)p_1 + (A + B - C)p_2 + 2p_2C - 2p_1\omega_\tau(v^*) \\ &= A + B + C - 2p_1\omega_\tau(v^*) \\ &\leq \omega_\tau(V \setminus \{v^*\}). \end{aligned}$$

Case 3: $v^* > v_{k+1}$ is symmetric to case 2. ◀

3.1 Proof of Theorem 1 (The expected strategy length)

► **Algorithm 13.** (The expected strategy length for binary search.)

Initialization: $\omega_0(v_i) \leftarrow 1$ for each $v_i \in V$.

Execute Algorithm 11 until in some step τ it holds $\frac{\omega_\tau(v_j)}{\omega_\tau(V)} \geq 1 - \delta$ for some v_j .

Return v_j .

To show correctness of Algorithm 13, we need to observe that in the case of binary search, our MWU updates are, in fact Bayesian updates, that is, the normalized weights follow a posterior distribution conditioned on the replies seen so far. We state this as a lemma below.

► **Lemma 14.** *After any step τ of Algorithm 13 we have for every $v_i \in V$*

$$\Pr[v^* = v_i \mid \tau \text{ observed replies}] = \frac{\omega_\tau(v_i)}{\omega(V)}.$$

Proof. The proof is by induction on τ . The base case is trivial, because we assign the weights uniformly in the initialization step. The inductive step follows immediately from our definition of MWU updates (Algorithm 8) and the Bayes' rule. ◀

The correctness of Algorithm 13 follows directly from Lemma 14 and the stopping condition. To prove Theorem 1 it remains to analyze the expected length of the strategy.

► **Lemma 15.** *Algorithm 13 terminates after the expected number of at most $\frac{1}{1-p}(\log_2 n + \log_2 \frac{1}{\delta} + 3)$ steps.*

Proof. We measure the progress at any given step by a random variable $\zeta_t = \log_2 \omega_t(v^*)$. If the answer in step $t + 1$ is erroneous, then $\zeta_{t+1} = \zeta_t + 1 + \log_2 p$ and otherwise $\zeta_{t+1} = \zeta_t + 1 + \log_2(1 - p)$.

For the sake of bounding the number of steps of the algorithm, we consider it running indefinitely. Let Q be the smallest integer such that $\frac{\omega_Q(v^*)}{\omega_Q(V \setminus \{v^*\})} \geq \frac{1-\delta}{\delta}$, that is v^* is $(1 - \delta)$ -heavy in round Q . Obviously Q upper bounds the strategy length. By the definition, Q is a stopping time.

First, let us show that $\mathbb{E}[Q]$ is finite. To this end, let $\xi_t = \log_2 \frac{\omega_t(v^*)}{\omega_t(V \setminus \{v^*\})}$ and $X_t = \xi_t - \xi_{t-1}$ for $t \geq 1$. Observe that X_t 's are i.i.d and $\mathbb{E}[X_t] = p(-\log_2 \Gamma) + (1 - p) \log_2 \Gamma = (1 - 2p) \log_2 \Gamma > 0$. Therefore, using Lemma 29 for sequence X_t , with $\ell = -\log \Gamma$, $r = \log \Gamma$ and $T = \log_2 \frac{1-\delta}{\delta} - \log_2 \frac{\omega_0(v^*)}{\omega_0(V \setminus \{v^*\})}$, we indeed obtain $\mathbb{E}[Q] < \infty$.

Let Q_i for any positive integer i be smallest value such that $\omega_{Q_i}(v^*) \geq \frac{n}{\delta} \cdot 2^i$ (for completeness of notation, we define $Q_0 = 0$). Consider an event $\{Q > Q_i\}$. It means that in round Q_i the target v^* is not yet $(1 - \delta)$ -heavy. Hence, $\omega_{Q_i}(V \setminus \{v^*\}) > \frac{\delta}{1-\delta} \omega_{Q_i}(v^*) \geq \delta \omega_{Q_i}(v^*) \geq n \cdot 2^i$. But we know from Lemma 12 that $\mathbb{E}[\omega_{Q_i}(V \setminus \{v^*\})] \leq \mathbb{E}[\omega_0(V \setminus \{v^*\})] \leq n$. Using Markov's inequality we conclude that $\Pr[Q > Q_i] \leq \Pr[\omega_{Q_i}(V \setminus \{v^*\}) > n \cdot 2^i] \leq 2^{-i}$.

Additionally, since $\omega_{Q_{i-1}}(v^*) < \frac{n}{\delta} \cdot 2^i$, there is $\omega_{Q_i}(v^*) < 2 \frac{n}{\delta} \cdot 2^i$. We can then bound

$$\begin{aligned} \mathbb{E}[\zeta_Q] &< \sum_{i=1}^{\infty} \Pr[Q_{i-1} < Q \leq Q_i] \log_2(2 \cdot \frac{n}{\delta} 2^i) \\ &= \log_2(2 \cdot \frac{n}{\delta}) + \sum_{i=1}^{\infty} \Pr[Q_{i-1} < Q \leq Q_i] \cdot i \\ &= \log_2(2 \frac{n}{\delta}) + \sum_{i=1}^{\infty} \Pr[Q > Q_{i-1}] \end{aligned}$$

29:12 Noisy (Binary) Searching: Simple, Fast and Correct

$$\begin{aligned} &\leq 1 + \log_2 n + \log_2 \frac{1}{\delta} + \sum_{i=0}^{\infty} 2^{-i} \\ &\leq \log_2 n + \log_2 \frac{1}{\delta} + 3. \end{aligned}$$

Let $Y_t = \zeta_t - \zeta_{t-1}$. Obviously, Y_i 's are independent. We have already established that Q is a stopping time and that $\mathbb{E}[Q] < \infty$. This means we can employ the Wald's identity (Proposition 7) to obtain (using $\zeta_0 = 0$) $\mathbb{E}[\zeta_Q] = \mathbb{E}[Y_1 + \dots + Y_Q] = \mathbb{E}[Q]I(p)$. Therefore,

$$\log_2 n + \log_2 \frac{1}{\delta} + 3 \geq \mathbb{E}[\zeta_Q] = \mathbb{E}[Q]I(p). \quad \blacktriangleleft$$

3.2 Proof of Theorem 3 (Worst-case strategy length)

Take Q to be the smallest positive integer for which

$$I(p)Q > \log_2 n + \log_2 \frac{2}{\delta} + \sqrt{2p(1-p)Q \ln \frac{2}{\delta}} \log_2 \Gamma. \quad (1)$$

The Q gives our strategy length (see Algorithm 16). To prove Theorem 3 we bound the strategy length and the failure probability (see Lemma 17 below). The algorithm essentially remains the same except for the stop condition (cf. Algorithm 16).

► **Algorithm 16.** (Worst-case strategy length for binary search.)

Initialization: $\omega_0(v_i) \leftarrow 1$ for each element v_i .

Execute Algorithm 11 for exactly Q steps with Q as in (1).

Return the heaviest element.

► **Lemma 17.** For any $0 < \delta < 1$, Algorithm 16 finds the target correctly with probability at least $1 - \delta$ in $\frac{1}{I(p)} \left(\log_2 n + \mathcal{O}(\log \delta^{-1}) + \mathcal{O}(\sqrt{\log n \log \delta^{-1}}) \right)$ steps.

Proof. Firstly, observe that solving (1) for Q using Lemma 28 with parameters $a = I(p)$, $b = \log_2 n + \log_2 \frac{2}{\delta}$ and $c = 2p(1-p)(\log_2 \Gamma)^2 \ln \frac{2}{\delta}$ yields

$$Q = \frac{1}{I(p)} \left(\log_2 n + \log_2 \frac{2}{\delta} + \mathcal{O} \left(\ln \frac{2}{\delta} + \sqrt{\log_2 n + \log_2 \frac{2}{\delta}} \sqrt{\ln \frac{2}{\delta}} \right) \right)$$

where we have used, by Proposition 6, that $\frac{p(1-p)(\log_2 \Gamma)^2}{I(p)} = \mathcal{O}(1)$. The above equation can be simplified to

$$Q = \frac{1}{I(p)} \left(\log_2 n + \mathcal{O}(\log \delta^{-1}) + \mathcal{O}(\sqrt{\log \delta^{-1} \log n}) \right).$$

It remains to prove correctness. By Lemma 9, with probability at least $1 - \delta/2$ we have

$$\omega_Q(v^*) \geq \Gamma^{-\sqrt{2p(1-p)Q \ln 2/\delta}} 2^{I(p)Q}. \quad (2)$$

From Lemma 12 we also get $\mathbb{E}[\omega_Q(V \setminus \{v^*\})] \leq \mathbb{E}[\omega_0(V \setminus \{v^*\})] \leq n$. Therefore, by Markov's inequality with probability $1 - \delta/2$ we have

$$\omega_Q(V \setminus \{v^*\}) \leq \frac{2n}{\delta}. \quad (3)$$

It remains to observe that our definition of Q (Equation (1)) is equivalent to

$$\Gamma^{-\sqrt{2p(1-p)Q \ln 2/\delta} 2^{I(p)Q}} > \frac{2n}{\delta}.$$

Thus, by the union bound applied to (2) and (3), with probability at least $1 - \delta$ we get $\omega_Q(v^*) > \omega_Q(V \setminus \{v^*\})$. Then, v^* is the heaviest element and Algorithm 16 returns it. ◀

4 Graph Searching Algorithm

Denoting by $d(u, v)$ the graph distance between u and v , i.e., the length of the shortest path between these vertices, a *median* of the graph is a vertex

$$q = \arg \min_{v \in V} \sum_{u \in V} d(u, v) \cdot \omega(u).$$

For a query v and a reply u , let $C(v, u) = \{x \in V \mid u \text{ lies on some shortest path from } v \text{ to } x\}$ for $v \neq u$, and $C(v, v) = \{v\}$. We note a fundamental bisection property of a median:

► **Lemma 18** (cf. [14] Lemma 4). *If q is a median, then $\max_{u \in N(q)} \omega(C(q, u)) \leq \omega(V)/2$.*

Proof. Denote for brevity $\Phi(x) = \sum_{v \in V} d(x, v) \cdot \omega(v)$ for any $x \in V$. Suppose towards the contradiction that $\omega(C(q, u)) > \omega(V)/2$ for some $u \in N(q)$. Observe that $\Phi(u) \leq \Phi(q) - \omega(C(q, u)) + \omega(V \setminus C(q, u))$ since by moving from q to u we get closer to all vertices in $C(q, u)$. But $\Phi(q) - \omega(C(q, u)) + \omega(V \setminus C(q, u)) = \Phi(q) + \omega(V) - 2\omega(C(q, u)) < \Phi(q)$ by our assumption, hence $\Phi(u) < \Phi(q)$, which yields a contradiction. ◀

We now analyze how the weights behave when in each step a median is queried and the MWU updates are made. This analysis is common for both graph searching algorithms given later. Essentially we prove that, in an amortized way, the total weight (with the heaviest vertex excluded) remains the same in each step. In absence of heavy vertices we use Lemma 19. Lemmas 20 and 21 refer to an interval of queries to the same heavy vertex x . If the interval ends (cf. Lemma 20), then the desired weight drop can be claimed at its end. For this, informally speaking, the crucial fact is that x received many no-answers during this interval. If a strategy is at a step that is within such interval, then Lemma 21 is used to bound the total weight with the weight of x excluded. Hence, at any point of the strategy the weight behaves appropriately, as summarized in Lemma 22.

► **Lemma 19** (see also [11, 14]). *If in a step t there is no heavy vertex, then $\omega_{t+1}(V) \leq \omega_t(V)$.*

Proof. Let q be a query and u an answer in step t . Note that if there is no heavy vertex, then $C(q, u)$ is the set of vertices compatible with the reply. If $q \neq u$ then $\omega_t(C(q, u)) \leq \omega_t(V)/2$ by Lemma 18 and in case $q = u$ we have $C(q, u) = \{q\}$ and thus the same bound holds. Then in both cases, $\omega_{t+1}(V) = 2(1-p) \cdot \omega_t(C(q, u)) + 2p \cdot \omega_t(V \setminus C(q, u)) \leq \omega_t(V)$. ◀

► **Lemma 20** (see also [11]). *Consider an interval $I = \{\tau, \tau + 1, \dots, \tau + k - 1\}$ of k queries such that some x is heavy in each query in I and is not heavy after the last query in the sequence. Then $\omega_{\tau+k}(V) \leq \omega_\tau(V)$.*

Proof. First note that in each query in the interval I the queried vertex is x . Consider any two queries i and j in I such that they receive different replies. The contribution of these two queries is that together they scale down each weight multiplicatively by $2p \cdot 2(1-p) \leq 1$. Also, for a single no-answer in a query $i \in I$ we get $\omega_{i+1}(V) = 2p\omega_i(x) + 2(1-p)\omega_i(V \setminus \{x\}) \leq \omega_i(V)$

29:14 Noisy (Binary) Searching: Simple, Fast and Correct

because $\omega_i(x) \geq \omega_i(V \setminus \{x\})$ for the heavy vertex x . By assumption, the number of no-answers is at least the number of yes-answers in I . Thus, the overall weight drop is as claimed in the lemma. \blacktriangleleft

► **Lemma 21.** *Consider an interval $I = \{\tau, \tau + 1, \dots, \tau + k - 1\}$ of k queries such that some x is heavy in each query in I , and x remains heavy after the last query in I . Then*

$$\omega_{\tau+k}(V \setminus \{x\}) \leq \omega_{\tau}(V).$$

Proof. Recall that in each query in the interval I , the queried vertex is x . Assume that there were a yes-answers in I and b no-answers, with $a + b = k$. If $a \geq b$, then $\omega_{\tau+k}(V \setminus \{x\}) = (2p)^a (2(1-p))^b \omega_{\tau}(V \setminus \{x\}) \leq \omega_{\tau}(V \setminus \{x\}) \leq \omega_{\tau}(V)$. If $a < b$, then we bound as follows: $\omega_{\tau+k}(V \setminus \{x\}) \leq \omega_{\tau+k}(x) = (2p)^b (2(1-p))^a \omega_{\tau}(x) \leq \omega_{\tau}(x) \leq \omega_{\tau}(V)$. \blacktriangleleft

The bound in the next lemma immediately follows from Lemmas 19, 20 and 21. We say that an element v is *heaviest* if $\omega(v) \geq \omega(u)$ for each $u \in V$. For each step i , we denote by x_i a heaviest vertex at this step, breaking ties arbitrarily.

► **Lemma 22.** $\omega_{\tau}(V \setminus \{x_{\tau}\}) \leq \omega_0(V) = n$.

Proof. We consider the first τ queries and observe that they can be partitioned into a disjoint union of maximal intervals in which either there is a heavy vertex present (in the whole interval) or there is no heavy vertex (in the whole interval). We apply Lemma 19 for intervals with no heavy vertex and Lemmas 20, 21 otherwise (note that Lemma 21 can be applied only to the last interval. The latter happens only when there exists a heavy vertex after we perform all τ queries). \blacktriangleleft

4.1 Proof of Theorem 5 (Worst-case strategy length)

In this section we prove Theorem 5. Take Q to be the smallest positive integer for which

$$I(p)Q \geq \log_2 n + \sqrt{2p(1-p)Q \ln \delta^{-1}} \log_2 \Gamma. \quad (4)$$

The Q gives our strategy length (see Algorithm 23). To prove Theorem 5 we bound the strategy length and the failure probability (see Lemma 24 below).

► **Algorithm 23.** (Worst-case strategy length for graph search.)

Initialization: $\omega_0(v) = 1$ for each $v \in V$.

In each step: query the median and perform the MWU updates (Algorithm 8).

Stop condition: do exactly Q queries with Q defined by (4) and return the heaviest vertex.

► **Lemma 24.** *For any $0 < \delta < 1$, Algorithm 23 finds the target correctly with probability at least $1 - \delta$ in $\frac{1}{I(p)} \left(\log_2 n + \mathcal{O}(\log \delta^{-1}) + \mathcal{O}(\sqrt{\log n \log \delta^{-1}}) \right)$ steps.*

Proof. The proof is very similar to that of Lemma 17 (worst-case noisy binary search). It is actually simpler, thanks to the fact that Lemma 22 gives even stronger bound than Lemma 12.

Using Lemma 28 we solve (4) for Q . We bound the result further with Proposition 6:

$$Q = \frac{\log_2 n + \mathcal{O}(\sqrt{\log n \log \delta^{-1}}) + \mathcal{O}(\log \delta^{-1})}{I(p)}. \quad (5)$$

By Lemma 9 and the definition of Q in (4) it holds with probability $1 - \delta$

$$\log_2 \omega_Q(v^*) \geq -\sqrt{2p(1-p)Q \ln \delta^{-1}} \log_2 \Gamma + I(p)Q \geq \log_2 n \geq \log_2 \omega_Q(V \setminus \{x_Q\}),$$

where the last inequality is due to Lemma 22. Since the weights are non-negative at all times, the only way for this to happen is to have $v^* = x_Q$, that is the target being found correctly. \blacktriangleleft

4.2 Proof of Theorem 4 (The expected strategy length)

The solution for this case (given in Algorithm 25) paraphrases Algorithm 11 except for the proper adjustment of the confidence threshold.

► **Algorithm 25.** (The expected strategy length for graph search.)

Let $\delta' = c(\delta^2 \cdot (\log n + \log 1/\delta)^{-2})$ for small enough constant $c > 0$.

Initialization: $\omega_0(v) = 1$ for each $v \in V$.

In each step: query the median and perform the MWU updates (Algorithm 8).

Stop condition: if for any v in some step τ it holds $\frac{\omega_\tau(v)}{\omega_\tau(V)} \geq 1 - \delta'$, then return v .

► **Lemma 26.** Algorithm 25 stops after the expected number of at most $\frac{1}{I(p)}(\log_2 n + \log_2 \frac{1}{\delta'} + 1)$ steps.

Proof. We argue that within the promised expected number of steps, target v^* reaches the threshold weight. This clearly upperbounds the runtime. We measure the progress at any given moment by a random variable $\zeta_t = \log_2 \omega_t(v^*)$. Observe that if the reply is erroneous in a step $t + 1$, then $\zeta_{t+1} = \zeta_t + 1 + \log_2 p$, and if it is correct, then $\zeta_{t+1} = \zeta_t + 1 + \log_2(1 - p)$.

For the sake of bounding the number of steps of the algorithm, we assume it is simulated indefinitely. Let Q be the smallest integer such that $\zeta_Q \geq \log_2 n + \log_2 \frac{1 - \delta'}{\delta'}$.

By Lemma 22 we have that $\zeta_Q = \log_2 \omega_Q(v^*) \leq \log_2 \frac{\omega_Q(v^*)}{\omega(V \setminus \{x_Q\})/n}$, thus $\frac{\omega_Q(v^*)}{\omega(V \setminus \{x_Q\})} \geq \frac{1 - \delta'}{\delta'} > 1$ since w.l.o.g. $\delta' < 1/2$. But if for any t there is $\frac{\omega_t(v^*)}{\omega_t(V \setminus \{x_t\})} > 1$, then $x_t = v^*$, since $\omega_t(v^*) > \omega_t(V \setminus \{x_t\})$ implies $v^* \notin V \setminus \{x_t\}$. Thus we deduce that $x_Q = v^*$. Additionally, from $\frac{\omega_Q(v^*)}{\omega(V \setminus \{v^*\})} \geq \frac{1 - \delta'}{\delta'}$ we get that v^* is $(1 - \delta')$ -heavy, hence Q bounds the strategy length.

From $\zeta_{t+1} \in \{\zeta_t + 1 + \log_2 p, \zeta_t + 1 + \log_2(1 - p)\}$ and the minimality of Q we deduce $\zeta_Q \leq \log_2 n + \log_2 \frac{1 - \delta'}{\delta'} + 1 + \log_2(1 - p) \leq \log_2 n + \log_2 \frac{1}{\delta'} + 1$. In particular

$$\mathbb{E}[\zeta_Q] \leq \log_2 n + \log_2 \frac{1}{\delta'} + 1. \quad (6)$$

Let $X_t = \zeta_t - \zeta_{t-1}$ and observe that $\mathbb{E}[X_t] = p(1 + \log_2 p) + (1 - p)(1 + \log_2(1 - p)) = I(p) > 0$. Also, X_i 's are independent and Q is a stopping time. Finally, we have $\mathbb{E}[Q] < \infty$ from Lemma 29². Therefore, we meet all conditions of the Wald's identity (Proposition 7) and we get (since $\zeta_0 = 0$) $\mathbb{E}[\zeta_Q] = \mathbb{E}[X_1 + \dots + X_Q] = \mathbb{E}[Q]I(p)$. Thus, by (6) we have $1 + \log_2 \frac{1}{\delta'} + \log_2 n \geq \mathbb{E}[\zeta_Q] = \mathbb{E}[Q]I(p)$, from which the claim follows. \blacktriangleleft

► **Lemma 27.** Algorithm 25 finds the target correctly with probability at least $1 - \delta$.

² By plugging in $\ell = 1 + \log_2 p$, $r = 1 + \log_2(1 - p)$ and $T = \log_2 \frac{1 - \delta'}{\delta'} + \log_2 n$.

Proof. We first show correctness. Denote by $A \leq \frac{\log \frac{1-\delta'}{p}}{\log \frac{1-p}{p}} + 1$ the number of yes-answers required to go from a vertex being $1/2$ -heavy to being $(1-\delta')$ -heavy. For now assume that $A \geq 2$, we will deal with the other case later. For a non-target vertex u to be declared by the algorithm as the target, it has to observe a suffix of the strategy being a random walk on a 1-dimensional discrete grid $[0, \dots, A]$ and transition probabilities p for $i \rightarrow i+1$ and $1-p$ for $i \rightarrow i-1$. We consider a random walk starting at position $A/2$ and ending when reaching either 0 or A and call it a *subphase* (w.l.o.g. assume that A is even). Any execution of the algorithm can be partitioned into maximal in terms of containment, disjoint subphases. Each subphase starts when one particular heavy vertex v receives $A/2$ more yes-answers than no-answers within the interval in which v is heavy. Then, a subphase ends when either the algorithm declares v to be the target or v stops being heavy. By the standard analysis of the gamblers ruin problem, each subphase (where the heavy vertex is not the target) has failure probability $\delta'' = \frac{1}{1 + (\frac{1-p}{p})^{A/2}} \leq \frac{1}{1 + \sqrt{\frac{1-\delta'}{\delta'}}} = O(\sqrt{\delta'})$. Let us denote by a random variable D the number of subphases in the execution of the algorithm. Let F_i be the length of i -th subphase. By the standard analysis of the gamblers ruin problem,

$$\mathbb{E}[F_i] = \frac{A/2}{1-2p} - \frac{A}{1-2p} \frac{1}{1 + (\frac{1-p}{p})^{A/2}} \geq \frac{A/2}{1-2p} \left(1 - \frac{2}{1 + \sqrt{\frac{1-\delta'}{\delta'}}} \right) = \Omega\left(\frac{1}{\varepsilon^2}\right),$$

where the asymptotic holds since w.l.o.g. $\delta' < 1/3$, and also since if $\varepsilon < 1/3$, then $A = \Omega(1/\varepsilon)$, and otherwise $A \geq 2 = \Omega(1/\varepsilon)$. Let $F = F_1 + \dots + F_D$ be the total length of all subphases. Observe that D is a stopping time, hence we have $\mathbb{E}[F] = \mathbb{E}[D] \cdot \Omega(\frac{1}{\varepsilon^2})$ by Proposition 7. By Lemma 26, $\mathbb{E}[Q] = \mathcal{O}(\varepsilon^{-2}(\log n + \log \delta'^{-1}))$ holds for the strategy length Q . Since $F \leq Q$, $\mathbb{E}[D] = \mathcal{O}(\log n + \log 1/\delta') = \mathcal{O}(\log n + \log 1/\delta)$.

By application of the union bound, the error probability for the whole procedure is bounded by $\delta''\mathbb{E}[D] \leq \delta$ for appropriately chosen constant in the definition of δ' .

We now deal with case of $A \leq 1$. This requires $p < \delta'$, and $\varepsilon > 1/3$ (since if $\varepsilon < 1/3$, appropriate choice of constant in δ' enforces $A \geq 2$) and so the expected strategy length is $\mathbb{E}[Q] = \mathcal{O}(\log n + \log 1/\delta)$. By the union bound, algorithm receives a single erroneous response with probability at most $p\mathbb{E}[Q] \leq \delta'\mathbb{E}[Q] = \mathcal{O}(\delta^2/(\log n + \log 1/\delta)) \leq \delta$. ◀

A Delegated Proofs

► **Lemma 28.** *The solution to $ax = b + \sqrt{cx}$ is of the form $x = \frac{1}{a} \left(b + \mathcal{O} \left(\frac{c}{a} + \sqrt{b} \cdot \sqrt{\frac{c}{a}} \right) \right)$.*

Proof. Solving the quadratic equation $a^2x^2 + b^2 - 2abx - cx = 0$, we get:

$$\Delta = (2ab + c)^2 - 4a^2b^2 = c(c + 4ab)$$

$$x = \frac{2ab + c + \sqrt{c^2 + 4abc}}{2a^2} = \frac{b}{a} + \mathcal{O} \left(\frac{c + \sqrt{abc}}{a^2} \right)$$

◀

► **Lemma 29.** *Let $(X_i)_{i \in \mathbb{N}_+}$ be a sequence of i.i.d random variables with $\Pr(X_i = \ell) = p$ and $\Pr(X_i = r) = (1 - p)$ for some $\ell, r \in \mathbb{R}$ and $0 < p < \frac{1}{2}$. Let us fix $T > 0$ and let $Q = \inf \left\{ m : \sum_{i=1}^m X_i \geq T \right\}$. If $\mathbb{E}[X_i] > 0$, then $\mathbb{E}[Q] < \infty$.*

Proof. Let $\zeta_m = \sum_{i=1}^m X_i$. If $Q > m$, then in particular $\zeta_m \leq T$, hence

$$\Pr(Q > m) \leq \Pr(\zeta_m \leq T) \tag{7}$$

for any $m \in \mathbb{N}_+$.

Let $\mu = \mathbb{E}[X_i]$. Obviously, $\mathbb{E}[\zeta_m] = m\mathbb{E}[X_i] = m\mu$. Now, let us define $N = \lceil \frac{T}{\mu} \rceil$. For any $m > N$ we have

$$\zeta_m \leq T \iff \zeta_m - m\mu \leq -(m\mu - T) \tag{8}$$

and $m\mu - T > 0$. Using Hoeffding bound [21] we get

$$\Pr(\zeta_m - m\mu \leq -(m\mu - T)) \leq \exp \left\{ \frac{-2(m\mu - T)^2}{m(\ell + r)^2} \right\} \leq \exp \left\{ \frac{-2m\mu^2}{(\ell + r)^2} + \frac{4\mu T}{(\ell + r)^2} \right\} = C\beta^m \tag{9}$$

with $C = e^{\frac{4\mu T}{(\ell + r)^2}}$ and $\beta = e^{\frac{-2\mu^2}{(\ell + r)^2}}$. Observe that $0 < \beta < 1$.

Putting together equations (7), (8) and (9) we get

$$\begin{aligned} \mathbb{E}[Q] &= \sum_{m=0}^{\infty} \Pr(Q > m) \\ &= \sum_{m \leq N} \Pr(Q > m) + \sum_{m > N} \Pr(Q > m) \leq \sum_{m \leq N} \Pr(Q > m) + C \sum_{m > N} \beta^m < \infty. \end{aligned} \quad \blacktriangleleft$$

Being Efficient in Time, Space, and Workload: a Self-Stabilizing Unison and Its Consequences

Abstract

We present a self-stabilizing algorithm for the unison problem which is efficient in time, workload, and space in a weak model. Precisely, our algorithm is defined in the atomic-state model and works in anonymous asynchronous connected networks in which even local ports are unlabeled. It makes no assumption on the daemon and thus stabilizes under the weakest one: the distributed unfair daemon.

In an n -node network of diameter D and assuming the knowledge $B \geq 2D + 2$, our algorithm only requires $\Theta(\log(B))$ bits per node and is fully polynomial as it stabilizes in at most $2D + 2$ rounds and $O(\min(n^2B, n^3))$ moves. In particular, it is the first self-stabilizing unison for arbitrary asynchronous anonymous networks achieving an asymptotically optimal stabilization time in rounds using a bounded memory at each node.

Furthermore, we show that our solution can be used to efficiently simulate synchronous self-stabilizing algorithms in asynchronous environments. For example, this simulation allows us to design a new state-of-the-art algorithm solving both the leader election and the BFS (Breadth-First Search) spanning tree construction in any identified connected network which, to the best of our knowledge, beats all existing solutions in the literature.

1 Introduction

1.1 Context

Self-stabilization is a general non-masking and lightweight fault tolerance paradigm [25, 3]. Precisely, a distributed system achieving this property inherently tolerates *any* finite number of transient faults.¹ Indeed, starting from an arbitrary configuration, which may be the result of such faults, a self-stabilizing system recovers within finite time, and without any external intervention, a so-called *legitimate configuration* from which it satisfies its specification.

¹ A *transient fault* occurs at an unpredictable time, but does not result in a permanent hardware damage. Moreover, as opposed to intermittent faults, the frequency of transient faults is considered to be low.

In this paper, we consider the most commonly used model in the self-stabilizing area: the *atomic-state* model [25, 3]. In this model, the state of each node is stored into registers and these registers can be directly read by neighboring nodes. Furthermore, in one atomic step, a node can read its state and that of its neighbors, perform some local computation, and update its state accordingly. In the atomic-state model, asynchrony is materialized by an adversary called *daemon* that can restrict the set of possible executions. We consider here the weakest (i.e., the most general) daemon: the *distributed unfair daemon*.

Self-stabilizing algorithms are mainly compared according to their *stabilization time*, i.e., the worst-case time to reach a legitimate configuration starting from an arbitrary one. In the atomic-state model, stabilization time can be evaluated in terms of *rounds* and *moves*. Rounds [13] capture the execution time according to the speed of the slowest nodes. Moves count the number of local state updates. So, the move complexity is rather a measure of work than a measure of time. It turns out that obtaining efficient stabilization times both in rounds and moves is a difficult task. Usually, techniques to design an algorithm achieving a stabilization time polynomial in moves make its round complexity inherently linear in n , the number of nodes (see, e.g., [2, 23, 19]). Conversely, achieving the asymptotic optimality in rounds, usually $O(D)$ where D is the network diameter, commonly makes the stabilization time exponential in moves (see, e.g., [22, 31]). Surprisingly, Cournier, Rovedakis, and Villain [14] manage to prove the first *fully polynomial* (i.e., with $Poly(n)$ move and $Poly(D)$ round complexities) *silent*² self-stabilizing algorithm. Their algorithm builds a BFS (Breadth-First Search) spanning tree in any rooted connected network and they prove that it stabilizes in $O(n^6)$ moves and $O(D^2)$ rounds using $\Theta(\log B + \log \Delta)$ bits per node, where B is an upper bound on D and Δ is the maximum degree of the network.

Up to now, fully polynomial self-stabilizing algorithms have only been proposed (see [14, 21]) for so called *static* problems [34], such as spanning tree constructions and leader election, which compute a fixed object in finite time. In this paper, we propose an algorithm for a fundamental *dynamic* (i.e., non static) problem: the *asynchronous unison* (*unison* for short). It consists in maintaining a local clock at each node. The domain of clocks can be bounded (like everyday clocks) or infinite. The liveness property of the problem requests each node to increment its own clock infinitely often. Furthermore, the safety property of the unison requires the difference between the clocks of any two neighbors to always be at most one increment. The usefulness of the unison comes from the fact that asynchrony often makes fault tolerance very difficult in distributed systems. The impossibility of achieving consensus in an asynchronous system in spite of at most one process crash [30] is a famous example illustrating this fact. Thus, fault tolerance, and in particular self-stabilization, often requires some kind of barrier synchronization, which the unison provides, to control the asynchronism of the system by making processes progress roughly at the same speed. Unison is thus a fundamental algorithmic tool that has numerous applications. Among others, it can be used to simulate synchronous systems in asynchronous environments [17], to free an asynchronous system from its fairness assumption (e.g., using the cross-over composition) [8], to facilitate the termination detection [9], to locally share resources [11], or to achieve infimum computations [10]. Thus, as expected, we also derive from our unison algorithm a *synchronizer* allowing us to obtain several new state-of-the-art self-stabilizing algorithms for various problems, including spanning tree problems and leader election.

² In the atomic-state model, a self-stabilizing algorithm is *silent* if all its executions terminate.

1.2 Related Work

Related Work on the Self-stabilizing Unison

The first self-stabilizing asynchronous unison for general graphs was proposed by Couvreur, Francez, and Gouda [15] in the link-register model (a locally-shared memory model without composite atomicity [27, 26]). However, no complexity analysis was given. Another solution, which stabilizes in $O(n)$ rounds, is proposed by Boulinier, Petit, and Villain [11] in the atomic-state model assuming a distributed unfair daemon. Its move complexity is shown in [24] to be in $O(Dn^3 + \alpha n^2)$, where α is a parameter of the algorithm that should satisfy $\alpha \geq L - 2$, where L is the length of the longest hole in the network. In his PhD thesis, Boulinier proposes a parametric solution that generalizes the solutions of both [15] and [11]. In particular, the time complexity analysis of this latter algorithm reveals an upper bound in $O(D \cdot n)$ rounds on the stabilization time of the atomic-state model version of the algorithm in [15]. Awerbuch, Kutten, Mansour, Patt-Shamir, and Varghese [4] propose a self-stabilizing unison that stabilizes in $O(D)$ rounds using an infinite state space. The move complexity of their solution is not analyzed. An asynchronous self-stabilizing unison algorithm is given in [23]. It stabilizes in $O(n)$ rounds and $O(\Delta \cdot n^2)$ moves using unbounded local memories. Emek and Keren [28] present in the stone age model a self-stabilizing unison that stabilizes in $O(B^3)$ rounds, where B is an upper bound on D known by all nodes. Their solution requires $\Theta(\log B)$ bits per node. Moreover, since node activations are required to be fair, the move complexity of their solution is unknown and may be unbounded.

Related Work on Simulations

Simulation is a useful tool to simplify the design of algorithms. In self-stabilization, simulation has been mainly investigated to emulate schedulers or to port solutions from a strong computational model to a weaker one. Awerbuch [7] introduced the concept of *synchronizer* in a non-self-stabilizing context. A synchronizer simulates a synchronous execution of an input algorithm into an asynchronous environment. The first two self-stabilizing synchronizers have been proposed in [4] for message-passing systems. Both solutions achieve a stabilization time in $O(D)$ rounds. The first solution is based on the previously mentioned unison, also proposed in the paper, that uses an infinite state space. To solve this latter issue, they then propose to mix it with the reset algorithm of [5] applied on links of a BFS spanning tree computed in $O(D)$ rounds. This reset algorithm is devoted, and so limits the approach, to locally checkable and locally correctable problems, and the BFS spanning tree construction uses a finite yet unbounded number of states per node and requires the presence of a distinguished node (a root). Again, the move complexity of their solutions is not analyzed. Awerbuch and Varghese [6] propose, still in the message-passing model, two synchronizers: the *rollback compiler* and the *resynchronizer*. The resynchronizer additionally requires the input algorithm to be locally checkable and assumes the knowledge of a common upper bound \mathcal{D} on the network diameter. Using the rollback, resp. the resynchronizer, method, a synchronous non-self-stabilizing algorithm can be turned into an asynchronous self-stabilizing algorithm that stabilizes in $O(T)$ rounds, resp. $O(T + \mathcal{D})$ rounds, using $\Omega(T \times S)$ space, resp. $\Theta(S)$ space, per node where T , resp. S , is the execution time, resp. the space complexity, of the input algorithm. Again, the move complexity of these synchronizers is not analyzed. Now, the straightforward atomic-state model version of the rollback compiler is shown to achieve exponential move complexities in [21]. Finally, the synchronizer proposed in [21] works in the atomic-state model and achieves round and space complexities similar to those of the rollback

compiler, but additionally offers polynomial move complexity. Hence, it allows to design fully polynomial self-stabilizing solutions for static problems, but still with an important memory requirement (using $\Omega(T \times S)$ space).

Simulation has been also investigated in self-stabilization to emulate other schedulers. For example, the *conflict manager* proposed in [32] allows to emulate an unfair locally central scheduler in fully asynchronous settings. Another example is fairness that can be enforced using a unison algorithm together with the *cross-over* composition [8].

Concerning now model simulations, Turau proposes in [35] a general procedure allowing to simulate any algorithm for the distance-two atomic-state model in the (classical) distance-one atomic-state model assuming that nodes have unique identifiers. Finally, simulation from the atomic-state model to the link-register one and from the link-register model to the message-passing one are discussed in [26].

1.3 Contributions

Fully Polynomial Self-stabilizing Unison

We propose a fully polynomial self-stabilizing bounded-memory unison in the atomic-state model assuming a distributed unfair daemon. It works in any anonymous network of arbitrary connected topology, and stabilizes in $O(D)$ rounds and $O(n^3)$ moves using $\Theta(\log B)$ bits per node, where $B \geq 2D + 2$ (see Table 1 below). To the best of our knowledge, our algorithm vastly improves on the literature as other self-stabilizing algorithms have at least one of the following drawbacks: an unbounded memory, an $\Omega(n)$ round complexity, a restriction on the daemon (synchronous, fair, ...). Note also that the computational model we use is at least as general as the *stone age* model of Emek and Wattenhofer [29]: it does not require any local port labeling at nodes, or knowing how many neighbors a node has.

Overall, our unison achieves outstanding performance in terms of time, workload, and space, which also makes it the first fully polynomial self-stabilizing algorithm for a *dynamic* problem.

Self-stabilizing Synchronizer

From our unison algorithm, we straightforwardly derive a self-stabilizing synchronizer that efficiently simulates synchronous executions of an input self-stabilizing algorithm in an asynchronous environment. More precisely, if the input algorithm Alg_I is silent, then the output algorithm $Sync(Alg_I)$ is silent as well and satisfies the same specification as Alg_I . The specification preservation property also holds for any algorithm, silent or not, solving a static problem. We analyze the complexity of this synchronizer and show that it mostly preserves the round and space complexities of the simulated algorithm (see Table 1 for details). This synchronizer is thus a powerful tool to ease the design of efficient *asynchronous* self-stabilizing algorithms. Indeed, for many tasks, the usual lower bound on the stabilization time in rounds is $\Omega(D)$. Now, thanks to our unison, one just has to focus on the design of a *synchronous* $O(D)$ -round self-stabilizing algorithm to finally obtain an asynchronous self-stabilizing solution asymptotically optimal in rounds, with a low overhead in space ($\Theta(\log B)$ bits per node) and a polynomial move complexity (i.e., a fully polynomial solution).

The transformer of [21] has similar round and move complexities. But this algorithm and ours are incomparable as they make different trade-offs. This paper prioritizes memory over generality, while the transformer of [21] makes the opposite choice by prioritizing generality over memory. More precisely, the transformer of [21] can simulate any synchronous algorithm (not necessarily self-stabilizing), by storing its whole execution. It thus has a much larger

space complexity than ours, which only stores two states of the simulated input algorithm. It turns out that the connections between our algorithm and the transformer of [21] are deeper than their move and round complexities. We further explain their similarities as well as their differences in Sections 3 and 4.5.

Implications of our Results

Using our synchronizer, one can easily obtain state-of-the-art (silent) self-stabilizing solutions for several fundamental distributed computing problems, e.g., BFS tree constructions, leader election, and clustering (see Table 1).

■ **Table 1** Complexities of the Unison, the Synchronizer, and some consequences.

	Moves	Rounds	Space
Unison	$O(\min(n^2B, n^3))$	$2D + 2$	$\lceil \log B \rceil + 2$
Synchronizer	$O(\min(n^2B, n^3) + nT)$	$5D + 3T$	$2M + \lceil \log B \rceil + 2$

Problem	Moves	Rounds	Space
BFS tree in rooted networks	$O(n^3)$	$O(D)$	$\Theta(\log B + \log \Delta)$
BFS tree in identified networks	$O(n^3)$	$O(D)$	$\Theta(\log N)$
Leader election	$O(n^3)$	$O(D)$	$\Theta(\log N)$
$O(\frac{n}{k})$ -clustering	$O(n^3)$	$O(D)$	$\Theta(\log k + \log N)$

T and M are the synchronous time and space complexities of the input algorithm, and B and N are input parameters satisfying $B \geq 2D + 2$ and $N \geq n$.

First, we obtain a new state-of-the-art asynchronous self-stabilizing algorithm for the BFS spanning tree construction in rooted and connected networks, by synchronizing the algorithm in [22] (which is a bounded-memory variant of the algorithm in [27]). This new algorithm converges in $O(n^3)$ moves and $O(D)$ rounds with $\Theta(\log B + \log \Delta)$ bits per node (the same round and space complexities as in [22]), where B is an upper bound on D and Δ is the maximum node degree. It improves both on the algorithm in [14], which only converges in $O(n^6)$ moves and $O(D^2)$ rounds, and on the algorithm in [21], which has similar complexities but uses $\Theta(B \cdot \log \Delta)$ bits per node.

In the following, we consider identified connected networks. In this setting, when nodes store identifiers, they usually know a bound k on the size of these identifiers. They thus know a bound $N = 2^k$ on n , and since N is a bound on D , we set $B = 2N + 2$.

In identified networks, a strategy to compute a BFS spanning tree is to compute a leader together with a BFS tree rooted at this leader. This is what the self-stabilizing algorithm in [33] actually does in a synchronous setting. Therefore, by synchronizing it, we obtain a new state-of-the-art asynchronous self-stabilizing algorithm for both the leader election and the BFS spanning tree construction in identified and connected networks. This new algorithm converges in $O(n^3)$ moves and $O(D)$ rounds with $\Theta(\log N)$ bits per node (i.e., the same round and space complexities as in [33]). To the best of our knowledge, no such efficient solutions exist until now in the literature. There are two incomparable asynchronous self-stabilizing algorithms that achieve an $O(D)$ round complexity [12, 1]. They operate in weaker models (resp. message-passing and link-register). However, their move complexity is not analyzed and the first one has a $\Theta(\log B \cdot \log N)$ space requirement (B being a known upper bound on D) while the second one uses an unbounded space.

Other memory-efficient fully polynomial self-stabilizing solutions can be easily obtained with our synchronizer, e.g., to compute the median or centers in anonymous trees by simulating algorithms proposed in [18]. Another application of our synchronizer is to remove fairness assumptions along with obtaining good complexities. For example, the silent self-stabilizing algorithm proposed in [16] computes a clustering of $O(\frac{n}{k})$ clusters in any rooted identified connected network. It assumes a distributed weakly fair daemon and its move complexity is unknown. With our synchronizer,³ we achieve a fully polynomial silent solution that stabilizes under the distributed unfair daemon and without the rooted network assumption, in $O(D)$ rounds, $O(n^3)$ moves, and using $\Theta(\log k + \log N)$ bits per node.

Note that, by using the compiler in [21], one can obtain similar time complexities for all the previous problems, but with a drastically higher space usage.

1.4 Roadmap

The rest of the paper is organized as follows. Section 2 is dedicated to the computational model and the basic definitions. We develop the links between the present paper and [21] in Section 3, and we present our algorithm in Section 4. We sketch its correctness and its time complexity in Section 5. In Section 6, the self-stabilizing synchronizer derived from our unison algorithm is presented and its complexity is also sketched. We conclude in Section 7.

2 Preliminaries

2.1 Networks

We model *distributed systems* as simple graphs, that is, pairs $G = (V, E)$ where V is a set of *nodes* and E is a set of *edges* representing communication links. We assume that communications are bidirectional. The set $N(p) = \{q \mid \{p, q\} \in E\}$ is the set of *neighbors* of p , with which p can communicate, and $N[p] = N(p) \cup \{p\}$ is the closed neighborhood of p . A *path* (from p_0 to p_l) of *length* l is a sequence $P = p_0 p_1 \cdots p_l$ of nodes such that consecutive nodes in P are neighbors. We assume that G is connected, meaning that any two nodes are connected by a path. We can thus define the *distance* $d(p, q)$ between two nodes p and q to be the minimum length of a path from p to q . The *diameter* D of G is then the maximum distance between nodes of G .

2.2 Computational Model: the Atomic-state Model

Our unison algorithm works in a variant of the *atomic-state model* in which each node holds locally shared registers, called *variables*, whose values constitute its *state*. The vector of all node states defines a *configuration* of the system.

An algorithm consists of a finite set of *rules* of the form *label* : *guard* \rightarrow *action*. In the variant that we consider, a *guard* is a boolean predicate on the state of the node and on the set of states of its neighbors. The *action* changes the state of the node. To shorten guards and increase readability, priorities between rules may be set. A rule whose guard is *true* is *enabled*, and can be executed. By extension, a node with at least one enabled rule is also *enabled*, and $Enabled(\gamma)$ contains the enabled nodes in a configuration γ . Note that

³ Also replacing the spanning tree construction used in [16] by the new BFS tree construction of the previous paragraph.

this model is quite weak. Indeed, in other variants, nodes may have, for example, distinct identifiers. In our case, the network is anonymous and since a node only accesses a set of states, it cannot even count how many neighbors it has.

An *execution* in this model is a maximal sequence of configurations $e = \gamma^0 \gamma^1 \dots \gamma^i \dots$ such that for each transition (called *step*) $\gamma^i \mapsto \gamma^{i+1}$, there is a nonempty subset \mathcal{X}^i of $\text{Enabled}(\gamma^i)$ whose nodes simultaneously and atomically execute one of their enabled rules, leading from γ^i to γ^{i+1} . We say that each node of \mathcal{X}^i executes a *move* during $\gamma^i \mapsto \gamma^{i+1}$. Note that e is either infinite, or ends at a *terminal* configuration γ^f where $\text{Enabled}(\gamma^f) = \emptyset$. An algorithm with no infinite executions is *terminating* or *silent*.

A *daemon* \mathcal{D} is a predicate over executions. An execution which satisfies \mathcal{D} is said to be *an execution under \mathcal{D}* . We consider the *synchronous daemon*, which is true if, at all steps, $\mathcal{X}^i := \text{Enabled}(\gamma^i)$, and the *fully asynchronous daemon*, also called *distributed unfair daemon* in the literature, which is always true. Note that under the distributed unfair daemon, a node may starve and may never be activated, unless it is the only enabled node.

In an execution, all the information in the states is not necessarily relevant for a problem. We thus use a *projection* to extract information (e.g., just an output boolean for the boolean consensus) from a node's state, and we canonically extend this projection to configurations and executions. A *specification* of a distributed problem is then a predicate over projected executions. A problem is *static* if its specification requires the projected executions to be constant, and it is *dynamic* otherwise.

An algorithm is *self-stabilizing* under a daemon \mathcal{D} if, for every network and input parameters, there exists a set of *legitimate* configurations such that (1) the algorithm *converges*, i.e., every execution under \mathcal{D} (starting from an arbitrary configuration) contains a legitimate configuration, and (2) the algorithm is *correct*, i.e., every execution under \mathcal{D} that starts from a legitimate configuration satisfies the specification.

We consider three complexity measures: *space*, *moves* which model the total workload, and *rounds* which model an analogous of the synchronous time by taking the speed of the slowest nodes into account. As done in the literature on the atomic-state model, the space complexity is the maximum space used by one node to store its own variables. As explained before, a move is the execution of a rule by a node. To define the round complexity of an execution $e = \gamma^0 \gamma^1 \dots$, we first need to define the notion of *neutralization*: a node p is *neutralized* in $\gamma^i \mapsto \gamma^{i+1}$, if p is enabled in γ^i and not in γ^{i+1} , but it does not apply any rule in $\gamma^i \mapsto \gamma^{i+1}$. Then, the rounds are inductively defined as follows. The first round of an execution $e = \gamma^0 \gamma^1 \dots$ is the minimal prefix e' such that every node that is enabled in γ^0 either executes a move or is neutralized during a step of e' . If e' is finite, then let e'' be the suffix of e that starts from the last configuration of e' ; the second round of e is the first round of e'' , and so on. For every $i > 0$, we denote by γ^{r^i} the last configuration of the i -th round of e , if it exists and is finite; we also conventionally let $\gamma^{r^0} = \gamma^0$. Consequently, $\gamma^{r^{i-1}}$ is also the first configuration of the i -th round of e . The *stabilization time* of a self-stabilizing algorithm is the maximum time (in moves or rounds) over every execution possible under the considered daemon (starting from any initial configuration) to reach (for the first time) a legitimate configuration.

3 A Glimpse of our Research Process

3.1 An Unbounded Unison Algorithm

We started this work on the bounded unison problem when we observed that an unbounded solution can easily be derived from [21]. This can be seen as follows. The algorithm given in [21] simulates a synchronous non self-stabilizing algorithm in an asynchronous

self-stabilizing setting. To do so, it uses a very natural idea. It stores, at each node, the whole execution of the algorithm so far as a list of states. Given its list and the lists of its neighbors, a given node can check for inconsistencies in the simulation and correct them.

Now if we implement this idea in an asynchronous algorithm which is not self-stabilizing, then the length of the lists satisfy the unison property. Indeed, to compute its $(i + 1)$ -th value, a node must wait for all its neighbors to have computed at least their i -th value.

Obviously, in a self-stabilizing setting, we cannot expect the length of the lists of the nodes to initially satisfy the unison property. It turns out that the error recovery mechanism in [21] not only solves the initial inconsistencies of the simulation, but also recovers the unison property.

If we simulate an algorithm “that does nothing”, we can compress the lists by only storing their lengths. We thus obtain a first (unbounded) unison algorithm, given below. Note that although we describe the whole algorithm, the reader does not need to fully understand it.

Each node p has a status $p.s \in \{E, C\}$ (Error/Correct) and a time $p.t \in \mathbb{N}$. Given these predicates,

$$\begin{aligned} \text{root}(p) &:= (p.s = E \wedge \neg(\exists q \in N(p), q.s = E \wedge q.t < p.t)) \vee \\ &\quad (p.s = C \wedge \exists q \in N(p), (q.t \geq p.t + 2)) \\ \text{activeRoot}(p) &:= \text{root}(p) \wedge (p.t > 0 \vee p.s = C) \\ \text{errProp}(p, i) &:= \exists q \in N(p), q.s = E \wedge q.t < i < p.t \\ \text{canClearE}(p) &:= p.s = E \wedge \forall q \in N(p), (|q.t - p.t| \leq 1 \wedge (q.t \leq p.t \vee q.s = C)) \\ \text{updatable}(p) &:= p.s = C \wedge (\forall q \in N(p), p.t \leq q.t \leq p.t + 1) \end{aligned}$$

the algorithm is defined by the following four rules

$$\begin{aligned} R_R &: \text{activeRoot}(p) \longrightarrow p.t := 0 ; p.s := E \\ R_P(i) &: \text{errProp}(p, i) \longrightarrow p.t := i ; p.s := E \\ R_C &: \text{canClearE}(p) \longrightarrow p.s := C \\ R_U &: \text{updatable}(p) \longrightarrow p.t := p.t + 1 \end{aligned}$$

in which R_R has the highest priority, and $R_P(i)$ has a higher priority than $R_P(i')$ for $i < i'$. The rules R_R , $R_P(i)$ and R_C are “error management” rules. Thus, once the algorithm has stabilized, the status of all nodes is C and only R_U is applicable.

This unbounded self-stabilizing unison algorithm is not really interesting by itself. Indeed, it converges in $2D + 2$ rounds in an asynchronous setting, but in this regard, the algorithm in [4] converges twice as fast, is simpler and operates in the message-passing model, which is more realistic. However, whereas nobody has been able to derive a bounded version of the algorithm in [4], we hoped that this could be done with this new algorithm.

In the following subsections, we present a first very natural attempt, which ultimately failed, and a more complex version, which we detail and prove in the next sections of the paper.

3.2 A Failed Bounded Unison Algorithm

The most natural strategy to turn an unbounded unison into a bounded one is simply to count modulo a large enough fixed bound B . To outline this change of paradigm from an ever-increasing time to a circular clock, we rename the variable $p.t$ into $p.c$ for any node p .

We thus modify the rule R_U as follows:

$$\begin{aligned} \text{updatable}(p) &:= p.s = C \wedge (\forall q \in N(p), q.c \in \{p.c, p.c + 1 \bmod B\}) \\ R_U : \text{updatable}(p) &\longrightarrow p.c := p.c + 1 \bmod B \end{aligned}$$

At first glance, we do not need to modify the other rules as their purpose is only to correct errors, but this intuition is wrong. Indeed, when two neighboring nodes p and q are such that $p.s = q.s = C$, $p.c = 0$ and $q.c = B - 1$, they satisfy the unison property, but p can apply the rule R_R , although there are no errors to correct. The problem comes from the term $\exists q \in N(p), (q.c \geq p.c + 2)$ in the *root* predicate which should detect out-of-sync neighbors. Hence, we must at least modify this predicate as follows:

$$\begin{aligned} \text{root}(p) &:= (p.s = E \wedge \neg(\exists q \in N(p), q.s = E \wedge q.c < p.c)) \vee \\ &\quad (p.s = C \wedge \exists q \in N(p), (q.c \geq p.c + 2) \wedge \neg(p.c = 0 \wedge q.c = B - 1)). \end{aligned}$$

Therefore, transforming the algorithm to implement this simple modulo- B idea is already not as straightforward as it may seem.

Moreover, even small modifications generally introduce new unforeseen behaviors, and the modified algorithm has no particular reasons to be efficient, or even correct. As a matter of fact, we failed to prove its correctness. To understand why, we must delve a bit into the proof scheme of [21].

An important observation is that rootless configurations (i.e., those without nodes satisfying the *root* predicate) satisfy the safety property of the unison. In [21], the correctness and the move complexity then follow from the key property that roots cannot be created, and that, in a “small” number of steps, at least one root disappears.

Sadly, this first attempt algorithm does not satisfy the “no root creations” property. To see this, consider a path $p - q - r$ and a configuration γ^a in which $p.c = q.c = B - 1$, $r.c = 3$, $p.s = q.s = C$ and $r.s = E$. In one step $\gamma^a \mapsto \gamma^b$,

- p applies the rule R_U and thus, in γ^b , $p.c = 0$ and $p.s = C$
- q applies the rule $R_P(4)$, and thus, in γ^b , $q.c = 4$.

Therefore, in γ^b , $p.s = C$ and p has a neighbor q such that $q.c \geq p.c + 2$ and $q.c \neq B - 1$. Thus, p is a root in γ^b , although it is not one in γ^a .

Note that the fact that roots can be created is not necessarily a problem. Indeed, if only a finite number of them appears, we recover the correctness of the algorithm. We actually believe that, for B large enough, any node can become a root only once per execution, and this would most likely imply that the move complexity remains polynomial. But n roots may appear sequentially, which would lead to an $\Omega(n)$ round complexity.

At this point, we cannot rule out that this algorithm is correct and has good properties. However, because of these problems, we took another approach.

3.3 Our Solution

In the end, our solution is obtained by a rather limited modification of the previous algorithm: we extend the range of the counters $p.c$ to the interval $[-B, B)$, but we restrict their range to $[-B, 0)$ when $p.s = E$.

Actually, this modification prevents *all* root creations. But, as with the previous attempt, we must be extra careful even with the smallest change, as proofs can easily break. We thus present the whole algorithm and its proofs in more details in the next sections, and further highlight the differences with [21] in Section 4.5.

4 A Unison Algorithm

4.1 Data Structures

Let $B \geq 2D + 2$ be an integer. Each node p maintains a single variable $p.v \in \{(C, x) \mid x \in [-B, B)\} \cup \{(E, x) \mid x \in [-B, 0)\}$. In the algorithm, $p.s$ and $p.c$, the *status* and the *clock* of p , respectively denote the left and right part of $p.v$. An assignment to $p.s$ or $p.c$ modifies the corresponding field of $p.v$.

We define the unison increment $a \oplus_B 1$ as $(B - 1) \oplus_B 1 = 0$ and $a \oplus_B 1 = a + 1$ if $a \in [-B, B - 2]$. Two clocks are *synchronized* if they are at most one increment apart. We then define $a \oplus_B b$ as the result of b iterations of $\oplus_B 1$ over a . Note that, as hinted in Section 3.2, we also use the usual addition and subtraction.

4.2 Some Predicates

Apart from its state, a node p has only access to the set $\{q.v \mid q \in N(p)\}$ of its neighbors' variables. A guard should thus not contain a direct reference to a neighbor q of p . This may look like a problem for we have already used such references. Nevertheless, these uses are legitimate as, for any predicate Pred , the semantics of $\exists(s, c) \in \{q.v \mid q \in N(p)\}, \text{Pred}(s, c)$ is precisely $\exists q \in N(p), \text{Pred}(q.s, q.c)$. We can similarly encode universal statements.

As a matter of fact, we use the following shortcuts to increase readability:

Shortcut1 $\exists q \in N(p), \text{Pred}(q.s, q.c) := \exists(s, c) \in \{q.v \mid q \in N(p)\}, \text{Pred}(s, c)$

Shortcut2 $\forall q \in N(p), \text{Pred}(q.s, q.c) := \forall(s, c) \in \{q.v \mid q \in N(p)\}, \text{Pred}(s, c)$

Below, we define the predicates used by our algorithm.

$$\begin{aligned} \text{root}(p) &:= (p.s = E \wedge \neg(\exists q \in N(p), q.s = E \wedge q.c < p.c)) \vee \\ &\quad (p.s = C \wedge \exists q \in N(p), (q.c \geq p.c + 2) \wedge \neg(p.c = 0 \wedge q.c = B - 1)) \\ \text{activeRoot}(p) &:= \text{root}(p) \wedge (p.c \neq -B \vee p.s = C) \\ \text{errorPropag}(p, i) &:= i < 0 \wedge \exists q \in N(p), q.s = E \wedge q.c < i < p.c \\ \text{canClearE}(p) &:= p.s = E \wedge \forall q \in N(p), (|q.c - p.c| \leq 1 \wedge (q.c \leq p.c \vee q.s = C)) \\ \text{updatable}(p) &:= p.s = C \wedge \forall q \in N(p), q.c \in \{p.c, p.c \oplus_B 1\} \end{aligned}$$

A node p is a *root* if $\text{root}(p)$. An *error rule* is either the rule R_R or a rule $R_P(i)$.

4.3 The Algorithm

A unison algorithm is rarely used alone. It is merely a tool to drive another algorithm. It thus makes sense that our algorithm depends on some properties which are external to the unison algorithm and its variables. Our algorithm uses a predicate P_{aux} which is not yet defined. As a matter of fact, its influence on the complexity analysis of the algorithm is very limited. To prove the correctness of the unison, we set $P_{\text{aux}} = \text{true}$, and we specialize P_{aux} differently in Section 6 when using our algorithm as a synchronizer.

$$\begin{aligned} R_R &: \text{activeRoot}(p) &\longrightarrow & p.c := -B ; p.s = E \\ R_P(i) &: \text{errorPropag}(p, i) &\longrightarrow & p.c := i ; p.s = E \\ R_C &: \text{canClearE}(p) &\longrightarrow & p.s := C \\ R_U &: \text{updatable}(p) \wedge P_{\text{aux}}(p) &\longrightarrow & p.c := p.c \oplus_B 1 \end{aligned}$$

The rule R_R has the highest priority, and $R_P(i)$ has a higher priority than $R_P(i')$ for $i < i'$.

4.4 An Overview of the Algorithm

Contrary to [4] which proceeds by only locally synchronizing out-of-sync clocks, i.e., the clocks of two neighboring nodes that differ by at least two increments, we organize the synchronizations in *error broadcasts*. Every node p involved in such a broadcast is *in error* and its status is $p.s = E$. Otherwise, it is *correct* and $p.s = C$.

If p is correct, in sync with its neighbors, and if its clock $p.c$ is a local minimum, then p can apply the rule R_U to increment its clock.

There is a *cliff* between r and one of its neighbors p if their clocks are out-of-sync and $p.c > r.c$. If r is correct and has a cliff with a neighbor, then r is said to be a *root* and should initiate an error broadcast by applying the rule R_R , which respectively sets $r.c$ to $-B$ and $r.s$ to E .

If there is a cliff between r and p , r is in error, and $r.c < -1$, then p should propagate the broadcast by applying the rule R_P which sets $p.c$ to $r.c + 1$ and $p.s$ to E . If p has several such neighbors r , it applies R_P according to the one with the minimum clock.

As a consequence, any node p in error with $p.c > -B$ should have at least one neighbor in error with a smaller clock. This way, the structure of an error broadcast is a *dag* (directed acyclic graph). We therefore extend the definition of root to include nodes in error with no “parents” in the broadcast dag.

Note that a node may decrease its clock multiple times using R_P , and in doing so may consecutively join several error dags or several parts of them. This way, nodes reduce the height of the error dags, which is a key element to achieve the $O(D)$ -round complexity. Furthermore, any node in error eventually has a clock smaller than $-B + D$ and all cliffs are eventually destroyed.

Finally, if p is in error, is not involved in any cliff (in which case an error must be propagated), and if all its neighbors with larger clocks are correct, then the broadcast from p is finished, and p can apply the rule R_C to switch back $p.s$ to C .

A key element to bound the move complexity is that a dag built during an error broadcast is cleaned from the larger clocks to the smaller, but nodes previously in the dag resume the “normal” increments (using the rule R_U) in the reverse order (i.e., from the smaller clocks to the larger). Indeed, a non-root node in an error broadcast is one increment ahead of its parents in the dag and so has to wait for their increment before being able to perform one itself. Hence, the first node in the dag that makes a R_U move after an error broadcast is its root.

4.5 Some Subtleties

Some statements and the corresponding proof arguments are very similar to the ones of [21] (rather its arXiv version [20]). However, the fact that the algorithm and its data structures are different imply that proofs are indeed different. As a matter of fact, we have tried but failed to unify both algorithms into a *natural* more general one.

Below, we outline subtleties which are specific to our algorithm.

- Since nodes in error are restricted to negative clocks, it is natural to expect that legitimate configurations require all clocks to be non-negative. This would suggest a $\Theta(B)$ round complexity, which is weaker than what we claim. But this intuition is false. For example, the configuration where all nodes are correct and all clocks are set to $-B$ is legitimate. This is one of the reasons for our $O(D)$ round complexity.
- In the unbounded unison algorithm above which we derive from [21], whenever two neighboring nodes p and q are such that $q.s = E$ and $p.c \geq q.c + 2$, the node p can always apply a rule $R_P(i)$. In our algorithm, this is not the case when $q.c = -1$. This could

introduce unexpected behaviors which could impact the complexities of our algorithm, or in the worst case, lead to deadlocks. We thus have to deal with this slight difference in the proofs.

- In [21], the proofs heavily rely on the fact that the counters increase when applying the rule R_U while they decrease when applying the rules R_R and $R_P(i)$. This monotony property is however not true in our setting. More generally, having two addition operators $+$ and \oplus_B requires special care throughout the proofs.
- Finally, to bound the memory, the maximum clock is $B - 1$, after which clocks go back to 0. Notice that to ensure the liveness property of the unison, we must have $B \geq 2D + 2$ (an example of deadlock is presented for $B = 2D + 1$ in Subsection 5.2).

5 Self-Stabilization and Complexity of the Unison Algorithm

As already mentioned, the unison algorithm corresponds to $P_{\text{aux}} = \text{true}$. However, since most proofs are valid regardless of the definition of P_{aux} , we only specify it when needed. We define the *legitimate* configurations as the configurations without roots. Let $e = \gamma^0 \gamma^1 \dots$ be an execution. We respectively denote by $p.s^i$ and $p.c^i$ the value of $p.s$ and $p.c$ in γ^i .

5.1 Convergence and Move Complexity of the Unison Algorithm

Although it is tedious, it is straightforward to prove, by case analysis, that roots cannot be created. Since roots are obstructions to legitimate configurations, it is natural to partition the steps of e into *segments* such that each step in which at least one root disappears is the last step of a segment. There are thus at most n segments with roots, which constitute the *stabilization phase*, and at most one root-less segment. We now show that the stabilization phase is finite by providing a (finite) bound on its move complexity.

In the following, s is any segment of the stabilization phase. The key fact is that in s , a node p in error cannot apply the rule R_U until the end of s . We prove this by induction on $p.c$. If $p.c = -B$, then p is a root, and the only rule that p can apply is R_C , which removes its root status. The base case thus follows. Now let p be in error with $p.c > -B$. If p does not move in s , then our claim holds. Otherwise let $\gamma^a \mapsto \gamma^b$ be the first step in which p moves. If p applies the rule R_R , then $p.c^b = -B$, and for the remainder of s , the claim holds by induction. Otherwise, p has a neighbor q such that $q.s^a = E$ and $q.c^a < p.c^a < 0$. By induction, $q.c$ cannot increase until the end of s . As long as $p.c > q.c$, p cannot apply the rule R_U and if, at some point, $p.c \leq q.c$, then p must have applied an error rule, thus decreasing its clock, at which point the claim holds by induction.

Since roots cannot be created, the number of R_R -moves is at most n . Moreover, since between two R_C -moves, there has to be at least one error move (R_R - or R_P -move), we have $\#R_C\text{-moves} \leq n + \#R_R\text{-moves} + \#R_P\text{-moves} \leq 2n + \#R_P\text{-moves}$. We thus only need to bound the number of R_U -moves and R_P -moves.

We now bound the number of R_U moves by a node in s . If a node q does not move between γ^a and γ^b in s with $a < b$, then a neighbor p can apply the rule R_U at most twice, to go from $q.c^a - 1$ to $q.c^a + 1$. More generally, if $p.c^b \geq p.c^a + 2 + i$ (we really mean the $+$ operator and not the \oplus_B operator), then every neighbor q of p must increase its clock by at least i between γ^a and γ^b . By induction on d , if $p.c^b = p.c^a + 2d + i$, then every node q at distance d from p increases its clock by at least i between γ^a and γ^b . Since roots cannot increase their clocks, this implies that $p.c^b \leq p.c^a + 2D$.

From this “linear” bound, we now derive a “circular” bound which takes into account the fact that the clock of a node may decrease while applying the rule R_U (from $B - 1$ to 0). In the worst case, p could apply the rule R_U $2D$ times to reach $p.c = B - 1$, then apply

R_U once so that $p.c = 0$, then reapply R_U $2D$ more times (recall that $B \geq 2D + 2$). To summarize, p may apply R_U at most $4D + 1$ times in s . This gives an $O(n^2D)$ bound on the number of R_U -moves done during the stabilization phase.

We now focus on the rule R_P in s . If a node p_0 applies a rule R_P in a step $\gamma^{j_1} \mapsto \gamma^{j_1+1}$ of s , it does so to “connect” to a neighbor p_1 which is already in error. Now p_1 may be in error in γ^{j_1} because it has applied a rule R_P in another step $\gamma^{j_2} \mapsto \gamma^{j_2+1}$ of s with $j_2 < j_1$, to connect to a neighbor p_2 , and so on. This defines a *causality chain* $p_0 \cdots p_l$ for some l . Since, according to the key fact, rules R_P and R_U do not alternate in s , a node cannot appear twice in the causality chain, thus $l < n$. Moreover, when considering a maximal causality chain, $p_l.c^{j_l}$ is either the value of $p_l.c$ at the beginning of s , or $-B$ if p_l has applied the rule R_R . The clock $p_0.c$ can thus take at most $n(n + 1)$ distinct values in s , which implies that the rule R_P is applied at most $O(n^2)$ times in s by a given node. This gives an overall $O(n^4)$ -bound on the number of rules R_P . Note that a more careful analysis gives an overall bound of $O(n^3)$ on the total number of R_P -moves.

We can also easily obtain a bound that involves B . Indeed, a node p has at most B R_P -moves and $4D + 1 = O(B)$ R_U -moves in s . This gives an $O(n^2B)$ -bound on the number of moves. To summarize, the stabilization phase terminates after at most $O(\min(n^3, n^2B))$ moves.

Note that any configuration γ with at least one root contains at least one enabled node. Indeed, if any two neighboring clocks are at most one increment apart, then any root is in error, and the rule R_C is enabled at any node p in error with $p.c$ maximum. Otherwise, there exist two neighbors p and q such that $p.c$ and $q.c$ are more than one increment apart. We choose them with $q.c < p.c$ and $q.c$ minimum. $q.c$ being minimum, we can show that either q is a root that is enabled for R_R , or p can apply the rule R_P because q is in error and satisfies $q.c \leq -B + D < -1$. Thus, the last configuration of the stabilization phase is legitimate.

Also, note that since roots cannot be created, being legitimate is a closed property, meaning that in a step $\gamma^a \mapsto \gamma^b$, if γ^a is legitimate, then so is γ^b .

5.2 Correctness of the Unison Algorithm

We now show that any legitimate configuration γ satisfies the safety property of the unison. First, γ cannot contain nodes in error, because any such node p with $p.c$ minimum would be a root. Moreover, if the clocks of two correct neighbors differ by more than one increment, then the node with the smaller clock is a root.

To prove the liveness property of the unison, we set $P_{\text{aux}} = \text{true}$ in this paragraph. In legitimate configurations, since neighboring clocks differ by at most one increment, any two clocks differ by at most D increments. And since $B \geq 2D + 2$, there exists $c \in [0, B)$ which is not the clock of any node. This implies that there exists at least one node p whose clock is not the increment of any other clock. Thus, p satisfies *updatable* and can apply R_U . This proves that at least one node applies R_U infinitely often, and thus so do all nodes. Observe that $B \geq 2D + 2$ is tight. Indeed, when $B = 2D + 1$, the configuration of the cycle p_0, p_1, \dots, p_{2D} in which all nodes are correct and $p_i.c = i$, is legitimate but is terminal.

5.3 Round Complexity of the Unison Algorithm

We claim that $\gamma^{T_{2D+2}}$ contains no roots and so is legitimate. Recall that for all $i \geq 1$, Round i is $\gamma^{r_{i-1}} \cdots \gamma^{r_i}$. We suppose that all γ^{r_i} with $i \leq 2D + 1$ contain roots otherwise our claim directly holds.

We now study the first $D + 1$ rounds. Let r be any root in $\gamma^{r_{D+1}}$. Since there are no root creations, r is already a root in γ^0 . By the end of the first round (using the rule R_R if needed), $r.c = -B$ and $r.s = E$. Now, since r is still a root in $\gamma^{r_{D+1}}$, it cannot make a move in the meantime, and its state does not change until $\gamma^{r_{D+1}}$. Furthermore, every neighbor p of r such that $p.c > -B + 1$ can apply the rule R_p . So, by the end of Round 2, and as long as r does not increment its clock, $p.c \leq -B + 1$. By induction on the distance $d(p, r)$ between p and r , we can prove that $p.c^{r_{D+1}} \leq -B + d(p, r)$ for every node p and every root r in $\gamma^{r_{D+1}}$.

We claim that $\gamma^{r_{D+1}}$ does not contain any *cliff*, i.e., a pair (q, p) of neighboring nodes whose clocks are out-of-sync and such that $q.c < p.c$. Suppose that (q, p) is a cliff in $\gamma^{r_{D+1}}$. The node q is in error as otherwise it would be a root not in error, which, as already mentioned, is impossible from γ^{r_1} . Moreover, we can prove by induction on $q.c$ that there is a root r in $\gamma^{r_{D+1}}$ such that $q.c \geq -B + d(q, r)$. Since $p.c \geq q.c + 2$, we have $p.c > -B + d(p, r)$, which contradicts the result of the previous paragraph.

We now consider the next $D + 1$ rounds. Since $\gamma^{r_{D+1}}$ contains no nodes which can apply R_R , and no cliffs, nodes can only apply the rules R_U or R_C . Furthermore, among nodes in error, those with the largest clock can apply the rule R_C , which implies that roots no longer exist by the end of Round $2D + 2$, and thus $\gamma^{r_{2D+2}}$ is legitimate.

6 A Synchronizer

Let us consider a variant of the atomic-state model which is at least as expressive as the model of our unison algorithm. This means that, in this model, we should be able to encode the shortcuts `Shortcut1` and `Shortcut2` (defined page 10).

In this model, let Alg_I be any silent algorithm which is self-stabilizing with a projection $proj$ for a static specification SP under the synchronous daemon. Using folklore ideas (see, e.g., [4] and [28]), we define in this section a synchronizer which uses our unison to transform Alg_I into an algorithm $Sync(Alg_I)$ which “simulates” synchronous executions of Alg_I in an asynchronous environment under a distributed unfair daemon.

6.1 The Synchronized Algorithm

On top of its unison variables, each node p stores two states of Alg_I , in the variables $p.old$ and $p.curr$. These variables ought to contain the last two states of p in a synchronous execution of Alg_I . When p applies the rule R_U , it also computes a next state of Alg_I . It does so by applying the function $\widehat{Alg_I}$ which selects $p.curr$ and, for each neighbor q , the variable $q.curr$ if $p.c = q.c$, and $q.old$ if $q.c = p.c \oplus_B 1$, and applies Alg_I on these values. We thus modify the rule R_U in the following way:

$$R_U : updatable(p) \wedge P_{aux}(p) \longrightarrow p.old := p.curr; p.curr := \widehat{Alg_I}(p); p.c := p.c \oplus_B 1.$$

The folklore algorithm corresponds to the case when $P_{aux}(p)$ is always *true*. In this case, the clocks of the unison constantly change. Thus, even if Alg_I is silent, its simulation is not. To obtain a silent simulation, we devise another strategy by defining $P_{aux}(p)$ as follows.

$$P_{aux}(p) = (\widehat{Alg_I}(p) \neq p.curr) \vee (\exists q \in N(p), q.c = p.c \oplus_B 1).$$

We define the legitimate configurations of $Sync(Alg_I)$ to be its terminal configurations. In the next sections, we sketch the proof that $Sync(Alg_I)$ is self-stabilizing for the same specification as Alg_I . As a matter of fact, our result is more general as the silent assumption is not necessary (we need a different definition for the legitimate configurations though).

6.2 Convergence and Move Complexity of the Synchronized Algorithm

In everyday life, we have a distinction between the value of a clock (modulo 24 hours) and the time. Both are obviously linked. We would like to make a similar distinction here. Let $e = \gamma^0 \gamma^1 \dots$ be an execution of legitimate configurations. Since γ^0 is legitimate, every two neighboring clocks differ by at most one increment.

Since $B \geq 2D + 2$, as already mentioned, at least one element of $[0, B)$ is the clock of no nodes in γ^0 . This implies that there is a node x such that $x.c^0 \oplus_B 1$ is not the clock of any node. We extend this local synchronization property by uniquely defining $time(p)^0 \in [-D, 0]$ by (1) $time(x)^0 = 0$, (2) if $p.c^0 = q.c^0$, then $time(p)^0 = time(q)^0$, and (3) if $p.c \oplus_B 1 = q.c$, then $time(p)^0 = time(q)^0 - 1$. Moreover, we also define $time(p)^{i+1} = time(p)^i + 1$ if p applies R_U in $\gamma^i \mapsto \gamma^{i+1}$, and $time(p)^{i+1} = time(p)^i$ otherwise.

For any $i, j \geq 0$ such that $time(p)^j = i$, we set $st_p^i := p.curr^j$. When st_p^i is defined for all p , let λ^i be the configuration in which the state of each node p is st_p^i . A careful analysis shows that, by definition of P_{aux} , λ^i exists as soon as some st_p^i does, and $\Lambda = \lambda^0 \lambda^1 \dots$ is precisely the synchronous execution of Alg_I from λ^0 .

Suppose that T is a bound on the number of rounds that Alg_I needs to reach silence. Thus, $\Lambda = \lambda^0 \dots \lambda^H$ for some $H \leq T$. In the simulation phase, a node makes at most D moves to have a non-negative time, and then at most T moves to finish the simulation. Together with the stabilization time of the unison, our simulated algorithm is also silent with an $O(\min(n^3, n^2B) + nD + nT) = O(\min(n^3, n^2B) + nT)$ move complexity.

6.3 Correctness of the Synchronized Algorithm

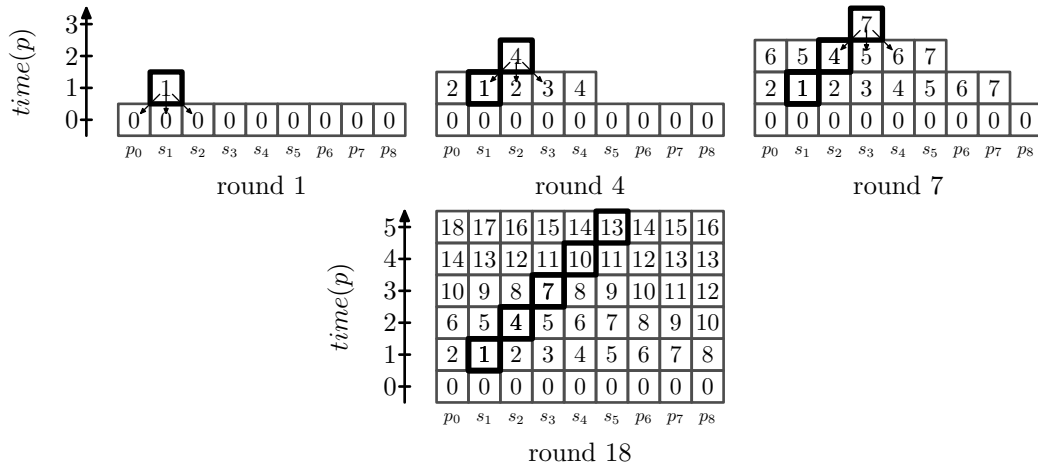

In $Sync(Alg_I)$, we define the *restriction* $rest(s)$ of the state s of any node p to be $p.curr$, and we canonically extend $rest$ to configurations and executions. Let us consider a legitimate configuration γ of $Sync(Alg_I)$. This configuration is terminal, and therefore there exists a unique execution e of $Sync(Alg_I)$ starting at γ (the one restricted to γ alone). Besides, since γ is terminal, its restriction is terminal too (for Alg_I). Therefore $rest(\gamma)$ is legitimate, and $proj(rest(e))$ satisfies the specification SP . Hence, the algorithm $Sync(Alg_I)$ also satisfies SP (for the projection $proj \circ rest$).

6.4 Round Complexity of the Synchronized Algorithm

The round complexity is analyzed by considering two stages: a first stage to have all times non-negative, and a second stage to have all times equal to H .

To give an intuition of our proof, as it is the more complex, we first consider the second stage. Figure 1 is an illustration of the following explanation. Suppose that all times are 0 in γ^0 , and only s_1 is such that $st_{s_1}^0 \neq st_{s_1}^1$. In the first round of the synchronous execution, s_1 applies R_U , and then, after each new round, nodes at distance 1 from s_1 , then 2, and so on will increase their time to 1. Now suppose that only $s_2 \in N[s_1]$ is such that $st_{s_2}^1 \neq st_{s_2}^2$. As soon as all nodes in $N[s_2]$ have a time of 1, s_2 applies R_U . This happens at Round 3 if $s_2 = s_1$ and at Round 4 otherwise. After this, after each new round, nodes at distance 1 from s_2 , then 2, and so on will increase their time to 2. If we consider some $s_3 \in N[s_2]$, and so on, then s_i increases its time to i at Round at most $3i - 2$, and all nodes do so at Round at most $3i + D - 2$. If nodes increase their time earlier, this only speed up the process.

Now, by definition of H , there is a node s_H whose state changes between λ_{H-1} and λ_H . If the states of all nodes in $N[p]$ were the same in λ_{H-2} and λ_{H-1} , then s_H would not have changed its state between λ_{H-1} and λ_H . There thus exists $s_{H-1} \in N[s_H]$ that changes its state between λ_{H-2} and λ_{H-1} . By repeating this process, we can prove that, unless $H = 0$,

■ **Figure 1** The intuition of the round complexity for the second stage.

Λ has a *starting sequence* that is a sequence $s_1 \cdots s_H$ verifying $st_{s_i}^{i-1} \neq st_{s_i}^i$ for $1 \leq i \leq H$, and $s_{i-1} \in N[s_i]$ for $1 < i \leq H$. We can then prove that, if all nodes have a positive time at Round X , then the algorithm becomes silent after at most $X + 3H + D - 2$ rounds.

Using similar ideas, we can prove that all times are non-negative after at most $X = 2D$ rounds. Taking into account the $3D + 2$ rounds of the stabilization phase, we obtain an overall $5D + 3T$ round complexity to reach the silence from any configuration.

7 Conclusion

We propose the first fully polynomial self-stabilizing unison algorithm for anonymous asynchronous bidirectional networks of arbitrary connected topology, and use it to obtain new state-of-the-art algorithms for various problems such as BFS constructions, leader election, and clustering.

A challenging perspective would be to generalize our approach to weaker models such as the message passing or the link-register models. We would also be curious to know the properties of the algorithm proposed in Section 3.2. Thirdly, although we could not do it, it would be nice to unify our result with that of [21] in a satisfactory manner. Finally, it would be interesting to know whether or not constant memory can be achieved by an asynchronous self-stabilizing unison for arbitrary topologies.

Efficient Approximation Schemes for Scheduling on a Stochastic Number of Machines

Abstract

We study three two-stage optimization problems with a similar structure and different objectives. In the first stage of each problem, the goal is to assign input jobs of positive sizes to unsplitable bags. After this assignment is decided, the realization of the number of identical machines that will be available is revealed. Then, in the second stage, the bags are assigned to machines. The probability vector of the number of machines in the second stage is known to the algorithm as part of the input before making the decisions of the first stage. Thus, the vector of machine completion times is a random variable. The goal of the first problem is to minimize the expected value of the makespan of the second stage schedule, while the goal of the second problem is to maximize the expected value of the minimum completion time of the machines in the second stage solution. The goal of the third problem is to minimize the ℓ_p norm for a fixed $p > 1$, where the norm is applied on machines' completion times vectors. Each one of the first two problems admits a PTAS as Buchem et al. showed recently. Here we significantly improve all their results by designing an EPTAS for each one of these problems. We also design an EPTAS for ℓ_p norm minimization for any $p > 1$.

1 Introduction

We consider scheduling problems where the goal is to assign jobs non-preemptively to a set of identical machines. Unlike traditional scheduling problems [22], the number of identical machines available to the scheduler, denoted as k , is not a part of the input, but it is drawn from a known probability distribution on the set of integers $\{1, 2, \dots, m\}$ for an integer $m \geq 2$ that is a part of the input, and it is given together with the probabilities. As a first stage, the decision maker completes an initial set of decisions, namely it assigns the jobs to m bags, forming a partition of all input jobs. Later, once the realization of the number of machines becomes known, it packs the bags to the machines, where the packing of a bag to a machine means that all its jobs are scheduled together to this machine. That is, in this later step, every pair of jobs that were assigned to a common bag will be assigned to a common machine, and the decision of the first stage (that is, the partition of input jobs into m bags) is irrecoverable. This two-stage stochastic scheduling problem was recently introduced by Buchem et al. [9].

Formally, the input consists of a set of jobs $\mathcal{J} = \{1, 2, \dots, n\}$ where each job $j \in \mathcal{J}$ has a positive rational size p_j associated with it. We are given an integer $m \geq 2$ and let $\mathcal{B} = \{1, 2, \dots, m\}$ denote the set of bags. We are also given a probability measure q over \mathcal{B} , where q_k is a rational non-negative number denoting the probability that the number of

identical machines in the resulting second stage instance is k . Here, we will use the property that $\sum_{k=1}^m q_k = 1$. In the first stage of our problem, the jobs are split into m bags by an algorithm. Namely, a feasible solution of the first stage is a function $\sigma_1 : \mathcal{J} \rightarrow \mathcal{B}$. In the second stage, after the value of k has been revealed, the bags are assigned to machines, such that all jobs of each bag are assigned together. Namely, the algorithm also computes assignment functions σ_2^k defined for every realization k in the support of q of the bags to the set of integers $\{1, 2, \dots, k\}$ denoting the indexes of machines in the instance of the second stage problem (corresponding to the realization of q that is equal to k). So if the realization of q is k , a job $j \in \mathcal{J}$ will be assigned to the machine of index $\sigma_2^{(k)}(\sigma_1(j))$. The first function σ_1 maps jobs to bags, and the second function which is based on the value of k , σ_2^k , maps bags to machines. The number of bags is m (and σ_1 is independent of k , so the partition into bags does not depend on k which is not known yet at the time of assignment into bags), and the number of machines is k , so for every realization of k the schedule of the jobs to the k machines is a feasible (non-preemptive) schedule for k identical machines.

We use the terminology of such scheduling problems and let W_i be the work (also called load) of machine i which is the total size of jobs assigned to machine i in a schedule. This is also the completion time of a unit speed machine processing continuously the set of jobs assigned to machine i starting at time 0 (in some order). The *makespan of the schedule in realization k* is the maximum work of a machine in the second stage solution in the realization k of q , and the *Santa Claus value of the schedule of realization k* is the minimum work of a machine (among the k machines) in the second stage solution in the realization k of q .

The expected value of the makespan is the expected value of the random variable of the makespan of the schedule in realization k . The expectation is computed based on all possible values of k . The first problem that we consider is the problem of minimizing the expected value of this random variable. We denote it as PR-MAKESPAN and refer to it as the *makespan minimization problem*. The expected value of the Santa Claus value is the expected value of the random variable of the Santa Claus value of the schedule in realization k . The second problem we consider is the problem of maximizing the expected value of this random variable. We denote it as PR-SANTACLUS and refer to it as the *Santa Claus maximization problem*. While the term makespan is used in the scheduling literature in this meaning the term Santa Claus is not traditional, and it is usually referred to as the minimum work of a machine in the schedule. Given the length of the resulting terminology for our settings, we prefer to use the non-traditional terminology of Santa Claus value. The expected value of the random variable is called cost or value for minimization problems, and it is called profit or value for maximization problems. In the ℓ_p norm minimization problem, the objective for k machines is $(\sum_{i=1}^k W_i^p)^{1/p}$. The cost of a solution of the third problem is the expected cost based on the random variable. This last problem is denoted by PR-NORM.

Since the stochastic nature of the problem results only from the different options for k (and once k is known, the problem is deterministic), we say that if the realization of q is k , then this is the scenario of index k or simply scenario k . We let OPT_k denote the objective function value of the second stage problem in scenario k for an optimal solution for the studied problem, and let $\text{OPT} = \sum_{k=1}^m q_k \cdot \text{OPT}_k$ denote the value of an optimal solution to our problem. An optimal solution needs to balance all scenarios, and we denote this optimal solution by OPT as well (that is, we use the same notation as the cost or the value). We stress that OPT_k is not necessarily the optimal objective function value for the input jobs and k machines, since the solution with a fixed set of bags may be inferior. We will assume that $\frac{1}{\varepsilon}$ is a positive integer such that $\frac{1}{\varepsilon} > 100$ (this can be done without loss of generality as one can first decrease ε to the minimum between its original value and $\frac{1}{100}$, and then it

is always possible to decrease the value of ε by a factor below 2 to satisfy the integrality condition on $\frac{1}{\varepsilon}$). The assumptions on ε will be used for all schemes (and in particular we will use $\varepsilon < \frac{1}{100}$). Let $p_{\max} = \max_{j \in \mathcal{J}} p_j$.

An overview of our results. Here, we study both minimization problems and a maximization problem. All types of algorithms defined here are required to have polynomial running times (and our algorithms will in fact have strongly polynomial running times). For a minimization problem, an \mathcal{R} -approximation algorithm is an algorithm that always finds a solution that is feasible and has a cost at most \mathcal{R} times the cost of an optimal solution. For a maximization problem, an \mathcal{R} -approximation algorithm is an algorithm that always finds a feasible solution of value at least $\frac{1}{\mathcal{R}}$ times the value of an optimal solution. The approximation ratio of a given algorithm is the infimum value of the parameter \mathcal{R} such that this algorithm is an \mathcal{R} -approximation algorithm.

A PTAS is a class of approximation algorithms such that for any $\varepsilon > 0$ the class has a $(1+\varepsilon)$ -approximation algorithm. An efficient polynomial time approximation scheme (EPTAS) is a stronger concept. This is a PTAS whose running time is of the form $h(\varepsilon) \cdot \text{poly}(N)$ where h is some (computable but not necessarily polynomial) function and $\text{poly}(N)$ is a polynomial function of the length N of the (binary) encoding of the input. We will justify the assumption $m \leq n$ later, and therefore the running time can be rewritten in this form when the polynomial is on m and n . A fully polynomial time approximation scheme (FPTAS) is an even stronger concept, defined like an EPTAS, but the function h must be a polynomial in $\frac{1}{\varepsilon}$. In this paper, we are interested in EPTAS's.

A PTAS may have time complexity of the form $n^{g(\varepsilon)}$, where g can be any function of $\frac{1}{\varepsilon}$ and even a power tower function. However, an EPTAS cannot have such a running time, which makes it more efficient. The concept of an EPTAS is related to fixed parameter tractable (FPT) algorithms [16].

In this paper, we focus on finding EPTAS's for the three objectives. We develop an EPTAS for the makespan minimization problem in Section 2. Then, in Section 3 we establish an EPTAS for the Santa Claus maximization problem PR-SANTACLAUS. Last, in the full version of this work we modify our scheme for PR-MAKESPAN in order to obtain an EPTAS for PR-NORM. Due to space limitations, some of the proofs of the first two results are given in the full version, and the last EPTAS for PR-NORM is presented in the full version as well. In the recent work [9], a PTAS was designed for PR-MAKESPAN, and another PTAS was designed for PR-SANTACLAUS. Those PTAS's are of forms that do not allow a simple modification of the PTAS into an EPTAS, and in particular for PR-SANTACLAUS a dynamic program over a state space whose size is exponential is used (a function of ε appears in the exponent of the input size), and for both schemes enumeration steps of such sizes are applied.

For all objectives, we assume that $n > m$ holds. If $n \leq m$, this means that every job can be assigned to its own bag. For each scenario, it is possible to apply an EPTAS for the corresponding problem (see for example [2], the details for previous work are discussed further below) and thereby get an EPTAS for the required problem.

The problems studied here generalize strongly NP-hard problems, and therefore one cannot expect to obtain an FPTAS (unless $P = NP$), and thus our results are the best possible. Specifically, the special case of each one of the three problems where the number of machines is known, i.e., the probability function has a single value q_m that is equal to 1, and other probabilities are equal to zero, is known to be NP-hard in the strong sense. The three objectives studied here are the three main objectives previously studied for scheduling on identical machines.

Related work. Stein and Zhong [33] introduced the scheduling problem with an unknown number of machines but in their model the number of machines is selected later by an adversary. The problem was mostly studied with respect to makespan minimization. In the deterministic variant [33], the goal is to assign a set of jobs with known properties to identical machines. However, only an upper bound m on the number of machines is given. Jobs have to be partitioned into m subsets, such that every subset will act as an inseparable bag. Then, the number of machines k (where $2 \leq k \leq m$) becomes known, and the schedule is created using the bags, without unpacking them, as in the problem that we study here, and after the number of machines is revealed, the bags are assigned to the machines, as in the problem that we study. Thus, this problem also has two steps or levels of computation, but the worst case out of all possible values of k is analyzed, where the comparison for each value of m is to an optimal offline solution for k identical machines and arbitrary bags. It is not hard to see that a constant approximation ratio (of at most 2) can be obtained using a round-robin approach even for jobs of arbitrary sizes (via pre-sorting). An improved upper bound of $\frac{5}{3} + \epsilon$ was shown using a much more careful assignment to bags [33].

A variant where machines have speeds (similar to uniformly related machines) was defined and studied by [18] with respect to makespan. In that version, the number of machines m is known, but not their speeds. The number of required bags is equal to the number of machines, but some machines may have speed zero, so the case of identical machines and the makespan objective is seen as binary speeds in this work. There are several input types of interest, which are arbitrary jobs, unit size jobs, sand (one large job that can be cut into any required parts), and pebbles (jobs that have arbitrary sizes, but they are relatively small) [18, 30]. Tight bounds were proved for the case of sand and makespan with and without speeds [33, 18], and for the Santa Claus objective without speeds [33]. All these values are strictly smaller than 1.6. For sand, since any partition of the input jobs is allowed, linear programming can be used to find the best partition. In the case with speeds for arbitrary sizes of jobs the algorithm of [18] has an approximation ratio of at most $2 - \frac{1}{m}$, while special cases allow smaller ratios [18, 30].

In [5], Balkanski et al. relate the problem of scheduling with an unknown number of machines and an unknown set of speeds to online algorithms with predictions. In online problems with predictions [31], the algorithm receives information on the input, where such information could have been computed via machine learning. This model takes into account both the situation where the input matches the prediction exactly and the case where it does not. It is required for the algorithm to have a relatively good performance for every input, but the performance has to be better if the input was predicted correctly. In many algorithms the performance improves as the input gets closer to the predicted input. The work of [5] provides results of this flavor.

Optimizing the worst scenario is pessimistic and does not allow one to take information learned from previous data into account, while the study of the expected value as in our stochastic problem allows us to prefer the typical scenarios in the bag assignment algorithm. See also [4, 8, 32, 17] for related work.

As we mentioned, the most relevant work to our work on the stochastic problem is [9], where two PTAS's are provided. It is also mentioned in that work that FPTAS's for the case where m is seen as a constant can be designed using standard methods. The problem is called *stochastic* due to the probability distribution on scenarios. However, since this distribution is simply a convex combination of the costs for different scenarios, the methods are related to those often used for deterministic algorithms and worst case analysis. The convex combination complicates the problem and it requires carefully tailored methods for

the algorithmic design. We follow the standard worst case studies of two-stage stochastic optimization problems, and we study the optimization problems of optimizing the expected value of the random variable.

All three objectives were studied initially for known numbers of identical machines, for which simple greedy approximation algorithms were presented first. Some time later PTAS's were designed. Finally EPTAS's were designed or it was observed that one of the known PTAS's is an EPTAS or can be converted into an EPTAS, which is the best possible result for each one of the three cases unless $P = NP$. We provide additional details for each one of the objectives. The makespan objective was introduced by Graham [22, 23], where greedy algorithms were studied (see also [13, 20]). Twenty years later a PTAS was designed [25]. Hochbaum [24] mentions that one of the approaches of assigning large jobs of rounded sizes (namely, solving an integer linear program in fixed dimension) gives an EPTAS, and attributes this approach to D. Shmoys (see [26, 11] for recent results). The Santa Claus objective (where the name was introduced much later [7]) was studied with respect to greedy heuristics [21, 15, 14]. A PTAS which is actually an EPTAS was designed by Woeginger [34]. The ℓ_p norm objective function was studied with respect to greedy heuristics [10, 12, 29], and a PTAS and an EPTAS were designed [1]. The same authors generalized their results for other objectives that satisfy natural conditions [2]. The ℓ_p norm of a vector is seen as a more suitable measure of fairness of a schedule compared to bottleneck measures [3, 6], and therefore we study this objective additionally to those studied in [9].

Our methods. We develop new techniques to address the uncertainty in the problems. We expect these techniques to be used in later work on approximating related variants.

We use rounding and discretization as in other work on scheduling, though we apply it not only on job sizes but also on bag sizes. The difficulty in relating new sizes to optimal solutions lies in the difference in objectives, since here the optimal value is not defined by a single schedule. However, we are still able to find such a relation using enumeration of sets of values, that is, via guessing. Since jobs are assigned to bags, we introduce configuration integer programs (IP's) on collections of bags, which can be seen as a generalization of previously known approaches. Our configuration IP's are based on the use of templates, where a template defines the contents of a bag, and configurations, where a configuration is an allocation of bags to one machine in a given scenario. We solve this IP using an algorithm for solving an IP in fixed dimension. All earlier steps of our schemes are highly motivated given the goal of creating such an IP and ensuring that it has a fixed dimension.

Machine numbers are split to intervals such that the most difficult interval for each guessed information is solved using an IP, while the others are solved using greedy approaches. The number of intervals for scenarios differs based on the specific problem.

While the sketched approach allows us to design an EPTAS for makespan minimization, the other objectives are harder to approximate. In order to tackle them, we develop an important tool called approximated histograms. Those are histograms of solution costs or values, and we use them in order to reduce the number of relevant scenarios to a constant. The condition for using the approximated histogram is a monotonicity assumption regarding the feasibility of solutions for different scenarios and the monotonicity of the costs for a given solution among scenarios in which it is feasible.

2 An EPTAS for the makespan minimization problem

We start with the makespan minimization problem, and continue to the other objectives in other sections. The first step will be to apply a discretization on bag sizes, and bound (from above) the set of relevant bag sizes as a function of OPT, where we enumerate possible values

of OPT and use rounding for this value as well. Our second step is to round the instance of jobs (which will be assigned to bags). We use standard guessing steps and rounding methods for these steps. Then, we are going to approximate the rounded instance by using templates of the assignment of jobs to bags, and configurations of assigning templates to machines in every realization of q . This will allow us to formulate an integer linear program that has a special structure, namely, it is a *two-stage stochastic integer linear program*. This special structure, as well as trivial bounds on the parameters of this formulation, provides us with an FPT algorithm to solve the problem. This algorithm has a running time dominated by a function of $\frac{1}{\varepsilon}$ times a polynomial in n , and therefore it is an EPTAS.

We will be able to reduce the number of variables such that we can apply Lenstra's algorithm [28, 27] on the integer linear program, and the running time for solving this program will be smaller than that of solving a two-stage stochastic integer linear program. This is the case also for the other two EPTAS's that we show, that is, we will apply Lenstra's algorithm for all objectives. The most difficult step in the current section is to reduce the number of different values of makespan for different scenarios. Without this step, the running time will not satisfy the requirements of an EPTAS. The reduction is based on linear grouping, which is typically used for bin packing [19] and not for scheduling. The other EPTAS's that we design require additional non-trivial steps, and we will discuss them later.

The optimal solution of this integer program is transformed into a set of decisions defining the functions σ_1 and $\sigma_2^{(k)} \forall k$. Next, we present the details of the scheme together with its analysis. In what follows we will present steps where in each of those steps the resulting approximation ratio of the scheme increases by at most a multiplicative factor of $1 + \Theta(\varepsilon)$. By scaling ε prior to applying the scheme, we get that the approximation ratio of the entire scheme will be at most $1 + \varepsilon$. We will use the next lemma for our proof.

► **Lemma 1.** *It holds that $OPT_k \in [p_{\max}, n \cdot p_{\max}]$ for any $k \leq m$. Thus, $OPT \in [p_{\max}, n \cdot p_{\max}]$.*

Guessing opt. Our first step is to guess the value of OPT within a multiplicative factor of $1 + \varepsilon$. That is, we would like to enumerate a polynomial number of candidate values, where the enumerated set will contain (at least one) value that is in the interval $[OPT, (1 + \varepsilon) \cdot OPT]$. We will show that for a guess in this interval we indeed find a solution of cost $(1 + \Theta(\varepsilon)) \cdot OPT$. The next lemma shows that it is possible to enumerate such a set of candidate values since $\log_{1+\varepsilon} n \leq \frac{n}{\varepsilon}$. Our algorithm performs this enumeration.

► **Lemma 2.** *There is a set consisting of $O(\log_{1+\varepsilon} n)$ values such that this set of values has at least one value in the interval $[OPT, (1 + \varepsilon)OPT]$.*

In what follows, with a slight abuse of notation, we let OPT be the value of this guessed candidate value (which is not smaller than OPT and it is larger by at most a factor of $1 + \varepsilon$ if the guess is correct). We will show that if there is a feasible solution to PR-MAKESPAN whose expected value of the cost is at most OPT, then we will construct a feasible solution with expected value of the cost being at most $(1 + \Theta(\varepsilon)) \cdot OPT$. By the above lemma, this means that the problem admits an EPTAS as desired.

Rounding bag sizes. Now, we provide a method to gain structure on the set of feasible solutions that we need to consider for finding a near optimal solution. Given a feasible solution, the size of bag i denoted as $P(i)$ is the total size of jobs assigned to this bag, that is, $P(i) = \sum_{j: \sigma_1(j)=i} p_j$.

► **Lemma 3.** *There exists a solution of cost at most $(1 + 3\varepsilon) \cdot OPT$ in which the size of every non-empty bag is in the interval $[\varepsilon \cdot OPT, (1 + \varepsilon) \cdot OPT]$.*

In what follows, we will increase the size of a bag to be the next value of the form $(\varepsilon + r\varepsilon^2) \cdot \text{OPT}$ for a non-negative integer r (except for empty bags for which the allowed size remains zero). Thus, we will not use precise sizes for bags but upper bounds on sizes, and we call them *allowed sizes*. We let $P'(i)$ be this increased (allowed) size of bag i , that is, $P'(i) = \min_{r: (\varepsilon + r\varepsilon^2)\text{OPT} \geq P(i)} (\varepsilon + r\varepsilon^2)\text{OPT}$. Since for every subset of bags, the total allowed size of the bags in the set is at most $1 + \varepsilon$ times the total size of the bags in the subset, we conclude that this rounding of the bag sizes will increase the cost of any solution by a multiplicative factor of at most $1 + \varepsilon$ (and therefore the expected value also increases by at most this factor). Thus, in what follows, we will consider only bag sizes that belong to the set $B = \{(\varepsilon + r\varepsilon^2)\text{OPT} : r = 0, 1, \dots, \frac{1}{\varepsilon^2}\} \cup \{0\}$. We use this set by Lemma 3. We conclude that the following holds.

► **Corollary 4.** *If the guessed value (OPT) is at least the optimal expected value of the makespan, then there is a solution of expected value of the makespan of at most $(1 + \varepsilon)(1 + 3\varepsilon) \cdot \text{OPT}$ that uses only bags with allowed sizes in B .*

Note that the allowed size of a bag may be slightly larger than the actual total size of jobs assigned to the bag. Later, the allowed size acts as an upper bound (without a lower bound), and we take the allowed size into account in the calculation of machine completion times in some cases (instead of the size).

Rounding job sizes. We apply a similar rounding method for job sizes. Recall that by our guess, every job j has size at most OPT (see Lemma 1). Next, we apply the following modification to the jobs of sizes at most $\varepsilon^2\text{OPT}$. Whenever there is a pair of jobs, each of which has size at most $\varepsilon^2\text{OPT}$, we unite the two jobs (i.e., we delete the two jobs, adding a new job whose size is the sum of the two sizes of the two deleted jobs). This is equivalent to restricting our attention to solutions of the first stage where we add the constraint that the two (deleted) jobs must be assigned to a common bag. We repeat this process as long as there is such a pair. If there is an additional job of size at most $\varepsilon^2\text{OPT}$, we delete it from the instance, and in the resulting solution (after applying the steps below on the resulting instance) we add the deleted job to bag 1. This is done after the entire algorithm completes running, so it may increase the makespan of every scenario and therefore the expected value of the makespan, but we do not take it into account in the algorithm or in calculating allowed sizes of bags. This addition of the deleted job increases the makespan of every scenario by at most $\varepsilon^2\text{OPT}$, so the resulting expected value of the makespan will be increased by a multiplicative factor of at most $1 + \varepsilon^2$. We consider the instance without this possible deleted job, and we prove the following.

► **Lemma 5.** *The optimal expected value of the makespan of the instance resulting from the above modification of the job sizes among all solutions with allowed bag sizes in the following modified set $B' = \{(\varepsilon + r\varepsilon^2)\text{OPT} : r = 0, 1, \dots, \frac{1}{\varepsilon^2} + 2\} \cup \{0\}$ is at most $(1 + 2\varepsilon)(1 + \varepsilon)(1 + 3\varepsilon) \cdot \text{OPT}$.*

We next round up the size of every job j to be the next value that is of the form $(1 + \varepsilon)^r \cdot \text{OPT}$ for an integer r . The size of every job cannot decrease and it may increase by a multiplicative factor of at most $1 + \varepsilon$. Job sizes are still larger $\varepsilon^2 \cdot \text{OPT}$ and the sizes do not exceed $(1 + \varepsilon) \cdot \text{OPT}$. Thus, the number of different job sizes is $O(\log_{1+\varepsilon} \frac{1+\varepsilon}{\varepsilon^2}) \leq \frac{2}{\varepsilon^3} - 1$. We increase the allowed size of each non-empty bag by another multiplicative factor of $1 + \varepsilon$, and round it up again to the next value of the form $\varepsilon + r\varepsilon^2$. Thus, the expected value of the makespan of a feasible solution increases by a multiplicative factor of at most $(1 + \varepsilon)^2$, where

one factor of $1 + \varepsilon$ is due to the rounding of jobs, and the second one is due to bringing allowed sizes back to the form $\varepsilon + r\varepsilon^2$. So by our guessing step, there is a feasible solution with expected value of the makespan of at most $(1 + \varepsilon)^3(1 + 2\varepsilon)(1 + 3\varepsilon)\text{OPT}$ that uses only bags with allowed size in $B'' = \{(\varepsilon + r\varepsilon^2)\text{OPT} : r = 0, 1, \dots, \frac{1+2\varepsilon}{\varepsilon^2} + 2\} \cup \{0\}$.

A bag is called *tight* if the set of jobs of this bag cannot use a bag of a smaller allowed size. Note that any solution where some bags are not tight can be converted into one where all bags are tight without increasing the cost. Note that the allowed size of a non-zero bag of allowed size $(\varepsilon + r\varepsilon^2)\text{OPT}$ can be written in the form $(r + \frac{1}{\varepsilon}) \cdot \varepsilon^2 \cdot \text{OPT}$, and since $\frac{1}{\varepsilon}$ is integral, the allowed size of each bag is an integer multiple of $\varepsilon^2 \cdot \text{OPT}$.

► **Lemma 6.** *For any tight bag it holds that the allowed size of the bag is at most $\frac{1}{\varepsilon}$ times its actual size (the total size of jobs assigned to the bag, where their rounded sizes are considered).*

Computing the maximum number of machines for which the assignment to bags does not matter. In our algorithm, we would like to focus on values of k for which the structure of bags is crucial. Now, we will detect values of k for which there always exists a good assignment of bags to machines (for reasonable sets of bags). Let P be the total size of all jobs (after the transformation applied on jobs for a fixed value of OPT). The total size (not the allowed size) of all bags is P , and we can compute the makespan based on the actual sizes of bags which are total sizes of jobs (after merging and rounding) assigned to the bags. The motivation is that for very small values of k the maximum bag size is so small compared to $\frac{P}{k}$ that bags can be seen as very small jobs, and one can apply a greedy algorithm [22] for assigning the bags, and still obtain a solution with a small makespan (based on bag sizes).

► **Lemma 7.** *If $k \leq \frac{\varepsilon \cdot P}{2 \cdot \text{OPT}}$, then any set of bags (such that every job is assigned to a bag) where every bag has an allowed size (and size) not exceeding 2OPT , leads to at least one schedule for k machines with makespan in $[\frac{P}{k}, (1 + \varepsilon) \cdot \frac{P}{k}]$. For other values of k , the makespan of an optimal schedule using tight bags (based on their allowed sizes) is at most $(3/\varepsilon^2) \cdot \text{OPT}$.*

We use the property that no bag has an allowed size above $2 \cdot \text{OPT}$. Our algorithm computes the maximum value of k for which $2\text{OPT} \leq \varepsilon \cdot \frac{P}{k}$ holds, and afterwards it excludes values of k for which $2\text{OPT} \leq \varepsilon \cdot \frac{P}{k}$ holds. We will have that the cost of the solution obtained for the scenario is at most $(1 + \varepsilon) \cdot \frac{P}{k}$, since bag sizes satisfy the condition for bags in the statement of Lemma 7, and therefore we can use the first part of this lemma. This is a valid approach as adding a scenario where $2\text{OPT} \leq \varepsilon \cdot \frac{P}{k}$ to the calculation of the approximation ratio will not increase the approximation ratio beyond the value $1 + \varepsilon$, and the running time for computing a good solution for such a value of k is polynomial in m, n . Thus, we assume that $2\text{OPT} > \varepsilon \cdot \frac{P}{k}$ holds for every k .

We consider the remaining scenarios. In what follows, we consider the assignment of jobs to bags and the assignment of the bags to machines in each scenario k subject to the condition that $2\text{OPT} > \varepsilon \cdot \frac{P}{k}$ and the optimal makespan of the scenario is at most $(3/\varepsilon^2) \cdot \text{OPT}$. In particular, it means that the number of bags of positive allowed sizes assigned to a machine in such a scenario is at most $3/\varepsilon^3$, since we consider allowed bag sizes not smaller than $\varepsilon \cdot \text{OPT}$ (if we exclude bags of allowed size zero).

Guessing an approximated histogram of the optimal makespan on all scenarios. Our next guessing step is motivated by linear grouping of the OPT_k values. To illustrate this step, consider a histogram corresponding to the costs of a fixed optimal solution satisfying all above structural claims, where the width of the bar corresponding to scenario k is q_k and its height is the value of the makespan in this scenario (that is, OPT_k). Observe that when k

Our next guessing step is motivated by linear grouping of the OPT_k values. To illustrate this step, consider a histogram corresponding to the costs of a fixed optimal solution satisfying all above structural claims, where the width of the bar corresponding to scenario k is q_k and its height is the value of the makespan in this scenario (that is, OPT_k). Observe that when k

is increased, the optimal makespan does not increase (without loss of generality, since the same assignment of bags can be used), so by plotting the bars in increasing order of k we get a monotone non-decreasing histogram, where the total area of the bars is the expected value of the makespan of the optimal solution and the total width of all the bars is 1 (since we assume that all scenarios are included in the histogram and every scenario κ satisfies the condition $2\text{OPT} > \varepsilon \cdot \frac{P}{\kappa}$ by scaling the probabilities of the remaining scenarios such that the total probability becomes 1). We sort the indexes of scenarios with (strictly) positive probabilities (q_k values) and we denote by K the resulting sorted list. For every $k \in K$, we compute the total width of the bars with indexes at most k (using the ordering in K , i.e., in increasing indexes), and denote this sum by Q_k . We also let $Q'_k = Q_k - q_k$. Thus, Q_k is the total probability of scenarios in $\{1, 2, \dots, k\}$, and Q'_k is the total probability of scenarios in $\{1, 2, \dots, k-1\}$. The set K does not contain scenarios with probability zero, but if $q_{k-1}, q_k > 0$, it holds that $Q_{k-1} = Q'_k$. According to the definitions, it holds that $Q_k - Q'_k = q_k$ for $k \in K$, and the interval $[Q'_k, Q_k)$ on the horizontal axis corresponds to scenario k .

The idea of the next parts is to get an overestimator for the histogram by extending the value of k to the right, and an underestimator by extending it to the left. The two areas below them will differ only by at most $O(\varepsilon \cdot \text{OPT})$, so the overestimator can also differ from the original histogram area by at most this amount.

Next, we compute an upper bound histogram W as follows. We start with selecting a sublist K' of K . The motivation is that schedules will be computed later only for scenarios in K' , and they will be copied to scenarios of some of the larger indexes. The set K' acts as a representative set, and we show that it is possible to restrict ourselves to such a set. Since we increase upper bounds on the makespan for some scenarios, the feasibility is not harmed.

An index $k \in K$ belongs to K' if there exists an integer ℓ such that $Q'_k \leq \varepsilon^3 \ell < Q_k$. The motivation is that we would like to consider points which are integral multiples of ε^3 and the set K' contains all values of $k \in K$ for which such special values belong to the interval $[Q'_k, Q_k)$. Values of makespan will be increased such that the makespan function will still be piecewise linear, but it will have a smaller number of image values.

For every $k \in K'$, the new upper bound histogram is defined as OPT_k for all points with horizontal value between Q'_k and up to $Q'_{k'}$ where $k' > k$ is the index just after k in the sublist K' or up to the last point where the histogram is defined (Q_t for the maximum value $t \in K$) if k is the largest element of K' . Since the original histogram was monotone non-increasing, the new histogram is pointwise not smaller than the original histogram. The possible modification is in the interval $[Q_k, Q'_{k'})$ if k is not the maximum value of K' , and in this case there may be a change for $k+1, \dots, k'-1$ (that is, if $k' \geq k+2$). If k is the largest element of K' but not of K , there may be a change for all $t \in K$ such that $t \geq k+1$. Thus, an upper bound on the total area below the histogram W is not smaller than the expected value of the makespan of the optimal solution.

We use the modified histogram W to obtain another bound. For that we see W as a step function whose values are the corresponding points in the upper edge of the histogram. We define a new histogram by letting it be $W(x + \varepsilon^3)$ for all $x \in [0, 1]$ (and zero for cases that W is undefined due to an argument above 1). In this way we delete a segment of length ε^3 from W and we shift the resulting histogram to the left. Since the makespan for every scenario never exceeds $(3/\varepsilon^2) \cdot \text{OPT}$, every point in W has a height of at most $\frac{3\text{OPT}}{\varepsilon^2}$ and we deleted a segment of width of ε^3 , the total area that we delete is at most $3\varepsilon\text{OPT}$. The resulting histogram is pointwise at most the original histogram (and thus also not larger than W). This property holds since every value OPT_k was extended to the right for an interval not longer than ε^3 . Thus, if we consider W instead of the original histogram, we increase the cost of the solution by a multiplicative factor not larger than $(1 + 3\varepsilon)$.

The guessing step that we use is motivated by this function W . We let W_k be the height of the histogram W in the bar corresponding to the scenario k . The relevant values of k are those in K' , and the histogram W only has values of the form OPT_k for $k \in K'$. We guess the histogram W . This means to guess the optimal makespan of $O(\frac{1}{\varepsilon^3})$ scenarios, where makespans can be one of at most $\frac{3}{\varepsilon^4}$ different values. This holds since all allowed bag sizes are integer multiples of $\varepsilon^2 \cdot \text{OPT}$, so makespans are also integer multiples of $\varepsilon^2 \cdot \text{OPT}$, and the makespan of each scenario is at most $\frac{3\text{OPT}}{\varepsilon^2}$. Thus, the number of possibilities of this guessing step is upper bounded by a function of $\frac{1}{\varepsilon}$ which is $O((\frac{1}{\varepsilon})^{O(1/\varepsilon^3)})$.

In what follows, we consider the iteration of the algorithm defined below when we use the value of the guess corresponding to the optimal solution. Algorithmically, we will try all possibilities, check the subset of those for which we can provide a feasible solution, and output the best feasible solution obtained in this exhaustive enumeration. The running time of the next algorithm is multiplied by the number of possibilities.

The template-configuration integer program. A *template* of a bag is a multiset of job sizes assigned to a common bag. We consider only multisets for which the total size of jobs is at most $(1 + 6\varepsilon) \cdot \text{OPT}$ since the largest allowed size of any bag is smaller. Since the number of distinct job sizes (in the rounded instance) is upper bounded by $\frac{2}{\varepsilon^3} - 1$ and there are at most $\frac{2}{\varepsilon^2}$ jobs assigned to a common bag (since the rounded size of each job is above $\varepsilon^2 \cdot \text{OPT}$), we conclude that the number of templates is at most $(\frac{2}{\varepsilon^3})^{(2/\varepsilon^2)}$, which is a constant depending only on $\frac{1}{\varepsilon}$. The reason is that each bag has $\frac{2}{\varepsilon^2}$ slots for jobs, such that each one may be empty or contain a job of one of the sizes. This calculation proves an upper bound on the number of possible templates, and we use a single template for every multiset of job sizes even when one multiset can be found in more than one way in the last calculation.

We are going to have a non-negative counter decision variable y_t for every template t , where this variable stands for the number of bags with template t . Let τ be the set of templates, and assume that a template is represented by a vector. The length of such a vector is the number of different (rounded) job sizes, and for every index ℓ , the ℓ -th component of the vector of the template (denoted by t_ℓ) is the number of jobs with size equal to the ℓ -th job size that are packed into a bag with this template. In order for such an assignment of the first stage to be feasible, we have the following constraints where n_ℓ denotes the number of jobs in the rounded instance whose size is the ℓ -th job size of the (rounded) instance.

$$\sum_{t \in \tau} y_t \leq m, \quad \sum_{t \in \tau} t_\ell \cdot y_t = n_\ell, \forall \ell.$$

The first constraint states that the number of bags is at most m . If this number is strictly smaller than m , then the remaining bags have allowed sizes of zero and they will not contain jobs. The second constraint, which is a family of constraints, states that the correct numbers of jobs of each size are assigned to templates, according to the number of copies of each template. Observe that the number of constraints in this family of constraints is a constant depending on ε (it is at most $\frac{2}{\varepsilon^3}$), and all coefficients in the constraint matrix are (non-negative) integers not larger than $\frac{2}{\varepsilon^2}$.

We augment K' with the minimum index in K if this index does not already belong to K' , in order to satisfy the condition that for every index of K there is some index of K' that is not larger. Consider a scenario $\kappa \in K'$ (satisfying the condition that $2\text{OPT} > \varepsilon \cdot \frac{P}{\kappa}$), and the optimal makespan of scenario κ , which is at most $\frac{3\text{OPT}}{\varepsilon^2}$. Recall that in scenario κ the number of non-empty bags assigned to each machine is at most $\frac{3}{\varepsilon^3}$. Define a configuration of a machine in scenario κ to be a multiset of templates such that the multiset has at most $\frac{3}{\varepsilon^3}$

templates (counting multiple copies of templates according to their multiplicities) and the total size of the templates encoded in the multiset is at most W_κ , which is the guess of a value of the histogram W . The number of configurations is at most $((\frac{2}{\varepsilon^3})^{(2/\varepsilon^2)})^{\frac{3}{\varepsilon^3}}$, and this is also an upper bound on the number of suitable configurations (whose total allowed size of bags does not exceed W_κ). Since our mathematical program will not limit the makespan of any scenario, we use an upper bound for it by not allowing configurations whose total allowed sizes exceed the planned makespan for the scenario. We let $C^{(\kappa)}$ denote the set of configurations for scenario κ , where $c \in C^{(\kappa)}$ is a vector of $|\tau|$ components where component c_t for $t \in \tau$ is the number of copies of template t assigned to configuration c . Components are non-negative integers not larger than $\frac{3}{\varepsilon^3}$. For scenario $\kappa \in K'$, we will have a family of non-negative decision variables $x_{c,\kappa}$ (for all $c \in C^{(\kappa)}$) counting the number of machines with this configuration.

For each such scenario κ , we have a set of constraints each of which involves only the template counters (acting as a family of global decision variables) and the family of the κ -th local family of decision variables, namely the ones corresponding to this scenario. The family of constraints for the scenario $\kappa \in K'$ are as follows.

$$\sum_{c \in C^{(\kappa)}} x_{c,\kappa} = \kappa, \quad \sum_{c \in C^{(\kappa)}} c_t \cdot x_{c,\kappa} - y_t = 0, \quad \forall t \in \tau.$$

Observe that the number of constraints in such a family of constraints is upper bounded by a constant depending only on ε (which is the number of possible templates plus 1) and the coefficients in the constraint matrix are again all integers of absolute value at most a constant depending only on ε (at most $\frac{3}{\varepsilon^3}$).

All decision variables are forced to be non-negative integers and we would like to solve the feasibility integer program defined above (with all constraints and decision variables). The right hand side vector consists of integers that are at most n (using $m \leq n$). Such an integer linear program is a two-stage stochastic IP. Using the property that the number of scenarios in K' is upper bounded by a function of $\frac{1}{\varepsilon}$, we conclude that the integer linear program has a fixed dimension. Thus, we use Lenstra's algorithm to solve it instead of an algorithm for two-stage stochastic IP.

We obtain a feasible solution (x, y) if such a solution exists. Based on such a feasible solution, we assign jobs to bags using the y variables. That is, for every $t \in \tau$, we schedule y_t bags using template t . By the constraint $\sum_{t \in \tau} y_t \leq m$ there are at most m bags, and the other bags will be empty. Next, for every bag and every size p of jobs in the rounded instance, if the template assigned to the bag has α jobs of this size, we will assign α jobs of this size to this bag. Doing this for all sizes and all bags is possible by the constraints $\sum_{t \in \tau} t_\ell \cdot y_t = n_\ell, \forall \ell$, and these constraints ensure that all jobs are assigned to bags. Note that the modification for jobs consisted of merging small jobs. When such a merged job is assigned, this means that a subset of jobs is assigned. Reverting jobs to their original sizes does not increase any of the costs, since no rounding steps decreased any sizes. Next consider the assignment of bags to machines in each scenario. Consider a scenario $\kappa' \in K$, and let κ be the largest index in K' such that $\kappa \leq \kappa'$. Assign $x_{c,\kappa}$ machines to configuration c (for all $c \in C^{(\kappa)}$). It is possible by the constraint $\sum_{c \in C^{(\kappa)}} x_{c,\kappa} = \kappa \leq \kappa'$. If a configuration c assigned to machine i is supposed to pack c_t copies of template t , we pick a subset of c_t bags whose assigned template is t and assign these bags to machine i . We do this for all templates and all machines. In this way we assign all bags by the constraints $\sum_{c \in C^{(\kappa)}} c_t \cdot x_{c,\kappa} - y_t = 0, \forall t \in \tau$. If $\kappa' > \kappa$, at least one machine will not receive any configuration and therefore it will not receive any bags or jobs, and we refer to such a machine as empty. Since the configurations we used in scenario κ have a total size of jobs of at most W_κ , we conclude the following.

► **Corollary 8.** *For every value of the guessed information for which the integer program has a feasible solution, there is a linear time algorithm that transform the feasible solution to the integer program into a solution to the rounded instance of PR-MAKESPAN of cost at most $\sum_{\kappa} q_{\kappa} \cdot W_{\kappa}$.*

Our scheme is established by noting that an optimal solution satisfying the assumptions of the guessed information provides us a multiset of templates all of which are considered in τ and a multiset of configurations (and all of them have total size of templates not larger than W) for which the corresponding counters satisfy the constraints of the integer program. Thus, we conclude our first main result.

► **Theorem 9.** *Problem PR-MAKESPAN admits an EPTAS.*

3 An EPTAS for the Santa Claus problem

In this section we apply additional ideas to obtain an EPTAS for the second problem. We present the details of the scheme together with its analysis. In what follows, and similarly to the scheme to PR-MAKESPAN, we will present steps, and in each of those steps the resulting approximation ratio of the scheme increases by at most a multiplicative factor of $1 + \Theta(\epsilon)$.

Preprocessing steps. We consider an optimal solution OPT, and analyze the information that one can guess in order to be able to approximate it. We assume without loss of generality that $\text{OPT}_k \leq \text{OPT}_{k'}$ for all $k > k'$, since a solution for scenario k can be used for scenario k' (by assigning the bags of $k - k'$ machines in an arbitrary way). Recall that we can assume that for every value of k in the support of q the instance has at least k non-zero sized jobs, since we assume $n > m$. We will use the next lemma for our proof.

► **Lemma 10.** *For any scenario k (such that $1 \leq k \leq m$) and an assignment of jobs to bags according to the solution OPT, there exists a job j^k for which it holds that $p_{j^k} \leq \text{OPT}_k \leq n \cdot p_{j^k}$.*

We would like to split the sequence of scenarios into four parts (where some of the parts may be empty). The suffix (with the largest numbers of machines) will contain scenarios for which the assignment of bags is unimportant since the gain from them in the objective function value OPT is small either because the probability is zero or because the number of machines is large. This suffix may be empty. There will also be a prefix (which could be empty) of machines for which the specific assignment to bags is unimportant because the number of machines is small and any reasonable assignment into bags allows a good schedule. For this prefix we will use different arguments from the ones we used for PR-MAKESPAN. For the remaining scenarios, the prefix will consist of scenarios for which the gain is also small, and a suffix of the most important scenarios.

The first step is to guess the maximum scenario k_{\max} for which $\text{OPT}_{k_{\max}} \geq \epsilon \cdot \text{OPT}$ holds, out of scenarios with strictly positive probabilities, that is, such that $q_{k_{\max}} > 0$ holds. This index is well-defined since there exists an index k for which $q_k > 0$ and $\text{OPT}_k \geq \text{OPT}$. There are at most m possible values for this guess. While OPT still denotes an optimal solution, we do not guess or use its value as a part of the algorithm. Let LB be equal to $\text{OPT}_{k_{\max}}$ rounded down to the next integer power of $1 + \epsilon$. For a fixed job $j^{k_{\max}}$ (see Lemma 10), the number of possible values for LB is $O(\frac{n}{\epsilon})$. Since the index $j^{k_{\max}}$ is also not known, the number of possible values for LB is $O(\frac{n^2}{\epsilon})$.

The proof of the next lemma is obtained by selecting a set of consecutive scenarios minimizing the total weighted profit out of $\frac{1}{\epsilon}$ disjoint sequences of scenarios of similar forms. The proof of the lemma requires the knowledge not only of OPT but of all values of the form

OPT_i . However, we use the lemma to obtain the information that given the correct value LB (this is a rounded value, so we will be able to guess it), there is a pair of values k, k' and a value ρ that specify the only properties of OPT that we use for our algorithm.

► **Lemma 11.** *There is a value of ρ which is an integer power of $\frac{1}{\varepsilon}$ that satisfies $\frac{1}{\varepsilon^2} \leq \rho \leq (\frac{1}{\varepsilon})^{1/\varepsilon+1}$ and there exist two indexes k, k' such that $0 \leq k' < k \leq k_{\max}$, where every non-zero index has to be a scenario in the support of q , such that the following conditions hold. $\text{OPT}_k \leq \rho \cdot LB$, if $k' \geq 1$, then $\text{OPT}_{k'} \geq \frac{\rho}{\varepsilon} \cdot LB, \sum_{\kappa=k'+1}^{k-1} q_{\kappa} \cdot \text{OPT}_{\kappa} \leq \varepsilon \cdot \text{OPT}$.*

The next guessing step. In this step we guess several additional values. As mentioned above, we guess the value of LB (which is a power of $1 + \varepsilon$ and it is equal to $\text{OPT}_{k_{\max}}$ within a multiplicative factor of $1 + \varepsilon$ since $\text{OPT}_{k_{\max}} \in [LB, LB \cdot (1 + \varepsilon))$), the value of ρ (by guessing ρ' from the proof of Lemma 11, that is, we guess the power of $\frac{1}{\varepsilon}$), and two indexes $k' < k \leq k_{\max}$. That is, we would like to enumerate a set of polynomial number of candidate values of four components vectors that contains at least one vector with first component value that is LB , with a second component whose value is ρ , and the two indexes $k' < k$ in the third and fourth components of that vector. The next lemma shows that it is possible to enumerate such a set of candidate values. Our algorithm performs this enumeration.

► **Lemma 12.** *There is a set consisting of $O((\frac{m-n}{\varepsilon})^2)$ vectors such that this set of vectors contains at least one vector with the required properties. Thus, the number of guesses including the guess of k_{\max} is at most $O((\frac{n}{\varepsilon})^2 \cdot m^3)$.*

In what follows, we let LB be the first component value of the guessed information, ρ be the second component value of the guessed information, and k, k' be the two guessed scenarios (where it is possible that $k' = 0$ is not an actual scenario). We will show that if there is a feasible solution to PR-SANTACLAUS for which the guessed information describes the solution and its expected value of the objective is OPT , then we will construct a feasible solution with expected value of the objective being at least $(1 - \Theta(\varepsilon)) \cdot \text{OPT}$. This means that the problem admits an EPTAS as desired.

We let $UB = LB \cdot \rho$. Furthermore, for every scenario κ with $k' < \kappa < k$, we set $q_{\kappa} = 0$. From now on we drop the assumption that the sum of all q values is 1 and instead of that we use the assumption that these are non-negative numbers with sum at most 1. This modification of the vector (q) decreases the expected value of the Santa Claus value of the optimal solution by at most $\varepsilon \cdot \text{OPT}$ (and it does not increase the objective function value of any feasible solution to our problem). The justification for this is as follows. From Lemma 11 it follows that there is a quadruple of integers $k, k', \rho, \log_{1+\varepsilon} LB$ (where each integer belongs to the set that we test for this integer) for which there is a solution of profit at least $\frac{\text{OPT}}{1+\varepsilon} - \varepsilon \cdot \text{OPT} \geq (1 - \varepsilon)^3 \cdot \text{OPT}$ with the first two properties stated in the lemma, and for every scenario κ such that $k' < \kappa < k$ the profit is at least zero.

Partitioning the input into two independent problems. Next, we use the above guessing step in order to partition the input into two independent inputs. First, a job $j \in \mathcal{J}$ is called huge if its size is strictly larger than UB , that is, if $p_j > UB$ (and otherwise it is non-huge).

We pack every huge job into its own bag and we let h denote the number of huge jobs (where we will show that $h \leq m - 1$ holds). Every huge job can cover one machine in every scenario $\kappa \geq k$ regardless of its exact size (because for all these scenarios we consider solutions for which OPT_{κ} is not larger than $\rho \cdot LB = UB$). On the other hand, the non-huge jobs (i.e., jobs of sizes at most UB) will be packed into bags of size at most $3 \cdot UB$. The packing of the non-huge jobs into bags will be optimized according to the scenarios of indexes at least k

(and at most k_{\max}), and we will ignore the scenarios of indexes smaller than k when we pack the non-huge jobs into bags. The resulting bags of the non-huge jobs together with the set of the huge jobs (which are bags consisting of a single job) will be packed into $\kappa \leq k'$ machines (in the corresponding scenario κ) based on existing EPTAS for the Santa Claus problem on identical machines (seeing bags as jobs). We will show that if indeed we use bags of sizes at most $3 \cdot UB$ when we pack the non-huge jobs into bags, then the scenarios of indexes at most k' can be ignored. We show that this holds for any collection of bags of this form, that is, where every huge job has its own bag and other bags have total sizes of jobs not exceeding $3 \cdot UB$. Thus, even though the bags are defined based on scenarios where the number of machines is at least k , still the scenarios with at most k' machines have good solutions. We will also show that it is possible to restrict ourselves to these types of collections of bags.

► **Lemma 13.** *If all guesses are correct, any partition into bags has at least one bag with a total size of jobs no larger than UB . In particular, there are at most $m - 1$ huge jobs.*

► **Lemma 14.** *An EPTAS for κ machines where $\kappa \leq k'$ which is applied on bags (instead of jobs) such that every huge job has its own bag and any additional bag has total size of jobs not exceeding $3 \cdot UB$ finds a solution of profit at least $\frac{OPT_\kappa}{(1-3\varepsilon)(1-\varepsilon)}$.*

Proof. Consider an optimal solution for κ machines and the original jobs. We show that this schedule can be modified into a schedule of the bags, such that the profit of the schedule is smaller by a factor not exceeding $1 - 3\varepsilon$. Thus, an optimal schedule of the bags is not worse, and by using an EPTAS the profit may decrease by another factor of $1 - \varepsilon$. The adaptation of the schedule is as follows. The huge jobs are assigned as before, since each of them has its own bag. All non-huge jobs are removed, and each machine receives bags until it is not possible to add another bag without exceeding the previous load or no unassigned bags remain. Given the property that the total size of bags is equal to the total size of jobs, it is either the case that the loads are equal to previous loads (in which case the value is unchanged) or there is at least one unassigned bag. In the latter case, no machine load decreased by more than an additive term of $3 \cdot UB$, and therefore the value is at least the previous one minus $3 \cdot UB$. To complete the assignment, all remaining bags are assigned arbitrarily. Since $OPT_\kappa \geq \frac{\rho \cdot LB}{\varepsilon} = \frac{UB}{\varepsilon}$ and the resulting value is at least $OPT_\kappa - 3 \cdot UB$, we find by $3 \cdot UB \leq 3\varepsilon \cdot OPT_\kappa$ that $OPT_\kappa - 3 \cdot UB \geq (1 - 3\varepsilon) \cdot OPT_\kappa$. ◀

► **Lemma 15.** *Consider the instance of our problem when we let $q_\kappa = 0$ for all $\kappa < k$ and for $\kappa > k_{\max}$. There exists a partition into bags where a profit at least OPT_κ can be obtained for any $\kappa \in [k, k_{\max}]$, the set of bags satisfies that every huge job is packed into its own bag, and each other bag consists of non-huge jobs of total size at most $2 \cdot UB$.*

Proof. The number of partitions into bags is finite for fixed m, n (it does not exceed m^n). Consider the set of partitions for which a solution of profit at least OPT_κ can be obtained for any $\kappa \in [k, k_{\max}]$. There is at least one such partition for the correct guess. For every partition it is possible to define a vector of m components, such that total sizes of bags appear in a non-increasing order. Consider the partition among the considered partitions for which the number of huge jobs that have their own bags is maximum, and out such partitions, one where the vector is lexicographically minimal. We claim that this partition satisfies the requirements.

Assume by contradiction that the number of huge jobs that do not have their own bags is not h . Consider a bag with a huge job that contains at least one additional job. This will be named the first bag. Consider a bag whose total size is at most UB , which must exist due to Lemma 13. This last bag does not have a huge job since the size of a huge job is above

UB , and we call it the second bag. Move all contents of the first bag into the second bag excluding one huge job. For any $\kappa \in [k, k_{\max}]$, since $\text{OPT}_\kappa \leq UB$, the assignment of bags to machines does not reduce the objective function value below OPT_κ . This holds because there is at most one machine whose total size was reduced (for every $\kappa \in [k, k_{\max}]$), but if such a machine exists, it still has a huge job whose size is above UB . Thus, the new partition is also one of the considered partitions. The new partition has a larger number of huge jobs assigned into their own bags, because the second bag was not such a bag and the first bag became such a bag. This contradicts the choice of assignment to bags. Thus, the partition into bags consists of h bags with huge jobs and $m - h \geq 1$ bags with non-huge jobs.

Next, consider only the components of the vector which do not correspond to bags of huge jobs. This vector is also minimal lexicographically out of vectors for partitions of the non-huge jobs into $m - h$ bags. Assume by contradiction that the first component is above $2 \cdot UB$. Consider the bag of the first component (called the first bag now) and a bag with a total size at most UB (called the second bag now). Move one job from the first bag to the second bag. The second bag now has a total size of at most $2 \cdot UB$ (since a non-huge job was moved). The first bag now has a smaller total size, but still larger than UB . The sorted vector is now smaller lexicographically, and it is still possible to obtain a solution of profit at least OPT_κ for any $\kappa \in [k, k_{\max}]$, similarly to the proof given here for huge jobs, which is a contradiction. \blacktriangleleft

In summary, we can focus on the scenarios interval $[k, k_{\max}]$, assume that huge jobs have their own bags, and remaining bags have total sizes not exceeding $2 \cdot UB$.

Modifying the input of scenarios with indexes at least k and at most k_{\max} . Motivated by the last partitioning of the original input into four parts, and the fact that only scenarios with indexes at least k and at most k_{\max} need to be considered, we apply the following transformation. First, for every $\kappa < k$ we let $q_\kappa = 0$, in the sense we can augment every solution to the remaining instance (with only a subset of scenarios) into an EPTAS for the original instance before this change to q . Furthermore, for every $\kappa > k_{\max}$ we let $q_\kappa = 0$ in the sense we can ignore the profit of such scenarios. Then, every huge job is packed into a separate bag. Such a bag suffices to cover one machine in every remaining scenario. Therefore, our second step in the transformation is the following one. We delete the huge jobs from \mathcal{J} , we decrease the index of each remaining scenario by h (in particular the new indexes in the support of q will be in the interval $[k - h, k_{\max} - h]$), and we enforce the condition that every bag size is at most $2 \cdot UB$.

As one can see, the transformations here are more complicated compared to those used in the previous section, and they have to be carefully designed and analyzed. However, now we are ready to apply methods that resemble the previous section. Using the fact that for every remaining scenario we have that OPT_κ is between LB and UB , and the fact that $\frac{UB}{LB} = \rho \leq (\frac{1}{\varepsilon})^{1/\varepsilon+1}$ we are able to apply the methods we have developed for the makespan minimization problem to obtain an EPTAS for PR-SANTACLUS, as we do next.

Rounding bag sizes. We next provide a method to gain structure on the set of feasible solutions that we need to consider for finding a near optimal solution. Given a feasible solution, the size of bag i denoted as $P(i)$ is the total size of jobs assigned to this bag, that is, $P(i) = \sum_{j: \sigma_1(j)=i} P_j$.

► **Lemma 16.** *There exists a solution of value at least $(1 - 3\varepsilon) \cdot \text{OPT}$ in which the size of every non-empty bag is in the interval $[\varepsilon \cdot LB, 2.5 \cdot UB]$.*

In what follows, we will decrease the size of a bag to be the next value of the form $(\varepsilon + r\varepsilon^2) \cdot LB$ for an integer $r \geq 0$ (except for empty bags for which the allowed size remains zero). Thus, we will not use precise sizes for bags but lower bounds on sizes, and we call them “allowed sizes” in what follows. For bags of allowed size zero the meaning remains that such a bag is empty. We let $P'(i)$ be this decreased (allowed) size of bag i , that is, $P'(i) = \max_{r: (\varepsilon + r\varepsilon^2) \cdot LB \leq P(i)} (\varepsilon + r\varepsilon^2) \cdot LB$. The allowed size is not smaller than $\varepsilon \cdot LB$ and it is smaller than the size by an additive term of at most $\varepsilon^2 \cdot LB$. Thus, for every subset of bags, the total allowed size of the bags in the set is at least $\frac{1}{1+\varepsilon}$ times the total size of the bags in the subset, we conclude that this rounding of the bag sizes will decrease the value of any solution by a multiplicative factor of at most $1 + \varepsilon$ (and therefore the expected value also decreases by at most this factor), and it will not increase the value of a solution for any scenario. Thus, in what follows, we will consider only bag sizes that belong to the set $B = \{(\varepsilon + r\varepsilon^2) \cdot LB : r \in \mathbb{Z}, r \geq 0, (\varepsilon + r\varepsilon^2) \cdot LB \leq 2.5 \cdot UB\} \cup \{0\}$. We use this set by Lemma 16. We conclude that the following holds.

► **Corollary 17.** *If the guessed information vector is satisfied by an optimal solution, then there is a solution of expected value of the Santa Claus value of at least $\frac{1-3\varepsilon}{1+\varepsilon} \cdot OPT$ that uses only bags with allowed sizes in B .*

Note that the allowed size of a bag may be slightly smaller than the actual total size of jobs assigned to the bag. Later, the allowed size acts as a lower bound (without an upper bound), and we sometimes take the allowed size into account in the calculation of machine completion times.

Rounding job sizes. We apply a similar rounding method for job sizes. Recall that by our transformation, every job j has size at most UB (since huge jobs were removed from the input). Next, we apply the following modification to the jobs of sizes at most $\varepsilon^2 \cdot LB$. While there is a pair of jobs of sizes at most $\varepsilon^2 \cdot LB$, we unite such a pair of jobs. If there is an additional job of size at most $\varepsilon^2 \cdot LB$, we delete it from the instance, and in the resulting solution (after applying the algorithm below on the resulting instance) we add the deleted job to an arbitrary bag. This deletion of the deleted job decreases the Santa Claus value of every scenario by at most $\varepsilon^2 \cdot LB$, so the resulting expected value of the Santa Claus value will be decreased by at most $\varepsilon^2 \cdot LB$. Adding the job back does not decrease the value. We consider the instance without this possibly deleted job, and we prove the following.

► **Lemma 18.** *The optimal expected value of the Santa Claus value of the instance resulting from the above modification of the job sizes among all solutions with allowed bag sizes in the following modified set $B' = \{(\varepsilon + r\varepsilon^2) \cdot LB : r \in \mathbb{Z}, r \geq -2, (\varepsilon + r\varepsilon^2) \cdot LB \leq 3 \cdot UB\} \cup \{0\}$ is at least $(1 - 2\varepsilon) \cdot \frac{1-3\varepsilon}{1+\varepsilon} \cdot OPT$.*

Next, we round down the size of every job j to be the next value that is of the form $(1 + \varepsilon)^r$ for an integer r . The size of every job cannot increase and it may decrease by a multiplicative factor of at most $1 + \varepsilon$. Job sizes are still larger than $\varepsilon^3 \cdot LB$ and not larger than $UB \leq (\frac{1}{\varepsilon})^{1/\varepsilon+1} \cdot LB$. Thus, the number of different job sizes is $O(\log_{1+\varepsilon}(\frac{1}{\varepsilon})^{1/\varepsilon+4}) \leq \frac{2}{\varepsilon^3} - 1$. We decrease the allowed size of each bag by another multiplicative factor of $1 + \varepsilon$. Bags sizes are rounded down again to the next value of the form $\varepsilon + r\varepsilon^2$, and since the smallest allowed size was $(\varepsilon - 2\varepsilon^2) \cdot LB$ and $\frac{\varepsilon - 2\varepsilon^2}{1+\varepsilon} \geq \varepsilon - 3\varepsilon^2$, the allowed bag sizes become $B'' = \{(\varepsilon + r\varepsilon^2) \cdot LB : r \in \mathbb{Z}, r \geq -3, (\varepsilon + r\varepsilon^2) \cdot LB \leq 3 \cdot UB\} \cup \{0\}$, and the expected value of the Santa Claus value of a feasible solution decreases by a multiplicative factor of at most $\frac{1-2\varepsilon}{1-3\varepsilon}$. By our guessing step and our transformation, there is a feasible solution with expected value of the Santa Claus value of at least $(1 - \varepsilon)(1 - 3\varepsilon)^2 \cdot OPT$.

A bag is called *tight* if the set of jobs of this bag cannot use a bag of a larger allowed size. Note that any solution where some bags are not tight can be converted into one where all bags are tight without decreasing the expected value of the objective.

► **Lemma 19.** *For any tight bag it holds that the allowed size of the bag is at least ϵ^2 times its actual size (the total size of jobs assigned to the bag, such that their rounded sizes are considered).*

The final steps of the EPTAS for Pr-SantaClaus. Our next step is to guess an approximated histogram of the optimal Santa Claus value in all scenarios. This step and the next step of formulating a template-configuration integer program of fixed dimension are similar to the ones we have established for PR-MAKESPAN. Using these additional steps we manage to prove our second main result.

► **Theorem 20.** *Problem PR-SANTACLUS admits an EPTAS.*

Abstract

In the Correlation Clustering problem we are given n nodes, and a preference for each pair of nodes indicating whether we prefer the two endpoints to be in the same cluster or not. The output is a clustering inducing the minimum number of violated preferences. In certain cases, however, the preference between some pairs may be too important to be violated. The constrained version of this problem specifies pairs of nodes that *must* be in the same cluster as well as pairs that *must not* be in the same cluster (hard constraints). The output clustering has to satisfy all hard constraints while minimizing the number of violated preferences.

Constrained Correlation Clustering is APX-Hard and has been approximated within a factor 3 by van Zuylen *et al.* [SODA '07]. Their algorithm is based on rounding an LP with $\Theta(n^3)$ constraints, resulting in an $\Omega(n^{3\omega})$ running time. In this work, using a more combinatorial approach, we show how to approximate this problem significantly faster at the cost of a slightly weaker approximation factor. In particular, our algorithm runs in $\tilde{O}(n^3)$ time (notice that the input size is $\Theta(n^2)$) and approximates Constrained Correlation Clustering within a factor 16.

To achieve our result we need properties guaranteed by a particular influential algorithm for (unconstrained) Correlation Clustering, the CC-PIVOT algorithm. This algorithm chooses a *pivot* node u , creates a cluster containing u and all its preferred nodes, and recursively solves the rest of the problem. It is known that selecting pivots at random gives a 3-approximation. As a byproduct of our work, we provide a derandomization of the CC-PIVOT algorithm that still achieves the 3-approximation; furthermore, we show that there exist instances where no ordering of the pivots can give a $(3 - \varepsilon)$ -approximation, for any constant ε .

Finally, we introduce a node-weighted version of Correlation Clustering, which can be approximated within factor 3 using our insights on Constrained Correlation Clustering. As the general weighted version of Correlation Clustering would require a major breakthrough to approximate within a factor $o(\log n)$, Node-Weighted Correlation Clustering may be a practical alternative.

1 Introduction

Clustering is a fundamental task related to unsupervised learning, with many applications in machine learning and data mining. The goal of clustering is to partition a set of nodes into disjoint clusters, such that (ideally) all nodes within a cluster are similar, and nodes in different clusters are dissimilar. As no single definition best captures this abstract goal, a lot of different clustering objectives have been suggested.

Correlation Clustering is one of the most well studied such formulations for a multitude of reasons: Its definition is simple and natural, it does not need the number of clusters to be part of the input, and it has found success in many applications. Some few examples include automated labeling [1, 15], clustering ensembles [10], community detection [19, 36], disambiguation tasks [30], duplicate detection [5] and image segmentation [31, 40].

In Correlation Clustering we are given a graph $G = (V, E)$, and the output is a partition (clustering) $C = \{C_1, \dots, C_k\}$ of the vertex set V . We refer to the sets C_i of C as *clusters*. The goal is to minimize the number of edges between different clusters plus the number of non-edges inside of clusters. More formally, the goal is to minimize $|E \Delta E_C|$, the cardinality of the symmetric difference between E and E_C , where we define $E_C = \bigcup_{i=1}^k \binom{C_i}{2}$. In other words, the goal is to transform the input graph into a collection of cliques with the minimal number of edge insertions and deletions. An alternative description used by some authors is that we are given a *complete* graph where the edges are labeled either “+” (corresponding to the edges in our graph G) or “−” (corresponding to the non-edges in our graph G).

The problem is typically motivated as follows: Suppose that the input graph models the relationships between different entities which shall be grouped. An edge describes that we prefer its two endpoints to be clustered together, whereas a non-edge describes that we prefer them to be separated. In this formulation the cost of a correlation clustering is the number of violated preferences.

1.1 Previous Results

Correlation Clustering was initially introduced by Bansal, Blum, and Chawla [7], who proved that it is NP-Hard, and provided a deterministic constant-factor approximation, the constant being larger than 15,000. Subsequent improvements were based on rounding the natural LP: Charikar, Guruswami and Wirt gave a deterministic 4-approximation [17], Ailon, Charikar and Newman gave a randomized 2.5-approximation and proved that the problem is APX-Hard [3], while a deterministic 2.06-approximation was given by Chawla, Makarychev, Schramm and Yaroslavtsev [18]. The last result is near-optimal among algorithms rounding the natural LP, as its integrality gap is at least 2. In a breakthrough result by Cohen-Addad, Lee and Newman [23] a $(1.994 + \epsilon)$ -approximation using the Sherali-Adams relaxation broke the 2 barrier. It was later improved to $1.73 + \epsilon$ [22] by Cohen-Addad, Lee, Li and Newman, and even to 1.437 by Cao *et al.* [13]. There is also a combinatorial 1.847-approximation (Cohen-Addad *et al.* [24]).

Given the importance of Correlation Clustering, research does not only focus on improving its approximation factor. Another important goal is efficient running times without big sacrifices on the approximation factor. As the natural LP has $\Theta(n^3)$ constraints, using a state-of-the-art LP solver requires time $\Omega(n^{3\omega}) = \Omega(n^{7.113})$.

In order to achieve efficient running times, an algorithm thus has to avoid solving the LP using an all-purpose LP-solver, or the even more expensive Sherali-Adams relaxation; such algorithms are usually called *combinatorial* algorithms¹. Examples of such a direction can

¹ On a more informal note, combinatorial algorithms are often not only faster, but also provide deeper insights on a problem, compared to LP-based ones.

be seen in [3] where, along with their LP-based 2.5-approximation, the authors also design a combinatorial 3-approximation (the CC-PIVOT algorithm); despite its worse approximation, it enjoys the benefit of being faster. Similarly, much later than the 2.06-approximation [18], Veldt devised a faster combinatorial 6-approximation and a 4-approximation solving a less expensive LP [35].

Another important direction is the design of *deterministic* algorithms. For example, [3] posed as an open question the derandomization of CC-PIVOT. The question was (partially) answered affirmatively by [34]. Deterministic algorithms were also explicitly pursued in [35], and are a significant part of the technical contribution of [18].

Correlation Clustering has also been studied in different settings such as parameterized algorithms [28], sublinear and streaming algorithms [6, 12, 8, 9, 12, 16], massively parallel computation (MPC) algorithms [21, 14], and differentially private algorithms [11].

PIVOT. The CC-PIVOT algorithm [3] is a very influential algorithm for Correlation Clustering. It provides a 3-approximation and is arguably the simplest constant factor approximation algorithm for Correlation Clustering. It simply selects a node uniformly at random, and creates a cluster \mathcal{C} with this node and its neighbors in the (remaining) input graph. It then removes \mathcal{C} 's nodes and recurses on the remaining graph. Due to its simplicity, CC-PIVOT has inspired several other algorithms, such as algorithms for Correlation Clustering in the streaming model [6, 12, 8, 9, 12, 16] and algorithms for the more general Fitting Ultrametrics problem [2, 20].

One can define a meta-algorithm based on the above, where we do not necessarily pick the pivots uniformly at random. Throughout this paper, we use the term PIVOT algorithm to refer to an instantiation of the (Meta-)Algorithm 1². Obviously CC-PIVOT is an instantiation of PIVOT, where the pivots are selected uniformly at random.

■ **Algorithm 1** The PIVOT meta-algorithm. CC-PIVOT is an instantiation of PIVOT where pivots are selected uniformly at random.

```

procedure PIVOT( $G = (V, E)$ )
1   $C \leftarrow \emptyset$ 
2  while  $V \neq \emptyset$  do
3    Pick a pivot node  $u$ 
      /* an instantiation of PIVOT() only needs to specify how the
      pivot is selected in each iteration */
4    Add a cluster containing  $u$  and all its neighbors to  $C$ 
5    Remove  $u$ , its neighbors and all their incident edges from  $G$ 
6  return  $C$ 

```

The paper that introduced CC-PIVOT [3] posed as an open question the derandomization of the algorithm. The question was partially answered in the affirmative by [34]. Unfortunately there are two drawbacks with this algorithm. First, it requires solving the natural LP, which makes its running time equal to the pre-existing (better) 2.5-approximation. Second, this

² This is not to be confused with the more general pivoting paradigm for Correlation Clustering algorithms. In that design paradigm, the cluster we create for each pivot is not necessarily the full set of remaining nodes with which the pivot prefers to be clustered, but can be decided in any other way (e.g. randomly, based on a probability distribution related to an LP or more general hierarchies such as the Sherali-Adams hierarchy).

algorithm does not only derandomize the order in which pivots are selected, but also decides the cluster of each pivot based on an auxiliary graph (dictated by the LP) rather than based on the original graph. Therefore it is not an instantiation of PIVOT.

Weighted Correlation Clustering. In the weighted version of Correlation Clustering, we are also given a weight for each preference. The final cost is then the sum of weights of the violated preferences. An $O(\log n)$ -approximation for weighted Correlation Clustering is known by Demaine, Emanuel, Fiat and Immorlica [25]. In the same paper they show that the problem is equivalent to the Multicut problem, meaning that an $o(\log n)$ -approximation would require a major breakthrough. As efficiently approximating the general weighted version seems out of reach, research has focused on special cases for which constant-factor approximations are possible [32, 33].

Constrained Correlation Clustering. Constrained Correlation Clustering is an interesting variant of Correlation Clustering capturing the idea of critical pairs of nodes. To address these situations, Constrained Correlation Clustering introduces hard constraints in addition to the pairwise preferences. A clustering is valid if it satisfies all hard constraints, and the goal is to find a valid clustering of minimal cost. We can phrase Constrained Correlation Clustering as a weighted instance of Correlation Clustering: Simply give infinite weight to pairs associated with a hard constraint and weight 1 to all other pairs.

To the best of our knowledge, the only known solution to Constrained Correlation Clustering is given in the work of van Zuylen and Williamson who designed a deterministic 3-approximation [34]. The running time of this algorithm is $O(n^{3\omega})$, where $\omega < 2.3719$ is the matrix-multiplication exponent. Using the current best bound for ω , this is $\Omega(n^{7.113})$.

1.2 Our Contribution

Our main result is the following theorem. It improves the $\Omega(n^{7.113})$ running time of the state-of-the-art algorithm for Constrained Correlation Clustering while still providing a constant (but larger than 3) approximation factor³.

► **Theorem 1** (Constrained Correlation Clustering). *There is a deterministic algorithm for Constrained Correlation Clustering computing a 16-approximation in time $\tilde{O}(n^3)$.*

We first show how to obtain this result, but with a randomized algorithm that holds with high probability, instead of a deterministic one. In order to do so, we perform a (deterministic) preprocessing step and then use the CC-PIVOT algorithm. Of course CC-PIVOT alone, without the preprocessing step, would not output a clustering respecting the hard constraints. Its properties however (and more generally the properties of PIVOT algorithms) are crucial; we are not aware of any other algorithm that we could use instead and still satisfy all the hard constraints of Constrained Correlation Clustering after our preprocessing step.

To obtain our deterministic algorithm we derandomize the CC-PIVOT algorithm.

► **Theorem 2** (Deterministic PIVOT). *There are the following deterministic PIVOT algorithms for Correlation Clustering:*

- A combinatorial $(3 + \epsilon)$ -approximation, for any constant $\epsilon > 0$, in time $\tilde{O}(n^3)$.
- A non-combinatorial 3-approximation in time $\tilde{O}(n^5)$.

³ We write $\tilde{O}(T)$ to suppress polylogarithmic factors, i.e., $\tilde{O}(T) = T(\log T)^{O(1)}$.

We note that the final approximation of our algorithm for Constrained Correlation Clustering depends on the approximation of the applied PIVOT algorithm. If it was possible to select the order of the pivots in a way that guarantees a better approximation, this would immediately improve the approximation of our Constrained Correlation Clustering algorithm. For this reason, we study lower bounds for PIVOT; currently, we know of instances for which selecting the pivots at random doesn't give a better-than-3-approximation in expectation [3]; however, for these particular instances there *does* exist a way to choose the pivots that gives better approximations. Ideally, we want a lower bound applying for any order of the pivots (such as the lower bound for the generalized PIVOT solving the Ultrametric Violation Distance problem in [20]). We show that our algorithm is optimal, as there exist instances where no ordering of the pivots will yield a better-than-3-approximation.

► **Theorem 3 (PIVOT Lower Bound).** *There is no constant $\epsilon > 0$ for which there exists a PIVOT algorithm for Correlation Clustering with approximation factor $3 - \epsilon$.*

We also introduce the Node-Weighted Correlation Clustering problem, which is related to (but incomparable, due to their asymmetric assignment of weights) a family of problems introduced in [36]. As weighted Correlation Clustering is equivalent to Multicut, improving over the current $\Theta(\log n)$ -approximation seems out of reach. The advantage of our alternative type of weighted Correlation Clustering is that it is natural and approximable within a constant factor.

In Node-Weighted Correlation Clustering we assign weights to the nodes, rather than to pairs of nodes. Violating the preference between nodes u, v with weights ω_u and ω_v incurs cost $\omega_u \cdot \omega_v$. We provide three algorithms computing (almost-)3-approximations for Node-Weighted Correlation Clustering:

► **Theorem 4 (Node-Weighted Correlation Clustering, Deterministic).** *There are the following deterministic algorithms for Node-Weighted Correlation Clustering:*

- *A combinatorial $(3 + \epsilon)$ -approximation, for any constant $\epsilon > 0$, in time $\tilde{O}(n^3)$.*
- *A non-combinatorial 3-approximation in time $O(n^{7.116})$.*

► **Theorem 5 (Node-Weighted Correlation Clustering, Randomized).** *There is a randomized combinatorial algorithm for Node-Weighted Correlation Clustering computing an expected 3-approximation in time $O(n + m)$ with high probability $1 - 1/\text{poly}(n)$.*

1.3 Overview of Our Techniques

Constrained Correlation Clustering. We obtain a faster algorithm for Constrained Correlation Clustering by

1. modifying the input graph using a subroutine aware of the hard-constraints, and
2. applying a PIVOT algorithm on this modified graph.

In fact, no matter what PIVOT algorithm is used, the output clustering respects all hard constraints when the algorithm is applied on the modified graph.

To motivate this two-step procedure, we note that inputs exist where *no* PIVOT algorithm, if applied to the unmodified graph, would respect the hard constraints. One such example is the cycle on four vertices, with two vertex-disjoint edges made into hard constraints.

The solution of [34] is similar to ours, as it also modifies the graph before applying a Correlation Clustering algorithm. However, both their initial modification and the following Correlation Clustering algorithm require solving the standard LP, which is expensive ($\Omega(n^{7.113})$ time). In our case both steps are implemented with deterministic and combinatorial algorithms which brings the running time down to $\tilde{O}(n^3)$.

For the first step, our algorithm carefully modifies the input graph so that on one hand the optimal cost is not significantly changed, and on the other hand any PIVOT algorithm on the transformed graph returns a clustering that respects all hard constraints. For the second step, we use a deterministic combinatorial PIVOT algorithm.

Concerning the effect of modifying the graph, roughly speaking we get that the final approximation factor is $(2 + \sqrt{5}) \cdot \alpha + 3$, where α is the approximation factor of the PIVOT algorithm we use. Plugging in $\alpha = 3 + \epsilon$ from Theorem 2 we get the first combinatorial constant-factor approximation for Constrained Correlation Clustering in $\tilde{O}(n^3)$ time.

Node-Weighted Correlation Clustering. We generalize the deterministic combinatorial techniques from before to the Node-Weighted Correlation Clustering problem. In addition, we also provide a very efficient randomized algorithm for the problem. It relies on a weighted random sampling technique.

One way to view the algorithm is to reduce Node-Weighted Correlation Clustering to an instance of Constrained Correlation Clustering, with the caveat that the new instance's size depends on the weights (and can thus even be exponential). Each node u is replaced by a set of nodes of size related to u 's weight and these nodes have constraints forcing them to be in the same cluster.

We show that we can simulate a simple randomized PIVOT algorithm on that instance, where instead of sampling uniformly at random, we sample with probabilities proportional to the weights. Assuming polynomial weights, we can achieve this in linear time. To do so, we design an efficient data structure supporting such sampling and removal of elements.

It is easy to implement such a data structure using any balanced binary search tree, but the time for constructing it and applying all operations would be $O(n \log n)$. Using a non-trivial combination of the Alias Method [38, 37] and Rejection Sampling, we achieve a linear bound.

Due to space constraints the presentation of our algorithms for Node-Weighted Correlation Clustering is deferred to the full version of the paper [26].

Deterministic PIVOT algorithms. Our algorithms are based on a simple framework by van Zuylen and Williamson [34]. In this framework we assign a nonnegative “charge” to each pair of nodes. Using these charges, a PIVOT algorithm decides which pivot to choose next. The approximation factor depends on the total charge (as compared with the cost of an optimal clustering), and the minimum charge assigned to any bad triplet (an induced subgraph $K_{1,2}$).

The reason why these bad triplets play an important role is that for any bad triplet, any clustering needs to pay at least 1. To see this, let uvw be a bad triplet with uv being the only missing edge. For a clustering to pay 0, it must be the case that both uw and vw are together. However, this would imply that uv are also together although they prefer not to.

Our combinatorial $(3 + \epsilon)$ -approximation uses the multiplicative weights update method, which can be intuitively described as follows: We start with a tiny charge on all pairs. Then we repeatedly find a bad triplet uvw with currently minimal charge (more precisely: for which the sum of the charges of uv, vw, wu is minimal), and scale the involved charges by $1 + \epsilon$. One can prove that this eventually results in an almost-optimal distribution of charges, up to rescaling.

For this purpose it suffices to show that the total assigned charge is not large compared to the cost of the optimal correlation clustering. We do so by observing that our algorithm $(1 + \epsilon)$ -approximates the covering LP of Figure 1, which we refer to as the *charging LP*.

Our faster deterministic non-combinatorial algorithm solves the charging LP using an LP solver tailored to covering LPs [4, 39]. An improved solver for covering LPs would directly improve the running time of this algorithm.

■ **Figure 1** The primal and dual LP relaxations for Correlation Clustering, which we refer to as the *charging LP*. $T(G)$ is the set of all bad triplets in G .

$$\begin{aligned} \min \quad & \sum_{uv \in \binom{V}{2}} x_{uv} \\ \text{s.t.} \quad & x_{uv} + x_{vw} + x_{wu} \geq 1 \quad \forall uvw \in T(G), \\ & x_{uv} \geq 0 \quad \forall uv \in \binom{V}{2} \end{aligned}$$

$$\begin{aligned} \max \quad & \sum_{uvw \in T(G)} y_{uvw} \\ \text{s.t.} \quad & \sum_{w:uvw \in T(G)} y_{uvw} \leq 1 \quad \forall uv \in \binom{V}{2}, \\ & y_{uvw} \geq 0 \quad \forall uvw \in T(G) \end{aligned}$$

Lower Bound. Our lower bound is obtained by taking a complete graph K_n for some even number of vertices n , and removing a perfect matching. Each vertex in the resulting graph is adjacent to all but one other vertex and so *any* PIVOT algorithm will partition the vertices into a large cluster of $n - 1$ vertices and a singleton cluster. A non PIVOT algorithm, however, is free to create just a single cluster of size n , at much lower cost. The ratio between these solutions tends to 3 with increasing n .

We note that in [3] the authors proved that CC-PIVOT's analysis is tight. That is, its expected approximation factor is not better than 3. However, their lower bound construction (a complete graph K_n minus one edge) only works for CC-PIVOT, not for PIVOT algorithms in general.

1.4 Open Problems

We finally raise some open questions.

1. Can we improve the approximation factor of Constrained Correlation Clustering from 16 to 3 while keeping the running time at $\tilde{O}(n^3)$?
2. We measure the performance of a PIVOT algorithm by comparing it to the best correlation clustering obtained by *any* algorithm. But as Theorem 3 proves, there is no PIVOT algorithm with an approximation factor better than 3. If we instead compare the output to the best correlation clustering obtained by a *PIVOT algorithm*, can we get better guarantees (perhaps even an exact algorithm in polynomial time)?
3. In the Node-Weighted Correlation Clustering problem, we studied the natural objective of minimizing the total cost $\omega_v \cdot \omega_u$ of all violated preferences uv . Are there specific applications of this problem? Can we achieve similar for other cost functions such as $\omega_v + \omega_u$?

2 Preliminaries

We denote the set $\{1, \dots, n\}$ by $[n]$. We denote all subsets of size k of a set A by $\binom{A}{k}$. The symmetric difference between two sets A, B is denoted by $A \triangle B$. We write $\text{poly}(n) = n^{O(1)}$ and $\tilde{O}(n) = n(\log n)^{O(1)}$.

In this paper all graphs $G = (V, E)$ are undirected and unweighted. We typically set $n = |V|$ and $m = |E|$. For two disjoint subsets $U_1, U_2 \subseteq V$, we denote the set of edges with one endpoint in U_1 and the other in U_2 by $E(U_1, U_2)$. The subgraph of G induced by vertex-set U_1 is denoted by $G[U_1]$. For vertices u, v, w we often abbreviate the (unordered) set $\{u, v\}$ by uv and similarly write uvw for $\{u, v, w\}$. We say that uvw is a *bad triplet* in G if the induced subgraph $G[uvw]$ contains exactly two edges (i.e., is isomorphic to $K_{1,2}$). Let $T(G)$ denote the set of bad triplets in G . We say that the edge set E_C of a clustering $C = \{C_1, \dots, C_k\}$ of V is the set of pairs with both endpoints in the same set in C . More formally, $E_C = \bigcup_{i=1}^k \binom{C_i}{2}$.

We now formally define the problems of interest.

► **Definition 6** (Correlation Clustering). *Given a graph $G = (V, E)$, output a clustering $C = \{C_1, \dots, C_k\}$ of V with edge set E_C minimizing $|E \triangle E_C|$.*

An algorithm for Correlation Clustering is said to be a PIVOT algorithm if it is an instantiation of Algorithm 1 (Page 3). That is, an algorithm which, based on some criterion, picks an unclustered node u (the *pivot*), creates a cluster containing u and its unclustered neighbors in (V, E) , and repeats the process until all nodes are clustered. In particular, the algorithm may not modify the graph in other ways before choosing a pivot.

The constrained version of Correlation Clustering is defined as follows.

► **Definition 7** (Constrained Correlation Clustering). *Given a graph $G = (V, E)$, a set of friendly pairs $F \subseteq \binom{V}{2}$ and a set of hostile pairs $H \subseteq \binom{V}{2}$, compute a clustering $C = \{C_1, \dots, C_k\}$ of V with edge set E_C such that no pair $uv \in F$ has u, v in different clusters and no pair $uv \in H$ has u, v in the same cluster. The clustering C shall minimize $|E \triangle E_C|$.*

We also introduce Node-Weighted Correlation Clustering, a new related problem that may be of independent interest.

► **Definition 8** (Node-Weighted Correlation Clustering). *Given a graph $G = (V, E)$ and positive weights $\{\omega_u\}_{u \in V}$ on the nodes, compute a clustering $C = \{C_1, \dots, C_k\}$ of V with edge set E_C minimizing*

$$\sum_{uv \in E \triangle E_C} \omega_u \cdot \omega_v.$$

For simplicity, we assume that the weights are bounded by $\text{poly}(n)$, and thereby fit into a constant number of word RAM cells of size $w = \Theta(\log n)$. We remark that our randomized algorithm would be a polynomial (but not linear) time one if we allowed the weights to be of exponential size.

The Node-Weighted Correlation Clustering problem clearly generalizes Correlation Clustering since we pay $w(u) \cdot w(v)$ (instead of 1) for each pair uv violating a preference.

3 Combinatorial Algorithms for Constrained Correlation Clustering

Let us fix the following notation: A connected component in (V, F) is a *supernode*. The set of supernodes partitions V and is denoted by SN . Given a node u , we let $s(u)$ be the unique supernode containing u . Two supernodes U, W are *hostile* if there exists a hostile pair uw with $u \in U, w \in W$. Two supernodes U, W are *connected* if $|E(U, W)| \geq 1$. Two supernodes U, W are β -*connected* if $|E(U, W)| \geq \beta \cdot |U| \cdot |W|$.

The first step of our combinatorial approach is to transform the graph G into a more manageable form G' , see procedure TRANSFORM of Algorithm 2. The high-level idea is that in G' :

1. If uv is a friendly pair, then u and v are connected and have the same neighborhood.
2. If uv is a hostile pair, then u and v are not connected and have no common neighbor.
3. An $O(1)$ -approximation of the G' instance is also an $O(1)$ -approximation of the G instance.

As was already noticed in [34], Properties 1 and 2 imply that a PIVOT algorithm on G' gives a clustering satisfying the hard constraints. Along with Property 3 and our deterministic combinatorial PIVOT algorithm for Correlation Clustering in Theorem 2, we prove Theorem 1. Properties 1 and 2 (related to correctness) and the running time ($\tilde{O}(n^3)$) of our algorithm are relatively straightforward to prove. Due to space constraints, their proofs can be found in the full version of the paper [26]. In this section we instead focus on the most technically challenging part, the approximation guarantee.

Our algorithm works as follows (see also Figure 2): If some supernode is hostile to itself, then it outputs that no clustering satisfies the hard constraints. Else, starting from the edge set E , it adds all edges within each supernode. Then it drops all edges between hostile supernodes. Subsequently, it repeatedly detects hostile supernodes that are connected with the same supernode, and drops one edge from each such connection. Finally, for each β -connected pair of supernodes, it connects all their nodes if $\beta > \frac{3-\sqrt{5}}{2}$, and disconnects them otherwise⁴.

From a high-level view, the first two modifications are directly related to the hard constraints: If u_1, u_2 are friendly and u_2, u_3 are friendly, then any valid clustering has u_1, u_3 in the same cluster, even if a preference discourages it. Similarly, if u_1, u_2 are friendly, u_3, u_4 are friendly, but u_1, u_3 are hostile, then any valid clustering has u_2, u_4 in different clusters, even if a preference discourages it. Our first two modifications simply make the preferences consistent with the hard constraints.

The third modification guarantees that hostile supernodes share no common neighbor. A PIVOT algorithm will thus never put their nodes in the same cluster, as the hostility constraints require. Concerning the cost, notice that if hostile supernodes U_1, U_2 are connected with supernode U_3 , then no valid clustering can put all three of them in the same cluster. Therefore we always need to pay either for the connections between U_1 and U_3 , or for the connections between U_2 and U_3 .

Finally, after the rounding step, for each pair of supernodes U_1, U_2 , the edge set $E(U_1, U_2)$ is either empty or the full set of size $|U_1| \cdot |U_2|$. This ensures that a PIVOT algorithm always puts all nodes of a supernode in the same cluster, thus also obeying the friendliness constraints. Concerning the cost of the rounded instance, a case analysis shows that it is always within a constant factor of the cost of the instance before rounding.

⁴ The constant $\frac{3-\sqrt{5}}{2}$ optimizes the approximation factor. The natural choice of 0.5 would still give a constant approximation factor, albeit slightly worse.

(a) The original graph. The set of friendly pairs is $F = \{\{1, 2\}, \{2, 3\}, \{4, 5\}, \{6, 7\}\}$, and the only hostile pair in H is $\{2, 5\}$.

(b) Line 3 introduces edge $\{1, 3\}$, and Line 4 disconnects the supernodes containing 2 and 5.

(c) Line 6 removes the pair of edges $\{1, 7\}$ and $\{4, 6\}$ because 1, 4 are in hostile supernodes while 6, 7 are in the same supernode.

(d) Line 9 introduces all edges connecting supernodes $\{4, 5\}$ and $\{6, 7\}$ because there were enough edges between them already.

■ **Figure 2** Illustrates an application of $\text{TRANSFORM}(G, F, H)$ (Algorithm 2). In the transformed graph, for any two supernodes U_1, U_2 , either all pairs with an endpoint in U_1 and an endpoint in U_2 share an edge, or none of them do. Furthermore, all pairs within a supernode are connected and no hostile supernodes are connected.

Formally, let E' be the edge set of the transformed graph G' , let E_3 be the edge set at Line 8 of Algorithm 2 (exactly before the rounding step), OPT be the edge set of an optimal clustering for E satisfying the hard constraints described by F and H , OPT' be the edge set of an optimal clustering for the preferences defined by E' , and E_C be the edge set of the clustering returned by our algorithm. Finally, let α be the approximation factor of the PIVOT algorithm used.

► **Lemma 9.** *Given an instance (V, E, F, H) of Constrained Correlation Clustering, if two nodes u_1, u_2 are in the same supernode, then they must be in the same cluster.*

Proof. The proof follows by “in the same cluster” being a transitive property.

More formally, u_1, u_2 are in the same connected component in (V, F) , as $s(u_1) = s(u_2)$. Thus, there exists a path from u_1 to u_2 . We claim that all nodes in a path must be in the same cluster. This is trivial if the path is of length 0 ($u_1 = u_2$) or of length 1 ($u_1 u_2 \in F$). Else, the path is $u_1, w_1, \dots, w_k, u_2$ for some $k \geq 1$. We inductively have that all of w_1, \dots, w_k, u_2 must be in the same cluster, and u_1 must be in the same cluster with w_1 because $u_1 w_1 \in F$. Therefore, all nodes in the path must be in the same cluster with w_1 . ◀

We now show that it is enough to bound the symmetric difference between E and E' .

■ **Algorithm 2** The procedure `CONSTRAINEDCLUSTER` is given a graph $G = (V, E)$ describing the preferences, a set of friendly pairs F and a set of hostile pairs H . It creates a new graph G' using the procedure `TRANSFORM` and uses any `PIVOT` algorithm on G' to return a clustering.

```

procedure TRANSFORM( $G = (V, E), F, H$ )
1  Compute the connected components of  $(V, F)$ 
   // Impossible iff some pair must both be and not be in the same
   // cluster.
2  if  $\exists U \in SN$  hostile to itself then return  $G' = (\emptyset, \emptyset)$ 
   // Connect nodes in the same supernode.
3   $E_1 \leftarrow E \cup \{uv \in \binom{V}{2} \mid s(u) = s(v)\}$ 
   // Disconnect pairs in hostile supernodes.
4   $E_2 \leftarrow E_1 \setminus \{uv \in \binom{V}{2} \mid s(u) \text{ and } s(v) \text{ are hostile}\}$ 
   // While hostile supernodes  $U_1, U_2$  are both connected with super-
   // node  $U_3$ , drop an edge between  $U_1, U_3$  and an edge between  $U_2, U_3$ 
5   $E_3 \leftarrow E_2$ 
6  while  $\exists U_1, U_2, U_3 \in \binom{SN}{3}$  such that  $U_1, U_2$  are hostile and
    $\exists u_1 \in U_1, u_2 \in U_2, u_3 \in U_3, u'_3 \in U_3$  such that  $u_1 u_3 \in E_3, u_2 u'_3 \in E_3$  do
7  |  $E_3 \leftarrow E_3 \setminus \{u_1 u_3, u_2 u'_3\}$ 
   // Round connections between pairs of supernodes
8   $E_4 \leftarrow E_3$ 
9  foreach  $\{U_1, U_2\} \in \binom{SN}{2}$  do
10 |  $E_{U_1, U_2} \leftarrow \{u_1 u_2 \mid u_1 \in U_1, u_2 \in U_2\}$ 
11 | if  $|E_{U_1, U_2} \cap E_4| > \frac{3-\sqrt{5}}{2} |U_1| \cdot |U_2|$  then  $E_4 \leftarrow E_4 \cup E_{U_1, U_2}$ 
12 | else  $E_4 \leftarrow E_4 \setminus E_{U_1, U_2}$ 
13 return  $G' = (V, E_4)$ 

procedure CONSTRAINEDCLUSTER( $G = (V, E), F, H$ )
14  $G' \leftarrow$  TRANSFORM( $G = (V, E), F, H$ )
15 if  $G' = (\emptyset, \emptyset)$  then return “Impossible”
16 return PIVOT( $G'$ )

```

► **Lemma 10.** *The cost of our clustering C is $|E \triangle E_C| \leq (\alpha + 1)|E \triangle E'| + \alpha|E \triangle \text{OPT}|$.*

Proof. The symmetric difference of sets satisfies the triangle inequality; we therefore have

$$|E \triangle E_C| \leq |E \triangle E'| + |E' \triangle E_C|.$$

C is an α -approximation for $G' = (V, E')$ and thus $|E' \triangle E_C| \leq \alpha|E' \triangle \text{OPT}'| \leq \alpha|E' \triangle \text{OPT}|$. Therefore:

$$|E \triangle E_C| \leq |E \triangle E'| + \alpha|E' \triangle \text{OPT}| \leq |E \triangle E'| + \alpha|E' \triangle E| + \alpha|E \triangle \text{OPT}|.$$

with the second inequality following by applying the triangle inequality again. ◀

In order to upper bound $|E \triangle E'|$ by the cost of the optimal clustering $|E \triangle \text{OPT}|$, we first need to lower bound the cost of the optimal clustering.

32:12 A Faster Algorithm for Constrained Correlation Clustering

► **Lemma 11.** *Let S be the set of all pairs of distinct supernodes U, W that are in the same cluster in OPT . Then $|E \triangle \text{OPT}| \geq \sum_{\{U, W\} \in S} |E(U, W) \triangle E_3(U, W)|$.*

Proof. The high-level idea is that when a node is connected to two hostile nodes, then any valid clustering needs to pay for at least one of these edges. Extending this fact to supernodes, we construct an edge set of size $\sum_{\{U, W\} \in S} |E(U, W) \triangle E_3(U, W)|$ such that the optimal clustering needs to pay for each edge in this set.

First, for any $\{U, W\} \in S$ it holds that $E(U, W) \triangle E_3(U, W) = E(U, W) \setminus E_3(U, W)$ because Line 3 (Algorithm 2) does not modify edges between pairs of distinct supernodes, and Lines 4 and 6 only remove edges.

Each edge of $E(U, W) \setminus E_3(U, W)$ is the result of applying Line 6, seeing as Line 4 only removes edges from hostile pairs of supernodes. Thus each edge $uw \in E(U, W) \setminus E_3(U, W)$ can be paired up with a unique edge $xy \in E$ which is removed together with uw . Without loss of generality it holds that $x \in U, y \in Z$ for some supernode Z different from U and W . Due to the way Line 6 chooses edges it must be the case that Z and W are hostile, hence $xy \in E \triangle \text{OPT}$.

Summing over all pairs of clustered supernodes gives the result stated in the lemma. ◀

We are now ready to bound $|E \triangle E'|$.

► **Lemma 12.** $|E \triangle E'| \leq (1 + \sqrt{5})|E \triangle \text{OPT}|$

Proof. To prove this, we first charge each pair of nodes in a way such that the total charge is at most $2|E \triangle \text{OPT}|$. Then we partition the pairs of nodes into 5 different sets, and show that the size of the intersection between $E \triangle E'$ and each of the 5 sets is at most $\frac{1+\sqrt{5}}{2}$ times the total charge given to the pairs in the given set.

The first three sets contain the pairs across non-hostile supernodes; out of them the first one is the most technically challenging, requiring a combination of Lemma 11 (related to Line 6 of Algorithm 2) and a direct analysis on $E \triangle \text{OPT}$, as neither of them would suffice on their own. The analysis of the second and third sets relate to the rounding in Line 9. The fourth set contains pairs across hostile supernodes, while the fifth set contains pairs within supernodes. Their analysis is directly based on the hard constraints.

Let us define our charging scheme: first, each pair of nodes is charged if the optimal clustering pays for it, i.e. if this pair is in $E \triangle \text{OPT}$. We further put a charge on the pairs $uw \in E \triangle E_3$ which connect supernodes that are clustered together in OPT . Notice that the number of such edges is a lower bound on $|E \triangle \text{OPT}|$ by Lemma 11. Therefore the total charge over all pairs of nodes is at most $2|E \triangle \text{OPT}|$ and no pair is charged twice.

Case 1. Consider two distinct supernodes U, W that are not hostile, which have more than $\frac{3-\sqrt{5}}{2}|U| \cdot |W|$ edges between them in E , and have at most $\frac{3-\sqrt{5}}{2}|U| \cdot |W|$ edges in E_3 . Then the rounding of Line 9 removes all edges between them. Therefore $|E(U, W) \triangle E'(U, W)| = |E(U, W)| \leq |U| \cdot |W|$. If OPT separates U and W , then the pairs are charged $|E(U, W)|$; else they are charged $|U| \cdot |W| - |E(U, W)|$ due to the part of the charging scheme related to $E \triangle \text{OPT}$. In the latter case, they are also charged $|E(U, W)| - |E_3(U, W)|$ due to the part of the charging scheme related to Lemma 11. Therefore they are charged at least

$$\begin{aligned} |U| \cdot |W| - |E(U, W)| + |E(U, W)| - |E_3(U, W)| &= |U| \cdot |W| - |E_3(U, W)| \\ &\geq |U| \cdot |W| - \frac{3-\sqrt{5}}{2}|U| \cdot |W|. \end{aligned}$$

Thus, in the worst case, these pairs contribute

$$\max \left\{ \frac{|E(U, W)|}{|E(U, W)|}, \frac{|E(U, W)|}{|U| \cdot |W| - \frac{3-\sqrt{5}}{2}|U| \cdot |W|} \right\} \leq \frac{1}{1 - \frac{3-\sqrt{5}}{2}} = \frac{1 + \sqrt{5}}{2}$$

times more in $|E \triangle E'|$ compared to their charge.

Case 2. Consider two distinct supernodes U, W that are not hostile, which have more than $\frac{3-\sqrt{5}}{2}|U| \cdot |W|$ edges between them in E , and more than $\frac{3-\sqrt{5}}{2}|U| \cdot |W|$ edges in E_3 . Then the rounding of Line 9 will include all $|U| \cdot |W|$ edges between them. Thus we have $|E(U, W) \triangle E'(U, W)| = |U| \cdot |W| - |E(U, W)| < (1 - \frac{3-\sqrt{5}}{2})|U| \cdot |W|$. If OPT separates U and W it pays for $|E(U, W)| > \frac{3-\sqrt{5}}{2}|U| \cdot |W|$ pairs. Otherwise it pays $|U| \cdot |W| - |E(U, W)|$. Thus, in the worst case, these pairs contribute $\frac{1 - \frac{3-\sqrt{5}}{2}}{\frac{3-\sqrt{5}}{2}} = \frac{1+\sqrt{5}}{2}$ times more in $|E \triangle E'|$ compared to their charge.

Case 3. If two distinct supernodes U, W are not hostile and have at most $\frac{3-\sqrt{5}}{2}|U| \cdot |W|$ edges between them in E , then they also have at most that many edges in E_3 as we only remove edges between such supernodes. There are thus no edges between them in E' , meaning that $|E(U, W) \triangle E'(U, W)| = |E(U, W)| \leq \frac{3-\sqrt{5}}{2}|U| \cdot |W|$. If OPT separates U, W it pays for $|E(U, W)|$ pairs related to the connection between U, W ; else it pays for $|U| \cdot |W| - |E(U, W)| \geq (1 - \frac{3-\sqrt{5}}{2})|U| \cdot |W| > \frac{3-\sqrt{5}}{2}|U| \cdot |W|$. Thus these pairs' contribution in $|E \triangle E'|$ is at most as much as their charge.

Case 4. Pairs uv with $s(u) \neq s(v)$ and $s(u)$ hostile with $s(v)$ are not present in E' . That is because by Line 4 no pair of hostile supernodes is connected; then Line 6 only removes edges, and Line 9 does not add any edge between $s(u)$ and $s(v)$ as they had $0 \leq \frac{3-\sqrt{5}}{2}|s(u)| \cdot |s(v)|$ edges between them. The edge uv is also not present in OPT as $s(u)$ and $s(v)$ are not in the same cluster because they are hostile. These pairs' contribution in $|E \triangle E'|$ is exactly equal to their charge.

Case 5. Pairs uv with $s(u) = s(v)$ are present in E' by Line 3 and the fact that all subsequent steps only modify edges whose endpoints are in different supernodes. The pair uv is also present in OPT, by Lemma 9. Therefore these pairs' contribution in $|E \triangle E'|$ is exactly equal to their charge.

In the worst case, the pairs of each of the five sets contribute at most $\frac{1+\sqrt{5}}{2}$ times more in $|E \triangle E'|$ compared to their charge, which proves our lemma. \blacktriangleleft

We are now ready to prove the main theorem.

Proof of Theorem 1. In Theorem 2 we established that there is a deterministic combinatorial PIVOT algorithm computing a Correlation Clustering with approximation factor $\alpha = 3 + \epsilon$ in time $\tilde{O}(n^3)$, for any constant $\epsilon > 0$. Using this algorithm in Algorithm 2 gives a valid clustering. By Lemmas 10 and 12, its approximation factor is bounded by $(\alpha + 1) \cdot (1 + \sqrt{5}) + \alpha$. This is less than 16 for $\epsilon = 0.01$. \blacktriangleleft

4 PIVOT Algorithms for Correlation Clustering

4.1 Lower Bound

First we prove Theorem 3 which states that there is no PIVOT algorithm for Correlation Clustering with approximation factor better than 3.

Proof of Theorem 3. Let $G = ([2n], E)$ for some integer n , where the edge set E contains all pairs of nodes except for pairs of the form $(2k + 1, 2k + 2)$. In other words, the edge set of G contains all edges except for a perfect matching.

Note that if we create a single cluster containing all nodes, then the cost is exactly n . On the other hand, let u be the first choice that a PIVOT algorithm makes. If u is even, let $v = u - 1$, otherwise let $v = u + 1$. By definition of G , v is the only node not adjacent

to u . Therefore, the algorithm creates two clusters – one containing all nodes except for v , and one containing only v . There are $2n - 2$ edges across the two clusters, and $n - 1$ missing edges in the big cluster, meaning that the cost is $3n - 3$.

Therefore, the approximation factor of any PIVOT algorithm is at least $(3n-3)/n = 3 - \frac{3}{n}$. This proves the theorem, as for any constant less than 3, there exists a sufficiently large n such that $3 - \frac{3}{n}$ is larger than that constant. ◀

4.2 Optimal Deterministic PIVOT: 3-Approximation

A *covering* LP is a linear program of the form $\min_x \{ cx \mid Ax \geq b \}$ where A, b, c , and x are restricted to vectors and matrices of non-negative entries. Covering LPs can be solved more efficiently than LPs in general and we rely on the following known machinery to prove Theorem 2:

► **Theorem 13** (Covering LPs, Combinatorial [29, 27]). *Any covering LP with at most N nonzero entries in the constraint matrix can be $(1 + \epsilon)$ -approximated by a combinatorial algorithm in time $\tilde{O}(N\epsilon^{-3})$.⁵*

► **Theorem 14** (Covering LPs, Non-Combinatorial [4, 39]). *Any covering LP with at most N nonzero entries in the constraint matrix can be $(1 + \epsilon)$ -approximated in time $\tilde{O}(N\epsilon^{-1})$.*

Of the two theorems, the time complexity of the algorithm promised by Theorem 14 is obviously better. However, the algorithm of Theorem 13 is remarkably simple in our setting and could thus prove to be faster in practice. Note that either theorem suffices to obtain a $(3 + \epsilon)$ -approximation for Correlation Clustering in $\tilde{O}(n^3)$ time, for constant $\epsilon > 0$.

For completeness, and in order to demonstrate how simple the algorithm from Theorem 13 is in our setting, we include the pseudocode as Algorithm 3. In [26] we formally prove that Algorithm 3 indeed has the properties promised by Theorem 13.

■ **Algorithm 3** The combinatorial algorithm to $(1 + O(\epsilon))$ -approximate the LP in Figure 1 (Page 7) using the multiplicative weights update method. The general method was given by Garg and Könemann [29] and later refined by Fleischer [27]. We here use the notation $m(x) = \min_{uvw \in T(G)} x_{uv} + x_{vw} + x_{wu}$.

```

procedure CHARGE( $G = (V, E)$ )
1  Initialize  $x_{uv}, x_{uv}^* \leftarrow 1$  for all  $uv \in \binom{V}{2}$ 
2  while  $\sum_{uv} x_{uv} < B := \binom{n}{2}(1 + \epsilon)^{1/\epsilon} / (1 + \epsilon)$  do
3      Find a bad triplet  $uvw$  minimizing  $x_{uv} + x_{vw} + x_{wu}$ 
4       $x_{uv} \leftarrow (1 + \epsilon) \cdot x_{uv}$ 
5       $x_{vw} \leftarrow (1 + \epsilon) \cdot x_{vw}$ 
6       $x_{wu} \leftarrow (1 + \epsilon) \cdot x_{wu}$ 
7      if  $(\sum_{uv} x_{uv}) / m(x) < (\sum_{uv} x_{uv}^*) / m(x^*)$  then
8          foreach  $uv \in \binom{V}{2}$  do  $x_{uv}^* \leftarrow x_{uv}$ 
9  return  $\{ x_{uv}^* / m(x^*) \}_{uv}$ 

```

⁵ The running time we state seems worse by a factor of ϵ^{-1} as compared to the theorems in [29, 27]. This is because the authors assume access to a machine model with exact arithmetic of numbers of size exponential in ϵ^{-1} . We can simulate this model using fixed-point arithmetic with a running time overhead of $\tilde{O}(\epsilon^{-1})$.

The solution found by Algorithm 3 is used together with the framework by van Zuylen and Williamson [34], see CLUSTER in Algorithm 4. CLUSTER is discussed further in the full version [26], where the following lemmas are proven.

■ **Algorithm 4** The PIVOT algorithm by van Zuylen and Williamson [34]. Given a graph G and a good charging $\{x_{uv}\}_{uv}$ (in the sense of Lemma 15), it computes a correlation clustering.

```

procedure CLUSTER( $G = (V, E), x = \{x_{uv}\}_{uv \in \binom{V}{2}}$ )
1   $C \leftarrow \emptyset$ 
2  while  $V \neq \emptyset$  do
3    Pick a pivot node  $u \in V$  minimizing
      
$$\frac{\sum_{vw:uvw \in T(G)} 1}{\sum_{vw:uvw \in T(G)} x_{vw}}$$

4    Add a cluster containing  $u$  and all its neighbors to  $C$ 
5    Remove  $u$ , its neighbors and all their incident edges from  $G$ 
6  return  $C$ 

```

► **Lemma 15** (Correctness of CLUSTER). *Assume that $x = \{x_{uv}\}_{uv}$ is a feasible solution to the LP in Figure 1. Then CLUSTER(G, x) computes a correlation clustering of cost $3 \sum_{uv} x_{uv}$. In particular, if x is an α -approximate solution to the LP (for some $\alpha \geq 1$), then CLUSTER(G, x) returns a 3α -approximate correlation clustering.*

► **Lemma 16** (Running Time of CLUSTER, [34]). *CLUSTER(G, x) runs in time $O(n^3)$.*

Given Theorems 13 and 14 we quickly prove Theorem 2.

Proof of Theorem 2. We compute a $(1 + \epsilon/3)$ -approximate solution x of the charging LP using Theorem 13 (that is, using the procedure CHARGE(G)). Plugging this solution x into CLUSTER(G, x) returns a $(3 + \epsilon)$ -approximate correlation clustering by Lemma 15. The total running time is bounded by $O(n^3)$ by Lemma 16 plus $\tilde{O}(n^3 \epsilon^{-3})$ by Theorem 13 (note that there are n^3 constraints, each affecting only a constant number of variables, hence the number of nonzeros in the constraint matrix is $N \leq O(n^3)$). For constant $\epsilon > 0$, this becomes $\tilde{O}(n^3)$.

To obtain a 3-approximation, we observe that any correlation clustering has cost less than $\binom{n}{2}$. Hence, we can run the previous algorithm with $\epsilon = 1/\binom{n}{2}$ and the $(3 + \epsilon)$ -approximate solution is guaranteed to also be 3-approximate. The running time would be bounded by $\tilde{O}(n^9)$. To improve upon this, we use the covering LP solver in Theorem 14 which runs in time $\tilde{O}(n^3 \epsilon^{-1})$. By again setting $\epsilon = 1/\binom{n}{2}$, the running time becomes $\tilde{O}(n^5)$. ◀

Abstract

For a graph G , a subset $S \subseteq V(G)$ is called a *resolving set* of G if, for any two vertices $u, v \in V(G)$, there exists a vertex $w \in S$ such that $d(w, u) \neq d(w, v)$. The METRIC DIMENSION problem takes as input a graph G on n vertices and a positive integer k , and asks whether there exists a resolving set of size at most k . In another *metric-based graph problem*, GEODETIC SET, the input is a graph G and an integer k , and the objective is to determine whether there exists a subset $S \subseteq V(G)$ of size at most k such that, for any vertex $u \in V(G)$, there are two vertices $s_1, s_2 \in S$ such that u lies on a shortest path from s_1 to s_2 .

These two classical problems are known to be intractable with respect to the natural parameter, i.e., the solution size, as well as most structural parameters, including the feedback vertex set number and pathwidth. We observe that both problems admit an FPT algorithm running in $2^{\mathcal{O}(\text{vc}^2)} \cdot n^{\mathcal{O}(1)}$ time, and a kernelization algorithm that outputs a kernel with $2^{\mathcal{O}(\text{vc})}$ vertices, where vc is the vertex cover number. We prove that unless the Exponential Time Hypothesis (ETH) fails, METRIC DIMENSION and GEODETIC SET, even on graphs of bounded diameter, do not admit

- an FPT algorithm running in $2^{\mathcal{O}(\text{vc}^2)} \cdot n^{\mathcal{O}(1)}$ time, nor
- a kernelization algorithm that does not increase the solution size and outputs a kernel with $2^{\mathcal{O}(\text{vc})}$ vertices.

We only know of one other problem in the literature that admits such a tight algorithmic lower bound with respect to vc . Similarly, the list of known problems with exponential lower bounds on the number of *vertices* in kernelized instances is very short.

1 Introduction

In this article, we study two *metric-based* graph problems, one of which is defined through distances, while the other relies on shortest paths. Metric-based graph problems are ubiquitous in computer science; for example, the classical (SINGLE-SOURCE) SHORTEST PATH, (GRAPHIC) TRAVELING SALESPERSON or STEINER TREE problems fall into this category. Those are fundamental problems, often stemming from applications in network design, for which a considerable amount of algorithmic research has been done. Metric-based graph packing and covering problems, like DISTANCE DOMINATION [29] or SCATTERED SET [30], have recently gained a lot of attention. Their non-local nature leads to non-trivial algorithmic properties that differ from most graph problems with a more local nature. We focus here on the METRIC DIMENSION and GEODETIC SET problems, which arise from network monitoring and network design, respectively. These two problems have far-reaching applications, as exemplified by, e.g., the recent work [3] where it was shown that enumerating minimal solution sets for METRIC DIMENSION and GEODETIC SET in (general) graphs and split graphs, respectively, is equivalent to the enumeration of minimal transversals in hypergraphs, whose solvability in total-polynomial time is arguably the most important open problem in algorithmic enumeration. Formally, these two problems are defined as follows.

METRIC DIMENSION

Input: A graph G on n vertices and a positive integer k .

Question: Does there exist $S \subseteq V(G)$ such that $|S| \leq k$ and, for any pair of vertices $u, v \in V(G)$, there exists a vertex $w \in S$ with $d(w, u) \neq d(w, v)$?

GEODETIC SET

Input: A graph G on n vertices and a positive integer k .

Question: Does there exist $S \subseteq V(G)$ such that $|S| \leq k$ and, for any vertex $u \in V(G)$, there are two vertices $s_1, s_2 \in S$ such that u lies on a shortest path from s_1 to s_2 ?

METRIC DIMENSION dates back to the 1970s [26, 38], whereas GEODETIC SET was introduced in 1993 [25]. The non-local nature of these problems has since posed interesting algorithmic challenges. METRIC DIMENSION was first shown to be NP-complete in general graphs in Garey and Johnson's book [22], and this was later extended to many restricted graph classes (see "Related work" below). GEODETIC SET was proven to be NP-complete in [25], and later shown to be NP-hard on restricted graph classes as well.

As these two problems are NP-hard even in very restricted cases, it is natural to ask for ways to confront this hardness. In this direction, the parameterized complexity paradigm allows for a more refined analysis of a problem's complexity. In this setting, we associate each instance I of a problem with a parameter ℓ , and are interested in algorithms running in $f(\ell) \cdot |I|^{\mathcal{O}(1)}$ time for some computable function f . Parameterized problems that admit such an algorithm are called fixed-parameter tractable (FPT for short) with respect to the considered parameter. Under standard complexity assumptions, parameterized problems that are hard for the complexity class $W[1]$ or $W[2]$ do not admit such algorithms.

This approach, however, had limited success for these two problems. In the seminal paper [28], METRIC DIMENSION was proven to be $W[2]$ -hard parameterized by the solution size k , even on subcubic bipartite graphs. Similarly, GEODETIC SET is $W[2]$ -hard parameterized by the solution size [15, 31], even on chordal bipartite graphs. These initial hardness results drove the ensuing meticulous study of the problems under structural parameterizations: we present an overview in the “Related work” below. In this article, we focus on the *vertex cover number*, denoted by vc , of the input graph and prove the following positive results.

► **Theorem 1.** *METRIC DIMENSION and GEODETIC SET admit*

- FPT algorithms running in $2^{\mathcal{O}(vc^2)} \cdot n^{\mathcal{O}(1)}$ time, and
- kernelization algorithms that output kernels with $2^{\mathcal{O}(vc)}$ vertices.

The second set of results follows from simple reduction rules, and was also observed in [28] for METRIC DIMENSION. The first set of results builds on the second set by using a simple, but critical observation. For METRIC DIMENSION, this also improves upon the $2^{2^{\mathcal{O}(vc)}} \cdot n^{\mathcal{O}(1)}$ algorithm mentioned in [28]. However, our main technical contribution is in proving that these results are optimal assuming the Exponential Time Hypothesis (ETH).

► **Theorem 2.** *Unless the ETH fails, METRIC DIMENSION and GEODETIC SET do not admit*

- FPT algorithms running in $2^{\mathcal{O}(vc^2)} \cdot n^{\mathcal{O}(1)}$ time, nor
- kernelization algorithms that do not increase the solution size and output kernels with $2^{\mathcal{O}(vc)}$ vertices,

even on graphs of bounded diameter.

Both these statements constitute a rare set of results. Indeed, we know of only one other problem that admits a lower bound of the form $2^{\mathcal{O}(vc^2)} \cdot n^{\mathcal{O}(1)}$ and a matching upper bound [1], whereas such results parameterized by pathwidth are mentioned in [36, 37]. Very recently, the authors in [7] also proved a similar result with respect to solution size. Similarly, the list of known problems with exponential lower bounds on the number of *vertices* in kernelized instances is very short. To the best of our knowledge, the only known results of this kind (i.e., ETH-based lower bounds on the number of vertices in a kernel) are for EDGE CLIQUE COVER [13], BICLIQUE COVER [9], STEINER TREE [35], STRONG METRIC DIMENSION [20], B-NCTD⁺ [8], LOCATING DOMINATING SET [7], and TELEPHONE BROADCASTING [39]. For METRIC DIMENSION, the above also improves a result of [24], which states that METRIC DIMENSION parameterized by $k + vc$ does not admit a polynomial kernel unless the polynomial hierarchy collapses to its third level. Indeed, the result of [24] does not rule out a kernel of super-polynomial or sub-exponential size.

Recently, Foucaud et al. [20] proved that, unless the ETH fails, METRIC DIMENSION and GEODETIC SET on graphs of bounded diameter do not admit $2^{2^{\mathcal{O}(tw)}} \cdot n^{\mathcal{O}(1)}$ -time algorithms, thereby establishing one of the first such results for NP-complete problems. Note that $n \succ vc \succ fvs \succ tw$ and $n \succ vc \succ td \succ pw \succ tw$ in the parameter hierarchy, where n is the order, fvs is the feedback vertex set number, td is the treedepth, pw is the pathwidth, and tw is the treewidth of the graph. They further proved that their lower bound also holds for fvs and td in the case of METRIC DIMENSION, and for td in the case of GEODETIC SET [20]. A simple brute-force algorithm enumerating all possible candidates runs in $2^{\mathcal{O}(n)}$ time for both of these problems. Thus, the next natural question is whether such a lower bound for METRIC DIMENSION and GEODETIC SET can be extended to larger parameters, in particular vc . Our first results answer this question in the negative. Together with the lower bounds with respect to vc , this establishes the boundary between parameters yielding single-exponential and double-exponential running times for METRIC DIMENSION and GEODETIC SET.

Before moving forward, we highlight the parallels and differences between Foucaud et al. [20] and our work. Their aim was to establish double-exponential lower bounds for NP-complete problems, and to do so they focused on the restriction of the problems to graphs of bounded treewidth and diameter. Our objective is to closely examine one of the very few tractable results for METRIC DIMENSION and GEODETIC SET on general graphs by focusing on the vertex cover parameter. While we use some gadgets from [20], overall our reductions significantly differ from the corresponding reductions in that article. Note that we need to “control” the vertex cover number of the reduced graph, whereas the corresponding reductions by Foucaud et al. [20] only need to “control” the treewidth.

Related Work. We mention here results concerning structural parameterizations of METRIC DIMENSION and GEODETIC SET, and refer the reader to the full version of [20] for a more comprehensive overview of applications and related work regarding these two problems.

As previously mentioned, METRIC DIMENSION is $W[2]$ -hard parameterized by the solution size k , even in subcubic bipartite graphs [28]. Several other parameterizations have been studied for this problem, on which we elaborate next (see also [21, Figure 1]). It was proven that there is an XP algorithm parameterized by the feedback edge set number [18], and FPT algorithms parameterized by the max leaf number [17], the modular-width and the treelength plus the maximum degree [2], the treedepth and the clique-width plus the diameter [23], and the distance to cluster (co-cluster, respectively) [21]. Recently, an FPT algorithm parameterized by the treewidth in chordal graphs was given in [5]. On the negative side, METRIC DIMENSION is $W[1]$ -hard parameterized by the pathwidth even on graphs of constant degree [4], para-NP-hard parameterized by the pathwidth [33], and $W[1]$ -hard parameterized by the combined parameter feedback vertex set number plus pathwidth [21].

The parameterized complexity of GEODETIC SET was first addressed in [31], in which it was observed that the reduction from [15] implies that the problem is $W[2]$ -hard parameterized by the solution size (even for chordal bipartite graphs). This motivated the authors of [31] to investigate structural parameterizations of GEODETIC SET. They proved the problem to be $W[1]$ -hard for the combined parameters solution size, feedback vertex set number, and pathwidth, and FPT for the parameters treedepth, modular-width (more generally, clique-width plus diameter), and feedback edge set number [31]. The problem was also shown to be FPT on chordal graphs when parameterized by the treewidth [6].

2 Preliminaries

For an integer a , we let $[a] = \{1, \dots, a\}$.

Graph theory. We use standard graph-theoretic notation and refer the reader to [14] for any undefined notation. For an undirected graph G , the sets $V(G)$ and $E(G)$ denote its set of vertices and edges, respectively. Two vertices $u, v \in V(G)$ are *adjacent* or *neighbors* if $(u, v) \in E(G)$. The *open neighborhood* of a vertex $u \in V(G)$, denoted by $N(u) := N_G(u)$, is the set of vertices that are neighbors of u . The *closed neighborhood* of a vertex $u \in V(G)$ is denoted by $N[u] := N_G[u] := N_G(u) \cup \{u\}$. For any $X \subseteq V(G)$ and $u \in V(G)$, $N_X(u) = N_G(u) \cap X$. Any two vertices $u, v \in V(G)$ are *true twins* if $N[u] = N[v]$, and are *false twins* if $N(u) = N(v)$. For a subset S of $V(G)$, we say that the vertices in S are true (false, respectively) twins if, for any $u, v \in S$, u and v are true (false, respectively) twins. The *distance* between two vertices $u, v \in V(G)$ in G , denoted by $d(u, v) := d_G(u, v)$, is the length of a (u, v) -shortest path in G . For a subset S of $V(G)$, we define $N[S] = \bigcup_{v \in S} N[v]$ and $N(S) = N[S] \setminus S$. For

a graph G , a set $X \subseteq V(G)$ is said to be a *vertex cover* if $V(G) \setminus X$ is an independent set. We denote by $\text{vc}(G)$ the size of a minimum vertex cover in G . When G is clear from the context, we simply say vc . A vertex is *simplicial* if its neighborhood forms a clique. Observe that any simplicial vertex v does not belong to any shortest path between any pair x, y of vertices (both distinct from v). Hence, the following holds.

► **Observation 3** ([10]). *If a graph G contains a simplicial vertex v , then v belongs to any geodesic set of G . Specifically, every degree-1 vertex belongs to any geodesic set of G .*

Metric Dimension. A subset of vertices $S' \subseteq V(G)$ *resolves* a pair of vertices $u, v \in V(G)$ if there exists a vertex $w \in S'$ such that $d(w, u) \neq d(w, v)$. A vertex $u \in V(G)$ is *distinguished* by a subset of vertices $S' \subseteq V(G)$ if, for any $v \in V(G) \setminus \{u\}$, there exists a vertex $w \in S'$ such that $d(w, u) \neq d(w, v)$.

Parameterized Complexity. An instance of a parameterized problem Π comprises an input I , which is an input of the classical instance of the problem, and an integer ℓ , which is called the parameter. A problem Π is said to be *fixed-parameter tractable* or in FPT if given an instance (I, ℓ) of Π , we can decide whether or not (I, ℓ) is a YES-instance of Π in $f(\ell) \cdot |I|^{\mathcal{O}(1)}$ time, for some computable function f whose value depends only on ℓ .

A *kernelization* algorithm for Π is a polynomial-time algorithm that takes as input an instance (I, ℓ) of Π and returns an *equivalent* instance (I', ℓ') of Π , where $|I'|, \ell' \leq f(\ell)$, where f is a function that depends only on ℓ . If such an algorithm exists for Π , we say that Π admits a kernel of *size* $f(\ell)$. If f is a polynomial or exponential function of ℓ , we say that Π admits a polynomial or exponential kernel, respectively. If Π is a graph problem, then I contains a graph, say G , and I' contains a graph, say G' . In this case, we say that Π admits a kernel with $f(\ell)$ vertices if the number of vertices of G' is at most $f(\ell)$.

It is typical to describe a kernelization algorithm as a series of reduction rules. A *reduction rule* is a polynomial-time algorithm that takes as an input an instance of a problem and outputs another (usually reduced) instance. A reduction rule said to be *applicable* on an instance if the output instance is different from the input instance. A reduction rule is *safe* if the input instance is a YES-instance if and only if the output instance is a YES-instance.

The Exponential Time Hypothesis (ETH) roughly states that n -variable 3-SAT cannot be solved in $2^{o(n)}$ time. For more on parameterized complexity and related terminologies, we refer the reader to the recent book by Cygan et al. [12].

3-Partitioned-3-SAT. Our lower bound proofs consist of reductions from the 3-PARTITIONED-3-SAT problem. This version of 3-SAT was introduced in [32] and is defined as follows.

3-PARTITIONED-3-SAT

Input: A formula ψ in 3-CNF form, together with a partition of the set of its variables into three disjoint sets $X^\alpha, X^\beta, X^\gamma$, with $|X^\alpha| = |X^\beta| = |X^\gamma| = N$, and such that no clause contains more than one variable from each of X^α, X^β , and X^γ .

Question: Determine whether ψ is satisfiable.

Organization of the paper. We start with the results for METRIC DIMENSION, which are then followed by those for GEODETIC SET. For each, we first present the algorithms and then the reductions. Since space requirements prohibit us from presenting our reductions in

detail, we give an outline that discusses the main technical ideas behind our reductions for getting the lower-bound results for both METRIC DIMENSION and GEODETIC SET. For the complete formal proofs, we refer the reader to the full version of this paper [19].

3 Metric Dimension: Algorithms for Vertex Cover Parameterization

In this section, we prove Theorem 1 for METRIC DIMENSION. The kernelization algorithm exhaustively applies the following reduction rule.

▷ **Reduction Rule 1.** If there exist three vertices $u, v, x \in I$ such that u, v, x are false twins, then delete x and decrease k by one.

Proof that Reduction Rule 1 is safe. Since u, v, x are false twins, $N(u) = N(v) = N(x)$. This implies that, for any vertex $w \in V(G) \setminus \{u, v, x\}$, $d(w, v) = d(w, u) = d(w, x)$. Hence, any resolving set that excludes at least two vertices in $\{u, v, x\}$ cannot resolve all three pairs $\{u, v\}$, $\{u, x\}$, and $\{v, x\}$. As the vertices in $\{u, v, x\}$ are distance-wise indistinguishable from the remaining vertices, we can assume, without loss of generality, that any resolving set contains both u and x . Hence, any pair of vertices in $V(G) \setminus \{u, x\}$ that is resolved by x is also resolved by u . In other words, if S is a resolving set of G , then $S \setminus \{x\}$ is a resolving set of $G - \{x\}$. This implies the correctness of the forward direction. The correctness of the reverse direction trivially follows from the fact that we can add x into a resolving set of $G - \{x\}$ to obtain a resolving set of G . ◀

► **Lemma 4.** METRIC DIMENSION, parameterized by the vertex cover number vc , admits a polynomial-time kernelization algorithm that returns an instance with $2^{\mathcal{O}(\text{vc})}$ vertices.

Proof. Given a graph G , let $X \subseteq V(G)$ be a minimum vertex cover of G . If such a vertex cover is not given, then we can find a 2-factor approximate vertex cover in polynomial time. Let $I := V(G) \setminus X$. By the definition of a vertex cover, the vertices of I are pairwise non-adjacent.

The kernelization algorithm exhaustively applies Reduction Rule 1. Now, consider an instance on which Reduction Rule 1 is not applicable. If the budget is negative, then the algorithm returns a trivial NO-instance of constant size. Otherwise, for any $Y \subseteq X$, there are at most two vertices $u, v \in I$ such that $N(u) = N(v) = Y$. This implies that the number of vertices in the reduced instance is at most $|X| + 2 \cdot 2^{|X|} = 2^{\text{vc}+1} + \text{vc}$. ◀

Next, we present an XP-algorithm parameterized by the vertex cover number. This algorithm, along with the kernelization algorithm above, imply¹ that METRIC DIMENSION admits an algorithm running in $2^{\mathcal{O}(\text{vc}^2)} \cdot n^{\mathcal{O}(1)}$ time.

► **Lemma 5.** METRIC DIMENSION admits an algorithm running in $n^{\mathcal{O}(\text{vc})}$ time.

Proof. The algorithm starts by computing a minimum vertex cover X of G in $2^{\mathcal{O}(\text{vc})} \cdot n^{\mathcal{O}(1)}$ time using an FPT algorithm for the VERTEX COVER problem, for example the one in [11] or [27]. Let $I := V(G) \setminus X$. Then, in polynomial time, it computes a largest subset F of I such that, for every vertex u in F , $I \setminus F$ contains a false twin of u . By the arguments in the previous proof, if there are false twins in I , say u, v , then any resolving set contains at least one of them. Hence, it is safe to assume that any resolving set contains F . If $k - |F| < 0$,

¹ Note that the application of Reduction Rule 1 does not increase the vertex cover number.

then the algorithm returns No. Otherwise, it enumerates every subset of vertices of size at most $|X|$ in $X \cup (I \setminus F)$. If there exists a subset $A \subseteq X \cup (I \setminus F)$ such that $A \cup F$ is a resolving set of G of size at most k , then it returns $A \cup F$. Otherwise, it returns No.

In order to prove that the algorithm is correct, we prove that $X \cup F$ is a resolving set of G . It is easy to see that, for a pair of distinct vertices u, v , if $u \in X \cup F$ and $v \in V(G)$, then the pair is resolved by u . It remains to argue that every pair of distinct vertices in $(I \setminus F) \times (I \setminus F)$ is resolved by $X \cup F$. Note that, for any two vertices $u, v \in I \setminus F$, $N(u) \neq N(v)$ as otherwise u can be moved to F , contradicting the maximality of F . Hence, there is a vertex in X that is adjacent to u , but not adjacent to v , resolving the pair $\langle u, v \rangle$. This implies the correctness of the algorithm. The running time of the algorithm easily follows from its description. ◀

4 Metric Dimension: Lower Bounds Regarding Vertex Cover

In this section, we prove Theorem 2 for METRIC DIMENSION. The first integral part of our technique is to reduce from a variant of 3-SAT known as 3-PARTITIONED-3-SAT [32]. In this problem, the input is a 3-CNF formula ψ , together with a partition of the set of its variables into three disjoint sets $X^\alpha, X^\beta, X^\gamma$, with $|X^\alpha| = |X^\beta| = |X^\gamma| = N$, and such that no clause contains more than one variable from each of X^α, X^β , and X^γ . The objective is to determine whether ψ is satisfiable. Unless the ETH fails, 3-PARTITIONED-3-SAT does not admit an algorithm running in $2^{o(N)}$ time [32, Theorem 3]. Our key result is the following.

► **Theorem 6.** *There is an algorithm that, given an instance ψ of 3-PARTITIONED-3-SAT on N variables, runs in $2^{\mathcal{O}(\sqrt{N})}$ time, and constructs an equivalent instance (G, k) of METRIC DIMENSION such that $\text{vc}(G) + k = \mathcal{O}(\sqrt{N})$ (and $|V(G)| = 2^{\mathcal{O}(\sqrt{N})}$).*

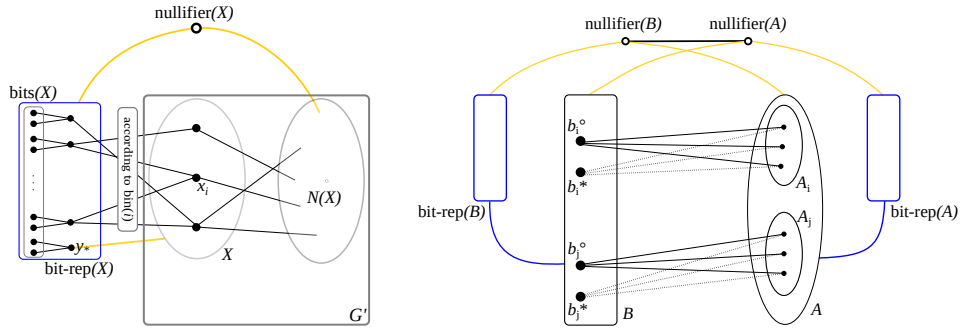

The above theorem, along with the arguments that are standard to prove the ETH-based lower bounds, immediately imply the following results.

► **Corollary 7.** *Unless the ETH fails, METRIC DIMENSION does not admit an algorithm running in $2^{o(\text{vc}^2)} \cdot n^{\mathcal{O}(1)}$ time.*

► **Corollary 8.** *Unless the ETH fails, METRIC DIMENSION does not admit a kernelization algorithm that does not increase the solution size k and outputs a kernel with $2^{o(k+\text{vc})}$ vertices.*

Proof. Toward a contradiction, assume that such a kernelization algorithm exists. Consider the following algorithm for 3-PARTITIONED-3-SAT. Given a 3-PARTITIONED-3-SAT formula on N variables, it uses Theorem 6 to obtain an equivalent instance of (G, k) such that $\text{vc}(G) + k = \mathcal{O}(\sqrt{N})$ and $|V(G)| = 2^{\mathcal{O}(\sqrt{N})}$. Then, it uses the assumed kernelization algorithm to construct an equivalent instance (H, k') such that H has $2^{o(\text{vc}(G)+k)}$ vertices and $k' \leq k$. Finally, it uses a brute-force algorithm, running in $|V(H)|^{\mathcal{O}(k')}$ time, to determine whether the reduced instance, or equivalently the input instance of 3-PARTITIONED-3-SAT, is a YES-instance. The correctness of the algorithm follows from the correctness of the respective algorithms and our assumption. The total running time of the algorithm is $2^{\mathcal{O}(\sqrt{N})} + (|V(G)| + k)^{\mathcal{O}(1)} + |V(H)|^{\mathcal{O}(k')} = 2^{\mathcal{O}(\sqrt{N})} + (2^{\mathcal{O}(\sqrt{N})})^{\mathcal{O}(1)} + (2^{o(\sqrt{N})})^{\mathcal{O}(\sqrt{N})} = 2^{o(N)}$. But this contradicts the ETH. ◀

The reduction, presented in Section 4.2, uses tools introduced in the next subsection.

■ **Figure 1 Set Identifying Gadget (left).** The blue box represents $\text{bit-rep}(X)$. The yellow lines represent that all possible edges exist between $\text{bit-rep}(X) \setminus \text{bits}(X)$ and $\text{nullifier}(X)$, $\text{nullifier}(X)$ and $N(X)$, and y_* and X . Note that G' is not necessarily restricted to the graph induced by the vertices in $X \cup N(X)$. **Vertex Selector Gadget (right).** For $X \in \{B, A\}$, the blue box represents $\text{bit-rep}(X)$, the blue link represents the connection with respect to the binary representation, and the yellow line represents that $\text{nullifier}(X)$ is adjacent to each vertex in $\text{bit-rep}(X) \setminus \text{bits}(X)$. Dotted lines highlight absent edges.

4.1 Preliminary Tools

4.1.1 Set Identifying Gadget

We redefine a gadget introduced in [20]. Suppose we are given a graph G' and a subset $X \subseteq V(G')$ of its vertices. Further, suppose that we want to add a vertex set X^+ to G' in order to obtain a new graph G such that (1) each vertex in $X \cup X^+$ will be distinguished by vertices in X^+ that must be in any resolving set S of G , and (2) no vertex in X^+ can resolve any pair of vertices in $V(G) \setminus (X \cup X^+)$ that are in the same distance class with respect to X .

The graph induced by the vertices of X^+ , along with the edges connecting X^+ to G' , is the Set Identifying Gadget for X [20]. Given a graph G' and a non-empty subset $X \subseteq V(G')$ of its vertices, to construct such a graph G , we add vertices and edges to G' as follows:

- The vertex set X^+ that we are aiming to add is the union of a set bit-rep and a special vertex denoted by $\text{nullifier}(X)$.
- Let $X = \{x_i \mid i \in [|X|]\}$ and set $q := \lceil \log(|X| + 2) \rceil + 1$. We select this value for q to (1) uniquely represent each integer in $[|X|]$ by its bit-representation in binary (note that we start from 1 and not 0), (2) ensure that the only vertex whose bit-representation contains all 1's is $\text{nullifier}(X)$, and (3) reserve one spot for an additional vertex y_* .
- For every $i \in [q]$, add three vertices y_i^a, y_i, y_i^b , and add the path (y_i^a, y_i, y_i^b) .
- Add three vertices y_*^a, y_*, y_*^b , and add the path (y_*^a, y_*, y_*^b) . Add all the edges to make $\{y_i \mid i \in [q]\} \cup \{y_*\}$ a clique. Make y_* adjacent to each vertex $v \in X$. Let $\text{bit-rep}(X) := \{y_i, y_i^a, y_i^b \mid i \in [q]\} \cup \{y_*, y_*^a, y_*^b\}$ and $\text{bits}(X) := \{y_i^a, y_i^b \mid i \in [q]\} \cup \{y_*^a, y_*^b\}$.
- For every integer $j \in [|X|]$, let $\text{bin}(j)$ denote the binary representation of j using q bits. Connect x_j with y_i if the i^{th} bit (going from left to right) in $\text{bin}(j)$ is 1.
- Add a vertex, denoted by $\text{nullifier}(X)$, and make it adjacent to every vertex in $\{y_i \mid i \in [q]\} \cup \{y_*\}$. One can think of $\text{nullifier}(X)$ as the only vertex whose bit-representation contains all 1's.
- For every vertex $u \in V(G) \setminus (X \cup X^+)$ such that u is adjacent to some vertex in X , add an edge between u and $\text{nullifier}(X)$. We add this vertex to ensure that vertices in $\text{bit-rep}(X)$ do not resolve any pairs of vertices in $V(G) \setminus (X \cup X^+)$ that are in the same distance class with respect to X .

This completes the construction of G . See Figure 1 for an illustration.

4.1.2 Gadget to Add Critical Pairs

Any resolving set needs to resolve *all* pairs of vertices in the input graph. As we will see, some pairs are harder to resolve than others.

Suppose that we need to have $m \in \mathbb{N}$ such “hard” pairs in a graph G . So, for each $i \in [m]$, we make a pair of vertices $\langle c_i^\circ, c_i^* \rangle$ *critical* as follows. Define $C := \{c_i^\circ, c_i^* \mid i \in [m]\}$. We then add $\text{bit-rep}(C)$ and $\text{nullifier}(C)$ as mentioned above (taking C as the set X), with the edges between $\{c_i^\circ, c_i^*\}$ and $\text{bit-rep}(C)$ defined by $\text{bin}(i)$, i.e., connect both c_i° and c_i^* with the j -th vertex of $\text{bit-rep}(C)$ if the j^{th} bit (going from left to right) in $\text{bin}(i)$ is 1. Hence, $\text{bit-rep}(C)$ can resolve any pair of the form $\langle c_i^\circ, c_\ell^\circ \rangle$, $\langle c_i^\circ, c_\ell^* \rangle$, or $\langle c_i^*, c_\ell^* \rangle$ as long as $i \neq \ell$. As before, $\text{bit-rep}(C)$ can also resolve all pairs with one vertex in $C \cup \text{bit-rep}(C) \cup \{\text{nullifier}(C)\}$, but no critical pair of vertices.

4.1.3 Vertex Selector Gadgets

Suppose that we are given a collection of sets A_1, A_2, \dots, A_q of vertices in a graph G , and we want to ensure that any resolving set of G includes at least one vertex from A_i for every $i \in [q]$. In the following, we construct a gadget that achieves a slightly weaker objective.

- Let $A = \bigcup_{i \in [q]} A_i$. Add a set identifying gadget for A as mentioned in Subsection 4.1.1.
- For every $i \in [q]$, add two vertices b_i° and b_i^* . Use the gadget mentioned in Subsection 4.1.2 to make all the pairs of the form $\langle b_i^\circ, b_i^* \rangle$ critical pairs (in the way it was introduced for $\langle c_i^\circ, c_i^* \rangle$).
- For every $a \in A_i$, add an edge (a, b_i°) . We highlight that we do not make a adjacent to b_i^* by a dotted line in Figure 1. Also, add the edges $(a, \text{nullifier}(B))$, $(b_i^\circ, \text{nullifier}(A))$, $(b_i^*, \text{nullifier}(A))$, and $(\text{nullifier}(A), \text{nullifier}(B))$.

This completes the construction. Note that the only vertices that can resolve a critical pair $\langle b_i^\circ, b_i^* \rangle$, apart from b_i° and b_i^* , are the vertices in A_i (see Figure 1, all other vertices are equidistant from both vertices of the pair). Hence, every resolving set contains at least one vertex in $\{b_i^\circ, b_i^*\} \cup A_i$.

4.2 Reduction

Consider an instance ψ of 3-PARTITIONED-3-SAT with $X^\alpha, X^\beta, X^\gamma$ the partition of the variable set, where each part contains N variables. By adding dummy variables in each of these sets, we can assume that \sqrt{N} is an integer. From ψ , we construct the graph G as follows. We describe the construction of the part of the graph G that corresponds to X^α , with the parts corresponding to X^β and X^γ being analogous. Rename the variables in X^α to $x_{i,j}^\alpha$ for $i, j \in [\sqrt{N}]$.

- We partition the variables of X^α into *buckets* $X_1^\alpha, X_2^\alpha, \dots, X_{\sqrt{N}}^\alpha$ such that each bucket contains \sqrt{N} variables. Let $X_i^\alpha = \{x_{i,j}^\alpha \mid j \in [\sqrt{N}]\}$ for all $i \in [\sqrt{N}]$.
- For every X_i^α , we construct a set A_i^α of $2^{\sqrt{N}}$ new vertices, $A_i^\alpha = \{a_{i,\ell}^\alpha \mid \ell \in [2^{\sqrt{N}}]\}$. Each vertex in A_i^α corresponds to a certain possible assignment of variables in X_i^α . Let A^α be the collection of all the vertices added in the above step, that is, $A^\alpha = \{a_{i,\ell}^\alpha \in A_i^\alpha \mid i \in [\sqrt{N}] \text{ and } \ell \in [2^{\sqrt{N}}]\}$. We add a set identifying gadget as mentioned in Subsection 4.1.1 in order to resolve every pair of vertices in A^α .
- For every X_i^α , we construct a pair $\langle b_i^{\alpha,\circ}, b_i^{\alpha,*} \rangle$ of vertices. Then, we add a gadget to make the pairs $\{\langle b_i^{\alpha,\circ}, b_i^{\alpha,*} \rangle \mid i \in [\sqrt{N}]\}$ critical as mentioned in Subsection 4.1.2. Let $B^\alpha = \{b_i^{\alpha,\circ}, b_i^{\alpha,*} \mid i \in [\sqrt{N}]\}$ be the collection of vertices in the critical pairs. We add edges in B^α to make it a clique.

33:10 Metric Dimension and Geodetic Set Parameterized by Vertex Cover

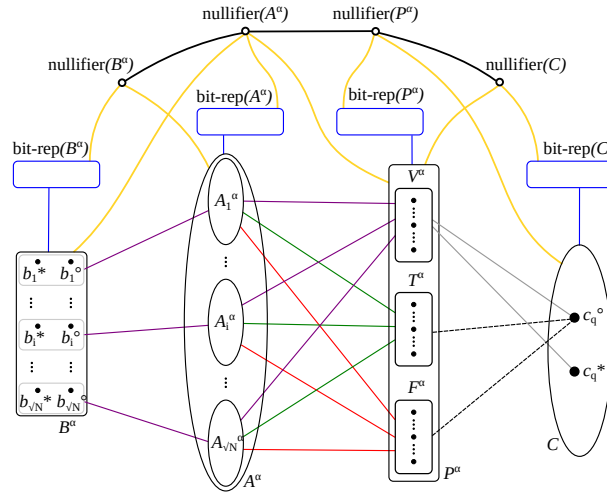

- We would like that any resolving set contains at least one vertex in A_i^α for every $i \in [\sqrt{N}]$, but instead we add the construction from Subsection 4.1.3 that achieves the slightly weaker objective as mentioned there. However, for every A_i^α , instead of adding two new vertices, we use $\langle b_i^{\alpha,\circ}, b_i^{\alpha,*} \rangle$ as the necessary critical pair. Formally, for every $i \in [\sqrt{N}]$, we make $b_i^{\alpha,\circ}$ adjacent to every vertex in A_i^α . We add edges to make $\text{nullifier}(B^\alpha)$ adjacent to every vertex in A^α , and $\text{nullifier}(A^\alpha)$ adjacent to every vertex in B^α . Recall that there is also the edge $(\text{nullifier}(B^\alpha), \text{nullifier}(A^\alpha))$.
- For every clause C_q in ψ , we have a pair of vertices $\langle c_q^\circ, c_q^* \rangle$. Let C be the collection of vertices in such pairs. We add *portals* that transmit information from vertices corresponding to assignments, i.e., vertices in A^α , to pairs corresponding to clauses. A portal is a clique on \sqrt{N} vertices in the graph G . We add three portals, the *truth portal* (denoted by T^α), *false portal* (denoted by F^α), and *validation portal* (denoted by V^α). Let $T^\alpha = \{t_1^\alpha, t_2^\alpha, \dots, t_{\sqrt{N}}^\alpha\}$, $F^\alpha = \{f_1^\alpha, f_2^\alpha, \dots, f_{\sqrt{N}}^\alpha\}$, and $V^\alpha = \{v_1^\alpha, v_2^\alpha, \dots, v_{\sqrt{N}}^\alpha\}$. Moreover, let $P^\alpha = V^\alpha \cup T^\alpha \cup F^\alpha$.
- We add a set identifying gadget for P^α as mentioned in Subsection 4.1.1. We add an edge between $\text{nullifier}(A^\alpha)$ and every vertex of P^α ; and the edge $(\text{nullifier}(P^\alpha), \text{nullifier}(A^\alpha))$. However, we note that we *do not* add edges between $\text{nullifier}(P^\alpha)$ and A^α , as can be seen in Figure 2. Lastly, we add edges in P^α to make it a clique.
- We add edges between A^α and the portals as follows. For $i \in [\sqrt{N}]$ and $\ell \in [2^{\sqrt{N}}]$, consider a vertex $a_{i,\ell}^\alpha$ in A_i^α . Recall that this vertex corresponds to an assignment $\pi : X_i^\alpha \mapsto \{\text{True}, \text{False}\}$, where X_i^α is the collection of variables $\{x_{i,j}^\alpha \mid j \in [\sqrt{N}]\}$. If $\pi(x_{i,j}^\alpha) = \text{True}$, then we add the edge $(a_{i,\ell}^\alpha, t_j^\alpha)$. Otherwise, $\pi(x_{i,j}^\alpha) = \text{False}$, and we add the edge $(a_{i,\ell}^\alpha, f_j^\alpha)$. We add the edge $(a_{i,\ell}^\alpha, v_i^\alpha)$ for every $\ell \in [2^{\sqrt{N}}]$.

Then, we repeat the above steps to construct $B^\beta, A^\beta, P^\beta, B^\gamma, A^\gamma, P^\gamma$. Now, we are ready to proceed through the final steps to complete the construction.

- For every clause C_q in ψ , as it has been already introduced above, we have a pair of vertices $\langle c_q^\circ, c_q^* \rangle$ and C is the collection of vertices in such pairs. Then, we add a gadget as was described in Subsection 4.1.2 to make each pair $\langle c_q^\circ, c_q^* \rangle$ a critical one.
- For each $\delta \in \{\alpha, \beta, \gamma\}$, we add an edge between $\text{nullifier}(P^\delta)$ and every vertex of C , and we add the edge $(\text{nullifier}(P^\delta), \text{nullifier}(C))$. Now, we add edges between C and the portals as follows for each $\delta \in \{\alpha, \beta, \gamma\}$. Consider a clause C_q in ψ and the corresponding critical pair $\langle c_q^\circ, c_q^* \rangle$ in C . As ψ is an instance of 3-PARTITIONED-3-SAT, there is at most one variable in X^δ that appears in C_q . If C_q does not contain a variable in X^δ , then we make c_q° and c_q^* adjacent to every vertex in V^δ , and they are not adjacent to any vertex in $T^\delta \cup F^\delta$. Otherwise, suppose that C_q contains the variable $x_{i,j}^\delta$ for some $i, j \in [\sqrt{N}]$. The first subscript decides the edges between $\langle c_q^\circ, c_q^* \rangle$ and the validation portal, whereas the second subscript decides the edges between $\langle c_q^\circ, c_q^* \rangle$ and either the truth portal or false portal in the following sense. We add all edges of the form $(v_{i'}^\delta, c_q^\circ)$ and $(v_{i'}^\delta, c_q^*)$ for every $i' \in [\sqrt{N}]$ such that $i' \neq i$. If $x_{i,j}^\delta$ appears as a positive literal in C_q , then we add the edge (t_j^δ, c_q°) . Otherwise, $x_{i,j}^\delta$ appears as a negative literal in C_q , and we add the edge (f_j^δ, c_q°) .

This concludes the construction of G . The reduction returns (G, k) as an instance of METRIC DIMENSION where

$$k = 3 \cdot \left(\sqrt{N} + (\lceil \log(|B^\alpha|/2 + 2) \rceil + 1) + (\lceil \log(|A^\alpha| + 2) \rceil + 1) + (\lceil \log(|P^\alpha| + 2) \rceil + 1) \right) + \lceil \log(|C|/2 + 2) \rceil + 1.$$

■ **Figure 2** Overview of the reduction. Sets in ellipses are independent sets and sets in rectangles are cliques. For $X \in \{B^\alpha, A^\alpha, P^\alpha, C\}$, the blue rectangle attached to it via the blue edge represents $\text{bit-rep}(X)$, and the yellow line between a vertex and $\text{bit-rep}(X)$ indicates that vertex is connected to every vertex in $\text{bit-rep}(X) \setminus \text{bits}(X)$. The remainder of the yellow lines represent that vertex is connected to every vertex in the set the edge goes to. Note the exception of $\text{nullifier}(P^\alpha)$ which is *not* adjacent to any vertex in A^α . Purple lines between two sets denote adjacencies with respect to indexing, i.e., $b_i^{\alpha,o}$ is adjacent only with all the vertices in A_i^α , and all the vertices in A_i^α are adjacent with v_i^α in validation portal V^α . Gray lines also indicate adjacencies with respect to indexing, but in a complementary way. If C_q contains a variable in B_i^α , then c_q^o and c_q^* are adjacent with all vertices $v_j^\alpha \in V^\alpha$ such that $j \neq i$. Green and red lines between the A^α and T^α and F^α roughly transfer, for each $a_{i,\ell}^\alpha \in A^\alpha$, the underlying assignment structure. If the j^{th} variable by $a_{i,\ell}^\alpha$ is assigned to **True**, then we add the green edge $(a_{i,\ell}^\alpha, t_j^\alpha)$, and otherwise the red edge $(a_{i,\ell}^\alpha, f_j^\alpha)$. Similarly, we add edges for each $c_i^\delta \in C$ depending on the assignment satisfying the variable from the part X^δ of a clause c_i , and in which block B_j^δ it lies, putting either an edge (c_i^δ, t_j^δ) or (c_i^δ, f_j^δ) accordingly ($\delta \in \{\alpha, \beta, \gamma\}$).

We give an informal description of the proof of correctness here. See Figure 3. Suppose $\sqrt{N} = 3$ and the vertices in the sets are indexed from top to bottom. For legibility, we omit some edges and only show 4 out of 8 vertices in each A_i^α for $i \in [3]$. We also omit bit-rep and nullifier for these sets. The vertex selection gadget and the budget k ensure that exactly one vertex in $\{b_i^{\alpha,o}, b_i^{\alpha,*}\} \cup A_i^\alpha$ is selected for every $i \in [3]$. If a resolving set contains a vertex from A_i^α , then it corresponds to selecting an assignment of variables in X_i^α . For example, the vertex $a_{2,2}^\alpha$ corresponds to the assignment $\pi : X_2^\alpha \mapsto \{\text{True}, \text{False}\}$. Suppose $X_2^\alpha = \{x_{2,1}^\alpha, x_{2,2}^\alpha, x_{2,3}^\alpha\}$, $\pi(x_{2,1}^\alpha) = \pi(x_{2,3}^\alpha) = \text{True}$, and $\pi(x_{2,2}^\alpha) = \text{False}$. Hence, $a_{2,2}^\alpha$ is adjacent to the first and third vertex in the truth portal T^α , whereas it is adjacent with the second vertex in the false portal F^α . Suppose the clause C_q contains the variable $x_{2,1}^\alpha$ as a positive literal. Note that c_q^o and c_q^* are at distance 2 and 3, respectively, from $a_{2,2}^\alpha$. Hence, the vertex $a_{2,2}^\alpha$, corresponding to the assignment π that satisfies clause C_q , resolves the critical pair $\langle c_q^o, c_q^* \rangle$. Now, suppose there is another assignment $\sigma : X_3^\alpha \mapsto \{\text{True}, \text{False}\}$ such that $\sigma(x_{3,1}^\alpha) = \sigma(x_{3,3}^\alpha) = \text{True}$ and $\sigma(x_{3,2}^\alpha) = \text{False}$. As ψ is an instance of 3-PARTITIONED-3-SAT and C_q contains a variable in $X_2^\alpha (\subseteq X^\alpha)$, C_q does not contain a variable in $X_3^\alpha (\subseteq X^\alpha)$. Hence, σ does not satisfy C_q . Let $a_{3,2}^\alpha$ be the vertex in X_3^α corresponding to σ . The connections via the validation portal V^α ensure that both c_q^o and c_q^* are at distance 2 from $a_{3,2}^\alpha$, and hence, $a_{3,2}^\alpha$ cannot resolve the critical pair $\langle c_q^o, c_q^* \rangle$. Hence, finding a resolving set in G corresponds to finding a satisfying assignment for ψ . These intuitions are formalized in the following subsection.

■ **Figure 3** An example to illustrate the reduction (bit-rep and nullifier are omitted for the sets).

4.3 Correctness of the Reduction

Suppose, given an instance ψ of 3-PARTITIONED-3-SAT, that the reduction of this subsection returns (G, k) as an instance of METRIC DIMENSION. We first prove the following lemma which will be helpful in proving the correctness of the reduction.

► **Lemma 9.** *For any resolving set S of G and for all $X \in \{C\} \cup \{B^\delta, A^\delta, P^\delta \mid \delta \in \{\alpha, \beta, \gamma\}\}$,*

1. S contains at least one vertex from each pair of false twins in $\text{bits}(X)$.
2. Vertices in $\text{bits}(X) \cap S$ resolve any non-critical pair of vertices $\langle u, v \rangle$ when $u \in X \cup X^+$ and $v \in V(G)$.
3. Vertices in $X^+ \cap S$ cannot resolve any critical pair of vertices $\langle b_i^{\delta', \circ}, b_i^{\delta', *}\rangle$ nor $\langle c_q^\circ, c_q^*\rangle$ for all $i \in [\sqrt{N}]$, $\delta' \in \{\alpha, \beta, \gamma\}$, and $q \in [m]$.

Proof.

1. Let G be a graph. For any false twins $u, v \in V(G)$ and any $w \in V(G) \setminus \{u, v\}$, $d(u, w) = d(v, w)$, and so, for any resolving set S of G , $S \cap \{u, v\} \neq \emptyset$. Hence, the statement follows for all $X \in \{C\} \cup \{B^\delta, A^\delta, P^\delta \mid \delta \in \{\alpha, \beta, \gamma\}\}$.
2. For all $X \in \{C\} \cup \{B^\delta, A^\delta, P^\delta \mid \delta \in \{\alpha, \beta, \gamma\}\}$, nullifier(X) is distinguished by $\text{bits}(X) \cap S$ as it is the only vertex in G at distance 2 from each vertex in $\text{bits}(X)$. We do a case analysis for the remaining non-critical pairs of vertices $\langle u, v \rangle$ assuming that nullifier(X) $\notin \{u, v\}$ (also, suppose that neither u nor v is in S , as otherwise, they are obviously distinguished):

Case i: $u, v \in X \cup X^+$.

Case i(a): $u, v \in X$ or $u, v \in \text{bit-rep}(X) \setminus \text{bits}(X)$. In the first case, let j be the bit in the binary representation of the subscript of u that is not equal to the j^{th} bit in the binary representation of the subscript of v (such a j exists since $\langle u, v \rangle$ is not a critical pair). In the second case, without loss of generality, let $u = y_i$ and $v = y_j$. By the first item of the statement of the lemma (1.), without loss of generality, $y_j^a \in S \cap \text{bits}(X)$. Then, in both cases, $d(y_j^a, u) \neq d(y_j^a, v)$.

Case i(b): $u \in X$ and $v \in \text{bit-rep}(X)$. Without loss of generality, $y_\star^a \in S \cap \text{bits}(X)$ (by 1.). Then, $d(y_\star^a, u) = 2$ and, for all $v \in \text{bits}(X) \setminus \{y_\star^b\}$, $d(y_\star^a, v) = 3$. Without loss of generality, let y_i be adjacent to u and let $y_i^a \in S \cap \text{bits}(X)$ (by 1.). Then, for $v = y_\star^b$, $3 = d(y_i^a, v) \neq d(y_i^a, u) = 2$. If $v \in \text{bit-rep}(X) \setminus \text{bits}(X)$, then, without loss of generality, $v = y_j$ and $y_j^a \in S \cap \text{bits}(X)$ (by 1.), and $1 = d(y_j^a, v) < d(y_j^a, u)$.

Case i(c): $u, v \in \text{bits}(X)$. Without loss of generality, $u = y_i^b$ and $y_i^a \in S$ (by 1.). Then, $2 = d(y_i^a, u) \neq d(y_i^a, v) = 3$.

Case i(d): $u \in \text{bits}(X)$ and $v \in \text{bit-rep}(X) \setminus \text{bits}(X)$. Without loss of generality, $v = y_i$ and $y_i^a \in S$ (by 1.). Then, $1 = d(y_i^a, v) < d(y_i^a, u)$.

Case ii: $u \in X \cup X^+$ and $v \in V(G) \setminus (X \cup X^+)$. For each $u \in X \cup X^+$, there exists $w \in \text{bits}(X) \cap S$ such that $d(u, w) \leq 2$, while, for each $v \in V(G) \setminus (X \cup X^+)$ and $w \in \text{bits}(X) \cap S$, we have $d(v, w) \geq 3$.

3. For all $X \in \{B^\delta, A^\delta, P^\delta \mid \delta \in \{\alpha, \beta, \gamma\}\}$, $u \in X^+$, $v \in \{c_q^\circ, c_q^*\}$, and $q \in [m]$, we have that $d(u, v) = d(u, \text{nullifier}(P^\delta)) + 1$. Further, for $X = C$ and all $u \in X^+$ and $q \in [m]$, either $d(u, c_q^\circ) = d(u, c_q^*) = 1$, $d(u, c_q^\circ) = d(u, c_q^*) = 2$, or $d(u, c_q^\circ) = d(u, c_q^*) = 3$ by the construction in Subsection 4.1.2 and since $\text{bit-rep}(X) \setminus \text{bits}(X)$ is a clique. Hence, for all $X \in \{C\} \cup \{B^\delta, A^\delta, P^\delta \mid \delta \in \{\alpha, \beta, \gamma\}\}$, vertices in $X^+ \cap S$ cannot resolve a pair of vertices $\langle c_q^\circ, c_q^* \rangle$ for any $q \in [m]$.

For all $\delta \in \{\alpha, \beta, \gamma\}$, if $v \in B^{\delta'}$, then, for all $X \in \{C\} \cup \{B^{\delta'}, A^{\delta'}, P^{\delta'} \mid \delta' \in \{\alpha, \beta, \gamma\}\}$ such that $\delta \neq \delta'$, and $u \in X^+$, we have that $d(u, v) = d(u, \text{nullifier}(A^\delta)) + 1$. Similarly, for all $\delta \in \{\alpha, \beta, \gamma\}$, if $v \in B^\delta$, then, for all $X \in \{A^\delta, P^\delta\}$ and $u \in X^+$, we have that $d(u, v) = d(u, \text{nullifier}(A^\delta)) + 1$. Lastly, for each $\langle b_i^{\delta, \circ}, b_i^{\delta, *}, \delta \in \{\alpha, \beta, \gamma\}$, and $i \in [\sqrt{N}]$, if $X = B^\delta$, then, for all $u \in X^+$, either $d(u, b_i^{\delta, \circ}) = d(u, b_i^{\delta, *}) = 1$, $d(u, b_i^{\delta, \circ}) = d(u, b_i^{\delta, *}) = 2$, or $d(u, b_i^{\delta, \circ}) = d(u, b_i^{\delta, *}) = 3$ by the construction in Subsection 4.1.2 and since $\text{bit-rep}(X) \setminus \text{bits}(X)$ is a clique. ◀

► **Lemma 10.** *If ψ is a satisfiable 3-PARTITIONED-3-SAT formula, then G admits a resolving set of size k .*

► **Lemma 11.** *If G admits a resolving set of size k , then ψ is a satisfiable 3-PARTITIONED-3-SAT formula.*

Proof of Theorem 6. In Subsection 4.2, we presented a reduction that takes an instance ψ of 3-PARTITIONED-3-SAT and returns an equivalent instance (G, k) of METRIC DIMENSION (by Lemmas 10 and 11) in $2^{\mathcal{O}(\sqrt{N})}$ time, where

$$k = 3 \cdot \left(\sqrt{N} + (\lceil \log(|B^\alpha|/2 + 2) \rceil + 1) + (\lceil \log(|A^\alpha| + 2) \rceil + 1) + (\lceil \log(|P^\alpha| + 2) \rceil + 1) \right) + (\lceil \log(|C|/2 + 2) \rceil + 1) = \mathcal{O}(\sqrt{N}).$$

Note that $V(G) = 2^{\mathcal{O}(\sqrt{N})}$. Further, note that taking all the vertices in B^δ and P^δ for all $\delta \in \{\alpha, \beta, \gamma\}$, and $X^+ \setminus \text{bits}(X)$ for all $X \in \{C\} \cup \{B^\delta, A^\delta, P^\delta \mid \delta \in \{\alpha, \beta, \gamma\}\}$, results in a vertex cover of G . Hence,

$$\text{vc}(G) \leq 3 \cdot ((\lceil \log(|B^\alpha|/2 + 2) \rceil + 2) + (\lceil \log(|A^\alpha| + 2) \rceil + 2) + (\lceil \log(|P^\alpha| + 2) \rceil + 2)) + 3 \cdot (|B^\alpha| + |P^\alpha|) + (\lceil \log(|C|/2 + 2) \rceil + 2) = \mathcal{O}(\sqrt{N}).$$

Thus, $\text{vc}(G) + k = \mathcal{O}(\sqrt{N})$. ◀

5 Geodetic Set: Algorithms for Vertex Cover Parameterization

To prove Theorem 1 for GEODETIC SET, we start with the following fact about false twins.

► **Lemma 12.** *If a graph G contains a set T of false twins that are not true twins and not simplicial, then any minimum-size geodetic set contains at most four vertices of T .*

Proof. Let $T = \{t_1, \dots, t_h\}$ be a set of false twins in a graph G , that are not true twins and not simplicial. Thus, T forms an independent set, and there are two non-adjacent vertices x, y in the neighborhood of the vertices in T . Toward a contradiction, assume that $h \geq 5$

33:14 Metric Dimension and Geodetic Set Parameterized by Vertex Cover

and G has a minimum-size geodetic set S that contains at least five vertices of T ; without loss of generality, assume $\{t_1, \dots, t_5\} \subseteq S$. We claim that $S' = (S \setminus \{t_1, t_2, t_3\}) \cup \{x, y\}$ is still a geodetic set, contradicting the choice of S as a minimum-size geodetic set of G .

To see this, notice that any vertex from $V(G) \setminus T$ that is covered by some pair of vertices in $T \cap S$ is also covered by t_4 and t_5 . Similarly, any vertex from $V(G) \setminus T$ covered by some pair $\langle t_i, z \rangle$ in $(S \cap T) \times (S \setminus T)$, is still covered by t_4 and z . Moreover, x and y cover all vertices of T , since they are at distance 2 from each other and all vertices in T are their common neighbors. Thus, S' is a geodetic set, as claimed. \blacktriangleleft

► **Lemma 13.** *GEODETIC SET, parameterized by the vertex cover number vc , admits a polynomial-time kernelization algorithm that returns an instance with $2^{\mathcal{O}(\text{vc})}$ vertices.*

Proof. Given a graph G , let $X \subseteq V(G)$ be a minimum-size vertex cover of G . If this vertex cover is not given, then we can find a 2-factor approximate vertex cover in polynomial time. Let $I := V(G) \setminus X$; I forms an independent set. The kernelization algorithm exhaustively applies the following reduction rules in a sequential manner.

▷ **Reduction Rule 2.** If there exist three simplicial vertices in G that are false twins or true twins, then delete one of them from G and decrease k by one.

▷ **Reduction Rule 3.** If there exist six vertices in G that are false twins but are not true twins nor simplicial, then delete one of them from G .

To see that Reduction Rule 2 is correct, assume that G contains three simplicial vertices u, v, w that are twins (false or true). We show that G has a geodetic set of size k if and only if the reduced graph G' , obtained from G by deleting u , has a geodetic set of size $k - 1$. For the forward direction, let S be a geodetic set of G of size k . By Observation 3, S contains each of u, v, w . Now, let $S' = S \setminus \{u\}$. This set of size $k - 1$ is a geodetic set of G' . Indeed, any vertex of G' that was covered in G by u and some other vertex z of S , is also covered by v and z in G' . Conversely, if G' has a geodetic set S'' of size $k - 1$, then it is clear that $S'' \cup \{u\}$ is a geodetic set of size k in G .

For Reduction Rule 3, assume that G contains six false twins (that are not true twins nor simplicial) as the set $T = \{t_1, \dots, t_6\}$, and let G' be the reduced graph obtained from G by deleting t_1 . We show that G has a geodetic set of size k if and only if G' has a geodetic set of size k . For the forward direction, let S be a minimum-size geodetic set of size (at most) k of G . By Lemma 12, S contains at most four vertices from T ; without loss of generality, t_1 and t_2 do not belong to S . Since the distances among all pairs of vertices in G' are the same as in G , S is still a geodetic set of G' . Conversely, let S' be a minimum-size geodetic set of G' of size (at most) k . Again, by Lemma 12, we may assume that one vertex among t_2, \dots, t_6 is not in S' , say, without loss of generality, that it is t_2 . Note that S' covers (in G) all vertices of G' . Thus, t_2 is covered by two vertices x, y of S' . But then, t_1 is also covered by x and y , since we can replace t_2 by t_1 in any shortest path between x and y . Hence, $S' \cup \{t_1\}$ is also a geodetic set of G .

Now, consider an instance on which the reduction rules cannot be applied. If $k < 0$, then we return a trivial NO-instance (for example, a single-vertex graph). Otherwise, notice that any set of false twins in I contains at most five vertices. Hence, G has at most $|X| + 5 \cdot 2^{|X|} = 2^{\mathcal{O}(\text{vc})}$ vertices. \blacktriangleleft

Next, we present an XP-algorithm parameterized by the vertex cover number. Together with Lemma 13, they imply Theorem 1 for GEODETIC SET.

► **Lemma 14.** *GEODETIC SET admits an algorithm running in $n^{\mathcal{O}(\text{vc})}$ time.*

Proof. The algorithm starts by computing a minimum vertex cover X of G in $2^{\mathcal{O}(\text{vc})} \cdot n^{\mathcal{O}(1)}$ time using an FPT algorithm for the VERTEX COVER problem, for example the one in [11] or [27]. Let $I := V(G) \setminus X$.

In polynomial time, we compute the set S of simplicial vertices of G . By Observation 3, any geodetic set of G contains all simplicial vertices of G . Note that $X \cup S$ is a geodetic set of G . Indeed, any vertex v from I that is not simplicial has two non-adjacent neighbors x, y in X , and thus, v is covered by x and y (which are at distance 2 from each other).

Hence, to enumerate all possible minimum-size geodetic sets, it suffices to enumerate all subsets S' of vertices of size at most $|X|$ in $(X \cup I) \setminus S$, and check whether $S \cup S'$ is a geodetic set. If one such set is indeed a geodetic set and has size at most k , we return YES. Otherwise, we return NO. The statement follows. ◀

6 Geodetic Set: Lower Bounds Regarding Vertex Cover

In this section, we follow the same template as in Section 4 and first prove the following theorem.

► **Theorem 15.** *There is an algorithm that, given an instance ψ of 3-PARTITIONED-3-SAT on N variables, runs in $2^{\mathcal{O}(\sqrt{N})}$ time, and constructs an equivalent instance (G, k) of GEODETIC SET such that $\text{vc}(G) + k = \mathcal{O}(\sqrt{N})$ (and $|V(G)| = 2^{\mathcal{O}(\sqrt{N})}$).*

The proofs of the following two corollaries are analogous to those for METRIC DIMENSION.

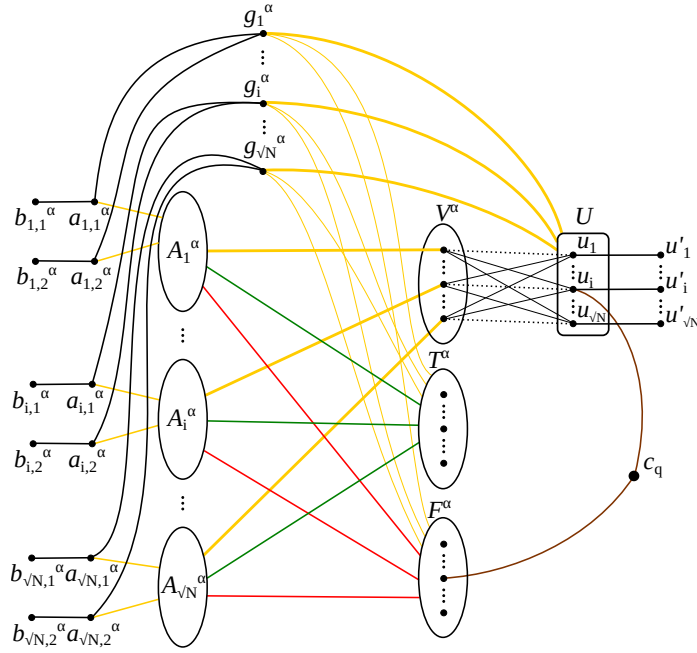

► **Corollary 16.** *Unless the ETH fails, GEODETIC SET does not admit an algorithm running in $2^{\mathcal{O}(\text{vc}^2)} \cdot n^{\mathcal{O}(1)}$ time.*

► **Corollary 17.** *Unless the ETH fails, GEODETIC SET does not admit a kernelization algorithm that does not increase the solution size k and outputs a kernel with $2^{\mathcal{O}(k+\text{vc})}$ vertices.*

6.1 Reduction

Consider an instance ψ of 3-PARTITIONED-3-SAT with $X^\alpha, X^\beta, X^\gamma$ the partition of the variable set, where $|X^\alpha| = |X^\beta| = |X^\gamma| = N$. By adding dummy variables in each of these sets, we can assume that \sqrt{N} is an integer. Further, let $\mathcal{C} = \{C_1, \dots, C_m\}$ be the set of all the clauses of ψ . From ψ , we construct the graph G as follows. We describe the construction for the part of the graph G corresponding to X^α , with the parts corresponding to X^β and X^γ being analogous. We rename the variables in X^α to $x_{i,j}^\alpha$ for $i, j \in [\sqrt{N}]$.

- We partition the variables of X^α into buckets $X_1^\alpha, X_2^\alpha, \dots, X_{\sqrt{N}}^\alpha$ such that each bucket contains \sqrt{N} many variables. Let $X_i^\alpha = \{x_{i,j}^\alpha \mid j \in [\sqrt{N}]\}$ for all $i \in [\sqrt{N}]$.
- For every bucket X_i^α , we add an independent set A_i^α of $2^{\sqrt{N}}$ new vertices, and we add two isolated edges $(a_{i,1}^\alpha, b_{i,1}^\alpha)$ and $(a_{i,2}^\alpha, b_{i,2}^\alpha)$. Let $B^\alpha = \{a_{i,j}^\alpha, b_{i,j}^\alpha \mid i \in [\sqrt{N}], j \in \{1, 2\}\}$. For all $i \in [\sqrt{N}]$ and $u \in A_i^\alpha$, we make both $a_{i,1}^\alpha$ and $a_{i,2}^\alpha$ adjacent to u (see Figure 4). Each vertex in A_i^α corresponds to a certain possible assignment of variables in X_i^α .
- Then, we add three independent sets T^α, F^α , and V^α on \sqrt{N} vertices each: $T^\alpha = \{t_i^\alpha \mid i \in [\sqrt{N}]\}$, $F^\alpha = \{f_i^\alpha \mid i \in [\sqrt{N}]\}$, and $V^\alpha = \{v_i^\alpha \mid i \in [\sqrt{N}]\}$.
- For each $i \in [\sqrt{N}]$, we connect v_i^α with all the vertices in A_i^α .
- For each $i \in [\sqrt{N}]$, we add edges between A_i^α and T^α and between A_i^α and F^α as follows. Consider a vertex $w \in A_i^\alpha$. Recall that this vertex corresponds to an assignment $\pi : X_i^\alpha \mapsto \{\text{True}, \text{False}\}$, where X_i^α is the collection of variables $\{x_{i,j}^\alpha \mid j \in [\sqrt{N}]\}$. If $\pi(x_{i,j}^\alpha) = \text{True}$, then we add the edge (w, t_j^α) , and otherwise, we add the edge (w, f_j^α) .

■ **Figure 4** Overview of the reduction. Sets in ellipses are independent sets, and sets in rectangles are cliques. For each $\delta \in \{\alpha, \beta, \gamma\}$, the sets V^δ and U almost form a complete bipartite graph, except for the matching (marked by dotted edges) that is excluded. Yellow lines from a vertex to a set denote that this vertex is connected to all the vertices in that set. The green and red lines between the A_i^α and $T^\alpha \cup F^\alpha$ transfer, in some sense, for each $w \in A_i^\alpha$, the underlying assignment structure. If an underlying assignment w sets the j^{th} variable to **True**, then we add the green edge (w, t_j^α) , and otherwise, we add the red edge (w, f_j^α) . For all $q \in [m]$ and $\delta \in \{\alpha, \beta, \gamma\}$, let $x_{i,j}^\delta$ be the variable in X^δ that is contained in the clause C_q in ψ . So, for all $q \in [m]$, if assigning **True** (**False**, respectively) to $x_{i,j}^\delta$ satisfies C_q , then we add the edge (c_q, t_j^δ) ((c_q, f_j^δ) , respectively).

- For each $i \in [\sqrt{N}]$, we add a special vertex g_i^α (also referred to as a g -vertex later on) that is adjacent to each vertex in $T^\alpha \cup F^\alpha$. Further, g_i^α is also adjacent to both $a_{i,1}^\alpha$ and $a_{i,2}^\alpha$ (see Figure 4).

This finishes the first part of the construction. The second step is to connect the three previously constructed parts for X^α , X^β , and X^γ .

- We introduce a vertex set $U = \{u_i \mid i \in [\sqrt{N}]\}$ that forms a clique. Then, for each u_i , we add an edge to a new vertex u'_i . Thus, we have a matching $\{(u_i, u'_i) \mid i \in [\sqrt{N}]\}$. Let $U' = \{u'_i \mid i \in [\sqrt{N}]\}$.
- For each $\delta \in \{\alpha, \beta, \gamma\}$, we add edges so that the vertices of $U \cup V^\delta$ almost form a complete bipartite graph, i.e., $E(G)$ contains edges between all pairs $\langle v, w \rangle$ where $v \in U$ and $w \in V^\delta$, except for the matching $\{(v_i^\delta, u_i) \mid i \in [\sqrt{N}]\}$.
- For each $\delta \in \{\alpha, \beta, \gamma\}$ and $i \in [\sqrt{N}]$, we make g_i^δ adjacent to each vertex in U .
- For each $C_q \in \mathcal{C}$, we add a new vertex c_q . Let $C = \{c_q \mid q \in [m]\}$. Since we are considering an instance of 3-PARTITIONED-3-SAT, for each $\delta \in \{\alpha, \beta, \gamma\}$, there is at most one variable in C_q that lies in X^δ . If there is one, then without loss of generality, let it be $x_{i,j}^\delta$ and do the following. Make c_q adjacent to u_i and if $x_{i,j}^\delta = \text{True}$ ($x_{i,j}^\delta = \text{False}$, respectively) satisfies C_q , then $(c_q, t_j^\delta) \in E(G)$ ($(c_q, f_j^\delta) \in E(G)$, respectively).

This concludes the construction of G . The reduction returns (G, k) as an instance of GEODETIC SET where $k = 10\sqrt{N}$.

6.2 Correctness of the Reduction

Suppose, given an instance ψ of 3-PARTITIONED-3-SAT, that the reduction above returns (G, k) as an instance of GEODETIC SET. We first prove the following lemmas which will be helpful in proving the correctness of the reduction, and note that we use distances between vertices to prove that certain vertices are not contained in shortest paths.

► **Lemma 18.** *For all $\delta, \delta' \in \{\alpha, \beta, \gamma\}$, the shortest paths between any two vertices in $B^\delta \cup U \cup U'$ do not cover any vertices in C nor $V^{\delta'}$.*

► **Lemma 19.** *For all $i \in [\sqrt{N}]$ and $\delta \in \{\alpha, \beta, \gamma\}$, v_i^δ can only be covered by a shortest path from a vertex in $A_i^\delta \cup \{v_i^\delta\}$ to another vertex in G .*

► **Lemma 20.** *If G admits a geodetic set of size k , then ψ is a satisfiable 3-PARTITIONED-3-SAT formula.*
