Contents

Preface
Oswin Aichholzer and Haitao Wang 0:xi–0:xii

Conference Organization
..... 0:xiii–0:xv

Additional Reviewers
..... 0:xvii–0:xxii

Regular Papers

Reconfiguration of Unit Squares and Disks: PSPACE-Hardness in Simple Settings
Mikkel Abrahamsen, Kevin Buchin, Maike Buchin, Linda Kleist, Maarten Löffler, Lena Schlipf, André Schulz, and Jack Stade 1:1–1:18

The Maximum Number of Digons Formed by Pairwise Intersecting Pseudocircles
Eyal Ackerman, Gábor Damásdi, Balázs Keszegh, Rom Pinchasi, and Rebeka Raffay 2:1–2:14

Convexity Helps Iterated Search in 3D
Peyman Afshani, Yakov Nekrich, and Frank Staals 3:1–3:14

A Subquadratic Algorithm for Computing the L_1-Distance Between Two Terrains
Pankaj K. Agarwal, Boris Aronov, Olivier Devillers, Christian Knauer, and Guillaume Moroz 4:1–4:17

Optimal Motion Planning for Two Square Robots in a Rectilinear Environment
Pankaj K. Agarwal, Mark de Berg, Benjamin Holmgren, Alex Steiger, and Martijn Struijs 5:1–5:17

A Sparse Multicover Bifiltration of Linear Size
Ángel Javier Alonso 6:1–6:18

Single-Source Shortest Path Problem in Weighted Disk Graphs
Shinwoo An, Eunjin Oh, and Jie Xue 7:1–7:15

Rapid Mixing of the Flip Chain over Non-Crossing Spanning Trees
Konrad Anand, Weiming Feng, Graham Freifeld, Heng Guo, Mark Jerrum, and Jiaheng Wang 8:1–8:18

Geometric Realizations of Dichotomous Ordinal Graphs
Patrizio Angelini, Sabine Cornelsen, Carolina Haase, Michael Hoffmann, Eleni Katsanou, Fabrizio Montecchiani, Raphael Steiner, and Antonios Symvonis 9:1–9:16

Steinhaus Filtration and Stable Paths in the Mapper
Dustin L. Arendt, Matthew Broussard, Bala Krishnamoorthy, Nathaniel Saul, and Amber Thrall 10:1–10:21

When Alpha-Complexes Collapse onto Codimension-1 Submanifolds
Dominique Attali, Mattéo Clémot, Bianca B. Dornelas, and André Lieutier 11:1–11:19

Higher-Order Color Voronoi Diagrams and the Colorful Clarkson–Shor Framework
Sang Won Bae, Nicolau Oliver, and Evanthia Papadopoulou 12:1–12:19

41st International Symposium on Computational Geometry (SoCG 2025).
Editors: Oswin Aichholzer and Haitao Wang
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

The Erdős–Szekeres Conjecture Revisited
Jineon Baek and Martin Balko 13:1–13:15

Extremal Betti Numbers and Persistence in Flag Complexes
Lies Beers and Magnus Bakke Botnan 14:1–14:18

When Distances Lie: Euclidean Embeddings in the Presence of Outliers and Distance Violations
Matthias Bentert, Fedor V. Fomin, Petr A. Golovach, M. S. Ramanujan, and Saket Saurabh 15:1–15:16

Signotopes with Few Plus Signs
Helena Bergold, Lukas Egeling, and Hung P. Hoang 16:1–16:14

Sparse Bounded Hop-Spanners for Geometric Intersection Graphs
Sujoy Bhore, Timothy M. Chan, Zhengcheng Huang, Shakhar Smorodinsky, and Csaba D. Tóth 17:1–17:15

Finding a Shortest Curve That Separates Few Objects from Many
Therese Biedl, Éric Colin de Verdière, Fabrizio Frati, Anna Lubiw, and Günter Rote 18:1–18:16

Polychromatic Coloring of Tuples in Hypergraphs
Ahmad Biniaz, Jean-Lou De Carufel, Anil Maheshwari, Michiel Smid, Shakhar Smorodinsky, and Miloš Stojaković 19:1–19:17

Polynomial-Time Algorithms for Contiguous Art Gallery and Related Problems
Ahmad Biniaz, Anil Maheshwari, Magnus Christian Ring Merrild, Joseph S. B. Mitchell, Saeed Odak, Valentin Polishchuk, Eliot W. Robson, Casper Moldrup Rysgaard, Jens Kristian Refsgaard Schou, Thomas Shermer, Jack Spalding-Jamieson, Rolf Svenning, and Da Wei Zheng 20:1–20:21

Structure and Independence in Hyperbolic Uniform Disk Graphs
Thomas Bläsius, Jean-Pierre von der Heydt, Sándor Kisfaludi-Bak, Marcus Wilhelm, and Geert van Wordragen 21:1–21:16

Transforming Dogs on the Line: On the Fréchet Distance Under Translation or Scaling in 1D
Lotte Blank, Jacobus Conradi, Anne Driemel, Benedikt Kolbe, André Nusser, and Marena Richter 22:1–22:16

On the Twin-Width of Smooth Manifolds
Édouard Bonnet and Kristóf Huszár 23:1–23:16

An 11/6-Approximation Algorithm for Vertex Cover on String Graphs
Édouard Bonnet and Paweł Rzążewski 24:1–24:15

Approximating Klee's Measure Problem and a Lower Bound for Union Volume Estimation
Karl Bringmann, Kasper Green Larsen, André Nusser, Eva Rotenberg, and Yanheng Wang 25:1–25:16

Geometric Spanners of Bounded Tree-Width
Kevin Buchin, Carolin Rehs, and Torben Scheele 26:1–26:15

Computing Oriented Spanners and Their Dilation
Kevin Buchin, Antonia Kalb, Anil Maheshwari, Saeed Odak, Carolin Rehs, Michiel Smid, and Sampson Wong 27:1–27:17

Small Triangulations of 4-Manifolds and the 4-Manifold Census
Rhuaidi Antonio Burke, Benjamin A. Burton, and Jonathan Spreer 28:1–28:16

Sparsification of the Generalized Persistence Diagrams for Scalability Through Gradient Descent
Mathieu Carrière, Seunghyun Kim, and Woojin Kim 29:1–29:17

Computation of Toroidal Schnyder Woods Made Simple and Fast: From Theory to Practice
Luca Castelli Aleardi, Eric Fusy, Jyh-Chwen Ko, and Razvan-Stefan Puscasu 30:1–30:19

A Linear Time Algorithm for the Maximum Overlap of Two Convex Polygons Under Translation
Timothy M. Chan and Isaac M. Hair 31:1–31:16

Faster Algorithms for Reverse Shortest Path in Unit-Disk Graphs and Related Geometric Optimization Problems: Improving the Shrink-And-Bifurcate Technique
Timothy M. Chan and Zhengcheng Huang 32:1–32:14

On Zarankiewicz's Problem for Intersection Hypergraphs of Geometric Objects
Timothy M. Chan, Chaya Keller, and Shakhar Smorodinsky 33:1–33:14

Simplification of Trajectory Streams
Siu-Wing Cheng, Haoqiang Huang, and Le Jiang 34:1–34:14

A Theory of Sub-Barcodes
Oliver A. Chubet, Kirk P. Gardner, and Donald R. Sheehy 35:1–35:16

Strongly Sublinear Separators and Bounded Asymptotic Dimension for Sphere Intersection Graphs
James Davies, Agelos Georgakopoulos, Meike Hatzel, and Rose McCarty 36:1–36:16

Nearest Neighbor Searching in a Dynamic Simple Polygon
Sarita de Berg and Frank Staals 37:1–37:15

An Algorithm for Tambara-Yamagami Quantum Invariants of 3-Manifolds, Parameterized by the First Betti Number
Colleen Delaney, Clément Maria, and Eric Samperton 38:1–38:15

Tiling with Three Polygons Is Undecidable
Erik D. Demaine and Stefan Langerman 39:1–39:16

Apex Representatives
Tamal K. Dey, Tao Hou, and Dmitriy Morozov 40:1–40:16

Decomposing Multiparameter Persistence Modules
Tamal K. Dey, Jan Jendrysiak, and Michael Kerber 41:1–41:19

Range Counting Oracles for Geometric Problems
Anne Driemel, Morteza Monemizadeh, Eunjin Oh, Frank Staals, and David P. Woodruff 42:1–42:16

On Spheres with k Points Inside
Herbert Edelsbrunner, Alexey Garber, and Morteza Saghafian 43:1–43:12

A Minor-Testing Approach for Coordinated Motion Planning with Sliding Robots
Eduard Eiben, Robert Ganian, Iyad Kanj, and M. S. Ramanujan 44:1–44:15

Higher Order Bipartiteness vs Bi-Partitioning in Simplicial Complexes
Marzieh Eidi and Sayan Mukherjee 45:1–45:12

Non-Euclidean Erdős–Anning Theorems
David Eppstein 46:1–46:15

Shelling and Sinking Graphs on the Sphere
Jeff Erickson and Christian Howard 47:1–47:18

Exact Algorithms for Minimum Dilation Triangulation
Sándor P. Fekete, Phillip Keldenich, and Michael Perk 48:1–48:18

On Sparse Covers of Minor Free Graphs, Low Dimensional Metric Embeddings, and Other Applications
Arnold Filtser 49:1–49:16

Immersions and Albertson's Conjecture
Jacob Fox, János Pach, and Andrew Suk 50:1–50:10

Quantum Combine and Conquer and Its Applications to Sublinear Quantum Convex Hull and Maxima Set Construction
Shion Fukuzawa, Michael T. Goodrich, and Sandy Irani 51:1–51:15

Uniform Bounds on Product Sylvester-Gallai Configurations
Abhibhav Garg, Rafael Oliveira, and Akash Kumar Sengupta 52:1–52:15

A PTAS for TSP with Neighbourhoods over Parallel Line Segments
Benyamin Ghaseminia and Mohammad R. Salavatipour 53:1–53:15

The Fréchet Distance Unleashed: Approximating a Dog with a Frog
Sariel Har-Peled, Benjamin Raichel, and Eliot W. Robson 54:1–54:13

A Practical Algorithm for Knot Factorisation
Alexander He, Eric Sedgwick, and Jonathan Spreer 55:1–55:15

Sublinear Data Structures for Nearest Neighbor in Ultra High Dimensions
Martin G. Herold, Danupon Nanongkai, Joachim Spoerhase, Nithin Varma, and Zihang Wu 56:1–56:15

Snap Rounding: A Cautionary Tale
John Hershberger 57:1–57:14

Tracking the Persistence of Harmonic Chains: Barcode and Stability
Tao Hou, Salman Parsa, and Bei Wang 58:1–58:16

Incremental Planar Nearest Neighbor Queries with Optimal Query Time
John Iacono and Yakov Nekrich 59:1–59:15

Improved Approximation Algorithms for Three-Dimensional Knapsack
Klaus Jansen, Debajyoti Kar, Arindam Khan, K. V. N. Sreenivas, and Malte Tutas 60:1–60:18

k-Dimensional Transversals for Fat Convex Sets
Attila Jung and Dömötör Pálvölgyi 61:1–61:12

On Approximability of ℓ_2^2 Min-Sum Clustering
Karthik C. S., Euiwoong Lee, Yuval Rabani, Chris Schwiegelshohn, and Samson Zhou 62:1–62:18

The Maximum Clique Problem in a Disk Graph Made Easy
J. Mark Keil and Debajyoti Mondal 63:1–63:16

Super-Polynomial Growth of the Generalized Persistence Diagram
Donghan Kim, Woojin Kim, and Wonjun Lee 64:1–64:20

Recognizing 2-Layer and Outer k-Planar Graphs
Yasuaki Kobayashi, Yuto Okada, and Alexander Wolff 65:1–65:16

Lipschitz Decompositions of Finite ℓ_p Metrics
Robert Krauthgamer and Nir Petruschka 66:1–66:14

Hard Diagrams of Split Links
Corentin Lunel, Arnaud de Mesmay, and Jonathan Spreer 67:1–67:17

Persistent (Co)Homology in Matrix Multiplication Time
Dmitriy Morozov and Primoz Skraba 68:1–68:16

Computing Betti Tables and Minimal Presentations of Zero-Dimensional Persistent Homology
Dmitriy Morozov and Luis Scoccola 69:1–69:15

Computing Geomorphologically Salient Networks via Discrete Morse Theory
Tim Ophelders, Anna Schenfisch, Willem Sonke, and Bettina Speckmann 70:1–70:17

Banana Trees for the Persistence in Time Series Experimentally
Lara Ost, Sebastiano Cultrera di Montesano, and Herbert Edelsbrunner 71:1–71:13

Geometric Bipartite Matching Based Exact Algorithms for Server Problems
Sharath Raghvendra, Pouyan Shirzadian, and Rachita Sowle 72:1–72:15

Embedding Graphs as Euclidean kNN-Graphs
Thomas Schibler, Subhash Suri, and Jie Xue 73:1–73:14

The Point-Boundary Art Gallery Problem Is $\exists\mathbb{R}$-Hard
Jack Stade 74:1–74:23

Levels in Arrangements: Linear Relations, the g-Matrix, and Applications to Crossing Numbers
Elizaveta Streltsova and Uli Wagner 75:1–75:18

A Note on the No-$(d+2)$-On-a-Sphere Problem
Andrew Suk and Ethan Patrick White 76:1–76:8

Dynamic Maximum Depth of Geometric Objects
Subhash Suri, Jie Xue, Xiongxin Yang, and Jiumu Zhu 77:1–77:13

Efficient Greedy Discrete Subtrajectory Clustering
Ivor van der Hoog, Lara Ost, Eva Rotenberg, and Daniel Rutschmann 78:1–78:20

CG Challenges

Computing Non-Obtuse Triangulations with Few Steiner Points
Mikkel Abrahamsen, Florestan Brunck, Jacobus Conradi, Benedikt Kolbe, and André Nusser 79:1–79:13

Incremental Algorithm and Local Search for Minimum Non-Obtuse Triangulations
Taehoon Ahn, Jaegun Lee, Byeonguk Kang, and Hwi Kim 80:1–80:8

Media Expositions

AmoebotSim 2.0: A Visual Simulation Environment for the Amoebot Model with Reconfigurable Circuits and Joint Movements
Matthias Artmann, Tobias Maurer, Andreas Padalkin, Daniel Warner, and Christian Scheideler 81:1–81:5

Software for the Thompson and Funk Polygonal Geometry
Hridhaan Banerjee, Carmen Isabel Day, Auguste H. Gezalyan, Olga Golovatskaia, Megan Hunleth, Sarah Hwang, Nithin Parepally, Lucy Wang, and David M. Mount 82:1–82:6

French Onion Soup, Ipelets for Points and Polygons
Klint Faber, Auguste H. Gezalyan, Adam Martinson, Aniruddh Mutnuru, Nithin Parepally, Ryan Parker, Mihil Sreenilayam, Aram Zaprosyan, and David M. Mount 83:1–83:6

Incremental and Interactive PQ- and PC-Trees
Simon D. Fink and Dominik Peters 84:1–84:4

Finding Shortest Reconfiguration Sequences for Modular Robots
UML Modular Robotics Group, Hugo A. Akitaya, Andrew Clements, Sam Downey, Jonathan Eisenbies, Soham Samanta, Gabriel Shahrouzi, and Frederick Stock 85:1–85:5

Preface

The 41st International Symposium on Computational Geometry (SoCG 2025) was held in Kanazawa, Japan, June 23–27, 2025, as part of the Computational Geometry Week (CG Week 2025).

The symposium received 225 submissions, the second highest in the symposium's history, and after a thorough review process, in which each paper was evaluated by three or more independent reviewers, the program committee accepted 78 papers for presentation. These proceedings contain extended abstracts of the accepted papers, limited to 500 lines (excluding references). If any supporting material does not fit in the line limit, the full paper is available at a public repository and referenced in the corresponding extended abstract.

The **Best Paper Award** of SoCG 2025 went to the paper "A Linear Time Algorithm for the Maximum Overlap of Two Convex Polygons Under Translation" by Timothy M. Chan and Isaac M. Hair; this paper has been invited to submit an extended version to the Journal of the ACM. The **Best Student Paper Award** of SoCG 2025 went to the paper "A Sparse Multicover Bifiltration of Linear Size" by Ángel Javier Alonso. This was the second year bestowing a best student paper award; all authors of the paper needed to be students at the time of submission to be eligible. The **Best Student Presentation Award** was determined and announced at the symposium, based on ballots cast by the attendees. For the second time since last year, a paper was selected for submission to the newly-established diamond open access journal TheoretiCS: "Levels in Arrangements: Linear Relations, the g-Matrix, and Applications to Crossing Numbers" by Elizaveta Streltsova and Uli Wagner. Additionally, a selection of papers was invited to submit extended versions to forthcoming special issues of Discrete & Computational Geometry and the Journal of Computational Geometry dedicated to the symposium.

The **SoCG Test of Time Awards** of this year went to "Linear Programming and Convex Hulls Made Easy" by Raimund Seidel, which was published in SoCG 1990, and to "Stability of Persistence Diagrams" by David Cohen-Steiner, Herbert Edelsbrunner, and John Harer, which was published in SoCG 2005.

The scientific program of CG Week 2025 was enriched by two distinguished invited speakers. An invited talk, entitled "Computational Origami for Art, Science, and Industry", was given by Tomohiro Tachi from The University of Tokyo. A second invited talk, entitled "Parameterized Computational Geometry: Visibility Problems, Geometric Intersection Graphs and Graph Drawing", was delivered by Meirav Zehavi from Ben-Gurion University of the Negev. We thank the plenary speakers for kindly accepting our invitation.

In addition to the technical papers, there were six submissions to the multimedia exposition. Submissions were reviewed and five of them were accepted for presentation. The extended abstracts that describe these submissions are included in this proceedings volume. The multimedia content can be found at `https://www.computational-geometry.org`.

The 7th Computational Geometry Challenge was part of CG Week 2025. The challenge problem was about minimum non-obtuse triangulations. This year, there were ten teams participating in the challenge, and these proceedings contain contributions by the two top-placed teams describing their winning approaches.

We thank the authors of all submitted works. We are most grateful to the members of the SoCG Program Committee, the Media Exposition Committee, and the CG Challenge Committee for their dedication, expertise, and hard work that ensured the high quality of the works in these proceedings. We are grateful for the assistance provided by the hundreds

of reviewers; without their help, it would have been impossible to run the selection process. Finally, we thank Philipp Kindermann for meticulous work as Proceedings Chair.

Many other people contributed to the success of SoCG 2025 and the entire CG Week. We are very grateful to the local organization committee for their work in organizing the event. Finally, we thank all the members of the Test of Time Award, Workshop, and Young Researchers Forum Committees, the CG Challenge Advisory Board, and the CG Week Steering Committee.

Abstract

We study well-known reconfiguration problems. Given a start and a target configuration of geometric objects in a polygon, we wonder whether we can move the objects from the start configuration to the target configuration while avoiding collisions between the objects and staying within the polygon. Problems of this type have been considered since the early 80s by roboticists and computational geometers. In this paper, we study some of the simplest possible variants where the objects are labeled or unlabeled unit squares or unit disks. In unlabeled reconfiguration, the objects are identical, so that any object is allowed to end at any of the targets positions. In the labeled variant, each object has a designated target position. The results for the labeled variants are direct consequences from our insights on the unlabeled versions.

We show that it is PSPACE-hard to decide whether there exists a reconfiguration of (unlabeled/labeled) unit squares even in a simple polygon. Previously, it was only known to be PSPACE-hard in a polygon with holes for both the unlabeled and labeled version [Solovey and Halperin, Int. J. Robotics Res. 2016]. Our proof is based on a result of independent interest, namely that reconfiguration between two satisfying assignments of a formula of Monotone-Planar-3-Sat is also PSPACE-complete. The reduction from reconfiguration of Monotone-Planar-3-Sat to reconfiguration of unit squares extends techniques recently developed to show NP-hardness of packing unit squares in a simple polygon [Abrahamsen and Stade, FOCS 2024]. We also show PSPACE-hardness of reconfiguration of (unlabeled/labeled) unit disks in a polygon with holes. Previously, it was known that unlabeled reconfiguration of disks of two different sizes was PSPACE-hard [Brocken, van der Heijden, Kostitsyna, Lo-Wong and Surtel, FUN 2021].

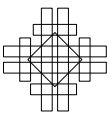

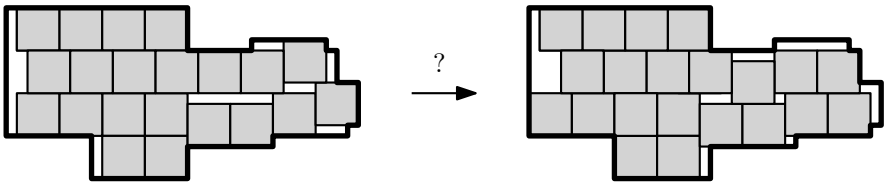

Figure 1 Can the left configuration of unit squares in a simple polygon be reconfigured to the right configuration of unit squares?

1 Introduction

In *geometric reconfiguration* we are given a start configuration of geometric *objects* and a desired target configuration. A particularly well-studied geometric configuration problem is *multi-robot motion planning*. The goal is to move the robots (or objects) from the start position to the target configuration while avoiding collisions. Problems of this type have been considered since the early 80s by roboticists and computational geometers. Hopcroft, Schwartz and Sharir [14] showed already in 1984 that reconfiguration of labeled rectangles moving in a rectangle is PSPACE-hard. The motivation of their work was "to find moving systems (necessarily involving arbitrarily many degrees of freedom) whose geometry is *as simple as possible*, but for which the motion planning problem is still PSPACE-hard".

In this paper, we study some of the simplest possible variants where the objects are unlabeled or labeled axis-aligned congruent squares or unit disks. In case of squares, the objects have to stay axis-aligned during the reconfiguration. For an example, consider Figure 1. Obstacles are modeled by the workspace in which the objects lie. At any time, the objects have to avoid the complement of the workspace. Depending on the variant, the workspace is given as a polygon, a simple polygon, or a grid polygon, that is an orthogonal polygon whose vertex coordinates are integers. In unlabeled reconfiguration, the objects are indistinguishable, so that any object is allowed to end at any of the target positions. In labeled reconfiguration the target position for every object is explicitly given. Table 1 presents an overview of the known results and the new results of this paper.

Table 1 Summary of results in motion planning for multiple objects.

Contribution	Labeled	Complexity	Objects	Workspace
[14]	yes	PSPACE-hard	rectangles	rectangle

easy exercise	no	trivial "yes"	unit squares	grid polygon
[21]	yes	strongly NP-hard	disks of three sizes	simple polygon
this work	yes	PSPACE-hard	unit disks	polygon (with holes)
[4]	no	PSPACE-hard	disks of two sizes	polygon (with holes)
this work	no	PSPACE-hard	unit disks	polygon (with holes)

Recent results of PSPACE-hardness of geometric reconfiguration problems have been proven by a reduction from Nondeterministic Constrained Logic (NCL) [11, 13]. This holds for instance for the works [4, 5, 12, 19]. Here, a polygon is built "on top of" an instance of NCL, which is in itself a plane graph (the problem NCL will be described in detail in Section 2). This technique inevitably leads to a polygon with holes, because the bounded faces of the NCL-instance are turned into holes of the polygon.

A similar phenomenon appears in many proofs of NP-hardness of two-dimensional geometric problems where the input is a polygon: Such reductions are often from a variant of Planar-3-Sat and work by building a polygon on top of the Planar-3-Sat-instance we are reducing from. Again, this leads to a polygon with a hole for every bounded face of the graph representing the Planar-3-Sat-formula.

Abrahamsen and Stade [1] recently overcame this obstacle by making a novel reduction from Planar-3-Sat in order to obtain NP-hardness of the well-known problem of packing unit squares in a simple polygon; a problem that had been known to be NP-hard for polygons with holes since 1981 [8]. Interestingly, Abrahamsen and Stade [1] used a non-planar geometric realization of a planar formula, where variables are represented as horizontal rows and edges are vertical columns. These rows and columns are allowed to cross, but the planarity of the graph ensures that the endpoints of all rows and columns are incident to the outer face of the drawing. This makes it possible to construct a simple polygon, following the boundary of the outer face, that "implements" the functionality of the rows and columns. The rows and columns of the drawing are represented by rows and columns of squares, and these likewise cross each other in the interior of the polygon. The crucial observation is that movement in one direction does not influence movement in the other direction, so binary values can be "transported" independently in both directions through a crossing.

Our contribution. In this paper we show PSPACE-hardness of reconfiguration of unit squares in a simple polygon. To this end, we first show a result of independent interest. The solution space of boolean formulas is given by an hypercube graph, where edges are formed between assignments which differ in exactly one variable. The satisfying assignments of a formula ϕ define a subgraph of this graph, which we call $G(\phi)$. We call two satisfying assignments *connected* if they are connected in $G(\phi)$. The reconfiguration problem for boolean formulas asks if two satisfying assignments are connected. We show the following result.

▶ **Theorem 1.** *The reconfiguration problem for Monotone-Planar-3-Sat formulas is* PSPACE*-complete.*

For some other versions of 3-Sat, the reconfiguration problem has likewise been shown to be PSPACE-hard, such as Monotone-Planar-Not-All-Equal-3-SAT [6]. In Table 2, we give a summary of some variants of 3-Sat and the complexity of their satisfyability and reconfiguration problems. Interestingly, most satisfiability and reconfiguration problems are hard, but there are some exceptions that can be solved in polynomial time.

Using Theorem 1, we show PSPACE-hardness for reconfiguration of squares.

▶ **Theorem 2.** *Unlabeled reconfiguration of* 8×8 *squares in simple grid polygons is* PSPACE*-complete.*

This implies PSPACE-hardness for reconfiguration of unit squares in simple polygons. We also remark that the size of the coordinates of the constructed polygon is $O(n^2)$, where n is the number of corners.

In our construction, the squares can only move locally. Hence, we exactly know the start and end position of each square and also obtain the same result for the labeled version.

Table 2 Overview of computational complexity for the satisfiability and reconfiguration problems of fundamental 3-Sat variants.

	Satisfiability	Reconfiguration
3-Sat	NP-complete [15]	PSPACE-complete [10]
Planar-3-Sat	NP-complete [17]	PSPACE-complete [6]
Positive-1-in-3-SAT	NP-complete [9]	P ('no' iff assignments differ)
Positive-Not-All-Equal-3-SAT	NP-complete [18]	PSPACE-complete [10]
Mon.-Planar-Not-All-Eequal-3-SAT	P [18]	PSPACE-complete [6]
Monotone-Planar-3-Sat	NP-complete [7]	PSPACE-complete [This work]

▶ **Corollary 3.** *Labeled reconfiguration of* 8×8 *squares in simple grid polygons is* PSPACE*-complete.*

Theorem 2 and Corollary 3 strengthen the results of Solovey and Halperin [19], who showed that the problem is PSPACE-hard for polygons with holes in the unlabeled and labeled variants. In contrast, in grid polygons, it is an easy exercise to show that reconfiguration of unlabeled unit squares is always doable (if the number of squares agrees) and reconfiguration of labeled unit squares is polynomial time decidable [16]. Hence, our result is close to the border of polynomial-time decidability.

Lastly, we consider the reconfiguration of unit disks.

▶ **Theorem 4.** *Reconfiguration of unlabeled unit disks in a polygon (possibly with holes) is* PSPACE*-hard.*

Before, it was only known that reconfiguration of unlabeled disks of two different sizes was PSPACE-hard, as shown by Brocken, van der Heijden, Kostitsyna, Lo-Wong and Surtel [4]. For disks of the same size so far only positive results were known under the assumption that there is sufficient separation between the start and target positions of the disks in a simple polygon [2, 3] and also in a polygon with holes [20]. The main technical challenge here is to artificially discretize the continuous space of disk configurations, to avoid allowing global states in which many gadgets are locally in an "in-between" state which would break the reduction. We overcome this challenge by designing a special edge gadget that enforces the consistent orientation of an edge, and argue that only one edge may be reoriented at a time. Thus, our results in particular show that an assumption such as the separation assumption in [20] is necessary if $\mathsf{P} \neq \mathsf{PSPACE}$.

In fact, our constructed polygon guarantees that no two disks may swap their positions. Therefore, hardness for the labeled version follows immediately.

▶ **Corollary 5.** *Reconfiguration of labeled unit disks in a polygon (possibly with holes) is* PSPACE*-hard.*

Previously, Spikaris and Yap [21] showed NP-hardness for labeled disks of three different sizes.

Organization of the paper. The rest of the paper is structured as follows. In Section 2, we briefly introduce NCL and and present the general idea of the NP-hardness proof for Monotone-Planar-3-Sat. In Section 3, we prove that the reconfiguration of unit squares in a simple polygon is PSPACE-hard, by reducing from reconfiguration of Monotone-Planar-3-Sat. Finally, in Section 4, we show that the reconfiguration of unit disks in a

polygon with holes is PSPACE-hard, by a reduction from NCL. We conclude with a discussion in Section 5. The proofs of all statements marked by ($\star$) and the full proof of Theorem 1 are presented in the full version.

2 Reconfiguration of Monotone-Planar-3-Sat

Here we sketch a proof of the PSPACE-hardness where we reduce from NCL. We start by reviewing the configuration-to-configuration variant of the NCL problem. An instance is given by an oriented planar cubic graph G and an reorientation G' of G. Each edge is colored red or blue, such that each vertex is incident to either three blue edges, or one blue edge and two red edge. The orientations of G and G' need to be *feasible*, that is, the indegree of every vertex is at least two, where blue edges count with multiplicity 2. An NCL-instance is positive, if and only if there is a sequence of edge reversals that transforms G to G' such that each intermediate orientation is feasible.

For the reduction we start with an embedding of G and modify G such that it becomes the vertex-clause-incidence graph of a formula ϕ. Any satisfying assignment of the variables of ϕ encodes a feasible orientation of G and vice versa. Furthermore, if two feasible orientations of G differ by the orientation of a single edge, the corresponding satisfying variable assignments differ by two variable flips. Moreover, any variable flip corresponds to two feasible orientations of G that differ by at most one edge reorientation. A key idea is to replace all vertices of G with one or two clause nodes and every edge with a variable node as sketched in Figure 2. A variable x_e for an edge e is `true`, if and only if the current orientation of e matches the orientation of e in G.

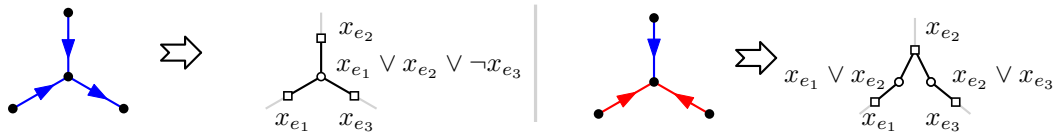

Figure 2 Mapping an NCL-Instance to an embedding of a planar 3-SAT formula. Variable nodes are drawn as squares, clause nodes are drawn as disks.

To prove that the embedding of the variable-clause incidence graph has the required properties we have to extend ϕ. In particular, we have to ensure that on every face in the planar embedding of the clause-variable incidence graph of ϕ positive and negative clauses alternate. See the full version for all details and a full proof of Theorem 1.

3 Unit squares in simple polygons

In this section, we prove Theorem 2 by reducing MONOTONE-PLANAR-3-SAT to the unlabeled reconfiguration of squares in simple grid polygons. We start with a MONOTONE-PLANAR-3-SAT formula ϕ and two satisfying assignments σ_0 and σ_1 of ϕ. In our reduction, we create a grid polygon P and use the assignments σ_0 and σ_1 to define two configurations c_0 and c_1 of 8×8 squares in P. We then show that there is a reconfiguration from c_0 to c_1 in P if and only if there is a reconfiguration from σ_0 to σ_1 in ϕ. The squares are axis-aligned and may move by translations only.

3.1 Reference centers

As a preliminary step we provide a helpful tool for verifying the correctness of the reduction. Let P be a grid polygon. A set $\mathcal{R}$ of k non-overlapping 4×4 squares, each contained in P, is called a set of *reference centers* for P if, for any packing of k 8×8 squares in P, each square in the packing contains one square in $\mathcal{R}$. Such a configuration of 8×8 squares in P is called *perfect*. For every $y \in \mathbb{Z}$, let b_y be an integer in $[0, 8)$. For $x, y \in \mathbb{Z}$, let $S_{xy} = [8x + b_y, 8x + b_y + 4] \times [8y, 8y + 4]$. Suppose that each S_{xy} is either fully contained in P or is interior-disjoint with P. Let $\mathcal{R}$ be the set of those S_{xy} that are fully contained in P. An example is shown in Figure 3. We will show that $\mathcal{R}$ is a set of reference centers for P.

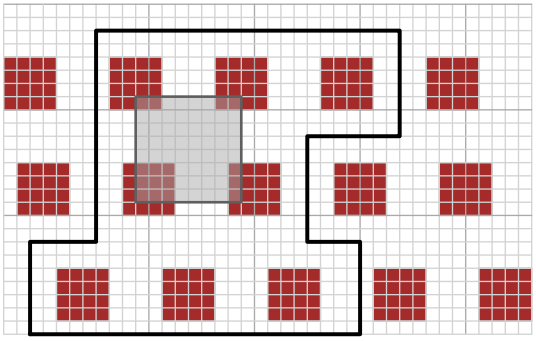

Figure 3 A grid polygon that has reference centers with $b_0 = 1, b_1 = 6, b_2 = 5$ and an 8×8 square intersecting four reference centers; the area of intersection is 16. (Note that in this example there exists no perfect configuration.)

▶ **Lemma 6.** ($\star$) *Let S be an 8×8 square placed in P. Then the area of the intersection of S with $\mathcal{R}$ is* 16.

▶ **Lemma 7.** ($\star$) *$\mathcal{R}$ is a set of reference centers for P.*

By Lemma 7, in any reconfiguration from one perfect configuration to another, each square contains the same reference center the whole time, i.e., the squares merely shift slightly sideways and up and down around the same reference center. In order to describe the mechanics of our intended reconfigurations, we only need to consider positions of squares that are extreme or centered in each direction with respect to their reference centers. This leaves us with the nine possible positions shown in Figure 4a. In Section 3.7, we prove that also arbitrary continuous reconfigurations in P correspond to reconfigurations of ϕ, but for understanding the key ideas of the reduction, it suffices to consider these nine discrete positions.

When the top (resp. bottom) edge of a square aligns with that of its reference center, we say that the square is *down* (resp. *up*). Otherwise, the midpoints of the reference center and the square have the same y-coordinate, in which case we say that the square is *vemid* (abbreviation of vertically in the middle). When the left (resp. right) edge of the square aligns with that of the reference center, the square is *right* (resp. *left*). Otherwise, the midpoints of the reference center and the square have the same x-coordinate, in which case we say that the square is *homid* (abbreviation of horizontally in the middle).

For most squares, several of the nine possible positions can be excluded, for instance due to being pushed by the boundary of P or another square. In our figures, we use a color scheme for the reference centers, to make the reader aware of what possible positions a square

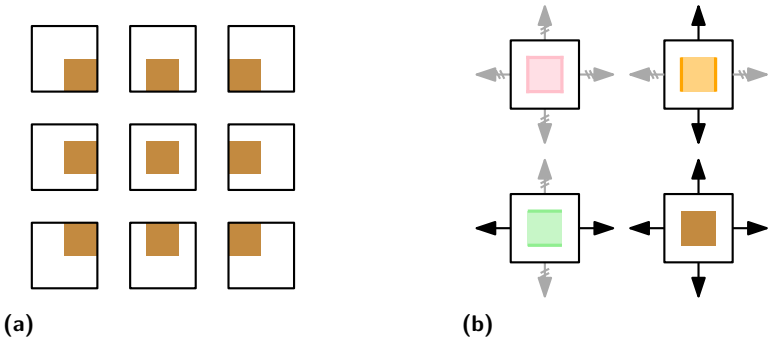

Figure 4 (a) The up to nine important placements of a square for a given reference center. (b) Examples of colored reference centers and how the squares containing them may move.

has. The colors have the following meanings: the square can not move (*pink*), only move vertically (*orange*), only move horizontally (*green*), move vertically and horizontally (*brown*). There might exist additional restrictions on the positions that are not indicated by the colors.

3.2 Schematics of the construction

On a big scale, our construction follows the ideas of Abrahamsen and Stade [1]. Therefore, we start by reviewing the high level ideas. Let ϕ be an instance of Monotone-Planar-3-Sat with variables $x_1, \ldots, x_k$ and consider the variable-clause-incidence graph G with a suitable embedding. We now describe schematically the construction of a grid polygon P. Each feasible solution to ϕ corresponds to a configuration of 8×8 squares in P, and there is a reconfiguration between two configurations if and only if there is a reconfiguration between the two solutions of ϕ.

In the first step, we introduce a *segment representation* that consists of horizontal segments for vertices and clauses, and of vertical segments for the edges of G, see in Figure 5b. The idea behind this representation is as follows: The horizontal segments will correspond to one or several rows of squares which transmit information horizontally. Similarly, the vertical segments will correspond to columns of squares that transmit information vertically. The endpoints of each segment should be on the outer face of the drawing, so that the smallest enclosing orthogonal polygon runs through all of the endpoints.

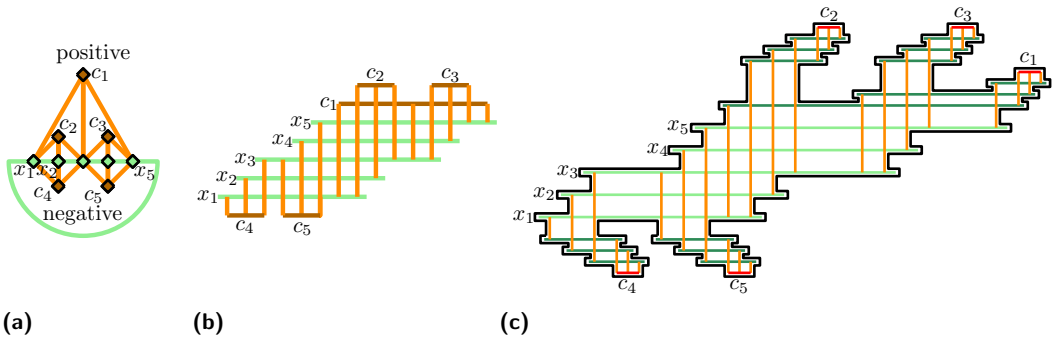

Figure 5 Schematic construction for transforming an instance of Monotone-Planar-3-Sat to a polygon. (a) a variable-clause incidence graph. (b) first step for constructing the segment representation of G (c) second step for constructing the segment representation of G: introducing the auxiliary variable rows and OR gadgets.

To construct the segment representation, we introduce a horizontal segment for each variable $x_1, \ldots, x_k$ in this order bottom-up, where the x-coordinates of the left and right endpoints are increasing, see Figure 5. Furthermore, the right endpoint of x_1 is to the right of the left endpoint of x_k, so that all the segments have a common horizontal overlap. These are the *primary* variable rows. The positive clauses are represented by horizontal segments above x_k and the negative clauses by horizontal segments below x_1. We say that a clause c' is *nested* in a clause c, if in G the clause node of c' lies inside a cycle defined by two incident edges of the node of c closed with a path between variable nodes. For instance, in Figure 5a, c_2 and c_3 are nested inside c_1. Note that the property of being nested defines a partial order. If a positive clause c_i is nested inside c_j, then we place the segment of c_i above that of c_j in the segment representation. If instead the clauses are negative, the segment of c_i is below that of c_j. Each edge $x_i c_j$ of G is realized by a vertical segment connecting the segments of x_i and c_j. All vertical segments to the positive clauses are placed to the right of all those to the negative clauses. The left-to-right ordering of the edges to the positive clauses along the variables $x_1, \ldots, x_k$ in G is preserved by the corresponding vertical segments, as well as the ordering of the edges to the negative clauses. The segment of a positive (resp. negative) clause c_j starts at the top (resp. bottom) endpoint of the vertical segment corresponding to the leftmost edge incident to c_j in G and ends at the top (resp. bottom) endpoint of the rightmost edge.

In the next step, illustrated in Figure 5c, we replace each clause segment by three *auxiliary* variable segments, one for each of the variables connected to the clause. In the right side of the auxiliary segments, we connect them using vertical segments to an OR gadget, represented by a red horizontal segment. As sketched in the figure, we construct (guided by the partial nested-order of the positive and negative clauses) a polygon whose boundary approximately follows the outer face of the resulting representation, but the finer details will be given later. The following lemma was proved in [1].

▶ **Lemma 8.** *There is a segment representation as described, where the segments representing the OR gadgets are not crossed by any vertical segments, and all segment endpoints are incident to the outer face of the drawing.*

Algebraically, the introduction of an auxiliary variable row for a clause c_t corresponds to the following equivalence:

$$(x_i \vee x_j \vee x_k) \Leftrightarrow \Big(\exists y_{t,i}, y_{t,j}, y_{t,k} : (y_{t,i} \Rightarrow x_i) \wedge (y_{t,j} \Rightarrow x_j) \wedge (y_{t,k} \Rightarrow x_k) \wedge (y_{t,i} \vee y_{t,j} \vee y_{t,k})\Big)$$

Here, x_i, x_j, x_k are the primary (original) variables and $y_{t,i}, y_{t,j}, y_{t,k}$ are the auxiliary variables introduced for that particular clause. We remark that the formula is not monotone anymore, but the only non-monotone clauses are implications. Note that the equivalence also preserves reconfiguration: If, say, x_i changes to `false`, then we change $y_{t,i}$ to `false` before changing x_i. If x_i changes to `true`, then we change $y_{t,i}$ to `true` after x_i. For a negative clause c_t , we use an analogous equivalence:

$$(\neg x_i \vee \neg x_j \vee \neg x_k) \Leftrightarrow$$
$$\Big(\exists y_{t,i}, y_{t,j}, y_{t,k} : (\neg y_{t,i} \Rightarrow \neg x_i) \wedge (\neg y_{t,j} \Rightarrow \neg x_j) \wedge (\neg y_{t,k} \Rightarrow \neg x_k) \wedge (\neg y_{t,i} \vee \neg y_{t,j} \vee \neg y_{t,k})\Big)$$

3.3 Components and gadgets

We informally distinguish between *gadgets* and *components* in our constructions, where a gadget is given by a set of segments on the boundary creating some simple functionality, and a component is thought of as a whole region of the polygon that can involve an arbitrary number of gadgets.

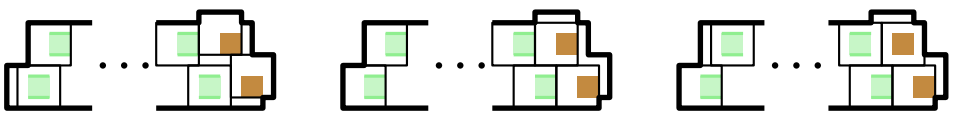
On a very high level the truth assignment of a variable of ϕ is encoded by a configuration of a so-called *variable component*; see Figure 6. The variable component (used to represent primary and auxiliary variables) has essentially three possible states, namely *plus*, *minus* and *transitional*. The first two correspond to the values `true` and `false` of a binary variable, while the truth value of the transitional state is defined to be the `true`/`false` value of the previous plus/minus state. In order to split the information represented in a variable component of a primary variable and transfer it to a variable component of an auxiliary variable we use PUSH gadgets. In particular, these gadgets are used to model the implication-clauses and they come in two versions: PUSH-UP-IF-MINUS and PUSH-DOWN-IF-PLUS. The former is used to model implications of the form $y \Rightarrow x$, the later for $\neg y \Rightarrow \neg x$. The gadgets use a vertically moving stack of square rows with growing width (called pyramid) to transmit information from primary to auxiliary variables, see for example Figure 8. For a PUSH-UP-IF-MINUS gadget representing an implication $y \Rightarrow x$ a pyramid that is raised enforces that the auxiliary variable component of y is set to minus, if the variable component of x is set to minus. Similarly, a PUSH-DOWN-IF-PLUS gadget modeling $\neg y \Rightarrow \neg x$ has the functionality that a pyramid that is lowered enforces that the auxiliary variable component of y is set to plus, if the variable component of x is set to plus. We will make sure that the vertically moving pyramid structure do not collide with the vertically operating variable components they "cross". To only allow satisfying assignments for every clause we place an *OR gadget* that is connected with the corresponding auxiliary variable components. We reuse the ideas for the PUSH Gadgets. For a clause $(y_i \vee y_j \vee y_k)$ the auxiliary variables will push a pyramid up into the clause gadget if the corresponding auxiliary variable is set to minus. The OR gadget has only room for two of these pyramids to push up. The clauses $(\neg y_i \vee \neg y_j \vee \neg y_k)$ are handled symmetrically. Here, an auxiliary variable set to plus would result in a pyramid pushing down and the OR gadget can only incorporate two lowered pyramids.

We continue with describing the gadgets and components in detail.

3.4 The variable component

The variable component has two *main* rows of squares and an arbitrary number of PUSH gadgets, ensuring dependency between the primary and auxiliary variables and between the auxiliary variables and the OR gadgets. The PUSH gadgets require the introduction of *helper rows* padded along the main rows, above the top row or below the bottom row. The construction of PUSH gadgets and helper rows will be explained in later sections.

The construction of the main rows of a variable component is shown in Figure 6. A perfect configuration of the component has three possible states, as defined by the horizontal position of the two rightmost squares (covering the brown reference centers). Note that none of the two squares can push right, and if one is homid, the other needs to be right.



(a) plus state **(b)** transitional state **(c)** minus state

Figure 6 A variable component and its three states, defined by the horizontal positions of the two rightmost squares with brown reference centers.

If the bottom is in the homid position, the state is *plus*. If the top is in the homid position, the state is *minus*. Otherwise, the state is *transitional*.

Now we describe what happens when a block of raised or lowered squares "crosses" a variable component. As discussed before, pyramids made of such blocks are used to create dependencies between two variable components, but it is important that they can cross other variable components without interacting with them.

When a stack of raised squares crosses a row of squares with a different horizontal alignment, the stack of raised squares will grow in width. Hence, the stack will be pyramid shaped if all rows have a different alignment than the neighboring rows. It is important that we know the width of a pyramid when it reaches the target variable component where it will end. Thus, we need to know exactly how many times the width is increased and which squares are raised in the top row. To this end, and in order to create a necessary amount of vertical spacing, we introduce *static* rows in between all neighboring pairs of variable components. A static row consists of squares in the beginning and in the end, which cannot move, and some squares in the middle, which can move vertically up and down, see Figure 7. So in particular, all squares in a static row have a fixed horizontal position.

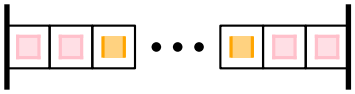


Figure 7 A static row. The squares have fixed horizontal positions, but some of the middle squares will be able to move up or down because of pyramids.

We ensure that the fixed horizontal position is never aligned with the rows of the variable component. Furthermore, the top row of a variable component is never aligned with the bottom row, see Figure 8. Hence, when a pyramid crosses a variable component, the specific horizontal positions of the rows do not affect which squares are raised/lowered on the other side of the variable. This is expressed in the following lemma.

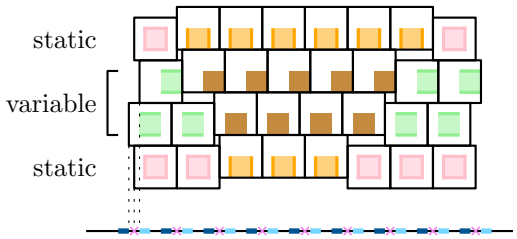

Figure 8 A pyramid crossing a variable component. The scale at the bottom shows the intervals of the possible x-coordinates of the left corners of the upper and lower squares in the variable rows (light and dark blue, respectively) and those of the squares in the static rows (pink). Since these three groups of intervals are pairwise disjoint, the pyramid grows in width by one square per row. Hence, the width of the pyramid always grows by three squares when crossing a variable component, regardless of the state of the variable component.

▶ **Lemma 9.** ($\star$) *Consider a perfect configuration. If a block of consecutive squares in a static row below (above) a variable component are up (down), then the corresponding squares in the static row above (below) the variable component must also be up (down) as well as two extra squares on the right (left) and one on the left (right).*

Recall that there may be helper rows above or below the main rows of a variable component, which will be explained in more detail in Section 3.5. Conceivably, these could be unaligned with the main rows, which would cause a pyramid to grow more in width when crossing the variable. However, if they are aligned (which is our "intended behavior" of the helper rows), then the width will not grow beyond what is expressed by Lemma 9.

3.5 PUSH gadgets and helper rows

Figures 9 and 10 show the PUSH-UP-IF-MINUS and PUSH-DOWN-IF-PLUS gadgets, respectively. The gadgets are mirror images of each other by a horizontal axis. In order to make PUSH gadgets, we need a square that is pushed up or down only when it is left. To this end, we introduce *helper rows*, which are extra rows above and below the main variable rows. Consider the PUSH-UP-IF-MINUS gadget, shown in Figure 9. If the squares of the lower main row are left, the squares of the helper row will be left as well, because the square a presses down b, which thus pushes c to the left. Therefore the square d will be up, and a pyramid of raised squares is created.

Figure 9 The plus and minus states of PUSH-UP-IF-MINUS. In minus, square d is pushed up.

The PUSH-DOWN-IF-PLUS gadget works by analogous mechanics. If the squares in the upper main row are left, two squares of the lower row are pushed down, see Figure 10.

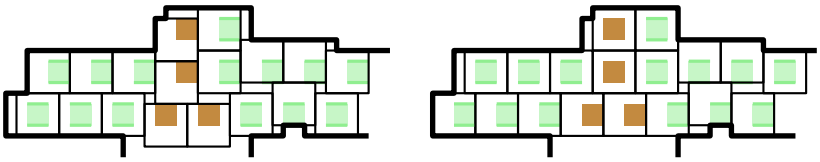

Figure 10 The plus and minus states of PUSH-DOWN-IF-PLUS. In plus, the squares with brown reference centers are pushed down.

All helper rows are created at the right end of the variable gadget and end at a PUSH gadget. Figure 11 shows schematically where the helper rows are placed, and Figure 12 shows a detailed example with multiple helper rows. Note that with multiple helper rows, the same principle is used as with a single helper row in order to ensure that when the lower main row is left, then all helper rows below are also left, so they all create pyramids of raised squares.

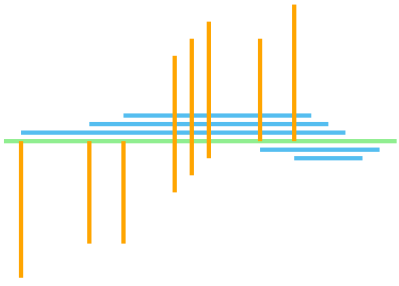

Figure 11 Schematic showing the horizontal span of the helper rows (blue) along a principal variable component. The variable connects to three auxiliary variables below and two above, so there are three helper rows above and two below. In between the two groups, pyramids from other principal variable components can cross, indicated as three orange vertical segments in the middle.

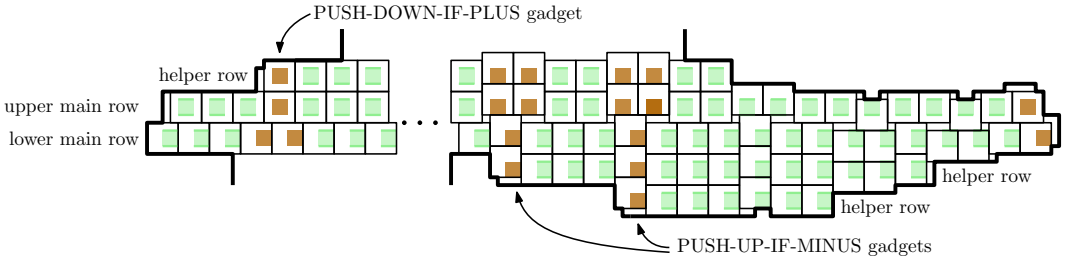

Figure 12 A variable component in the minus position with two PUSH-UP-IF-MINUS gadgets and one PUSH-DOWN-IF-PLUS gadget. Thus, there are two helper rows at the bottom and one at the top. Other pyramids may cross the variable in the region indicated by the dots.

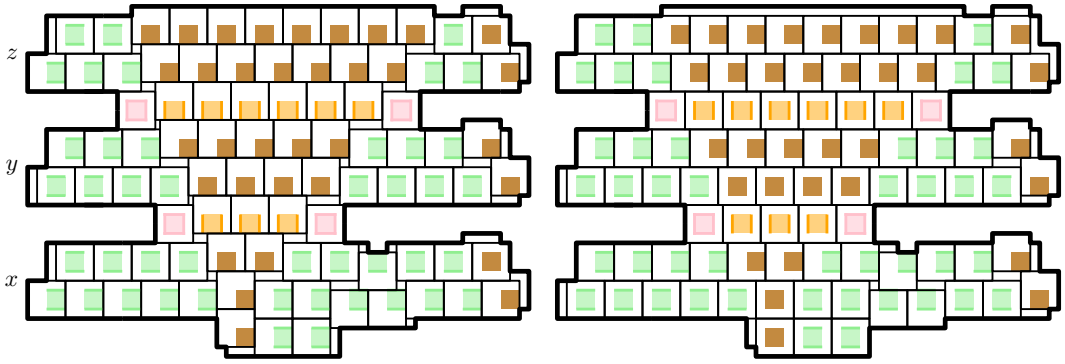

Figure 13 There is a PUSH-UP-IF-MINUS gadget on the bottom variable x, which connects x to the top variable z. When x is minus, a pyramid of raised squares is created. The boundary of the polygon at z forces z to also be minus. The state of y has no influence. When x is plus, the pyramid does not have to raise, so z is not restricted.

We now describe how a pyramid ends at an auxiliary variable component; see Figure 13 for a concrete example to support the description. When we make a PUSH-UP-IF-MINUS gadget from a primary variable x to an auxiliary variable y, we create a pocket in the boundary of P along the upper primary row of y to enable the squares of the pyramid to raise. We place the pocket so that the squares can only raise if they are homid (and if the pyramid has grown in width by exactly three squares every time it crossed another variable component). Thus, the rightmost square of the top row of y is also homid, so y must be minus. We have thus made the implication $y \Rightarrow x$.

In minus, pyramids are created to the positive auxiliary variables, which in turn create pyramids to the positive clauses. Likewise, in plus, pyramids are created to the negative clauses. In transitional, pyramids are created to all clauses. As we will see in Section 3.6, there will only be room for two pyramids for each clause. Hence, each clause ensures that one of the variables is in the plus/minus state that represents the `true`/`false` value that satisfies the clause. This gives the following lemma.

▶ **Lemma 10.** *In every perfect configuration, the following holds. If a variable is not plus (minus), a pyramid of raised squares appears from any PUSH-UP-IF-MINUS (PUSH-DOWN-IF-PLUS) gadget, and if the pyramid is received by an auxiliary variable, that variable must be minus (plus). As a consequence, we can realize the implications $y \Rightarrow x$ and $\neg y \Rightarrow \neg x$, i.e., ensure that the values of variables encoded by the configuration satisfy the implications.*

3.6 OR gadget

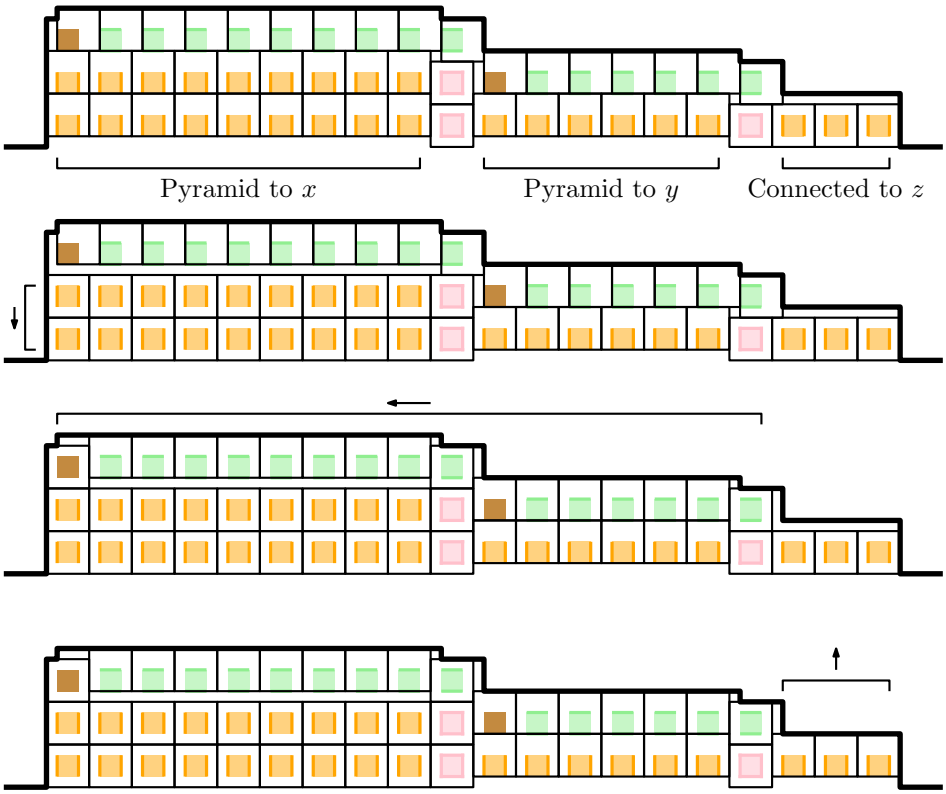

Figure 14 The OR gadget for a clause $x \vee y \vee z$. Initially, there is a pyramid from x and y. The pyramid from x is removed, and it is shown how the top squares reconfigure so that a pyramid from z can raise.

Figure 14 shows the positive OR gadget. The gadget is connected to three auxiliary variable components. Using PUSH-UP-IF-MINUS gadgets, pyramids can raise from the variables and end in the OR gadget. The gadget allows for two pyramids to be raised, but not all three at once. Hence, one variable must be plus. When at most one pyramid is raised, the squares in the top of the gadget can reconfigure so that there is room for any of the other two pyramids to raise. An example is shown in the figure – the reader can easily check that it is likewise possible in the other five cases where one pyramid is raised and we need to make room for one of the other two to raise as well. This corresponds to a reconfiguration of the formula ϕ: If $x \vee y \vee z$ is a clause and one of the variables, say z, changes from positive to negative, then x or y must have been positive before z changes (otherwise the clause would not be satisfied after z changing). Hence, there was only one pyramid, so the squares in the gadget can reconfigure to accommodate raising the pyramid from z.

Figure 15 shows how the OR gadget is connected to the variable components. The negative OR gadget is obtained by reflection along a horizontal axis.

▶ **Lemma 11.** *In a positive OR gadget, at least one of the connected auxiliary variables is plus. In a negative OR gadget, at least one of the connected auxiliary variables is minus.*

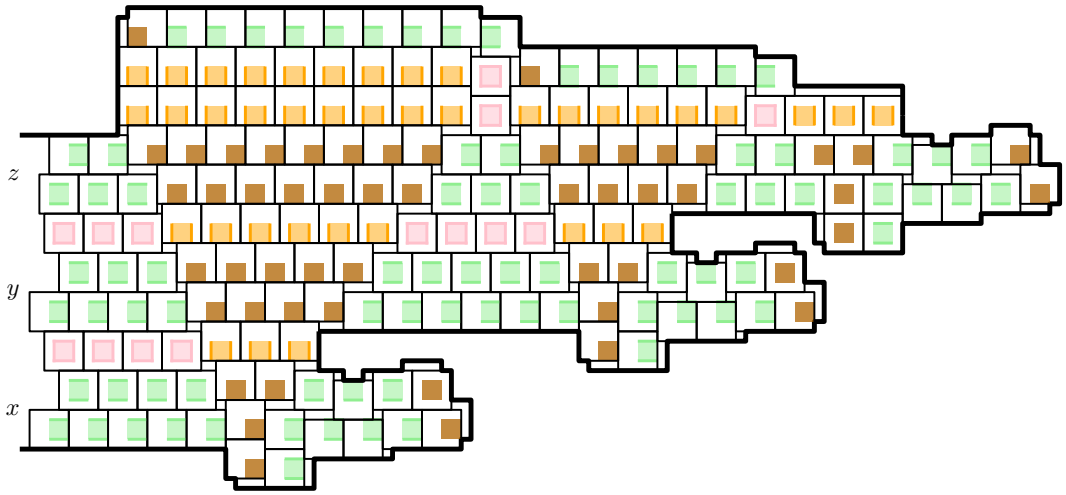

Figure 15 The positive OR gadget connected to the auxiliary variable components for x, y and z. Here, x and y are minus, so they create pyramids, but z is plus, which allows for a reconfiguration.

3.7 Verification

Recall that we start with a Monotone-Planar-3-Sat formula ϕ and two satisfying assignments σ_0 and σ_1 of ϕ. In our reduction, we create a polygon P as described. We define start and target configurations c_0 and c_1 according to σ_0 and σ_1: We place squares in all primary and auxiliary variable components in c_i in the plus/minus state corresponding to the value of the variable in σ_i. By construction there is room for the pyramids created by PUSH gadgets. We now need to verify that there is a reconfiguration between σ_0 and σ_1 in ϕ if and only if there is one between c_0 and c_1 in P. This is expressed by the following two lemmas.

▶ **Lemma 12.** ($\star$) *If ϕ has a reconfiguration between two satisfying assignments σ_0 and σ_1, then there is also a reconfiguration between the corresponding start and target configurations c_0 and c_1 in P.*

▶ **Lemma 13.** ($\star$) *If there is a reconfiguration in P from the start configuration c_0 to the target c_1 in P, then there is a reconfiguration in the formula ϕ from the satisfying assignment σ_0 to σ_1.*

Finally, we prove the containment in PSPACE.

▶ **Lemma 14.** ($\star$) *Unlabeled reconfiguration of 8×8 squares in simple grid polygons is contained in* PSPACE.

Theorem 2 result now follows from Theorem 1 and Lemmas 12–14.

As we only consider perfect configurations in our reduction, by Lemma 7 each square always contains its reference center. Thus, we can easily label each square and obtain hardness for the labeled variant, i.e., Corollary 3.

4 Unit disks in polygons with holes

We now present the ideas for showing PSPACE-hard of reconfiguration of unit disks in a polygon possibly with holes. As a first step, we prove it for an *arc-gon*, that is, a shape whose boundary consists of straight line segments and circular arcs.

▶ **Proposition 15.** *Reconfiguration of unlabeled unit disk robots in an arc-gon is* PSPACE*-hard.*

Proof-Sketch. As in Section 2, we reduce from the configuration-to-configuration variant of Nondeterministic Constrained Logic (NCL) [11, 12, 13]. From a given NCL instance, specified by two orientations of a plane cubic graph G and a reorientation G', we construct an arc-gon and two configurations of unit disks such that the NCL instance is a yes-instance if and only of the two configurations of unit disks can be reconfigured into one another.

Similar to [4], we lay out G using five types of *tiles* as illustrated in Figure 16. Here we ensure that each edge has a at least one straight tile.

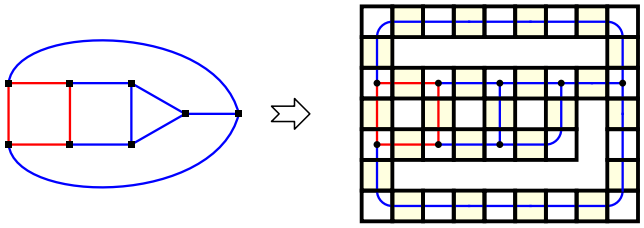

Figure 16 A layout of an NCL instance using a limited set of tiles.

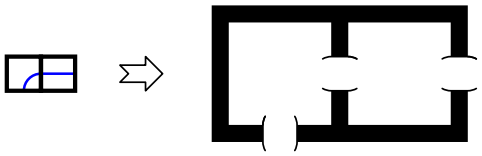
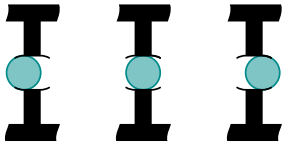
Each tile is then realized as a *room*, where small "hooks" limit the movement of the disks in the opening of the room which is called the *door* of the room, see Figures 17a and 17b.



(a) Each tiles becomes a room, and an edge through tile sides implies a door.



(b) Each door has a (green) *door disk* that must stay within the door opening.

Figure 17

The interiors of the rooms mimic the behavior of the vertices and edges of G during a reconfiguration, see Figure 18. In particular, it is essential to guarantee that an edge can only have one orientation at a time; we implement this in our *straight* tile gadget where we guarantee that at least one door disks is "pushed out" and implies that the AND and OR tiles behave as required, see Figure 19. ◀

Then, we turn the arc-gon constructed in the proof of Proposition 15 into a polygon with holes and thereby complete the proof of Theorem 4. Observing that no two disks may swap within the polygon implies PSPACE-hardness for the labeled variant, i.e., Corollary 5.

5 Discussion

We proved that reconfiguration of Monotone-Planar-3-Sat is PSPACE-hard, and thereby complemented a sequence of recent results establishing the relationships between 3-Sat variants and their reconfiguration counterparts. This result was a stepping stone towards showing PSPACE-hardness of reconfiguration of 8×8-squares in a simple grid polygon. While the reduction reuses ideas from Abrahamsen and Stade [1], we also needed several new ideas. Most importantly, the reduction to the packing problem uses very rigid configurations whereas our setting inherently requires to allow for some movements. While the computational complexity of reconfiguring $k \times k$-squares in simple grid polygons is trivial for $k = 1$, the cases $k \in \{2, \ldots, 7\}$ remain an interesting open problem.

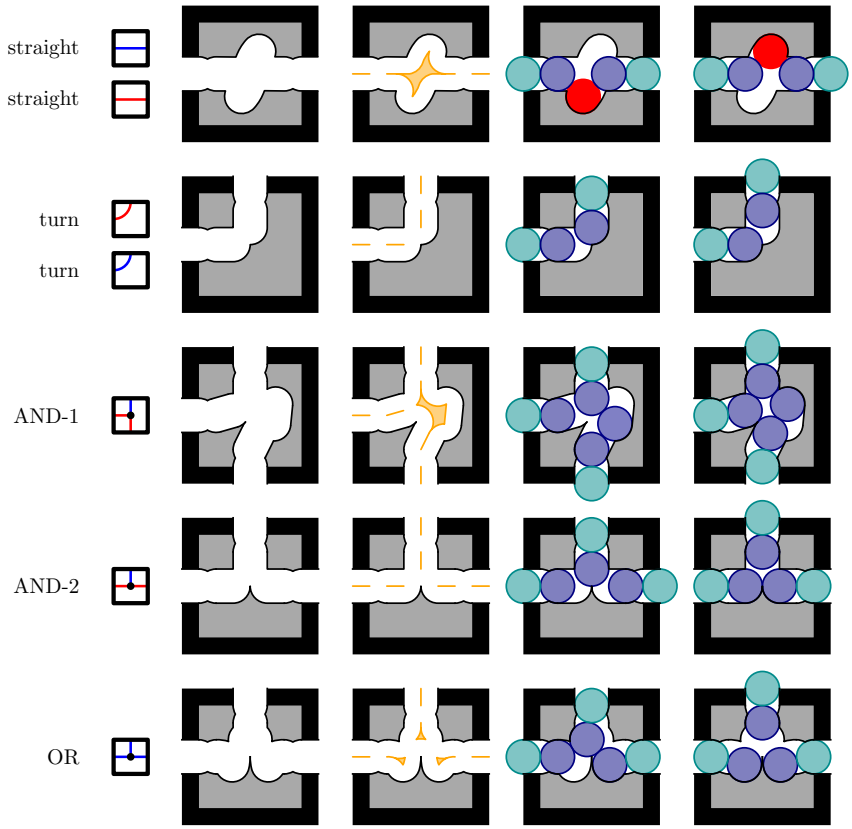


Figure 18 Geometric realizations of the five tile types. Marked in orange is the *dilation* of the shapes by 1; these are possible locations of disk centers. On the right two different valid configurations of disks with different extremal positions of the door disks.

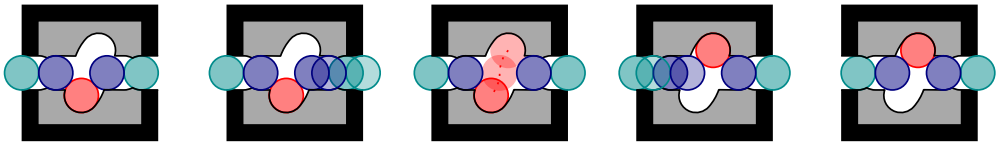

Figure 19 A sequence of moves that imitates the reorientation of an edge.

We have also shown that reconfiguration of unit disks in a polygon with holes is PSPACE-hard. A natural next question is unit disks in a simple polygon. At a first glance, it seems difficult to extend our insights in the square setting to this case, because it is troublesome to propagate movement independently in multiple directions in a large region filled with disks. Therefore, we expect that a PSPACE-hardness proof, if it exists, will likely require different techniques.

Abstract

In 1972, Branko Grünbaum conjectured that any nontrivial arrangement of $n > 2$ pairwise intersecting pseudocircles in the plane can have at most $2n-2$ digons (regions enclosed by exactly two pseudoarcs), with the bound being tight. While this conjecture has been confirmed for cylindrical arrangements of pseudocircles and more recently for geometric circles, we extend these results to any simple arrangement of pairwise intersecting pseudocircles.

1 Introduction

In this paper we focus on families of pairwise intersecting pseudocircles. A *family of pseudocircles* is a set $\mathcal{F}$ of simple closed Jordan curves in the plane such that every two of them are either disjoint, meet at exactly one point in which they touch or intersect at exactly two points in which they properly cross each other. The *arrangement* $\mathcal{A}(\mathcal{F})$ is the cell complex into which the plane is decomposed by the pseudocircles in $\mathcal{F}$. It consists of vertices, edges and faces. The arrangement is called *trivial* if there are two points that lie

© Eyal Ackerman, Gábor Damásdi, Balázs Keszegh, Rom Pinchasi, and Rebeka Raffay;

on every pseudocircle in $\mathcal{F}$. If there is no point that lies on three pseudocircles, then both the arrangement and $\mathcal{F}$ are called *simple*. Note that every simple arrangement of more than two pseudocircles is nontrivial. The arrangement is called *pairwise intersecting* if any two pseudocircles intersect in exactly two points.

A *digon* is a face in the arrangement that is bounded by exactly two edges. If the two edges of a digon are contained in pseudocircles c_1 and c_2, respectively, then we say that c_1 and c_2 *form* that digon and that each of c_1 and c_2 *supports* it.

A trivial arrangement of n pseudocircles contains $2n$ digons for $n > 1$. In his 1972 monograph "Arrangements and Spreads" [11] Branko Grünbaum conjectured that for nontrivial arrangements of pairwise intersecting pseudocircles the maximum number of digons is $2n - 2$.

▶ **Conjecture 1** (Grünbaum's digon conjecture [11, Conjecture 3.6])**.** *Every nontrivial arrangement of $n > 2$ pairwise intersecting pseudocircles has at most $2n - 2$ digons.*

This conjecture was accompanied by a construction with exactly $2n - 2$ digons, see Figure 1 for an example with six pseudocircles. This example can be easily extended by adding new pseudocircles to the four in the middle, which illustrates that the bound in Conjecture 1 is tight. With some care, this construction can even be realized with geometric circles. A different construction appears in [8].

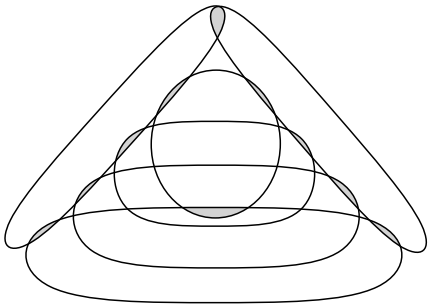

Figure 1 A family of 6 pseudocircles forming 10 digons.

Conjecture 1 was shown to be true in several special cases (assuming simple arrangements). Agarwal et al. [3] showed that Conjecture 1 is true for *cylindrical* arrangements, these are arrangements for which there is a point that is surrounded by each of the pseudocircles. More recently, Conjecture 1 was studied and advertised by Felsner, Roch and Scheucher [8] who showed that it holds for arrangements in which there are three pseudocircles such that every two of them form a digon. This new interest in Grünbaum's conjecture has also motivated us to study the problem. First, we were able to show in [1] that Grünbaum's conjecture is true for simple arrangements of pairwise intersecting geometric circles. Here, using ideas from [1] and [3] we prove:

▶ **Theorem 2.** *Every simple arrangement of $n > 2$ pairwise intersecting pseudocircles has at most $2n - 2$ digons. This bound is tight.*

Our proof is inspired by the proof technique introduced in [3] for bounding the number of digons in cylindrical arrangements of n pairwise intersecting pseudocircles. In that paper, a bipartite graph is associated to a cylindrical arrangement in a way that each pseudocircle is represented by a single point which is its intersection with a common fixed transversal line. The edges of this graph correspond to digons and are drawn according to a simple yet clever rule such that every two independent edges cross an even number of times. The Strong Hanani-Tutte Theorem (see below) then implies that the drawn (bipartite) graph is planar and hence by Euler's formula has at most $2n - 4$ edges.

For the general case of Grünbaum's conjecture, we combine a modification of this graph drawing technique and a graph *doubling* technique that was used for the case of geometric circles in [1]. Namely, a bipartite graph is drawn such that every pseudocircle is represented by *two* points which are its intersection with a common transversal pseudocircle. Furthermore, every digon is represented by *two* edges that are drawn following a rule in the spirit of [3] such that every two independent edges cross an even number of times. Therefore, the drawn (bipartite) graph is planar and hence has at most $2(2n) - 4 = 4n - 4$ edges, representing at most $2n - 2$ digons.

Note that our result can be applied for bounding the number of *touching points* in simple arrangements where any two pseudocircles intersect or touch. In any such arrangement of $n > 2$ pseudocircles, one can turn each touching point into exactly one digon between the two pseudocircles that support the touching. Therefore, for simple arrangements, an upper bound on the number of digons translates directly to a bound on the number of touching pairs or equivalently (in this case) touching points. One can also turn each digon into exactly one touching point in the case of simple arrangements if $n > 3$, but for $n = 3$, two pseudocircles may touch the third one at separate points forming a single digon (the region bounded by the entire third pseudocircle), see Figure 2. In this scenario, turning the digon into a touching point would reduce the third pseudocircle to a single point, which is degenerate, and the final arrangement would violate the assumptions on the number of crossings.

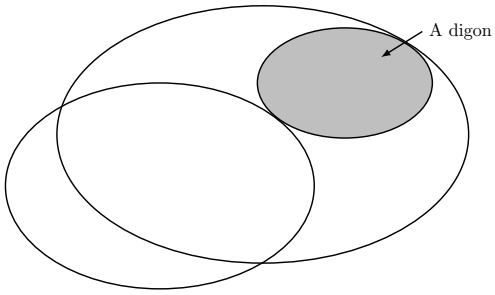

Figure 2 If we allow touchings and $n = 3$, then a digon might be surrounded by only one pseudocircle.

The transformation from digons to touching points or vice versa keeps their sum constant at every step (except for $n = 2$ or in the above-mentioned case), therefore they are equivalent for $n > 3$. From Theorem 2, we have:

▶ **Corollary 3.** *Every simple arrangement of pseudocircles where any two pseudocircles intersect or touch has at most $2n - 2$ touching pairs of pseudocircles. For $n > 3$, the sum of digons and touching pairs is at most $2n - 2$.*

1.1 Outline

In Section 2 we collect useful observations and results that we need for the main proof. In Section 3 we prove Theorem 2, and in Section 4 we discuss some open questions.

2 Some terminology and tools

We begin with some simple definitions and observations, some of which also appear in [1] in the context of circles.

Let $\mathcal{F}$ be a simple family of $n > 2$ pairwise intersecting pseudocircles in the plane. We may assume (and we will assume from now on) that every pseudocircle in $\mathcal{F}$ supports at least one digon. Otherwise, we can remove any pseudocircle from $\mathcal{F}$ that does not satisfy this condition and argue for the remaining family of pseudocircles.

As touchings are forbidden in a pairwise intersecting family, each digon is supported by exactly two pseudocircles. A digon is called a *lens* if it is surrounded by both supporting pseudocircles, and it is called a *lune* otherwise. A lune must be surrounded by precisely one of its supporting pseudocircles, while lying outside the region surrounded by the other (see Figure 3). Here we ignore the case where the unbounded face is a digon. This indeed can be avoided by means of a simple inversion of the plane.

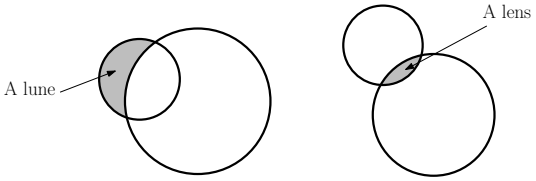

Figure 3 A lens and a lune.

A pseudocircle α is *internal* if it supports a digon that is surrounded by α and it is called *external* if it supports a digon (necessarily a lune) that is not surrounded by α. The following simple observation is important for the proof.

▶ **Proposition 4.** *A pseudocircle in $\mathcal{F}$ cannot be both internal and external.*

Proof. Assume to the contrary that there is a pseudocircle $c \in \mathcal{F}$ which is both external and internal. This means that there exist $c_1, c_2 \in \mathcal{F}$ such that c and c_1 form a digon not surrounded by c while c and c_2 form a digon that is surrounded by c (see Figure 4).

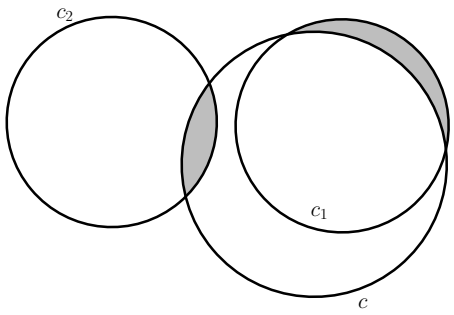

Figure 4 A pseudocircle cannot be both internal and external.

In such a case c_1 and c_2 cannot intersect, contradicting our assumption that we have an arrangement of pairwise intersecting pseudocircles. Indeed, c_1 and c_2 cannot cross in the region surrounded by c because that subarc of c_2 is an edge of a digon. Similarly, c_1 and c_2 cannot intersect in the complementary region of the plane because that subarc of c_1 is an edge of an other digon. ◀

Any simple closed Jordan curve in the plane divides the plane into two parts, one bounded (the *interior*) and the other unbounded (the *exterior*). We will refer to these two parts as the *regions* of the curve. For a pseudocircle $\alpha \in \mathcal{F}$, we will call the region that contains the digons supported by α the *digon-region* of α. By Proposition 4 and because we assume

that every pseudocircle supports at least one digon, every pseudocircle in $\mathcal{F}$ has exactly one digon-region. One advantage of this definition is that we can treat lunes and lenses in a uniform way: every digon is just the intersection of the digon-regions of the two corresponding pseudocircles supporting it.[1] This will simplify the case-analysis in some of the proofs.

It is well-known that any family of pairwise intersecting pseudocircles can be extended to a larger family of pairwise intersecting pseudocircles, and the following lemma shows that we can also do it without destroying the existing digons.

▶ **Lemma 5.** *Let $\mathcal{F}$ be a simple family of $n > 2$ pairwise intersecting pseudocircles. Then there is a closed curve c such that $\mathcal{F} \cup \{c\}$ is a simple family of pairwise intersecting pseudocircles, and furthermore c does not intersect any of the digons in $\mathcal{A}(\mathcal{F})$.*

Proof. Let α be a pseudocircle in $\mathcal{F}$. From Proposition 4 we know that one of the two regions of α (the one that is not the digon-region of α) does not contain any digon supported by α. Let c be a curve that is running very close to α outside of the digon-region of α. Then c intersects each pseudocircle in $\mathcal{F} \setminus \{\alpha\}$ exactly twice and it intersects no digon of $\mathcal{A}(\mathcal{F})$. However, c does not intersect α. In order to fix this, we notice that because $\mathcal{F}$ is a simple arrangement of pseudocircles, there is a subarc s of α that is disjoint from any digon supported by α and consequently it is disjoint from any digon in $\mathcal{A}(\mathcal{F})$. We can modify c along s such that the resulting simple closed curve crosses α at two points yielding the desired extension of $\mathcal{F}$ (see Figure 5). ◀

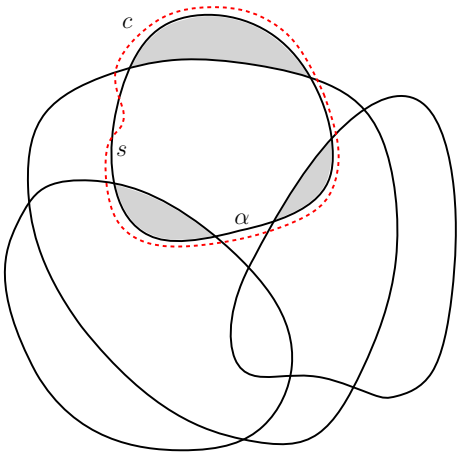

Figure 5 Extending $\mathcal{F}$ with a curve c which avoids the digons in $\mathcal{A}(\mathcal{F})$ and intersects every pseudocircle in $\mathcal{F}$ exactly twice.

For a pseudocircle α with a given orientation as a closed curve and points v_1, v_2 on α we denote by $[v_1, v_2]_\alpha$ (resp., $(v_1, v_2)_\alpha$) the closed (resp., open) segment of α from v_1 to v_2 following α in the given orientation.

▶ **Proposition 6.** *Let $\{\alpha_1, \alpha_2, c\}$ be a simple family of pairwise intersecting pseudocircles such that α_1 and α_2 form a digon. Suppose that c is oriented and let α_j^{in} (resp., α_j^{out}) be the intersection point of c and α_j in which c enters (resp., leaves) the digon-region of α_j, for $j = 1, 2$. Then $\alpha_1^{\text{in}}, \alpha_1^{\text{out}}, \alpha_2^{\text{in}}, \alpha_2^{\text{out}}$ is the cyclic order along c of the four intersection points of α_1 and α_2 with c.*

[1] Another way to think about this is to imagine that we work on a sphere, and we have caps corresponding to the digon-regions.

Proof. If $\alpha_2^{\text{in}} \in (\alpha_1^{\text{in}}, \alpha_1^{\text{out}})_c$ or $\alpha_2^{\text{out}} \in (\alpha_1^{\text{in}}, \alpha_1^{\text{out}})_c$, then we have a point from $\alpha_2 \cap c$ which lies in the digon-region of α_1. However, the intersection of α_2 with the digon-region of α_1 consists only of the subarc of α_2 which bounds the digon formed by α_1 and α_2. This implies that c intersects this digon which is impossible. Therefore, α_1^{out} must follow α_1^{in} in the cyclic order and, similarly, α_2^{out} must follow α_2^{in}. ◀

A *topological graph* is a graph drawn in the plane such that its vertices are drawn as distinct points and its edges are drawn as Jordan arcs connecting the corresponding points. Apart from its endpoints, an edge of a topological graph cannot contain any drawn vertex. Furthermore, every two edges in a topological graph intersect at a finite number of points, each of which is either a common endpoint or a crossing point. A graph is *planar* if it can be drawn as a topological graph where no pair of edges crosses. By the Strong Hanani-Tutte Theorem, it is enough to require an even number of crossings between independent edges.[2]

▶ **Theorem 7** (Strong Hanani-Tutte Theorem [20]). *A graph is planar if and only if it can be drawn as a topological graph in which every two independent edges cross an even number of times.*

3 Proof of Theorem 2

As we noted in the beginning of Section 2, we can suppose that $\mathcal{F}$ is a simple family of $n > 2$ pairwise intersecting pseudocircles in the plane such that every pseudocircle in $\mathcal{F}$ supports at least one digon. By Lemma 5 there is a simple closed curve c that intersects each pseudocircle in $\mathcal{F}$ twice but does not intersect the digons of the arrangement $\mathcal{A}(\mathcal{F})$. We fix the counterclockwise orientation on c. Whenever we traverse c or consider a cyclic order of points on it, we do it according to this orientation. Recall that c is an auxiliary pseudocircle and it is not a member of $\mathcal{F}$; in particular we do not care about digons supported by c.

Every pseudocircle $\alpha \in \mathcal{F}$ intersects c at two points such that at one of them c enters the digon-region of α and at the other c leaves this digon-region. We denote these points by α^{in} and α^{out}, respectively. See for example Figure 6. In this figure, the digon-regions of α and γ are the interior regions of these curves, whereas the digon-region of β is its exterior region.

3.1 The digon graph and its double cover

In order to bound from above the number of digons in $\mathcal{A}(\mathcal{F})$ we consider the graph G_d whose vertex set corresponds to the pseudocircles in $\mathcal{F}$ and whose edge set corresponds to pairs of pseudocircles which form a digon in $\mathcal{A}(\mathcal{F})$ (since $\mathcal{A}(\mathcal{F})$ is nontrivial and intersecting a pair of pseudocircles may not form more than one digon). We call G_d the *digon graph* of the arrangement. Bounding the number of edges in G_d is equivalent to bounding the number of digons in $\mathcal{A}(\mathcal{F})$.

For our proof, we consider the *bipartite double cover* of G_d - this graph, denote it by G, has two vertices, α^{in} and α^{out} for every vertex α of G_d, and two edges, $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\beta^{\text{out}}, \alpha^{\text{in}})$ for every edge (α, β) of G_d. Thus, the number of edges of G is twice the number of digons in $\mathcal{A}(\mathcal{F})$. By construction G is bipartite. It remains to show that G is also planar and therefore has at most $2|V(G)| - 4 = 4n - 4$ edges. This will prove Theorem 2.

[2] Two edges are *independent* if they do not share an endpoint.

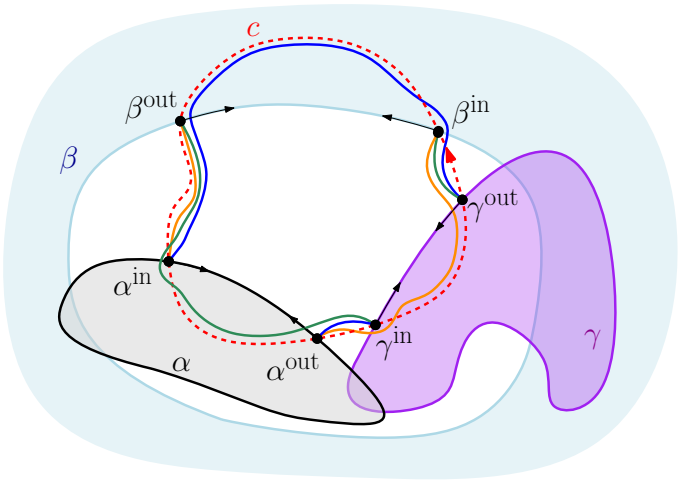

Figure 6 Three pseudocircles α, β and γ and a drawing of the corresponding bipartite double cover graph G. For example, α and γ form a digon, hence we draw the edges $(\alpha^{\text{out}}, \gamma^{\text{in}})$ and $(\gamma^{\text{out}}, \alpha^{\text{in}})$ along c. Considering the (blue) edge $(\gamma^{\text{out}}, \alpha^{\text{in}})$, starting at β^{in} (resp., β^{out}) and following β towards the interior of c, we first encounter α (resp., γ). Therefore, the drawn edge $(\gamma^{\text{out}}, \alpha^{\text{in}})$ "passes by" β^{in} (resp., β^{out}) within the exterior (resp., interior) of c. Each pseudocircle's label is placed within the digon-region associated with that pseudocircle.

3.2 Drawing G in the plane

We draw G as a topological graph in the plane. By abuse of notation, we will not distinguish between G and its drawing. The vertices of G are represented by the points $\{\alpha^{\text{in}} \mid \alpha \in \mathcal{F}\} \cup \{\alpha^{\text{out}} \mid \alpha \in \mathcal{F}\}$ as defined above. Thus, for every two pseudocircles $\alpha, \beta \in \mathcal{F}$ that form a digon in $\mathcal{A}(\mathcal{F})$ there should be two drawn edges $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\beta^{\text{out}}, \alpha^{\text{in}})$. These edges will satisfy the following properties:

- **(i)** An edge $(\alpha^{\text{out}}, \beta^{\text{in}})$ connects α^{out} and β^{in}, while avoiding all other vertices of G;
- **(ii)** every two edges intersect finitely many times; and
- **(iii)** an edge $(\alpha^{\text{out}}, \beta^{\text{in}})$ follows very closely the subarc of c starting at α^{out} and ending at β^{in}, counterclockwise along c. It may cross the curve c several times, but it does not intersect the digon-regions of neither α nor β.

Properties (i), (ii), and (iii) can be easily satisfied. For the second part of (iii) note that Proposition 6 implies that when following c from α^{out} to β^{in} we remain outside the digon-regions of α and β.

We need one more property that the drawing of $(\alpha^{\text{out}}, \beta^{\text{in}})$ should satisfy. This is the most crucial property for the proof and it has to do with how $(\alpha^{\text{out}}, \beta^{\text{in}})$ is drawn with respect to the intermediate vertices of G along the arc on c from α^{out} to β^{in}. We use a modification of the drawing rule that appears in [3].

Let $v \in V$ be an intermediate vertex of G on c along the arc from α^{out} to β^{in}. We will need to indicate whether the edge $(\alpha^{\text{out}}, \beta^{\text{in}})$ passes near v in the interior region of c or in its exterior region. In the first case, we say that the edge *passes v from the inside* whereas in the second case it *passes v from the outside*. Other than these inside/outside decisions and properties (i)-(iii), $(\alpha^{\text{out}}, \beta^{\text{in}})$ can be drawn arbitrarily.

We determine whether $(\alpha^{\text{out}}, \beta^{\text{in}})$ passes v from the inside or from the outside according to the value $d(v, (\alpha^{\text{out}}, \beta^{\text{in}}))$ that we define in the following way. Let γ be the pseudocircle in $\mathcal{F}$ that intersects c at v. It follows from Proposition 6 that γ must be different from α and β.

We follow the curve γ starting from v in the direction *entering the interior region of* c. If we intersect α sooner than we intersect β, then $d(v, (\alpha^{\text{out}}, \beta^{\text{in}})) = 1$, otherwise $d(v, (\alpha^{\text{out}}, \beta^{\text{in}})) = 2$.[3] Since $\mathcal{F}$ is a simple family of pairwise intersecting curves, $d(v, (\alpha^{\text{out}}, \beta^{\text{in}}))$ is well-defined. If $d(v, (\alpha^{\text{out}}, \beta^{\text{in}})) = 1$, then we pass v from the inside. Otherwise $d(v, (\alpha^{\text{out}}, \beta^{\text{in}})) = 2$ and we pass v from the outside. See Figure 6 for examples.

Having described the drawing of the graph G in the plane, we will conclude the proof by showing that every two independent edges of G cross an even number of times which implies that G is planar by the Strong Hanani-Tutte Theorem (Theorem 7).

3.3 Independent edges cross evenly

Let $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ be two independent edges of G. The parity of the number of crossings between two edges depends solely on how one edge passes by a vertex of the other edge. For example, if the cyclic order of their endpoints is $\alpha^{\text{out}}, \gamma^{\text{out}}, \delta^{\text{in}}, \beta^{\text{in}}$, then the two edges cross evenly if and only if $(\alpha^{\text{out}}, \beta^{\text{in}})$ passes by both of γ^{out} and δ^{in} from the inside or both of them from the outside. Therefore, it is enough to consider all the possible topologically different arrangements of the at most four involved pseudocircles (actually five because of c) and verify that in each of them $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ cross an even number of times. Using a computer we have verified this, still, for the remainder of the section (and of the proof) we provide a non-computer-aided proof.

We begin by observing that it is enough to consider the case that the involved pseudocircles α, β, γ, and δ are distinct. Indeed, $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ are independent edges, therefore, $\alpha \neq \gamma$ and $\beta \neq \delta$. Still, it is possible that $\alpha = \delta$ or $\beta = \gamma$. If $\alpha = \delta$ and $\beta = \gamma$ then by Proposition 6 the edges do not cross. Otherwise, we add a new pseudocircle as a substitute in the following way. Suppose without loss of generality that $\beta = \gamma$ (if $\alpha = \delta$ we switch the labels α and γ and the labels β and δ). Then we add a new pseudocircle γ' that goes very close to $\beta = \gamma$ outside of the digon-region of $\beta = \gamma$ except for near the vertices of the digon formed by $\beta = \gamma$ and δ. There, the pseudocircle γ' goes into the digon-region of $\beta = \gamma$ thus destroying the digon formed by $\beta = \gamma$ and δ and creating a new digon with δ that is fully contained in the digon that was destroyed. See Figure 7 for an example.

The edge $(\gamma'^{\text{out}}, \delta^{\text{in}})$ starts at γ'^{out} and follows the edge $(\gamma^{\text{out}}, \delta^{\text{in}})$, while $(\alpha^{\text{out}}, \beta^{\text{in}})$ passes by γ'^{in} according the above rules. The number of crossings of the two independent edges $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma'^{\text{out}}, \delta^{\text{in}})$ is equal to that of the original edges because $(\gamma'^{\text{out}}, \delta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ are drawn in precisely the same way as far as passing from the inside or from the outside of intermediate vertices of G. Note that the new vertex γ'^{in} becomes an intermediate vertex for $(\alpha^{\text{out}}, \beta^{\text{in}})$, however, it is not an endpoint of $(\gamma'^{\text{out}}, \delta^{\text{in}})$, thus it does not matter whether $(\alpha^{\text{out}}, \beta^{\text{in}})$ passes it from the inside or from the outside.

Henceforth we assume that the pseudocircles α, β, γ and δ are distinct. We proceed by considering the six possible cyclic orders of the vertices α^{out}, β^{in}, γ^{out} and δ^{in}. If the cyclic order is $(\alpha^{\text{out}}, \beta^{\text{in}}, \gamma^{\text{out}}, \delta^{\text{in}})$, then $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ do not intersect. The cyclic orders $(\alpha^{\text{out}}, \gamma^{\text{out}}, \beta^{\text{in}}, \delta^{\text{in}})$ and $(\alpha^{\text{out}}, \delta^{\text{in}}, \beta^{\text{in}}, \gamma^{\text{out}})$ are symmetric (by switching the labels α and γ and the labels β and δ), and the same goes for the cyclic orders $(\alpha^{\text{out}}, \beta^{\text{in}}, \delta^{\text{in}}, \gamma^{\text{out}})$ and $(\alpha^{\text{out}}, \gamma^{\text{out}}, \delta^{\text{in}}, \beta^{\text{in}})$. Therefore, it is enough to consider the cyclic orders $(\alpha^{\text{out}}, \gamma^{\text{out}}, \beta^{\text{in}}, \delta^{\text{in}})$, $(\alpha^{\text{out}}, \gamma^{\text{out}}, \delta^{\text{in}}, \beta^{\text{in}})$ and $(\alpha^{\text{out}}, \delta^{\text{in}}, \gamma^{\text{out}}, \beta^{\text{in}})$.

[3] Thus, the value 1 or 2 represents whether we encounter the first or the second pseudocircle among the two pseudocircles of the ordered pair $(\alpha^{\text{out}}, \beta^{\text{in}})$.

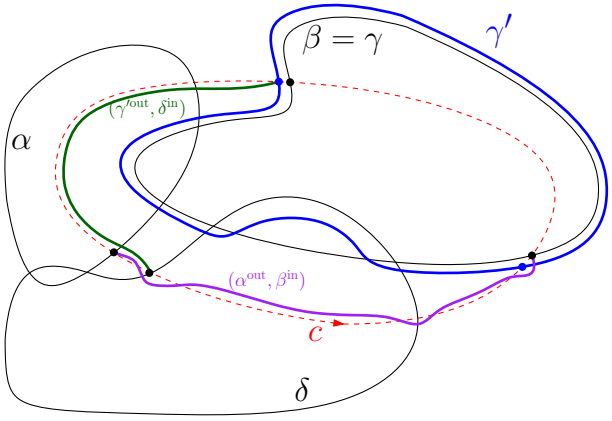

Figure 7 If $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ are edges and $\beta = \gamma$, then we can replace γ with γ' such that $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma'^{\text{out}}, \delta^{\text{in}})$ maintain the same number of crossings as the original edges. Each pseudocircle's label is placed within the digon-region associated with that pseudocircle.

Recall that we only care about how each edge passes by the vertices of the other edge. The following proposition summarizes the desired properties.

▶ **Proposition 8.** *Assume that the following conditions are satisfied:*

(A) *If $\alpha^{\text{out}}, \gamma^{\text{out}}, \beta^{\text{in}}$ and δ^{in}, appear in this cyclic order along c, then $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) \neq d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}}))$;*

(B) *if $\alpha^{\text{out}}, \gamma^{\text{out}}, \delta^{\text{in}}$ and β^{in} appear in this cyclic order along c, then $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = d(\delta^{\text{in}}, (\alpha^{\text{out}}, \beta^{\text{in}}))$; and*

(C) *if $\alpha^{\text{out}}, \delta^{\text{in}}, \gamma^{\text{out}}$ and β^{in} appear in this cyclic order along c, then $d(\alpha^{\text{out}}, (\gamma^{\text{out}}, \delta^{\text{in}})) \neq d(\delta^{\text{in}}, (\alpha^{\text{out}}, \beta^{\text{in}}))$ and $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) \neq d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}}))$.*

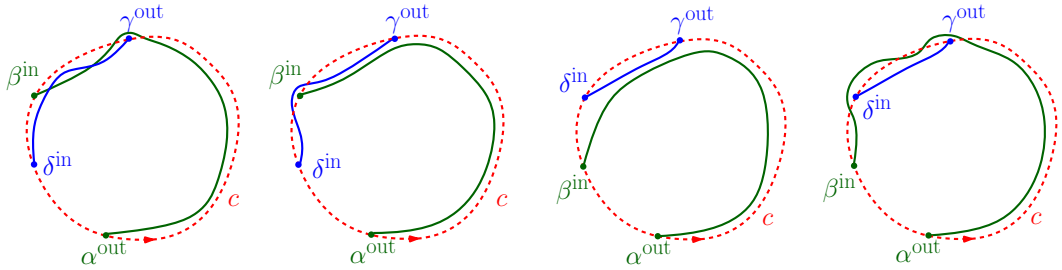
Then $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ cross an even number of times.

Proof. From properties (i), (ii) and (iii) it follows that the parity of the number of crossings between $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ depends only on the inside/outside decisions at the vertices $\alpha^{\text{out}}, \beta^{\text{in}}, \gamma^{\text{out}}$ and δ^{in}. This means that it is enough to check a single drawing for each set of inside/outside decisions that are allowed by the claim. The proof follows by a case analysis that is easy to verify by inspection, see Figure 8 for illustrations of the possible cases. ◀

It remains to prove that the drawing of G satisfies the conditions stated in Proposition 8. Conditions (A) and (C) are shown to hold in Proposition 9 while (B) is handled in Proposition 10. Note that in Condition (C) there is a symmetry between the two edges, namely, the cyclic order can also be written as $(\gamma^{\text{out}}, \beta^{\text{in}}, \alpha^{\text{out}}, \delta^{\text{in}})$. Therefore it is enough to prove, say, that $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) \neq d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}}))$ holds for the given cyclic order of the endpoints, this is shown in the following Proposition 9.

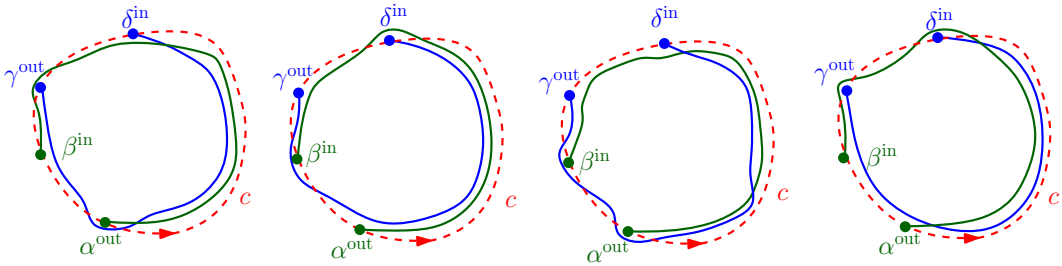
▶ **Proposition 9.** *If the cyclic of order of $\alpha^{\text{out}}, \beta^{\text{in}}, \gamma^{\text{out}}$ and δ^{in} along c is either $(\alpha^{\text{out}}, \delta^{\text{in}}, \gamma^{\text{out}}, \beta^{\text{in}})$ or $(\alpha^{\text{out}}, \gamma^{\text{out}}, \beta^{\text{in}}, \delta^{\text{in}})$, then $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) \neq d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}}))$.*

Proof. Orient β and γ such that they enter the interior of c at β^{in} and γ^{out}, respectively (recall that $\beta \neq \gamma$). We will show that if $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 2$, then $d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}})) = 1$. A symmetric argument (reflect the arrangement and switch the role of β and γ and also of α and δ) shows that if $d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}})) = 1$, then $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 2$. Together, these two assertions imply the claim.



(a) The cyclic order $(\alpha^{\text{out}}, \gamma^{\text{out}}, \beta^{\text{in}}, \delta^{\text{in}})$ implies $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) \neq d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}}))$.

(b) The cyclic order $(\alpha^{\text{out}}, \gamma^{\text{out}}, \delta^{\text{in}}, \beta^{\text{in}})$ implies $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = d(\delta^{\text{in}}, (\alpha^{\text{out}}, \beta^{\text{in}}))$.



(c) The cyclic order $(\alpha^{\text{out}}, \delta^{\text{in}}, \gamma^{\text{out}}, \beta^{\text{in}})$ implies $d(\alpha^{\text{out}}, (\gamma^{\text{out}}, \delta^{\text{in}})) \neq d(\delta^{\text{in}}, (\alpha^{\text{out}}, \beta^{\text{in}}))$ and $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) \neq d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}}))$.

Figure 8 $(\alpha^{\text{out}}, \beta^{\text{in}})$ and $(\gamma^{\text{out}}, \delta^{\text{in}})$ cross evenly if the conditions of Proposition 8 hold.

Suppose that $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 2$. This means that as we follow γ starting from γ^{out} it intersects β before it intersects α. Let x denote this first intersection point of γ and β (see Figure 9). We will show that $[\beta^{\text{in}}, x]_\beta$ does not intersect δ, and hence $d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}})) = 1$.

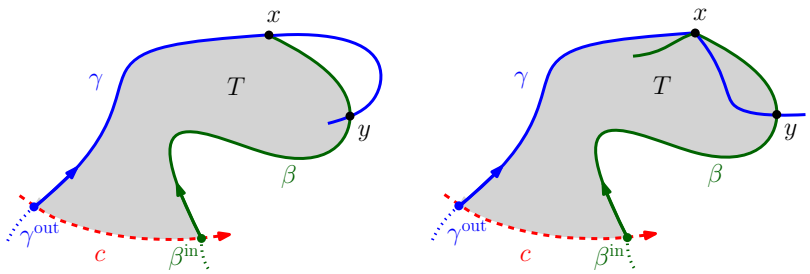
Let t be the closed curve which consists of $[\gamma^{\text{out}}, x]_\gamma$, $[\beta^{\text{in}}, x]_\beta$ and $[\gamma^{\text{out}}, \beta^{\text{in}}]_c$. We claim that t is a simple curve that is not crossed by any of α, β, and γ.

Consider first β and observe that it does not cross itself nor can it cross $[\gamma^{\text{out}}, x]_\gamma$ by the definition of x. From Proposition 6, it follows that $\beta^{\text{out}} \in (\beta^{\text{in}}, \alpha^{\text{out}})_c$ and therefore β does not cross $[\gamma^{\text{out}}, \beta^{\text{in}}]_c$, and hence it does not cross t.

Next, consider γ and observe that it does not cross itself nor can it cross $[\gamma^{\text{out}}, \beta^{\text{in}}]_c$ since it follows from Proposition 6 that $\gamma^{\text{in}} \in (\delta^{\text{in}}, \gamma^{\text{out}})_c$. Therefore, t is a simple curve (recall that β and $(\gamma^{\text{out}}, x)_\gamma$ cannot intersect by the definition of x). Let T be the "triangular" region which is bounded by t and is to the right of γ (and to the left of β and c).

Returning to γ, it remains to show that it cannot intersect $(\beta^{\text{in}}, x)_\beta$. Suppose for contradiction that it does intersect $(\beta^{\text{in}}, x)_\beta$ at a point y. Then either γ enters T at y or it leaves T at y. In the first case, following γ from y, it must leave T since the part of γ just before γ^{out} lies outside T. However, this means that γ must cross t and hence $(\beta^{\text{in}}, x)_\beta$ at another point which is impossible since β and γ already intersect at x and y, see Figure 9a. Considering the second case, if γ leaves T at y, then it implies that γ enters T at x, which in turn implies that β is also entering T at x (otherwise β and γ would touch at x which is impossible), see Figure 9b. However, following β from x, we would have to cross t since the part of β just before β^{in} lies outside T. Since we have already observed that β does not cross t we conclude that γ does not cross t either.

We now show that α cannot intersect t. By the definition of x it cannot intersect $[\gamma^{\text{out}}, x]_\gamma$. By Proposition 6 we have $\alpha^{\text{in}} \in (\beta^{\text{in}}, \alpha^{\text{out}})_c$ and it follows that α cannot intersect $[\gamma^{\text{out}}, \beta^{\text{in}}]_c$. Finally, if α crosses $[\beta^{\text{in}}, x]_\beta$, then it must cross it twice since α does not cross the other



(a) If γ enters T at y, then it must intersect $(\beta^{\text{in}}, x)_\beta$ once more.

(b) If γ leaves T at y, then β enters T at x and must cross t at some other point.

Figure 9 Illustrations for the proof of Proposition 9: when following γ into the interior of c we meet β sooner than α at a point x. Suppose for contradiction that γ intersects $[\beta^{\text{in}}, x]_\beta$ at another point y. Each pseudocircle's label is placed within the digon-region associated with that pseudocircle.

parts of t. The digon formed by α and β must lie outside of T since T lies outside the digon-region of β. Consequently, apart from its subarc that bounds this digon α is contained in T. However, this is impossible since then γ and α do not intersect.

We are now ready to show that δ cannot intersect $[\beta^{\text{in}}, x]_\beta$ which would imply that $d(\beta^{\text{in}}, (\gamma^{\text{out}}, \delta^{\text{in}})) = 1$. Assume to the contrary that δ intersects $[\beta^{\text{in}}, x]_\beta$. Notice that $\delta^{\text{in}}, \delta^{\text{out}}, \gamma^{\text{out}}$, and β^{in} appear in this cyclic order on c. This follows from Proposition 6 and the assumptions of the claim. This implies that δ does not intersect $[\gamma^{\text{out}}, \beta^{\text{in}}]_c$. It follows that the two simple closed curves δ and t must either cross twice or four times, since crossing six times or more would imply that δ intersects γ or β more than twice. If δ and t cross four times, then δ crosses twice each of $[\beta^{\text{in}}, x]_\beta$ and $[\gamma^{\text{out}}, x]_\gamma$. Therefore, the only part of δ that is outside the digon-region of γ and the digon-region of β must be in T. The curves α and δ cannot cross in the digon-region of γ, because δ and γ form a digon. Similarly, α and δ cannot cross in the digon-region of β because α and β form a digon. Since α is disjoint from T we conclude that α and δ do not intersect which is a contradiction. We reach a similar contradiction in the case where δ crosses t precisely at two points that happen to be on $[\beta^{\text{in}}, x]_\beta$, once again α and δ cannot intersect.

It remains to consider the case where δ crosses $[\beta^{\text{in}}, x]_\beta$ once and crosses $[\gamma^{\text{out}}, x]_\gamma$ once. The latter implies that either x or γ^{out} belong to the digon formed by δ and γ, which is impossible since neither β nor c intersects this digon. ◀

▶ **Proposition 10.** *If $\alpha^{\text{out}}, \gamma^{\text{out}}, \delta^{\text{in}}$ and β^{in} appear in this cyclic order along c, then we have $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = d(\delta^{\text{in}}, (\alpha^{\text{out}}, \beta^{\text{in}}))$.*

Proof. Orient γ and δ such that they enter the interior region of c at γ^{out} and δ^{in}, respectively. Recall that c is oriented counterclockwise and its interior region lies to its left. Thus, the digon-region of γ lies to its left whereas the digon-region of δ lies to its right. Let $\{A'_1, A'_2\} = \delta \cap \alpha$ and $\{B'_1, B'_2\} = \delta \cap \beta$, such that the cyclic order of these four points along δ is A'_1, A'_2, B'_1, B'_2 (since α and β form a digon it follows from Proposition 6 that A'_1 and A'_2 must be consecutive and so are B'_1 and B'_2). Similarly, let $\{A''_1, A''_2\} = \gamma \cap \alpha$ and $\{B''_1, B''_2\} = \gamma \cap \beta$, such that the cyclic order of these four points along γ is $A''_1, A''_2, B''_1, B''_2$.

Considering the cyclic order of A'_1, A'_2, A''_1 and A''_2 along α (under some orientation of α), it follows from Proposition 6 that the first two are consecutive and so are the last two (since γ and δ form a digon). Therefore, if we orient α such that A'_2 follows A'_1, then the cyclic order of those four points is either A'_1, A'_2, A''_1, A''_2 or A'_1, A'_2, A''_2, A''_1.

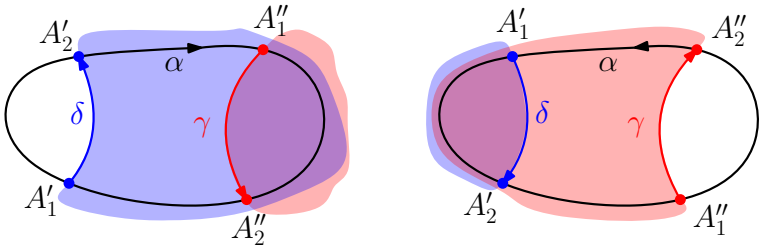


Figure 10 Suppose that A_1', A_2', A_1'', A_2'' appear in this cyclic order on α and B_1', B_2', B_1'' and B_2'' are in the exterior of α. Then the intersection of the digon-region of δ (which is to its right) and the digon-region of γ (which is to its left) contains either $[A_1'', A_2'']_\alpha$ or $[A_1', A_2']_\alpha$ which is impossible.

We claim that the former is impossible. Indeed, suppose that A_1', A_2', A_1'' and A_2'' appear in this cyclic order on α. Note that it follows from the cyclic order on δ (resp., γ) that both of B_1' and B_2' (resp., B_1'' and B_2'') must be in the same region (interior or exterior) of α. If B_1', B_2', B_1'' and B_2'' are in the exterior of α, then either $[A_1'', A_2'']_\alpha$ or $[A_1', A_2']_\alpha$ is contained in the intersection of the digon-regions of γ and δ (see Figure 10), which is impossible. By a symmetric argument, it is impossible that B_1', B_2', B_1'', and B_2'' are in the interior of α. Therefore, either B_1' and B_2' are in the digon-region of α or B_1'' and B_2'' are there. However, this implies that the subarc of β in the digon-region of α intersects either γ or δ which is impossible since α and β form a digon.

Thus $A_1', A_2'', A_2'', A_1''$ appear in this cyclic order on α, and similarly, B_1', B_2', B_2'', B_1'' appear in this cyclic order on β if it is oriented such that B_2' immediately follows B_1'. Next, we redraw α close to the digon it forms with β such that these two pseudocircles become disjoint (see Figure 11). In a similar way, we redraw δ such that δ and γ become disjoint. Note that no other intersection points but $\alpha \cap \beta$ and $\gamma \cap \delta$ are destroyed and no new intersection points are introduced. Therefore, the vertex set of $\mathcal{A}(\{\alpha, \beta, \gamma, \delta\})$ is precisely $\{A_1', A_2', A_1'', A_2'', B_1', B_2', B_1'', B_2''\}$ and its edge set consists of the edges $[A_1', A_2']_\alpha$, $[A_2', A_2'']_\alpha$, $[A_2'', A_1'']_\alpha$, $[A_1'', A_1']_\alpha$, $[B_1', B_2']_\beta$, $[B_2', B_2'']_\beta$, $[B_2'', B_1'']_\beta$, $[B_1'', B_1']_\beta$, $[A_1'', A_2'']_\gamma$, $[A_2'', B_1'']_\gamma$, $[B_1'', B_2'']_\gamma$, $[B_2'', A_1'']_\gamma$, $[A_1', A_2']_\delta$, $[A_2', B_1']_\delta$, $[B_1', B_2']_\delta$ and $[B_2', A_1']_\delta$. It is not hard to see that this implies that the face set of $\mathcal{A}(\{\alpha, \beta, \gamma, \delta\})$ consists of four digons whose boundaries are $\{[A_1', A_2']_\alpha, [A_1', A_2']_\delta\}$, $\{[A_1'', A_2'']_\alpha, [A_1'', A_2'']_\gamma\}$, $\{[B_1', B_2']_\beta, [B_1', B_2']_\delta\}$ and $\{[B_1'', B_2'']_\beta, [B_1'', B_2'']_\gamma\}$, and six faces of size four whose boundaries are (refer to Figure 11 for an illustration):
$\{[A_1', A_2']_\delta, [A_2', A_2'']_\alpha, [A_2'', A_1'']_\gamma, [A_1'', A_1']_\alpha\}$, $\{[A_1', A_2']_\alpha, [A_2', B_1']_\delta, [B_1', B_2']_\beta, [B_2', A_1']_\delta\}$,
$\{[B_1', B_2']_\delta, [B_2', B_2'']_\beta, [B_2'', B_1'']_\gamma, [B_1'', B_1']_\beta\}$, $\{[A_1'', A_2'']_\alpha, [A_2'', B_1'']_\gamma, [B_1'', B_2'']_\beta, [B_2'', A_1'']_\delta\}$,
$\{[A_1', A_1'']_\alpha, [A_1'', B_2'']_\gamma, [B_2'', B_2']_\beta, [B_2', A_1']_\delta\}$ and $\{[A_2', A_2'']_\alpha, [A_2'', B_1'']_\gamma, [B_1'', B_1']_\beta, [B_1', A_2']_\delta\}$.

Note that $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 1$ and $d(\delta^{\text{in}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 2$ iff $\gamma^{\text{out}} \in (B_2'', A_2'')_\gamma$ and $\delta^{\text{in}} \in (A_2', B_2')_\delta$. Similarly, $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 2$ and $d(\delta^{\text{in}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 1$ iff $\gamma^{\text{out}} \in (A_2'', B_2'')_\gamma$ and $\delta^{\text{in}} \in (B_2', A_2')_\delta$. Suppose for contradiction that one of these cases holds. Then, on the one hand, there is a curve, namely $[\gamma^{\text{out}}, \delta^{\text{in}}]_c$, which connects γ^{out} and δ^{in} while not crossing any of α, β, γ and δ (this follows from the given cyclic order and Proposition 6). However, on the other hand, there is no face of $\mathcal{A}(\{\alpha, \beta, \gamma, \delta\})$ whose boundary contains segments of both $(B_2'', A_2'')_\gamma$ and $(A_2', B_2')_\delta$ or segments of both $(A_2'', B_2'')_\gamma$ and $(B_2', A_2')_\delta$, contradicting the existence of a curve as above. ◀

This completes the proof of Theorem 2.

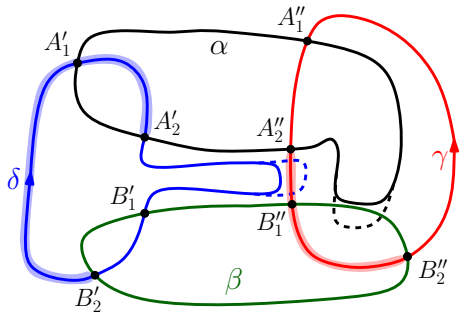

Figure 11 $\mathcal{A}(\{\alpha, \beta, \gamma, \delta\})$ after redrawing α and δ such that they do not form digons with β and γ, respectively. If $d(\gamma^{\text{out}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 2$ and $d(\delta^{\text{in}}, (\alpha^{\text{out}}, \beta^{\text{in}})) = 1$, then $\gamma^{\text{out}} \in (A_2'', B_2'')_\gamma$ and $\delta^{\text{in}} \in (B_2', A_2')_\delta$.

4 Concluding remarks

What can we say about drawings on other surfaces? For example, we can draw K_7 on the torus, which implies the existence of 7 curves such that they pairwise form a digon, giving us 21 digons in total. This suggests that we need a significantly different approach since an argument based on the embeddability of the double cover would give roughly $2n$ as an upper bound.

▶ **Problem 11.** *What is the maximum number of digons in a pairwise intersecting family of pseudocircles on a closed orientable connected surface M_g of genus g?*

We note that graphs with planar bipartite double covers were extensively studied in topological graph theory, see for example the works of Negami [14, 15]. Negami also considered general covers of graphs and formulated the following nice conjecture:

▶ **Conjecture 12** (Negami 1988). *A graph G has a finite planar cover if and only if G embeds in the projective plane.*

Indeed, with some extra work, one can show that digon graphs are embeddable in the projective plane, but we omit the proof.

Another natural question is to consider the number of triangles in intersecting pseudocircle arrangements. Felsner and Scheucher [9] showed that the maximal number of triangles is $2n^2/3+O(n)$, and this is asymptotically tight. In their proof, they use the bound $O(n)$ from [3] for the maximum number of digons in pairwise intersecting arrangements of pseudocircles. By applying Theorem 2 instead, we achieve the following improvement for simple arrangements.

▶ **Corollary 13.** *Every simple arrangement of $n \geqslant 4$ pairwise intersecting pseudocircles has at most $\frac{2}{3}n^2$ triangles.*

On the other hand, triangles are unavoidable, they showed that there are at least $2n/3$ triangles and made the subsequent conjecture.

▶ **Conjecture 14.** *Every pairwise intersecting arrangement of $n \geqslant 3$ pseudocircles has at least $n - 1$ triangles.*

On a final remark, we were able to extend our proof of Theorem 2 to nontrivial pairwise intersecting arrangements of pseudocircles. However, it involves dealing with several delicate subcases. Therefore, we have chosen to omit the full proof here.

Convexity Helps Iterated Search in 3D

Abstract

Inspired by the classical fractional cascading technique [13, 14], we introduce new techniques to speed up the following type of iterated search in 3D: The input is a graph $\mathbf{G}$ with bounded degree together with a set H_v of 3D hyperplanes associated with every vertex of v of $\mathbf{G}$. The goal is to store the input such that given a query point $q \in \mathbb{R}^3$ and a connected subgraph $\mathbf{H} \subset \mathbf{G}$, we can decide if q is below or above the lower envelope of H_v for every $v \in \mathbf{H}$. We show that using linear space, it is possible to answer queries in roughly $O(\log n + |\mathbf{H}|\sqrt{\log n})$ time which improves trivial bound of $O(|\mathbf{H}| \log n)$ obtained by using planar point location data structures. Our data structure can in fact answer more general queries (it combines with shallow cuttings) and it even works when $\mathbf{H}$ is given one vertex at a time. We show that this has a number of new applications and in particular, we give improved solutions to a set of natural data structure problems that up to our knowledge had not seen any improvements.

We believe this is a very surprising result because obtaining similar results for the planar point location problem was known to be impossible [15].

1 Introduction

The idea of "iterated searching" was introduced with the classical fractional cascading technique [13, 14] and it can be described as follows: consider an abstract data structure problem where given an input I, we need to preprocess it to answer a given q more efficiently. Now imagine that instead of having one input set, I, we have multiple independent input sets $I_1, I_2, \cdots$ and at the query time, we would like to answer the same query q on *some* of the data sets. This is typically modeled as follows: the input contains a catalog graph $\mathbf{G}$ and each vertex $v \in \mathbf{G}$ is associated with a different input set I_v. The goal is to preprocess the input, that is $\mathbf{G}$ and the sets I_v, so that given a query q and a connected subgraph $\mathbf{H} \subset \mathbf{G}$ we can find the answer to querying q on every data set I_v for each $v \in \mathbf{H}$. The trivial solution is to have a separate data structure for every I_v and to query them individually. Thus, the main research interest is to improve upon this trivial solution.

1.1 Fractional Cascading

Chazelle and Guibas improved upon the aforementioned "trivial solution" for the predecessor search problem. To be more precise, for each $v \in \mathbf{G}$, I_v is an ordered list of values and the query q is also a value and the goal is to find the predecessor of q in I_v for every $v \in \mathbf{H}$.

Chazelle and Guisbas showed how to build a data structure that uses linear space to answer such queries in $O(\log n + |\mathbf{H}|)$ time [13, 14], essentially, reducing the cost of a predecessor search to $O(1)$, after an initial investment of $O(\log n)$ time. This is clearly optimal and since its introduction has found plenty of applications.

The origin of this technique can be traced back to 1982 and to a paper by Vaishnai and Wood [22] and also the notion of "downpointers" from a 1985 paper by Willard [23] but the seminal work in this area was the aforementioned work by Chazelle and Guibas [13, 14].

1.2 2D Fractional Cascading

Due to its numerous applications, Chazelle and Liu [15] studied "2D fractional cascading" which is the iterated 2D point location problem. In particular, each vertex $v \in \mathbf{G}$ is associated with a planar subdivision, the query q is a point in $\mathbb{R}^2$, and the goal is to output for every $v \in \mathbf{H}$ the cell of the subdivion of v that contains q. Chazelle and Liu showed that in this case all hope is lost because there is an almost quadratic space lower bound for data structures with $O(\log n + |\mathbf{H}|)$ query time. Actually, their techniques prove an $\Omega(n^{2-\varepsilon})$ space lower bound for data structures with $O(\log^{O(1)} n) + o(|\mathbf{H}| \log n)$ query time. As $O(|\mathbf{H}| \log n)$ is the trivial upper bound, the lower bound "dashes all such hopes" (as Chazelle and Liu put it) for obtaining a general technique in dimensions two and beyond. However, the lower bound only applies to non-orthogonal subdivisions and only for data structures for sub-quadratic space consumption. Relatively recently, the barrier has been overcome via exploring those two directions. Afshani and Cheng [3] studied various cases involving orthogonal subdivisions and obtained almost tight results, e.g., the problem can be solved using linear space and with roughly $O(\log n + |\mathbf{H}|\sqrt{\log n})$ query time for axis-aligned subdivisions. Chan and Zheng [11] studied the non-orthogonal version but they allowed quadratic space usage and they showed that queries can be answered in $O(\log n + |\mathbf{H}|)$ time. Finally, we need to mention that a more general form of iterated search which allows $\mathbf{H}$ to be any subgraph of $\mathbf{G}$ has also been studied for 2D queries but the bounds are weaker [7].

1.3 A Brief Statement of Our Results

We introduce a general technique to solve the iterated search problem for a certain 3D query problem. Then, we show that our technique has a number of non-trivial applications.

1.3.1 A General Framework for Iterated Searching for Lower Envelopes

The exact statement of our technique requires familiarity with concepts such as shallow cuttings and therefore we postpone it to after the "Preliminaries" section. Here, we only state it informally: we study the *lower envelope iterated search (LEIS) problem*, where we are given a catalog graph $\mathbf{G}$ and each vertex $v \in \mathbf{G}$ is associated with a catalog which is a set H_v of hyperplanes. The goal is to preprocess the input into a data structure such that given a query point q and a connected subgraph $\mathbf{H} \subset \mathbf{G}$, the data structure should report whether q is below or above the lower envelope of H_v, for all $v \in \mathbf{H}$. In the shallow cutting variant of LEIS, the input has a parameter k and the data structure stores a number of lists of size $O(k)$ explicitly. Then at the query time the data structure has two options: (i) report that q is above the k-level of H_v or (ii) return a constant number, c, of pointers to c stored lists $L_1, \cdots, L_c$ such that the union of $L_1, \cdots, L_c$ contains all the hyperplanes that pass below q. In the *on-demand* version of the problem, $\mathbf{H}$ is given one vertex v at a time such that all the given vertices form a connected subgraph of $\mathbf{G}$ but the query must answer q on v before the next vertex is given. See Figure 1 for an illustration of our problem.

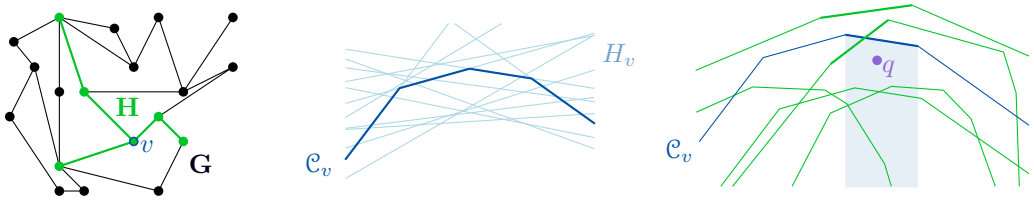

Figure 1 A schematic drawing of the LEIS Problem (with hyperplanes in $\mathbb{R}^2$ rather than $\mathbb{R}^3$). Each vertex v of $\mathbf{G}$ is associated with a set of hyperplanes H_v. For each vertex v in the query subgraph $\mathbf{H} \subset \mathbf{G}$ we wish to find the triangle in the k-shallow cutting $\mathcal{C}_v$ above the query point q.

Our main result is that all the above variants can be solved with a linear-space data structure that has $O(\log n + |\mathbf{H}|\sqrt{\log n})$ query time. This improves upon the trivial solution which results in $O(|\mathbf{H}| \log n)$ query time.

We believe this is a surprising result since a LEIS query (which is very commonly used in combination with shallow cuttings, see Lemma 3) is typically answered via a point location query and as Chazelle and Liu's lower bound [15] shows, it is hopeless to have an efficient data structure for iterated point location queries.

1.3.2 Some Applications of Our Technique

Chazelle and Liu [15] cite numerous potential applications of iterated 2D point location, if such a thing were to exist, before presenting their lower bound. The lower bound applies to some of those applications but not to all of them. In particular, it turns out that for some geometric problems, we are able to give improvements. One main problem is answering *halfspace max queries* which currently has only a basic "folklore" solution in 3D, despite being used in "blackbox" reductions in at least two general frameworks (more on this below).

▶ **Problem 1** (3D halfspace max queries). *Let P be an input set of n points in $\mathbb{R}^3$ each associated with a real-valued weight. Store them in a data structure such that given a query halfspace q one can find the point with the largest weight inside q.*

Currently, we are only aware of a "folklore" solution that uses $O(n \log n)$ space and has the query time of $O(\log^2 n)$ [6]. Using our framework, we get the following improvements.

- 3D halfspace max queries can be answered in $O(\log^{3/2} n)$ time with $O(n \log n)$ space.
- The current best solution for *3D halfspace range sampling* uses a "blackbox" data structure for weighted range sampling queries [6]. As a result, we improve the query time of the data structure in [6] from $O(\log^2 + k)$ (for sampling k points from a given query halfspace) to $O(\log^{3/2} n + k)$ by simply plugging in our solution for 3D halfspace max queries.
- Range sampling queries can be used as a blackbox to obtain solutions for other approximate aggregate queries [4] and thus our improve carries over to such queries as well.
- We get improved results for *colored halfspace reporting*, in which we store a set of n colored points so that given a query halfspace we can efficiently report all k distinct colors of the points that appear in the halfspace. We can achieve $O(\log n \log\log n + m \log\log n)$ query time using linear space, where m is the number of colors, or $O(\log n + k \log(m/k)\sqrt{\log n})$ time using $O(n \log n)$ space. This improves the query time of current solutions by a $O(\log n)$, respectively $O(\sqrt{\log n})$ factor.
- Some weighted range reporting problems can also be solved more efficiently: (*weighted halfspace range reporting*) store a given set of weighted points such that given a query halfspace q and an interval $[w_1, w_2]$, report all the points inside q whose weight is between

w_1 and w_2. (*weighted halfspace stabbing*) This is similar to the previous problem with the role of points and halfspaces swapped.

- The general framework of [19] combines weighted reporting and max reporting to give a general solution for "top-k reporting" (report the k heaviest points). Using our results, we can obtain a data structure for 3D halfspaces with $O(\log^{3/2} n + k)$ query time. This was the result "missing" in [19] where they only list new results for $d = 2$ and $d \geq 4$.
- Range reporting can also be used to obtain "approximate counting" results and a number of general reductions are available [18, 8, 17, 1] and so we can obtain improved results for "approximate counting" version of the above weighted reporting problems.
- The *offline* version of halfspace range reporting can also be improved: given a set P of n points, where a point p_i is given with an insertion time s_i and a deletion time d_i, store them in a data structure such that given a query halfspace h and a timestamp t, we can report all the points in h that exist in time t.
- Via standard lifting maps, problems involving circles in 2D can be reduced to those involving halfspaces in 3D.

2 Preliminaries

We adopt the following notations and definitions. In $\mathbb{R}^3$, a *triangle* is the convex hull of three points whereas a *simplex* is the convex hull of four points. The Z-coordinate is assumed to be the vertical direction and a *vertical prism* $\tau^{\downarrow}$ is defined by a triangle τ and it consists of all the points that are on τ or directly below τ (wrt to the Z-coordinate). For a point $q \in \mathbb{R}^3$, $q^{\downarrow}$ represents a downward ray starting from q. Given a set A of geometric objects and another geometric object r, the *conflict list* of r wrt A, denoted by $\Diamond(A, r)$, is the subset of A that intersects R. For example, if A is a set of polytopes and r is a point, then $\Diamond(A, r)$ is the set of of polytopes that contain r or if A is a set of hyperplanes and r is a point, then $\Diamond(A, r^{\downarrow})$ is the subset of hyperplanes that pass through or below r; in this latter case, $|\Diamond(A, r^{\downarrow})|$ is denoted as the *level* of r (wrt A). For a given parameter k, $1 \leq k \leq n$, the $(\leq k)$-level of A is the set of all the points in $\mathbb{R}^3$ with level at most k and the k-level of A is defined as the boundary of the $(\leq k)$-level; in particular, the 0-level of A is the lower envelope of A.

▶ **Observation 2** ([9]). *Let τ be a triangle and let $\Delta = \tau^{\downarrow}$ be the vertical prism defined by it. Let v_1, v_2, and v_3 be the vertices of τ. Any hyperplanes that intersects Δ, passes below at least one of the vertices of τ. In other words, for any set H of hyperplanes we have*

$$\Diamond(H, \Delta) \subset \Diamond(H, v_1^{\downarrow}) \cup \Diamond(H, v_2^{\downarrow}) \cup \Diamond(H, v_3^{\downarrow}).$$

We will extensively use shallow cuttings in our techniques. By now, this is a standard tool that is used very often in various 3D range searching problems.

▶ **Lemma 3** ([10, 20, 21]). *There exists a fixed constant $\alpha > 1$ such that for any given set H of n hyperplanes in 3D and a given parameter k, $1 \leq k \leq n$, the following holds: There exists a set of $O(n/k)$ hyperplanes such that their lower envelope lies above the k-level of H but below the (αk)-level of H. The lower envelope can be triangulated and for every resulting triangle τ, one can also build the conflict list $\Diamond(H, \tau^{\downarrow})$ in $O(n \log n)$ time in total (over all triangles τ). The shallow cutting $\mathcal{C}$ is taken to be the set of all the triangles and each triangle stores a pointer to its explicitly stored conflict list.*

Finally, one can store the projection of the shallow cutting in a 2D point location data structure that uses $O(n/k)$ space such that given a query point $q \in \mathbb{R}^3$, in $O(\log(n/k))$ time one can decide whether q lies below any triangle in $\mathcal{C}$ and if it does, then one can find the triangle directly above q, denoted by $\mathcal{C}(q)$. The subset of hyperplanes passing below q is a subset of the conflict list of $\mathcal{C}(q)$, i.e., $\Diamond(H, q^{\downarrow}) \subset \Diamond(H, \mathcal{C}(q)^{\downarrow})$.

Remark. The above is a "modern" statement of shallow cuttings in 3D. These were originally discovered by Matoušek [21]. However, a simple observation by Chan [9] (Observation 2) allows one to simplify the structure of shallow cuttings into the lower envelope of some hyperplanes. We will be strongly using convexity in our techniques so this treatment is extremely crucial for our purposes.

We now define the main iterated search problems that we will be studying.

▶ **Problem 4** (LEIS3D). *Let* $\mathbf{G}$ *be an input graph of constant degree, called the catalog graph, where each vertex* $v \in G$ *is associated with an input set* H_v *of hyperplanes in* $\mathbb{R}^3$*. Let* n *be the total input size and let* k*,* $1 \leq k \leq n$*, be a parameter given with the input. Store the input in a structure to answer queries that are given by a point* $q \in \mathbb{R}^3$ *and a connected subgraph* $\mathbf{H} \subset \mathbf{G}$*. For each vertex* $v \in \mathbf{G}$*, the data structure should store a* k*-shallow cutting of* H_v*. Then, for each* $v \in \mathbf{H}$ *at the query time, it must either (i) return a triangle* τ *above* q *together with a list of* c *pointers, for a constant* c*, to* c *conflict lists* $L_1, \cdots, L_c$ *in the* k*-shallow cutting of* H_v*, such that* $\Diamond(H_v, \tau) \subset \cup_{i=1}^{c} L_i$ *or (ii) indicate that* q *lies above the* k*-level of* H_v*.*

In the anchored version of the problem, for every $v \in \mathbf{G}$ *the data structure must explicitly store a set* T_v *of triangles such that the triangle* τ_v *returned at query time must be an element of* T_v*. In the on-demand version of the problem,* q *is given first but* $\mathbf{H}$ *is initially hidden and is revealed one vertex at a time at query time. The data structure must answer the query on each revealed vertex before the next vertex can be revealed. For simplicity, we assume that* $\mathbf{H}$ *is a walk, i.e., each revealed vertex is connected to the previously revealed vertex.*

Note for $k = 0$, we have a special case where during the query it suffices to simply return a triangle τ that is below the lower envelope and above q. Also the restriction that $\mathbf{H}$ must be a walk for the on-demand version is not strictly necessary in RAM models. However, removing this restriction creates some technical issues in some variants of the pointer machine model and thus it is added to avoid needless complications. Furthermore, a walk is sufficient in all the applications that we will consider. Our main technical result is the following.

▶ **Theorem 5.** *The on-demand LEIS3D problem for an input of size* n *on catalog graph* $\mathbf{G}$ *can be solved with a data structure that uses* $O(n)$ *space and has the following query time: (i)* $O(\log n \log\log n + |\mathbf{H}| \log\log n)$ *if* $\mathbf{G}$ *is a path and (ii)* $O(\log n + |\mathbf{H}|\sqrt{\log n})$ *when* $\mathbf{G}$ *is a graph of constant degree.*

3 Building the Tools

In this section, we will prove a number of auxiliary results that will later be combined to build our main results.

3.1 Point Location in 3D Convex Overlays

The following observation is our starting point. The proof is not too difficult and is available in the full version [5].

▶ **Lemma 6.** *Let* $\mathcal{P}_1, \cdots, \mathcal{P}_m$ *be* m *convex polytopes in* $\mathbb{R}^3$ *of total complexity* n*. Let* $\mathcal{A}$ *be their overlay. The overlay* $\mathcal{A}$ *has* $O(nm^2)$ *complexity.*

It is critical to observe that an equivalent lemma for 2D subdivision does not hold. For example, the overlay of two subdivisions of the plane into n "tall and thin" and "wide and narrow" slabs has $\Omega(n^2)$ size. Thus, the above lemma captures a fundamental impact of adding convexity to the picture. The next lemma shows that we can perform point location in 3D via a simple idea and a small query overhead.

▶ **Lemma 7** (basic point location). *Let $S = \{\mathcal{P}_1, \cdots, \mathcal{P}_m\}$ be a set of m convex polytopes in $\mathbb{R}^3$ of total complexity n. We can build a data structure that uses $O(nm^2)$ space that does the following: The data structure stores a set T of "anchors" (triangles) such that each anchor is either inside a polytope or lies completely outside it. Then, given a query point q, it can output an anchor $\tau \in T$ such that $\Diamond(S, q)$ is equal to the subset of polytopes that contain τ. The time to answer the query is $O(\log n \log m)$.*

Proof sketch (see the full version [5] for the full proof). The plan is to do a binary search via point location queries. To do that, we decompose each polytope into an upper and lower hull and then turn each hull into an everywhere defined surface (a function from $\mathbb{R}^2$ to $\mathbb{R}$). We overlay them, triangulate them, and then decompose them into "levels" where each level ends up being a Z-monotone surface whose projection will be a planar decomposition which will be stored in a point location data structure. The level (and the triangle) immediately above a query point can be found with $O(\log m)$ steps of a binary search process that uses the point location queries for a total query time of $O(\log n \log m)$. ◀

For some applications, the above lemma is sufficient but for our most general result, we need to remove the factor $\log m$ in the above query time.

▶ **Lemma 8** (advanced point location). *Let $S = \{\mathcal{P}_1, \cdots, \mathcal{P}_m\}$ be a set of m convex polytopes in $\mathbb{R}^3$ of total complexity n, where $m = O(2^{\sqrt{\log n}})$. We can build a data structure that uses $O(n2^{O(\sqrt{\log n})})$ space that does the following: The data structure stores a set T of "anchors" (triangles) such that each anchor is either inside a polytope or lies completely outside it. Then, given a query point q, it can output an anchor $\tau \in T$ such that $\Diamond(S, q)$ is equal to the subset of polytopes that contain τ. The query time is $O(\log n)$.*

The rest of this subsection is devoted to the proof of Lemma 8.

3.1.1 Preliminaries

A modified Dobkin-Kirkpatrick hierarchy. First, we describe a process of simplifying polytopes in 3D which is a modified version of building Dobkin-Kirkpartrick hierarchies [16] but in a randomized way. We refer to the standard Dobkin-Kirkpartrick simplification as DK-simplification and to our modified randomized simplification as RDK-simplification. Let $\mathcal{P}$ be a convex polytope in 3D. An *outer simplification* of $\mathcal{P}$ is obtained by considering $\mathcal{P}$ as the intersection of halfspaces that bound its faces. Then, we select a subset I of independent faces of $\mathcal{P}$ (i.e., no two adjacent faces are selected) and such that each face has $O(1)$ complexity and $|I| = \Omega(|\mathcal{P}|)$. In DK-simplification, I is simply deleted, instead in RDK-simplification, we delete each element of I with probability 0.5, independently. Observe that the deletion of I' is equivalent to attaching $|I'|$ disjoint convex cells of constant complexity to the faces of $\mathcal{P}$. To define an *inner simplification* of $\mathcal{P}$ we do a similar process but this time we consider $\mathcal{P}$ as the convex of hull of its vertices and select an independent set I of the vertices of $\mathcal{P}$ of size $\Omega(|\mathcal{P}|)$ such that each vertex has constant degree. In the standard DK-simplification, I is simply deleted, but in RDK-simplification, we delete each vertex in I with probability 0.5, independently. This creates a convex polytope that is contained inside $\mathcal{P}$ (or shares some boundaries). This process can be thought of as removing disjoint convex cells of constant complexity from $\mathcal{P}$. See Figure 2 for an illustration.

We can repeatedly apply DK- or RDK-simplifications until the inner polytope is reduced to a simplex and the outer polytope to a halfspace. This results in a hierarchy which is denoted by $\mathcal{H}(\mathcal{P})$. An easy observation that we will be using is the following.

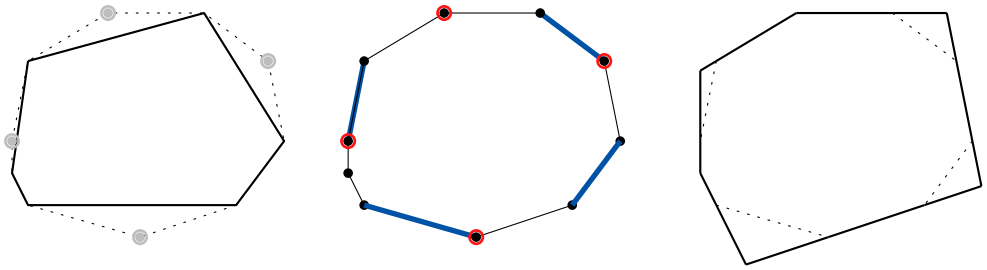

Figure 2 The inner and outer simplifications are shown in 2D, for clarity. The central polytope is being simplified here. To the left, we have its inner simplification after deleting the vertices marked with red and to the right, we have the outer simplification after deleting the edges marked with blue.

▶ **Observation 9.** *If every simplification reduces the complexity of $\mathcal{P}$ by a constant factor, then, $\mathcal{H}(\mathcal{P})$ consists of $O(\log n)$ convex polytopes, i.e., it is the overlay of $O(\log n)$ convex polytopes which decomposes $\mathbb{R}^3$ into $O(|\mathcal{P}|)$ convex cells of constant complexity.*

A simplification round. Let T be a parameter that will be defined later (T will actually be set to $\sqrt{\log n}$). Given a convex polytope $\mathcal{P}$, *one round of simplification of $\mathcal{P}$* is defined as follows. If the complexity of $\mathcal{P}$ is at most 2^T, then $\mathcal{P}$ is simplified via DK-simplification, reducing the complexity of $\mathcal{P}$ by a constant factor at each simplification to yield a hierarchy of $O(\log |\mathcal{P}|) = O(T)$ simplifications. Otherwise, starting from $\mathcal{P}$, we repeatedly apply inner (resp. outer) RDK-simplification T times to obtain T progressively smaller (resp. larger) polytopes. The smallest and the largest polytopes that are obtained are called the *boundary* polytopes. Based on this, we perform the following steps for every polytope $\mathcal{P}_i$ in the input.

1. Initialize a list $X = \{\mathcal{P}_i\}$ and the set $S = \{\mathcal{P}_i\}$ of simplifications of $\mathcal{P}_i$. Each element of S will maintain a *counter* that counts how many rounds it has been simplified for, and for $\mathcal{P}_i$ this counter is initialized to zero.
2. While X is not empty:
   a. Remove the first polytope $\mathcal{P}$ from X and let c be the counter of $\mathcal{P}$.
   b. Simplify $\mathcal{P}$ for one round, resulting in $O(T)$ simplifications which are added to S; all of these simplifications have their counter set to $c + 1$.
   c. If any boundary polytope is produced (i.e., if $\mathcal{P}$ had complexity at least 2^T), then they are added to X.

We also define a subdivision $\mathcal{A}_j$ is as the overlay of all the polytopes (over all sets S) whose counter is at least j. The following lemma captures some of the important properties of our construction.

▶ **Lemma 10.** *Assuming $T \geq c + \log\log n$ for a large enough constant c, the following properties hold with probability at least $1 - n^2$ (whp).*

(I) *Let x be the maximum value of the counters of the polytopes in $\mathcal{A}_0$. We have $x = O\left(\frac{\log n}{T}\right)$ (whp).*
(II) *Let M be the number of polytopes in $\mathcal{A}_0$. We have $M = O(m2^x T)$.*
(III) *The size of $\mathcal{A}_j$ is $O(nM^2)$, for all j.*
(IV) *$\mathcal{A}_j$ decomposes $\mathbb{R}^3$ into convex cells of complexity $O(M)$.*
(V) *Let Δ be a cell in $\mathcal{A}_j$ and let $\mathcal{P}$ be a polytope in $\mathcal{A}_{j-1}$. Then, the number of vertices of $\mathcal{P}$ that are contained in Δ as well as the number of edges of $\mathcal{P}$ that intersect Δ is bounded by $O(2^{O(T)}\log n) = O\left(2^{O(T)}\right)$. (whp).*
(VI) *The size of $\mathcal{A}_x$ is $O\left(\left(m2^x T 2^T\right)^{O(1)}\right)$.*

Proof. For claim (I), observe that if a polytope $\mathcal{P} \in X$ has size 2^T, then it is simplified with a standard DK-simplification and it adds no additional polytopes to X. Thus, it suffices to consider polytopes that have complexity at least $2^T \geq \log^c n$. Now the claim (I) follows from a standard Chernoff bound: Since in our RDK-simplification, we will select an independent set I of size $\Omega(|\mathcal{P}|) = \Omega(c \log n)$ and on expectation, we will delete half of elements but since $\mathbb{E}[|I|] \geq c \log n$, it follows that with with high probability at least $|I|/4$ of the elements of I are deleted. This reduces the complexity of polytope by a constant fraction. Consequently, the number of RDK-simplifications steps an input polytope can go through is bounded by $O(\log n)$ and thus the number of rounds is $O(\frac{\log n}{T})$ which implies claim (I).

Claim (II) follows from the observation that during each round, each polytope creates two additional polytopes (whose counters are incremented by one). In other words, the number of polytopes of counter $c+1$ is at most double the number of polytopes with counter c. Combined with (I) this implies that the total number of polytopes ever added to X is $O(m2^x)$. For each such a polytope (whose counter is at least j) the overlay $\mathcal{A}_j$ includes T additional polytopes in S.

Claim (III) is a consequence of Lemma 6 and (II).

To see (IV), consider one polytope $\mathcal{P}$ in $\mathcal{A}_j$. Observe that all the inner and outer simplifications of $\mathcal{P}$ are also included in $\mathcal{A}_j$ this is because our simplification process continues until the inner simplification of $\mathcal{P}$ is reduced to a simplex and the outer simplification of $\mathcal{P}$ is reduced to a halfspace. All of these simplifications have a counter value that is at least j and thus by definition of $\mathcal{A}_j$ they are included in $\mathcal{A}_j$. Thus, some DK-hierarchy, $\mathcal{H}(\mathcal{P})$, of $\mathcal{P}$ is included in $\mathcal{A}_j$. By Observation 9, $\mathcal{H}(\mathcal{P})$ decomposes $\mathbb{R}^3$ into cells of constant complexity. The number of such hierarchies that are included in $\mathcal{A}_j$ is upper bounded by the number of polytopes, M. Each cell Δ of $\mathcal{A}_j$ is thus the intersection of at most M convex cells of constant complexity and thus Δ will have complexity at most $O(M)$.

Now consider claim (V). Observe that if $\mathcal{P}$ is included in $\mathcal{A}_j$, then Δ cannot contain any vertex of $\mathcal{P}$ or intersect any of its edges. Thus, we can assume $\mathcal{P}$ is not included in $\mathcal{A}_j$. But this also implies that the counter of $\mathcal{P}$ must have value exactly $j-1$. At some point $\mathcal{P}$ will be considered during our simplification process. Assume that Δ is intersected by Y edges of $\mathcal{P}$ and $Y = \Omega(2^T \log n)$. This implies that $\mathcal{P}$ must have undergone our RDK-simplification process. Consider one step of our randomized DK-simplification: regardless of whether we are dealing with inner or outer simplification and regardless of which independent set is chosen, each of these Y edges are kept with probability at least $\frac{1}{4}$. By a standard Chernoff bound, it follows that with high probability, at least $\frac{1}{8}$ fraction of them are kept. $\mathcal{P}$ undergoes at most T such simplification steps until its counter is incremented by one and the resulting boundary polytopes are added to $\mathcal{A}_j$. This implies that with high probability, the resulting boundary polytopes have at least $\frac{Y}{8^T}$ edges intersecting Δ. If $Y \geq c8^T \log n$, this is a contradiction and thus the claim follows. A similar argument applies to the vertices of $\mathcal{P}$ contained in Δ.

Finally, the claim (VI) follows by the observation that at the last round, all polytopes must have complexity at most 2^T and there can be at most $m2^x T$ of them by claim (II) and now we plug these values in Lemma 6 to prove this claim. ◀

The next lemma enables us to give an upper bound on the number of cells of $\mathcal{A}_{j-1}$ that can intersect the cells of $\mathcal{A}_j$. This is a very crucial part of our point location data structure but the proof is relatively technical so it is postponed to the full version [5].

▶ **Lemma 11.** *Let A and B be the overlay of at most L convex polytopes each such that they form a decomposition of $\mathbb{R}^3$ into convex cells of complexity at most δ. In addition, assume that for every cell Δ in B, and every polytope $\mathcal{P}$ in A, the number of vertices of $\mathcal{P}$ that are contained in Δ and the number of edges of $\mathcal{P}$ that intersect Δ are bounded by X.*

Then, every cell Δ of B is intersected by at most $O(L^3X + L^3\delta + L^2\delta^2 + L\delta^3)$ cells of A.

3.1.2 Proof of Lemma 8 (Advanced Point Location)

Our data structure is as follows. Set $T = \sqrt{\log n}$. Observe that we have $2^T = 2^{\frac{\log n}{T}}$. We build the previously mentioned overlays $\mathcal{A}_i$ for $i = 1, \cdots, O(\log_T n)$. Then, for each cell Δ in $\mathcal{A}_j$, we find all the cells Δ' in $\mathcal{A}_{j-1}$ that intersect Δ and then store the hyperplanes that define them in what we call a *fast data structure*. Given a set of ℓ hyperplanes, such a fast data structure can store them using $O(\ell^3)$ space such that point location queries can be answered in $O(\log \ell)$ time [12]. This concludes our data structure. Our query algorithm is relatively simple: if we know the cell Δ in $\mathcal{A}_j$ that contains the query point, then by querying the fast data structure built for Δ, we can find the cell Δ' in $\mathcal{A}_{j-1}$ that contains the query point and then we can continue until we finally point locate the query. We now bound the space and the query time of the data structure.

The query time. By Lemma 10 (VI), we can locate the query point q in a cell of $\mathcal{A}_x$ in $O(\log m + x + \log T + T) = O(\sqrt{\log n})$ time. Thus, assume, we know q is in a cell Δ of $\mathcal{A}_j$. By Lemma 10, each $\mathcal{A}_j$ will have total complexity $O(n2^{O(T)})$ and is composed of $2^{O(T)}$ polytopes with cells of complexity $2^{O(T)}$. By Lemma 11 (using $\delta, L = M, X$ all set to $2^{O(T)}$) and Lemma 10(II,IV,V), Δ will intersect at most $2^{O(T)}$ cells Δ', whp. Note that we can assume this holds in the worst-case because if a cell intersects more than this amount, then we can simply rebuild the data structure and the expected number of such trials is $O(1)$. Thus, querying the fast data structure will take $O(T)$ time. Finally, observe that the depth of the recursion is $x = \frac{\log n}{T}$. So we get the query time of $O(\log n)$.

The space analysis. As mentioned each $\mathcal{A}_i$ will have complexity $O(n2^{O(T)})$. For each cell we store a fast data structure that uses $2^{O(T)}$ space, leading to $O(n2^{O(T)})$ total space usage.

3.2 Solving LEIS3D

In this section, we prove our main technical tool.

▶ **Theorem 5.** *The on-demand LEIS3D problem for an input of size n on catalog graph $\mathbf{G}$ can be solved with a data structure that uses $O(n)$ space and has the following query time: (i) $O(\log n \log\log n + |\mathbf{H}| \log\log n)$ if $\mathbf{G}$ is a path and (ii) $O(\log n + |\mathbf{H}|\sqrt{\log n})$ when $\mathbf{G}$ is a graph of constant degree.*

Proof. Note that when $\mathbf{G}$ is a general graph of maximum degree $d = O(1)$, we can assume that its maximum degree is 3 by replacing a vertex of degree $d' \leq d$ with a binary tree of depth $\log d'$ which only blows up the query time by a constant factor.

Recall that our data structure should store a k-shallow cutting of H_v for each vertex $v \in \mathbf{G}$, and let c be a large enough constant. When $\mathbf{G}$ is a path we set $\ell = \log n \cdot \log\log n$ and $x = k(2\ell)^c$ and when $\mathbf{G}$ is a general graph, we set $\ell = \sqrt{\log n}$ and $x = k2^{c\ell}$. We say a vertex $u \in \mathbf{G}$ is *light* if $|H_v| \leq x$, and *heavy* otherwise. For a vertex v, its *ℓ-neighborhood*, denoted by $\mathcal{N}_\ell(v)$, is the set of all the vertices of $\mathbf{G}$ that have distance at most ℓ to v.

The data structure. For every vertex v, we build a x-shallow cutting $\mathcal{C}_v$ for the set of hyperplanes H_v. If v is heavy, $\mathcal{C}_v$ is built via Lemma 3 (together with the all the corresponding apparatus in the lemma) and thus $\mathcal{C}_v$ is assumed to be convex (i.e., the lower envelope of some hyperplanes). However, if v is light, then $\mathcal{C}_v$ is assumed to consist of just one triangle τ, the hyperplane $Z = +\infty$ as an infinite triangle and the conflict list of τ in this case is H_v. In either case, for every triangle τ in the shallow cutting $\mathcal{C}_v$, we compute and store the

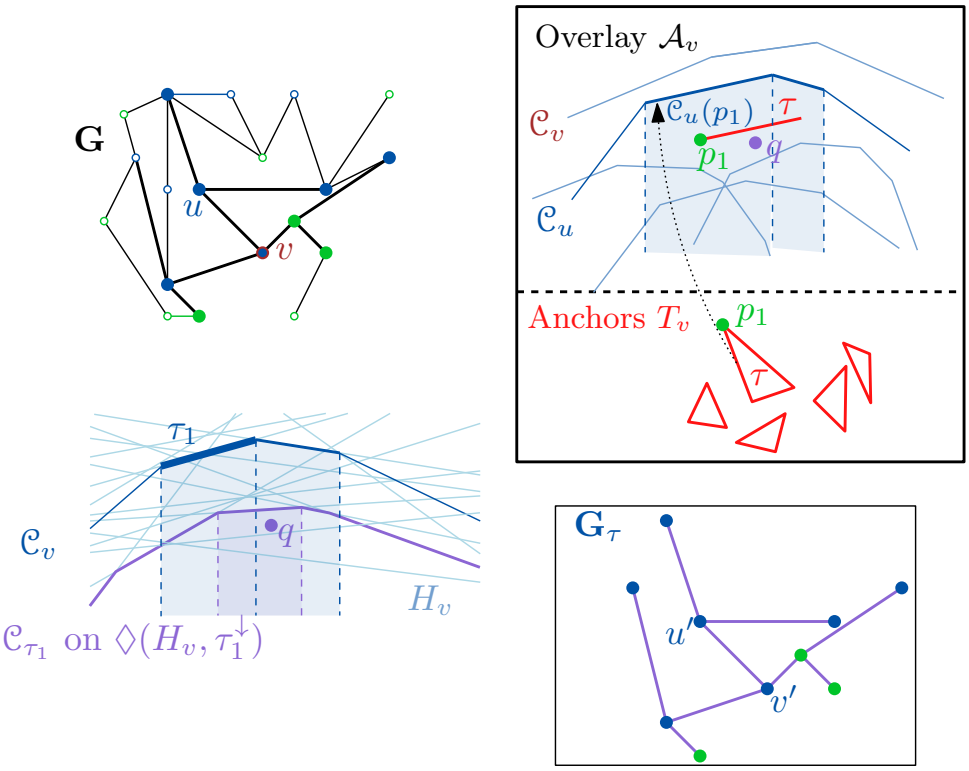

Figure 3 An overview of the data structure. Light nodes shown in green, heavy nodes in blue, and $\mathcal{N}_2(v)$ is marked with large disks. Each triangle τ in the point location data structure on $\mathbf{G}_u$ stores a pointer to a copy of this neighborhood. From there, we can jump to cells in $\mathcal{C}_v$.

conflict list, $\Diamond(H_v, \tau^{\downarrow})$, and then we build a k-shallow cutting, $\mathcal{C}_\tau$, on $\Diamond(H_v, \tau^{\downarrow})$; we call $\mathcal{C}_\tau$ *the secondary shallow cutting*. This is also built via Lemma 3. Note that as $x \geq k$, these secondary shallow cuttings cover the $\leq k$-level of H_v.

The overlays. Next, we consider each heavy vertex v: we consider all the vertices $u \in \mathcal{N}_\ell(v)$ and the shallow cuttings $\mathcal{C}_u$ as convex polytopes and create a 3D point location data structure on the overlay all the convex polytopes $\mathcal{C}_u$, for all u. Let $\mathcal{A}_v$ be this overlay. When $\mathbf{G}$ is a path, $\mathcal{N}_\ell(v)$ contains at most 2ℓ vertices and this overlay is built via Lemma 7. When $\mathbf{G}$ is a graph, it contains at most $2^{\ell+1}$ vertices and we use Lemma 8. In either case, the data structure will store a number of triangles as anchors, denoted by T_v. For each anchor $\tau \in T_v$ we consider its corners (vertices) p_1, p_2 and p_3. Then, consider every $u \in \mathcal{N}_\ell(v)$ and its shallow cutting $\mathcal{C}_u$; store a pointer from τ to the triangle, $\mathcal{C}_u(p_i)$, in $\mathcal{C}_u$ that lies above p_i, for $1 \leq i \leq 3$. Observe that for the anchor τ, we store at most $3\mathcal{N}_\ell(v)$ pointers (at most three per $u \in \mathcal{N}_\ell(v)$). These pointers are arranged in a particular way: we make a copy of $\mathcal{N}_\ell(v)$, denoted by $\mathbf{G}_\tau$, where each vertex $u \in \mathcal{N}_\ell(v)$ has a copy $u' \in \mathbf{G}_\tau$ and we store the three pointers from u' to $\mathcal{C}_u(p_i)$, for $1 \leq i \leq 3$.

The query. Consider a query, consisting of a point $q \in \mathbb{R}^3$ and an initial vertex u of the query subgraph $\mathbf{H}$.

1. If u is light, $\mathcal{C}_u$ contains one triangle τ which is the plane $Z = +\infty$ and one cell which is the entire $\mathbb{R}^3$. We look at the secondary shallow cutting $\mathcal{C}_\tau$ and locate $\mathcal{C}_\tau(q)$ if it exists and return conflict list $\Diamond(H_u, \mathcal{C}_\tau(q)^{\downarrow})$ which by Lemma 3 contains $\Diamond(H_u, q^{\downarrow})$.

2. This process can be repeated until we encounter the first heavy vertex u. We query the 3D point location data structure (Lemma 8 for general graphs and Lemma 7 for when $\mathbf{G}$ is a path) to get an anchor triangle τ with corners p_1, p_2 and p_3. We use the pointers associated with the copy u' of u in $\mathbf{G}_\tau$ to find the triangle $\tau_i = \mathcal{C}_u(p_i)$, $1 \leq i \leq 3$. The 3D point location data structure guarantees that the corners of τ all lie below $\mathcal{C}_u$, and thus all three of these triangles τ_i exist, if and only if q lies below $\mathcal{C}_u$.
   We query the secondary shallow cuttings $\mathcal{C}_{\tau_i}$, $1 \leq i \leq 3$, and for each, we find $\mathcal{C}_{\tau_i}(q)$, if it exists and then report the pointer to the corresponding secondary conflict list.
3. Now assume the query is given a sequence of vertices of $\mathbf{G}$, $u_0 = u, u_1, \cdots, u_m$, one by one, such that they all belong to $\mathcal{N}_\ell(u)$. Let τ be the triangle found in the previous step. The crucial observation is that τ does not intersect any triangle in the shallow cuttings $\mathcal{C}_w$, for any $w \in \mathcal{N}_\ell(u)$ since τ was a triangle in the overlay of all the shallow cuttings. Thus, in this case, the anchor does not change. In this case, for each revealed vertex u_j, we simply need to follow the pointer from u'_{j-1} to u'_j in $\mathbf{G}_{u,\tau}$ and from u'_j to $\mathcal{C}_{u_j}(p_i)$, for $1 \leq i \leq 3$. The rest of the algorithm is the same as Step 2.
4. Eventually, the algorithm will reveal a vertex u_{m+1} that is outside the $\mathcal{N}_\ell(u)$. In this case, we simply go to Step 1 or 2, i.e., we assume u_{m+1} is the initial vertex.

The query time. Step 1 takes $O(\log(\frac{x}{k}))$ time by Lemma 3 since each conflict in $\mathcal{C}_v$ has size $O(x)$ and we have a k-shallow cutting for them. In Step 2, we use $Q = O(\log n \log\log n)$ time for when $\mathbf{G}$ is a path by Lemma 7 and $Q = O(\log n)$ time for a general graph to identify the anchor τ. Obtaining the triangles $\mathcal{C}_u(p_i)$ for $1 \leq i \leq 3$ is a constant time operation and then we again query the secondary shallow cuttings which takes $O(\log(\frac{x}{k}))$ time. In Step 3, the query time is only $O(\log(\frac{x}{k}))$ because we do not need to find the anchor τ, and the cost is simply the cost of querying the secondary shallow cutting. Finally, observe that whenever we reach Step 2, at least ℓ other vertices of $\mathbf{H}$ must be revealed until we exceed $\mathcal{N}_\ell(u)$. In other words, Step 2 is only repeated once ℓ additional vertices of $\mathbf{H}$ have been revealed. Summing this up, we get that the query time is asymptotically bounded by

$$Q + \log\left(\frac{x}{k}\right)|\mathbf{H}| + \frac{|\mathbf{H}|}{\ell} \cdot Q.$$

By plugging in the corresponding parameters, when $\mathbf{G}$ is a path, the query time is

$$O(\log n \log\log n + |\mathbf{H}| \log\log n)$$

and for a general graph $\mathbf{G}$ it is

$$O(\log n + |\mathbf{H}|\sqrt{\log n}).$$

The space analysis. The total size of the shallow cuttings $\mathcal{C}_v$ and the secondary shallow cuttings is $O(n)$. Let M be the maximum size of $\mathcal{N}_\ell(v)$, i.e., for a path $\mathbf{G}$ we have $M = 2\ell$ and for a general graph of maximum degree three we have $M = 2^\ell$. Observe that the parameter x is at least M^c in both cases, for some constant c that we can choose. The number of heavy vertices is at most $\frac{n}{x}$ and each heavy vertex can appear in the ℓ-neighborhood of at most M other vertices. Thus, the total number of overlays that we will create is at most $\frac{nM}{x}$ and each overlay will contain at most M convex polytopes. By choosing c large enough and by plugging the bounds from Lemma 7 and Lemma 8, we get that the total space of the 3D point location can be bounded by $O\left(\frac{n}{M}\right)$ which is also an upper bound for the number of anchors. Finally, for every anchor, we store at most M pointers for a total of $O(n)$ space. ◀

4 Some Applications

Here, we briefly mention quick applications of Theorem 5. Note that by lifting map, similar problems for 2D disks can also be solved.

▶ **Theorem 12.** *Let P be a set of n points in 3D, each associated with a real-valued weight. We can store P in a data structure that uses $O(n \log n)$ space such that given a query halfspace h and two values w_1 and w_2, we can find all the points P that lie inside h and whose weight lies between w_1 and w_2 in $O(\log^{3/2} n + t)$ query time where t is the size of the output.*

Proof. Use duality to get a set of n hyperplanes and let q be point dual to the query halfspace h. Store the hyperplanes in a balanced binary tree $\mathbf{G}$, ordered by weight. Every node v of $\mathbf{G}$ defines a *canonical set* H_v which is the subset of hyperplanes stored in the subtree of v. Store H_v in a data structure of Afshani and Chan [2]. This uses $O(n \log n)$ space in total. Then, answering the query can be reduced to answering $O(\log n)$ 3D halfspace range reporting queries on two root to leaf paths in the tree. Simply querying the data structure of [2] gives $O(\log^2 n + t)$ query time which is already optimal if $t \geq \log^2 n$. To improve the query time, it thus suffices to assume $t \leq \log^2 n$. In which case, we use Theorem 5 with parameter $k = \log^2 n$ and store each conflict list stored by Theorem 5 in a data structure of [2]. This combination still uses linear space and when $t \leq \log^2 n$, it returns $O(1)$ conflict lists of size $O(\log^2 n)$ each. Querying the data structure of [2] on the conflist lists gives the claimed query time. ◀

Note that offline halfspace range reporting queries can also be solved with a very similar technique. We now consider 3D halfspace max queries.

▶ **Theorem 13.** *3D halfspace range max queries can be solved $O(n \log n)$ space and $O(\log^{3/2} n)$ query time.*

Proof. Use duality and let $H = \{h_1, .., h_n\}$ be the dual input hyperplanes ordered by increasing weights, and let w_i be the weight of h_i. We construct a balanced binary tree $\mathbf{G}$, whose leaves correspond to the hyperplanes $h_1, .., h_n$. For each node v, let H_v denote the subset of hyperplanes stored in the leaves below v. We now build the data structure of Theorem 5, with parameter $k = 0$. Total number of hyperplanes is $O(n \log n)$, the data structure uses $O(n \log n)$ space.

Consider the query point $q \in \mathbb{R}^3$ dual to the query halfspace, and let h_i be the (unknown) heaviest plane that passes below q. To find h_i, we construct a path $\mathbf{H}$ of length $O(\log n)$ in an on-demand manner. The main idea is as follows. At node v, with left child ℓ and right child r, we want to test if q lies below the lower envelope (the 0-level) of H_r. If so, then h_i must lie in the left subtree rooted at ℓ, hence we continue the search there. If q lies above the lower envelope of H_r, we continue the search in the subtree rooted at r. The process finishes after we find the leaf containing h_i in $O(\log n)$ rounds. This process generates a path $\mathbf{H}$ of length $O(\log n)$. Hence, the total query time is $O(\log^{3/2} n)$ as claimed. ◀

As discussed, this also improves the query time of the best range sampling data structures for weighted points. See [6]. It can also be combined with Theorem 12 to answer "top-k" reporting queries of halfspaces in 3D [19] as well as approximate counting queries [18].

▶ **Theorem 14.** *Let P be a set of points, each associated with a color from the set $[m]$. We can store P in a data structure, s.t., given a query halfspace h, we can report the t distinct colors of the points in h in (i) $O(\log n \log\log + m \log\log n)$ time using $O(n)$ space or (ii) $O(\log n + t \log(m/t)\sqrt{\log n})$ time using $O(n \log m)$ space.*

Proof. Once again use duality and let H be the of dual halfspaces. Let H_i be the hyperplanes of color i, $1 \leq i \leq m$. For the first claim (i), simply use a path of length m as graph $\mathbf{G}$ and invoke Theorem 5 where all query subgraphs $\mathbf{H}$ are equal to $\mathbf{G}$.

For the second claim (ii), add a balanced binary tree of height $\log m$ on the path and let $\mathbf{G}$ be the resulting graph. For every node $v \in \mathbf{G}$, define H_v to be the union of hyperplanes stored in the subtree of v. We now build the Theorem 5 data structure with $k = 0$ the graph $\mathbf{G}$. The total size of all sets H_v, and thus of our data structure is $O(n \log m)$. Now, consider the query point $q \in \mathbb{R}^3$ dual to h. Once again, we use the on-demand capability and at every node $v \in \mathbf{G}$ we decide whether either child of v has any output color, and if so, we recurse into that child. Let $\mathbf{H}$ denote the subtree of $\mathbf{G}$ visited by this procedure. By classical results, size of $\mathbf{H}$ is $O(t \log(n/t))$, when t is the number of leaves visited (and thus the number of distinct colors reported). Note that $\mathbf{H}$ can be assumed to be a walk by simpling fully finishing the recursion on each child of v, then backing up to v and then potentially recursing on the other child. The total query time is $O(\log n + t \log(m/t)\sqrt{\log n})$. ◀

Abstract

We study the problem of computing the L_1-distance between two piecewise-linear bivariate functions f and g, defined over a bounded polygonal domain $\mathbb{M} \subset \mathbb{R}^2$, that is, computing the quantity $\|f-g\|_1 = \int_{\mathbb{M}} |f(x,y)-g(x,y)|\,dx\,dy$. If f and g are defined by linear interpolation over triangulations $\mathbf{T}_f$ and $\mathbf{T}_g$, respectively, of $\mathbb{M}$ with a total of n triangles, we show that $\|f-g\|_1$ can be computed in $\tilde{O}(n^\alpha)$ time, where $\alpha = \max\{(\omega+1)/2, 8/5\}$, ω is the matrix multiplication exponent, and $\tilde{O}$ notation hides factors of the form n^ε for any $\varepsilon > 0$. This bound holds for the currently best known value of ω, which is approximately 2.37. More generally, if the complexity of the overlay of $\mathbf{T}_f$ and $\mathbf{T}_g$ is κ, then the runtime of our algorithm is $\tilde{O}(\kappa^{\alpha-1}n^{2-\alpha})$.

1 Introduction

Combining tools from computational geometry and computer algebra has led to new results that defy intuitive lower bounds. For example, using algebraic tools, it is possible to compute the centroid of the vertices in an arrangement of n lines in the plane in $O(n \log^2 n)$ operations, without computing the $\Theta(n^2)$ vertices [5]. One notable algebraic tool used for this problem is an algorithm to evaluate efficiently a univariate polynomial on multiple points [13]. This tool

was used to speed up, among others, the computation of Shapley values in the plane [10], the location of points among wireless transmitters [6], and the computation of the L_2-distance between two piecewise-linear bivariate functions f and g [16].

Bivariate functions over a planar domain are ubiquitous in geographical information systems, where they are used to represent a digital elevation model of a geospatial area, or, more generally, a function over a two-dimensional region such as precipitation, air pollution, population density, or quantities of wine production. One way to represent such a function is to triangulate the underlying domain and define a linear function over each triangle, resulting in a piecewise-linear function, often referred to as a *triangulated irregular network* (TIN). In this paper, we design an efficient algorithm for computing the L_1-distance between two piecewise-linear bivariate functions.

Problem statement. Let $\mathbb{M}$ be a bounded polygonal region of $\mathbb{R}^2$, and let $f, g : \mathbb{M} \to \mathbb{R}$ be two piecewise-linear functions defined over their common domain $\mathbb{M}$. Each of f, g is associated with a triangulation of $\mathbb{M}$, denoted by $\mathbf{T}_f, \mathbf{T}_g$, respectively, and f (resp., g) is defined to be linear over each triangle of $\mathbf{T}_f$ (resp., $\mathbf{T}_g$). Note that $\mathbf{T}_f$ and $\mathbf{T}_g$ are not assumed to be the same. Let n be sum of the numbers of vertices in $\mathbf{T}_f$ and $\mathbf{T}_g$. The graph of f (or g) is a xy-monotone polyhedral surface in $\mathbb{R}^3$, referred to as a *terrain*. For any integer $p > 0$, we define the L_p-distance between f and g to be

$$\|f - g\|_p = \left(\int_{\mathbb{M}} |f - g|^p \, dx \, dy \right)^{1/p}. \tag{1}$$

The goal in this paper is to compute $\|f - g\|_1$.

We will work in the Real RAM model [18], where inputs and intermediate values are real numbers and where algebraic operations and comparisons on real values can be performed in constant time, but modulus or rounding-to-an-integer operations are not allowed. We assume that the coefficients of the piecewise-linear functions f and g and the coordinates of the triangles in $\mathbf{T}_f$ and $\mathbf{T}_g$ are real numbers.

Related work. The problem of comparing two terrains, defined over the same polygonal domain, has been addressed in previous work [2, 16]. Their focus was on identifying a linear dependence between two functions or terrains. Agarwal et al. [2] studied the problem of computing the minimal distance

$$\sigma_p(f, g) = \min_{s,t} \|sf + t - g\|_p \tag{2}$$

for $p = 1, \infty$, minimizing over scaling factor s and translation t. They showed that $\sigma_\infty(f, g)$ can be computed in $\tilde{O}(n^{4/3})$ time (as stated in the abstract, $\tilde{O}$ notation hides polylogarithmic factors), and that an $(1 + \varepsilon)$-approximation of $\sigma_1(f, g)$ can be computed in $O(n/\varepsilon)$ time if $\mathbf{T}_f$ and $\mathbf{T}_g$ are identical. However if $\mathbf{T}_f$ and $\mathbf{T}_g$ are different, the runtime of their algorithm is $O(\kappa/\varepsilon)$, where κ is the complexity of the overlay of the two triangulations; $\kappa = \Theta(n^2)$ in the worst case.

Moroz and Aronov [16] showed that even for unaligned triangulations, $\|f - g\|_2$ and $\sigma_2(f, g)$ can be computed in $O(n \log^4 n \log \log n)$ time. This bound also applies to computing the L_{2p}-distance, where p is a constant positive integer. Unfortunately, these approaches do not extend to computing $\sigma_1(f, g)$ or $\|f - g\|_1$ in subquadratic time in the general case. One notable obstacle is that the L_1-distance involves the absolute value function, which is not polynomial. One key algebraic tool used in [16] to expedite the computation of $\|f - g\|_2$

is the evaluation of a *univariate* polynomial of degree n on n points in $\tilde{O}(n)$ operations. Fast *univariate multipoint evaluation* algorithms in the Real RAM model have been known since 1972 [13]. A subquadratic multipoint-evaluation algorithm for bivariate polynomials was not known until much later [17], and developing fast multipoint-evaluation algorithms for multivariate polynomials is still an active research area [19]. We note that, if the coefficients of polynomials as well as coordinates of points are integers or in finite fields, then algorithms for multipoint evaluation are known to be near-linear in the size of the output [9, 14].

Our results. The main result of the paper is a subquadratic algorithm for computing $\|f-g\|_1$. Its runtime depends on ω, the standard matrix multiplication exponent, which is known to be less than 2.371552 [20] and conjectured by some to be 2.

▶ **Theorem 1.** *Let f and g be two bivariate functions defined by linear interpolation over triangulations $\mathbf{T}_f$ and $\mathbf{T}_g$, respectively, over a common bounded domain $\mathbb{M}$ with a total of n triangles, then $\|f-g\|_1$ can be computed in $\tilde{O}(n^\alpha)$ time, where $\alpha = \max\{(\omega+1)/2, 8/5\}$ and $O(n^\omega)$ is the time required to multiply two $n\times n$ matrices; currently the best known value of ω is around 2.37. If the complexity of the overlay of $\mathbf{T}_f$ and $\mathbf{T}_g$ is κ, then $\|f-g\|_1$ can be computed in $\tilde{O}(\kappa^{\alpha-1}n^{2-\alpha})$ time.*

This result is based on three main ideas: we first show that the problem can be reduced to computing a double sum of rational functions, where the denominators depend only on two variables of the outer sum (Section 2). Those sums are defined over pairs of geometric objects that satisfy some specific algebraic inequalities. Next, we use geometric cuttings to obtain a sign-invariant biclique decomposition of those pairs of geometric objects (Section 3). Finally, we employ fast multipoint polynomial evaluation to evaluate those sums efficiently (Section 4).

Recently, we became aware of a preprint improving the bound on fast multipoint polynomial evaluation [19]. This seems to strengthen the bound of Theorem 1 to $O(n^{8/5+\varepsilon})$ for any $\varepsilon > 0$. We discuss this (possible) improvement at the end of the paper.

2 Reduction to Multi-point Evaluation

In this section, we first express the desired quantity $\|f-g\|_1$ as a sum of integrals associated with vertices of the overlay of $\mathbf{T}_f$ and $\mathbf{T}_g$ (in Section 2.1) and ultimately as a double sum of low-degree rational expressions of the parameters of f and g (in Section 2.2).

We assume hereafter, without loss of generality, that the (x,y)-coordinate system has been rotated so that none of the edges of $\mathbf{T}_f$ and $\mathbf{T}_g$ are parallel to the y-axis, and that $\mathbb{M}$ lies strictly to the right of the y-axis. Moreover, for any two triangles $T_1 \in \mathbf{T}_f$ and $T_2 \in \mathbf{T}_g$, if $f(T_1)$ and $g(T_2)$ are not parallel, with no loss of generality, we assume that the intersection line of their supporting planes crosses the vertical plane $x = 0$.

2.1 Reduction to overlay vertices

Let V_f (resp., V_g) be the set of vertices of $\mathbf{T}_f$ (resp., $\mathbf{T}_g$), and let E_f (resp. E_g) is the set of edges of $\mathbf{T}_f$ (resp. $\mathbf{T}_g$) that do not lie on the boundary of $\mathbb{M}$. Let Σ be the overlay of $\mathbf{T}_f$ and $\mathbf{T}_g$, a convex subdivision of $\mathbb{M}$ that is a refinement of both $\mathbf{T}_f$ and $\mathbf{T}_g$. Let V (resp., C) be the set of vertices (resp., cells) of Σ, and let $\mathsf{X} \subseteq \mathsf{E}_f \times \mathsf{E}_g$ be the family of pairs of segments that intersect. Following the same argument as in [16, Corollary 4], $\|f-g\|_1$ can be expressed as

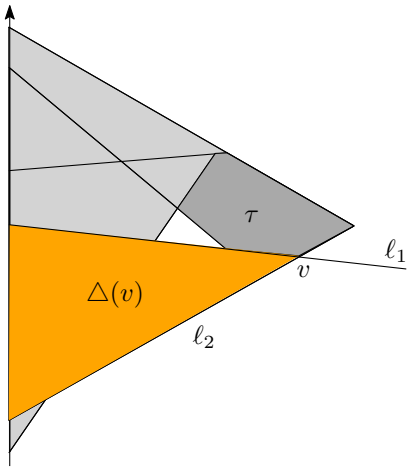

Figure 1 A typical triangle $\triangle(v)$ associated with vertex $v = \ell_1 \cap \ell_2$ in the xy-plane (adapted from [16]).

$$\|f - g\|_1 = \sum_{v \in \mathsf{V}} \sum_{\tau \in \mathsf{C}: \partial\tau \ni v} F(v, \tau, h_\tau), \tag{3}$$

where the function $F(v, \tau, h_\tau)$ is defined as follows. Let e_1, e_2 be the two edges of τ incident on v, let ℓ_i be the line supporting e_i for $i = 1, 2$, and let f_τ (resp. g_τ) be the linear function of f (resp. g) over τ. By our assumption, v lies to the right of the y-axis. Let $\triangle(v)$ be the triangle defined by the y-axis and the lines ℓ_1, ℓ_2 (lying to the right of the y-axis), let

$$h_\tau(x, y) = |f_\tau(x, y) - g_\tau(x, y)| \quad \text{and} \quad \delta(v, \tau) = \begin{cases} +1 & \tau \text{ lies between } \ell_1, \ell_2, \\ -1 & \text{otherwise.} \end{cases}$$

Then

$$F(v, \tau, h_\tau) = \delta(v, \tau) \int_{(x,y) \in \triangle(v)} h_\tau(x, y)\, dx\, dy. \tag{4}$$

A vertex in Σ is either an original vertex of $\mathbf{T}_f$ or $\mathbf{T}_g$ or an intersection point of an edge of E_f with an edge of E_g. We can rewrite (3) as:

$$\|f - g\|_1 = \sum_{v \in \mathsf{V}_f \cup \mathsf{V}_g} \sum_{\tau \in \mathsf{C}: \partial\tau \ni v} F(v, \tau, h_\tau) + \sum_{(e_1, e_2) \in \mathsf{X}} \sum_{\tau \in \mathsf{C}: \partial\tau \ni e_1 \cap e_2} F(e_1 \cap e_2, \tau, h_\tau). \tag{5}$$

By preprocessing $\mathbf{T}_f$ and $\mathbf{T}_g$ for planar point-location queries, the cells of C incident on the vertices of $\mathsf{V}_f \cup \mathsf{V}_g$ can be computed in a total time of $O(n \log n)$, and thus the first term in (5) can be computed in $O(n \log n)$ time; see [16] for details. We thus focus on computing the second term, which we denote by $\Phi(\mathsf{E}_f, \mathsf{E}_g)$.

For an intersecting pair of edges $(e_1, e_2) \in \mathsf{X}$, the vertex $e_1 \cap e_2 \in \mathsf{V}$ is incident on four cells of Σ, and thus it contributes to four terms in $\Phi(\mathsf{E}_f, \mathsf{E}_g)$. Each of these terms has the following form: Let f_{11}, f_{12} (resp., g_{21}, g_{22}) be the bivariate linear functions of f (resp., g) associated with the triangles of $\mathbf{T}_f$ (resp. $\mathbf{T}_g$) lying above and below e_1 (resp., e_2) respectively. For $i, j \in \{1, 2\}$, define

$$h_{ij}(x, y) = |f_{1i}(x, y) - g_{2j}(x, y)|, \qquad \mathbb{1}(i = j) = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{otherwise.} \end{cases}$$

and

$$F_{ij}(e_1, e_2) = (-1)^{\mathbb{1}(i=j)} \int_{(x,y)\in\triangle(e_1\cap e_2)} h_{ij}(x, y)\, dx\, dy;$$

in words, $F_{ij}(e_1, e_2)$ is the signed volume between the graphs of f_{1i} and g_{2j} over $\triangle(e_1 \cap e_2)$. Using these definitions, for a pair $(e_1, e_2) \in \mathsf{X}$, we can write

$$\sum_{\tau\in\mathsf{C}:\partial\tau\ni e_1\cap e_2} F(e_1 \cap e_2, \tau, h_\tau) = \sum_{i,j\in\{1,2\}} F_{ij}(e_1, e_2) \tag{6}$$

and thus

$$\Phi(\mathsf{E}_f, \mathsf{E}_g) = \sum_{i,j\in\{1,2\}} \sum_{(e_1,e_2)\in\mathsf{X}} F_{ij}(e_1, e_2). \tag{7}$$

In the next subsection we show that each F_{ij} can be written as the sum of at most five rational functions of constant degree each.

2.2 Reduction to a sum of rational expressions

We now reexamine the integrals that appear in the previous section and express them as sums of low-degree rational functions, with appropriate signs. We first focus on a single function $F_{ij}(e_1, e_2)$. This function can be seen as the volume between the two halfplanes $h_1 \colon z = f_{1i}(x, y)$ and $h_2 \colon z = g_{2j}(x, y)$ above the triangle $\triangle(e_1 \cap e_2)$.

Let $f_{1i}(x, y) = a_1x + b_1y + c_1$ and $g_{2j}(x, y) = a_2x + b_2y + c_2$ be two linear functions in x, y. By abuse of notation, we let $e_1(x) = \alpha_1x + y_1$ and $e_2(x) = \alpha_2x + y_2$ be the two linear functions in x extending the edges e_1 and e_2. After the same preprocessing as in [16], we can assume that $y_1 > y_2$, $\alpha_1 < \alpha_2$, so that the projection of the edges intersect at $x = \frac{y_1-y_2}{\alpha_2-\alpha_1} > 0$. Let h_1 and h_2 be the two halfplanes in $\mathbb{R}^3$ defined by $z = f_{1i}(x, y), y \le e_1(x)$ and $z = g_{2j}(x, y), y \ge e_2(x)$ respectively. Below we consider the triangle $T = \triangle ABC$ defined as the set of points (x, y) with $x \ge 0$ and $e_2(x) \le y \le e_1(x)$; refer to Figure 2, where $h_1^\downarrow$ and $h_2^\downarrow$ are respectively the projections of h_1 and h_2 to the xy-plane, restricted to $x \ge 0$.

The goal of this section is to prove that the volume between h_1 and h_2 over T is a sum of rational expressions in the parameters of h_1 and h_2. Their exact form depends on the sign variables $\delta_A, \delta_B, \delta_C$ defined as $+1$ or -1, where $+1$ indicates that h_1 has a higher z-coordinate than h_2 over the corresponding vertex of T. Explicit formulas for those signs are given in Section 2.2.1.

More precisely, the halfplane h_1 is contained in the plane π_1 defined by $z = f_{1i}(x, y)$ and bounded by the edge $e_1^\uparrow$, while h_2 is contained in π_2 defined by $z = g_{2j}(x, y)$ and bounded by $e_2^\uparrow$ such that:

$$h_1 \left| \begin{array}{ll} \pi_1: & z = a_1x + b_1y + c_1 \\ e_1^\uparrow: & \begin{pmatrix} t \\ y_1 + \alpha_1 t \\ z_1 + \beta_1 t \end{pmatrix} \end{array} \right. \qquad h_2 \left| \begin{array}{ll} \pi_2: & z = a_2x + b_2y + c_2 \\ e_2^\uparrow: & \begin{pmatrix} t \\ y_2 + \alpha_2 t \\ z_2 + \beta_2 t \end{pmatrix} \end{array} \right. \tag{8}$$

Moreover, since $e_1^\uparrow \subset \pi_1$ and $e_2^\uparrow \subset \pi_2$, the following relations hold:

$$\begin{cases} z_1 = b_1y_1 + c_1 \\ \beta_1 = a_1 + b_1\alpha_1 \end{cases} \qquad \begin{cases} z_2 = b_2y_2 + c_2 \\ \beta_2 = a_2 + b_2\alpha_2 \end{cases} \tag{9}$$

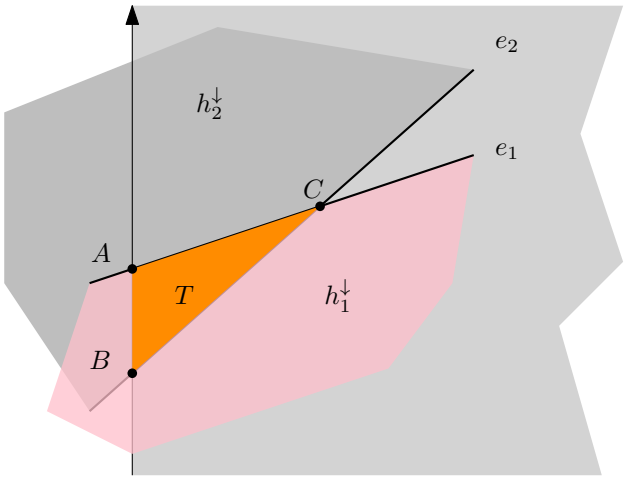

Figure 2 A typical triangle $T = \triangle ABC$ in the xy-plane.

Thus, on the xy-plane, the triangle T has three vertices A, B, C:

$$A \left| \begin{matrix} 0 \\ y_1 \end{matrix} \right. \qquad B \left| \begin{matrix} 0 \\ y_2 \end{matrix} \right. \qquad C \left| \begin{matrix} \frac{y_1 - y_2}{\alpha_2 - \alpha_1} \\ \frac{\alpha_2 y_1 - \alpha_1 y_2}{\alpha_2 - \alpha_1} \end{matrix} \right. \tag{10}$$

2.2.1 Explicit sign conditions

The explicit rational expressions for $\int_T |f_{1i} - g_{2j}|$ will depend on the value of $\delta_A, \delta_B, \delta_C$, namely the sign of the difference $f_{1i} - g_{2j}$ above A, B, and C respectively. Combining eqs. (8), (9), and (10) and using the assumption $\alpha_2 > \alpha_1$, we can explicitly expand the formula for δ_A, δ_B, and δ_C:

$$\begin{aligned} \delta_A &= \operatorname{sign}(z_1 - b_2 y_1 - c_2) \\ \delta_B &= \operatorname{sign}(b_1 y_2 + c_1 - z_2) \\ \delta_C &= \operatorname{sign}\left(\frac{(z_1 - z_2)(\alpha_2 - \alpha_1) + (\beta_1 - \beta_2)(y_1 - y_2)}{\alpha_2 - \alpha_1} \right) \\ &= \operatorname{sign}\left((z_1 - z_2)(\alpha_2 - \alpha_1) + (\beta_1 - \beta_2)(y_1 - y_2) \right) \\ &= \operatorname{sign}\left(\gamma_1 + \gamma_2 + z_1\alpha_2 + z_2\alpha_1 - \beta_1 y_2 - \beta_2 y_1 \right) \end{aligned} \tag{11}$$

where $\gamma_i = \beta_i y_i - z_i \alpha_i$, and $\operatorname{sign}(x) = +1$ if $x \geq 0$ and -1 otherwise. Note that, after the introduction of γ_i, each of $\delta_A, \delta_B, \delta_C$ is the sign of a *bilinear* expression in at most five variables. Each of those variables can also be expressed as a polynomial function of the five parameters $a_i, b_i, c_i, \alpha_i, y_i$ describing each of the two halfplanes.

2.2.2 Explicit rational expressions

The volume $\int_T |f_{1i} - g_{2j}|$ will be written as a weighted sum of three rational expressions. For that, we introduce the intersection point D of the line $e_1^{\uparrow}$ with the plane π_2, the intersection point E of $e_2^{\uparrow}$ and π_1, and the intersection point F of the line DE with the vertical plane $x = 0$. These points exist due to our general position assumptions, as soon as δ_A, δ_B and δ_C don't all have the same sign. Figures 3 and 4 illustrate those notations in different cases.

Let $D^{\downarrow}$, $E^{\downarrow}$, and $F^{\downarrow}$ be projections of D, E, and F respectively to the xy-plane. Finally, the points A_1, B_1, C_1 are the points above A, B, C respectively, with z-coordinates $f_{1i}(x_A, y_A)$, $f_{1i}(x_B, y_B)$ and $f_{1i}(x_C, y_C)$, and the points A_2, B_2, C_2 are the points above A, B, C respectively, with z-coordinates $g_{2j}(x_A, y_A)$, $g_{2j}(x_B, y_B)$ and $g_{2j}(x_C, y_C)$.

We will express the volume between h_1 and h_2 over T as a weighted sum of volumes of polytopes spawned by C, D, and E respectively, toward the vertical plane $x = 0$. The following expressions represent the signed volumes of the polytopes between the planes π_1 and π_2, above the triangles $T = \triangle ABC$, $\triangle AD^{\downarrow}F^{\downarrow}$, and $\triangle BE^{\downarrow}F^{\downarrow}$ respectively. More precisely, letting $R_C = \int_T (f_{1i} - g_{2j})$, $R_D = \int_{\triangle AD^{\downarrow}F^{\downarrow}} (f_{1i} - g_{2j})$ and $R_E = \int_{\triangle BE^{\downarrow}F^{\downarrow}} (f_{1i} - g_{2j})$, we have:

$$\begin{aligned} R_C &= \frac{1}{6} x_C (y_A - y_B) \sum_{X \in \{A,B,C\}} (f_{1i}(x_X, y_X) - g_{2j}(x_X, y_X)), \\ R_D &= \frac{1}{6} x_D (y_F - y_A)(f_{1i}(x_A, y_A) - g_{2j}(x_A, y_A)), \text{ and} \\ R_E &= \frac{1}{6} x_E (y_F - y_B)(f_{1i}(x_B, y_B) - g_{2j}(x_B, y_B)). \end{aligned} \tag{12}$$

We now proceed to express R_C, R_D, and R_E as fractions in the parameters of h_1 and h_2. In particular, we will show that the denominator of each fraction depends only on either two parameters of h_1, or two parameters of h_2.

Rational representation of R_C

Using the formula for the signed volume R_C in eq. (12), we expand the evaluation of f_{1i} and g_{2j} at A, B, C to obtain

$$\begin{aligned} R_C &= \frac{1}{6}(y_1 - y_2) \frac{y_1 - y_2}{\alpha_2 - \alpha_1} \left(\left\langle \begin{pmatrix} a_1 - a_2 \\ b_1 - b_2 \end{pmatrix}, A + B + C \right\rangle + 3(c_1 - c_2) \right) \\ &= \frac{(y_1 - y_2)^2 \left[\begin{array}{r} (\alpha_2 - \alpha_1)\big[(b_1 - b_2)(y_1 + y_2) + 3(c_1 - c_2)\big] \\ + (a_1 - a_2)(y_1 - y_2) + (b_1 - b_2)(\alpha_2 y_1 - \alpha_1 y_2) \end{array} \right]}{6\,(\alpha_2 - \alpha_1)^2}, \end{aligned} \tag{13}$$

where $\langle \cdot, \cdot \rangle$ is the dot product. This implies that R_C is a rational expression with denominator $(\alpha_2 - \alpha_1)^2$.

Rational representation of R_D and R_E

For quantities R_D and R_E, we need to compute the coordinates of D, E, and F. Using eq. (8), the abscissa t_D of D satisfies $z_1 + \beta_1 t_D = a_2 t_D + b_2 y_1 + b_2 \alpha_1 t_D + c_2$. A similar relation for the abscissa t_E of E leads to

$$\begin{aligned} t_D &= \frac{z_1 - b_2 y_1 - c_2}{b_2 \alpha_1 + a_2 - \beta_1} & t_E &= \frac{z_2 - b_1 y_2 - c_1}{b_1 \alpha_2 + a_1 - \beta_2} \\ &= \frac{(b_1 - b_2) y_1 + c_1 - c_2}{(b_2 - b_1)\alpha_1 + a_2 - a_1} & &= \frac{(b_1 - b_2) y_2 + c_1 - c_2}{(b_2 - b_1)\alpha_2 + a_2 - a_1} \end{aligned}$$

Moreover, F is at the intersection of h_1, h_2, and the vertical plane $x = 0$. In particular, its coordinates are the solution of $x = 0, z = b_1 y + c_1 = b_2 y + c_2$, so we have

$$D \left| \begin{array}{c} t_D \\ y_1 + \alpha_1 t_D \\ z_1 + \beta_1 t_D \end{array} \right. \qquad E \left| \begin{array}{c} t_E \\ y_2 + \alpha_2 t_E \\ z_2 + \beta_2 t_E \end{array} \right. \qquad F \left| \begin{array}{c} 0 \\ \frac{c_2 - c_1}{b_1 - b_2} \\ \frac{b_1 c_2 - b_2 c_1}{b_1 - b_2} \end{array} \right. \tag{14}$$

Also, the points A_1, A_2, B_1, B_2 have coordinates

$$\begin{array}{c|c|c|c|c|c|c|c} A_1 & \begin{matrix}0\\ y_1\\ b_1y_1+c_1\end{matrix} & A_2 & \begin{matrix}0\\ y_1\\ b_2y_1+c_2\end{matrix} & B_1 & \begin{matrix}0\\ y_2\\ b_1y_2+c_1\end{matrix} & B_2 & \begin{matrix}0\\ y_2\\ b_2y_2+c_2\end{matrix} \end{array} \tag{15}$$

Finally, replacing the coordinates in eq. (12), this leads to:

$$\begin{aligned} R_D &= \frac{1}{6}\frac{(b_1-b_2)y_1+c_1-c_2}{(b_2-b_1)\alpha_1+a_2-a_1}\left(\frac{c_2-c_1}{b_1-b_2}-y_1\right)(b_1y_1+c_1-b_2y_1-c_2) \\ &= \frac{1}{6}\frac{((b_1-b_2)y_1+c_1-c_2)^3}{(b_2-b_1)\left((b_2-b_1)\alpha_1+a_2-a_1\right)} \end{aligned} \tag{16}$$

and

$$\begin{aligned} R_E &= \frac{1}{6}\frac{(b_1-b_2)y_2+c_1-c_2}{(b_2-b_1)\alpha_2+a_2-a_1}\left(\frac{c_2-c_1}{b_1-b_2}-y_2\right)(b_1y_2+c_1-b_2y_2-c_2) \\ &= \frac{1}{6}\frac{((b_1-b_2)y_2+c_1-c_2)^3}{(b_2-b_1)\left((b_2-b_1)\alpha_2+a_2-a_1\right)}. \end{aligned} \tag{17}$$

2.2.3 Case distinctions for the volume expression

Our goal is to provide a formula for the volume of the polyhedron between π_1 and π_2 above the triangle ABC, as a linear combination of fractions where the denominators depend only on two variables from the triangulation $\mathbf{T}_f$ or on two variables from $\mathbf{T}_g$. This will allow us to use fast multipoint evaluation algorithms for bivariate polynomials (see Section 4).

We will see that for the different cases of signs of $\delta_A, \delta_B, \delta_C$, the volume above T can be expressed as a weighted signed sum of R_C, R_D, and R_E. We consider the cases where the vector of signs $(\delta_A, \delta_B, \delta_C)$ is $(+1,+1,+1)$, $(+1,+1,-1)$, or $(+1,-1,-1)$. The other cases are deduced by symmetry. In the following, we denote by $V_{\delta_A\delta_B\delta_C}$ the volume between π_1 and π_2 above ABC for the corresponding vector of signs.

When $\delta_A, \delta_B, \delta_C$ are positive: the halfplanes don't meet above the triangle

In this case, $V_{+++}(h_1, h_2) = R_C$, a rational expression with denominator $(\alpha_2 - \alpha_1)^2$. By symmetry, when $\delta_A, \delta_B, \delta_C$ are -1, we have $V_{---}(h_1, h_2) = -R_C$.

When δ_A, δ_B are positive and δ_C is negative

Using the notation of Section 2.2.2, the volume between the planes over T in this case is the sum of the volumes $\mathrm{vol}(A_1A_2B_2B_1DE)$ and $\mathrm{vol}(DEC_2C_1)$; refer to Figure 3. With δ_A, δ_B positive, and δ_C negative, the signed volume R_C is equal to $\mathrm{vol}(A_1A_2B_1DE) - \mathrm{vol}(DEC_2C_1)$. Thus, the volume V_{++-} can be expressed as

$$V_{++-}(h_1, h_2) = 2\,\mathrm{vol}(A_1A_2B_2B_1DE) - R_C\,.$$

The volume of the polytope $A_1A_2B_2B_1DE$ is computed as the difference of volumes of the two simplices B_1B_2FE and A_1A_2FD. When δ_A and δ_B are positive, the y-coordinate of the point F can be either (i) greater than y_A, or (ii) less than y_B.

In case (i), we have $\mathrm{vol}(A_1A_2B_2B_1DE) = \mathrm{vol}(B_1B_2FE) - \mathrm{vol}(A_1A_2FD)$. Moreover $\mathrm{vol}(A_1A_2FD) = R_D$ and $\mathrm{vol}(B_1B_2FE) = R_E$, so that $\mathrm{vol}(A_1A_2B_2B_1DE) = R_E - R_D$.

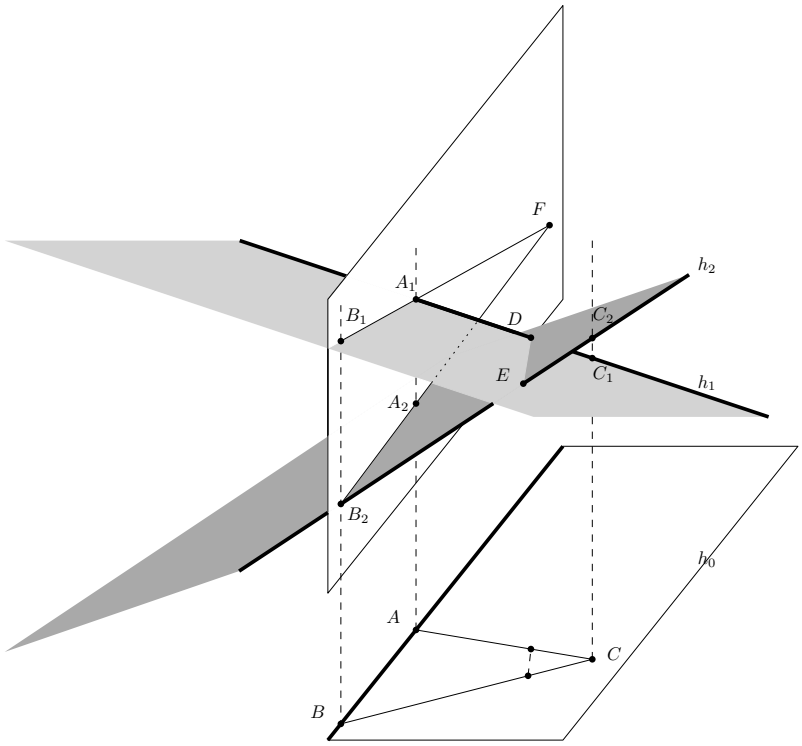

Figure 3 Case where δ_C has a sign different from δ_A and δ_B.

In case (ii), we have $\mathrm{vol}(A_1A_2B_2B_1DE) = \mathrm{vol}(A_1A_2FD) - \mathrm{vol}(B_1B_2FE)$, $\mathrm{vol}(A_1A_2FD) = -R_D$, and $\mathrm{vol}(B_1B_2FE) = -R_E$, so that once again $\mathrm{vol}(A_1A_2B_2B_1DE) = R_E - R_D$.

Thus, in both cases, we have $\mathrm{vol}(A_1A_2B_2B_1DE) = R_E - R_D$, and therefore

$$V_{++-}(h_1, h_2) = 2R_E - 2R_D - R_C\,.$$

Similarly, by symmetry, we have $V_{--+} = -2R_E + 2R_D + R_C$.

When δ_A is positive and δ_B, δ_C are negative

This case is illustrated in Figure 4. Using the notation of the previous section the volume between the two halfplanes is the sum of volumes of the polytopes A_1A_2FD and $B_1B_2C_2C_1DF$. First, with δ_A positive and δ_B, δ_C negative, the signed volume R_C is $\mathrm{vol}(A_1A_2FD) - \mathrm{vol}(B_1B_2C_2C_1DF)$. Moreover, since δ_A is positive and δ_B is negative, the y-coordinate of F is in the interval $[y_B, y_A]$ and we have $\mathrm{vol}(A_1A_2FD) = -R_D$. Thus, the volume V_{+--} can be expressed as

$$V_{+--}(h_1, h_2) = 2\,\mathrm{vol}(A_1A_2FD) - R_C = -2R_D - R_C\,. \tag{18}$$

By symmetry, we have $V_{-++} = 2R_D + R_C$. Moreover, the role of D and E are symmetric, and when δ_A, δ_C are negative, and δ_B is positive, we have similarly $V_{-+-} = 2\,\mathrm{vol}(B_2B_1FE) - R_C = 2R_E - R_C$ and $V_{+-+} = -2R_E + R_C$.

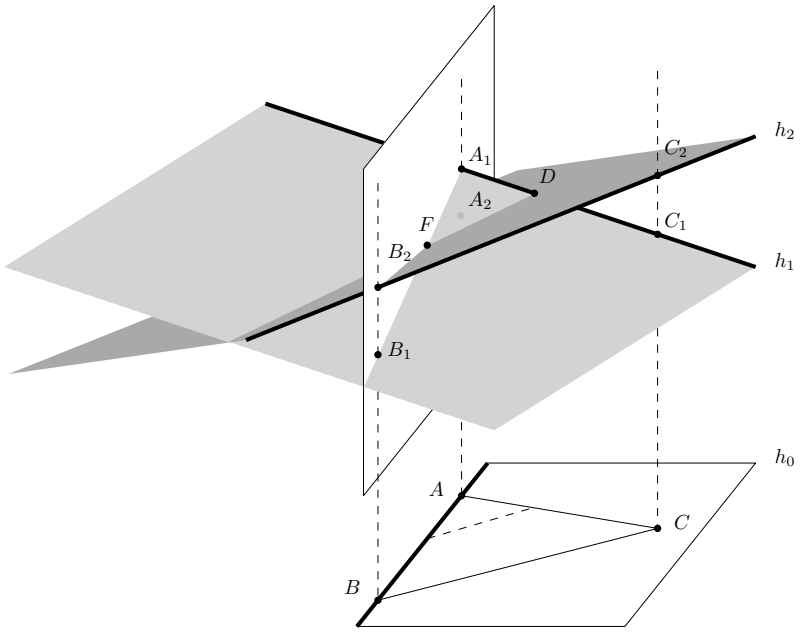

Figure 4 Case where δ_A has a sign different from δ_B and δ_C.

2.2.4 Gathering all the cases

Depending on the signs δ_A, δ_B, and δ_C, we have different formulas for the volume between the planes over T. We can gather them all within one expression that is bilinear in $\delta_A, \delta_B, \delta_C$ on one side, and R_A, R_B, R_C on the other side.

▶ **Lemma 2.** *Assume that $v_1 = (a_1, b_1, c_1, y_1, \alpha_1)$ and $v_2 = (a_2, b_2, c_2, y_2, \alpha_2)$ are vectors of real numbers such that $y_1 > y_2$ and $\alpha_1 < \alpha_2$. Let $T \subset \mathbb{R}^2$ be a triangular cell defined by the set of points (x, y) such that $x \geq 0$, $y \leq y_1 + \alpha_1 x$, and $y \geq y_2 + \alpha_2 x$. And let f_{1i} and g_{2j} be two linear functions defined by $f_{1i}(x, y) = a_1 x + b_1 y + c_1$ and $g_{2j}(x, y) = a_2 x + b_2 y + c_2$. Then the volume $\int_T |f_{1i} - g_{2j}|$ can be expressed as:*

$$\int_{(x,y)\in T} |f_{1i}(x, y) - g_{2j}(x, y)|\, dx\, dy = \delta_C(R_D - R_E + R_C) - \delta_A R_D + \delta_B R_E$$

where $\delta_A, \delta_B, \delta_C$, defined in eq. (11), depend on at most four entries of v_1 and four entries of v_2, and:

$$R_C(v_1; v_2) = \frac{p_C(v_1; v_2)}{q_C(\alpha_1; \alpha_2)} \qquad R_D(v_1; v_2) = \frac{p_A(v_1, v_2)}{q_A(v_1; (a_2, b_2))} \qquad R_E(v_1; v_2) = \frac{p_B(v_1, v_2)}{q_B((a_1, b_1); v_2)}$$

are rational functions of constant degrees defined in eqs. (13), (16) and (17).

▶ Remark. If instead of the assumptions $y_1 > y_2$ and $\alpha_1 < \alpha_2$, we have the assumptions $y_2 < y_1$ and $\alpha_2 < \alpha_1$, then the signed volume above the triangle ABC becomes $-R_C$, and δ_C becomes $-\delta_C$ since we factored out the sign of $\alpha_2 - \alpha_1$ in eq. (11). Without assumption on the order between α_1 and α_2, letting $\sigma = \text{sign}(\alpha_2 - \alpha_1)$, the formula for the volume becomes:

$$\int_{(x,y)\in T} |f_{1i}(x, y) - g_{2j}(x, y)|\, dx\, dy = \delta_C R_C + \delta_C \sigma(R_D - R_E) - \delta_A R_D + \delta_B R_E\,.$$

Returning to expressing (7) as a sum of rational functions, we introduce the following notation. For the edge $e_1 \in \mathsf{E}_f$, e_{11}^* (resp., e_{12}^*) is the point $(a_1, b_1, c_1, y_1, \alpha_1)$ in $\mathbb{R}^5$ corresponding to the linear function associated with the triangle of $\mathbf{T}_f$ lying below (resp., above) the line supporting e_i. The same notation holds for edges of E_g.

$$F_{ij}(e_1, e_2) = (-1)^{\mathbb{1}(i=j)} \Big[\delta_C(e_{1i}^*, e_{2j}^*) R_C(e_{1i}^*, e_{2j}^*) + \sigma(e_{1i}^*, e_{2j}^*) \delta_C(e_{1i}^*, e_{2j}^*)(R_D(e_{1i}^*, e_{2j}^*) - R_E(e_{1i}^*, e_{2j}^*)) - \delta_A(e_{1i}^*, e_{2j}^*) R_D(e_{1i}^*, e_{2j}^*) + \delta_B(e_{1i}^*, e_{2j}^*) R_E(e_{1i}^*, e_{2j}^*) \Big].$$

Since there are five terms in the above expression for F_{ij}, eq. (7) can be expressed as follows:

▶ **Corollary 3.** *Let $\mathsf{E}_f, \mathsf{E}_g$ be the set of non-boundary edges in $\mathbf{T}_f$ and $\mathbf{T}_g$ respectively, and $\mathsf{X} \subseteq \mathsf{E}_f \times \mathsf{E}_g$ be the intersecting pairs of segments. Then*

$$\Phi(\mathsf{E}_f, \mathsf{E}_g) = \sum_{k=1}^{5} \sum_{i,j \in \{1,2\}} \sum_{(e_1,e_2) \in \mathsf{X}} (-1)^{\mathbb{1}(i=j)} \sigma_{ijk}(e_{1i}^*, e_{2j}^*) \cdot \xi_{ijk}(e_{1i}^*, e_{2j}^*) \cdot F_{ijk}(e_{1i}^*, e_{2j}^*), \quad (19)$$

where σ_{ijk} is either σ or the constant function 1, $\xi_{ijk} \in \{\pm\delta_A, \pm\delta_B, \pm\delta_C\}$, and $F_{ijk} \in \{R_C, R_D, R_E\}$.

3 Computing a Biclique Partition

Using Corollary 3, $\Phi(\mathsf{E}_f, \mathsf{E}_g)$ can be computed in $O(\kappa)$ time, where $\kappa = |\mathsf{X}|$ is the number of intersecting pairs of edges in $\mathsf{E}_f \times \mathsf{E}_g$, in a straightforward manner if we have the overlay Σ of $\mathbf{T}_f$ and $\mathbf{T}_g$ at our disposal. In this section, we show how to group the terms in Equation (19) using biclique partitions of X, so that the total time spent in evaluating the sum is always subquadratic. We describe the algorithm for computing

$$\Phi_C(\mathsf{E}_f, \mathsf{E}_g) = \sum_{(e_1^*, e_2^*) \in \mathsf{X}} \sigma(e_1, e_2) \delta_C(e_{11}^*, e_{22}^*) R_C(e_{11}^*, e_{22}^*).$$

The other terms (those involving R_D and R_E) can be evaluated in an analogous manner. For simplicity, we use e_i^* to denote e_{i1}^* (resp. e_{i2}^*) if e_i is a segment of E_f (resp. E_g). We compute the desired biclique partition of X in two stages. The first stage is similar to that described in [16], but the second stage is more involved and relies on geometric cuttings [11, 3].

First stage. As in Chazelle et al. [12] (see also [16]), we compute, in time $O(n \log^2 n)$, a *biclique partition* $\mathcal{B} = \{(R_1, B_1), \ldots, (R_s, B_s)\}$ of X such that

- **(i)** for every $k \le s$, $R_k \subseteq \mathsf{E}_f$ and $B_k \subseteq \mathsf{E}_g$ and every segment in R_k intersects every segment in B_k;
- **(ii)** every segment in R_k has lower slope than that of every segment in B_k, or vice-versa;
- **(iii)** for every intersecting pair $(e_1, e_2) \in \mathsf{X}$, there exists exactly one $k \le s$ with $e_1 \in R_k$ and $e_2 \in B_k$; and
- **(iv)** $\sum_k (|R_k| + |B_k|) = O(n \log^2 n)$ and $\sum_k |R_k| \times |B_k| = \kappa$.

For any $1 \le k \le s$, $\sigma(e_1^*, e_2^*)$ is the same for all $(e_1, e_2) \in R_k \times B_k$, which we denote by $\sigma(R_k, B_k)$. Therefore, we express $\Phi_C(\mathsf{E}_f, \mathsf{E}_g)$ in terms of $\mathcal{B}$ as follows:

$$\Phi_C(\mathsf{E}_f, \mathsf{E}_g) = \sum_{k=1}^{s} \sigma(R_k, B_k) \sum_{(e_1,e_2) \in R_k \times B_k} \delta_C(e_1^*, e_1^*) \cdot R_C(e_1^*, e_2^*). \quad (20)$$

We fix a biclique $(R_k, B_k) \in \mathcal{B}$. Without loss of generality, assume that $\sigma(R_k, B_k) = 1$. We describe how to compute

$$\Phi_C(R_k, B_k) = \sum_{(e_1,e_2)\in R_k\times B_k} \delta_C(e_1^*, e_2^*) \cdot R_C(e_1^*, e_2^*).$$

Second stage. We thus have the following problem at hand. Let $\mathsf{R} \subseteq \mathsf{E}_f$ and $\mathsf{B} \subseteq \mathsf{E}_g$ be two sets of segments in $\mathbb{R}^2$ such that every pair of segments in $\mathsf{R} \times \mathsf{B}$ intersects and the slope of every segment in R is less than that of any segment in B; set $m = |\mathsf{R}|$ and $n = |\mathsf{B}|$. Without loss of generality assume that $m \le n$. We compute a *sign-invariant* (biclique) partition $\Pi = \{(\mathsf{R}_1, \mathsf{B}_1), \ldots, (\mathsf{R}_u, \mathsf{B}_u)\}$ of $\mathsf{R} \times \mathsf{B}$, as described below, such that for all $1 \le k \le u$, the value of $\delta_C(e_i^*, e_j^*)$ is the same for all pairs $(e_i, e_j) \in (\mathsf{R}_k, \mathsf{B}_k)$, which we denote by $\delta_C(\mathsf{R}_k, \mathsf{B}_k)$, so that

$$\Phi_C(\mathsf{R}, \mathsf{B}) = \sum_{k=1}^{u} \left(\delta_C(\mathsf{R}_k, \mathsf{B}_k) \cdot \sum_{(e_i,e_j)\in \mathsf{R}_k\times \mathsf{B}_k} R_C(e_i^*, e_j^*) \right). \tag{21}$$

We show below in Section 4 how $\Phi_C(\mathsf{R}_k, \mathsf{B}_k) = \sum_{(e_i,e_j)\in \mathsf{R}_k\times \mathsf{B}_k} \Phi_C(e_i^*, e_j^*)$ can be computed efficiently. It thus suffices to describe how we compute Π and to analyze the overall run time.

By eq. (11), δ_C is the sign function of a bilinear function $P(\boldsymbol{\varphi}, \boldsymbol{\psi})$, where $\boldsymbol{\varphi}$ (resp. $\boldsymbol{\psi}$) is a set of five variables representing the parameters $y_i, z_i, \alpha_i, \beta_i, \gamma_i$ corresponding to the edges e_i of R (resp., B) used in the definition of δ_C; note that four of these parameters are independent and $\gamma_i = z_i\alpha_i - \beta_i y_i$ depends on them. Let Γ denote the quadratic surface $\gamma_i = z_i\alpha_i - y_i\beta_i$. Abusing the notation slightly, we continue to represent an edge $e_i \in \mathsf{R}$ as a point e_i^* in $\mathbb{R}^5$ with the new set of parameters. We also map e_i to a hyperplane $\tilde{e}_i \colon P(e_i^*, \boldsymbol{\psi}) = 0$ in $\mathbb{R}^5$. Similarly, we map an edge $e_j \in \mathsf{B}$ to a point $e_j^* \in \mathbb{R}^5$ and a hyperplane $\tilde{e}_j \colon P(\boldsymbol{\varphi}, e_j^*) = 0$ in $\mathbb{R}^5$. For a subset A of R (or B), we define $\mathsf{A}^* = \{e_j^* \mid e_j \in \mathsf{A}\}$ and $\widetilde{\mathsf{A}} = \{\tilde{e}_j \mid e_j \in \mathsf{A}\}$. By definition, $\mathsf{A}^* \subset \Gamma$. Our goal is to compute a partition Π of $\mathsf{R} \times \mathsf{B}$ such that for any pair $(\mathsf{R}_k, \mathsf{B}_k) \in \Pi$, all points of B_k^* lie on the same side of all hyperplanes in $\widetilde{\mathsf{R}}_k$, or equivalently all points of R_k^* lie on the same side of all hyperplanes in $\widetilde{\mathsf{B}}_k$.

Let H be a set of m hyperplanes in $\mathbb{R}^d$ and Δ be a simplex. For a parameter $r > 1$, a partition of Δ into a family Ξ of simplices, referred to as *cells*, is called a $(1/r)$-*cutting* of H within Δ if every cell of Ξ is crossed by at most m/r hyperplanes of H. (For $r > m$, cells of Ξ are not crossed by any hyperplane of H, i.e., Ξ is a refinement of $\mathcal{A}(\mathsf{H})$.) The *conflict list* of a cell $\triangle \in \Xi$, denoted by $\mathsf{H}_\triangle$, is the subset of hyperplanes that cross $\triangle$. It is well known that a $(1/r)$-cutting of H of size $O(r^d)$ along with the conflict lists of all of its cells can be computed in $O(mr^{d-1})$ time [11, 15]. For any point set $P \subset \mathbb{R}^d$, one can compute $P \cap \triangle$ for every $\triangle \in \Xi$ in additional $O(|P| \log r)$ time.

In our context, we compute the desired sign-invariant partition Π of $\mathsf{R} \times \mathsf{B}$ using geometric cuttings in a round-robin manner as in [4, 15]. We choose r to be a sufficiently large constant, see below. We assume that the input is *balanced*, i.e., $n/2 \le m \le n$. Otherwise (i.e., $m < n/2$), we use the standard batching technique – we partition B into $\ell = \lfloor n/m \rfloor$ subsets $\mathsf{B}_1, \ldots, \mathsf{B}_\ell$, each of size between m and $2m$, and compute the desired partition for each pair $(\mathsf{R}, \mathsf{B}_j)$, $1 \le j \le \ell$, independently.

Each round of the algorithm works in two stages. In the first stage, we map R to the set $\widetilde{\mathsf{R}}$ of hyperplanes in $\mathbb{R}^5$ and compute a $(1/r)$-cutting Ξ of size $O(r^5)$. For each cell $\triangle \in \Xi$, let $\widetilde{\mathsf{R}}_\triangle \subseteq \widetilde{\mathsf{R}}$ be the conflict list of $\triangle$, let $\widetilde{\mathsf{R}}_\triangle^+$ (resp., $\widetilde{\mathsf{R}}_\triangle^-$) be the set of hyperplanes of $\widetilde{\mathsf{R}}$ that lie above (resp., below) $\triangle$. Let $\mathsf{R}_\triangle, \mathsf{R}_\triangle^+, \mathsf{R}_\triangle^- \subseteq \mathsf{R}$ be the sets of segments correspondig to $\widetilde{\mathsf{R}}_\triangle, \widetilde{\mathsf{R}}_\triangle^+, \widetilde{\mathsf{R}}_\triangle^-$, respectively. Let $\mathsf{B}_\triangle^* = \mathsf{B}^* \cap \triangle$ and $\mathsf{B}_\triangle = \{e_j \mid e_j^* \in \mathsf{B}_\triangle^*\}$. Set $m_\triangle = |\mathsf{R}_\triangle|$ and

$n_\triangle = |\mathsf{B}_\triangle|$. It follows from known results [8, 7, 1] that the surface Γ intersects a subset $\widetilde{\Xi}$ of $O(r^4 \log r)$ simplices of Ξ. Therefore $\mathsf{B}_\triangle \neq \emptyset$ implies that $\triangle \in \widetilde{\Xi}$, so we focus on $\widetilde{\Xi}$ and ignore the cells of $\Xi \setminus \widetilde{\Xi}$. If $n_\triangle \geq n/r^4$ for any cell $\triangle \in \widetilde{\Xi}$, we partition $\triangle$ further into subcells each of which contains at most n/r^4 points of B^*. With a slight abuse of notation, we will continue to use $\widetilde{\Xi}$ to denote the set of refined cells that contain a point of B^*. The number of cells even after this refinement is at most $c_0 r^4 \log r$ for some constant $c_0 > 0$. For every cell $\triangle \in \widetilde{\Xi}$, we add $(\mathsf{R}^+_\triangle, \mathsf{B}_\triangle)$ and $(\mathsf{R}^-_\triangle, \mathsf{B}_\triangle)$ as bicliques to the partition Π. This completes the description of the first stage. which takes $O(mr^4 + n \log r) = O(n)$ since $r = O(1)$ and $m \leq n$.

In the second stage, for each cell $\triangle \in \Xi$, we map $\mathsf{B}_\triangle$ to the set $\widetilde{\mathsf{B}}_\triangle$ of hyperplanes and compute a $(1/r)$ cutting $\Xi_\triangle$ of $\widetilde{\mathsf{B}}_\triangle$ of size $O(r^5)$. For a cell $\tau \in \Xi_\triangle$, we define $\mathsf{B}_\tau, \mathsf{B}^+_\tau, \mathsf{B}^-_\tau, \mathsf{R}_\triangle$ as in the first stage (but reversing the roles of R and B). Let $\widetilde{\Xi}_\triangle$ be the subset of cells of $\Xi_\triangle$ that contain a point of $\mathsf{R}^*_\triangle$. If $|\mathsf{R}_\tau| \geq m/r^5$, we split τ into subcells each of which contains at most m/r^5 points of R_τ. Let $m_\tau = |\mathsf{R}_\tau|$ (after the refinement) and $n_\tau = |\mathsf{B}_\tau|$. By construction, $m_\tau \leq m/r^5$ and $n_\tau \leq n_\triangle/r \leq n/r^5$ for all $\tau \in \widetilde{\Xi}_\triangle$ and for all $\triangle \in \widetilde{\Xi}$. For every $\triangle \in \widetilde{\Xi}$ and $\tau \in \widetilde{\Xi}_\triangle$, we add $(\mathsf{R}_\tau, \mathsf{B}^+_\tau)$ and $(\mathsf{R}_\tau, \mathsf{B}^-_\tau)$ as bicliques to the partition Π.

For every cell τ of a second-stage cutting, we recursively compute a partition of $(\mathsf{R}_\tau, \mathsf{B}_\tau)$. The recursion stops when $\min\{|\mathsf{R}_\tau|, |\mathsf{B}_\tau|\} < r$, in which case we add each pair $(e_i, e_j) \in \mathsf{R}_\tau \times \mathsf{B}_\tau$ as a singleton biclique to Π. This completes the description of computing Π. The correctness follows using a standard argument, see, e.g., [3].

Finally, for each biclique $(\mathsf{R}_k, \mathsf{B}_k) \in \Pi$, we compute $\Phi_C(\mathsf{R}_k, \mathsf{B}_k)$ using Corollary 7. This completes the description of the algorithm.

Analysis. We now analyze the overall runtime of the algorithm, including the time spent in computing $\Phi_C(\mathsf{R}_k, \mathsf{B}_k)$ for each clique $(\mathsf{R}_k, \mathsf{B}_k) \in \Pi$. First, we focus on the run time for the balanced case. For notational simplicity, assume that $|\mathsf{R}| = |\mathsf{B}| = n$. Let $T(n)$ be the total time spent in computing the partition Π plus the time spent in computing $\Phi_C(\cdot, \cdot)$ for each biclique in Π.

If $n < n_0$, where n_0 is a constant that depends on r, the algorithm takes $O(1)$ time. Otherwise, the algorithm spends $O(n)$ time in the two stages of the first round to compute the cuttings, the conflict lists, and the bicliques. Then it solves at most $c_1 r^8 \log^2 r$ recursive problems, where $c_1 > 0$ is a constant independent of r, each of size at most n/r^5. Furthermore, the first round generates at most $O(r^8 \log^2 r)$ bicliques, and by Corollary 7, computing Φ_C for each biclique takes $\tilde{O}(n^{(\omega+1)/2})$. Thus the total time spent in the first round in computing the bicliques and Φ_C for all these is at most $c_3 n^{(\omega+1)/2} \log^{c_2} n$, where $c_2 > 0$ is a constant independent of r and $c_3 > 0$ is a constant that depends on r. Hence, we obtain the following recurrence for $T(n)$:

$$T(n) \leq \begin{cases} c_1 r^8 \log^2 r \cdot T(n/r^5) + c_3 n^{(\omega+1)/2} \log^{c_2} n & n \geq n_0, \\ c_4 & n < n_0, \end{cases} \tag{22}$$

where $c_4 > 0$ and $n_0 > 0$ are constants that depend on r. Note that the recursive subproblems may not be balanced but the total time spent in a round with subproblem size $t \geq n_0$ is still at most $c_3 t^{(\omega+1)/2} \log^{c_2} t$, so the above recurrence holds.

Assuming r is chosen sufficiently large, the solution of the above recurrence is

$$T(n) \leq A n^\alpha \log^{c_2} n, \qquad \text{where } \alpha = \max\{8/5 + \varepsilon, (\omega+1)/2\} \tag{23}$$

for any constant $\varepsilon > 0$, where A is an appropriate constant that depends on r. Since the current best known value of ω is roughly 2.37, we simply write the solution of the recurrence as $T(n) = \tilde{O}(n^{(\omega+1)/2})$.

For general values of m and n with $m \leq n$, the batching technique implies that the total time spent in computing $\Phi_C(\mathsf{R}, \mathsf{B})$ is $(1 + n/m) \cdot \tilde{O}(m^\alpha) = \tilde{O}(nm^{\alpha-1})$. For $m > n$, we flip the roles of R and B, and the run time is $\tilde{O}(mn^{\alpha-1})$. Hence, we obtain the following:

▶ **Lemma 4.** *For a biclique (R_k, B_k) in the biclique partition computed in the first stage, with $|R_k| = m_k$ and $|B_k| = n_k$, $\Phi_C(R_k, B_k)$ can be computed in $\tilde{O}(m_k n_k^{\alpha-1} + n_k m_k^{\alpha-1})$ time.*

To bound the total time spent in computing $\Phi(\mathsf{E}_f, \mathsf{E}_g)$, we sum the bound in Lemma 4 over all bicliques of $\mathcal{B}$. Using Hölder's inequality and property (iv) of the biclique partition $\mathcal{B}$, we obtain the following:

$$\begin{aligned}\sum_{k=1}^{s} m_k n_k^{\alpha-1} &= \sum_{k=1}^{s} (m_k n_k)^{\alpha-1} m_k^{2-\alpha} \\ &\leq \left(\sum_{k=1}^{s} m_k n_k\right)^{\alpha-1} \cdot \left(\sum_{k=1}^{s} m_k\right)^{2-\alpha} \\ &= \tilde{O}(\kappa^{\alpha-1} n^{2-\alpha}),\end{aligned}$$

which is $\tilde{O}(n)$ for $\kappa = n$ and $\tilde{O}(n^\alpha)$ for $\kappa = n^2$. Similarly, we can argue that $\sum_k n_k m_k^{\alpha-1} = \tilde{O}(\kappa^{\alpha-1} n^{2-\alpha})$. Adding the $O(n \log n)$ time spent in evaluating (5) at the vertices of $\mathsf{V}_f \cup \mathsf{V}_g$, the total time spent in computing $\|f - g\|_1$ is $\tilde{O}(\kappa^{\alpha-1} n^{2-\alpha})$. This proves Theorem 1.

4 Multipoint Evaluation of Bivariate Rational Functions

In this section, we show how computing the quantities $\Phi_C(\mathsf{R}, \mathsf{B})$ associated to each $m \times n$ biclique $\mathsf{R} \times \mathsf{B}$ can be reduced to computing a double sum of m rational functions $\frac{1}{q_j(x,y)}$ over n points $p_i = (x_i, y_i)$. This sum can then be evaluated using fast multipoint evaluation techniques for bivariate polynomials ([17]), based on fast modular composition and linear algebra ([21, Chapter 12, §12.2]). Recall that we work in the Real RAM model of computation, where the fastest known algorithm for achieving this runs in subquadratic time [17]. As in the previous section, the other terms appearing in $\Phi(\mathsf{E}_f, \mathsf{E}_g)$ can be computed in an analogous manner. We start with a technical lemma on the fast multipoint evaluation of a batch of bivariate polynomials.

▶ **Lemma 5.** *Given n polynomials $f_j(x, y)$ of degree n and n^2 points $p_i \in \mathbb{R}^2$, it is possible to evaluate all the $f_j(p_i)$ in $\tilde{O}(n^{\omega+1})$ arithmetic operations.*

Proof. The main idea is to reduce this question to a problem of fast multipoint evaluation of univariate polynomials.

First, we interpolate two polynomials $g(x)$ and $h(x)$ of degree n^2, such that, for each root r of h, the point $(r, g(r))$ is a point p_i. More formally we require that

$$\{p_1, \ldots, p_{n^2}\} = \{(x_i, g(x_i)) \mid h(x_i) = 0\}.$$

(For clarity of presentation, we assume that all the coordinates x_i are distinct; the general case can be handled by introducing a generic shear transformation of the xy-plane at no asymptotic cost; see [17, §6].) Polynomials $g(x)$ and $h(x)$ can be computed in $\tilde{O}(n^2)$ operations using fast interpolation algorithms [21, Chapter 10.2].

Then, denoting by $\widetilde{f}_j(x)$ the univariate polynomial $f_j(x, g(x)) \bmod h(x)$, note that $f_j(x_i, y_i) = \widetilde{f}_j(x_i)$ for all i. Hence, if we know the coefficients of $\widetilde{f}_j$, we can evaluate each $\widetilde{f}_j$ at all x_i in $\tilde{O}(n^2)$ arithmetic operations, and all $\widetilde{f}_j$ at all x_i in $\tilde{O}(n^3)$ operations.

Finally, computing all the $\widetilde{f_j}$ can be done in $\tilde{O}(n^{\omega+1})$ arithmetic operations using Lemma 10(iii) of [17], which can be seen as a variation of the fast composition algorithm 12.3 in [21, Chapter 12, §12.2]. Thus, the final complexity is in $\tilde{O}(n^{\max(3,\omega+1)}) = \tilde{O}(n^{\omega+1})$. ◀

We can now deduce our corollaries for computing the sum of rational functions. First we start with the case where the numerators are all 1.

▶ **Corollary 6.** *Given n constant-degree polynomials $q_j(x,y)$ and n points $p_i \in \mathbb{R}^2$, the n sums $\sum_j \frac{1}{q_j(p_i)}$ for all $1 \leq i \leq n$ can be computed in $\tilde{O}(n^{\frac{\omega+1}{2}})$ arithmetic operations.*

Proof. First, partitioning the set of indices j into $O(\sqrt{n})$ subsets J_ℓ of size $O(\sqrt{n})$, for each ℓ, there exists a polynomial $f_\ell(x,y)$ of degree $O(\sqrt{n})$ such that $\sum_{j\in J_\ell} \frac{1}{q_j(x,y)} = \frac{f_\ell(x,y)}{\prod_{j\in J_\ell} q_j(x,y)}$. Each f_ℓ can be computed in $\tilde{O}(n)$ arithmetic operations, using fast bivariate multiplication [21, §8.4]. Then, using Lemma 5, we can evaluate all the $O(\sqrt{n})$ polynomials f_ℓ on all the n points p_i in $\tilde{O}(n^{\frac{\omega+1}{2}})$ operations. With the same approach, we can expand the denominators and evaluate them on the points p_j in $\tilde{O}(n^{\frac{\omega+1}{2}})$ operations. ◀

Then we generalize this result to sums of general rational functions.

▶ **Corollary 7.** *For positive integers k, n, j, with $j \leq n$, let f_j and g_j be polynomials of constant degree and in constant number of variables, k and 2 respectively. Let $A \subset \mathbb{R}^k$ contain at most n points. In the Real RAM model, the sum*

$$S = \sum_{(a_1,\ldots,a_k)\in A} \sum_{1\leq j\leq n} \frac{f_j(a_1,\ldots,a_k)}{g_j(a_1,a_2)}$$

can be computed in $\tilde{O}(n^{\frac{\omega+1}{2}})$ arithmetic operations.

Proof. Given k symbolic variables $X_1,\ldots,X_k$, all the polynomials $f_j(X_1,\ldots,X_k)$ can be written as a weighted sum of s monomials M_ℓ, where $M_\ell = X_1^{e_{\ell,1}} \cdots X_k^{e_{\ell,k}}$ with $(e_{\ell,1},\ldots,e_{\ell,k}) \in \mathbb{N}^k$. In particular, each polynomial $f_j(X_1,\ldots,X_k)$ can be expanded as

$$c_{j,1}M_1 + \cdots + c_{j,s}M_s\,.$$

According to Lemma 6, letting $q_j = \frac{g_j}{c_{j,1}}$, we can compute for all the points in $(a_1,\ldots,a_k) \in A$ the sums $\sum_{j=1}^n \frac{1}{q_j(a_1,a_2)}$ in $\tilde{O}(n^{\frac{\omega+1}{2}})$ operations. Since the number s of monomials is constant, we can compute with the same complexity for all $1 \leq j \leq s$ and all points $p = (a_1,\ldots,a_k) \in A$ the sums :

$$S_{p,\ell} = \sum_{j=1}^{n} \frac{c_{j,\ell}}{g_j(a_1,a_2)}\,.$$

On the other hand, since s and the degrees of the f_j are constant, we can directly compute all the monomials M_ℓ at all the points of A in $O(n)$ operations. Using an additional number of operations linear in n, this allows us to compute, for all the points in $p \in A$,

$$S_p = \sum_{j=1}^{n} \frac{f_j(a_1,\ldots,a_k)}{g_j(a_1,a_2)} = \sum_{\ell=1}^{s} S_{p,\ell}M_\ell(p)\,.$$

Finally, we get the desired result by summing the quantities S_p over all $p \in A$. ◀

This concludes the description of the multipoint evaluation tools needed in Section 3 to complete our algorithm.

5 Conclusion

A recent preprint improves the bound on multipoint evaluation for multivariate polynomials. It shows that we could evaluate $n^{\omega-1}$ bivariate polynomials of degree n^2 on n^2 points in $\tilde{O}(n^{\omega+1})$ operations [19, Theorem 3.8]. Compared to Lemma 5 derived from earlier work [17], this allows us to evaluate more polynomials with the same number of operations. In turn, that would improve Corollary 7, and the complexity of evaluating the sum of rational functions on a biclique of size $n \times n$ would become $\tilde{O}(n^{2-1/\omega})$ instead of $O(n^{(\omega+1)/2})$, by summing over batches of $n^{2/\omega}$ points. With the currently known bound on ω, $2-1/\omega$ is approximately 1.58, which is below 8/5. Thus the cost of computing the biclique decomposition would become dominant, and the total cost of computing $\|f-g\|_1$ could be further improved to $O(n^{8/5+\varepsilon})$, for any constant $\varepsilon > 0$.

Abstract

Let $\mathcal{W} \subset \mathbb{R}^2$ be a rectilinear polygonal environment (that is, a rectilinear polygon potentially with holes) with a total of n vertices, and let A, B be two robots, each modeled as an axis-aligned unit square, that can move rectilinearly inside $\mathcal{W}$. The goal is to compute an optimal *collision-free motion plan* $\boldsymbol{\pi}$ for A and B between a given pair of *source* and *target* configurations. We study two variants of this problem and obtain the following results.

- Min-Sum: Here the goal is to compute a motion plan that minimizes the sum of the lengths of the paths of the robots. We present an $O(n^4 \log n)$-time algorithm for computing an optimal solution to the min-sum problem. This is the first polynomial-time algorithm to compute an optimal, collision-free motion of two robots amid obstacles in a planar polygonal environment.
- Min-Makespan: Here the robots can move with at most unit speed, and the goal is to compute a motion plan that minimizes the maximum time taken by a robot to reach its target location. We prove that the min-makespan variant is NP-hard.

1 Introduction

A wide range of applications have led to extensive work on designing efficient algorithms for computing high-quality motion plans in a structured or an unstructured environment for a system of robots; see e.g. [7, 45] for recent surveys. Several criteria have been proposed to measure the quality of a motion plan, including the total length of the robot paths, the makespan (i.e., the maximum time taken by a robot to complete its motion), and the utility of the plan (i.e., how well it performs the underlying task). Already for two simple robots, such as unit squares or disks, translating in a planar polygonal environment, little is known

about computing an optimal motion plan. Although polynomial-time algorithms are known for computing a collision-free motion plan of two simple robots [8,35], no polynomial-time algorithm is known for computing a plan such that the sum (or the maximum) of the path lengths of the two robots is minimized, nor is the problem known to be NP-hard. In this paper we study the problem of computing an optimal motion plan for two simple robots, each modeled as a unit square.

Problem statement. Let $\square := \{x \in \mathbb{R}^2 \mid ||x||_\infty \leqslant 1/2\}$ denote the axis-aligned square of unit side length – referred to as a *unit square* for short – centered at the origin. Let A and B be two robots, each modeled as a unit square, that can translate inside the same closed rectilinear polygonal environment $\mathcal{W} \subset \mathbb{R}^2$. In other words, the shared *workspace* $\mathcal{W}$ is a rectilinear polygon, possibly with holes. Let n be the number of vertices of $\mathcal{W}$. A placement of A (and, similarly, of B) is represented by the position of its center in the workspace $\mathcal{W}$. For such a placement to be free of collision with the boundary $\partial\mathcal{W}$ of $\mathcal{W}$, the representing point should be at ℓ_∞-distance at least $1/2$ from $\partial\mathcal{W}$. (Note that the robot is allowed to touch an obstacle, since we define $\mathcal{F}$ to be a closed set.) We let $\mathcal{F} \subset \mathcal{W}$ denote the *free space* of a single robot, which is the subset of $\mathcal{W}$ consisting of all collision-free placements. A (joint) *configuration* $\boldsymbol{p}$ of A and B is represented as a pair $\boldsymbol{p} = (p_A, p_B) \in \mathcal{W} \times \mathcal{W}$, where p_A and p_B are the placements of A and B, respectively. The *configuration space*, called *C-space* for short, is the set of all configurations, and is thus represented as $\mathcal{W} \times \mathcal{W} \subset \mathbb{R}^4$. A configuration $\boldsymbol{p} = (p_A, p_B) \in \mathbb{R}^4$ is called *free* if $p_A, p_B \in \mathcal{F}$ and $||p_A - p_B||_\infty \geqslant 1$. Let $\boldsymbol{F} \subseteq \mathcal{F} \times \mathcal{F}$ denote the *four-dimensional free space*, comprising the set of all free configurations.

Let $\boldsymbol{s} = (s_A, s_B)$ be a given *source configuration* and let $\boldsymbol{t} = (t_A, t_B)$ be a given *target configuration*. An $(\boldsymbol{s}, \boldsymbol{t})$*-plan* is a continuous function $\boldsymbol{\pi} : [0, T] \to \mathcal{W} \times \mathcal{W}$, for some $T \in \mathbb{R}_{\geqslant 0}$, with $\boldsymbol{\pi}(0) = \boldsymbol{s}$ and $\boldsymbol{\pi}(T) = \boldsymbol{t}$. The image of $\boldsymbol{\pi}$ is a continuous curve in the C-space, referred to as an $(\boldsymbol{s}, \boldsymbol{t})$*-path*. With a slight abuse of notation, we use $\boldsymbol{\pi}$ to denote its image as well. If $\boldsymbol{\pi} \subset \boldsymbol{F}$ we say that $\boldsymbol{\pi}$ is *feasible*, and if there exists a feasible $(\boldsymbol{s}, \boldsymbol{t})$-plan we say that the pair $(\boldsymbol{s}, \boldsymbol{t})$ is *reachable*. For a plan $\boldsymbol{\pi} : [0, T] \to \mathcal{W} \times \mathcal{W}$, let $\pi_A : [0, T] \to \mathcal{W}$ and $\pi_B : [0, T] \to \mathcal{W}$ be the projections of $\boldsymbol{\pi}$ onto the two-dimensional plane spanned by the first two coordinates and the last two coordinates, respectively. The functions π_A and π_B specify the motions of A and B that $\boldsymbol{\pi}$ induces, that is, $\boldsymbol{\pi}(\lambda) = (\pi_A(\lambda), \pi_B(\lambda))$ for all $\lambda \in [0, T]$. Again, with a slight abuse of notation, we also use π_A and π_B to denote the paths followed by A and B, respectively. We define two versions of optimal motion planning.

- Min-Sum. For a path γ in $\mathcal{W}$, let $\|\gamma\|$ denote its ℓ_1-length. We define $\|\boldsymbol{\pi}\|$, the *cost* of an $(\boldsymbol{s}, \boldsymbol{t})$-plan $\boldsymbol{\pi}$, by $\|\boldsymbol{\pi}\| := \|\pi_A\| + \|\pi_B\|$, that is, $\|\boldsymbol{\pi}\|$ is the sum of the ℓ_1-lengths of the paths of the two robots. The problem is to decide whether a given pair $\boldsymbol{s}, \boldsymbol{t} \in \boldsymbol{F}$ is reachable, and, if so, compute a minimum-cost feasible $(\boldsymbol{s}, \boldsymbol{t})$-plan. As explained later, we can restrict our attention to rectilinear paths because we work with the ℓ_1-metric inside a rectilinear environment.
- Min-Makespan. We define the *makespan* of an $(\boldsymbol{s}, \boldsymbol{t})$-plan $\boldsymbol{\pi} : [0, T] \to \mathcal{W} \times \mathcal{W}$, denoted by $¢(\boldsymbol{\pi})$, to be T. The problem is to decide for a given pair $\boldsymbol{s}, \boldsymbol{t} \in \boldsymbol{F}$ if $(\boldsymbol{s}, \boldsymbol{t})$ is reachable and, if so, compute a feasible $(\boldsymbol{s}, \boldsymbol{t})$-plan that minimizes the makespan under the condition that the maximum speed of each robot is at most 1. Note that we do not require the $(\boldsymbol{s}, \boldsymbol{t})$-plan to be C^1 continuous, so the speed of A or B may instantaneously change from 0 to 1, and the robots may take sharp turns.

Both variants of the optimal motion planning problem are interesting in their own right. The first minimizes the total work done by the robots, while the second minimizes the total time taken until both robots have reached their destination.

Related work. It is beyond the scope of this paper to review the known results on motion-planning algorithms; for an overview of key results, we refer the reader to recent books and surveys on the topic [7, 22, 23, 30, 31, 33]. We mention here only a small sample of results – ones that are most closely related to the problem at hand.

Computing an optimal motion plan for a single translating square robot, or more generally for a single convex polygonal translating robot with a constant number of vertices, is equivalent – through C-space formulation – to computing a shortest path for a point robot amid polygonal obstacles with $O(n)$ vertices, and it can be solved in $O(n \log n)$ time [16,25,44]. If the robot is allowed to rotate, the problem becomes much harder and it is NP-hard in some cases [1, 9, 10, 34]. Computing the shortest path for a point robot amid polyhedral obstacles in $\mathbb{R}^3$ is NP-hard [15], and fast $(1+\varepsilon)$-approximation algorithms are known [5, 17].

Computing a feasible (not necessarily optimal) plan for a team of translating unit square robots in a polygonal environment is PSPACE-hard [38]; see [13, 14, 24, 26, 41, 46] for related intractability results. Notwithstanding a rich literature [18, 33, 36, 42, 43] on multi-robot motion planning, little is known about algorithms for computing plans with provable quality guarantees. Even in the absence of obstacles, computing the min-sum motion plan for two unit squares/disks is non-trivial under the ℓ_2-metric [21, 29]. Variants with more than two robots in a setting without obstacles have been studied as well [19, 20, 27]. Recently, Agarwal et al. [4] presented the first polynomial-time approximation algorithm for the min-sum motion-planning problem for two squares that computes an $(1+\varepsilon)$-approximate solution in $\varepsilon^{-O(1)} n^2 \log n$ time (under both the ℓ_1- and ℓ_2-metrics). They leave it as an open problem whether an optimal plan in this case can be computed in polynomial time. Approximation algorithms have been proposed for min-sum multi-robot motion planning under the assumption that the source and target positions of robots are *separated* from each other and from the obstacles [3, 37, 40]; see also [2, 11]. There is also work on the *unlabeled* version of the problem, where each robot can end up at any of the (collective) target positions, as long as all of the target positions are occupied by robots at the end of the motion. Finally, we remark that sampling-based approaches have been proposed for optimal multi-robot motion planning [18, 28, 36, 39]; and that there is extensive work on the discrete version of the problem, where robots are moving on graphs; see e.g., [7, 42] for recent surveys.

Our contributions. Our main result is that Min-Sum is in P, while Min-Makespan is NP-hard. This is stated in the two following theorems.

▶ **Theorem 1.** *Let $\mathcal{W}$ be a closed rectilinear polygonal environment with n vertices, let A, B be two axis-parallel unit-square robots translating inside $\mathcal{W}$, and let $\boldsymbol{s}, \boldsymbol{t}$ be source and target configurations of A, B. We can compute an optimal min-sum motion plan from $\boldsymbol{s}$ to $\boldsymbol{t}$ under the ℓ_1-metric, or determine that no feasible motion exists, in $O(n^4 \log n)$ time.*

▶ **Theorem 2.** *Let $\mathcal{W}$ be a closed rectilinear polygonal environment with n vertices, let A, B be two axis-parallel unit-square robots translating inside $\mathcal{W}$, let $\boldsymbol{s}, \boldsymbol{t}$ be source and target configurations of A, B, and let $T_{\max}$ be a given maximum time. It is NP-hard to determine whether there is a feasible $(\boldsymbol{s}, \boldsymbol{t})$-plan $\boldsymbol{\pi}^*$ such that the maximum speed of each robot is at most 1 and the makespan of $\boldsymbol{\pi}^*$ is at most $T_{\max}$.*

We prove Theorem 2 by a reduction from the Partition problem, which is to decide whether a given set Y of integers admits a partition into subsets Y_A, Y_B such that $\sum_{y_i \in Y_A} p = \sum_{y_i \in Y_B} q$. The idea of the reduction is to build a workspace $\mathcal{W}$ that consists of gadgets $\mathcal{W}_1, \ldots, \mathcal{W}_m$,

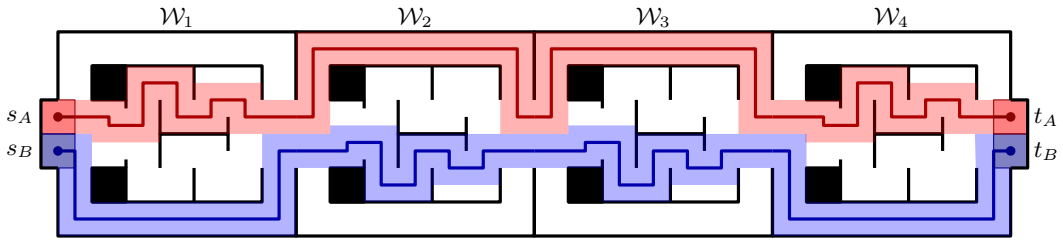

Figure 1 The workspace created for a set $Y = \{y_1, ..., y_4\}$. The paths shown for the two robots correspond to the partition $Y_A = \{y_1, y_4\}$ and $Y_B = \{y_2, y_3\}$. The black areas are obstacles, and the red/blue regions are the areas swept by the two robots. The detour made by a robot in a gadget $\mathcal{W}_i$ when it goes via the top (for A) or bottom (for B) of the gadget, is equal to y_i. Hence, a solution with certain makespan can only be achieved if there is an equal partition of Y.

each corresponding to an element of Y and to choose a parameter $\mu \geqslant 0$, so that both robots must pass through every gadget and there is a plan with makespan at most μ if and only if there is a valid partition of Y. See Figure 1.

Our main technical contribution is a polynomial-time exact algorithm for Min-Sum, as stated in Theorem 1. The crucial step toward designing this algorithm is to prove the existence of an optimal plan that is a *canonical-grid plan*, in which the path followed by each robot lies on an $O(n) \times O(n)$ non-uniform predefined grid; see Theorem 4.

For a single robot translating in a rectilinear environment in $\mathbb{R}^2$, it is well known that there is an optimal path, under the ℓ_1-metric, on the grid defined by the horizontal and vertical lines through the source and target positions and the lines containing the edges of the free space $\mathcal{F}$ [32]. For a pair of robots, the existence of an optimal plan on a suitably defined grid seems intuitive as well. Indeed, consider an optimal plan $\boldsymbol{\pi}^*(\boldsymbol{s}, \boldsymbol{t})$. As argued in Section 2, we can assume each robot follows a rectilinear path (in $\mathcal{F}$) under the plan $\boldsymbol{\pi}^*$. Imagine trying to push a horizontal (resp. vertical) segment of π_A^* to a horizontal (resp. vertical) line of the (nonuniform) grid formed by the lines supporting the edges of $\mathcal{F}$ or the lines at distance 1 from $\partial\mathcal{F}$. It may happen that we fail to push the segment onto the grid because robot B is blocking it. The hope is that we can continue to push the segment of π_A and push the appropriate segment of π_B in the same direction – essentially A is pushing B out of the way – until B hits $\partial\mathcal{W}$– without increasing the total cost. Thus, we have pushed a segment of π_B onto a line containing an edge of $\mathcal{F}$ and the segment of π_A onto a line at distance 1 from that line. Making this idea work is highly nontrivial, though. For instance, we must choose the direction into which we push a specific segment of π_A in such a way that $\|\pi_A\|$ does not increase, but this may force us to push π_B in such a way that $\|\pi_B\|$ increases. This is further complicated by the fact that B may be on different sides of a segment of π_A at different moments in time. Finally, a major complication is that pushing (a segment of) one robot onto a line at distance i from an edge of $\mathcal{F}$, so that its length does not increase, may cause the other robot to end up on a line at distance $i + 1$ from this edge, and this may cause a cascading effect so that the final grid will be too large.

To overcome these issues, we combine local pushing operations with global re-routing operations in such a way that the transformed paths lie on lines at distance 0, 1, or 2 from the edges of $\mathcal{F}$. These operations may increase the length of one path, but we prove that whenever this happens, the length of the other path decreases by at least the same amount. Thus we obtain an optimal plan that lies on a grid of size $O(n) \times O(n)$ and is still optimal.

After having established the existence of an optimal canonical-grid plan, we show that we can construct a 4-dimensional weighted grid graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, with $\boldsymbol{s}, \boldsymbol{t} \in \mathcal{V}$, of size $O(n^4)$, in $\boldsymbol{F}$ such that a shortest $(\boldsymbol{s}, \boldsymbol{t})$-path in $\mathcal{G}$ corresponds to a min-sum $(\boldsymbol{s}, \boldsymbol{t})$-plan.

2 A polynomial-time algorithm for Min-Sum

This section describes a polynomial-time algorithm for Min-Sum. We first define a *canonical-grid plan* in Section 2.1 – an $(\boldsymbol{s},\boldsymbol{t})$-plan where both robots move on a predefined $O(n)\times O(n)$ nonuniform grid – and claim that for any reachable pair $\boldsymbol{s},\boldsymbol{t}\in\boldsymbol{F}$, there exists an optimal $(\boldsymbol{s},\boldsymbol{t})$-plan that is a canonical-grid plan. In Section 2.2 we give a high-level overview of the proof of this claim; a more detailed sketch of the proof is deferred to Section 3. Finally, we describe our algorithm in Section 2.3.

2.1 Canonical-grid plans

Rectilinear, decoupled plans. Since $\mathcal{W}$ is a rectilinear environment and A, B are squares, it is easily seen that $\boldsymbol{F}$ is a polyhedral region. Hence, if there is a feasible $(\boldsymbol{s},\boldsymbol{t})$-plan, then there is a piecewise-linear optimal $(\boldsymbol{s},\boldsymbol{t})$-plan, that is, an optimal plan whose image is a polygonal chain in $\boldsymbol{F}$ [4]. We thus focus on piecewise-linear plans. We refer to the vertices of such a plan as *breakpoints*. For a path $\boldsymbol{\pi}=(\pi_A,\pi_B)$, the breakpoints of π_A and π_B are the projections of the breakpoints of $\boldsymbol{\pi}$.

An $(\boldsymbol{s},\boldsymbol{t})$-plan $\boldsymbol{\pi}$ is *decoupled* if only one robot moves at any given time; the other robot is then *parked* somewhere in the free space. A decoupled plan can be represented as a sequence of *moves*, with each move specifying the parking location of one robot and the motion of the other robot. By definition of breakpoints, each parking spot of A (resp. B) is a breakpoint of π_A (resp. π_B). Agarwal et al. [4] proved that for any pair $\boldsymbol{s},\boldsymbol{t}$ of reachable configurations, there is an optimal $(\boldsymbol{s},\boldsymbol{t})$-plan that is decoupled. Since only one robot moves at a time, the parked robot can be considered as a rectilinear obstacle during the move, and (since we measure path length in the ℓ_1-metric) we can ensure that each robot follows a rectilinear path in $\mathcal{F}$ in each move. We refer to such a plan as a *rectilinear* plan. The breakpoints of π_A and π_B in a rectilinear plan $\boldsymbol{\pi}=(\pi_A,\pi_B)$ are the parking spots of A and B and the points at which they switch between horizontal and vertical segments. We conclude the following.

▶ **Proposition 3.** *For any reachable pair of configurations $\boldsymbol{s},\boldsymbol{t}\in\boldsymbol{F}$, there is an optimal $(\boldsymbol{s},\boldsymbol{t})$-plan that is rectilinear and decoupled.*

The canonical grid. For an integer $i\geqslant 0$, we define an *i-line* to be a horizontal or vertical line ℓ that lies at distance i from an edge of $\partial\mathcal{F}$ parallel to ℓ, or that lies at distance i from one of the points s_A, s_B, t_A, t_B. Note that 0-lines support an edge of $\partial\mathcal{F}$ or pass through one of the points s_A, s_B, t_A, t_B. Let L_i denote the set of all i-lines, and set $L_{\leqslant i}:=\cup_{j=0}^{i}L_j$. We will be mostly interested in $L_{\leqslant 2}$. The *arrangement* [6] of $L_{\leqslant 2}$, denoted by $\mathcal{A}(L_{\leqslant 2})$, is the subdivision of $\mathbb{R}^2$ induced by $L_{\leqslant 2}$. Since each edge of $\mathcal{F}$ is contained in a 0-line, each face of $\mathcal{A}(L_{\leqslant 2})$ is a rectangle that is either contained in $\mathcal{F}$ or disjoint from $\mathcal{F}$. The vertices and edges of $\mathcal{A}(L_{\leqslant 2})$ form a planar grid graph. Let $G=(V,E)$ denote the subgraph of this graph that lies in $\mathcal{F}$, that is, V and E are the sets of vertices and edges, respectively, of $\mathcal{A}(L_{\leqslant 2})$ that lie in $\mathcal{F}$. Note that $|V|=O(n^2)$ and $|E|=O(n^2)$. We refer to G as a *grid*, to a vertex of V as a *grid point*, to an edge of E as a *grid edge*, and to a line of $L_{\leqslant 2}$ as a *grid line*. We call a rectilinear, decoupled $(\boldsymbol{s},\boldsymbol{t})$-plan $\boldsymbol{\pi}=(\pi_A,\pi_B)$ a *canonical-grid plan* if each breakpoint of π_A and π_B is a grid point. Thus each segment of the path is the union of a number of consecutive collinear grid edges. By definition, each parking spot of A or B in a canonical-grid plan is a grid point. Our main technical result is the following theorem.

▶ **Theorem 4.** *Let $\mathcal{W}$ be a closed rectilinear polygonal environment with n vertices, let A, B be two axis-parallel unit-square robots translating inside $\mathcal{W}$. For a reachable pair of configurations $(\boldsymbol{s},\boldsymbol{t})$, there is an optimal $(\boldsymbol{s},\boldsymbol{t})$-plan that is a canonical-grid plan.*

2.2 Converting an optimal plan to a canonical-grid plan

We give an overview of how we convert an optimal $(\boldsymbol{s}, \boldsymbol{t})$-plan $\boldsymbol{\pi}$ to an optimal $(\boldsymbol{s}, \boldsymbol{t})$-plan that is a canonical-grid plan. By Proposition 3, we can assume $\boldsymbol{\pi}$ is rectilinear and decoupled.

Alternating plans. We assume that π_A alternates between vertical and horizontal segments; hence, each breakpoint of π_A is incident on a horizontal and a vertical segment and is thus a *vertex* of π_A. This *alternation property* for π_A can be ensured by adding zero-length segments at breakpoints where necessary. The alternation property, which we also assume for π_B, implies that all parking spots of A and B lie on the vertices of their respective paths.

We convert $\boldsymbol{\pi}$ into a canonical-grid plan in two phases: the first phase modifies the plan $\boldsymbol{\pi}$ such that all horizontal segments of π_A and π_B lie on grid lines, and the second phase does the same for the vertical segments. Here we describe the first phase; the second phase proceeds analogously, with the roles of the x and y-axis exchanged.

The first phase. We define a *bad horizontal segment* to be a horizontal segment on π_A or π_B that does not lie on a grid line. As long as $\boldsymbol{\pi}$ contains a bad horizontal segment e, we modify $\boldsymbol{\pi}$ into a new plan $\boldsymbol{\pi}^* = (\pi_A^*, \pi_B^*)$ so that the following conditions are satisfied:

- (P1) Feasibility: The new plan $\boldsymbol{\pi}^*$ is feasible.
- (P2) Optimality: The cost of the plan does not increase, that is, $\|\boldsymbol{\pi}^*\| \leqslant \|\boldsymbol{\pi}\|$.
- (P3) Progress: The plan $\boldsymbol{\pi}^*$ has at least one fewer bad horizontal segment than $\boldsymbol{\pi}$.
- (P4) Vertical alignment: Any vertical segment of π_A^* is collinear with a vertical segment of π_A or π_B, or it is contained in a vertical grid line; and the same holds for any vertical segment of π_B^*.
- (P5) Alternation: $\boldsymbol{\pi}^*$ is an alternating, rectilinear, decoupled plan.

The Progress property guarantees that by applying the procedure finitely many times, starting with the optimal plan $\boldsymbol{\pi}$, we obtain a plan without bad horizontal segments. The Feasibility and Optimality properties imply that $\boldsymbol{\pi}^*$ is an optimal $(\boldsymbol{s}, \boldsymbol{t})$-plan. Furthermore, the Alternation property implies that $\boldsymbol{\pi}^*$ is also a rectilinear, decoupled, alternating plan, so we can indeed apply the procedure iteratively.

After eliminating all bad horizontal segments in the first phase, we eliminate all bad vertical segments in the second phase. The Vertical Alignment property, which in the second phase applies to horizontal segments, guarantees that the horizontal segments are not moved off the grid in the second phase. So, all segments of $\boldsymbol{\pi}^*$ lie on grid lines, and since $\boldsymbol{\pi}^*$ is alternating, its breakpoints therefore lie on grid points. Hence, at the end of the second phase, we obtain an optimal, canonical-grid plan.

Note: Our transformation of the original plan $\boldsymbol{\pi}$ into a $\boldsymbol{\pi}^*$ satisfying (P1)–(P5) is done via several intermediate steps. When describing these steps, we typically denote, with a slight abuse of notation, the current plan by $\boldsymbol{\pi}$ and the next plan by $\boldsymbol{\pi}^*$.

Corridors. To be able to push bad horizontal segments onto horizontal grid lines without creating a cascading effect, we classify the horizontal grid lines into two classes: *primary* grid lines, which are the horizontal 0- and 1-lines, and *secondary* grid lines, which are the horizontal 2-lines. Let $\textsc{hor}(\mathcal{F})$ be the subdivision of $\mathcal{F}$ induced by the primary grid lines; see Figure 2. Each face of $\textsc{hor}(\mathcal{F})$ is a rectangle because every vertex of $\mathcal{F}$ is contained in a horizontal 0-line. We refer to the faces of $\textsc{hor}(\mathcal{F})$ as *corridors*. Note that the interior of a corridor may be intersected by secondary grid lines.

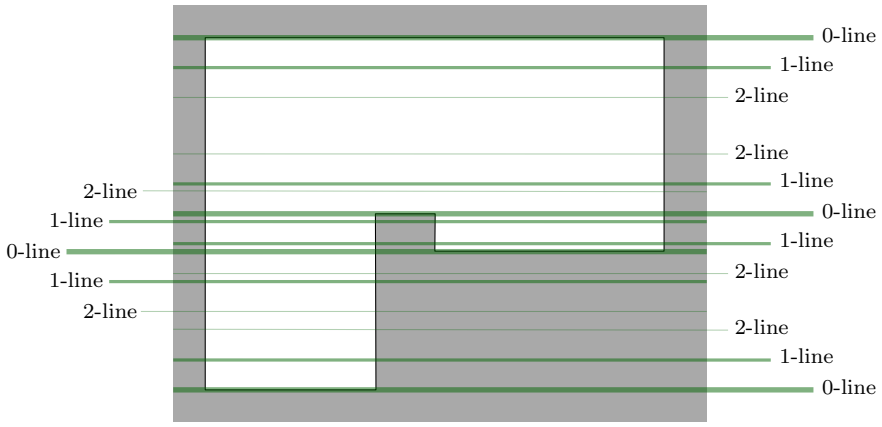

Figure 2 The 0-lines and 1-lines define $\textsc{hor}(\mathcal{F})$, the subdivision of $\mathcal{F}$ into corridors. To avoid cluttering the figure, the start and target configurations and the grid lines they define are omitted.

By definition, (the relative interior of) every bad horizontal segment lies in the interior of a corridor. At each step, we pick a bad segment e, say of π_A. We perform surgery on π_A and π_B so that e is *aligned* with one of the horizontal edges of the corridor R containing e, and so that the resulting plan $\boldsymbol{\pi}^*$ satisfies (P1)–(P5). The surgery and its proof of correctness are quite delicate because the topology of $\mathcal{F}$ in the neighborhood of R can be complex.

2.3 Computing an optimal canonical-grid plan

The configuration graph. Let $G = (V, E)$ be the canonical grid described in Section 2.1. We construct an edge-weighted *configuration graph* $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with weight function $w : \mathcal{E} \to \mathbb{R}_{\geqslant 0}$ whose nodes correspond to free configurations $\boldsymbol{u} \in \boldsymbol{F}$. More precisely,

$$\mathcal{V} := \{\boldsymbol{u} = (u_A, u_B) \in V \times V : \|u_A - u_B\| \geqslant 1\}.$$

By construction, $\boldsymbol{s}, \boldsymbol{t} \in \mathcal{V}$. The set $\mathcal{E}$ of edges of the configuration graph is defined as

$$\mathcal{E} := \Big\{(\boldsymbol{u}, \boldsymbol{v}) \in \mathcal{V} \times \mathcal{V} : (u_A = v_A \text{ and } (u_B, v_B) \in E) \text{ or } (u_B = v_B \text{ and } (u_A, v_A) \in E)\Big\}.$$

An edge $((p, u_B), (p, v_B)) \in \mathcal{E}$ corresponds a move in which robot A is parked at p while robot B moves from u_B to an adjacent grid point v_B. Similarly, an edge $((u_A, q), (v_A, q)) \in \mathcal{E}$ corresponds to a move in which A moves from a grid point u_A to an adjacent grid point v_A while B is parked at q. (We can prove that such moves are feasible.) The weight of an edge $(\boldsymbol{u}, \boldsymbol{v}) \in \mathcal{E}$ is defined to be $w(\boldsymbol{u}, \boldsymbol{v}) := \|\boldsymbol{uv}\|$, which is the ℓ_1-distance between $\boldsymbol{u}$ and $\boldsymbol{v}$ in $\mathbb{R}^4$.

The algorithm. We first compute $\mathcal{F}$ in $O(n \log n)$ time in a standard manner [12, Chapter 13]. Next, we compute $L_{\leqslant 2}$ in $O(n)$ time and then compute the grid graph G in $O(n^2 \log n)$ time using a sweep-line algorithm. After computing G, we compute the configuration graph $\mathcal{G}$ in $O(n^4)$ time. Finally, we compute a shortest path from $\boldsymbol{s} \in \mathcal{V}$ to $\boldsymbol{t} \in \mathcal{V}$ in $\mathcal{G}$ in $O(n^4 \log n)$ time using Dijkstra's algorithm. If we find that no path from $\boldsymbol{s}$ to $\boldsymbol{t}$ exists in $\mathcal{G}$, we report the instance to be infeasible, otherwise we return the $(\boldsymbol{s}, \boldsymbol{t})$-plan corresponding to the shortest path in $\mathcal{G}$. The total run time is $O(n^4 \log n)$. This completes the proof of Theorem 1.

3 Existence of an optimal canonical-grid plan

Let $\boldsymbol{\pi}$ be an optimal plan that contains a bad horizontal segment e, say of π_A. Let $R = I_x \times I_y$ where $I_x = [x_R^-, x_R^+]$ and $I_y = [y_R^-, y_R^+]$, be the corridor that contains e. This section describes how to modify $\boldsymbol{\pi}$ so that e becomes aligned with a grid line and the resulting plan satisfies (P1)–(P5). We begin by introducing some notation. For an axis-aligned rectangle $\rho = \delta_x \times \delta_y$, let $\mathsf{top}(\rho)$ and $\mathsf{bot}(\rho)$ be the top and bottom edge of ρ, respectively, and let $\mathsf{ht}(\rho) := |\delta_y|$ denote its height. For $0 \leqslant \mu_1 \leqslant \mu_2$, let $\boldsymbol{\pi}[\mu_1, \mu_2]$ denote the subplan of $\boldsymbol{\pi}$ (or its image) during the closed interval $[\mu_1, \mu_2]$, and let $\boldsymbol{\pi}(\mu_1, \mu_2)$ denote the subplan during the open interval (μ_1, μ_2). We define $\pi_A[\mu_1, \mu_2]$ and $\pi_A(\mu_1, \mu_2)$, and $\pi_B[\mu_1, \mu_2]$ and $\pi_B(\mu_1, \mu_2)$, in the same manner. For a horizontal segment g, let $y(g)$ be its y-coordinate, and for a point p let p_x and p_y denote its x- and y-coordinates.

Let $[\lambda', \lambda'']$ be the time interval associated with e; thus $e = \pi_A[\lambda', \lambda'']$. We now define two critical time values related to the bad segment e:

$$\begin{aligned} \lambda_1 &= \max\{\lambda < \lambda' \mid \pi_A(\lambda) \in \mathsf{top}(R) \cup \mathsf{bot}(R)\}, \text{ and} \\ \lambda_2 &= \min\{\lambda > \lambda'' \mid \pi_A(\lambda) \in \mathsf{top}(R) \cup \mathsf{bot}(R)\}. \end{aligned} \tag{1}$$

Thus, $\pi_A(\lambda_1)$ (resp. $\pi_A(\lambda_2)$) is the last (resp. first) point on π_A before (resp. after) e at which A lies on a horizontal edge of R. Note that $e \subset \pi_A(\lambda_1, \lambda_2) \subset R \setminus (\mathsf{top}(R) \cup \mathsf{bot}(R))$ and that $\pi_A(\lambda_1, \lambda_2)$ may touch a vertical edge of R. The goal of our surgery is to push $\pi_A[\lambda_1, \lambda_2]$ to $\mathsf{top}(R)$ or $\mathsf{bot}(R)$ to align it with a grid line. This may cause collisions with $\pi_B[\lambda_1, \lambda_2]$, so we have to proceed carefully. Sometimes we push part of $\pi_A[\lambda_1, \lambda_2]$ to $\mathsf{top}(R)$ and part to $\mathsf{bot}(R)$, and in one case we even modify the paths outside the interval $[\lambda_1, \lambda_2]$. In all cases, we resolve the collisions by pushing B out of the way, without increasing the overall length of the paths.

In the remainder of this section, we sketch the ideas underlying our pushing strategy. We first define a neighborhood of R, called the *influence region* of R and denoted by $\mathcal{I}(R)$, and prove a few key properties of $\mathcal{I}(R)$. Next, we define *unsafe* and *swap* time intervals, subintervals of $[\lambda_1, \lambda_2]$ during which the surgery on $\boldsymbol{\pi}$ requires more care, and we state the crucial structural properties of an optimal plan during these intervals. With these properties at our disposal, we describe the surgery and give some ideas about the correctness proof. Before proceeding, we state a simple but important property of $\mathcal{F}$ that we will use repeatedly.

▶ **Observation 5.** *For any axis-aligned line ℓ, the length of each connected component of $\ell \setminus \mathcal{F}$ is more than* 1*. Consequently, for any axis-aligned segment pq of length at most* 1 *such that $p, q \in \mathcal{F}$, we have $pq \subseteq \mathcal{F}$.*

The influence region. Let $\square$ be the unit square as defined in Section 1. Let $R_\square := R \oplus 2\square$. Thus, $R_\square = I_x^\oplus \times I_y^\oplus$ where $I_x^\oplus := [x_R^- - 1, x_R^+ + 1]$ and $I_y^\oplus := [y_R^- - 1, y_R^+ + 1]$. For any pair $p, q \in \mathbb{R}^2$, if $p \in R$ and $(p + \square) \cap (q + \square) \neq \emptyset$, then $q \in R_\square$. Next, we define two different extensions of R that play a role in our analysis; see Figure 3. Let $R_\leftrightarrow := I_x^\oplus \times I_y$, that is, $R_\leftrightarrow$ is obtained by extending R by unit length to the left and to the right. Similarly, $R_\updownarrow := I_x \times I_y^\oplus$ is the extension of R by unit length in the upward and downward directions. Observe that $R_\square \setminus (R_\updownarrow \cup R_\leftrightarrow)$ consists of four semi-open unit squares, which we refer to as the *corner squares* of $R_\square$. Finally, we define $Z = I_x^\oplus \times [y_R^+ - 1, y_R^- + 1]$, and $Z^- = I_x^\oplus \times [y_R^- - 1, y_R^+ - 1)$, and $Z^+ = I_x^\oplus \times (y_R^- + 1, y_R^+ + 1]$. Note that $\mathsf{ht}(Z) = 1 + \delta$ and $\mathsf{ht}(Z^-) = \mathsf{ht}(Z^+) = 1 - \delta$. The closures of Z^-, Z^+ are translates of $R_\leftrightarrow$ by distance 1 in the y-direction, and Z^-, Z, Z^+ is a

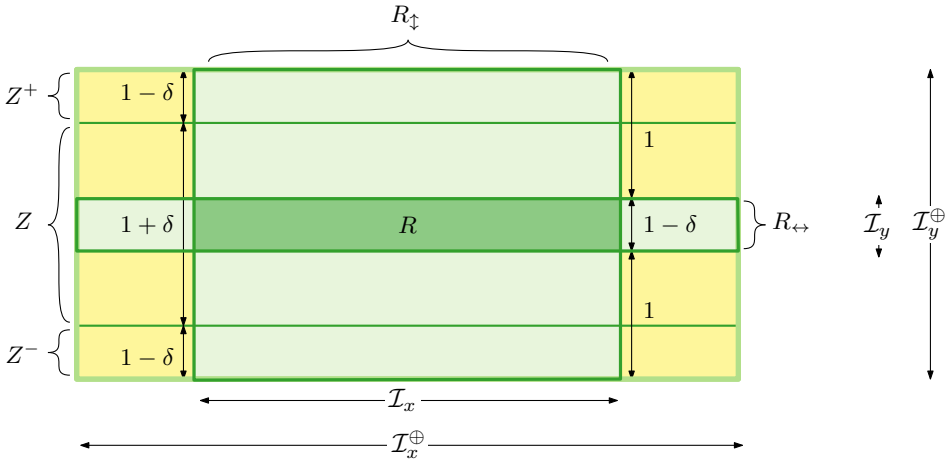

Figure 3 An overview of the various regions inside $R_{\square}$ (not to scale). The regions Z^-, Z, Z^+ partition $R_{\square}$. Corner squares are yellow.

partition of $R_{\square}$. Since no primary grid line of $L_{\leqslant 1}$ intersects $\mathrm{int}(R)$, the regions Z^+ and Z^- do not contain any vertices of $\mathcal{F}$. By Observation 5, the connected components of $Z^+ \cap \mathcal{F}$ and $Z^- \cap \mathcal{F}$ are therefore rectangles, and $R_{\updownarrow} \cap \mathcal{F}$ is an x-monotone rectilinear polygon.

We define the *influence region* of R to be $\mathcal{I}(R) := \mathcal{F} \cap R_{\square}$. For $\lambda \in [\lambda_1, \lambda_2]$, if $\pi_B(\lambda) \notin \mathcal{I}(R)$ then $\pi_A(\lambda)$ can be pushed to $\mathsf{top}(R)$ or $\mathsf{bot}(R)$ without colliding with B, so we have to worry about subintervals of $[\lambda_1, \lambda_2]$ during which π_B lies in $\mathcal{I}(R)$. As illustrated in Figure 4, the influence region $\mathcal{I}(R)$ may consist of several connected components: a *giant* component $\gamma(R)$ that contains R, and several *tiny* components, each of which lies inside a corner square of $R_{\square}$. Tiny components are xy-monotone by Observation 5. Note that the giant component may intersect the corner squares. In particular, let ρ be a corner square that lies, say, to the left of $R_{\updownarrow}$. By Observation 5, there is at most one connected component ϕ of $\rho \cap \mathcal{F}$ adjacent to the right edge of ρ. If such a component ϕ exists, then $\phi = \rho \cap \gamma(R)$ and (like the tiny components) ϕ is xy-monotone. Other components of $\rho \cap \mathcal{F}$ are tiny components of $\mathcal{I}(R)$. Let ρ, ρ' be two corner squares on the same side of $R_{\updownarrow}$. If both $\rho \cap \mathcal{F}$ and $\rho' \cap \mathcal{F}$ have non-empty connected components inside $\gamma(R)$, denoted by ϕ and ϕ' respectively, then we refer to pairs of points in $\phi \times \phi'$ as *blocked pairs*. The next lemma states the significance of blocked pairs.

▶ **Lemma 6.** *Let p, q be two points lying in the same connected component of $\mathcal{I}(R)$. Then the shortest paths from p to q in $\mathcal{F}$ are x-monotone if and only if p, q is not a blocked pair.*

Thus, if $\pi_B[\lambda_1, \lambda_2]$ contains a blocked pair, then the surgery of $\boldsymbol{\pi}$ and the proof of its correctness become significantly harder.

Unsafe and swap intervals. We next define critical subintervals of the time interval $[\lambda_1, \lambda_2]$ during which the surgery of $\boldsymbol{\pi}$ requires more care, and then prove some structural properties of $\boldsymbol{\pi}$ during these intervals. Again, we begin with a few definitions. A configuration $\boldsymbol{p} = (p_A, p_B)$ is called *x-separated* if $|(p_A)_x - (p_B)_x| \geqslant 1$ and *y-separated* if $|(p_A)_y - (p_B)_y| \geqslant 1$. We say that two x-separated configurations $\boldsymbol{p}, \boldsymbol{q}$ have the *same x-order* if $\mathrm{sign}((p_A)_x - (p_B)_x) = \mathrm{sign}((q_A)_x - (q_B)_x)$; otherwise the x-order is *swapped*. An interval $[\nu_1, \nu_2]$ is called *x-separated* if $\boldsymbol{\pi}(\nu_1)$ and $\boldsymbol{\pi}(\nu_2)$ are both x-separated. Note that this definition does not require that $\boldsymbol{\pi}(\nu)$ is x-separated for all $\nu \in [\nu_1, \nu_2]$.

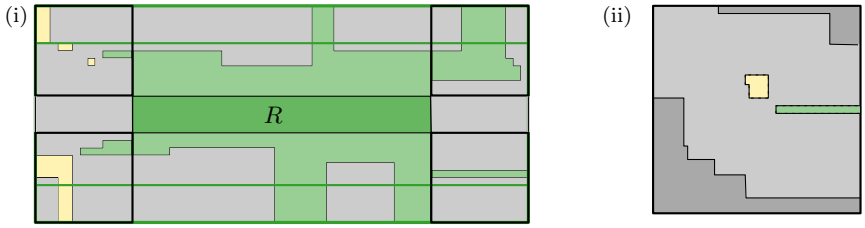

Figure 4 (i) An example influence region within $R_\square$ (not to scale), with the giant component $\gamma(R)$ drawn in green, and tiny components in the corner squares in yellow. (ii) Example of tiny components in a corner square, with obstacles in dark gray and the forbidden space in light gray.

▶ **Definition 7.** *An interval* $[\nu_1, \nu_2] \subseteq [\lambda_1, \lambda_2]$ *is* unsafe *if*

(i) $[\nu_1, \nu_2]$ *is a maximal interval such that* $\pi_B(\nu) \in \mathcal{I}(R)$ *and* $\boldsymbol{\pi}(\nu)$ *is* y*-separated for all* $\nu \in [\nu_1, \nu_2]$*; and*

(ii) *there is a time* $\nu \in [\nu_1, \nu_2]$ *such that* $\boldsymbol{\pi}(\nu)$ *is not* x*-separated.*

For any unsafe interval $[\nu_1, \nu_2]$, either robot B lies above A throughout the interval – that is, $\pi_B(\nu)_y \geqslant \pi_A(\nu)_y$ for all $\nu \in [\nu_1, \nu_2]$ – or B lies below A throughout the interval. Indeed, the robots cannot change their y-order during an unsafe interval, because they must remain y-separated. If an endpoint $\nu_i \in \{\nu_1, \nu_2\}$ is not x-separated then either $\nu_i = \lambda_i$ or $\pi_B(\nu_i) \in \partial\mathcal{I}(R)$. An important type of unsafe interval is the so-called swap interval, as defined next.

▶ **Definition 8.** *A* swap interval *is an* x*-separated unsafe interval such that the* x*-orders at* $\boldsymbol{\pi}(\nu_1)$ *and* $\boldsymbol{\pi}(\nu_2)$ *are swapped.*

Roughly speaking, the roles of unsafe and swap intervals are as follows. If a time $\lambda \in [\lambda_1, \lambda_2]$ does not lie in an unsafe interval, translating $\pi_A(\lambda)$ vertically within R does not cause a conflict with $\pi_B(\lambda)$ because $\boldsymbol{\pi}(\lambda)$ is x-separated or $\pi_B(\lambda) \notin \mathcal{I}(R)$. If an unsafe interval is not x-separated, we show that we can modify π_B to avoid conflicts after translating $\pi_A(\lambda)$ vertically without increasing the length of π_B. We prove the following crucial property of x-separated unsafe intervals using Lemma 6. Suppose $\lambda, \mu \in [\lambda_1, \lambda_2]$ are the endpoints of x-separated unsafe intervals, not necessarily endpoints of the same unsafe interval, such that $\lambda < \mu$ and $\boldsymbol{\pi}(\lambda), \boldsymbol{\pi}(\mu)$ have the same x-order. If $\pi_B(\lambda)$, $\pi_B(\mu)$ lie in the same component of $\mathcal{I}(R)$ and are not a blocked pair, then we can obtain another feasible plan $\boldsymbol{\pi}^*[\lambda, \mu]$ by re-parametrizing $\boldsymbol{\pi}[\lambda, \mu]$ such that the configuration $\boldsymbol{\pi}^*(\nu)$ is x-separated for all $\nu \in [\lambda, \mu]$. Thus, we can eliminate all such unsafe intervals during $[\lambda, \mu]$ and push $\pi_A[\lambda, \mu]$ vertically to $\mathsf{top}(R) \cup \mathsf{bot}(R)$ as above.

Hence, the challenging case is to perform surgery when $[\lambda_1, \lambda_2]$ contains a swap interval. We keep the situation under control using Lemma 9, which bounds the number of swap intervals and which relies on the above property of x-separated unsafe intervals. The proof of this lemma is involved and needs a sequence of intermediate lemmas; see the full version.

We say that a modification $\boldsymbol{\pi}^*$ of $\boldsymbol{\pi}$ is *compliant* if the Feasibility (P1), Optimality (P2), Vertical alignment (P4) and Alternation (P5) properties hold, and all bad segments of $\boldsymbol{\pi}^*$ are either present in $\boldsymbol{\pi}$ or are a segment of $\pi_A^*[\lambda_1, \lambda_2]$.

▶ **Lemma 9.** *Let* $\boldsymbol{\pi}$ *be an optimal* $(\boldsymbol{s}, \boldsymbol{t})$*-plan, let* e *be a bad horizontal segment on* π_A*, and let* $[\lambda_1, \lambda_2]$ *be as defined in (1). Then there is a compliant modification* $\boldsymbol{\pi}^*$ *of* $\boldsymbol{\pi}$ *such that any unsafe* x*-separated interval is a swap interval with the following properties.*

(i) *The plan* $\boldsymbol{\pi}^*[\lambda_1, \lambda_2]$ *has at most one swap interval with* B *above* A *and at most one swap interval with* B *below* A*.*

(ii) *If* $\boldsymbol{\pi}^*[\lambda_1, \lambda_2]$ *has two swap intervals* $[\mu_0, \mu_1]$ *and* $[\mu_2, \mu_3]$*, then* $\mathcal{I}(R)$ *is connected,* $\pi_B^*[\lambda_1, \lambda_2]$ *contains a blocked pair, and* $\boldsymbol{\pi}_B^*[\mu_0, \mu_3]$ *leaves* $\mathcal{I}(R)$*.*

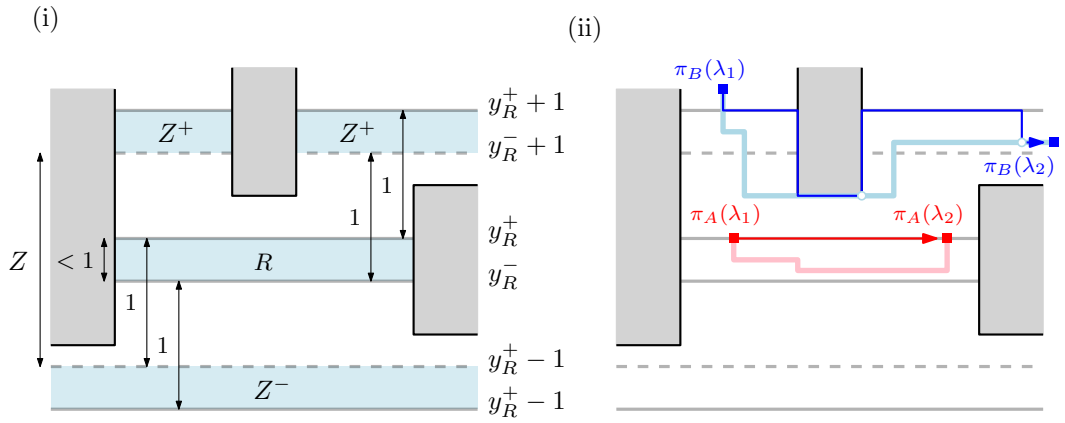

Figure 5 (i) Example of a corridor R, the surrounding lines and areas within $R + 2\square$. (ii) The modification in Case I. The original paths are shown in pink and light blue. The light-blue disks mark the endpoints of a swap interval on π_B.

We now describe the surgery we perform on π_A and π_B to align a given bad horizontal segment e of π_A with a grid line. The surgery consists of a sequence of one or more PUSH operations, described below, which push a part of π_A or π_B vertically onto a grid line. Let $\boldsymbol{\pi}^*$ denote the (modified) plan after the surgery.

The Push procedure. A PUSH operation takes three parameters: a robot $X \in \{A, B\}$, a time interval $I = [\mu_1, \mu_2]$, and a y-coordinate y^* of a horizontal grid line – a line from the set $L_{\leqslant 2}$ – and it pushes the subpath $\pi_X[I]$ onto the grid line $\ell : y = y^*$. More formally, the new plan $\boldsymbol{\pi}^*_X$ resulting from the operation $\textsc{Push}(X, I, y^*)$ is obtained by setting

$$\pi^*_X(\mu)_x := \pi_X(\mu)_x \text{ for all } \mu, \qquad \text{and} \qquad \pi^*_X(\mu)_y := \begin{cases} y^* & \text{if } \mu \in I, \\ \pi_X(\mu)_y & \text{otherwise.} \end{cases}$$

Thus a PUSH operation only changes the y-coordinates on the subpath $\pi_X[I]$. The exact surgery – the values of the parameters X, I, y^* used in the PUSH operations that we perform – depends on the location of $\pi_A(\lambda_1)$, the set of unsafe and swap intervals during $[\lambda_1, \lambda_2]$, and the position of B during the swap intervals, as explained later.

A PUSH operation may have two side effects that we need to address. First, $\textsc{Push}(X, I, y^*)$ may introduce a discontinuity at μ_1 and/or μ_2, the endpoints of I. In other words, for $\mu \in \{\mu_1, \mu_2\}$ we may have $p^-(\mu) \neq p^+(\mu)$, where $p^-(\mu) := \lim_{\lambda \uparrow \mu} \pi^*_X(\lambda)$ and $p^+(\mu) := \lim_{\lambda \downarrow \mu} \pi^*_X(\lambda)$. This happens when $\pi_X(\mu) \neq \pi^*_X(\mu)$. We can resolve the discontinuity by adding the vertical segment $p^-(\mu)p^+(\mu)$, called a *ghost segment*, to π^*_X to make the path continuous, and by re-parametrizing the motion along the ghost segments so that the resulting motion plan is feasible. The second side effect of pushing $\pi_X[I]$ to $\pi^*_X[I]$ is that X may collide with the other robot during the interval I. When this happens we perform a set of *secondary pushes*, as described later.

The overall surgery. Without loss of generality, we assume that $\pi_A(\lambda_2) \in \mathsf{top}(R)$. Our modification of $\boldsymbol{\pi}$ into $\boldsymbol{\pi}^*$ follows three main cases:

- *Case I:* $\pi_A(\lambda_1) \in \mathit{top}(R)$.
  We perform one push operation: $\textsc{Push}(A, [\lambda_1, \lambda_2], y(\mathsf{top}(R)))$; see Figure 5(ii).

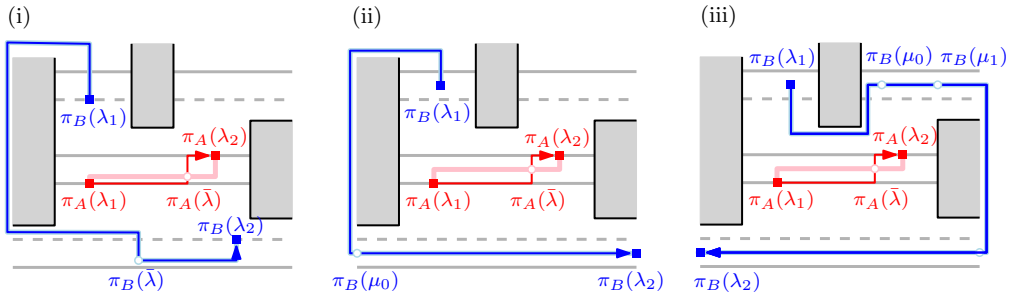

Figure 6 The modifications in the subcases of Case II. The original paths are shown in pink and light blue. In all cases, π_A^* jumps to $\mathsf{top}(R)$ at a suitable time $\bar{\lambda}$. (i) The modification in Case II(a). $\bar{\lambda}$ is the moment when $\boldsymbol{\pi}$ enters the last y-separated interval. (ii) The modification in Case II(b). $\bar{\lambda} = \mu_1$ is the moment when $\boldsymbol{\pi}$ enters the swap interval with B below A. (iii) The modification in Case II(c). $\bar{\lambda} = \mu_2$ is the moment when $\boldsymbol{\pi}$ leaves the swap interval with B above A.

- *Case II: $\pi_A(\lambda_1) \in \mathsf{bot}(R)$. Furthermore, either there is at most one swap interval, or there are two swap intervals and π_B lies above π_A during the first swap interval.*
  In this case, we pick $\bar{\lambda} \in [\lambda_1, \lambda_2]$ suitably and perform two push operations: $\textsc{Push}(A, [\lambda_1, \bar{\lambda}], y(\mathsf{bot}(R)))$ and $\textsc{Push}(A, [\bar{\lambda}, \lambda_2], y(\mathsf{top}(R)))$. Thus, robot A moves along $\mathsf{bot}(R)$ from time λ_1 to $\bar{\lambda}$, and then it switches to moving along $\mathsf{top}(R)$ until time λ_2. We have three subcases for the choice of $\bar{\lambda}$, illustrated in Figure 6.
  - *Case II(a): There are no swap intervals.* If every configuration in $\boldsymbol{\pi}[\lambda_1, \lambda_2]$ is y-separated, then either B lies below A, or above A, during the entire interval $[\lambda_1, \lambda_2]$. If B lies below (resp. above) A during $[\lambda_1, \lambda_2]$, set $\bar{\lambda} = \lambda_1$ (resp. $\bar{\lambda} = \lambda_2$). On the other hand, if there is a configuration in $\boldsymbol{\pi}[\lambda_1, \lambda_2]$ that is not y-separated, set $\bar{\lambda} := \sup\{\lambda \in [\lambda_1, \lambda_2] : \boldsymbol{\pi}(\lambda) \text{ is not } y\text{-separated}\}$.
  - *Case II(b): There is one swap interval and π_B is below π_A during this swap interval.* Let $[\mu_0, \mu_1]$ be this swap interval. Set $\bar{\lambda} := \mu_0$.
  - *Case II(c): There is at least one swap interval and π_B lies above π_A during the first one.* Let $[\mu_0, \mu_1]$ be this swap interval. Set $\bar{\lambda} := \mu_1$.

- *Case III: $\pi_A(\lambda_1) \in \mathsf{bot}(R)$ and there are exactly two swap intervals, and π_B lies below π_A the during the first swap interval.*
  Let $[\mu_0, \mu_1]$ and $[\mu_2, \mu_3]$ be the two swap intervals, with $\mu_1 < \mu_2$. Since all configurations in $\boldsymbol{\pi}[\mu_0, \mu_1]$ are y-separated and B lies below A during $[\mu_0, \mu_1]$, the path $\pi_B[\mu_0, \mu_1]$ lies in a connected component of $\mathcal{F} \cap Z^-$, which is a rectangle Q'. We prove that $\pi_B[\mu_0, \mu_1]$ is contained in a rectangle $Q \supseteq Q'$ of the subdivision of $\mathcal{F}$ induced by the lines of L_0. Let $[\nu_0, \nu_1]$ be the maximal interval containing $[\mu_0, \mu_1]$ such that $\pi_B(\nu_0, \nu_1) \subset \mathrm{int}(Q)$. The push operations depend on which of $\pi_B(\nu_0), \pi_B(\nu_1)$ lie on $\mathsf{top}(Q)$.
  - *Case III(a): $\pi_B(\nu_0) \in \mathsf{bot}(Q)$ and $\pi_B(\nu_1) \in \mathsf{top}(Q)$.* We perform two push operations, $\textsc{Push}(A, [\lambda_1, \lambda_2], y(\mathsf{bot}(R)))$ and $\textsc{Push}(B, [\nu_0, \mu_1], y(\mathsf{bot}(Q)))$.
  - *Case III(b): $\pi_B(\nu_0) \in \mathsf{top}(Q)$ and $\pi_B(\nu_1) \in \mathsf{bot}(Q)$.* Symmetric to the previous case.
  - *Case III(c): $\pi_B(\nu_0), \pi_B(\nu_1) \in \mathsf{top}(Q)$.* Again, we perform two push operations. The first is $\textsc{Push}(A, [\lambda_1, \lambda_2], y(\mathsf{top}(R)))$. (Note that, unlike in the previous two subcases, we pushed A to $\mathsf{top}(R)$ instead of $\mathsf{bot}(R)$.) Recall that $\pi_B[\mu_0, \mu_1] \subset \mathcal{F} \cap Z^-$, and let $[\rho_0, \rho_1] \supseteq [\mu_0, \mu_1]$ be the maximal interval such that $\pi_B[\rho_0, \rho_1]$ lies on or below the horizontal line $\ell^- : y = y(\mathsf{top}(R)) - 1$ that contains $\mathsf{top}(Z^-)$. The second push operation is $\textsc{Push}(B, [\rho_0, \rho_1], y(\mathsf{top}(R)) - 1)$.
  - *Case III(d): $\pi_B(\nu_0), \pi_B(\nu_1) \in \mathsf{bot}(Q)$.* We argue that this case does not occur.

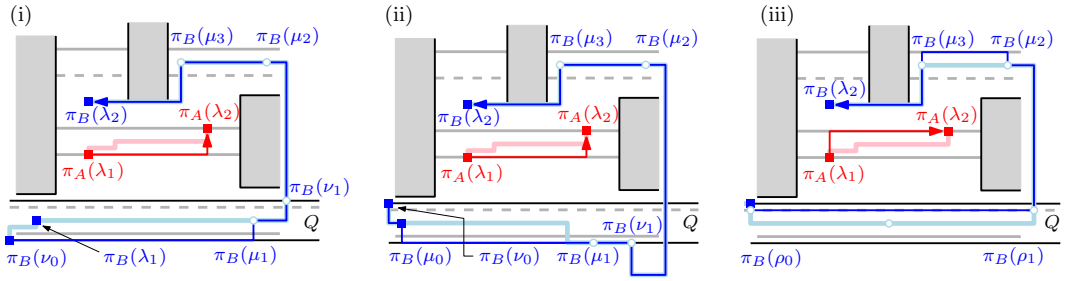

Figure 7 The modifications in the subcases of Case III. The original paths are shown in pink and light blue. (i) In Case III(a) we push $\pi_A[\lambda_1, \lambda_2]$ onto $\mathsf{bot}(R)$, and we push $\pi_B[\nu_0, \mu_1]$ onto $y(\mathsf{bot}(Q))$. (ii) In Case III(b) we also push $\pi_A[\lambda_1, \lambda_2]$ onto $\mathsf{bot}(R)$, and we push $\pi_B[\lambda_1, \nu_1]$ onto $y(\mathsf{bot}(Q))$. In this example, we have $\mu_0 = \lambda_1$. (iii) In Case III(c) we push $\pi_A[\lambda_1, \lambda_2]$ onto $\mathsf{top}(R)$, and we push $\pi_B[\rho_0, \rho_1]$ onto $\mathsf{top}(R) - 1$. We also have a secondary push, namely $\pi_B[\mu_2, \mu_3]$ onto $\mathsf{top}(R) + 1$.

Secondary pushes. After applying the above surgery, we possibly apply secondary pushes to π_B, as follows. For every unsafe interval $[\nu_1, \nu_2]$, if there is a time $\nu \in [\nu_1, \nu_2]$ such that $\pi_A^*(\nu)$ conflicts with $\pi_B^*(\nu)$, then we execute $\textsc{Push}(B, (\nu_1, \nu_2), y^*)$, where

$$y^* := \begin{cases} y(\mathsf{top}(R)) + 1 & \text{if } \pi_B(\nu)_y > \pi_A(\nu)_y, \\ y(\mathsf{bot}(R)) - 1 & \text{if } \pi_B(\nu)_y < \pi_A(\nu)_y. \end{cases} \tag{2}$$

Correctness proof (sketch). To prove the correctness of the surgery, we need to prove that the new plan has properties (P1)–P(5). The proofs of (P3)–(P5) are not difficult – they are essentially satisfied by construction. The proof of Feasibility (P1) for the surgery performed in Cases (I) and (II) is not hard either, but it is highly nontrivial for Case (III) because π_B might get modified beyond the interval $[\lambda_1, \lambda_2]$, e.g. during the interval $[\nu_0, \mu_1]$ with $\nu_0 < \lambda_1$ in Case III(a) or during the interval $[\rho_0, \mu_1]$ in Case III(c). Since A might not lie in R during $[\nu_0, \mu_1]$ (or $[\rho_0, \mu_1]$), we have to prove that the modified plan $\boldsymbol{\pi}^*$ during the interval $[\nu_0, \lambda_1]$ (or $[\rho_0, \lambda_1]$) remains feasible. We can prove the feasibility of $\boldsymbol{\pi}^*[\nu_0, \lambda_1]$ in Case III(a) by showing that if $\boldsymbol{\pi}^*[\nu_0, \lambda_1]$ were not feasible then $\boldsymbol{\pi}$ would not have been an optimal plan. We prove the feasibility of $\boldsymbol{\pi}^*[\rho_0, \mu_1]$ in Case III(c) by showing the existence of an optimal plan with additional structural properties, performing a compliant modification on $\boldsymbol{\pi}$, if necessary, to ensure these properties, and arguing that these properties ensure that $\boldsymbol{\pi}^*[\rho_0, \mu_1]$ is feasible. Finally, we need to prove Optimality (P2) of the modified path, which is also nontrivial because the surgery may increase the length of one of the paths. To illustrate this, we show that the surgery in Case I does not increase the total length of the plan, even though it may increase the length of the plan of robot A.

▶ **Lemma 10.** *The modification in Case I yields a plan $\boldsymbol{\pi}^*$ that is optimal.*

Proof. By construction, $\|\pi_A^*[\lambda_1, \lambda_2]\| \leqslant \|\pi_A[\lambda_1, \lambda_2]\|$. If π_B remains unchanged then trivially $\|\boldsymbol{\pi}^*\| \leqslant \|\boldsymbol{\pi}\|$, so assume there is an unsafe interval $[\nu_1, \nu_2]$ in which π_B lies in Z^+ and is pushed to $\mathsf{top}(R_\square)$. If $\boldsymbol{\pi}(\nu_1)$ is not x-separated then either $\nu_1 = \lambda_1$ or π_B enters $\mathcal{I}(R)$ through $\mathsf{top}(R_\square)$. (It cannot enter through the right or left edge of $R_\square$, because then $\boldsymbol{\pi}(\nu_1)$ would be x-separated.) Since $\pi_A(\lambda_1) \in \mathsf{top}(R)$, we have $\pi_B(\nu_1) \in \mathsf{top}(R_\square)$ if $\nu_1 = \lambda_1$; this is true since $\boldsymbol{\pi}(\nu)$ is y-separated for all $\nu \in [\nu_1, \nu_2]$. Hence, if $\boldsymbol{\pi}(\nu_1)$ is not x-separated then $\pi_B(\nu_1)_y = y_R^+ + 1$. Since π_B is pushed to $\mathsf{top}(R_\square)$ during $[\nu_1, \nu_2]$, we prove that this push procedure does not increase the length of the path of B. The same holds if $\boldsymbol{\pi}(\nu_2)$ is not x-separated. Hence, $\boldsymbol{\pi}^*$ is still optimal in these cases.

Now assume that both $\boldsymbol{\pi}(\nu_1)$ and $\boldsymbol{\pi}(\nu_2)$ are x-separated. By Lemma 9, we know that $[\nu_1, \nu_2]$ is a swap interval. Since there is at most one swap interval with B above A, by Lemma 9, there is at most one swap interval $[\nu_1, \nu_2]$ during which π_B is modified. Pushing B to $\mathsf{top}(R_\square)$ during $[\nu_1, \nu_2]$ increases $\|\pi_B^*\|$ by at most the total length of the ghost segments $g(\nu_1)$ and $g(\nu_2)$, which is $2y_R^+ + 2 - \pi_B(\nu_1)_y - \pi_B(\nu_2)_y$. Pushing A to $\mathsf{top}(R)$ during $[\nu_1, \nu_2]$ decreases the length of its path by at least $2y_R^+ - \pi_A(\nu_1)_y - \pi_A(\nu_2)_y$. By definition, the configurations $\boldsymbol{\pi}(\nu_i)$ are y-separated for $i = 1, 2$, so $\pi_B(\nu_i)_y - \pi_A(\nu_i)_y \geqslant 1$. Hence,

$$\begin{aligned}\|\boldsymbol{\pi}\| - \|\boldsymbol{\pi}^*\| &\geqslant \Big(2y_R^+ - \pi_A(\nu_1)_y - \pi_A(\nu_2)_y\Big) - \Big(2y_R^+ + 2 - \pi_B(\nu_1)_y - \pi_B(\nu_2)_y\Big) \\ &= \Big(\pi_B(\nu_1)_y - \pi_A(\nu_1)_y - 1\Big) + \Big(\pi_B(\nu_2)_y - \pi_A(\nu_2)_y - 1\Big) \geqslant 0.\end{aligned}$$

We thus conclude that $\boldsymbol{\pi}^*$ is optimal. ◀

Omitting further details of the correctness, we conclude that Theorem 4 holds, which is the crucial ingredient for Theorem 1. This concludes our sketch of the proof of our main result.

4 Conclusion

We presented an $O(n^4 \log n)$ algorithm to compute a plan of minimum total length for two unit squares in a rectilinear environment; this is the first polynomial algorithm for 2-robot optimal motion planning in a polygonal environment. In contrast, we showed that minimizing the makespan is weakly NP-hard. We conclude with some open problems:

- Can the runtime of our algorithm for the Min-Sum problem be improved to $O(n^2 \log n)$? Can our algorithm be extended to k unit squares with $n^{O(k)}$ runtime?
- Is the Min-Sum problem for two squares in a general polygonal environment in P?
- Is there a pseudo-polynomial-time algorithm for the Min-Makespan problem for two unit squares translating in a rectilinear environment?

A Sparse Multicover Bifiltration of Linear Size

Ángel Javier Alonso
Graz University of Technology, Austria

Abstract

The k-cover of a point cloud X of $\mathbb{R}^d$ at radius r is the set of all those points within distance r of at least k points of X. By varying r and k we obtain a two-parameter filtration known as the multicover bifiltration. This bifiltration has received attention recently due to being choice-free and robust to outliers. However, it is hard to compute: the smallest known equivalent simplicial bifiltration has $O(|X|^{d+1})$ simplices. In this paper we introduce a $(1+\varepsilon)$-approximation of the multicover bifiltration of linear size $O(|X|)$, for fixed d and ε. The methods also apply to the subdivision Rips bifiltration on metric spaces of bounded doubling dimension yielding analogous results.

1 Introduction

This paper aims to approximate the multicover bifiltration of a finite subset X of $\mathbb{R}^d$, depicted in Figure 1. The *k-cover* $\mathrm{Cov}_{r,k}$ for a scale $r \geq 0$ is given by all those points covered by at least k balls of radius r around the points of X:

$$\mathrm{Cov}_{r,k} \coloneqq \{p \in \mathbb{R}^d \mid \|x - p\| \leq r \text{ for at least } k \text{ points } x \in X\}.$$

For any $r \leq r'$ and $k \geq k'$, we have that $\mathrm{Cov}_{r,k} \subset \mathrm{Cov}_{r',k'}$ and as such the $\mathrm{Cov}_{r,k}$ assemble into a *bifiltration* known as the *multicover bifiltration*.

The multicover bifiltration offers a view into the topology of the point cloud X across multiple scales, in a way that is robust to outliers [7]. However, computing the multicover bifiltration remains a challenge. Current exact combinatorial (simplicial or polyhedral) methods [28, 34] are expensive, of size $O(|X|^{d+1})$, and previous approximate methods [9, 12] are in general exponential and only linear on $|X|$ when taking k to be at most a constant.

For general metric spaces, instead of subsets of $\mathbb{R}^d$, an analogue of the multicover is the subdivision Rips bifiltration [53]. As the multicover, it has received attention recently, both in its theoretical [7] and computational aspects [41, 42, 43], where it faces similar challenges as the multicover. Previous approximation schemes [7, 41, 42, 43, 44] are of size polynomial (but not linear) in $|X|$, see the related work section below.

In this paper, we define a simplicial bifiltration, the *sparse subdivision bifiltration* (Definition 13), that $(1+\varepsilon)$-approximates the multicover and that is of linear size $O(|X|)$, independently of k and for fixed ε and d. It can be computed in time $O(|X| \log \Delta)$, where Δ is the *spread* of X, the ratio between the longest and shortest distances between points in X. In addition, the methods extend to obtain analogous results for the subdivision Rips bifiltration for metric spaces of bounded doubling dimension, as we discuss in Section 6.

The sparse subdivision bifiltration is (homotopically) equivalent to the *sparse multicover bifiltration* SCov (Definition 6), a bifiltration of subsets of $\mathbb{R}^d$. It is via SCov that the sparse subdivision bifiltration $(1+\varepsilon)$-approximates the multicover, by which we mean that

$$\mathrm{Cov}_{r,k} \subset \mathrm{SCov}_{(1+3\varepsilon)r,k} \text{ and } \mathrm{SCov}_{r,k} \subset \mathrm{Cov}_{(1+\varepsilon)r,k}$$

for any r and k, as shown in Theorem 8. In other words, the sparse subdivision bifiltration and the multicover are *(multiplicatively)* $(1+\varepsilon)$*-homotopy-interleaved* [6].

This approximation is analogous to the one obtained by Cavanna, Jahanseir and Sheehy [16] for the case of fixed $k = 1$, and our techniques can be traced back to their work; see the related work section. A key principle is that instead of balls of radius r, the sparse multicover bifiltration is based on *sparse balls* (Definition 1), understood as balls with a lifetime of three phases: on the first phase they grow normally (at scale r they have radius r), and then they are slowed down (they keep growing but at scale r they have radius less than r), before eventually disappearing. Cavanna, Jahanseir and Sheehy [16] (there is a video [15]) do the same, with technical differences that include stopping balls from growing, rather than growing slow. The size bounds here are also an adaptation of their methods, as well as the technique of lifting the construction one dimension higher, as in the *cones* of Section 3.1.

We guarantee that when a sparse ball disappears it is approximately covered by another present sparse ball, and we keep track of which present sparse ball covers which disappeared sparse ball via a *covering map* (Definition 4). A sparse ball is weighted by as many sparse balls it approximately covers according to the covering map – the *sparse k-cover* $\mathrm{SCov}_{r,k}$ consists of those points covered by sparse balls whose total weight is at least k.

1.1 Motivation and related work

For $k = 1$, the 1-cover is the union of balls of radius r around points of X. The union of balls is commonly used in reconstructing submanifolds from samples [3, 4, 46] and is a cornerstone of *persistent homology* methods in topological data analysis, being homotopy equivalent to the Čech complex and the alpha complex [31, 32], and related to the (Vietoris-)Rips complex. The union of balls assembles into a 1-parameter filtration: by increasing the scale parameter r we obtain inclusions $\mathrm{Cov}_{r,1} \hookrightarrow \mathrm{Cov}_{r',1}$, for $r \leq r'$. Taking the homology of each $\mathrm{Cov}_{r,1}$, we obtain a *persistence module*, an algebraic descriptor of the topology of the filtration across the different scales. Such a persistence module is stable to perturbations of the points [25, 26], but is not robust to outliers (already appreciated in the first column of Figure 1) and insensitive to differences in density in the point cloud.

There are multiple methods that address the lack of robustness to outliers and changes in density within the 1-parameter framework. These include density estimation [8, 20, 47], distance to a measure [1, 2, 10, 11, 18, 19, 38, 39], and subsampling [5]. However, they all depend on choosing a parameter. The problem is that it is not clear how to choose such a parameter for all cases, and such a choice might focus on a specific range of scales or densities. We refer to [7, Section 1.7] for a complete overview of the methods and their limitations.

It is then natural to consider constructions over two parameters, scale and density. Examples include the density bifiltration [13], degree bifiltration [44], and the multicover, closely related to both the distance to a measure [18] and k-nearest neighbors [53]. The advantage of the multicover is that it does not depend on any further choices (like choosing a density estimation function) and that it is robust to outliers, as a consequence of its strong stability properties [7].

However, one currently problematic aspect of the multicover is its computation. Sheehy [53] introduced an influential simplicial model of the multicover called the *subdivision Čech bifiltration*, based on the barycentric subdivision of the Čech filtration. It has exponentially many vertices on the number of input points, making its computation infeasible. A crucial ingredient in the theory is the *multicover nerve theorem* [7, 14, 53] that establishes the topological equivalence (see Section 3.1 for a precise definition) of the subdivision Čech and multicover bifiltrations. Such a multicover nerve theorem has its analogue for the sparse multicover, the *sparse multicover nerve theorem* (Theorem 14).

Dually to an hyperplane arrangement in $\mathbb{R}^{d+1}$, Edelsbrunner and Osang [33, 34] define the *rhomboid tiling* and use it to compute, up to homotopy, slices (fixing k and varying r or viceversa) of the multicover bifiltration. Corbet, Kerber, Lesnick and Osang [27, 28] build on it to define two bifiltrations topologically equivalent to the multicover, of size $O(|X|^{d+1})$.

Recently, Buchet, Dornelas and Kerber [12] introduced an elegant $(1+\varepsilon)$-approximation of the multicover whose m-skeleton has size that is linear on $|X|$ but that incurs an exponential dependency on the maximum order k we want to compute. A crucial difference between our work and the Buchet-Dornelas-Kerber (BDK) sparsification is that BDK work at the level of intersection of balls, while we work directly at the level of balls. This starting point is what allows us to ultimately obtain a construction of linear size, independently of k.

In addition, BDK work by freezing the lenses: at a certain scale they stop growing. It is not clear (or is technically challenging, in the words of BDK) how to compute exactly the first scale at which freezing lenses first intersect – a problem they sidestep by discretizing the scale parameter (at no complexity cost). In contrast, by letting sparse balls grow slowly at a certain rate, rather than freezing them completely, we can compute their first intersection time exactly, as we explain in Section 5.3.

Sparsification. Our methods are part of a line that can be traced to the seminal work of Sheehy [52, 54] to obtain a linear size approximation of the Vietoris-Rips filtration. Subsequently, Cavanna, Jahanseir and Sheehy [16] simplified and generalized Sheehy's methods to obtain a linear size $(1+\varepsilon)$-approximation of the union-of-balls filtration $\mathrm{Cov}_{r,1}$. They construct a filtration S such that $S_r \subset \mathrm{Cov}_{r,1} \subset S_{(1+\varepsilon)r}$, resembling Theorem 8 here. Moreover, the *sparse balls* we use here are directly inspired by their methods: they use balls that grow normally, stop growing, and eventually disappear.

These methods, broadly referred to as *sparsification*, have also been applied to the Delaunay triangulation [55] and, as already mentioned, the multicover itself [12]. A fundamental ingredient in many of these constructions is the greedy permutation [30, 37, 49], or variants of it, that we also use in the form of *persistent nets* (Section 2.1).

General metric spaces. In general metric spaces, an analogue of the subdivision Čech bifiltration of Sheehy is the *subdivision Rips bifiltration*. Its computation faces similar challenges, and, in fact, no subexponential size simplicial model of it exists [42]. Thus, there has been recent interest in approximations of subdivision Rips. Indeed, the *degree Rips bifiltration* [44], which can be shown to be a $\sqrt{3}$-approximation [7] whose m-skeleton has size $O(|X|^{m+2})$, and has been implemented [44, 48, 50]. Furthermore, it was recently shown that subdivision Rips admits $\sqrt{2}$-approximations whose k-skeleta have the same size as degree Rips [41, 42]. Most recently, Lesnick and McCabe [42, 43], in the more particular case of metric spaces of bounded doubling dimension (which include Euclidean spaces), give a $(1+\varepsilon)$-approximation of subdivision Rips whose m-skeleton has $O(|X|^{m+2})$ simplices, for fixed ε and dimension. Our methods also apply to the subdivision Rips setting, yielding analogous results, as discussed in Section 6.

Miniball. In Section 5.3, we compute the first scale at which a set of sparse balls have non-empty intersection, for Euclidean space. If instead of sparse balls we would be using usual balls, such a scale would be the radius of the minimum enclosing ball of the centers of the balls – the *miniball problem*, first stated by Sylvester in 1857 [56]. Our solution to the analogous problem for sparse balls has its origin in Welzl algorithm [57], which takes randomized linear time on the number of centers. The miniball problem is of *LP-type* as introduced later by Matoušek, Sharir and Welzl [45], and Welzl algorithm for the miniball can be generalized to the Matoušek-Sharir-Welzl (MSW) algorithm for LP-type problems. Fischer and Gärtner [35] solve the problem of computing the minimum enclosing ball of balls – generalizing the miniball – via the MSW-algorithm in a way that is practical and efficient, as in the implementation in the CGAL library [36]. Here, we frame the problem of computing the first scale of intersection of sparse balls as an LP-type algorithm and show how to solve it as an extension of Fischer and Gärtner's methods. The miniball and similar problems have also been stated and solved through the geometric optimization point of view, see [17, 29] and references therein.

2 A sparse multicover bifiltration

In this section we introduce the *sparse multicover bifiltration*. As already noted in the introduction, instead of using balls of radius r, the sparse multicover involves balls with a lifetime of three phases: they start as usual balls of radius r at scale r, at some point they start to *grow slowly*, that is, they have radii smaller than r at scale r, and eventually they disappear. We call this version of balls *sparse balls*. For their definition and the subsequent proofs we use the notion of *persistent nets*, which we define first.

2.1 Persistent nets

Persistent nets, defined below, are a reinterpretation of farthest point sampling, or greedy permutations, as known in the sparsification literature [12,16,55], and as such are guaranteed to exist by Gonzalez algorithm [37]. We will revisit these concepts in Section 5.

Let (X, ∂) be a finite metric space. We say that a subset $S \subset X$ is a *r-net* for a radius $r \geq 0$, if it is

1. a r-covering: for every $x \in X \setminus S$ there is an $a \in S$ with $\partial(x, a) < r$, and
2. a r-packing: for every two $a, b \in S$ we have $\partial(a, b) \geq r$.

In the spirit of persistence, a *persistent net* $\mathcal{S}$ of X is a collection of r-nets $\mathcal{S}(r) \subset X$, one for each $r \geq 0$, such that for any two $r' \geq r$ we have $\mathcal{S}(r') \subset \mathcal{S}(r)$.

The *insertion radius* $\mathrm{ins}(x) \in \mathbb{R} \cup \{\infty\}$ of a point $x \in X$, with respect to a persistent net $\mathcal{S}$, is the supremum of those r such that $x \in \mathcal{S}(r)$. There is a large enough r so that $\mathcal{S}(r)$ is a single point (it has to be a r-packing), and so there is only one point x with $\mathrm{ins}(x) = \infty$.

2.2 Sparse balls

In what follows, we work over a fixed finite subset $X \subset \mathbb{R}^d$, with $\mathbb{R}^d$ equipped with any norm. We also fix an error parameter $\varepsilon > 0$ and a persistent net $\mathcal{S}$ of X, that we often drop from the notation. We define the *slowing time* $\mathrm{slow}(x)$ of a point $x \in X$ by

$$\mathrm{slow}(x) \coloneqq \frac{1+\varepsilon}{\varepsilon}\,\mathrm{ins}(x).$$

▶ **Definition 1.** *We define the* sparse ball $\mathrm{SB}(x, r)$ *of $x \in X$ at scale r as:*

$$\mathrm{SB}(x, r) \coloneqq \begin{cases} B(x, \rho_x(r)) & r \leq (1+3\varepsilon)\,\mathrm{slow}(x), \\ \varnothing & r > (1+3\varepsilon)\,\mathrm{slow}(x), \end{cases}$$

where $B(x, s)$ denotes the closed ball around x of radius s, and $\rho_x \colon \mathbb{R} \to \mathbb{R}$ is a radius function*: any strictly increasing function such that*

- *on the interval $[0, \mathrm{slow}(x)]$, is $\rho_x(r) = r$, and*
- *on the interval $(\mathrm{slow}(x), (1+3\varepsilon)\,\mathrm{slow}(x)]$, satisfies*

$$L_x(r) \leq \rho_x(r) \leq U_x(r), \text{ where}$$
$$L_x(r) \coloneqq \frac{1}{1+3\varepsilon} r + \frac{\varepsilon}{1+\varepsilon}\,\mathrm{slow}(x) \text{ and } U_x(r) \coloneqq \frac{1}{3(1+\varepsilon)} r + \frac{2+3\varepsilon}{3(1+\varepsilon)}\,\mathrm{slow}(x).$$

For example, the radius function of a point $x \in X$ can be

$$\rho_x(r) = \begin{cases} r, & r < \mathrm{slow}(x), \\ U_x(r), & r \geq \mathrm{slow}(x), \end{cases}$$

but other options are useful for computation (Section 5.3). In any case, the sparse ball of x has radius r up to scale $\mathrm{slow}(x)$, it then starts to grow slowly with radius at most $U_x(r) < r$, until eventually disappearing at scale $(1+3\varepsilon)\,\mathrm{slow}(x)$. We say that the sparse ball around $x \in X$ is *slowed* at scale r if $r \geq \mathrm{slow}(x)$.

The functions $L_x(r)$ and $U_x(r)$ are defined in this way for technical reasons related to properties of the sparse multicover that we will prove shortly. For now, let us say that whenever a sparse ball disappears (that is, at scale $(1+3\varepsilon)\,\mathrm{slow}(x)$), it is covered by another non-slowed sparse ball:

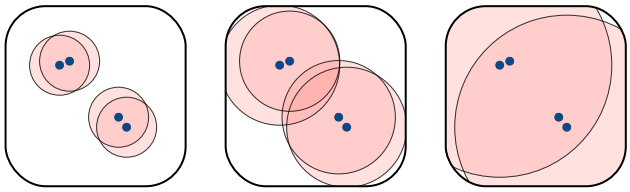

Figure 2 Sparse balls around four points in the plane. On the left square, they are not slowed yet. On the middle square, two of them are growing slow, and are starting to get covered by the other two. On the right square, two of the sparse balls have disappeared.

▶ **Lemma 2.** *Let $x \in X$ be a point and write $\gamma \coloneqq (1+3\varepsilon)\operatorname{slow}(x)$. There exists a point $y \in X$ such that $\operatorname{slow}(y) \geq \gamma$ and $\operatorname{SB}(x,\gamma) \subset \operatorname{SB}(y,\gamma)$.*

Proof. Note that the sparse ball of x has radius at most $L_x(\gamma) = U_x(\gamma) = \frac{1+2\varepsilon}{1+\varepsilon}\operatorname{slow}(x)$. At scale γ, the centers of the non-slowed balls are precisely the $\frac{\varepsilon}{1+\varepsilon}\gamma$-net $\mathcal{S}(\frac{\varepsilon}{1+\varepsilon}\gamma)$. Thus, since $\frac{\varepsilon}{1+\varepsilon}\gamma + \frac{1+2\varepsilon}{1+\varepsilon}\operatorname{slow}(x) < \gamma$, there is a y in $\mathcal{S}(\frac{\varepsilon}{1+\varepsilon}\gamma)$ such that the sparse ball around y covers the ball around x of radius $\frac{1+2\varepsilon}{1+\varepsilon}\operatorname{slow}(x)$,

$$\operatorname{SB}(x,\gamma) \subset B\left(x, \frac{1+2\varepsilon}{1+\varepsilon}\operatorname{slow}(x)\right) \subset B(y,\gamma) = \operatorname{SB}(y,\gamma). \qquad \blacktriangleleft$$

2.3 Covering map

One of the intuitive principles behind the sparse multicover is that, at every scale $r \geq 0$, the non-empty sparse balls *approximately cover* the balls of radius r around all the points of X. Below, we formally define a map that takes each point x to the non-empty sparse ball that approximately covers the ball of x.

▶ **Definition 3.** *We define the* covering sequence $(x_0, \ldots, x_m)$ *of a point $x \in X$ as follows: we set $x_0 = x$ and, recursively, given x_{i-1} and if $\operatorname{slow}(x_{i-1}) < \infty$, we set x_i to be the nearest neighbor (breaking ties arbitrarily) of x among those points y with $\operatorname{slow}(y) \geq (1+3\varepsilon)\operatorname{slow}(x_{i-1})$. In other words, the nearest neighbor among those points whose sparse balls are non-slowed when the sparse ball of x_{i-1} disappears.*

▶ **Definition 4.** *For each scale $r \geq 0$, the* covering map $\mathcal{C}_r \colon X \to X$ *takes x to the first x_i in its covering sequence whose sparse ball is non-empty at scale r.*

For a point $x \in X$ and $r \geq 0$, we say that $c_r(x) \coloneqq |\mathcal{C}_r^{-1}(x)|$, the cardinality of its preimage under the covering map, is its covering weight.

We will use the following lemma multiple times. It describes how the covering map inherits covering and packing properties from the persistent net.

▶ **Lemma 5.** *The covering map has the following properties, for each $r \geq 0$:*

1. *The image $\mathcal{C}_r(X)$ is the set of points whose sparse balls at radius r are non-empty,*
2. *the points in $\mathcal{C}_r(X)$ are $\frac{\varepsilon}{(1+\varepsilon)(1+3\varepsilon)}r$-packed, and*
3. *for each $x \in X$ and writing $y \coloneqq \mathcal{C}_r(x)$, $\|x-y\| \leq \frac{\varepsilon}{1+\varepsilon}\min(r, \operatorname{slow}(y))$.*

Proof. The first property is by definition.

For the second, by the previous property the sparse ball of a $x \in \mathcal{C}_r(X)$ has not disappeared at scale r, and thus $r \leq (1+3\varepsilon)\operatorname{slow}(x) = (1+3\varepsilon)\frac{1+\varepsilon}{\varepsilon}\operatorname{ins}(x)$. This gives that $\frac{\varepsilon}{(1+\varepsilon)(1+3\varepsilon)}r \leq \operatorname{ins}(x)$, which implies what we want by the definition of $\operatorname{ins}(x)$ and persistent net.

For the third, if $x = y$ there is nothing to prove. Otherwise, let z be the point directly before y in the covering sequence of x, and write $\gamma \coloneqq (1+3\varepsilon)\operatorname{slow}(z)$. By construction, $\gamma < r$ and $\gamma \leq \operatorname{slow}(y) = \frac{1+\varepsilon}{\varepsilon}\operatorname{ins}(y)$. Thus, y is in $\mathcal{S}(\frac{\varepsilon}{1+\varepsilon}\gamma)$, and y is the nearest neighbor of x in such subset. We conclude that $\|x-y\| \leq \frac{\varepsilon}{1+\varepsilon}\gamma \leq \frac{\varepsilon}{1+\varepsilon}\min(r, \operatorname{slow}(y))$. ◀

2.4 The sparse multicover

We can write the k-cover $\operatorname{Cov}_{r,k}$ for a scale $r \geq 0$ as

$$\operatorname{Cov}_{r,k} \coloneqq \left\{ p \in \mathbb{R}^d \mid \text{exists } S \subset X \text{ with } p \in \bigcap_{x \in S} B_r(x) \text{ and } |S| \geq k \right\}.$$

In parallel, the sparse multicover uses sparse balls instead of balls, and the covering weight instead of the number of balls:

▶ **Definition 6.** *The* sparse k-cover $\operatorname{SCov}_{r,k}$*, for $r \geq 0$ and $k \in \mathbb{N}$, is the set of points $p \in \mathbb{R}^d$ covered by sparse balls at scale r whose sum of covering weights at scale r is at least k,*

$$\operatorname{SCov}_{r,k} \coloneqq \left\{ p \in \mathbb{R}^d \mid \textit{exists } S \subset X \textit{ with } p \in \bigcap_{x \in S} \operatorname{SB}(x,r) \textit{ and } \sum_{x \in S} c_r(x) \geq k \right\}.$$

The *sparse multicover* is the bifiltration given by the sparse covers:

▶ **Proposition 7.** *For $r \leq r'$ and $k \geq k'$, we have $\operatorname{SCov}_{r,k} \subset \operatorname{SCov}_{r',k'}$.*

Proof. Let $p \in \operatorname{SCov}_{r,k}$ and let S be a subset whose sparse balls of radius r cover p with covering weight at least k. Take $A \coloneqq \mathcal{C}_r^{-1}(S)$ and note that there are at least k points in A. For each $a \in A$, we claim that the sparse ball of $\mathcal{C}_{r'}(a)$ (the point that "covers" a at scale r') also contains p. Proving the claim finishes the proof, as the sum of covering weights of $\mathcal{C}_{r'}(A)$ is at least $k \geq k'$.

We write $x \coloneqq \mathcal{C}_r(a)$ and $y \coloneqq \mathcal{C}_{r'}(a)$. The claim is immediate if $x = y$. Otherwise, note that necessarily $\operatorname{ins}(x) < \infty$, because the point with infinite insertion radius is unique. Also note that $x \notin \mathcal{C}_{r'}(X)$ and, thus, $(1+3\varepsilon)\operatorname{slow}(x) \leq \min(r', \operatorname{slow}(y))$. This fact, together with the triangle inequality and Lemma 5, gives

$$\begin{aligned}
\|y-p\| &\leq \|y-a\| + \|a-x\| + \|x-p\| \\
&\leq \frac{\varepsilon}{1+\varepsilon}\min(r', \operatorname{slow}(y)) + \frac{\varepsilon}{1+\varepsilon}\min(r, \operatorname{slow}(x)) + \rho_x(r). \\
&\leq \frac{\varepsilon}{1+\varepsilon}\min(r', \operatorname{slow}(y)) + \frac{\varepsilon}{1+\varepsilon}\operatorname{slow}(x) + \frac{1+2\varepsilon}{1+\varepsilon}\operatorname{slow}(x) \\
&\leq \frac{\varepsilon}{1+\varepsilon}\min(r', \operatorname{slow}(y)) + \frac{1+3\varepsilon}{1+\varepsilon}\operatorname{slow}(x) \\
&\leq \left(\frac{\varepsilon}{1+\varepsilon} + \frac{1}{1+\varepsilon}\right)\min(r', \operatorname{slow}(y)) \\
&= \min(r', \operatorname{slow}(y)) \leq \rho_y(r').
\end{aligned}$$ ◀

The sparse multicover approximates the multicover:

▶ **Theorem 8.** *Writing $\delta \coloneqq \frac{1+2\varepsilon}{1+\varepsilon} < 1+\varepsilon$, we have*

$$\operatorname{Cov}_{r,k} \subset \operatorname{SCov}_{(1+3\varepsilon)r,k} \textit{ and } \operatorname{SCov}_{r,k} \subset \operatorname{Cov}_{\delta r,k}.$$

Proof. We start with the first inclusion. Let $p \in \mathrm{Cov}_{r,k}$, which implies that there is a subset $S \subset X$ of k points such that $\|a - p\| \leq r$ for all $a \in S$.

Let $S' = \mathcal{C}_{(1+3\varepsilon)r}(S)$ and note that the sum of covering weights $\sum_{x \in S'} c_{(1+3\varepsilon)r}(x)$ is at least k. It is left to show that every sparse ball around points of S' at scale $(1+3\varepsilon)r$ contains p. Consider a point $a \in S$ and write $x \coloneqq \mathcal{C}_{(1+3\varepsilon)r}(a) \in S'$. Note that necessarily $r \leq \mathrm{slow}(x)$, because otherwise the sparse ball of x has disappeared by scale $(1+3\varepsilon)r$. We have

$$\|x - p\| \leq \|x - a\| + \|a - p\| \leq \frac{\varepsilon}{1+\varepsilon} \min((1+3\varepsilon)r, \mathrm{slow}(x)) + r.$$

Now we do a case distinction. If $(1+3\varepsilon)r < \mathrm{slow}(x)$, we have

$$\|x - p\| \leq \frac{\varepsilon}{1+\varepsilon}(1+3\varepsilon)r + r \leq (1+3\varepsilon)r = \rho_x((1+3\varepsilon)r),$$

and otherwise $(1+3\varepsilon)r \geq \mathrm{slow}(x)$, so we have

$$\|x - p\| \leq \frac{\varepsilon}{1+\varepsilon} \mathrm{slow}(x) + r = L_x((1+3\varepsilon)r) \leq \rho_x((1+3\varepsilon)r).$$

We now prove the second inclusion. Let $p \in \mathrm{SCov}_{r,k}(X)$. This means that there exists a subset $S \subset \mathcal{C}_r(X)$ whose sparse balls cover p at radius r with covering weight at least k. Consider $A \coloneqq \mathcal{C}_r^{-1}(S)$. Then, by definition, $|A| \geq k$ and it is left to show that for each $a \in A$ we have $\|a - p\| \leq \delta r$. Indeed, writing $x \coloneqq \mathcal{C}_r(a)$,

$$\|a - p\| \leq \|a - x\| + \|x - p\| \leq \frac{\varepsilon}{1+\varepsilon} \min(r, \mathrm{slow}(x)) + \rho_x(r).$$

We do a case distinction again. If $r \leq \mathrm{slow}(x)$, then

$$\|a - p\| \leq \frac{\varepsilon}{1+\varepsilon} r + r = \frac{1+2\varepsilon}{1+\varepsilon} r.$$

Otherwise, if $r > \mathrm{slow}(x)$,

$$\begin{aligned} \|a - p\| &\leq \frac{\varepsilon}{1+\varepsilon} \mathrm{slow}(x) + U_x(r) \\ &= \frac{\varepsilon}{1+\varepsilon} \mathrm{slow}(x) + \frac{1}{3(1+\varepsilon)} r + \frac{2+3\varepsilon}{3(1+\varepsilon)} \mathrm{slow}(x) \leq \frac{1+2\varepsilon}{1+\varepsilon} r. \end{aligned}$$

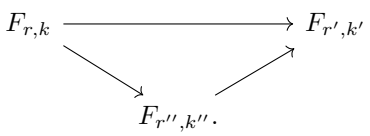
◀

3 An equivalent simplicial bifiltration

We look for a bifiltration of simplicial complexes that is homotopically equivalent, as defined shortly, to the sparse multicover bifiltration. This will be the *sparse subdivision bifiltration*, which is an extension of the subdivision Čech bifiltration of Sheehy [53].

3.1 Homotopically equivalent bifiltrations

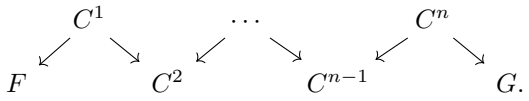
We now recall the fundamental definitions of the homotopy theory of filtrations, where filtrations are viewed as diagrams, as is standard; see, e.g., [7]. Let F be a bifiltration of topological spaces indexed, in our case, by radii $r \in [0, \infty)$ and order $k \in \mathbb{N}$; that is, a collection of topological spaces $F_{r,k}$, one for each $r \geq 0$ and $k \in \mathbb{N}$, together with a continuous map $F_{(r,k)\to(r',k')} \colon F_{r,k} \to F_{r',k'}$ for every $r \leq r'$ and $k \geq k'$, such that $F_{(r,k)\to(r,k)}$ is the identity and the following diagram commutes



A *pointwise weak equivalence* $F \xrightarrow{\cong} G$ between two bifiltrations F and G, is a collection of weak homotopy equivalences $\alpha_{r,k} \colon F_{r,k} \to G_{r,k}$ such that the following diagram commutes for every $r \leq r'$ and $k \geq k'$:

$$\begin{array}{ccc} F_{r,k} & \longrightarrow & F_{r',k'} \\ {\scriptstyle \alpha_{r,k}}\downarrow & & \downarrow{\scriptstyle \alpha_{r',k'}} \\ G_{r,k} & \longrightarrow & G_{r',k'} \,. \end{array}$$

Pointwise weak equivalence is not a equivalence relation, but the following is. Two bifiltrations F and G are *weakly equivalent* if there exists a zigzag of pointwise homotopy equivalences that connect them:



3.2 The sparse subdivision bifiltration

We now define the *sparse subdivision bifiltration* and prove that is weakly equivalent to the multicover bifiltration. As already mentioned, the sparse subdivision bifiltration is an extension of Sheehy's *subdivision Čech bifiltration* [53], which we review first.

Subdivision Čech bifiltration. We start with the following extension of the Čech complex:

▶ **Definition 9.** *For a given scale $r \in [0, \infty)$ and order $k \in \mathbb{N}$, the* k-Čech poset $\check{\mathrm{C}}_{r,k}$ *is*

$$\check{\mathrm{C}}_{r,k} \coloneqq \left\{ \sigma \subset X \mid \bigcap_{x \in \sigma} B(x, r) \neq \varnothing \text{ and } |\sigma| \geq k \right\}$$

with the order given by inclusion.

The 1-Čech poset is (the face poset of) the usual Čech simplicial complex. The collection of the Čech posets $\check{\mathrm{C}}_{r,k}$ assemble into a bifiltration that we call the *multi-Čech bifiltration* $\check{\mathrm{C}}$: for any $r \leq r'$ and $k \geq k'$, we have $\check{\mathrm{C}}_{r,k} \subset \check{\mathrm{C}}_{r',k'}$.

To obtain a bifiltration of simplicial complexes we take the order complex pointwise, as below. By *order complex* $\Delta(P)$ of a poset P we mean the simplicial complex whose set of vertices is P and whose m-simplices are the chains of P of length $m + 1$.

▶ **Definition 10.** *The* subdivision Čech bifiltration Sub *is given by* $\mathrm{Sub}_{r,k} \coloneqq \Delta(\check{\mathrm{C}}_{r,k})$ *with the internal maps being the inclusions.*

The subdivision Čech bifiltration is usually defined directly at the level of the subdivision of the Čech complex [53], rather than through the multi-Čech bifiltration. Now we can state the multicover nerve theorem [7, 14, 53]:

▶ **Theorem 11** (Multicover nerve theorem)**.** *The multicover bifiltration* Cov *is weakly equivalent to the subdivision Čech bifiltration* Sub*.*

Sparsification. We now extend the subdivision Čech bifiltration and the multicover nerve theorem to the sparse multicover bifiltration. As in the definition of the sparse multicover, we replace the balls with sparse balls and the cardinality with the covering weight, resulting in the following definition; to be compared with the definition of k-Čech poset (Definition 9.)

▶ **Definition 12.** *For a given scale $r \in [0,\infty)$ and order $k \in \mathbb{N}$, we define the* sparse Čech poset $\mathrm{S\check{C}}_{r,k}$ *to be*

$$\mathrm{S\check{C}}_{r,k} \coloneqq \bigcup_{s \le r} \left\{ \sigma \subset X \mid \bigcap_{x \in \sigma} \mathrm{SB}(x,s) \neq \varnothing \text{ and } \sum_{x \in \sigma} c_s(x) \ge k \right\}$$

with the order given by inclusion.

In the definition, the union is there to guarantee that the $\mathrm{S\check{C}}_{r,k}$ assemble into a bifiltration, because now sparse balls disappear, unlike before; this is the combinatorial analogue of taking *cones* as in Cavanna, Jahanseir and Sheehy's work [16]. Again taking the order complex:

▶ **Definition 13.** *The* sparse subdivision bifiltration SSub *is given by taking* $\mathrm{SSub}_{r,k} \coloneqq \Delta(\mathrm{S\check{C}}_{r,k})$*, the order complex of the sparse intersection poset* $\mathrm{S\check{C}}_{r,k}$*.*

In other words, the m-simplices of $\mathrm{SSub}_{r,k}$ are sequences $\sigma_0 \subset \cdots \subset \sigma_m$ of $m+1$ subsets of points, all in $\mathrm{S\check{C}}_{r,k}$ and where each containment is strict.

▶ **Theorem 14** (Sparse multicover nerve theorem)**.** *The sparse subdivision bifiltration* SSub *is weakly equivalent to the sparse multicover* SCov*.*

The proof is in the full version. It reduces to the multicover nerve theorem, incorporating the covering weight and using the *cones* strategy of Cavanna, Jahanseir and Sheehy [16].

4 Size

We are now ready to bound the size of the sparse subdivision bifiltration. Specifically, we bound the number of simplices in the largest complex in the bifiltration, and show that each simplex is born at a constant number of *critical grades*. We say that the grade $(r,k) \in [0,\infty) \times \mathbb{N}$ is *critical* for a simplex σ, if $\sigma \in \mathrm{SSub}_{r',k'}$ for all $r < r'$ and $k \ge k'$, but $\sigma \notin \mathrm{SSub}_{s,l}$ for any $s < r$ and $l > k$.

4.1 Number of simplices

The rest of this section is dedicated to proving the following theorem. We write SSub to refer both to the bifiltration and to the largest complex in the bifiltration, $\mathrm{SSub} = \bigcup_{r,k} \mathrm{SSub}_{r,k}$, when no confusion is possible.

▶ **Theorem 15.** *The bifiltration* SSub *has $O(|X|)$ simplices for fixed ε and dimension d.*

The following argument is analogous to the one used in previous sparse filtrations [16, 54]. Consider the map $\min\colon \mathrm{SSub} \to X$ that takes each simplex $\sigma = \sigma_0 \subset \cdots \subset \sigma_m$ to the minimum point x in σ_m with respect to the order given by their insertion radius $\mathrm{ins}(x)$, breaking ties arbitrarily. The points in each preimage of this map $\min\colon \mathrm{SSub} \to X$ are not too far from each other:

▶ **Lemma 16.** *Let $\sigma = \sigma_0 \subset \cdots \subset \sigma_m \in \mathrm{SSub}$ be a simplex and let $x \coloneqq \min(\sigma)$. The points σ_m are contained in a ball of radius $2(1+3\varepsilon)\,\mathrm{slow}(x)$ around x.*

Proof. Since the sparse ball around x is empty at scales greater than $\alpha \coloneqq (1+3\varepsilon)\,\mathrm{slow}(x)$, any intersection between the sparse balls of σ_m must happen at a scale $r \le \alpha$. Let p be any point in this intersection. It follows that for any other $y \in \sigma_m$ we have $\|x-y\| \le \|x-p\| + \|p-y\| \le 2\alpha$. ◀

▶ **Lemma 17.** *For each $x \in X$, the number of simplices mapped to x under* min *is $O(1)$, for fixed ε and dimension d.*

Proof. Let $A \coloneqq \bigcup_{\sigma_0 \subset \cdots \subset \sigma_m \in \min^{-1}(x)} \sigma_m$ be the set of all points in simplices σ such that $\min \sigma = x$. It suffices to show that A has $O(1)$ points, for fixed ε and d. Let $\alpha \coloneqq (1+3\varepsilon)\operatorname{slow}(x)$. We claim that $A \subset \mathcal{C}_\alpha(X)$. Indeed, for every $a \in A$ we have $\operatorname{ins}(a) \geq \operatorname{ins}(x)$, by the definition of min, and thus the sparse ball of a is non-empty at scale α.

By Lemma 16, the points in A are contained in a ball of radius 2α, and, by Lemma 5, they are $\frac{\varepsilon}{(1+\varepsilon)(1+3\varepsilon)}\alpha$-packed, because $A \subset \mathcal{C}_\alpha(X)$ as shown. By comparing the volume of balls of radius 2α and $\frac{\varepsilon}{(1+\varepsilon)(1+3\varepsilon)}\alpha$, we conclude that A consists of $O\left(\left(\frac{(1+\varepsilon)(1+3\varepsilon)}{\varepsilon}\right)^d\right)$ points. ◀

All in all, there can be at most $O(|X|)$ simplices, since at most a constant number, for a fixed ε and d, of simplices is mapped to each point, finishing the proof of the theorem.

4.2 Critical grades

The sparse subdivision bifiltration, unlike the subdivision Čech bifiltration, is *multicritical*, which means that each simplex may have multiple critical grades. Let us briefly describe the critical grades of a simplex $\sigma = \sigma_0 \subset \cdots \subset \sigma_m \in \mathrm{SSub}$. Ordering the critical grades by scale r, the first critical grade has scale r equal to the first scale at which the sparse balls around the points σ_m intersect, and order k equal to the sum of the covering weights of the points of σ_0 at such an scale. Further critical grades of σ correspond to scales r' at which the covering weight of the points of σ_0 increase, until one of the associated sparse balls disappears. Still, there are not many critical grades, as another packing argument shows:

▶ **Theorem 18.** *Each simplex in* SSub *has $O(1)$ critical grades, for fixed d and ε.*

Proof. Let $\sigma = \sigma_0 \subset \cdots \subset \sigma_m \in \mathrm{SSub}$ and let $x \coloneqq \min \sigma$. The simplex σ has no critical grade with scale greater than $\alpha \coloneqq (1+3\varepsilon)\operatorname{slow}(x)$, because the sparse ball of x disappears then. Thus, we bound the number of scales $s \leq \alpha$ at which the sum of covering weights $\sum_{x \in \sigma_0} c_s(x)$ of the points of σ_0 increases, which bounds the number of critical grades of σ.

By the proof of the Lemma 17, the points in σ_0 are a 2β-packing, where $\beta \coloneqq \frac{\varepsilon}{2(1+\varepsilon)(1+3\varepsilon)}\alpha$. Thus, any intersection between balls around points in σ_0 must happen at scales at least β, and thus we are interested in the range of scales $[\beta, \alpha]$.

Let $A \subset X$ be the subset of points $a \in X \setminus \sigma_0$ whose sparse ball disappears in the interval $[\beta, \alpha)$, meaning $(1+3\varepsilon)\operatorname{slow}(a) \in [\beta, \alpha)$ and, as a result, the covering weight of a point in σ_0 increases, meaning there is a point $y \in X$ such that a and a point $w \in \sigma_0$ are one after the other in the covering sequence of y, that is, $y_i = a$ and $y_{i+1} = w$. To finish the argument, it suffices to show that $|A| = O(1)$. First, note that $A \subset \mathcal{C}_\beta(X)$. It follows that the points in A are $\frac{\varepsilon}{(1+\varepsilon)(1+3\varepsilon)}\beta$-packed, by Lemma 5.

Let $a \in A$, and let $y \in X$ and $w \in \sigma_0$ as in the definition of A. By Lemma 5 and Lemma 16,

$$\begin{aligned}\|x - a\| &\leq \|x - w\| + \|w - y\| + \|y - a\| \\ &\leq 2\alpha + (1+3\varepsilon)\operatorname{slow}(a) + \frac{\varepsilon}{1+\varepsilon}\operatorname{slow}(a) \leq 4\alpha.\end{aligned}$$

All in all, the points of A are contained in a ball of radius 4α and are all $\frac{\varepsilon}{(1+\varepsilon)(1+3\varepsilon)}\beta = \frac{\varepsilon^2}{2(1+\varepsilon)^2(1+3\varepsilon)^2}\alpha$ apart. The result follows by comparing the volume of disjoint balls around points in A and the volume of a ball of radius 4α. ◀

5 Computation

We show how to compute the sparse subdivision bifiltration. The first step is computing a persistent net and the covering map. As already mentioned in Section 2.1 this reduces to computing a *greedy permutation*. The next step is to compute all potential simplices that appear in the bifiltration, as those consisting of points around balls like those of Lemma 16; for which we use a suitable proximity data structure. Finally, to obtain the critical grades of the simplices we can use the covering map and the minimum scale at which a subset of the sparse balls intersect. The problem of computing this minimum scale, in the Euclidean case, can be written as a LP-type problem [45], and we show how to solve it, much like computing the smallest enclosing ball of balls [35]. All these steps can be done in $O(|X| \log \Delta)$ time, where Δ is the *spread* of X, the ratio between the longest and shortest distances in X.

5.1 Greedy permutations

Let $(x_1, \dots, x_n)$ be an ordering of the n points in X. Such a sequence is called *greedy* if for every x_{i+1} and prefix $X_i \coloneqq \{x_1, \dots, x_i\}$, one has

$$d(x_{i+1}, X_i) = \max_{x \in X} d(x, X_i),$$

where $d(x, X_i) = \min_{x_j \in X_i} \|x - x_j\|$. The distance $r_{i+1} \coloneqq d(x_{i+1}, X_i)$ is the *insertion radius* r_{i+1} of x_{i+1}, where we take $r_1 = \infty$ by convention. A greedy permutation gives a persistent net $\mathcal{S}$ by taking $\mathcal{S}_r \coloneqq \{x_i \mid r \leq r_i\}$.

Gonzalez [37] gives a method to compute a greedy permutation. It consists of n phases, divided in an initialization phase and $|X| - 1$ update phases. At the end of phase i, it maintains a subset $S_i = \{x_1, \dots, x_i\} \subset X$ and for each $x_j \in S_i$ its *Voronoi set*: the subset of points in X that are closer to x_j than to any other point in S_i. We break ties arbitrarily but consistently (say, by minimum index in S_i), so that the Voronoi sets form a partition of X. In the initialization phase we pick a random point x_1 and we set its Voronoi set to be every other point. In the update phase i, we obtain the new set of leaders S_i by adding to S_{i-1} the point x_i whose distance to S_{i-1} is maximal, and updating the Voronoi sets. This algorithm can be implemented in $O(|X|^2)$-time by going over the whole set of points during each phase. An algorithm of Clarkson [23, 24], which also maintains the Voronoi sets, can be shown to take $O(|X| \log \Delta)$-time [40], and has been implemented [24, 51].

As mentioned, at every phase of the algorithm, each point $x \in X$ is assigned a Voronoi set of a point $x_j \in S_i$: its nearest neighbor among those in S_i. We call the sequence of such points x_j, as the algorithm progresses, the *sequence of leaders* of a point x. Such a sequence necessarily starts with x_1 and ends with the point itself.

From the sequence of leaders we can obtain the covering map. The covering sequence of a point is a subsequence of its sequence of leaders, in reverse order. To see this, note that the covering sequence of x starts with x itself, as in the reversed sequence of leaders. Then, when the sparse ball of x disappears the next point in its covering sequence is its nearest neighbor among those points with non-slowed sparse ball. This set of points with non-slowed sparse ball is necessarily equal to one of the subsets S_i we have encountered through the execution of the algorithm. In addition, balls are slowed in the same order as the reversed sequence of leaders. All in all, we conclude the following:

▶ **Lemma 19.** *A persistent net, the insertion radius of all the points, and the covering map can be computed in time $O(|X| \log \Delta)$.*

5.2 Neighborhoods

We also need to find those subsets of points whose sparse balls have a non-empty intersection, at any scale. By Lemma 16, any such subset A is contained in a ball of radius $2(1+3\varepsilon)\operatorname{slow}(x)$ around x, where x is the point of minimal insertion point in A. Making use of this observation, and following [12], given a point $x \in X$, we call the points of higher insertion radius than the one of x and within distance $2(1+3\varepsilon)\operatorname{slow}(x)$ its *friends*. Note that the number of friends of a point is $O(1)$, because we are only considering points of higher insertion radius, as in Lemma 17. Once we have computed the friends of x, we can go over every possible subset and check whether the associated sparse balls intersect at some scale, which is done in the following section. This procedure is similar to other sparsification schemes [12, 16].

To compute the friends of every point, we can use a proximity search data structure as follows. First, we initialize it empty. In decreasing order of insertion radius (that is, the order given by the greedy permutation), we add the points one by one. After adding a point x, we query all the points within $2(1+3\varepsilon)\operatorname{slow}(x)$ distance from x.

Cavanna, Jahanseir and Sheehy [16] gives such a data structure to compute all friends in such a way in time $O(|X|)$, again for fixed ε and d. In practice one can also use the related greedy trees [22], which have been implemented [51].

▶ **Lemma 20.** *Computing the friends of all points can be done in $O(|X|)$ time.*

5.3 Intersection of sparse balls

We now show how to compute the scale at which a subset of sparse balls first intersect, if they do so. We do it only for the Euclidean case; the l^∞-norm, which is also of interest, is an easier case, since it is enough to compute the intersection times pairwise. We show that this problem is of LP-type [45] and can be solved efficiently following the blueprint of the LP-algorithm for computing the smallest enclosing ball of balls [35], which is efficient in practice and implemented in CGAL [36].

A specific radius function. Let us choose a specific radius function first, with the added restriction that $0 < \varepsilon \leq 1$. For a point $x \in X$, we take

$$\rho_x(r) = \begin{cases} r & r \leq \operatorname{slow}(x), \\ \sqrt{K_\varepsilon r^2 + (1-K_\varepsilon)\operatorname{slow}(x)^2} & \operatorname{slow}(x) \leq r, \end{cases} \tag{1}$$

where, $K_\varepsilon = \frac{1}{3(1+\varepsilon)^2}$. See Figure 3. It can be checked that $\rho_x(r)$ is indeed a radius function.

Solving a problem. Equipped with the radius function above and given a subset of points $A \subset X$, we consider the problem

$$\begin{aligned} \min_{z\in\mathbb{R}^d, r\geq 0} \quad & r^2, & \\ \text{subject to} \quad & \|a-z\|^2 \leq r^2, & a \in A, \\ & \|a-z\|^2 \leq K_\varepsilon r^2 + (1-K_\varepsilon)\operatorname{slow}(x)^2, & a \in A. \end{aligned} \tag{2}$$

Now it is apparent why we chose the specific radius function of Equation (1): the right side of the inequalities above is linear on r^2. We claim that the solution of this problem gives the minimum scale at which the sparse balls of A have non-empty intersection, if such a scale exists. Let $z_{\text{opt}} \in \mathbb{R}^d$ and $r_{\text{opt}} \geq 0$ be the solution of the problem above (a

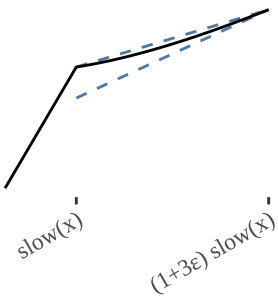


Figure 3 Graph of $\rho_x(r)$ of (1), for some values $\text{slow}(x)$ and $0 < \varepsilon < 1$. The dashed lines are the functions $L_x(r)$ and $U_x(r)$, as in Definition 1.

unique solution always exists, see the full version). One can check that r_{opt} is the minimum scale at which the balls $B(a, \rho_a(r))$ around points $a \in X$ first intersect, by noting that $r^2 \leq K_\varepsilon r^2 + (1 - K_\varepsilon)\,\text{slow}(x)^2$ whenever $r \leq \text{slow}(x)$. Thus, r_{opt} is the minimum scale at which the sparse balls of A intersect, unless a sparse ball disappears before then, that is, unless $r_{\text{opt}} > (1 + 3\varepsilon)\,\text{slow}(a)$ for any $a \in A$.

We solve the problem of Equation (2) via a more general problem. Given a set H of m constraints, each being a triple consisting of a point $p_i \in \mathbb{R}^d$, a positive real constant $\alpha_i \in \mathbb{R}$ and a non-negative real constant $\beta_i \in \mathbb{R}$, we look for

$$\begin{aligned} &\min_{z \in \mathbb{R}^d, s \geq 0} \quad s, \\ &\text{subject to} \quad \|p_i - z\|^2 \leq \alpha_i s + \beta_i, \quad i = 1, \ldots, m. \end{aligned} \tag{M}$$

The problem of Equation (2) is an instance of (M) with $2|A|$ constraints.

Note that by taking a set of points $p_1, \ldots, p_m$ and setting $\alpha_i = 1$ and $\beta_i = 0$, the solution to (M) above is the smallest enclosing ball of the points (with radius $\sqrt{s}$). As already hinted, the smallest enclosing ball can be computed as a LP-type problem [45]. In the full version, we show how to solve (M) as a LP-type problem following the strategy of the smallest enclosing ball of balls [35, 58].

6 Discussion

We have introduced a $(1 + \varepsilon)$-approximation of the multicover that is of linear size, which is optimal, for fixed dimension d and error ε. As it is usual in sparsification and similar approximations, such a bound on the size (and computation) hides constants that have an exponential dependency on d. The computation time is dominated by the computation of the greedy permutation, which is $O(|X| \log \Delta)$, where Δ is the spread. We remark that one can compute a $(1 + \frac{1}{\text{poly}(|X|)})$-approximate greedy permutation in $O(|X| \log |X|)$ time [21, 40].

Although so far we have focused on the multicover (and subdivision) bifiltration in $\mathbb{R}^d$, the sparsification scheme works in general metric spaces, where one takes the subdivision Rips bifiltration. Indeed, and as expanded upon in the full version, the construction presented here, for the same reasons as the construction of Cavanna, Jahanseir and Sheehy [16] that inspired it, does not depend on the chosen norm, and the size bounds can be seen to extend to spaces with bounded doubling dimension. Thus, we can isometrically embed any finite metric space X into $(\mathbb{R}^{|X|}, l^\infty)$, where the Rips complex is equal to the Čech complex, and take the sparse multicover there.

Single-Source Shortest Path Problem in Weighted Disk Graphs

Shinwoo An

Jie Xue
New York University Shanghai, China

Abstract

In this paper, we present efficient algorithms for the single-source shortest path problem in weighted disk graphs. A disk graph is the intersection graph of a family of disks in the plane. Here, the weight of an edge is defined as the Euclidean distance between the centers of the disks corresponding to the endpoints of the edge. Given a family of n disks in the plane whose radii lie in $[1, \Psi]$ and a source disk, we can compute a shortest path tree from a source vertex in the weighted disk graph in $O(n \log^2 n \log \Psi)$ time. Moreover, in the case that the radii of disks are arbitrarily large, we can compute a shortest path tree from a source vertex in the weighted disk graph in $O(n \log^4 n)$ time. This improves the best-known algorithm running in $O(n \log^6 n)$ time presented in ESA'23.

1 Introduction

Geometric intersection graphs are a fundamental class of graphs representing spatial relationships among geometric objects. In this paper, we focus on the intersection graph of disks in the plane. More formally, for a set P of n points in the plane, where each point $v \in P$ has an associated radius r_v, the *disk graph* G of P is defined as the graph where each vertex corresponds to a point P, and two vertices u and v of P are connected by an edge if and only if the disks with center u, v and radii r_u, r_v intersect. For an *edge-weighted* disk graph, the weight of an edge uv is defined as $|uv|$. In the special case that all radii are the same, the disk graph is also called a *unit disk graph*. Disk graphs can be used as a model for broadcast networks: The disks of P represent transmitter-receiver stations with transmission power. One can view a broadcast range of a transmitter as a disk.

In this paper, we consider the *single-source shortest path* (SSSP) problem for edge-weighted disk graphs: Given a set P of points associated with radii and a specified point $s \in P$, compute a shortest path tree of the edge-weighted disk graph of P rooted at s. One straightforward way to deal with a disk graph is to construct the disk graph explicitly, and then run algorithms designed for general graphs. However, a disk graph might have complexity $\Theta(n^2)$ in the worst case even though it can be (implicitly) represented as n disks.

Therefore, it is natural to seek faster algorithms for a disk graph implicitly represented as its underlying set of disks. Besides the SSSP problem, many graph-theoretic problems have much more efficient solutions in disk graphs than in general graphs [1, 2, 4, 7, 10, 13, 15, 17].

Related work. As the single-source shortest path problem is fundamental in computer science, there are numerous work on this problem and its variant for unit disk graphs [5, 6, 8, 9, 11, 14, 16, 20]. In the case of unweighted unit disk graphs where all edge weights are one, the SSSP problem can be solved in $O(n \log n)$ time, and this is optimal [6, 8]. For edge-weighted unit disk graphs, the best known exact algorithm for the SSSP problem takes $O(n\frac{\log^2 n}{\log\log n})$ time [5], and the best known $(1+\varepsilon)$-approximation algorithm takes $O(n \log n + n \log^2(\frac{1}{\varepsilon}))$ time [20]. For general disk graphs, the best known exact algorithms for the unweighted and weighted SSSP problem takes $O(n \log^2 n)$ and $O(n \log^6 n)$ time, respectively [13, 15].

Another variant of the problem is the reverse shortest path problem, where the input is an edge-weighted graph G, a start vertex, a target vertex, and a threshold value. The problem is to find a minimum value r such that the length of the shortest path from the start vertex to the target vertex in G_r is at most the threshold. Here, G_r is the subgraph of G consisting of edges whose weights are at most r. The problem was considered in various metrics in the weighted and unweighted cases. The best-known algorithms for both weighted and unweighted unit disk graph metric take $O^*(n^{6/5})$ randomized time [13, 21]. In addition, the best-known algorithm for weighted disk graph metric takes $O^*(n^{5/4})$ randomized time [13].

Our results. In this paper, we present two algorithms for the SSSP problem for edge-weighted disk graphs with n vertices. The first algorithm runs in $O(n \log^2 n \log \Psi)$ time, where Ψ is the maximum radius ratio of P. The second algorithm runs in $O(n \log^4 n)$ time. This improves the best-known algorithm for this problem running in $O(n \log^6 n)$ time [13].

Model of computation. In Section 3, our algorithm uses a compressed quadtree. To implement this efficiently, we need to extend the real RAM model [18] by an *floor function* that rounds a real number down to the next integer [12]. While the floor function is generally considered too powerful, it is widely regarded as reasonable for tasks such as finding the cell of a given level of the grid that contains a given point in constant time [12]. On the other hand, our algorithm in Section 2 operates within the standard real RAM model.

Preliminaries. Throughout this paper, we let P be a set of n points in the plane, where each point $v \in P$ has an associated radius r_v, and G be the edge-weighted disk graph of P. We interchangeably denote $v \in P$ as a point or as a vertex of G if it is clear from the context. Also, we let s be a source vertex of P. We assume that $1 \leq r_v$ for all $v \in P$, and thus in the case of *bounded radius ratio*, all radii must come from the range $[1, \Psi]$ for a constant Ψ. The *length* of a path of G is defined as the sum of the weights of the edges contained in the path. The *distance* between u and v is defined as the minimum length among all u-v paths of G. For a vertex $v \in G$, we simply let $d(v)$ denote the distance between s and v.

2 SSSP on Disk Graphs of Bounded Radius Ratio Ψ

In this section, we describe our algorithm for the SSSP problem on disk graphs. Given a set P of n points with associated radii in $[1, \Psi]$, our goal is to compute a shortest path tree from a specified source vertex s in the edge-weighted disk graph G of P in $O(n \log^2 n \log \Psi)$ time. More precisely, our goal is to compute $\mathrm{dist}(v)$ and $\mathrm{prev}(v)$ for all vertices $v \in P$ such that $\mathrm{dist}(v) = d(v)$, and $\mathrm{prev}(v)$ is the predecessor of t in the shortest s-t path.

2.1 Sketch of Our Algorithm

We review the well-known Dijkstra's algorithm that computes a shortest path tree from a source vertex. Initially, the algorithm sets all dist-values to infinity except a source vertex, and sets $Q = P$. The algorithm sequentially applies the following steps until Q is empty.

- **(D1)** Pick the vertex u with smallest dist-value.
- **(D2)** For all neighbors $v \in Q$ of u, update $\mathrm{dist}(v) \leftarrow \min\{\mathrm{dist}(v), \mathrm{dist}(u) + |uv|\}$.
- **(D3)** Remove u from Q.

In the worst case, Dijkstra's algorithm takes quadratic time since a disk graph can have $\Theta(n^2)$ edges. In our algorithm, we simultaneously update the dist-values of several vertices by the UPDATE subroutine that was introduced in [20]. For any two vertex set U and V of G, UPDATE(U, V) does the following: For all $v \in V$,

- **(U1)** Compute $u := \arg\min\{\mathrm{dist}(u) + |uv|\}$ among all $u \in U$ s.t. uv is an edge of G.
- **(U2)** Update $\mathrm{dist}(v) \leftarrow \min\{\mathrm{dist}(v), \mathrm{dist}(u) + |uv|\}$.

That is, the subroutine updates the dist-values of all vertices of V using the dist-values of the vertices of U. The subroutine gets input U and V from a *hierarchical grid*. For each integer $0 \le i \le \lceil \log \Psi \rceil$, we use Γ_i to denote a *grid* of level i, which consists of axis-parallel square cells of diameter 2^i. Then we use Γ to denote the union of grid cells of Γ_i's. For a grid cell $c \in \Gamma$, we use $p(c)$ to denote the center of c, use $|c|$ to denote the diameter of c, and use $\square_c$ to denote the axis-parallel square of diameter $69|c|$ centered at $p(c)$. We use $\boxplus_c$ to denote the set of grid cells of Γ_{i-1}, Γ_i and Γ_{i+1} which are contained in $\square_c$. We say $c' \in \Gamma_{i-1}$ a *child cell* of c if c' is nested in c. Throughout the paper, we assume that no points of P lie on the boundary of any grid cell. We define two sets of vertices contained in c as follows.

$$P_{\mathrm{mid}}(c) := \{v \in P \mid v \in c, r_v \in [8|c|, 16|c|)\};\ P_{\mathrm{small}}(c) := \{v \in P \mid v \in c, r_v \in [1, 8|c|)\}.$$

Intuitively, $P_{\mathrm{mid}}(c)$ consists of vertices contained in c with radii *similar* to $|c|$ while $P_{\mathrm{small}}(c)$ consists of vertices with radii *smaller* than that of $P_{\mathrm{mid}}(c)$. Note that $P_{\mathrm{mid}}(c)$ forms a clique in G. For a vertex v in P, we let c_v be the (unique) cell such that $P_{\mathrm{mid}}(c_v)$ contains v.

Regular edge and Irregular edge. Let uv be an edge of G with $r_u \le r_v$. We call uv a *regular edge* if $\frac{r_v}{r_u} < 2$, and an *irregular edge* if $\frac{r_v}{r_u} \ge 2$. We can identify all edges of G efficiently by using $\boxplus_c$, $P_{\mathrm{mid}}(c)$ and $P_{\mathrm{small}}(c)$.

▶ **Lemma 1.** *Let uv be a regular edge. Then $c_u \in \boxplus_{c_v}$. Symmetrically, $c_v \in \boxplus_{c_u}$.*

▶ **Lemma 2.** *Let uv be an edge and $2r_u \le r_v$. There is a cell $c \in \boxplus_{c_v}$ such that $u \in P_{\mathrm{small}}(c)$.*

Basic strategy of [20]. We utilize the strategic adaptation of Dijkstra's algorithm in a cell-by-cell manner with $P_{\mathrm{small}}(\cdot)$ and $P_{\mathrm{mid}}(\cdot)$. This strategy was used in [20] to design an efficient algorithm for the weighted SSSP problem on unit disk graphs. For concreteness, we describe the details of the strategy below. Let v be the vertex with the smallest dist-value among all vertices not processed so far. As an invariant, we shall guarantee that all vertices of G which have been processed have correct dist-values, and v has a correct dist-value if its predecessor in the shortest s-v path has been processed. We want to process not only v but also all vertices in $P_{\mathrm{mid}}(c_v)$ simultaneously. However, notice that, at this moment, the vertices in $P_{\mathrm{mid}}(c_v)$ do not necessarily have correct dist-values.

Thus, as a first step, we compute the correct dist-values for all vertices in $P_{\mathrm{mid}}(c_v)$. If the predecessor w of a vertex $v' \in P_{\mathrm{mid}}(c_v)$ in the shortest s-v' path already has the correct dist-value, we can simply update the dist-values of $P_{\mathrm{mid}}(c_v)$ by considering all edges whose one endpoint is in $P_{\mathrm{mid}}(c_v)$. However, it is possible that w has not been processed yet so far and does not have the correct dist-value. Fortunately, even in this case, we can show that w has a correct dist-value. To see this, let u be the predecessor of w in the shortest s-w path. Then uv' cannot be an edge of the graph since otherwise u is the predecessor of v' in the shortest s-v' path. Therefore, $|uv'| > r_{v'}$. As $v, v' \in P_{\mathrm{mid}}(c_v)$, $|uv'| > r_{v'} > |vv'|$. Hence, $d(u) = d(v') - (|v'w| + |wu|) \leq d(v') - |v'u| < d(v') - |vv'| \leq d(v)$. The last inequality follows since the concatenation of vv' and the shortest s-v path is longer than the shortest s-v' path. Now u must have been processed since v is the vertex with the smallest dist-value among all vertices not processed so far. Due to the invariant, w must have the correct dist-value. Consequently, we can update the dist-values of all vertices of $P_{\mathrm{mid}}(c_v)$ by applying $\textsc{Update}(N(c_v), P_{\mathrm{mid}}(c_v))$ where $N(c_v)$ denotes the set of neighbors of $P_{\mathrm{mid}}(c_v)$ in G.

The second step is to transmit the correct dist-values of $P_{\mathrm{mid}}(c_v)$ into their neighbors in order to satisfy the second invariant. Lastly, we remove $P_{\mathrm{mid}}(c_v)$ from the graph.

Main obstacles and lazy update scheme. The complexity of this strategy primarily depends on the cost of searching all neighbors of $P_{\mathrm{mid}}(c_v)$. This was not a big deal in [20], as in a unit disk graph, each cell interacts with only a constant number of other cells. In the case of disk graphs, however, a vertex with radius $\Theta(\Psi)$ can be adjacent to vertices in $P_{\mathrm{mid}}(c)$ for $O(\Psi^2)$ distinct grid cells c. To avoid polynomial dependency on Ψ, we handle regular edges and irregular edges separately. More specifically, we can search all regular edges by considering $P_{\mathrm{mid}}(c)$ for all $c \in \boxplus_{c_v}$ by Lemma 1. Since $\boxplus_{c_v}$ consists of $O(1)$ cells, we can avoid the polynomial dependency on Ψ through the appropriate use of the Update subroutine.

However, the same approach cannot be used to search all irregular edges as up to $\Theta(\Psi^2)$ sets of $P_{\mathrm{mid}}(\cdot)$ may interact with $P_{\mathrm{mid}}(c_v)$ in the worst case. We address this issue with a novel approach, which we call *lazy update scheme*. We say w is a *small neighbor* of a vertex u if uw is an irregular edge and $r_u > r_w$. Furthermore, we say w is a *small neighbor* of a cell c if there is a vertex $u \in P_{\mathrm{mid}}(c)$ forming an irregular edge with w and $r_u > r_w$. In the basic strategy, we transmit the correct dist-value of v to *all* neighbors whenever we process v. In the lazy update scheme, we postpone the transmission to $P_{\mathrm{mid}}(c)$ for all cells c such that v is a *small* neighbor of c. We handle several postponed update requests at once at some point. More specifically, let V_x be the set of small neighbors of c whose dist-values are in the range $[x, x + 2|c|]$. We transmit the dist-values of V_x into $P_{\mathrm{mid}}(c)$ right after all vertices of V_x have been processed. Due to the following lemma, we can bound the number of lazy updates into $O(1)$ for each cell c, and this enables us to avoid the polynomial dependency on Ψ.

▶ **Lemma 3.** *Let u and u' be small neighbors of c. Then $|d(u) - d(u')| \leq 65|c|$.*

However, this may cause an *inconsistency issue* during the first step. When we process the vertices of $P_{\mathrm{mid}}(c_v)$, now the first update does not transmit the dist-values of the small neighbors of c_v. If a predecessor w of $v' \in P_{\mathrm{mid}}(c_v)$ in the shortest s-v' path is a small neighbor of v', it is possible that the lazy update has not occurred even though w has already been processed. We show that this cannot happen using the following geometric lemma.

▶ **Lemma 4.** *Let $u \neq s$ be the predecessor of v in the shortest s-v path. Then $|uv| \geq |r_v - r_u|$ unless $r_v < r_u$ and v is a leaf in the shortest path tree.*

By this lemma, $d(w) + 2|c_{v'}| < d(w) + \frac{1}{4}r_{v'} < d(w) + |r_w - r_{v'}| < d(w) + |wv'| = d(v')$. Subsequently, roughly speaking, the lazy update that transmits dist-values of w into v' occurs in advance when we process the vertices of $P_{\mathrm{mid}}(c_{v'})$.

2.2 Algorithm

We present our algorithm for the SSSP problem on disk graphs with radius ratio Ψ. The goal is to compute $d(v)$ for all $v \in P$. Initially, we set $\mathrm{dist}(v)$, the *dist-value* of v, as infinity for all vertices other than a source vertex s, and set $\mathrm{dist}(s) = 0$. Eventually, the algorithm will modify $\mathrm{dist}(v)$ into $d(v)$ for all $v \in P$. In addition, for each nonempty $P_{\mathrm{mid}}(c)$ for $c \in \Gamma$, we maintain a value $\mathrm{alarm}(c)$ initialized to ∞. These alarm values will take care of the moment of the lazy update. We set R by the set of points of P that has not been processed yet.

Pre-processing. We compute $d(v)$ for all $v \in P$ adjacent to s in G and set $\mathrm{dist}(v)$ to $|sv|$. Furthermore, for each grid cell c, let $\bar{L}(c)$ be the set of grid cells c' where $P_{\mathrm{mid}}(c)$ contains a small neighbor of c'. For technical reasons, we compute a superset $L(c)$ of $\bar{L}(c)$ which contains all cells c' with $|c| < |c'|$ such that there is an edge between a vertex of $P_{\mathrm{mid}}(c)$ and a vertex of $P_{\mathrm{mid}}(c')$. Furthermore, we set $L(c_s)$ as an empty set where c_s is the grid cell such that the source s is contained in $P_{\mathrm{mid}}(c_s)$. We will use the information of $L(c)$ to deal with the lazy update. Then the algorithm consists of several rounds. In each round, we check $\mathrm{dist}(v)$ for all $v \in R$ and $\mathrm{alarm}(c)$ for all $c \in \Gamma$. Subsequently, we find the minimum value k among these values, and proceed depending on the type of k. The algorithm terminates when R becomes empty. We utilize $\textsc{Update}(U, V)$ subroutine for both cases.

Algorithm 1 $\textsc{Update}(U, V)$.

1. **for** $v \in V, u \in U$ **do**
2. **if** uv is an edge of G **then**
3. **if** $\mathrm{dist}(v) > \mathrm{dist}(u) + |uv|$ **then**
4. $\mathrm{dist}(v) \leftarrow \mathrm{dist}(u) + |uv|$; $\mathrm{prev}(v) \leftarrow u$

Intuitively, if $u \in U$ has correct dist-values and u is the predecessor of $v \in V$ in the shortest s-t path, then all such v gets the correct dist-values after the subroutine $\textsc{Update}(U, V)$. The rest of this section is devoted to giving detailed instructions on case studies of k.

Algorithm 2 $\mathrm{SSSP}(P)$.

1. $R \leftarrow P$
2. **while** $R \neq \emptyset$ **do**
3. $k \leftarrow \min(\{\mathrm{dist}(v) : v \in R\} \cup \{\mathrm{alarm}(c) : c \in \Gamma\})$
4. **if** $k = \mathrm{dist}(v)$ for $v \in R$ **then**
5. $\textsc{Update}(\bigcup_{c \in \boxplus_{c_v}} P_{\mathrm{mid}}(c), P_{\mathrm{mid}}(c_v))$
6. $\textsc{Update}(P_{\mathrm{mid}}(c_v), \bigcup_{c \in \boxplus_{c_v}} P_{\mathrm{mid}}(c) \cup P_{\mathrm{small}}(c))$
7. **for** $c \in L(c_v)$ **do**
8. **if** $\mathrm{alarm}(c) = \infty$ **then**
9. $\mathrm{alarm}(c) \leftarrow \mathrm{dist}(v) + 2|c|$
10. $R \leftarrow R \setminus P_{\mathrm{mid}}(c_v)$
11. **if** $k = \mathrm{alarm}(c)$ for $c \in \Gamma$ **then**
12. $\textsc{Update}(\bigcup_{c' \in \boxplus_c} P_{\mathrm{small}}(c'), P_{\mathrm{mid}}(c))$
13. $\mathrm{alarm}(c) \leftarrow \infty$

Case 1: $k = \mathrm{dist}(v)$ for a vertex $v \in R$. In this case, we first apply the subroutine $\textsc{Update}(\bigcup_{c \in \boxplus_{c_v}} P_{\mathrm{mid}}(c), P_{\mathrm{mid}}(c_v))$. Interestingly, we will see later that after this, all vertices in $P_{\mathrm{mid}}(c_v)$ have the correct dist-values. Then using the correct dist-values of $P_{\mathrm{mid}}(c_v)$, we update the dist-values of the neighbors of the vertices in $P_{\mathrm{mid}}(c_v)$. This is done by applying $\textsc{Update}(P_{\mathrm{mid}}(c_v), \bigcup_{c \in \boxplus_{c_v}} P_{\mathrm{mid}}(c) \cup P_{\mathrm{small}}(c))$ and setting $\mathrm{alarm}(c) = \mathrm{dist}(v) + 2|c|$ for all $c \in L(c_v)$ with $\mathrm{alarm}(c) = \infty$, where the former takes care of the neighbors of the vertices in $P_{\mathrm{mid}}(c_v)$ connected by regular edges and the small neighbors of c_v, and the latter takes care of the other neighbors. Finally, we remove $P_{\mathrm{mid}}(c_v)$ from R.

Case 2: $k = \mathrm{alarm}(c)$ for a grid cell $c \in \Gamma$. In this case, we shall correct the dist-values of all $v \in P_{\mathrm{mid}}(c)$ such that the predecessor of v is a small neighbor of v. This is done by applying $\textsc{Update}(\bigcup_{c' \in \boxplus_c} P_{\mathrm{small}}(c'), P_{\mathrm{mid}}(c))$. After this, we reset $\mathrm{alarm}(c)$ to ∞.

2.3 Correctness

In this section, we show that the algorithm correctly computes a shortest path tree. For a vertex v, we use $\mathrm{prev}(v)$ to denote the predecessor of v in the shortest path tree. We shall maintain a simple invariant during the algorithm: $d(v) \leq \mathrm{dist}(v)$ for every $v \in P$. The following lemma is the simple corollary of Lemma 4.

▶ **Corollary 5.** *Suppose the shortest s-v path contains an irregular edge uv and $u \neq s$. Then $|uv| \geq \frac{1}{2} r_v$ unless $r_u > r_v$ and v is a leaf on the shortest path tree.*

Then we prove the key invariant of our algorithm.

▶ **Lemma 6.** *The following statements hold during the execution of Algorithm 2.*
(1) *At the onset of line 5,* $\mathrm{dist}(v) = d(v)$.
(2) *After line 5,* $\mathrm{dist}(u) = d(u)$ *if* $u \in P_{\mathrm{mid}}(c_v)$ *is not a leaf on the shortest path tree.*
(3) *After line 12,* $\mathrm{dist}(u) = d(u)$ *if* $u \in P_{\mathrm{mid}}(c)$, $\mathrm{prev}(u) \in \bigcup_{c' \in \boxplus_c} P_{\mathrm{small}}(c')$, *and* $\mathrm{prev}(u) \notin R$.

Proof sketch. We apply induction on the index i of the round. For the base case, the first round of the algorithm is a round of **Case 1** of $k = \mathrm{dist}(s)$, where s is a source vertex. The shortest s-u path with $u \in P_{\mathrm{mid}}(c_s)$ is su and $\mathrm{dist}(u) = d(u)$ due to the pre-processing.

Now we assume that Lemma 6 holds up to the $(i-1)$-th round. Suppose the i-th round performs line 5. First we show **(1)**. Let x be the closest vertex to v along the shortest s-v path such that $d(x) = \mathrm{dist}(x)$. Note that $x \neq s$ because all children of s have correct-dist values due to the pre-processing. If $x = v$, we are done. Otherwise, $x \notin R$ since $d(x) < d(v)$. Then by induction hypothesis on the round which removes x from R, a child y of x satisfies $d(y) = \mathrm{dist}(y)$ unless x is a small neighbor of y. If x is a small neighbor of y, $\mathrm{alarm}(c_y)$ was at most $d(x) + 2|c_y|$ after that round. Since $y \in P_{\mathrm{mid}}(c_y)$, $8|c_y| \leq r_y$. Hence, $\mathrm{alarm}(c_y) \leq d(x) + \frac{1}{4} r_y < d(x) + |xy| = d(y)$ due to Corollary 5. Thus, $d(y) = \mathrm{dist}(y)$ by induction hypothesis **(3)** on the round of $k = \mathrm{alarm}(c_y)$. This contradicts the choice of x.

Next we show **(2)**. We may assume u is not a source vertex s. Let $w = \mathrm{prev}(u)$. We show that $d(w) = \mathrm{dist}(w)$. If $w = s$ or ws is an edge of G, we are done by the preprocessing. Hence, we may assume that $x := \mathrm{prev}(w)$ exists and x is not a source vertex s. Note that the proof of **(1)** implicitly says that for any vertex v' with $d(v') \leq k$, $d(v') = \mathrm{dist}(v')$ at the onset of line 5. Hence, we are enough to consider the case that $d(w) > d(v)$. Notice that xu is not an edge of G since otherwise, x is the predecessor of u. Then $d(x) < d(x) + |xu| - r_u - r_x < d(x) + |xw| + |wu| - r_u = d(u) - r_u < d(v)$, where the

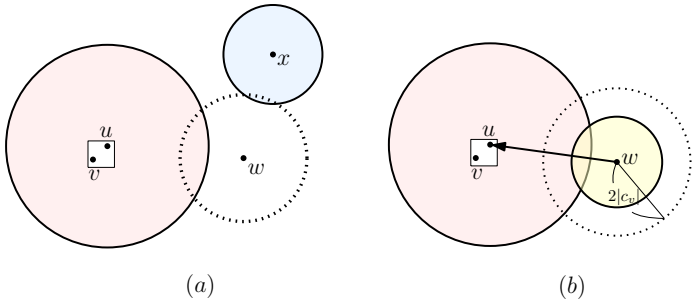

Figure 1 Illustrating some points in the proof of Lemma 6-(2). (a) An edge xu is not an edge of G. (b) If w is a small neighbor of u. alarm(c_v) rings before the round of $k = \text{dist}(v)$.

last inequality comes from $u, v \in P_{\text{mid}}(c_v)$. Hence, $d(x) = \text{dist}(x)$ and therefore $x \notin R$ due to the choice of v. Thus, by induction hypothesis on the round which removes x from R, $d(w) = \text{dist}(w)$ unless x is a small neighbor of w and $k < d(x) + 2|c_w|$. If x is a small neighbor of w, alarm(c_w) is set to at most $d(x) + 2|c_w|$ after that round. After a similar computation as we did in **(1)**, we can derive $d(x) + 2|c_w| < d(v)$ using the facts that $d(u) - \frac{1}{4}r_v < d(v)$ and Corollary 5. Now $d(w) = \text{dist}(w)$ due to induction hypothesis **(3)**.

Hence, for all cases, $d(w) = \text{dist}(w)$. Since u is not a leaf on the shortest path tree, $|wu| \geq \frac{1}{2}r_u$ due to Corollary 5. The only problematic case occurs when w is a small neighbor of u and the lazy update from w to $P_{\text{mid}}(c_u)$ has not occurred. In this case, $d(w)+2|c_u| > d(v)$ due to induction hypothesis **(3)**. Then $d(v) < d(w)+2|c_u| \leq d(w)+\frac{1}{4}r_u \leq d(w)+|wu|-\frac{1}{4}r_u = d(u) - \frac{1}{4}r_u < d(v)$ leads to a contradiction. Finally, **(3)** is followed by **(2)** and the fact that $\text{prev}(u) \notin R$ due to the choice of k. ◀

▶ **Lemma 7.** *Algorithm 2 returns a shortest path tree rooted at s.*

2.4 Time Complexity

In this section, we show that Algorithm 2 can be implemented in $O(n \log^2 n \log \Psi)$ time. For convenience, we assume that the subroutine Update(U, V) takes $O((|U| + |V|) \log^2 n)$ time (see the full version), and analyze the overall running time based on this assumption.

▶ **Lemma 8.** *The subroutine Update(U, V) takes $O((|U| + |V|) \log^2 n)$ time.*

Pre-processing. In the pre-processing step, we compute $\text{dist}(v)$ for all neighbors v of s, and $L(c)$ for all grid cells c. Here, $L(c)$ denotes the set of cells c' such that $P_{\text{mid}}(c)$ contains a small neighbor of c'. The former part takes $O(n)$ time by checking $|sv| - r_s - r_v$ for all $v \in P$. We *do not* use the floor function on the real RAM model to implement the hierarchical grid.

▶ **Lemma 9.** *One can compute a hierarchical grid Γ, and $P_{\text{mid}}(c)$ and $P_{\text{small}}(c)$ for all cells $c \in \Gamma$ in $O(n(\log n + \log \Psi))$ time on the real RAM model.*

▶ **Lemma 10.** *If $P_{mid}(c)$ contains a small neighbor of c', $c' \in L(c)$. Furthermore, one can compute $L(c)$ for all cells c in $O(n \log n \log \Psi)$ time.*

Time complexity of all rounds of Case 1. Let n_i be the number of vertices involved in $P_{\text{mid}}(c_v) \cup \bigcup_{c \in \boxplus c_v} (P_{\text{mid}}(c) \cup P_{\text{small}}(c))$ in the i-th round of line 5-6. If i-th round is a round of **Case 2**, we set n_i to 0. The time complexity of this part is then $\Sigma_i O(n_i \log^2 n)$. We show that

each $P_{\mathrm{mid}}(c)$ and $P_{\mathrm{small}}(c)$ appears in $O(1)$ rounds. First, since we remove $P_{\mathrm{mid}}(c_v)$ from R after the round $k = \mathrm{dist}(v)$, each $P_{\mathrm{mid}}(c)$ appears exactly once in the term $P_{\mathrm{mid}}(c_v)$. Suppose $c \in \boxplus_{c'}$. Then c is contained in axis-parallel square of diameter $64|c'|$ centered at $p(c)$ and $|c| \leq 2|c'|$. Conversely, c' is contained in the axis-parallel square of diameter $65|c|$ centered at $p(c)$. Therefore, the number of different c' with $c \in \boxplus_{c'}$ is $O(1)$ for a fixed c. Hence, each $P_{\mathrm{mid}}(c)$ and $P_{\mathrm{small}}(c)$ appears $O(1)$ rounds through the term $\bigcup_{c \in \boxplus_{c_v}} (P_{\mathrm{mid}}(c) \cup P_{\mathrm{small}}(c))$. Note that each vertex v is contained in one $P_{\mathrm{mid}}(c)$ and $O(\log \Psi)$ $P_{\mathrm{small}}(c)$ for $c \in \Gamma$. Thus,

$$\Sigma_i O(n_i \log^2 n) = \Sigma_c O(|P_{\mathrm{mid}}(c)| + \log \Psi |P_{\mathrm{small}}(c)|) \times O(\log^2 n) = O(n \log^2 n \log \Psi). \quad (1)$$

Time complexity of all rounds of Case 2. Let n'_i be the number of vertices involved in $P_{\mathrm{mid}}(c) \cup \bigcup_{c' \in \boxplus_c} (P_{\mathrm{small}}(c'))$ in the i-th round of line 12. If i-th round runs a round of **Case 1**, we set n'_i to 0. The time complexity of this part is then $\Sigma_i O(n'_i \log^2 n)$. Since alarm$(c)$ always set to $d(v) + 2|c|$ for some $v \in P$ and by Lemma 3, each cell c is referenced by line 11 $O(1)$ times. Again, there are $O(1)$ grid cells c' such that $\boxplus_{c'}$ contains a fixed cell c, and each v is contained in one $P_{\mathrm{mid}}(c)$ and $O(\log \Psi)$ $P_{\mathrm{small}}(c)$ sets. Thus, the total time complexity is

$$\Sigma_i O(n'_i \log^2 n) = \Sigma_c O(|P_{\mathrm{mid}}(c)| + \log \Psi |P_{\mathrm{small}}(c)|) \times O(\log^2 n) = O(n \log^2 n \log \Psi). \quad (2)$$

Priority queue. We maintain two priority queues, one of which stores vertex $v \in R$ with priority dist(v), and the other queue stores cell $c \in \Gamma$ with priority alarm(c). Once the algorithm performs line 3, we peek an element with minimum priority for each queue, and then choose k as the minimum value among them. The total cost of the queue operations is dominated by the total cost caused by UPDATE subroutines.

▶ **Theorem 11.** *There is an $O(n \log^2 n \log \Psi)$-time algorithm that solves the single-source shortest path problem on disk graphs with n vertices and radius ratio Ψ.*

3 SSSP on Disk Graphs of Arbitrary Radius Ratio

In this section, we extend the approach of Section 2 to devise an $O(n \log^4 n)$-time algorithm for the SSSP problem on disk graphs with arbitrary radius ratio. Basically, the $O(n \log^2 n \log \Psi)$ term in Theorem 11 came from the total size of $P_{\mathrm{mid}}(\cdot)$ and $P_{\mathrm{small}}(\cdot)$, which depends on the height ($=\Theta(\log \Psi)$) of the hierarchical grid. In the case of an arbitrary radius ratio, we cannot bind the height of the grid. To resolve this, we follow the approach presented in [2]. More specifically, we use a *compressed quadtree* (See Section 3.1) instead of a hierarchical grid. The height of the compressed quadtree might be $\Theta(n)$, which is still large. Hence, we use a *heavy path decomposition* (See Section 3.1) to compute $O(n)$ vertical paths in the compressed quadtree, which we call *canonical paths*, such that every root-node path of the compressed quadtree can be uniquely represented by the concatenation of $O(\log n)$ canonical paths. In this way, we can encode the edge information using near-linear time and space.

This approach has been applied to design efficient algorithms on disk graphs of arbitrary radius ratios, such as the dynamic connectivity problem [2] and the unweighted SSSP problem [15]. By integrating this approach with our lazy update scheme in a more sophisticated way, we can design an $O(n \log^4 n)$-time algorithm for the SSSP problem on weighted disk graphs with arbitrary radius ratios.

Throughout this section, we alternatively define the notions of $P_{\mathrm{mid}}(c), \square_c, \boxplus_c$, and regular/irregular edges. Let $h = 2^{10}$ and $\alpha > 2\pi / \arcsin(\frac{1}{100})$ be the integer constants.

▶ **Definition 12.** *For a grid cell c in $\mathcal{Q}$,*
- $P_{mid}(c) := \{v \in c : r_v \in [h|c|, 2h|c|)\}$.
- $\square_c$:= *Axis-parallel square of diameter* $8h^2|c|$ *centered at* $p(c)$.
- $\boxplus_c := \{c' \in \mathcal{Q} : c' \subset \square_c, |c'| \in [\frac{1}{h}|c|, h|c|]\}$.

▶ **Definition 13.** *For an edge uv of G with $r_u \le r_v$, uv is a* regular edge *if $\frac{r_v}{r_u} < h$, and an irregular edge otherwise.*

▶ **Lemma 14.** *Let uv be a regular edge. Then $c_u \in \boxplus_{c_v}$.*

3.1 Preliminaries: technical tools

In this section, we first briefly introduce technical items. Klost [15] implemented an efficient breadth-first search using these components. In contrast, our goal is to implement Dijkstra's algorithm over weighted graphs, which requires more sophisticated update strategies. We conclude this section by outlining the modified lazy update scheme that plays the central role in our algorithm for arbitrary radius ratios in Section 3.2.

Compressed quadtree. For an integer $i \ge 0$, let Γ_i be a grid of level i, which consists of axis-parallel square cells of diameter 2^i. Among all grid cells of $\bigcup_i \Gamma_i$, let c be the grid cell of the smallest level that contains P. A *compressed quadtree* $\mathcal{Q}$ is a rooted tree defined as follows. We start from c as the root of the tree and iteratively expand the tree. More specifically, whenever we process $c \in \Gamma_i$, we stop the expansion if c contains exactly one point of P. Otherwise, we compute at most four cells of Γ_{i-1} that are nested in c, and contain at least one point of P. If there is exactly one such child c', we remove c and connect c' to the parent node of c. Then we move on to children of c.

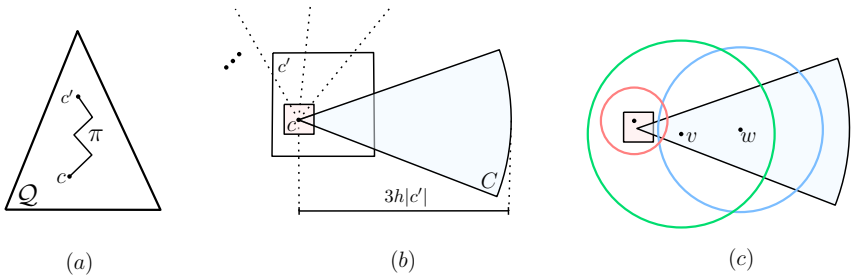
▶ **Lemma 15** ([12])**.** *In $O(n \log n)$ time, one can compute a compressed quadtree $\mathcal{Q}$ having $O(n)$ nodes and $O(n)$ height.*

For our purpose, the compressed quadtree is extended to contain all grid cells of $\boxplus_{c_v}$ for all $v \in P$. It also takes an $O(n \log n)$ time to compute the extended tree [2].

Heavy path decomposition and canonical paths. As the height of $\mathcal{Q}$ is $O(n)$, the direct use of Algorithm 2 is expensive: each vertex may be contained in $\Theta(n)$ grid cells, which was $O(\log \Psi)$ in Section 2. Our goal is to compute a path system in $\mathcal{Q}$ such that every root-node path of $\mathcal{Q}$ can be represented by the concatenation of $O(\log n)$ paths in the path system. We say an edge $cc' \in \mathcal{Q}$ is *heavy* if c' is the first child of c in the order of children, where we give an order by the total number of nodes in the subtree rooted at c' among all children of c. We say cc' *light* otherwise. A *heavy path* of $\mathcal{Q}$ is the maximal path on $\mathcal{Q}$ that consists of only heavy edges. The *heavy path decomposition* is the collection of all heavy paths in $\mathcal{Q}$.

▶ **Lemma 16** ([19])**.** *Let $\mathcal{Q}$ be the tree of n nodes. Then,*
1. *every root-leaf path of $\mathcal{Q}$ contains $O(\log n)$ light edges,*
2. *every node of $\mathcal{Q}$ lies on exactly one heavy path, and*
3. *the heavy path decomposition can be computed in $O(n)$ time.*

Then we use the approach of [2] as a black box. That is, we define a set Π of $O(n)$ *canonical paths*, such that every root-node path of $\mathcal{Q}$ can be uniquely represented by the concatenation of $O(\log n)$ disjoint canonical paths. Also, each canonical path is a subpath of a heavy path, and each node of $\mathcal{Q}$ is contained in $O(\log n)$ canonical paths. We can compute Π in $O(n \log n)$ time using standard data structures. See [2] for details.



(a) (b) (c)

Figure 2 (a) Canonical path π. (b) Illustration of $\lambda = (c, C)$. (c) A disk of $P_{\text{post}}(\lambda)$ (green) contains the disks of $P_{\text{small}}(\lambda)$ (red), while a disk of $P_{\text{large}}(\lambda)$ (blue) may not.

Handling irregular edges. We primarily follow the notion of a proxy graph as presented in [2, 15], with slight modifications to the notation for our purpose. For an irregular edge uv with $r_u < r_v$, we call u a *small neighbor* of v, and v a *large-neighbor* of u. For a canonical path π, we use c_π to denote the lowest cell of π. Also, we use $|\pi_\ell|(= |c_\pi|)$ and $|\pi_t|$ to denote the diameter of the lowest cell and the topmost cell of π, respectively. We then define a set $\mathcal{C}_\pi$ of α congruent cones of radius $3h|\pi_t|$, all sharing the same apex at $p(c_\pi)$. Let Λ be the set of all pairs (c_π, C) for all canonical paths π and all cones $C \in \mathcal{C}_\pi$. See Figure 2(a-b).

We say an irregular edge uv is *redundant* if $|uv| < |r_u - r_v|$. Due to Lemma 4, if a redundant edge uv appears on the shortest path tree, then one endpoint, say u, is a leaf on the tree. Therefore, we can postpone the correction of $\text{dist}(u)$ until the last, as no shortest s-$w(\neq u)$ path intersects u. In fact, our algorithm handles these edges during post-processing.

For a pair $\lambda = (c, C) \in \Lambda$, let $r(C)$ be the radius of C. For a vertex $v \in P$, recall that c_v is a grid cell such that $v \in P_{\text{mid}}(c_v)$. Let $\bar{c}_v$ be the smallest grid cell on the root-c_v path in $\mathcal{Q}$ whose diameter is at least $h|c_v|$. We let Π_v be the set of $O(\log n)$ consecutive canonical paths representing the root-$\bar{c}_v$ path. We define three subsets of P with respect to λ. Here, $p(c)$ is the center point of c.

$$P_{\text{small}}(\lambda) := \{v \in c \mid \exists \pi \in \Pi_v \text{ s.t. the lowest cell of } \pi \text{ is } c\}, \tag{3}$$

$$P_{\text{large}}(\lambda) := \{v \in C \mid r_v \in [h|c|, \frac{2}{3}r(C)] \text{ and } |r_v - |vp(c)|| < 5|c|\}, \text{ and} \tag{4}$$

$$P_{\text{post}}(\lambda) := \{v \in C \mid r_v \in [h|c|, \frac{2}{3}r(C)] \text{ and } 5|c| \leq r_v - |vp(c)|\}. \tag{5}$$

Intuitively, for any irregular edge uv, some λ encodes uv as $u \in P_{\text{small}}(\lambda)$ and $v \in P_{\text{large}}(\lambda) \cup P_{\text{post}}(\lambda)$. Moreover, $v \in P_{\text{large}}(\lambda)$ if uv is a non-redundant. Later, our algorithm runs Dijkstra's algorithm in a cell-by-cell manner w.r.t. $P_{\text{mid}}(\cdot), P_{\text{small}}(\cdot)$, and $P_{\text{large}}(\cdot)$.

▶ **Lemma 17.** *Suppose v is a small neighbor of u. There exists a pair $\lambda \in \Lambda$ such that $v \in P_{\text{small}}(\lambda)$ and $u \in P_{\text{large}}(\lambda) \cup P_{\text{post}}(\lambda)$. Moreover, if uv is non-redundant, $u \in P_{\text{large}}(\lambda)$.*

▶ **Corollary 18** (Corollary of Lemma 4)**.** *Suppose the shortest s-v path contains an irregular edge uv and v is not a leaf. Then $|uv| \geq (1 - \frac{1}{h})r_v$.*

▶ **Lemma 19.** *$\sum_{\lambda \in \Lambda} |P_{\text{small}}(\lambda)| = O(n \log n)$ and $\sum_{\lambda \in \Lambda} |P_{\text{large}}(\lambda)| + |P_{\text{post}}(\lambda)| = O(n \log n)$.*

Two-way lazy update scheme. Recall that Algorithm 2 updates small neighbors of v once it corrects the dist-values of $P_{\text{mid}}(c_v)$, whereas it postpones the update to (informal) large neighbors of v. In this section, we apply the lazy update scheme for both large and small

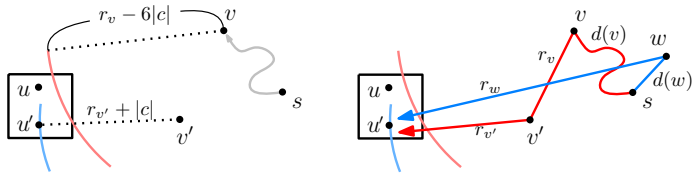


Figure 3 Illustration of some points in the proof of Lemma 20. (a) If $r_{v'} \leq r_v$, v' is contained in a disk of radius $r_v - 6|c|$ centered at v. (b) If $r_w >> r_v$, $d(w) << d(v)$ since the asymptotic lengths of the (shortest) blue path and the red path are $d(w) + r_w$ and $d(v) + r_v + r_{v'}$, respectively.

neighbors of v. The main reason is as follows. Due to Lemma 6-(2), all vertices of $P_{\text{mid}}(c_v)$ simultaneously get correct dist-values after the call of line 5. This property heavily relies on the geometric property of $P_{\text{mid}}(c_v)$ such that for any $u, w \in P_{\text{mid}}(c_v)$, $|uw| \leq \frac{1}{8} r_u$. However, this property no longer holds for $P_{\text{large}}(\lambda)$. More specifically, once we handle $v \in P_{\text{large}}(\lambda)$, there might be a vertex $u \in P_{\text{large}}(\lambda)$ whose predecessor in the shortest s-u has not been processed, and therefore, we cannot get correct dist-values of $P_{\text{large}}(\lambda)$ at this point.

Hence, one might consider a lazy update scheme to resolve this issue: delay the transmission of dist-values of $P_{\text{large}}(\lambda)$ in the range $[x, x + f(\lambda)]$ for some function f of λ until all dist-values smaller than $x + f(\lambda)$ have been processed. Unfortunately, this naive approach itself is not useful. Recall that for $v \in P_{\text{large}}(\lambda)$ with $\lambda = (c, C)$, r_v is in range $[h|c|, \frac{2}{3} r(C)]$ and $r(C)/|c|$ can be very large. Hence, we cannot partition the dist-values of $P_{\text{large}}(\lambda)$ into a constant number of ranges $[x, x + f(\lambda)]$, and the number of updates from $P_{\text{large}}(\lambda)$ to $P_{\text{small}}(\lambda)$ might be $\Theta(n)$, which leads to quadratic running time in total. We reduce the running time using the following geometric observation. See also Figure 3. Let $\lambda = (c, C)$.

▶ **Lemma 20.** *Let $v, v' \in P_{large}(\lambda)$, $u, u' \in P_{small}(\lambda)$, $r_v > r_{v'}$, the shortest s-u path contains vu, and $v'u'$ is an edge of G. Then $d(w) < d(v) + r_v - 6|c|$ where $w \in P_{large}(\lambda)$ is a predecessor of u' in the shortest s-u' path.*

Suppose we know the subset $P(\lambda)$ of $P_{\text{large}}(\lambda)$ whose dist-values have been corrected, and our algorithm will transmit dist-values of $P(\lambda)$ to $P_{\text{small}}(\lambda)$ right after all dist-values smaller than $d(v) + r_v - 6|c|$ have been processed for some $v \in P(\lambda)$. Then, Lemma 20 guarantees that $P(\lambda)$ contains all vertices of $P_{\text{large}}(\lambda)$ whose radii are smaller than r_v. Furthermore, after the lazy update, all vertices of $P_{\text{small}}(\lambda)$ adjacent to $u \in P_{\text{large}}(\lambda)$ with $r_u \leq r_v$ will have correct dist-values. Hence, the following procedure works.

- **Step 1.** Maintain a priority queue that stores $v \in P(\lambda)$ with priority $d(v) + r_v - 6|c|$.
- **Step 2.** Once we handle the lazy update caused by $d(v) + r_v - 6|c|$, we update dist-values of the vertices of $P_{\text{small}}(\lambda)$ which are adjacent to a vertex $v' \in P(\lambda)$ with $r_{v'} \leq r_v$.
- **Step 3.** After the update, we remove the updated vertices from $P_{\text{small}}(\lambda)$.

Recall that the running time of $\textsc{Update}(U, V)$ is $O((|U| + |V|) \log^2 n)$ time. Although there might $\Theta(n)$ calls of $\textsc{Update}$ for $(P_{\text{large}}(\lambda), P_{\text{small}}(\lambda))$, the total size of $|V|$ can be bounded by $\tilde{O}(n)$ due to **Step 3** and Lemma 19. Notice that U always corresponds to a subset $P(\lambda)$ of $P_{\text{large}}(\lambda)$, which starts as an empty set and grows as the algorithm progresses. Hence, we implement incremental data structures with near-linear construction time by carefully dynamizing $\textsc{Update}$ subroutine, inspired by the spirit of [3].

▶ **Definition 21.** *Let* Update-Inc(W) *be the incremental data structure with respect to* W *that supports the following operations:*

- *Initialize: set* $U = \emptyset$*,*
- *Insert(*v*): add a vertex* $v \in W$ *into* U *together with a dist-value* $d(v)$*, and*
- *Query(*V*): given a set* V *of vertices, perform* Update(U, V)*.*

▶ **Lemma 22.** *There is a data structure* Update-Inc$(P_{large}(\lambda))$ *that supports insert operation* $O(n \log^4 n)$ *time in total, and supports query operation on* V *in* $|V| \cdot O(\log^3 n)$ *time.*

Remark. We introduced an incremental data structure to handle the $\Theta(n)$ updates from $P_{\text{large}}(\lambda)$ to $P_{\text{small}}(\lambda)$. However, due to a similar reason, the number of lazy updates from $P_{\text{small}}(\lambda)$ to $P_{\text{large}}(\lambda)$ might be $\Theta(n)$. Fortunately, we can implement this direction of lazy update using solely Update subroutine carefully.

3.2 Algorithm

In this section, we present an $O(n \log^4 n)$-time algorithm for the SSSP problem on disk graphs of arbitrary radius ratio. Due to the lack of space, we mainly focus on the differences from Algorithm 2 in Section 2. During the pre-processing, we maintain two alarms alarm-up(λ), alarm-down(λ) together with a priority queue $Q(\lambda)$ for each pair $\lambda \in \Lambda$. Furthermore, we compute the set $L_1(v)$ (and $L_2(v)$) of pairs $\lambda \in \Lambda$ where $v \in P_{\text{small}}(\lambda)$ (and $v \in P_{\text{large}}(\lambda)$) and v has a neighbor in $P_{\text{large}}(\lambda)$ (and $P_{\text{small}}(\lambda)$) for each $v \in P$. In each round, we check dist(v) for all $v \in R$ and alarm-up(λ), alarm-down(λ) for all $\lambda \in \Lambda$. Then we find the minimum value k among them and proceed depending on the type of k. The algorithm moves to the post-processing step when R becomes empty. The algorithm utilizes the Update subroutine from Section 2.

Case 1: $k =$ dist(v) for a vertex $v \in R$. After correcting the dist-values of $P_{\text{mid}}(c_v)$ except those are leaves on the shortest path tree, we update the dist-values of the neighbors of $P_{\text{mid}}(c_v)$ through one direct update and two-way lazy updates. This is done by executing subroutine Update$(P_{\text{mid}}(c_v), \bigcup_{c \in \boxplus_{c_v}} P_{\text{mid}}(c))$, setting alarm-up$(\lambda) =$ dist$(v) + \frac{1}{4}v(\lambda)$ for every $\lambda \in L_1(v)$ with alarm-up$(\lambda) = \infty$, and inserting u with the priority dist$(u) + r_u - 6|c|$ into $Q(\lambda)$ and inserting u into Update-Inc$(P_{\text{large}}(\lambda))$ for every $u \in P_{\text{mid}}(c_v)$ and every $\lambda \in L_2(u)$. Here, $v(\lambda)$ is the smallest radius of the vertex of $P_{\text{large}}(\lambda)$ forming an edge with $P_{\text{mid}}(c_v)$. Intuitively, the subroutine takes care of the neighbors connected by regular edges, and alarm-up$(\cdot)$ and alarm-down$(\cdot)$ take care of large neighbors and small neighbors of the vertices of $P_{\text{mid}}(c_v)$, respectively.

Case 2: $k =$ alarm-up(λ) for a pair $\lambda \in \Lambda$. In this case, we shall correct the dist-values of all $v \in P_{\text{large}}(\lambda)$ whose predecessor u is in $P_{\text{small}}(\lambda)$ with $d(u) < k$. This is done by applying Update$(U_{\text{small}}(\lambda, k), U_{\text{large}}(\lambda, k))$ where $U_{\text{small}}(\lambda, k)$ and $U_{\text{large}}(\lambda, k)$ are carefully computed subsets of $P_{\text{small}}(\lambda)$ and $P_{\text{large}}(\lambda)$, respectively. See the exact computation of $U_{\text{small}}(\lambda, k), U_{\text{large}}(\lambda, k)$ and its correctness in the full version.

Case 3: $k =$ alarm-down(λ) for a pair $\lambda \in \Lambda$. We shall correct the dist-values of all $v \in P_{\text{small}}(\lambda)$ which are adjacent to $u \in P_{\text{large}}(\lambda)$ with $r_u \leq r_{u_k}$, where u_k is the vertex stored in $Q(\lambda)$ with minimum priority. This is done by the query operation on $D_{\text{small}}(\lambda, k)$ to Update-Inc$(P_{\text{large}}(\lambda, k))$. Here, $D_{\text{small}}(\lambda, k)$ denotes the set of vertices in $P_{\text{small}}(\lambda)$ such that (i) form an edge with $u \in P_{\text{large}}(\lambda)$ with $r_u \leq r_{u_k}$, and (ii) have not been considered in a preceding round of $k =$ alarm-down(λ). After the update, we modify $Q(\lambda)$ appropriately.

Algorithm 3 SSSP2(P).

1. $R \leftarrow P$ and initialize Update-Inc($P_{\text{large}}(\lambda)$) for all $\lambda \in \Lambda$
2. **while** $R \neq \emptyset$ **do**
3. $k \leftarrow \min(\{\text{dist}(v) : v \in R\} \cup \{\text{alarm-up}(\lambda) : \lambda \in \Lambda\} \cup \{\text{alarm-down}(\lambda) : \lambda \in \Lambda\})$
4. **if** $k = \text{dist}(v)$ for $v \in R$ **then**
5. Update($\bigcup_{c \in \boxplus_{c_v}} P_{\text{mid}}(c), P_{\text{mid}}(c_v)$)
6. Update($P_{\text{mid}}(c_v), \bigcup_{c \in \boxplus_{c_v}} P_{\text{mid}}(c)$)
7. **for** $\lambda \in L_1(v)$ **do**
8. **if** alarm-up$(\lambda) = \infty$ **then**
9. alarm-up$(\lambda) \leftarrow \text{dist}(v) + \frac{1}{4}v(\lambda)$
10. **for** $u \in P_{\text{mid}}(c_v)$ **do**
11. **for** $\lambda = (c, C) \in L_2(u)$ **do**
12. $Q(\lambda) \leftarrow \text{insert}(u, \text{dist}(u) + r_u - 6|c|)$
13. Update-Inc($P_{\text{large}}(\lambda)$).insert($u$)
14. alarm-down$(\lambda) \leftarrow$ min-priority($Q(\lambda)$)
15. $R \leftarrow R \setminus P_{\text{mid}}(c_v)$
16. **if** $k =$ alarm-up(λ) for $\lambda \in \Lambda$ **then**
17. Update($U_{\text{large}}(\lambda, k), U_{\text{small}}(\lambda, k)$)
18. alarm-up$(\lambda) \leftarrow \infty$
19. **if** $k =$ alarm-down(λ) for $\lambda \in \Lambda$ **then**
20. Update-Inc($P_{\text{large}}(\lambda)$).query($D_{\text{small}}(\lambda, k)$)
21. alarm-down$(\lambda) \leftarrow$ min-priority(delete($Q(\lambda)$))

Post-processing. In the post-processing step, we correct the dist-values for the remaining vertices. We execute Update($P_{\text{post}}(\lambda), P_{\text{small}}(\lambda)$) for every pair λ in Λ.

3.3 Correctness and Time Complexity

▶ **Lemma 23.** *The correctness of Algorithm 3 mainly follows from the following lemma, which is a counterpart to Lemma 7 from Section 2. The following statements hold during the execution of Algorithm 3.*

(1) *At the onset of line 5,* $\text{dist}(v) = d(v)$ *unless* v *is a leaf.*

(2) *After line 5,* $\text{dist}(u) = d(u)$ *if* $u \in P_{\text{mid}}(c_v)$ *and* u *is not a leaf.*

(3) *After line 17,* $\text{dist}(u) = d(u)$ *if* $u \in P_{\text{large}}(\lambda)$, $\text{prev}(u) \in P_{\text{small}}(\lambda)$, *and* $d(\text{prev}(u)) < k$.

(4) *After line 20, let* v *be the vertex in* $Q(\lambda)$ *with minimum priority. Then* $\text{dist}(u) = d(u)$ *if* $u \in P_{\text{small}}(\lambda)$ *and* u *is adjacent to* $v' \in P_{\text{large}}(\lambda)$ *with* $r_{v'} \leq r_v$.

▶ **Lemma 24.** *Algorithm 3 returns the shortest path tree rooted at* s.

Time Complexity. The main bottleneck of Algorithm 3 comes from the incremental data structure Update-Inc($P_{\text{large}}(\lambda)$). Due to Lemmas 19 and 22, we conclude the following.

▶ **Theorem 25.** *There is an algorithm to solve the single-source shortest path problem on disk graphs with* n *vertices in* $O(n \log^4 n)$ *time.*

Abstract

We show that the flip chain for non-crossing spanning trees of $n+1$ points in convex position mixes in time $O(n^8 \log n)$. We use connections between Fuss-Catalan structures to construct a comparison argument with a chain similar to Wilson's lattice path chain (Wilson 2004).

1 Introduction

The reconfiguration of planar objects is an intensively studied topic in computational geometry. Given a set of points, such a planar structure can be a triangulation, a non-crossing perfect matching, or a *non-crossing spanning trees* (NCST), etc. In this paper we focus on the last one. Given $n+1$ points in a plane, an NCST is a spanning tree such that no two edges intersect or overlap (except on the joint vertex) when all edges are drawn as straight line segments on the plane. The reconfiguration of NCSTs is done by *flips*, which remove an edge of the current tree, and then add an edge back so that the resulting graph is still a valid NCST. See Figure 1 for an example. Given two NCSTs over the same point set in general position, Avid and Fukuda [8] first proved that it takes at most $2n-2$ flips to move from

one to the other. On the other hand, Hernando, Hurtado, Márquez, Mora and Noy [28] constructed an example where it takes at least $1.5n - O(1)$ flips, even when the points are *in convex position*. These bounds have not been improved until recently [1, 12, 11]. Very recently, Bjerkevik, Kleist, Ueckerdt, and Vogtenhuber [10] improved the upper bound to $5/3n - 3$ and the lower bound to $14/9n - O(1)$ when all points are in convex position.

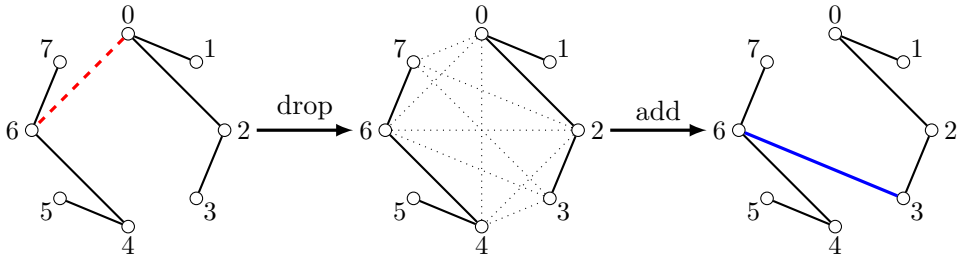

Figure 1 Illustration of a flip move. The red, dashed edge in the leftmost figure is dropped. This gives 9 possible edges (dotted in the middle figure) that can be added back to form a valid NCST. The blue, thick edge in the rightmost figure is picked.

Another classic topic in computational geometry is to count these planar structures. Traditional combinatorial studies focus on asymptotic upper and lower bounds of these structures (see e.g. [33, 43, 44]). Motivations for counting these structures have appeared in other topics, such as quantum gravity [32, 35], plane curves [47], algebraic geometry [20, 22], and the theory of discriminants [27]. From the computational perspective, the complexity of the counting problem seems to remain elusive in most cases, with an exception of counting triangulations of (not necessarily simple) polygons known to be #**P**-hard [25]. On the other hand, counting the number of triangulations of a given set of points remains unresolved (but it is conjectured to be #**P**-hard, see e.g. [21] or [17, §6.7]). Similarly, counting NCSTs over a set of points in general position apparently is also not known to be #**P**-hard nor polynomial-time solvable, although we conjecture the former to be the case. To cope with the apparent intractability, sub-exponential time and fixed-parameterised approximation algorithms have been studied [2, 3, 34], but the complexity of approximate counting NCSTs does not appear to be known either.

On the other hand, when these $n + 1$ points are in convex position, the corresponding counting problem becomes easy to solve. One can show that the number of NCSTs, denoted by $C_{2,n}$, is subject to the following recursion: (see e.g. [42])

$$C_{2,0} = 1,\ C_{2,n} = \sum_{\substack{i,j,k\in\mathbb{Z}_{\geq 0},\\ i+j+k=n-1}} C_{2,i}C_{2,j}C_{2,k}, \qquad \Longrightarrow \qquad C_{2,n} = \frac{1}{2n+1}\binom{3n}{n}. \tag{1}$$

Sharing a similar form as the famous *Catalan numbers*, this kind of generalisation is called the 2-*Fuss-Catalan numbers*. The (k-Fuss-)Catalan numbers capture more than 200 natural combinatorial structures. For example, the Catalan numbers count the number of triangulations, non-crossing perfect matchings and non-crossing partitions when the points are in convex position. The k-Fuss-Catalan numbers count the number of k-rooted plane trees, $(k + 1)$-ary trees, k-Dyck paths, and many more. We refer interested readers to Stanley's monograph [46] for an exhaustive survey about these Fuss-Catalan structures.

In this paper, we are interested in where reconfiguration and approximate counting meet. We consider a Markov chain whose steps are random flip moves over NCSTs, denoted the *flip chain*. In each step, we drop an edge chosen uniformly at random, and then add back

an edge uniformly at random among all valid choices. (This chain is formally defined in (7).) Reconfiguration results [8, 28, 10] thus imply that the flip chain is *irreducible* (namely, the state space of all NCSTs is connected via flip moves), and when the points are in convex position, the *diameter* of the chain is bounded between $14/9n - O(1)$ and $5/3n - 3$. Markov chains are also the most common approach to approximately count the number of combinatorial structures [30, 24, 31]. While the size of the state space (namely the total number of structures to count) can be exponentially large, the hope is that the Markov chain converges to the uniform distribution within polynomially many steps. The time to converge is called the *mixing time* (defined in Section 2). When the mixing time is bounded by a polynomial, the chain is said to be rapid mixing, and rapid mixing Markov chains usually lead to efficient approximate counting algorithms.

The mixing times of these geometrically defined Markov chains have received considerable attention from the Markov chain community in the past few decades, even when restricted to points in convex position, such as the chains over convex polygon triangulations [39, 38, 26], over triangulations on lattices and spheres [15, 14], or over lattice paths and (1-)Dyck paths [37, 48, 16]. See Cohen's thesis [18] for a more detailed explanation and comprehensive overview about random walks over 1-Fuss-Catalan structures. Beyond the fields of computational geometry and Markov chain analysis, these chains also find numerous applications, often thanks to the wide connections of Fuss-Catalan numbers, such as for quantum spin systems [13, 41, 40] or even in algebraic geometry [9].

In this paper we give the first polynomial upper bound on the mixing time of the flip chain over NCSTs for points in convex position.

▶ **Theorem 1.** *For $n+1$ points on the plane in convex position, the mixing time of the flip chain over their non-crossing spanning trees is $O(n^8 \log n)$.*

The main feature that sets Theorem 1 apart from the results mentioned above is that NCSTs for points in convex position are 2-Fuss-Catalan structures. This renders some tools unavailable and others, such as the path comparison method [23], a lot more intricate to use. We also note that while the very similarly defined bases-exchange chain over spanning trees of a graph is known to have an optimal mixing time [6, 19], NCSTs do not form the bases of a matroid and these results apparently do not apply. We give an overview of our proofs next.

1.1 Technical overview

Our main strategy is to compare the flip chain with another chain that is easier to analyse. Naturally we would choose a chain over structures that have a bijection with NCSTs. There are a few candidates (see e.g. [45]), and we choose 2-Dyck paths. The bijection is defined through the same recursive structure, such as (1), for both 2-Dyck paths and NCSTs. Note that while these structures share the same count and have bijections among them, a local move in one structure may cause drastic changes in another through the bijection. Thus we need to pick a starting point chain so that the distortion caused by the bijection is manageable and the overhead of the comparison can be bounded by a polynomial.

We represent a 2-Dyck path by a string consisting of $2n$ ups ($\nearrow$) and n downs ($\searrow$) such that any prefix of the string contains no fewer ups than twice the number of downs. The formal definition is given in Section 3.1. One can verify that the positions of the down arrows form a basis of a matroid. This generalises the so-called Catalan matroid introduced by Ardila [7]. Since the bases-exchange walk for these matroids has an $O(n \log n)$ mixing time [19], a natural choice would be to compare this chain with the flip chain over NCSTs. This chain randomly chooses a down arrow and moves it to a random valid location. However, as mentioned before, one move in the bases-exchange walk may change NCSTs drastically. See Example 2.

▶ **Example 2.** Consider two 2-Dyck paths of length 39:

$W_1 =$,

$W_2 =$.

They differ at position 20 (coloured by orange) and 38 (coloured by cyan). As W_2 can be obtained from W_1 through moving the position of one down arrow, they are connected by one move of the bases-exchange chain. However, their corresponding NCSTs induced by the bijection of the Fuss-Catalan recurrence (see Section 3) do not share any edge in common, and there is no obvious pattern to note. The corresponding trees are illustrated as W_1 and W_2 in Figure 2.

Since the bases-exchange chain appears to be difficult to compare with, we choose a different chain to control the changes in the corresponding NCSTs, and that is the adjacent move chain. Instead of moving a down arrow to a random location, we restrict the movement to be either left or right one position. More formally, each transition of this chain chooses two adjacent coordinates uniformly at random. If swapping them results in a valid path, we do so with probability 1/2, and otherwise make no change. For example, suppose the current state is ↗↗↘↗↗↘. If, with probability 1/5, we choose the second and third positions, then the path will not change as swapping them leads to an invalid 2-Dyck path. On the other hand, if (with probability 1/5) we choose the third and fourth positions, then the chain will move to ↗↗↗↘↗↘ with probability 1/2 and remain unchanged otherwise.

While this chain is not directly studied before, we verify that the coupling method of Wilson [48] still applies here. Wilson's original argument is applied to Lattice paths or the Bernoulli-Laplacian model (the uniform distribution over *all* strings with a fixed number of ups and downs). Without too much change, the same argument implies that the adjacent move chain over 2-Dyck paths mixes in $O(n^3 \log n)$ steps.

Our main technical contribution is then to compare the adjacent move chain over 2-Dyck paths with the flip chain over NCSTs. We need to characterise how one adjacent move changes the NCSTs. Consider again W_2 in Example 2, and another 2-Dyck path W_3 that can be reached from W_2 by a single adjacent move:

$W_2 =$,

$W_3 =$.

The adjacent move swaps the position 20 and 21. The corresponding NCST of W_3 is shown in Figure 2. Note that there are still a lot of altered edges, and in fact, one can also construct examples where $\Omega(n)$ edges get changed after an adjacent move. This time, however, the reader may have observed a pattern of the changes: the blue part in the NCST of W_3 is the same as the red part in that of W_2, but shifted clockwise once. As formally proved in Section 5.1, each adjacent move corresponds to at most two edge flips, plus one shifting in a particular form (see (9)).

To apply the path method for Markov chain comparison [23], we need to simulate an adjacent move with a sequence of flip moves, and to be able to recover the initial and final states of the adjacent move, given the two states of the flip move and at most polynomial amount of additional information. The main task is to simulate the shift. We do so by identifying a hierarchical structure of the shift, and only flip edges following a particular pattern. This design allows us to uniquely recover the initial and final states of the shift, as long as we know the current transition, the recursion depth, and constant amount of extra information. This is the crux of our whole argument and is given in Section 5.

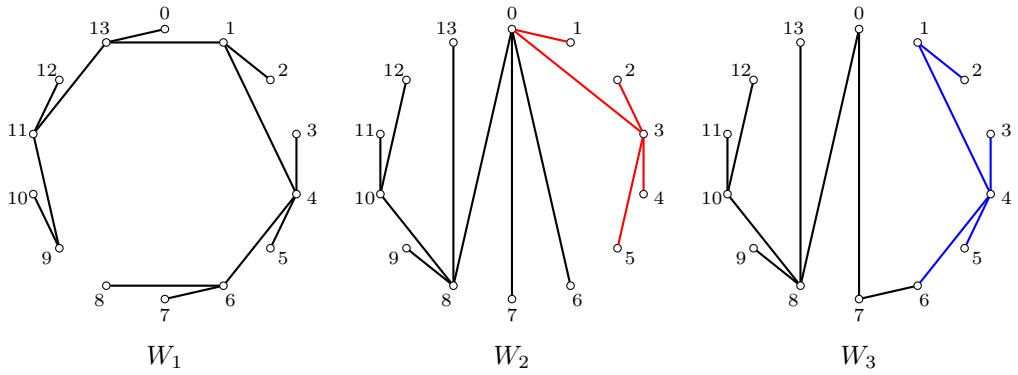

Figure 2 NCSTs corresponding to the 2-Dyck paths in Example 2.

Theorem 1 is shown by combining the comparison argument with the $O(n^3 \log n)$ mixing time of the adjacent move chain. The comparison has an overhead of $O(n^4)$, which, roughly speaking, consists of $O(n)$ for the encoding, $O(n)$ for the path length, and $O(n^2)$ to account for the transition probability difference. Finally, together with the $O(n)$ overhead resulting from spectral gaps, we obtain our mixing time bound of $O(n^8 \log n)$.

1.2 Related work

McShine and Tetali's mixing time argument for convex triangulations [38] is similar to our result in spirit, which is also built on a comparison argument with Wilson's lattice path chain [48]. However, in their case the starting point is 1-Dyck path and the argument is more straightforward. The idiosyncrasies of non-crossing spanning trees warrant a more complicated path construction.

We have mentioned that the down arrows of 2-Dyck paths form bases of a matroid. However it appears difficult to directly relate that matroid and related dynamics with the flip chain. Another very similar structure is the *graphic matroid*, whose bases are spanning trees of a graph. The bases-exchange walk for matroids is known to mix very rapidly [6, 19]. However, with the non-crossing restriction, even when the points are in convex position, NCSTs do *not* form the bases of a matroid if we take all possible edges as the ground set. To see this, we give an example where the basis exchange property of matroids fails. Consider 4 points $\{0, 1, 2, 3\}$ on a circle, a tree T_1 consisting of edges $(0, 1)$, $(1, 3)$ and $(2, 3)$, and another tree $T_2 = \{(0, 2), (1, 2), (2, 3)\}$. Remove the edge $(0, 1)$ from T_1. The possible choices of the new edge to add are $T_2 \setminus T_1 = \{(0, 2), (1, 2)\}$, but neither of them results in a valid non-crossing spanning tree, contradicting to the basis exchange property. Nonetheless, it is an interesting open problem to utilise techniques for the rapid mixing of graphic spanning trees to obtain better bounds in the non-crossing spanning trees context.

There has been a flurry of new tools building upon [6, 19] for analysing Markov chains, most notable among which is the spectral independence technique [5]. However, the results utilising spectral independence or its variants mostly focus on spin systems, and non-crossing trees are not spin systems. The trees all have the same size, which is a constraint usually not present in spin systems. There are some exceptions, such as the optimal mixing time of the down-up walk of independent sets of the same size [29]. These analyses rely heavily on the relationship between the fixed size distribution with the one without size restrictions. There is no similar connection to be utilised for non-crossing trees.

1.3 Open problems

The most straightforward open problem is to establish the correct order of the mixing time for the NCST flip chain. The $O(n^8 \log n)$ bound in Theorem 1 is unlikely to be tight. Our starting point, the adjacent move chain for 2-Dyck paths, has diameter $\Omega(n^2)$ by a simple potential argument,[1] and thus does not mix very fast. On the other hand, reconfiguration results [8, 10] imply that the flip chain has diameter $O(n)$. Therefore, we expect the flip chain to mix at least no slower than the adjacent move chain, instead of the polynomial slow-down in our current bound. On the other hand, there is no known lower bound on the mixing time other than the trivial $\Omega(n)$ obtained via the diameter bound. It would be interesting to close or shrink this gap.

Another interesting problem is to study the flip chain when points are *not necessarily* in convex position. Recall that the complexity of counting NCSTs with input points in general position, either exactly or approximately, is not known. Studying the flip chain would be helpful in resolving the approximate counting complexity. Constructing a set of points such that the flip chain mixes torpidly (i.e., not mixing in polynomial time) would rule out direct MCMC approaches, and often torpid-mixing instances help people construct gadgets for hardness reductions. On the other hand, if this chain always mixes in polynomial time, then efficient approximate counting would be possible.

2 Markov chain comparison

In this section we review some notions of discrete-time Markov chains over discrete state spaces. For detailed backgrounds we refer the reader to the book [36]. Let Ω be a finite discrete state space and π a distribution on Ω. Let $P : \Omega \times \Omega \to \mathbb{R}_{\geq 0}$ be the transition matrix of a Markov chain with stationary distribution π. We say P is reversible if $\pi(x)P(x, y) = \pi(y)P(y, x)$ for any $x, y \in \Omega$.

Given two distributions π and π' over Ω, the total variation distance between them is defined as $d_{\mathrm{TV}}(\pi, \pi') := \frac{1}{2}\sum_{x\in\Omega} |\pi(x) - \pi'(x)|$. For a Markov chain P with stationary distribution π, let $d(t) = \max_{x\in\Omega} \{d_{\mathrm{TV}}(P^t(x, \cdot), \pi)\}$. Then the mixing time of P is defined as $t_{\mathrm{mix}}(P) := \min\{t : d(t) \leq \frac{1}{2e}\}$. The constant $1/(2e)$ here is not usually important, as the error decays exponentially as t increases.

Let f, g be two real valued functions on Ω. The Dirichlet form of P with the stationary distribution π is

$$\mathcal{E}_P(f, g) := \frac{1}{2} \sum_{x,y\in\Omega} [f(x) - f(y)][g(x) - g(y)]\pi(x)P(x, y).$$

Define the variance of a function $f : \Omega \to \mathbb{R}$ by $\mathrm{Var}_\pi(f) := \mathbb{E}[f^2] - (\mathbb{E}[f])^2$. Then the *spectral gap* of the Markov chain P is

$$\lambda(P) := \inf \left\{ \frac{\mathcal{E}_P(f, f)}{\mathrm{Var}_\pi(f)} \mid f : \Omega \to \mathbb{R}, \mathrm{Var}_\pi(f) \neq 0 \right\}. \tag{2}$$

Equivalently, the spectral gap is the difference between the largest and second largest eigenvalues of the transition matrix of P, but the definition in (2) will be more convenient for us later.

[1] One can also consider how the area below the path evolves and show that the mixing time is at least $\Omega(n^3/\log n)$, so Wilson's bound is almost tight.

The mixing time of any reversible Markov chain P can be bounded using the inverse spectral gap (also called the *relaxation time*) (see e.g. [36, Theorem 12.4, 12.5]):

$$\frac{1}{\lambda(P)} - 1 \leq t_{\text{mix}}(P) \leq \frac{1}{\lambda(P)} \left(1 + \frac{1}{2} \log \pi_{\min}\right), \tag{3}$$

where $\pi_{\min} := \min_{x \in \Omega} \pi(x)$. This $\pi_{\min}$ term is usually a single inverse exponential, which means the mixing time bound obtained this way typically differs from the relaxation time by a linear factor.

2.1 Path method

The path method [23] is a way to compare two Markov chains P and $\widetilde{P}$, with stationary distributions π and $\widetilde{\pi}$, by simulating any transition in $\widetilde{P}$ using a series of transitions in P. This is a generalisation of the canonical path method by Jerrum and Sinclair [30].

For every pair of $x, y \in \Omega$, let $\Gamma_{xy} = (x = x_0, x_1, ..., x_{\ell-1}, x_\ell = y)$ be a path of length $\ell = |\Gamma_{xy}|$ in the state space where $P(x_{i-1}, x_i) > 0$ for all $i \in [\ell]$. The congestion ratio B for a collection of paths $\Gamma = \{\Gamma_{xy}\}_{x,y \in \Omega}$ is defined as

$$B := \max_{(x',y'):P(x',y')>0} \left(\frac{1}{\pi(x')P(x',y')} \sum_{\substack{x,y \\ \Gamma_{xy} \ni (x',y')}} \widetilde{\pi}(x)\widetilde{P}(x,y)|\Gamma_{xy}| \right). \tag{4}$$

▶ **Theorem 3** (Theorem 2.1 of [23]). *Let P and $\widetilde{P}$ be two reversible Markov chains. Let B be the congestion ratio for paths $\Gamma = \{\Gamma_{xy}\}$ using transitions in P. Then for all $f : \Omega \to \mathbb{R}$,*

$$\mathcal{E}_{\widetilde{P}}(f, f) \leq B\mathcal{E}_P(f, f).$$

Roughly speaking, the congestion bounds how much of a slowdown the path method can cause. It gives an upper bound on how much of a bottleneck can result from our simulated transitions.

3 Fuss-Catalan numbers and structures

This section introduces the combinatorial structures that we frequently utilise. These structures are closely related to the famous *Fuss-Catalan number*.

▶ Remark 4. Different authors appear to index Fuss-Catalan numbers differently in the literature. We adopt the definition used in Stanley's monograph [46].

3.1 Dyck paths

▶ **Definition 5** (k-Dyck path). *Let k be a positive integer. A sequence $(a_1, a_2, \cdots, a_{(k+1)n}) \in \{+1, -k\}^{(k+1)n}$ forms a* k-Dyck path *of length $(k+1)n$, if*

$$\forall j \in [(k+1)n], \qquad \sum_{i=1}^{j} a_i \geq 0, \qquad \text{and} \qquad \sum_{i=1}^{(k+1)n} a_i = 0.$$

Imagine that there is a hiking frog starting from the sea level. Each time it takes a step forward, it either lifts itself up by 1 meter, or drops by k meters. The two conditions are interpreted as (1) at any point it cannot go below the sea level, and (2) after $(k+1)n$ steps

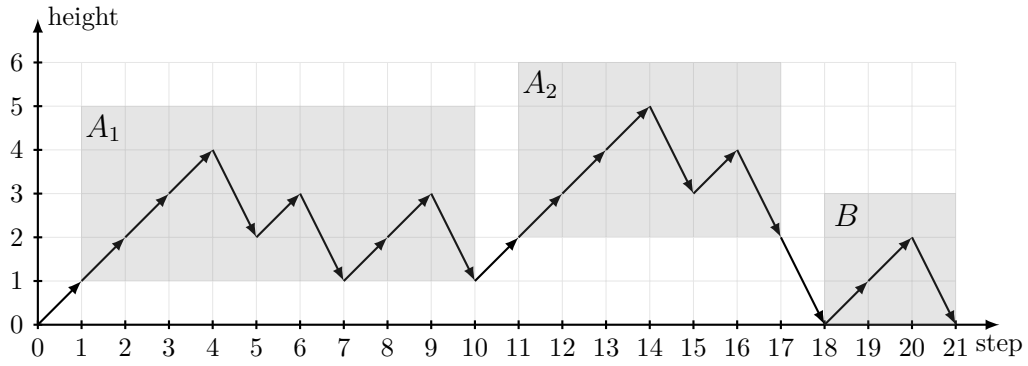

Figure 3 Decomposing Example 6 by Fact 7.

it must land on the sea level. This view leads to the following terminology for k-Dyck paths. We replace $+1$ with an *up-step* $\nearrow$, and $-k$ with a *down-step* $\searrow$. The partial sum

$$\mathrm{ht}(j) := \sum_{i=1}^{j} a_i$$

indicates the *height* of the frog after j steps. Below is an example of a valid 2-Dyck path of length 21.

▶ **Example 6.** $\nearrow\nearrow\nearrow\nearrow\searrow\nearrow\searrow\nearrow\nearrow\searrow\nearrow\nearrow\nearrow\nearrow\searrow\nearrow\searrow\searrow\nearrow\nearrow\searrow$ is a 2-Dyck path.

The following simple fact is useful later.

▶ **Fact 7.** *Any non-empty k-Dyck path W can be uniquely written in the form*

$$W = \nearrow A_1 \nearrow A_2 \cdots \nearrow A_k \searrow B,$$

where A_i's and B are (possibly empty) k-Dyck paths.

The decomposition can be obtained as follows. The B part begins at the position where the height *first* reaches 0 (except the starting point), namely $\mathsf{Start}(B) = \min\{j : \mathrm{ht}_W(j) = 0, j \geq 1\}$. Each A_i part begins at the position one step after where the height reaches $i-1$ for the *last* time before the B part, namely $\mathsf{Start}(A_i) = 1 + \max\{j : \mathrm{ht}_W(j) = i-1, 0 \leq j < \mathsf{Start}(B)\}$. See Figure 3 for an example of such a decomposition for a 2-Dyck path.

Fact 7 immediately implies the recurrence on the number of k-Dyck paths of length $(k+1)n$, denoted by $C_{k,n}$:

$$C_{k,0} = 1,\ C_{k,n} = \sum_{\substack{i_1,\cdots,i_{k+1}\in\mathbb{Z}_{\geq 0},\\ \sum_{j=1}^{k+1} i_j = n-1}} C_{k,i_1} C_{k,i_2} \cdots C_{k,i_{k+1}},\ \Longrightarrow\ C_{k,n} = \frac{1}{kn+1}\binom{(k+1)n}{n}. \quad (5)$$

This is called the *k-Fuss-Catalan number* [46, Chapter 4, A14], a generalisation of the Catalan number. It is well-known that the number of 1-Dyck paths equals the Catalan number.

3.2 Non-crossing spanning trees

Non-crossing spanning trees for points in convex position have a one-to-one correspondence with 2-Dyck paths. It will be more convenient to consider the following alternative way to draw the trees (see [45, Exercise 5.46]). Instead of putting points in convex position, we

arrange them on a line. Each edge is represented by a curve, drawn above the line segment. A tree is *non-crossing* if and only if it can be drawn this way without any two edges intersecting (except at the endpoints). See Figure 4(a)(b) for the two drawings of the same tree. In other words, each edge is represented by a pair of integers (a, b) where $0 \le a < b \le n$, and there does not exist any two edges (a, b) and (c, d) that $a < c < b < d$. As a result, any subtree must consist of points labeled by consecutive numbers. For this reason, if a subtree is spanned by $s, s+1, \cdots, t$, we use a shorthand $[s, t]$ for it. A subtree is empty (consists of no edges) if $s = t$.

▶ **Fact 8.** *Any n-edge non-empty non-crossing spanning tree T on points labeled $0, 1, \cdots, n$ can be uniquely decomposed into a tuple of three non-crossing trees (T_A, T_B, T_C), with the edge counts summing up to $n-1$, in the following way:*

- *Let t be the maximum index that there is an edge $(0, t)$.*
- *Let s be the index such that, after removing the edge $(0, t)$, the subtree $[0, s]$ is connected, but $[0, s+1]$ is not. In other words, there is a gap between s and $s+1$.*
- *The first tree T_A is the subtree $[0, s]$. It is empty if $s = 0$.*
- *The second tree T_B is the subtree $[s+1, t]$. It is empty if $t = s+1$.*
- *The last tree T_C is the subtree $[t, n]$. It is empty if $n = t$.*

Resembling Fact 7 for 2-Dyck paths, the above decomposition not only suggests exactly the same recurrence (1) for the number of n-edge non-crossing spanning trees, but also a *one-to-one correspondence* between 2-Dyck paths and non-crossing spanning trees. Compare Figure 4(c) and Figure 3 for instance.

▶ **Corollary 9.** *The following ruleset, when applied inductively, gives a one-to-one correspondence between 2-Dyck paths of length $3n$ and non-crossing spanning trees containing n edges.*

- *An empty path corresponds to an empty tree.*
- *If a tree T is decomposed into (T_A, T_B, T_C) by Fact 8, with each part corresponding to paths A, B and C respectively, then T corresponds to the path $\nearrow A \nearrow B \searrow C$.*

The decomposition has the following useful property.

▶ **Proposition 10.** *Let U and V be two 2-Dyck paths of length $3n_U$ and $3n_V$ respectively, and let T_U and T_V be their corresponding non-crossing spanning trees. Then, the non-crossing spanning tree T_{UV} corresponding to the concatenated Dyck path UV is a concatenation of T_U and T_V, meaning that the subtree $[0, n_U]$ of T_{UV} is T_U, and the subtree $[n_U, n_U + n_V]$ of T_{UV} is T_V (up to a shift in indexing).*

The proof of Proposition 10 can be found in the full version [4]. Inspired by the decomposition, we introduce the following terminology that will be useful later.

▶ **Definition 11.** *In the context of Fact 8:*

(pivot edge)	*the edge $(0, t)$ is called the* pivot edge *of T;*
(gap)	*the vertices between s and t are called the* gap *beneath the pivot edge $(0, t)$; the pivot edge is called the* overarching edge *of the gap;*
(overarching edge)	*an edge (a, b) is the* overarching edge *of another edge (c, d), if $a \le c < d \le b$, and there does not exist any other edge (a', b') that $a \le a' \le c < d \le b' \le b$;*
(minimal segment)	*a subtree $[c, d]$ is a* minimal segment *under an edge (a, b), if the edge (c, d) exists, and (a, b) is the overarching of (c, d); a subtree $[c, d]$ is an outmost minimal segment, if the edge (c, d) exists, and there is no overarching edge of (c, d).*

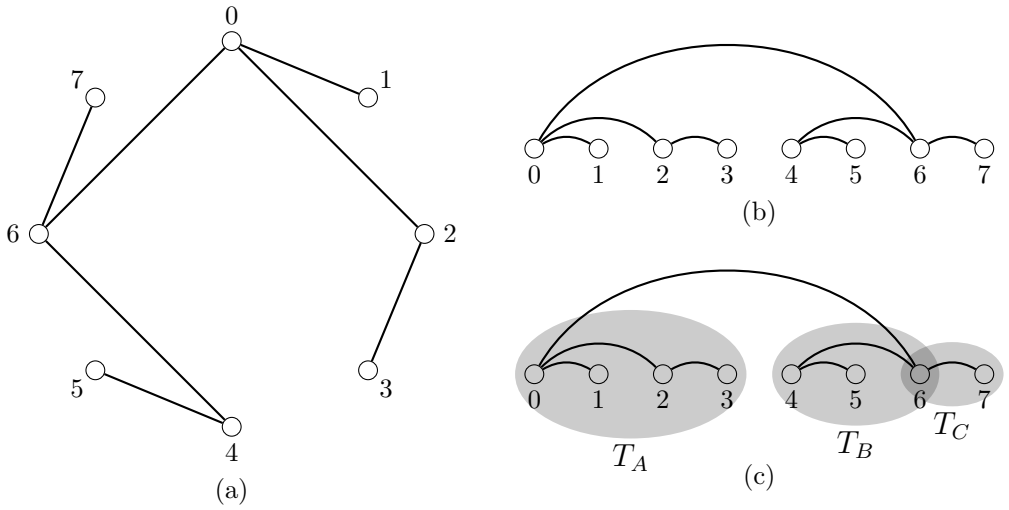

Figure 4 (a)(b) Two ways of representing a non-crossing spanning tree. The tree is corresponded to the 2-Dyck path in Example 6. (c) Decomposing the tree by Fact 8.

▶ **Example 12.** Consider the tree in Figure 4.

- The pivot edge of the whole tree is $(0, 6)$. The pivot edge of the subtree $[0, 3]$ is $(0, 2)$.
- The gap beneath the edge $(0, 6)$ is after 3. The gap beneath the edge $(4, 6)$ is after 5.
- The overarching edge of the edge $(0, 1)$ is $(0, 2)$, whose overarching edge is $(0, 6)$, which does not have any overarching edge.
- The minimal segments under the edge $(0, 6)$ are $[0, 2]$, $[2, 3]$ and $[4, 6]$. The outmost minimal segments are $[0, 6]$ and $[6, 7]$.

4 Spectral gap of the adjacent move chain

Over the state space of 2-Dyck paths of length $3n$, define the following *adjacent move chain*:

(1) starting from the current path X, choose a position $i \in [3n - 1]$;
(2) let X' be the same as X except that the steps at positions i and $i + 1$ are swapped;
(3) if X' is invalid, then the chain stays at X. Otherwise, it moves to X' with probability $1/2$ and stays at X with probability $1/2$.

Formally, let $B(X)$ be the set of 2-Dyck paths that can be obtained from X by swapping two adjacent coordinates. Trivially, $|B(X)| < n$. The transition probability of this chain is

$$P_{\mathrm{AM}}(X, X') = \begin{cases} 1 - \dfrac{B(X)}{6n-2} & \text{if } X = X'; \\ \dfrac{1}{6n-2} & \text{if } X' \in B(X); \\ 0 & \text{otherwise.} \end{cases} \tag{6}$$

Note that $P_{\mathrm{AM}}(X, X) \geq 4/5$. It is easy to see that P_{AM} is irreducible and verify that $P(X, X') = P(X', X)$, so P_{AM} is reversible.

We have the following bound on the mixing time of this chain.

▶ **Theorem 13.** $t_{\mathrm{mix}}(P_{\mathrm{AM}}) = O(n^3 \log n)$.

The proof essentially follows Wilson's coupling argument [48]. We use the same potential function and verify that the key properties for the mixing time upper bound still hold. (The properties in [48] for the mixing time lower bound no longer hold.) More details are given in the full version [4]. Combining Theorem 13 and (3) has an immediate corollary.

▶ **Corollary 14.** $1/\lambda(P_{\mathrm{AM}}) = O(n^3 \log n)$.

5 Adjacent move versus flip move

In this section we analyse the mixing time of the flip chain by comparing it with the adjacent move chain and using Corollary 14. The flip chain P_{FM} is a random walk on non-crossing spanning trees (or non-crossing trees), where in each step we remove an edge uniformly at random, and add back a non-crossing edge between the two components. Such a move is called an (edge) flip. Formally, given two non-crossing spanning trees S and T, the probability of moving from S to T is

$$P_{\mathrm{FM}}(S,T) = \begin{cases} \displaystyle\sum_{T':\ |S\cap T'|=n-1} \frac{1}{n\delta(S,T')} & \text{if } S = T; \\ \dfrac{1}{n\delta(S,T)} & \text{if } |S\cap T| = n-1; \\ 0 & \text{otherwise,} \end{cases} \tag{7}$$

where $\delta(S,T)$ is the number of edges that one can add to $S \cap T$ to make it a non-crossing spanning tree. Note that

$$P_{\mathrm{FM}}(S,S) \geq 1/n, \quad \text{and } P_{\mathrm{FM}}(S,T) \geq \Omega(n^{-3}) \text{ if it is non-zero.} \tag{8}$$

It is easy to see that P_{FM} is irreducible. Note when $|X\cap Y| = n-1$, $P(X,Y) = \frac{1}{n\delta(S,T)} = \frac{1}{n\delta(T,S)} = P(Y,X)$, and it is trivial to see that $P(X,Y) = P(Y,X)$ in the other two cases, so P_{FM} is symmetric, thus is reversible.

5.1 Characterise the adjacent move via flip moves

A single adjacent move on non-crossing spanning trees still requires altering an $\Omega(n)$ number of edges. Yet, we will show that it consists of a constant number of flip moves, plus one subtree *shifting*, taking the form of

moving from to or vice versa, (9)

where the bubble does not change. Note that the overarching edge of the subtree remains unchanged. This is formally defined as follows, using the non-crossing tree decomposition.

▶ **Definition 15** (shifting). *Let T be a non-crossing spanning tree of size m decomposing into (T_A, T_B, T_C) by Fact 8, where T_B and T_C are empty. Let T' be another non-crossing spanning tree of size m decomposing into (T'_A, T'_B, T'_C), where both T'_A and T'_C are empty, and $T'_B = T_A$. A* shifting *is the transformation from T to T' (right shifting) or from T' to T (left shifting).*

This particular form of shifting may look strange at first sight. A more intuitive version would be just moving a subtree left or right, without caring about the overarching edge or the other side of the gap. However, as it will become clear later when we bound the congestion of the paths, it is this form of shifting that allows an efficient encoding.

Next is the characterisation of an adjacent move via flip moves and shifting.

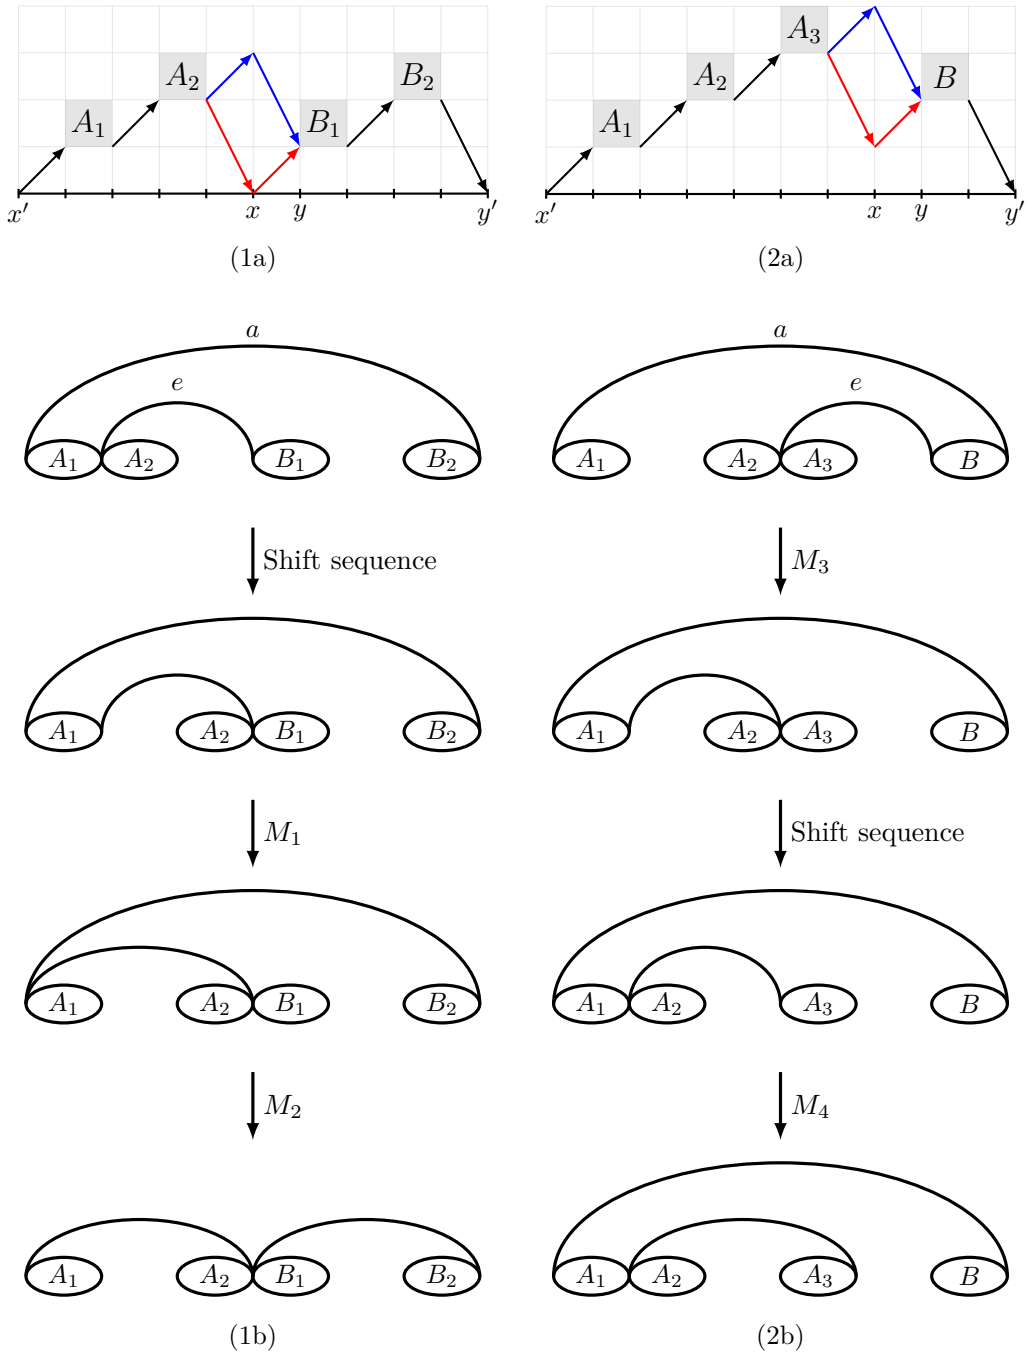

Figure 5 (∗a) The 2-Dyck path representations of $\tilde{I}$. In the adjacent move, the blue part is changed into red. (∗b) The corresponding flip move sequences. (1∗) Corresponding to **Type 1**. (2∗) Corresponding to **Type 2**.

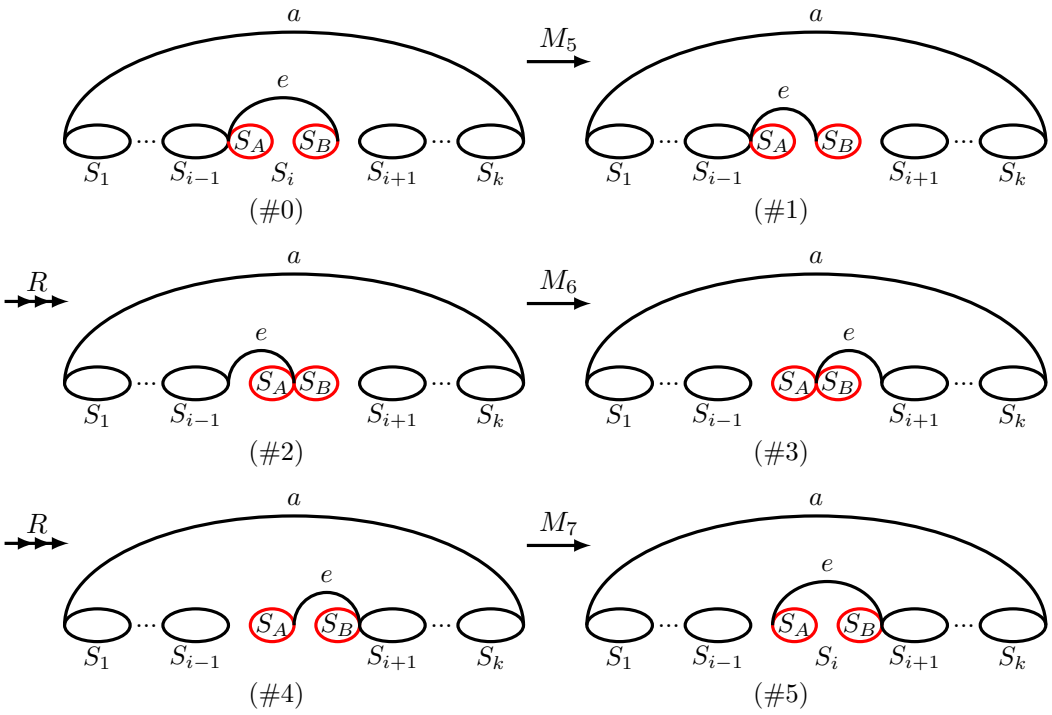

Figure 6 An example of a shift sequence. The black longer bubbles represent minimal segments, and there may be 0 or more of them. The red shorter bubbles represent valid sub-trees and are not necessarily minimal. The minimal segments $S_{i+1}, \ldots, S_k$ have finished moving, and $S_1, \ldots, S_{i-1}$ are yet to be moved, with S_i being the current one moving. M_5, M_6, M_7 are edge flips, and R represents a recursive move.

▶ **Lemma 16.** *Let $I \to F$ be a transition in the adjacent move P_{AM} such that $I \neq F$. This transition can be simulated from T_I to T_F by at most two edge flippings in P_{FM}, plus at most one shifting.*

The proof of Lemma 16 can be found in the full version [4]. There are two cases in this lemma, depending on whether one or two steps the first time the 2-Dyck path goes below the end of the adjacent move, which we call Type-1 and Type-2 moves. See Figure 5 (1a) and (2a) for illustrations of the two types of transitions. The flip moves to simulate the adjacent move are also intuitive. See the illustrations in Figure 5 (1b) and (2b).

The next step is to resolve the shifting, by designing a sequence of flippings that simulates it. We call this sequence of flip moves a *shift sequence*. The design of the shift sequence is the trickiest part of the whole comparison argument, because we have to be able to recover the initial and final states by just looking at a transition with some succinct extra encoding. We only need to deal with right shifting, as for left shifting we just reverse the sequence.

▶ **Lemma 17.** *Let T be a non-crossing spanning tree of m edges decomposing into (T_A, T_B, T_C) by Fact 8, where T_B and T_C are empty, and T_A is not empty. Then we can use $\ell \leq 3m$ flip moves to simulate a right shifting, i.e., reach a non-crossing spanning tree T' decomposing into (T'_A, T'_B, T'_C) where both T'_A and T'_C are empty, and $T'_B = T_A$.*

The proof of Lemma 17 can be found in the full version [4]. Essentially, we design a recursive way of simulating shifts. We decompose the subtree to shift into minimal segments, and then move them one at a time. To move a minimal segment, we perform edge flips so that subtrees of the minimal segment are in the form of a shift, and finish moving it using recursion. See Figure 6 for an illustration of an example.

Algorithm 1 Constructing the canonical path.

Input: two 2-Dyck paths $I \neq F$ of length $3n$ that $P_{\mathrm{AM}}(I, F) > 0$
Output: a canonical path $I = Z_0, Z_1, \cdots, Z_\ell$

Decide if I to F is a Type-1 or Type-2 move as in Lemma 16;
if *it is a Type-1 move* **then return** Transition1(I, F) **else return** Transition2(I, F);
procedure Transition1(I, F): `// Requiring` $I \to F$ `to be a Type-1 move.`
  Let $Z_0 \leftarrow I$;
  Find $a = (a_1, a_2)$, $e = (p, g_e + 1)$ and g_a as in Lemma 16;
  if $p \leq g_e - 1$ **then** let $(\ell - 2, Z_1, \cdots, Z_{\ell-2}) \leftarrow$ShiftRight$(p, g_e + 1, 1, 1)$;
  Perform an M_1 move of e to obtain $Z_{\ell-1}$;
  Let $Z_\ell \leftarrow F$, which is obtained by an M_2 move of e from $Z_{\ell-1}$;
  return $Z_0, \cdots, Z_\ell$;
procedure ShiftRight$(s, t, \mathsf{depth}, \mathsf{step})$:
  Let $k \geq 1$ be the number of minimal segments $S_1, \cdots, S_k$ beneath the edge (s, t);
  $\mathsf{last} \leftarrow \mathsf{step}$;
  for i *from* k *down to* 1 **do**
    Let $e = (p, q)$ be the pivot edge of S_i and g_e, g_{e+1} be the gap beneath e; `// (#0)`
    if $q \geq g_e + 2$ **then**
      Perform an M_5 move of e to obtain Z_{last}, and $\mathsf{last} \leftarrow \mathsf{last} + 1$; `// (#1)`
    if $p \leq g_e - 1$ **then**
      $(\ell', Z_{\mathsf{last}}, \cdots, Z_{\mathsf{last}+\ell'-1}) \leftarrow$ShiftRight$(p, g_e + 1, \mathsf{depth} + 1, \mathsf{last})$;
      Update $\mathsf{last} \leftarrow \mathsf{last} + \ell'$; `// (#2)`
    Perform an M_6 move of e to obtain Z_{last}, and update $\mathsf{last} \leftarrow \mathsf{last} + 1$; `// (#3)`
    if $q \geq g_e + 2$ **then**
      $(\ell'', Z_{\mathsf{last}}, \cdots, Z_{\mathsf{last}+\ell''-1}) \leftarrow$ShiftRight$(g_e + 1, q + 1, \mathsf{depth} + 1, \mathsf{last})$;
      Update $\mathsf{last} \leftarrow \mathsf{last} + \ell''$; `// (#4)`
    if $p \leq g_e - 1$ **then**
      Perform an M_7 move of e to obtain Z_{last}, and $\mathsf{last} \leftarrow \mathsf{last} + 1$; `// (#5)`
  return $(\mathsf{last} - \mathsf{step}, Z_{\mathsf{step}}, \cdots, Z_{\mathsf{last}})$;

5.2 Path construction

We are going to apply the path method, namely Theorem 3, to compare P_{AM} and P_{FM}. Because of the bijection between 2-Dyck paths and NCSTs, we simply treat P_{AM} and P_{FM} as having the same stationary distribution. To compare the two chains, we will need to construct a path (namely, a sequence of transitions) for any two 2-Dyck paths I and F where $P_{\mathrm{AM}}(I, F) > 0$ using only transitions in P_{FM}. We summarise the construction in Algorithm 1, with half of the procedure omitted due to redundancy. This construction follows closely the simulation of an adjacent move via two flip moves and one shifting in Lemma 16, and then simulating the shifting via flip moves in Lemma 17. The edges $a = (a_1, a_2)$, $e = (p, g_e + 1)$ and g_a in Transition1(I, F) are defined in the proof of Lemma 16. Intuitively, a and e are the distinguished edges marked in Figure 5, and $g_a, g_a + 1$ is the unique gap beneath a. The markers `(#0)` to `(#5)` are used in the proof of Lemma 19. We expand out the Type-1 move

and omit the details of the Type-2 move to avoid redundancy. (The flip moves for Type-2 moves are described in the proof of Lemma 16 and Figure 5(2∗), and the ShiftLeft sequence is the reverse of ShiftRight.)

Let T_I and T_F be the non-crossing spanning trees corresponding to I and F. The construction yields a path $T_I = Z_0 \to Z_1 \to \cdots \to Z_\ell = T_F$ where $P_{\mathrm{FM}}(Z_i, Z_{i+1}) > 0$ for any $i \le \ell - 1$. Its validity, namely that each transition is valid, is implied by Lemma 16 and Lemma 17. These two lemmas also imply an upper bound on the length of the path $\ell \le 3n + 2$ ($3n$ for the shift sequence and 2 for the two simple flips).

5.3 Bound the congestion

The goal of the Markov chain comparison argument is to show the following lemma:

▶ **Lemma 18.** *Let $\mathcal{E}_{\mathrm{AM}}$ be the Dirichlet form of the adjacent move chain P_{AM} over the uniform distribution of 2-Dyck paths of length $3n$, and $\mathcal{E}_{\mathrm{FM}}$ be the Dirichlet form of the flip chain P_{FM} over the uniform distribution of non-crossing spanning trees containing n edges. Then for all functions f, it holds that $\mathcal{E}_{\mathrm{FM}}(f, f) \ge \Omega(n^{-4}) \cdot \mathcal{E}_{\mathrm{AM}}(f, f)$.*

Lemma 18 is a straightforward application of Theorem 3 where we bound the congestion using Equation (8) and Corollary 20. The proof can be found in the full version [4].

The next lemma shows that our canonical path construction ensures that each transition in the flip move P_{FM} is used by a limited number of (I, F) pairs in the adjacent move P_{AM}. This is proved by designing an encoding such that we can uniquely recover the (I, F) pair from the current transition and the encoding. The number of (I, F) pairs is then bounded by the number of possible encodings, which we ensure to be linear in n.

▶ **Lemma 19** (encoding). *Let $Z \to Z'$ be a transition of P_{FM} over non-crossing spanning trees containing n edges. Let $I \ne F$ be two 2-Dyck paths such that $P_{\mathrm{AM}}(I, F) > 0$, and that the path constructed according to Algorithm 1 contains the transition $Z \to Z'$. Then there exists an injective mapping*

$$\varphi_{Z \to Z'} : \mathcal{T}_n \times \mathcal{T}_n \to \{\mathsf{Left}, \mathsf{Right}\} \times \{M_1, M_2, M_3, M_4, S_1, S_2\} \times [n]$$

where $\mathcal{T}_n$ is the set of all non-crossing spanning trees of n edges. In other words, given $Z \to Z'$, and (dir, M, d), we can uniquely determine I, F such that $\varphi_{Z \to Z'}(T_I, T_F) = (\mathsf{dir}, M, d)$, where $\mathsf{dir} \in \{\mathsf{Left}, \mathsf{Right}\}$, $M \in \{M_1, M_2, M_3, M_4, S_1, S_2\}$, and $d \in [n]$.

Proof sketch. We provide a proof sketch here, and the full proof can be found in the full version [4]. The mapping is defined as $\varphi_{Z \to Z'}(T_I, T_F) = (\mathsf{dir}, M, d)$, where

- dir indicates the direction of adjacent move from I to F,
- M indicates where the current transition $Z \to Z'$ is located in the construction of the canonical path, as in Algorithm 1, and
- d indicates the depth of the recursion of the shift sequence construction. It is defined only when $M \in \{S_1, S_2\}$, and otherwise arbitrary.

In particular, the six possibilities of M correspond to the six types of moves in Figure 5 (1b) and (2b), where $M_1, \cdots, M_4$ denote edge flips, and S_1 and S_2 denote shifting sequences.

To show the mapping is injective, we just need to be able to recover T_I and T_F given (dir, M, d). The transition $Z \to Z'$ gives the edge which is being moved in this step, and dir indicates if it is a left shifting or right shifting. First, we use M to determine where the current move is in the construction of the canonical path. If it is neither S_1 nor S_2, then the initial and final states can be reconstructed easily. Otherwise, the current step is in the

recursive construction of the canonical path. Starting from this edge being moved, together with the number d in the mapping above, we can find the sequence of overarching edges which the initial shifting involves. Furthermore, by looking at the current edge and the gap beneath its overarching edge, we can determine which step in the subroutine ShiftRight (or ShiftLeft) the current transition is in. This information allows us to rewind all the edge flips that have been performed and recover the initial state T_I. The final state T_F is recovered similarly. ◀

Let Γ_{IF} be the path from I to F. We write $(Z, Z') \in \Gamma_{IF}$ if the (Z, Z') transition is in the path Γ_{IF}. Lemma 19 immediately implies the following.

▶ **Corollary 20.** *For each (Z, Z') with $P_{\mathrm{FM}}(Z, Z') > 0$, there are at most $12n$ pairs (I, F) such that $(Z, Z') \in \Gamma_{IF}$.*

Proof of Theorem 1. We have

$$
\begin{aligned}
t_{\mathrm{mix}}(P_{\mathrm{FM}}) &\le \left(1 + \frac{1}{2}\log \pi_{\min}\right) \frac{1}{\lambda(P_{\mathrm{FM}})} = \left(1 + \frac{1}{2}\log \pi_{\min}\right) \frac{1}{\inf\left\{\frac{\mathcal{E}_{\mathrm{FM}}(f,f)}{\mathrm{Var}_\pi(f)}\right\}} && \text{(by (2))} \\
&\le \left(1 + \frac{1}{2}\log \pi_{\min}\right) \frac{O(n^4)}{\inf\left\{\frac{\mathcal{E}_{\mathrm{AM}}(f,f)}{\mathrm{Var}_\pi(f)}\right\}} && \text{(by Lemma 18)} \\
&= \left(1 + \frac{1}{2}\log \pi_{\min}\right) \frac{O(n^4)}{\lambda(P_{\mathrm{AM}})} && \text{(by (2))} \\
&= \left(1 + \frac{1}{2}\log \pi_{\min}\right) O(n^7 \log n) && \text{(by Corollary 14)} \\
&= O(n^8 \log n). && \blacktriangleleft
\end{aligned}
$$

Abstract

A *dichotomous ordinal graph* consists of an undirected graph with a partition of the edges into *short* and *long* edges. A *geometric realization* of a dichotomous ordinal graph G in a metric space X is a drawing of G in X in which every long edge is strictly longer than every short edge. We call a graph G *pandichotomous* in X if G admits a geometric realization in X for every partition of its edge set into short and long edges.

We exhibit a very close relationship between the degeneracy of a graph G and its *pandichotomic Euclidean or spherical dimension*, that is, the smallest dimension k such that G is pandichotomous in $\mathbb{R}^k$ or the sphere $\mathcal{S}^k$, respectively. First, every d-degenerate graph is pandichotomous in $\mathbb{R}^d$ and $\mathcal{S}^{d-1}$ and these bounds are tight for the sphere and for $\mathbb{R}^2$ and almost tight for $\mathbb{R}^d$, for $d \geq 3$. Second, *every* n-vertex graph that is pandichotomous in $\mathbb{R}^k$ has at most μkn edges, for some absolute constant $\mu < 7.23$. This shows that the pandichotomic Euclidean dimension of any graph is linearly tied to its degeneracy and in the special case $k \in \{1, 2\}$ resolves open problems posed by Alam, Kobourov, Pupyrev, and Toeniskoetter.

Further, we characterize which complete bipartite graphs are pandichotomous in $\mathbb{R}^2$: These are exactly the $K_{m,n}$ with $m \leq 3$ or $m = 4$ and $n \leq 6$. For general bipartite graphs, we can guarantee realizations in $\mathbb{R}^2$ if the short or the long subgraph is constrained: namely if the short subgraph is outerplanar or a subgraph of a rectangular grid, or if the long subgraph forms a caterpillar.

1 Introduction

For an *ordinal embedding*, we are given a set of objects $x_1, \ldots, x_n$ in an abstract space, together with a set of *ordinal constraints* of the form $\text{dist}(x_i, x_j) < \text{dist}(x_k, x_\ell)$. The objective is to compute a set of points $p_1, \ldots, p_n$ in a metric space while preserving as many ordinal constraints as possible. Ordinal embeddings were first studied in the 1960's by Shepard [20, 21] and Kruskal [13, 14] in the context of psychometric data analysis. Recently,

there have been applications in the field of Machine Learning [23]. The computation of ordinal embeddings is also known in the literature as *non-metric multi-dimensional scaling*. For an extensive literature review on ordinal embeddings refer to [24].

Of particular interest in relation to our work is the application of ordinal embeddings to the problem of recognizing multidimensional preferences [5, 7, 19] in the field of Computational Social Science. The objects are either *voters* or *options*, which, together with the ordinal constraints (i.e., the voters' preferences), naturally define a bipartite graph. However, the goal is to find an embedding in $\mathbb{R}^d$ where all constraints are satisfied rather than to seek for an approximation. Efficient algorithms exist when $d = 1$ [6, 7], while for any $d \geq 2$ the problem is as hard as the existential theory of the reals [19]. In the simplest case, the preferences form a *dichotomy*, that is, a voter may either support or reject an option [9, 19].

This setting is naturally modeled as a *dichotomous ordinal graph*, which consists of an undirected graph $G = (V, E_s \cup E_\ell)$ together with a partition of the edges into a set E_s of *short* edges and a set E_ℓ of *long* edges. A *geometric realization* of a dichotomous ordinal graph G is a drawing Γ of G in some metric space along with a threshold $\delta > 0$ such that the short edges of G are exactly those that have length at most δ in Γ. In this work we consider two natural classes of drawings in which edges are drawn as geometrically shortest paths: (1) straight-line drawings in the Euclidean space $\mathbb{R}^d$ and (2) geodesic drawings on the sphere $\mathcal{S}^d$. Figure 1 shows two straight-line drawings of the same dichotomous ordinal graph in $\mathbb{R}^2$. The drawing in (a) is a valid geometric realization, whereas the drawing in (b) is not.

A dichotomous ordinal graph may or may not be realizable in any particular space. For instance, it is easy to see that K_4 where the short edges induce a star cannot be realized in $\mathbb{R}^1$. In general, it is NP-hard to decide whether a dichotomous ordinal graph admits a geometric realization in $\mathbb{R}^2$, even if the underlying graph is a complete graph and the short edges induce a planar graph [3, Lemma 1]. According to Peters [19, Theorem 4] the problem is $\exists\mathbb{R}$-complete for bipartite graphs.[1]

(a) valid drawing of $\triangle uvw$. **(b)** invalid drawing of $\triangle uvw$.

Figure 1 A dichotomous ordinal triangle. Short edges are shown blue/solid, long edges red/dashed.

In light of the motivation, it is desirable that a geometric realization always exists, no matter the preferences of the voters. We call a graph $G = (V, E)$ *pandichotomous* in a metric space X if G admits a geometric realization in X for every partition of E into short and long edges. Graphs that are pandichotomous in $\mathbb{R}^1$ are also called total-threshold-colorable [1, 2] or total weak unit interval graphs [3]. Angelini, Bekos, Gronemann, and Symvonis [4] exhibited some graph classes that are pandichotomous in $\mathbb{R}^2$, such as *double-wheels* (a cycle and two

[1] But even the full version of the paper [18] does not contain an explicit proof but only refers to the work of Kang and Müller [12, Theorem 1]. The graph constructed in this proof is not bipartite. While it is plausible that the construction could be adapted, it does not seem immediately obvious to us.

additional vertices connected to all vertices of the cycle), *2-degenerate* graphs (can be reduced to the empty graph by repeatedly removing a vertex of degree at most two), and *subcubic* graphs (vertex degree at most three). On the negative side, there exists a dichotomous ordinal graph G whose underlying graph can be obtained from a double-wheel by adding a single edge such that G does not admit a geometric realization in $\mathbb{R}^2$ [4]. Clearly, being pandichotomous is a *monotone* graph property, that is, if a graph G is pandichotomous in X, then so is every subgraph of G. For $X = \mathbb{R}^d$, being pandichotomous is also closed under taking disjoint unions, but for $X = \mathcal{S}^d$ this is not immediate.

A related question is the existence of a realization of a graph as a *unit disk graph*, where vertices are represented by unit disks, and they are connected by an edge if and only if the corresponding disks intersect. More generally, the *sphericity* [10, 15] of a graph G is the smallest d such that G can be realized as an intersection graph of unit balls in $\mathbb{R}^d$. The main difference between geometric realizations of dichotomous ordinal graphs and unit ball realizations lies in the different types of edges. In a unit disk realization there are only two types: edge and non-edge, and all of them have to be faithfully represented. In a geometric realization of dichotomous ordinal graphs there are three types of edges: long, short, and non-edges, and we have no constraints concerning the last type. Therefore, only upper bounds on the sphericity carry over to the dichotomous setting. Since every graph on n vertices has sphericity at most n [15], every graph on n vertices is also pandichotomous in $\mathbb{R}^n$. So for every finite graph G we can define its *pandichotomic Euclidean dimension* $\mathrm{ped}(G)$ to be the smallest dimension d such that G is pandichotomous in $\mathbb{R}^d$. Analogously, we define the *pandichotomic spherical dimension* $\mathrm{psd}(G)$. Trivially, $\mathrm{ped}(G) \leq \mathrm{psd}(G) + 1$.

Results. In this paper, we initiate the study of the pandichotomic dimension of graphs, with a focus on the bipartite case. In Section 3, we characterize the complete bipartite graphs that are pandichotomous in $\mathbb{R}^2$. Specifically, we show that $K_{m,n}$ is pandichotomous in $\mathbb{R}^2$ if and only if either (1) $m \leq 3$ or (2) $m = 4$ and $n \leq 6$.

A dichotomous ordinal graph has two natural induced subgraphs: The *short* subgraph, induced by the short edges, and the *long* subgraph, induced by the long edges. In Section 4, we show that if either of these subgraphs is sufficiently constrained, then a realization in $\mathbb{R}^2$ always exists. Specifically, this is the case if (1) the graph is bipartite and the short subgraph is outerplanar (Theorem 8); (2) the short subgraph forms a subgraph of a rectangular grid (Theorem 9); or (3) the long subgraph forms a caterpillar (Theorem 10). In (1) and (2), we can also ensure that the short subgraph is realized without edge crossings. However, there are bipartite dichotomous ordinal graphs that do not admit a geometric realization in $\mathbb{R}^2$, even though the short subgraph is planar (see, e.g., Lemma 6).

In Section 5, we study the pandichotomic Euclidean dimension and show that it is very closely related to the degeneracy. A graph is *k-degenerate* if it can be constructed starting from the empty graph by iteratively applying the following operation: Add a new vertex and make it adjacent to at most k existing vertices. The *degeneracy* $\mathrm{d}(G)$ of a graph G is the smallest k such that G is k-degenerate.

We show that all d-degenerate graphs are pandichotomous on $\mathcal{S}^{d-1}$ and in $\mathbb{R}^d$, for $d \geq 2$ (Theorem 11). In particular, it follows that all bipartite planar graphs are pandichotomous on $\mathcal{S}^2$ and in $\mathbb{R}^3$ (Corollary 12). Our bounds imply $\mathrm{ped}(G) \leq \mathrm{d}(G)$ and $\mathrm{psd}(G) \leq \mathrm{d}(G) - 1$, for every graph G with $\mathrm{d}(G) \geq 2$. We also show that these bounds are tight for the sphere (Corollary 14) and for $\mathbb{R}^2$ (Theorem 15) and almost tight for $\mathbb{R}^d$, for $d \geq 3$ (Theorem 13).

We also show that *every* n-vertex graph that is pandichotomous in $\mathbb{R}^d$ has at most μdn edges, for some constant $\mu < 7.23$ (Theorem 16), and this bound is optimal up to the value of μ. In the special cases $d \in \{1, 2\}$, this affirmatively answers two open problems posed explicitly by

Alam, Kobourov, Pupyrev, and Toeniskoetter [3]. Consequently, $\mathrm{d}(G)/(2\mu) \leq \mathrm{ped}(G) \leq \mathrm{d}(G)$ and $\mathrm{d}(G)/(2\mu) - 1 \leq \mathrm{psd}(G) \leq \mathrm{d}(G) - 1$, for every graph G (Corollary 19). In other words, the pandichotomic Euclidean and spherical dimensions are linearly tied to the degeneracy. As a direct consequence of these bounds (Corollary 20), we determine up to a constant factor the smallest dimension d for which every n-vertex (bipartite) dichotomous ordinal graph is realizable in $\mathbb{R}^d$ (or $\mathcal{S}^{d-1}$).

2 Preliminaries

For two points $p, q \in \mathbb{R}^d$ we denote by $\|p - q\|$ the Euclidean distance between p and q. For a point $c \in \mathbb{R}^d$ and a positive real number r, the *ball* $\mathrm{B}(c, r)$ of radius r around c is the set $\{p \in \mathbb{R}^d \colon \|p - c\| \leq r\}$ of all points that have Euclidean distance at most r to c. For a set $A \subset \mathbb{R}^d$ we denote by ∂A the *boundary* of A. The boundary of $\mathrm{B}(c, r)$ is formed by the *sphere* $\mathrm{S}(c, r) = \{p \in \mathbb{R}^d \colon \|p - c\| = r\}$. A *unit* ball or sphere has a radius of $r = 1$. The *geodesic distance* $\mathrm{d}_\gamma(p, q) \in [0, 2\pi]$ between two points $p, q \in \mathcal{S}_d$ is determined by the central angle of a shortest great circle arc between p and q.

Given a finite set X of geometric objects, such as hyperplanes or spheres, in $\mathbb{R}^d$, the *arrangement* $\mathcal{A}(X)$ of X is the partition of $\mathbb{R}^d$ induced by X into so-called cells of various dimension. The maximal connected open subsets of $\mathbb{R}^d \setminus \bigcup_{R \in X} R$ are the *d-cells* of $\mathcal{A}(X)$. And every relatively open k-dimensional intersection of two or more d-cells forms a k-cell of $\mathcal{A}(X)$. The d-cells are also called *full-dimensional cells* or even just *cells* of $\mathcal{A}(X)$. The 0-cells and 1-cells are also called *vertices* and *edges* of $\mathcal{A}(X)$, respectively.

For geometric realizations of dichotomous ordinal graphs in $\mathbb{R}^d$ we may fix a global scale and assume without loss of generality a threshold of $\delta = 1$. Furthermore, as we consider finite graphs only, we may assume that no two vertices have distance exactly one.

▶ **Observation 1.** *If a dichotomous ordinal graph admits a geometric realization in $\mathbb{R}^d$, then it admits a realization in $\mathbb{R}^d$ where no two vertices have distance exactly one.*

In contrast, such a global rescaling does not work in general for geometric realizations on $\mathcal{S}^d$. If the short subgraph of a dichotomous ordinal graph has several connected components, then we can draw these components mutually far apart. This yields the following.

▶ **Observation 2.** *A dichotomous ordinal graph admits a geometric realization in $\mathbb{R}^d$ if and only if each subgraph induced by a connected component of its short subgraph does.*

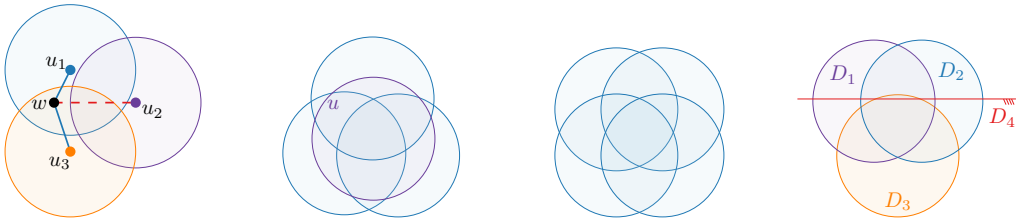
3 Complete Bipartite Graphs

In this section, we prove the following theorem. The proof is split into Lemmas 4, 6, and 7, in combination with the fact that being pandichotomous is a monotone graph property.

▶ **Theorem 3.** *The complete bipartite graph $K_{m,n}$ is pandichotomous in $\mathbb{R}^2$ if and only if either (1) $m \leq 3$ or (2) $m = 4$ and $n \leq 6$.*

A convenient way to reason about geometric realizations for bipartite graphs is in terms of arrangements of spheres. Consider a bipartite dichotomous ordinal graph $G = (U \cup W, E)$ and suppose that the vertices of U are already drawn as points in $\mathbb{R}^d$. Then, to obtain a geometric realization for G the task is to place each $w \in W$ such that for each $u \in U$ with $uw \in E$ we have $w \in \mathrm{B}(u, 1)$ if and only if the edge uw is short; see Figure 2a.

Let $U = \{u_1, \ldots, u_n\}$, let $D_i = \mathrm{B}(u_i, 1)$, let $C_i = \partial D_i$, and let $\mathcal{C}$ denote the arrangement of $C_1, \ldots, C_n$. To every vertex $w \in W$ we associate a set $V(w) \subseteq U$ such that $u \in V(w)$ if and only if uw is a short edge in G. We refer to $V(w)$ as a *singleton*, a *pair*, or a *triple*



(a) $K_{3,m}$ **(b)** $K_{4,m}$ all pairs **(c)** $K_{4,m}$ all triples **(d)** arbitrary radii

Figure 2 Arrangements of circles to represent one color class of a bipartite graph in $\mathbb{R}^2$.

if $|V(w)| = 1$, 2, or 3, respectively. A subset $X \subseteq U$ is *realized* by a drawing of U if there is a cell r in $\mathcal{C}$ such that $r \subseteq D_i$ if and only if $u_i \in X$. Then G admits a geometric realization if and only if there exists a drawing of U where $V(w)$ is realized, for all $w \in W$.

▶ **Lemma 4.** *The complete bipartite graph $K_{3,m}$ is pandichotomous in $\mathbb{R}^2$, for all $m \in \mathbb{N}$. The complete bipartite graph $K_{4,m}$ is pandichotomous in $\mathbb{R}^2$, for all $1 \leq m \leq 6$.*

Proof. For $K_{3,m}$ we can draw $U = \{u_1, u_2, u_3\}$ so that all eight subsets of U are realized; see Figure 2a. Therefore, any dichotomous ordinal $K_{3,m}$ admits a geometric realization. For $|U| \geq 4$ such a universal placement is not possible because an arrangement of n circles has at most $n(n-1)+2$ cells [22]. So an arrangement of four circles has at most 14 cells, whereas a four-element set has 16 subsets. However, for $|U| = 4$ and $|W| \leq 6$ we can always obtain a geometric realization as follows. Let $V(W) = \{V(w) \colon w \in W\} \subset 2^U$.

If there are at least three pairs in $V(W)$, then, given that $|V(W)| \leq |W| \leq 6$, the number of triples plus the number of singletons in $V(W)$ together is at most three. Thus, as $|U| = 4$, there exists a vertex $u \in U$ such that $\{u\} \notin V(W)$ and $U \setminus \{u\} \notin V(W)$. So we can use the drawing depicted in Figure 2b, where we assign u to the central disk. As all subsets of U other than $\{u\}$ and $U \setminus \{u\}$ are realized, this is a valid geometric realization of G.

Otherwise, there are at most two pairs in $V(W)$. We use the drawing depicted in Figure 2c, where we assign the vertices of U to the disks so that both pairs in $V(W)$ appear consecutively in the circular order of disks. (This works regardless of whether or not these pairs share a vertex.) As all subsets of U other than the two pairs that correspond to opposite circles in the drawing are realized, this is a valid geometric realization of G. ◀

The following elementary lemma about unit disks turns out helpful.

▶ **Lemma 5.** *Let D, E be unit disks in $\mathbb{R}^2$, let c be a chord of D, and let A be a closed part of D bounded by c and ∂D whose interior A° does not contain the center of D. Then $c \subset E \iff A \subset E$.*

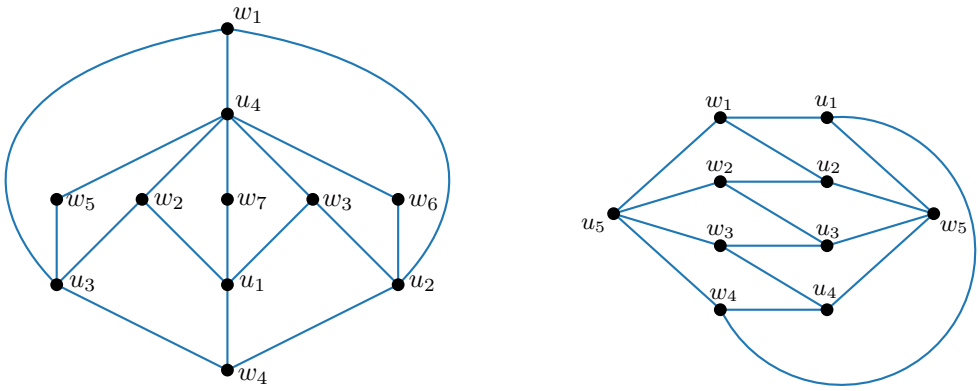
▶ **Lemma 6.** *There exists a dichotomous ordinal $K_{4,7}$ that is not realizable in $\mathbb{R}^2$.*

Proof Sketch. Let $U = \{u_1, u_2, u_3, u_4\}$ and $W = \{w_1, \ldots, w_7\}$ denote the vertex partition. For each w_i, we can specify an associated set $U_i \subseteq U$ (such that exactly the edges between w_i and U_i are short; see Figure 3a). We choose all four subsets of size three and the three subsets of size two that contain u_4, and distribute them among the vertices of W arbitrarily. In any geometric representation, each set U_i corresponds to a cell in the induced arrangement $\mathcal{C}$ of unit circles. Two more cells are required implicitly: The outer cell, which corresponds to $\emptyset \subset U$, and a cell that corresponds to the whole set U and is required by Helly's Theorem [11] because disks are convex and we specified all triples to be among the sets U_i.

Using these properties of $\mathcal{C}$ we can show that it cannot be realized using unit circles. It is crucial that the circles must have the same radius: If arbitrary radii are allowed, then a geometric realization exists (Figure 2d). ◀

▶ **Lemma 7.** *There exists a dichotomous ordinal $K_{5,5}$ that is not realizable in $\mathbb{R}^2$.*

Proof. First we specify a dichotomous ordinal $K_{5,5}$, see Figure 3 for an illustration.



(a) short edges of $K_{4,7}$ **(b)** short edges of $K_{5,5}$

Figure 3 A dichotomous ordinal $K_{4,7}$ and $K_{5,5}$, respectively, that does not admit a geometric realization. The drawn edges are the short edges. Edges between vertices labeled u on one hand and w on the other hand, that are not drawn, are long.

Let $U = \{u_1, u_2, u_3, u_4, u_5\}$ and $W = \{w_1, w_2, w_3, w_4, w_5\}$ denote the partition of the vertex set. To each $w_i \in W$, for $1 \leq i \leq 5$, we associate a set $\alpha(w_i) \subseteq U$ as follows:

$$\alpha(w_i) = \{u_i, u_{i\oplus 1}, u_5\}, \text{for } 1 \leq i \leq 4, \text{ and } \alpha(w_5) = U \setminus \{u_5\},$$

where $i \oplus 1 = (i \bmod 4) + 1$. Now consider an arbitrary but fixed geometric realization of this dichotomous ordinal $K_{5,5}$. In a slight abuse of notation we identify the vertices with the corresponding points in the geometric realization. Denote by D_i the unit disk centered at u_i, which represents the region of points that are in short distance to u_i. Let $W^- = \{w_1, w_2, w_3, w_4\}$. As $W^- \subset D_5$, whereas $w_5 \notin D_5$, by convexity of D_5 all points of W^- lie in an open halfplane through w_5. Let $\phi_1, \phi_2, \phi_3, \phi_4$ denote the counterclockwise order of the points from W^- around w_5 within this halfplane. By symmetry of W^- we may assume that $\phi_1 = w_1$ without loss of generality. We consider two cases.

Case 1: The set $\alpha(\phi_4)$ contains one of u_1 or u_2. Then by symmetry between u_1 and u_2 we may assume without loss of generality that $\phi_4 = w_4$. See Figure 4 (left) for illustration. By convexity of D_1, the triangle $\triangle = w_1w_4w_5 = \phi_1\phi_4w_5$ is contained in D_1. As $w_2, w_3 \notin D_1$, we have $\phi_2, \phi_3 \notin \triangle$. As $w_2, w_3, w_5 \in D_3$ but $w_1, w_4 \notin D_3$, the circle ∂D_3 crosses the line segment w_1w_4 twice in D_5, and it also crosses both of the line segments $\phi_1\phi_2$ and $\phi_3\phi_4$. Similarly, as $\triangle \subset D_1$ but $w_2, w_3 \notin D_1$, the circle ∂D_1 crosses both line segments w_5w_2 and w_5w_3, and it also crosses both of the line segments $\phi_1\phi_2$ and $\phi_3\phi_4$. Let c denote the chord of D_3 induced by $\phi_1\phi_4$. As $D_1 \supset c$, by Lemma 5 we know that D_1 contains the part A of D_3 on the side of c that does not contain the center of D_3. This is the part that contains w_5 because the other part contains $\phi_2, \phi_3 \notin D_1$. Similarly, as $D_5 \supset c$, by Lemma 5 it follows that also $D_5 \supset A$, which is a contradiction to $w_5 \notin D_5$. Thus, this case is impossible.

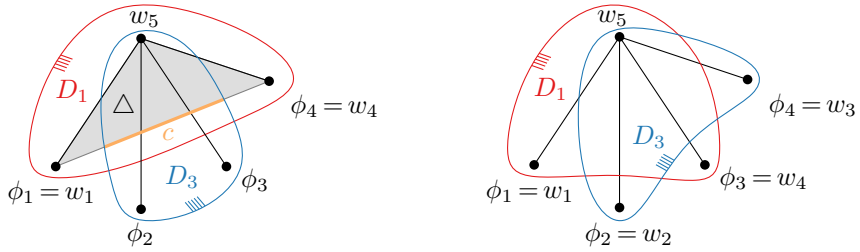


Figure 4 The two cases in the proof of Lemma 7.

Case 2: The set $\alpha(\phi_4)$ does not contain any of u_1 or u_2. Then we have $\phi_4 = w_3$ and both $|\alpha(\phi_1) \cap \alpha(\phi_3)| = 1$ and $|\alpha(\phi_2) \cap \alpha(\phi_4)| = 1$. By symmetry we may assume without loss of generality that $\phi_2 = w_2$ and $\phi_3 = w_4$. See Figure 4 (right) for illustration. Consider the two disks D_1 and D_3. They both contain w_5, and so the corresponding circles ∂D_1 and ∂D_3 intersect all of the rays $w_5\phi_i$, for $1 \leq i \leq 4$. As $\phi_1, \phi_3 \in D_1 \setminus D_3$ and $\phi_2, \phi_4 \in D_3 \setminus D_1$, the rays $w_5\phi_1$ and $w_5\phi_3$ intersect ∂D_1 before ∂D_3, whereas the rays $w_5\phi_2$ and $w_5\phi_4$ intersect ∂D_3 before ∂D_1. But then ∂D_1 and ∂D_3 cross in each of the cones $\phi_i w_5 \phi_{i+1}$, for $1 \leq i \leq 3$, which is impossible, since any two distinct circles intersect in at most two points.

As we arrived at a contradiction in both cases, we conclude that no geometric realization of this dichotomous ordinal $K_{5,5}$ exists. If, however, we allow disks with arbitrary radii, then a geometric realization exists, as depicted in Figure 5. ◀

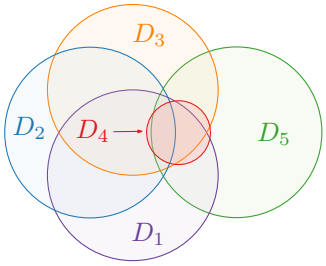

Figure 5 A realization of the dichotomous ordinal $K_{5,5}$ from Lemma 7 by disks of arbitrary radii.

4 Graphs with Constrained Short or Long Subgraphs

We show that every bipartite dichotomous ordinal graph admits a geometric realization if the short subgraph G_s is outerplanar or a subgraph of the rectangular grid or if the long subgraph G_ℓ is a caterpillar. In the first case, we construct a plane drawing of G_s in which the BFS-layers are drawn on horizontal lines (Figure 7b). In the second case, we suitably perturb the grid (Figure 6). And in the third case, we suitably place points on $\mathcal{S}^2$.

▶ **Theorem 8.** *A bipartite dichotomous ordinal graph admits a geometric realization if the subgraph induced by the short edges is outerplanar.*

Proof Sketch. Let $G = (V, E_s \cup E_\ell)$ be a bipartite dichotomous ordinal graph such that $G_s = (V, E_s)$ is outerplanar. By Observation 2, we may assume that G_s is connected. We root G_s at an arbitrary vertex r. Let V_k, $k = 0, \ldots$, be the BFS layers of G_s rooted at r, i.e., $V_0 = \{r\}$, V_1 is the set of neighbors of r, and V_{k+1}, $k \geq 1$ is the set of neighbors of the vertices in V_k that are not already in V_{k-1}. We say that w is a *child* of v and v is a *parent* of w if vw is an edge of G_s, $v \in V_k$ and $w \in V_{k+1}$ for some k. By outerplanarity, each vertex has at most two parents. We construct a planar drawing of G_s with the following properties.

- The root r is drawn with y-coordinate $y_0 = 0$. All vertices in layer V_k, $k > 0$ are on a horizontal line ℓ_k with y-coordinate y_k strictly between $k-1$ and k.
- The distance between a vertex and its children is at most 1 while the distance between two vertices on consecutive layers is greater than 1 if they are not adjacent in G_s.
- For each vertex v there is a vertical strip S_v such that
  - v is in S_v,
  - S_w is contained in the union of the strips of w's parents,
  - S_u and S_v are internally disjoint if u and v are on the same layer.

Special care has to be taken if a vertex $w \in V_{k+1}$ has two parents u and v, i.e., if w closes an internal face. In that case, we want to draw w on line ℓ_{k+1}, on the common boundary of S_u and S_v, and with distance exactly one to both u and v. ◀

▶ **Theorem 9.** *A dichotomous ordinal graph $G = (V, E_s \cup E_\ell)$ admits a geometric realization if the set of short edges induces a subgraph of the grid.*

Proof Sketch. Extend $G_s = (V, E_s)$ by the remaining grid edges and require the new edges to be long. Use the construction in Figure 6 to place the vertices. Then the short edges are shorter than $n^2 + 1/2$, while the long edges have length at least $n^2 + 1$. Scale the drawing. ◀

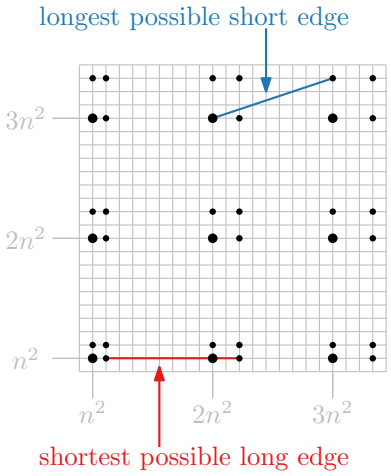

Figure 6 For each grid point (i, j), $1 \le i \le n$, $1 \le j \le n$ there are four possible points. If $i > 1$, the x-coordinate is in^2 if the edge between $(i-1, j)$ and (i, j) is short and $in^2 + i$ otherwise. If $j > 1$, the y-coordinate is jn^2 if the edge between $(i, j-1)$ and (i, j) is short and $jn^2 + j$ otherwise.

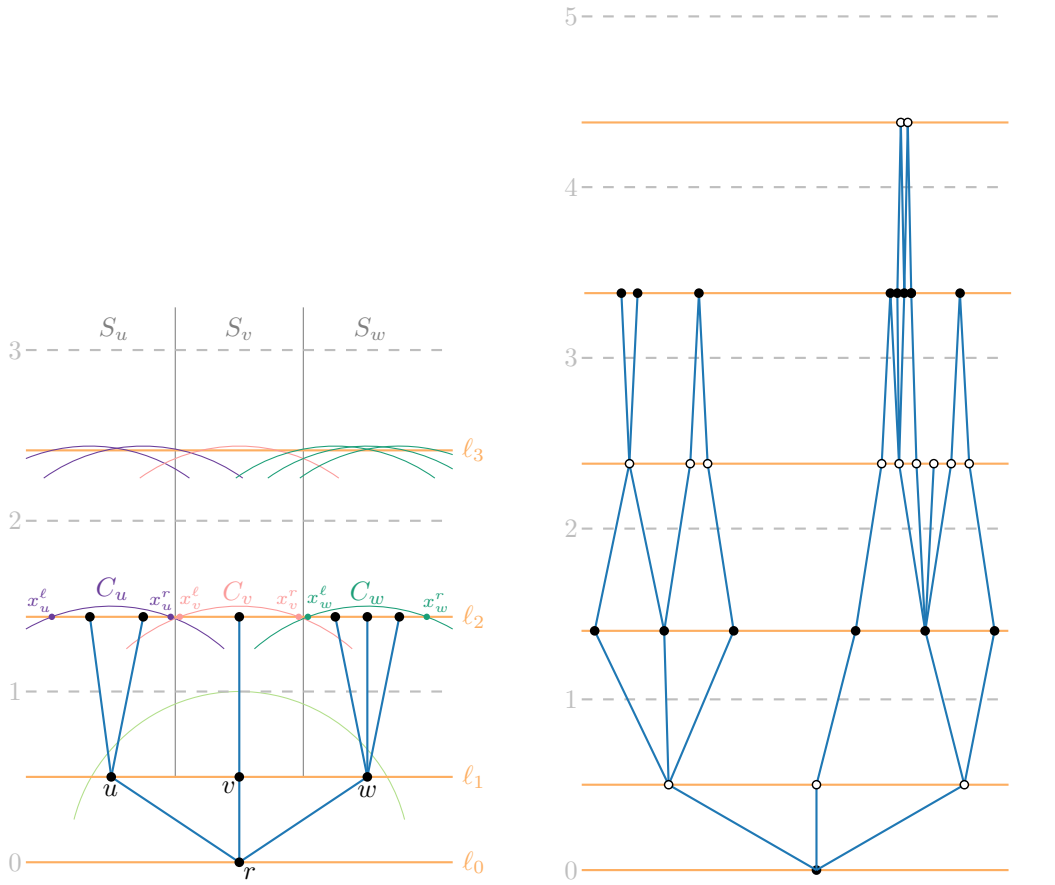
▶ **Theorem 10.** *A dichotomous ordinal graph admits a geometric realization in $\mathbb{R}^2$ and on $\mathcal{S}^2$ if each component of the long subgraph forms a caterpillar.*

Proof Sketch. We draw the vertices on a circle C of radius $\frac{1}{2} + \epsilon$, for some small $\epsilon > 0$. For each point $p \in C$ there is a region $R(p) \subset C$ around its antipodal point $\overline{p}$ such that for a point $q \in C$ we have $||p - q|| > 1 \iff q \in R(p)$. We draw the vertices $v_1, \ldots, v_k$ on the spine such that for $i = 1, \ldots, k-1$ the vertex v_{i+1} lies at the counterclockwise boundary of $R(v_i)$. Then we place the leaves (if any) attached to v_i within a very short arc around the point v_i' close to $\overline{v_i}$. More precisely, we obtain v_i' by shifting $\overline{v_i}$ counterclockwise along C by a small angle that monotonically increases with i. In this way, we ensure that the leaves of v_i are far from v_i but close to the leaves of the neighbors of v_i along the spine. ◀



(a) construction for a tree

Figure 7 How to construct a geometric realization of a bipartite dichotomous ordinal graph if the short edges induce an outerplanar graph.

5 Pandichotomic Dimension and Degeneracy

In this section, we exhibit a strong connection between the degeneracy of a graph and its pandichotomic dimension. Among others, we show that the pandichotomic dimension is bounded both from above and from below by a linear function of the degeneracy, and we give bounds on the coefficients in these linear functions.

▶ **Theorem 11.** *Every d-degenerate graph, for $d \geq 2$, is pandichotomous on $\mathcal{S}^{d-1}$ and in $\mathbb{R}^d$.*

Proof. Let G be a d-degenerate dichotomous ordinal graph, for $d \geq 2$, and let $u_1, \ldots, u_n$ be a vertex ordering such that u_i has at most d neighbors in $\{u_1, \ldots, u_{i-1}\}$, for $1 \leq i \leq n$. To obtain a geometric realization of G we place the vertices on the sphere $S = \{p \in \mathbb{R}^d \colon \|p\| = \sqrt{2}/2\}$ such that for every d-tuple of vertices the corresponding vectors are linearly independent. For a vertex $p \in S$ denote by $\vec{v}_p$ the corresponding vector; the points in distance less than one to p on S form a hemisphere, which consists of all points $q \in S$ such that $\vec{v}_p \vec{v}_q > 0$, where $\vec{v}_p \vec{v}_q$ denotes the scalar product between $\vec{v}_p$ and $\vec{v}_q$.

We place the vertices $u_1, \ldots, u_n$ in this order. The first vertex u_1 is placed arbitrarily on S. Then for each u_i, for $2 \leq i \leq n$, we have a set $Q = \{q_1, \ldots, q_t\} \subset S$ of points, which correspond to the $t \leq d$ neighbors of u_i in $u_1, \ldots, u_{i-1}$. Further, for each point in Q we know whether it should be close to or far from u_i. Now we need to find a suitable point on S that satisfies these constraints. We obtain the set $Q' = \{q'_1, \ldots, q'_t\}$ from Q by setting $q'_j = q_j$, if q_j should be close to u_i and setting q'_j to the point antipodal to q_j on S if q_j should be far from u_i. As Q is linearly independent, so is Q'. Furthermore, the linear system $\vec{v}_{q'_j} \vec{x} = \vec{1}$, for $1 \leq j \leq t$, has a (unique) solution $\vec{x}_0$. Normalizing $\vec{x}_0$ we obtain a point $r \in S$, such that $\vec{v}_r \vec{v}_{q'_j} > 0$, for all $1 \leq j \leq t$. Thus, we can place u_i at r such that all constraints with respect to Q are satisfied. The points on S that lie in a k-dimensional subspace spanned by k vertices, for $k < d$, can easily be avoided when selecting r. In this way we ensure that for all d-tuples of vertices on S the corresponding vectors are linearly independent. This realization also works for geodesic distances on $\mathcal{S}^{d-1}$ if we take an arc with angle $\pi/2$ as a unit. ◀

▶ **Corollary 12.** *Every bipartite planar graph is pandichotomous on $\mathcal{S}^2$ and in $\mathbb{R}^3$.*

Proof. Let $G = (V, E)$ be a planar bipartite graph on n vertices. As a consequence of Euler's formula, we have $|E| \leq 2n - 4$. By the handshaking lemma $\sum_{v \in V} \deg(v) = 2|E| \leq 4n - 8$ and, thus, the average degree in G is strictly less than 4. Consequently, every planar bipartite graph is 3-degenerate, and the statement follows by Theorem 11. ◀

We contrast the upper bound on the pandichotomic dimension in terms of the degeneracy provided by Theorem 11 by an almost matching lower bound in the Euclidean (Theorem 13) and a matching lower bound in the spherical case (Corollary 14), even for bipartite graphs. Note that every lower bound example is not just sporadic but spans an infinite family of examples, given that being pandichotomous is a monotone graph property.

▶ **Theorem 13.** *For every $d \geq 2$, there exists a $(d+2)$-degenerate bipartite graph that is not pandichotomous in $\mathbb{R}^d$.*

Proof. We build a graph $G = (V, E)$ starting with a set V_0 of $d + 2$ isolated vertices. Then for each of the 2^{d+2} many choices of assigning short or long to the vertices of V_0 we add a new vertex and connect it by edges to V_0 accordingly. Observe that G is bipartite and $(d + 2)$-degenerate by construction. Consider a geometric realization of G and the corresponding arrangement $\mathcal{A}$ of the $d + 2$ unit spheres centered at the vertices of V_0. In order to bound the number of full-dimensional cells in $\mathcal{A}$, we consider the standard parabolic lifting map λ, which orthogonally projects a point in $\mathbb{R}^d$ to the unit paraboloid in $\mathbb{R}^{d+1}$. This map has a number of useful properties, see, for instance, Edelsbrunner's book [8, Section 1.4]. Specifically, the image $\lambda(S)$ of a sphere $S \subset \mathbb{R}^d$ lies on a hyperplane $h_S \subset \mathbb{R}^{d+1}$ such that a point $p \in \mathbb{R}^d$ lies inside S if and only if its image $\lambda(p)$ lies below h_S. It follows that we may regard $\mathcal{A}$ as an arrangement of $d + 2$ hyperplanes in $\mathbb{R}^{d+1}$. As such an arrangement has at most $\sum_{i=0}^{d+1} \binom{d+2}{i} = 2^{d+2} - 1 < 2^{d+2}$ many full-dimensional cells [16, Proposition 6.1.1], for at least one of the vertices in $V \setminus V_0$ its distance requirements with respect to V_0 are violated. Thus, there is no geometric realization of G in $\mathbb{R}^d$. ◀

▶ **Corollary 14.** *For every $d \geq 2$, there exists a $(d+1)$-degenerate bipartite dichotomous ordinal graph that is not realizable on $\mathcal{S}^{d-1}$.*

Proof. We use the same graph G as in the proof of Theorem 13, except that we start with a set V_0 of $d+1$ rather than $d+2$ isolated vertices. We consider $\mathcal{S}^{d-1}$ as a unit sphere $S \subset \mathbb{R}^d$. For a point $p \in S$, the set of points on S in distance at most some fixed unit from p can be expressed as an intersection $S \cap u_p$ where u_p is a halfspace.

Suppose there is some geometric realization of G, and let $P \subset S$ denote the set of $d+1$ points that represent the vertices of V_0 in this realization. Consider the set H of the $d+1$ bounding hyperplanes of the halfspaces u_p, for $p \in P$. The arrangement $\mathcal{A}$ of H has at most $\sum_{i=0}^{d} \binom{d+1}{i} = 2^{d+1} - 1 < 2^{d+1}$ many full-dimensional cells [16, Proposition 6.1.1]. Thus, for at least one of the vertices in $V \setminus V_0$ there is no cell that satisfies its distance requirements with respect to V_0. It follows that there is no geometric realization of G in $\mathcal{S}^{d-1}$. ◀

In the Euclidean case, we give a tight lower bound in $\mathbb{R}^2$, albeit not for bipartite graphs.

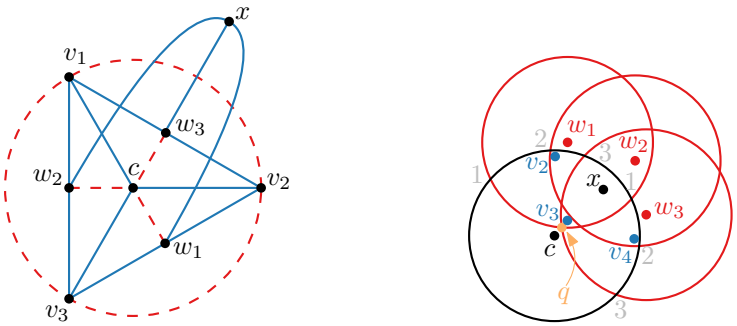

Figure 8 A 3-degenerate graph that cannot be realized in the plane along with a sketch of the proof. Long edges are dashed. The three points v_1, v_2, v_3 would have to lie in the intersection of the disk $B(c,1)$ and a unit disk within $B(w_1,1) \cup B(w_2,1) \cup B(w_3,1)$. But there is not enough space for three points with pairwise distance at least one.

▶ **Theorem 15.** *There exists a 3-degenerate graph that is not pandichotomous in $\mathbb{R}^2$.*

Proof. We build a dichotomous ordinal graph G on eight vertices as follows (Figure 8). Start with a set $V = \{v_1, v_2, v_3\}$ and a complete graph on V, all edges long. Then insert a vertex c and connect it to all vertices in V by a short edge. Next, insert a set $W = \{w_1, w_2, w_3\}$ of vertices as follows: the vertex w_i, for $i \in \{1,2,3\}$, is connected to c by a long edge and to each vertex in $V_i^- := V \setminus \{v_i\}$ by a short edge. Finally, we add a vertex x that is connected to all vertices in W by a short edge. Observe that G is 3-degenerate as constructed.

Consider any geometric realization Γ of G. In a slight abuse of notation we identify the vertices of G with the corresponding points that represent them in Γ. For a set $P \subset \mathbb{R}^2$ denote $I(P) = \bigcap_{p \in P} \mathrm{B}(p,1)$ and $U(P) = \bigcup_{p \in P} \mathrm{B}(p,1)$. As $x \in I(W)$, we have $I(W) \neq \emptyset$ and $U(W)$ is simply connected. The constraints imposed by G enforce $c \notin U(W)$ and $V \subset \mathrm{B}(c,1) \cap U(W)$. In particular, for each $i \in \{1,2,3\}$, the set V_i^- is contained in the lens $L_i = I(\{c, w_i\})$. As $c \notin U(W)$, each L_i has diameter strictly smaller than $\sqrt{3}$. Any lens in $\mathbb{R}^2$ of diameter strictly smaller than $\sqrt{3}$ contains at most two points at a pairwise distance at least one. Thus, in particular, we have $v_i \notin L_i$, for all $i \in \{1,2,3\}$.

We analyze the interaction of the circles $S_i = \mathrm{S}(w_i, 1)$, for $i \in \{1,2,3\}$, with $C = \mathrm{S}(c,1)$. As $|L_i \cap V| \geq 2$ and as any two points in V are at distance strictly larger than one, we have $|S_i \cap C| = 2$, for all $i \in \{1,2,3\}$. As $c \notin U(W)$ and as $U(W)$ is simply connected, some

part of C is disjoint from $U(W)$. We use such a part to break up the circular sequence of intersection points between C and the S_i into a linear sequence $\mathcal{I}$ of six points (some but not all of which may coincide). On the one hand, as $|L_i \cap V| \geq 2$, for all $i \in \{1,2,3\}$, and as $|V| = 3$, we have $L_i \cap L_j \neq \emptyset$, for all $i,j \in \{1,2,3\}$. On the other hand, if $L_i \subseteq L_j$, for some $i,j \in \{1,2,3\}$ with $i \neq j$, then, given that $v_j \in V_i$ we also have $v_j \in L_j$, a contradiction. It follows that up to the indexing of W we have $\mathcal{I} = 1,2,3,1,2,3$, where we write an integer i to indicate an intersection $C \cap S_i$.

Let q denote the intersection point of $S_1 \cap S_3$ in $\mathrm{B}(c,1)$. Note that $q \notin L_2$ because $q \in L_2$ would imply $L_1 \cap L_3 \subseteq L_2$ and thus $v_2 \in L_2$, a contradiction. We continuously move a unit disk D starting from $D = \mathrm{B}(w_2,1)$ towards c such that the center d of D is on the line segment w_2c. We stop the movement as soon as $d \in \mathrm{S}(q,1)$. This process is well defined because $q \notin \mathrm{B}(w_2,1)$ and $q \in L_1 \cap L_3 \subset \mathrm{B}(c,1)$. Furthermore, during the whole movement we have $L_2 \subset D \subset U(W)$ and the disk D' at the end of the movement also contains $L_1 \cap L_3$. Thus, the lens $L = D' \cap \mathrm{B}(c,1)$ contains all of V and given that $L \subset U(W)$ it has diameter strictly smaller than $\sqrt{3}$, a contradiction. ◀

The examples discussed above demonstrate that the bound from Theorem 11 is tight in the worst case, that is, for *some* graphs. In the following, we will show that the bound is also tight for *all* graphs, up to a multiplicative constant. We first estimate the edge density of pandichotomous graphs in $\mathbb{R}^d$ and show that it is linearly bounded in d. In fact, we prove a stronger result, namely that every sufficiently dense graph G not only is not pandichotomous in $\mathbb{R}^d$, but in fact, asymptotically *almost all* partitions of the edge-set of G into short and long edges yield dichotomous ordinal graphs that are not realizable in $\mathbb{R}^d$.

▶ **Theorem 16.** *Let $d \in \mathbb{N}$, let $\varepsilon > 0$, and let $G = (V,E)$ be a graph with n vertices and m edges. Let $c < 7.182$ denote the unique positive root of the function $x - 3 - x \cdot H(1/x)$, where $H\colon (0,1) \to \mathbb{R}$ is the binary entropy function $H(x) = -x\log_2(x) - (1-x)\log_2(1-x)$.*

If $m > (c+\varepsilon)dn$, then for asymptotically almost all[2] partitions $E = E_s \cup E_\ell$ of the edge-set of G, the dichotomous ordinal graph $(V, E_s \cup E_\ell)$ has no geometric realization in $\mathbb{R}^d$. In particular, every graph that is pandichotomous in $\mathbb{R}^d$ has at most $(c+o(1))dn$ edges. The $o(1)$ term approaches zero quickly as $dn \to \infty$. For illustration, we also show that $m < \mu dn$, for all $n \in \mathbb{N}$ and $d \geq 2$ and some explicit constant $\mu < 7.23$.

In the proof of Theorem 16, we will use the following result by Warren [25] on the number of sign-patterns of a collection of multivariate polynomials.

▶ **Theorem 17** (Warren [25, Theorem 2])**.** *Let $q_1, \ldots, q_m$ be real polynomials in N variables, each of degree at most d. Then the number of connected components of the set*

$$\left\{ \mathbf{x} \in \mathbb{R}^N \;\middle|\; \forall i \in \{1,\ldots,m\} : q_i(\mathbf{x}) \neq 0 \right\}$$

is at most

$$2(2d)^N \sum_{k=0}^{N} 2^k \binom{m}{k}.$$

The following is an immediate consequence of the above.

[2] That is, a fraction of the partitions that tends to 1 as $dn \to \infty$.

▶ **Corollary 18.** *Let $q_1, \ldots, q_m$ be real polynomials in N variables, each of degree at most d and let $\mathcal{S} := \{(\mathrm{sgn}(q_1(\mathbf{x})), \ldots, \mathrm{sgn}(q_m(\mathbf{x}))) \,|\, \forall i \in \{1, \ldots, m\} : q_i(\mathbf{x}) \neq 0\} \subseteq \{+1, -1\}^m$. Then we have*

$$|\mathcal{S}| \leq 2(2d)^N \sum_{k=0}^{N} 2^k \binom{m}{k}.$$

Proof. Let $X := \{\mathbf{x} \in \mathbb{R}^N \,|\, \forall i \in \{1, \ldots, m\} : q_i(\mathbf{x}) \neq 0\}$. Consider the map $f : X \to \{+1, -1\}^m$, defined by $f(\mathbf{x}) = (\mathrm{sgn}(q_1(\mathbf{x})), \ldots, \mathrm{sgn}(q_m(\mathbf{x})))$. It is easy to see, using the continuity of the polynomials $q_1, \ldots, q_m$, that f is continuous. Let C be a topological component of X. The restriction of f to C is a continuous map on a connected topological space that takes on only finitely many (at most 2^m) values. Since every such map is constant, we find that f is constant on every component of X. Hence, the size of $\mathcal{S} = \mathrm{im}(f)$ is bounded by the number of components of X. The statement now follows from Theorem 17. ◀

Proof of Theorem 16. Assume w.l.o.g. that $G = (V, E)$ has vertex set $V = \{1, \ldots, n\}$. Let $(\mathbf{x}_1, \ldots, \mathbf{x}_n)$ be an n-tuple of points in $\mathbb{R}^d$, no two of which are at distance exactly one. The *distance-pattern* of $(\mathbf{x}_1, \ldots, \mathbf{x}_n)$ w.r.t. G is the map $s_G(\mathbf{x}_1, \ldots, \mathbf{x}_n) : E \to \{+1, -1\}$, where

$$s_G(\mathbf{x}_1, \ldots, \mathbf{x}_n)(ij) := \begin{cases} +1, & \text{if } \|\mathbf{x}_i - \mathbf{x}_j\| > 1, \\ -1, & \text{if } \|\mathbf{x}_i - \mathbf{x}_j\| < 1, \end{cases}$$

for every edge $ij \in E$. In other words, given a configuration of points $(\mathbf{x}_1, \ldots, \mathbf{x}_n)$ in $\mathbb{R}^d$, the distance-pattern captures the information of which edges of G in a geometric realization placing vertices $1, \ldots, n$ at points $\mathbf{x}_1, \ldots, \mathbf{x}_n$, respectively, are long or short.

Next, we estimate the size of the set $\mathcal{S}$ of all possible distance-patterns for G. Concretely, $\mathcal{S}$ is the set of all mappings $s_G(\mathbf{x}_1, \ldots, \mathbf{x}_n)$ where $(\mathbf{x}_1, \ldots, \mathbf{x}_n)$ ranges over all n-tuples of points in $\mathbb{R}^d$, no two of which are at distance 1. Let us denote by M the number of partitions $E_s \cup E_\ell = E$ of the edge-set of G such that the dichotomous ordinal graph $(V, E_s \cup E_\ell)$ is realizable in $\mathbb{R}^d$. Let p denote the fraction of such partitions compared to all possible partitions of E. Note that $M = p2^m$ and that $p = 1$ if and only if G is pandichotomous.

▷ Claim 1. $|\mathcal{S}| \geq M$.

Proof of Claim 1. Consider any one of the M partitions $E_s \cup E_\ell$ of the edge-set E for which $(V, E_s \cup E_\ell)$ is realizable in $\mathbb{R}^d$. By Observation 1 we may assume a threshold of $\delta = 1$ and that we use a set of points with no unit distances. The distance-pattern of the corresponding tuple of n points in d-space then has value $+1$ for every long and -1 for every short edge.

Since any two distinct partitions of E into short and long edges result in different distance-patterns in $\mathcal{S}$ this way, it follows that $|\mathcal{S}| \geq M$, as claimed. ◁

Next, we obtain an upper bound on $|\mathcal{S}|$ using Theorem 17.

▷ Claim 2. $|\mathcal{S}| \leq 2 \cdot 4^{dn} \cdot \sum_{k=0}^{dn} 2^k \binom{m}{k}$.

Proof of Claim 2. For any two points $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$, we have $\|\mathbf{x} - \mathbf{y}\| > 1$ if and only if $\|\mathbf{x} - \mathbf{y}\|^2 - 1 > 0$, and $\|\mathbf{x} - \mathbf{y}\| < 1$ if and only if $\|\mathbf{x} - \mathbf{y}\|^2 - 1 < 0$. Further, the expression

$$\|\mathbf{x} - \mathbf{y}\|^2 - 1 = (x_1 - y_1)^2 + (x_2 - y_2)^2 + \ldots + (x_d - y_d)^2 - 1$$

is a polynomial of degree two in the coordinates of $\mathbf{x}, \mathbf{y}$. It is therefore natural to associate with every edge $ij \in E$ of G a polynomial $q_{i,j}$, defined as $q_{i,j}(\mathbf{x}_1, \ldots, \mathbf{x}_n) := \|\mathbf{x}_i - \mathbf{x}_j\|^2 - 1$. The collection $\left(q_{i,j} \,\middle|\, ij \in E\right)$ then forms a set of m polynomials, each of degree 2, in the $N := dn$ variables corresponding to the coordinates of $\mathbf{x}_1, \ldots, \mathbf{x}_n$. For every tuple $(\mathbf{x}_1, \ldots, \mathbf{x}_n)$ of points in $\mathbb{R}^d$, no two at unit distance, we have $s_G(\mathbf{x}_1, \ldots, \mathbf{x}_n)(ij) = \operatorname{sgn}(q_{i,j}(\mathbf{x}_1, \ldots, \mathbf{x}_n))$.

Hence, the set $\mathcal{S}$ defined before coincides with the set $\mathcal{S}$ defined in Corollary 18 for the collection $\left(q_{i,j} \,\middle|\, ij \in E\right)$ of m multivariate polynomials. We therefore obtain, using the degree bound 2 for the polynomials,

$$|\mathcal{S}| \leq 2 \cdot (2 \cdot 2)^N \cdot \sum_{k=0}^{N} 2^k \binom{m}{k} = 2 \cdot 4^{dn} \cdot \sum_{k=0}^{dn} 2^k \binom{m}{k}. \qquad \lhd$$

Using Claims 1 and 2, we obtain the inequality

$$p2^m = M \leq |\mathcal{S}| \leq 2 \cdot 4^{dn} \cdot \sum_{k=0}^{dn} 2^k \binom{m}{k}.$$

Since $c > 2$, we have $m \geq (c+\varepsilon)dn > 2dn$. This implies that the term $\binom{m}{k}$ is monotonically increasing for $k = 0, 1, \ldots, dn$. Hence, we may bound the right hand side above by

$$2 \cdot 4^{dn} \cdot \binom{m}{dn} \cdot \sum_{k=0}^{dn} 2^k = 2 \cdot 4^{dn} \cdot \binom{m}{dn} \cdot (2^{dn+1} - 1) < 4 \cdot 8^{dn} \cdot \binom{m}{dn}.$$

Let $x := \frac{m}{dn} \geq c + \varepsilon$. Using the estimate $\binom{a}{\lambda a} \leq 2^{aH(\lambda)}$, which holds for any $a \in \mathbb{N}$ and $\lambda \in (0,1)$, see e.g., [17, Lemma 9.2], we find

$$p2^{xdn} = p2^m < 4 \cdot 8^{dn} 2^{xdn \cdot H(1/x)}.$$

Taking logarithms and dividing by dn this simplifies to

$$x < \frac{2 - \log_2(p)}{dn} + 3 + x \cdot H(1/x). \tag{1}$$

Consider the function $f(x) = x - 3 - x \cdot H(1/x) = x - 3 - x \log_2 x + (x-1)\log_2(x-1)$. Observe that f is strictly monotonically increasing and continuous for $x \geq 2$ and that it has a unique positive root $c \approx 7.1815$.

It follows that $f(c+\varepsilon) > f(c) = 0$, and, since $x \geq c + \varepsilon$, Equation (1) above implies that

$$f(c+\varepsilon) \leq f(x) \leq \frac{2 - \log_2(p)}{dn} \Longrightarrow \log_2(p) \leq 2 - f(c+\varepsilon)dn.$$

Since the right hand side of the last inequality tends to $-\infty$ as $dn \to \infty$, it follows that $p \to 0$ for $dn \to \infty$. Hence, it is indeed true that asymptotically almost all partitions $E_s \cup E_\ell = E$ of the edge-set of G into short and long edges yield dichotomous ordinal graphs with no geometric representation in $\mathbb{R}^d$. This completes the proof of the first statement.

It remains to show that if G is pandichotomous ($p = 1$), then the explicit bound $m \leq \mu dn$ with $\mu := 7.2240208$ holds for all $n \in \mathbb{N}$ and $d \geq 2$. Set $\phi(z) = 2/z$ and observe that $\phi \to 0$ for $z \to \infty$. We can then express Equation (1) as $f(x) < \phi(dn)$. The trivial bound $m \leq \binom{n}{2}$ suffices to show that $m \leq \mu dn$, unless $\mu dn < \binom{n}{2}$, i.e., unless $\lceil 4\mu + 1 \rceil \leq n$. As ϕ is monotonically decreasing, it follows that $f(x) < \phi(dn) \leq \phi(2n) \leq \phi(2 \cdot \lceil 4\mu + 1 \rceil)$. For the value $\mu = 7.2240208$ we obtain $f(x) < \phi(60) = 1/30$, whereas $f(\mu) > 0.033333334 > 1/30$. Therefore, as f is monotonically increasing, it follows that $\frac{m}{dn} = x < \mu$, as claimed. $\blacktriangleleft$

▶ **Corollary 19.** *For some absolute constant* $\mu < 7.23$ *we have* $\frac{\mathrm{d}(G)}{2\mu} \leq \mathrm{ped}(G) \leq \mathrm{d}(G)$ *for every graph* G *and* $\frac{\mathrm{d}(G)}{2\mu} - 1 \leq \mathrm{psd}(G) \leq \mathrm{d}(G) - 1$ *for every graph* G *with* $\mathrm{d}(G) \geq 2$.

Proof. By Theorem 16 every graph G that is pandichotomous in $\mathbb{R}^d$ has at most μdn edges, for some absolute constant $\mu < 7.23$. Thus, the minimum degree of G is at most $\lfloor 2\mu d \rfloor$ and so G is k-degenerate, for $k = \lfloor 2\mu d \rfloor$. This implies $\mathrm{d}(G) \leq 2\mu \cdot \mathrm{ped}(G)$ and so $\frac{\mathrm{d}(G)}{2\mu} \leq \mathrm{ped}(G) \leq \mathrm{d}(G)$. Since $\mathrm{psd}(G) \geq \mathrm{ped}(G) - 1$ we obtain the lower bound for the spherical dimension. The upper bounds follow from Theorem 11. ◀

▶ **Corollary 20.** *Every* n*-vertex graph is pandichotomous in* $\mathcal{S}^{n-2}$ *and* $\mathbb{R}^{n-1}$*. But there exists an absolute constant* $\mu < 7.23$ *such that for every* $d < \frac{n-1}{4\mu}$ *there exist* n*-vertex bipartite graphs that are not pandichotomous in* $\mathbb{R}^d$ *or* $\mathcal{S}^{d-1}$*.*

Proof. Since n-vertex graphs are $(n-1)$-degenerate, the first statement is a direct consequence of Theorem 11. The complete bipartite n-vertex graph $K_{\lfloor n/2 \rfloor, \lceil n/2 \rceil}$ has minimum degree $\lfloor n/2 \rfloor$. Hence, Corollary 19 implies that $K_{\lfloor n/2 \rfloor, \lceil n/2 \rceil}$ is not pandichotomous in $\mathbb{R}^d$ for any dimension d such that $2\mu d < \lfloor n/2 \rfloor$, so in particular for $d < (n-1)/(4\mu)$. ◀

6 Conclusion

We study pandichotomous graphs with an emphasis on bipartite graphs on one hand and the relationship between the degeneracy and the pandichotomous dimension on the other hand. Some interesting open questions remain, such as:

- Is every planar graph, planar 3-tree, or planar bipartite graph pandichotomous in $\mathbb{R}^2$?
- Are bipartite dichotomous ordinal graphs realizable in $\mathbb{R}^2$ if the short graph is a 2-tree?
- Characterize the (complete) bipartite graphs that are pandichotomous in $\mathbb{R}^k$, for $k \geq 3$.
- Given $d \geq 3$, is there a bipartite d-degenerate graph that is not pandichotomous in $\mathbb{R}^{d-1}$? We believe that the answer to this question should be positive.

Abstract

We define a new filtration called the *Steinhaus filtration* built from a single cover based on a generalized Steinhaus distance, a generalization of Jaccard distance. The homology persistence module of a Steinhaus filtration with infinitely many cover elements may not be q-tame, even when the covers are in a totally bounded space. While this may pose a challenge to derive stability results, we show that the Steinhaus filtration is stable when the cover is finite. We show that while the Čech and Steinhaus filtrations are not isomorphic in general, they are isomorphic for a finite point set in dimension one. Furthermore, the VR filtration completely determines the 1-skeleton of the Steinhaus filtration in arbitrary dimension.

We then develop a language and theory for stable paths within the Steinhaus filtration. We demonstrate how the framework can be applied to several applications where a standard metric may not be defined but a cover is readily available. We introduce a new perspective for modeling recommendation system datasets. As an example, we look at a movies dataset and we find the stable paths identified in our framework represent a sequence of movies constituting a gentle transition and ordering from one genre to another.

For explainable machine learning, we apply the Mapper algorithm for model induction by building a filtration from a single Mapper complex, and provide explanations in the form of stable paths between subpopulations. For illustration, we build a Mapper complex from a supervised machine learning model trained on the FashionMNIST dataset. Stable paths in the Steinhaus filtration provide improved explanations of relationships between subpopulations of images.

1 Introduction

The need to rigorously seed a solution with a notion of stability in topological data analysis (TDA) has been addressed primarily using topological persistence [4, 11, 17]. Persistence arises when we work with a sequence of objects built on a dataset, a *filtration*, rather than with a single object. One line of focus of this work has been on estimating the homology of the dataset. This typically manifests itself as examining the persistent homology represented as a diagram or barcode, with interpretations of zeroth and first homology as capturing significant clusters and holes, respectively [1, 14, 15, 37]. In practice it is not always clear how to interpret higher dimensional homology (even holes might not make obvious sense in certain cases). A growing focus is to use persistence diagrams to help compare different datasets rather than interpret individual homology groups [2, 8, 34].

The implicit assumption in most such TDA applications is that the data is endowed with a natural metric, e.g., points exist in a high-dimensional space or pairwise distances are available. In certain applications, it is also not clear how one could assign a meaningful metric. For example, memberships of people in groups of interest is captured simply as sets specifying who belongs in each group. An instance of such data is that of recommendation systems, e.g., as used in Netflix to recommend movies to the customer. Graph based recommendation systems have been an area of recent research. Usually these systems are modeled as a bipartite graph with one set of nodes representing recommendees and the other representing recommendations. In practice, these systems are augmented in bespoke ways to accommodate whichever type of data is available. It is highly desirable to analyze the structure without prescribing some ill-fit or incomplete metric to the data.

Another TDA approach for structure discovery and visualization of high-dimensional data is based on a construction called *Mapper* [32]. Defined as the nerve of a refined pullback cover of the data (See Figure 1), Mapper has found increasing use in diverse applications in the past several years [23]. Attention has recently focused on interpreting parts of the 1-skeleton of the Mapper complex, which is a simplicial complex, as significant features of the data. Paths, flares, and cycles have been investigated in this context [21, 26, 33]. The framework of persistence has been applied to this construction to define a *multi-scale* Mapper, which permits one to derive results on stability of such features [13]. At the same time, the associated computational framework remains unwieldy and still most applications base their interpretations on a single Mapper object.

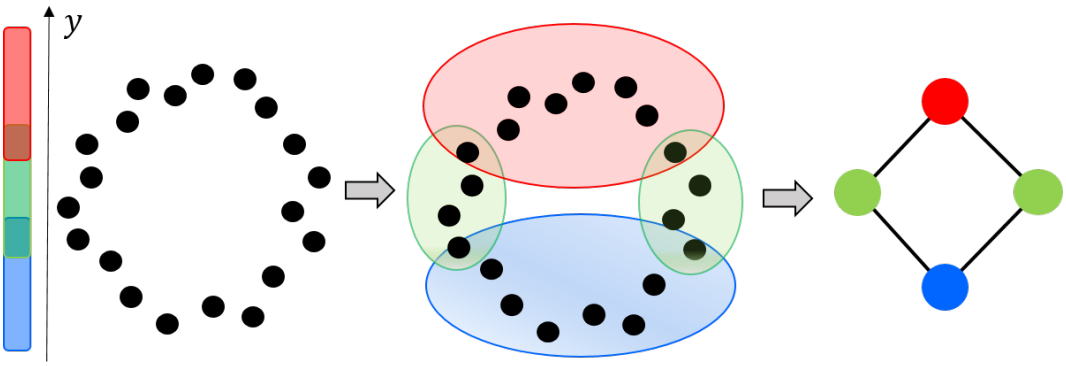

Figure 1 Mapper (Right) constructed on a noisy point set sampled from a circle (Left). The cover consists of three overlapping intervals (in blue, green, red) covering the range of y-coordinate values of the points.

The Mapper construction works with covers. By default, one starts with overlapping hypercubes that cover a parameter space (usually a subset of $\mathbb{R}^d$ for some dimension d) and consider the pullback of this cover to the space of data. In recommendation systems, the cover is just a collection of abstract sets providing membership info. Could we define a topological construction on such abstract covers that still reveals the topology of the dataset?

We could study paths in this construction, but as the topological constructions are noisy, we would want to define a notion of stability for such paths. With this goal in mind, could we define a *filtration* from the abstract cover? But unlike in the setting of, e.g., multiscale Mapper [13], we do not have a sequence of covers (called a tower of covers) – we want to work with a *single* cover. How do we define a filtration on a single abstract cover? And could we prove is is stable? Finally, could we use our construction on real data?

1.1 Our Contributions

We introduce a new type of filtration defined on a single abstract cover. Termed *Steinhaus filtration*, our construction uses Steinhaus distances between elements of the cover. We generalize the Steinhaus distance between two elements to those of multiple elements in the cover, and define a filtration on a single cover using the generalized Steinhaus distance as the filtration index. The homology persistence module of a Steinhaus filtration with infinitely many cover elements may not be q-tame, even when the covers are in a totally bounded space (Lemma 3.1). While this may pose a challenge to derive stability results, we show a stability result on the Steinhaus filtration when the cover is finite – the largest change in generalized Steinhaus distance provides an upper bound for the bottleneck distance of their homologies (Theorem 3.10). We prove that in 1-dimension the Steinhaus filtration is isomorphic to the standard Čech filtration built on the dataset (Theorem 4.1) and independently that the Vietoris-Rips (VR) filtration completely determines the 1-skeleton of the Steinhaus filtration in arbitrary dimensions (Lemma 4.2). We show by example that the Steinhaus filtration is not isomorphic to the Čech filtration in higher dimensions (Proposition 4.3).

This filtration is quite general, and enables the computation of persistent homology for datasets without requiring strong assumptions or defining ill-fit metrics. With real life applications in mind, we study paths in our construction. Paths provide intuitive explanations of the relationships between the objects that the terminal vertices represent. Our perspective of path analysis is that shortest may not be more descriptive – see Figure 2 for an illustration. Instead, we define a notion of *stability* of paths in the Steinhaus filtration. Under this notion, a stable path is analogous to a highly persistent feature as identified by persistent homology.

We demonstrate the utility of stable paths in Steinhaus filtrations on two real life applications: a problem in movie recommendation system and Mapper. We first show how recommendation systems can be modeled using the Steinhaus filtration, and then show how stable paths within this filtration suggest a sequence of movies that represent a "smooth" transition from one genre to another (Section 6.1). We then define an extension of the traditional Mapper [32] termed the *Steinhaus Mapper Filtration*, and show how its stable paths provide valuable explanations of populations in the Mapper complex, focusing on explainable machine learning (Section 6.2). Code for our computations is available at `https://github.com/AmberThrall/SteinhausNotebooks/`.

1.2 Related Work

Cavanna and Sheehy [7] developed theory for a *cover filtration*, built from a cover of a filtered simplicial complex. But we work from more general covers of arbitrary spaces.

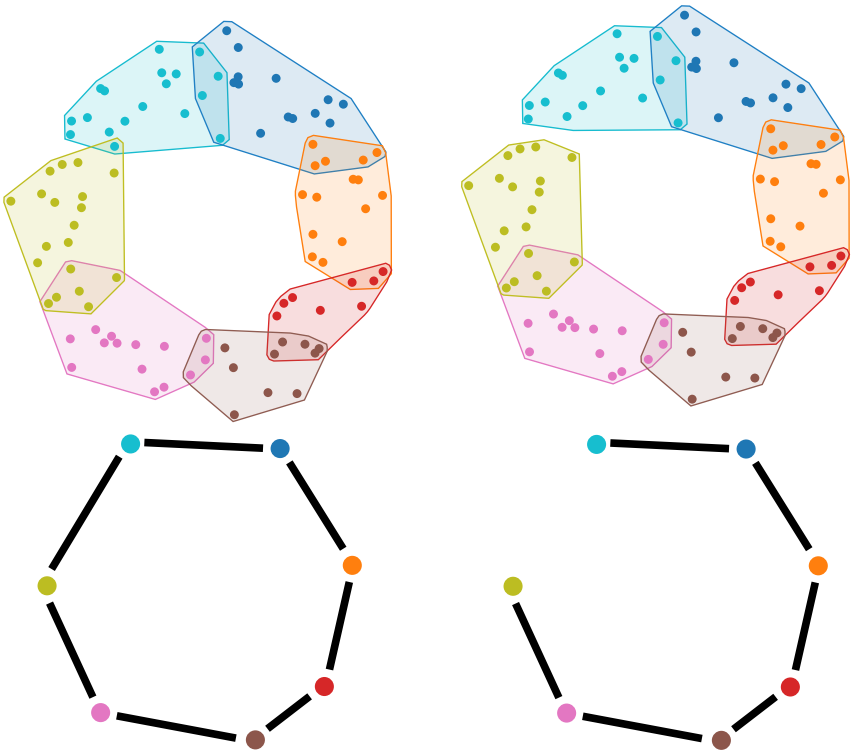

Figure 2 A cover with 7 elements, and its nerve (left column). The cyan and green vertices are connected by a single edge generated by a *single* point in intersection of cyan and green cover elements. Removing this point gives the cover and nerve shown in the right column. The path from cyan to green node now has six edges.

We are inspired by similar goals as those of previous work addressing stability of the Mapper construction by Dey, Mémoli, and Wang [13] and by Carrière and Oudot [6]. Our goal is to provide some consistency, and thus interpretability, to the Mapper construction. We incorporate ideas of persistence in a different manner into our construction using a *single* cover, which considerably reduces the effort of generating results.

The multi-scale Mapper defined by Dey, Mémoli, and Wang [13] builds a filtration on the Mapper complex by varying the parameters of a cover. This construction yields nice stability properties, but is unwieldy in practice and difficult to interpret. Carrière, Michel, and Oudot develop ways based on extended persistence to automatically select a hypercube cover that best captures the topology of the data [5]. This approach constructs one final Mapper that is easy to interpret, but is restricted to the use of hypercube covers, which is just one option of myriad potential covering schemes.

Kalyanaraman, Kamruzzaman, and Krishnamoorthy developed methods for tracking populations within the Mapper graph by identifying *interesting paths* [19] and *interesting flares* [20]. Interesting paths maximize an interestingness score, and are manifested in the Mapper graph as long paths that track particular populations that show trending behavior. Flares capture subpopulations that diverge, i.e., show branching behavior. In our context, we are interested in shorter paths, under the assumption that they provide the most succinct explanations for relationships between subpopulations.

Our work is similar to that of Parthasarathy, Sivakoff, Tian, and Wang [27] in that they use the Jaccard Index of an observed graph to estimate the geodesic distance of the underlying graph. We take an approach more akin to persistence and make far fewer assumptions.We cannot make rigorous estimates of distances but provide many possible representative paths.

The notion of S-paths [29] is similar to stable paths if we model covers as hypergraphs, and vice versa. Stable paths incorporate the size of each cover element (or hyperedges), normalizing the weights by relative size. This perspective allows us to compare different parts of the resulting structure which may have wildly difference sizes of covers. In this context, a large overlap of small elements is considered more meaningful than a proportionally small intersection of large elements.

In Section 6.1, we show how the Steinhaus filtration and stable paths can be applied in the context of recommendation systems. Our viewpoint on recommendation systems is similar to work of graph-based recommendation systems. This is an active area of research and we believe our new perspective of interpreting such systems as covers and filtrations will yield useful tools for advancing the field. The general approach of graph-based recommendation systems is to model the data as a bipartite graph, with one set of nodes representing the recommendation items and the other set representing the recommendees. We can interpret a bipartite graph as a cover, either with elements being the recommendees covering the items, or elements being the items covering the recommendees.

2 Steinhaus Filtrations

We define the Steinhaus distance, a generalization of the Jaccard distance between two sets, and further generalize it to an arbitrary collection of subsets of a cover. These generalizations take a measure μ and assume that all sets are taken mod differences by sets of measure 0.

▶ **Definition 2.1** (Steinhaus Distance [24]). *The* Steinhaus distance *between sets A, B given a measure μ is* $d_{St}(A,B) = 1 - \dfrac{\mu(A \cap B)}{\mu(A \cup B)} = \dfrac{\mu(A \cup B) - \mu(A \cap B)}{\mu(A \cup B)}$.

This distance lies in $[0,1]$, is 0 when sets are equal and 1 when they do not intersect.

▶ **Definition 2.2** (Generalized Steinhaus distance). *Define the* generalized Steinhaus distance *of a collection of sets $\{U_i\}$ as* $d_{St}(\{U_i\}) = 1 - \dfrac{\mu(\bigcap U_i)}{\mu(\bigcup U_i)}$.

We make use of this generalized distance to associate birth times to simplices in a nerve. Given a cover, we define the Steinhaus filtration as the filtration induced from sublevel sets of the generalized Steinhaus distance function. In other words, consider a cover of the space and the nerve of this cover. For each simplex in the nerve, we assign as birth time the value of its Steinhaus distance of its corresponding cover elements. This filtration captures information about similarity of cover elements and overall structure of the cover.

▶ **Definition 2.3** (Nerve). *A* nerve *of a cover $\mathcal{U} = \{U_i\}_{i \in C}$ is an abstract simplicial complex defined such that each subset $\{U_j\}_{j \in J} \subseteq \mathcal{U}$ with $J \subseteq C$, defines a simplex if $\bigcap_{j \in J}\{U_j\} \neq \emptyset$. In this construction, each cover element $U_i \in \mathcal{U}$ defines a vertex.*

▶ **Definition 2.4** (Steinhaus Nerve). *The* Steinhaus nerve *of a cover $\mathcal{U}$, denoted* $\mathrm{Nrv}_{St}(\mathcal{U})$*, is defined as the nerve of $\mathcal{U}$ with each simplex assigned their generalized Steinhaus distance as weight:* $w_\sigma = d_{St}(\{U_i \mid i \in \sigma\}) \quad \forall \sigma \in \mathcal{U}$.

Note that $w_\sigma < 1$ by definition for every simplex $\sigma \in \mathcal{U}$. We will use Nrv_{St} when the cover $\mathcal{U}$ is evident from context. The weighting scheme satisfies the conditions of a filtration.

▶ **Theorem 2.5.** *The Steinhaus nerve of a cover $\mathcal{U}$ is a filtered simplicial complex.*

Proof. This proof makes use of standard set theory results. Let $\mathcal{U}$ be an arbitrary cover of some set X and let Nrv_{St} be its Steinhaus nerve. We consider Nrv_{St} as a filtration by assigning as the birth time of simplex $\sigma \in \text{Nrv}_{St}$ its weight w_σ. To show this is indeed a filtration, we focus on a single simplex σ and a face $\tau \preceq \sigma$ to show that the face always appears in the filtration before the simplex.

Suppose σ is generated from cover elements $\{U_i\}_{i\in I}$ over some index set I. Let a face $\tau \preceq \sigma$ be generated by cover elements indexed by a subset $J \subset I$. The birth time of τ is

$$d_{St}(\{U_i\}_{i\in J}) = 1 - \frac{\mu(\cap_{i\in J} U_i)}{\mu(\cup_{i\in J} U_i)} \quad \text{and that of } \sigma \text{ is} \quad d_{St}\left(\{U_i\}_{i\in I}\right) = 1 - \frac{\mu(\cap_{i\in I} U_i)}{\mu(\cup_{i\in I} U_i)}.$$

Clearly, with $\{U_i\}_{i\in J} \subset \{U_i\}_{i\in I}$, we have that $\mu(\cap_{i\in J} U_i) \geq \mu(\cap_{i\in I} U_i)$ and $\mu(\cup_{i\in J} U_i) \leq \mu(\cup_{i\in I} U_i)$. It follows then that $d_{St}(\tau) \leq d_{St}(\sigma)$. With K_α denoting the subcomplex that includes all simplices in Nrv_{St} with birth time at most $\alpha \in [0, 1)$, for any $\alpha, \beta \in [0, 1)$ with $\alpha < \beta$, we have $K_\alpha \subseteq K_\beta$. Hence $\text{Nrv}_{St}(\mathcal{U})$ is a monotonic filtration. ◀

Following this result, we refer to the construction as the Steinhaus *filtration*.

We could study an adaptation of Steinhaus filtration to an analog of the VR complex by building a weighted clique rank filtration from the 1-skeleton of the Steinhaus filtration [28]. This adaptation drastically reduces the number of intersection and union checks required for the construction. The *weight rank clique filtration* is a way of generating a flag filtration from a weighted graph [28]. We can use this idea to build a VR analog of the Steinhaus filtration.

3 Stability

We provide a brief overview of persistence modules and the bottleneck distance. For details, see the book by Chazal, de Silva, Glisse, and Oudot [9].

Given a poset T, we define a *persistence module* $\mathbb{V}$ over T to be an indexed family of vector spaces $\{V_a\}_{a\in T}$ with a family of linear maps $\{v_a^b : V_a \to V_b\}$ that satisfy $v_b^c \circ v_a^b = v_a^c$ whenever $a \leq b \leq c$. The homologies of the Steinhaus filtered simplicial complex $H_*(\text{Nrv}_{St}(\mathcal{V}))$ defines a persistence module where each space $V_a \in H_*(\text{Nrv}_{St}(\mathcal{V}))$ is the homology of the simplicial complex consisting of simplices whose corresponding Steinhaus distance is at most a. Herein, we use simplicial homology with coefficients in some field k.

Given two persistence modules $\mathbb{U}$ and $\mathbb{V}$ over $\mathbb{R}$ and $\epsilon \in \mathbb{R}$, a *homomorphism of degree* ϵ is a collection of linear maps $\Phi = \{\phi_a : U_a \to V_{a+\epsilon}\}_{a\in\mathbb{R}}$ such that $v_{a+\epsilon}^{b+\epsilon} \circ \phi_a = \phi_b \circ u_a^b$. We denote the set of homomorphisms of degree ϵ by $\text{Hom}^\epsilon(\mathbb{U}, \mathbb{V})$. The composition of a homomorphism of degree ϵ and a homomorphism of degree ϵ' is a homomorphism of degree $\epsilon + \epsilon'$ given by the composition of their linear maps. For $\epsilon \geq 0$, a crucial endomorphism of degree ϵ is the shift map $1_{\mathbb{V}}^\epsilon \in \text{Hom}^\epsilon(\mathbb{V}, \mathbb{V})$ given by the maps

$$1_{\mathbb{V}}^\epsilon = \{v_a^{a+\epsilon} : V_a \to V_{a+\epsilon}\}_{a\in\mathbb{R}}.$$

We say that two persistence modules $\mathbb{U}$ and $\mathbb{V}$ are ϵ-*interleaved* if there are homomorphisms $\Phi \in \text{Hom}^\epsilon(\mathbb{U}, \mathbb{V})$ and $\Psi \in \text{Hom}^\epsilon(\mathbb{V}, \mathbb{U})$ such that $\Psi\Phi = 1_{\mathbb{U}}^{2\epsilon}$ and $\Phi\Psi = 1_{\mathbb{V}}^{2\epsilon}$.

When a persistence module $\mathbb{V}$ is q-tame, i.e., $\text{rank}(v_a^b) < \infty$ whenever $a < b$, then the persistence module decomposes into the direct sum of interval modules $\mathbb{V} = \bigoplus_{k\in K} \mathbb{I}(p_k^*, q_k^*)$. Each term $\mathbb{I}(p_k^*, q_k^*)$ represent the birth time and death time of a particular feature. This decomposition is often represented by the multiset of points (p_k, q_k) in the extended plane $\overline{\mathbb{R}}^2$. This multiset is called the *persistence diagram* of $\mathbb{V}$ and denoted $\text{dgm}(\mathbb{V})$.

In typical applications, the simplicial complex is finite. As a result, their homologies are finite and any map between their homologies will have finite rank. In other words, in typical cases the homologies of the Steinhaus filtration will be q-tame. However, if we allow for infinitely many cover elements then $H_*(\mathrm{Nrv}_{St}(\mathcal{V}))$ may not be q-tame.

▶ **Lemma 3.1.** *There is a Steinhaus filtered simplicial complex in a totally bounded space whose homology persistence module is not q-tame.*

Proof. Consider the Mapper complex in Figure 3. Each cover element is a rectangle of size

$$R = 11 \times 14, \; G = 6 \times 11, \quad \text{and} \quad B = 11 \times 12$$

with rectangular intersections of size $R \cap G = 2.5 \times 4$ and $B \cap G = 2.5 \times 3$. Under the Lebesgue measure, we get the Steinhaus distances of $d_{St}(R, G) = 200/210$ and $d_{St}(B, G) = 366/381$. Hence, under our Steinhaus filtration the cycles going around the red-green-red-green diamonds in the complex are born at $200/210$ and the remaining cycles are born at $366/381$. Since these cycles form a linearly independent set, we get that in the first homology persistence module the map from $200/210$ to $366/381$ has infinite rank.

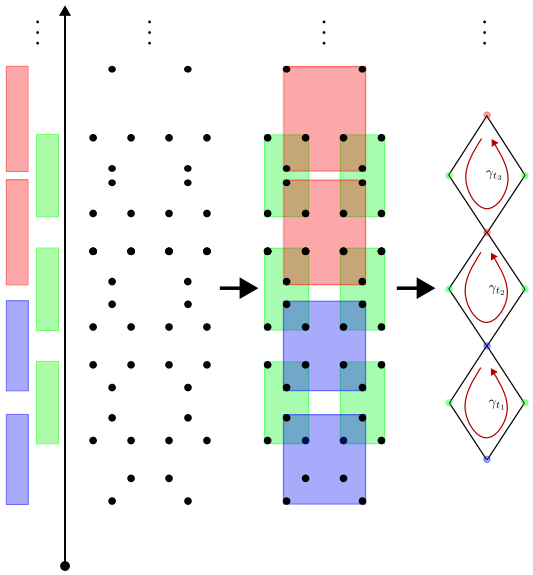

Figure 3 A non q-tame Steinhaus filtered Mapper complex. The center boxes follow the pattern of blue, blue, red, red, blue, blue, etc. For each diamond in the complex there is a cycle that traverses around the diamond.

We modify this construction to get a non q-tame example in a totally bounded space by shrinking each subsequent cover by factor of two. Thus, if we make the covers have sizes

$$R_n = 11 \times \frac{14}{2^n}, \; G_n = 6 \times \frac{11}{2^n}, \quad \text{and} \quad B_n = 11 \times \frac{12}{2^n}$$

and position them such that

$$R_n \cap G_n = 2.5 \times \frac{4}{2^n} \qquad R_n \cap G_{n+1} = 2.5 \times \frac{4}{2^{n+1}}$$
$$B_n \cap G_n = 2.5 \times \frac{3}{2^n} \qquad B_n \cap G_{n+1} = 2.5 \times \frac{3}{2^{n+1}}$$

then the covers are contained in a finite rectangle and the map in the first homology persistence module from $354/364$ to $630/645$ will have infinite rank. ◀

▶ **Definition 3.2.** *A partial matching between multisets A and B is a collection of pairs $M \subseteq A \times B$ such that for every $a \in A$, there is at most one $b \in B$ such that $(a, b) \in M$ and for every $b \in B$, there is at most one $a \in A$ such that $(a, b) \in M$.*

Let $\Delta \subset \overline{\mathbb{R}}^2$ be the diagonal. The cost of a partial matching M is given by

$$\text{cost}(M) := \max\left\{\max_{a\in A} \delta(a), \max_{b\in B} \delta(b)\right\}, \text{ where}$$

$$\delta(p) = \begin{cases} \|p - p'\|_\infty & \text{if there is some } p' \text{ such that } (p, p') \in M \text{ or } (p', p) \in M, \text{ and} \\ \inf_{q\in\Delta} \|p - q\|_\infty & \text{otherwise.} \end{cases}$$

▶ **Definition 3.3** (Bottleneck distance)**.** *The bottleneck distance between A and B is given by*

$$d_b(A, B) = \inf\{\text{cost}(M) : M \text{ is a partial matching between } A \text{ and } B\}.$$

▶ **Theorem 3.4** ([9])**.** *If $\mathbb{U}$ is a q-tame persistence module then it has a well-defined persistence diagram* $\text{dgm}(\mathbb{U})$*. If $\mathbb{U}, \mathbb{V}$ are q-tame persistence modules that are ϵ-interleaved then $d_b(\text{dgm}(\mathbb{U}), \text{dgm}(\mathbb{V})) \leq \epsilon$.*

We define a multivalued map C between X and Y, denoted $C : X \rightrightarrows Y$, to be a subset of $X \times Y$ such that the projection onto X is surjective. A multivalued map $C : X \rightrightarrows Y$ is said to be a *correspondence* if the projection onto Y is surjective, or equivalently,

$C^\top := \{(y, x) : (x, y) \in C\}$ is a multivalued map.

▶ **Definition 3.5** (ϵ-simplicial [10])**.** *Let $\mathbb{S} = \{S_\alpha\}$ and $\mathbb{T} = \{T_\beta\}$ be filtered simplicial complexes with vertex sets X and Y. A multivalued map $C : X \rightrightarrows Y$ is ϵ-simplicial if for any $\alpha \in \mathbb{R}$ and any simplex $\sigma \in S_\alpha$, every finite subset of $C(\sigma)$ is a simplex of $T_{\alpha+\epsilon}$.*

▶ **Proposition 3.6** ([10])**.** *Let $\mathbb{S}$ and $\mathbb{T}$ be filtered simplicial complexes with vertex sets X and Y. If $C : X \rightrightarrows Y$ is a correspondence such that C and $C^\top$ are both ϵ-simplicial, then they induce an ϵ-interleaving between $H_*(\mathbb{S})$ and $H_*(\mathbb{T})$ given by $H_*(C)$ and $H_*(C^\top)$.*

Let $\text{Nrv}_{St}(\mathcal{U})$ and $\text{Nrv}_{St}(\mathcal{V})$ be two Steinhaus filtered simplicial complexes. Given a correspondence $C : \mathcal{U} \rightrightarrows \mathcal{V}$, we define the *distortion* of C to be

$$\text{dis}(C) := \sup\{|d_{St}(\{U_i \mid i \in \sigma\}) - d_{St}(\{V_i \mid i \in \tau\})| : (\sigma, \tau) \in C\},$$

i.e., the largest change in birth times across each simplex. We then define the pseudometric by finding the correspondence with the smallest distortion:

$$d(\mathcal{U}, \mathcal{V}) = \inf\{\text{dis}(C) \mid C : \mathcal{U} \rightrightarrows \mathcal{V} \text{ is a correspondence}\}.$$

▶ **Lemma 3.7.** *$d(\mathcal{U}, \mathcal{V})$ is a pseudometric.*

$d(\mathcal{U}, \mathcal{V})$ does not satisfy the positivity requirement to be a metric. Consider the covers $\mathcal{U}$ and $\mathcal{V}$ given in Figure 4. The simplicial complexes are not isomorphic, but $d(\mathcal{U}, \mathcal{V}) = 0$.

▶ **Proposition 3.9.** *Let $\text{Nrv}_{St}(\mathcal{U})$ and $\text{Nrv}_{St}(\mathcal{V})$ be two Steinhaus filtered simplicial complexes. If $\epsilon > d(\mathcal{U}, \mathcal{V})$, then the persistence modules $H_*(\text{Nrv}_{St}(\mathcal{U}))$ and $H_*(\text{Nrv}_{St}(\mathcal{V}))$ are ϵ-interleaved.*

▶ **Theorem 3.10.** *Let $\text{Nrv}_{St}(\mathcal{U})$ and $\text{Nrv}_{St}(\mathcal{V})$ be two Steinhaus filtered simplicial complexes with q-tame homology persistence modules. Then*

$$d_b(\text{dgm}(H_*(\text{Nrv}_{St}(\mathcal{U}))), \text{dgm}(H_*(\text{Nrv}_{St}(\mathcal{V})))) \leq d(\mathcal{U}, \mathcal{V}).$$

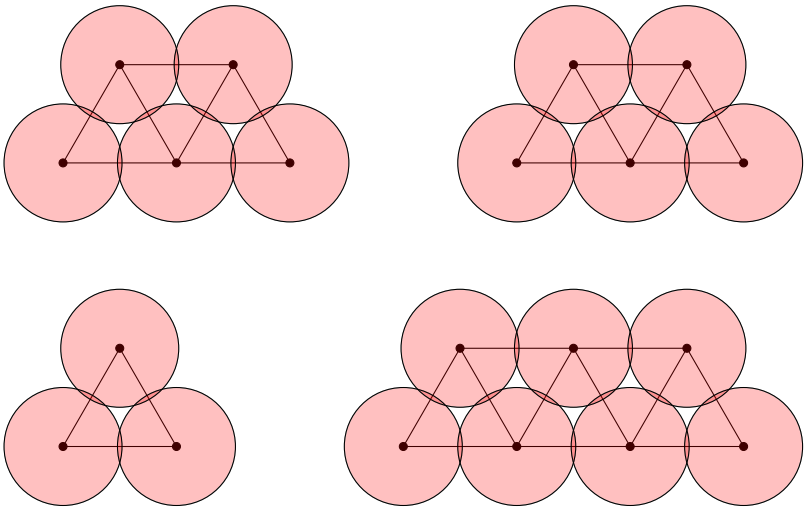

Figure 4 Nonisomorphic simplicial complexes for covers $\mathcal{U}, \mathcal{V}$ (top, bottom rows) with $d(\mathcal{U}, \mathcal{V}) = 0$.

4 Equivalence

To situate the Steinhaus filtration in the context of standard filtrations built on point clouds in Euclidean space, we wish to show the equivalence of the Steinhaus filtration to the Čech and VR filtrations under certain conditions. We first show that the Čech filtration on a finite set of points in dimension one, i.e., the nerve of balls with radius r around each point and over a sequence of r, and the Steinhaus Nerve constructed from the terminal cover of the Čech filtration are isomorphic (see Theorem 4.1).

We provide experimental evidence for the 1-skeletons of the Steinhaus filtration and the VR filtration being isomorphic. We prove one direction of this equivalence in arbitrary dimension – that the VR filtration completely determines the 1-skeleton of the Steinhaus filtration (see Lemma 4.2). We prove by example that the Steinhaus filtration and the Čech filtration in two (or higher) dimension(s) may not be isomorphic (see Proposition 4.3).

Let $\check{C}_r(X)$ be cover of X by balls of radius r centered on points in X. The Čech complex is the nerve of this cover. The Čech filtration is sequence of simplicial complexes for all r.

▶ **Theorem 4.1.** *Given a finite dataset $X \subset \mathbb{R}$ in dimension one and some radius $R > \texttt{diam}(X)$ the Čech filtration constructed from X is isomorphic to the Steinhaus filtration on X constructed from $\check{C}_R(X)$, given the Lebesgue (i.e., volume) measure.*

Proof. We set $\check{C}(\{v_i\})$ as birth radius of the simplex defined by $\{v_i\}$, computed as

$$\check{C}(\{v_i\}) = \frac{\max_i(v_i) - \min_i(v_i)}{2}$$

since in 1D space the simplex is born when balls around the two outermost points intersect.

Let $\{V_i\}$ be the set of balls of radius R centered on the set $\{v_i\}$. Recall that we are using the Steinhaus distance for Lebesgue measure, so μ computes volume here. Then the generalized Steinhaus distance for those balls is given by $d_{St}(\{V_i\}) = 1 - \frac{\min(v_i+R)-\max(v_i-R)}{\max(v_i+R)-\min(v_i-R)}$, since the mutual intersection of all the balls in this one dimensional space is the interval bounded by the minimum right endpoint of all the balls and the maximum of all left endpoints of all the balls and the union of all the balls has the minimum left endpoint amongst left endpoints and maximum right endpoint amongst right endpoints.

$$d_{St}(\{V_i\}) = 1 - \frac{\min(v_i) - \max(v_i) + 2R}{\max(v_i) - \min(v_i) + 2R}$$
$$= 1 - \frac{-2\check{C}(\{v_i\}) + 2R}{2\check{C}(\{v_i\}) + 2R} = 1 - \frac{R - \check{C}(\{v_i\})}{R + \check{C}(\{v_i\})}.$$

Solving for $\check{C}(\{v_i\})$, we get $\check{C}(\{v_i\}) = \dfrac{Rd_{St}(\{V_i\})}{2 - d_{St}(\{V_i\})}$, giving a bijection between birth times.

Now since $R > \texttt{diam}(X)$ and $\{v_i\} \subseteq X$, $0 \leq \check{C}(\{v_i\}) \leq R$. Also, $\frac{R-x}{R+x}$ decreases monotonically over the range $x \in [0, R]$. Thus, $1 - \frac{R-x}{R+x}$ increases monotonically on $x \in [0, R]$. Thus, if we order the subsets of X by increasing birth radius $(s_1, \ldots, s_n)$, then the Steinhaus distances $(d_{St}(s_1), \ldots, d_{St}(s_n))$ are also in increasing order, showing the isomorphism. ◀

▶ **Lemma 4.2.** *There is a map from the birth time of an edge in the VR filtration to its birth time in the Steinhaus filtration. Hence the VR filtration determines the* 1*-skeleton of the Steinhaus filtration in arbitrary dimensions.*

Proof. The volume of the intersection of two hyperspheres was derived by Li [22]. The volume of intersection of two hyperspheres of equal radius R in $\mathbb{R}^n$ with centers distance d apart is defined as

$$V_{\cap}^n(R, d) = \frac{\pi^{n/2}}{\Gamma(\frac{n}{2} + 1)} R^n I_{1-(d/2)/R^2}\left(\frac{n+1}{2}, \frac{1}{2}\right)$$

where Γ is the gamma function and I is the regularized incomplete beta function:

$$I_z(a, b) = \frac{\Gamma(a+b)\int_0^z u^{a-1}(1-u)^{b-1}du}{\Gamma(a)\Gamma(b)}.$$

We can reduce this equation to

$$V_{\cap}^n(R, d) = R^n \pi^{(n-1)/2} \frac{\int_0^{1-(d/2)/R^2} u^{(n-1)/2}(1-u)^{-1/2}du}{\Gamma(\frac{n+1}{2})}.$$

The volume of an n-sphere of radius R is $V_{\circ}(R) = \dfrac{\pi^{n/2}}{\Gamma(\frac{n}{2}+1)} R^n$ and hence we get

$$V_{\cup}^n(R, d) = 2V_{\circ}^n(R) - V_{\cap}^n(R, d).$$

We then compute the Steinhaus distance with Lebesgue measure of two spheres in $\mathbb{R}^n$ and radius R with Euclidean distance d apart as

$$d_{St}^n(R, d) = \frac{2V_{\circ}^n(R) - 2V_{\cap}^n(R, d)}{2V_{\circ}^n(R) - V_{\cap}^n(R, d)}$$
$$= \frac{2\Gamma(\frac{n+1}{2}) - n\Gamma(\frac{n}{2})\pi^{-1/2}\int_0^{1-(d/2)/R^2} u^{(n-1)/2}(1-u)^{-1/2}du}{2\Gamma(\frac{n+1}{2}) - \frac{n}{2}\Gamma(\frac{n}{2})\pi^{-1/2}\int_0^{1-(d/2)/R^2} u^{(n-1)/2}(1-u)^{-1/2}du}.$$

This equation provides a mapping from the birth time of the edge in the VR filtration to the birth time of the edge in the Steinhaus filtration. Once an n and R are chosen, the equation readily reduces, producing the birth times of a simplex in the Steinhaus filtration. ◀

Next we provide detailed experimental results suggesting that the 1-skeletons of the Steinhaus and the VR filtrations are isomorphic. We estimate the area of intersection of 1-spheres using Monte Carlo integration with uniform sampling. The first plot in Figure 5 shows the 50 landmark points along with 20,000 points uniformly sampled around the landmarks for ease of computation. The middle plot shows the persistence diagrams of dimension 0 and 1 for the VR filtration on the landmarks. Finally, we show the Steinhaus filtration on the landmarks using balls with radii 0.5 as the covers.

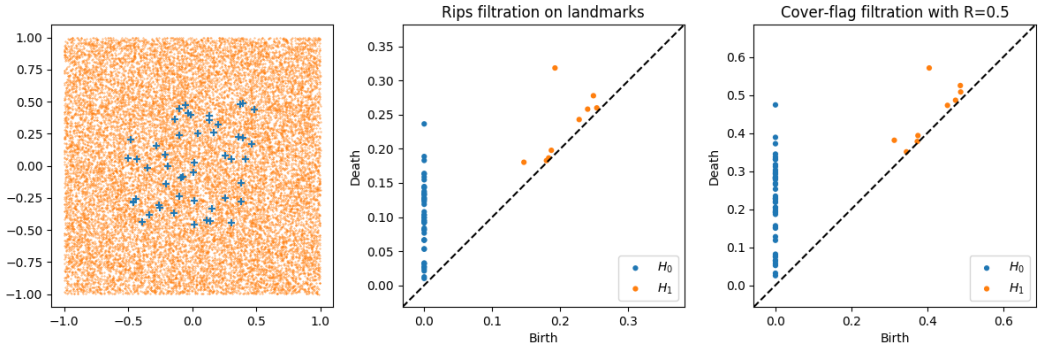

Figure 5 Persistence diagrams for the Vietoris-Rips filtration and the approximate Steinhaus filtration of a set of uniformly sampled points in the plane.

▶ **Proposition 4.3.** *The Čech and Steinhaus filtrations are not isomorphic in general.*

Proof. Let $X \subset \mathbb{R}^2$ be the four corners of a unit square. We construct a cover where at each point in X there is a ball of radius one (see Figure 6). In the Steinhaus filtration, four 2-simplices are born approximately at 0.935 before the 3-simplex is born around 0.959 under the volume measure. However, in the Čech complex the 2-simplices are born at the same time as the 3-simplex. ◀

5 Stable Paths

We develop a theory of stable paths within a Steinhaus filtration. We provide an algorithm for computing a most stable path from one vertex to another. Note that a most stable path might not be a shortest path in terms of number of edges. Conversely, a shortest path might not be highly stable. Since the two objectives are at odds with each other, we provide an algorithm to identify a family of shortest paths as we vary the stability level.

We were studying shortest paths in a Mapper graph constructed on a machine learning model as ways to illustrate the relations between the data as identified by the model. In this context, shortest paths found could have low Steinhaus distance, and thus could be considered noise. This motivated our desire to find stable paths, as they would intuitively be most representative of data and stable with respect to changing or data.

▶ **Definition 5.1** (ρ-Stable Path). *A path P is said to be* ρ-stable *for Steinhaus distance ρ if* $\max\{d_{St}(e) \mid e \in P\} \leq \rho$ *where $d_{St}(e)$ is the Steinhaus distance associated with edge e.*

It follows that a ρ_1-stable path is also ρ_2-stable for any $\rho_2 \geq \rho_1$. Also, a ρ_1-stable path P_1 is more stable than a ρ_2-stable path P_2 when $\rho_1 < \rho_2$. In this case, we have a higher confidence that the edges in P_1 do exist, and are not due to noise, than the edges in P_2.

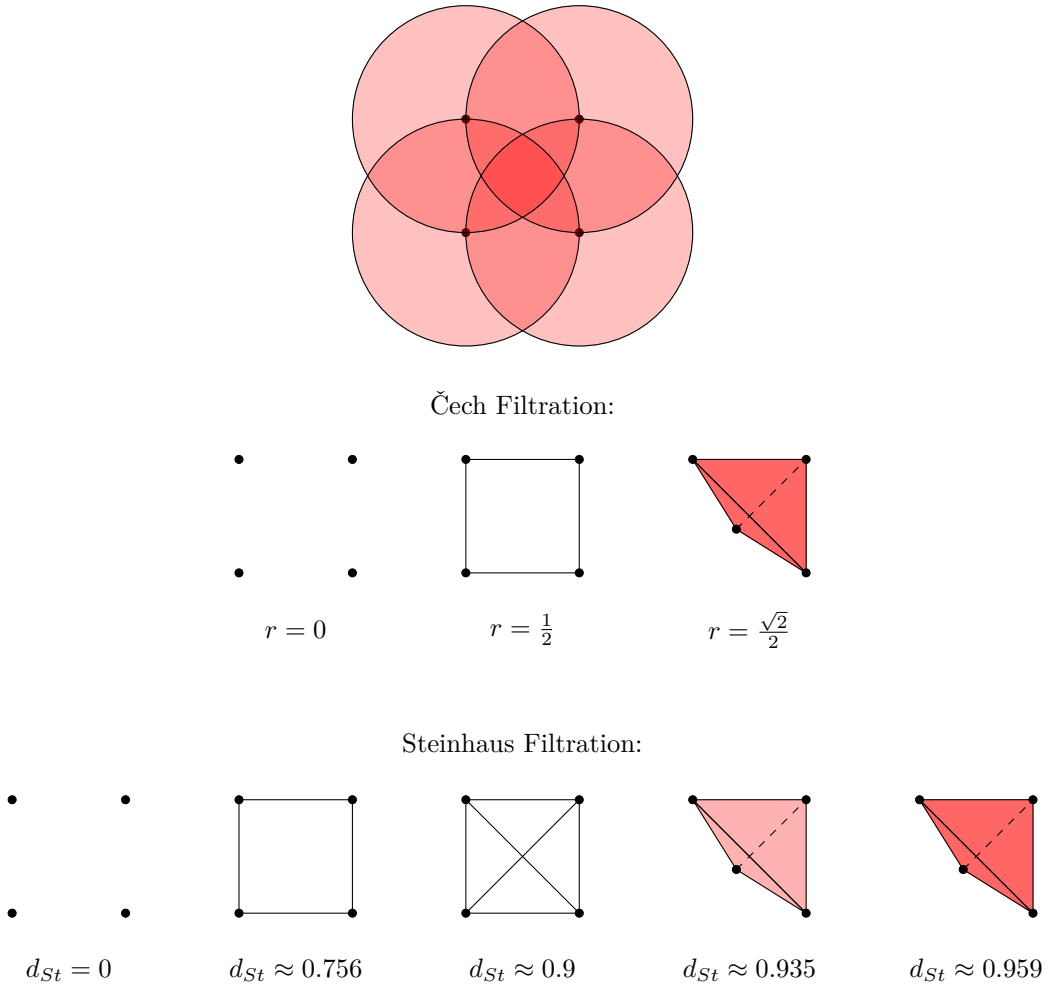

Figure 6 Example showing that the Čech filtration and Steinhaus filtration are not isomorphic in general. The Čech filtration (middle) goes from 1-simplices directly to a 3-simplex whereas the Steinhaus filtration (bottom) of the cover (top) has four 2-simplices born before the 3-simplex.

▶ **Definition 5.2** (Most Stable Path). *Given a pair of vertices s and t, a* most stable s-t path *is a ρ-stable path between s and t for the smallest value of ρ. If there are multiple s-t paths at the same minimum ρ value, a shortest path among them is defined as a most stable path.*

The problem of finding the most stable s-t path can be solved as a minimax path problem on an undirected graph, which can solved efficiently using, e.g., range minimum queries [12].

We are then left with two paths between vertices s and t, the shortest and the most stable. As these two notions, stable and short, are at odds with each other, we are interested in computing the entire Pareto frontier between the short and stable path. Algorithm 1 identifies the Pareto frontier, and its sample output is shown in Figure 7.

The blue points in Figure 7 are on the Pareto frontier, while the orange points are the pairs $[P', \rho']$ that get replaced from the LIST in the course of the algorithm. We then visualize the paths on the Pareto frontier in Figure 8. Continuing our analogy to persistence, the path corresponding to a point on the Pareto frontier which sees a steep rise to the left is considered highly persistent, e.g., the path with length 21 on the frontier.

Algorithm 1 Algorithm to identify the Pareto frontier between shortest and most stable paths.

Input: 1-skeleton G of Steinhaus filtration and vertices s, t
Output: A list LIST consisting of pairs $[P, \rho]$
set LIST $= \emptyset$
while s, t are connected in G **do**
  find a shortest path P between s and t
  $\rho = \max\{d_{St}(e) \mid e \in P\}$
  if LIST has no pair $[P', \rho']$ with $|P| = |P'|$ **then**
    add $[P, \rho]$ to LIST
  else
    if $\rho < \rho'$ for $[P', \rho'] \in$ LIST with $|P| = |P'|$ **then**
      replace $[P', \rho']$ with $[P, \rho]$ in LIST
    end if
  end if
  remove all edges e from G with $d_{St}(e) \geq \rho$
end while

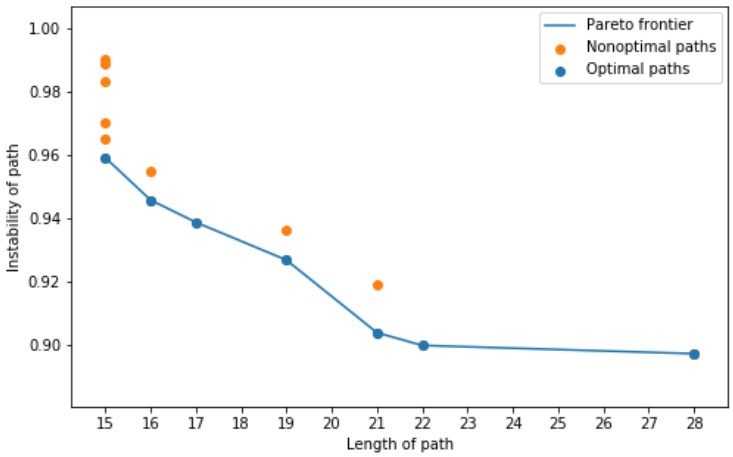

Figure 7 Pareto frontier between length of path and stability of path.

6 Applications

We apply the Steinhaus filtration and stable paths to recommendation systems and Mapper analysis. We show how recommendation systems can be modeled using the Steinhaus

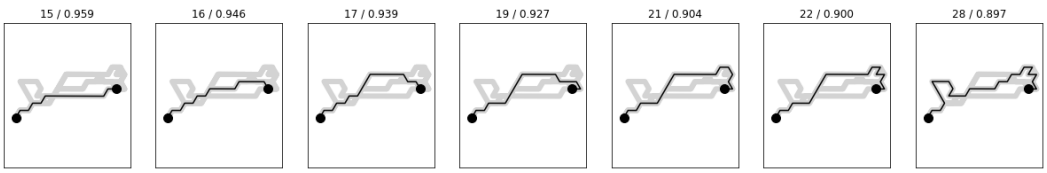

Figure 8 Visualization of each path on the Pareto frontier shown in Figure 7.

filtration and then show how stable paths in this filtration can answer the question *what movies should I show my friend first, to wean them into my favorite (but potentially weird) movie?* We then define an extension of the traditional Mapper complex [32, 6] called the Steinhaus Mapper Filtration, and show how stable paths within this filtration can provide valuable explanations of populations in the Mapper construction. As a direct illustration, we focus on the case of explainable machine learning, where the Mapper complex is constructed with a supervised machine learning model as the filter function, and address the question *what can we learn about the model?*

6.1 Recommendation Systems

We apply the Steinhaus filtration to a recommendation system dataset and employ the stable paths analysis to compute sequences of movies that ease viewers from one title to another title. Suppose you have only ever seen the movie *Mulan* and your partner wants to show you *Moulin Rouge*. It would be jarring to watch that movie, so your partner might gently build up to it by showing movies similar to both *Mulan* and *Moulin Rouge*. We compute stable paths that identify such a gentle sequence.

We use the MovieLens-20m dataset [18], comprised of 20 million ratings by 138,493 users of 27,278 movies. Often, these types of datasets are interpreted as bipartite graphs. We note that a bipartite graph can be equivalently represented as a covering of one node set with the other, and apply the Steinhaus filtration to build a filtration. In our case, we interpret each movie as a cover element of the users who have rated the movie. To reduce computational expenses and noise, we remove all movies with less than 10 ratings and then sample 4000 movies at random from the remaining movies.

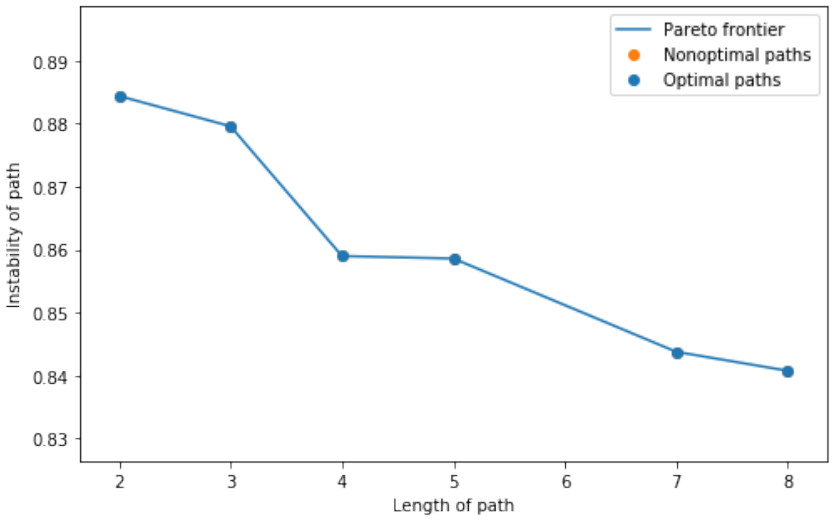

Figure 9 Pareto frontier of stable paths between *Mulan* and *Moulin Rouge*.

Figure 9 shows the computed Pareto frontier of stable paths for the case of *Mulan* and *Moulin Rouge*. In Table 1, we show two stable paths. The stable path with length 4 is found after a large drop in instability. As the length and stability must be traded off, we think this would be a decent path to choose if you want to optimize both. The second path is the most stable. For readers familiar with the movies, the relationship between each edge is clear.

Table 1 Two sequences of movie transitions.

Shortest Path	Most Stable Path
1. Mulan (1998)	1. Mulan (1998)
2. Dumbo (1941)	2. Robin Hood (1973)
3. The Sound of Music (1965)	3. Dumbo (1941)
4. Moulin Rouge (2001)	4. The Sound of Music (1965)
	5. Gone with the Wind (1939)
	6. Psycho (1960)
	7. High Fidelity (2000)
	8. Moulin Rouge (2001)

6.2 Steinhaus Mapper Filtration

We develop a method of model induction for inspecting a machine learning model. The goal is to develop an understanding of the model structure by characterizing the relationship between the feature space and the prediction space. The Mapper construction [32] is aptly suited for visualizing this functional structure.

This application is based on the work of using paths in the Mapper graph to provide explanations for supervised machine learning models [31]. In a similar approach, Rathore, Chalapathi, Palande, and Wang [30] used the Mapper construction to visually explore shapes of activations in deep learning. They focused mostly on bifurcations in the Mapper graph, and did not directly address the question of stability of the features. We build a Mapper from the predicted probability space of a logistic regression model. We then extend that Mapper to be a *Steinhaus Mapper Filtration* and analyze its stable paths.

Given topological spaces X, Y, function $f : X \to Y$, and a cover of Y, the Mapper complex is the nerve of the refined, i.e., with each cover element split into path-connected components, pullback cover of $f(Y)$. Typically, a clustering algorithm is used to compute the pullback of each cover element.

▶ **Definition 6.1** (Steinhaus Mapper filtration). *Given data X, a function $f : X \to Y$, and a cover U of Y, we define the* ***Steinhaus Mapper*** *as the Steinhaus nerve (Definition 2.4) of the refined pullback cover of $f(U)$:* $\mathrm{Nrv}_{St}(f^*U)$.

Figure 10 shows the Steinhaus Mapper filtration constructed from a logistic regression model built on the Fashion-MNIST dataset [36], with 70,000 images of clothing items from 10 classes. Each image is 28 pixels. The Fashion-MNIST dataset is typically considered to be a more difficult application than the MNIST handwritten digits.

We first reduce the dataset to 100 dimensions using Principal Components Analysis, and then a logistic regression classifier with l_1 regularization is trained on the reduced data using 5-fold cross validation on a training set of 60,000 images. The model evaluated at 93% accuracy on the remaining 10,000 images. We then extract the 10-dimensional predicted probability space and use UMAP [25] to reduce it to 2 dimensions. This 2-dimensional space is taken as the filter function of the Mapper complex, using a cover consisting of 40 bins along each dimension with 50% overlap between each bin. DBSCAN is used as the clustering algorithm in the refinement step [16]. KeplerMapper [35] is used to construct the Mapper complex. Finally, the cover is extracted and the Steinhaus Mapper filtration is constructed.

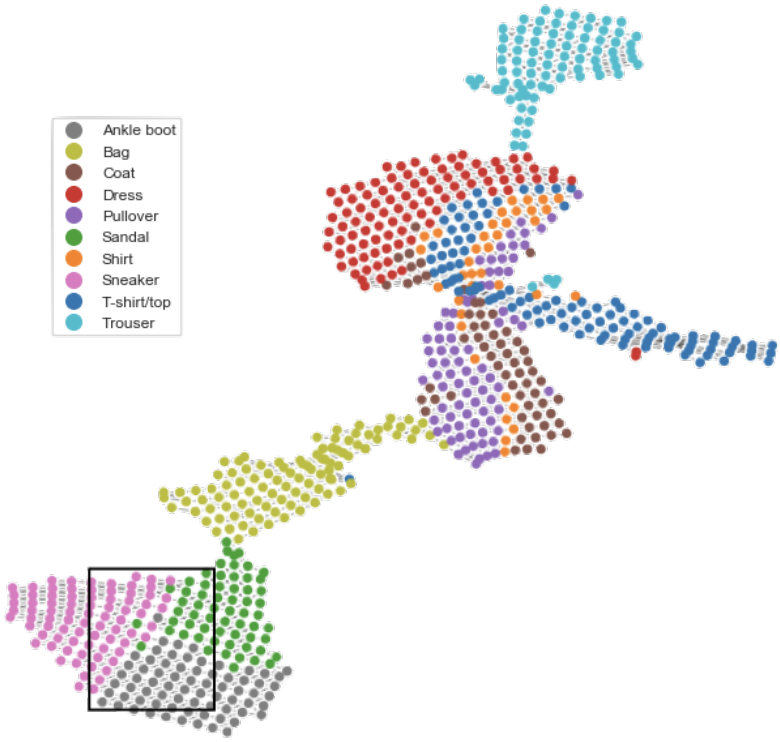

Figure 10 Mapper from logistic regression on Fashion-MNIST data. Window is frame of Fig. 11.

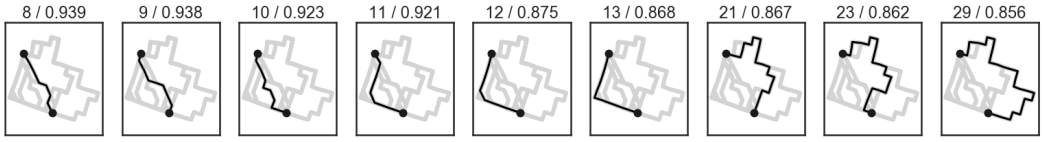

Figure 11 Depiction of stable paths found along Pareto frontier in Figure 12.

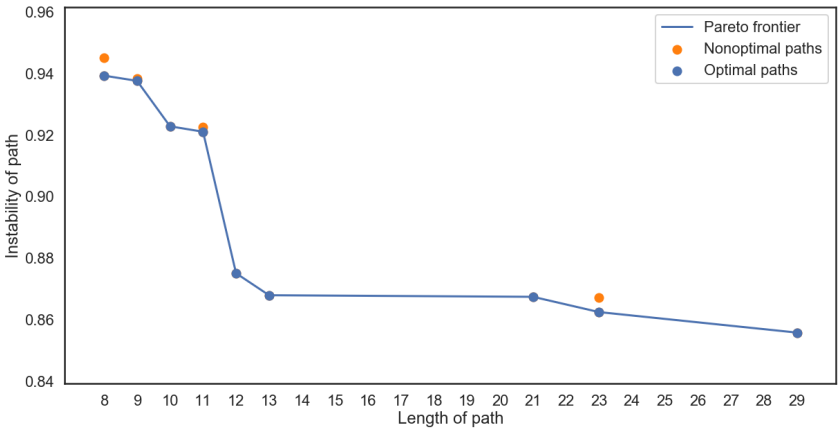

Figure 12 Pareto frontier of stable paths between predominately sneaker and ankle boot vertices.

To illustrate path explanations, we take two vertices selected from the sneaker and ankle boot regions of the resulting graph. The three regions of shoes (sneaker, ankle boot, and sandals) are understandably confusing to the model, and we are interested in where these confusions arise. Figure 11 shows the paths associated with the Pareto frontier (Figure 12).

Figure 13 shows representatives from each vertex in the path for the shortest and the stable path with length 12. Each row corresponds to one vertex and the columns show a representative from each class represented in the vertex. Each image shows the multiplicity of that type of shoe in the vertex.

In both paths, vertices start with mostly sneakers and sneaker-like sandals. They then transition to contain larger proportions of ankle boots, with all three classes showing higher cut tops or high heels.

Along each path we see the relationships between nodes change. In the most stable path (Right), we see slow transition from sneaker to ankle boot space, with some sandals spread throughout. Along the path, shoes from all three classes become taller. Near the middle, images from sneakers and ankle boots are indistinguishable.

7 Discussion

We introduced the Steinhaus filtration, a new kind of filtration that enables application of TDA to previously inaccessible types of data. We then developed a theory of stable paths in the Steinhaus filtration, and provide algorithms for computing the Pareto frontier between short and stable paths. As proof of their utility to real world applications, we show how these two ideas can be applied to the analysis of recommendation systems and of Mapper in the context of explainable machine learning.

Our results suggest many new questions. The application of recommendation systems leaves us curious if the Steinhaus filtration along with new results such as the one on predicting links in graphs using persistent homology [3] could help answer the main question in recommendation system research: *what item to recommend to the user next?*

While paths and connected components are most amenable to practical interpretations, could other structures in the Steinhaus filtration also suggest insights? What would holes and loops in the Steinhaus filtration for recommendation systems mean?

We showed that when the cover is finite, the Steinhaus filtration is stable to small changes within the cover. The example showing non q-tameness for instances with infinite covers even when it is in a totally bounded space motivates this following question: can we find a finite subcover that *approximates* such infinite covers?

Abstract

Given a finite set of points P sampling an unknown smooth surface $\mathcal{M} \subseteq \mathbb{R}^3$, our goal is to triangulate $\mathcal{M}$ based solely on P. Assuming $\mathcal{M}$ is a smooth orientable submanifold of codimension 1 in $\mathbb{R}^d$, we introduce a simple algorithm, *Naive Squash*, which simplifies the α-complex of P by repeatedly applying a new type of collapse called *vertical* relative to $\mathcal{M}$. Naive Squash also has a practical version that does not require knowledge of $\mathcal{M}$. We establish conditions under which both the naive and practical Squash algorithms output a triangulation of $\mathcal{M}$. We provide a bound on the angle formed by triangles in the α-complex with $\mathcal{M}$, yielding sampling conditions on P that are competitive with existing literature for smooth surfaces embedded in $\mathbb{R}^3$, while offering a more compartmentalized proof. As a by-product, we obtain that the restricted Delaunay complex of P triangulates $\mathcal{M}$ when $\mathcal{M}$ is a smooth surface in $\mathbb{R}^3$ under weaker conditions than existing ones.

1 Introduction

Given a finite set of points P that sample an unknown smooth surface $\mathcal{M} \subseteq \mathbb{R}^3$ (example in Figure 1a), we aim to approximate $\mathcal{M}$ based solely on P. This problem, known as *surface reconstruction*, has been widely studied [2,11,14,17,36–38,41]. Several algorithms based on computational geometry have been developed, such as Crust [3], PowerCrust [5], Cocone [4], Wrap [27] and variants based on flow complexes [13,25,34,35]. These algorithms rely on the Delaunay complex of P and offer theoretical guarantees, summarized in [23].

The most desirable guarantee is that the reconstruction outputs a triangulation of $\mathcal{M}$, that is, a simplicial complex whose support is *homeomorphic* to $\mathcal{M}$, in which case we call the algorithm *topologically correct*. That has been established for many of the aforementioned algorithms, assuming that P is noiseless ($P \subseteq \mathcal{M}$) and sufficiently dense. Specifically, let $\mathcal{R} > 0$ be a lower bound on the reach of $\mathcal{M}$, and $\varepsilon \geq 0$ an upper bound on the distance between any point of $\mathcal{M}$ and its nearest point in P. Both Crust and Cocone are topologically correct under the condition $\frac{\varepsilon}{\mathcal{R}} \leq 0.06$ [24], which, to our knowledge, is the weakest such constraint guaranteeing topological correctness for surface reconstruction algorithms in $\mathbb{R}^3$.

Surface reconstruction generalizes to approximating an unknown smooth submanifold $\mathcal{M} \subseteq \mathbb{R}^d$ from a finite sample P. One approach in that case, similar to the Wrap algorithm in $\mathbb{R}^3$, involves *collapses*, which are typically applied to complexes like the α-*complex* [12]. The α-complex of P [28,29,31] includes simplices whose circumspheres have radius $\leq \alpha$ and enclose no other points of P [30]. For well-chosen α, the α-complex has the same homotopy type as $\mathcal{M}$ [8,18,19,40], provided that P is sufficiently dense and has low noise relative to the reach of $\mathcal{M}$. However, it may still fail to capture the topology of $\mathcal{M}$, as illustrated in Figure 1b: for $\mathcal{M} \subseteq \mathbb{R}^3$, the α-complex of P includes *slivers*, tetrahedra that have one dimension more than $\mathcal{M}$, preventing the existence of a homeomorphism. Slivers complicate reconstructing k-dimensional submanifolds in $\mathbb{R}^d$ for $k \geq 2$ for all Delaunay-based reconstruction attempts.

Contributions. We introduce a simple algorithm, `NaiveVerticalSimplification`, which takes as input a simplicial complex K and simplifies it by applying collapses guided by the knowledge of $\mathcal{M}$. We call it naive because this knowledge is non-realistic in practice. We find conditions under which the algorithm is topologically correct for smooth orientable submanifolds $\mathcal{M}$ of $\mathbb{R}^d$ with codimension one. Its variant, `PracticalVerticalSimplification`, does not rely on $\mathcal{M}$ and remains topologically correct, though it requires stricter conditions. When applying both algorithms to the α-complex of P and returning the result, we obtain two reconstruction algorithms which we refer to as `NaiveSquash` and `PracticalSquash`, respectively. We determine conditions on the inputs P and α that guarantee the topological correctness of these squash algorithms. Moreover, for $d = 3$, we show that `PracticalSquash` is correct under the sampling condition $\frac{\varepsilon}{\mathcal{R}} \leq 0.178$ (see Figure 1c for an example output), while `NaiveSquash` is correct for $\frac{\varepsilon}{\mathcal{R}} \leq 0.225$, assuming suitable choice of α. We also show that the *restricted Delaunay complex* [16] is generically homeomorphic to $\mathcal{M}$ when $\frac{\varepsilon}{\mathcal{R}} \leq 0.225$.

In addition, while proving these results, we derive an upper bound for when triangles with vertices on a smooth submanifold $\mathcal{M} \subseteq \mathbb{R}^d$ form a small angle with $\mathcal{M}$: for a triangle abc with $a, b, c \in \mathcal{M}$, longest edge bc, and circumradius ρ, we show that the angle between the affine space spanned by abc and the tangent space to $\mathcal{M}$ at a satisfies:

$$\sin \angle \operatorname{Aff}(abc), \mathbf{T}_a\mathcal{M} \leq \frac{\sqrt{3}\,\rho}{\mathcal{R}}. \tag{1}$$

Techniques. Our proof of correctness for the squash algorithms is more compartmentalized than the ones present in the literature: we first consider a smooth orientable submanifold $\mathcal{M} \subseteq \mathbb{R}^d$ with codimension one and a general simplicial complex K embedded in $\mathbb{R}^d$ and contained within a small tubular neighborhood of $\mathcal{M}$. We introduce *vertical* collapses

(relative to $\mathcal{M}$) in K which remove d-simplices of K that either have no d-simplices of K above them in directions normal to $\mathcal{M}$ or no d-simplices of K below them in directions normal to $\mathcal{M}$. `NaiveVerticalSimplification` iteratively applies vertical collapses relative to $\mathcal{M}$. `PracticalVerticalSimplification` does not depend on knowledge of $\mathcal{M}$ and applies vertical collapses relative to a hyperplane, constructed dynamically based on the simplex currently considered for collapse.

We examine conditions for the correctness of these algorithms. Apart from the requirement that K has no vertical i-simplices relative to $\mathcal{M}$ for $0 < i < d$ and that its support projects onto $\mathcal{M}$ and fully covers it, we require the *vertical convexity* of K relative to $\mathcal{M}$. This means that each normal line to $\mathcal{M}$ at a point m (restricted to a small ball around m) intersects the support of K in a convex set. For `PracticalVerticalSimplification`, an additional requirement is that the $(d-1)$-simplices of K must form an angle of at most $\frac{\pi}{4}$ with $\mathcal{M}$.

Afterwards, we present `PracticalSquash` and `NaiveSquash`, which initialize the previous algorithms with K as the α-complex of a point set $P \subseteq \mathbb{R}^d$ that samples $\mathcal{M}$. We show that correctness is guaranteed when the i-simplices in the α-complex form small angles with $\mathcal{M}$ for $0 < i < d$. We provide explicit upper bounds for these angles, expressed in terms of ε, δ, and α, where ε and δ control the sample density and noise in P.

We analyze the case $d = 3$ and provide numerical bounds on the ratios $\frac{\varepsilon}{\mathcal{R}}$ and $\frac{\alpha}{\mathcal{R}}$ that ensure the correctness of both squash algorithms. Instrumental to this step, we derive (1) which enables us to upper bound the angles of triangles in the α-complex relative to the manifold and is of independent interest.

Related work. The Squash algorithms (both practical and naive) are similar to Wrap [12,31] in that they compute a subcomplex K of the Delaunay complex of P and then perform a sequence of collapses. However, the selection of K and the nature of the collapses differ between the two methods: in the naive squash, definitions are relative to $\mathcal{M}$, unlike Wrap, which uses flow lines derived from P to guide the collapsing sequence. This distinction allows us to address the general case first and then focus on the specific case of the α-complex. Moreover, while we guarantee correctness for a larger interval of the ratio $\frac{\varepsilon}{\mathcal{R}}$ compared to previous literature, most existing work addresses non-uniform sampling cases, whereas our work focuses on uniform sampling.

The vertical convexity assumption, crucial for the correctness of our algorithms, has been employed in various forms to establish collapsibility of certain classes of simplicial complexes [1,10,20]. Similarly, bounding the angle between the manifold and the simplices used for reconstruction has been essential in prior work [6,9,21–23]. Our bound (1) remains true when replacing $\mathcal{R}$ with the local feature size of a, as explained in [7, App. A]. The thus modified bound improves upon the known bound [23, Lemma 3.5].

At last, for $d = 3$, we show in the full version [7] that the restricted Delaunay complex is generically homeomorphic to $\mathcal{M}$ for $\frac{\varepsilon}{\mathcal{R}} \leq 0.225$. In contrast, it is proven to be homeomorphic to $\mathcal{M}$ only if $\frac{\varepsilon}{\mathcal{R}} \leq 0.09$ [22, Theorem 13.16], a result based on the Topological Ball Theorem [22, Theorem 13.1]. Our proof bypasses this requirement, relying instead on `NaiveSquash`.

Outline. After the preliminaries in Section 2, Section 3 defines vertically convex simplicial complexes. We introduce the concepts of upper and lower skins for these complexes and prove that both are homeomorphic to their orthogonal projection onto $\mathcal{M}$. Section 4 presents general conditions under which a simplicial complex K can be transformed into a triangulation of $\mathcal{M}$ through either Naive or Practical vertical simplification. Section 5 provides conditions ensuring the topological correctness of both the naive and practical Squash algorithms and the restricted Delaunay complex. All missing proofs can be found in the full version [7].

2 Preliminaries

Subsets and submanifold

Given a subset $X \subseteq \mathbb{R}^d$, we define several important geometric concepts. The convex hull of X is denoted as $\mathrm{conv}(X)$ and the affine space spanned by X as $\mathrm{Aff}(X)$. The interior of X is denoted as X°. The *relative interior* of X, denoted as $\mathrm{relint}(X)$, represents the interior of X within $\mathrm{Aff}(X)$. For any point x and radius r, we denote the closed ball with center x and radius r as $B(x,r)$. The r-offset of X, denoted as $X^{\oplus r}$, is the union of closed balls centered at each point in X with radius r: $X^{\oplus r} = \bigcup_{x\in X} B(x,r)$. The *medial axis* of X, denoted as $\mathrm{axis}(X)$, is the set of points in $\mathbb{R}^d$ that have at least two nearest points in X. The *reach* of X, denoted as $\mathrm{Reach}(X)$, is the infimum of distances between X and $\mathrm{axis}(X)$. Furthermore, we define the projection map $\pi_X : \mathbb{R}^d \setminus \mathrm{axis}(X) \to X$, which associates each point x with its unique closest point in X. This projection map is well-defined on every subset of $\mathbb{R}^d$ that does not intersect $\mathrm{axis}(X)$, particularly on every r-offset of X with $r < \mathrm{Reach}(X)$.

> Throughout the paper, we designate $\mathcal{M}$ as a compact C^2 submanifold of $\mathbb{R}^d$ of codimension one, and, therefore, orientable (see e.g. [42]).

Given $m \in \mathcal{M}$, we denote the affine tangent space to $\mathcal{M}$ at m as $\mathbf{T}_m\mathcal{M}$ and the affine normal space as $\mathbf{N}_m\mathcal{M}$. As $\mathcal{M}$ has codimension one, $\mathbf{T}_m\mathcal{M}$ is a hyperplane and $\mathbf{N}_m\mathcal{M}$ is a line. Additionally, since $\mathcal{M}$ is C^2, it has a positive reach [43]. For all real numbers r such that $0 < r < \mathrm{Reach}(\mathcal{M})$, the r-offset of $\mathcal{M}$ can be partitioned into the set of normal segments $\{\mathbf{N}_m\mathcal{M} \cap B(m,r)\}_{m\in\mathcal{M}}$ [26], that is,

$$\mathcal{M}^{\oplus r} = \dot{\bigcup}_{m\in\mathcal{M}} \mathbf{N}_m\mathcal{M} \cap B(m,r).$$

> We define $\mathbf{n} : \mathcal{M} \to \mathbb{R}^d$ as a differentiable field of unit normal vectors of $\mathcal{M}$ [26]. We let $\mathcal{R}$ be a finite arbitrary number such that $0 < \mathcal{R} \leq \mathrm{Reach}(\mathcal{M})$, fixed throughout.

Abstract simplicial complexes and collapses

We recall some classical definitions of algebraic topology [29,39]. An *abstract simplicial complex* is a collection K of finite non-empty sets with the property that if σ belongs to K, so does every non-empty subset of σ. Each element σ of K is called an *abstract simplex* and its *dimension* is one less than its cardinality: $\dim\sigma = \mathrm{card}\,\sigma - 1$. A simplex of dimension i is called an i-simplex and the set of i-simplices of K is denoted as $K^{[i]}$. If τ and σ are two simplices such that $\tau \subseteq \sigma$, then τ is called a *face* of σ, and σ is called a *coface* of τ. The $(d-1)$-dimensional faces of σ are the *facets* of σ. The *vertex set* of K is $\mathrm{Vert}\,K = \bigcup_{\sigma\in K}\sigma$. A *subcomplex* L of K is a simplicial complex whose elements belong to K. The *link* of σ in K, denoted $\mathrm{Lk}(\sigma,K)$, is the set of simplices τ in K such that $\tau\cup\sigma \in K$ and $\tau\cap\sigma = \emptyset$. It is a subcomplex of K. The *star* of σ in K, denoted as $\mathrm{St}(\sigma,K)$, is the set of cofaces of σ. The simplicial complex formed by all the faces of σ is the *closure* of σ, $\mathrm{Cl}\,\sigma$.

Consider next an abstract simplex $\sigma \subseteq \mathbb{R}^d$. One can associate it to the geometric simplex $\mathrm{conv}(\sigma) \subseteq \mathbb{R}^d$, called the *support* of σ. In general, $\dim(\mathrm{Aff}(\sigma)) \leq \dim(\sigma)$ and we say that σ is *non-degenerate* whenever $\dim(\mathrm{Aff}(\sigma)) = \dim\sigma$. Given a simplicial complex K with vertices in $\mathbb{R}^d$, we say that K is *canonically embedded* if the following two conditions are satisfied:

1. $\dim\sigma = \dim(\mathrm{Aff}(\sigma))$ for all $\sigma \in K$;
2. $\mathrm{conv}(\alpha\cap\beta) = \mathrm{conv}(\alpha)\cap\mathrm{conv}(\beta)$ for all $\alpha,\beta \in K$.

In this paper we consider exclusively abstract simplicial complexes K with vertex sets in $\mathbb{R}^d$ and which are canonically embedded.

Given such a simplicial complex, its *underlying space* (or *support*) is the point set $|K| = \bigcup_{\sigma \in K} \text{conv}(\sigma)$. If $|K|$ is homeomorphic to $\mathcal{M}$, then K is called a *triangulation* of $\mathcal{M}$ or is said to triangulate $\mathcal{M}$. Since K is canonically embedded, the link of every i-simplex of K falls into one of the following two categories: (1) it is a triangulation of the sphere of dimension $d-i-1$ or (2) it is a proper[1] subcomplex of such a triangulation. The *boundary complex* of a simplicial complex K is the subset of simplices in the second category, denoted ∂K, and it holds that $|\partial K| = \partial |K|$. Simplices in ∂K are referred to as *boundary simplices* of K. Given a set of abstract simplices Σ, if $\sigma \in \Sigma$ has no coface in Σ besides itself, then σ is said to be *inclusion-maximal* in Σ.

Suppose that $\tau \in K$ is a simplex whose star in K has a unique inclusion-maximal element $\sigma \neq \tau$. Then τ is said to be *free* in K. Equivalently, τ is free in K if and only if the link of τ in K is the closure of a simplex. Consequently, free simplices of K are always boundary simplices of K. However, not all boundary simplices of K are necessary free. There are instances where none of them are free, such as the famous example when K triangulates the 2-dimensional subspace of $\mathbb{R}^3$, known as the "house with two rooms". A *collapse* in K is the operation that removes from K a free simplex τ along with all its cofaces. This operation is known to preserve the homotopy-type of $|K|$.

Delaunay complexes, α-complexes, and α-shapes

Consider a finite collection of points $P \subseteq \mathbb{R}^d$. The Voronoi region of $q \in P$ is the collection of points $x \in \mathbb{R}^d$ that are closer to q than to any other points of P:

$$V(q,P) = \{x \in \mathbb{R}^d \mid \|x-q\| \leq \|x-p\|, \text{ for all } p \in P\}.$$

Given a subset $\sigma \subseteq P$, let $V(\sigma,P) = \bigcap_{q\in\sigma} V(q,P)$. The *Delaunay complex* is defined as

$$\text{Del}(P) = \{\sigma \subseteq P \mid \sigma \neq \emptyset \text{ and } V(\sigma,P) \neq \emptyset\}.$$

A simplex $\sigma \in \text{Del}(P)$ is called a *Delaunay simplex* of P and it is *dual* to its corresponding *Voronoi cell* $V(\sigma,P)$. Henceforth, we assume that the set of points P is in *general position*. This means that no $d+2$ points of P lie on the same d-dimensional sphere and no $k+2$ points of P lie on the same k-dimensional flat for $k < d$. In that case, $\text{Del}(P)$ is canonically embedded [33]. For $\alpha \geq 0$, the α-complex of P is the subcomplex of $\text{Del}(P)$ defined by:

$$\text{Del}(P,\alpha) = \{\sigma \subseteq P \mid \sigma \neq \emptyset \text{ and } V(\sigma,P) \cap P^{\oplus\alpha} \neq \emptyset\}.$$

Its underlying space $|\text{Del}(P,\alpha)| = \bigcup_{\sigma\in\text{Del}(P,\alpha)} \text{conv}(\sigma)$ is called the *α-shape* of P. It has the properties: (i) $|\text{Del}(P,\alpha)| \subseteq P^{\oplus\alpha}$ and (ii) $|\text{Del}(P,\alpha)|$ is homotopy equivalent to $P^{\oplus\alpha}$; see [28] for more details.

3 Vertically convex simplicial complexes

In this section, we define the concept of vertical convexity relative to $\mathcal{M}$ for both a set and a simplicial complex. We then study the boundary of a vertically convex simplicial complex K. Specifically, we divide the boundary of its underlying space into an upper and a lower skins,

[1] A *proper* subset A of B is such that $A \neq B$.

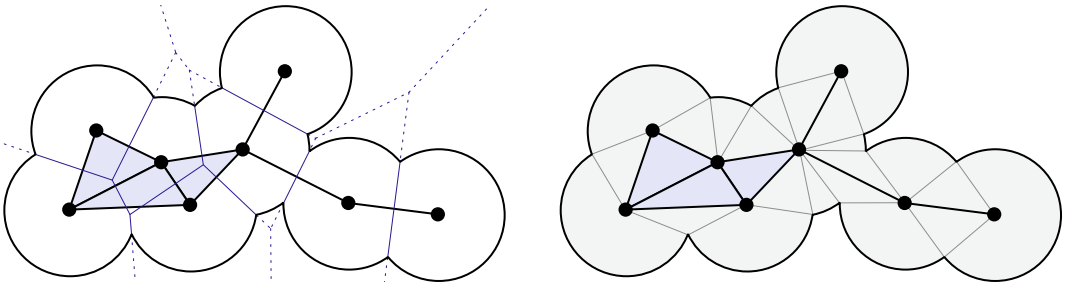

Figure 2 Left: P is such that neither $P^{\oplus\alpha}$ nor $\mathrm{Del}(P,\alpha)$ are vertically convex relative to a horizontal line. Right: Decomposition of $P^{\oplus\alpha} \setminus |\mathrm{Del}(P,\alpha)|^{\circ}$ in joins as described in [28].

enabling us to identify two boundary subcomplexes: an upper and a lower ones. Furthermore, we show that each of these subcomplexes triangulates the orthogonal projection of $|K|$ onto $\mathcal{M}$ (Lemma 6). We also extend the definitions for a single d-simplex.

▶ **Definition 1** (Vertical convexity). *A set $X \subseteq \mathbb{R}^d$ is* vertically convex *relative to $\mathcal{M}$ if $\exists\, r \in [0, \mathrm{Reach}(\mathcal{M}))$ such that*

1. *$X \subseteq \mathcal{M}^{\oplus r}$ and*
2. *$\forall\, m \in \mathcal{M}$, $\mathbf{N}_m\mathcal{M} \cap B(m,r) \cap X$ is convex.*

In other words, for any $m \in \mathcal{M}$, the set $\mathbf{N}_m\mathcal{M} \cap B(m,r) \cap X$ is either empty or a line segment (possibly of zero-length). A simplicial complex K is vertically convex *relative to $\mathcal{M}$ if its underlying space $|K|$ is.*

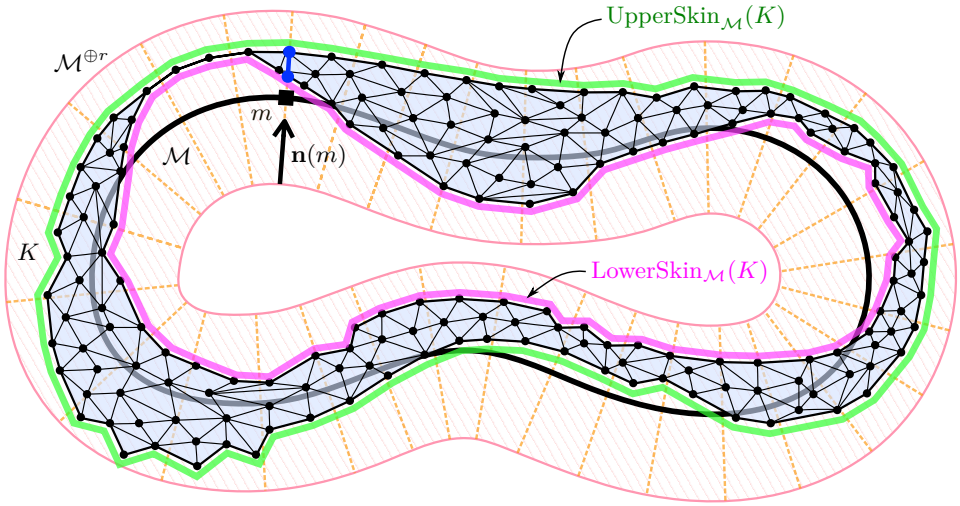

Figure 3 A simplicial complex K vertically convex relative to the curve $\mathcal{M}$. Each segment $\mathbf{N}_m\mathcal{M} \cap B(m,r)$ (in dashed orange) intersects $|K|$ in a line segment, as highlighted (blue) for the point m (represented by a black square). Lemma 4 shows that each of the two skins of $|K|$, depicted in green and pink according to the labeling arrows, is homeomorphic to $\mathcal{M}$.

Examples of a non-vertically convex and a vertically convex simplicial complexes are provided in Figures 2 and 3, respectively.

3.1 Upper and lower skins

Assume that $X \subseteq \mathbb{R}^d$ is vertically convex relative to $\mathcal{M}$ and let $m \in \pi_{\mathcal{M}}(X)$. The endpoints (possibly equal) of the segment $\mathbf{N}_m\mathcal{M} \cap B(m,r) \cap X$ are denoted by $\mathrm{low}_X(m)$ and $\mathrm{up}_X(m)$, with $\mathrm{up}_X(m)$ being above $\mathrm{low}_X(m)$ along the direction of the unit normal vector $\mathbf{n}(m)$. With this notation, X can be expressed as a union of disjoint normal segments:

$$X = \dot{\bigcup}_{m \in \pi_{\mathcal{M}}(X)} [\mathrm{low}_X(m), \mathrm{up}_X(m)].$$

The *upper skin* and *lower skin* of X are, respectively:

$$\mathrm{UpperSkin}_{\mathcal{M}}(X) = \{\mathrm{up}_X(m) \mid m \in \pi_{\mathcal{M}}(X)\},$$
$$\mathrm{LowerSkin}_{\mathcal{M}}(X) = \{\mathrm{low}_X(m) \mid m \in \pi_{\mathcal{M}}(X)\}.$$

Figure 3 displays an example. Our goal is to study the skins of $|K|$, for which we need two extra definitions.

▶ **Definition 2** (Vertical simplex). *A simplex $\sigma \subseteq \mathbb{R}^d$ such that $\mathrm{conv}(\sigma) \subseteq \mathbb{R}^d \setminus \mathrm{axis}(\mathcal{M})$ is* vertical *relative to $\mathcal{M}$ if there exists a pair of distinct points in $\mathrm{conv}(\sigma)$ sharing the same projection onto $\mathcal{M}$.*

▶ **Definition 3** (Non-vertical skeleton). *Assume that $|K| \subseteq \mathbb{R}^d \setminus \mathrm{axis}(\mathcal{M})$. We say that K has a* non-vertical skeleton *relative to $\mathcal{M}$ if K contains no vertical i-simplices relative to $\mathcal{M}$ for all integers $0 < i < d$.*

The next lemma is a key property of vertically convex simplicial complexes:

▶ **Lemma 4.** *Suppose that K is vertically convex and has a non-vertical skeleton relative to $\mathcal{M}$. Then, the upper and lower skins of $|K|$ are closed sets, each homeomorphic to $\pi_{\mathcal{M}}(|K|)$. The homeomorphism is realized in both cases by $\pi_{\mathcal{M}}$. In addition,*

$$\partial|K| = \mathrm{UpperSkin}_{\mathcal{M}}(|K|) \cup \mathrm{LowerSkin}_{\mathcal{M}}(|K|). \tag{2}$$

A simple consequence follows:

▶ **Lemma 5.** *Let K be vertically convex and with non-vertical skeleton relative to $\mathcal{M}$. If $\mathrm{UpperSkin}_{\mathcal{M}}(|K|) = \mathrm{LowerSkin}_{\mathcal{M}}(|K|)$, then $K = \partial K$.*

Aiming for a simplicial version of Equation (2), we define the *upper complex* of K and the *lower complex* of K relative to $\mathcal{M}$ as follows:

$$\mathrm{UpperComplex}_{\mathcal{M}}(K) = \{\nu \subseteq \partial K \mid \mathrm{conv}(\nu) \subseteq \mathrm{UpperSkin}_{\mathcal{M}}(|K|)\},$$
$$\mathrm{LowerComplex}_{\mathcal{M}}(K) = \{\nu \subseteq \partial K \mid \mathrm{conv}(\nu) \subseteq \mathrm{LowerSkin}_{\mathcal{M}}(|K|)\}.$$

By construction, both are subcomplexes of ∂K. A combinatorial equivalent of Lemma 4 is:

▶ **Lemma 6.** *Let K be vertically convex with non-vertical skeleton relative to $\mathcal{M}$. Then,*

$$|\,\mathrm{UpperComplex}_{\mathcal{M}}(K)| = \mathrm{UpperSkin}_{\mathcal{M}}(|K|),$$
$$|\,\mathrm{LowerComplex}_{\mathcal{M}}(K)| = \mathrm{LowerSkin}_{\mathcal{M}}(|K|) \quad \textit{and}$$
$$\partial K = \mathrm{UpperComplex}_{\mathcal{M}}(K) \cup \mathrm{LowerComplex}_{\mathcal{M}}(K).$$

Moreover, if $\pi_{\mathcal{M}}(|K|) = \mathcal{M}$, both $\mathrm{UpperComplex}_{\mathcal{M}}(K)$ and $\mathrm{LowerComplex}_{\mathcal{M}}(K)$ are triangulations of $\mathcal{M}$.

3.2 Upper and lower facets of a d-simplex

Let σ be a non-degenerate d-simplex of $\mathbb{R}^d$ such that $\mathrm{conv}(\sigma) \subseteq \mathcal{M}^{\oplus r}$ for some $r < \mathrm{Reach}(\mathcal{M})$. In that case, $\mathrm{Cl}\,\sigma$ is embedded and vertically convex relative to $\mathcal{M}$. The facets of σ can be partitioned into *upper facets* and *lower facets* of σ relative to $\mathcal{M}$ as follows:

$$\mathrm{UpperFacets}_{\mathcal{M}}(\sigma) = \{\nu \text{ facet of } \sigma \mid \nu \in \mathrm{UpperComplex}_{\mathcal{M}}(\mathrm{Cl}\,\sigma)\}$$
$$\mathrm{LowerFacets}_{\mathcal{M}}(\sigma) = \{\nu \text{ facet of } \sigma \mid \nu \in \mathrm{LowerComplex}_{\mathcal{M}}(\mathrm{Cl}\,\sigma)\}.$$

An example can be seen in Figure 4, where one can also observe the following property:

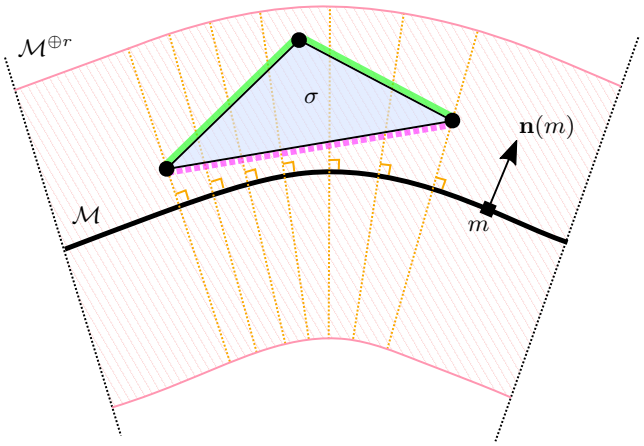

Figure 4 Upper (smooth green edges) and lower (dotted pink edge) facets of a 2-simplex $\sigma \subseteq \mathbb{R}^2$.

▶ **Lemma 7.** *Consider a non-degenerate d-simplex $\sigma \subseteq \mathbb{R}^d$ such that $\mathrm{conv}(\sigma) \subseteq \mathcal{M}^{\oplus r}$ for some $r < \mathrm{Reach}(\mathcal{M})$. If σ has no vertical facets relative to $\mathcal{M}$, then $\mathrm{UpperFacets}_{\mathcal{M}}(\sigma)$ and $\mathrm{LowerFacets}_{\mathcal{M}}(\sigma)$ are non-empty sets that partition the facets of σ.*

4 Vertically collapsing simplicial complexes

In this section, assuming that $|K| \subseteq \mathcal{M}^{\oplus r}$ for some $r < \mathrm{Reach}(\mathcal{M})$, we introduce an algorithm for simplifying K using vertical collapses relative to $\mathcal{M}$ (Section 4.1) and establish conditions for when it outputs a triangulation of $\mathcal{M}$ (Section 4.2). We first present a naive version that requires the knowledge of $\mathcal{M}$ and then present a practical version (Section 4.3).

4.1 Naive algorithm

▶ **Definition 8** (Vertically free simplices). *A simplex τ is said to be* free from above (resp., free from below) *in K relative to $\mathcal{M}$ if*

- *τ is a free simplex of K;*
- *the unique inclusion-maximal simplex σ in $\mathrm{St}(\tau, K)$ has dimension d;*
- *the set of $(d-1)$-simplices in $\mathrm{St}(\tau, K)$ is exactly the set of upper (resp., lower) facets of σ relative to $\mathcal{M}$.*

We say that τ is vertically free *in K relative to $\mathcal{M}$ if τ is either free from above or from below in K relative to $\mathcal{M}$. See Figures 5 and 7 for a depiction.*

▶ Remark 9. Definition 8 can be naturally extended to non-compact submanifolds $\mathcal{M}$. In particular, it holds for hyperplanes, a fact that we use in Algorithm 2.

▶ **Definition 10** (Vertical collapse). *A* vertical collapse *of K relative to $\mathcal{M}$ is the operation of removing the star of a simplex $\tau \in K$ that is vertically free relative to $\mathcal{M}$.*

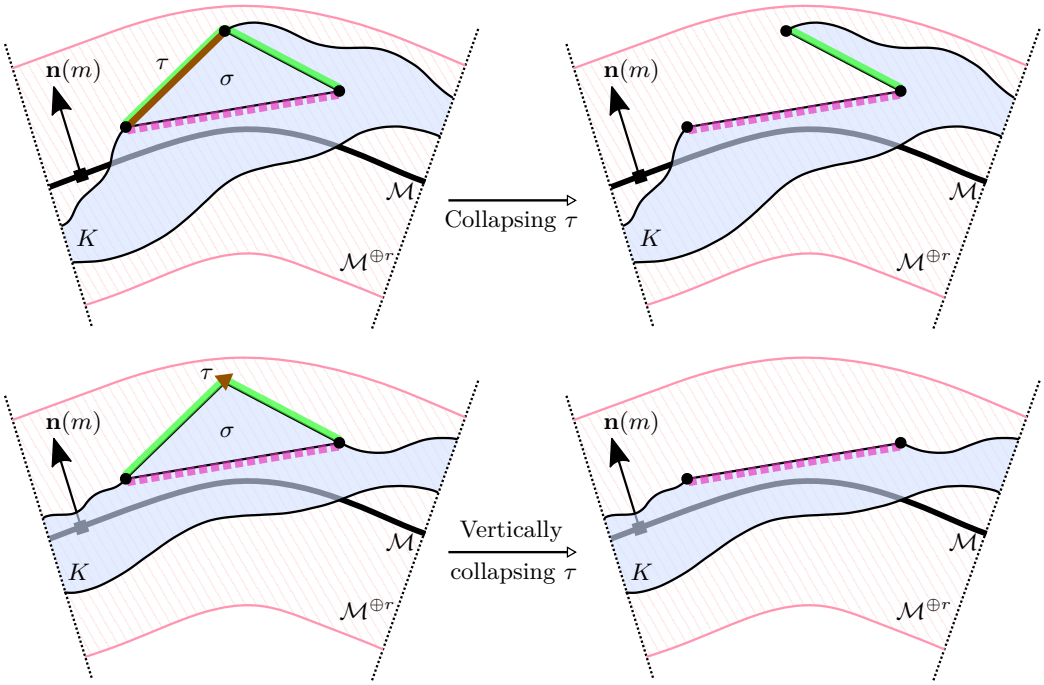

Figure 5 Schematic drawings of K in blue (smooth filled areas). Top row: the edge τ is free but not vertically free relative to $\mathcal{M}$ and collapsing τ does not preserve the vertical convexity of K. Bottom row: the vertex τ is free from above relative to $\mathcal{M}$, so that collapsing τ preserves the vertical convexity of K (Lemma 14). The $(d-1)$-simplices of K that disappear with τ are precisely the upper facets of σ (smooth edges, in green).

A vertical collapse of K can be seen as compressing the underlying space of K by shifting its upper or lower skin along directions normal to $\mathcal{M}$; see Figure 5. Our first algorithm, outlined in Algorithm 1, simplifies K by iteratively applying vertical collapses relative to $\mathcal{M}$. It is worth noting that the algorithm operates on any simplicial complex K with $|K| \subseteq \mathcal{M}^{\oplus r}$ for $r < \text{Reach}(\mathcal{M})$, irrespective of whether K is vertically convex relative to $\mathcal{M}$ or not.

Algorithm 1 `NaiveVerticalSimplification`(K).

4.2 Correctness

We now establish conditions under which `NaiveVerticalSimplification`(K) transforms K into a triangulation of $\mathcal{M}$. For that, we introduce a binary relation over d-simplices:

▶ **Definition 11** (Below relation $\prec_{\mathcal{M}}$). *Let $\sigma_0, \sigma_1 \subseteq \mathbb{R}^d$ be two d-simplices sharing a common facet $\nu = \sigma_0 \cap \sigma_1$ and let $\text{conv}(\sigma_0) \cup \text{conv}(\sigma_1) \subseteq \mathcal{M}^{\oplus r}$ for some $r < \text{Reach}(\mathcal{M})$. We say that σ_0 is* below *σ_1 (or that σ_1 is* above *σ_0) relative to $\mathcal{M}$, denoted $\sigma_0 \prec_{\mathcal{M}} \sigma_1$, if ν is an upper facet of σ_0 and a lower facet of σ_1 relative to $\mathcal{M}$.*

Note that the relation $\prec_{\mathcal{M}}$ is not acyclic in general, see Figure 6.

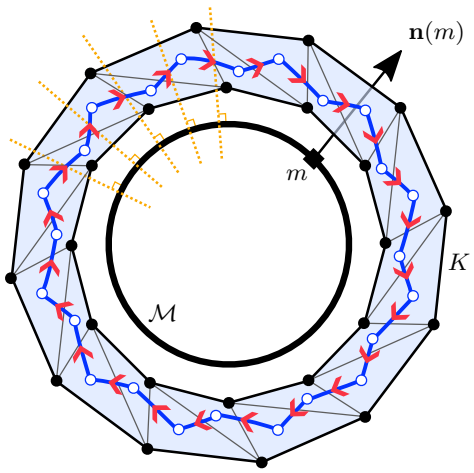

Figure 6 Non-Delaunay triangles that form a cycle in the $\prec_{\mathcal{M}}$ relation and their dual graph.

▶ **Theorem 12** (Correctness). *Consider K such that $|K| \subseteq \mathcal{M}^{\oplus r}$ for some $r < \mathrm{Reach}(\mathcal{M})$ and assume the following:*
Injective projection: *K has a non-vertical skeleton relative to $\mathcal{M}$.*
Covering projection: *$\pi_{\mathcal{M}}(|K|) = \mathcal{M}$.*
Vertical convexity: *K is vertically convex relative to $\mathcal{M}$.*
Acyclicity: *$\prec_{\mathcal{M}}$ is acyclic over d-simplices of K.*
Then, `NaiveVerticalSimplification`(K) *transforms K into a triangulation of $\mathcal{M}$.*

The remaining of this section aims to prove Theorem 12 and we consider K such that $|K| \subseteq \mathcal{M}^{\oplus r}$ for some $r < \mathrm{Reach}(\mathcal{M})$. Using the relation $\prec_{\mathcal{M}}$, associate to K its dual graph $G_{\mathcal{M}}(K)$ that has one node for each d-simplex of K and one arc for each pair of d-simplices $\sigma_0, \sigma_1 \in K$ that share a common facet $\sigma_0 \cap \sigma_1$. Direct an arc from σ_0 to σ_1 if $\sigma_0 \prec_{\mathcal{M}} \sigma_1$, and from σ_1 to σ_0 otherwise. Since either $\sigma_0 \prec_{\mathcal{M}} \sigma_1$ or $\sigma_1 \prec_{\mathcal{M}} \sigma_0$, this yields a well-defined orientation for each arc in the dual graph. Figures 6 and 7 show examples.

In a directed graph, a *source* is a node with only outgoing arcs, while a *sink* is a node with only incoming arcs. The next lemma states that a vertical collapse in K corresponds to the removal of either a sink or a source in $G_{\mathcal{M}}(K)$ and conversely. For that, given a finite set of abstract simplices $\Sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_k\}$, let $\bigcap \Sigma = \bigcap_{i=1}^{k} \sigma_i$ denote the set of vertices that belong to all simplices in Σ. If $\bigcap \Sigma \neq \emptyset$, it forms an abstract simplex.

▶ **Lemma 13** (Sinks and sources). *Consider K such that $|K| \subseteq \mathcal{M}^{\oplus r}$ for some $r < \mathrm{Reach}(\mathcal{M})$ and assume that K satisfies the injective projection, covering projection and vertical convexity assumptions of Theorem 12. Consider a d-simplex $\sigma \in K$ and let $\tau = \bigcap \mathrm{UpperFacets}_{\mathcal{M}}(\sigma)$ and $\tau' = \bigcap \mathrm{LowerFacets}_{\mathcal{M}}(\sigma)$. Then,*
- *τ is a free simplex of K from above relative to $\mathcal{M}$ $\iff$ σ is a sink of $G_{\mathcal{M}}(K)$.*
- *τ' is a free simplex of K from below relative to $\mathcal{M}$ $\iff$ σ is a source of $G_{\mathcal{M}}(K)$.*

The next lemma provides an invariant for the while-loop of Algorithm 1.

▶ **Lemma 14** (Loop invariant). *Consider K such that $|K| \subseteq \mathcal{M}^{\oplus r}$ for some $r < \mathrm{Reach}(\mathcal{M})$. Let τ be a vertically free simplex in K relative to $\mathcal{M}$. Let K' be obtained from K by collapsing τ in K. If K satisfies the assumptions of Theorem 12, then so does K'.*

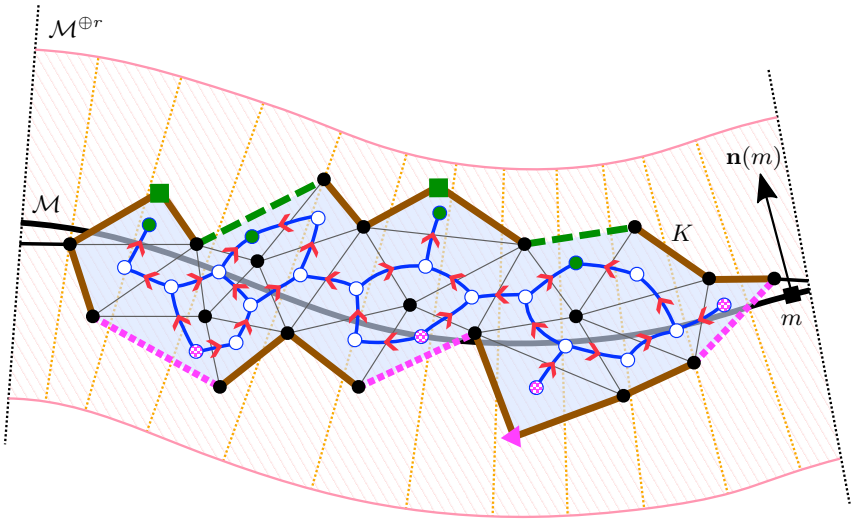

Figure 7 A vertically convex simplicial complex K relative to $\mathcal{M}$. All free simplices are highlighted by thickness. There are four simplices free from below (represented by three dotted edges and one triangular vertex, in pink) and four simplices free from above (represented by two dashed edges and two square vertices, in green). The dual graph (oriented edges, in blue) has four sources (vertices filled by dots, in pink) and four sinks (vertices with a smooth filling, in green), in one-to-one correspondence with the free simplices from below and above.

▶ **Lemma 15** (Upon termination). *Consider K such that $|K| \subseteq \mathcal{M}^{\oplus r}$ for some $r < \mathrm{Reach}(\mathcal{M})$ and assume that K satisfies the injective projection and vertical convexity assumptions of Theorem 12. If $G_{\mathcal{M}}(K) = \emptyset$, then* $\mathrm{LowerSkin}_{\mathcal{M}}(|K|) = \mathrm{UpperSkin}_{\mathcal{M}}(|K|)$.

Proof. We establish the contrapositive:

$$\mathrm{LowerSkin}_{\mathcal{M}}(|K|) \neq \mathrm{UpperSkin}_{\mathcal{M}}(|K|) \quad \Longrightarrow \quad G_{\mathcal{M}}(K) \neq \emptyset$$

Suppose that the two skins are distinct, in other words, that there exists $m \in \mathcal{M}$ such that $\mathrm{low}_{|K|}(m) \neq \mathrm{up}_{|K|}(m)$ and let us show that the segment $[\mathrm{low}_{|K|}(m), \mathrm{up}_K(m)]$ intersects the support of at least one d-simplex of K, implying $G_{\mathcal{M}}(K) \neq \emptyset$. Suppose, for a contradiction, that $[\mathrm{low}_{|K|}(m), \mathrm{up}_{|K|}(m)]$ only intersects the support of i-simplices of K for $i < d$. As $\mathrm{low}_{|K|}(m) \neq \mathrm{up}_{|K|}(m)$ and K has a finite number of simplices, at least one of these i-simplices, say ν, intersects $[\mathrm{low}_{|K|}(m), \mathrm{up}_{|K|}(m)]$ in a non-zero length segment containing distinct points $x, y \in \mathrm{conv}(\nu) \cap [\mathrm{low}_{|K|}(m), \mathrm{up}_{|K|}(m)]$. Hence, x and y share the same orthogonal projection m onto $\mathcal{M}$, implying that ν is vertical relative to $\mathcal{M}$. This contradicts the injective projection assumption on K and therefore establishes the contrapositive. ◀

We now prove the correctness of `NaiveVerticalSimplification`(K).

Proof of Theorem 12. The algorithm starts with K that satisfies the theorem assumptions. By Lemma 14, after each iteration of the while-loop we obtain a new K that continues to satisfy those assumptions. Since each iteration involves a vertical collapse of K relative to $\mathcal{M}$, the number of d-simplices of K is reduced. Thus, the algorithm must terminate. Upon termination, there are no vertically free simplices in K relative to $\mathcal{M}$. By Lemma 13, this implies that, when Algorithm 1 terminates, $G_{\mathcal{M}}(K)$ has no terminal node (neither a source nor a sink) and is therefore empty. By Lemma 15, it follows that $\mathrm{LowerSkin}_{\mathcal{M}}(|K|) = \mathrm{UpperSkin}_{\mathcal{M}}(|K|)$. By Lemma 5, we have $K = \partial K$ and Lemma 6 implies

$$K = \partial K = \mathrm{UpperComplex}_{\mathcal{M}}(K) = \mathrm{LowerComplex}_{\mathcal{M}}(K),$$

with K being a triangulation of $\mathcal{M}$. ◀

4.3 Practical version

Algorithm 1 relies on knowledge of $\mathcal{M}$, which renders it impractical for implementation since $\mathcal{M}$ is typically unknown. In this section, we introduce Algorithm 2, a feasible variant that is correct if the $(d-1)$-simplices of K form a sufficiently small angle with $\mathcal{M}$; see [7, App. A] for a definition of the angle between affine spaces. In this variant, we assign an affine space $\mathcal{H}_\tau$ to each $\tau \in K$: for a free simplex τ with a d-dimensional coface σ, $\mathcal{H}_\tau$ is defined as the hyperplane spanned by any facet of σ. Otherwise, set $\mathcal{H}_\tau = \emptyset$. We also use the notion of vertically free simplices relative to $\mathcal{H}_\tau$, extending Definition 8 as indicated in Remark 9.

Algorithm 2 `PracticalVerticalSimplification`(K).

while there is a simplex τ vertically free in K relative to $\mathcal{H}_\tau$ **do**
  Collapse τ in K;
end while

▶ **Theorem 16** (Correctness). *Suppose that K satisfies the assumptions of Theorem 12 and, in addition, for all $(d-1)$-simplices ν of K*

$$\max_{a \in \nu} \angle(\mathrm{Aff}(\nu), \mathbf{T}_{\pi_{\mathcal{M}}(a)}\mathcal{M}) < \frac{\pi}{4}. \tag{3}$$

Then, `PracticalVerticalSimplification`(K) *transforms K into a triangulation of $\mathcal{M}$.*

5 Correct reconstructions from α-complexes

In this section, we assume that $\mathcal{M}$ is sampled by a finite point set P and consider Algorithms 3 and 4, which apply vertical collapses to $\mathrm{Del}(P, \alpha)$ either straightforwardly or practically. We introduce two parameters, $\varepsilon \geq 0$ and $\delta \geq 0$, to control the sample density and noise of P, respectively, and a scale parameter $\alpha \geq 0$. Section 5.1 establishes conditions ensuring the correctness of Algorithms 3 and 4, with the proof outlined in Section 5.2. Section 5.3 shows how these conditions hold for a wide range of $\frac{\varepsilon}{\mathcal{R}}$ and $\frac{\alpha}{\mathcal{R}}$ when $\mathcal{M}$ is a surface in $\mathbb{R}^3$ and P is noiseless. This result is extended to the restricted Delaunay complex of P in Section 5.4.

Algorithm 3 `NaiveSquash`(P, α).

$K \leftarrow \mathrm{Del}(P, \alpha)$; `NaiveVerticalSimplification`$(K)$; **return** K;

Algorithm 4 `PracticalSquash`(P, α).

$K \leftarrow \mathrm{Del}(P, \alpha)$; `PracticalVerticalSimplification`$(K)$; **return** K;

5.1 Sampling and angular conditions in $\mathbb{R}^d$

The next definition enables us to express our results in $\mathbb{R}^d$ more concisely.

▶ **Definition 17** (Strict homotopy condition). *We say that $\varepsilon, \delta \geq 0$ satisfy the* strict homotopy condition *if $(\mathcal{R}-\delta)^2 - \varepsilon^2 > (4\sqrt{2}-5)\mathcal{R}^2$ for $\delta \leq \varepsilon$ and $\varepsilon + \sqrt{2}\delta < (\sqrt{2}-1)\mathcal{R}$ for $\delta \geq \varepsilon$.*

Let $I(\varepsilon, \delta)$ be an interval of α values so that $P^{\oplus\alpha}$ is vertically convex with relation to $\mathcal{M}$. The exact definition can be found in [7, App. D.1]. The fact that this interval guarantees vertical convexity follows from the specialization of Propositions 5 and 7 in [8] to the case where $\mathcal{M}$ has codimension-one:

▶ **Theorem 18** (Specialization of [8]). *Suppose that $\mathcal{M} \subseteq P^{\oplus\varepsilon}$ and $P \subseteq \mathcal{M}^{\oplus\delta}$ with $\varepsilon, \delta \geq 0$ that satisfy the strict homotopy condition. Then, for all $\alpha \in I(\varepsilon, \delta)$, $\pi_{\mathcal{M}}(P^{\oplus\alpha}) = \mathcal{M}$ and $P^{\oplus\alpha}$ is vertically convex relative to $\mathcal{M}$. Thus, $P^{\oplus\alpha}$ has associated upper and lower skins and deformation-retracts onto $\mathcal{M}$ along $\pi_{\mathcal{M}}$. In addition, the two skins partition $\partial P^{\oplus\alpha}$.*

The above concepts can be put together to state our main theorem:

▶ **Theorem 19.** *Assume $\mathcal{M} \subseteq P^{\oplus\varepsilon}$ and $P \subseteq \mathcal{M}^{\oplus\delta}$ for $\varepsilon, \delta \geq 0$ that satisfy the strict homotopy condition. Let $\alpha \in \left[\delta, \frac{2(\mathcal{R}-\delta)}{3}\right) \cap I(\varepsilon, \delta)$ and $\beta > 0$ such that $\mathcal{M}^{\oplus\beta} \subseteq P^{\oplus\alpha}$. Suppose that for all i-simplices $\tau \in \mathrm{Del}(P, \alpha)$, $0 < i < d$ and all $(d-1)$-simplices $\nu \in \mathrm{Del}(P, \alpha)$ it holds:*

$$\max_{x \in \mathrm{conv}(\tau)} \angle(\mathrm{Aff}(\tau), \mathbf{T}_{\pi_{\mathcal{M}}(x)}\mathcal{M}) < \frac{\pi}{2}, \tag{4}$$

$$\min_{a \in \tau} \angle(\mathrm{Aff}(\tau), \mathbf{T}_{\pi_{\mathcal{M}}(a)}\mathcal{M}) < \arcsin\left(\frac{(\mathcal{R}+\beta)^2 - (\mathcal{R}+\delta)^2 - \alpha^2}{2(\mathcal{R}+\delta)\alpha}\right) \text{ and} \tag{5}$$

$$\min_{x \in \mathrm{conv}(\nu)} \angle(\mathrm{Aff}(\nu), \mathbf{T}_{\pi_{\mathcal{M}}(x)}\mathcal{M}) < \frac{\pi}{2} - 2\arcsin\left(\frac{\alpha}{2(\mathcal{R}-\delta-\alpha)}\right). \tag{6}$$

Then, $\mathrm{Del}(P, \alpha)$ satisfies the injective projection, covering projection, vertical convexity and acyclicity assumptions of Theorem 12. Furthermore, both the upper and lower complexes of $\mathrm{Del}(P, \alpha)$ relative to $\mathcal{M}$ are triangulations of $\mathcal{M}$ and $\texttt{NaiveSquash}(P, \alpha)$ returns a triangulation of $\mathcal{M}$.

One can check that Conditions (4), (5) and (6) are well-defined; see Remark E1 in [7].

▶ **Corollary 20.** *Suppose the assumptions of Theorem 19 are satisfied and furthermore that for all $(d-1)$-simplices $\nu \in \mathrm{Del}(P, \alpha)$,*

$$\max_{a \in \nu} \angle(\mathrm{Aff}(\nu), \mathbf{T}_{\pi_{\mathcal{M}}(a)}\mathcal{M}) < \frac{\pi}{4}. \tag{7}$$

Then, $\texttt{PracticalSquash}(P, \alpha)$ returns a triangulation of $\mathcal{M}$.

5.2 Partial proof technique for Theorem 19

In this section, we establish the covering projection and vertical convexity of $\mathrm{Del}(P, \alpha)$, as guaranteed by Theorem 19. The complete proof of that theorem, which is unfortunately too lengthy to include here, can be found in [7, App. E].

▶ **Lemma 21.** *Assume $\mathcal{M} \subseteq P^{\oplus\varepsilon}$ and $P \subseteq \mathcal{M}^{\oplus\delta}$ for $\varepsilon, \delta \geq 0$ that satisfy the strict homotopy condition. Let $\alpha \in [\delta, \mathcal{R} - \delta) \cap I(\varepsilon, \delta)$ and $\beta > 0$ be such that $\mathcal{M}^{\oplus\beta} \subseteq P^{\oplus\alpha}$. Suppose that for all i-simplices $\tau \in \mathrm{Del}(P, \alpha)$ with $0 < i < d$, Conditions (4) and (5) hold. Then, $\pi_{\mathcal{M}}(|\mathrm{Del}(P, \alpha)|) = \mathcal{M}$ and $\mathrm{Del}(P, \alpha)$ is vertically convex relative to $\mathcal{M}$.*

Upper and lower joins. For proving this lemma, we introduce upper and lower joins. Consider $\mathcal{M}$, P, ε, δ, α and β that satisfy the assumptions of Lemma 21 and notice that they also meet the conditions of Theorem 18. Therefore, $P^{\oplus\alpha}$ has associated upper and lower skins and the two skins form a partition of $\partial P^{\oplus\alpha}$. Using that partition, we decompose the set difference $P^{\oplus\alpha} \setminus |\mathrm{Del}(P, \alpha)|^\circ$ into upper and lower joins, slightly adapting what is done in [28]; see Figures 2 and 8. For that, notice that $\partial P^{\oplus\alpha}$ can be decomposed into faces, each face being the restriction of $\partial P^{\oplus\alpha}$ to a Voronoi cell of P. There is a one-to-one correspondence

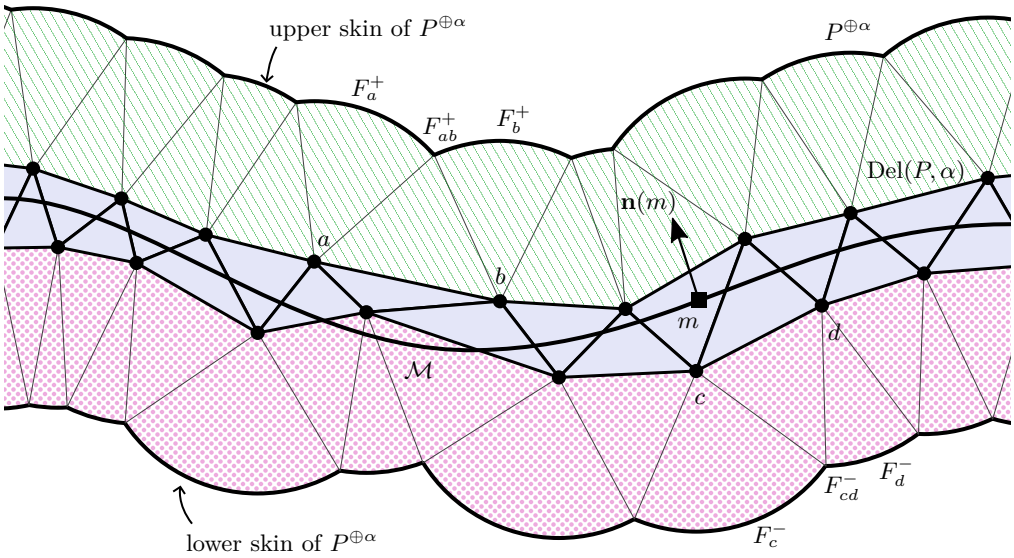

Figure 8 Decomposing $P^{\oplus\alpha} \setminus |\mathrm{Del}(P,\alpha)|^\circ$ into upper joins (hashed, in green) and lower joins (dotted, in pink).

between simplices of $\partial\,\mathrm{Del}(P,\alpha)$ and faces of $\partial P^{\oplus\alpha}$: the simplex $\tau \in \partial\,\mathrm{Del}(P,\alpha)$ corresponds to the face $F_\tau = V(\tau,P) \cap \partial P^{\oplus\alpha}$ and conversely. We can further partition each face F_τ of $\partial P^{\oplus\alpha}$ into a portion F_τ^+ that lies on the upper skin of $\partial P^{\oplus\alpha}$ and a portion F_τ^- that lies on the lower skin of $\partial P^{\oplus\alpha}$. Note that F_τ^+ or F_τ^- can be empty. We refer to F_τ^+ as an upper face and F_τ^- as a lower face. The set of upper faces decompose the upper skin, while the set of lower faces decompose the lower skin. A *join* $X * Y$ is defined as the set of segments $[x,y]$ where $x \in X$ and $y \in Y$ [28]. We call $F_\tau^+ * \mathrm{conv}(\tau)$ an *upper join* and $F_\tau^- * \mathrm{conv}(\tau)$ a *lower join*. The next lemma, proved in [7, App. E.2], identifies points in $\partial|\,\mathrm{Del}(P,\alpha)|$ that are connected to upper or lower joins.

▶ Remark 22. The collection of upper and lower joins cover the set $P^{\oplus\alpha} \setminus |\,\mathrm{Del}(P,\alpha)|^\circ$.

▶ Remark 23. If an upper join and a lower join have a non-empty intersection, the common intersection belongs to $|\,\mathrm{Del}(P,\alpha)|$.

▶ **Lemma 24.** *Under the assumptions of Lemma 21, let* $\gamma \in \mathrm{Del}(P,\alpha)$ *and* $x \in \mathrm{relint}(\mathrm{conv}(\gamma))$. *If for some* $\lambda > 0$ *(*resp. $\lambda < 0$*), the segment* $(x, x + \lambda\mathbf{n}(\pi_{\mathcal{M}}(x))]$ *lies outside* $|\,\mathrm{Del}(P,\alpha)|$, *then it intersects an upper (*resp. lower *join).*

Proof of Lemma 21. Consider $\mathcal{M}$, P, ε, δ, α and β that satisfy the assumptions of Lemma 21. As noted before, they also meet the conditions of Theorem 18. Therefore, $\pi_{\mathcal{M}}(P^{\oplus\alpha}) = \mathcal{M}$ and $P^{\oplus\alpha}$ is vertically convex relative to $\mathcal{M}$. Hence, there exists $r < \mathrm{Reach}(\mathcal{M})$ such that $P^{\oplus\alpha} \subseteq \mathcal{M}^{\oplus r}$ and $P^{\oplus\alpha} \cap \mathbf{N}_m\mathcal{M} \cap B(m,r)$ is a line segment for any $m \in \mathcal{M}$. Fix $m \in \mathcal{M}$ arbitrarily. We show that $|\,\mathrm{Del}(P,\alpha)| \cap \mathbf{N}_m\mathcal{M} \cap B(m,r)$ is also a line segment.

First, we show by contradiction that it is non-empty. Let u^+ (*resp.* u^-) be the endpoint of the segment $P^{\oplus\alpha} \cap \mathbf{N}_m\mathcal{M} \cap B(m,r)$ that lies on the upper (*resp.* lower) skin of $P^{\oplus\alpha}$ and hence is contained in an upper (*resp.* lower) join. By Remark 22, the entire segment $[u^+,u^-]$ is covered by upper and lower joins. Thus, at some point c of $[u^+,u^-]$, an upper join and a lower join intersect. By Remark 23, such an intersection places c on $|\,\mathrm{Del}(P,\alpha)|$ as well.

Second, we show by contradiction that $|\,\mathrm{Del}(P,\alpha)| \cap \mathbf{N}_m\mathcal{M} \cap B(m,r)$ is connected. Suppose that $a,b \in |\,\mathrm{Del}(P,\alpha)| \cap \mathbf{N}_m\mathcal{M} \cap B(m,r)$ are such that $[a,b] \cap |\,\mathrm{Del}(P,\alpha)| = \{a,b\}$ with a being above b along the direction of $\mathbf{n}(m)$. Since $a,b \in |\,\mathrm{Del}(P,\alpha)| \subseteq P^{\oplus\alpha}$ and $P^{\oplus\alpha}$ is

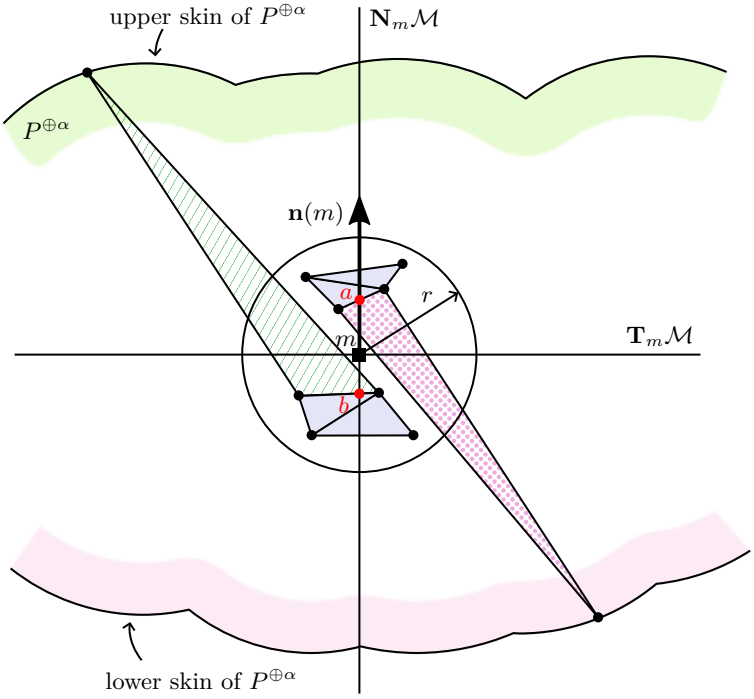

Figure 9 Reaching a contradiction in the proof of Lemma 21. We see the simplices of $\mathrm{Del}(P,\alpha)$ whose support intersects $\mathbf{N}_m\mathcal{M} \cap B(m,r)$ (smooth filling, in pale blue) and one upper (hashed, in green) and one lower (dotted, in pink) joins that intersect $[a,b]$.

vertically convex, the segment $[a,b]$ is contained in $P^{\oplus\alpha}$. By Remark 22, the entire segment $[a,b]$ is covered by upper and lower joins. Let γ_a and γ_b be the simplices of $\mathrm{Del}(P,\alpha)$ that contain a and b, respectively, in their relative interior. Letting $\lambda = \frac{\|a-b\|}{2}$, then both segments $(a, a-\lambda\mathbf{n}(m)]$ and $(b, b+\lambda\mathbf{n}(m)]$ lie outside $|\mathrm{Del}(P,\alpha)|$. It follows, by Lemma 24, that there are at least one lower and one upper joins among the joins that cover (a,b); see Figure 9. Hence, an upper and a lower joins intersect at a point c of the segment (a,b). By Remark 23, c lies in $|\mathrm{Del}(P,\alpha)|$, a contradiction. Therefore, for all $m \in \mathcal{M}$, $|\mathrm{Del}(P,\alpha)| \cap \mathbf{N}_m\mathcal{M} \cap B(m,r)$ is non-empty and connected, thus forming a line segment. ◀

5.3 Sampling conditions for surfaces in $\mathbb{R}^3$

Theorem 19 requires that the i-simplices of $\mathrm{Del}(P,\alpha)$ form a small angle with the manifold $\mathcal{M}$, for $0 < i < d$. Ensuring this can be challenging in practice, especially for $i \geq 3$. However, in the specific case of noiseless edges ($i = 1$) or triangles ($i = 2$), it is possible to upper bound the angle these simplices form with $\mathcal{M}$. For edges, it is known that:

▶ **Lemma 25** ([15, Lemma 7.8]). *If ab is a non-degenerate edge with $a, b \in \mathcal{M}$, then*

$$\sin\angle\,\mathrm{Aff}(ab), \mathbf{T}_a\mathcal{M} \;\leq\; \frac{\|b-a\|}{2\,\mathcal{R}}.$$

For triangles, let $\rho(\tau)$ be the radius of the smallest $(d-1)$-sphere circumscribing τ. We establish a simple bound that is tighter than the previous one (see [23, Lemma 3.5]):

▶ **Lemma 26.** *If abc is a non-degenerate triangle with longest edge bc, for $a, b, c \in \mathcal{M}$, then*

$$\sin \angle \operatorname{Aff}(abc), \mathbf{T}_a\mathcal{M} \leq \frac{\rho(abc)}{\mathcal{R}} \qquad \text{if } abc \text{ is an obtuse triangle and}$$

$$\sin \angle \operatorname{Aff}(abc), \mathbf{T}_a\mathcal{M} \leq \frac{\sqrt{3}\,\rho(abc)}{\mathcal{R}} \qquad \text{if } abc \text{ is an acute triangle.}$$

If abc is obtuse, the bound is tight and happens when $\mathcal{M}$ is a sphere of radius $\mathcal{R}$.

The proof is technical and is therefore provided in [7, App. A]. For the same reason, the proof of the following result, where we use the bounds for edges and triangles to establish sampling conditions for surfaces in $\mathbb{R}^3$, is in [7, App. F]. Let us define

$$\beta_{\varepsilon,\alpha} = -\frac{\varepsilon^2}{2\mathcal{R}} + \sqrt{\alpha^2 + \frac{\varepsilon^4}{4\mathcal{R}^2} - \varepsilon^2},$$

which is one particular value of β that guarantees $\mathcal{M}^{\oplus\beta} \subseteq P^{\oplus\alpha}$; see [7, App. D.2].

▶ **Theorem 27.** *Let $\mathcal{M}$ be a C^2 surface in $\mathbb{R}^3$ whose reach is at least $\mathcal{R} > 0$. Let P be a finite point set such that $P \subseteq \mathcal{M} \subseteq P^{\oplus\varepsilon}$.*

1. *For all $\varepsilon, \alpha \geq 0$ that satisfy $\frac{\sqrt{3}\,\alpha}{\mathcal{R}} < \min\left\{\frac{(\mathcal{R}+\beta_{\varepsilon,\alpha})^2 - \mathcal{R}^2 - \alpha^2}{2\mathcal{R}\alpha}, \cos\left(2\arcsin\left(\frac{\alpha}{2\mathcal{R}}\right)\right)\right\}$,*
   - *the upper and lower complexes of $\operatorname{Del}(P, \alpha)$ relative to $\mathcal{M}$ are triangulations of $\mathcal{M}$;*
   - *$\texttt{NaiveSquash}(P, \alpha)$ returns a triangulation of $\mathcal{M}$.*
2. *For all $\varepsilon, \alpha \geq 0$ that satisfy in addition $\frac{\sqrt{3}\,\alpha}{\mathcal{R}} < \sin\left(\frac{\pi}{4} - 2\arcsin\left(\frac{\alpha}{2\mathcal{R}}\right)\right)$,*
   - *$\texttt{PracticalSquash}(P, \alpha)$ returns a triangulation of $\mathcal{M}$.*

The pairs of $(\frac{\varepsilon}{\mathcal{R}}, \frac{\alpha}{\mathcal{R}})$ that satisfy **1** and **2** are depicted in Figures 10a and 10b, respectively.

▶ Remark 28. In particular, **1** holds for $\frac{\varepsilon}{\mathcal{R}} \leq 0.225$ and $\frac{\alpha}{\mathcal{R}} = 0.359$; and **2** for $\frac{\varepsilon}{\mathcal{R}} \leq 0.178$ and $\frac{\alpha}{\mathcal{R}} = 0.207$, better bounds than the previous existing ones [22, Theorem 13.16][24].

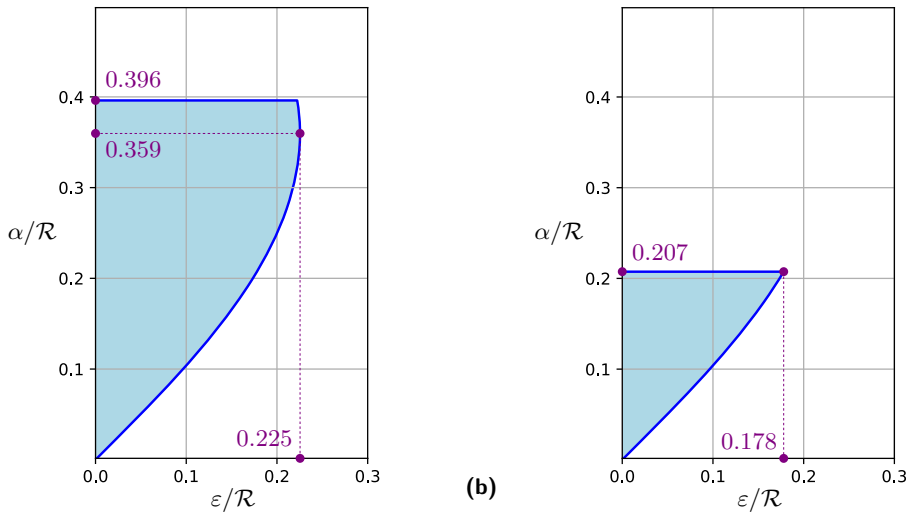

Figure 10 Pairs of $(\frac{\varepsilon}{\mathcal{R}}, \frac{\alpha}{\mathcal{R}})$ for which $\texttt{NaiveSquash}(P, \alpha)$ (a) and $\texttt{PracticalSquash}(P, \alpha)$ (b) are correct, for $P \subseteq \mathcal{M} \subseteq P^{\oplus\varepsilon}$ and $d = 3$.

5.4 The restricted Delaunay complex

We recall from [32] that the *restricted Delaunay complex* is

$$\mathrm{Del}_{\mathcal{M}}(P) = \{\sigma \subseteq P \mid \sigma \neq \emptyset \text{ and } V(\sigma, P) \cap \mathcal{M} \neq \emptyset\}.$$

▶ **Theorem 29.** *Let $\mathcal{M}$ be a C^2 surface in $\mathbb{R}^3$ whose reach is at least $\mathcal{R} > 0$. Let P be a finite set such that $P \subseteq \mathcal{M} \subseteq P^{\oplus\varepsilon}$ for $0 \leq \frac{\varepsilon}{\mathcal{R}} \leq 0.225$. Under the additional generic assumption that all Voronoi cells of P intersect $\mathcal{M}$ transversally, $\mathrm{Del}_{\mathcal{M}}(P)$ is a triangulation of $\mathcal{M}$.*

Abstract

Given a set S of n colored sites, each $s \in S$ associated with a distance-to-site function $\delta_s \colon \mathbb{R}^2 \to \mathbb{R}$, we consider two distance-to-color functions for each color: one takes the minimum of δ_s for sites $s \in S$ in that color and the other takes the maximum. These two sets of distance functions induce two families of higher-order Voronoi diagrams for colors in the plane, namely, the minimal and maximal order-k color Voronoi diagrams, which include various well-studied Voronoi diagrams as special cases. In this paper, we derive an exact upper bound $4k(n-k)-2n$ on the total number of vertices in both the minimal and maximal order-k color diagrams for a wide class of distance functions δ_s that satisfy certain conditions, including the case of point sites S under convex distance functions and the L_p metric for any $1 \leqslant p \leqslant \infty$. For the L_1 (or, L_∞) metric, and other convex polygonal metrics, we show that the order-k minimal diagram of point sites has $O(\min\{k(n-k),(n-k)^2\})$ complexity, while its maximal counterpart has $O(\min\{k(n-k),k^2\})$ complexity. To obtain these combinatorial results, we extend the Clarkson–Shor framework to colored objects, and demonstrate its application to several fundamental geometric structures, including higher-order color Voronoi diagrams, colored j-facets, and levels in the arrangements of piecewise linear/algebraic curves/surfaces. We also present iterative algorithms to compute higher-order color Voronoi diagrams.

1 Introduction

Let S be a set of n *sites*, each of which is assigned a color from a set $K = \{1, \ldots, m\}$ of m colors. Let $S_i \subseteq S$ be the set of sites in color $i \in K$. We consider two *distance-to-color* functions from any point $x \in \mathbb{R}^2$ to each color $i \in K$:

$$d_i(x) := \min_{s \in S_i} \delta_s(x) \quad \text{and} \quad \bar{d}_i(x) := \max_{s \in S_i} \delta_s(x),$$

where $\delta_s(x)$ denotes the prescribed distance-to-site function from $x \in \mathbb{R}^2$ to site $s \in S$.

Based on the two sets of point-to-color distances, we can define two different Voronoi diagrams of m colors in K. For each $1 \leqslant k \leqslant m-1$ and subset $H \subseteq K$ with $|H| = k$, define

$$R_k(H;S) := \{x \in \mathbb{R}^2 \mid d_i(x) < d_j(x) \text{ for all } i \in H \text{ and } j \in K \setminus H\}$$
$$\overline{R}_k(H;S) := \{x \in \mathbb{R}^2 \mid \bar{d}_i(x) > \bar{d}_j(x) \text{ for all } i \in H \text{ and } j \in K \setminus H\},$$

called the *minimal* and *maximal color Voronoi regions* of H with respect to S. We then define the *order-k minimal color Voronoi diagram* of S, $\mathsf{CVD}_k(S)$, to be the partition of $\mathbb{R}^2$ into the minimal regions $R_k(H;S)$, for all $H \subset K$ with $|H| = k$; the *order-k maximal color Voronoi diagram* of S, $\overline{\mathsf{CVD}}_k(S)$, to be the partition of $\mathbb{R}^2$ into the maximal regions $\overline{R}_k(H;S)$. In other words, $\mathsf{CVD}_k(S)$ partitions $\mathbb{R}^2$ by k *nearest colors* under the minimal distances $\{d_i\}_{i \in K}$, while $\overline{\mathsf{CVD}}_k(S)$ partitions $\mathbb{R}^2$ by k *farthest colors* under the maximal distances $\{\bar{d}_i\}_{i \in K}$.

These two families of color Voronoi diagrams generalize various conventional counterparts. For $k = 1$, $\mathsf{CVD}_1(S)$ and $\overline{\mathsf{CVD}}_1(S)$ correspond to the ordinary nearest-site and farthest-site Voronoi diagrams of S, $\mathsf{VD}(S)$ and $\mathsf{FVD}(S)$, respectively, where adjacent faces of a common color are merged. See Figure 1(a) and (b).

- If $m = n$, that is, each site in S has a distinct color, then $\mathsf{CVD}_k(S) = \mathsf{VD}_k(S)$, the ordinary order-$k$ Voronoi diagram without colors [13, 29, 30, 40]. In this case, it holds that $\overline{\mathsf{CVD}}_k(S) = \mathsf{VD}_{n-k}(S)$, also known as the *order-k farthest-site Voronoi diagram* or the *order-k maximal Voronoi diagram* [5].
- The *farthest color Voronoi diagram* $\mathsf{FCVD}(S)$ [1, 9, 24, 32] partitions the plane $\mathbb{R}^2$ into regions of colors $i \in K$ that consist of all points $p \in \mathbb{R}^2$ whose *farthest* color is i with respect to the minimal distances $\{d_i\}_{i\in K}$. The *Hausdorff Voronoi diagram* $\mathsf{HVD}(S)$, also known as the *min-max* or *cluster* Voronoi diagram [22, 37, 38], similarly partitions $\mathbb{R}^2$ into regions of *nearest* colors with respect to the maximal distances $\{\bar{d}_i\}_{i\in K}$. We thus have $\mathsf{FCVD}(S) = \mathsf{CVD}_{m-1}(S)$ and $\mathsf{HVD}(S) = \overline{\mathsf{CVD}}_{m-1}(S)$. These two diagrams are often refined so that the region of each color $i \in K$ is subdivided into subregions of sites in S_i that determine the distance-to-color d_i or $\bar{d}_i$. We denote these refined versions by $\mathsf{FCVD}^*(S)$ and $\mathsf{HVD}^*(S)$, respectively. See Figure 1(c) and (d).

In this paper, we initiate the study of higher-order color Voronoi diagrams, $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$, with general distance functions δ_s for $s \in S$. Our main results are as follows:

(1) We prove an exact upper bound $4k(n-k) - 2n$ on the total number of vertices of both order-k diagrams $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ for each $1 \leqslant k \leqslant m-1$, when the sites $s \in S$ are points and $\delta_s(x)$ is given as the *convex distance* from $x \in \mathbb{R}^2$ to s based on any convex and compact subset of $\mathbb{R}^2$, which includes the L_p distance for any $1 \leqslant p \leqslant \infty$. This result is in fact a corollary of our more general result: we derive an exact equation under certain conditions on functions δ_s, which only requires relations on the numbers of vertices and unbounded edges in $\mathsf{VD}(S')$ and $\mathsf{FVD}(S')$ for $S' \subseteq S$. The bound $4k(n-k) - 2n$ can be realized, for example, when $m = n$, so it is tight and best possible.

(2) Under the L_1 or the L_∞ metric, we prove that $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ consist of at most $\min\{4k(n-k) - 2n, 4(n-k)^2\}$ and $\min\{4k(n-k) - 2n, 2k^2\}$ vertices, respectively. Similar bounds are derived for any convex distance function based on a convex polygon.

(3) We present an iterative algorithm that computes color Voronoi diagrams of order 1 to k in $O(k^2 n + n \log n)$ expected or $O(k^2 n \log n)$ worst-case time, provided that S and $\{\delta_s\}_{s\in S}$ satisfy the requirements of abstract Voronoi diagrams [28] and an additional condition (see Section 5), which includes colored points S under any smooth convex distance function. For points S in the Euclidean plane, it can be reduced to $O(k^2 n + n \log n)$ worst-case time.

Our combinatorial results generalize previously known bounds for the ordinary higher-order Voronoi diagrams $\mathsf{VD}_k(S)$ of uncolored sites S, which is a special case of $m = n$ in our setting. The asymptotically tight bound $O(k(n-k))$ on the complexity of $\mathsf{VD}_k(S)$ has been proved not only for points [29, 30] under the L_p metric but also for line segments [40] and even in the abstract setting [13]. Under the L_1 (or L_∞) metric, the complexity of $\mathsf{VD}_k(S)$ is known to be $O(\min\{k(n-k), (n-k)^2\})$ for a set S of points or line segments [30, 40].

In particular, the same exact number $4k(n-k) - 2n$ can be derived for the ordinary order-k diagram $\mathsf{VD}_k(S)$ and order-$(n-k)$ diagram $\mathsf{VD}_{n-k}(S)$ under the Euclidean metric from previous results [20, 21, 29]. In his book [21, Chapter 13], Edelsbrunner showed that the number of vertices of $\mathsf{VD}_k(S)$ is *exactly* $(4k-2)n - 2k^2 - e_k - 2\sum_{i=1}^{k-1} e_i$, if S is in general position, where e_k denotes the number of unbounded edges in $\mathsf{VD}_k(S)$ (or, equivalently, *k-sets* in S). One can easily verify that the total number of vertices in $\mathsf{VD}_k(S)$ and $\mathsf{VD}_{n-k}(S)$ is exactly $4k(n-k) - 2n$ by using the identities: $e_k = e_{n-k}$ and $\sum_{k=1}^{n-1} e_k = n(n-1)$. This can also be verified from the inductive approach of Lee [29]. As a recent result related to ours, Biswas et al. [12] derived exact relations for the complexity of 3D Euclidean higher-order Voronoi diagrams with Morse theory, extending the inductive argument by Lee.

Another remarkable special case of our results is when $k = m - 1$, which yields the $O(m(n - m + 1))$ bound for the farthest color Voronoi diagram $\mathsf{FCVD}(S) = \mathsf{CVD}_{m-1}(S)$ and the Hausdorff Voronoi diagram $\mathsf{HVD}(S) = \overline{\mathsf{CVD}}_{m-1}(S)$. The worst-case complexity of $\mathsf{FCVD}(S)$ and $\mathsf{HVD}(S)$ is known to be $\Theta(mn)$ or $\Theta(n^2)$, if S is a set of points or line segments under the Euclidean or L_1 metric [1, 9, 22, 24, 38]. While the upper bounds $O(mn)$ and $O(n^2)$ are shown to be tight by matching lower bound constructions [1, 22, 24], they become significantly loose when n is close to m; if $n = m$, we have $\mathsf{FCVD}(S) = \mathsf{FVD}(S)$ and $\mathsf{HVD}(S) = \mathsf{VD}(S)$, where both have linear complexity. Hence, our new results not only prove tight upper bounds simultaneously on both diagrams, but also formally reveal a smooth extension upon the previous knowledge about the ordinary Voronoi diagrams for any $m \leqslant n$. Prior to our results, it was known that the complexity of $\mathsf{FCVD}(S)$ and $\mathsf{HVD}(S)$ can range from $\Theta(n)$ to $\Theta(m(n - m + 1))$ expressed in terms of geometric parameters, called *straddles* for $\mathsf{FCVD}(S)$ [33] and *crossings* for $\mathsf{HVD}(S)$ [38]. Conditions under which these diagrams have linear complexity have also been discussed [8, 33, 38].

Our combinatorial results are based on a color-augmented extension of the Clarkson–Shor framework [20], so-called the *colorful Clarkson–Shor framework*, which has its own interest with various applications. Our notions of colored objects and configurations are naturally inherited from any set system that fits in the original Clarkson–Shor framework, and yield a systematic scheme to deal with objects that are collections of primitive elements. Our new framework provides a unifying approach to derive the complexity of higher-order color Voronoi diagrams under general distances δ_s, including the well-studied diagrams $\mathsf{FCVD}(S)$, $\mathsf{HVD}(S)$, and the ordinary higher-order diagram $\mathsf{VD}_k(S)$. In deriving our results, we make use of a close relation between the color diagrams $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ and the *colored* k-facets of S. An analogous relation for the Euclidean ordinary case (without colors) has been shown by Clarkson and Shor [20] and Edelsbrunner [21]. We also derive lower and upper bounds on the number of colored k-facets in $\mathbb{R}^2$. We also demonstrate more applications of the colorful Clarkson–Shor framework that result in several new bounds on levels of arrangements of piecewise linear or algebraic curves and surfaces; see [10].

Our algorithm follows the principle of iteratively computing all order-i Voronoi diagrams for $1 \leqslant i \leqslant k$, and compares to the $O(k^2 n \log n)$-time counterpart of Lee [29] for computing $\mathsf{VD}_1(S), \ldots, \mathsf{VD}_k(S)$ for points in the Euclidean metric. After a series of improvements [2, 3, 7, 16, 18, 36, 41], the first optimal $O(n \log n + kn)$-time algorithm that computes $\mathsf{VD}_k(S)$ for points S in the Euclidean plane was eventually presented in 2024 by Chan et al. [17]. Efficient algorithms of different approaches are also known for computing $\mathsf{VD}_k(S)$ of line segments S [40] or under the model of abstract Voronoi diagrams [14, 15]; and for computing $\mathsf{FCVD}^*(S)$ [1, 9, 24, 33] and $\mathsf{HVD}^*(S)$ [4, 22, 38].

Due to space limit, proofs are omitted but can be found in the full version [10].

2 Color Voronoi diagrams and arrangements

Let S be a set of n *sites*, which can be any abstract objects, and $\delta_s \colon \mathbb{R}^2 \to \mathbb{R}$ for $s \in S$ be a given continuous function. We assume that the functions δ_s are in *general position*, similarly to [26]. More precisely, let γ_s be the graph of δ_s, that is, the xy-monotone surface $\{(p, \delta_s(p)) \mid p \in \mathbb{R}^2\}$ in $\mathbb{R}^3$, and $\Gamma := \{\gamma_s \mid s \in S\}$. By the general position of functions δ_s, we mean the following: no more than three surfaces in Γ meet at a common point, no more than two surfaces in Γ meet at a one-dimensional curve, no two surfaces in Γ are tangent to each other, and none of the surfaces in Γ is tangent to the intersection curve of two others in Γ.

We denote the minimization diagram of Γ by $\mathsf{VD}(S)$, the *nearest-site Voronoi diagram* of S, and the maximization diagram of Γ by $\mathsf{FVD}(S)$, the *farthest-site Voronoi diagram* of S. It is well known that the ordinary (uncolored) higher-order Voronoi diagrams $\mathsf{VD}_k(S)$ of S are determined by levels of the arrangement $\mathcal{A}(\Gamma)$ of Γ as established in earlier work [5, 23]. In the following, we discuss an analogous relation between order-k color Voronoi diagrams and levels of certain surfaces in $\mathbb{R}^3$.

Let us assume that the sites in S are colored with m colors in $K = \{1, \ldots, m\}$. Let $\kappa\colon S \to K$ denote a color assignment such that the color of $s \in S$ is $\kappa(s) \in K$. Let $S_i := \{s \in S \mid \kappa(s) = i\}$ and $\Gamma_i := \{\gamma_s \mid s \in S_i\}$ for $i \in K$. Define E_i and $\overline{E}_i$ to be the lower and upper envelopes of surfaces in Γ_i, respectively, and consider the two arrangements $\mathcal{A}_\Gamma = \mathcal{A}(\{E_1, \ldots, E_m\})$ and $\overline{\mathcal{A}}_\Gamma = \mathcal{A}(\{\overline{E}_1, \ldots, \overline{E}_m\})$. Note that E_i is the graph of the minimal distance function d_i of color $i \in K$, and $\overline{E}_i$ is the graph of the maximal distance $\bar{d}_i$. We then consider the levels of the arrangements $\mathcal{A}_\Gamma$ and $\overline{\mathcal{A}}_\Gamma$. For $1 \leqslant k \leqslant m$, let L_k be the k-level of $\mathcal{A}_\Gamma$ *from below* and $\overline{L}_k$ be the k-level of $\overline{\mathcal{A}}_\Gamma$ *from above*. So, L_1 is the lower envelope of $E_1, \ldots, E_m$, and $\overline{L}_1$ is the upper envelope of $\overline{E}_1, \ldots, \overline{E}_m$. Thus, projecting L_1 and $\overline{L}_1$ down onto $\mathbb{R}^2$ yields $\mathsf{VD}(S)$ and $\mathsf{FVD}(S)$, respectively. On the other hand, L_m is the upper envelope of the lower envelopes $E_1, \ldots, E_m$, and $\overline{L}_m$ is the lower envelope of the upper envelopes $\overline{E}_1, \ldots, \overline{E}_m$. Projecting L_m and $\overline{L}_m$ down onto $\mathbb{R}^2$ yields the refined diagrams $\mathsf{FCVD}^*(S)$ and $\mathsf{HVD}^*(S)$, respectively [22, 24].

From the viewpoint of [5, 23], we observe the following.

- The order-k color Voronoi diagrams, $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$, for $1 \leqslant k \leqslant m-1$ are the projections of $L_k \cap L_{k+1}$ and of $\overline{L}_k \cap \overline{L}_{k+1}$, respectively, onto $\mathbb{R}^2$.
- For each $1 \leqslant k \leqslant m$, let $\mathsf{CVD}^*_k(S)$ denote the planar map obtained by projecting L_k down onto $\mathbb{R}^2$; analogously, let $\overline{\mathsf{CVD}}^*_k(S)$ be the map obtained by projecting $\overline{L}_k$ onto $\mathbb{R}^2$. By definition, $\mathsf{CVD}^*_k(S)$ and $\overline{\mathsf{CVD}}^*_k(S)$ refine $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$, respectively. Each face f of $\mathsf{CVD}^*_k(S)$ (or of $\overline{\mathsf{CVD}}^*_k(S)$) is *associated with* a site $s \in S_i$ such that, for any point $p \in f$, $d_i(p) = \delta_s(p)$ and $i \in K$ is the *k-th nearest color* from p with respect to $\{d_i\}_{i\in K}$ (resp. $\bar{d}_i(p) = \delta_s(p)$ and $i \in K$ is the *k-th farthest color* from p with respect to $\{\bar{d}_i\}_{i\in K}$). This way, the refined diagrams $\mathsf{CVD}^*_k(S)$ and $\overline{\mathsf{CVD}}^*_k(S)$ partition the plane $\mathbb{R}^2$ by the k-th nearest and k-th farthest colors, respectively.

From the construction, it is clear that $\mathsf{CVD}^*_1(S) = \mathsf{VD}(S)$ and $\overline{\mathsf{CVD}}^*_1(S) = \mathsf{FVD}(S)$. Note also that $\mathsf{CVD}^*_m(S) = \mathsf{FCVD}^*(S)$ and $\overline{\mathsf{CVD}}^*_m(S) = \mathsf{HVD}^*(S)$, whereas $\mathsf{FCVD}(S) = \mathsf{CVD}_{m-1}(S)$ and $\mathsf{HVD}(S) = \overline{\mathsf{CVD}}_{m-1}(S)$.

Figures 2 and 3 illustrate an example under the Euclidean metric, where S consists of $n = 9$ points and $m = 4$ colors: $S_1 = \{s_1, s_2, s_5\}$, $S_2 = \{s_3, s_9\}$, $S_3 = \{s_4, s_6, s_8\}$, and $S_4 = \{s_7\}$, in red, blue, purple, and black, respectively; selected regions of $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ are labeled in (a)–(c); faces associated with $s_6 \in S_3$ and those with $s_9 \in S_2$ in $\mathsf{CVD}^*_k(S)$ and $\overline{\mathsf{CVD}}^*_k(S)$ are shaded in purple and blue, respectively, in (d)–(g).

Now, consider the vertices and edges of the arrangements $\mathcal{A}_\Gamma$ and $\overline{\mathcal{A}}_\Gamma$. By the general position assumption, each vertex v of $\mathcal{A}_\Gamma$ or of $\overline{\mathcal{A}}_\Gamma$ is determined by exactly three sites $s, s', s'' \in S$ in such a way that v is a common intersection of three surfaces $\gamma_s, \gamma_{s'}, \gamma_{s''} \in \Gamma$. Such a vertex v is called *c-chromatic* for $c \in \{1, 2, 3\}$ if $|\{\kappa(s), \kappa(s'), \kappa(s'')\}| = c$. (Note that any 1-chromatic vertex is a vertex of some single envelope E_i or $\overline{E}_i$.) Similarly, each edge of $\mathcal{A}_\Gamma$ and of $\overline{\mathcal{A}}_\Gamma$ is determined by exactly two sites in S, and is either 1- or 2-chromatic according to the number of involved colors. We identify each vertex or edge of $\mathsf{CVD}^*_k(S)$ or of $\overline{\mathsf{CVD}}^*_k(S)$ by its original lifted copy in $\mathcal{A}_\Gamma$ or in $\overline{\mathcal{A}}_\Gamma$. Observe that any c-chromatic vertex or edge of $\mathcal{A}_\Gamma$ or of $\overline{\mathcal{A}}_\Gamma$ appears in c consecutive levels, as it lies in the intersection of

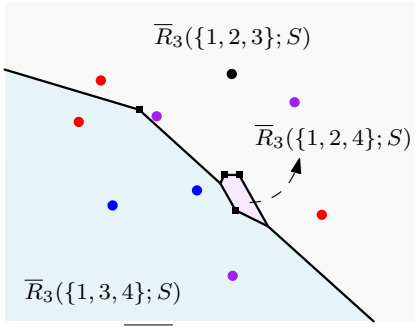
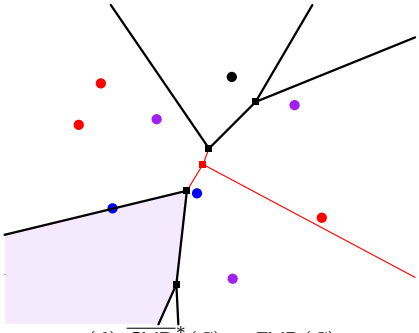
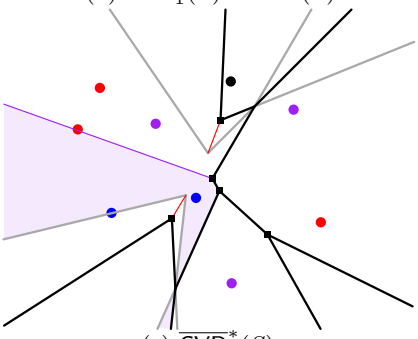
(b) $\overline{\mathsf{CVD}}_2(S)$



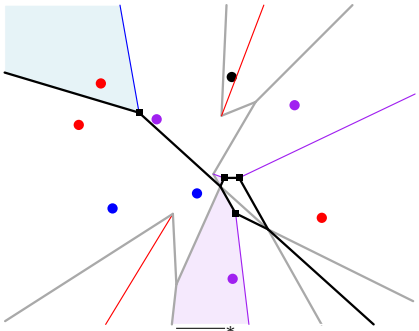
(c) $\overline{\mathsf{CVD}}_3(S) = \mathsf{HVD}(S)$



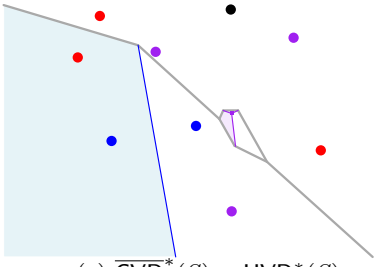
(d) $\overline{\mathsf{CVD}}_1^*(S) = \mathsf{FVD}(S)$



(e) $\overline{\mathsf{CVD}}_2^*(S)$



(f) $\overline{\mathsf{CVD}}_3^*(S)$



(g) $\overline{\mathsf{CVD}}_4^*(S) = \mathsf{HVD}^*(S)$

Figure 3 The maximal color diagrams $\overline{\mathsf{CVD}}_k(S)$ and the refined diagrams $\overline{\mathsf{CVD}}_k^*(S)$.

c surfaces from $\{E_i\}_{i\in K}$ or from $\{\overline{E}_i\}_{i\in K}$, respectively. Thus, c-chromatic vertices appear in c consecutive orders of the refined diagrams. We call a vertex or an edge of $\mathsf{CVD}^*_k(S)$ or of $\overline{\mathsf{CVD}}^*_k(S)$ *new* if it does not appear in $\mathsf{CVD}^*_{k-1}(S)$ or in $\overline{\mathsf{CVD}}^*_{k-1}(S)$, respectively; and *old*, otherwise. By definition, the vertices and edges of $\mathsf{CVD}^*_1(S)$ and $\overline{\mathsf{CVD}}^*_1(S)$ are all new. Note that every edge of $\mathsf{CVD}_k(S)$ (or, of $\overline{\mathsf{CVD}}_k(S)$) is 2-chromatic and new, and appears both in $\mathsf{CVD}^*_k(S)$ and $\mathsf{CVD}^*_{k+1}(S)$ (in $\overline{\mathsf{CVD}}^*_k(S)$ and $\overline{\mathsf{CVD}}^*_{k+1}(S)$, resp.), being first new and then old. See Figures 2 and 3, where new 2-chromatic edges are in black, old 2-chromatic edges in gray, 1-chromatic edges in their own color, and new vertices marked by small squares.

We define $v_{c,j} = v_{c,j}(S)$ for $1 \leqslant c \leqslant 3$ and $0 \leqslant j \leqslant m-1$ to be the number of c-chromatic vertices in $\mathcal{A}_\Gamma$ below which there are exactly j surfaces from $\{E_i\}_{i\in K}$; $\bar{v}_{c,j} = \bar{v}_{c,j}(S)$ to be the number of c-chromatic vertices in $\overline{\mathcal{A}}_\Gamma$ above which there are exactly j surfaces from $\{\overline{E}_i\}_{i\in K}$.

▶ **Lemma 1.** *For any $1 \leqslant c \leqslant 3$ and $1 \leqslant k \leqslant m$, the following hold:*

(i) *The number of new c-chromatic vertices of $\mathsf{CVD}^*_k(S)$ is exactly $v_{c,k-1}$, and the number of new c-chromatic vertices of $\overline{\mathsf{CVD}}^*_k(S)$ is exactly $\bar{v}_{c,k-1}$.*

(ii) *The number of vertices of $\mathsf{CVD}^*_k(S)$ is exactly $v_{3,k-1}+v_{3,k-2}+v_{3,k-3}+v_{2,k-1}+v_{2,k-2}+v_{1,k-1}$, and the number of vertices of $\overline{\mathsf{CVD}}^*_k(S)$ is exactly $\bar{v}_{3,k-1}+\bar{v}_{3,k-2}+\bar{v}_{3,k-3}+\bar{v}_{2,k-1}+\bar{v}_{2,k-2}+\bar{v}_{1,k-1}$, where $v_{c,j} = \bar{v}_{c,j} = 0$ for $j < 0$.*

(iii) *The number of vertices of $\mathsf{CVD}_k(S)$ is exactly $v_{3,k-1}+v_{3,k-2}+v_{2,k-1}$, and the number of vertices of $\overline{\mathsf{CVD}}_k(S)$ is exactly $\bar{v}_{3,k-1}+\bar{v}_{3,k-2}+\bar{v}_{2,k-1}$.*

3 The colorful Clarkson–Shor framework

The Clarkson–Shor technique [20] is based on a general framework dealing with so-called configurations or ranges defined by a set of objects. Specifically, the following three ingredients are supposed to be given with a constant integer parameter $d \geqslant 1$, see also Sharir [42]:

- A set S of n *objects*.
- A set $\mathcal{F}(S)$ of *configurations*, each of which is defined by exactly d objects in S.
- A *conflict relation* $\chi \subseteq S \times \mathcal{F}(S)$ between objects $s \in S$ and configurations $f \in \mathcal{F}(S)$ with the requirement that none of the d objects defining f are in conflict with f.

In the original framework, the number of objects that define a configuration does not have to be exactly d, but at most d. This restriction can be achieved by adding dummy objects to S.

Let us call such a triplet $(S, \mathcal{F}(S), \chi)$ a *CS-structure*. Given any CS-structure $(S, \mathcal{F}(S), \chi)$ with parameter d, we now impose a *color* assignment $\kappa\colon S \to K$ to the objects in S, where $K = \{1, 2, \ldots, m\}$ denotes the set of m colors with $m \leqslant n$. For each color $i \in K$, let $S_i := \{s \in S \mid \kappa(s) = i\}$. For $f \in \mathcal{F}(S)$ and set $D_f \subseteq S$ of d objects defining f, $\kappa(D_f) = \{\kappa(s) \mid s \in D_f\}$ is called a set of colors defining f. We build a *color-to-configuration conflict relation* $\chi_\kappa \subseteq K \times \mathcal{F}(S)$ such that a color $i \in K$ is in conflict with a configuration $f \in \mathcal{F}(S)$ if an object $s \in S_i$ is in conflict with f, that is, $(i, f) \in \chi_\kappa$ if and only if $(s, f) \in \chi$ for some $s \in S_i$. We are then interested in those configurations $f \in \mathcal{F}(S)$ such that none of its defining colors in $\kappa(D_f)$ are in conflict with f. Let $\mathcal{F}(S, \kappa) \subseteq \mathcal{F}(S)$ be the set of these configurations, called *colored configurations with respect to κ*. We call $f \in \mathcal{F}(S, \kappa)$ *c-chromatic* if $|\kappa(D_f)| = c$ for $1 \leqslant c \leqslant d$, and let the *weight* of f be the number of colors in K that are in conflict with f. Let $\mathcal{F}_{c,j}(S, \kappa) \subseteq \mathcal{F}(S, \kappa)$ be the set of c-chromatic weight-j colored configurations in $\mathcal{F}(S, \kappa)$.

Considering the colors in K as new *objects*, each of which is a collection of objects in S, observe that this color-augmented structure $(K, \bigcup_j \mathcal{F}_{c,j}(S, \kappa), \chi_\kappa)$ for each $1 \leqslant c \leqslant d$ is again a CS-structure with parameter c. Therefore, the main lemma of Clarkson and Shor [20, Lemma 2.1] automatically implies the following.

▶ **Lemma 2.** *With the above notations, let $1 \leqslant c \leqslant d$, $r \geqslant 0$, and $a \geqslant 0$ be integers, and $R \subseteq K$ be a random subset of r colors. Then,*

$$\binom{m}{r} \mathbf{E}[|\mathcal{F}_{c,a}(S_R, \kappa_R)|] \geqslant \sum_{j=0}^{m-c} |\mathcal{F}_{c,j}(S,\kappa)| \binom{j}{a} \binom{m-c-j}{r-c-a},$$

where $S_R = \bigcup_{i\in R} S_i$ and $\kappa_R \colon S_R \to R$ denotes the restriction of κ to S_R. The equality holds if each configuration in $\mathcal{F}(S,\kappa)$ is defined by a unique set of d objects in S.

In probabilistic arguments dealing with CS-structures, it is usually necessary to have an upper bound on the number of weight-0 configurations. For any subset $S' \subseteq S$, let $\mathcal{F}_0(S') \subseteq \mathcal{F}(S')$ be the set of (uncolored) configurations f of weight 0, that is, $(s,f) \notin \chi$ for all $s \in S'$. Let $T_0(n')$ be any nondecreasing function with $T_0(0) = 0$ that upper bounds the number $|\mathcal{F}_0(S')|$ of these configurations for any set S' of n' uncolored objects. The following is obvious by definition.

▶ **Lemma 3.** *Let $S' \subseteq S$ be any subset and κ' be any color assignment for S'. Then,*

$$\sum_{c=1}^{d} |\mathcal{F}_{c,0}(S',\kappa')| = |\mathcal{F}_0(S')| \leqslant T_0(|S'|).$$

In many applications, such an upper bound function T_0 is either known from previous work or relatively easy to obtain. Once we have T_0, we can derive general upper bounds on the number of corresponding colored configurations of weight at most k in such a procedural way as done for uncolored cases [20, 34, 43].

▶ **Theorem 4.** *With the above notations, suppose T_0 is a convex function. For each $1 \leqslant c \leqslant d$, the total number of $(\leqslant c)$-chromatic colored configurations is bounded by*

$$\sum_{b=1}^{c} \sum_{j=0}^{m-b} \binom{m-b-j}{c-b} |\mathcal{F}_{b,j}(S,\kappa)| \leqslant \binom{m}{c} \cdot \frac{1}{m} \sum_{i\in K} T_0(c|S_i|) = O(m^{c-1} \cdot T_0(cn)).$$

Also, for each $2 \leqslant c \leqslant d$ and $0 \leqslant k \leqslant \lfloor \frac{m}{c} \rfloor - 1$, it holds that

$$\sum_{j=0}^{k} |\mathcal{F}_{c,j}(S,\kappa)| = O\left(\frac{(k+1)^c}{m} \cdot \sum_{i\in K} T_0\left(\frac{m|S_i|}{k+1}\right)\right) = O\left(\frac{(k+1)^c}{m} \cdot T_0\left(\frac{mn}{k+1}\right)\right).$$

Remark that the left-hand side of the first bound can be seen as a "weighted" count of $(\leqslant c)$-chromatic colored configurations, and that the second bound in Theorem 4 for $n = m$ implies Clarkson and Shor's original bound, $O((k+1)^c \cdot T_0(n/(k+1)))$, for uncolored cases [20, Theorem 3.1]. Note that Theorem 4 still implies the same Clarkson–Shor bound if T_0 is linear. Moreover, if the colors are assigned in a favorably uniform way, we can derive similar bounds as well without assuming the convexity of T_0.

▶ **Theorem 5.** *With the above notations, suppose $|S_i| \leqslant \rho \cdot \frac{n}{m}$ for every $i \in K$ for some $\rho \geqslant 1$. Then, for $1 \leqslant c \leqslant d$,*

$$\sum_{b=1}^{c} \sum_{j=0}^{m-b} \binom{m-b-j}{c-b} |\mathcal{F}_{b,j}(S,\kappa)| \leqslant \binom{m}{c} T_0\left(c\rho \cdot \frac{n}{m}\right),$$

and for $2 \leqslant c \leqslant d$ and $0 \leqslant k \leqslant \lfloor \frac{m}{c} \rfloor - 1$,

$$\sum_{j=0}^{k} |\mathcal{F}_{c,j}(S,\kappa)| = O\left((k+1)^c \cdot T_0\left(\rho \cdot \frac{n}{k+1}\right)\right).$$

3.1 Colored j-facets

Let S be a set of n points in $\mathbb{R}^d$. A *j-facet* in S is an oriented $(d-1)$-simplex σ with its vertices chosen from S such that the open half-space on its positive side σ^+ contains exactly j points of S. Among the first applications of the original Clarkon–Shor framework was the tight upper bound $O(k^{\lceil d/2\rceil}n^{\lfloor d/2\rfloor})$ on the number of $(\leqslant k)$-facets [20], implying the same asymptotic bound on the $(\leqslant k)$-level in the arrangement of hyperplanes via the point-to-hyperplane duality [21]. Many variants of j-facets have been discussed in the literature; we refer to a survey article by Wagner [44].

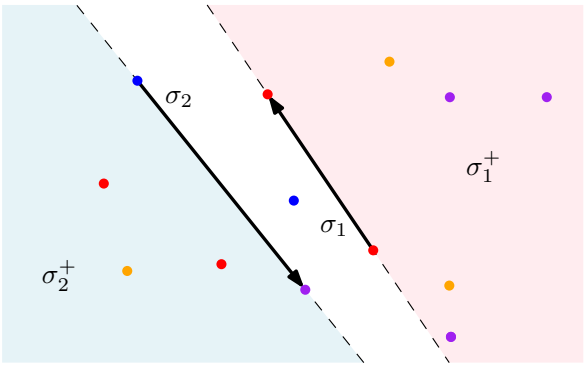


Figure 4 Colored j-facets in colored points in $\mathbb{R}^2$: a 1-chromatic 2-facet σ_1 and a 2-chromatic 2-facet σ_2 are shown, which choose half-planes σ_1^+ and σ_2^+ on their right side.

Now, we assume that the points in S are colored by a color assignment κ with m colors K. For any subset $A \subset \mathbb{R}^d$, we shall say that A *intersects* a color $i \in K$, if A contains some $s \in S_i$. According to our notion of colored configurations, a *colored j-facet* σ in S with respect to κ is an oriented simplex defined by d points $D_\sigma \subseteq S$ such that exactly j colors, but none of the defining colors in $\kappa(D_\sigma)$, are intersected by σ^+. See Figure 4. Notice that colored j-facets correspond to vertices of the arrangement of m lower/upper envelopes of hyperplanes dual to S_i for $i \in K$; see the full version [10] for a more detailed discussion.

For $1 \leqslant c \leqslant d$ and $j \geqslant 0$, let $e_{c,j}(S)$ be the number of c-chromatic j-facets in S and $e_j(S) := \sum_c e_{c,j}(S)$ be the number of all j-facets. Katoh and Tokuyama [27, Proposition 15] proved that $e_k(S) = O(k^{1/3}n)$ in $\mathbb{R}^2$ and $e_k(S) = O(k^{2/3}n^2)$ in $\mathbb{R}^3$ based on a generalized Lovász's Lemma. Theorems 4 and 5 directly imply the following bounds.

▶ **Corollary 6.** *For a set S of n colored points in $\mathbb{R}^d$ with m colors and any $0 \leqslant k \leqslant \lfloor \frac{m}{d} \rfloor - 1$, the number of $(\leqslant k)$-facets in S is $\sum_{j=0}^{k} e_j(S) = O(m^{\lfloor d/2\rfloor - 1}k^{\lceil d/2\rceil}n^{\lfloor d/2\rfloor})$. If there is a constant $\rho \geqslant 1$ such that $|S_i| \leqslant \rho \cdot \frac{n}{m}$ for every $i \in K$, then the bound is improved to $\sum_{j=0}^{k} e_j(S) = O(k^{\lceil d/2\rceil}n^{\lfloor d/2\rfloor})$.*

Note that for large k with $k \geqslant \lfloor \frac{m}{d} \rfloor$, the above bound on the number of $(\leqslant k)$-facets is asymptotically the same as the total number of configurations (see Theorems 4 and 5).

We continue our discussion for the case of $d = 3$. Lemma 3 implies that $e_0(S)$ counts the number of facets of the convex hull of S in $\mathbb{R}^3$. Using this fact, we observe the following.

▶ **Lemma 7.** *Let $2 \leqslant r \leqslant m$ and $R \subseteq K$ be a random set of r colors. It holds that*

$$\binom{m}{r}\mathbf{E}[e_0(S_R)] \leqslant 2\binom{m-1}{r-1}n - 4\binom{m}{r}$$

with equality when the points in S are in convex and general position.

Now, suppose that S is in convex and general position. Then, Lemmas 2 and 7 provide two different ways of exactly counting $\binom{m}{r}\mathbf{E}[e_0(S_R)]$ for $2 \leqslant r \leqslant m$, resulting in:

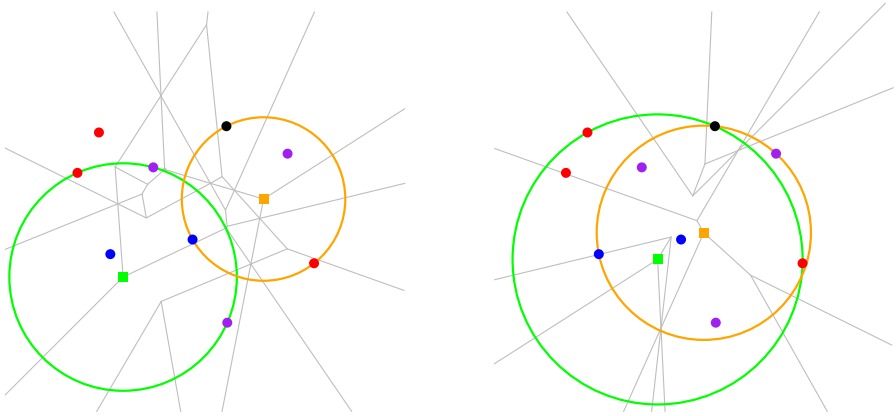
▶ **Theorem 8.** *Let $S \subset \mathbb{R}^3$ be a set of n points in convex and general position, each of which is colored by one of m colors. Then, it holds that for each $0 \leqslant j \leqslant m-2$*

$$e_{3,j}(S) + \sum_{i=0}^{j} e_{2,i}(S) + \sum_{i=0}^{j}(j-i+1)e_{1,i}(S) = 2(j+1)(n-j-2).$$

Note that Theorem 8 reveals an exact equation on $e_j(S) = e_{3,j}(S) + e_{2,j}(S) + e_{1,j}(S)$ for each $0 \leqslant j \leqslant m-2$. If $m = n$, that is, $|S_i| = 1$ for all $i \in K$, we have $e_{1,j}(S) = e_{2,j}(S) = 0$ for every j, so the equality $e_j(S) = 2(j+1)(n-j-2)$ holds. This exact number for the case of $m = n$ was proved earlier by Clarkson and Shor [20, Theorem 3.5].

3.2 Euclidean color Voronoi diagrams

Suppose that S consists of n points in general position in $\mathbb{R}^2$, with a given color assignment $\kappa\colon S \to K = \{1, \ldots, m\}$, and $\delta_s(x) = \|x - s\|_2$ is the Euclidean distance for each $s \in S$ and any $x \in \mathbb{R}^2$. Consider $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ for $1 \leqslant k \leqslant m-1$ in this setting.



(a) $\mathsf{CVD}_2^*(S)$ (b) $\overline{\mathsf{CVD}}_2^*(S)$

Figure 5 Selected new vertices (small squares) in $\mathsf{CVD}_2^*(S)$ and $\overline{\mathsf{CVD}}_2^*(S)$ and their corresponding circles. Green vertices are 2-chromatic, while orange ones are 3-chromatic. Observe that exactly one color is intersected by the interior $\hat{C}$ of each circle C in (a) and the exterior $\overline{C}$ of each circle C in (b).

We consider all circles through any three points in S with no regards of colors and let $\mathcal{F}(S)$ and $\overline{\mathcal{F}}(S)$ be the sets of the interiors and exteriors, respectively, of these circles. Also, define two conflict relations $\chi \subseteq S \times \mathcal{F}(S)$ and $\bar{\chi} \subseteq S \times \overline{\mathcal{F}}(S)$ to be the inclusion relation. We then consider colored configurations $\mathcal{F}(S,\kappa)$ and $\overline{\mathcal{F}}(S,\kappa)$ with respect to the given color assignment κ. Observe that each colored configuration of weight j in $\mathcal{F}(S,\kappa)$ or in $\overline{\mathcal{F}}(S,\kappa)$ corresponds to a new vertex of $\mathsf{CVD}_{j+1}^*(S)$ or of $\overline{\mathsf{CVD}}_{j+1}^*(S)$, respectively, by Lemma 1 and the discussions in Section 2, see Figure 5 illustrating the case of $j = 1$. Therefore, for each $1 \leqslant c \leqslant 3$ and $0 \leqslant j \leqslant m-c$, we have $v_{c,j}(S) = |\mathcal{F}_{c,j}(S,\kappa)|$ and $\bar{v}_{c,j}(S) = |\overline{\mathcal{F}}_{c,j}(S,\kappa)|$.

Now, consider the well-known lifting that maps points $p = (x,y)$ in $\mathbb{R}^2$ onto the unit paraboloid $U = \{z = x^2+y^2\}$ in $\mathbb{R}^3$: $p = (x,y) \mapsto p^\cup = (x,y,x^2+y^2)$. Let $S^\cup = \{s^\cup \mid s \in S\}$ be the set of lifted colored points in $\mathbb{R}^3$. (The horizontal plane $\{z = 0\}$ is identified as the original plane $\mathbb{R}^2$.) Consider colored j-facets in $S^\cup$ as in the previous section, and recall that $e_{c,j}(S^\cup)$ denotes the number of c-chromatic j-facets in $S^\cup$. We then observe the following.

▶ **Lemma 9.** *For $1 \leqslant c \leqslant 3$ and $0 \leqslant j \leqslant m - c$, we have $v_{c,j}(S) + \bar{v}_{c,j}(S) = e_{c,j}(S^{\cup})$.*

Since $S^{\cup}$ is in convex and general position, Theorem 8, together with Lemmas 1 and 9, implies an exact equation on the number of vertices in $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$.

▶ **Theorem 10.** *Let S be a set of n points with m colors in general position in the Euclidean plane, and $1 \leqslant k \leqslant m-1$. The total number of vertices in $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ is exactly*

$$4k(n-k) - 2n - 2\sum_{i=0}^{k-2} e_{2,i}(S^{\cup}) - \sum_{i=0}^{k-1}(2k-2i-1)e_{1,i}(S^{\cup}).$$

Theorem 10 implies the $O(k(n-k))$ bound on the complexity of $\mathsf{CVD}^*_k(S)$ and $\overline{\mathsf{CVD}}^*_k(S)$ by Lemma 1. An interesting special case of the above result is the following.

▶ **Corollary 11.** *Given a set S of n colored points with m colors in the Euclidean plane, the complexity of both $\mathsf{FCVD}^*(S)$ and $\mathsf{HVD}^*(S)$ is bounded by $O(m(n-m+1))$.*

4 Color Voronoi diagrams under general distance functions

We extend our results for the Euclidean case to general distance functions. We continue the discussions from Section 2, so S is a set of n sites, colored with m colors from K by a color assignment κ, and the functions $\delta_s \colon \mathbb{R}^2 \to \mathbb{R}$ for $s \in S$ are in general position.

Notice that the vertices of the arrangements $\mathcal{A}_\Gamma$ and $\overline{\mathcal{A}}_\Gamma$ form two set systems that fit in our colorful framework. More precisely, let $\mathcal{F}(S)$ be the set of vertices of the arrangement of n surfaces in Γ, and consider two conflict relations $\chi, \bar{\chi} \subseteq S \times \mathcal{F}(S)$ such that $(s,v) \in \chi$ if $v \in \mathcal{F}(S)$ lies above surface $\gamma_s \in \Gamma$ and $(s,v) \in \bar{\chi}$ if v lies below γ_s. Based on two CS-structures $(S, \mathcal{F}(S), \chi)$ and $(S, \mathcal{F}(S), \bar{\chi})$, we consider their colored configurations with respect to κ, denoted by $\mathcal{F}(S,\kappa)$ and $\overline{\mathcal{F}}(S,\kappa)$, respectively. By this construction, we have $v_{c,j}(S) = |\mathcal{F}_{c,j}(S,\kappa)|$ and $\bar{v}_{c,j}(S) = |\overline{\mathcal{F}}_{c,j}(S,\kappa)|$, counting c-chromatic weight-j colored configurations in $\mathcal{F}(S,\kappa)$ and in $\overline{\mathcal{F}}(S,\kappa)$, respectively, and, simultaneously, counting new c-chromatic vertices in $\mathsf{CVD}^*_{j+1}(S)$ and in $\overline{\mathsf{CVD}}^*_{j+1}(S)$ by Lemma 1.

For each $S' \subseteq S$, let $v_0(S')$ and $u_0(S')$ denote the numbers of vertices and unbounded edges[1], respectively, in $\mathsf{VD}(S')$; let $\bar{v}_0(S')$ and $\bar{u}_0(S')$ denote the numbers of vertices and unbounded edges, respectively, in $\mathsf{FVD}(S')$. We consider the following conditions.

V1 $v_0(S') = 2|S'| - 2 - u_0(S')$ for any $S' \subseteq S$.
V2 $\bar{v}_0(S') = \bar{u}_0(S') - 2$ for any $S' \subseteq S$.

Note that if every region in $\mathsf{VD}(S')$ is nonempty and simply connected, then Euler's formula and the general position assumption imply condition **V1**. If $\mathsf{FVD}(S')$ forms a tree, then every face of $\mathsf{FVD}(S')$ is unbounded and thus condition **V2** holds by Euler's formula.

In addition, for $c \in \{1,2\}$ and $j \geqslant 0$, let $u_{c,j} = u_{c,j}(S)$ be the number of c-chromatic unbounded edges in $\mathcal{A}_\Gamma$ that lie *above* exactly j surfaces in $\{E_i\}_{i\in K}$, and $\bar{u}_{c,j} = \bar{u}_{c,j}(S)$ be the number of c-chromatic unbounded edges in $\overline{\mathcal{A}}_\Gamma$ that lie *below* exactly j surfaces in $\{\overline{E}_i\}_{i\in K}$. From the discussion in Section 2, observe that $u_{c,j}$ and $\bar{u}_{c,j}$ are equal to the numbers of new c-chromatic unbounded edges in $\mathsf{CVD}^*_{j+1}(S)$ and in $\overline{\mathsf{CVD}}^*_{j+1}(S)$, respectively. Further, as for $v_{c,j}$ and $\bar{v}_{c,j}$, note that $u_{c,j}$ and $\bar{u}_{c,j}$ indeed count c-chromatic weight-j colored configurations based on two CS-structures for unbounded edges in the arrangement of n surfaces in Γ. Hence, assuming **V1** and **V2**, Lemma 3 implies: for any subset $R \subseteq K$,

[1] Hereafter, by counting unbounded edges, we mean counting vertices at infinity. So, if an unbounded edge separates the plane $\mathbb{R}^2$, then it is counted twice.

$$\sum_{c=1}^{3} v_{c,0}(S_R) = 2|S_R| - 2 - \sum_{c=1}^{2} u_{c,0}(S_R) \quad \text{and} \quad \sum_{c=1}^{3} \bar{v}_{c,0}(S_R) = \sum_{c=1}^{2} \bar{u}_{c,0}(S_R) - 2,$$

since $\mathsf{CVD}_1^*(S_R) = \mathsf{VD}(S_R)$ and $\overline{\mathsf{CVD}}_1^*(S_R) = \mathsf{FVD}(S_R)$. Combining these equations and the others obtained by Lemma 2, we have two systems of linear equations that can be solved in a similar way as done in Theorem 8. For $0 \leqslant j \leqslant m-1$, define

$$V_j := v_{3,j} + \sum_{i=0}^{j}(v_{2,i} + (j-i+1)v_{1,i}), \qquad U_j := \sum_{i=0}^{j}(u_{2,i} + (j-i+1)u_{1,i}),$$

$$\overline{V}_j := \bar{v}_{3,j} + \sum_{i=0}^{j}(\bar{v}_{2,i} + (j-i+1)\bar{v}_{1,i}), \quad \text{and} \quad \overline{U}_j := \sum_{i=0}^{j}(\bar{u}_{2,i} + (j-i+1)\bar{u}_{1,i}).$$

▶ **Lemma 12.** *With the above notations, let $0 \leqslant j \leqslant m-2$. Condition **V1** implies $V_j + U_j = (j+1)(2n-j-2)$; condition **V2** implies $\overline{V}_j - \overline{U}_j = -(j+1)(j+2)$.*

▶ **Theorem 13.** *Given S and $\{\delta_s\}_{s\in S}$ in general position as above, let $1 \leqslant k \leqslant m-1$ be an integer. If condition **V1** is true, then the number of vertices in $\mathsf{CVD}_k(S)$ is exactly*

$$2k(2n-k) - 2n - 2\sum_{i=0}^{k-2} v_{2,i}(S) - \sum_{i=0}^{k-1}(2k-2i-1)v_{1,i}(S) - U_{k-1} - U_{k-2};$$

*if condition **V2** is true, the number of vertices in $\overline{\mathsf{CVD}}_k(S)$ is exactly*

$$\overline{U}_{k-1} + \overline{U}_{k-2} - 2k^2 - 2\sum_{i=0}^{k-2} \bar{v}_{2,i}(S) - \sum_{i=0}^{k-1}(2k-2i-1)\bar{v}_{1,i}(S).$$

Remark that condition **V1** already implies the asymptotic complexity $O(k(n-k))$ of $\mathsf{CVD}_k(S)$ for $k \leqslant \frac{n}{2}$ as $2n-k \leqslant 3(n-k)$, while we have $O(kn)$ for $k > \frac{n}{2}$. Further, to show the $O(k(n-k))$ bound for any value of k for both $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$, it suffices to show that $U_j \geqslant (j+1)(j+2) - o(j^2)$ and $\overline{U}_j \leqslant (j+1)(2n-j-2) + o(j^2)$. In this way, Theorem 13 reduces the problem of bounding the complexity of higher-order color Voronoi diagrams to that of bounding the number of their unbounded edges. Also, note that Lemma 12 implies $U_j \leqslant (j+1)(2n-j-2)$ and $\overline{U}_j \geqslant (j+1)(j+2)$, if conditions **V1** and **V2** hold.

Remark also that if $\mathsf{VD}(S')$ and $\mathsf{FVD}(S')$ fall under the umbrella of abstract Voronoi diagrams, then conditions **V1** and **V2** hold [28,35], so Theorem 13 implies:

▶ **Corollary 14.** *Suppose that S and $\{\delta_s\}_{s\in S}$ imply a bisector system that satisfies the conditions of abstract Voronoi diagrams [28]. Then, the complexity of $\mathsf{CVD}_k(S)$ and $\mathsf{CVD}_k^*(S)$ is $O(k(n-k))$ for $1 \leqslant k \leqslant \lfloor \frac{n}{2} \rfloor$ and $O(kn)$ for $\lfloor \frac{n}{2} \rfloor + 1 \leqslant k \leqslant m$.*

The quantities U_j and $\overline{U}_j$, related to the number of unbounded edges, often turn out to be equal; the very typical example is the Euclidean case for point sites S, where the equality $u_{c,j}(S) = \bar{u}_{c,j}(S) = e_{c,j}(S)$ holds. This inspires us to consider the following third condition:

V3 $u_0(S') = \bar{u}_0(S')$ for any $S' \subseteq S$.

▶ **Lemma 15.** *Condition **V3** implies $U_j = \overline{U}_j$ for any $0 \leqslant j \leqslant m-1$.*

Assuming conditions **V1**–**V3**, we obtain the same exact number as in Theorem 10.

▶ **Theorem 16.** *Given S and $\{\delta_s\}_{s\in S}$ in general position as above, if conditions **V1**–**V3** hold, then the total number of vertices in $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ for $1 \leqslant k \leqslant m-1$ is exactly*

$$4k(n-k) - 2n - 2\sum_{i=0}^{k-2}(v_{2,i}(S) + \bar{v}_{2,i}(S)) - \sum_{i=0}^{k-1}(2k-2i-1)(v_{1,i}(S) + \bar{v}_{1,i}(S)).$$

Below, we discuss some specific cases of functions δ_s for a set S of points in the plane $\mathbb{R}^2$, in which new results are derived by applying Theorems 13 and 16.

Convex distance functions. From now on, suppose S consists of n colored points in $\mathbb{R}^2$. Let $B \subset \mathbb{R}^2$ be any convex and compact body whose interior contains the origin. Define $\delta_s(x) = \|x-s\|_B$ for point $s \in S$ to be the *convex distance* from $x \in \mathbb{R}^2$ to s based on B [19,31]. Since Voronoi diagrams of point sites under a convex distance function fall under the model of abstract Voronoi diagrams [28,35], conditions **V1** and **V2** hold.

Condition **V3**, however, is not guaranteed in general; a popular example is the L_1 or L_∞ metric, under which $\mathsf{VD}(S')$ may have $\Theta(|S'|)$ parallel unbounded edges while $\mathsf{FVD}(S')$ has at most four. In the following, we first assume that B is *smooth* that is, there is a unique line tangent to B at each point on its boundary [31]. We then make the following observation for a smooth B, stronger than condition **V3**, which has been known for the Euclidean metric even in higher dimensions [11].

▶ **Lemma 17.** *Given S and δ_s for $s \in S$ as above, suppose B is smooth. For $c \in \{1,2\}$ and $0 \leqslant j \leqslant m-1$, we have $u_{c,j}(S) = \bar{u}_{c,j}(S) = e_{c,j}(S)$, the number of c-chromatic j-facets in S.*

By Lemma 17, Theorem 16 implies the same upper bound $4k(n-k)-2n$ on the total number of vertices in both $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ under any smooth convex distance function.

We then relax the smoothness of B by a limit argument, so let B be any convex and compact body. Consider a sequence of smooth and convex bodies $B_0, B_1, \ldots$ that converges to B. Obviously, there exists $\hat{B} = B_i$ sufficiently close to B so that: (a) the functions $\hat{\delta}_s(x) = \|x-s\|_{\hat{B}}$ for $s \in S$ are in general position (see Section 2), and (b) for any scaled and translated copy B_{pqr} of B having three points $p, q, r \in S$ on its boundary, there is also a scaled and translated copy $\hat{B}_{pqr}$ of $\hat{B}$, whose boundary goes through p, q, r and the separation of S by $\hat{B}_{pqr}$ is the same as that by B_{pqr}.

This implies that the vertices in $\mathsf{CVD}_k(S)$ and in $\overline{\mathsf{CVD}}_k(S)$ under the convex distance function based on B are preserved in their counterpart diagrams under the convex distance function based on $\hat{B}$. Furthermore, the general position assumption can be relaxed, as it does not decrease the number of vertices in the diagrams. Hence, we conclude:

▶ **Corollary 18.** *Let S be a set of n colored points in $\mathbb{R}^2$ with m colors. For $1 \leqslant k \leqslant m-1$, the total number of vertices in $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ under any L_p metric for $1 \leqslant p \leqslant \infty$ or any convex distance function is at most $4k(n-k)-2n$.*

It is worth noting that Lemmas 12 and 17 imply bounds for colored j-facets in $\mathbb{R}^2$.

▶ **Corollary 19.** *Let S be a set of n colored points in $\mathbb{R}^2$ with m colors. For $0 \leqslant k \leqslant m-2$,*

$$(k+1)(k+2) \leqslant \sum_{j=0}^{k} e_{2,j}(S) + \sum_{j=0}^{k}(k-j+1)e_{1,j}(S) \leqslant (k+1)(2n-k-2).$$

More on polygonal convex distance functions. First, we consider the L_∞ metric, so B is the unit square centered at the origin. Liu, Papadopoulou, and Lee [30] proved an upper bound of $O((n-k)^2)$ for ordinary order-k Voronoi diagrams of n points under the L_∞ metric using the *Hanan grid*. An analogous argument can also be applied to our color diagrams.

▶ **Lemma 20.** *Under the L_∞ metric, the number of vertices in $\mathsf{CVD}_k(S)$ is at most $4(n-k)^2$.*

Hence, the complexity of $\mathsf{CVD}_k(S)$ under the L_∞ metric is $O(\min\{k(n-k),(n-k)^2\})$. For the maximal counterpart $\overline{\mathsf{CVD}}_k(S)$, we prove the following.

▶ **Lemma 21.** *Under the L_∞ metric, for any $0 \leqslant j \leqslant m-2$, we have $\overline{U}_j \leqslant 2(j+1)(j+2)$. Therefore, the number of vertices of $\overline{\mathsf{CVD}}_k(S)$ for $1 \leqslant k \leqslant m-1$ is at most $2k^2$.*

Summarizing, we obtain:

▶ **Theorem 22.** *Let S be a set of n colored points with m colors in the L_∞ or L_1 plane. For $1 \leqslant k \leqslant m-1$, the number of vertices in $\mathsf{CVD}_k(S)$ is at most $\min\{4k(n-k)-2n, 4(n-k)^2\}$ and the number of vertices in $\overline{\mathsf{CVD}}_k(S)$ is at most $\min\{4k(n-k)-2n, 2k^2\}$.*

The above approach also works for polygonal convex distances, concluding the following.

▶ **Corollary 23.** *Let B be a convex $2b$-gon with $2b \geqslant 4$, centrally symmetric around the origin, and S a set of n colored points with m colors. For $1 \leqslant k \leqslant m-1$, $\mathsf{CVD}_k(S)$ and $\overline{\mathsf{CVD}}_k(S)$ under the convex distance function based on B consist of at most $\min\{4k(n-k)-2n, 2(b^2-b)(n-k)^2\}$ and $\min\{4k(n-k)-2n, 2(b^2-b-1)k^2\}$ vertices, respectively.*

Remark that a more careful analysis could reduce the factor depending on b, and relax the central symmetry of B.

5 Iterative algorithms for color Voronoi diagrams

In this section, we present an iterative approach to compute the order-k color Voronoi diagrams and their refined counterparts for an increasing order of k. Recall that S is a set of n sites associated with distance functions δ_s for $s \in S$. We assume the general position assumption on $\{\delta_s\}_{s\in S}$ given in Section 2. We first establish some key structural properties, which add the concept of color to well-known properties of order-k Voronoi diagrams.

Consider a face f of an order-k Voronoi region $R_k(H;S)$ of $\mathsf{CVD}_k(S)$, or a region $\overline{R}_k(H;S)$ of $\overline{\mathsf{CVD}}_k(S)$, where $H \subseteq K$ with $|H| = k$. Recall that $S_H \subseteq S$ is the set of sites whose colors are included in H. Let $S_f \subseteq S$ be the set of sites that, together with sites in S_H, define the edges along the boundary of f. The following property is directly derived from the definitions.

▶ **Lemma 24.** *Let $f \subseteq R_k(H;S)$ be a face of $\mathsf{CVD}_k(S)$ for $1 \leqslant k \leqslant m-1$. It holds that:*

- **(i)** $\mathsf{CVD}_1(S_f) \cap f = \mathsf{CVD}_{k+1}(S) \cap f$ *and* $\mathsf{VD}(S_f) \cap f = \mathsf{CVD}^*_{k+1}(S) \cap f$.
- **(ii)** $\mathsf{FCVD}(S_H) \cap f = \mathsf{CVD}_{k-1}(S) \cap f$ *and* $\mathsf{FCVD}^*(S_H) \cap f = \mathsf{CVD}^*_k(S) \cap f$.

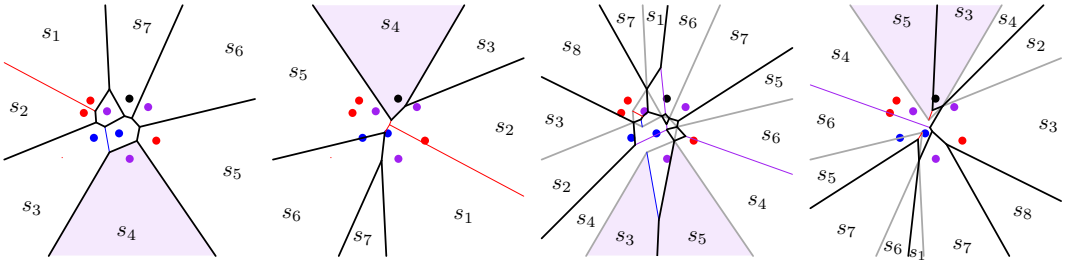
Analogous claims hold for the maximal diagrams, however, for an unbounded face f of $\overline{\mathsf{CVD}}_k(S)$, the set S_f is no longer adequate to derive the portion of $\overline{\mathsf{CVD}}_{k+1}(S)$ that lies within f. We need the set $S_f^+ \subseteq S \setminus S_H$ that defines the unbounded faces of $\overline{\mathsf{CVD}}_{k+1}(S) \cap f$.

▶ **Lemma 25.** *Let $f \subseteq \overline{R}_k(H;S)$ be a face of $\overline{\mathsf{CVD}}_k(S)$ for $1 \leqslant k \leqslant m-1$. Let $S_f^+ \subseteq S \setminus S_H$ be the set of sites that define unbounded faces in $\overline{\mathsf{CVD}}_{k+1}(S) \cap f$; $S_f^+ = \emptyset$ if f is bounded. The following hold:*

(i) $\overline{\mathsf{CVD}}_1(S_f \cup S_f^+) \cap f = \overline{\mathsf{CVD}}_{k+1}(S) \cap f$ *and* $\mathsf{FVD}(S_f \cup S_f^+) \cap f = \overline{\mathsf{CVD}}^*_{k+1}(S) \cap f$.
(ii) $\mathsf{HVD}(S_H) \cap f = \overline{\mathsf{CVD}}_{k-1}(S) \cap f$ *and* $\mathsf{HVD}^*(S_H) \cap f = \overline{\mathsf{CVD}}^*_k(S) \cap f$.

Using Lemma 24(i), we can iteratively compute $\mathsf{CVD}^*_{k+1}(S)$, given $\mathsf{CVD}^*_k(S)$. However, to iteratively compute $\overline{\mathsf{CVD}}_{k+1}(S)$, we first need to identify the sites that define the new unbounded edges of $\overline{\mathsf{CVD}}_{k+1}(S)$. This information, however, is not encoded in $\overline{\mathsf{CVD}}_k(S)$. We give a condition, related to condition **V3**, under which we can use $\mathsf{CVD}^*_{k+1}(S)$ to derive the information missing from $\overline{\mathsf{CVD}}^*_{k+1}(S)$. This condition is satisfied if, for example, S is a set of points and δ_s for $s \in S$ is a convex distance based on a smooth body.

V3′ The unbounded faces of $\mathsf{VD}(S')$ and $\mathsf{FVD}(S')$ are defined by the same sequence of sites, for any $S' \subseteq S$.



(a) $\mathsf{CVD}^*_1(S) = \mathsf{VD}(S)$ (b) $\overline{\mathsf{CVD}}^*_1(S) = \mathsf{FVD}(S)$ (c) $\mathsf{CVD}^*_2(S)$ (d) $\overline{\mathsf{CVD}}^*_2(S)$

Figure 6 Illustration of condition **V3′** and Lemma 26 with the same set $S = \{s_1, \ldots, s_9\}$ as in Figures 2–3 under the Euclidean metric. In (a)(b), $\mathsf{VD}(S')$ and $\mathsf{FVD}(S')$ have the same sequence of sites that define unbounded faces for any $S' \subseteq S$, so condition **V3′** holds. The shaded region in (a) is a face f of $\mathsf{CVD}_1(S)$ corresponding to face f' of $\overline{\mathsf{CVD}}_1(S)$ shaded in (b). In (c)(d), shaded regions show how the portions of f and f' at infinity are subdivided in $\mathsf{CVD}^*_2(S)$ and $\overline{\mathsf{CVD}}^*_2(S)$.

▶ **Lemma 26.** *Condition **V3′** implies that the unbounded faces of* $\mathsf{CVD}^*_k(S)$ *and of* $\overline{\mathsf{CVD}}^*_k(S)$ *are defined by the same sequence of sites for any* $1 \leqslant k \leqslant m$. *(See Figure 6.)*

Now, we assume that the sites S and their distance functions δ_s fall under the model of *abstract Voronoi diagrams* [28]. Furthermore, we assume that any distance or bisector can be computed in $O(1)$ time. We then conclude the following using procedures in [3, 6, 25, 39].

▶ **Theorem 27.** *Let* S *and* $\{\delta_s\}_{s \in S}$ *be a set of* n *colored sites with* m *colors and distance functions that satisfy the conditions of abstract Voronoi diagrams. Then, for* $1 \leqslant k \leqslant m$, *in* $O(k^2 n + n \log n)$ *expected time or in* $O(k^2 n \log n)$ *worst-case time, we can compute* $\mathsf{CVD}^*_1(S), \ldots, \mathsf{CVD}^*_k(S)$. *If in addition condition **V3′** holds, then we can also compute* $\overline{\mathsf{CVD}}^*_1(S), \ldots, \overline{\mathsf{CVD}}^*_k(S)$ *in the same time bound. If* S *consists of points and* $\delta_s(x)$ *is the Euclidean distance to* $s \in S$, *the time bound is reduced to* $O(k^2 n + n \log n)$ *in the worst case.*

The convex distance functions satisfy the conditions of Theorem 27, hence we have:

▶ **Corollary 28.** *Let* B *be a convex and compact body in* $\mathbb{R}^2$ *of a constant complexity that contains the origin in its interior. Given a set* S *of* n *colored points in* $\mathbb{R}^2$ *with* m *colors and an integer* $1 \leqslant k \leqslant m$, *we can compute* $\mathsf{CVD}^*_1(S), \ldots, \mathsf{CVD}^*_k(S)$ *in* $O(k^2 n + n \log n)$ *expected time or in* $O(k^2 n \log n)$ *worst-case time. If* B *is smooth, then we can also compute* $\overline{\mathsf{CVD}}^*_1(S), \ldots, \overline{\mathsf{CVD}}^*_k(S)$ *in the same time bound.*

The Erdős–Szekeres Conjecture Revisited

Abstract

The famous and still open *Erdős–Szekeres Conjecture* from 1935 states that every set of at least $2^{k-2}+1$ points in the plane with no three being collinear contains k points in *convex position*, that is, k points that are vertices of a convex polygon. In this paper, we revisit this conjecture and show several new related results.

First, we prove a relaxed version of the Erdős–Szekeres Conjecture by showing that every set of at least $2^{k-2}+1$ points in the plane with no three being collinear contains a *split k-gon*, a relaxation of k-tuple of points in convex position. Moreover, we show that this is tight, showing that the value $2^{k-2}+1$ from the Erdős–Szekeres Conjecture is exactly the right threshold for split k-gons.

We obtain an analogous relaxation in a much more general setting of ordered 3-uniform hypergraphs where we also show that, perhaps surprisingly, a corresponding generalization of the Erdős–Szekeres Conjecture is not true. Finally, we prove the Erdős–Szekeres Conjecture for so-called *decomposable sets* and provide new constructions of sets of 2^{k-2} points without k points in convex position, generalizing all previously known constructions of such point sets and allowing us to computationally tackle the Erdős–Szekeres Conjecture for large values of k.

1 Introduction

A finite set of points on a plane is in *general position* if there are no three points on a single line and in *convex position* if they form the vertices of a convex polygon. We consider finite point sets in general position where no two points have the same x- or y-coordinate.

Motivated by a problem posed by Esther Klein, Erdős and Szekeres [7] showed that for any positive integer k there is a minimum integer $ES(k)$ such that any set of $ES(k)$ points in the plane in general position contains k points in convex position. This famous result, called the *Erdős–Szekeres Theorem*, was a starting point of both discrete geometry and Ramsey theory and was obtained as one of the first applications of Ramsey's Theorem, which was independently discovered by Erdős and Szekeres [7] in the same paper. Ramsey's Theorem, however, yields a poor bound on the minimum size $ES(k)$ of a planar point set in general position that guarantees the existence of k points in convex position. Thus, Erdős and Szekeres [7] also provided an alternative proof that yields a much better estimate on $ES(k)$. This alternative argument uses more geometry and is based on so-called *caps* and *cups*.

For a positive integer a, we say that a points in the plane form an *a-cap* if they lie on a graph of a concave function. Similarly, for $u \in \mathbb{N}$, a set of u points in the plane forms a *u-cup* if its points lie on a graph of a convex function. Using this notion, Erdős and Szekeres [7] proved the following result known as the *Erdős–Szekeres Cap-Cup Theorem*.

▶ **Theorem 1** (The Erdős–Szekeres Cap-Cup Theorem [7]). *For all integers $a, u \geq 2$, every set of at least $\binom{a+u-4}{a-2}+1$ points in the plane in general position contains an a-cap or a u-cup.*

Moreover, this is tight. That is, for all integers $a, u \geq 2$, there are sets of $\binom{a+u-4}{a-2}$ points in the plane in general position with neither an a-cap nor a u-cup.

Since points of an a-cap and a u-cup are in convex position, Theorem 1 gives

$$ES(k) \leq \binom{2k-4}{k-2} + 1 \tag{1}$$

for any integer $k \geq 2$. In fact, observe that every set of k points in convex position is a union of an *a-cap* and a *u-cup* that share common endpoints and satisfy $a + u = k + 2$.

The bound (1) gives roughly $ES(k) \leq 4^k$. Erdős–Szekeres believed that this could be significantly improved and posed the following conjecture.

▶ **Conjecture 2** (The Erdős–Szekeres Conjecture [7]). *For every integer $k \geq 2$, we have*

$$ES(k) = 2^{k-2} + 1.$$

When posed in 1935, the conjecture was known to be true only for $k \leq 4$. Later, it was proved for $k = 5$, and Peters and Szekeres [19] proved it also for $k = 6$ in 2006 using a computer-assisted approach. In the 1960s, Erdős and Szekeres [8] showed $ES(k) \geq 2^{k-2} + 1$ for any integer $k \geq 2$, further supporting the conjecture. Despite many efforts, this conjecture is still open for $k \geq 7$, and Erdős himself offered \$500 reward for its solution. For many decades, the bound (1) was the best known, but then several smaller-order improvements appeared [5, 14, 16, 18, 21, 22]. In 2017, Suk [20] made a breakthrough on this conjecture by proving $ES(k) \in 2^{k+O(k^{2/3}\log k)}$ and his bound was then slightly improved by Holmsen, Mojarrad, Pach, and Tardos [13] to $ES(k) \in 2^{k+O(\sqrt{k \log k})}$. Although these bounds are fairly close to $2^{k-2} + 1$, there is still a gap between the known lower and upper bounds, and this famous conjecture thus remains open.

2 Our results

In this paper, we introduce a natural relaxed variant of the Erdős–Szekeres Conjecture for which the number $2^{k-2} + 1$ is exactly the right threshold. To our knowledge, this is the first version of this famous conjecture where the conjectured value $2^{k-2} + 1$ appears as the right threshold. We discuss abstract combinatorial extensions of this result and connections to the original Erdős–Szekeres Conjecture, some of which indicate that this conjecture might be false. We also prove the Erdős–Szekeres Conjecture restricted to special point sets, and we provide new examples of 2^{k-2} point sets with no k points in convex position.

2.1 Split polygons

For a positive integer N, let P be a set of N points in the plane in general position. For a positive integer k, a *split k-gon* in P is a set of points from P that is formed by an a-cap and a u-cup that share the rightmost point and that satisfy $a + u = k + 2$; see Figure 1. Note that a split k-gon can contain k or $k + 1$ points and that if the a-cap and the u-cup share also the leftmost point, then the points of the split k-gon are in convex position.

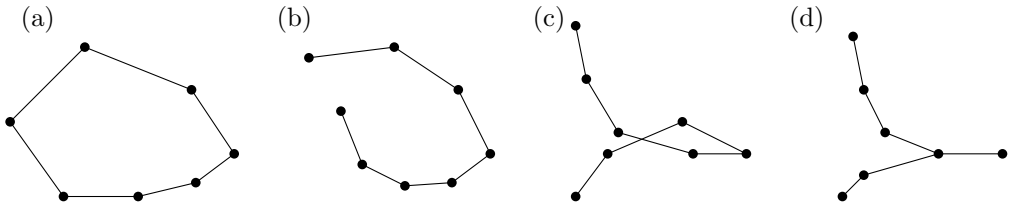

Figure 1 (a–d) Examples of split 7-gons. Note that the split 7-gons in (a) and (d) have only 7 points while the remaining split 5-gons contain 8 points.

We consider a variant of the Erdős–Szekeres Theorem for split polygons. More specifically, for a positive integer k, let $ES_{split}(k)$ be the minimum positive integer N such that every finite set of at least N points in the plane in general position contains a split k-gon. Since $ES_{split}(k) \leq ES(k)$, we have $ES_{split}(k) \leq 2^{(1+o(1))k}$ by the result of Suk [20].

As our first main result, we prove that the numbers $ES_{split}(k)$ attain exactly the value $2^{k-2}+1$ from the Erdős–Szekeres Conjecture.

▶ **Theorem 3.** *For every integer $k \geq 2$, we have $ES_{split}(k) = 2^{k-2}+1$.*

In fact, we can prove a stronger statement in the setting corresponding to a refinement of the Erdős–Szekeres Conjecture as introduced by Erdős, Tuza, and Valtr [9]. In their refinement, one tries to find k-tuples of points in convex position in point sets that do not contain a-caps and u-cups of prescribed sizes a and u.

We state this formally in our setting. For integers $a, u, k \geq 2$, let $ES_{split}(a, u, k)$ be the minimum positive integer N such that every finite set of at least N points in the plane in general position contains an a-cap, a u-cup, or a split k-gon. We are mostly interested in the cases $\max\{a, u\} \leq k \leq a + u - 2$ as otherwise at least one parameter from a, u, k is unnecessary. Therefore, we define

$$T = \{(a, u, k) : a, u \geq 2 \text{ and } \max\{a, u\} \leq k \leq a + u - 2\}.$$

For any triple $(a, u, k) \in T$, we can then determine the numbers $ES_{split}(a, u, k)$ exactly.

▶ **Theorem 4.** *For every $(a, u, k) \in T$, we have*

$$ES_{split}(a, u, k) = 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}.$$

Note that $ES_{split}(k) = ES_{split}(k, k, k)$. Thus, Theorem 3 follows from Theorem 4 by setting $a = u = k$ as then

$$ES_{split}(k) = 1 + \sum_{i=2}^{k} \binom{k-2}{i-2} = 2^{k-2} + 1.$$

Also, observe that Theorem 1 is a special case of Theorem 4 for $k = a + u - 2$.

We also remark that if $ES(a, u, k)$ is the minimum positive integer N such that every finite set of at least N points in the plane in general position contains an a-cap, a u-cup, or k points in convex position, then it is conjectured that

$$ES(a, u, k) = 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2} \tag{2}$$

for all $(a, u, k) \in T$. However, this equality is known to be true only in the trivial case $k \geq a + u - 3$ and Baek [1] proved it when a or u equals 4. Surprisingly, Erdős, Tuza, and Valtr [9] showed that the Erdős–Szekeres conjecture is equivalent to (2).

2.2 Abstract split polygons

The proof of the upper bound in Theorem 4 is based on techniques used by Moshkovitz and Shapira [17] when estimating ordered Ramsey numbers of so-called monotone paths. It turns out that the proof can be generalized to this abstract combinatorial setting. To state this extension, we need to introduce some definitions.

For a positive integer N, let $\mathcal{K}_N^3$ be the ordered complete 3-uniform hypergraph with the vertex set $[N] = \{1, \dots, N\}$ ordered by the standard ordering $<$ of the positive integers. A *2-coloring* of $\mathcal{K}_N^3$ is a function χ that assigns either a red or blue color to each hyperedge of $\mathcal{K}_N^3$. A *monotone path* $\mathcal{P}_n^3$ is an ordered 3-uniform hypergraph on $n \geq 2$ vertices where the hyperedges are formed by triples of vertices that are consecutive in the vertex ordering of $\mathcal{P}_n^3$.

Let $P = \{p_1, \dots, p_N\}$ be a set of points in the plane in general position with $x(p_1) < \cdots < x(p_N)$ where $x(p_i)$ is the x-coordinate of a point p_i. The *2-coloring induced by* P is a 2-coloring χ_P of $\mathcal{K}_N^3$ that colors a hyperedge $\{i, j, k\}$ with $i < j < k$ red if the points p_i, p_j, p_k form a 3-cap and blue if p_i, p_j, p_k form a 3-cup. Observe that, for each n, red monotone paths on n vertices in χ_P correspond to n-caps in P and that blue monotone paths on n vertices in χ_P correspond to n-cups in P.

In 2014, Moshkovitz and Shapira [17] proved the following result, whose first part vastly generalizes the first part of the Erdős–Szekeres Cap-Cup Theorem (Theorem 1) as it deals with all 2-colorings of $\mathcal{K}_N^3$ and not only with those induced by a point set of size N.

▶ **Theorem 5** ([7, 11, 17]). *For all integers $a, u \geq 2$ and $N \geq \binom{a+u-4}{a-2} + 1$, every 2-coloring of $\mathcal{K}_N^3$ contains either a red copy of $\mathcal{P}_a^3$ or a blue copy of $\mathcal{P}_u^3$.*

Moreover, this is tight. That is, there are 2-colorings of $\mathcal{K}_N^3$ with $N = \binom{a+u-4}{a-2}$ that do not contains red copy of $\mathcal{P}_a^3$ nor a blue copy of $\mathcal{P}_u^3$.

In other words, Theorem 5 states that the *ordered Ramsey number* [3, 6] of $\mathcal{P}_a^3$ and $\mathcal{P}_u^3$ equals $\binom{a+u-4}{a-2} + 1$. We extend this result similarly as Theorem 4 extends Theorem 1.

We start by generalizing split polygons. Let χ be a 2-coloring of $\mathcal{K}_N^3$ with colors red and blue. For $k \in \mathbb{N}$, an *abstract split k-gon* in χ is an ordered subhypergraph of $\mathcal{K}_N^3$ that is formed by a red monotone path $\mathcal{P}_a^3$ and a blue monotone path $\mathcal{P}_u^3$ that share the rightmost vertex and that satisfy $a + u = k + 2$. Observe that an abstract split k-gon can have at most $k+1$ vertices. Also, note that, for every abstract split k-gon C in a coloring χ_P induced by a point set P, the two monochromatic monotone paths in C can share only their endpoint pair and that abstract split k-gons in χ_P are in one-to-one correspondence with split k-gons in P.

Generalizing the definition of $ES_{split}(a, u, k)$, we let $C_{split}(a, u, k)$ be the minimum positive integer N such that every 2-coloring of $\mathcal{K}_N^3$ with colors red and blue contains a red copy of $\mathcal{P}_a^3$, a blue copy of $\mathcal{P}_u^3$, or an abstract split k-gon. Observe that considering the 2-colorings induced by P gives, for every $(a, u, k) \in T$,

$$ES_{split}(a, u, k) \leq C_{split}(a, u, k). \tag{3}$$

As our next result, we fully determine the numbers $C_{split}(a, u, k)$ by showing that $ES_{split}(a, u, k) = C_{split}(a, u, k)$ for every $(a, u, k) \in T$.

▶ **Theorem 6.** *For every $(a, u, k) \in T$, we have*

$$C_{split}(a, u, k) = 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}.$$

Similarly as before, note that Theorem 5 is a special case of Theorem 6 for $k = a + u - 2$.

2.3 Finding polygons that are not split

The only difference between the setting in the Erdős–Szekeres Conjecture and the setting in Theorem 3 is that in the latter one, we allow the leftmost endpoints of the a-cap and the u-cup to be different. Enforcing these two endpoints to meet without increasing the size of the considered point sets would resolve the Erdős–Szekeres Conjecture. However, the combinatorial structure used to prove Theorem 3 does not seem strong enough to ensure this. Moreover, we will show that this strengthening is not true in the abstract combinatorial setting from Subsection 2.2.

First, we generalize the concept of convex position. For a positive integer N, let χ be a 2-coloring of $\mathcal{K}_N^3$. For a positive integer k, a *weak k-gon* in χ is an ordered subhypergraph of $\mathcal{K}_N^3$ that is formed by a red monotone path $\mathcal{P}_a^3$ and a blue monotone path $\mathcal{P}_u^3$ that share both their end-vertices and satisfy $a + u = k + 2$. That is, a weak k-gon is a particular case of an abstract split k-gon. Note that the red and the blue monotone path can share other vertices, not only their two end-vertices. If we exclude this possibility and allow the two paths to share only their end-vertices, then we call such ordered subhypergraph a *strong k-gon* in χ. If χ_P is a 2-coloring induced by a point set P, then every weak k-gon is a strong k-gon in χ_P and corresponds to a set of k points from P that are in convex position.

Let $C_{weak}(k)$ be the minimum $N \in \mathbb{N}$ such that every 2-coloring of $\mathcal{K}_N^3$ contains a weak k-gon. An analogous number for strong k-gons is denoted by $C_{strong}(k)$. Clearly,

$$C_{strong}(k) \geq C_{weak}(k) \geq C_{split}(k, k, k) = 2^{k-2} + 1,$$

where the equality follows from Theorem 6. Moreover, if $C_{weak}(k) \leq 2^{k-2} + 1$, then the Erdős–Szekeres Conjecture is true.

We do not have $C_{strong}(k) \leq 2^{k-2} + 1$ as Balko and Valtr [4] proved $C_{strong}(7) > 33$ with SAT solvers, disproving a conjecture of Peters and Szekeres [19]. Our SAT-solver-based proofs show that this is also the case for weak k-gons.

▶ **Theorem 7.** *We have $C_{weak}(7) > 33$.*

Thus, there is no hope for extending the Erdős–Szekeres Conjecture to the abstract setting with weak k-gons. This also suggests that the Erdős–Szekeres Conjecture might be false and that one might look for counterexamples. A natural candidate for a counterexample is a subset of the point sets that were used by Erdős–Szekeres to prove the tightness in Theorem 1 for a-caps and u-cups since such a set used by Erdős–Szekeres [7] contains a subset of 2^{k-2} points with no k points in convex position.

However, we prove that it is impossible to find a counterexample to Erdős–Szekeres Conjecture by restricting ourselves to these sets. In fact, we show this for a larger class of so-called *decomposable sets* (see Section 4 for their definition). These sets include, for example, the point sets with no long caps nor cups used by Erdős–Szekeres [7] as well as the *Horton sets* defined by Valtr [23].

▶ **Theorem 8.** *Let a, u, k be positive integers satisfying $a, u \leq k$. Then, every decomposable set of more than $\sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$ points contains an a-cap, a u-cup, or k points in convex position.*

In particular, since every non-empty subset of a decomposable set is decomposable, we obtain, by choosing $a = u = k$, that every subset of more than 2^{k-2} points from a decomposable set contains k points in convex position. Therefore, if we restrict ourselves to decomposable sets, the Erdős–Szekeres Conjecture is true. The proof of Theorem 8 is omitted.

Finally, when exploring the validity of the Erdős–Szekeres Conjecture, we discovered new constructions of sets of 2^{k-2} points in general position with no k points in convex position. As our last main result, we introduce a "blow-up" method that generalizes all previously known constructions of such point sets; see Section 4 for their brief description. Our new method is captured by Lemma 14 in Section 6. We show that all previously known examples follow rather easily from this lemma and that it also gives new examples of such point sets.

We also tried to computationally tackle the Erdős–Szekeres conjecture for large k using a non-linear optimization solver based on a genetic algorithm and this new construction. However, despite finding numerous new examples of 2^{k-2} points without k points in convex position even for $k = 20$, our experiments never produced such points sets with more than 2^{k-2} points; see Section 6 for more details.

3 Open problems

We showed that the variant of the Erdős–Szekeres Conjecture is true for split k-gons, even in an abstract combinatorial setting, while the original Erdős–Szekeres Conjecture does not admit such an abstract strengthening; these results are summarized in Table 1. Each cell corresponds to a variant statement of the Erdős–Szekeres Conjecture.

Table 1 Variants of the Erdős–Szekeres Conjecture and their status.

	Point sets	**Ordered hypergraphs**
Split k-gons	True (Theorem 6)	True (Theorem 3)
Weak k-gons	Open (Erdős–Szekeres [7])	False (Theorem 7)

It also follows from Theorem 7 that any proof of the Erdős–Szekeres Conjecture has to use some assumptions on the 2-colorings. Natural candidates for such 2-colorings are so-called *signotopes* that appear under many different names in the literature (see [2, 10], for example). For $N \in \mathbb{N}$, a 2-coloring χ of $\mathcal{K}_N^3$ is a *signotope* if for every 4-tuple $a < b < c < d$ of vertices of $\mathcal{K}_N^3$ there is at most one change of color in the sequence $(\chi(a,b,c), \chi(a,b,d), \chi(a,c,d), \chi(b,c,d))$.

Signotopes on $\mathcal{K}_N^3$ are in one-to-one correspondence with pseudoline arrangements determined by N points [10] and thus offer a natural and frequently used combinatorial generalization of point sets. Moreover, if we have $\chi(a,b,c) = \chi(b,c,d)$ for some vertices $a < b < c < d$ in a signotope χ, then $\chi(a,b,c) = \chi(a,b,d) = \chi(a,c,d) = \chi(b,c,d)$. It follows that any weak k-gon in χ is also a strong k-gon in χ.

In our computer experiments, we were not able to find a signotope on at least $1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$ vertices that would contain neither a red copy of $\mathcal{P}_a^3$, nor a blue copy of $\mathcal{P}_u^3$, nor a weak k-gon. Thus, it is still possible that the Erdős–Szekeres Conjecture is true even if we do not restrict ourselves to 2-colorings induced by point sets but we consider all signotopes. Such a generalization is equivalent to a conjecture of Goodman and Pollack [12].

Another natural open problem is to obtain better bounds on $C_{weak}(k)$ and $C_{strong}(k)$. We know that both numbers can be larger than $2^{k-2} + 1$, but the strongest upper bound that we are aware of follows from Theorem 5 for $a = u = k$ and gives

$$C_{weak}(k) \leq C_{strong}(k) \leq \binom{2k-4}{k-2} + 1.$$

4 Preliminaries and notation

In this section, we introduce some useful notation and definitions and briefly describe all known constructions of sets of 2^{k-2} that avoid subsets of k points in convex position. Some of these constructions are used later in our proofs.

For a point p in the plane, we use $x(p)$ and $y(p)$ to denote the x- and y-coordinate of p, respectively. Let A and B be two sets of points in the plane in general position. We write $x(A) < x(B)$ (or $y(A) < y(B)$) if A is to the left (or below, respectively) of B, that is, $x(a) < x(b)$ ($y(a) < y(b)$, respectively) for every $a \in A$ and $b \in B$. We say that A is *deep below* B if $y(A) < y(B)$ and all points from B lie above every line determined by two points from A and all points from A lie below every line determined by two points from B.

For integers $a, u \geq 2$, we now describe the sets of $\binom{a+u-4}{a-2}$ points without a-caps and u-cups that were used by Erdős and Szekeres [7] to prove the tight lower bound in Theorem 1. We denote these sets by $P(a, u)$ and we construct them by induction on $a + u$. If $a = 2$ or $u = 2$, then we let $P(a, u)$ be a set of one point. For $a, u \geq 3$, we let $P(a, u)$ be the point set that is obtained by adding a translated copy of $P(a, u-1)$ to $P(a-1, u)$ that is to the left of $P(a-1, u)$ and deep below $P(a-1, u)$. It is then easy to show that $P(a, u)$ does not contain a-cap nor a u-cup [7, 15].

A set P is *decomposable* if either $|P| = 1$ or if $|P| \geq 2$ and P can be partitioned into two decomposable sets A and B such that A is deep below B. Note that the sets $P(a, u)$ are decomposable and that every non-empty subset of a decomposable set is decomposable.

Let a, u, and k be integers satisfying $(a, u, k) \in T$. We use $S(a, u, k)$ to denote the sum $\sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$. For $a, u, k \in \mathbb{N}$ with $a, u \leq k$, we also define $S(a, u, k) = 0$ if $a = 1$ or $u = 1$. These cases agree with the formula $\sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$ as the sum is then empty.

We now describe all known constructions of $S(a, u, k)$ points in general position without a-caps, u-cups, or k points in general position. Let Q be an arbitrary set of $a + u - k - 1$ points $q_{k-a+2}, \ldots, q_u$ in the plane in general position sorted by increasing y-coordinate. Let P be the point set obtained by replacing each q_i with a set Q_i of $\binom{k-2}{i-1}$ points without $(k - i + 2)$-cap and i-cup in a sufficiently small neighborhood of q_i such that Q_i is deep below Q_{i+1} for every $i \in \{k - a + 2, \ldots, u - 1\}$. Then, it can be shown that P does not contain a-cap, u-cup, nor k points in convex position [8, 9]. We call the resulting point set *Valtr's construction* as it was described to us by Valtr [24]. To our knowledge, it is not described in the literature. If, in addition, Q is a $(a + u - k - 1)$-cup and each Q_j is the set $P(k + 1 - j, j + 1)$, then we call the set P the *Erdős–Szekeres construction* and we denote it by $P(a, u, k)$. For $a = u = k$, this is the point set constructed by Erdős and Szekeres [8] to prove $ES(k) \geq 2^{k-2} + 1$.

5 Proofs of Theorems 4 and 6

Here, we prove Theorems 4 and 6 by determining the values $ES_{split}(a, u, k)$ and $C_{split}(a, u, k)$ for every $(a, u, k) \in T$. It follows from (3) that in order to prove both these results, it suffices to prove the upper bound $C_{split}(a, u, k) \leq 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$ from Theorem 6 and the lower bound $ES_{split}(a, u, k) \geq 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$ from Theorem 4.

5.1 Upper bound from Theorem 6

Let m and n be positive integers. We use $\preceq$ to denote the partial ordering on $[m]\times[n]$ satisfying $(x_1, y_1) \preceq (x_2, y_2)$ if and only if $x_1 \leq x_2$ and $y_1 \leq y_2$ for all $(x_1, y_1), (x_2, y_2) \in [m] \times [n]$. A subset D of $[m] \times [n]$ is a *down-set* if $y \in D$ implies $x \in D$ for every $x \preceq y$; see Figure 2.

There is a one-to-one correspondence between down-sets in $[m] \times [n]$ and $m \times n$ *line partitions* with entries from $\{0, 1, \ldots, n\}$ which are sequences $(a_1, \ldots, a_m)$ of numbers satisfying $n \geq a_1 \geq a_2 \geq \cdots \geq a_m \geq 0$; see [17]. It is well-known and easy to see that the number of such line partitions (and thus also the number of down-sets in $[m] \times [n]$) is $\binom{m+n}{m}$.

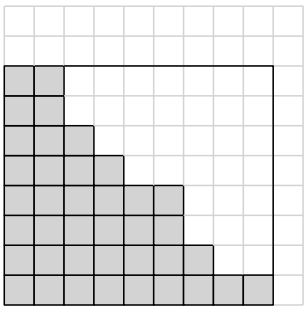

Figure 2 An example of a down-set in $[10] \times [10]$ with the bounding box 9×8.

Given a non-empty down-set D in $[m] \times [n]$, we say that D has the *bounding box* $r \times s$ if r is the maximum integer such that $a_r > 0$ and $a_1 = s$. We say that the empty down-set has the bounding box 0×0.

▶ **Lemma 9.** *For $(a, u, k) \in T$, the number of down-sets in $[a-2] \times [u-2]$ with the bounding box $r \times s$ where $r + s \leq k - 1$ is*

$$\sum_{i=k-a+2}^{u} \binom{k-2}{i-2}.$$

The proof of Lemma 9 is omitted. We now prove the upper bound on $C_{split}(a, u, k)$.

▶ **Lemma 10.** *For every $(a, u, k) \in T$, we have*

$$C_{split}(a, u, k) \leq 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}.$$

Proof. For a positive integer N, let χ be a 2-coloring of $\mathcal{K}_N^3$ with colors red and blue such that there is neither a red copy of $\mathcal{P}_a^3$, a blue copy of $\mathcal{P}_u^3$, nor an abstract split k-gon. We show that $N \leq \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$.

For vertices u and v of $\mathcal{K}_N^3$ with $u < v$, we let $D(u, v) = (n_r - 1, n_b - 1)$ where n_r (n_b, respectively) is the maximum number of vertices of a red (blue, respectively) monotone path ending with u and v. By the choice of χ, we have $D(u, v) \in [a-2] \times [u-2]$. Next, we define

$$D(v) = \{x \in [a-2] \times [u-2] \colon x \preceq D(u, v) \text{ for some } u < v\}.$$

By definition, $D(v)$ is a down-set in $[a-2] \times [u-2]$. Moreover, since there is no abstract split k-gon in χ, $D(v)$ has the bounding box $r \times s$ where $r + s \leq k - 1$.

Consider the mapping $v \mapsto D(v)$. We show that this mapping is injective. Suppose for contradiction that $D(u) = D(v)$ for some vertices $u < v$. By definition, we have $D(u, v) \in D(v)$. Since $D(u) = D(v)$, we obtain $D(u, v) \in D(u)$ and thus, by the definition of $D(u)$, there is a vertex t such that $t < u$ and $D(u, v) \preceq D(t, u)$. However, if $\chi(t, u, v)$ is red, the longest red monotone path ending at u, v is longer than the longest red monotone path ending at t, u. An analogous claim holds for blue monotone paths if $\chi(t, u, v)$ is blue. In either case, we cannot have $D(u, v) \preceq D(t, u)$ and we obtain a contradiction.

Thus, N is at most as large as the number of down-sets in $[a-2]\times[u-2]$ with the bounding box $r \times s$ where $r+s \leq k-1$. By Lemma 9, this number equals $\sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$. ◀

By combining Lemma 10 with (3), we obtain the upper bounds from Theorems 4 and 6.

5.2 Lower bound from Theorem 4

Now, we prove the lower bounds. First, we provide a general construction of 2-colorings that avoid long monochromatic monotone paths and abstract split k-gons, obtaining the lower bound $C_{split}(a,u,k) \geq 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$ from Theorem 6. Then, we show that a special case of this construction can be realized by points in the plane, obtaining a tight lower bound $ES_{split}(a,u,k) \geq 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$ from Theorem 4.

▶ **Lemma 11.** *For every $(a,u,k) \in T$, we have*

$$C_{split}(a,u,k) \geq 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}.$$

Proof. We use $\mathcal{E} := \mathcal{D}(a,u)$ to denote the set of all down-sets in $[a-2]\times[u-2]$. In this proof, we let $\mathcal{D} := \mathcal{D}(a,u,k)$ be the set of all down-sets in $[a-2]\times[u-2]$ with the bounding box $r \times s$ where $r+s \leq k-1$ and we set $N = |\mathcal{D}|$. Note that $\mathcal{D} \subseteq \mathcal{E}$. We know, by Lemma 9, that $N = \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$. The set $\mathcal{E}$ is partially ordered by inclusion $\subseteq$. We let $\leq_{\mathcal{E}}$ be an arbitrary linear extension on $\mathcal{E}$ that extends $\subseteq$ on $\mathcal{E}$.

For two down-sets $A, B \in \mathcal{E}$ with $A <_{\mathcal{E}} B$, choose an arbitrary element $\delta(A,B)$ of $B \setminus A$. This is possible, as the fact that $\leq_{\mathcal{E}}$ extends $\subseteq$ implies that the set $B \setminus A$ is non-empty if $A <_{\mathcal{E}} B$. For $i \in \{1,2\}$, we let $\delta(A,B)_i$ be the ith coordinate of $\delta(A,B)$.

We let $\mathcal{K}^3_{|\mathcal{E}|}$ be the ordered complete 3-uniform hypergraph with the vertex set $\mathcal{E}$ ordered by $\leq$. We now define the following 2-coloring $\chi_{a,u} = \chi_{a,u}(\delta, \leq_{\mathcal{E}})$ of $\mathcal{K}^3_{|\mathcal{E}|}$, which is used later in the paper. The color $\chi_{a,u}(A,B,C)$ of an edge $\{A,B,C\}$ of $\mathcal{K}^3_{|\mathcal{E}|}$ with $A<B<C$ is red if $\delta(A,B)_1 < \delta(B,C)_1$ and blue otherwise. Note that $\delta(A,B) \in B$ and $\delta(B,C) \notin B$ and thus $\delta(A,B) \neq \delta(B,C)$. Also, if $\chi_{a,u}(A,B,C)$ is blue, then $\delta(A,B)_2 < \delta(B,C)_2$ as we cannot have $\delta(B,C) \preceq \delta(A,B)$, because otherwise the fact that B is a down-set in $[a-2]\times[u-2]$ together with $\delta(A,B) \in B$ implies $\delta(B,C) \in B$, which is impossible as $\delta(B,C) \in C \setminus B$. Let $\chi = \chi(\delta, \leq_{\mathcal{E}})$ be the coloring $\chi_{a,u}$ restricted to the copy of $\mathcal{K}^3_N$ in $\mathcal{K}^3_{|\mathcal{E}|}$ induced by $\mathcal{D}$.

It remains to show that χ contains neither a red copy of $\mathcal{P}^3_a$, a blue copy of $\mathcal{P}^3_u$, nor an abstract split k-gon as then we have $C_{split}(a,u,k) \geq N+1$. To do so, we first prove by induction on $\ell \geq 2$ that any monochromatic copy of $\mathcal{P}^3_\ell$ in χ with last two vertices $B<C$ satisfies $\delta(B,C)_1 \geq \ell - 1$ if all its hyperedges are red in χ and $\delta(B,C)_2 \geq \ell - 1$ if they are blue. If $\ell = 2$, then the claim is trivially true as $(1,1) \preceq \delta(B,C)$. Thus, consider $\ell \geq 3$. Let $A<B<C$ be the last three vertices of the monochromatic copy of $\mathcal{P}_\ell$ in χ. If all the hyperedges are red, then the induction hypothesis and the definition of χ give $\delta(B,C)_1 > \delta(A,B)_1 \geq \ell - 2$. Similarly, if the hyperedges are blue, we obtain $\delta(B,C)_2 > \delta(A,B)_2 \geq \ell - 2$. Since all down-sets from $\mathcal{D}$ are contained in $[a-2]\times[u-2]$, it follows that there is no red copy of $\mathcal{P}^3_a$ nor a blue copy of $\mathcal{P}^3_u$ in χ. Since every down-set from $\mathcal{D}$ has the bounding box $r \times s$ where $r+s \leq k-1$, we also see that there is no abstract split k-gon in χ. Thus, we have $C_{split}(a,u,k) \geq N+1$. ◀

We now prove $ES_{split}(a,u,k) \geq N+1$. This can be shown directly using the Erdős–Szekeres construction $P(a,u,k)$ from Section 4. We prove this claim by showing that a special case of the construction from the proof of Lemma 11 corresponds to $\chi_{P(a,u,k)}$.

▶ **Lemma 12.** *For every $(a, u, k) \in T$, we have*

$$ES_{split}(a, u, k) \geq 1 + \sum_{i=k-a+2}^{u} \binom{k-2}{i-2}.$$

The proof of Lemma 12 is omitted. Finally, we remark that using the Erdős–Szekeres construction in the proof of the tight lower bound on $ES_{split}(a, u, k)$ is important. For example, in the case $a = u = k$, some of the sets P of 2^{k-2} points constructed in Section 4 do not have k points in convex position but contain split $(2k-4)$-gons.

6 Avoiding k points in convex position

Here, we introduce new constructions of sets of 2^{k-2} points in general position with no k points in convex position, generalizing all previously known constructions of such point sets.

For integers $a, u, k \geq 2$, let $P'(a, u)$ be an arbitrary set of $\binom{a+u-4}{a-2}$ points in general position in the plane with no a-cap and no u-cup. If $(a, u, k) \in T$, let $P'(a, u, k)$ and $P(a, u, k)$ be sets of $\sum_{i=k-a+2}^{u} \binom{k-2}{i-2}$ points in general position in the plane with no a-cap, no u-cup, and no k points in convex position where $P(a, u, k)$ is the point configuration given by the Erdos-Szekeres construction and $P'(a, u, k)$ is an arbitrary such point configuration. Both sets are described in Section 4.

We let S be a set of points $p_1, \ldots, p_N$ sorted by increasing x-coordinates. We use the term *factor* for an integer k that is used as a parameter that corresponds to the forbidden size of a subset in convex position of an enlarged point set obtained from S. For integers i and j with $1 \leq i < j \leq N$, we let $s_{i,j}$ be the maximum number of points from S that are in convex position and have p_i and p_j as their leftmost and rightmost points, respectively.

We now define a blow-up operation that is the core of our construction and will help us obtain large sets with few points in convex position; see Figure 3 for an illustration.

▶ **Definition 13** ((X, Y)-blow-up of S)**.** *Let $X = (x_1, \ldots, x_N)$ and $Y = (y_1, \ldots, y_N)$ be sequences of non-negative integers. For a factor $k \in \mathbb{N}_0$, an (X, Y)-*blow-up *$b_{X,Y,k}(S)$ of S with respect to k is a point set obtained from S by replacing each point p_i of S with $i \in \{2, 3, \ldots, N-1\}$ with an affine image C_{p_i} of $P'(y_i + 2, x_i + 2)$ that is rotated clockwise by $\pi/2$, is almost vertical and lies in a small neighborhood of p_i. The point p_1 is replaced with an affine image C_{p_1} of $P'(k, x_1 + 2, k)$, where this copy is rotated clockwise by $\pi/2$, is almost vertical and lies in a small neighborhood of p_1. Similarly, the point p_N is analogously replaced with an affine image C_{p_N} of $P'(y_N + 2, k, k)$. We choose the neighborhoods small enough so that they are disjoint for different sets C_{p_i} and for all triples i_1, i_2, i_3 with $1 \leq i_1 < i_2 < i_3 \leq N$, the triple $(p_{i_1}, p_{i_2}, p_{i_3})$ has the same orientation as each triple $(q_{i_1}, q_{i_2}, q_{i_3})$ where $q_{i_j} \in C_{p_{i_j}}$. Also, C_{p_i} is almost vertical, meaning that for every $p_j \in S$ with $j \neq i$ any line determined by two points of C_{p_i} has all points of C_{p_j} on the same side as the vertical line containing p_i. We call the sets C_{p_i}* clusters.

For each p_i, every a-cap in the pre-image of C_{p_i} corresponds to a *left convex chain* of size a in C_{p_i} and every u-cup in the pre-image of C_{p_i} corresponds to a *right convex chain* of size u in C_{p_i}. We note that the constructions could be stated without the rotation by $\pi/2$, but this version will be more natural in later constructions. In the following result, we state how (X, Y)-blows-ups of arbitrary point sets affect the size of the largest subset in convex position in the resulting point sets and also describe how large these point sets are.

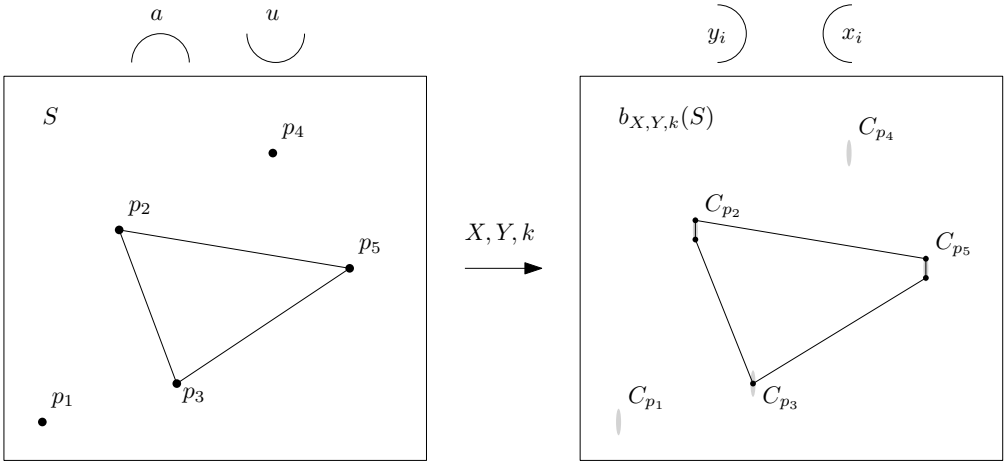

Figure 3 An illustration of an (X, Y)-blow-up of a point set S and its subset in convex position.

▶ **Lemma 14** (General blow-up construction). *For $k, N \in \mathbb{N}$, and a set S of N points in the plane in general position, let $X = (x_1, \ldots, x_N)$ and $Y = (y_1, \ldots, y_N)$ be sequences of non-negative integers satisfying*

(a) *$x_i + y_i \leq k - 1$ for every $i \in [N]$ and*

(b) *$x_i + y_j \leq k - 1 - s_{i,j}$ for all $i, j \in [N]$ with $i < j$.*

Then, the (X, Y)-blow-up $b_{X,Y,k}(S)$ of S does not contain k points in convex position and

$$|b_{X,Y,k}(S)| = \sum_{l=0}^{x_1} \binom{k-2}{l} + \sum_{i=2}^{N-1} \binom{x_i + y_i}{x_i} + \sum_{l=0}^{y_N} \binom{k-2}{l}.$$

The proof of Lemma 14 is omitted. Observe that it follows from the second condition that the factor k is larger than the size of the largest convex subset of S as the numbers x_i and y_i must be non-negative.

6.1 All known constructions

We now show that for each set S and factor $k = |S| + 1$ there are sequences X and Y such that $|b_{X,Y,k}(S)| = 2^{k-2}$ with no k points in convex position. It will follow that all known constructions of sets of 2^{k-2} points in general position with no k points in convex position are a special case of an (X, Y)-blow-up. We recall that all such known constructions fall within Valtr's construction. Now, let S be an arbitrary set of $N \leq k - 1$ points in general position. We set $x_i = i - 1$, and $y_i = k - i - 1$ for every $i \in [N]$. Then, clearly, $x_i + y_i = k - 2 \leq k - 1$ and $x_i, y_i \geq 0$ for every $i \in [N]$ as $|S| = N \leq k - 1$. We have $x_i + y_j \leq k - 1 - s_{i,j}$ for all $i, j \in [N]$ with $i < j$, as $s_{i,j} \leq j - i + 1$ and $(i-1)+(k-j-1) = k-1-(j-i+1) \leq k-1-s_{i,j}$. Thus, all assumptions in Lemma 14 are met, and $b_{X,Y,k}(S)$ does not contain k points in convex position. If $N = k - 1$, then we also get

$$\begin{aligned} |b_{X,Y,k}(S)| &= \sum_{l=0}^{0} \binom{k-2}{l} + \sum_{i=2}^{N-1} \binom{x_i + y_i}{x_i} + \sum_{l=0}^{0} \binom{k-2}{l} \\ &= 1 + \sum_{i=2}^{k-2} \binom{k-2}{i-1} + 1 = 2^{k-2} \end{aligned}$$

and $b_{X,Y,k}(S)$ corresponds to Valtr's construction rotated by $\pi/2$.

6.2 New construction

The previous choices of X and Y are not the only ones that work, we describe another choice of an (X, Y)-blow-up to obtain a set of 2^{k-2} points with no k-tuple in convex position for any $k \geq 3$. This time, the sequence X will not be increasing, and we allow $k < |S|$.

We now proceed with the construction. For each point p_i, each subset of S in convex position with p_i as its rightmost point (leftmost point) is called a *left-gon at* p_i (*right-gon at* p_i, respectively). For a *threshold* $L \in \{0, 1, \ldots, N\}$, we call points p_i with $i \in [L]$ *left* and points p_j with $j \in [N] \setminus [L]$ *right*. For each left (right, respectively) point p_i, we define s_i as the maximum size of left-gon at p_i (right-gon at p_i, respectively). Note that if $L \in [N-1]$ there are exactly two points p_i of S with $s_i = 1$, namely, the leftmost and the rightmost point of S. For every positive integer j, let $v_{j,L}(S)$ be the number of points p_i of S with $s_i = j$.

If $x_i = x$ and $y_i = k - 1 - x - s_i$ for every $i \in [L]$ and $x_i = k - 1 - x - s_i$ and $y_i = x$ for each $i \in [N] \setminus [L]$, then we call the set $b_{X,Y,k}(S)$ an *x-blow-up of S with respect to threshold L and factor k* and denote it by $b_{x,k,L}(S)$. We now show that the size of the x-blow-up of S can be expressed in terms of the numbers $v_{j,L}(S)$.

▶ **Corollary 15.** *For a set S of N points in the plane in general position, let x be a non-negative integer and choose $m = k - 2x$ for some threshold $L \in [N-1]$ and factor $k \geq 1$. If S does not contain m points in convex position, then the x-blow-up $b_{x,k,L}(S)$ of S does not contain k points in convex position and*

$$|b_{x,k,L}(S)| = 2\sum_{l=0}^{x} \binom{k-2}{l} + \sum_{j=2}^{k-2x-1} v_{j,L}(S) \cdot \binom{k-j-1}{x}.$$

The proof of Corollary 15 is omitted. It follows from Corollary 15 that in order to produce large x-blow-ups without k points in convex position, point sets S with suitable values $v_{j,L}(S)$ for some threshold L are useful. We now provide a simple formula for the values $v_{j,N}(P)$ in the Erdős–Szekeres construction $P = P(k, k, k)$ where all points are labeled as left.

▶ **Lemma 16.** *For every integer $k \geq 2$, if we set the threshold $L = 2^{k-2}$, then, for $P = P(k, k, k)$, we have*

$$v_{j,L}(P) = \begin{cases} 1, & \text{for } j = 1, \\ 2^{j-2}, & \text{for } j \in \{2, \ldots, k-1\}, \\ 0, & \text{otherwise.} \end{cases}$$

The proof of Lemma 16 is omitted. Analogously, we get the same values $v_{j,0}(P)$ if all points of $P(k, k, k)$ are labeled as right, that is, if we set $L = 0$.

We now construct a point set M with $|M| = 2^{m-2}$ and without m points in convex position that has larger x-blow-ups than $P = P(m, m, m)$.

▶ **Definition 17** (Point set M)**.** *We construct the following set M that contains $2m-2$ points $\ell_1, \ldots, \ell_{m-1}, , r_1, \ldots, r_{m-1}$ in the plane in general position. We let $\ell_1 = (-m, 0)$, $r_1 = (m, \varepsilon)$, $\ell_2 = (-m+1, 1)$, and $r_2 = (m-1, 1+\varepsilon)$ for some small $\varepsilon > 0$. We now specify the placement of the remaining points $\ell_3, \ldots, \ell_{m-1}$ and $r_3, \ldots, r_{m-1}$ inductively; see Figure 4. Assume that we have placed points $\ell_1, \ldots, \ell_i$ and $r_1, \ldots, r_i$ for some $i \geq 2$. We now let ℓ_{i+1} be a point above the lines $\overline{\ell_{i-1}\ell_i}$ and $\overline{r_{i-1}r_i}$ to the right of ℓ_{i-1} and to the left of the line $x = 0$ and we let r_{i+1} be a point above the lines $\overline{\ell_{i-1}\ell_i}$ and $\overline{r_{i-1}r_i}$ to the left of r_i and to the right of the line $x = 0$ so that $y(r_{i+1}) > y(\ell_{i+1})$.*

We let P' be a point set obtained by replacing each point ℓ_i with $i \in [m-1]$ with a copy of the set $P(m-i+1, i)$ that lies in a sufficiently small neighborhood of ℓ_i. We denote this copy as C_{ℓ_i}. Note that $C_{\ell_1} = \emptyset$. We then let P'' be a point set obtained by replacing each point r_i with $i \in [m-1]$ with a copy of the set $P(m-i, i+1)$ that lies in a sufficiently small neighborhood of r_i. We use C_{r_i} to denote this copy and note that $C_{r_{m-1}} = \emptyset$. Note that the point sets P' and P'' then form affine copies of the point set $P(m-1, m-1, m-1)$. Let $M = P' \cup P''$ and note that $|M| = 2^{m-2}$.

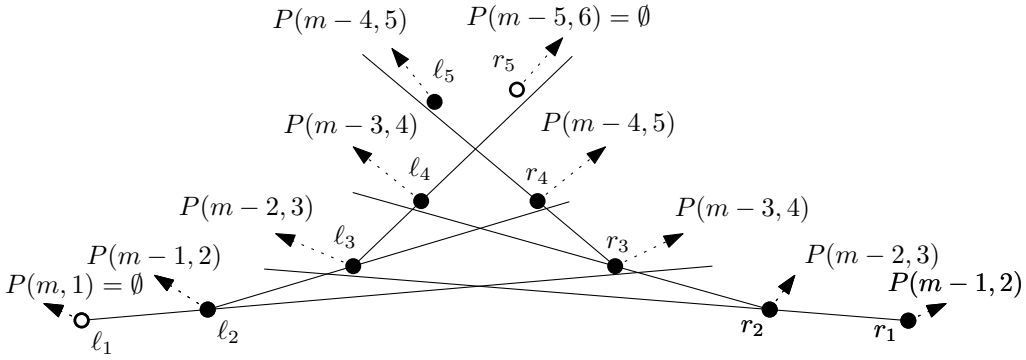

Figure 4 Example of the construction of the point set M for $m = 6$.

Now, if we set the threshold $L = 2^{m-3}$, then the left points of M are the points from P', and the right points of M are the points of P''. We also obtain the following formulas.

▶ **Lemma 18.** *For every integer $m \geq 3$, the set M does not contain m points in convex position and, for the threshold $L = 2^{m-3}$, satisfies*

$$v_{j,L}(M) = \begin{cases} 2, & \text{for } j = 1, \\ 2^{j-1}, & \text{for } j \in \{2, \dots, m-2\}, \\ 0, & \text{otherwise.} \end{cases} \tag{4}$$

The proof of Lemma 18 is omitted. We now prove that suitable x-blow-ups of M produce new sets of 2^{k-2} points in the plane in general position that do not contain k points in convex position, obtaining a new construction of such point sets.

▶ **Theorem 19.** *For each positive integer x and $k \geq 2x+3$, let $m = k - 2x$. The x-blow-up $b_{x,k,L}(M)$ of the point set M with respect to the threshold $L = 2^{m-3}$ does not contain k points in convex position and $|b_{x,k,L}(M)| = 2^{k-2}$.*

Proof. By applying the x-blow-up from Corollary 15 with parameters x, k, and $L = 2^{m-3}$ to M, we obtain a set $b_{x,k,L}(M)$ of

$$|b_{x,k,L}(M)| = \sum_{l=0}^{x} \binom{k-2}{l} + \sum_{j=2}^{k-2x-2} 2^{j-1} \cdot \binom{k-j-1}{x} + \sum_{l=k-x-2}^{k-2} \binom{k-2}{l}$$

points in the plane in general position that contains no k points in convex position.

To show that $|b_{x,k,L}(M)|$ equals 2^{k-2} it suffices to prove that

$$\sum_{l=x+1}^{k-x-3} \binom{k-2}{l} = \sum_{j=2}^{k-2x-2} 2^{j-1} \cdot \binom{k-j-1}{x}$$

if $k \geq 2x+3$, as then $|b_{x,k,L}(S)| = 2^{k-2}$ follows by the binomial theorem. This equality is true because both sides count the number of subsets of $[k-2]$ of size at least $x+1$ and at most $k-x-3$. This is trivial for the left-hand side. To prove the right-hand side, let $\mathcal{F}$ be the set of subsets of $[k-2]$ of size at least $x+1$ and at most $k-x-3$. For $F \in \mathcal{F}$, we let j be the minimum element from $[k-2]$ such that either F or its complement contains exactly $x+1$ elements in $\{j-1,\ldots,k-2\}$. Note that such j is uniquely determined for each $F \in \mathcal{F}$ and that $j \in \{2,\ldots,k-2x-2\}$. On the other hand, we can uniquely determine set F from $\mathcal{F}$ by selecting $j-1$, deciding whether F or its complement has exactly $x+1$ elements in $\{j-1,\ldots,k-2\}$ and then select the remaining x of them from $\{j,\ldots,k-2\}$ to F (or to its complement, respectively) and, finally, select an arbitrary subset of $[j-2]$ to F (or its complement, respectively). ◀

6.3 Computational experiments

Since there are other possible choices for X and Y, one might wonder whether some of them yield constructions of more than 2^{k-2} points without k points in convex position. We implemented a simple program in *Matlab* based on a non-linear optimization solver to find as large (X,Y)-blow-up of a given point set as possible. Given a set of N points in the plane in general position and a factor k, this solver tries to find a solution $(x_1,\ldots,x_N,y_1,\ldots,y_N)$ that satisfies the linear constraints from Lemma 14 and that has as large value of the function

$$\sum_{l=0}^{x_1}\binom{k-2}{l} + \sum_{i=2}^{N-1}\binom{x_i+y_i}{x_i} + \sum_{l=0}^{y_N}\binom{k-2}{l}$$

as possible. Since the objective function is not linear, we used a solver based on a genetic algorithm that does not guarantee finding a true optimum solution. We tried various point sets on the input, including subsets of $P(a,u)$ and random point sets. Using this program, we obtained many examples of 2^{k-2} points for various choices of S and k up to 20. Even though there is some freedom in choosing X and Y, the size of the (X,Y)-blow-up never exceeded 2^{k-2}. So the Erdős–Szekeres conjecture remains open.

Abstract

We investigate several problems concerning extremal Betti numbers and persistence in filtrations of flag complexes. For graphs on n vertices, we show that $\beta_k(X(G))$ is maximal when $G = \mathcal{T}_{n,k+1}$, the Turán graph on $k+1$ partition classes, where $X(G)$ denotes the flag complex of G. Building on this, we construct an edgewise (one edge at a time) filtration $\mathcal{G} = G_1 \subseteq \cdots \subseteq \mathcal{T}_{n,k+1}$ for which $\beta_k(X(G_i))$ is maximal for all graphs on n vertices and i edges. Moreover, the persistence barcode $\mathcal{B}_k(X(G))$ achieves a maximal number of intervals, and total persistence, among all edgewise filtrations with $|E(\mathcal{T}_{n,k+1})|$ edges.

For $k = 1$, we consider edgewise filtrations of the complete graph K_n. We show that the maximal number of intervals in the persistence barcode is obtained precisely when $G_{\lceil n/2 \rceil \cdot \lfloor n/2 \rfloor} = \mathcal{T}_{n,2}$. Among such filtrations, we characterize those achieving maximal total persistence. We further show that no filtration can optimize $\beta_1(X(G_i))$ for all i, and conjecture that our filtrations maximize the total persistence over all edgewise filtrations of K_n.

Acknowledgements We thank Ulrich Bauer for suggesting the problem of maximizing the number of intervals in the barcode of a Vietoris–Rips filtration.

1 Introduction

A central theme in topological data analysis (TDA) is the computation of homological invariants from simplicial complexes. These complexes are often constructed from point cloud data, with the *Vietoris–Rips* complex being one of the most widely used constructions. For a finite set P in a metric space (M, d), the Vietoris–Rips complex at scale r, denoted $\mathrm{VR}_r(P)$, includes all simplices $\sigma = \{p_0, \ldots, p_n\}$ such that $d(p_i, p_j) \leq 2r$ for all $0 \leq i, j \leq n$. This complex is a *flag complex*, meaning it is the largest simplicial complex with a given underlying graph (the 1-skeleton). In particular, the edges in the connectivity graph of P at scale r fully determine the higher-dimensional simplices in $\mathrm{VR}_r(P)$. Varying the scale parameter r induces a filtration of simplicial complexes:

$$\mathrm{VR}(P)_{r_0} \hookrightarrow \mathrm{VR}(P)_{r_1} \hookrightarrow \cdots \hookrightarrow \mathrm{VR}(P)_{r_m},$$

where $r_0 < r_1 < \cdots < r_m$. Applying k-dimensional homology over a field $\mathbf{k}$ to this filtration yields a persistence barcode in degree k, denoted $\mathcal{B}_k(\mathrm{VR}(P))$. This barcode, consisting of intervals $[a, b)$, encodes the birth and death of topological features across scales and serves as a powerful tool for extracting topological information from P. When P is a sufficiently dense sampling of an underlying space X, the number of "long bars" in $\mathcal{B}_k(\mathrm{VR}(P))$ determines the k-th Betti number $\beta_k(X)$, which describes the k-dimensional topological features of X [7]. For a comprehensive introduction to topological data analysis, we refer the reader to [8].

Given the central role of such filtrations in TDA, this paper addresses a fundamental question: how many topological features can arise in a data set of n points? Specifically, we investigate bounds on quantities such as the maximal value of $\beta_k(\mathrm{VR}_r(P))$, the maximal number of intervals in $\mathcal{B}_k(\mathrm{VR}(P))$, the length of the longest interval, and the sum of the lengths of the intervals (the total persistence).

▶ Remark 1. In this paper, we focus on edgewise filtrations of graphs, i.e., sequences of graphs $\mathcal{G} = G_1 \subseteq G_2 \subseteq \cdots \subseteq G_m = \{G_i\}_{i=1}^m$, on n vertices, where G_{i+1} and G_i differ by precisely one edge. Notably, every filtration of flag complexes can be realized as the Vietoris–Rips filtration of an appropriate metric on the vertices of G_m; see the full version of this paper [3, A]. Thus, our results are directly applicable to data analysis using persistent homology.

1.1 Overview and contributions

In Section 2, we introduce the relevant background material and compute the Betti numbers of flag complexes on Turán graphs.

In Section 3, we examine extremal Betti numbers and establish tight upper bounds on $\beta_k(F)$, where F is a flag complex on n vertices (Theorem 10). This upper bound is achieved by the Turán graph $\mathcal{T}_{n,k+1}$.

In Section 4, we study filtrations of flag complexes on n vertices with at most e edges, where e is the number of edges in $\mathcal{T}_{n,k+1}$. We prove that our filtration maximizes β_k at all filtration steps (Theorem 16).

In Section 5, we analyze the longest possible interval in the barcode of a filtration of flag complexes on n vertices (Corollary 21).

Additionally, in Section 6, we focus on degree 1 homology and show that any filtration of flag complexes on n vertices will achieve the maximal number of intervals in its degree 1 barcode if and only if the filtration contains $\mathcal{T}_{n,2}$ (Corollary 25).

In Section 7, we explore flag filtrations in homology degree 1 that achieve both a maximal number of intervals and maximal total persistence. Equivalently, we maximize the total persistence of all filtrations of graphs containing $G_{\lceil n/2 \rceil \cdot \lfloor n/2 \rfloor} = \mathcal{T}_{n,2}$. Given the importance of Turán graphs in extremal graph theory, we believe that identifying extremal filtrations of Turán graphs is interesting in its own right. Our result relies on an elaborate combinatorial analysis that precisely classifies the extremal filtrations (Theorem 31).

Finally, the paper concludes with a discussion in which we outline several important conjectures for future work.

1.2 Related work

The study of extremal values of $\mathbb{Z}$-linear functions on the f- and β-vectors of simplicial complexes with n vertices has a rich history. Classical questions include determining the extremal Euler characteristic and the maximal sum of Betti numbers. These problems were addressed for general simplicial complexes in [4] and later extended to arbitrary $\mathbb{Z}$-linear functions in [11]. Specifically, [11, Theorem 3.4] shows that for flag complexes, extremal values are always realized by $\mathcal{T}_{n,k}$ for some k. Consequently, Theorem 10 follows directly from [11, Theorem 3.4].

Our proof of Theorem 10 adapts the approach of [1, Theorem 1.1], which gives an alternative proof for the extremal total Betti number of flag complexes. The key observation in our proof of Theorem 10 plays a central role in our results on extremal interval lengths (Section 5).

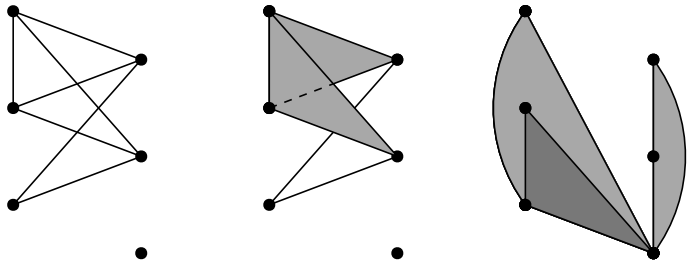

Figure 1 A graph (left), its flag complex (middle) and independence complex (right).

Another related work is [10], which examines asymptotic bounds for β_k in Vietoris–Rips complexes of point samples in $\mathbb{R}^d$. Similar questions have been explored for Čech complexes; see, e.g., [9].

Our work diverges from earlier work by considering *filtered* flag complexes. This approach is closely tied to the problem of finding extremal values for complexes with precisely n vertices and e edges; we return to this in Section 8. Importantly, and in contrast to classical work, graphs achieving extremal values need not have $\mathcal{T}_{n,k}$ as a subgraph.

2 Background

Graphs and Simplicial Complexes. Let $G = (V, E)$ be a graph. We write $\{v, w\}$ for the edge connecting the vertices v and w. For a vertex $v \in V$, the *neighborhood* is $N_G(v) \coloneqq \{w \colon \{v, w\} \in E\}$, and the *closed neighborhood* is $N_G[v] \coloneqq N_G(v) \cup \{v\}$. The *degree* of v is $\deg(v) \coloneqq \deg_G(v) \coloneqq |N_G(v)|$. The complete graph on n vertices is denoted K_n.

The *complement* of G, denoted $\overline{G}$, is the graph on the same vertex set as G, where two distinct vertices of $\overline{G}$ are adjacent if and only if they are non-adjacent in G. The *join* of disjoint graphs G_1 and G_2 is the graph $G_1 \vee G_2$ with vertex set $V(G_1) \sqcup V(G_2)$ and edge set $E(G_1) \cup E(G_2) \cup \big\{\{v_1, v_2\} \colon v_1 \in V(G_1), v_2 \in V(G_2)\big\}$. The *complete bipartite graph* K_{n_1,n_2} is defined as the join $G_1 \vee G_2$, where each G_i is an empty graph on n_i vertices. The sets $V(G_1)$ and $V(G_2)$ are called the *partition classes* of K_{n_1,n_2}.

For a vertex v in a simplicial complex K, the *link* and *(closed) star* of v are the simplicial complexes given respectively by

$$\mathrm{lk}_K(v) = \{\tau \in K : v \notin \tau, \{v\} \cup \tau \in K\} \qquad \mathrm{st}_K(v) = \{\tau \in K : \{v\} \cup \tau \in K\}.$$

We write $K - v$ for the simplicial complex with simplices $\tau \in K$ for which $v \notin K$.

For a graph G, we let $X(G)$ denote the simplicial complex with m-simplices given by the $(m+1)$-cliques in G. A simplicial complex K is called a *flag complex* if $K = X(G)$ for some graph G. The *independence complex* of G is the simplicial complex $\mathrm{Ind}(G) = X(\overline{G})$. Examples of flag and independence complexes are given in Figure 1.

Homology. For a simplicial complex K, we let $\beta_k(K)$ denote the dimension of the reduced homology group $\tilde{H}_k(K; \mathbf{k})$, and let $C_k(K)$ denote the vector space of k-chains. We use coefficients in a fixed, but arbitrary, field $\mathbf{k}$; our optimal constructions are torsion-free and thus our results do not depend on the choice of coefficient field. For that reason, we simply write $\tilde{H}_k(K)$. We also employ the notation $\beta_k^{\mathrm{FL}}(G) = \beta_k(X(G))$ for a graph G.

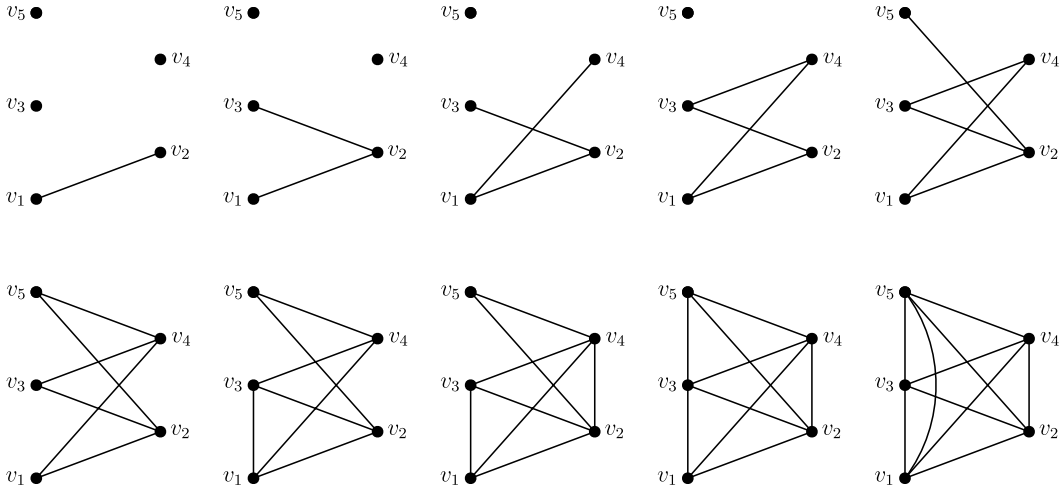

Figure 2 An edgewise filtration of K_5.

Persistent Homology. A filtration $\mathcal{K}$ of simplicial complexes is a collection of simplicial complexes $\{K_i\}_{i=1}^m$ such that $K_i \subseteq K_j$ for $i \leq j$. Applying $\tilde{H}_k(-;\mathbf{k})$ to a filtration yields a sequence of vector spaces and linear maps $\tilde{H}_k(\mathcal{K}) : \tilde{H}_k(K_1) \to \cdots \to \tilde{H}_k(K_m)$ called a *persistence module*. Provided all the vector spaces are finite-dimensional, $\tilde{H}_k(\mathcal{K})$ is uniquely described by a collection of intervals in $\{1,\ldots,m\}$, called the *degree k barcode of $\mathcal{K}$*. We shall denote this barcode by $\mathcal{B}_k(\mathcal{K})$. The *total persistence* of $\mathcal{K}$ is given by

$$T\beta_k(\mathcal{K}) = \sum_{[a,b)\in\mathcal{B}_k(\mathcal{K})} \big(b-a\big) = \sum_{i=1}^{m} \beta_k(K_i).$$

For a more thorough introduction to persistent homology, (generalized) persistence modules, and examples, see, e.g., [8, Chapter 3] or [5].

For a filtration $\mathcal{G}$ of graphs (1-dimensional simplicial complexes), we get a filtration $X(\mathcal{G})$ of simplicial complexes by taking the flag complex at every index. If $G_{i+1} - G_i$ is a single edge for all i, then we say that the filtration $\mathcal{G}$ is *edgewise*. We shall employ the notation $\mathcal{B}_k^{\mathrm{FL}}(G) = \mathcal{B}_k(X(\mathcal{G}))$.

▶ **Example 2.** An edgewise filtration of K_5 can be found in Figure 2.

2.1 Elementary homological properties

The following two lemmas are well-known and important in combinatorial topology. For completeness, their proofs can be found in the full version [3, B.1].

▶ **Lemma 3.** *Let K be a simplicial complex and $v \in V(K)$ a vertex. Then, for all $k \geq 1$,*

$$\beta_k(K) \leq \beta_k(K - v) + \beta_{k-1}(\mathrm{lk}_K(v)).$$

▶ **Lemma 4.** *For any two graphs G and H, and $k \geq -1$,*

$$\beta_k(\mathrm{Ind}(G \sqcup H)) = \sum_{i,j\geq -1; i+j=k-1} \beta_i(\mathrm{Ind}(G))\beta_j(\mathrm{Ind}(H)).$$

The following observation is essential for our work in Section 7.

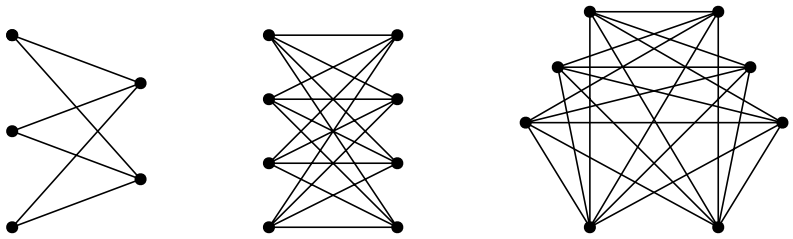

Figure 3 From left to right: the Turán graphs $\mathcal{T}_{5,2}$, $\mathcal{T}_{8,2}$ and $\mathcal{T}_{8,3}$.

▶ **Proposition 5.** *Let $V(G) = V_1 \sqcup V_2$ be the vertex set of a graph G containing all edges of the form $\{v, w\}$ where $v \in V_1$ and $w \in V_2$. Let $d_i \geq 1$ denote the number of connected components of G restricted to V_i. Then, $\beta_1^{\mathrm{FL}}(G) = \beta_0^{\mathrm{FL}}(G_1)\beta_0^{\mathrm{FL}}(G_2) = (d_1 - 1)(d_2 - 1)$.*

Proof. Let $\overline{G}$ denote the complement graph of G and observe that $\overline{G} = \overline{G}_1 \sqcup \overline{G}_2$ where G_1 and G_2 are the full subgraphs of G with vertices V_1 and V_2, respectively. From Lemma 4,

$$\beta_1^{\mathrm{FL}}(G) = \beta_1(\mathrm{Ind}(\overline{G})) = \beta_0(\mathrm{Ind}(\overline{G}_1))\beta_0(\mathrm{Ind}(\overline{G}_2)) = \beta_0(X(G_1))\beta_0(X(G_2)).$$ ◀

2.2 Turán graphs

▶ **Definition 6.** *Let $n \geq 0$ and $k \geq 1$, and let n' be the smallest positive integer such that $n' \equiv n \bmod k$. Then, the (n, k)* graph $\mathcal{T}_{n,k}$ *is the complement graph of the graph*

$$\overline{\mathcal{T}_{n,k}} = \bigsqcup_{i=1}^{k} K_{n_i}, \qquad n_i = \begin{cases} \lceil n/k \rceil & \text{if } 1 \leq i \leq n', \\ \lfloor n/k \rfloor & \text{otherwise.} \end{cases}$$

▶ **Example 7.** See Figure 3 for some examples of Turán graphs.

The proof of the following can be found in the full version [3, B.1].

▶ **Proposition 8.** *For all integers $n \geq 1$ and $k \geq 1$, we let n' be the smallest positive integer such that $n' \equiv n \bmod k$. We have*

$$\beta_i^{\mathrm{FL}}(\mathcal{T}_{n,k}) = \begin{cases} (\lceil n/k \rceil - 1)^{n'} \cdot (\lfloor n/k \rfloor - 1)^{k-n'} & \text{if } i = k - 1, \\ 0 & \text{otherwise.} \end{cases}$$

In particular, if n is a multiple of k, then $\beta_{k-1} = (n/k - 1)^k$.

3 The maximum value of $\beta_k(X(G))$

The following is well-known; see the full version [3, B.2] for a proof.

▶ **Lemma 9.** *Let S be a positive integer, and $x_i \geq 1$ be integers satisfying $\sum_{i=1}^{n} x_i = S$. Then, $\prod_{i=1}^{n}(x_i - 1) \leq \prod_{i=1}^{n}(y_i - 1)$ where*

$$y_i = \begin{cases} \lceil S/n \rceil & \text{if } 1 \leq i \leq S \bmod n \\ \lfloor S/n \rfloor & \text{otherwise.} \end{cases} \tag{1}$$

As said in Section 1.2, the following proof is a modification of the proof of [1, Theorem 1.1].

▶ **Theorem 10.** *Let G be a graph on n vertices. Then, for all $k \geq 0$,*

$$\beta_k^{\mathrm{FL}}(G) \leq (\lceil n/(k+1) \rceil - 1)^{(n \bmod k+1)} \cdot (\lfloor n/(k+1) \rfloor - 1)^{(k+1)-(n \bmod k+1)}.$$

Proof. We shall work inductively on n. The result is trivially true for $n = 1$, so assume that it holds for all $n' < n$.

Note that $X(G) = \mathrm{Ind}(\overline{G})$. Let d denote the minimal degree over all $v \in V(\overline{G})$. Assume that v is a vertex with $\deg(v) = d$, and let $\{v_1, \ldots, v_d\}$ denote the neighbours of v in $\overline{G}$. Moreover, let $\overline{G}_i = \overline{G} - \{v_1, \ldots, v_i\}$ for $i = 1, \ldots, d$ and $\overline{G}_0 = \overline{G}$. Applying Lemma 3,

$$\begin{aligned}
\beta_k(\mathrm{Ind}(\overline{G})) &\leq \beta_k(\mathrm{Ind}(\overline{G}_1)) + \beta_{k-1}(\mathrm{Ind}(\overline{G} - N_{\overline{G}}[v_1]) \\
&\leq \beta_k(\mathrm{Ind}(\overline{G}_2)) + \beta_{k-1}(\mathrm{Ind}(\overline{G}_1 - N_{\overline{G}_1}[v_2])) + \beta_{k-1}(\mathrm{Ind}(\overline{G} - N_{\overline{G}}[v_1]))) \\
&\vdots \\
&\leq \beta_k(\mathrm{Ind}(\overline{G}_d)) + \sum_{i=0}^{d-1} \beta_{k-1}(\mathrm{Ind}(\overline{G}_i - N_{\overline{G}_i}[v_{i+1}]))
\end{aligned}$$

Here $\overline{G}_d$ has an isolated vertex and thus $\mathrm{Ind}(\overline{G}_d)$ is a cone, and therefore $\beta_k(\mathrm{Ind}(\overline{G}_d)) = 0$. Since every vertex of $\overline{G}$ has degree at least d, it follows that $\overline{G}_i - N_{\overline{G}_i}(v_{i+1})$ contains at most $n - (d+1) = n - d - 1$ vertices. By the induction hypothesis it follows that

$$\beta_k(\mathrm{Ind}(\overline{G})) \leq d \cdot (x_1 - 1) \cdots (x_k - 1) = ((d+1) - 1) \cdot (x_1 - 1) \cdots (x_k - 1)$$

for integers $x_i \geq 1$ for which $(d+1) + \sum_{i=1}^{k} x_i = d + 1 + n - d - 1 = n$. Hence, by Lemma 9,

$$\beta_k(\mathrm{Ind}(\overline{G})) \leq (\lceil n/(k+1) \rceil - 1)^{(n \bmod k+1)} \cdot (\lfloor n/(k+1) \rfloor - 1)^{(k+1)-(n \bmod k+1)}.$$ ◀

Let $\mathbf{G}(n) = \{G\colon \text{ graph on } n \text{ vertices}\}$. Combining Theorem 10 and Proposition 8, we have

▶ **Corollary 11.** *Of all graphs on n vertices, $\mathcal{T}_{n,k+1}$ maximizes the k-th Betti number. I.e.,*

$$\max_{G \in \mathbf{G}(n)} \beta_k^{\mathrm{FL}}(G) = \beta_k^{\mathrm{FL}}(\mathcal{T}_{n,k+1}).$$

In particular, if n is a multiple of k, then $\max_{G \in \mathbf{G}(n)} \beta_k^{\mathrm{FL}}(G) = (n/k - 1)^k$.

4 The maximum value of $\beta_k(X(G))$ for $|E(G)| \leq |E(\mathcal{T}_{n,k+1})|$

In this section, we fix $n, k \geq 1$, and the notation

$$e_{n,k+1} \coloneqq |E(\mathcal{T}_{n,k+1})| \text{ and } \Delta_{m-1,m}^{k+1} \coloneqq e_m^{k+1} - e_{m-1}^{k+1}. \tag{2}$$

The following result follows from combining Lemma 3 and Corollary 11, and will be integral in proving the main result of this section.

▶ **Corollary 12.** *Let v be a vertex of degree $d \geq 1$ in a graph G. Then,*

$$\beta_k^{\mathrm{FL}}(G) \leq \beta_k^{\mathrm{FL}}(G - v) + \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d,k}).$$

Proof. If $K = X(G)$, then $K - v = X(G - v)$, and Lemma 3 implies that

$$\beta_k^{\mathrm{FL}}(G) \leq \beta_k^{\mathrm{FL}}(G - v) + \beta_{k-1}(\mathrm{lk}_{X(G)}(v)).$$

Now observe that $\mathrm{lk}_{X(G)}(v) = X(N_G[v])$, and since $\mathrm{lk}_{X(G)}(v)$ has d vertices, it follows from Corollary 11 that $\beta_{k-1}(\mathrm{lk}_K(v)) \leq \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d,k})$. ◀

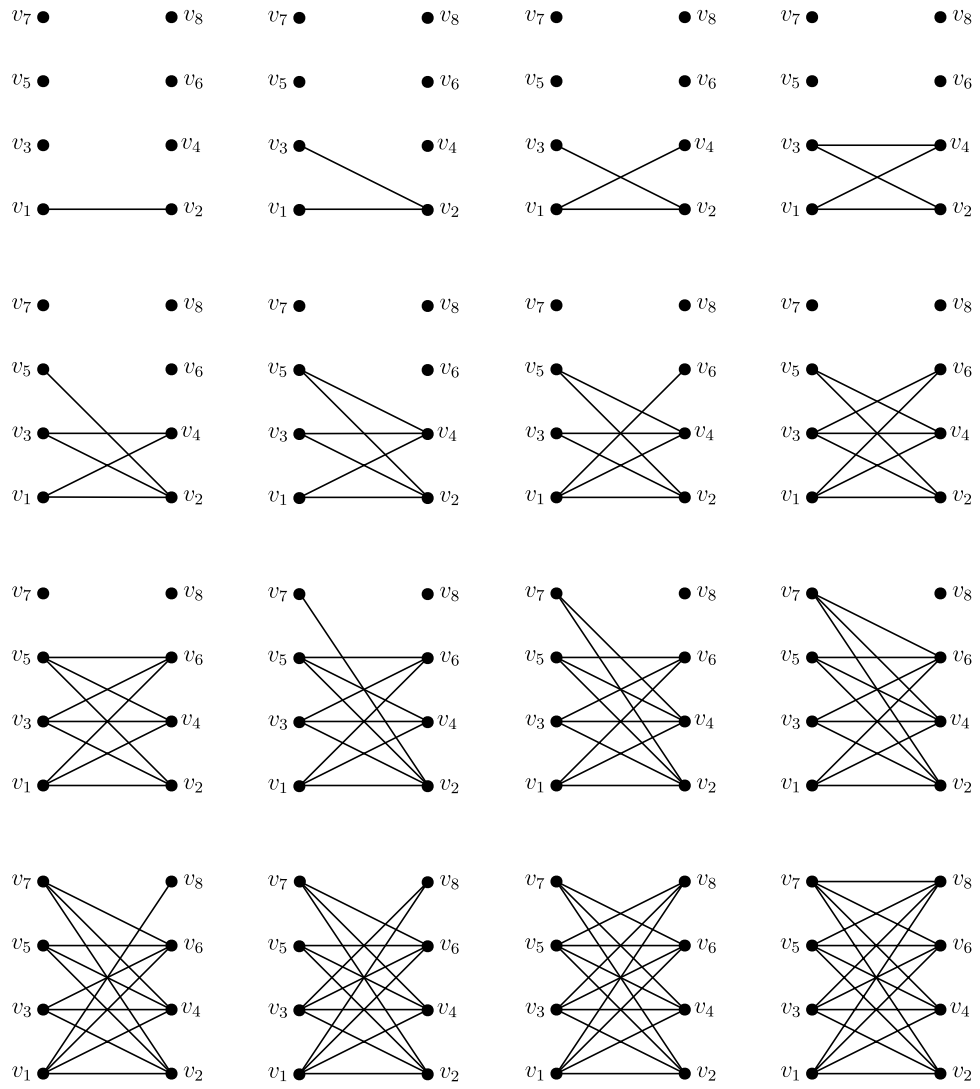

Figure 4 The filtration $\mathcal{H}$ of $\mathcal{T}_{8,2}$ from Definition 13.

We now define an edgewise filtration $\mathcal{H}^{n,k+1} = \mathcal{H} = \{H_i\}_{i=1}^{e_{n,k+1}} = \{H_i^{n,k+1}\}_{i=1}^{e_{n,k+1}}$ of the Turán graph $\mathcal{T}_{n,k+1}$. In this section, we shall show, for $m = 1, \ldots, |\mathcal{T}_{n,k+1}|$, that $\beta_k^{\mathrm{FL}}(H_m)$ is maximal over all graphs with m edges, i.e., that $\mathcal{H}$ is *fiberwise optimal*.

▶ **Definition 13.** *Let V denote the vertices of $\mathcal{T}_{n,k+1}$ and label the elements of V such that v_i and v_{i+k+1} are in the same partition. Writing each edge as $e_{i,j} = \{v_i, v_j\}$ for $i < j$, we order the edges by the following co-lexicographic order: $e_{i,j} < e_{k,l}$ if $\max\{i,j\} < \max\{k,l\}$, or if $i = k$ and $j < l$, or if $j = l$ and $i < k$. Following this order, let $H_i = H_i^{n,k+1}$ denote the subgraph of $\mathcal{T}_{n,k+1}$ with the first i edges.*

Note that, since $\mathcal{T}_{n,k+1}$ contains no $k+1$-simplices, $\beta_k(H_i)$ is increasing as a function of i.

▶ **Example 14.** See Figure 2 for an edgewise filtration $\mathcal{G} = \{G_i\}_{i=1}^{6}$ of K_5, where $G_i \cong H_i^{5,2}$ for $i = 1, \ldots, 6$. Furthermore, in Figure 4 one can find the filtration $\mathcal{H}^{8,2}$ of $\mathcal{T}_{8,2}$.

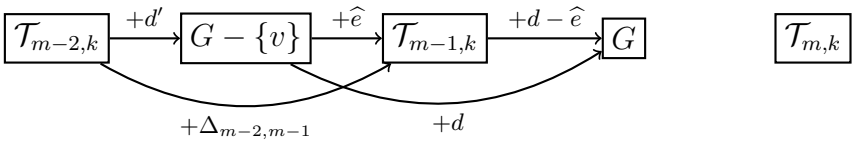

Figure 5 An illustration of Case 2 from the proof of Theorem 16.

The next lemma shows that, once a vertex has been connected to the growing component, and until the next vertex gets connected, the change in β_k^{FL} from adding a single edge increases with the number of edges already added. Its proof, similar to that of Corollary 12, can be found in the full version [3, B.3].

▶ **Lemma 15.** *For e edges, let m be maximal such that $\mathcal{T}_{m,k+1}$ is a subgraph of H_e. Then,*

$$\beta_k^{\mathrm{FL}}(H_e) = \beta_k^{\mathrm{FL}}(\mathcal{T}_{m,k+1}) + \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{e-e_m^{k+1},k}).$$

In particular, for $e_m^{k+1} \le e_1 < e_2 < e_{m+1}^{k+1}$, we have that

$$\beta_k^{\mathrm{FL}}(H_{e_1+1}) - \beta_k^{\mathrm{FL}}(H_{e_1}) \le \beta_k^{\mathrm{FL}}(H_{e_2+1}) - \beta_k^{\mathrm{FL}}(H_{e_2}).$$

▶ **Theorem 16.** *Let $e \le e_{n,k+1}$, let H_e be as above, and let G be any other graph on n vertices and e edges. Then, $\beta_k^{\mathrm{FL}}(G) \le \beta_k^{\mathrm{FL}}(H_e)$.*

Proof. We prove this inductively on the number of edges e. The statement is clearly true for $e = 1$, so let's assume that the result holds for all $e' < e$.

Let m be the number of vertices in H_e with positive degree, and let n' denote the number of vertices in G with positive degree. If $n' < m$, then by Theorem 10,

$$\beta_k^{\mathrm{FL}}(G) \le \beta_k^{\mathrm{FL}}(\mathcal{T}_{m-1,k+1}) \le \beta_k^{\mathrm{FL}}(H_e).$$

Hence, we may assume that $n' \ge m$. In particular, the average degree of the positive-degree-vertices in G is no larger than the average degree of positive-degree-vertices in H_e.

Choose a vertex v in G with minimal positive degree d, and observe that

$$d \le e_m^{k+1} - e_{m-1}^{k+1} = \Delta_{m-1,m},$$

since $\mathcal{T}_{m-1,k+1} \subsetneq H_e \subseteq \mathcal{T}_{m,k+1}$. In fact, if $d = \Delta_{m-1,m}$, then we must have that the average degree in H_e is at least d. Importantly, this happens if and only if $H_e = \mathcal{T}_{m,k+1}$ and m is a multiple of $k+1$.

By the induction assumption,

$$\beta_k^{\mathrm{FL}}(G - v) \le \beta_k^{\mathrm{FL}}(H_{e-\deg(v)}), \text{ and thus, by Corollary 12,}$$
$$\beta_k^{\mathrm{FL}}(G) \le \beta_k^{\mathrm{FL}}(H_{e-\deg(v)}) + \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d,k}).$$

If $d = \Delta_{m-1,m}$, then this becomes, by Lemma 15,

$$\beta_k^{\mathrm{FL}}(G) \le \beta_k^{\mathrm{FL}}(\mathcal{T}_{m-1,k+1})) + \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d,k}) = \beta_k^{\mathrm{FL}}(\mathcal{T}_{m,k+1}) = \beta_k^{\mathrm{FL}}(H_e).$$

We may therefore assume that $d \le \Delta_{m-1,m} - 1 \le \Delta_{m-2,m-1}$.

Let $\hat{e}$ denote the number of edges that is added to H_{e-d} before a new vertex gets positive degree in the filtration $\mathcal{H}$. Let d' be the degree of the last vertex in H_{e-d} that obtained positive degree in $\mathcal{H}$. We consider two cases.

- **Case 1:** $\mathcal{T}_{m-1,k} \subseteq H_{e-d}$**.** Then,

$$\begin{aligned}\beta_k^{\mathrm{FL}}(G) &\leq \beta_k^{\mathrm{FL}}(H_{e-d}) + \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d,k}) \\ &= \beta_k^{\mathrm{FL}}(H_{e-d}) + \beta_k^{\mathrm{FL}}(H_{e_m^{k+1}+d}) - \beta_k^{\mathrm{FL}}(H_{e_m^{k+1}}) \\ &\leq \beta_k^{\mathrm{FL}}(H_{e-d}) + \beta_k^{\mathrm{FL}}(H_e) - \beta_k^{\mathrm{FL}}(H_{e-d}) \\ &= \beta_k^{\mathrm{FL}}(H_e).\end{aligned}$$

- **Case 2:** $\mathcal{T}_{m-2,k} \subseteq H_{e-d} \subset \mathcal{T}_{m-1,k}$**.** Note that $d' + \hat{e} = \Delta_{m-2,m-1} \geq d$ and $d - \hat{e} \geq 0$ (see Figure 5). In particular,

$$\begin{aligned}\beta_k^{\mathrm{FL}}(G) &\leq \beta_k^{\mathrm{FL}}(H_{e-d}) + \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d,k}) \\ &= \beta_k^{\mathrm{FL}}(H_{e-d}) + \left(\beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d,k}) - \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d-\hat{e},k})\right) + \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d-\hat{e},k}) \\ &\leq \beta_k^{\mathrm{FL}}(H_{e-d}) + \left(\beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d'+\hat{e},k}) - \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d',k})\right) + \beta_{k-1}^{\mathrm{FL}}(\mathcal{T}_{d-\hat{e},k}) \\ &= \beta_k^{\mathrm{FL}}(H_e).\end{aligned}$$

In both cases, the inequality follows from Corollary 12 and Lemma 15. ◀

5 Tight bounds on the vanishing of homology and extremal interval lengths

For a graph G with n vertices, it is guaranteed that there exists a vertex of degree $n-1$ when the average degree exceeds $n-2$. Specifically, if the number of edges satisfies $m > \frac{n(n-2)}{2}$, then $X(G)$ must be a cone, implying that $\beta_k^{\mathrm{FL}}(G) = 0$ for all k. In practical scenarios, however, the primary interest is with $\beta_k^{\mathrm{FL}}(G)$ for small k. In this section, we provide tight bounds for the vanishing of $\beta_k^{\mathrm{FL}}(G)$ for a fixed k.

▶ **Lemma 17.** *Let G be a graph with minimum degree u. Let v be a vertex of degree u and let $N_G(v) = \{v_1, \ldots, v_u\}$. Let $d_i := \deg(v_i)$. If G has n vertices and m edges, then*

$$\left|V\left(G - N_G[v_i]\right)\right| = n - d_i - 1 \text{ and } \left|E\left(G - N_G[v_i]\right)\right| \leq m - \left(d_i + \left\lceil \frac{(u-1)d_i}{2} \right\rceil\right).$$

Proof. Let $\widehat{G} := G - N_G[v_i]$. The fact that $\left|V\left(\widehat{G}\right)\right| = n - d_i - 1$ is trivial. For showing the inequality, note that, by removing $N_G[v_i]$ from G, we remove the d_i edges containing v_i, and all edges containing the vertices of $N_G(v_i)$. Those vertices all have degree at least u, which means that they have at least $u-1$ neighbors apart from v_i. Because it might be the case that $N_G\left(N_G[v_i]\right) = N_G[v_i]$, it follows that

$$\left|E\left(\widehat{G}\right)\right| \leq m - \left(d_i + \left\lceil \frac{(u-1)d_i}{2} \right\rceil\right).$$ ◀

▶ **Theorem 18.** *Let G be a graph with n vertices and $m > \binom{n-1}{2} + k$ edges. Then $\beta_k^{\mathrm{FL}}(G) = 0$.*

Proof. Let us first consider the case $k = 0$. This case is immediate from the fact that the maximal number of edges in a graph on n vertices with an isolated vertex is $\binom{n-1}{2}$.

Working inductively on k, assume that result holds for all $k' < k$, and that $m > \binom{n-1}{2} + k$. Let $\overline{G}$ be the complement graph of G, and note that the number of edges $\overline{m} = |E(\overline{G})|$ satisfies

$$\overline{m} = \binom{n}{2} - m < \binom{n}{2} - \binom{n-1}{2} - k = n - 1 - k.$$

From the proof of Theorem 10, we have that

$$\beta_k^{\mathrm{FL}}(G) = \beta_k(\mathrm{Ind}(\overline{G})) \leq \sum_{i=0}^{d-1} \beta_{k-1}(\mathrm{Ind}(\overline{G}_i - N_{\overline{G}_i}[v_{i+1}])),$$

where $\overline{G}_i = \overline{G} - \{v_1, \ldots, v_i\}$, and $\{v_1, \ldots, v_u\}$ are the neighbors of a vertex $v \in V(\overline{G})$ with minimal degree u. We shall show that all the terms in the sum are zero.

If we let $u' \geq u - i$ denote the minimal degree of a vertex in $V(\overline{G}_i - N_{\overline{G}_i}[v_{i+1}])$,

$$\begin{aligned}
&\left|E\big(\overline{G}_i - N_{\overline{G}_i}[v_{i+1}]\big)\right| \\
&\overset{(i)}{\leq} |E(\overline{G}_i)| - \left(\deg_{\overline{G}_i}(v_{i+1}) + \left\lceil \frac{(u'-1)\deg_{\overline{G}_i}(v_{i+1})}{2} \right\rceil\right) \\
&\overset{(ii)}{\leq} |E(\overline{G}_i)| - \left(u - i + \left\lceil \frac{(u-i-1)(u-i)}{2} \right\rceil\right) = |E(\overline{G}_i)| - \sum_{j=1}^{u-i} j \\
&\overset{(iii)}{\leq} |E(\overline{G})| - \sum_{j=u-i+1}^{u} j - \sum_{j=1}^{u-i} j = |E(\overline{G})| - \sum_{j=1}^{u} j = \overline{m} - \left(\frac{u(u+1)}{2}\right).
\end{aligned}$$

Here, (i) follows from Lemma 17, (ii) from $\deg_{\overline{G}_i}(v_i) \geq u'$, and (iii) from the fact that $\overline{G}_i$ is obtained by removing i vertices from $\overline{G}$ with degree at least u in $\overline{G}$. Now write

$$n' = |V(\mathrm{Ind}(\overline{G}_i - N_{\overline{G}_i}[v_{i+1}]))| \leq n - u - 1,$$

and observe that

$$|E(\mathrm{Ind}(\overline{G}_i - N_{\overline{G}_i}[v_{i+1}]))| \geq \binom{n'}{2} - \overline{m} + u(u+1)/2.$$

It follows that,

$$\begin{aligned}
&|E(\mathrm{Ind}(\overline{G}_i - N_{\overline{G}_i}[v_{i+1}]))| - \binom{n'-1}{2} \\
&\geq \binom{n'}{2} - \overline{m} + u(u+1)/2 - \binom{n'-1}{2} \\
&= n' - 1 - \overline{m} + u(u+1)/2 > n' - 1 - (n-1-k) + u(u+1)/2 \geq k + u(u+1)/2 \geq k.
\end{aligned}$$

Hence, $\beta_{k-1}(\mathrm{Ind}(\overline{G}_i - N_{\overline{G}_i}[v_{i+1}])) = 0$ by the induction hypothesis. ◀

▶ Remark 19. Observe that the difference between the bound for a cone and the bound given in Theorem 18 is $n/2 - k - 1$. While this difference is linear in the number of vertices, it can result in a significant reduction in the number of higher-dimensional simplices; a reduction which has the potential to speed up current implementations of persistent homology for flag complexes, e.g., Ripser [2].

In the following example, we show that that bounds in the previous theorem are tight.

▶ **Example 20.** Let $n = (k+1)p$, and let $K_{1,p-1}$ be a star graph on p vertices and $p-1$ edges, i.e., a central vertex connected to all other vertices. Observe that $\beta_0(\mathrm{Ind}(K_{1,p-1})) = 1$ as one vertex is completely disconnected in the complement graph. If, $H = \bigsqcup_{i=1}^{k+1} K_{1,p-1}$, then it follows from repeated application of Lemma 4 that $\beta_k(\mathrm{Ind}(H)) \geq \prod_{i=1}^{k+1} \beta_0(\mathrm{Ind}(K_{1,p-1})) = 1$. The number of edges in $\mathrm{Ind}(H)$ is

$$\binom{n}{2} - (k+1)(p-1) = \binom{n}{2} - n + (k+1) = \binom{n}{2} - (n-1) + k = \binom{n-1}{2} + k.$$

▶ **Corollary 21.** *Let $\mathcal{G}$ be an edgewise filtration on n vertices. Then for any $[a,b) \in \mathcal{B}_k^{\mathrm{FL}}(\mathcal{G})$, we have*

$$2k(k+1) \leq a < b \leq \binom{n-1}{2} + k.$$

Proof. The bound on a follows from Theorem 16, and the bound on b from Theorem 18. ◀

It is straightforward to define a filtration $\mathcal{F}$ of the complement graph of H from Example 20 such that $\mathcal{B}_k^{\mathrm{FL}}(\mathcal{F})$ contains the interval $[a,b)$ from Corollary 21.

6 The maximum value of $|\beta_1^{\mathrm{FL}}(\mathcal{G})|$

▶ **Proposition 22.** *Let $\mathcal{G} = \{G_i\}_{i=1}^m$ be an edgewise filtration. Then, there exists a triangle-free subgraph H of G_m such that $\beta_1^{\mathrm{FL}}(H) \geq |\mathcal{B}_1^{\mathrm{FL}}(\mathcal{G})|$.*

Proof. Choose a representative cycle $c_{[a,b]}$ for each non-empty interval $[a,b) \in \mathcal{B}_1^{\mathrm{FL}}(\mathcal{G})$, e.g., by running the standard algorithm for persistent homology. For a cycle c, let $e(c)$ denote the set of edges on which the cycle has a non-zero coefficient, and let H be the subgraph of G_m with edges given by

$$\bigcup_{[a,b)\in\mathcal{B}_1^{\mathrm{FL}}(\mathcal{G})} e(c_{[a,b)]}).$$

Note that the cycles $\{c_{[a,b)} : [a,b) \in \mathcal{B}_1^{\mathrm{FL}}(\mathcal{G})\}$ are linearly independent (as elements of $C_1(G)$) by virtue of being representatives for non-trivial intervals.

If $X(H)$ contains a 2-simplex $\tau = \{v_1, v_2, v_3\}$, then any cycle $c_{[a,b)}$ supported on the edge $\{v_2, v_3\}$ is homologous in $\tilde{H}_1(X(H))$ to the cycle $c'_{[a,b)} = c_{[a,b)} - \partial_2(\tau)$. Hence, we can remove $\{v_2, v_3\}$ from H, without reducing the 1st Betti number. Doing this for all triangles, we end up with a triangle-free graph $\hat{H}$ containing at least $|\mathcal{B}_1^{\mathrm{FL}}(\mathcal{G})|$ linearly independent 1-cycles. In particular, $\beta_1^{\mathrm{FL}}(\hat{H}) \geq |\mathcal{B}_1^{\mathrm{FL}}(\mathcal{G})|$. ◀

▶ Remark 23. This argument does not apply to homology in higher degrees. For instance, the removal of an edge can result in the removal of many 2-simplices, some of which are faces of 3-simplices, and others that are not.

The previous result actually gives a short proof of Corollary 11 for the case $k = 1$. We shall include this proof here, as it ensures uniqueness of the extremal complex.

▶ **Proposition 24.** *For any graph on n vertices, we have $\beta_1^{\mathrm{FL}}(G) \leq \beta_1^{\mathrm{FL}}(\mathcal{T}_{n,2})$ with equality if and only if $G = \mathcal{T}_{n,2}$.*

Proof. Define any edgewise filtration $\mathcal{G} = \{G_i\}_{i=1}^m$ for which $G_m = G$. Then, by Proposition 22, there exists a triangle-free graph H such that $\beta_1^{\mathrm{FL}}(H) \geq \mathcal{B}_1^{\mathrm{FL}}(\mathcal{G}) \geq \beta_1^{\mathrm{FL}}(G)$. Hence, it suffices to maximize $\beta_1^{\mathrm{FL}}(G)$ over triangle-free graphs. By the Euler-Poincaré formula,

$$\beta_1^{\mathrm{FL}}(G) = -\beta_0^{\mathrm{FL}}(G) - 1 - |V(G)| + |E(G)|.$$

In conclusion, we are seeking a triangle-free graph with a maximal number of edges, but this is well-known to be uniquely the graph $\mathcal{T}_{n,2}$ by Turán's theorem [6, Theorem 11.17]. ◀

Combined we arrive at the following.

▶ **Corollary 25.** *If $\mathcal{G}$ is a filtration of K_n, then $|\mathcal{B}_1^{\mathrm{FL}}(\mathcal{G})| \leq \beta_1^{\mathrm{FL}}(\mathcal{T}_{n,2})$ with equality if and only if $G_{\lceil n/2\rceil \cdot \lfloor n/2\rfloor} = \mathcal{T}_{n,2}$.*

7 Extremal filtrations for degree 1 persistent homology

In this section, we consider edgewise filtrations $\mathcal{G} = G_1 \subseteq \cdots \subseteq G_{\binom{n}{2}}$ of the complete graph K_n that maximize the total persistence and the number of bars for degree 1 homology. We shall answer the following question:

For a fixed number of vertices n and for $k = 1$, which edgewise filtrations of the complete graph K_n with a maximal number of bars achieve maximal total persistence?

By Corollary 25, this translates to finding

$$\max\left\{\sum_{i=1}^{n(n-1)/2} \beta_1^{\mathrm{FL}}(G_i) \colon \mathcal{G} = \left\{G_i \colon 1 \le i \le \binom{n}{2}, G_{|E(\mathcal{T}_{n,2})|} = \mathcal{T}_{n,2} \text{ and } G_{n(n-1)/2} = K_n\right\}\right\}.$$

First, we give some preliminaries and establish some notation.

- All graphs $G = (V, E)$ have n vertices. The join of two graphs G_1 and G_2, notation $G_1 \vee G_2$, is as in Section 2.
- For a filtration $\mathcal{G} = \{G_i\}_{i=1}^m$, we write $T\beta_1^{\mathrm{FL}}(\mathcal{G}) = \sum_{i=1}^m \beta_1^{\mathrm{FL}}(G_i)$ for its total persistence of degree 1.
- Denote $e_n := |E(\mathcal{T}_{n,2})|$. If $|E(G)| \ge e_n$, then G has $\mathcal{T}_{n,2}$ as a subgraph, with partition classes V_1 and V_2 of sizes $|V_1| = \lceil n/2 \rceil$ and $|V_2| = \lfloor n/2 \rfloor$.
- Let d_i be the number of connected components of $G|_{V_i}$. Then, by Proposition 5,

$$\beta_1^{\mathrm{FL}}(G) = (d_1 - 1)(d_2 - 1). \tag{3}$$

We also define what it means for two graphs and two filtrations to be (fiberwise) isomorphic.

▶ **Definition 26.** *Two graphs G_1 and G_2 with vertex sets $V(G_i)$ and edge sets $E(G_i)$ are* isomorphic, *notation $G_1 \cong G_2$, if there is a bijection $\varphi \colon V(G_1) \to V(G_2)$, such that $\{u_1, u_2\} \in E(G_1)$ if and only if $\{\varphi(u_1), \varphi(u_2)\} \in E(G_2)$. Furthermore, two filtrations $\mathcal{G}^1 = \{G_i^1\}_{i=1}^m$ and $\mathcal{G}^2 = \{G_i^2\}_{i=1}^m$ are* fiberwise isomorphic *if $G_i^1 \cong G_i^2$ for all $i = 1, \ldots, m$.*

First, by Corollary 25, any filtration with a maximal number of bars must contain the Turán graph $\mathcal{T}_{n,2}$. Moreover, Theorem 16 establishes that the filtration $\mathcal{H} = \{H_i\}_{i=1}^{e_n}$ from Definition 13 is fiberwise optimal, reducing our problem to maximizing the total persistence of an edgewise filtration of the complete graph, beginning with the Turán graph plus one edge. This is a bit more involved, because we cannot find a fiberwise optimal filtration of the complete graph, as is shown in the following example.

▶ **Example 27.** If $|E| = e_n + 2$, then one gets optimal degree 1 homology by adding one edge to V_1 and one edge to V_2 (left graph in Figure 6). However, if $|E| = e_n + 3$, then optimal degree 1 homology is obtained by adding all three edges to V_1 to form a K_3 (second-to-left graph in Figure 6). It is clear that a filtration of K_n cannot contain both graphs.

We can prove the following about the structure of the graphs in an optimal filtration of K_n.

▶ **Lemma 28.** *Let $\mathcal{G}$ be an edgewise filtration $\{G_i\}_{i=1}^{\binom{n}{2}}$ of K_n with maximal total persistence that includes $\mathcal{T}_{n,2}$. Then, for $t = 1, 2$ and $i = e_n + 1, \ldots, \binom{n-1}{2} + 1$, one of the subgraphs $G_i|_{V_t}$ consists of isolated vertices and a single component K_m, and the other subgraph $G_i|_{V_t}$ consists of isolated vertices, and a single component with l vertices, such that K_{l-1} is a subgraph of this component.*

▶ **Example 29.** Cf. Figure 6 for four examples of graphs with the properties from Lemma 28.

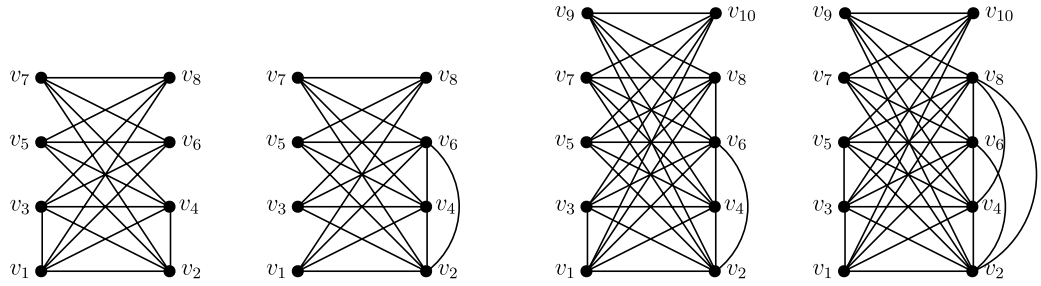

Figure 6 The graphs from Example 27 and 29.

Proof. Suppose that for some i, $E(G_i) \setminus E(G_{i-1}) = \{w_1, w_2\}$, where w_1 and w_2 are isolated vertices in $G_{j-1}|_{V_1}$ (without loss of generality). Also assume that $G_{j-1}|_{V_1}$ contains a component C of size $|C| > 1$. To maximize total persistence, it is more optimal to connect w_1 to C, since this allows us to add $|C| - 1$ edges of the form $\{w_1, c\}$ (where $c \in C$) without increasing the number of connected components (cf. (3)). Because these additional edges do not decrease the degree 1 homology, we should add them as early in the filtration as possible to maximize total persistence. Hence, by this same argument, $G_{j-1}|_{V_2}$ should be isomorphic to K_m and some isolated vertices.

Furthermore, note that we added the restriction $j \leq \binom{n-1}{2} + 1$ because Theorem 18 ensures that beyond this point, $\beta_1^{\mathrm{FL}}(G_j) = 0$. This means that

$$G_{\binom{n-1}{2}+1} = (K_1 \sqcup K_{\lceil n/2 \rceil - 1}) \vee (K_1 \sqcup K_{\lfloor n/2 \rfloor - 1}), \tag{4}$$

but if $j > \binom{n-1}{2} + 1$, then G_j could be any graph containing $G_{\binom{n-1}{2}+1}$ as a subgraph. ◀

Because of this, we restrict our focus to edgewise filtrations of the graph $G_{\binom{n-1}{2}+1}$ from (4).

Moreover, by Lemma 28, we only have to consider filtrations of the described form. We can represent them by a sequence of tuples of the form

$$(K_1, K_1) = (K_{l_1}, K_{r_1}), (K_{l_2}, K_{r_2}), \ldots, (K_{l_c}, K_{r_c}) = (K_{\lceil n/2 \rceil - 1}, K_{\lfloor n/2 \rfloor - 1}), \tag{5}$$

such that $l_i \geq l_{i-1}$ and $r_i \geq r_{i-1}$. The representation from (5) corresponds to the filtration $\mathcal{G} = \{G_i\}_{i=1}^m$, where, for $i \geq 1$,

$$G_{e_n + |E(K_{l_i})| + |E(K_{r_i})|} \cong \left(K_{l_i} \sqcup \bigsqcup_{j=l_i+1}^{\lceil n/2 \rceil} K_1\right) \bigvee \left(K_{r_i} \sqcup \bigsqcup_{j=r_i+1}^{\lfloor n/2 \rfloor} K_1\right) \text{ and}$$

$$G_{e_n + |E(K_{l_{i+1}})| + |E(K_{r_i})|} \cong \left(K_{l_{i+1}} \sqcup \bigsqcup_{j=l_i+1}^{\lceil n/2 \rceil} K_1\right) \bigvee \left(K_{r_i} \sqcup \bigsqcup_{j=r_i+1}^{\lfloor n/2 \rfloor} K_1\right).$$

In other words, the representation from (5) means that, starting from the Turán graph $\mathcal{T}_{n,2}$:

1. we begin adding edges by forming a K_{l_2} in V_1,
2. then add edges to form a K_{r_2} in V_2,
3. increase the sizes of the complete subgraphs in V_1 and V_2 by constructing a K_{l_3} (containing the smaller K_{l_2}) in V_1, a K_{r_3} in V_2, and so on.

Note that this representation is not unique ((K_3, K_1) is equivalent to $(K_2, K_1), (K_3, K_1)$).

▶ **Example 30.** In Figure 7, one finds a filtration and a corresponding representation.

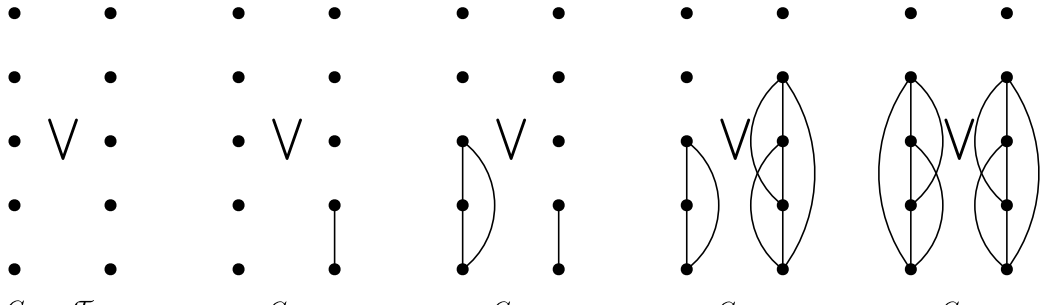

Figure 7 A filtration and its representation. Here, $\bigvee$ denotes the join of the left and right graphs.

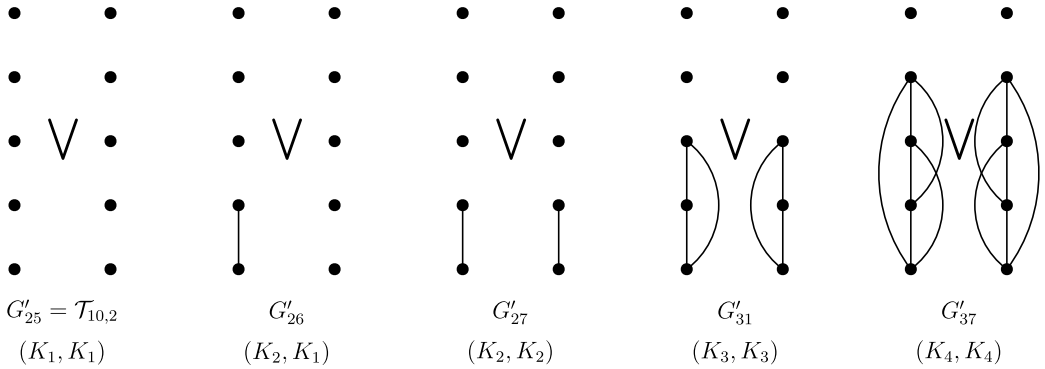

Figure 8 A filtration with the same total persistence as the one from Figure 7.

Surprisingly, the optimal strategy is to first construct two large cliques in V_1 and V_2 of sizes approximately $\frac{3}{4}|V_1|$ and $\frac{3}{4}|V_2|$, respectively, and then, alternating between V_1 and V_2, increase the sizes of the cliques one by one. We prove this in the main result of this section.

▶ **Theorem 31.** *Let $n \geq 4$ and let $j_n := \lfloor (3n-2)/8 \rfloor$ and $k_n := \lfloor (3n+7)/8 \rfloor$. Up to fiberwise isomorphism, the edgewise filtration $\mathcal{G}_{n,\max} = \{G_i\}_{i=1}^{\binom{n-1}{2}+1}$ of $G_{\binom{n-1}{2}+1}$ with maximal total persistence and a maximum number of bars is given by $G_i \cong H_i$ (Definition 13) for $i = 1, \ldots, e_n$. After $G_{e_n} = \mathcal{T}_{n,2}$, for $n \not\equiv 0 \mod 8$, the filtration is unique up to fiberwise isomorphism and represented by a sequence of tuples (cf. (5)) as follows*

$$\begin{cases} (K_1,K_1),(K_{j_n},K_{j_n}),(K_{j_n+1},K_{j_n+1}),\ldots,(K_{n/2-1},K_{n/2-1}), & \text{if } n \equiv 2,4,6 \mod 8, \\ (K_1,K_1),(K_{k_n},K_{k_n-1}),(K_{k_n+1},K_{k_n}),\ldots,(K_{(n-1)/2},K_{(n-3)/2}), & \text{if } n \equiv 1 \mod 2. \end{cases}$$

If $n \equiv 0 \mod 8$, then there are, up to fiberwise isomorphism, two optimal filtrations, represented by

$$(K_1,K_1),(K_{j_n},K_{j_n}),(K_{j_n+1},K_{j_n+1}),\ldots,(K_{n/2-1},K_{n/2-1}) \text{ and}$$
$$(K_1,K_1),(K_{j_n+1},K_{j_n+1}),(K_{j_n+2},K_{j_n+2}),\ldots,(K_{n/2-1},K_{n/2-1}).$$

▶ Remark 32. We prove the even case. The proof of the odd case is more or less the same (although the values are slightly different). However, we need to prove that, for any representation as in (5), $l_i \geq r_i$ for $i = 1, \ldots, c$. In the even case, we may assume this.

See Figure 8 for an example of and the full version [3, B.4] for a proof of this assumption.

Proof. It follows from Corollary 25 that, for a filtration $\mathcal{G}$ to have a maximum number of bars, we must have $G_{e_n} = \mathcal{T}_{n,2}$. For a filtration $\mathcal{G}$ to also have maximal total persistence, it immediately follows by Theorem 16 that $G_i \cong H_i$ for $i = 1, \dots, e_n$.

Any filtration $\mathcal{G}$ that we consider in this proof will therefore be such that $G_i \cong H_i$ for $i = 1, \dots, e_n$. We are interested in the remainder of the filtration, which we can represent by a sequence of tuples as in (5). Within the proof, we will further reduce it by writing

$$\big(l_1, r_1\big), \big(l_2, r_2\big), \dots, \big(l_c, r_c\big) \text{ instead of } \big(K_{l_1}, K_{r_1}\big), \big(K_{l_2}, K_{r_2}\big), \dots, \big(K_{l_c}, K_{r_c}\big). \tag{6}$$

Furthermore, given a filtration $\mathcal{G}$ represented by $\big(l_1, r_1\big), \big(l_2, r_2\big), \dots, \big(l_c, r_c\big)$, we define its *alternation depth* $d_{\mathcal{G}}$ as follows:

- We let $d_{\mathcal{G}} \coloneqq 1$ if $\big(l_i, r_i\big) = \big(l_{i-1} + 1, r_{i-1} + 1\big)$ for all $i = 2, \dots, c$.
- Otherwise, let $d_{\mathcal{G}} \geq 2$ be such that $\big(l_i, r_i\big) = \big(l_{i-1} + 1, r_{i-1} + 1\big)$ for all $i = d_{\mathcal{G}} + 1, \dots, c$, but $\big(l_{d_{\mathcal{G}}}, r_{d_{\mathcal{G}}}\big) \neq \big(l_{d_{\mathcal{G}}-1} + 1, r_{d_{\mathcal{G}}-1} + 1\big)$.

The idea of the proof is to start with a filtration $\mathcal{G} = \big\{G_i\big\}_{i=1}^{\binom{n-1}{2}+1}$, with a representation as in (6), and show that we can change the filtration in steps, to obtain in every step a filtration $\mathcal{G}'$ such that $T\beta_1^{\mathrm{FL}}\big(\mathcal{G}'\big) \geq T\beta_1^{\mathrm{FL}}\big(\mathcal{G}\big)$, and end up with an optimal solution.

Now, writing $n = 2p$, let $\mathcal{G}$ be a filtration, represented by

$$\big(1,1\big) = \big(l_1, r_1\big), \big(l_2, r_2\big), \dots, \big(l_c, r_c\big) = \big(n/2 - 1, n/2 - 1\big) = \big(p-1, p-1\big).$$

We shall show that

1. If the alternation depth $d_{\mathcal{G}} > j_n$, then we can change $\mathcal{G}$ to a filtration $\mathcal{G}'$ such that $d_{\mathcal{G}'} < d_{\mathcal{G}}$ and $T\beta_1^{\mathrm{FL}}\big(\mathcal{G}'\big) \geq T\beta_1^{\mathrm{FL}}\big(\mathcal{G}\big)$.
2. If $l_2 < j_n$, then we can change $\mathcal{G}$ to a filtration $\mathcal{G}'$ represented by $\big(l'_1, r'_1\big), \dots, \big(l'_{c'}, r'_{c'}\big)$ with $l'_2 = l_2 + 1$, such that $c' = c - 1$ or $c' = c$ (depending on $\mathcal{G}$) and $T\beta_1^{\mathrm{FL}}\big(\mathcal{G}'\big) \geq T\beta_1^{\mathrm{FL}}\big(\mathcal{G}\big)$.

For the first part, let $\mathcal{G}$ be a filtration with alternation depth $d_{\mathcal{G}} > j_n$. Its representation, substituting n by $2p$, is of the form

$$(1,1), \dots, (t,u), (v,w), \big(d_{\mathcal{G}}, d_{\mathcal{G}}\big), \big(d_{\mathcal{G}}{+}1, d_{\mathcal{G}}{+}1\big), \dots, \big(p{-}1, p{-}1\big) \text{ with } \big(v,w\big) \neq \big(d_{\mathcal{G}}{-}1, d_{\mathcal{G}}{-}1\big).$$

Since we assumed that $v \geq w$, we must have $w < d_{\mathcal{G}} - 1$. We transform $\mathcal{G}$ into a filtration $\mathcal{G}'$ which is the same as $\mathcal{G}$, except that we add an extra alternation step. We consider two cases.

- Case 1: $v < d_{\mathcal{G}} - 1$. In this case, $\mathcal{G}'$ is represented by

$$(1,1), \dots (t,u), (v,w), \big(d_{\mathcal{G}} - 1, d_{\mathcal{G}} - 1\big), \big(d_{\mathcal{G}}, d_{\mathcal{G}}\big), \big(d_{\mathcal{G}} + 1, d_{\mathcal{G}} + 1\big), \dots, \big(p-1, p-1\big).$$

- Case 2: $v = d_{\mathcal{G}} - 1$. In this case, $\mathcal{G}'$ is represented by

$$(1,1), \dots (t,u), \big(v = d_{\mathcal{G}} - 1, d_{\mathcal{G}} - 1\big), \big(d_{\mathcal{G}}, d_{\mathcal{G}}\big), \big(d_{\mathcal{G}} + 1, d_{\mathcal{G}} + 1\big), \dots, \big(p-1, p-1\big).$$

In both cases, we see that $d_{\mathcal{G}'} < d_{\mathcal{G}}$. Moreover, as we show in more detail in [3, B.4],

$$T\beta_1^{\mathrm{FL}}\big(\mathcal{G}'\big) - T\beta_1^{\mathrm{FL}}\big(\mathcal{G}\big) = \frac{1}{6}\big(d_{\mathcal{G}} - 1 - w\big)\big(d_{\mathcal{G}} - w\big)\big(4d_{\mathcal{G}} + 2w - 3p - 2\big) \geq 0. \tag{7}$$

To see that this difference is non-negative, first recall that $w < d_{\mathcal{G}} - 1$, so the first two terms are strictly positive. Furthermore, since $d_{\mathcal{G}} > \lfloor 3p/4 - 1/4 \rfloor$, we have $d_{\mathcal{G}} \geq \lceil 3p/4 \rceil \geq 3p/4$, so

$$4d_{\mathcal{G}} + 2w - 3p - 2 \geq 2w - 2 \geq 0,$$

since $w \geq 1$. Note that $T\beta_1^{\mathrm{FL}}\big(\mathcal{G}'\big) - T\beta_1^{\mathrm{FL}}\big(\mathcal{G}\big) = 0$ if and only if $w = 1$ and $d_{\mathcal{G}} = 3p/4$.

We now show the second part. We let $\mathcal{G}$ be a filtration with representation

$(1,1),(j,k),(l,m),\ldots,(p-1,p-1)$ with $j \leq 3p/4-1$.

We transform $\mathcal{G}$ into a filtration $\mathcal{G}'$ such that its start is different from $\mathcal{G}$'s, but from the tuple (l,m) onwards, $\mathcal{G}$ and $\mathcal{G}'$ are the same. We again consider two cases.

- Case 1: $l > j+1$. In this case, $\mathcal{G}'$ is represented by $(1,1),(j+1,k),(l,m),\ldots,(p-1,p-1)$.
- Case 2: $l = j+1$. In this case, $\mathcal{G}'$ is represented by $(1,1),(j+1=l,m),\ldots,(p-1,p-1)$.

In both cases, as we show in more detail in the full version [3, B.4], we have

$$T\beta_1^{\mathrm{FL}}(\mathcal{G}') - T\beta_1^{\mathrm{FL}}(\mathcal{G}) = (k-1)\big(j(p-j-1) - \frac{k}{6}(3p-2k-2)\big) \overset{(i)}{\geq} 2\big((j-k+1)(j-k)\big) \overset{(ii)}{\geq} 0, \quad (8)$$

where we use in (i) that $j \leq 3p/4-1$, and in (ii) that $j \geq k$. If $n \equiv 2,4,6 \mod 8$, then $j \leq 3p/4-1$ implies that $j \leq \lfloor 3p/4-1 \rfloor = \lfloor 3p/4-5/4 \rfloor = j_n - 1$. If $n \equiv 0 \mod 8$, then $j \leq 3p/4-1 = j_n$. Only in this case, and if $j = k = 3p/4-1$, then the inequality is sharp.

Hence, if we start with an arbitrary filtration $\mathcal{G}$, then we can transform it step by step into a more optimal filtration $\mathcal{G}^1$ with $d_{\mathcal{G}^1} \leq j_n$, by the first part. Then, by the second part, we can transform $\mathcal{G}^1$ step by step into a more optimal filtration $\mathcal{G}^2$ that starts with $(1,1),(j_n,j_n)$, with alternation depth $d_{\mathcal{G}^2} = j_n$. Hence, $\mathcal{G}^2$ is the optimal filtration as described in the statement for $n \equiv 2,4,6 \mod 8$.

In the case that $n \equiv 0 \mod 8$, we saw in the proof of case 1 and case 2, that the filtration $\mathcal{G}^3$ starting with $(1,1),\big(j_n+1,j_n+1\big)$ and having alternation depth $d_{\mathcal{G}^3} = j_n+1$ satisfies $T\beta_1^{\mathrm{FL}}(\mathcal{G}^3) = T\beta_1^{\mathrm{FL}}(\mathcal{G}^2)$, hence both $\mathcal{G}^2$ and $\mathcal{G}^3$ are optimal. ◀

8 Discussion

In this paper, we have answered several key questions in the context of topological data analysis. However, many questions remain open, and we propose the following conjectures.

▶ **Conjecture 33.** *If $\mathcal{G}$ is a filtration on n vertices, then the number of intervals in the barcode of $\mathcal{G}$ in homology degree k satisfies $|\mathcal{B}_k^{\mathrm{FL}}(\mathcal{G})| \leq \beta_k^{\mathrm{FL}}(\mathcal{T}_{n,k+1})$.*

▶ **Conjecture 34.** *The extremal filtrations described in Section 7 achieve the maximal total persistence over any edgewise filtration of flag complexes in homology degree 1.*

Proving the latter conjecture likely requires new ideas, as no filtration $\mathcal{G}$ can maximize $\beta_1^{\mathrm{FL}}(G_i)$ for all i. In fact, extremal values need not be realized by graphs containing Turán graphs as spanning subgraphs, as illustrated by the following example.

▶ **Example 35.** Let $n = 8$ and $m = 16+5$. Suppose G contains the Turán graph $\mathcal{T}_{8,2}$. By Proposition 5, we seek to add 5 edges to the Turán graph to maximize the product $(d_1-1)(d_2-1)$. It is easy to see that this product can be at most 1. However, by partitioning the vertices as $V = V_1 \cup V_2$, with $|V_1| = 3$ and $|V_2| = 5$, and adding all edges between V_1 and V_2, we need to add 6 more edges. Adding these as a K_4 in the larger partition gives $d_1 = 2$ and $d_2 = 1$; see Figure 9. The value 2 is extremal; see Figure 10.

Finding extremal values of $\mathbb{Z}$-linear functions defined on simplicial complexes with *precisely* n vertices and m edges presents a challenging and interesting direction for future research.

▶ **Conjecture 36.** *Let $\mathbf{G}(n,m)$ denote the collection of graphs on n vertices and m edges. If $G \in \mathbf{G}(n,m)$ and $\beta_1^{\mathrm{FL}}(G) = \max_{H \in \mathbf{G}(n,m)} \beta_1^{\mathrm{FL}}(H)$, then G contains a complete bipartite spanning subgraph.*

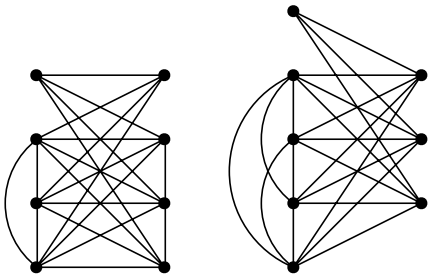

Figure 9 Two graphs G_l (left) and G_r (right) such that $\beta_1^{\mathrm{FL}}(G_l) = 1$ and $\beta_1^{\mathrm{FL}}(G_r) = 2$.

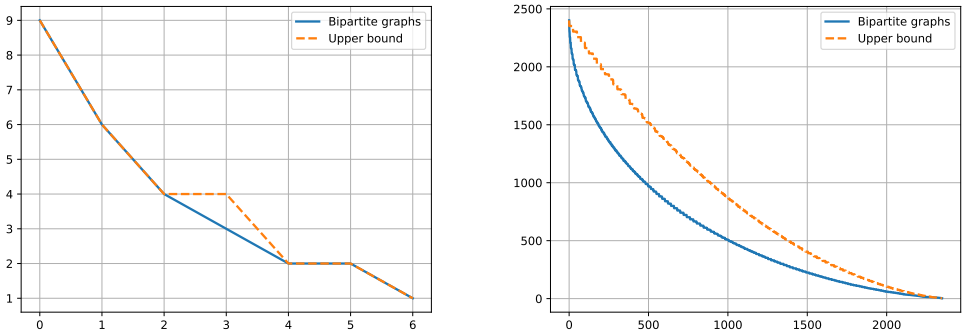

Figure 10 The vertical axis is β_1^{FL}, and the value k along the x-axis represents $(n/2)^2 + k$ edges. Here n is the number of vertices in the underlying graph; $n = 8$ (left) and $n = 100$ (right). The solid curves give the optimal value of $\beta_1^{\mathrm{FL}}(G)$ for any graph G containing a complete bipartite spanning subgraph, and the dashed line is an upper bound derived from the proof of Theorem 10 in conjuction with Lemma 17 (details omitted).

Abstract

Distance geometry explores the properties of distance spaces that can be exactly represented as the pairwise Euclidean distances between points in $\mathbb{R}^d$ ($d \geq 1$), or equivalently, distance spaces that can be isometrically embedded in $\mathbb{R}^d$. In this work, we investigate whether a distance space can be isometrically embedded in $\mathbb{R}^d$ after applying a limited number of modifications. Specifically, we focus on two types of modifications: *outlier deletion* (removing points) and *distance modification* (adjusting distances between points). The central problem, Euclidean Embedding Editing, asks whether an input distance space on n points can be transformed, using at most k modifications, into a space that is isometrically embeddable in $\mathbb{R}^d$.

We present several fixed-parameter tractable (FPT) and approximation algorithms for this problem. Our first result is an algorithm that solves Euclidean Embedding Editing in time $(dk)^{\mathcal{O}(d+k)} + n^{\mathcal{O}(1)}$. The core subroutine of this algorithm, which is of independent interest, is a polynomial-time method for compressing the input distance space into an equivalent instance of Euclidean Embedding Editing with $\mathcal{O}((dk)^2)$ points.

For the special but important case of Euclidean Embedding Editing where only outlier deletions are allowed, we improve the parameter dependence of the FPT algorithm and obtain a running time of $\min\{(d+3)^k, 2^{d+k}\} \cdot n^{\mathcal{O}(1)}$. Additionally, we provide an FPT-approximation algorithm for this problem, which outputs a set of at most $2 \cdot \mathsf{Opt}$ outliers in time $2^d \cdot n^{\mathcal{O}(1)}$. This 2-approximation algorithm improves upon the previous $(3+\varepsilon)$-approximation algorithm by Sidiropoulos, Wang, and Wang [SODA '17]. Furthermore, we complement our algorithms with hardness results motivating our choice of parameterizations.

1 Introduction

The Euclidean Distance Matrix (EDM) is a matrix containing the squared Euclidean distances between points in a set. A central problem in Distance Geometry is determining whether a given matrix is an EDM [5, 25, 11, 13]. That is, the task is to identify whether a given distance space can be isometrically embedded into ℓ_2-spaces, or equivalently, the pairwise Euclidean distances among points in $\mathbb{R}^d$ ($d \geq 1$). This problem has a rich history, originating with Cayley [7], whose observations were formalized by Menger [28], leading to Cayley-Menger determinants. Schoenberg [30] further advanced the field by characterizing ℓ_2-embeddable distances using negative type inequalities. Blumenthal's monograph [5] remains a foundational text, documenting the theoretical underpinnings of this area.

This problem has numerous applications, including sensor network localization [29, 14], molecular conformation [21], data visualization [6], statistics [17], psychology [34, 31], learning image manifolds [36], handwriting recognition [24], studying musical rhythms [12], and signal processing [15]. The complexity of determining whether a matrix is an EDM is well understood, and it can be efficiently addressed using Singular Value Decomposition (SVD) [6, 35].

In many practical applications involving EDMs, errors due to noise, missing values, or approximation inaccuracies are common. To address these challenges, several heuristic approaches based on Multidimensional Scaling, Low-Rank Matrix Approximation, and Semidefinite Programming have been developed to reconstruct the matrix and create an embedding that minimizes the impact of these errors. We refer readers to [6, 15] for a comprehensive overview of the extensive literature on this topic.

Despite the importance and numerous practical applications of the EDM recognition problem with noise and errors, little was known about its computational complexity until recently. A notable exception is the work of Sidiropoulos, Wang, and Wang [32], which initiates the study of EDM in the presence of outliers. The work of Sidiropoulos et al. serves as the initial foundation for our studies.

In this paper, we address the algorithmic question of minimizing the number of edits required to transform a given distance matrix into EDM. Specifically, we aim to apply the minimum number of modifications to a given *distance space* (X, ρ) with distance function ρ, such that the resulting distance space can be isometrically embedded into a d-dimensional Euclidean space $\mathbb{R}^d$. We consider two types of editing operations.

The first operation is *element deletion*. In matrix terms, this operation corresponds to deleting the row and column associated with the element we choose to remove. Following Sidiropoulos, Wang, and Wang [32], we refer to the elements removed from the distance space as *outliers*.

The second operation is *distance modification*. Let $X^{(2)}$ denote the set of unordered pairs of distinct elements in $X = \{x_1, x_2, \ldots\}$. For a pair of elements $x_i, x_j \in X$, the modification operation alters the distance $\rho(x_i, x_j)$. In terms of the distance matrix, this operation changes the ij-th and the ji-th entries. The problem of minimizing the number of modification operations to embed the resulting distance space in general metric spaces was studied in [18, 9], and embedding into ultrametric spaces was investigated in [9, 8].

Our primary algorithmic question is as follows: given integers k_O and k_M, can a distance space (X, ρ) be transformed into a distance space that is embeddable in $\mathbb{R}^d$ by removing at most k_O outliers and performing at most k_M modifications? In fact, we address an even more general weighted version of this problem, where each operation (outlier deletion or distance modification) is assigned a specific weight. More precisely, we study:

Euclidean Embedding Editing

Input: Distance space $\mathcal{X} = (X, \rho)$, weight functions $w_O \colon X \to \mathbb{Z}_{\geq 0}$ and $w_M \colon X^{(2)} \to \mathbb{Z}_{\geq 0}$, integers $W, k_O, k_M \geq 0$, and $d \geq 1$.

Question: Is there a subset of at most k_O outliers $O \subseteq X$ and a set $D \subseteq X^{(2)}$ of at most k_M distances with $w_O(O) + w_M(D) \leq W$ such that the distance subspace $(X \setminus O, \rho')$ where ρ' is obtained by modifying the values $\rho(x, y)$ for $\{x, y\} \in D$ is isometrically embeddable into $\mathbb{R}^d$?

Two special cases of Euclidean Embedding Editing are of particular importance. The variant of the problem with $k_M = 0$, that is, of placing all but k_O outlier points of a distance space (X, ρ) into a Euclidean space $\mathbb{R}^d$ of a given dimension d such that the Euclidean distance between any pair of points x, is equal to $\rho(x, y)$, is called Euclidean Embedding with Outliers [32]. For the variant with $k_O = 0$, that is, without deletion of outliers, following [18], we use the name Euclidean Metric Violation Distance.

EXAMPLE: The distance space $\mathcal{X} = (X, \rho)$ with $X = \{1, \ldots, 9\}$ and ρ defined by distance matrix D, where the ij-th entry of D is $\rho^2(i, j)$

$$D = \begin{bmatrix} 0 & 7 & 1 & 2 & 4 & 5 & 1 & 4 & 5 \\ 7 & 0 & 2 & 1 & 1 & 2 & 10 & 5 & 4 \\ 1 & 2 & 0 & 1 & 11 & 4 & 4 & 1 & 2 \\ 2 & 1 & 1 & 0 & 2 & 1 & 8 & 2 & 1 \\ 4 & 1 & 11 & 2 & 0 & 1 & 12 & 8 & 5 \\ 5 & 2 & 4 & 1 & 1 & 0 & 7 & 5 & 2 \\ 1 & 10 & 4 & 8 & 12 & 7 & 0 & 8 & 9 \\ 4 & 5 & 1 & 2 & 8 & 5 & 8 & 0 & 1 \\ 5 & 4 & 2 & 1 & 5 & 2 & 9 & 1 & 0 \end{bmatrix},$$

and $k_O = 1$, $k_M = 2$, $d = 2$, all weights equal to one, and $W = 3$, is a yes-instance of Euclidean Embedding Editing. Indeed, the distance space $\mathcal{X}' = (X', \rho')$ defined by distance matrix D' in Fig. 1 that can be obtained from $\mathcal{X}$ by modifying distances between $\{1, 2\}$ and $\{3, 5\}$ and deleting outlier 7, is isometrically embeddable in $\mathbb{R}^2$.

Our results. First, we present a compression for Euclidean Embedding Editing– a polynomial-time algorithm that reduces an instance of the problem to an equivalent instance with the number of points bounded by $\mathcal{O}(k^2 d^2)$ (Theorem 8), where $k = k_O + k_M$. As part of this compression, we also propose a $(d + 3)$-approximation algorithm for Euclidean Embedding with Outliers, which runs in polynomial time (Lemma 10). Using this compression algorithm, we design an FPT algorithm for Euclidean Embedding Editing with a running time of $(dk)^{\mathcal{O}(d+k)} + n^{\mathcal{O}(1)}$ (Theorem 20).

For Euclidean Embedding with Outliers, a particular but important special case of Euclidean Embedding Editing – where the goal is to determine whether the distance space, excluding up to k_O outliers, can be embedded in $\mathbb{R}^d$ – we obtain better dependence on the parameters with a running time of $\min\{(d + 3)^{k_O}, 2^{d+k_O}\} \cdot n^{\mathcal{O}(1)}$ (Theorem 21).

$$D' = \begin{bmatrix} 0 & 1 & 1 & 2 & 4 & 5 & 4 & 5 \\ 1 & 0 & 2 & 1 & 1 & 2 & 5 & 4 \\ 1 & 2 & 0 & 1 & 5 & 4 & 1 & 2 \\ 2 & 1 & 1 & 0 & 2 & 1 & 2 & 1 \\ 4 & 1 & 5 & 2 & 0 & 1 & 8 & 5 \\ 5 & 2 & 4 & 1 & 1 & 0 & 5 & 2 \\ 4 & 5 & 1 & 2 & 8 & 5 & 0 & 1 \\ 5 & 4 & 2 & 1 & 5 & 2 & 1 & 0 \end{bmatrix}$$

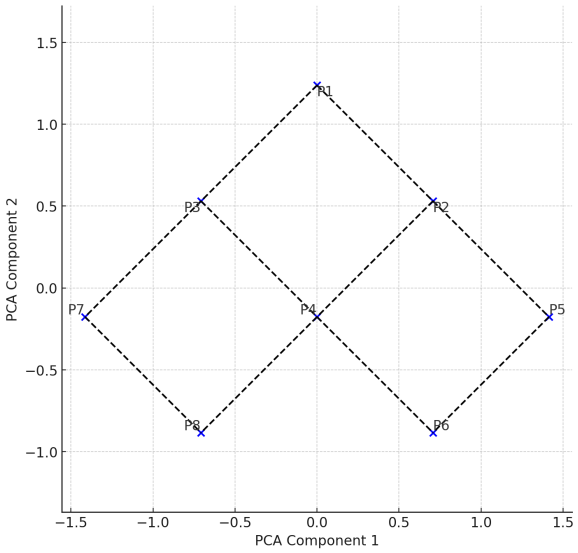

Figure 1 Matrix D' and an embedding of its distance space in $\mathbb{R}^2$.

Furthermore, for this problem, we propose a 2-approximation algorithm (Theorem 22). This randomized algorithm, with a running time of $2^d \cdot n^{\mathcal{O}(1)}$, guarantees a solution with at most $2 \cdot \mathsf{Opt}$ outliers. As is common in Computational Geometry, all our algorithms operate under the *real RAM* computational model, assuming that basic operations over real numbers can be executed in unit time.

We also complement our algorithmic results with lower-bound proofs, establishing that both Euclidean Embedding with Outliers and Euclidean Metric Violation Distance are NP-hard even when $d = 1$ (Theorems 26 and 27). So, FPT algorithms for these problems parameterized by d alone appears to be out of reach, motivating our FPT-approximation algorithm. Additionally, we prove that Euclidean Embedding with Outliers is W[1]-hard when parameterized by k_O alone (Theorem 28). These lower bounds indicate that to get an FPT algorithm for Euclidean Embedding Editing, it is important that we parameterize by *both* d and the solution size $k_O + k_M$. Importantly, our lower-bound results remain valid even in the unweighted case.

Related work. The computational complexity study of Euclidean Embedding with Outliers was initiated by Sidiropoulos, Wang, and Wang [32]. They demonstrated that, assuming the Unique Games Conjecture, the problem of computing a minimum outlier embedding into d-dimensional Euclidean space for any $d \geq 2$ is NP-hard to approximate within a factor of $2 - \varepsilon$ for any $\varepsilon > 0$. On the algorithmic side, they showed that a 2-approximation can be achieved in $\mathcal{O}(n^{d+3})$ time. Additionally, they established that a $(3 + \varepsilon)$-approximation is achievable in $(2/\varepsilon)^d d^{\mathcal{O}(1)} n^2 \log n$ time. For exact solutions, they noted an algorithm with a runtime of $\mathcal{O}(n^{d+3}) + 2^{k_O} n^2$.

They also obtained results related to bicriteria approximation involving nonisomorphic embeddings, approximation of the number of outliers, and distortion. The first result, is $(\mathcal{O}(\sqrt{\delta}), (2d+2)k_O)$-relative outlier embedding in $\mathbb{R}^d$ in time $\frac{1}{\delta^{\mathcal{O}(1)}} 2^{\mathcal{O}(d)} n^2 \log n$. The second result, $(\mathcal{O}(\sqrt{\delta}), 2k_O)$-relative outlier embedding in time $\frac{1}{\delta^{\mathcal{O}(1)}} {k_O}^{\mathcal{O}(d)} n^2$. (They define an algorithm as an $\mathcal{O}(f(\delta), g(k_O))$-relative outlier embedding of $\mathcal{X} = (X, \rho)$ to $\mathbb{R}^d$, for some functions f and g, if it either correctly decides that no embedding with distortion at most δ exists after removing k_O outliers, or outputs a set Y of size $g(k_O)$ such that there is an

embedding $X \setminus Y$ into $\mathbb{R}^d$ of distortion $\mathcal{O}(f(\delta))$.) Since allowing distortion could significantly decrease the number of outliers, our 2-approximation algorithm for Euclidean Embedding with Outliers, Theorem 22, is incomparable with these results.

We are not aware of any algorithms with guaranteed performance for Euclidean Metric Violation Distance. Parameterized and approximation algorithms for metric violation distance problems for general metric, tree distances and ultrametric could be found in [18, 8, 9, 20]. More generally, embeddings of various metric spaces are a fundamental primitive in the design of algorithms [22, 23, 27, 26, 2, 3], though prior work often focuses on minimizing embedding distortion.

2 Preliminaries

Let X be a set. A function $\rho\colon X \times X \to \mathbb{R}_{\geq 0}$ is a *distance* on X if: (i) ρ is symmetric, that is, for any $x, y \in X$, $\rho(x, y) = \rho(y, x)$, and (ii) $\rho(x, x) = 0$ for all $x \in X$. Then, (X, ρ) is called a *distance space*. If, in addition ρ satisfies a triange inequality: $\rho(x, z) \leq \rho(x, y) + \rho(y, z)$, for any $x, y, z \in X$, then ρ is called a semimetric on X. And if $\rho(x, y) = 0$ only for $x = y$, then ρ is called a *metric*, and (X, ρ) a *metric space*.

More precisely, recall that for two points $p, q \in \mathbb{R}^d$, the Euclidean distance between p and q is $\|p - q\|_2 = \sqrt{\langle p, p\rangle + \langle q, q\rangle - 2\langle p, q\rangle}$. We say that distance space (X, ρ) is *isometrically embeddable* into $\mathbb{R}^d$ if there is a map, called *isometric embedding*, $\varphi\colon X \to \mathbb{R}^d$ such that $\rho(x, y) = \|\varphi(x) - \varphi(y)\|_2$ for all $x, y \in X$. Notice that we do not require φ to be injective, that is, several points of (X, ρ) may be mapped to the same point of $\mathbb{R}^d$. Throughout the paper, whenever we mention an embedding, we mean an isometric embedding. Moreover, when we use the term d-embedding, we are referring to embedding into $\mathbb{R}^d$. A d-embeddable distance space is *strongly d-embeddable* if it is not $(d-1)$-embeddable. We use $X^{(2)}$ to denote the set of unordered pairs of two distinct elements of X. As convention, we assume that the empty set of points is d-embeddable for every d.

Let $\mathcal{X} = (X, \rho)$ be a distance space where $X = \{x_1, \ldots, x_n\}$, and let $\rho_{i,j} = \rho(x_i, x_j)$ for all $i, j \in \{1, \ldots, n\}$. Then $\mathcal{X}$ is equivalently defined by the *distance matrix* $D(\rho)$, where $D(\rho)_{i,j} = \rho_{i,j}^2$.

We drop the explicit reference to ρ when it is clear from the context and instead of $D(\rho)$, simply write D. Suppose that $\mathcal{X}$ is embeddable into $\mathbb{R}^d$. The ordered set $P = (p_1, \ldots, p_n)$ of points in $\mathbb{R}^d$ is said to be a *realization* of $\mathcal{X}$ if there is an embedding $\varphi\colon X \to \mathbb{R}^d$ such that $\varphi(x_i) = p_i$ for all $i \in \{1, \ldots, n\}$. We use the well-known property (see e.g. [15]) that a realization is unique up to *rigid transformations* of $\mathbb{R}^d$, that is, distance-preserving transformations of Euclidean space (rotations, reflections, translations).

▶ **Proposition 1** ([15]). *Let $(p_1, \ldots, p_n)$ and $(q_1, \ldots, q_n)$ be ordered set of points in $\mathbb{R}^d$. Then $\|p_i - p_j\|_2 = \|q_i - q_j\|_2$ for all $i, j \in \{1, \ldots, n\}$ if and only if there is a rigid transformation of $\mathbb{R}^d$ mapping p_i to q_i for all $i \in \{1, \ldots, n\}$.*

A realization can be constructed (if it exists) in polynomial time.

▶ **Proposition 2** ([1, 33]). *Given a distance space $\mathcal{X} = (X, \rho)$ with n points and a positive integer d, in $\mathcal{O}(n^3)$ time, it can be decided whether $\mathcal{X}$ can be embedded into $\mathbb{R}^d$ and, if such an embedding exists, then a realization can be constructed in this running time.*

▶ **Definition 3** (Metric basis). *Let (X, ρ) be a d-embeddable distance space. A set $Y \subseteq X$ is a* metric basis *if, given an isometric embedding φ of (Y, ρ) into $\mathbb{R}^d$, there is a unique way to extend φ to an isometric embedding of (X, ρ). Equivalently, if a realization of (Y, ρ) is fixed then the embedding of any point of $X \setminus Y$ in a d-embedding of (X, ρ) is unique.*

We will use the well-known characteristic of strong embeddability of a distance space into a Euclidean space. For $r+1$ points $x_0, x_1, \ldots, x_r$ of distance space (X, ρ) the *Cayley-Menger determinant* is the determinant of the matrix obtained from the distance matrix by prepending a row and a column whose first element is zero and the other elements are one. Formally, let $\rho_{i,j} = \rho(x_i, x_j)$, $i, j \in \{0, \ldots, r\}$. Then the Cayley-Menger determinant is

$$CM(x_0, x_1, \ldots, x_r) = \det \begin{pmatrix} 0 & 1 & 1 & 1 & \ldots & 1 \\ 1 & 0 & \rho_{0,1}^2 & \rho_{0,2}^2 & \ldots & \rho_{0,r}^2 \\ 1 & \rho_{0,1}^2 & 0 & \rho_{1,2}^2 & \ldots & \rho_{1,r}^2 \\ 1 & \rho_{0,2}^2 & \rho_{1,2}^2 & 0 & \ldots & \rho_{2,r}^2 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \rho_{0,r}^2 & \rho_{1,r}^2 & \rho_{2,r}^2 & \ldots & 0 \end{pmatrix}$$

▶ **Proposition 4** ([5, Chapter IV]). *A distance space $\mathcal{X} = (X, \rho)$ with n points is strongly d-embeddable if and only if there exist $d+1$ points, say $X_d = \{x_0, \ldots, x_d\}$, such that:*
1. $(-1)^{j+1} CM(x_0, x_1, \ldots, x_j) > 0$ *for* $1 \le j \le d$, *and*
2. *for any* $x, y \in X \setminus X_d$,

$$CM(x_0, x_1, \ldots, x_d, x) = CM(x_0, x_1, \ldots, x_d, y) = CM(x_0, x_1, \ldots, x_d, x, y) = 0.$$

Equivalently (see, for example, [32]), $\mathcal{X}$ is strongly d-embeddable if and only if there is a set of $d+1$ points $X_d = \{x_0, \ldots, x_d\}$ such that $(\{x_0, \ldots, x_j\}, \rho)$ is strongly j-embeddable for all $j \in \{1, \ldots, d\}$, and for every $x, y \in X \setminus X_d$, $(X_d \cup \{x\} \cup \{y\})$ is d-embeddable.

Thus, the embedding of the distance space $\mathcal{X} = (X, \rho)$ into $\mathbb{R}^d$ is essentially characterized by $d+1$ "anchor" points of X. Note that in a realization of $\mathcal{X}$ that is strongly d-embeddable, the anchor points correspond to a set of $d+1$ points in general position in $\mathbb{R}^d$.

Following [5], we define sets of *independent points*.

▶ **Definition 5.** *Let (X, ρ) be a distance space. For a nonnegative integer r, we say that $Y \subseteq X$ of size $r+1$ is* independent *if (Y, ρ) is strongly r-embeddable.*

Then our "anchors" are independent sets of size $d+1$. We use the following fact that the family of independent sets has matroid-like properties (implicit in [5, Chapter IV]).

▶ **Proposition 6** ([5, Chapter IV]). *Let (X, ρ) be a strongly d-embeddable distance space. Then, (i) any single-element set is independent, (ii) if $Y \subseteq X$ is independent, then any $\emptyset \subset Z \subseteq Y$ is independent, (iii) if $Y, Z \subseteq X$ are independent and $|Y| > |Z|$ then there is a $y \in Y \setminus Z$ such that $Z \cup \{y\}$ is independent. Furthermore, the maximum size of an independent set is $d+1$ and any independent set Y of size $d+1$ is a metric basis.*

▶ **Lemma 7** (⋆). *Suppose (X, ρ) is a d-embeddable distance space, $Y \subset X$ is independent and $x \in X \setminus Y$. Then, $(Y \cup \{x\}, \rho)$ is $|Y|$-embeddable.*

For statements marked with (⋆), the proofs are omitted in this extended abstract and is deferred to the full version.

3 Compression for Euclidean Embedding Editing

In this section, we show that, given an instance of Euclidean Embedding Editing, one can in polynomial time construct an equivalent instance where the number of points is upper-bounded by a polynomial of $k = k_O + k_M$ and d and, moreover, the encoding of the weights is also polynomial in these parameters.

▶ **Theorem 8.** *There is a polynomial-time algorithm that, given an instance* $(\mathcal{X} = (X, \rho), w_O, w_M, W, k_O, k_M, d)$ *of* Euclidean Embedding Editing*, either solves the problem or constructs an equivalent instance* $(\mathcal{X}' = (X', \rho), w'_O, w'_M, W', k'_O, k'_M, d)$ *such that* $X' \subseteq X$*, and for* $k = k_O + k_M$*, it holds that* $|X'| = \mathcal{O}((kd)^2)$*,* $W' = 2^{\mathcal{O}((kd)^{12})}$*,* $w'_O(x) = 2^{\mathcal{O}((kd)^{12})}$ *for* $x \in X'$*, and* $w'_M(x, y) = 2^{\mathcal{O}((kd)^{12})}$ *for all* $\{x, y\} \in X'^{(2)}$*.*

We remark that Theorem 8 does not provide a kernelization algorithm according to the standard definition [10] as the size of the output instance is not upper-bounded by a function of the parameter – the distances between the points remain the same as in the input instance. Moreover, since Euclidean Embedding Editing is a decision problem, the word "solve" in the statement of Theorem 8 technically only refers to deciding correctly whether the instance is a yes-instance. However, if the instance is determined to be a yes-instance, then our algorithm can also output a solution that witnesses this, i.e., the outlier set and modified new distance values (if any). This additional feature of our compression algorithm will be used later in our FPT algorithm for Euclidean Embedding Editing.

In the proof of Theorem 8, we first design a polynomial-time $(d + 3)$-approximation algorithm (Section 3.1). This algorithm allows us, given an instance of the problem, either find a set of at most $(d+3)k$ points A such that $(X \setminus A, \rho)$ is d-embeddable or conclude that we have a no-instance.

In the first case, we iteratively construct a sequence of metric bases $Y_1, \ldots, Y_\ell$ for (Z, ρ) using Proposition 6, where initially $Z := X \setminus A$ and in each iteration, we delete the points of the constructed basis from Z. If $X \setminus A$ is sufficiently large, then there is a subsequence of bases of the same size with at least $2(k_O + 2k_M) + 1$ elements. We select the first subsequence with this property. The crucial property exploited by our algorithm is that this subsequence uniquely defines embeddings of the majority of the points assuming that we have a yes-instance of the problem. We use this to give a series of reduction rules that identify points in A that should be outliers in any solution and irrelevant points of $X \setminus A$ that could be deleted.

3.1 Bootstrapping the Compression through an Approximation

For a distance space $\mathcal{X} = (X, \rho)$, a *d-outlier set* is a set A of points such that $(X \setminus A, \rho)$ is d-embeddable. In unweighted Euclidean Embedding with Outliers (which we call UEEO), the function w_O assigns unit weight to every point. Sidiropoulos et al. [32] observed that this problem admits a simple greedy $(d + 3)$-approximation running in $n^{\mathcal{O}(d)}$. We show that this algorithm can be sped up to run in $n^{\mathcal{O}(1)}$ time, i.e., independent of d in the exponent. To do so, we give a polynomial-time subroutine that produces a small hitting set for all minimal solutions. This subroutine will later be used as the first step of our compression algorithm for Euclidean Embedding Editing.

▶ **Lemma 9.** *There is a polynomial-time algorithm that, given a distance space* $\mathcal{X} = (X, \rho)$ *and an integer* $d \geq 1$*, outputs a set of points* $\hat{A}$ *of size at most* $(d + 3)$ *such that if* $\mathcal{X}$ *is not* d*-embeddable, then* $\hat{A}$ *intersects every inclusionwise minimal* d*-outlier set of* $\mathcal{X}$*.*

Proof. Assume that the distance space $\mathcal{X} = (X, \rho)$ does not admit a d-embedding. Note that, in particular, this means that $|X| \geq 3$. We then do the following.

1. Set $A := \{p\}$ for an arbitrary point $p \in X$.
2. While
   $|A| \leq d$, do the following:
   a. If there is a point $x \in X \setminus A$ such that $(A \cup \{x\}, \rho)$ is not $|A|$-embeddable, then set $\hat{A} := A \cup \{x\}$ and return $\hat{A}$.
   b. If there is a point $x \in X \setminus A$ such that $A \cup \{x\}$ is independent, then set $A := A \cup \{x\}$ and continue the loop, else exit the loop.
3. If there are two distinct points $x, y \in X \setminus A$ such that $(A \cup \{x, y\}, \rho)$ is not $(|A| - 1)$-embeddable, then $\hat{A} := A \cup \{x, y\}$ and return $\hat{A}$.

Clearly, the algorithm runs in polynomial time. Since the while loop has at most d iterations, the set A when the loop is exited has size at most $d+1$ and so, the returned set $\hat{A}$ has size at most $d + 3$. ◀

We can now use Lemma 9 as a subroutine in the greedy approximation for the minimization variant of *unweighted* Euclidean Embedding with Outliers.

▶ **Lemma 10** (⋆). *There is a polynomial-time algorithm that, given a distance space $\mathcal{X} = (X, \rho)$ and an integer $d \geq 1$, outputs a set of points A of size at most $(d + 3) \cdot \mathsf{Opt}$ such that $(X \setminus A, \rho)$ is embeddable into $\mathbb{R}^d$ where Opt is the size of a smallest d-outlier set.*

3.2 Compression

We are now ready to give the compression algorithm for Euclidean Embedding Editing.

Proof of Theorem 8. Let $(\mathcal{X} = (X, \rho), w_O, w_M, W, k_O, k_M, d)$ be an instance of Euclidean Embedding Editing. First, we preprocess the instance to reduce the number of points and then we explain how to reassign the weights.

Notice that if $(\mathcal{X}, w_O, w_M, W, k_O, k_M, d)$ is a yes-instance, then it is possible to delete $k = k_O + k_M$ points to obtain a distance space embeddable in $\mathbb{R}^d$. In the first step of our algorithm, we call the algorithm from Lemma 10 for the instance $(\mathcal{X}, k, d)$ of Euclidean Embedding with Outliers *without* weights. This algorithm outputs a set of points A of size at most $(d+3) \cdot \mathsf{Opt}$ such that $(X \setminus A, \rho)$ is embeddable into $\mathbb{R}^d$ where Opt is the minimum number of outliers. If $|A| > (d + 3)k$ then we conclude that $(\mathcal{X}, w_O, w_M, W, k_O, k_M, d)$ is a no-instance of Euclidean Embedding Editing and stop. From now on, we assume that $|A| \leq (d + 3)(k_O + k_M)$.

Let $Y = X \setminus A$. We first show that if Y has bounded size, then we can return the original instance of the problem and stop.

▶ **Reduction Rule 1.** *If $|Y| \leq 2(k_O + 2k_M)(d + 1)^2$ then return $(\mathcal{X}, w_O, w_M, W, k_O, k_M, d)$.*

We can apply this rule because if $|Y| \leq 2(k_O + 2k_M)(d + 1)^2$ then $|X| = |Y| + |A| \leq 2(k_O + 2k_M)(d + 1)^2 + (k_O + k_M)(d + 3) \leq 5(k_O + k_M)(d + 3)^2 = \mathcal{O}((kd)^2)$. From now on, we assume that $|Y| > 2(k_O + 2k_M)(d + 1)^2$.

Because A is a feasible solution to Euclidean Embedding with Outliers, (Y, ρ) can be embedded into $\mathbb{R}^d$. In the subsequent steps, we may delete some points in A and reduce the parameter k_O. This may result in a trivial instance which we solve by applying the following rule whenever possible.

▶ **Reduction Rule 2.** *If $k_O < 0$ then return a no-answer and stop. If $k_O \geq 0$ and $A = \emptyset$ then return a yes-answer and stop.*

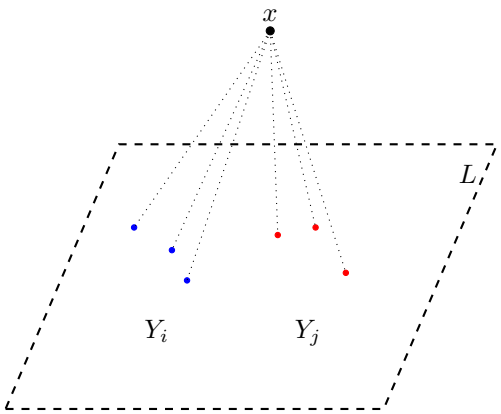

Figure 2 A pair (Y_i, Y_j) of x-compatible sets. Notice that if $j \geq i$ and $|Y_j| \leq |Y_i| = t+1$ then $(Y_i \cup Y_j, \rho)$ admits a strong embedding into $\mathbb{R}^t$ by Proposition 6 because Y_i is a metric basis for $(Y_i \cup Y_j, \rho)$. Furthermore, given a realization of (Y_i, ρ) such that the points are mapped into an affine subspace L of dimension t, the points of Y_j are mapped into L and the mapping is unique. If $(Y_i \cup \{x\}, \rho)$ is strongly t-embeddable then x is embedded in L and the embedding is unique. If $(Y_i \cup \{x\}, \rho)$ is strongly $(t+1)$-embeddable, that is, $Y_i \cup \{x\}$ is independent then by Proposition 1, the distance space is embedded into a subspace L' of dimension $t+1$ containing L and the embedding of x is unique up to the reflection with respect to L.

We greedily partition Y into sets $Y_1, \ldots, Y_\ell$ of size at most $d+1$ such that each Y_i is an inclusion-maximal independent set of points of $Y \setminus \bigcup_{j=1}^{i-1} Y_j$, that is, Y_i is an inclusion-maximal subset such that (Y_i, ρ) is strongly $(|Y_i|-1)$-embeddable.

Assume that $i \geq 1$ and the sets $Y_1, \ldots, Y_{i-1}$ are already constructed. We set $Z := Y \setminus \bigcup_{j=1}^{i-1} Y_j$. If $Z = \emptyset$, then the partition is constructed. If $Z \neq \emptyset$, then we do the following:

1. To initiate the construction of Y_i, we set $Y_i = \{x\}$ for an arbitrary point $x \in Z$ and set $h = 1$.
2. While there is a point $y \in Z \setminus Y_i$ such that $Y_i \cup \{y\}$ is independent, set $Y_i := Y_i \cup \{y\}$ and $h := h + 1$.

Because Y is d-embeddable, Z is strongly t-embeddable for some $t \leq d$ and contains an independent set of size t by Proposition 4. By Proposition 6, the described procedure will construct a set Y_i of size $t+1 \leq d+1$ such that (Y_i, ρ) is strongly t-embeddable. Notice that by Proposition 6, Y_i is a metric basis for (Z, ρ).

Let $x \in A$. We say that Y_i for $i \in \{1, \ldots, \ell\}$ is *x-compatible* if $(Y_i \cup \{x\}, \rho)$ is embeddable in $\mathbb{R}^d$. Otherwise, Y_i is *x-incompatible*. Similarly, for two distinct sets Y_i, Y_j for $i, j \in \{1, \ldots, \ell\}$, the pair (Y_i, Y_j) is *x-compatible* if $(Y_i \cup Y_j \cup \{x\}, \rho)$ is embeddable in $\mathbb{R}^d$, and (Y_i, Y_j) is *x-incompatible* otherwise (see Figure 2).

Notice that if Y_i is x-incompatible then for each solution to the instance either x is an outlier, or Y_i contains an outlier, or at least one distance between the points $Y_i \cup \{x\}$ should be modified.

For each $i \in \{1, \ldots, l\}$, $1 \leq |Y_i| \leq d+1$. We partition the family $\{Y_1, \ldots, Y_\ell\}$ of sets into parts $C_1, \ldots, C_{d+1}$ according to their size (some parts may be empty). Formally, for $h \in \{1, \ldots, d+1\}$, $C_h = \{Y_i \mid 1 \leq i \leq \ell \text{ and } |Y_i| = h\}$.

Consider the part C_h for some $h \in \{1, \ldots, d+1\}$. For a point $x \in A$, we say that two x-compatible sets $Y_i, Y_j \in C_h$ are *x-equivalent* if the pair (Y_i, Y_j) is x-compatible, that is, $(Y_i \cup Y_j \cup \{x\}, \rho)$ is embeddable into $\mathbb{R}^d$. We show the following claim.

▷ Claim 11 (⋆). x-equivalency is an equivalence relation on the family of x-compatible sets in C_h. Furthermore, if $Y_i, Y_j \in C_h$ are x-equivalent and the pair (Y_j, Y_s) for $Y_s \in C_{h'}$ with $h' \leq h$ is x-compatible then (Y_i, Y_s) is x-compatible.

The definition of x-equivalency implies the following property.

▷ Claim 12. Let R_1 and R_2 be two distinct classes of x-equivalent x-compatible sets. Then for any solution (O, D) to the considered instance, either (i) $x \in O$, or (ii) for each set Y_i in R_1 there is a $y \in Y_i$ such that $y \in O$ or there exists a z such that $\{y, z\} \in D$, or (iii) for each set Y_j in R_2 there is a $y \in Y_j$ such that $y \in O$ or there exists a z such that $\{y, z\} \in D$.

We use this property in the following rule. Because $|Y| > 2(k_O + 2k_M)(d+1)^2$ and each Y_i is of size at most $d+1$, there is $h \in \{1, \ldots, d+1\}$ with C_h being of size at least $2(k_O + 2k_M) + 1$. Let h^* be the maximum value of $h \in \{1, \ldots, d+1\}$ with this property.

▶ **Reduction Rule 3.** *If there is $x \in A$ such that each x-equivalence class R of x-compatible sets of C_{h^*} has size at most $|C_{h^*}| - (k_O + 2k_M) - 1$, then set $X := X \setminus \{x\}$, $A := A \setminus \{x\}$, and $k_O := k_O - 1$.*

After the exhaustive application of Reduction Rule 3, we have that for each $x \in A$, there is an x-equivalence class R_x of x-compatible sets in C_{h^*} that contains at least $|C_{h^*}| - k_O - 2k_M \geq (k_O + 2k_M) + 1$ sets and all other classes in C_{h^*} contain at most $k_O + 2k_M$ elements combined. We say that R_x is *large*. We exhaustively apply the following rule using the fact that R_x contains at least $(k_O + 2k_M) + 1$ sets.

▶ **Reduction Rule 4.** *If there is $x \in A$ such that there are at least $k_O + k_M + 1$ sets $Y_j \in C_h$ for any $h \leq h^*$ such that (Y_i, Y_j) is x-incompatible for some $Y_i \in R_x$, then set $X := X \setminus \{x\}$, $A := A \setminus \{x\}$, and $k_O := k_O - 1$.*

In the next crucial step of our algorithm, we identify *important* sets Y_i for $\in \{1, \ldots, \ell\}$ and delete all other sets that are irrelevant.

We apply the following *marking* procedure that labels important sets Y_i for $i \in \{1, \ldots, \ell\}$. For every $x \in A$, we do the following:

- mark every Y_i in C_h for $h > h^*$,
- for each $x \in A$, mark arbitrary $(k_O + 2k_M) + 1$ sets of R_x,
- for each $x \in A$ and each $h \in \{1, \ldots, h^*\}$, mark each set $Y_j \in C_h$ such that there is a set $Y_i \in R_x$ such that the pair (Y_i, Y_j) is x-incompatible.

We set $I = \{i \mid 1 \leq i \leq \ell \text{ and } Y_i \text{ is marked}\}$ and $Y' = \bigcup_{i \in I} Y_i$, and define $X' = A \cup Y'$.

▷ Claim 13 (⋆). The instance $(\mathcal{X} = (X, \rho), w_O, w_M, W, k_O, k_M, d)$ of Euclidean Embedding Editing is equivalent to the instance $(\mathcal{X}' = (X', \rho), w_O, w_M, W, k_O, k_M, d)$.

We have that the original instance $(\mathcal{X} = (X, \rho), w_O, w_M, W, k_O, k_M, d)$ and the obtained instance $(\mathcal{X}' = (X', \rho), w_O, w_M, W, k_O, k_M, d)$ of Euclidean Embedding Editing are equivalent. We prove that $|X'| = \mathcal{O}(k^2 d^2)$.

▷ Claim 14 (⋆). $|X'| \leq 9(k_O + k_M)^2 (d+3)^2$.

▷ Claim 15 (⋆). The overall running time of our algorithm is polynomial.

To compress the weights, we use the standard technique (see [16]) based on the algorithm of Frank and Tardos [19]. ◀

4 FPT algorithm for Euclidean Embedding Editing parameterized by solution size and dimension

In this section, we give our FPT algorithm for Euclidean Embedding Editing.

We prepare for it by recalling the relevant definitions and facts from [4]. In what follows, let R be a real closed field and $\ell \in \mathbb{N}$. Let $\mathcal{P}_\ell \subset R[X_1, \ldots, X_t]$ be a finite set of s polynomials each of degree at most ℓ.

▶ **Definition 16** ([4]). *A $\mathcal{P}_\ell$-*atom *is one of $P = 0, P \neq 0, P \geq 0, P \leq 0$, where P is a polynomial in $\mathcal{P}_\ell$ and a* quantifier-free $\mathcal{P}_\ell$-formula *is a formula constructed only from $\mathcal{P}_\ell$-atoms together with the logical connectives $\wedge$, $\vee$ and $\neg$.*

▶ **Proposition 17** (Theorem 13.13, [4]). *Let $(\exists X_1) \ldots (\exists X_t) F(X_1, \ldots, X_t)$, be a sentence, where $F(X_1, \ldots, X_t)$ is a quantifier free $\mathcal{P}_\ell$-formula. There exists an algorithm to decide the truth of the sentence with complexity*[1] *$s^{t+1} \cdot \ell^{\mathcal{O}(t)}$ in D where D is the ring generated by the coefficients of the polynomials in $\mathcal{P}_\ell$.*

▶ **Definition 18.** *Consider points $x_0, x_1, \ldots, x_r$ of distance space (X, ρ) and a set Z of pairs in X. For every $i < j \in \{0, \ldots, r\}$, if $\{x_i, x_j\} \notin Z$, then $\hat{\rho}_{i,j} = \rho(x_i, x_j)$, otherwise $\hat{\rho}_{i,j} = z_{i,j}$ where $z_{i,j}$ is an indeterminate. Then the* Z-Augmented Cayley-Menger determinant *is obtained from the Cayley-Menger determinant by replacing each $\rho_{i,j}$ with $\hat{\rho}_{i,j}$.*

▶ **Observation 19.** *Consider $r+1$ points $x_0, x_1, \ldots, x_r$ of distance space (X, ρ) and a set Z of pairs in X. The Z-Augmented Cayley-Menger determinant is a multi-variate polynomial with real coefficients, over the set $\{z_{i,j} \mid i < j,\ \{x_i, x_j\} \in Z\}$ of indeterminates and where each monomial has degree at most $2 \cdot (r+1)$.*

▶ **Theorem 20.** *Euclidean Embedding Editing is solvable in $(d(k_O + k_M))^{\mathcal{O}(d+k_M+k_O)} + n^{\mathcal{O}(1)}$ time.*

Proof. Our FPT algorithm for Euclidean Embedding Editing works as follows. We begin by running the compression algorithm (Theorem 8). Following this, based on insights from Proposition 4, we reduce the task of solving the resulting instance to the task of testing a bounded number (in terms of k, d) of sentences with purely existential quantifications as described in Proposition 17, where s, ℓ, t are all bounded by functions of k and d.

We now formalize this idea. Let $(\mathcal{X} = (X, \rho), w_O, w_M, W, k_O, k_M, d)$ be the given instance of Euclidean Embedding Editing. We run the algorithm of Theorem 8 on this instance. Recall that this algorithm either solves the instance or produces an equivalent instance $(\mathcal{X}' = (X', \rho), w'_O, w'_M, W', k'_O, k'_M, d)$ such that $X' \subseteq X$, and for $k = k_O + k_M$ and a bound $\tau(k, d) = 2^{\mathcal{O}((kd)^{12})}$, we have that $|X'| = \mathcal{O}((kd)^2)$. Note that since X' has size bounded by $\mathcal{O}((kd)^2)$, we may assume that k'_O is bounded by $\mathcal{O}((kd)^2)$ and k'_M is bounded by $\mathcal{O}((kd)^4)$.

Since we now have a bounded number of points in X', it is straightforward to guess a set $Z_O \subseteq X'$ of at most k'_O outliers and a subset Z_M of pairs from $X'' = X' \setminus Z_O$ of size at most k'_M such that (i) $w'_O(Z_O) + w'_M(Z_M) \leq W'$ and (ii) if there is a solution to the given instance, then there is a modification of the pairs in Z_M such that (X'', ρ'') is embeddable into $\mathbb{R}^d$, where ρ'' differs from ρ (restricted to X'') only among the pairs in Z_M. We next guess the embedding dimension of (X'', ρ''), denoted by r. Note that $r \leq d$.

[1] The measure of complexity here is the number of field operations.

By Proposition 4, we know that (X'', ρ'') is r-embeddable if and only if there is a subset $\hat{X} = \{x_0, \ldots, x_r\}$ of X'' such that (i) $(-1)^{j+1} CM(x_0, x_1, \ldots, x_j) > 0$ for $1 \leq j \leq r$, and (ii) for any $x, y \in X'' \setminus \hat{X}$, $CM(x_0, x_1, \ldots, x_r, x) = CM(x_0, x_1, \ldots, x_r, y) = CM(x_0, x_1, \ldots, x_r, x, y) = 0$, where the matrices are derived from the distance matrix $D(\rho'')$.

We next guess $\hat{X}$. It remains to verify that there is a modification of the distances between each pair in Z such that the resulting space (X'', ρ'') is r-embeddable, i.e., satisfies the above two properties. To test this, we construct the formula F obtained by taking the conjunction of the atoms below and invoke Proposition 17 on the sentence ϕ obtained by prepending F with existential quantifications for every indeterminate $\{z_{i,j} \mid i < j,\ \{x_i, x_j\} \in Z\}$:

1. $(-1)^{j+1} CM_{Z_M}(x_0, x_1, \ldots, x_j) > 0$, where $1 \leq j \leq r$.
2. $CM_{Z_M}(x_0, x_1, \ldots, x_r, x) = 0$ for every $x \in X'' \setminus \hat{X}$.
3. $CM_{Z_M}(x_0, x_1, \ldots, x_r, x, y) = 0$ for every $x, y \in X'' \setminus \hat{X}$.
4. $z_{i,j} \geq 0$ for each indeterminate defined by Z_M. ◀

In the conclusion of the section, we remark that the parameter dependence can be improved for Euclidean Embedding with Outliers.

▶ **Theorem 21** (⋆). *Euclidean Embedding with Outliers can be solved in time* $n^{O(1)} \cdot min\{(d+3)^k, 2^{d+k}\}$.

5 FPT-Approximation for Unweighted Euclidean Embedding with Outliers

In this section, we give an FPT-time 2-approximation for Unweighted Euclidean Embedding with Outliers (UEEO) parameterized by the dimension d. Recall that in the optmization version of this problem, the input is $(\mathcal{X} = (X, \rho), d)$ where (X, ρ) is a distance space and the goal is to output a d-outlier set of minimum size.

Our main idea is to give a randomized algorithm generating sequences $U_0, \ldots, U_{d+1}$ and $A_1, \ldots, A_{d+2}$, where each A_i is a d-outlier set that is associated with the independent set U_{i-1} of size $i-1$. The construction of these sequences is roughly as follows, starting from $U_0 = \emptyset$ and proceeding iteratively. For each U_{i-1}:

1. Any element that cannot be d-embedded along with U_{i-1} gets added to A_i.
2. We compute those elements that can be added to U_{i-1} without increasing its embedding dimension, and associate a graph with these such that every d-outlier set disjoint from U_{i-1} includes a vertex cover of this graph. We then 2-approximate the minimum vertex cover of this graph and add it to A_i.
3. For the remaining elements (call this set W):
   a. Take all of W in A_i (which makes A_i a 2-approximation if at least half of W is in the solution),
   b. Uniformly at random add an element of W to U_{i-1}, resulting in U_i (which gives an independent set with sufficiently high probability if at least half of W is *not* in some fixed minimum d-outlier set).

▶ **Theorem 22.** Unweighted *Euclidean Embedding with Outliers can be 2-approximated in* $2^d \cdot n^{\mathcal{O}(1)}$ *time by a randomized algorithm with one-sided constant probability of error.*

Proof. Let S_{opt} be a hypothetical minimum sized d-outlier set. Let $X^\star = X \setminus S_{\mathsf{opt}}$. Let us assume that $(X^\star, \rho)$ is strongly d-embeddable. Else, it is strongly d'-embeddable for some $d' \leq d$, in which case we guess d' and set $d := d'$. In what follows, we give a randomized algorithm that aims to obtain a metric basis of $(X^\star, \rho)$ if certain pre-conditions are satisfied.

Alg-3(X, ρ, d):

1. Set $U_0 := \emptyset$.
2. For $i = 1$ to $d + 2$ do as follows.
   a. Construct $\mathcal{C}^i_{\mathsf{comp}}$, the set of elements $y \in X \setminus U_{i-1}$ such that $(U_{(i-1)} \cup \{y\}, \rho)$ is $(i-2)$-embeddable.
   b. Construct $\mathcal{C}^i_{\mathsf{def}}$, the set of elements $y \in X \setminus U_{i-1}$ such that $(U_{(i-1)} \cup \{y\}, \rho)$ is not d-embeddable.
   c. Construct $\mathcal{C}^i_{\mathsf{incomp}}$, the set of elements $y \in X \setminus (U_{i-1} \cup \mathcal{C}^i_{\mathsf{comp}} \cup \mathcal{C}^i_{\mathsf{def}})$ such that $(U_{(i-1)} \cup \{y\}, \rho)$ is not $(i-2)$-embeddable.
   d. Select an element u_i uniformly at random from $\mathcal{C}^i_{\mathsf{incomp}}$.
   e. Set $U_i := U_{(i-1)} \cup \{u_i\}$.

▷ Claim 23 (⋆). For every $i \in \{0, \ldots, d+1\}$, the following holds:

1. $\mathcal{C}^i_{\mathsf{def}}$ and $\mathcal{C}^i_{\mathsf{comp}}$ are disjoint.
2. Every d-outlier set of (X, ρ) disjoint from U_i contains $\mathcal{C}^{i+1}_{\mathsf{def}}$.
3. If for all $j \leq i$, $\mathcal{C}^j_{\mathsf{incomp}} \neq \emptyset$, then U_i is an independent set of size i.

We next argue that for each $i \in [d+1]$, the independent set U_i is preserved in $X^\star = X \setminus S_{\mathsf{opt}}$, with sufficiently high probability if certain conditions are met.

▷ Claim 24 (⋆). Let $i \in [d+1]$ such that for all $j \leq i$, $|\mathcal{C}^j_{\mathsf{incomp}} \cap S_{\mathsf{opt}}| < \frac{|\mathcal{C}^j_{\mathsf{incomp}}|}{2}$. Then, $\Pr[U_i \subseteq X^\star] \geq \frac{1}{2^i}$ and U_i is an independent set of size i.

Next, we build a series of d-outlier sets $A_1, \ldots, A_{d+2}$ as follows. For each $i \in [d+2]$, create an instance of the Vertex Cover problem on the graph G^i_{comp}, where $V(G^i_{\mathsf{comp}}) = \mathcal{C}^i_{\mathsf{comp}}$, and there is an edge between two elements $x, y \in \mathcal{C}^i_{\mathsf{comp}}$ if they $U_{i-1} \cup x, y$ is not $(i-2)$-embeddable. Using a factor-2 approximation algorithm for Vertex Cover, obtain a set Q_i such that $|Q_i| \leq 2|O_i|$, where O_i is a minimum vertex cover of G^i_{comp}. Finally, set $A_i := Q_i \cup \mathcal{C}^i_{\mathsf{incomp}} \cup \mathcal{C}^i_{\mathsf{def}}$. Once every A_i is computed, we compute $i^\star = \arg\min_{i \in [d+2]} |A_i|$ and return $A_{i^\star}$.

▷ Claim 25 (⋆). Let $\ell \in [d+1]$ be the least integer such that for all $j < \ell$, it holds that

$$|\mathcal{C}^j_{\mathsf{incomp}} \cap S_{\mathsf{opt}}| < \frac{|\mathcal{C}^j_{\mathsf{incomp}}|}{2}.$$

Then, A_ℓ is a factor-2 approximation with probability at least $\frac{1}{2^\ell}$.

Since we compute $i^\star = \arg\min_{i \in [d+2]} |A_i|$ and return $A_{i^\star}$, by Claim 25 we are guaranteed that $|A_{i^\star}| \leq 2|S_{\mathsf{opt}}|$ with probability at least $\frac{1}{2^{d+1}}$.

Running Time Analysis. We have already argued that we succeed with probability $\frac{1}{2^{d+1}}$. Thus, we can boost the success probability by independently running our polynomial-time algorithm 2^{d+1} times and returning the minimum size solution among these runs. Thus, the probability that the algorithm fails in all of the independent runs is upper bounded by $(1 - \frac{1}{2^{d+1}})^{2^{d+1}} \leq 1 - \frac{1}{e}$. Moreover, the total running time is upper bounded by $2^d n^{\mathcal{O}(1)}$. ◀

6 Lower bounds

In this section, we complement our algorithmic results by proving computational lower bounds. These lower bounds also motivate our choice of parameterizations. First, we show that Euclidean Embedding Editing is Para-NP-hard when parameterized by d. More precisely, we show that even the *unweighted* versions of both Euclidean Embedding with Outliers and Euclidean Metric Violation Distance are NP-hard even for $d = 1$.

▶ **Theorem 26** ($\star$). *Euclidean Embedding with Outliers is strongly* NP*-hard even for instances with unit weights, integer distances, and* $d = 1$.

▶ **Theorem 27** ($\star$). *Euclidean Metric Violation Distance is strongly* NP*-hard for the instances with unit weights, integer distances, and* $d = 1$.

Finally, we prove that Euclidean Embedding Editing is W[1]-hard when parameterized by $k_O + k_M$ only. Moreover, the hardness holds even for the unweighted variant of Euclidean Embedding with Outliers.

▶ **Theorem 28** ($\star$). *Euclidean Embedding with Outliers parameterized by* k *is* W[1]*-hard for* n*-point instances with unit weights and integer distance matrices with entries in* $\mathcal{O}(n)$.

Abstract

Arrangements of pseudohyperplanes are widely studied in computational geometry. A rich subclass of pseudohyerplane arrangements, which has gained more attention in recent years, is the so-called signotopes. Introduced by Manin and Schechtman (1989), the higher Bruhat order is a natural order of r-signotopes on n elements, with the signotope corresponding to the cyclic arrangement as the minimal element. In this paper, we show that the lower (and by symmetry upper) levels of this higher Bruhat order contain the same number of elements for a fixed difference $n - r$. This result implies that given the difference $d = n - r$ and p, the number of one-element extensions of the cyclic arrangement of n hyperplanes in $\mathbb{R}^d$ with at most p points on one side of the extending pseudohyperplane does not depend on n, as long as $n \geq d + p$.

1 Introduction

Arrangements of geometrical and topological objects play an important role in computational geometry. A classical example is line arrangements, which consist of a family of pairwise intersecting lines. For various occasions, it is useful to study the combinatorial structure instead of the actual geometry. For this reason, pseudoline arrangements have gotten more and more attention after Levi's introductory paper [12]. In contrast to the geometric setting, it is possible to encode the structure of pseudolines efficiently. To determine the size of an optimal encoding for point sets, Knuth [11] studied the number of the so-called CC-Systems. By duality, there are the same number of pseudoline arrangements, which is $2^{\Theta(n^2)}$ [11, 7]. However, the precise leading constant in the exponent is still unknown, which leaves Knuth's question about the optimal encoding size open [11]. Recently, Cortés Kühnast, Dallant, Felsner, and Scheucher [6] determined the best-known lower bound of $2^{0.2721n^2}$ pseudoline arrangements. To tackle this challenging task, they used 3-signotopes for an encoding. Since the order on the elements itself is fixed, the set of 3-signotopes has less symmetric copies, which makes the encoding easier. As shown by Felsner and Weil [9] there is a bijection between pseudoline arrangements and 3-signotopes.

In this paper, we consider higher dimensions. Pseudohyperplane arrangements in $\mathbb{R}^d$ are combinatorially encoded as uniform acyclic oriented matroids of rank $r = d + 1$. For more about oriented matroids, see [5]. The asymptotic number of oriented matroids of rank r is $2^{\Theta(n^{r-1})}$. However, little is known about the constant in the exponent. Instead of the general case, we consider signotopes of rank r, a rich subclass of pseudohyperplane arrangements, of which there are also $2^{\Theta(n^{r-1})}$, see [2, 4]. The leading constant is also unknown. In this paper, we determine the number of signotopes with few plus (or symmetrically, few minus) signs. This may be a step towards determining the precise number of all signotopes in the future.

To formally define signotopes, let $[a, b]$ denote the set $\{x \in \mathbb{Z} \mid x \geq a \wedge x \leq b\}$ for two integers a and b. Moreover, let $[n]$ be $[1, n]$ and $\binom{[a,b]}{r}$ denote the set of all subsets of size r of $[a, b]$. We call such a subset an *r-subset* of $[a, b]$.

▶ **Definition 1** (Signotope). *For $r \geq 1$, a* signotope of rank r *(or an* r-signotope*) on n elements is a sign function $\sigma : \binom{[n]}{r} \to \{+, -\}$, such that for every $(r + 1)$-subset $X = \{x_1, \ldots, x_{r+1}\}$ of $[n]$ with $x_1 < \cdots < x_{r+1}$, there is at most one sign change in the sequence*

$$\Big(\sigma(X \setminus \{x_1\}), \ldots, \sigma(X \setminus \{x_{r+1}\})\Big).$$

The set of all r-signotopes on n elements is denoted by $\mathcal{S}(n, r)$.

For fixed n and r, we can define an order on the set $\mathcal{S}(n, r)$ of all r-signotopes on n elements based on the number of $+$-signs. Specifically, two sign functions σ and $\tilde{\sigma}$ differ in a *single step*, if $\sigma^{-1}(+) \subset \tilde{\sigma}^{-1}(+)$ and $|\tilde{\sigma}^{-1}(+)| = |\sigma^{-1}(+)| + 1$. The transitive closure of the single step relation gives the higher Bruhat order.

▶ **Definition 2** (Higher Bruhat Order). *For $r \geq 1$, the* higher Bruhat order $B(n, r)$ *is the partial order $\preceq$ on the elements of $\mathcal{S}(n, r)$ with the transitive closure of the single step.*

Signotopes are the elements of the higher Bruhat order, which were introduced by Manin and Schechtman [13] as a higher dimensional equivalence of the weak Bruhat order for permutations. They were further studied by Kapranov and Voevodsky [10], Ziegler [15], and later Felsner and Weil [8]. In these works they give several geometric interpretations. The most important one for our purposes is the representation of an r-signotope on $[n]$ as a one-element extension of the cyclic arrangement of n hyperplanes in $\mathbb{R}^{n-r}$ [15].

▶ **Definition 3** (Cyclic arrangement). *The* cyclic arrangement $\mathbf{X}_c^{n,d}$ *is the set $\{H_1, \ldots, H_n\}$ in $\mathbb{R}^d$ given by*

$$H_i = \{(x_1, \ldots, x_d) \in \mathbb{R}^d : x_1 + t_i x_2 + \cdots + t_i^{d-1} x_d + t_i^d = 0\}$$

for $i \in [d]$, with arbitrary real parameters $t_1 < \cdots < t_n$.

A *point* of the cyclic arrangement $\mathbf{X}_c^{n,n-r}$ is the intersection of $n - r$ hyperplanes and can be identified with the $n - (n - r) = r$ hyperplanes which do not contain this point. In $\mathbf{X}_c^{n,n-r}$, along each *line* (i.e., the intersection of $n - r - 1$ hyperplanes), the corresponding r-subsets of the crossing points are ordered lexicographically. A *one-element extension* of $\mathbf{X}_c^{n,n-r}$ is obtained by adding a pseudohyperplane to $\mathbf{X}_c^{n,n-r}$ in general position (i.e., the pseudohyperplane does not contain any point of $\mathbf{X}_c^{n,n-r}$). Additionally, the *extending pseudohyperplane* (i.e., the new pseudophyperplane) is oriented; that is, it divides $\mathbb{R}^d$ into two sides, a positive and a negative side. If a point lies in the positive side, the corresponding r-subset is mapped to $+$, and that correpsonding to a point in the negative side is mapped to $-$. Monotonicity of this sign mapping on r-subsets follows from the lexicographical order of the r-subsets along the lines. For an illustration see Figure 1.

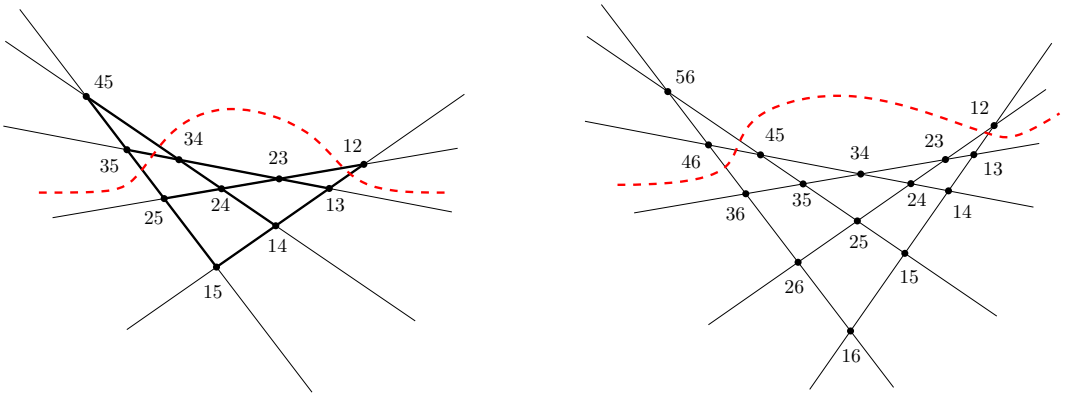

Figure 1 Two examples of one-element extensions of the cyclic arrangements $\mathbf{X}_c^{5,2}$ (left) and $\mathbf{X}_c^{6,2}$ (right). The red dashed lines are the extending pseudolines. To avoid clusters, we label each point of the arrangement by the lines that contain it (e.g., point 12 is the intersection of lines H_1 and H_2). The positive sides are the sides above the extending pseudolines. The corresponding two signotopes are mapped to each other in our bijection for Theorem 1.

In this paper, we count the number of signtopes in a given level of the higher Bruhat order (i.e., the number of signotopes with a given number of +-signs). We show that the bottom (and by symmetry the top) levels in the Bruhat order are the same whenever $n-r$ is the same. More precisely, we denote by $\mathcal{S}_{\leq p}(n,r)$ the set of all r-signotopes σ on n elements with at most p +-signs (i.e., $|\sigma^{-1}(+)| \leq p$). Our main result is then stated as follows.

▶ **Theorem 1.** *Let $n, \tilde{n}, r, \tilde{r}, d, p$ be natural numbers such that $n - r = \tilde{n} - \tilde{r} = d$ and $p \leq \min\{r, \tilde{r}\}$. Then there exists a bijection between $\mathcal{S}_{\leq p}(n,r)$ and $\mathcal{S}_{\leq p}(\tilde{n},\tilde{r})$ that preserves the relation $\preceq$.*

In other words the theorem states that the lower levels of the higher Bruhat order contain the same number of elements for a fixed difference $n-r$. Note that by symmetry the same holds for the upper levels, i.e., if there are $\leq r$ minus signs. Using the representation of signotopes as one-element extensions of the cyclic arrangement, the geometric interpretation of the theorem above is as follows.

▶ **Corollary 4.** *Given $d, p \geq 0$, for any $n \geq d+p$, the number of one-element extensions of the cyclic arrangement $\mathbf{X}_c^{n,d}$ with at most p points on one side of the extending pseudohyperplane is a constant (which depends only on d and p).*

The representation also allows us to prove the theorem. It turns out that whenever there are $\leq r$ plus signs (respectively minus signs), we only need to consider the local structure of the one-element extension. In particular, this local structure only depends on p and $n-r$, and not the exact values of n and r themselves; this insight gives rise to the bijection in Theorem 1. In Section 2 we give a more detailed outline and in Sections 3–6 we give the technical proof. In order to show this dependency, we use a generalization of the Ferrers diagrams. These diagrams are geometric illustrations of integer partitions [1], which are classical objects in number theory and combinatorics. This connection allows us not only to prove the bijection but also to quantify the size of $\mathcal{S}_{\leq p}(n,r)$ in Section 7.

2 Proof overview for Theorem 1

In this paper, since we discuss r-signotopes on $[n]$ where $n-r$ is fixed, it is more convenient to work with the complements of the r-subsets. Hence in Section 2.1, we introduce the notion of co-signotopes with related definitions analogous to the signotopes and rephrase Theorem 1 in terms of this new notion. Afterwards, we provide an overview of the proof.

2.1 Co-signotopes

For convenience, we write each subset as a sequence of its elements in the increasing order; that is we consider an r-subset $\{a_1, \ldots, a_r\}$ with $a_1 < \cdots < a_r$ as the tuple $(a_1, \ldots, a_r)$. This way, we can order the subsets in the lexicographical order of the tuple representations.

- For a function f, a d-subset $B = (b_1, \ldots, b_d)$ of $[n]$, and an index $i \in [d]$, let $B_i := B \setminus \{b_i\}$. Then the (f, B, i)-*series* is the sequence of $f(B_i \cup \{x\})$ for $x \in [n] \setminus B_i$ in the increasing order. In other words, if $[n] \setminus B_i = \{x_1, \ldots, x_{n-d+1}\}$ with $x_1 < \cdots < x_{n-d+1}$, then the (f, B, i)-series is exactly the sequence

  $$(f(B_i \cup \{x_1\}), \ldots, f(B_i \cup \{x_{n-d+1}\})).$$

  When f is the identity function, then this corresponds to the sequence $(B_i \cup \{x_1\}, \ldots, B_i \cup \{x_{n-d+1}\})$, and we call it simply the (B, i)-series. Note that the (B, i)-series contains B.
- For $0 \leq d < n$, a *co-signotope of rank* d (or a d*-co-signotope*) on n elements is a sign function $\tau : \binom{[n]}{d} \to \{+, -\}$, such that for every d-subset B of $[n]$ and index $i \in [d]$, there is at most one sign change in the (τ, B, i)-series.
- The set of all d-co-signotopes on n elements is denoted by $\bar{\mathcal{S}}(n, d)$.
- Given a sign function τ, a subset R is a $+$*-subset* of τ if $\tau(R) = +$, and it is a $-$*-subset* of τ if $\tau(R) = -$. The set of all d-co-signotopes on n elements with exactly p $+$-subsets is denoted by $\bar{\mathcal{S}}_p(n, d)$. The set of all d-co-signotopes on n elements with at most p $+$-subsets is denoted by $\bar{\mathcal{S}}_{\leq p}(n, d)$.
- The *complementary higher Bruhat order* $\bar{B}(n, d)$ is the partial order $\preceq_{\bar{\mathcal{S}}}$ on the elements of $\bar{\mathcal{S}}(n, d)$ with the transitive closure of the single step.

The following observation follows immediately from the definitions of signotopes and co-signotopes.

▶ **Observation 5.** *For non-negative integers n, d, p such that $d \leq n$, there is an isomorphism between $S_p(n, n-d)$ and $\bar{S}_p(n, d)$ that preserves the single step relation.*

Then we can rephrase Theorem 1 in terms of co-signotopes as follows.

▶ **Theorem 1** (Rephrased). *Let $n, \tilde{n}, d, p$ be integers such that $0 \leq p \leq \min\{n, \tilde{n}\} - d$. Then there exists a bijection between $\bar{\mathcal{S}}_{\leq p}(n, d)$ and $\bar{\mathcal{S}}_{\leq p}(\tilde{n}, d)$ that preserves the relation $\preceq_{\bar{\mathcal{S}}}$.*

2.2 Proof strategy of Theorem 1

Let $G_{n,d}$ be the underlying graph of the cyclic arrangement $\mathbf{X}_c^{n,d}$; that is, its vertices are the points of $\mathbf{X}_c^{n,d}$, and its edges are the segments of the lines of $\mathbf{X}_c^{n,d}$ such that the segments have two points of $\mathbf{X}_c^{n,d}$ as endpoints and contain no other points in the interior. In other words, the vertices of $G_{n,d}$ are the d-subsets, and two d-subsets B and B' are connected by an edge, if they are adjacent in the (B, i)-series for some $i \in [d]$. For illustration, the bold line segments in Figure 1(left) form the edges of the graph $G_{n,d}$.

The proof of Theorem 1 hinges on the following main idea. For a co-signotope $\tau \in \bar{\mathcal{S}}_{\leq p}(n,d)$, we consider the induced subgraph of $G_{n,d}$ on the $+$-subsets of τ. Then each connected component in this induced subgraph (which we also call the $+$-component of τ) can be characterized by a structure around a "source" subset (defined in the next section). In particular, locally, the $+$-component appears like a generalized version of the Ferrers diagrams. Further, this characterization is independent from that of other $+$-components and depends only on the source subset, d, and p. With this observation, we can independently map each $+$-component of τ to that of a co-signotope in $\bar{\mathcal{S}}_{\leq p}(\tilde{n},d)$.

In order to rigorously execute the idea above, we first provide some preliminary structural insights on the $+$-subsets of a co-signotope $\tau \in \bar{\mathcal{S}}_{\leq p}(n,d)$ in Section 3. Next, in Section 4, we show how we can map one $+$-component of a co-signotope $\tau \in \bar{\mathcal{S}}_{\leq p}(n,d)$ to that of a co-signotope $\tilde{\tau} \in \bar{\mathcal{S}}_{\leq p}(\tilde{n},d)$. To ease the explanation, in this section, we assume that there is exactly one $+$-component for τ and for $\tilde{\tau}$. Here is also where we explain the connection with the Ferrers diagrams. Then in Section 5, we show how we can map one signotope in $\bar{\mathcal{S}}_{\leq p}(n,d)$ to a signotope in $\bar{\mathcal{S}}_{\leq p}(\tilde{n},d)$ based on their sets of $+$-components. Finally, Section 6 wraps up the proof and provides a simple bijection as required by Theorem 1.

3 Structure of $+$-subsets of a co-signotope in $\bar{\mathcal{S}}_p(n,d)$

Consider a co-signotope in $\bar{\mathcal{S}}_p(n,d)$ that has only one $+$-subset. This unique $+$-subset needs to be a subset which appears at the start or end of every sequence it is contained in. The only d-subsets which fulfill this requirement are $S_{n,d,i}$ where $S_{n,d,i} = (1,\dots,i,n-d+i+1,\dots,n)$. We call such an $S_{n,d,i}$ a *source subset*. For convenience, we drop the subscripts n and d, when they are clear.

Recall that $G_{n,d}$ is the underlying graph of the cyclic arrangement $\mathbf{X}_c^{n,d}$, as defined in Section 2.2. We have the following lemma on the distance from a subset to a source subset.

▶ **Lemma 6.** *Let n,d,i be integers such that $1 \leq i \leq d \leq n$. Let $B = (b_1,\dots,b_d)$ be a d-subset. Then every path between B and $S_{n,d,i}$ in $G_{n,d}$ has length at least $b_i - b_{i+1} + n - d + 1$, where we define $b_0 := 0$ and $b_{d+1} := n+1$.*

Proof. We represent each d-subset as a set of d tokens, one placed on the real line at each element of the subset. Then the act of going from one d-subset to an adjacent d-subset in $G_{n,d}$ can be seen as moving a token along the real line (in an arbitrary direction) to the next free integer. Suppose that $b_i > i$. Note that $[b_i - 1]$ contains at least i elements of S_i and exactly $i-1$ elements of B. Hence, in the process of going along a path from S_i to B in $G_{n,d}$, there must be at least one token from the interval $[b_i - 1]$ going to the interval $[b_i, n]$. Therefore, every integer in $[i+1, b_i]$ must be visited by a token at some point in the process (these integers may or may not be visited by the same token). Note that this statement is vacuously true when $b_i = i$ or when $i = 0$.

Using a symmetric argument, we also deduce that every integer in $[b_{i+1}, n-d+i]$ must also be visited by a token at some point in the process above. Further, at any step, we only move one token, and hence, at most one integer in $[i+1, b_i] \cup [b_{i+1}, n-d+i]$ is visited at any step. Hence, we conclude that the path from S_i to B must have length at least $(b_i - i) + (n - d + i - b_{i+1} + 1)$. The lemma then follows. ◀

For a d-co-signotope τ, let $G_{n,d}[\tau]$ be the induced subgraph of $G_{n,d}$ on $\tau^{-1}(+)$ (i.e., the $+$-subsets of τ). A maximal connected induced subgraph of $G_{n,d}[\tau]$ is called a *$+$-component* of τ. Then it is easy to see that each $+$-component of τ contains at least one source subset. This is actually tight for all components when $\tau \in \bar{\mathcal{S}}_p(n,d)$ with $p \leq n-d$, as stated in the following lemma.

▶ **Lemma 7.** *Let n, d, p be non-negative integers such that $p \leq n - d$. Then for $\tau \in \bar{\mathcal{S}}_p(n, d)$, each $+$-component of τ has exactly one source subset.*

Proof. Suppose we have two source subsets S_i and S_j with $i < j$. Applying Lemma 6 with $B = S_j$, a path between two source subsets S_i and S_j with $i < j$ has length at least $i - (i + 1) + n - d + 1 = n - d$. This shows that every $+$-component containing S_i and S_j has at least $n - d + 1 > p$ $+$-subsets. Since τ has p $+$-subsets, it follows that no component of $G_{n,d}[\tau]$ can contain more than one source subset. Combined with the fact that each component needs to have at least one source subset, the lemma then follows. ◀

Motivated by the lemma above, for a co-signotope $\tau \in \bar{\mathcal{S}}(n, d)$ and for $i \in [0, d]$, we denote by $\mathcal{C}_i^\tau$ the $+$-component that contains S_i ($\mathcal{C}_i^\tau$ may be empty.)

For a co-signotope $\tau \in \bar{\mathcal{S}}(n, d)$, a d-subset B, and an index $j \in [d]$, we say the (τ, B, j)-series is *left-aligned* if it starts with a $+$-subset and ends with a $-$-subset, *right-aligned* if it starts with a $-$-subset and ends with a $+$-subset, and *flat* if there is no sign change. Since every (τ, B, j)-series has $n - d + 1$ subsets, if τ has at most $(n - d)$ $+$-subsets, then no flat series has only $+$-subsets. Hence, we have the following simple observation.

▶ **Observation 8.** *Let n, d, p be non-negative integers such that $p \leq n - d$. Then for every $+$-subset B of a co-signotope $\tau \in \bar{\mathcal{S}}_p(n, d)$ and for every index $j \in [d]$, the (τ, B, j)-series is not flat.*

The following lemma characterizes which d-subsets can be in the same $+$-component as some source subset S_i.

▶ **Lemma 9.** *Let n, d, c, p, i be integers such that $1 \leq c \leq p \leq n - d$ and $0 \leq i \leq d$. Further, let τ be a co-signotope in $\bar{\mathcal{S}}_p(n, d)$. Then if the $+$-component $\mathcal{C}_i^\tau$ has size c and contains a $+$-subset $B = (b_1, \ldots, b_d)$, then we have*

(a) *For all $j \in [i]$, $b_j \leq c + j - 1$ and the (τ, B, j)-series is left-aligned; and*

(b) *For all $j \in [i + 1, d]$, $b_j \geq n - (c + d - j) + 1$ and the (τ, B, j)-series is right-aligned.*

Proof. We first consider the case when $j \in [i]$. By Lemma 6, the shortest path between B and S_i is at least $b_i - b_{i+1} + n - d + 1$. Since B and S_i are in the same $+$-component $\mathcal{C}_i^\tau$ of size c, this implies $b_i - b_{i+1} + n - d + 1 \leq c - 1$. Moreover since $b_{i+1} < b_{i+2} < \cdots < b_d \leq n$, we obtain $b_{i+1} \leq n - d + i + 1$. Together this implies

$$b_i \leq (c - 1) - (-b_{i+1} + n - d + 1) = c + i - 1 + b_{i+1} - (n - d + i + 1) \leq c + i - 1.$$

Combining this with the fact that $b_j \leq b_i - (i - j)$, we have $b_j \leq c + j - 1$ as required.

We now prove by contradiction that the (τ, B, j)-series is left-aligned. Suppose this is not the case. Combined with Observation 8, (τ, B, j)-series must then be right-aligned, i.e., all of the subsets after B in the (B, j)-series then have to be $+$-subsets. That means each element in $[b_j, n]$ appears in some $+$-subset. If $b_j = j$, then also all elements in $[b_j]$ appear in S_i, a $+$-subset. Otherwise, using the same token argument as in the proof of Lemma 6, each element in $[i + 1, b_i]$ is contained in some $+$-subset along the path from S_i to B in $\mathcal{C}_i^\tau$. Combining with the fact that $[i] \subseteq S_i$, we obtain that each element in $[b_i]$ appears in some $+$-subset. Overall, each element in $[n]$ appears in some $+$-subset.

Next, observe that going from a subset to an adjacent subset in $G_{n,d}$, we remove one element and add one element. Hence, since $\mathcal{C}_i^\tau$ has at most p elements, the number of elements appearing in at least one $+$-subset is at most $d + p - 1 \leq n - 1$. This contradicts with the conclusion above that each element in $[n]$ appears in some $+$-subset.

Hence, (a) holds. With a symmetric argument, we also obtain (b), completing the proof of the lemma. ◀

A direct consequence of the lemma above is that for a given $\tau \in \bar{\mathcal{S}}_p(n,d)$, we can identify to which $+$-component a $+$-subset belongs.

▶ **Corollary 10.** *Let n, d, p be integers such that $1 \leq p \leq n-d$. Further, let τ be a co-signotope in $\bar{\mathcal{S}}_p(n,d)$ and $B = (b_1, \ldots, b_d)$ be a $+$-subset of τ. Then B is contained in the $+$-component $\mathcal{C}_i^\tau$, where i is either the largest index in $[d]$ such that the (τ, B, i)-series is left-aligned or zero if such an index does not exist.*

4 Co-signotopes with only one $+$-component

As a building block for the bijection, in this section, we consider $\tau \in \bar{\mathcal{S}}_p(n,d)$ such that $n \geq d+p$ and τ has exactly one $+$-component. We give a characterization of such a co-signotope via a variant of high-dimensional Ferrers diagrams. For convenience, we denote by $\bar{\mathcal{S}}_{p,i}(n,d)$ the set of all co-signotopes $\tau \in \bar{\mathcal{S}}_p(n,d)$ such that $\mathcal{C}_i^\tau$ is the only non-empty $+$-component of τ.

To facilitate the proof of the bijection we define a function $g_{n,d,i}$ for integers n, d, i such that $0 \leq i \leq d < n$. This function allows us to consider the $+$-component locally with new coordinates, where S_i has coordinate $(1, \ldots, 1)$, and to allude to the Ferrers diagrams. In the first step, we consider the following auxiliary function:

$$f_{n,d,i,j}(x) = \begin{cases} x - j + 1 & \text{if } 1 \leq j \leq i \\ (n-x) - (d-j) + 1 & \text{if } i < j \leq d. \end{cases}$$

Then we can now define $g_{n,d,i}$ that maps a d-subset to a point in the d-dimenional space.

▶ **Definition 11.** *Let n, d, i be integers such that $0 \leq i \leq d < n$. Then the function $g_{n,d,i}$ maps each d-subset $B = (b_1, \ldots, b_d)$ to the tuple*

$$\big(f_{n,d,i,1}(b_1), f_{n,d,i,2}(b_2) \ldots, f_{n,d,i,d}(b_d)\big).$$

We have the following observation on this function $g_{n,d,i}$.

▶ **Observation 12.** *The function $f_{n,d,i,j}$ is injective and has an inverse, and hence, the same holds for $g_{n,d,i}$. Further, if B is a $+$-subset of a co-signotope $\tau \in \bar{\mathcal{S}}_p(n,d)$, then by Lemma 9 and the fact that $b_j \in [j, n-(d-j)]$, each index of $g_{n,d,i}(B)$ is in $[p]$. In particular, $g_{n,d,i}(S_i) = (1, \ldots, 1)$.*

As mentioned before, $g_{n,d,i}$ allows us to make a connection with the Ferrers diagram of an integer partition [1]. An *integer partition* of a non-negative integer n is a way of writing n as a sum of positive integers, where the summands are sorted in the nonincreasing order. The *graphical representation* or *Ferrers diagram* of an integer partition of n is a set of points with positive integral indices in the plane such that (i,j) is in the set only if (i',j') is also in the set for all $i' \leq i$, $j' \leq i$. It is easy to see the one-to-one correspondence between an integer partition and its graphical representation. See Figure 2(left) for an illustration.

We define the following generalization of the Ferrers diagram.

▶ **Definition 13** ((d,i)-Ferrers diagram)**.** *Let $Z(d,i)$ be the set of all points $(a_1, \ldots, a_d)$ in $\mathbb{Z}^d_{>0}$ that satisfy $a_j \geq a_{j-1}$ for all $j \in [2,i]$, and $a_j \geq a_{j+1}$ for all $j \in [i+1, d-1]$. A* (d,i)-Ferrers diagram *with respect to p is a set $\mathcal{F}$ of p points in $Z(d,i)$ such that $(a_1, \ldots, a_d)$ is in $\mathcal{F}$ only if $(a'_1, \ldots, a'_d)$ is also in $\mathcal{F}$, for all $(a'_1, \ldots, a'_d) \in Z(d,i)$ that satisfies $a'_j \leq a_j$, $j \in [d]$.*

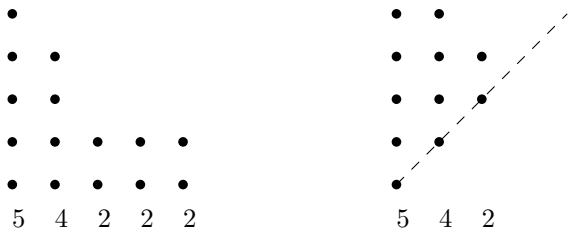

Figure 2 Left: A Ferrers diagram with the corresponding integer partition of 15, where the bottom-leftmost point corresponds to (1,1). Note that this is also a $(2,1)$-Ferrers diagram with respect to 15. **Right**: A $(2,2)$-Ferrers diagram with respect to 11. Since $a_2 \geq a_1$, there cannot be any point below the dashed line. The numbers are the count of points in each vertical line. Observe that these numbers must be strictly decreasing.

See Figure 2(right) for an illustration of a (d,i)-Ferrers diagram. Note that (2,1)-Ferrers diagrams are exactly the Ferrers diagrams.

We are now ready to characterize the co-signotopes in $\bar{\mathcal{S}}_{p,i}(n,d)$.

▶ **Lemma 14.** *Let n,d,p,i be integers such that $1 \leq p \leq n-d$ and $0 \leq i \leq d$. There is a one-to-one correspondence between a co-signotope τ in $\bar{\mathcal{S}}_{p,i}(n,d)$ and a (d,i)-Ferrers diagram $\mathcal{F}_\tau$ with respect to p. Further, this correspondence is described by $\mathcal{F}_\tau = \{g_{n,d,i}(B) \mid B \in \tau^{-1}(+)\}$.*

Proof. Suppose we have a co-signotope $\tau \in \bar{\mathcal{S}}_{p,i}(n,d)$, we show that for $\mathcal{F}_\tau := \{g_{n,d,i}(B) \mid B \in \tau^{-1}(+)\}$, the set $\mathcal{F}_\tau$ is a (d,i)-Ferrers diagram with respect to p. By Observation 12, the elements of $\mathcal{F}_\tau$ have positive integral indices, and $g_{n,d,i}$ is injective. Combined with the fact that τ has p $+$-subsets, this implies that $\mathcal{F}_\tau$ has p elements.

We start by showing that $\mathcal{F}_\tau \subset Z(d,i)$, for $Z(d,i)$ as defined in Definition 13. Consider a $+$-subset $B = (b_1, \ldots, b_d)$. For $j \in [2,i]$, we have $b_j > b_{j-1}$ by our convention of a subset. Hence, $f_{n,d,i,j}(b_j) + j - 1 > f_{n,d,i,j-1}(b_{j-1}) + (j-1) - 1$, which is equivalent to $f_{n,d,i,j}(b_j) \geq f_{n,d,i,j-1}(b_{j-1})$. Similarly, for $j \in [i+1, n-1]$, we obtain $f_{n,d,i,j}(b_j) \geq f_{n,d,i,j+1}(b_{j+1})$. It follows that $\mathcal{F}_\tau \subset Z(d,i)$. Then Lemma 9 implies that $\mathcal{F}_\tau$ satisfies the condition of a (d,i)-Ferrers diagram with respect to p in Definition 13.

For the other direction, suppose we have a (d,i)-Ferrers diagram $\mathcal{F}$ with respect to p. We show that the sign function τ such that $\tau^{-1}(+) = \{g^{-1}_{n,d,i}(X) \mid X \in \mathcal{F}\}$ is a co-signotope in $\bar{\mathcal{S}}_{p,i}(n,d)$. We first show that for every $X = (a_1, \ldots, a_d) \in \mathcal{F}$, $g^{-1}_{n,d,i}(X)$ is a d-subset. Indeed, since $\mathcal{F} \subset Z(d,i)$, it is easy to see that for $j \in [2,i] \cup [i+2,n]$, $f^{-1}_{n,d,i,j}(a_j) > f^{-1}_{n,d,i,j-1}(a_{j-1})$. For $j = i+1$, note that if the sum of the indices of X is s, then by Definition 13, it is easy to see that for $k \in [d,s]$, there exists an element Y in $\mathcal{F}$ whose sum of indices is exactly k. Combining this with the fact that there are p elements in $\mathcal{F}$, we obtain that $s \leq p+d-1$, and consequently, $a_i + a_{i+1} \leq p+1$. This implies

$$f^{-1}_{n,d,i,i+1}(a_{i+1}) - f^{-1}_{n,d,i,i}(a_i) = (n - a_{i+1} - d + i + 2) - (a_i + i - 1) = (n - d + 3) - (a_{i+1} + a_i) \geq 2.$$

This completes the proof that $g^{-1}_{n,d,i}(X)$ is a d-subset.

Next, we show that τ is a co-signotope, i.e., for every d-subset B and index j, the (τ, B, j)-series has at most one sign change. This is implied by the condition of a (d,i)-Ferrers diagram in Definition 13.

Lastly, observe that for any element $X = (a_1, \ldots, a_d)$ in $\mathcal{F}$, if it is not $(1, \ldots, 1)$, then we can find an index j such that the element X' obtained from X by replacing a_j with $a_j - 1$ is in $Z(d,i)$. Hence, X' is in $\mathcal{F}$. Repeating this process, we obtain a sequence of elements in $\mathcal{F}$ starting from X and ending at $(1, \ldots, 1)$. This corresponds to a walk in the graph $G_{n,d}$ from

a $+$-subset of τ to S_i. (Recall from Observation 12 that $g^{-1}_{n,d,i}((1,\dots,1)) = S_i$.) This implies that all $+$-subsets of τ are connected to S_i in $G_n[\tau]$. Hence, there is only one $+$-component, and this $+$-component contains S_i. Since $g^{-1}_{n,d,i}$ is injective, the $+$-component has p subsets. This completes the proof of the lemma. ◀

Observe that the set $\mathcal{F}_\tau$ in Lemma 14 depends only on d, i, and p, but not on n. Hence, this lemma straighforwardly implies a bijection between $\bar{\mathcal{S}}_{p,i}(n,d)$ and $\bar{\mathcal{S}}_{p,i}(\tilde{n},d)$ such that $\min\{n,\tilde{n}\} \geq p+d$, as follows.

▶ **Corollary 15.** *Let $n,\tilde{n},d,p,i$ be integers such that $1 \leq p \leq \min\{n,\tilde{n}\} - d$ and $0 \leq i \leq d$. Let $h_{n,\tilde{n},d,p,i}$ map a co-signotope τ in $\bar{\mathcal{S}}_{p,i}(n,d)$ to a sign function $\tilde{\tau} : \binom{[\tilde{n}]}{d} \to \{+,-\}$ such that*

$$\tilde{\tau}^{-1}(+) = \left\{ g^{-1}_{\tilde{n},d,i}\big(g_{n,d,i}(B)\big) \mid B \in \tau^{-1}(+) \right\}.$$

Then $h_{n,\tilde{n},d,p,i}$ is a bijection between $\bar{\mathcal{S}}_{p,i}(n,d)$ and $\bar{\mathcal{S}}_{p,i}(\tilde{n},d)$ that preserves the single step relation.

5 The $+$-component decomposition of a co-signotope

In the previous section, we studied co-signotopes with only one $+$-component. In this section, we go a step further and investigate how the $+$-subsets of a general co-signotope in $\bar{\mathcal{S}}_p(n,d)$ can be decomposed into several $+$-components. The *p-sequence* of a co-signotope τ in $\bar{\mathcal{S}}_p(n,d)$ is the $(d+1)$-tuple $(p_0,\dots,p_d)$, where p_i is the size of the $+$-component that contains S_i for $i \in [0,d]$ (i.e., $p_i = |\mathcal{C}^\tau_i|$). If we restrict the co-signotope τ such that we keep only one of its $+$-components as a $+$-component and set all remaining $+$-components to $-$, we still get a co-signotope. More precisely, we define the *$+$-component decomposition* of a co-signotope $\tau \in \bar{\mathcal{S}}_p(n,d)$, denoted by $\Delta(\tau)$, as the $(d+1)$-tuple $(\tau_0,\tau_1,\dots,\tau_d)$ such that for $i \in [0,d]$, each τ_i is a sign function with domain $\binom{[n]}{d}$, where $\tau_i^{-1}(+)$ is exactly $\mathcal{C}^\tau_i$. The following lemma shows that each τ_i is still a co-signotope.

▶ **Lemma 16.** *Let n,d,p be integers such that $0 \leq p \leq n-d$. For every co-signotope τ in $\bar{\mathcal{S}}_p(n,d)$ with $\Delta(\tau) = (\tau_0,\tau_1,\dots,\tau_d)$, τ_i is a co-signotope in $\bar{\mathcal{S}}_{|\mathcal{C}^\tau_i|,i}(n,d)$ for $i \in [0,d]$.*

Proof. For every d-subset B of $[n]$ and every index j, the $+$-subsets in the (τ,B,j)-series form a path in $G_{n,d}$. Hence τ_i is a co-signotope in $\bar{\mathcal{S}}_{|\mathcal{C}^\tau_i|,i}(n,d)$ for $i \in [0,d]$. ◀

Note that not every tuple $(p_0,\dots,p_d)$ such that $\sum_{i=0}^d p_i = p$ is the p-sequence of a co-signotope. There are some necessary conditions which turn out to be sufficient as well. For this we define a *sparse composition* of an integer p as a $(d+1)$-tuple $(c_0,\dots,c_d)$ of non-negative integers such that $\sum_{i=0}^n c_i = p$ and either $c_i = 0$ or $c_{i-1} = 0$ for all $i \in [d]$.

▶ **Lemma 17.** *Let n,d,p be non-negative integers such that $p \leq n-d$. For every $\tau \in \bar{\mathcal{S}}_p(n,d)$ its p-sequence $(p_0,\dots,p_d)$ is a sparse composition of p. Moreover, for every sparse composition $(c_0,\dots,c_d)$ of p and every co-signotopes $\tau_0,\dots,\tau_d$ such that $\tau_i \in \bar{\mathcal{S}}_{c_i,i}(n,d)$, there exists a unique co-signotope τ in $\bar{\mathcal{S}}_p(n,d)$ such that its p-sequence is $(c_0,\dots,c_d)$ and $\Delta(\tau) = (\tau_0,\tau_1,\dots,\tau_d)$.*

Proof. To show the first part, note that by Lemma 7, we obtain $\sum_{i=0}^d p_i = p$. We argue that for all $i \in [p]$, either $p_i = 0$ or $p_{i-1} = 0$. Indeed, if this is not the case, S_i and S_{i-1} are both $+$-subsets by definition. Then the (τ,S_i,i)-series starts with a $+$-subset S_i and

ends with a +-subset S_{i-1}. This implies that all subsets in (τ, B, i)-series are +-subsets, and hence this series is flat, a contradiction to Observation 8. Therefore, $(p_0, \dots, p_d)$ is a sparse composition of p.

Now let τ be the sign function over $\binom{[n]}{d}$ such that $\tau^{-1}(+) = \bigcup_{i=0}^{d} \tau_i^{-1}(+)$. By construction, τ has at most p +-subsets.

We start by arguing that τ is a co-signotope. Suppose that this is not the case. Then for some d-subset $B = (b_1, \dots, b_d)$ and an index j, the (τ, B, j)-series has more than one sign change. By definition of τ and by the fact that τ_i is a co-signotope in $\bar{\mathcal{S}}_{c_i,i}(n, d)$ for $i \in [0, d]$, we must have that for some $i, i' \in [0, d]$, the (τ_i, B, j)-series is left-aligned and $(\tau_{i'}, B, j)$-series is right-aligned. Because $(c_0, \dots, c_d)$ is a sparse composition, we have $|i - i'| \geq 2$. Let $B^\alpha = (b_1^\alpha, \dots, b_d^\alpha)$ and $B^\omega = (b_1^\omega, \dots, b_d^\omega)$ be the first and the last subsets of the (B, j)-series, respectively. We use the convention that $b_k = 0$ for $k < 1$ and $b_k = d + 1$ for $k > d$. It is easy to see the following:

(a) If $j \geq i$, then $[b_i^\alpha, b_{i+1}^\alpha] \subseteq [b_{i-1}, b_{i+1}]$;
(b) If $j < i$, then $[b_i^\alpha, b_{i+1}^\alpha] \subseteq [b_i, b_{i+1}]$;
(c) If $j \leq i' + 1$, then $[b_{i'}^\omega, b_{i'+1}^\omega] \subseteq [b_{i'}, b_{i'+2}]$;
(d) If $j > i' + 1$, then $[b_{i'}^\omega, b_{i'+1}^\omega] \subseteq [b_{i'}, b_{i'+1}]$.

From the above case distinction, we observe that when $j > i' + 1$, the interiors of $[b_i^\alpha, b_{i+1}^\alpha]$ and $[b_{i'}^\omega, b_{i'+1}^\omega]$ are disjoint, since $|i' - i| \geq 2$. When $j \leq i' + 1$ and $i' \geq i + 2$, these interiors are also disjoint. When $j \leq i' + 1$ and $i' \leq i - 2$, then (b) and (c) are applicable, and the two interiors are also disjoint.

Hence, we always have that the two interiors above are disjoint. Further, from (a)–(d) above, these interiors contain only integers from $[n] \setminus B \cup \{b_i, b_{i'+1}\}$. These two statements imply that $b_{i+1}^\alpha - b_i^\alpha + b_{i'+1}^\omega - b_{i'}^\omega \leq n - d + 4$.

By Lemma 6, the shortest path between S_i and B^α is $b_i^\alpha - b_{i+1}^\alpha + n - d + 1$, whereas the shortest path between $S_{i'}$ and B^ω is $b_{i'}^\omega - b_{i'+1}^\omega + n - d + 1$. Then the sum of the distances is

$$b_i^\alpha - b_{i+1}^\alpha + n - d + 1 + b_{i'}^\omega - b_{i'+1}^\omega + n - d + 1 \geq 2(n - d + 1) - (n - d + 4) \geq n - d - 2 \geq p - 2.$$

This implies that $c_i + c_{i'} \geq p + 1$, a contradiction to the fact that $(c_0, \dots, c_d)$ is a sparse composition of p.

Next, by Lemma 7, each +-component of τ contains exactly one source subset. Hence, no subset is a +-subset of more than one co-signotope among $\tau_0, \dots, \tau_d$. Therefore, τ has exactly p +-subsets, and each +-component of τ that contains S_i corresponds exactly to the +-component of τ_i. This also implies that τ is unique and $\Delta(\tau) = (\tau_0, \tau_1, \dots, \tau_d)$. It follows that $(c_0, \dots, c_d)$ is the p-sequence of τ, completing the proof of the lemma. ◀

6 Proof of Theorem 1

Equipped with Corollary 15, Lemma 16, and Lemma 17, we are now ready to prove Theorem 1.

▶ **Theorem 1** (Restated from Section 2.1)**.** *Let $n, \tilde{n}, d, p$ be integers such that $0 \leq p \leq \min\{n, \tilde{n}\} - d$. Then there exists a bijection between $\bar{\mathcal{S}}_{\leq p}(n, d)$ and $\bar{\mathcal{S}}_{\leq p}(\tilde{n}, d)$ that preserves the relation $\preceq_{\bar{S}}$.*

Proof of Theorem 1. Consider the following mapping $\zeta_{n,\tilde{n},d,p}$ from a co-signotope $\tau \in \bar{\mathcal{S}}_{\leq p}(n, d)$ to a co-signotope $\tilde{\tau} \in \bar{\mathcal{S}}_{\leq p}(\tilde{n}, d)$. Let $(p_0, \dots, p_d)$ be the p-sequence of τ. We first obtain the +-component decomposition $(\tau_0, \tau_1, \dots, \tau_d)$ of τ. Next, we use the bijection

$h_{n,\tilde{n},d,p_i,i}$ in Corollary 15 to map each of $\tau_i \in \bar{\mathcal{S}}_{p_i,i}(n,d)$ to $\tilde{\tau}_i \in \bar{\mathcal{S}}_{p_i,i}(\tilde{n},d)$. Then from the tuple $(\tilde{\tau}_0, \tilde{\tau}_1, \ldots, \tilde{\tau}_d)$, we can combine their $+$-subsets to construct $\tilde{\tau}$. By Lemma 17, $\tilde{\tau} \in \bar{\mathcal{S}}_p(\tilde{n},d)$.

By Corollary 15, Lemma 16, and Lemma 17, the mapping $\zeta_{n,\tilde{n},d,p}$ is injective. Also by these corollary and lemmas, the mapping $\zeta_{\tilde{n},n,d,p}$ maps $\tilde{\tau}$ back to τ and generally this mapping maps a signotope in $\bar{S}_p(\tilde{n},d)$ to $\bar{S}_p(n,d)$. This implies that $\zeta_{n,\tilde{n},d,p}$ is a bijection between $\bar{S}_p(n,d)$ and $\bar{S}_p(\tilde{n},d)$.

It remains to prove that $\zeta_{n,\tilde{n},d,p}$ preserves the relation $\preceq_{\bar{S}}$. For this, it is sufficient to prove that $\zeta_{n,\tilde{n},d,p}$ preserves the single step relation. Let τ and ρ be two d-co-signotopes in $\bar{\mathcal{S}}_{\leq p}(n,d)$ such that $\tau^{-1}(+) \subset \rho^{-1}(+)$ and $|\rho^{-1}(+)| = |\tau^{-1}(+)| + 1 = k+1$ for some k. Let $(\tau_0, \ldots, \tau_d) = \Delta(\tau)$ and $(\rho_0, \ldots, \rho_d) = \Delta(\rho)$. This implies that $\Delta(\tau)$ and $\Delta(\rho)$ agree in all coordinates, except for some i-th coordinate, where τ_i and ρ_i differ by a single step. Let $\tilde{\tau}$ and $\tilde{\rho}$ be the images of τ and ρ, respectively, in the bijection above. By Corollary 15, it follows that $\Delta(\tilde{\tau})$ and $\Delta(\tilde{\rho})$ also agree in all coordinates, except for some i-th coordinate, where the two corresponding co-signotopes differ by a single step. This in turns implies that $\tilde{\tau}$ and $\tilde{\rho}$ differ by a single step. This completes the proof of the theorem. ◀

A simple bijection

Although the mapping $\zeta_{n,\tilde{n},d,p}$ in the proof above satisfies the conditions of Theorem 1, its description is rather complicated. We now provide a simpler description of the bijection. In other words, we will prove that the mapping $\zeta_{n,\tilde{n},d,p}$ is identical to the mapping $\phi_{n,\tilde{n},d,p}$ as described below.

For a co-signotope $\tau \in \bar{\mathcal{S}}_p(n,d)$, a d-subset $B = (b_1, \ldots, b_d)$, we define $\gamma_{\tau,\tilde{n}}(B)$ as the tuple obtained from B by replacing b_j by $b_j + \tilde{n} - n$ if the (τ, B, j)-series is right-aligned.

▶ **Definition 18.** *Let $n, \tilde{n}, d, p$ be positive integers. Let $\phi_{n,\tilde{n},d,p}$ map a co-signotope $\tau \in \bar{\mathcal{S}}_{\leq p}(n,d)$ to a sign function $\tilde{\tau} : \binom{\tilde{n}}{d} \to \{+,-\}$ such that*

$$\tilde{\tau}^{-1}(+) = \Big\{\gamma_{\tau,\tilde{n}}(B) \mid B \in \tau^{-1}(+)\Big\}.$$

▶ **Lemma 19.** *$\phi_{n,\tilde{n},d,p}$ is a bijection as guaranteed by Theorem 1.*

Proof. Consider the mapping $\zeta_{n,\tilde{n},d,p}$ as described in the proof of Theorem 1. We prove that it is identical to $\phi_{n,\tilde{n},d,p}$. Note that the mapping $\zeta_{n,\tilde{n},d,p}$ essentially maps each $+$-subset of τ to a $+$-subset of $\tilde{\tau}$. In the step of computing the $+$-component decomposition of τ and the step of combining $(\tilde{\tau}_0, \tilde{\tau}_1, \ldots, \tilde{\tau}_d)$ into $\tilde{\tau}$, the $+$-subsets do not change, or rather, each $+$-subset is mapped to itself. In the middle step when we apply $h_{n,\tilde{n},d,s_i,i}$, the mapping of the $+$-subsets is done through $g^{-1}_{\tilde{n},d,i} \circ g_{n,d,i}$, by the definition of $h_{n,\tilde{n},d,i}$ in Corollary 15. By Definition 11, we can describe $g^{-1}_{\tilde{n},d,i} \circ g_{n,d,i}$ as follows: For a d-subset $B = (b_1, \ldots, b_d)$ in the same $+$-component of τ as S_i, $g^{-1}_{\tilde{n},d,i}(g_{n,d,i}(B))$ is obtained by replacing b_j with b_j for $j \in [i]$ and with $b_j + \tilde{n} - n$ for $j \in [i+1, d]$. Combining this description with Lemma 9, we obtain that $g^{-1}_{\tilde{n},d,i}(g_{n,d,i}(B)) = \gamma_{\tau,\tilde{n}}(B)$. It follows that $\zeta_{n,\tilde{n},d,p} \equiv \phi_{n,\tilde{n},d,p}$, as claimed. ◀

7 Plus count

Theorem 1 implies that given d and p, $\bar{S}_p(n,d)$ is a fixed number for all $n \geq p+d$. This motivates the following definition.

▶ **Definition 20.** *For two integers $d \geq 1$ and $p \geq 0$, the* plus count *with respect to d and p, denoted by $P_{d,p}$, is the size of $\bar{S}_p(n,d)$ for any $n \geq p+d$.*

Table 1 The values of $P_{d,p}$ for small d (vertical) and p (horizontal).

d / p	0	1	2	3	4	5	6	7	8	9	10
1	1	2	2	2	2	2	2	2	2	2	2
2	1	3	5	9	14	21	33	47	68	96	135
3	1	4	9	20	41	78	146	264	465	804	1368
4	1	5	14	36	86	192	413	857	1732	3422	6633
5	1	6	20	58	155	386	920	2110	4691	10176	21604
6	1	7	27	87	255	693	1790	4438	10636	24799	56485
7	1	8	35	124	394	1154	3192	8444	21534	53292	128571

From computer experiment, we obtain the values of $P_{d,p}$ for small d and p, as presented in Table 1.

We can provide a characterization of the plus counts based on the correspondences in Lemmas 14, 16, and 17. Let $F_{d,i}(p)$ be the number of (d,i)-Ferrers diagrams with respect to p, and let $\mathcal{D}_{d+1,p}$ be the set of all sparse compositions of p. Then the lemmas above give the following formula

$$P_{d,p} = \sum_{(c_0,\ldots,c_d)\in\mathcal{D}_{d+1,p}} \prod_{i=0}^{d} F_{d,i}(c_i). \tag{1}$$

For the remainder of this section, we discuss a few values of d and p. Due to space constraints, all the proofs in this section are presented in the full version [3]. We start with a few simple observations.

▶ **Lemma 21.** *It holds:*
(a) *For all $d \geq 1$: $P_{d,0} = 1$.*
(b) *For all $p > 0$: $P_{1,p} = 2$/*
(c) *For all $d \geq 1$: $P_{d,1} = d + 1$.*

Next, to prove the formulae for higher values of p, we show a few observations on $F_{d,i}$.

▶ **Lemma 22.** *For non-negative integers d, i, p with $d \geq i$, it holds:*
(a) $F_{d,i}(p) = F_{d,d-i}(p)$.
(b) $F_{d,i}(p) = \sum_{c=1}^{p} F_{i,0}(c)F_{d-i,0}(p+1-c)$.
(c) *For $d = 1$, $F_{d,i}(p) = 1$.*
(d) *For $d > 1$, $F_{d,i}(0) = 1$, $F_{d,i}(1) = 1$, $F_{d,0}(2) = 1$, and $F_{d,0}(3) = 2$.*
(e) *For $0 < i < d$, $F_{d,i}(2) = 2$.*
(f) $F_{d,1}(3) = F_{d,d-1}(3) = 4$. *For $1 < i < d-1$, $F_{d,i}(3) = 5$.*

Equipped with the lemma above, we can show the following.

▶ **Lemma 23.** *For $d \geq 1$, $P_{d,2} = \frac{1}{2}d^2 + \frac{3}{2}d$ and $P_{d,3} = \frac{1}{6}d^3 + d^2 + \frac{17}{6}d - 2$.*

Lastly, recall that an integer partition of n is the number of ways of writing n as the (unordered) sum of positive integers. Let $\pi(n)$ be the number of integer partitions of n. Further, let $\delta(n)$ be the number of ways of writing n as the (unordered) sum of distinct positive integers.

▶ **Lemma 24.** $P_{2,p} = \pi(p) + \sum_{i=0}^{p} \delta(i) \cdot \delta(p-i)$.

Note that $\pi(n)$ and $\delta(n)$ are counted by the OEIS sequences A000041 and A000009 [14], respectively. Further, the sum $\sum_{i=0}^{p} \delta(i) \cdot \delta(p-i)$ is counted by the OEIS sequence A022567. Hence, $P_{2,p}$ is counted by the sum of the two sequences A000041 and A022567.

8 Concluding remarks

Firstly, we note that Theorem 1 is tight in the sense that we cannot relax the condition $p \leq \min\{n, \tilde{n}\} - d$. As an example, consider the case when $d = n - 1 = \tilde{n} - 2$ and $p = 2$. In other words, we consider the possibility of a bijection between $\bar{S}_{\leq 2}(n, n-1)$ and $\bar{S}_{\leq 2}(n+1, n-1)$ or equivalently a bijection between $S_{\leq 2}(n, 1)$ and $S_{\leq 2}(n+1, 2)$. As shown in [3], we have

$$|S_{\leq 2}(n,1)| = 1 + n + \binom{n}{2}, \qquad |S_{\leq 2}(n+1,2)| = 1 + n + \binom{n}{2} + n - 1.$$

Hence, there cannot be any bijection between $S_{\leq 2}(n, 1)$ and $S_{\leq 2}(n+1, 2)$.

An intuitive reason is that when $p > n - d$, Observation 8 no longer holds. That is, there can be a flat series with only $+$-subsets. For example, when $p = n - d + 1$, there exists a co-signotope $\tau \in \bar{S}_p(n, d)$ such that its $+$-subsets form exactly the whole (τ, S_i, i)-series for some $i \in [0, d]$. In other words, its only $+$-component contains both S_i and S_{i+1}. However, for $\tilde{n} > n$ (i.e., $p \leq \tilde{n} - d$), Observation 8 holds again, and it is unclear if τ should be mapped to a co-signotope $\tilde{\tau} \in \bar{S}_p(\tilde{n}, d)$ with a nonempty $C_i^{\tilde{\tau}}$ or a nonempty $C_{i+1}^{\tilde{\tau}}$.

Secondly, from Figure 1, it seems that the bijection of Theorem 1 could be proved by the following simple geometric argument: Suppose $n < \tilde{n}$; we remove $\tilde{n} - n$ hyperplanes that are completely in the negative side of the extending hyperplane of the one-element extension of $\mathbf{X}_c^{\tilde{n},d}$. However, this argument does not work in a high dimension. For example, the positive side may consist of these two points: the intersection of the hyperplanes $H_1, \ldots, H_d$ and that of $H_{\tilde{n}-d+1}, \ldots, H_{\tilde{n}}$. For d and $\tilde{n}$ such that $d > \tilde{n} - d + 1$, there are then no hyperplanes completely on the negative side.

Lastly, it would be interesting to obtain understanding on more values of the plus counts, for example, their exact counts, generating function, or more relations. As a starter, we conjecture that $P_{d,3} = P_{d-1,3} + P_{d-1,2} + P_{d-1,1} + 3$.

Abstract

We present new results on 2- and 3-hop spanners for geometric intersection graphs. These include improved upper and lower bounds for 2- and 3-hop spanners for many geometric intersection graphs in $\mathbb{R}^d$. For example, we show that the intersection graph of n balls in $\mathbb{R}^d$ admits a 2-hop spanner of size $O^*\left(n^{\frac{3}{2}-\frac{1}{2(2\lfloor d/2\rfloor+1)}}\right)$ and the intersection graph of n fat axis-parallel boxes in $\mathbb{R}^d$ admits a 2-hop spanner of size $O(n\log^{d+1} n)$.

Furthermore, we show that the intersection graph of general semi-algebraic objects in $\mathbb{R}^d$ admits a 3-hop spanner of size $O^*\left(n^{\frac{3}{2}-\frac{1}{2(2D-1)}}\right)$, where D is a parameter associated with the description complexity of the objects. For such families (or more specifically, for tetrahedra in $\mathbb{R}^3$), we provide a lower bound of $\Omega(n^{\frac{4}{3}})$. For 3-hop and axis-parallel boxes in $\mathbb{R}^d$, we provide the upper bound $O(n\log^{d-1} n)$ and lower bound $\Omega\left(n(\frac{\log n}{\log\log n})^{d-2}\right)$.

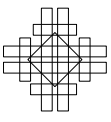
1 Introduction

A *spanner* of a graph G is a subgraph G' that approximately preserves the distances between pairs of vertices in G. More formally, let $G=(V,E)$ be a simple graph. A spanning subgraph $G'=(V,E')$ is called a *t-spanner* for G if for every two vertices $x,y\in V$ $d_{G'}(x,y)\leq t\cdot d_G(x,y)$ where $d_G(x,y)$ denotes the shortest path distance between x and y in G. Here, $t\geq 1$ is a constant called the *stretch factor* (or *stretch* for short). Spanners are an important concept in graph theory and computer science, particularly in the context of geometric intersection graphs, where vertices represent geometric objects and edges represent intersections between

© Sujoy Bhore, Timothy M. Chan, Zhengcheng Huang, Shakhar Smorodinsky, and Csaba D. Tóth;
licensed under Creative Commons License CC-BY 4.0



these objects. The ability to construct spanners for geometric intersection graphs with fewer edges is crucial because it enables efficient algorithms for problems such as shortest path computation, network design, and routing while maintaining proximity to the original geometric distances. By using spanners, one can often reduce the complexity of geometric problems without sacrificing the quality of the solution (see, e.g., [31, 35, 38, 39, 40]).

The following theorem is a cornerstone in the theory of spanners for general graphs:

▶ **Theorem 1.1** ([3]). *Let $G = (V, E)$ be a simple undirected graph on n vertices. Let $t \geq 1$ be a fixed integer parameter. Then G contains a $(2t-1)$-spanner G' with $O(n^{1+\frac{1}{t}})$ edges.*

Note that the above theorem is non-trivial only for $t \geq 2$ or stretch factor at least 3. Indeed, one cannot hope to obtain a 2-spanner with $o(n^2)$ edges in general as is exemplified by the complete bi-partite graph $K_{\lfloor \frac{n}{2} \rfloor, \lceil \frac{n}{2} \rceil}$. The general bound $O(n^{1+\frac{1}{t}})$ is conjectured to be optimal due to the *Erdős Girth Conjecture* [25], and the spanner G' of this size can be computed by a greedy algorithm. It would be interesting to ask what families of graphs admit 2-spanners with $o(n^2)$ edges or 3-spanners with $o(n^{3/2})$ edges.

The **intersection graph** of a set system $(X, \mathcal{F})$ is a graph $G = (\mathcal{F}, E)$, where the vertices correspond to the sets in $\mathcal{F}$, and there is an edge between sets $A, B \in \mathcal{F}$ if and only if $A \cap B \neq \emptyset$. Every edge has unit weight. For intersection graphs, t-spanners are also called *t-hop spanners* to emphasize the use of hop distance. In this paper, our goal is to obtain hop spanners for geometric intersection graphs that are smaller than guaranteed by Theorem 1.1.

Previous work on spanners in intersection graphs. Initial work on spanners for geometric intersection graphs was motivated by wireless communication, and was limited to unit disk graphs in the plane. In this setting, spanners for weighted graphs were also considered, where the weight of an edge is the distance between the disk centers [28, 29, 30]. Recent work focused on hop spanners for unit disk graphs [10, 11, 22], and intersection graphs of other geometric objects (including string graphs) [16, 20]. Most previous bounds are constrained to objects in the plane. Chan and Huang [16] use shallow cuttings to show that any family of n objects, with union complexity bounded by $\mathcal{U}(n)$, admits a 2-hop spanner of size $O(\mathcal{U}(n) \log n)$. This yields an $O(n \log n)$ bound for disks or pseudodisks in the plane [33]; $n \log n \cdot 2^{O(\log^* n)}$ for fat objects of constant algebraic description complexity [4], and in particular $O(n \log n \log^* n)$ for fat triangles in the plane [4]. Lower bounds can be derived from constructions for geometric intersection graphs with girth $2t+1$, as a t-spanner contains the entire graph [7, 21, 41]. In particular, Davies [21] constructed families of axis-aligned boxes in $\mathbb{R}^3$ whose intersection graph has unbounded girth and $\omega(n)$ edges. The boxes in Davies' construction project to squares in the xy-plane, so they can be lifted to hypercubes in $\mathbb{R}^4$ with the same intersection pattern. See Table 1 for a list of known results.

1.1 New results

In this paper, we focus on 2- and 3-spanners. Recall that in general there is no hope to obtain a 2-spanner of sub-quadratic size (in n) nor a 3-spanner of $o(n^{3/2})$ size for general graphs with n vertices. No sub-quadratic bounds were previously known for 2-spanners for intersection graphs in dimension 3 or more even for unit balls. And no sub-$n^{3/2}$ bounds were previously known for 3-spanners for intersection graphs of non-fat objects in dimension above 2, even for simplices. We give the first 2-spanner constructions of sub-quadratic size (in fact, $O(n^{3/2})$ or better) for many types of fat objects, including balls, and we give the first 3-spanner constructions of sub-$n^{3/2}$ size for many types of non-fat objects, including

Table 1 Summary of previously known results. The trivial lower bound in each case is $\Omega(n)$. The upper bound in $(*)$ generalizes to $O(\mathcal{U}(n)\log n)$ for objects with union complexity $\mathcal{U}(.)$; and the lower bound holds for homothets of any convex body in the plane. The upper bound in $(**)$ holds for fat objects of constant algebraic description complexity. The function $\alpha_k(.)$ denotes the k-th function in the inverse Ackermann hierarchy: $\alpha_0(n) = n/2$, $\alpha_1(n) = \log n$, $\alpha_2(n) = \log^* n$ (the iterated logarithm), $\alpha_3(n) = \log^{**} n$ (the iterated iterated logarithm), etc.

simplices. Furthermore, we complement our upper bounds with a number of lower bounds ruling out near-linear-size spanners for many types of objects. See Table 2 for a detailed list of all results.[1] Our results answer open questions by Chan and Huang [16].[2]

One of our main results deals with 2- and 3-spanners for semi-algebraic graphs. The notion of semi-algebraic graphs was the focus of several recent papers. Most notably, Fox et al. [27] provided improved bounds on Zarankiewicz's problem for the class of semi-algebraic graphs. Informally, a semi-algebraic graph $G = (V, E)$ is a bipartite graph where the vertices can be represented as points in $\mathbb{R}^d$ for some fixed small constant dimension d and for every pair of vertices u, v we have that $\{u, v\} \in E$ if some boolean combination of a constant number of inequalities involving $2d$-variate polynomials of constant degree is satisfied, where the variables in the polynomials are the coordinates of the two points representing u and v (see below for a formal definition). Almost all intersection graphs in the literature are, in fact, semi-algebraic. One of our main results is a bound of the form $O(n^{\frac{3}{2}-\delta_d})$ for 3-hop spanner for arbitrary intersection graphs of semi-algebraic sets in $\mathbb{R}^d$ and for 2-hop for semi-algebraic sets that are also "fat" where δ_d is a constant that depends on the description complexity of the objects. In this regard, it is important to note that without the fatness assumption, no sub-quadratic 2-hop spanner can be obtained as the graph $K_{n,n}$, which has n^2 edges, can be realized as the intersection of n horizontal and n vertical narrow rectangles, and any 2-hop spanner must contain all n^2 edges. Also, a common property for semi-algebraic intersection graphs is that they all have bounded VC-dimension. However, bounded VC-dimension by itself does not guarantee $o(n^{\frac{3}{2}})$ edges as demonstrated later in Theorem 4.6. Thus, the extra geometric properties that these graphs possess are crucial in order to obtain such bounds. Perhaps not surprisingly, one of our main tools for tackling this problem is an application of the divide-and-conquer, specifically the **polynomial partitioning** technique. This technique was introduced by Guth and Katz in their groundbreaking work on the *Erdős distinct distances* problem [32]. This method involves partitioning the space into cells defined by low-degree polynomials. A key result states that for a set of n points in $\mathbb{R}^d$, and for any $D > 0$, there exists a d-variate polynomial f of degree D such that the zero set $Z(f)$ of f partitions $\mathbb{R}^d$ into $O(D^d)$ cells (i.e., connected components of $\mathbb{R}^d \setminus Z(f)$), each containing in its interior at most $\frac{n}{D^d}$ points.

2 Upper Bounds for 3 Hops

In this section, we prove new upper bounds for 3-hop spanners for geometric intersection graphs. We begin with an easy lemma about general bipartite graphs in a lop-sided case:

▶ **Lemma 2.1.** *Let $G = (U \cup V, E)$ be a graph where $|U| = m$, $|V| = n$, and V is an independent set. Then G has a 3-hop spanner of size $O(m^2 + n)$.*

Proof. We construct a subgraph H of G as follows. For each $v \in V$ with $\deg(v) \geq 1$, let e_v be an arbitrary edge incident to v in G, and add e_v to H. Add $G[U]$ to H. Furthermore, for each pair of vertices $u, u' \in U$, let $\pi_{u,u'}$ be a 2-hop path between u and u' in G, if such

[1] In this paper, we use the O^* notation to hide n^ε factors for an arbitrarily small constant $\varepsilon > 0$.

[2] At the very end of their paper, Chan and Huang [16] specifically wrote: "Another question is whether near-linear bounds are possible for other intersection graphs not addressed here, e.g., for simplices in $\mathbb{R}^3$. Here, one might want to start more modestly with any upper bound better than for general graphs." Our $\Omega(n^{4/3})$ lower bound answers the question in the first sentence in the negative for simplices in $\mathbb{R}^3$, while our upper bounds show that the goal in the second sentence is attainable at least in the case of 3 hops.

a path exists, and add $\pi_{u,u'}$ to H. Clearly, H has $O(m^2+n)$ edges. We show that H is a 3-spanner of G. By construction, for each edge $e = uu'$ in $G[U]$, the distance between u and u' in H is one. Consider an edge uv in G with $u \in U$ and $v \in V$. If $e_v = uv$, then we can go from u to v in 1 hop. Otherwise, $e_v = u'v$, for some $u' \neq u$. Notice that in that case a 2-hop path $\pi_{u,u'}$ indeed exists and we can go from u to v in 3 hops by concatenating $\pi_{u,u'}$ with $u'v$. ◀

The above lemma allows us to almost immediately recover the standard $O(n^{3/2})$ upper bound on 3-hop spanners for general graphs (greedy algorithm yields same bound [3]):

▶ **Corollary 2.2.** *Every graph $G = (V, E)$ with n vertices has a 3-hop spanner of size $O(n^{3/2})$.*

Proof. Partition the vertices $V = \bigcup_{i=1}^{k} V_i$ into $k = \sqrt{n}$ groups of size $\sqrt{n}$ each, and apply Lemma 2.1 to each of the graphs $G_i = (V, E_i)$ where $E_i = E(G[V_i]) \cup E[V_i, V \setminus V_i]$. Namely, the edges in each graph comprise the inter-group edges and the bipartite edges between the group and its complement. Take the union of the spanners, with combined size $O(\sqrt{n} \cdot ((\sqrt{n})^2 + n)) = O(n^{3/2})$. It is easy to check that the resulting graph is indeed a 3-hop spanner as any original edge belongs to at least one of the graphs G_i as it is either induced by the U part of one of the graphs or a bipartite edge in one of the graphs. ◀

2.1 Semi-algebraic graphs

Here we improve the general bound $O(n^{3/2})$ for 3-hop spanners for semi-algebraic graphs. A natural approach is to apply known geometric divide-and-conquer and partitioning techniques to obtain biclique covers of sub-quadratic size, which then yields sub-quadratic upper bounds for 3-hop spanners. Unfortunately, for many higher-dimensional families of objects, the biclique cover bound can be much worse than $O(n^{3/2})$. Nevertheless, we show that these divide-and-conquer techniques can work synergistically with Lemma 2.1 to beat $O(n^{3/2})$: Specifically, we stop the recursion early when subproblems become sufficiently lop-sided and it is advantageous to switch to the $O(m^2+n)$ bound. In order to apply a divide-and-conquer we apply the polynomial partitioning technique as follows.

▶ **Theorem 2.3** (Guth and Katz [32, Theorem 4.1])**.** *Let P be a set of m points in $\mathbb{R}^D$ for a constant $D \in \mathbb{N}$. For every parameter $1 < k < m$, there exists a polynomial $f \in \mathbb{R}[x_1, \ldots, x_D]$ of degree $\deg(f) \in O(k^{1/D})$ such that every connected component of $\mathbb{R}^d \setminus Z(f)$ contains at most m/k points.*

This result generalizes to points lying in an irreducible variety.

▶ **Theorem 2.4** (Fox et al. [27, Theorem 4.3])**.** *Let P be a set of m points in a d-dimensional irreducible variety $V \subseteq \mathbb{R}^D$ for constant $1 \leq d \leq D \in \mathbb{N}$. For every parameter $1 < k < m$, there exists a polynomial $f \in \mathbb{R}[x_1, \ldots, x_D]$ of degree $\deg(f) \in O(k^{1/d})$ such that f is not in the (prime) ideal $I(V)$ and every connected component of $\mathbb{R}^d \setminus Z(f)$ contains at most m/k points.*

▶ **Corollary 2.5.** *Let P be a set of m points in a D-dimensional variety $V \subset \mathbb{R}^D$ for constants $1 \leq d \leq D \in \mathbb{N}$. For every parameter $1 < k < m$, there exists a partition $P = \bigcup_{i=1}^{q} P_i$ into $q = O(k)$ sets such that $|P_i| \leq m/k$; and for every $i = 1, \ldots q$, there is a connected set $\Delta_i \subset \mathbb{R}^d$, called a* cell*, such that $P_i \subset \Delta_i$ and the zero set $Z(h)$ of any polynomial of bounded degree crosses[3] $O(k^{1-1/D})$ cells (consequently, any semi-algebraic set crosses $O(k^{1-1/D})$ cells).*

[3] A set S *crosses* a cell Δ if both $\Delta \cap S$ and $\Delta \setminus S$ are nonempty.

Proof of Corollary 2.5 is deferred to arXiv [9].

▶ Remark 2.6. Corollary 2.5 uses a decomposition of the zero set of a partitioning polynomial into a union of irreducible varieties. For the algorithmic problem of constructing a partition $P = \bigcup_{i=1}^{q} P_i$ and corresponding cells Δ_i, one can avoid computing irreducible components with a multilevel partition; see [36] or [1].

▶ **Theorem 2.7.** *Let U and V be two sets of n elements. We are given points $p_1(u), \ldots, p_\ell(u) \in \mathbb{R}^D$ for each $u \in U$ and semi-algebraic sets $S_1(v), \ldots, S_\ell(v) \subset \mathbb{R}^D$ of constant description complexity for each $v \in V$, where D and ℓ are constants. For any ℓ-variate Boolean formula Φ, the graph*

$$G_\Phi[U,V] \;:=\; (U \cup V,\ \{(u,v) \in U \times V :\ \Phi([p_1(u) \in S_1(v)], \ldots, [p_\ell(u) \in S_\ell(v)])\})$$

has a 3-hop spanner with $O^*(n^{\frac{3D-2}{2D-1}}) = O^*(n^{\frac{3}{2} - \frac{1}{2(2D-1)}})$ edges.

Proof. We consider the more general setting, where $|U| = m$ and $|V| = n$. Let $T_\ell(m,n)$ denote the worst-case optimal size of a 3-hop spanner.

Let r be a parameter. By Corollary 2.5[4], we can partition $\mathbb{R}^D$ into $O(r^D)$ cells such that each cell contains at most m/r^D points of $\{p_\ell(u) : u \in U\}$, and each semi-algebraic set $S_\ell(v)$ crosses $O(r^{D-1})$ cells. For each cell Δ, let $U_\Delta = \{u \in U : p_\ell(u) \in \Delta\}$, $V_\Delta = \{v \in V : \partial S_\ell(v) \text{ crosses } \Delta\}$, $V'_\Delta = \{v \in V : S_\ell(v) \text{ contains } \Delta\}$, and $V''_\Delta = \{v \in V : S_\ell(v) \text{ does not intersect } \Delta\}$. Arbitrarily partition V_Δ into $\left\lceil \frac{|V_\Delta|}{n/r} \right\rceil$ subsets $V_\Delta^{(j)}$ of size at most n/r each, and recursively construct a 3-hop spanner for $G_\Phi[U_\Delta, V_\Delta^{(i)}]$ for each $V_\Delta^{(i)}$. Since $\sum_\Delta |V_\Delta| = O(nr^{D-1})$, the number of such recursive calls is $O(r^D)$. Furthermore, for each cell Δ, recursively construct a 3-hop spanner for $G_{\Phi'}[U_\Delta, V'_\Delta]$ and a 3-hop spanner for $G_{\Phi''}[U_\Delta, V''_\Delta]$, where Φ' (resp., Φ'') is the $(\ell-1)$-variate Boolean formula obtained by setting the ℓ-th variable to true (resp., false). The union of these spanners yields a 3-hop spanner for $G_\Phi[U,V]$. We thus obtain the following recurrence for $\ell \geq 1$:

$$T_\ell(m,n) \;\leq\; O(r^D)\left(T_\ell\left(\frac{m}{r^D}, \frac{n}{r}\right) + T_{\ell-1}(m,n)\right). \tag{1}$$

For base cases, we have $T_0(m,n) = O(m+n)$ (since a biclique $U \times V$ has a 3-hop spanner of linear size, consisting of two stars, centered at a fixed vertex of U and a fixed vertex of V), and we can use the upper bound $T_\ell(m,n) \leq O(m^2+n)$ for every ℓ by Lemma 2.1.

Assume inductively that $T_{\ell-1}(m,n) = O^*(m^{\frac{2D-2}{2D-1}} n^{\frac{D}{2D-1}})$ for $\sqrt{n} \leq m \leq n^D$. Choose r to be a large constant. Expand the recurrence for k levels so that $(m/r^{Dk})^2 \approx n/r^k$, i.e., $r^k \approx (m^2/n)^{\frac{1}{2D-1}}$. Then the recurrence (1) yields

$$\begin{aligned} T_\ell(m,n) \;&\leq\; \sum_{i=1}^{k} O(1)^i O(r^D) O(r^{Di}) \left(\frac{m}{r^{Di}}\right)^{\frac{2D-2}{2D-1}} \left(\frac{n}{r^i}\right)^{\frac{D}{2D-1}} \;+\; O(1)^k O(r^{Dk}) \left(\left(\frac{m}{r^{Dk}}\right)^2 + \frac{n}{r^k}\right) \\ &\leq\; O(1)^k r^D \cdot \left(m^{\frac{2D-2}{2D-1}} n^{\frac{D}{2D-1}} \;+\; n r^{k(D-1)}\right) \\ &=\; O(1)^k r^D \cdot \left(m^{\frac{2D-2}{2D-1}} n^{\frac{D}{2D-1}} \;+\; n(m^2/n)^{\frac{D-1}{2D-1}}\right) \;=\; O(1)^{\log_r m} r^D \cdot m^{\frac{2D-2}{2D-1}} n^{\frac{D}{2D-1}}. \end{aligned}$$

Making r an arbitrarily large constant, this yields $T_\ell(m,n) = O^*(m^{\frac{2D-2}{2D-1}} n^{\frac{D}{2D-1}})$ for $\sqrt{n} \leq m \leq n^D$. ◀

[4] For $D \leq 4$, we may alternatively use traditional $(1/r)$-*cuttings* [2, 18, 34] (in fact, later in Theorem 2.9, we will switch back to using cuttings), but for $D \geq 5$, optimal bounds on *vertical decompositions* are open and polynomial partitioning gives better results.

Theorem 2.7 immediately implies an $o(n^{3/2})$ bounds on 3-hop spanners for intersection graphs of any family of objects with constant description complexity.

▶ **Corollary 2.8.** *The intersection graph of every set of n simplices (or polyhedra each of constant complexity) in a constant dimension d has a 3-hop spanner with $O\left(n^{\frac{3}{2}-\frac{1}{O(d^2)}}\right)$ edges. Specifically, for $d=3$, the bound is $O^*(n^{10/7})$.*

Proof. Polyhedra of constant complexity can be decomposed into $O(1)$ simplices. A simplex in $\mathbb{R}^d$ has $d+1$ vertices, so it can be encoded as a point in $\mathbb{R}^{d(d+1)}$, and the set of all simplices intersecting a given simplex maps to a semi-algebraic set in $\mathbb{R}^{d(d+1)}$. We can thus apply Theorem 2.7 with $D=d^2+d$.

We can decrease D with more care. For example, for $d=3$, two simplices s and s' intersect if and only if (a) a vertex of s is inside s', or (b) an edge pq of s intersects a facet τ of s', or vice versa. The toughest case concerns (b), which is equivalent to: (i) the line through pq intersects τ, and (ii) p lies above the plane through τ, and (iii) q lies below the plane through τ, or vice versa. In (i), the line through pq can be encoded as a point in $\mathbb{R}^4$, whereas in (ii) or (iii), p or q is already a point in $\mathbb{R}^3$. We can thus apply Theorem 2.7 with $D=4$ (rather than $d(d+1)=12$). ◀

2.2 Improvement for point-halfspace incidence graphs

For incidence graphs between points and halfspaces, we can improve the exponent by switching to shallow cuttings [37] for the geometric divide-and-conquer:

▶ **Theorem 2.9.** *Let P be a set of n points and S be a set of n halfspaces in a constant dimension D. Then their incidence graph $G[P,S] := (P \cup S,\ \{(p,s) \in P \times S : p \in s\})$ has a 3-hop spanner with $O^*\left(n^{\frac{3\lfloor D/2\rfloor-2}{2\lfloor D/2\rfloor-1}}\right) = O^*\left(n^{\frac{3}{2}-\frac{1}{2(2\lfloor D/2\rfloor-1)}}\right)$ edges.*

Proof of Theorem 2.9 is deferred to arXiv version [9]. As one application, we obtain improved bounds for the case of balls, by a standard lifting mapping from balls to halfspaces:

▶ **Corollary 2.10.** *Every bipartite intersection graph between n red balls and n blue balls in a constant dimension d has a 3-hop spanner with $O^*(n^{\frac{3\lfloor d/2\rfloor+1}{2\lfloor d/2\rfloor+1}}) = O^*(n^{\frac{3}{2}-\frac{1}{2(2\lfloor d/2\rfloor+1)}})$ edges. For example, for $d=3$, the bound is $O^*(n^{4/3})$; for $d \in \{4,5\}$, it is $O^*(n^{7/5})$.*

Proof. A red ball with center $(x_1,\ldots,x_d)$ and radius y intersects a blue ball with center $(a_1,\ldots,a_d)$ and radius b iff $(x_1-a_1)^2+\cdots+(x_d-a_d)^2 \le (y+b)^2$, i.e., the point $(x_1,\ldots,x_d,y,x_1^2+\cdots+x_d^2-y^2) \in \mathbb{R}^{d+2}$ lies inside the halfspace $\{(x_1,\ldots,x_d,y,z) \in \mathbb{R}^{d+2} : z-2a_1x_1-\cdots-2a_dx_d-2by+a_1^2+\cdots+a_d^2-b^2 \le 0\}$. Thus, we can apply Theorem 2.9 with $D=d+2$. ◀

Note that in the non-bipartite case, an $O(n \log n)$ bound is known for 3-hop spanners [16], by exploiting the fatness of balls. In the next section, we show that the bound in Corollary 2.10 actually holds for *2-hop* spanners for balls in the non-bipartite setting.

3 Upper Bounds for 2 Hops

As mentioned in the introduction, for many families of objects, e.g., rectangles in $\mathbb{R}^2$, subquadratic bounds for 2-hop spanners of their (non-bipartite) intersection graphs are not possible. In this section, we show that nontrivial upper bounds for 2-hop spanners are possible for intersection graphs of *fat* objects (including balls).

3.1 When one side forms a clique

We begin by observing that most of the results in Section 2 works for 2 hops if one side of the bipartite graph forms a clique. This very simple observation will be the key to deriving our fat-object results later:

▶ **Lemma 3.1.** *Let $G = (U \cup V, E)$ be a bipartite graph where $|U| = m$ and $|V| = n$. Let G^+ be the union of G and a clique on U. Then G^+ has a 2-hop spanner of size $O(m^2 + n)$.*

Proof. We construct a spanner subgraph H^+ of G^+ as follows. For each vertex $v \in V$, $\deg(v) \geq 1$, let e_v be an arbitrary edge incident to v, and add e_v to H^+. Furthermore, add the clique on U to H^+. We show that H^+ is a 2-hop spanner of G^+. Consider an edge uv in G. If $e_v = uv$, then we can go from u to v in 1 hop. Otherwise, say e_v is $u'v$. We can go from u to v in 2 hops via the edges uu' and $u'v$. ◀

The above lemma implies an $O(n^{3/2})$ upper bound on 2-hop spanners in this setting, by the same grouping trick from the proof of Corollary 2.2:

▶ **Corollary 3.2.** *Let $G = (U \cup V, E)$ be a bipartite graph where $|U| + |V| = n$. Let G^+ be the union of G and a clique on U. Then G^+ has a 2-hop spanner of size $O(n^{3/2})$.*

We also immediately obtain the following analogs to Theorems 2.7 and 2.9:

▶ **Theorem 3.3.** *Let U and V be two sets of n elements. We are given points $p_1(u), \ldots, p_\ell(u) \in \mathbb{R}^D$ for each $u \in U$ and semi-algebraic sets $S_1(v), \ldots, S_\ell(v) \subset \mathbb{R}^D$ of constant description complexity for each $v \in V$, where D and ℓ are constants. For any ℓ-variate Boolean formula Φ, the graph*

$$G \;=\; (U \cup V,\; \{(u,v) \in U \times V :\; \Phi([p_1(u) \in S_1(v)], \ldots, [p_\ell(u) \in S_\ell(v)])\} \;\cup\; (U \times U))$$

has a 2-hop spanner with $O^*(n^{\frac{3D-2}{2D-1}}) = O^*(n^{\frac{3}{2} - \frac{1}{2(2D-1)}})$ edges.

Proof. We follow the proof of Theorem 2.7, but using Lemma 3.1 in place of Lemma 2.1. We also add a 2-hop spanner for $U \times U$ of $O(m)$ size (namely, a star). ◀

▶ **Theorem 3.4.** *Let P be a set of n points and S be a set of n halfspaces in a constant dimension D. Then the graph $G = (P \cup S,\; \{(p,s) \in P \times S : p \in s\} \cup (P \times P))$ has a 2-hop spanner with $O^*(n^{\frac{3\lfloor D/2 \rfloor - 2}{2\lfloor D/2 \rfloor - 1}}) = O^*(n^{\frac{3}{2} - \frac{1}{2(2\lfloor D/2 \rfloor - 1)}})$ edges.*

Proof. We follow the proof of Theorem 2.7, but using Lemma 3.1 in place of Lemma 2.1, and just replacing the path $\pi_{p,p'}$ with an edge pp'. ◀

3.2 Intersection graphs of fat objects

To obtain our results for fat objects, our idea is to adapt one of the methods by Chan and Huang [16, Section 3.1], originally developed for constructing 3-hop spanners of $O(n \log n)$ size. In adapting their method to construct 2-hop spanners, we realize that the main subproblems arising from the recursion correspond to the case when one side forms a clique – a case which fortunately has already been addressed by the previous subsection! If the fat objects are all of similar size, then a simple grid approach will easily reduce to the one-sided clique case. For fat objects of arbitrary sizes, Chan and Huang [16] used a divide-and-conquer approach based on shifted quadtrees.

We use the following definition of fatness [13]: A family of objects is *fat* if for every axis-aligned hypercube γ with side length ℓ, there exist $O(1)$ points hitting all objects that intersect γ and have diameter at least ℓ. There exists a number of different definitions

of fatness in the geometry literature (e.g., see [8, 23]). We find the above definition most appropriate for our purpose. It is not difficult to see that arrangements of Euclidean balls or hyperrectangles of bounded aspect ratios in $\mathbb{R}^d$ are fat according to this definition.

▶ **Theorem 3.5.** *Let V be a set of n fat objects in $\mathbb{R}^d$ for constant d. Then the intersection graph G of V has a 2-hop spanner with $O(n^{3/2})$ edges.*

Proof. Recall that a *quadtree cell* is an axis-aligned box of the form $[i_1/2^k, (i_1+1)/2^k) \times \cdots \times [i_d/2^k, (i_d+1)/2^k)$ for some integers $i_1, \ldots, i_d, k$. An object u of diameter ℓ is *C-aligned* if it is contained in a quadtree cell of side length $C\ell$. As argued in [16, Section 3.1], as a consequence of a known shifting lemma [13], one can find $O(d)$ vectors $\tau_1, \ldots, \tau_{O(d)}$ with the property that for every pair of objects u and v, there exists at least one vector τ_j such that $u+\tau_j$ and $v+\tau_j$ are both C-aligned for some $C = O(d)$. For each τ_j, it suffices to construct a 2-hop spanner for the subset of all objects u such that $u+\tau_j$ is C-aligned; we can then output the union of these $O(d)$ spanners. From now on, we may thus assume that all objects are C-aligned. Let $T(n)$ be the worst-case optimal 2-hop spanner size under this assumption.

1. First find a quadtree cell γ such that there are at most αn objects completely inside γ and at most αn objects completely outside γ, with $\alpha := \frac{2^d}{2^d+1}$; see [16, Lemma 10] (based on earlier work in [5, 12]). This cell corresponds to a "centroid" of the quadtree. Recursively construct a 2-hop spanner for the objects completely inside γ and a 2-hop spanner for the objects completely outside γ.
2. Let Q_γ be a set of points hitting all objects that intersect $\partial\gamma$. By alignedness, these objects have diameter at least ℓ_γ/C, where ℓ_γ denotes the side length of γ. By fatness, a hitting set of size $|Q_\gamma| = O(1)$ exists (since $\partial\gamma$ can be covered by C^d hypercubes of side length ℓ_γ/C).
3. For each point $q \in Q_\gamma$, let U_q be the subset of all objects hit by q (this subset induces a clique). Let G_q be the bipartite intersection graph between U_q and V. Construct a 2-hop spanner for $G_q \cup (U_q \times U_q)$ by Corollary 3.2.

We claim that the union of the spanners found is a 2-hop spanner of G. To see this, consider an edge uv in G. If u and v are both inside γ or both outside γ, then u and v are reachable by 2 hops by induction. Otherwise, one of the objects, say u, intersects $\partial\gamma$. Then u is hit by some point $q \in Q_\gamma$, and so $uv \in G_q$ and u and v are reachable by 2 hops.

We thus obtain the following recurrence:

$$T(n) \;\le\; \max_{n_1,n_2 \le \alpha n:\; n_1+n_2 \le n} \Big(T(n_1) + T(n_2)\Big) + O(n^{3/2}).$$

This solves to $T(n) = O(n^{3/2})$. ◀

We similarly obtain improvements when the fat objects are semialgebraic with constant description complexity:

▶ **Theorem 3.6.** *Let V be a set of n fat objects in $\mathbb{R}^d$ for constant d. We are given points $p_1(v), \ldots, p_\ell(v) \in \mathbb{R}^D$ and semi-algebraic set $S_1(v), \ldots, S_\ell(v) \subset \mathbb{R}^D$ of constant description complexity for each $v \in V$, where D and ℓ are constants, satisfying the following property: two objects $u, v \in V$ intersect iff $\Phi([p_1(u) \in S_1(v)], \ldots, [p_\ell(u) \in S_\ell(v)])$, where Φ is an ℓ-variate Boolean formula. Then the intersection graph G of V has a 2-hop spanner with $O^*(n^{\frac{3D-2}{2D-1}}) = O^*(n^{\frac{3}{2}-\frac{1}{2(2D-1)}})$ edges.*

Proof. Same as the proof of Theorem 3.5, but using Theorem 3.3 instead of Corollary 3.2. ◀

▶ **Corollary 3.7.** *The intersection graph of every set of n fat simplices (or fat polyhedra each of constant complexity, e.g., non-axis-aligned hypercubes) in a constant dimension d has a 2-hop spanner with $O(n^{\frac{3}{2}-\frac{1}{O(d^2)}})$ edges. Specifically, for $d = 3$, the bound is $O^*(n^{10/7})$.*

Proof. As in the proof of Corollary 2.8, this follows by setting $D = d^2$, or in the $d = 3$ case, $D = 4$. ◀

▶ **Theorem 3.8.** *Let V be a set of n fat objects in a constant dimension d. We are given a point $p(v) \in \mathbb{R}^D$ and a halfspace $S(v) \subset \mathbb{R}^D$ for each $v \in V$, for a constant D, satisfying the following property: two objects u and v intersect iff $p(u) \in S(v)$. Then the intersection graph G of V has a 2-hop spanner with $O^*(n^{\frac{3\lfloor D/2\rfloor-2}{2\lfloor D/2\rfloor-1}}) = O^*(n^{\frac{3}{2}-\frac{1}{2(2\lfloor D/2\rfloor-1)}})$ edges.*

Proof. Same as the proof of Theorem 3.5, but using Theorem 3.4 instead of Corollary 3.2. ◀

▶ **Corollary 3.9.** *The intersection graph of n balls in a constant dimension d has a 2-hop spanner with $O^*(n^{\frac{3\lfloor d/2\rfloor+1}{2\lfloor d/2\rfloor+1}}) = O^*(n^{\frac{3}{2}-\frac{1}{2(2\lfloor d/2\rfloor+1)}})$ edges. For example, for $d = 3$, the bound is $O^*(n^{4/3})$; for $d \in \{4, 5\}$, the bound is $O^*(n^{7/5})$.*

Proof. As in the proof of Corollary 2.10, this follows from Theorem 3.8 by setting $D = d + 2$. ◀

For fat axis-aligned boxes, we have the following theorem, which generalizes a result by Conroy and Tóth [20] from $d = 2$ to higher dimensions:

▶ **Theorem 3.10.** *For every $d \geq 2$, the intersection graph of n fat axis-aligned boxes (e.g., axis-aligned hypercubes) in a constant dimension d has a 2-hop spanner with $O(n \log^{d+1} n)$ edges.*

Proof. Same as the proof of Theorem 3.6, but to construct a 2-hop spanner for $G_p \cup (U_q \times U_q)$, we use a known *biclique cover* construction for the bipartite intersection graph G_p of boxes: this gives a collection of bicliques of the form $U_i \times V_i$, covering all the edges of G_p, with total size $\sum_i (|U_i| + |V_i|) = O(n \log^d n)$. (The construction is obtained by range-tree-style divide-and-conquer; e.g., see [14].) When the clique $U_i \times U_i$ is added to the biclique $U_i \times V_i$, there is a trivial 2-hop spanner of size $O(|U_i| + |V_i|)$ (namely, take a star centered at an arbitrary point in U_i). We just take the union of these spanners (together with a linear-size 2-hop spanner for $U_q \times U_q$) and obtain a spanner of size $O(n \log^d n)$ for $G_p \cup (U_q \times U_q)$. The recursion in the proof of Theorem 3.6 causes one more logarithmic factor. ◀

We note that the known $O(n \log n)$-size 3-hop spanner construction for axis-aligned rectangles in $\mathbb{R}^2$ by Chan and Huang [16] can be extended to give an $O(n \log^{d-1} n)$-size 3-hop spanner for axis-aligned boxes in $\mathbb{R}^d$. We defer this result to arXiv [9].

4 Lower Bounds

In this section, we prove lower bounds for 3-hop and 2-hop spanners, by relating the problem to the combinatorial question of bounding the size of geometric graphs avoiding $K_{2,2}$. Our lower bounds for 3-hop spanners are obtained from the following simple observation:

▶ **Observation 4.1.** *If a bipartite graph G does not contain any 4-cycle, i.e., $K_{2,2}$, then any 3-hop spanner of G must include all its edges.*

For 2-hop spanners, one could similarly derive lower bounds from constructions of graphs without 3-cycles (i.e., triangle-free graphs). However, for fat objects, triangle-free intersection graphs actually are known to have linear size. Instead, we propose the following lemma, showing that constructions of large bipartite intersection graphs between two sets of objects that avoid $K_{2,2}$ (where objects within each set are allowed to intersect) can also yield lower bounds for 2-hop spanners for (not-necessarily bipartite) intersection graphs:

▶ **Lemma 4.2.** *If $G = (U \cup V, E)$ is a graph (with $U \cap V = \emptyset$), and the bipartite subgraph $E' = E \cap (U \times V)$ does not contain $K_{2,2}$, then any 2-hop spanner of G must have at least $|E'|$ edges.*

Proof. Basically, we want to show that extra edges in $U \times U$ and $V \times V$ do not help. We use a charging argument. Let H be a 2-hop spanner of G. For each edge $uv \in E'$ with $u \in U$ and $v \in V$, if $uv \in H$, we charge the edge uv to itself. Otherwise, H must contain edges ux and xv for some x. Without loss of generality, say $x \in U$. We charge the edge uv to the edge ux.

Since the total charge is $|E'|$, it suffices to show that no edge in H receives more than one charge. Suppose that some edge e in H receives charges from two different edges $f_1, f_2 \in E'$. For f_1 to be charged to e, there must exist an edge $g_1 \in E'$ such that e, f_1, g_1 form a triangle. Similarly, there must exist an edge $g_2 \in E'$ such that e, f_2, g_2 form a triangle. Since $f_1, f_2 \notin H$ and $g_1, g_2 \in H$, the edges f_1, g_1, f_2, g_2 are distinct and form a $K_{2,2}$ in E': a contradiction. ◀

We can use known combinatorial results to construct $K_{2,2}$-free intersection graphs:

▶ **Lemma 4.3.** *For every positive integer n, the following hold:*

(a) *There exist n points and n lines in $\mathbb{R}^2$ whose incidence graph does not contain $K_{2,2}$ and has $\Omega(n^{4/3})$ edges.*

(b) *There exist n tetrahedra in $\mathbb{R}^3$ whose intersection graph is bipartite, does not contain $K_{2,2}$, and has $\Omega(n^{4/3})$ edges.*

(c) *There exist n red/blue congruent regular tetrahedra (or congruent non-axis-aligned cubes) in $\mathbb{R}^3$ such that the bipartite intersection graph between the red tetrahedra and the blue tetahedra does not contain $K_{2,2}$ and has $\Omega(n^{4/3})$ edges.*

(d) *There exist n points and n halfspaces in $\mathbb{R}^5$ whose incidence graph does not contain $K_{2,2}$ and has $\Omega(n^{4/3})$ edges.*

(e) *There exist n red/blue congruent balls in $\mathbb{R}^5$ such that the bipartite intersection graph between the red balls and the blue balls does not contain $K_{2,2}$ and has $\Omega(n^{4/3})$ edges.*

(f) *There exist n points and n axis-aligned boxes in $\mathbb{R}^d$ whose incidence graph does not contain $K_{2,2}$ and has $\Omega(n(\log n/\log\log n)^{d-1})$ edges.*

(g) *There exist n axis-aligned boxes in $\mathbb{R}^d$ whose intersection graph is bipartite, does not contain $K_{2,2}$, and has $\Omega(n(\log n/\log\log n)^{d-2})$ edges.*

(h) *There exist n red/blue congruent axis-aligned hypercubes in $\mathbb{R}^d$ such that the bipartite intersection graph between the red hypercubes and blue hypercubes does not contain $K_{2,2}$ and has $\Omega(n(\log n/\log\log n)^{\lfloor d/2\rfloor-1})$ edges.*

Proof.

(a) This is well-known, by a construction of Erdős [26] (see also [6, 24]) and incidence graphs between points and lines in $\mathbb{R}^2$ automatically do not contain $K_{2,2}$.

(b) Let P be the set of points and L be the set of lines in $\mathbb{R}^2$ from (a). Map each point $p \in P$ to the red vertical line $\varphi(p) = p \times (-\infty, \infty)$ in $\mathbb{R}^3$. Map the i-th line $\ell \in L$ to a blue line $\psi(\ell) = \ell \times \{i\}$ in $\mathbb{R}^3$ (which lies on the horizontal plane $z = i$). Then $\varphi(p)$ intersects $\psi(\ell)$ iff p lies on ℓ. Moreover, there are no red-red or blue-blue intersections. The result then follows by viewing these red/blue lines as thin tetrahedra.

(c) Let P be the set of points and L be the set of lines in $\mathbb{R}^2$ from (a). We may clip each line $\ell \in L$ to a line segment of a sufficiently large length M. Map each point $p \in P$ to some red regular tetrahedron $\varphi(p)$ in $\mathbb{R}^3$ that has side length M, lies inside the halfspace $z \geq 0$, and touches the plane $z = 0$ precisely at the point $p \times \{0\}$. Map each line segment $\ell \in P$ to some blue regular tetrahedron $\psi(\ell)$ in $\mathbb{R}^3$ that has side length M, lies inside the halfspace $z \leq 0$, and touches the plane $z = 0$ precisely at the line segment $\ell \times \{0\}$. Then $\varphi(p)$ intersects $\psi(\ell)$ iff p lies on ℓ. The construction is similar for non-axis-aligned cubes.

(d) This was noted by Chan and Har-Peled [15]. Specifically, let P be the set of points and L be the set of lines in $\mathbb{R}^2$ from (a). A point $(x, y) \in P$ is incident on a line in L with equation $ax + by = 1$ iff $(ax + by - 1)^2 \leq \delta$, i.e., $a^2x^2 + 2abxy + b^2y^2 - 2ax - 2by + 1 \leq \delta$, for a sufficiently small $\delta > 0$. Map each point $p = (x, y) \in P$ to a point $\varphi(p) = (x^2, xy, y^2, x, y) \in \mathbb{R}^5$. Map each line $\ell \in L$ with equation $ax + by = 1$ to a halfspace $\psi(\ell) = \{(\xi_1, \xi_2, \xi_3, \xi_4, \xi_5) \in \mathbb{R}^5 : a^2\xi_1 + 2ab\xi_2 + b^2\xi_3 - 2a\xi_4 - 2b\xi_5 + 1 \leq \delta\}$. Then $\varphi(p)$ lies inside $\psi(\ell)$ iff p lies on ℓ.

(e) Let P be the set of points and S be the set of halfspaces in $\mathbb{R}^5$ from (d). We can view each halfspace of S as a giant ball, of a fixed and sufficiently large radius M. Now map each point $p \in P$ to a red ball $\varphi(p)$ centered at p of radius $M/2$. Map each ball $s \in S$ to a blue ball $\psi(s)$ with the same center of radius $M/2$. Then $\varphi(p)$ intersects $\psi(s)$ iff p lies inside s.

(f) This follows from a construction by Chazelle [17], as noted by Chan and Har-Peled [15].

(g) Let P be the set of points and S the set of boxes in $\mathbb{R}^{d-1}$ from (f). Map each point $p \in P$ to a red vertical line $\varphi(p) = p \times (-\infty, \infty)$ in $\mathbb{R}^d$. Map the i-th box $s \in S$ to a blue box $\psi(s) = s \times \{i\}$ in $\mathbb{R}^d$. Then $\varphi(p)$ intersects $\psi(s)$ iff p is inside s. Moreover, there are no red-red or blue-blue intersections. The result then follows by viewing the red lines as thin boxes.

(h) Say d is even. Let P be the set of points and S be the set of boxes in $\mathbb{R}^{d/2}$ from (f). Map each point $p = (x_1, \ldots, x_{d/2}) \in P$ to a red hypercube $\varphi(p) = [-x_1, -x_1 + M] \times [x_1, x_1 + M] \times \cdots \times [-x_{d/2}, -x_{d/2} + M] \times [x_{d/2}, x_{d/2} + M]$ in $\mathbb{R}^d$ for a sufficiently large side length M. Map each box $s = [a_1, b_1] \times \cdots \times [a_{d/2}, b_{d/2}] \in S$ to a blue hypercube $\psi(s) = [-a_1 - M, -a_1] \times [b_1 - M, b_1] \times \cdots \times [a_{d/2} - M, a_{d/2}] \times [b_{d/2} - M, b_{d/2}]$ in $\mathbb{R}^d$. Then $\varphi(p)$ intersects $\psi(s)$ iff p lies inside s. ◀

Lower bounds for 3-& 2-hop spanners for various intersection graphs now follows.

▶ **Theorem 4.4.** *For every positive integer n, the following holds:*

(i) *There exist n tetrahedra in $\mathbb{R}^3$ such that any 3-hop spanner of their intersection graph requires $\Omega(n^{4/3})$ edges.*

(ii) *There exist n congruent regular tetrahedra (or congruent non-axis-aligned cubes) in $\mathbb{R}^3$ such that any 2-hop spanner of their intersection graph requires $\Omega(n^{4/3})$ edges.*

(iii) *There exist n congruent balls in $\mathbb{R}^5$ such that any 2-hop spanner of their intersection graph requires $\Omega(n^{4/3})$ edges.*

(iv) *There exist n axis-aligned boxes in $\mathbb{R}^d$ such that any 3-hop spanner of their intersection graph requires $\Omega(n(\log n/\log\log n)^{d-2})$ edges.*

(v) *There exist n congruent axis-aligned hypercubes in $\mathbb{R}^d$ such that any 2-hop spanner of their intersection graph requires $\Omega(n(\log n/\log\log n)^{\lfloor d/2 \rfloor - 1})$ edges.*

Proof.

(i) By Lemma 4.3(b) and Observation 4.1.

(ii) By Lemma 4.3(c) and Lemma 4.2.

(iii) By Lemma 4.3(e) and Lemma 4.2.

(iv) By Lemma 4.3(g) and Observation 4.1.

(v) By Lemma 4.3(h) and Lemma 4.2. ◀

▶ Remark 4.5. It remains open to prove better lower bounds for simplices in dimensions $d > 3$ or balls in dimensions $d > 5$, ideally with exponent converging to $3/2$ as d increases. It is possible to adapt Observation 4.1 and Lemma 4.2 to avoid $K_{2,c}$ instead of $K_{2,2}$ for any constant c (while losing some $c^{O(1)}$ factors), but we are not aware of any stronger lower bounds on geometric graphs avoiding $K_{2,c}$ that could be exploited here (except in some lop-sided bipartite cases).

One common property to all the geometric intersection graphs mentioned in this paper is that they all have bounded VC-dimension[5]. As already noted in the introduction, bounded VC-dimension alone does not guarantee a 3-spanner with $o(n^{3/2})$ edges, as demonstrated in the following theorem:

▶ **Theorem 4.6.** *For any $n \in \mathbb{N}$, there exists a graph $G = (V_1 \cup V_2, E)$ with VC-dimension at most 2 so that any 3-spanner for G has $\Omega(n^{3/2})$ edges.*

Proof. The construction consists of the known constructions of bipartite graphs without C_4 with $\Omega(n^{3/2})$ edges (e.g., the construction with projective planes over finite fields $(F_p)^2$). Its easy to see that the VC-dimension of such graphs is at most 2. By Observation 4.1, any 3-spanner must use all bipartite edges. ◀

▶ Remark 4.7. Bounded VC-dimension is known to imply the existence of spanning trees with sublinear crossing number [19], biclique covers with subquadratic size, and various other properties often used in geometric range searching. Along the same lines, one may wonder whether general set systems with bounded VC-dimension admit some analog to $(1/r)$-cuttings [18] or polynomial partitioning. Interestingly, our work provides a negative answer to this question: An analog to cuttings would imply an $o(n^{3/2})$ upper bound for 3-hop spanners, by following the method in the proof of Theorems 2.7 and 2.9, and this would contradict Theorem 4.6.

Abstract

We present a fixed-parameter tractable (FPT) algorithm to find a shortest curve that encloses a set of k required objects in the plane while paying a penalty for enclosing unwanted objects.

The input is a set of interior-disjoint simple polygons in the plane, where k of the polygons are *required* to be enclosed and the remaining *optional* polygons have non-negative penalties. The goal is to find a closed curve that is disjoint from the polygon interiors and encloses the k required polygons, while minimizing the length of the curve plus the penalties of the enclosed optional polygons. If the penalties are high, the output is a shortest curve that separates the required polygons from the others. The problem is NP-hard if k is not fixed, even in very special cases. The runtime of our algorithm is $O(3^k n^3)$, where n is the number of vertices of the input polygons.

We extend the result to a graph version of the problem where the input is a connected plane graph with positive edge weights. There are k required faces; the remaining faces are optional and have non-negative penalties. The goal is to find a closed walk in the graph that encloses the k required faces, while minimizing the weight of the walk plus the penalties of the enclosed optional faces. We also consider an inverted version of the problem where the required objects must lie outside the curve. Our algorithms solve some other well-studied problems, such as geometric knapsack.

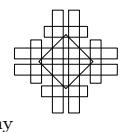

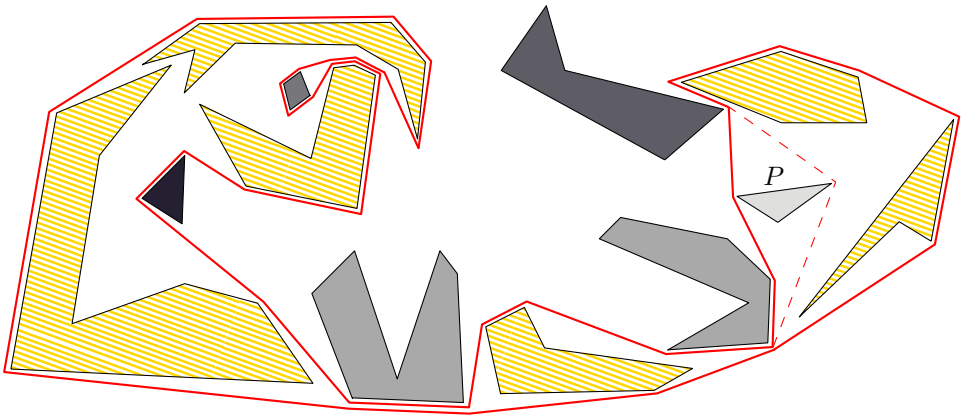

Figure 1 The Geometric-Enclosure-with-Penalties problem. The weakly simple polygon W (in red) encloses the required polygons R (yellow hatched) while paying a penalty for enclosing any of the optional polygons O (in gray, darker for larger penalties). Overlapping paths are slightly displaced for visibility. Changing W via the dashed path to put polygon P outside would be preferable if the increase in length is less than the penalty of P.

1 Introduction

We investigate the separation problem of finding a shortest curve that encloses a subset of objects while excluding other objects. A very basic setting is for points in the plane: given n points in the plane and a subset of size k, find a minimum-perimeter polygon containing the specified k points and excluding the other $n - k$ points. This problem is NP-hard when k may be large, as proved by Eades and Rappaport [11] for the case $k = n/2$ via a simple reduction from the Travelling Salesman Problem.

As a special case of our main result, we give the first algorithm for this problem that is fixed-parameter tractable (FPT) in k. Our result is far more general and applies in two settings, a geometric setting and a graph-theoretic setting.

Geometric-Enclosure-with-Penalties. We generalize from point objects to objects that are interior-disjoint simple polygons in the plane, and we consider a *weighted* form of exclusion.

Input. The input is a set of simple interior-disjoint polygons partitioned into a set R of k **required polygons** and the remaining set O of **optional polygons**. Each optional polygon $P \in O$ comes with a non-negative **penalty** π_P where we allow $\pi_P = +\infty$.

Output. The goal is to find a weakly simple polygon W that does not intersect the interior of any input polygon and encloses all polygons of R while minimizing the **cost** $c(W)$, which is defined to be the Euclidean length of W plus the penalties of the polygons of O that are inside W. See Figure 1 for an example. A polygon with penalty $+\infty$ must be excluded. A polygon with penalty 0 may be included or excluded without making a difference, so it only acts as an obstacle to the solution curve. As Figure 1 illustrates, the problem would be ill-defined if we required the solution curve W to be a simple polygon. The natural condition is that W should be a **weakly simple polygon**, whose boundary may touch or overlap itself but not cross itself. We give a precise definition in Section 2.1. An important property is that a weakly simple polygon encloses a well-defined region. Our first main result is:

▶ **Theorem 1.** Geometric-Enclosure-with-Penalties *for k required polygons can be solved in $O(3^k n^3)$ time and $O(2^k n^2)$ space, if the input polygons have n vertices in total.*

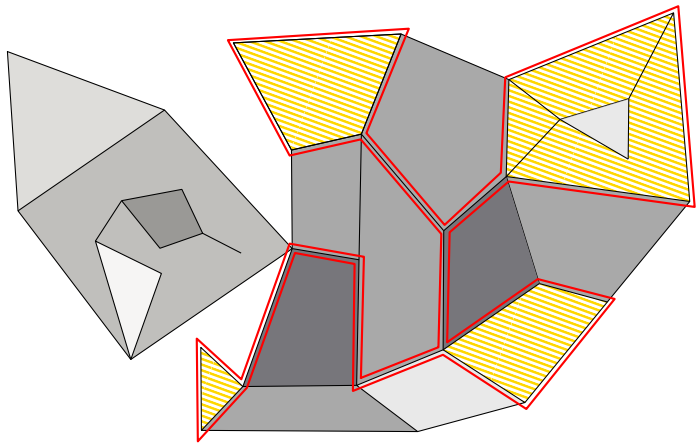

Figure 2 The Graph-Enclosure-with-Penalties problem. The colors have the same meaning as in Figure 1. A weakly simple closed walk W which is a solution for the instance is red (bold). The edge weights, which are not shown, are unrelated to the Euclidean lengths.

If all objects are points, this can be handled by approximating each point by a small triangle. An exact solution for an arbitrary mix of point and polygon objects appears in [5, Appendix I].

Graph-Enclosure-with-Penalties. In this setting, the objects are faces of a plane graph.

Input. The input is a simple connected plane graph G and positive edge weights. The bounded faces of G are partitioned into a set R of k **required faces** and the remaining set O of **optional faces**. Each optional face F has a penalty π_F from $\mathbb{R}_{\geq 0} \cup \{+\infty\}$.

Output. The goal is to find a weakly simple closed walk W in G such that faces of R are inside W while minimizing the cost $c(W)$ which is defined to be the sum of the weights of the edges of W plus the penalties of the faces of O that are inside W. See Figure 2 for an example. Intuitively, a **weakly simple** closed walk is one without crossings; we give a more precise definition in the full version of this paper [5, Appendix A]. For a weakly simple closed walk, the notions of inside and outside are well-defined. Our second main result is:

▶ **Theorem 2.** Graph-Enclosure-with-Penalties *can be solved in* $O(3^k n^3)$ *time and* $O(2^k n^2)$ *space, where* k *is the number of required faces and* n *is the number of vertices of* G.

A common framework. Although the two settings described above seem different, we resolve them into a common geometric framework, which we call Enclosure-with-Penalties. Our algorithm applies to this general problem. The basic idea is to transform the graph problem into a geometric problem by taking a straight-line embedding of the graph. The bounded faces of the graph become polygons slightly more general than simple polygons. We also consider the outer face as an unbounded polygon. Then the "free space" between the polygons consists only of the graph edges. This gives us a geometric problem, albeit with arbitrary positive edge weights defined on edges that have a polygon on each side. In Section 3 we define the Enclosure-with-Penalties problem by generalizing the Geometric-Enclosure-with-Penalties problem to include these instances.

We remark that the resulting algorithm for Theorem 2 makes essential use of the straight-line embedding of the input graph. In particular, the subproblems that we solve depend on the embedding. This imposition of geometry seems artificial, but oddly enough, we do not know how to formulate our algorithm in a purely combinatorial setting.

Our approach. We use dynamic programming (Section 4) to build a polygon W that is locally correct – we use segments that do not intersect the interior of any object and we account for required objects and tally the penalties as we add triangles to W. We will prove that the cost computed by the algorithm is correct, but this is tricky because W itself will not necessarily be weakly simple. "Inside" is no longer well-defined. Instead, we use winding numbers to give a measure of the cost of W that matches the cost computed by the algorithm.

In Section 5 we give an algorithm to *uncross* W to a weakly simple polygon without increasing its cost, which provides our final output. Correctness is proved in Section 6.

The run-time for the Uncrossing Algorithm is dominated by the run-time for the dynamic program. To obtain our claimed run-time we speed up the dynamic program in Section 7.

Lower bounds. To complement our algorithms we prove that, under the Exponential Time Hypothesis (ETH), the Geometric- and Graph-Enclosure-with-Penalties problems cannot be solved in $2^{o(k)} \cdot n^{O(1)}$ time, implying that the linear dependence on k in the exponent of the running time of our algorithms is the best possible assuming ETH. The proof is a reduction from unweighted Planar Steiner Tree, which admits a lower bound by a result by Marx, Pilipczuk, and Pilipczuk [15, Theorem 1.2]. See [5, Appendix K].

Swapping the inside with the outside. We extend our algorithm to an **inverted** version of the Enclosure-with-Penalties problem where the required objects have to be *outside* W, and the objective is to minimize the length of W plus the penalties of the polygons of O that are *outside* W. The runtime remains the same, see Section 8. This algorithm provides a new faster solution to the geometric knapsack problem discussed below.

Negative penalties. We can allow some number ℓ of objects with negative penalties (rewards); in this case, the runtime is increased by a factor of 3^ℓ. See [5, Appendix J].

1.1 Related work

Cut problems and separator problems in graphs have a long history, and separation problems in geometric settings are a natural and well studied counterpart.

Geometric knapsack problem. Geometric separation problems were first explored by Eades and Rappaport [11] (as discussed above) and by Arkin, Khuller, and Mitchell, who introduced the *geometric knapsack problem* [4], which corresponds to the *inverted* version of the Geometric-Enclosure-with-Penalties problem in the special case where there are no required objects. (In their equivalent formulation, each object has a finite nonnegative value, and the goal is to compute a curve that maximizes the total value of the enclosed objects minus its length.) They gave an algorithm with running time $O(n^4)$ [4, Theorem 6]. In the full version [5, Appendix M], we note some issues regarding weak simplicity and interior/exterior of their output. Since there are no required objects, our algorithm for the inverted problem solves the geometric knapsack problem in time $O(n^3)$.

Relation to homotopy and homology. Our problem has a topological flavor and is therefore, in principle, amenable to homotopy and homology techniques. However, these techniques are unlikely to lead to algorithms that are FPT in k, even assuming only infinite penalties. In particular, for the Graph-Enclosure-with-Penalties problem, enumerating a set of candidate homotopy classes, i.e., the possible ways how a solution winds around the objects to

enclose the required objects and avoid the most undesirable ones, is possible using a technique by Chambers, Colin de Verdière, Erickson, Lazarus, and Whittlesey [7] (specifically, because the exchange argument [7, Proposition 4.2] is also valid for our problem), but this results in an algorithm with runtime $K^{O(K)} \cdot n \log n$, where K is the number k of required objects *plus* the number of objects with nonzero penalty. Similarly, the technique of *homology covers*, by Chambers, Erickson, Fox, and Nayyeri [8], is applicable, but yields algorithms with runtime $K^{O(K)} \cdot n \log \log n$ or $2^{O(K)} \cdot n \log n$, thus again with an exponential dependence on K. If there are many objects with nonzero penalty, our algorithm with runtime $O(3^k n^3)$ is faster.

Specifying only the number of objects to be enclosed. If we are just given a set of n points in general position and the exact *number* $k \leq n$ of points to be enclosed, a minimum-perimeter polygon enclosing at least k points is convex, contains exactly k points, and can be found in polynomial time by an algorithm of Eppstein, Overmars, Rote, and Woeginger [12, Corollary 5.3, Case 3]. This algorithm could for example be used to identify an unusual cluster in an otherwise uniformly distributed point set. However, if the input consists of polygons instead of points, we are not aware of a better method than guessing the k polygons to be enclosed and applying our main result, resulting in an algorithm of running time $O(\binom{N}{k} 3^k n^3) = O(N^k n^3)$ if there are N objects.

More variations. Some related separation and enclosure problems have been recently studied. Abrahamsen, Giannopoulos, Löffler, and Rote [1] investigated the problem of separating two or more groups of polygonal objects by a shortest system of fences. These fences may form an arbitrary plane graph, not necessarily a cycle. For separating *two* groups of polygons by a shortest fence, there is an algorithm of running time $O(n^4 \log^3 n)$, based on minimum-cut techniques [1]. For separating more than two groups, only approximation algorithms are known. While we study a problem in the same spirit, a key difference is that we require a single (weakly) simple cycle, which makes the techniques of this article not applicable for us.

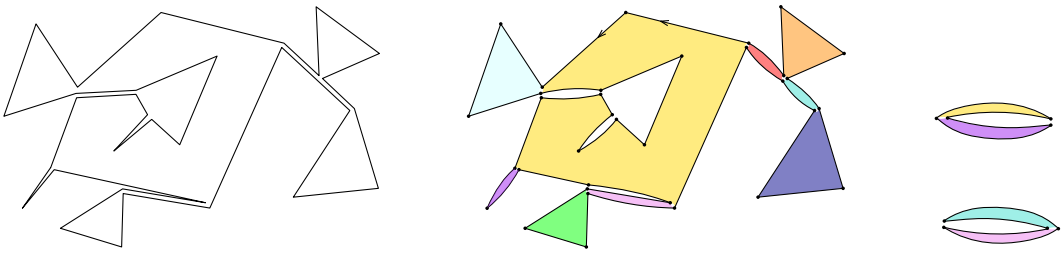
Chan, He, and Xue [9] studied the problem of choosing a smallest subset of objects from a given set whose union encloses a given point set. For this problem, there are only approximation algorithms. Klost, van Kreveld, Perz, Rote, and Tkadlec [13] have recently investigated optimum "blob-trees", where the objective is to *connect* a set of points by a combination of curves and edges.

2 Preliminaries

2.1 Weakly simple polygons

A polygon is **weakly simple** if it has fewer than three vertices, or it has at least three vertices and for any $\varepsilon > 0$, the vertices can be perturbed by at most ε to yield a simple polygon [2, 10]. We traverse a weakly simple polygon counterclockwise, i.e., with the interior to the left of each edge. Our proof uses a combinatorial characterization of a weakly simple polygon in terms of a non-crossing Euler tour in a plane multigraph [5, Lemma 16 in Appendix A]. This allows us to partition the edges of a weakly simple polygon into boundary walks of interior faces, see Figure 3. Note that we first subdivide an edge when a vertex lies in its interior.

A vertex of a weakly simple polygon with incoming edge e and outgoing edge f is a **transition vertex** if e and f belong to different interior faces. An interior face of two edges is a **corridor** and an interior face of more than two edges is a **chamber**. A chamber is not necessarily a simple polygon, but it is almost simple (see Figure 3(b)). More formally, a **bounded almost-simple polygon** is the boundary walk of an interior face of a connected straight-line



(a) (b) (c)

Figure 3 (a) A weakly simple polygon drawn via its ε-approximation. (b) The edges, after subdividing at interior vertices (forks), are partitioned into interior faces. Four faces are corridors and five are chambers. The largest chamber (in yellow) is almost-simple but not simple. (c) Non-uniqueness of the faces for a weakly simple polygon that traverses a line segment four times. In the top figure the two vertices on the left are transition vertices; this is reversed in the bottom figure.

graph drawing in the plane. We also allow an **unbounded almost-simple polygon** by traversing the boundary of the outer face clockwise. An almost-simple polygon has a connected interior and a bounded almost-simple polygon can be triangulated. Almost-simple polygons play two roles: the bounded ones arise as chambers; and our general Enclosure-with-Penalties problem allows almost-simple input polygons (including a single unbounded one).

All these concepts are made rigorous in [5, Appendix A]. We note that the partition of the edges of a weakly simple polygon into interior faces (and hence the definition of corridors and transition vertices) is not unique, see Figure 3(c). This non-uniqueness, which is inherent in the ε-approximation definition of weakly simple polygons, does not affect our proofs.

2.2 Winding number and winding parity

Our algorithm will construct intermediate polygons that are not necessarily weakly simple; so it will be useful to generalize "enclosed by" in terms of winding numbers. For a polygon W and a point x not lying on a vertex or edge of W, the **winding number** $\text{wind}(W, x)$ of x with respect to W is defined as follows. Take a ray ρ from x that avoids vertices of W. If an edge of W crosses ρ from right to left, we count this as $+1$; a crossing from left to right is counted as -1, and the total count gives the winding number. This is well-defined independent of the choice of ρ. The winding number is undefined for points x on W. Observe that, for a weakly simple polygon W traversed counterclockwise, point x lies in the interior of W if and only if $\text{wind}(W, x) = 1$. The **winding parity** of x with respect to W is $\text{wind}(W, x) \bmod 2$.

3 Our Common Framework: Enclosure-with-Penalties

In this section we formally define the Enclosure-with-Penalties problem that provides a common framework for both the geometric and graph settings.

Input:

- A set of interior-disjoint almost-simple polygons in the plane. We allow a single polygon to be unbounded. We subdivide polygon edges to ensure that no polygon vertex lies in the interior of an edge of another polygon. The **free space** is the plane minus the interiors of the polygons.
- A partition of the input polygons into a set R of k **required** polygons and the remaining set O of **optional** polygons. If there is an unbounded polygon, it must lie in O.

- For each polygon $P \in O$, a **penalty** $\pi_P \in \mathbb{R}_{\geq 0} \cup \{+\infty\}$.
- The weight w_{ab} of a line segment ab in the free space is its Euclidean length, except for *squeezed edges*. A squeezed edge is a polygon edge that is incident to polygons on both sides. We may specify an *arbitrary* positive weight for a squeezed edge. Subsegments of a squeezed edge get proportional weight, and combinations of different squeezed or non-squeezed segments have their weights added.

Output: A weakly simple polygon W that lies in the free space and contains all polygons of R while minimizing the **cost** $c(W)$, which is defined as

$$c(W) := w(W) + \pi(W), \tag{1}$$

where $w(W)$ is the sum of the weights of the edges of W, and $\pi(W)$ is the sum of the penalties of the polygons of O that are inside W. Our main result is:

▶ **Theorem 3.** Enclosure-with-Penalties *for k required polygons can be solved in $O(3^k n^3)$ time and $O(2^k n^2)$ space, if the input polygons have n vertices in total.*

Theorem 1 is an immediate consequence of Theorem 3. Theorem 2 follows from Theorem 3 via a straight-line embedding of the graph, as outlined in Section 1 and detailed in the full version [5, Appendix B].

The Enclosure-with-Penalties problem as defined above does not allow point objects. (They are not almost-simple.) [5, Appendix I] shows how to deal with point objects.

4 Dynamic Programming Algorithm

The algorithm builds a polygon composed of free-space edges, where a **free-space edge** is an inclusionwise minimal line segment in the free space whose endpoints are vertices of the input polygons. We prove in Section 6 that this restriction to free-space edges is valid. We refer to a solution interchangeably as a polygon or as a closed walk in the graph of free-space edges.

The intuition for the algorithm is based on the decomposition of a weakly simple polygon W into corridors and chambers joined at "cutpoints", see Figure 3. A cutpoint separates W into subpolygons and partitions the set of enclosed objects. Our first type of subproblem finds polygons that enclose a specified subset of R and go through a specified vertex.

A corridor is a digon, and a chamber can be triangulated by adding chords, where a chord may cut through polygons. We therefore use digons and triangles as the basic building blocks to construct our solutions. A chord cuts off part of the solution. Our second type of subproblem finds polygons that use a walk of free-space edges between two given vertices p and q together with the chord pq (called the *mouth*) to enclose a specified subset of R.

Since a mouth may cut through polygons, we choose a **reference point** r_P in the interior of every input polygon P, and aim to enclose r_P for $P \in R$. Observe that a weakly simple polygon W in the free space encloses P if and only if r_P lies in the interior of W.

The dynamic program explicitly keeps track of the subset of required objects that are enclosed by partial solutions (2^k possibilities). However, when combining two partial solutions, the algorithm does not have enough information to check whether they cross. Thus, we allow self-crossing solutions. In particular, our use of the word "enclosing" is aspirational, and will only be made precise in terms of winding numbers, see Section 4.2. When we state the algorithm, we invite the reader to think of a weakly simple solution without crossings.

Types of subproblems. A subproblem of type C ("closed") is rooted at a vertex p, and we build a closed walk that goes through p and is composed of free-space edges. A subproblem of type M ("mouth") is rooted at a segment pq between vertices of input polygons, called the **mouth**, and we build an open walk of free-space edges from p to q; adding segment qp closes the walk. In addition to the root, each subproblem has two more parameters, B and t: The set $B \subseteq R$ specifies the precise subset of required objects that must be enclosed, and the integer $t \geq 0$ is an upper bound on the number of edges of the walk. In each case, the subproblem looks for a *minimum-cost* solution with the required properties.

4.1 Dynamic programming recursion

We now give recursive formulas for C and M, preceded in each case by an explanation of the formulas. The formulas with the respective partitions of the walk are illustrated in Figure 4.

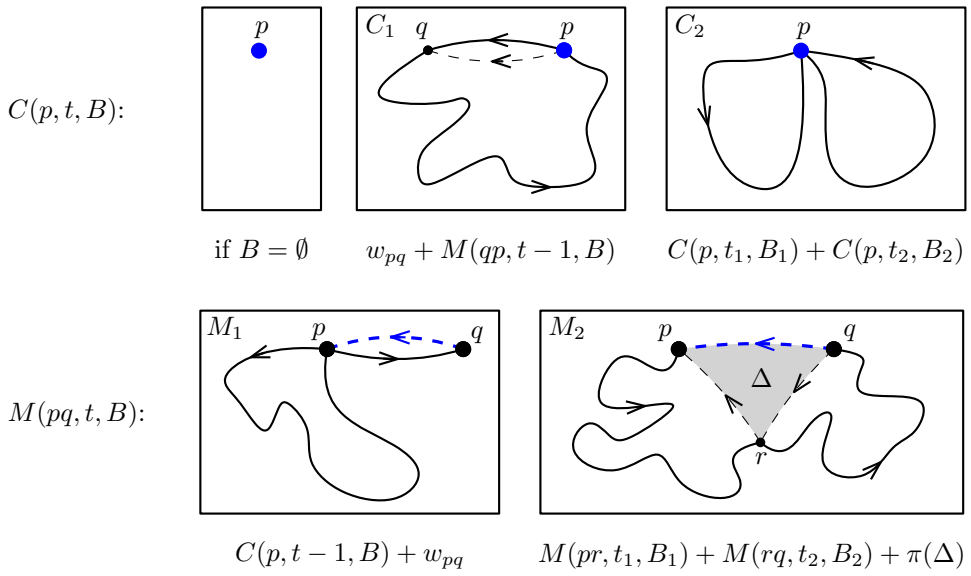


Figure 4 Cases of the recursion. Solid edges are free-space edges; dashed edges are mouths.

For $C(p,t,B)$ we have two base cases: if $B = \emptyset$, then the shortest closed walk is just the point p and its cost is 0 (Equation (2)); and if $B \neq \emptyset$ and $t \leq 1$, there is no solution, and we set the cost to ∞ (Equation (3)). Otherwise we have two general cases: the closed walk uses an edge pq of the free space (for some q) plus a solution $M(qp, t-1, B)$ (Equation (4)); or the closed walk is composed of two smaller closed walks that both go through p (Equation (5)). The notation $\sqcup$ means disjoint union: we partition the objects in B into two sets, each "enclosed" by exactly one of the two closed walks.

The base cases define $C(p,t,B)$ for $B = \emptyset$ and for $t \leq 1$:

$$C(p,t,\emptyset) := 0, \text{ for } t \geq 0 \tag{2}$$

$$C(p,t,B) := \infty, \text{ for } B \neq \emptyset \text{ and } t \leq 1 \tag{3}$$

In the general case, for $B \neq \emptyset$ and $t \geq 2$, we set

$$C(p,t,B) := \min\{C_1, C_2\}, \text{ where}$$

$$C_1 := \min\big\{ w_{pq} + M(qp, t-1, B) \;\big|\; pq \text{ is a free-space edge} \big\} \tag{4}$$

$$C_2 := \min\big\{ C(p,t_1,B_1) + C(p,t_2,B_2) \;\big|\; t = t_1 + t_2;\ B = B_1 \sqcup B_2;\ B_1, B_2 \neq \emptyset \big\} \tag{5}$$

For $M(pq, t, B)$ there are two possibilities: if pq is a free-space edge, we can use a closed walk at p plus the edge pq (Equation (6)); or we can attach a triangle $\Delta = prq$ to the mouth pq (Equation (7)). In the first case we add the weight of the edge pq. In the triangle case we take into account the polygons $R(\Delta)$ with reference points in Δ, where we consider Δ to be closed on pr and rq and open on pq, and we define $\pi(\Delta)$ to be the sum of the penalties of polygons of O with reference points in Δ.

$M(pq, t, B)$ is defined only for $t \geq 1$:

$$M(pq, t, B) := \min\{M_1, M_2\}, \text{ where}$$

$$M_1 := \begin{cases} C(p, t-1, B) + w_{pq} & \text{if } pq \text{ is a free-space edge} \\ \infty, & \text{otherwise} \end{cases} \tag{6}$$

$$M_2 := \min\Big\{ M(pr, t_1, B_1) + M(rq, t_2, B_2) + \pi(\Delta) \;\Big|\; \Delta = prq \text{ is a counterclockwise triangle}, \; t = t_1 + t_2,\ t_1 \geq 1, t_2 \geq 1,\ B = B_1 \sqcup B_2 \sqcup R(\Delta) \Big\} \tag{7}$$

As we shall see later in Lemma 13, the optimal walk has at most $6n$ edges. Thus, we define the solution to the whole problem as

$$c_{\mathrm{DP}} := \min\{\, C(p, 6n, R) \mid p \text{ a vertex} \,\}. \tag{8}$$

When we allow point objects, the algorithm needs a few refinements, see [5, Appendix I]. In the following sections we prove that c_{DP} is the correct value. Although not required by our proof, we note for completeness in [5, Appendix L] that the class of polygons over which the algorithm optimizes is the class of *immersed* or *self-overlapping* weakly simple polygons.

Runtime and Space. A routine analysis shows that the runtime of the dynamic program is $O(3^k n^5)$, see the full version [5, Appendix C.1]. A more efficient version of the dynamic program, given in Section 7, eliminates the parameter t and runs in time $O(3^k n^3)$.

4.2 Extracting the solution

With every finite value computed in the dynamic program we can naturally associate an open or closed walk of free-space edges that has this value as its cost (with "partially enclosed" objects taken into account according to their reference points): Figure 4 illustrates how each value is computed from the values of subproblems; the walks corresponding to those subproblems are composed accordingly. (For more details, see [5, Appendix C.2].) We will prove in Section 6 that c_{DP} is finite; so the associated closed walk exists:

▶ **Definition 4.** *W_{DP} is the polygon associated with the optimum solution value c_{DP} in (8).*

The polygon W_{DP} uses free-space edges, but it might not be weakly simple, and there is no notion of enclosed objects. Instead, we use winding numbers: we show that the reference point of any object in R has winding number 1 in W_{DP}, and we define a cost measure for W_{DP} in terms of winding numbers and prove equality with c_{DP}.

▶ **Definition 5.** *For any polygon W in the free space, define the **cost** to be*

$$c(W) := w(W) + \sum_{P \in O} \mathrm{wind}(W, r_P) \cdot \pi_P.$$

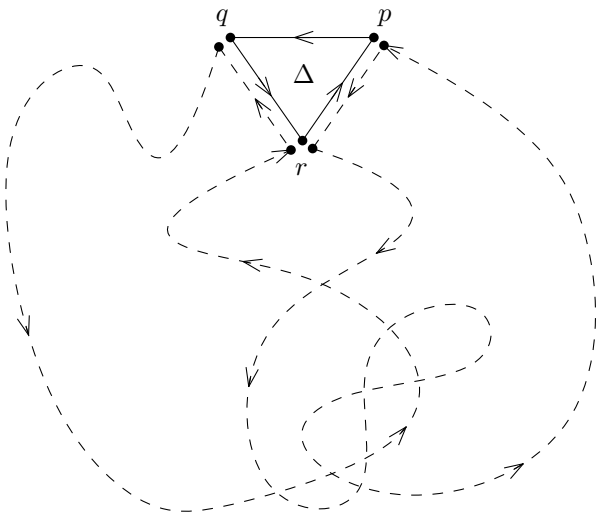

Figure 5 Gluing together closed walks, which may cross each other and are possibly self-crossing.

When W is a counterclockwise weakly simple polygon, this matches the previous definition $c(W) = w(W) + \pi(W)$, see Equation (1). The solution W_{DP} produced by the algorithm has the following properties:

▶ **Lemma 6.**
(A) $c_{\mathrm{DP}} = c(W_{\mathrm{DP}})$;
(B) *for all* $P \in R$, $\mathrm{wind}(W_{\mathrm{DP}}, r_P) = 1$;
(C) *for all points* x *that do not lie on* W_{DP}, $\mathrm{wind}(W_{\mathrm{DP}}, x) \geq 0$.

Lemma 6 is proved in [5, Appendix C.2] by induction as the dynamic program builds solutions by gluing together open/closed walks. The induction must apply also to open walks, and we use the fact that winding numbers add when gluing walks together, see Figure 5.

5 Uncrossing Algorithm and Final Output W_{ALG}

The final step of our algorithm "uncrosses" the closed walk W_{DP} produced by the dynamic program and turns it into a weakly simple polygon W_{ALG} without increasing the cost. To do so, we cut it into subpaths, eliminate some, and reorder the rest.

Our algorithm uses a known result about taking a plane multigraph (specified via its rotation system) and finding a **non-crossing Euler tour** in which successive visits to a vertex do not cross each other. (See [5, Appendix A] for more detailed definitions.) The existence of such a tour in an Eulerian plane multigraph is an easy exercise, see [17] or [18, Lemma 3.1], and a linear-time algorithm was given by Akitaya and Tóth [3]. We summarize it in the following proposition, and give a self-contained proof in [5, Appendix D].

▶ **Proposition 7** (Uncrossing Eulerian plane multigraphs)**.** *Given a plane connected Eulerian multigraph* H *with* m *edges, specified by its combinatorial map, we can, in* $O(m)$ *time, compute a non-crossing Euler tour of* H*.*

We now sketch our algorithm to uncross any polygon W to a weakly simple polygon W'. An **interior crossing** is a point that is in the relative interiors of two (or more) edges that are not collinear. A **fork** (or *interior vertex*) is a vertex in the relative interior of an edge.

▶ **Algorithm 8** (Uncrossing Algorithm).

1. *Subdivide every edge of W at every fork and interior crossing.*
2. *In the resulting multiset of edges (line segments in the plane) reduce multiplicities to* 1 *or* 2 *by repeatedly discarding pairs of equal line segments. The result is a plane connected Eulerian multigraph.*
3. *Apply Proposition 7 to find a non-crossing Euler tour. This corresponds to a weakly simple polygon W'.*

In the full version of our paper [5, Appendix D], we give further details of the algorithm and an implementation with runtime $O(t \log t + s)$ where t is the number of edges of W and $s \in O(t^2)$ is the number of interior crossings of W (with multiple crossings counted once). For input W_{DP} we show that there are no interior crossings, so the runtime is $O(n \log n)$.

We use the following important property of the Uncrossing Algorithm. Recall the definition of winding parity from Section 2.2.

▶ **Lemma 9.** *Every point x in the plane that does not lie on W has the same winding parity in W and in W'.*

Proof. For any ray r from x to infinity that avoids vertices of W, the parity of the number of edges it crosses is the same for W and W' since we have discarded pairs of equal line segments. The direction in which W' traverses an edge does not affect the winding parity. ($+1$ and -1 have the same parity.) ◀

▶ **Definition 10.** *W_{ALG} is the output of the Uncrossing Algorithm on input W_{DP}, oriented in counterclockwise direction.*

▶ **Lemma 11.** *W_{ALG} is a weakly simple polygon in the free space. W_{ALG} encloses R and $c(W_{\mathrm{ALG}}) \le c_{\mathrm{DP}}$.*

Proof. Consider a polygon $P \in R$. By Lemma 6(B), $\mathrm{wind}(W_{\mathrm{DP}}, r_P) = 1$. By Lemma 9, r_P has the same winding parity in W_{ALG}. Since W_{ALG} is weakly simple, every point has winding number 0 or 1. Thus $\mathrm{wind}(W_{\mathrm{ALG}}, r_P) = 1$ and W_{ALG} encloses P.

Next we consider costs. The definition of the costs in Equation (1) gives

$$c(W_{\mathrm{ALG}}) = w(W_{\mathrm{ALG}}) + \pi(W_{\mathrm{ALG}}),$$

where $\pi(W_{\mathrm{ALG}})$ is the sum of the penalties of objects of O enclosed by W_{ALG}.

By Lemma 6(A) and the definition of $c(W_{\mathrm{DP}})$,

$$c_{\mathrm{DP}} = c(W_{\mathrm{DP}}) = w(W_{\mathrm{DP}}) + \sum_{P \in O} \mathrm{wind}(W_{\mathrm{DP}}, r_P) \cdot \pi_P.$$

The Uncrossing Algorithm ensures that $w(W_{\mathrm{ALG}}) \le w(W_{\mathrm{DP}})$. It remains to compare the penalties. Let P be a polygon of O enclosed by W_{ALG}, i.e., with $\mathrm{wind}(W_{\mathrm{ALG}}, r_P) = 1$. By Lemma 9, the reference point r_P has the same winding parity in W_{DP}, and by Lemma 6(C), $\mathrm{wind}(W_{\mathrm{DP}}, r_P) \ge 0$. Thus $1 \le \mathrm{wind}(W_{\mathrm{DP}}, r_P)$ and

$$\pi(W_{\mathrm{ALG}}) = \sum_{P \in O} \mathrm{wind}(W_{\mathrm{ALG}}, r_P) \cdot \pi_P \le \sum_{P \in O} \mathrm{wind}(W_{\mathrm{DP}}, r_P) \cdot \pi_P$$

Therefore $c(W_{\mathrm{ALG}}) \le c_{\mathrm{DP}}$. (In fact, equality holds, as shown in the next section.) ◀

6 Correctness Proof

In defining W_{ALG}, we relied on the assumption that c_{DP} is finite. In this section we prove this fact, which implies that W_{ALG} exists, and we prove our main correctness result:

▶ **Theorem 12.** *W_{ALG} is an optimum solution to the* Enclosure-with-Penalties *problem.*

We defined the Enclosure-with-Penalties problem over the continuous space of all weakly simple polygons, but our algorithm only explores the discrete space of weakly simple polygons composed of at most $6n$ free-space edges. So we first prove that there is an optimum solution in this discrete space. A *feasible* solution is a weakly simple polygon that lies in the free space and encloses R.

▶ **Lemma 13.** *For the* Enclosure-with-Penalties *problem, there exists an optimum solution W_{OPT} of finite cost that consists of at most $6n$ free-space edges.*

Proof idea (Details in [5, Appendix E]). Let $\mathcal{S}$ be the discrete set of feasible solutions that consist of free-space edges each traversed at most twice. Because a planar graph on n vertices has at most $3n$ edges, any solution in $\mathcal{S}$ has at most $6n$ free-space edges.

We next prove that $\mathcal{S}$ contains a feasible solution that encloses R and excludes O, and thus has finite cost. The idea is to take the cycle boundaries of polygons in R and join them by paths traversed twice.

Since $\mathcal{S}$ is finite and nonempty, this implies that, among the solutions in $\mathcal{S}$, there is a solution W^* of minimum cost.

Finally, we prove that any feasible solution not in $\mathcal{S}$ can be homotopically shortened and then uncrossed to get a solution in $\mathcal{S}$ of no greater cost. Thus W^* is an optimum solution. ◀

We prove that the solution W_{OPT} from Lemma 13 is one of the candidate solutions over which the dynamic program optimizes. As a consequence:

▶ **Lemma 14.** $c_{\mathrm{DP}} \leq c(W_{\mathrm{OPT}})$.

Theorem 12 then follows: Lemmas 13 and 14 establish that c_{DP} is finite. Thus W_{ALG} exists. By Lemma 11, W_{ALG} is a feasible solution and $c(W_{\mathrm{ALG}}) \leq c_{\mathrm{DP}}$. Combining with Lemma 14 yields $c(W_{\mathrm{OPT}}) \leq c(W_{\mathrm{ALG}}) \leq c_{\mathrm{DP}} \leq c(W_{\mathrm{OPT}})$. Thus W_{ALG} is optimal.

We say a few words about the proof of Lemma 14. By the definition of c_{DP}, it suffices to show that $C(p, 6n, R) \leq c(W_{\mathrm{OPT}})$ for a vertex p on W_{OPT}. We give an inductive proof of the more general statement that $C(p, t, B)$ is at most the cost of any weakly simple polygon W with at most t free-space edges that encloses B and goes through p. Since W_{OPT} has at most $6n$ edges, this implies Lemma 14. The following lemma, which is proved in [5, Appendix E], includes an analogous inductive statement for $M(pq, t, B)$, with a suitable definition of the cost $c(W_0)$ of an open walk W_0. It refers to transition vertices, which were defined in Section 2.1.

▶ **Lemma 15.** (A) *Let W be a weakly simple polygon with ℓ free-space edges, going through vertex p, and let B be the objects of R that are enclosed by W. Then, for all $t \geq \ell$, $C(p, t, B) \leq c(W)$.*

(B) *Let W_0 be an open walk with ℓ free-space edges from p to q such that the polygon $W = W_0 + qp$ is weakly simple and q is not a transition vertex of W. Let B be the objects of R whose reference points lie inside W and not on pq. Then, for all $t \geq \ell$, $M(pq, t, B) \leq c(W_0)$.*

7 Reducing the Runtime with a Dijkstra-Style Algorithm

The runtime of our algorithm to solve the Enclosure-with-Penalties problem can be reduced by a $\Theta(n^2)$ factor, leading to the bound of Theorem 3.

The dynamic programming algorithm in Section 4 is guided by a parameter t, which limits the number of edges of the walk. We have proved (Lemma 13) that there is an optimal solution with at most $6n$ edges. Hence, the solution cannot be improved by allowing larger values of t; the iteration stabilizes, and the algorithm can stop when t reaches $6n$. The parameter t has been useful for ensuring that the quantities in the dynamic programming algorithm are well-defined, and it is essential as an induction variable for the proofs. We will now eliminate t and solve the recursion in the style of Dijkstra's algorithm for shortest paths. In particular, we use a generalization of Dijkstra's algorithm as proposed by Knuth [14].

More specifically, we define $C(p,B) := C(p,6n,B)$ and $M(pq,B) := M(pq,6n,B)$ in terms of the quantities from Section 4. By the above observations, $C(p,B) = C(p,t,B)$ and $M(pq,B) = M(pq,t,B)$ for all $t \geq 6n$. Therefore, the limit quantities $C(p,B)$ and $M(pq,B)$ fulfill a variation of the recursions (2–7) where the parameter t is eliminated:

$$C(p,\emptyset) = 0 \tag{9}$$

$$C(p,B) = \min\{C_1(p,B), C_2(p,B)\} \text{ for } B \neq \emptyset, \text{ where} \tag{10}$$

$$C_1(p,B) = \min\big\{\, w_{pq} + M(qp,B) \;\big|\; pq \text{ is a free-space edge} \,\big\} \tag{11}$$

$$C_2(p,B) = \min\big\{\, C(p,B') + C(p,B'') \;\big|\; B = B' \sqcup B'';\ B', B'' \neq \emptyset \,\big\} \tag{12}$$

$$M(pq,B) = \min\{M_1(pq,B), M_2(pq,B)\}, \text{ where} \tag{13}$$

$$M_1(pq,B) = \begin{cases} w_{pq} + C(q,B), & \text{if } pq \text{ is a free-space edge} \\ \infty, & \text{otherwise} \end{cases} \tag{14}$$

$$\begin{aligned} M_2(pq,B) = \min\big\{\, & M(pr,B') + M(rq,B'') + \pi(\Delta) \;\big|\; \\ & prq = \Delta \text{ is a counterclockwise triangle;} \\ & B = B' \sqcup B'' \sqcup \{P \in R \mid r_P \in \Delta\} \,\big\} \end{aligned} \tag{15}$$

As in Equation (8), we define the solution to the whole problem as

$$c_{\mathrm{DP}} := \min\{\, C(p,R) \mid p \text{ is a vertex} \,\}. \tag{16}$$

By Lemma 13 and by the definition of $C(p,B)$ and $M(pq,B)$, the value of c_{DP} resulting from (16) is the same as the one resulting from (8).

The system (9–15) is a *system of equations* that involves cyclic dependencies. Nevertheless, we can show that it has a unique solution [5, Appendix F.1, Lemma 22]. The reason is that on the right-hand side of the equations, the result of any expression combining some quantities of the form $C(p,B)$ and $M(pq,B)$ is always *larger* than these quantities.

Similar to Dijkstra's shortest-path algorithm, our algorithm maintains tentative values $C(p,B)$ and $M(pq,B)$. The smallest of the tentative values is made permanent, and all right-hand side expressions where this value appears are evaluated and used to update the corresponding tentative left-hand side values. The algorithm that carries out this idea is shown in the full version [5, Appendix F.2, Algorithm 1].

The most numerous quantities are the $O(2^k n^2)$ values $M(pq,B)$, and hence the space complexity is $O(2^k n^2)$. Compared to the running time for the dynamic programming algorithm in Section 4, we save a factor n^2: The elimination of t reduces the number of recursions by a factor $\Theta(n)$, and we save another factor $\Theta(n)$ because we need not go through all decompositions $t = t_1 + t_2$ on the right-hand side. The analysis of the full algorithm is given in [5, Appendix F.3]. The total running time is $O(3^k n^3)$, as claimed in Theorem 3.

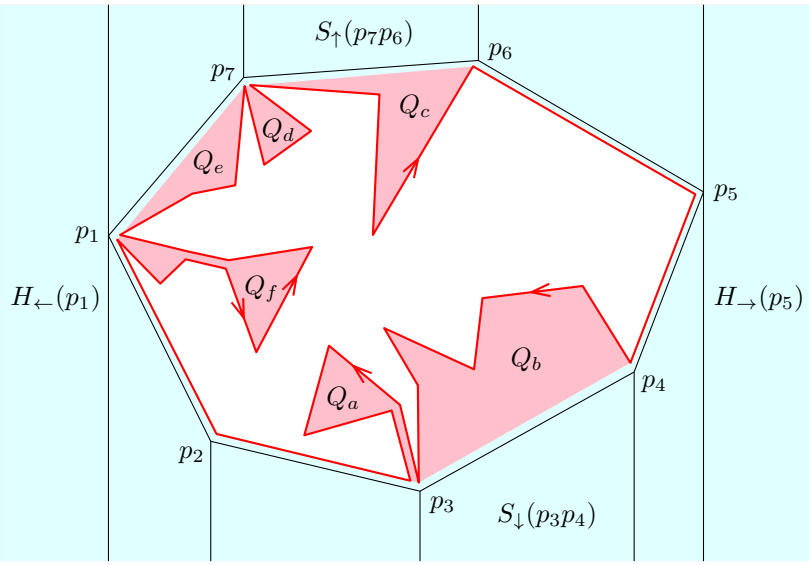

Figure 6 Partition of the outside into pockets $Q_a, \ldots, Q_f$, two half-planes, and seven planks.

8 The Inverted Problem

In the inverted problem, the required objects have to be outside the weakly simple polygon W, and the penalties of the polygons that are outside W are counted (see the introduction). The approach for the original problem has to be adapted accordingly. To derive a suitable dynamic programming formulation, we decompose the *outside* of W into elementary pieces, as shown in Figure 6: We form the convex hull of W and extend vertical rays upward and downward from the convex hull vertices. This leads to two additional types of regions:

- a left and a right half-plane, each bounded by a vertical line through an object vertex;
- vertical *planks*, that is, regions bounded by a line segment and two vertical upward rays or two vertical downward rays. We discuss such regions in [5, Appendix F.4].

We stick to the convention that the interior of the region of interest lies on the left side of W. Accordingly, the solution polygon W is now oriented clockwise.

In the algorithm, we build the region of interest outside-in, see Figure 7, starting from a left half-plane bounded by two vertical rays through an object vertex. We add planks from left to right along common rays, and, as in Section 4, we may also attach triangles along common edges and digons along common vertices. In addition to the usual bounded walks, we now also consider polygonal walks $W^{\updownarrow}$ that start from the endpoint of a vertical downward ray and end at a vertical upward ray. More precisely, for each pair of vertices p, q, we consider a subproblem of type U ("unbounded"), which considers regions bounded by a vertical ray down from p, a walk W from p to q, and a vertical ray up from q, see Figure 7 for an example; $p = q$ is allowed. Accordingly, the algorithm computes quantities $U(p, q, t, B)$ for all $B \subseteq R$ and $t \leq 6n$. The two unbounded rays jointly play the role of the mouth.

The full paper [5, Appendix G] describes how the dynamic programming recursion and the correctness proof of Section 6 for the non-inverted problem is adapted for the inverted problem.

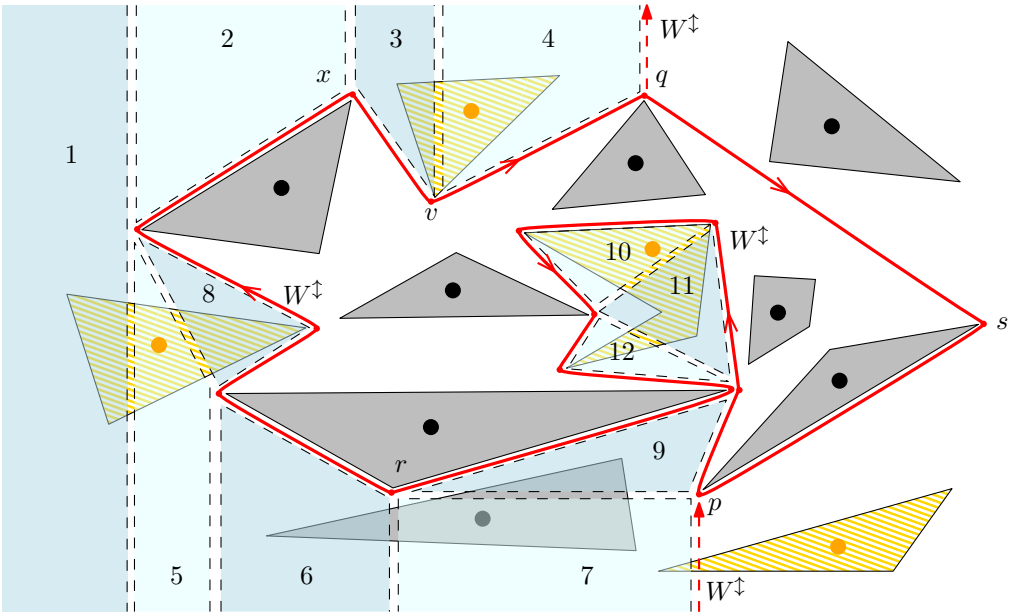

Figure 7 A weakly simple polygon W (red/bold) that has the four required objects (yellow/hatched) on the outside. The penalties of two optional (grey) objects is added to the length when the cost is computed. We grow the outer region triangle by triangle, considering also "triangles" that extend to $-\infty$ or $+\infty$ (vertical planks), or both, like the left half-plane (number 1). The union of the shaded blue regions is bounded by vertical rays from p downward and from q upward plus a weakly simple walk between p and q. The extended walk $W^{\updownarrow}$ is a candidate solution considered for the subproblem $U(p, q, B, t)$, when $t \geq 13$ and B consists of the three leftmost required objects. (The fourth required object has its reference point (thick dot) outside the region.) Two more planks, spanned by ps and qs, plus the right half-plane through s, would complete the outside region of W.

9 Applications, Extensions, and Open Problems

Splitting a surface. Our result may shed some light on the following open problem by Bulavka, Colin de Verdière, and Fuladi [6, Conclusion]: given an orientable combinatorial surface of genus g, and an integer g', $1 \leq g' < g$, is it FPT in g' to compute a shortest weakly simple closed curve that cuts off a surface of genus g'? The problem is FPT in g [7, Theorem 6.1]. Our algorithm for Graph-Enclosure-with-Penalties shows that the answer is yes when restricting to some (admittedly very special) instances, see [5, Appendix H], and thus provides some hope for a positive answer in general, although this remains open.

Curved objects and line segments. We believe that our approach carries over to more general objects. Curved objects that are sufficiently well behaved can be treated by considering all bitangents as free-space edges. We can handle point objects [5, Appendix I]; line segments without other vertices in their interior should also be doable. However, extending to weakly simple polygon objects seems difficult. Even for a path object consisting of two line segments joined at point p it is a challenge to prevent a solution from cutting through the path at p.

Recognizing weakly simple self-overlapping polygons. As mentioned, our dynamic program optimizes over the class of weakly simple self-overlapping polygons, see [5, Appendix L]. Weakly simple polygons can be recognized in $O(n \log n)$ time [2], and self-overlapping polygons in time $O(n^3)$ [16]. Can weakly simple self-overlapping polygons be recognized efficiently?

Abstract

A hypergraph H consists of a set V of vertices and a set E of hyperedges that are subsets of V. A *t-tuple* of H is a subset of t vertices of V. A t-tuple *k-coloring* of H is a mapping of its t-tuples into k colors. A coloring is called *(t,k,f)-polychromatic* if each hyperedge of E that has at least f vertices contains tuples of all the k colors. Let $f_H(t,k)$ be the minimum f such that H has a (t,k,f)-polychromatic coloring. For a family of hypergraphs $\mathcal{H}$ let $f_{\mathcal{H}}(t,k)$ be the maximum $f_H(t,k)$ over all hypergraphs H in $\mathcal{H}$. Determining $f_{\mathcal{H}}(t,k)$ has been an active research direction in recent years. This is challenging even for $t=1$. We present several new results in this direction for $t \geq 2$.

- Let $\mathcal{H}$ be the family of hypergraphs H that is obtained by taking any set P of points in $\mathbb{R}^2$, setting $V := P$ and $E := \{d \cap P \colon d \text{ is a disk in } \mathbb{R}^2\}$. We prove that $f_{\mathcal{H}}(2,k) \leq 3.7^k$, that is, the pairs of points (2-tuples) can be k-colored such that any disk containing at least 3.7^k points has pairs of all colors. We generalize this result to points and balls in higher dimensions.
- For the family $\mathcal{H}$ of hypergraphs that are defined by grid vertices and axis-parallel rectangles in the plane, we show that $f_{\mathcal{H}}(2,k) \leq \sqrt{ck \ln k}$ for some constant c. We then generalize this to higher dimensions, to other shapes, and to tuples of larger size.
- For the family $\mathcal{H}$ of shrinkable hypergraphs of VC-dimension at most d we prove that $f_{\mathcal{H}}(d{+}1,k) \leq c^k$ for some constant $c = c(d)$. Towards this bound, we obtain a result of independent interest: Every hypergraph with n vertices and with VC-dimension at most d has a $(d{+}1)$-tuple T of depth at least $\frac{n}{c}$, i.e., any hyperedge that contains T also contains $\frac{n}{c}$ other vertices.
- For the relationship between t-tuple coloring and vertex coloring in any hypergraph H we establish the inequality $\frac{1}{e} \cdot tk^{\frac{1}{t}} \leq f_H(t,k) \leq f_H(1, tk^{\frac{1}{t}})$. For the special case of $k=2$, referred to as the bichromatic coloring, we prove that $t+1 \leq f_H(t,2) \leq \max\{f_H(1,2), t+1\}$; this improves upon the previous best known upper bound.
- We study the relationship between tuple coloring and epsilon nets. In particular we show that if $f_H(1,k) = O(k)$ for a hypergraph H with n vertices, then for any $0 < \epsilon < 1$ the t-tuples of H can be partitioned into $\Omega\left(\left(\frac{\epsilon n}{t}\right)^t\right)$ ϵ-t-nets. This bound is tight when t is a constant.

1 Introduction

Polychromatic coloring and cover-decomposition of hypergraphs have rich backgrounds. They have been studied for both abstract and geometric hypergraphs as early as 1980 (see, e.g., [39, 40, 42, 43]) and are still active research areas (see, e.g., [1, 2, 14, 16, 18, 46]). Perhaps the study of these topics gained more attention after a question of Pach [39] in 1980:[1]

> *Does there exist a constant f such that every finite set of points in the plane can be colored with two colors in such a way that any unit disk that contains f points contains points of both colors?*

This question initiated the study of polychromatic coloring in geometric hypergraphs. Surprisingly enough, the answer to the question turned out to be negative, as it was proved in 2016 by Pach and Pálvölgyi [44]. In particular, they showed that for any natural number f, there is a finite set P of points in the plane such that for any 2-coloring of P, one can find a unit disk containing at least f points of one color and no point of the other color. The same question can be asked for other convex bodies and for more than two colors: Given a convex body C and any natural number $k \geq 2$, is there a function $f\colon \mathbb{N} \mapsto \mathbb{N}$ such that any finite point set in the plane can be k-colored such that any translate of C that contains at least $f(k)$ points, contains points of all the k colors? For instance, Pálvölgyi and Tóth [45] proved that $f(k)$ exists when C is a convex polygon – it was shown later [8, 26] that $f(k) = O(k)$. The negative answer of [44] to the original question of Pach implies that $f(2)$ does not exist if C is a disk. More results and details in this direction can be found in the survey article by Pach, Pálvölgyi and Tóth [41] and the webpage maintained by Keszegh and Pálvölgyi [30].

The containment of points in disks (and other convex bodies) can be represented by geometric hypergraphs, also known as range spaces. A *hypergraph* $H = (V, E)$ consists of a set V of vertices and a set E of hyperedges that are subsets of V. A (possibly infinite) set of hypergraphs is called a *family* of hypergraphs. Let $f_{\mathcal{H}}(k)$ be the smallest natural number such that the vertices of any hypergraph H in $\mathcal{H}$ can be k-colored such that any hyperedge of H that has at least $f_{\mathcal{H}}(k)$ vertices contains points of all colors. If no such number exists, then $f_{\mathcal{H}}(k) := \infty$. If $f_{\mathcal{H}}(2)$ exists, then $\mathcal{H}$ is called *cover-decomposable* – a term that Pach introduced for $k = 2$.

[1] This is a dual form of the original question that is stated in terms of f-folds and coverings; see [44].

Determining $f_{\mathcal{H}}(k)$ is an active research direction in both abstract and geometric hypergraphs; see e.g. [2, 14, 16, 17, 18, 20] and the references therein. Geometric hypergraphs, in particular, have received special attention. These hypergraphs are typically defined by points and convex bodies in some fixed constant dimension. For instance, let C be a convex body in $\mathbb{R}^2$ and let $\mathcal{H}$ be the family of all hypergraphs H that is obtained by taking any set P of points in $\mathbb{R}^2$, setting $V := P$ and $E := \{C' \cap P \colon C' \text{ is a translate of } C\}$. As mentioned above, if C is a disk then $f_{\mathcal{H}}(2)$ does not exist and hence $\mathcal{H}$ is not cover-decomposable [44], and if C is a convex polygon then $f_{\mathcal{H}}(2)$ exists and $\mathcal{H}$ is cover-decomposable [45]. Finding $f_{\mathcal{H}}(k)$ could be more challenging if we could scale or rotate the convex body. For example if C is the family of axis-parallel squares then $f_{\mathcal{H}}(2) \leq 215$ [2], and if C is the family of axis-parallel rectangles then $f_{\mathcal{H}}(2)$ does not exist [21].

A natural question thus arises: For hypergraphs that are not cover-decomposable with respect to the coloring of vertices, such as those defined by disks and axis-parallel rectangles, can we prove a positive result when we color subsets rather then the vertices? This leads to a natural generalization of the problem: color pairs, triples, or tuples of points. This generalization is referred to as *tuple coloring*. Let $H = (V, E)$ be a hypergraph. For a natural number t, a *t-tuple* of H is a subset of t vertices of V. The number of t-tuples of H is $\binom{|V|}{t}$. A t-tuple *k-coloring* of H is mapping of its t-tuples into k colors. For $t = 1$, this is equivalent to vertex coloring. A coloring is called *(t, k, f)-polychromatic* if each hyperedge of E that has at least f vertices contains tuples of all the k colors. Let $f_H(t, k)$ denote the least integer f such that H has a (t, k, f)-polychromatic coloring. For a hypergraph family $\mathcal{H}$ let $f_{\mathcal{H}}(t, k)$ denote the maximum $f_H(t, k)$ over all hypergraphs H in $\mathcal{H}$. In other words, $f_{\mathcal{H}}(t, k)$ is the minimum number for which every hypergraph in $\mathcal{H}$ has a $(t, k, f_{\mathcal{H}}(t, k))$-polychromatic coloring. For the standard vertex coloring, where $t = 1$, the value $f_{\mathcal{H}}(1, k)$ is equal to $f_{\mathcal{H}}(k)$ as defined above. With this definition, $\mathcal{H}$ is cover-decomposable if $f_{\mathcal{H}}(1, 2)$ exists. The family $\mathcal{H}$ is called *t-cover-decomposable*, for $t \geq 2$, if $f_{\mathcal{H}}(t, 2)$ exists.

1.1 Other related results

There is a rich literature for vertex-coloring (i.e. when $t = 1$) of geometric hypergraphs. In these hypergraphs, the vertices are usually defined by points and the hyperedges are defined by geometric shapes such as disks, rectangles, squares, bottomless rectangles, strips, quadrants, triangles, octants, and halfplanes; see, for example [2, 7, 8, 10, 16, 20, 21, 26, 31, 44, 45] and a recent article by Planken and Ueckerdt [46] that gives a summary of the results.

For $t \geq 2$, coloring t-tuples in hypergraphs is closely related to Ramsey-type problems (see [35] for Ramsey problems in hypergraphs). In particular, it follows from Ramsey's theorem that for any two natural numbers t and d, where $t \leq d$, the family of complete d-uniform hypergraphs is not t-cover-decomposable, i.e., $f_{\mathcal{H}}(t, 2)$ is unbounded.

A recent work of Ackerman, Keszegh, and Pálvölgyi [1] is devoted to determining $f_{\mathcal{H}}(t, k)$ for $t \geq 2$ in geometric hypergraphs that are defined by halfspaces, pseudo-disks, and boxes. In particular, for the family $\mathcal{H}$ of hypergraphs that are defined by points and axis-parallel boxes in dimension $d \geq 2$ they show that $f_{\mathcal{H}}(t, k) \leq k^{2^{d-1}} + t - 1$ when $t \geq 2$ (to better appreciate this bound we shall recall that $f_{\mathcal{H}}(t, k)$ is unbounded when $t = 1$, as shown in [21]). From this result it follows that for the family $\mathcal{H}$ of hypergraphs that are defined by points and homothets[2] of a fixed convex polytope with h facets in some dimension it holds that $f_{\mathcal{H}}(t, k) \leq k^{2^{h-1}} + t - 1$ [1].

[2] A homothet of an object is obtained by translating and scaling the object.

1.2 Preliminaries

When the family or hypergraphs or a particular hypergraph is clear from the context we may drop the subscript and simply write $f(t,k)$ for $f_{\mathcal{H}}(t,k)$ and $f_H(t,k)$. First we define the notion of shrinkability which is a common property of many geometric hypergraphs.

▶ **Definition 1.1** (Shrinkability). *A hypergraph H is shrinkable if for every hyperedge $e \in H$ and for every integer $1 \leq i \leq |e|$ there exists a hyperedge e' in H such that $e' \subseteq e$ and $|e'| = i$.*

The VC-dimension of a hypergraph is a measure of its complexity, and it plays a central role in statistical learning, computational geometry, and other areas of computer science and combinatorics (see, e.g., [4, 13, 33, 36]).

▶ **Definition 1.2** (VC-dimension). *The VC-dimension of a hypergraph $H = (V, E)$ is the size of the largest subset $S \subseteq V$ such that for every subset $B \subseteq S$ there is a hyperedge $e \in E$ where $e \cap S = B$. Such a subset S is said to be "shattered" by H.*

The following inequality, usually referred to as the Sauer-Shelah-Perles lemma [15, 48, 50], relates the number of vertices and hyperedges of a hypergraph of VC-dimension d:

$$|E| \leq \sum_{i=0}^{d} \binom{|V|}{i}.$$

For a hypergraph $H = (V, E)$ and a subset $X \subseteq V$ the *projection* of H to X is the hypergraph $H[X] = (X, \{e \cap X \colon e \in E\})$. The VC-dimension of $H[X]$ is, at most, the VC-dimension of H because any subset that is shattered by $H[X]$ is also shattered by H.

Let P be a set of points in the plane. The *depth* of a pair $\{x, y\}$ of points in P, denoted by $d_P(x, y)$, is defined as the maximum integer i such that any disk containing x and y contains at least i other points of P. Notice that $0 \leq d_P(x, y) \leq |P| - 2$. The existence of pairs of large depth (also known as deep pairs) is studied in [11, 24, 28, 29, 38, 47]. The notion of depth can be generalized to tuples of points and to higher dimensions as the maximum number i such that any ball containing a deep tuple also contains i other points. We extend the notion of depth further into hypergraphs.

▶ **Definition 1.3** (Depth). *Let $H = (V, E)$ be a hypergraph and S be a subset of V. The depth $d_H(S)$ of S is defined as the maximum integer such that for every hyperedge $e \in E$ that contains S, we have $|e \backslash S| \geq d_H(S)$. If no hyperedge contains S then $d_H(S) := |V \backslash S|$.*

Note that if S has depth i, then in particular every hyperedge that contains S contains at least i other vertices. The notion of depth is monotone with respect to projections, in the sense that for any $X \subseteq V$, we have $d_{H[X]}(S) \leq d_H(S)$.

Let H be a hypergraph and $0 < \epsilon < 1$ be a real number. A subset S of vertices is called an *ϵ-net* for H if any hyperedge e of size at least $\epsilon|V|$ contains a vertex from S. This notion was introduced by Haussler and Welzl [27]. It was then generalized by Mustafa and Ray [37] to tuples and appears under *ϵ-t-nets*; see also [5, 23].

▶ **Definition 1.4** (ϵ-t-Net). *Let $H = (V, E)$ be a hypergraph, $\epsilon \in (0, 1)$ be a real number, and t be a natural number. A subset N of t-tuples of V is called an ϵ-t-net if any hyperedge e in E of size at least $\epsilon|V|$ contains at least one of the t-tuples in N.*

1.3 Our contributions

We present upper bounds on $f(t,k)$ for several families of geometric hypergraphs and hypergraphs of bounded VC-dimension. Some of our bounds are new, and some improve over previously known bounds. These bounds are interesting because, for abstract hypergraphs, $f(t,k)$ is unbounded even if the hypergraph is uniform and $k=2$ (due to Ramsey's theorem; see [35]). We also study the relationship between vertex-coloring, tuple-coloring, cover-decomposability, and epsilon t-nets.

Recall that $f(t,2)$, with $t=1$, is unbounded for hypergraphs that are defined by points and disks in the plane [44] . We prove, however, that it is bounded for $t=2$. A point set P in dimension d is said to be in *general position* if no $(d+2)$ points of P lie on a sphere.

▶ **Theorem 1.5.** *Let $\mathcal{H}$ be the family that contains any hypergraph H that can be obtained by taking a finite set P of points in $\mathbb{R}^2$ in general position setting $V(H) := P$ and $E(H) := \{d \cap P : d \text{ is a disk in } \mathbb{R}^2\}$. Then for any natural number k it holds that $f_{\mathcal{H}}(2,k) \leq 3.7^k$.*

In other words, for any finite set P of points in the plane, the $\binom{|P|}{2}$ pairs of points can be k-colored such that any disk containing at least 3.7^k points must also contain a pair (of points) from each of the k color classes. To obtain this bound, we show some properties of containment of points in disks and also employ a result about the depth of pairs of points – a well-studied topic in discrete and computational geometry [24, 47]. We then generalize this result to tuples and balls in higher dimensions. The parameter e below denotes Euler's number.

▶ **Theorem 1.6.** *Let $d \geq 3$ be an integer and set $t := \lfloor \frac{d+3}{2} \rfloor$. Let $\mathcal{H}$ be the family of all hypergraphs H that can be obtained by taking a finite set P of points in $\mathbb{R}^d$ in general position setting $V(H) := P$ and $E(H) := \{b \cap P : b \text{ is a ball in } \mathbb{R}^d\}$. Then for any natural number k it holds that $f_{\mathcal{H}}(t,k) \leq \left(\frac{4}{5ed^3}\right)^k$.*

For points and axis-parallel rectangles in the plane, we know from [21] that $f(t,2)$ is unbounded when $t=1$. However for $t=2$ a result of [1] implies that $f(2,k) \leq k^2+1$. We study the same problem but for grid points.

▶ **Theorem 1.7.** *Let $\mathcal{H}$ be the family of all hypergraphs H that can be obtained by taking the vertex set P of a regular grid in $\mathbb{R}^2$ setting $V(H){:=}P$ and $E(H){:=}\{r \cap P : r \text{ is an axis-parallel rectangle in } \mathbb{R}^2\}$. Then for any natural number $k \geq 2$ it holds that $f_{\mathcal{H}}(2,k) \leq \sqrt{ck \ln k}$, for some constant $c \geq 126$.*

To better appreciate this bound, observe that $f(2,k) = \Omega(\sqrt{k})$ for any hypergraph (see also Section 5). Theorem 1.8 (proven in the full version of the paper [12]) generalizes this result.

▶ **Theorem 1.8.** *Let $\mathcal{H}$ be the family of all hypergraphs that can be obtained by grid points and boxes (or balls) in any fixed dimension $d \geq 2$. Then for any natural numbers $t \geq 1$ and $k \geq 2$ it holds that $f_{\mathcal{H}}(t,k) = O\left((k \ln k)^{1/t}\right)$.*

We also study hypergraphs of bounded VC-dimension.

▶ **Theorem 1.9.** *For every shrinkable hypergraph H with VC-dimension at least 2 and at most d and with $n \geq 2d+2$ vertices it holds that $f_H(d+1,k) \leq c^{k-1}$ for any $k \geq 1$ and any $c \geq 4(d+1)^{d+1}$.*

This result applies to many families of geometric hypergraphs. For example, hypergraphs defined by points and halfspaces, boxes, or balls in $\mathbb{R}^d$ are shrinkable and have bounded VC dimensions. Along with a proof of this result, we show the existence of a tuple of large depth in hypergraphs of bounded VC-dimension, which is of independent interest.

▶ **Theorem 1.10.** *For every hypergraph H with VC-dimension at least 2 and at most d and with $n \geq 2d+2$ vertices there exists a $(d+1)$-tuple T of vertices such that $d_H(T) \geq \frac{n}{c}$, for $c = 4(d+1)^{d+1}$.*

For hypergraphs where $f(1,x)$ is linear in x, we prove the following asymptotic tight bounds for their tuple-coloring and for decomposition of their tuples into epsilon t-nets.

▶ **Theorem 1.11.** *Let H be a hypergraph for which $f_H(1,x) = O(x)$, for any $x \geq 1$. Then for any natural numbers t and k with $tk^{1/t} \geq 1$ we have $f_H(t,k) = \Theta(tk^{\frac{1}{t}})$.*

▶ **Theorem 1.12.** *Let H be a hypergraph with n vertices such that $f_H(1,x) = O(x)$, for any $x \geq 1$. Then for any $0 < \epsilon < 1$ and any $t \geq 1$ the t-tuples of vertices of H can be decomposed into $\Omega\left((\frac{\epsilon n}{t})^t\right)$ pairwise disjoint ϵ-t-nets for H. This bound is asymptotically tight when t is a constant.*

For an implication of Theorem 1.11 consider the family $\mathcal{H}$ of hypergraphs that are defined by points and halfplanes in $\mathbb{R}^2$. From a result of Smorodinsky and Yuditsky [52] we know that $f_{\mathcal{H}}(1,x) \leq 2x-1$, i.e., any set of points in the plane can be colored by x colors such that any halfplane containing at least $2x-1$ points contains points of all colors. Therefore, Theorem 1.11 implies that $f_{\mathcal{H}}(t,k) = \Theta(tk^{\frac{1}{t}})$.

Finally, we study the relationship between $f(1,k)$ and $f(t,k)$ for $k = 2$, which is usually referred to as bichromatic coloring. It is implied from a result of Ackerman, Keszegh, and Pálvölgyi [1, Proposition 4] that $f_H = (t,2) \leq \max\{f_H(1,2), 2t-1\}$ for any family H and any $t \geq 2$. We present the following improved upper bound.

▶ **Theorem 1.13.** *For any hypergraph H and any integer $t \geq 2$ it holds that*

$$t+1 \leq f_H(t,2) \leq \max\{f_H(1,2), t+1\}.$$

The matching term $t+1$ in the lower and upper bounds of Theorem 1.13 determines the exact value of $f(t,2)$ for some classes of hypergraphs. For instance, when H is defined by points and halfplanes in $\mathbb{R}^2$, the result of Smorodinsky and Yuditsky [52] gives $f_H(1,2) = 3$, and thus Theorem 1.13 implies the following corollary.

▶ **Corollary 1.14.** *Let $t \geq 2$ be an integer. For the family $\mathcal{H}$ of hypergraphs that are defined by points and halfplanes in $\mathbb{R}^2$, it holds that $f_{\mathcal{H}}(t,2) = t+1$.*

2 Coloring Tuples of Points with respect to Disks and Balls

In this section, we prove Theorem 1.5 and Theorem 1.6. Our proofs relies on some simple structural properties of the containment of points in disks and balls. They also employ some results about the existence of deep tuples in point sets. Without loss of generality, all point sets that are considered in this section are assumed to be in general position.

2.1 Points and disks in $\mathbb{R}^2$

Let $\mathcal{H}$ be the family of hypergraphs defined by points and disks in the plane. That is, $\mathcal{H}$ contains any hypergraph H that can be obtained by taking a finite set P of points in $\mathbb{R}^2$ setting $V(H) := P$ and $E(H) := \{d \cap P : d \text{ is a disk in } \mathbb{R}^2\}$. In this section we prove that $f_{\mathcal{H}}(2,k) \leq 3.7^k$. We say that a disk d *contains* a point p if p is in the interior or on the boundary of d. Alternatively, we say that p is in d.

One part of our proof employs the following result of Ramos and Viaña [47]; this is a stronger version of a result that previously appeared in [24].

▶ **Lemma 2.1** (Ramos and Viaña [47]). *In any set of n points in the plane, there is a pair of points such that any circle through them has, both inside and outside, at least $\frac{n}{4.7}$ points (excluding the two points themselves).*

This result is obtained by using the duality (of circles in $\mathbb{R}^2$ and planes in $\mathbb{R}^3$) and some known results on facets of points in $\mathbb{R}^3$. The pair that is obtained by Lemma 2.1 has the property that any circle through them has at least $\frac{n}{4.7}$ and at most $n-\frac{n}{4.7}-2$ points inside. Combining this with the notion of depth, we get the following corollary.

▶ **Corollary 2.2.** *In any set of n points in the plane there is a pair $\{x, y\}$ such that*

$$\frac{n}{4.7} \leq d_P(x, y) < \frac{3.7n}{4.7}.$$

The following lemmas, though very simple, play important roles in our proof. We denote the boundary circle of a disk D by ∂D.

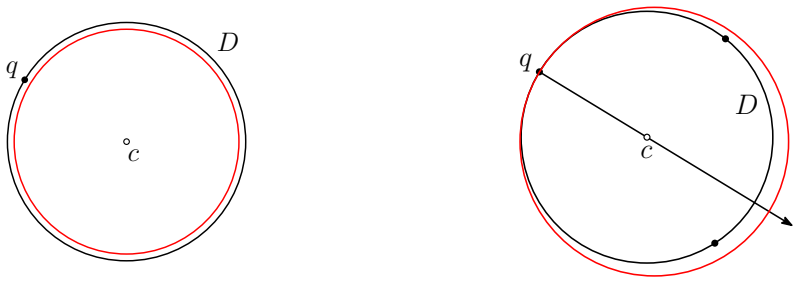

Figure 1 (a) Shrinking D to lose q. (b) Enlarging D along the ray from q to c.

▶ **Lemma 2.3.** *Let P be a finite set of points in the plane and let D be a disk with $|D \cap P| = j$ for some $j \geq 1$. There exists a disk D' such that $(D' \cap P) \subseteq D$ and $|D' \cap P| = j - 1$.*

Proof. Fix D at its center c and shrink it until a point $q \in P$ appears on ∂D for the first time. If q is the only point of P on ∂D, we shrink D slightly to lose q, as in Figure 1(a). Assume that there are other points of P on ∂D. Fix D at q and enlarge it slightly along the ray from q to c such that all other points on ∂D fall inside D and no new point appears in D, as in Figure 1(b). Now, q is the only point on ∂D. Again, we fix D at the center of the new disk and shrink it slightly to lose q. ◀

By repeatedly applying Lemma 2.3, one can shrink/enlarge a disk D to lose 1, 2, 3, or more points of P. Therefore, we get the following more general lemma.

▶ **Lemma 2.4.** *Let P be a finite set of points and D be a disk with $|D \cap P| = j$. For any integer $0 \leq i \leq j$ there exists a disk D' such that $(D' \cap P) \subseteq D$ and $|D' \cap P| = i$.*

▶ **Lemma 2.5.** *Let D be a disk and x, y be two points in the interior of D. There exists a disk that is contained in the interior of D such that its boundary passes through x and y.*

Proof. Fix D at its center c and shrink it until a point, say x, appears on ∂D for the first time. Then fix D at x and shrink it along the segment cx until y appears on ∂D. This disk satisfies the constraints of the lemma. ◀

▶ **Lemma 2.6.** *Let P be a finite set of points in the plane, and let S be a subset of P. Then for any pair $\{x, y\}$ in S it holds that $d_S(x, y) \leq d_P(x, y)$.*

Proof. This is true because for any disk D in the plane, the number of points of P in D is at least the number of points of S in D. ◀

We are ready for the proof of Theorem 1.5.

Proof of Theorem 1.5. Consider any hypergraph H in $\mathcal{H}$ with vertex set P. We color each pair $\{x, y\}$ of points in P with one of the k colors $\{0, 1, \ldots, k-1\}$ as follows:

$$\text{color of } \{x,y\} = \begin{cases} 0 & \text{if } d_P(x,y) = 0 \\ i+1 & \text{if } 3.7^i \leq d_P(x,y) < 3.7^{i+1} \text{ for some } i \in \{0,1,\ldots,k-3\} \\ k-1 & \text{if } d_P(x,y) \geq 3.7^{k-2}. \end{cases}$$

We prove that any disk D containing at least 3.7^k points has pairs of all the k colors.

By an application of Lemma 2.4 there is a disk D_0 such that $(D_0 \cap P) \subseteq D$ and $|D_0 \cap P| = 2$. The two points in D_0 have depth 0 and thus are colored 0.

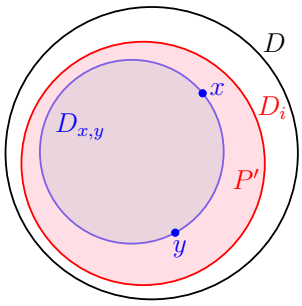

Figure 2 Illustration of the proof of Theorem 1.5.

For each $i \in \{0, \ldots, k-2\}$, we show that there is a pair of points with color $i{+}1$ in D. Let D_i be a disk such that $(D_i \cap P) \subseteq D$ and $|D_i \cap P| = 4.7 \cdot 3.7^i$ (such a disk exists by Lemma 2.4 and the fact that $4.7 \cdot 3.7^i < 3.7^k \leq |D \cap P|$). Let P' be the set of points in D_i. See Figure 2. By Corollary 2.2 the set P' contains a pair $\{x, y\}$ such that any disk through them has at least $\frac{|P'|}{4.7} = 3.7^i$ and at most $\frac{3.7|P'|}{4.7} - 2 = 3.7^{i+1} - 2$ points of P' inside. Thus $3.7^i \leq d_{P'}(x, y) < 3.7^{i+1}$. We argue that these bounds also hold with respect to P, that is $3.7^i \leq d_P(x, y) < 3.7^{i+1}$. The lower bound is implied from Lemma 2.6 because $d_{P'}(x, y) \leq d_P(x, y)$. To verify the upper bound, we take an arbitrary disk D_{xy} through x and y in the interior of D_i (such a disk exists by Lemma 2.5). The disk D_{xy} contains at most 3.7^{i+1} points of P'. Since D_{xy} does not contain any point outside D, it has at most 3.7^{i+1} points of P. This verifies the upper bound on $d_P(x, y)$. Therefore, the pair $\{x, y\}$ has color $i{+}1$. ◀

▶ Remark. To assist the readability of the proof of Theorem 1.5 we avoided rounding when applying Lemma 2.4; this has a negligible impact on the proof. The disk D_i would be chosen to have $\lceil 4.7 \cdot 3.7^i \rceil$ points, which is smaller than 3.7^k. The depth of the pair $\{x, y\}$ in P' would be at least $\frac{\lceil 4.7 \cdot 3.7^i \rceil}{4.7} \geq 3.7^i$ and at most $|P'| - \frac{|P'|}{4.7} - 2 \leq \frac{3.7\lceil 4.7 \cdot 3.7^i \rceil}{4.7} - 2 < 3.7^{i+1}$.

▶ Remark. Ramos and Viaña [47] conjectured that the correct bound in Lemma 2.1 should be $\lfloor \frac{n}{4} \rfloor - 1$. This bound, if true, would be the best achievable [29]. Moreover, it would immediately improve the bound of Theorem 1.5 to 3^k.

2.2 Points and balls in $\mathbb{R}^d$

Our previous result for pairs and disks can be generalized for tuples and balls in higher dimensions. We only need results analogous to Lemma 2.1 (or Corollary 2.2) and Lemma 2.4 in higher dimensions. The following lemma is analogous to Lemma 2.1.

▶ **Lemma 2.7** (Smorodinsky, Sulovský, and Wagner [51]). *In any set of n points in $\mathbb{R}^d$ there is a subset S of size $\lfloor \frac{d+3}{2} \rfloor$ such that any ball containing S contains at least $\frac{4n}{5ed^3}$ points.*

The coefficient $\frac{4}{5ed^3}$ in the lemma is an improvement over the previous (smaller) constant due to Bárány et al. [11]. It is surprising that the bound $\lfloor \frac{d+3}{2} \rfloor$ in the lemma is strongly sharp as proved in [11], in the sense that, there is a set P of points in $\mathbb{R}^d$ (obtained on the moment curve) such that for any subset S of P with $|S| < \lfloor \frac{d+3}{2} \rfloor$ there is a ball that contains S but no other point of P. An analogue to Lemma 2.4 can be obtained in a similar fashion by repeatedly shrinking the ball to lose one point in each iteration.

▶ **Lemma 2.8.** *Let P be a finite set of points in $\mathbb{R}^d$ and B be a ball with $|B \cap P| = j$ for some $j \geq 1$. There exists a ball B' such that $(B' \cap P) \subseteq B$ and $|B' \cap P| = j - 1$.*

Proof. Fix B at its center c and shrink it until, for the first time, a point $q \in P$ appears on ∂B. If ∂B contains other points of P, fix B at q and enlarge slightly along cq so that q becomes the only point on ∂B. Then fix B at c and shrink slightly to lose q. ◀

We sketch a proof of Theorem 1.6, which is somewhat analogous to that of Theorem 1.5.

Proof Sketch for Theorem 1.6. Our proof uses a coloring approach similar to that in the proof of Theorem 1.5. We color every tuple T of size t as follows. If the depth of T is 0 then color it 0 if the depth is at least $\left(\frac{4}{5ed^3}\right)^{k-2}$ then color it $k-1$, and if the depth is at least $\left(\frac{4}{5ed^3}\right)^{i}$ but smaller than $\left(\frac{4}{5ed^3}\right)^{i+1}$ then color it i+1. Then by applications of Lemma 2.8 and Lemma 2.7 one can show that any ball containing at least $\left(\frac{4}{5ed^3}\right)^{k}$ points contains t-tuples of all the k colors. ◀

▶ Remark. The proof of Theorem 1.6 is not completely analogous to that of Theorem 1.5. The proof of Theorem 1.5 relies on the existence of a pair whose depth is large but also not too large (Corollary 2.2). The latter part, however, is not given by Lemma 2.7, and thus the proof of Theorem 1.6 relies on the existence of a pair of large depth; later we will see a similar argument in the proof of Theorem 1.9. Such a proof would also work for Theorem 1.5, giving a bound of 4.7^k instead of 3.7^k.

▶ Remark. The bound of Theorem 1.6 also applies to hypergraphs defined by points and halfspaces in dimension d because a halfspace can be seen as a very large ball.

3 Coloring Tuples of Grid Points

Here we prove Theorem 1.7. Our main tool is the Lovász local lemma [25]. Recall that $\mathcal{H}$ is the family of all hypergraphs H that is obtained by taking the vertex set P of a regular grid in $\mathbb{R}^2$ setting $V(H)$:=P and $E(H)$:=$\{r \cap P : r$ is an axis-parallel rectangle in $\mathbb{R}^2\}$. We prove for any natural number $k \geq 2$ that $f_{\mathcal{H}}(2,k) \leq \sqrt{ck \ln k}$, for some constant $c \geq 126$.

Proof of Theorem 1.7. Set $m := \sqrt{ck \ln k}$. Consider any hypergraph in $\mathcal{H}$. It suffices to prove the statement for hyperedges (i.e. rectangles) that contain at least m and at most $2m$ points, because any rectangle with more than $2m$ points can be shrunk to have between m and $2m$ points. Any polychromatic coloring with respect to shrunk rectangles is also polychromatic coloring with respect to original rectangles.

We prove the existence of a k-coloring of pairs of P using the probabilistic method and the Lovász local lemma [25]; the coloring itself can be computed by the constructive proof of the local lemma that is given by Moser and Tardos [34]. We color the pairs in P by one of the colors from $\{0, \dots, k-1\}$ uniformly at random. Let R be any rectangle containing at least m and at most $2m$ points. The number of pairs in R is at least $\binom{m}{2} \geq \frac{1}{4}ck \ln k$. Consider any color $i \in \{0, \dots, k-1\}$. The probability that a pair $\{x, y\}$ is not colored i is

$$\Pr(\{x, y\} \text{ is not colored } i) = 1 - \frac{1}{k} \leq e^{\frac{-1}{k}}.$$

Since the pairs are colored independently, the probability that no pair in R is colored i is

$$\Pr(\text{no color } i \text{ in } R) \leq \left(e^{\frac{-1}{k}}\right)^{\frac{1}{4}ck \ln k} = \frac{1}{k^{c/4}}.$$

Summing over all the k colors, the union bound implies that the probability of a "bad" event E_R that the rectangle R is not polychromatic (not having at least one of the k colors) is

$$p = \Pr(E_R) \leq \frac{1}{k^{\frac{c}{4}-1}}.$$

Notice that for two rectangles R and R' that do not overlap on any grid point the events E_R and $E_{R'}$ are independent.

Fix a rectangle R. The length and width of R is at most $2m$. Thus, R lies in a square S of side length $2m$. The rectangle R can overlap only with rectangles that are at most $2m$ points away from R in each direction. Thus, the overlapping rectangles must lie in a (bigger) square S^+ of side length $6m$. The number of points in S^+ is $(6m)^2$. Thus, the number of overlapping rectangles is at most $(6m)^4$ because each such rectangle can be defined by two points (say bottom left and top right points). Therefore, any bad event E_R is independent of all but at most

$$d = 6^4 m^4 = 6^4 c^2 k^2 \ln^2 k \leq 6^4 c^2 k^4$$

other events. We claim that $4pd < 1$. Indeed, notice that

$$4pd \leq 4 \frac{1}{k^{\frac{c}{4}-1}} 6^4 c^2 k^4 = \frac{4 \cdot 6^4 c^2}{k^{\frac{c}{4}-5}} \leq \frac{4 \cdot 6^4 c^2}{2^{\frac{c}{4}-5}},$$

where the last inequality is valid because $k \geq 2$. The last expression is a decreasing function in c over the interval $[126, +\infty)$, and its value is less than 1 at $c = 126$. Since $4pd < 1$, the local lemma implies that with a positive probability none of the bad events occur, which in turn implies the existence of a k-coloring of pairs in P such that every rectangle containing at least m points is polychromatic. This completes the proof. ◀

▶ Remark 3.1. Due to our desire to have a short proof, we did not optimize the constant c in Theorem 1.7. It can be improved in several ways, for instance, (i) one can shrink rectangles to have between m and $m + \sqrt{m}$ points instead of m and $2m$ points, (ii) one can consider the neighborhood of R itself instead of the neighborhood of the enclosing square S^+ which is larger, (iii) to count rectangles intersecting R one can exclude those that contain less than m points, and (iv) by using the stronger threshold of $epd < 1$ for the local lemma [49].

4 Coloring Tuples in Hypergraphs of Bounded VC-Dimension

In this section we first prove Theorem 1.10 – the existence of a $(d+1)$-tuple of depth at least $\frac{n}{c}$, with $c = 4(d+1)^{d+1}$, in any hypergraph H of VC-dimension at least 2 and at most d and with $n \geq 2d+2$ vertices. This result, of independent interest, is analogous to Lemma 2.1 and Lemma 2.7. Our proof uses the probabilistic method, which is a common technique in combinatorics and discrete geometry [6, 22]. We then use this result to prove Theorem 1.9.

Proof of Theorem 1.10. Let V be the vertex set of H and $\mathcal{E}$ be the hyperedge set of H. Let k be the maximum depth of a $(d+1)$-tuple in V with respect to H.

If H has a $(d+1)$-tuple T that is not in any hyperedge of $\mathcal{E}$ then, by definition, $d_H = n - (d+1) \geq \frac{n}{2}$ and the lemma holds. Therefore, we assume that each $(d+1)$-tuple T belongs to some hyperedge of $\mathcal{E}$. Let $e_T \in \mathcal{E}$ be a hyperedge that identifies the depth of T, i.e, $T \subseteq e_T$ and $d_H(T) = |e_T| - (d+1)$.

Let $X \subseteq V$ be a random sample of the vertices from V where each vertex is chosen from X independently with a fixed probability $1/n \leq p \leq 1$ (to be determined). Let $\mathcal{E}'$ be the set of all hyperedges in $H[X]$ with cardinality equal to $d+1$. Notice that $|X|$ and $|\mathcal{E}'|$ are random variables. Also, notice that the VC-dimension d' of the projection $H[X]$ is at most d. Thus by the Sauer-Shelah-Perles lemma [48, 50, 15] we have $|\mathcal{E}'| \leq \sum_{i=0}^{d'} \binom{|X|}{i}$. This inequality also holds for the expectations, and we have

$$
\begin{aligned}
\mathbb{E}(|\mathcal{E}'|) &\leq \mathbb{E}\left(\sum_{i=0}^{d'} \binom{|X|}{i}\right) \\
&\leq \mathbb{E}\left(\sum_{i=0}^{d} \binom{|X|}{i}\right) \\
&\leq \mathbb{E}\Big(|X|(|X|-1)\cdots(|X|-d+1)\Big) \\
&= \sum_{i=0}^{n} i(i-1)\cdots(i-d+1)\binom{n}{i} p^i (1-p)^{n-i} \\
&= \sum_{i=d}^{n} \frac{n(n-1)\cdots(n-i+1)}{(i-d)!} p^i (1-p)^{n-i} \\
&= n(n-1)\cdots(n-d+1)p^d \sum_{i=d}^{n} \frac{(n-d)\cdots(n-i+1)}{(i-d)!} p^{i-d}(1-p)^{(n-d)-(i-d)} \\
&= n(n-1)\cdots(n-d+1)p^d \\
&\leq (np)^d.
\end{aligned}
$$

For each $(d+1)$-tuple T in V the probability that $T \in \mathcal{E}'$ is at least the probability that $e_T \cap X = T$ which is exactly $p^{d+1}(1-p)^{d_H(T)}$. Each such probability is at least $p^{d+1}(1-p)^k$ because $d_H(T) \leq k$ for all T. By interpreting $|\mathcal{E}'|$ as the sum of binary indicator variables (one for each $(d+1)$-tuple) and then applying the linearity of expectation, we get

$$
p^{d+1}(1-p)^k \binom{n}{d+1} \leq \mathbb{E}(|\mathcal{E}'|).
$$

Combining this with the upper bound $(np)^d$ and setting $p := \frac{1}{k}$ we get

$$
\binom{n}{d+1} \leq \frac{kn^d}{(1-\frac{1}{k})^k}.
$$

Since $(1-1/k)^k \geq \frac{1}{4}$, we have

$$\binom{n}{d+1} \leq 4kn^d.$$

So $k \geq \frac{\binom{n}{d+1}}{4n^d} \geq \frac{n}{c}$ for $c = 4(d+1)^{d+1}$. This completes the proof. ◀

Now we use Theorem 1.10 to prove Theorem 1.9 which states that for every shrinkable hypergraph H with VC-dimension at least 2 and at most d and with $n \geq 2d+2$ we have $f_H(d+1,k) \leq c^{k-1}$, for any $k \geq 1$ and any $c \geq 4(d+1)^{d+1}$.

Proof of Theorem 1.9. Our proof is somewhat similar to that of Theorem 1.5. We color each $(d+1)$-tuple of vertices of H with one of the k colors $\{0,1,\ldots,k-1\}$ as follows:

$$\text{color of } T = \begin{cases} 0 & \text{if } d_H(T) = 0 \\ i+1 & \text{if } c^i \leq d_H(T) < c^{i+1} \text{ for some } i \in \{0,1,\ldots,k-3\} \\ k-1 & \text{if } d_H(T) \geq c^{k-2}. \end{cases}$$

We prove that any hyperedge e of H that contains at least c^{k-1} vertices, has $(d+1)$-tuples of all the k colors. Since H is shrinkable there is a hyperedge e_0 such that $e_0 \subset e$ and $|e_0| = d+1$. The hyperedge e_0 itself is a $(d+1)$-tuple of depth 0, and hence is colored 0.

For each $i \in \{0,\ldots,k-2\}$ we show that there is a $(d+1)$-tuple with color $i+1$ in e. Let e_i be a hyperedge such that $e_i \subseteq e$ and $|e_i| = c^{i+1}$ (e_i exists by shrinkability of H and the fact that $c^{i+1} \leq c^{k-1} \leq |e|$). Let V be the set of vertices in e_i. The VC-dimension of $H[V]$ is at most the VC-dimension of H, which is at most d. The number of vertices of $H[V]$ is $|V| = c^{i+1} \geq c \geq 4(d+1)^{d+1} \geq 2d+2$. Hence by Theorem 1.10 the hypergraph $H[V]$ has a $(d+1)$-tuple T of depth at least $\frac{|V|}{c} = c^i$. On the other hand, the depth of T in $H[V]$ is at most $c^{i+1} - (d+1)$ because this is the most number of vertices (other than T) that an edge of $H[V]$ can have. Thus $c^i \leq d_{H[V]}(T) < c^{i+1}$. We argue that these bounds also hold with respect to H, that is $c^i \leq d_H(T) < c^{i+1}$. The lower bound is implied from the monotonicity of depth with respect to projections. The upper bound is verified by the edge e_i itself, which is an edge of H, it contains T, and it has at most $c^{i+1} - (d+1)$ other vertices of H. Therefore, T has color $i+1$. ◀

5 Relationships Between $f(1,k)$, $f(t,k)$, and ϵ-t-Nets

To have a $(t,k,f(t,k))$-*polychromatic* coloring, every edge with at least $f(t,k)$ vertices must have t-tuples of all the k colors. This implies that $\binom{f(t,k)}{t} \geq k$. By the standard upper bound for the binomial coefficient, we have $\binom{f(t,k)}{t} \leq \left(\frac{e \cdot f(t,k)}{t}\right)^t$. Combining the two inequalities yields the lower bound

$$f(t,k) \geq \frac{1}{e} \cdot tk^{\frac{1}{t}}. \tag{1}$$

The following folklore result, though very simple, gives an upper bound on $f(t,k)$ in terms of $f(1,tk^{\frac{1}{t}})$. We have not seen a proof of this result elsewhere; we give a short proof.

▶ **Lemma 5.1.** *For any hypergraph H and natural numbers t and k with $tk^{\frac{1}{t}} \geq 1$ it holds that $f_H(t,k) \leq f_H(1,tk^{\frac{1}{t}})$.*

Proof. Set $x := tk^{\frac{1}{t}}$ and color the vertices with x colors such that any edge with $f_H(1,x)$ vertices is polychromatic. Let C_1 be the set of these x colors. Now consider all combinations of t different colors in C_1. We have $\binom{x}{t}$ many such combinations. Consider each combination as a new color class, and let C_t be the set of the new colors (there is a one-to-one correspondence between the colors in C_t and the combinations of t colors in C_1). The standard lower bound for binomial coefficient yields

$$\binom{x}{t} = \binom{tk^{\frac{1}{t}}}{t} \geq \left(\frac{tk^{\frac{1}{t}}}{t}\right)^t = k.$$

Thus C_t has at least k colors. We use the colors in C_t to color each t-tuple T of vertices of H. If the vertices of T are colored by t different colors in C_1, we color T by the corresponding color in C_t. If the vertices of T are colored by less than t colors in C_1 (i.e., some vertices have the same color), we color T by an arbitrary color in C_t.

To prove that our coloring is polychromatic, consider any hyperedge e with at least $f_H(1,x)$ vertices. Since e is polychromatic with respect to the vertex coloring by C_1, it contains x vertices of distinct colors. Of these vertices, each combination of size t would be a t-tuple that is colored by a unique color in C_t. Based on this and the one-to-one correspondence introduced earlier, we conclude that all colors of C_t appear in t-tuples of e, and hence e is polychromatic with respect to t-tuple coloring by C_t. ◀

Proof of Theorem 1.11. A combination of (1) and Lemma 5.1 gives an asymptotically tight bound for $f_H(t,k)$ when $f_H(1,x)$ is linear in x. The statement of the theorem then follows by setting $x := tk^{1/t}$. ◀

5.1 Relationship to ϵ-t-nets

The existence of small-size ϵ-nets was first shown by Haussler and Welzl [27] who proved that any finite hypergraph with VC-dimension d has an ϵ-net of size $O((d/\epsilon)\log(d/\epsilon))$, a bound that was later improved to $O((d/\epsilon)\log(1/\epsilon))$ in [32]. The ϵ-nets are studied extensively in computer science and have found applications in areas such as computational geometry, algorithms, machine learning, and social choice theory; see, e.g., [3, 9, 13, 19]. Alon et al. [5] showed the existence of small-size ϵ-t-nets in various geometric hypergraphs and hypergraphs with bounded VC-dimension.

Here, we prove Theorem 1.12 that gives a decomposition of t-tuples into ϵ-t-nets. It shows the existence of $\Omega\left((\frac{\epsilon n}{t})^t\right)$ pairwise disjoint ϵ-t-nets in a hypergraph H with n vertices for which $f_H(1,x) = O(x)$.

Proof of Theorem 1.12. From Theorem 5.1 and linearity of $f_H(1,x)$ we have $f_H(t,k) = f_H(1,tk^{\frac{1}{t}}) = O(tk^{\frac{1}{t}})$, for any k where $tk^{\frac{1}{t}} \geq 1$. Let k', with $tk'^{\frac{1}{t}} \geq 1$, be the largest integer such that $f_H(t,k') \leq \epsilon n$ (notice that $f_H(t,k'+1) > \epsilon n$). Then, every hyperedge of size at least ϵn contains tuples of all color classes. This means that each of the k' color classes is an ϵ-t-net. To estimate k' we have $\epsilon n < f_H(t,k'+1) = O(t(k'+1)^{\frac{1}{t}})$. This would imply that $k' = \Omega\left((\frac{\epsilon n}{t})^t\right)$. When t is a constant this gives $\Omega(\epsilon^t n^t)$.

To verify the tightness of this bound for constant t, consider a hyperedge e with exactly ϵn vertices. The number of distinct t-tuples in e is $\binom{\epsilon n}{t} \leq \left(\frac{e\cdot\epsilon n}{t}\right)^t = O(\epsilon^t n^t)$. This means that we cannot decompose t-tuples into more than $O(\epsilon^t n^t)$ families of ϵ-t-nets because otherwise e would violate the ϵ-t-net property of some color class. ◀

5.2 Cover-decomposability

The case $k = 2$ is usually referred to as bichromatic coloring. The notion of cover-decomposability is also derived from this case. Recall that a hypergraph is cover-decomposable if $f(1,2)$ is bounded, and it is t-cover-decomposable if $f(t,2)$ is bounded.

Below we prove that $t+1 \leq f_H(t,2) \leq \max\{f_H(1,2), t+1\}$ for any hypergraph H. This improves upon the previous upper bound of $\max\{f_H(1,2), 2t-1\}$, given in [1, Proposition 4].

Proof of Theorem 1.13. The lower bound is obvious because in order for an edge to be polychromatic, it must contain at least two distinct t-tuples, and hence at least $t+1$ vertices ($t-1$ vertices could be shared between the two t-tuples).

Now we prove the upper bound. The upper bound holds if $f_H(1,2)$ is unbounded. Assume that $f_H(1,2)$ is bounded. Let V be the set of vertices of H, and let $\phi\colon V \to \{\text{red}, \text{blue}\}$ be a two-coloring of the vertices in V that achieves $f_H(1,2)$. We use ϕ to obtain a two-coloring ξ of the t-tuples of V such that $\xi\colon \binom{V}{t} \to \{\text{odd}, \text{even}\}$, where $\binom{V}{t}$ denotes the set of all t-element subsets of V. We color each t-tuple T by the parity of the number of its blue vertices. If the number of blue vertices in T is odd, then we color it odd, and if the number of blue vertices in T is even, then we color it even. We show that this is a valid two-coloring of t-tuples, in the sense that any hyperedge $e \in H$ of cardinality at least $\max\{f_H(1,2), t+1\}$ contains two t-tuples such that one is colored odd and the other is colored even.

Since $|e| \geq f_H(1,2)$, e is polychromatic under ϕ. Thus, there are two vertices in e, say r and b, colored red and blue, respectively. Since $|e| \geq t+1$, $e \backslash \{r,b\}$ has at least $t-1$ vertices. Pick an arbitrary subset t' of $e \backslash \{r,b\}$ of size exactly $t-1$. Then $t' \cup \{r\}$ and $t' \cup \{b\}$ are two t-tuples in e and the cardinality of their blue vertices differs by 1. Therefore, one of them is colored odd, and the other is colored even. ◀

6 Conclusions

We presented several new results on polychromatic coloring of tuples in hypergraphs. In particular we gave an exponential bound (in terms of the number of colors) for polychromatic coloring of pairs of points in the plane with respect to disks (Theorem 1.5) – such a bound does not exist for coloring each point individually. One natural question is whether a polynomial upper bound is achievable for coloring pairs. Another natural question is to close the gap between $\Omega(\sqrt{k})$ and $O(\sqrt{k \ln k})$ for polychromatic coloring of pairs of grid points with respect to axis-aligned rectangles. It would also be interesting to explore similar bounds for other point sets and other objects, for example, one may relate the bounds to the fatness of objects.

Abstract

We introduce the *contiguous art gallery problem* which is to guard the boundary of a simple polygon with a minimum number of guards such that each guard covers *exactly one* contiguous portion of the boundary. Art gallery problems are often NP-hard. In particular, it is NP-hard to minimize the number of guards to see the boundary of a simple polygon, without the contiguity constraint.

This paper is a merge of three concurrent works [17, 53, 62] each showing that (surprisingly) the contiguous art gallery problem is solvable in polynomial time. The common idea of all three approaches is developing a greedy function that maps a point on the boundary to the furthest point on the boundary so that the contiguous interval along the boundary between them could be guarded by one guard. Repeatedly applying this function immediately leads to an OPT+1 approximation. By studying this greedy algorithm, we present three different approaches that achieve an optimal solution. The first and second approach apply this greedy algorithm from different points on the boundary that could be found in advance or on the fly while traversing along the boundary (respectively). The third approach represents this function as a piecewise linear rational function, which can be reduced to an abstract arc cover problem involving infinite families of arcs. We identify other problems that can be represented by similar functions, and solve them via the third approach.

From the combinatorial point of view, we show that any n-vertex polygon can be guarded by at most $\lfloor \frac{n-2}{2} \rfloor$ guards. This bound is tight because there are polygons that require this many guards.

Acknowledgements We are grateful to the anonymous reviewers for helpful suggestions, and we thank Joseph O'Rourke for organizing the open problem session at the Canadian Conference on Computational Geometry 2024 (CCCG24), where Thomas C. Shermer proposed the contiguous art gallery problem. The authors further thank the participants of CCCG24 for their lively discussions of the problem at the conference. We thank the members of the Stony Brook CG Group open problem seminar (2022), where Joe Mitchell posed questions regarding a greedy algorithm for the "CBG" (Contiguous Boundary Guarding) problem and its variants.

1 Introduction

The *art gallery problem*, introduced in 1973 by Victor Klee [20, 58], asks for a minimum number of guards that see every point of a given polygon P – the guards can lie anywhere in the polygon. This problem is central to computational geometry and is an active research area. It is long known to be NP-hard [48] and APX-hard [32]; see also [5, 58, 60]. A recent result by Abrahamsen, Adamaszek, and Miltzow [3, 2] shows that the problem is $\exists\mathbb{R}$-complete even if the vertices have integer coordinates. In fact, [1] and [52] present instances with optimal solutions of size 3 and 2 that require guards with irrational coordinates. The problem is notoriously difficult, as the best known approximation algorithms have logarithmic approximation factors [18, 27, 30, 31]; see also [32] for hardness of approximation.

The *boundary guarding* problem is a variant of the art gallery problem in which the goal is to guard only the boundary of P with a minimum number of guards that can lie anywhere in P. One may think of this as guarding only the walls of an art gallery, with no interior sculptures. By extending ideas of [3, 2], Stade has shown that this variant is also $\exists\mathbb{R}$-complete [67]. In this paper we introduce the *contiguous* version of this problem. In the *contiguous art gallery* problem, the goal is to guard the boundary of P such that each guard covers a contiguous portion of the boundary. While the visibility polygon of a guard may have several connected components on the boundary, the guard is assigned to only one component.

The contiguous art gallery problem is a natural modification of the boundary guarding problem: Here, the responsibility of a guard is a part of the boundary that could be contiguously scanned by a rotating security camera (or human) that cannot pause its rotation to completely re-focus (or perform an autofocus). The problem appeared in open problems from CCCG 2024 [8], motivated by the fact that the hardness proofs for typical art gallery variants [3, 2, 67] require guards to cover several connected components on the boundary. Figure 1 illustrates the difference between standard boundary guarding and the contiguous version. In this paper, we give polynomial-time algorithms for contiguous boundary guarding.

We present three approaches to the problem. All three start from the observation that there is a function G called the *greedy function*, mapping points along the boundary of the polygon to maximal point counterclockwise along the boundary so that a guard point exists that can guard the entire boundary between the two points. We discuss this function in Section 1.4, including how it can be used to obtain an additive $+1$ approximation. At a high-level, the three different approaches extend this in different manners: The first applies G repeatedly until it produces an optimal solution, going around the polygon a polynomial number of times. The second studies the specific structure of an optimal solution, showing that a polynomial-sized finite subset of the domain of G needs to be considered. The third shows that G has a representation as a piecewise linear rational function, which can be reduced to an abstract arc cover problem involving infinite families of arcs, resulting in the *analytic arc cover problem*. This third approach can also be applied to solve minimum polygon separation (see Figure 2) and polytope carving (see Figure 3) in polynomial time.

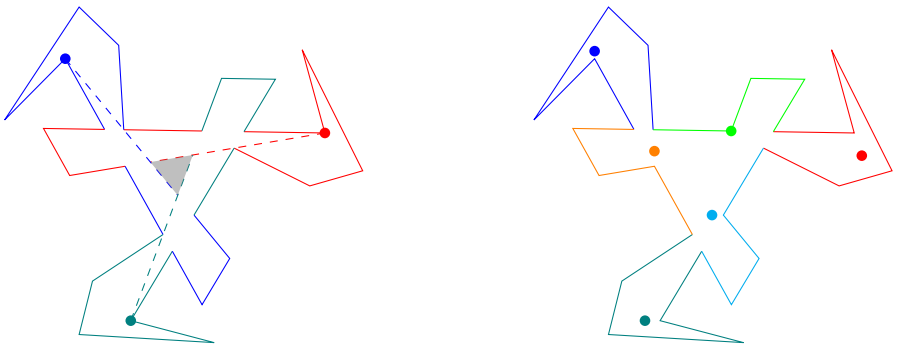

Figure 1 (Left) 3 optimal boundary-covering guards (the interior gray triangle is not seen). (Right) 6 guards that optimally contiguously cover the boundary. Guards are visualized as points whose color matches the boundary portion they guard.

1.1 Related work and results

The art gallery problem and its variants have been extensively studied. Variants arise from constraints on the allowable input polygon, the allowable guard locations, and the portion of the polygon that must be guarded. Essentially all nontrivial variants are NP-hard.

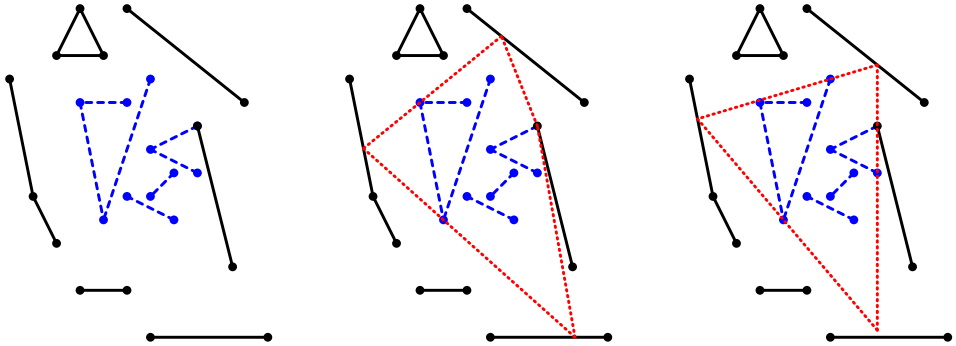

Figure 2 (Left) An instance of the *segment separation problem*, which asks for a convex polygon with the fewest vertices that separates two input sets of line segments. (Middle) A suboptimal solution. (Right) One possible optimal solution.

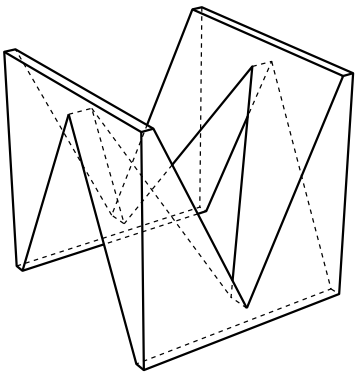

Figure 3 The *polytope half-plane carving problem* asks for the minimum number of half-plane cuts needed to separate a specific target polytope from the ambient material. Pictured is a polytope that can be carved by 10 half-plane cuts.

Hardness and approximations. The *vertex-guard problem* requires guards to be at vertices of the polygon. This version is also NP-hard [48, 60] and APX-hard [32] with known logarithmic factor [37] and sub-logarithmic factor [43] approximation algorithms. A similar sub-logarithmic approximation is known for the case where the guards can lie anywhere on the boundary of the polygon [43]. Better approximation algorithms are known for monotone polygons [46] and weakly-visible polygons [11, 12, 14].

Terrain guarding is a related problem in which we are given a 1.5-dimensional terrain (i.e., an x-monotone polygonal chain), and we want to guard the terrain with a minimum number of guards on the terrain – this is a variant of the boundary guarding problem. This problem is also NP-hard [19, 45, 44], and admits a polynomial time approximation scheme [11, 12, 38].

Both versions of the problem (point-guard and vertex-guard) remain NP-hard in orthogonal polygons [65], even if we want to guard only the vertices of the polygon [42].

Polynomial-time exact algorithms. For some trivial versions, the art gallery problem can be solved in polynomial time, such as for convex, star-shaped, and spiral polygons. Finding non-trivial instances that admit polynomial-time algorithms is of particular interest. To the best of our knowledge, there are only a few such versions. These instances usually enforce constraints on the polygon itself or on the definition of visibility. For example, the authors in [21] present polynomial-time algorithms when the polygon is uni-monotone (i.e., it is

monotone and one of its two monotone polygonal chains is a straight line segment)[1] and for 1.5-dimensional terrains where all the guards must be placed on a horizontal line above the terrain. The art gallery problem can also be solved in polynomial time on orthogonal polygons under *rectilinear* visibility [76] and *staircase* visibility [56, 55]. In the former case, two points are visible if their minimum orthogonal bounding box lies in the polygon, and in the latter case, two points are visible if there is an x- and y-monotone path between them in the polygon. All of these algorithms [21, 56, 55, 76] employ the notion of *perfectness* [9, 10] of P, which means that the minimum number of guards is equal to the maximum number of points that can be placed in P such that their visibility polygons are pairwise disjoint.

Combinatorial bounds. While most variants of the art gallery problem are algorithmically hard, tight combinatorial bounds are known on the numbers of guards that are always sufficient and sometimes necessary to guard a polygon with n vertices. For the original art gallery problem the bound is $\lfloor n/3 \rfloor$ for both point-guards and vertex-guards [20, 35], and it is $\lfloor n/4 \rfloor$ for orthogonal polygons [40, 50, 64, 74]. Tight bounds are also known for variants in which an entire edge or diagonal can serve as a guard [15, 57, 66].

Contiguity. The contiguous guarding is particularly related to guarding polygons with cameras/guards that have a bounded field of view (i.e., the maximum angle a camera can cover is limited) [71, 72] and to the so-called *floodlight* [59, 73] and *city guarding* problems [13, 16, 24]. It is also related to contiguous guarding of points on a 1.5-dimensional terrain by placing at most k watchtowers such that each watchtower sees a contiguous sequence of points [41].

Circle-cover minimization. When partitioning the boundary of a simple polygon, it is natural to view it as a circle and the polygonal chains as arcs or intervals; see Figure 4. By doing so, finding a minimal partition is similar to finding a *minimal circle-cover* among a set of intervals C. This problem was studied by Lee and Lee [47] for finite cardinality C, giving an algorithm that runs in $\mathcal{O}(|C| \log |C|)$ time. Thus, given a finite set C of polygon chains of the boundary of P such that an optimal solution is contained in C, the problem can be solved in $\mathcal{O}(|C| \log |C|)$ time, see Figure 4. However, it is not easy to define a set C that is guaranteed to contain an optimal solution.

Minimum Polygon Separation. Given a convex polygon P contained inside another convex polygon Q, the minimum polygon separation problem asks for a polygon S with the minimum number of vertices such that S contains P and is contained within Q. This is the *polygon separation problem*. Polygon separation was first studied by Aggarwal, Booth, O'Rourke, Suri, and Yap [6, 7], and generalized to multiple connected domains by Mitchell and Suri [54]. One can consider a similar problem: The problem of separating two collections of line segments by a polygon with the minimum number of vertices. This is the *segment separation* problem.

Polytope Carving. Related to polygon separation is the problem of *carving* one shape out of another, or out of an ambient space. Two-dimensional carving was first studied by Overmars and Welzl [61], where they aimed to find the cheapest sequence of line cuts to carve a convex polygon out of a piece of flat material. This has also been studied in the context of rays cuts [22, 23, 69] and line segments cuts [25, 26, 28, 29], as well as in 3D with half-plane cuts [63].

[1] This type of polygons are also referred to as monotone mountains.

1.2 Preliminaries

Let P be a simple polygon with n vertices. We denote the boundary of P by ∂P. A *reflex vertex* of P is a vertex with an interior angle greater than π. A non-reflex vertex is a *convex vertex*. For two points p and q in the plane, we denote by $\overline{p\,q}$ the straight line segment between p and q. The *ray* from p toward q is denoted $\overrightarrow{p\,q}$. A *wedge* is a region of the plane bounded by two rays starting from the same point known as the *apex* of the wedge.

We assume that ∂P is a directed cycle, with vertices ordered counter-clockwise. We index the edges e_i and the vertices v_i of P modulo n, that is, $e_n = e_0$ and $v_n = v_0$. We define a *polygonal chain* as a connected portion of ∂P. For an ordered pair (p_1, p_2) of two points on ∂P, we denote by $[p_1, p_2]$ the interval of ∂P from p_1 to p_2 in counter-clockwise direction – $[p_1, p_2]$ is a directed path, see Figure 4. We refer to p_1 and p_2 as the *first* and the *last* endpoints of $[p_1, p_2]$, respectively. Since $[p_1, p_2]$ is directed, for any two points p and q on $[p_1, p_2]$, we can tell if p appears *before* or *after* q. We define a *guardable* interval $[p_1, p_2]$ to be one for which there exists a point $g \in P$ (guard) such that for all $x \in [p_1, p_2]$ we have $\overline{x\,g} \subset P$. Now, a *contiguous boundary guarding (CBG)* is a collection of guards $\Gamma = \{g_i\}_i$ with guardable intervals $\partial(g_i) = [a_i, b_i]$ such that $\cup_i \partial(g_i) = \partial P$. Multiple guards could be collocated ($g_i = g_j$) while guarding different intervals ($\partial(g_i) \neq \partial(g_j)$). We say that Γ is *minimal* if the removal of any guard from Γ results in an uncovered portion of ∂P. The goal of the *contiguous art gallery problem* is to find a smallest minimal guarding, and we define k^* to be the size of such a guarding.

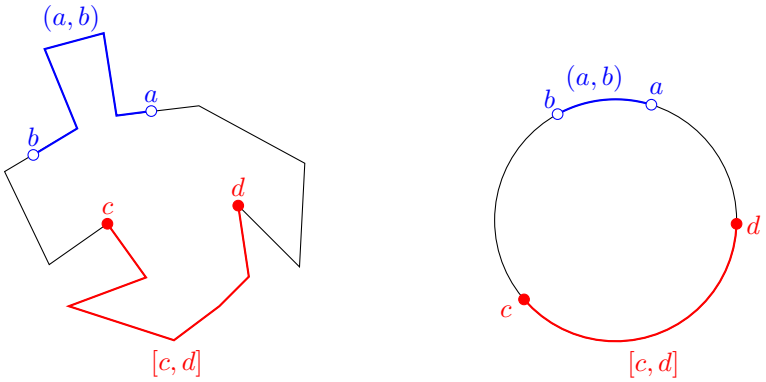

Figure 4 A simple polygon visualized as a circle, with intervals of the polygonal boundary represented as arcs on the circle.

Let $p_1(g)$ and $p_2(g)$ denote the first and last endpoints of $\partial(g)$. We denote by $w(g)$ the wedge from the ray $\overrightarrow{g\,p_1(g)}$ to the ray $\overrightarrow{g\,p_2(g)}$ intersected with P, see Figure 5. Further note that for every guard g in a minimal contiguous guarding, there exists a point g_p of ∂P that is guarded by g alone, because otherwise we could remove g from the guard set. For any (minimal) contiguous guarding Γ, the counter-clockwise order of $\{g_p : g \in \Gamma\}$ along ∂P induces an order of the guards in Γ. Thus, the terms *previous* guard, *next* guard, and *consecutive* guards are well defined. The following simple observation is valid for any guarding with at least two guards.

▶ **Observation 1.** *Let g be a guard in a guarding of ∂P. Then, the first endpoint of $\partial(g)$ is covered by g and by the previous guard. Similarly, the last endpoint of $\partial(g)$ is covered by g and the next guard.*

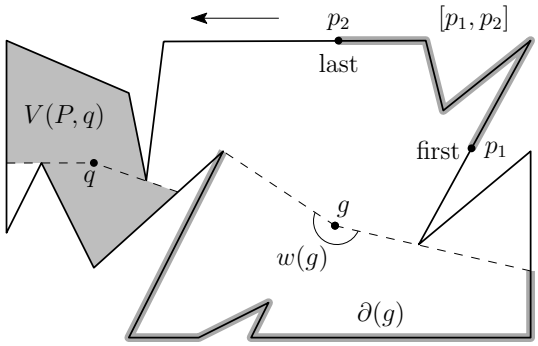

Figure 5 The boundary of the polygon is assumed to be directed counter-clockwise.

1.3 Combinatorial Bounds

In this section, we determine the number of guards that are always sufficient and sometimes necessary to guard an n-vertex polygon. It is easily seen that a chain with n edges can be covered by $\lfloor \frac{n+1}{2} \rfloor$ guards – this can be achieved by placing a guard at every second vertex. Thus it follows that a polygon with n vertices (and hence n edges) can be covered by $\lfloor \frac{n+1}{2} \rfloor$ guards. As we will see later, this bound is very close to the best achievable bound but is not tight. We need stronger ingredients, such as the following lemma, to obtain a tight bound. In this section we say that a vertex "covers" an edge if the vertex sees both endpoints.

▶ **Lemma 2.** *For any polygon P with at least 8 vertices, one of the following statements holds.*

1. *There is a vertex that covers 6 consecutive edges of ∂P.*
2. *There are two vertices that collectively cover 7 consecutive edges of ∂P.*
3. *There are two vertices that collectively cover 8 edges of ∂P such that each vertex covers 4 consecutive edges.*

▶ **Theorem 3.** *In any polygon P with $n \geq 4$ vertices there exists a set of at most $\lfloor \frac{n-2}{2} \rfloor$ points that guard the boundary of P contiguously. This bound is tight.*

Proof. If $n = 4, 5$, then one vertex of the polygon covers the entire boundary (to verify this, observe that in any triangulation of a 5-gon, there is a vertex that is incident to the three resulting triangles). If $n = 6$, then any triangulation contains a diagonal that partitions the boundary of P into 2 and 4 consecutive edges;[2] each partite can be covered by one vertex. If $n = 7$, then there is a diagonal that partitions the boundary of P into 3 and 4 consecutive edges; again, each partite can be covered by one vertex.

Assume that $n \geq 8$. Then, at least one of the cases in Lemma 2 holds. For each case, we show how to cover ∂P by the number of guards that is claimed.

- *Statement 1 holds.* We cover 6 consecutive edges by 1 guard and the remaining chain of $n-6$ edges by at most $\lfloor \frac{n-5}{2} \rfloor$ guards. Thus, the total number of guards is at most $\lfloor \frac{n-3}{2} \rfloor$.
- *Statement 2 holds.* We cover 7 consecutive edges by 2 guards and the remaining chain of $n-7$ edges by at most $\lfloor \frac{n-6}{2} \rfloor$ guards. The total number of guards is at most $\lfloor \frac{n-2}{2} \rfloor$.
- *Statement 3 holds.* We cover the 8 edges by two guards. If 8 edges are consecutive, then we cover the remaining chain as in the previous case. Assume they are not consecutive and thus split into two sets, each having four consecutive edges. The remaining $n-8$ edges of ∂P form two disjoint chains of n_1 and n_2 edges that can be covered by at

[2] For any $k \geq 2$ there is a diagonal that cuts off at least k and at most $2k-2$ edges of the polygon; see [15].

most $\lfloor \frac{n_1+1}{2} \rfloor$ and $\lfloor \frac{n_2+1}{2} \rfloor$ guards, respectively. The total number of guards is at most $\lfloor \frac{n_1+1}{2} \rfloor + \lfloor \frac{n_2+1}{2} \rfloor + 2 \leq \frac{n-2}{2}$. This equals $\lfloor \frac{n-2}{2} \rfloor$ when n is even. When n is odd, one of the chain sizes, say n_1, is even, and hence the chain itself can be covered by at most $\lfloor \frac{n_1}{2} \rfloor$ guards, which would result in at most $\frac{n-3}{2} \leq \lfloor \frac{n-2}{2} \rfloor$ total guards.

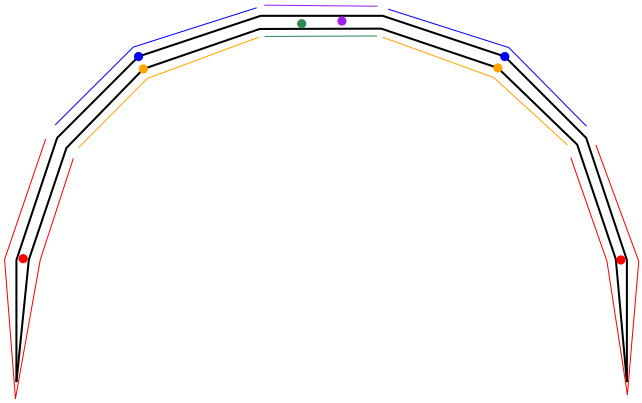

Figure 6 Illustration of the lower bound $\lfloor \frac{n-2}{2} \rfloor$ guards. The polygonal arcs around the boundary are maximal chains that can each be guarded by a single guard.

To verify the lower bound, see the polygon in Figure 6 of size $n = 4k+2$, for some integer k, which consists of two convex chains of odd length $\frac{n}{2}$. We need at least $2\lfloor \frac{n/2+1}{2} \rfloor - 2 = \lfloor \frac{n-2}{2} \rfloor$ guards to cover the boundary of this polygon contiguously. By adding a vertex on any edge of the polygon in Figure 6, a lower bound example for odd n is obtained. ◀

1.4 Greedy Steps

Our overall approach to solving the contiguous art gallery problem studied in this paper is based on the idea to take a point $x \in \partial P$ and find the furthest counter clockwise point $\mathrm{G}(x) \in \partial P$ such that $[x, \mathrm{G}(x)]$ is guardable. We introduce the GreedyInterval algorithm that given x on edge $e_{i-1} = \overline{v_{i-1}\, v_i}$ computes $\mathrm{G}(x)$ progressively by intersecting the visibility polygons (V) of vertices $v_i, \ldots, v_{i+j}$ such that the feasible region $F_j := \cap_{h=0}^{j} V(P, v_{i+h}) \neq \emptyset$ and $F_{j+1} = \emptyset$, then the feasible region can be used to compute the maximal point $\mathrm{G}(x)$ on edge $e_{i+j} = \overline{v_{i+j}\, v_{i+j+1}}$ such that a guard can be placed in P that can see from x to $\mathrm{G}(x)$, here maximality means that $\mathrm{G}(x)$ is closest possible to v_{i+j+1} on ∂P such that $[x, \mathrm{G}(x)]$ is guardable.

▶ **Lemma 4.** *The* GreedyInterval *algorithm can be computed in* $\mathcal{O}(jn \log n)$ *arithmetic operations using poly*(n) *bits on* $x \in \partial P$ *where* j *is the number of vertices in* $[x, G(x)]$.

Proof Sketch. Visibility polygons can be computed in $\mathcal{O}(n)$ by an algorithm of Gindy and Avis [33]. The number of vertices of the feasible region can be shown to be $\mathcal{O}(n)$, independent of j. An algorithm by Martínez, Rueda, and Feito [51] shows that the intersections can be computed in $\mathcal{O}((n_1 + n_2 + h) \log(n_1 + n_2))$ time which together implies that the final feasible region can be computed in $\mathcal{O}(jn \log n)$ time. Finally, to compute how far along edge $\overline{v_{i+j}\, v_{i+j+1}}$ $\mathrm{G}(x)$ can be placed, we construct a new blocking polygon from following the rightmost tangent of F_j through v_{i+j+1} and the pieces of ∂P that stick below this tangent. If this would touch F_j, we instead connect it to a point r above the tangent and finish the construction by connecting this back to v_{i+j+1}. Now, $\mathrm{G}(x)$ can be computed using a common

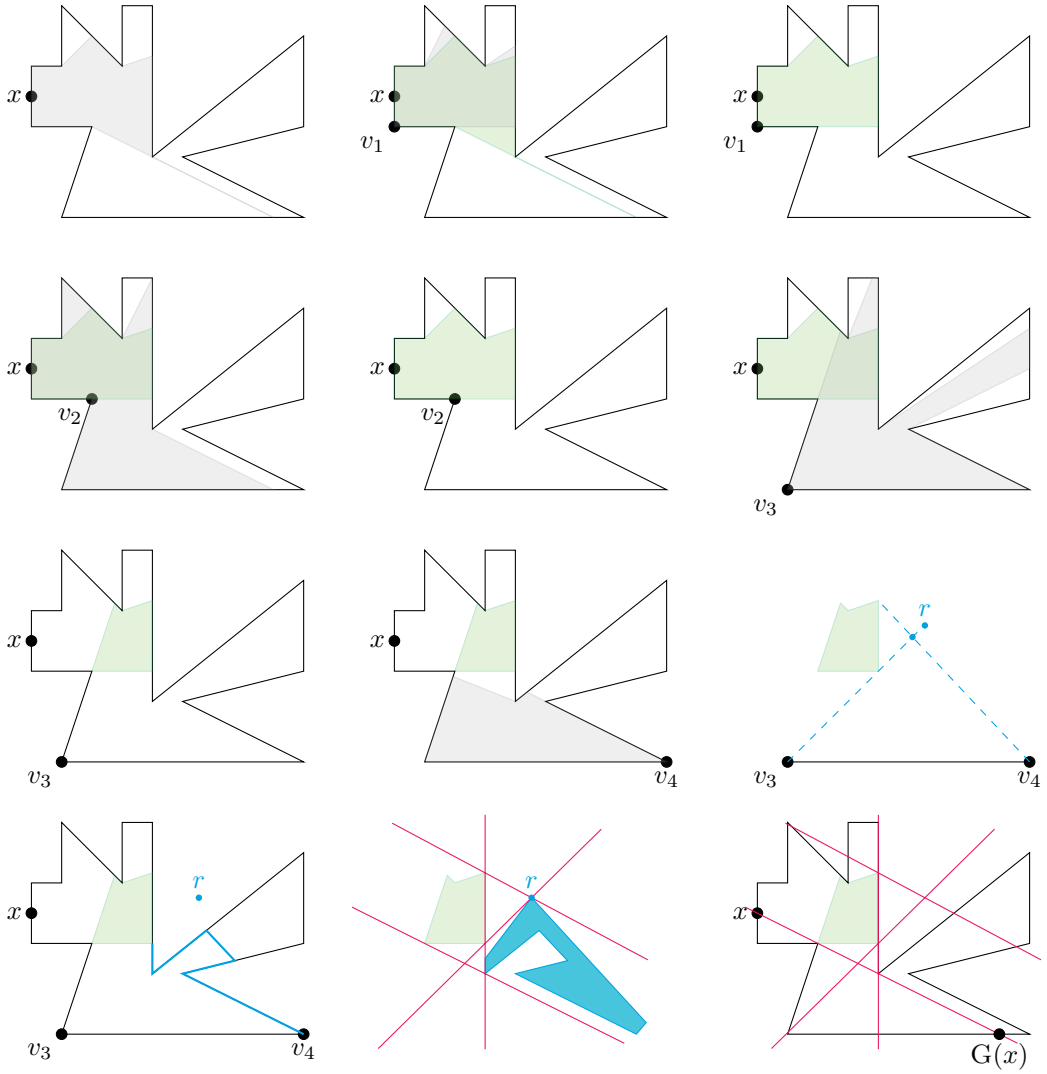

Figure 7 The steps of the GreedyInterval algorithm animated. First successive iterations of computing visibility polygons (in gray) and intersecting with previous feasible regions (in green) and finally computing the blocking polygon (in blue), to find $\mathrm{G}(x)$ through a common tangent.

tangent between F_j and the blocking polygon. This common tangent can be computed with an algorithm of Abrahamsen and Walczak [4]. This process takes $\mathcal{O}(n \log n)$ time, so in total, we use $\mathcal{O}(jn \log n)$ time to compute $\mathrm{G}(x)$. The algorithm is illustrated in Figure 7. ◀

The GreedyRevolution algorithm starts at some point x_0 on the boundary and computes a sequence $x_{i+1} = \mathrm{G}(x_i)$ until x_k is between x_0 and x_1.

▶ **Theorem 5.** *The* GreedyRevolution *algorithm, starting from an arbitrary point $x \in \partial P$, returns a guarding Γ of size at most k^*+1 in $\mathcal{O}\big(n^2 \log n\big)$ arithmetic operations. Moreover, if x is covered by two guards in some optimal solution, then $|\Gamma| = k^*$.*

There is a natural trade-off when guards are moved a little which motivates that it is indeed difficult to check if a candidate solution is optimal or not, see Figure 8.

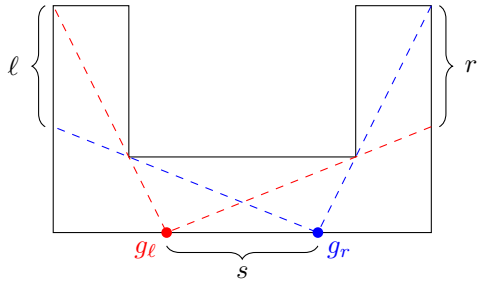

Figure 8 A polygon where the blue guard g_r sees all of r and none of ℓ, and vice-versa for g_ℓ. Any guard placed along s will yield a trade-off between how much of ℓ and r it sees.

In the remainder of this paper, we present three approaches to proving that the contiguous art gallery problem can be solved using GreedyRevolution in polynomial time.

▶ **Theorem 6.** *The contiguous art gallery problem is a member of the complexity class P, with a runtime of* $\mathcal{O}(n^5 k^* \log n)$

1.5 Organization

This paper is the combination of three independent studies [17, 53, 62] of the contiguous art gallery problem. In Section 2 we show that if we continue applying GreedyRevolution $\mathcal{O}(n^3 k^*)$ times then the last candidate solution will be optimal. In Section 3 we show that generating $\mathcal{O}(n^4)$ candidate solutions by starting GreedyRevolution from a carefully selected set of points, at least one of these will be optimal. Finally, in Section 4 we explore how GreedyInterval can be expressed as a piecewise linear rational function and show that repeatedly composing GreedyInterval with itself leads to a piecewise linear rational function representing *all* optimal solutions.

2 Finding an Optimal Solution via Repeated GreedyRevolution

The approach of Merrild, Rysgaard, Schou and Svenning [53] to solve the contiguous art gallery problem is to define the infinite *greedy sequence* $(x_i)_{i=0}^{\infty}$ with $x_0 = x$ and $x_i = \mathrm{G}(x_{i-1})$ and prove that after at most $\mathcal{O}(n^3 k^*)$ revolutions the sequence has converged to an optimal solution, leading to $\mathcal{O}(n^5 k^* \log n)$ runtime.

2.1 Combinatorial optimality conditions

We initially study finite greedy sequences that do not contain optimal solutions to the contiguous art gallery problem, which we define as non-optimal greedy sequences.

If P is star-shaped, i.e., one guard can see all of P and thus all of ∂P we will be guarded after one call to GreedyInterval. Thus, we assume that this is not the case. This together with some elementary properties of G and guardable intervals gives the following lemma, which acts like combinatorial axioms:

▶ **Lemma 7** (Properties of G and guardable intervals). *Let x, y, z, w be points on ∂P.*

1. $G(x) \neq x$.
2. *If $[x, y] \subseteq [z, w]$ and $[z, w]$ is guardable then $[x, y]$ is guardable.*
3. $[x, y] \subseteq [x, G(x)]$ *if and only if* $[x, y]$ *is guardable.*

Using these properties, we derive the following

▶ **Proposition 8** (Behavior of non-optimal greedy sequences). *Let $x \in \partial P$ and assume that the finite greedy sequence $(x_i)_{i=0}^{k \cdot N}$ starting at x does not contain an optimal solution to the* ContiguousArtGallery *problem, where k is the length of a revolution and N is some positive integer. Let $y_0, y_1, \ldots, y_{k^*-1}$ be an optimal solution with $y_0 \in (x_0, x_1]$. Then $x_{ik+m} \in [y_{m-1}, x_{(i-1)k+m})$ for all $m \in \{1, \ldots, k\}$ and $i \in \{1, 2, \ldots, N-1\}$.*

The proof of this proposition follows from considering the greedy steps performed and bounding the result with previous greedy endpoints and optimal endpoints, see Figure 9.

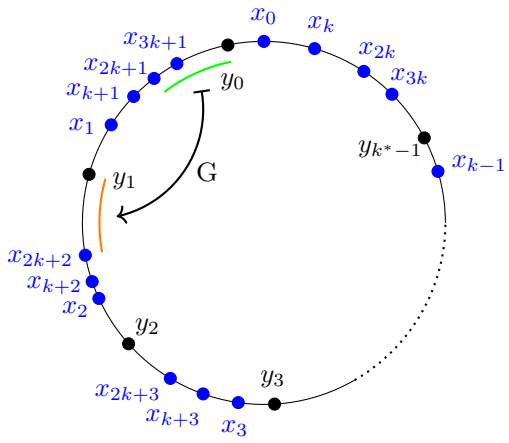

Figure 9 For a non-optimal greedy sequence G maps points from $[y_0, x_{2k+1}]$ (green) to $[y_1, x_{2k+2}]$ (orange), and in the next revolution from $[y_0, x_{3k+1}]$ to $[y_1, x_{3k+2}]$.

From this we see that the subsequence $x_1, x_{k+1}, x_{2k+1}, \ldots$ must be in the interval $[y_0, y_1]$ and the endpoints get closer and closer to y_0. Likewise, all subsequences $x_m, x_{k+m}, x_{2k+m}, \ldots$ lie in $[y_{m-1}, y_m]$ and approach y_{m-1}. Thus, we give these subsequences a name:

▶ **Definition 9** (Local Greedy Sequence). *Let $x \in \partial P$, consider the greedy sequence $(x_i)_{i=0}^{\infty}$ starting at x. Then $(x_i^m)_{i=0}^{\infty}$ for $m = 1, \ldots, k$ are* local greedy sequences, *where $x_i^m = x_{ik+m}$.*

Now, any greedy sequence that does not look like those classified in Proposition 8 must contain an optimal solution. The next step of our analysis is to study geometric polygonal patterns that lead to deviations from this.

2.2 Achieving optimality conditions using Geometry

We now define patterns in which progress toward an optimal solution is achieved:

▶ **Definition 10** (Fingerprint). *Let $(x_i^m)_{i=0}^{\infty}$ be the m'th local greedy sequence. For $i \geq 1$ we say that x_i^m has a* negative fingerprint *if $x_i^m \in [x_{m-1}, x_{i-1}^m)$. Otherwise, we say that x_i^m has a* positive fingerprint.

▶ **Definition 11** (Edge jumps). *Let $(x_i^m)_{i=0}^{\infty}$ be the m'th local greedy sequence. We say that $(x_i^m)_{i=0}^{\infty}$ has an* edge jump *at i if x_i^m is a vertex of P or x_i^m and x_{i+1}^m are on different edges of P and neither is a vertex of P.*

By comparing these with Proposition 8, we get the following optimality conditions:

▶ **Lemma 12** (Progress conditions). *If any of the following three conditions are met, the greedy sequence will contain an optimal solution to the* ContiguousArtGallery *problem:*

1. *If there is a positive fingerprint.*
2. *If there is repetition in the greedy sequence.*
3. *If there are $n+1$ edge jumps.*

Thus, the intermediate goal is to prove the following:

▶ **Theorem 13** (GreedyRevolution will reach a progress condition). *Running* GreedyRevolution $\mathcal{O}(k^* n^2)$ *times guarantees the appearance of a progress condition.*

We show the theorem by zooming in on one greedy step from one local greedy sequence to another. We let $(y_i)_{i=0}^{\infty}$ and $(z_i)_{i=0}^{\infty}$ be two local greedy sequences such that $z_i = \mathrm{G}(y_i)$.

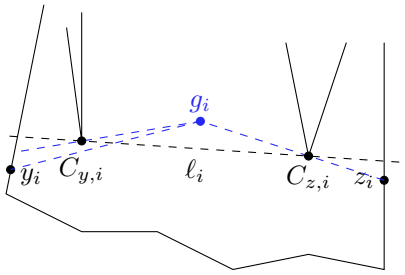

Figure 10 A greedy step from y_i to $z_i := \mathrm{G}(y_i)$ guarded by g_i. The pivot point $C_{z,i}$ blocks g_i from seeing further than z_i and the other pivot $C_{y,i}$ blocks g_i in the other direction. The relative position of the line $\ell_i := L(C_{z,i}, C_{y,i})$ between pivot points to g_i is essential for the casework.

We denote the guard, which can see $[y_i, z_i]$ by g_i and let $C_{z,i}$ and $C_{y,i}$ be the vertices of P that block g_i from seeing more than, respectively z_i and y_i on ∂P, see Figure 10. We define these vertices as *pivot points*. We let ℓ_i be the line through $C_{y,i}$ and $C_{z,i}$. We define this line as the *pivot line* and consider the cases where g_i lies above or below ℓ_i.

If g_i is above ℓ_i, we define the shadow $S(a)$ of a point a as the region bounded by the lines $L(C_{y,i}, a)$ and $L(C_{z,i}, a)$ and above a, see Figure 11. If we let F denote the feasible region of the vertices of ∂P between y_i and z_i, one gets the following:

▶ **Lemma 14** (The feasible region is contained in the shadow). *Assume that F lies above ℓ_i and let a be a vertex of F closest to ℓ_i. Then $F \subseteq S(a)$.*

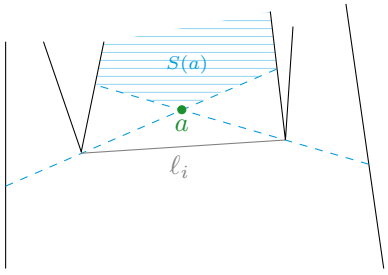

Figure 11 Placing a guard in the shadow $S(a)$ of a leads to a worse guard.

That is, when F lies above ℓ_i, there is only one best guard that guards this interval (we do not have the trade-off as in Figure 8). So we have:

▶ **Proposition 15** (Feasible region over repeated pivot line implies a progress condition)**.** *If $\ell_i = \ell_j$ for some $i < j$ and F lies above ℓ_i, then we get a progress condition.*

If the guard g_i lies below the pivot line ℓ_i, we can consider the guard that guards one of the pivot points and get the following result:

▶ **Proposition 16** (Guard placed below pivot implies other guard placed strictly above pivot)**.** *Let g_i lie below the pivot line, then one of the following will occur:*

1. *In the next revolution, we will see a progress condition.*
2. *There is some guard $\widehat{g}$ found in the next revolution, which is below its pivot line $\widehat{\ell}$.*

We can now use Proposition 15 and Proposition 16 to prove Theorem 13: There are $\mathcal{O}(k^*)$ greedy steps that take place around ∂P at a time, and each of them has $\mathcal{O}(n^2)$ possible pivot lines to consider. Each time we see a guard below a pivot line, it either gives a progress condition or forces another guard to lie above its pivot line. By the pigeonhole principle, after seeing $\mathcal{O}(k^* n^2)$ guards above their pivot lines, we must have seen a guard above the same pivot line twice, and Proposition 15 gives that we must have achieved a progress condition.

2.3 Proof of Theorem 6

Proof of Theorem 6. Running GreedyRevolution for $\mathcal{O}(kn^2) = \mathcal{O}(k^* n^2)$ revolutions guarantees a progress condition, i.e., a positive fingerprint, a repetition, or an edge jump by Theorem 13. Thus, repeating $n+1$ times guarantees at least one positive fingerprint, at least one repetition, or $n+1$ edge jumps. By Lemma 12 the greedy sequence will contain optimal revolutions. Finally, it can be proven that once an optimal solution appears in the greedy sequence, all subsequent revolutions will also be optimal. This requires $\mathcal{O}(k^* n^2 \cdot (n+1) \cdot n^2 \log n) = \mathcal{O}(n^5 k^* \log n)$ arithmetic operations. ◀

An open source implementation using CGAL [34, 36, 39, 70, 75] in C++ is available online [68].

3 Simplifying the Domain of GreedyInterval

In this section we present a polynomial-time exact algorithm for contiguous guarding of the boundary ∂P of a simple polygon P. Recall the notation from Figure 5 in subsection 1.2. We assume that P is not star-shaped, so at least 2 guards are needed.

Without loss of generality, we assume this maximality property: *any guard g covers a maximal contiguous portion of ∂P, i.e., $\partial(g)$ is maximal.* This implies the following lemma.

▶ **Lemma 17.** *Let g be a guard in a guarding of ∂P such that $\partial(g)$ is maximal. Then, each boundary ray of $w(g)$ goes through at least one reflex vertex of P.*

Algorithm (in a nutshell)**.** Our algorithm is fairly simple. It finds a polynomial-size set S of starting points on ∂P such that at least one of the points is covered by two guards in some optimal solution. We execute the greedy algorithm for each point in S and return the smallest guard set over all the points in S. From Theorem 5, it follows that the algorithm returns an optimal solution. The algorithm takes polynomial time because S has a polynomial size, and the greedy algorithm runs in polynomial time.

It remains to compute S. This is the most crucial part of the algorithm. First, we find a polynomial-size point set Q such that at least one guard in some optimal solution lies at a point of Q. For each point $q \in Q$, we compute a set $S(q)$ of all potential first endpoints of $\partial(q)$ for a guard at q. By Lemma 17, these points are the intersections of ∂P with the rays

that start from q and pass through reflex vertices of P. Thus, for every reflex vertex r that is visible from q, we add the first intersection point of the ray $\overrightarrow{qr}$ with ∂P to $S(q)$. We then define the set S as the union of $S(q)$ over all points $q \in Q$. The set S has a polynomial size because $|Q|$ and the number of reflex vertices are bounded by polynomials.

Let g^* be a guard in an optimal solution Γ^* that lies at a point $q \in Q$. Then the first endpoint f^* of $\partial(g^*)$ is in $F(q)$, and hence in S. By Observation 1, f^* is covered by g^* and the previous guard in Γ^*. Therefore, f^* is a point in S with our desired property of being covered by two guards in an optimal solution.

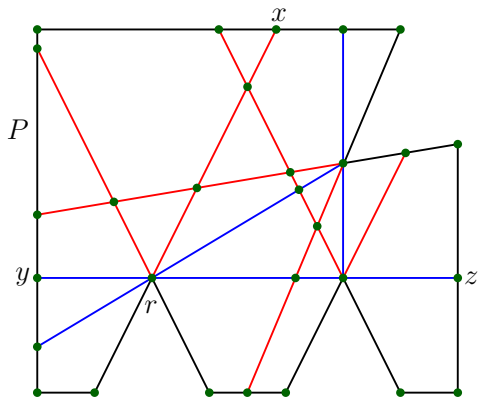

Figure 12 Edge-extensions are in red and vertex-extensions are in blue. The points in Q are represented by small green disks.

Now it remains to compute Q. For every reflex vertex r of P, extend each edge incident to r inside P until hitting ∂P at some point x; see Figure 12. We refer to the segment rx as an *edge-extension*. Add a segment between every two reflex vertices of P that are visible to each other and extend it from both endpoints inside P until hitting ∂P at points y and z. We refer to the segment yz by *vertex-extension*. An *extension* is either an edge-extension or a vertex-extension. We define Q as the set containing the following points

- all vertices of P,
- all intersection points between extensions and ∂P,
- all intersection points between edge-extensions,
- all intersection points between an edge-extension and a vertex-extension.

The following structural lemma shows that Q has our desired property.

▶ **Lemma 18.** *Some optimal solution has a guard at a point of Q.*

If P has n vertices, then Q has $O(n^3)$ points because there are $O(n)$ edge-extensions and $O(n^2)$ vertex-extensions. The set S has size $O(n^4)$. Recall that the greedy algorithm takes $O(n^2 \log n)$ time for a given starting point. Therefore, the total running time of the optimal algorithm, which invokes the greedy algorithm from each starting point in S, is $O(n^6 \log n)$. This is a conservative upper bound on the running time and surely can be improved. For example, one might adopt ideas from the $O(n)$-time incremental algorithm for the kernel of a polygon [49] to achieve a better running time for the greedy algorithm. Our main goal here is a proof that the decision version of the contiguous boundary guarding problem is in the complexity class **P**. The following theorem summarizes our result.

▶ **Theorem 19.** *The problem of contiguous boundary guarding of a polygon with the minimum number of guards can be solved in polynomial time.*

Remark. One might wonder if Lemma 18 holds for every optimal solution, i.e., whether every optimal solution has a guard in Q. Also, one might wonder whether there always exists an optimal solution in which two guards cover the same vertex of the polygon. If this were true, then running the greedy algorithm from all vertices of the polygon would suffice. However, none of these statements are true as shown in Figure 13. (For the second statement, one can verify that no guard can cover a red cross and a blue cross simultaneously. Therefore, any optimal solution must have a guard in the red triangle and a guard in the blue triangle. Then, the contiguous coverages of such guards do not have any vertex in common.)

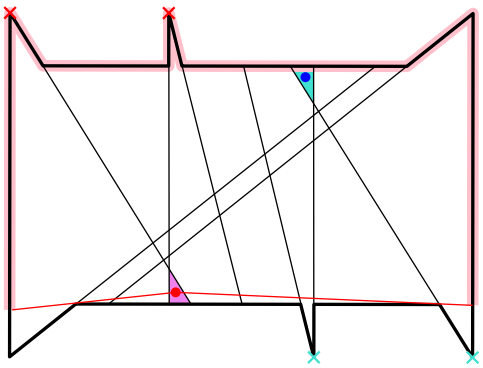

Figure 13 An optimal solution, with two guards, none of which is in Q. The coverages of no two guards, in any optimal solution, share a vertex of the polygon.

4 The Analytic Arc Cover Problem

The approach of Robson, Spalding-Jamieson, and Zheng [62] for the contiguous art gallery problem was to consider the *analytic arc cover problem*. This problem is a version of the interval cover problem on a circle with infinite number of intervals. Each interval is described by the counterclockwise segment between two points a and b on the circle S^1, denoted by $[a, b]$. This infinite set of intervals is given implicitly as a function, as can be seen in the following definition.

▶ **Definition 20.** *Let $G : S^1 \to S^1$ be a function that maps points on the unit circle S^1 to other points on the unit circle S^1. The* analytic arc cover problem *asks to find the minimum set $X \subset S^1$ such that the set of counter-clockwise arcs $\{[x, G(x)] : x \in X\}$ covers S^1.*

Note that we require some additional properties for this problem to be algorithmically solvable and avoid pathalogical examples (e.g. that there exists a finite cover). We leave these details to the full version of this approach [62].

We show that the contiguous boundary art gallery problem reduces to analytic arc cover with piecewise linear-rational functions over a unit-interval representation, i.e., the function G is a piecewise-continuous function that is decomposable into linear rational functions $f_1, f_2, \ldots, f_\ell$. See Figure 14 for an illustration of this. We crucially use the fact that a compositions of two linear rational functions yields another linear rational function. Using this fact, we show that these instances of the analytic arc cover problem are solvable in polynomial time. In addition, we show that minimizing the number of half-plane cuts to carve a 3D polytope reduces to multiple instances of segment separation. We can conclude that finding the minimum cuts to carve a polytope is also solvable in polynomial time.

▶ **Theorem 21.** *Minimizing the number of half-plane cuts to carve a 3D polytope is in* P.

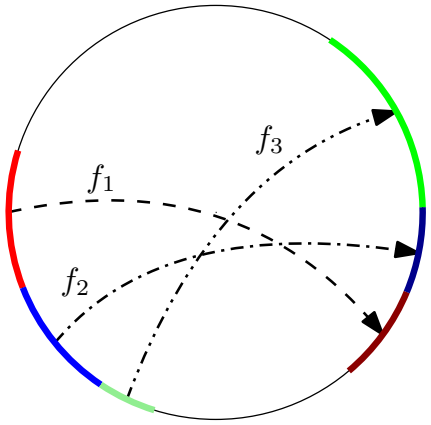

Figure 14 A mapping between parts of the unit circle where the functions f_1, f_2, and f_3 are linear rational functions.

4.1 Outline of approach

At a high level, we show that for instances of the analytic arc cover problem where we can compute a greedy function G that is piecewise linear, then the problem can be solved in polynomial time.

Analytic Arc Cover

We show that the analytic arc cover problem is solvable in polynomial time when the input function G is a piecewise linear rational function with rational coefficients.

▶ **Observation 22.** *The following is true of piecewise linear rational functions.*

- *For two piecewise linear rational functions G_1 and G_2, where G_1 consists of n_1 pieces and G_2 has n_2 pieces, the composition $G = G_1 \circ G_2$ is a piecewise linear rational function of $n_1 + n_2$ parts.*
- *For a piecewise linear rational function $G : S^1 \to S^1$ that consists of n pieces, it is possible to determine if the function "wraps around" in $O(n)$ time.*

The formal definition of "wrapping around" the circle is omitted for brevity (this requires lifting to a covering space), and is given in full detail in [63]. Using these observations, it is straightforward to prove the following theorem.

▶ **Theorem 23.** *Let $G : S^1 \to S^1$ be a piecewise linear rational function. Let I^* be a solution to the analytic arc cover problem that consists of k arcs. Then the analytic arc cover problem on can be solved in $O(nk)$ time.*

Proof. Let $\mathrm{G}^{(j)}$ denote the function $\widetilde{G}$ composed with itself j times, so $\mathrm{G}^{(j)} = \mathrm{G} \circ \mathrm{G}^{(j-1)}$. Thus we can compute $\mathrm{G}^{(j)}$ for each i via function compositions. For each $\mathrm{G}^{(j)}$ we can determine if there is a solution of size j, and halt if so. Note that $\mathrm{G}^{(j)}$ is a piecewise linear rational function with jn pieces. This algorithm terminates after $k-1$ function compositions, taking a total of $O(nk)$ time. ◀

Contiguous Art Gallery

We reduce the contiguous art gallery problem to the analytic arc cover problem for the greedy function G which is piecewise linear rational. (See Figure 8 for an illustration of this).

To prove this (in a constructive manner), we give a series of piecewise linear rational functions mapping an individual "input" segment of the polygon to an "output" segment of the polygon. The final in each series are combined to form one piecewise linear rational function for the entire polygon. Each function in the sequence leverages the last, so that each one incorporates more elements of the problem constraining the final function in various ways. In particular, the constraints that are progressively introduced are:

- The input and output segments themselves constraint the possible guard locations.
- The segments between the input and output segment must be guarded and thus constrain the possible guard locations.
- The portion of the polygon *not* being guarded constrains the possible guard locations.

In the full version [62], the functions presented in "most-constraining" to "least-constraining" order. At each step, functions for different subsets of constraints can be combined with min and max operators, which preserve the piecewise linear rational structure. Some care is needed for this part to ensure that the number of pieces is polynomial, and that the endpoints attained in the algorithm do not have exponential bit complexity.

Polygon Separation and Polytope Carving

Similarly, we can reduce the problem of segment separation, where we wish to separate two sets of line segments to an instance of analytic arc cover with a piecewise rational function. The function is in some sense less complex than the one for the contiguous art gallery problem, in that it requires fewer steps, but we make use of a special case of piecewise linear rational functions over two variables instead of one.

We also show that the problem of determining the minimum number of cuts to cut out a 3D polytope reduces to a polynomial number of instances of segment separation, and hence this problem can also be solved in strongly polynomial time.

5 Future work

In this paper, we have presented an $\mathcal{O}(n^5 k^* \log n)$ solution to the contiguous art gallery problem. We believe that the solution using repeated GreedyRevolution can find an optimal solution in as few as $\mathcal{O}(\text{polylog}\, n)$ revolutions, maybe only constantly many, as our experiments never needed more than four revolutions. Furthermore, we believe that GreedyRevolution can be implemented to run in $\mathcal{O}(n \log n)$ time; we are unsure if, in fact, linear time may be possible. In total, a final runtime of $\mathcal{O}(n\, \text{polylog}\, n)$ should be possible. Variants of the contiguous art gallery problem can be considered. For instance, 3D contiguous art gallery problem or higher-dimensional contiguous art gallery problem, or variants where each guard can see at most m contiguous intervals. We believe that all these variants are NP-hard.

Abstract

We consider intersection graphs of disks of radius r in the hyperbolic plane. Unlike the Euclidean setting, these graph classes are different for different values of r, where very small r corresponds to an almost-Euclidean setting and $r \in \Omega(\log n)$ corresponds to a firmly hyperbolic setting. We observe that larger values of r create simpler graph classes, at least in terms of separators and the computational complexity of the Independent Set problem.

First, we show that intersection graphs of disks of radius r in the hyperbolic plane can be separated with $\mathcal{O}((1 + 1/r) \log n)$ cliques in a balanced manner. Our second structural insight concerns Delaunay complexes in the hyperbolic plane and may be of independent interest. We show that for any set S of n points with pairwise distance at least $2r$ in the hyperbolic plane, the corresponding Delaunay complex has outerplanarity $1 + \mathcal{O}(\frac{\log n}{r})$, which implies a similar bound on the balanced separators and treewidth of such Delaunay complexes.

Using this outerplanarity (and treewidth) bound we prove that Independent Set can be solved in $n^{\mathcal{O}(1+\frac{\log n}{r})}$ time. The algorithm is based on dynamic programming on some unknown sphere cut decomposition that is based on the solution. The resulting algorithm is a far-reaching generalization of a result of Kisfaludi-Bak (SODA 2020), and it is tight under the Exponential Time Hypothesis. In particular, Independent Set is polynomial-time solvable in the firmly hyperbolic setting of $r \in \Omega(\log n)$. Finally, in the case when the disks have ply (depth) at most ℓ, we give a PTAS for Maximum Independent Set that has only quasi-polynomial dependence on $1/\varepsilon$ and ℓ. Our PTAS is a further generalization of our exact algorithm.

1 Introduction

Given a set of disks in the plane, one can assign to them a *geometric intersection graph* whose vertices are the disks, and edges are added between pairs of intersecting disks. The study of intersection graphs is usually motivated by physically realized networks: such networks require spatial proximity between vertices for successful connections, and the simplest model allows for connections within a distance 2, which is equivalent to the intersection graph induced by disks of radius 1 centered at the vertices. Such graphs are called *unit disk graphs*.

Unit disk graphs have received a lot of attention in the theoretical computer science literature. Their intriguing structural properties yield profound mathematical insights and facilitate the development of efficient algorithms. Historically, unit disk graphs have been studied in the Euclidean plane, where they are well motivated due to their relevance for, e.g., sensor networks. The relevance of unit disk graphs in the hyperbolic plane is less obvious. However, originating in the network science community, it has been observed [26] that the intersection graph of randomly sampled disks of equal radius r yields graphs that resemble complex real-world networks in regards to important properties[1]. They are, e.g., heterogeneous with a degree distribution following a power law [19], have high clustering coefficient [19], and exhibit the small-world property [18, 35].

Besides numerous structural results, these hyperbolic random graphs also allow for the design of more efficient algorithms [7, 8, 4, 5]. However, all these results rely on the fact that the disks are chosen randomly. So far, there is only little research on hyperbolic uniform disk graphs from a deterministic, more graph-theoretic perspective. It is important to note that for the intersection graphs of radius-r disks the resulting graph classes are different for different values of r. Moreover, it is natural to allow for the radius r to be a (monotone) function of the number of vertices. Unlike the Euclidean setting where a simple scaling shows that the choice of "unit" does not matter, it is a crucial parameter in the hyperbolic setting.

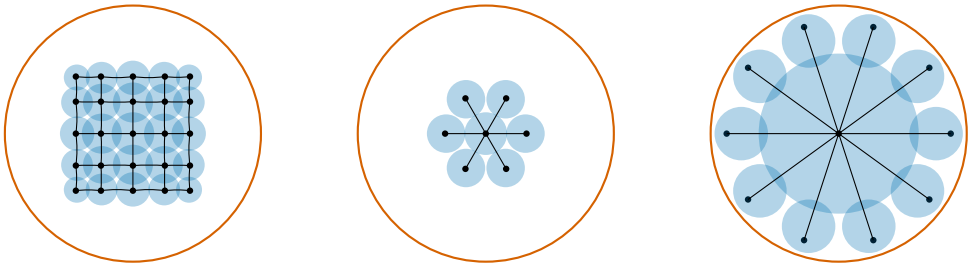
For those unfamiliar with hyperbolic geometry there is a way to conceptually understand these graphs in a Euclidean setting as follows. One can think of a hyperbolic disk graph of radius r disks as a Euclidean disk graph where the radius of a disk of center p is set to $f_r(\text{dist}(o,p))$, where f_r is decreasing very quickly at a rate set by r, and $\text{dist}(o,p)$ is the distance between the origin and the disk center p. In particular, as r goes to 0, the rate of decrease is negligible, and we get almost Euclidean unit disk graphs, while large r corresponds to a very different graph class. See Figure 1 for an illustration.

This observation is formalized by stating that hyperbolic disk graphs of uniform (that is, equal) radius $1/n^3$ and uniform radius $\log n$ are incomparable: The former class contains the $k \times k$ grid graph with $n = k^2$ for all k, but does not contain stars of size $n \geq 8$. The latter contains all star graphs but does not contain any $k \times k$ grid of size $k \geq 5$. See Figure 1 for an illustration and the full version of this paper for a formal proof of these claims. We call the regime $r \leq 1/\sqrt{n}$ *almost Euclidean*, while $r \in \Omega(\log n)$ is called *firmly hyperbolic*.

The primary goal of our paper is to explore the following:

How does the structure of hyperbolic uniform disk graphs depend on the radius $r = r(n)$?

[1] For this to work, the choice of the radius r is crucial. It is chosen as $r = \log n + c$ for a constant c that controls the average degree, and the disk centers are all sampled within a disk of radius $2r$.



(a) Smaller r enables larger grids. **(b)** Only small stars for small r. **(c)** Larger r enables larger stars.

Figure 1 Realizing a grid is only possible for small radii, while large stars are only possible in the firmly hyperbolic setting of $r \in \Omega(\log n)$.

We note that one of the main challenges for large radii is that unlike the Euclidean plane, the kissing number[2] of hyperbolic disks of large radius is unbounded, and as a result, there may be arbitrarily many "nearby disks" to any given disks in the independent set. At the same time the larger the hyperbolic disks are, the harder it is to "surround" them with equal radius disks, which intuitively leads to a simpler structure.

The case of constant radius hyperbolic disks (with constant kissing number) has been studied by Kisfaludi-Bak [23], but these methods fail for super-constant kissing number. The case of radius roughly $\log n$ has only been studied in a more specialized setting (inspired by hyperbolic random graph models) in [6]. They call the relevant graph class *strongly hyperbolic uniform disk graphs*. The above-mentioned hyperbolic random graphs are randomly sampled strongly hyperbolic uniform disk graphs. Apart from these particular choices of the radius, we have very limited understanding about the structure of hyperbolic uniform disk graphs, and the results of [6] do not imply anything for our hyperbolic uniform disk graphs.

The radius' impact on problem complexity was studied in the context of the traveling salesman problem, where one can use the minimum distance between points as a parameter with a similar flavor. In the hyperbolic plane, Kisfaludi-Bak [24] showed that the complexity of TSP decreases as one increases the minimum pairwise distance r among input points. In this paper, we show that the structure of hyperbolic uniform disk graphs behaves similarly: their structure becomes easier for larger values of r, and Independent Set can be solved faster for larger r.

Let $\mathrm{HUDG}(r(n))$ denote the set of intersection graphs where each n-vertex graph can be realized as the intersection graph of disks of uniform (equal) radius $r(n)$ in the hyperbolic plane of Gaussian curvature[3] -1. We denote by HUDG the union of these classes for all radii, that is, $\mathrm{HUDG} = \bigcup_{\rho>0} \mathrm{HUDG}(\rho)$. Let UDG denote the class of unit disk graphs in the Euclidean plane. The authors in [6] have shown that $\mathrm{UDG} \subset \mathrm{HUDG}$. When a graph is given without the geometric realization, it is NP-hard (even $\exists\mathbb{R}$-complete) to decide if the graph is a UDG [33] or HUDG [3]; for this reason, we will assume throughout this article that the input intersection graphs of our algorithms are given by specifying their geometric realization. In the hyperbolic setting, one can specify the disk centers using a so-called *model* of the hyperbolic plane, which is simply an embedding of the hyperbolic plane into some specific part of the Euclidean plane, e.g., inside the Euclidean unit disk. See our preliminaries for a brief introduction to Euclidean models of the hyperbolic plane.

[2] The kissing number of radius r disks is the maximum number of interior-disjoint disks of radius r that can touch a fixed disk of radius r.

[3] Equivalently, one can fix the radius to be 1 and set the Gaussian curvature to be $-r^2$.

From the perspective of graph algorithms, unit disk graphs in the Euclidean plane have been serving an important role as a graph class that is not comparable, but similar to planar graphs. The circle packing theorem [25] states that every planar graph can be realized as an intersection graph of disks (of arbitrary radii); thus, disk graphs serve as a common generalization of planar and unit disk graphs. Using *conformal* hyperbolic models, one can observe that hyperbolic disks appear as Euclidean disks[4] in the model, which means that all HUDGs are realized as Euclidean disk graphs. Denoting Euclidean disk graphs with DG, we thus have UDG $\subseteq$ HUDG $\subseteq$ DG[5].

A key structural tool in the study of both planar and (unit) disk graphs has been *separator theorems*. By a result of Lipton and Tarjan[27], any n-vertex planar graph can be partitioned into three vertex sets, A, B, and the separator S, such that no edges go between A and B, the separator set S has size $\mathcal{O}(\sqrt{n})$, and $\max\{|A|, |B|\} \leq \frac{2}{3}n$. Separator theorems are closely related to the *treewidth*[6] of graphs [10], for example, the above separator implies a treewidth bound of $\mathcal{O}(\sqrt{n})$ on planar graphs.

For (unit) disk graphs, similar separators and treewidth bounds are not possible, because one can represent cliques of arbitrary size. There have been at least three different approaches to deal with large cliques. The first option is to bound the cliques in some way. One can, for example, obtain separators for a set of disks of bounded *ply*, i.e., assuming that each point of the ambient space is included in at most ℓ disks. There are several separators for disks (and even balls in higher dimensions) that involve ply. The strongest and most general among these is by Miller, Teng, Thurston, and Vavasis [34]. The second way to deal with large cliques is to use so-called clique-based separators [15, 16], where the separator is decomposed into cliques and the cliques are sometimes assigned some small weight depending on their size. In the hyperbolic setting, Kisfaludi-Bak [23] showed that for any constant c, the graph class HUDG(c) admits a balanced separator consisting of $\mathcal{O}(\log n)$ cliques. The same paper shows that HUDG(c) also has clique-based separators of weight $\mathcal{O}(\log^2 n)$ and extends these techniques to balls of constant radius in higher-dimensional hyperbolic spaces, along with much of the machinery of [15]. The third option is to use random disk positions to disperse large cliques with high probability. Bläsius, Friedrich, and Krohmer [7] gave high-probability bounds on separators and treewidth for certain radius regimes in hyperbolic random graphs.

The above separators and treewidth can be used to obtain fast divide-and-conquer or dynamic programming algorithms [28, 15]. In the Independent Set problem, the goal is to decide if there are k pairwise non-adjacent vertices in the graph. In general graphs, the best known algorithms run in $2^{\mathcal{O}(n)}$ or $n^{\mathcal{O}(k)}$ time, and these running times are optimal under the Exponential Time Hypothesis (ETH) [14] (see [22] for the definition of ETH). In planar and disk graphs however, the separators allow algorithms with running time $2^{\mathcal{O}(\sqrt{n})}$ or $n^{\mathcal{O}(\sqrt{k})}$ [14, 32]. Moreover, the separator implies that planar graphs have treewidth[6] $\mathcal{O}(\sqrt{n})$ and unit disk graphs have so-called $\mathcal{P}$*-flattened treewidth* $\mathcal{O}(\sqrt{n})$ for some clique-partition $\mathcal{P}$. As a consequence, one can adapt treewidth-based algorithms [14] to these graph classes. In the hyperbolic setting, the ($\mathcal{P}$-flattened) treewidth bounds yield an $n^{\mathcal{O}(\log n)}$ quasi-polynomial algorithm for Independent Set and many other problems on graphs in HUDG(c) for any constant c, which is matched by a lower bound under ETH [23] in case of Independent Set.

[4] In the Poincaré disk and half-plane models, all hyperbolic disks are Euclidean disks, but the Euclidean and hyperbolic radii of these disks are different.
[5] With a little effort, one can show that both containments are strict: UDG $\subsetneq$ HUDG $\subsetneq$ DG.
[6] See the full version of this paper for definitions of treewidth and $\mathcal{P}$-flattened treewidth.

When approximating Independent Set, the main algorithmic tool in planar graphs is Baker's shifting technique [2] that gives a $(1-\varepsilon)$-approximate independent set in $2^{\mathcal{O}(1/\varepsilon)}n$ time. A conceptually easier grid shifting was discovered for unit disks by Hochbaum and Maas [21], which was later (implicitly) improved by Agarwal, van Kreveld, and Suri [1]. This line of research culminated in the algorithm of Chan [13] with a running time of $n^{\mathcal{O}(1/\varepsilon)}$ for disks, which also can be generalized for balls in higher dimensions. Baker's algorithm and Chan's algorithm (even for unit disks) are optimal under standard complexity assumptions [30]. To the best of our knowledge, there are no published approximation algorithms for HUDG$(r(n))$ or HUDG other than what is already implied from the algorithms on disk graphs. However, for hyperbolic random graphs, there is an $\mathcal{O}(m \log n)$ algorithm that yields a $1 - o(1)$-approximation for Independent Set asymptotically almost surely [5].

An interesting setting, where the treewidth of planar graphs has been used for intersection graphs, is that of covering and packing problems in the work of Har-Peled and later Marx and Pilipczuk [20, 32]. For the Independent Set problem on unit disk graphs, they consider the *Voronoi diagram* of the disk centers of a maximum independent set of size k. For a set of points (often called *sites*) S, the Voronoi diagram is a planar subdivision (a planar graph) that partitions the plane according to the closest site of S, that is, the *cell* of a site $s \in S$ consists of those points whose nearest neighbor from S is s. As the Voronoi diagram is a planar graph on $\mathcal{O}(k)$ vertices, it has a balanced separator of size $\mathcal{O}(\sqrt{k})$. Although this Voronoi diagram is based on the solution, and thus unknown from the algorithmic perspective, the idea of Marx and Pilipczuk is that one can enumerate all possible separators of the Voronoi diagram in $n^{\mathcal{O}(\sqrt{k})}$ time, and one of these separators can then be used to separate the (still unknown) solution in a balanced manner. A similar "separator guessing" technique has been used elsewhere in approximation and parameterized algorithms [31, 12].

Our contribution. Our first structural result is a balanced clique-based separator theorem. We note that all of our results in hyperbolic uniform disk graphs assume that the graph is given via some geometric representation, i.e., with the Euclidean coordinates of its disk centers in some Euclidean model of the hyperbolic plane.

▶ **Theorem 1.** *Let G be a hyperbolic uniform disk graph with radius r. Then G has a separator S that can be covered with $\mathcal{O}\big(\log n \cdot \big(1 + \frac{1}{r}\big)\big)$ cliques, such that all connected components of $G - S$ have at most $\frac{2}{3}n$ vertices. The separator can be computed in $\mathcal{O}(n \log n)$ time.*

Our separator is a carefully chosen line; the proof bounds the number of cliques intersecting the separator via decomposing some neighborhood of the chosen line into a small collection of small diameter regions. Notice that the theorem guarantees a separator with $\mathcal{O}(\log n)$ cliques in the hyperbolic setting, and deteriorates linearly as a function of $1/r$. In the almost-Euclidean setting of $r = 1/\sqrt{n}$ the separator has $\mathcal{O}(\sqrt{n} \log n)$ cliques, which almost matches the $\mathcal{O}(\sqrt{n})$ clique separator for unit disk graphs [15]. This is also a direct generalization of the 2-dimensional separator of Kisfaludi-Bak [23] from $r \in \Theta(1)$ to general radii.

Moreover, we observe that the techniques of [15, 23] can be utilized as the above separator implies $\mathcal{P}$-flattened treewidth $\mathcal{O}\left(\log^2 n \left(1 + \frac{1}{r}\right)\right)$ for any natural clique partition $\mathcal{P}$.

▶ **Corollary 2.** *Let G be a hyperbolic uniform disk graph with radius r. Then a maximum independent set of G can be computed in $n^{\mathcal{O}((1+1/r)\log^2 n)}$ time.*

Thus, a quasi-polynomial $n^{\mathcal{O}(\log^2 n)}$ algorithm is possible for all $r \in \Omega(1)$. If $r \leq 1$ – or even $r \in \mathcal{O}(1)$ – then for any $G \in$ HUDG(r) the neighborhood of a disk can be covered by a constant number of cliques of G (see also [23] for the case $r \in \Theta(1)$). Together with our separator in Theorem 1, the machinery of [15, 23] now yields the following result.

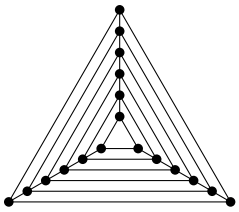


Figure 2 A Euclidean Delaunay complex of n points with outerplanarity $n/3$.

▶ **Corollary 3.** *Let G be a hyperbolic uniform disk graph with radius $r \in \mathcal{O}(1)$. Then* Dominating Set, Vertex Cover, Feedback Vertex Set, Connected Dominating Set, Connected Vertex Cover, Connected Feedback Vertex Set *can be solved in $n^{\mathcal{O}((1/r)\log n)}$ time, and q-*Coloring *for $q \in \mathcal{O}(1)$,* Hamiltonian Path *and* Hamiltonian Cycle *can be solved in $n^{\mathcal{O}(1/r)}$ time.*

While the above separator is already powerful and can be used as a basis for quasi-polynomial divide-and-conquer algorithms, the separator size stops improving when increasing the radius r beyond a constant. Nonetheless, a more powerful result is possible for super-constant radius r, which requires a different type of separator. Rather than separating hyperbolic uniform disk graphs, our second structural result is about separating the Delaunay complex, which is the dual of the Voronoi diagram, of a set of sites with pairwise distance at least $2r$. Note that in some graph $G \in \mathrm{HUDG}(r)$, the disk centers corresponding to an independent set will have pairwise distance more than $2r$, which is what motivated us to study such point sets.

A plane graph (a planar graph with a fixed planar embedding) is called *outerplanar* or 1-*outerplanar* if all of its vertices are on the unbounded face. A plane graph is called k-outerplanar if deleting the vertices of the unbounded face (and all edges incident to them) yields a $(k-1)$-outerplanar graph. Our result concerns the outerplanarity of a Delaunay complex. We prove the following tight result on the outerplanarity of the Delaunay complex $\mathcal{D}(S)$ of such a site set S. We believe that this result may be of independent interest.

▶ **Theorem 4.** *Let S be a set of n sites (points) in $\mathbb{H}^2$ with pairwise distance at least $2r$. Then the Delaunay complex $\mathcal{D}(S)$ is $1 + \mathcal{O}\big(\frac{\log n}{r}\big)$-outerplanar.*

In plane graphs, the treewidth, the outerplanarity, and the dual graph's treewidth and outerplanarity are all within a constant multiplicative factor of each other [10, 11]. Consequently, we get the bound $\mathcal{O}\big(1 + \frac{\log n}{r}\big)$ for the treewidth and outerplanarity of the Voronoi diagram and Delaunay complex of such point sets. Note that this implies constant outerplanarity for the firmly hyperbolic setting of $r \in \Omega(\log n)$.

In particular, the theorem shows that for some constant c and $r > c \log n$ the Delaunay complex is outerplanar. We recover the outerplanarity bound of [23] for $r = \Theta(1)$, and get a sublinear outerplanarity bound ($\mathcal{O}(\sqrt{n}\log n)$) even in the almost-Euclidean setting of $r = 1/\sqrt{n}$. This is surprising in light of the fact that Delaunay-triangulations can have outerplanarity $\Omega(n)$ in the Euclidean setting, as demonstrated by the set of sites in Figure 2. Notice however that the construction requires a point set where the ratio of the maximum and minimum distance among the points is $\Omega(n)$; mimicking this construction in $\mathbb{H}^2$ with a point set of minimum distance $r = 1/\sqrt{n}$ is not possible, as at distance $n \cdot r = \sqrt{n}$ the hyperbolic distortion is very significant compared to the Euclidean setting.

Using the outerplanarity bound, we are able to give the following algorithm for Independent Set.

▶ **Theorem 5.** *Let G be a hyperbolic uniform disk graph with radius r and let $k \geq 0$. Then we can decide if there is an independent set of size k in G in* $\min\left\{n^{\mathcal{O}\left(1+\frac{1}{r}\log k\right)}, 2^{\mathcal{O}(\sqrt{n})}, n^{\mathcal{O}(\sqrt{k})}\right\}$ *time.*

Our algorithm yields the first component of the running time ($n^{\mathcal{O}\left(1+\frac{1}{r}\log k\right)}$), but for very small r we can switch to the general disk graph algorithms with running times $2^{\mathcal{O}(\sqrt{n})}$ by the authors in [15] and $n^{\mathcal{O}(\sqrt{k})}$ by Marx and Pilipczuk [32]. Our algorithm is best possible under ETH for $r = \Theta(1)$ as [23] showed a lower bound of $n^{\Omega(\log n)}$ (for large k). Notice moreover that the almost-Euclidean case of $r = 1/\sqrt{n}$ gives a running time of $n^{\mathcal{O}(\sqrt{n}\log k)}$, which almost recovers the Euclidean running time of $2^{\mathcal{O}(\sqrt{n})}$. Recall that the Euclidean running time is also ETH-tight for Euclidean unit disks [15]. While this Euclidean lower bound cannot be directly applied to HUDG$(1/\sqrt{n})$, it can be adapted to the this setting, so the running time lower bound $2^{\Omega(\sqrt{n})}$ holds also in the hyperbolic plane (assuming ETH). See [24] for a similar adaptation of a Euclidean lower bound to the setting of $r = 1/\sqrt{n}$.

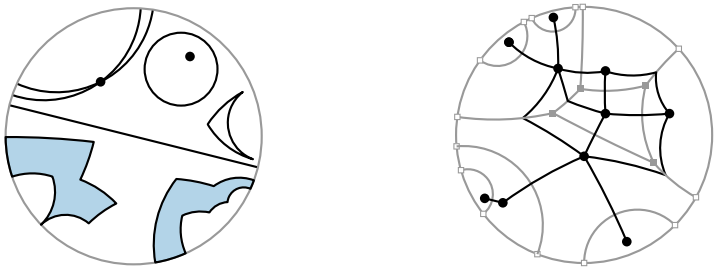
Finally, but most surprisingly, we get a polynomial running time for Independent Set in the firmly hyperbolic setting of $r \in \Omega(\log n)$; in fact, our algorithm is polynomial already for $r \in \Omega(\log k)$. In particular, this provides a polynomial exact algorithm for hyperbolic random graphs. It thereby directly generalizes the algorithm of [4] which gives a polynomial running time in hyperbolic random graphs with high probability: our algorithm has no assumptions on the input distribution and provides a polynomial worst-case running time.

The underlying idea of our exact algorithm can be regarded as a dynamic programming algorithm along the (unknown) tree decomposition of the Voronoi diagram of the solution disks, inspired by Marx and Pilipczuk [32]. More precisely, both [32] and the present paper use so-called *sphere cut decompositions*, a variant of branch decompositions for plane graphs [17] to guide the algorithm. However, due to our setting, a simple adaptation of the divide-and-conquer approach of [32] does not give the desired running time for us (it loses another logarithmic factor in the exponent). To get around this problem, we extend Marx and Pilipczuk's technique of noose-based separators to a noose-based dynamic programming algorithm. Additionally, we introduce *well-spaced* and *valid* sphere cut decompositions, and prove that they are in one-to-one correspondence with independent sets of G.

Finally, we consider approximation algorithms for Maximum Independent Set when the graph in question has low ply, that is, each point of $\mathbb{H}^2$ is covered by at most ℓ disks. We show the following.

▶ **Theorem 6.** *Let $\varepsilon \in (0,1)$ and let G be a hyperbolic uniform disk graph of radius r and ply ℓ. Then a $(1-\varepsilon)$-approximate maximum independent set of G can be found in* $\mathcal{O}\left(n^4 \log n\right) + n \cdot \left(\frac{\ell}{\varepsilon}\right)^{\mathcal{O}(1+\frac{1}{r}\log\frac{\ell}{\varepsilon})}$ *time.*

An important component of the algorithm's correctness proof is bounding the so-called *degeneracy* of hyperbolic uniform disk graphs in terms of their clique size and in terms of their ply. This generalizes the Euclidean results of [29]. When compared to the $n^{\mathcal{O}(1/\varepsilon)}$ algorithm for disk graphs by Chan [13] or the $2^{\mathcal{O}(1/\varepsilon)}n$ algorithm in planar graphs by Baker [2], both of which are conditionally optimal [30], our algorithm has a surprising quasi-polynomial dependence on $1/\varepsilon$ rather than exponential. The dependence on r exhibits the classic Euclidean-to-hyperbolic scaling seen in our earlier structural results. For $\varepsilon = 1/n$, we are guaranteed to get the optimal solution, and setting $\ell = n$ covers the general case. The resulting running time for $1/\varepsilon = \ell = n$ is $n^{\mathcal{O}\left(1+\frac{1}{r}\log n\right)}$, which matches our exact algorithm. Consequently, our approximation scheme is a generalization of our exact algorithm.



(a) (b)

Figure 3 Part (a) shows a visualization of the Poincaré disk including (parallel) lines, a circle with its center, a triangle, and polygons that include ideal points. Part (b) shows a set of sites $S \subseteq \mathbb{H}^2$ in the Poincaré disk model, $\mathcal{D}(S)$ (black), and $\mathcal{V}(S)$ (gray); Voronoi vertices are filled squares, ideal Voronoi vertices are empty squares.

2 Preliminaries

We introduce fundamental definitions and notation used throughout the paper. Additional concepts and notation are introduced in their relevant sections as needed.

Problem definition. An *independent set* in a graph is a set of pairwise non-adjacent vertices. In the Independent Set problem, we are given[7] a graph G and a number k, and the goal is to decide if there is an independent set of size k. In Maximum Independent Set, the input is a graph G, and the goal is to output the maximum value k such that G has an independent set of size k.

Let $G = (V, E)$ be a graph. A vertex set $S \subseteq V$ is a *separator* if V can be partitioned into non-empty subsets S, V_1, and V_2 such that there is no edge between V_1 and V_2, i.e., for every $v_1 \in V_1$ and $v_2 \in V_2$, it holds that $\{v_1, v_2\} \notin E$. The separator is *β-balanced* if $|V_1|, |V_2| \leq \beta n$ for some $\beta < 1$.

Hyperbolic geometry. We write $\mathbb{H}^2$ to refer to the hyperbolic plane and $\mathbb{R}^2$ to refer to the Euclidean plane. The *Poincaré disk* is a model of $\mathbb{H}^2$ that maps the whole hyperbolic plane into the interior of a Euclidean unit disk; see Figure 3a. We refer to the center of the Poincaré disk as *origin*. Straight lines in $\mathbb{H}^2$ are represented as circular arcs perpendicular to the boundary of the Poincaré disk or as chords through the origin. Hyperbolic circles are represented as Euclidean circles. The center of the hyperbolic circle is, however, farther from the origin than the Euclidean center of its representation. The Poincaré disk is *conformal*, i.e., angle preserving. Points on the boundary of the Poincaré disk are called *ideal* points. These are not part of the hyperbolic plane, but form a boundary of infinitely far points.

Let a be the sum of interior angles of a hyperbolic triangle. Then $a < \pi$ and the area of the triangle is $\pi - a$. Note that this implies that the area of a triangle is upper bounded by π. More generally, the area of a k-gon is bounded by $(k-2)\pi$. The area of a disk with hyperbolic radius r is $4\pi \sinh^2(r/2)$, which is in $\Theta(e^r)$ for $r \to \infty$ and in $\Theta(r^2)$ for $r \to 0$.

Delaunay complexes and Voronoi diagrams. We consider Voronoi diagrams with, for the most part, the usual definition: given a set $S \subset \mathbb{H}^2$ of sites, the Voronoi diagram $\mathcal{V}(S)$ is a plane graph where every inner face (*Voronoi cell*) corresponds to a site $s \in S$ and consists

[7] In this article, the graphs are always intersection graphs given through their geometric representation.

of the points in $\mathbb{H}^2$ for which s is the closest site. However, we deviate from the Euclidean definition by setting the outer face of $\mathcal{V}(S)$ to be the boundary of the Poincaré disk, which means that some of the Voronoi vertices are ideal points. This is shown in Figure 3b.

The weak dual of the Voronoi diagram is called the *Delaunay complex* and denoted by $\mathcal{D}(S)$; it is illustrated in black in Figure 3b. Here, sites $s_1 \in S$ and $s_2 \in S$ are connected in $\mathcal{D}(S)$ if and only if their Voronoi cells share a boundary.

3 Overview of our techniques

3.1 Balanced separators in HUDGs

Let G be a hyperbolic uniform disk graph with n vertices and radius r. We show that G has a balanced separator that can be covered by $\mathcal{O}((1+1/r)\log n)$ cliques; see Theorem 1. The overall argument is as follows. We find a double wedge bounded by two lines ℓ_1 and ℓ_2 that contains no vertex in its interior and separates the other vertices of G in a balanced fashion, which is ensured by selecting the center of the double wedge to be the hyperbolic *centerpoint* [24]. In Figure 4a, the double wedge with apex p is shaded gray and contains no vertices and the regions above and below the wedge each contain a constant fraction of the vertices.

Let m be the angular bisector of the wedge. As separator, we use the set of all vertices that have distance at most r from m. The set of points with distance exactly r from m forms two curves that are called *hypercycles* with axis m. Thus, vertices belong to the separator if they lie on or between the two hypercycles. The hypercycles are shown in Figure 4a and the region where separator vertices can lie is shaded blue. In the Poincaré disk, hypercycles are arcs of Euclidean circles that meet the boundary of the disk at the same ideal points as their axis but at a non-right angle. Observe that any vertex from above the top hypercycle has distance greater than $2r$ to any vertex below the bottom hypercycle. Thus, the vertices in the blue region indeed form a balanced separator.

It remains to show that the graph induced by vertices in the blue region can be covered with few cliques. For this, we cover the blue region with boxes as shown in Figure 4b. We show that each of these boxes has diameter at most $2r$, implying that the vertices within one box induce a clique. Moreover, we show that we only need $\mathcal{O}((1+1/r)\log n)$ such boxes. For the latter, we need a lower bound on the opening angle of the empty double wedge. Observe that a larger opening angle, φ, in Figure 4c, shrinks the blue region, which reduces the number of boxes required to cover it.

In the full version of this article, we first give a bound on the number of cliques required to cover the separator, parameterized by the opening angle of the empty double wedge. Afterwards, we show that there is a wedge with not too small opening angle that yields a balanced separator. The proof is constructive, i.e., given the graph with vertex positions, we can efficiently find the wedge and thereby the balanced separator of Theorem 1.

3.2 Outerplanarity of hyperbolic Delaunay complexes

Let S be a set of n sites in $\mathbb{H}^2$ with pairwise distance at least $2r$. Note that S interpreted as a hyperbolic uniform disk graph with radius r forms an independent set. To prove Theorem 4, giving an upper bound on the outerplanarity of the Delaunay complex $\mathcal{D}(S)$, we use two different types of arguments. The first argument is based on the observation that sufficiently large radius implies that any inner vertex of $\mathcal{D}(S)$ requires many other sites around it to shield it from being an outer vertex. This is similar to the observation in the introduction

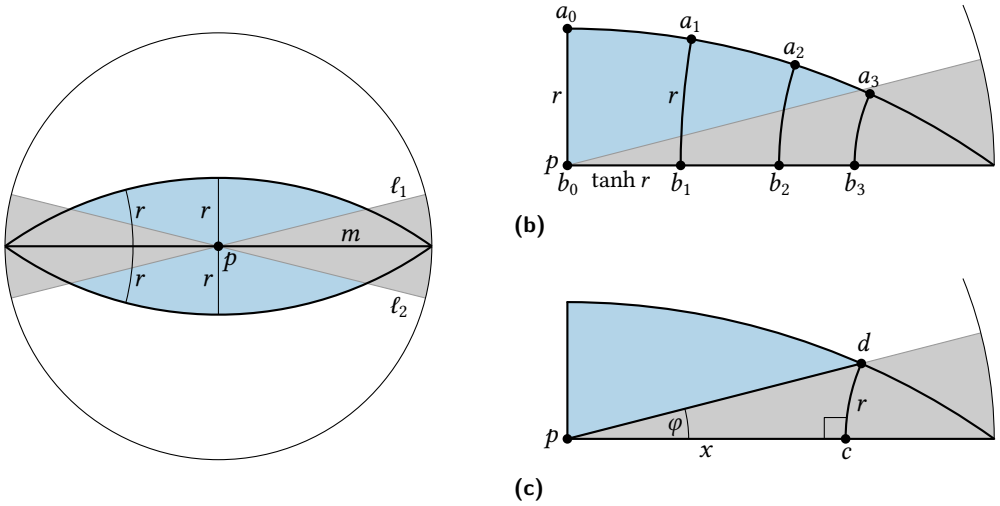


Figure 4 Illustration of our separator using the Poincaré disk model. (a) The axis m is chosen such that it separates the vertices in a balanced fashion. The double wedge between ℓ_1 and ℓ_2 contains no vertices. The separator consists of the blue set of all vertices of distance at most r to the axis m. (b) We cover the separator with boxes that have diameter $2r$ and thus form cliques. (c) If the opening angle φ is sufficiently large, then x is sufficiently small and we only need few boxes to cover the whole separator.

(recall Figure 1) that for high radius r, large stars can be realized. The argument then goes roughly as follows: If all inner vertices have degree more than 6, then we need a linear fraction of vertices on the outer face to account for the fact that the average degree in planar graphs is bounded by 6. This already implies that iteratively deleting the vertices on the outer face takes at most $\log n$ steps as each step deletes a constant fraction of the vertices. A larger radius r leads to higher degrees of inner vertices, which in turn yields stronger bounds for the outerplanarity.

This type of argument can only work if the radius r is sufficiently large. For smaller radii, the second type of argument considers layers of bounded Voronoi cells (which correspond to inner vertices of $\mathcal{D}(S)$) around one fixed center cell. As the union of these layers is bounded by a polygon with a linear number of vertices, its area is linear. In contrast to that, we will see that the area of the layers grows exponentially with the layer (with the base depending on r), showing that there cannot be too many layers.

In the following, we give a sketch of how the second argument based on area works for small radii. Although this is the argument of choice for radii that are small constants or even decreasing with n, we first give a simple area-based argument for why $r \geq \log n$ implies that the Delaunay complex has no inner vertices. This gives a good intuition how the area behaves in the hyperbolic plane and how this can help us in proving outerplanarity, even though our argument for small radii is more involved. Let $s \in S$ be a site. If s is an inner vertex of $\mathcal{D}(S)$, then its Voronoi cell is bounded and its boundary is a polygon of at most $n-1$ vertices. Thus, the area of this Voronoi cell is less than $(n-3)\pi$. Simultaneously, the disk of radius r around s is included in the Voronoi cell of s as all sites have pairwise distance at least $2r$. The area of this disk is $4\pi \sinh^2(\frac{r}{2})$ which is larger than e^r for sufficiently large r. From this it follows that bounded cells can only exist when $r < \log n$.

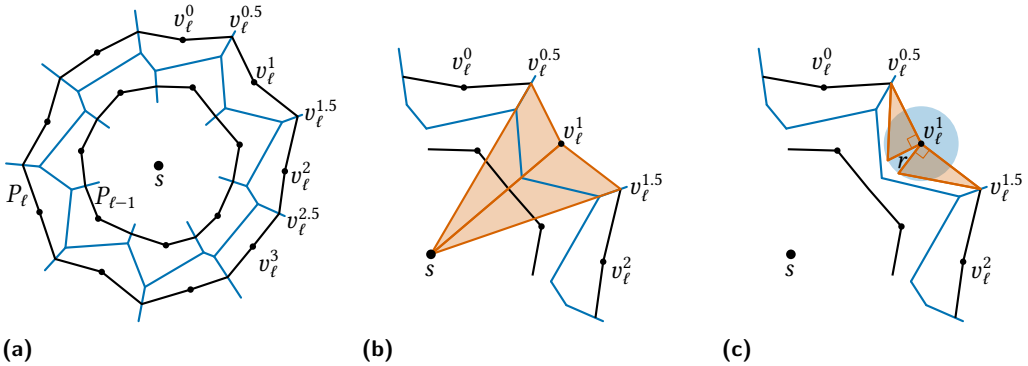

Figure 5 Illustration of the small-radius case. (a) shows two consecutive layer polygons $P_{\ell-1}$ and P_ℓ in the Delaunay complex around s. The Voronoi diagram is shown in blue. We show an upper bound of the area inside P_ℓ by covering it with the red triangles (b). We show a lower bound for the area between $P_{\ell-1}$ to P_ℓ via the red triangles in (c). Relating these two bounds yields an exponential area growth with a basis depending on r.

To make an argument that works for smaller r, let $s \in S$ be an arbitrary but fixed vertex of the Delaunay complex $\mathcal{D}(S)$. We partition the vertices of $\mathcal{D}(S)$ into *layers* by hop distance from s in $\mathcal{D}(S)$, i.e., V_ℓ is the set of vertices with distance ℓ from s. Let L be the largest integer such that for all $\ell \leq L$ the layer V_ℓ contains only inner vertices. Note that our goal is to prove an upper bound on L, as this bounds the distance of s to the outer face.

As the Delaunay complex is an internally triangulated plane graph, each layer V_ℓ induces a cycle. We denote the vertices in V_ℓ with v_ℓ^i and number the vertices modulo $|V_\ell|$, such that vertex v_ℓ^i is adjacent to vertices v_ℓ^{i-1} and v_ℓ^{i+1}; see Figure 5a. Moreover, we assume the Delaunay graph to be drawn as follows. For every edge $\{v_\ell^i, v_\ell^{i+1}\}$ we choose a point on its dual edge, i.e., the boundary between the two corresponding Voronoi cells, denote it with $v_\ell^{i+0.5}$, and connect v_ℓ^i and v_ℓ^{i+1} with two line segments via $v_\ell^{i+0.5}$. We denote the resulting polygon with P_ℓ and call it a *layer polygon* of s. Note that this yields a sequence of nested polygons where $P_{\ell-1}$ lies in the interior of P_ℓ.

Our goal then is to show that the area inside P_ℓ, denoted by $\text{Area}(P_\ell)$, grows exponentially in ℓ with a basis $b(r)$ depending on r. As $\text{Area}(P_L)$ for the outermost layer L is upper bounded by something linear in n, there cannot be too many layers. The interesting part is proving the exponential growth. For this, we show that the area gain $\text{Area}(P_\ell) - \text{Area}(P_{\ell-1})$ in layer ℓ makes up at least some sufficiently large fraction of the area $\text{Area}(P_\ell)$. For this, we give an upper bound for $\text{Area}(P_\ell)$ and relate it to a lower bound for $\text{Area}(P_\ell) - \text{Area}(P_{\ell-1})$.

How we derive these bounds is illustrated in Figure 5b and Figure 5c, respectively. For the upper bound on $\text{Area}(P_\ell)$, we cover P_ℓ with triangles connecting every edge of P_ℓ with the vertex s; see the two red triangles in Figure 5b for the two edges $\{v_\ell^{0.5}, v_\ell^1\}$ and $\{v_\ell^1, v_\ell^{1.5}\}$ of P_ℓ. For the lower bound, we find a set of disjoint triangles that lie between P_ℓ and $P_{\ell-1}$. For this, observe that for every vertex $v_\ell^i \in V_\ell$ in layer ℓ, the Voronoi cell of v_ℓ^i completely contains the disk of radius r around v_ℓ as the sites have pairwise distance at least $2r$. Thus, the two triangles illustrated in red for v_ℓ^1 in Figure 5c satisfy the property of lying between P_ℓ and $P_{\ell-1}$. As the two triangles can in principle intersect, we choose for each vertex in layer ℓ the larger of the two triangles. Note that this gives a collection of $|V_\ell|$ disjoint triangles, as each chosen triangle lies in a different Voronoi cell. Thus, the total area of these triangles gives a lower bound for $\text{Area}(P_\ell) - \text{Area}(P_{\ell-1})$.

It then remains to relate the upper bound for $\text{Area}(P_\ell)$, i.e., the area of the red triangles in Figure 5b, with the lower bound for $\text{Area}(P_\ell) - \text{Area}(P_{\ell-1})$, i.e., the area of larger red triangle in Figure 5c. Intuitively, this does not seem too far fetched for the following reasons. First, the triangles in Figure 5b share a side with the triangles in Figure 5c. Secondly, the other sides of the triangles in Figure 5c have length at least r. Thus, the triangles in Figure 5c cannot be too much smaller than those in Figure 5b.

The details of this area-based argument for small radii can be found in the full version of this paper. Together with the degree-based bound for large radii we obtain Theorem 4.

3.3 Exact algorithm

We give a brief description of the exact algorithm for Theorem 5 and refer to the full version of this paper for the remaining details. Instead of computing the independent set directly, we define some additional structure for a given independent set. The algorithm then finds this additional structure such that the corresponding independent set is maximized. The additional structure is illustrated for two example independent sets in Figure 6. In the following, we explain this from top to bottom.

Let G be a hyperbolic uniform disk graph of radius r together with an independent set S (top row in Figure 6). As there are no edges between vertices in S, they have pairwise distance at least $2r$. Thus, the Delaunay complex $\mathcal{D}(S)$ (second row in Figure 6) has low outerplanarity due to Theorem 4. Low outerplanarity implies small treewidth, which implies small branchwidth [36]. Moreover, as $\mathcal{D}(S)$ is a planar graph, we can wish for a so-called *sphere cut decomposition* of low width, which is a branch decomposition with some additional properties [37, 17, 32]. In a nutshell, we get a hierarchy of *nooses*, where each noose is a closed curve that intersects the graph only at vertices and functions as a vertex separator, splitting interior edges from exterior ones. The hierarchy is a binary tree in the sense that every noose containing more than one edge in its interior has two child nooses partitioning these edges further. Row three in Figure 6 shows three nooses of the Delaunay complex $\mathcal{D}(S)$. The solid blue noose is the parent of the dashed red and green noose.

The width of a sphere cut decomposition is the maximum number of vertices on a noose. As $\mathcal{D}(S)$ has low outerplanarity, we have a low-width sphere cut decomposition, i.e., each noose goes through only few vertices. As a last step, we normalize the nooses by specifying their exact geometry, keeping their combinatorial structure intact; see the last row of Figure 6. At its core, the normalized nooses are polygons that alternate between vertices in S and Voronoi vertices, with some special treatment for the outer face of $\mathcal{D}(S)$.

Observe that the two examples (left and right column) illustrate different independent sets S, but share the green normalized noose. This is not a coincidence, but actually happens a lot. In fact, despite the potentially exponential number of independent sets, we can bound the total number of normalized nooses that we can obtain in this way by $n^{\mathcal{O}(1+\frac{\log n}{r})}$. This follows from the fact that each noose visits only $\mathcal{O}(1 + \frac{\log n}{r})$ vertices due to Theorem 4. Thus, the normalized nooses are essentially polygons with $\mathcal{O}(1 + \frac{\log n}{r})$ corners and the set of potential corners is polynomial, as each corner is a vertex of G or a Voronoi vertex (which is defined by three vertices of G).

Our independent set algorithm works as follows. We start by listing all candidates for normalized nooses. We then use a dynamic program to combine nooses into a hierarchy of polygons. We make sure that the resulting hierarchy is valid in the sense that it corresponds to a sphere cut decomposition. Additionally, we enforce that it is *well-spaced*, which lets us show that all vertices of G visited by the polygons in the hierarchy form an independent set. Then, finding a maximum independent set is equivalent to maximizing the number of vertices visited by polygons in this polygon hierarchy, which can be done with the dynamic program.

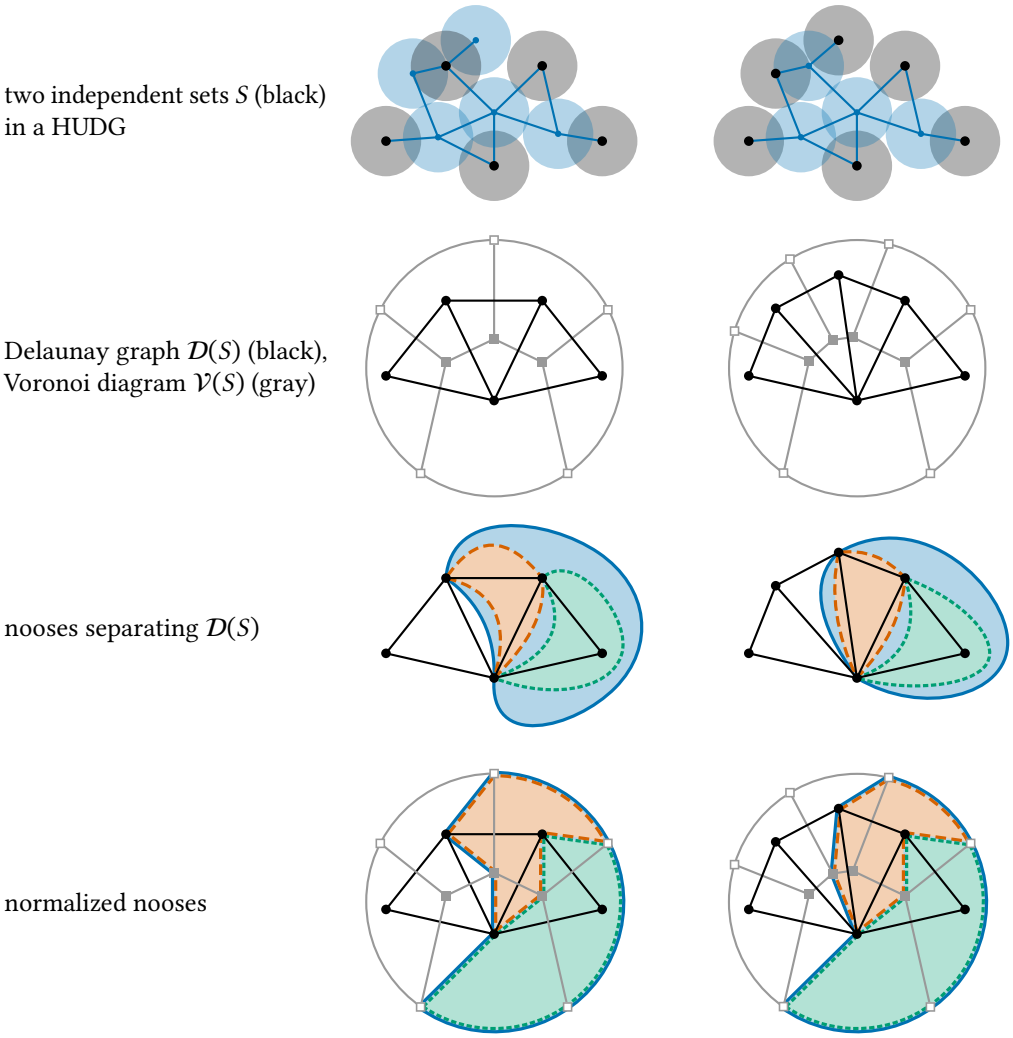

Figure 6 Illustration of our exact algorithm in Theorem 5.

3.4 Approximation algorithm

The approximation algorithm of Theorem 6 (see also the full version of this paper) works similarly to Lipton and Tarjan's version for planar graphs [28]: we repeatedly apply a separator until we get small patches and then solve each patch individually using the exact algorithm of Theorem 5. Vertices in the separators get ignored, so we get an $(1-\varepsilon)$-approximation when these make up only an ε fraction of the maximum independent set. We guarantee this using a lower bound of $\Omega(n/\ell)$ on the size of a maximum independent set, which follows from a proof that hyperbolic uniform disk graphs of ply ℓ always have a vertex of degree at most $4\ell-1$, making them $(4\ell-1)$-degenerate.

4 Future directions

There are several intriguing future directions to explore in this space. First, is there a fully polynomial approximation scheme for Independent Set for $r \geq 1$? If not, is there at least an approximation scheme that is polynomial in n, quasi-polynomial in $1/\varepsilon$, but independent of the ply?

Second, it would be interesting to explore separators in higher-dimensional hyperbolic spaces. The only case studied there is $r = \Theta(1)$ [23]. One may expect that separator size should also decrease with growing r. Is there a constant c_d such that Independent Set can be solved in polynomial time in $\mathbb{H}^d$ when $r \geq c_d \log n$?

Third, we should explore uniform disk graphs in surfaces of constant curvature, i.e., on the sphere, flat torus, and especially hyperbolic surfaces. What is the size of the best clique-based separator for a uniform disk graph of radius r on a hyperbolic surface of genus g?

Fourth, it would be interesting to investigate the complexity of problems other than Independent Set, and study how their complexity scales with the radius of the disks, or equivalently, with the curvature of the underlying space.

Finally, it is unclear whether our bound on balanced separators is tight for all values of r. For constant r, regular hyperbolic tilings are hyperbolic uniform disk graphs with constant clique number and logarithmic treewidth, making our bound asymptotically tight. However, for larger radii, it could be possible to reduce the logarithmic factor.

Abstract

The Fréchet distance is a computational mainstay for comparing polygonal curves. The Fréchet distance under translation, which is a translation invariant version, considers the similarity of two curves independent of their location in space. It is defined as the minimum Fréchet distance that arises from allowing arbitrary translations of the input curves. This problem and numerous variants of the Fréchet distance under some transformations have been studied, with more work concentrating on the discrete Fréchet distance, leaving a significant gap between the discrete and continuous versions of the Fréchet distance under transformations. Our contribution is twofold: First, we present an algorithm for the Fréchet distance under translation on 1-dimensional curves of complexity n with a running time of $\mathcal{O}(n^{8/3}\log^3 n)$. To achieve this, we develop a novel framework for the problem for 1-dimensional curves, which also applies to other scenarios and leads to our second contribution. We present an algorithm with the same running time of $\mathcal{O}(n^{8/3}\log^3 n)$ for the Fréchet distance under scaling for 1-dimensional curves. For both algorithms we match the running times of the discrete case and improve the previously best known bounds of $\tilde{\mathcal{O}}(n^4)$. Our algorithms rely on technical insights but are conceptually simple, essentially reducing the continuous problem to the discrete case across different length scales.

1 Introduction

The Fréchet distance [26] is one of the most well-studied distance measures for polygonal curves, with a long history in both applications [7, 17, 13] and algorithmic research [1, 21, 27]. For many areas of interest, including the analysis of stock market trends, electrocardiograms or electroencephalograms, the underlying behavior to be analyzed crucially involves the behavior of 1-dimensional curves, or *time series* [5, 29]. One of the advantages that the Fréchet distance offers over competing distance measures such as the Hausdorff distance is that the Fréchet distance considers a joint traversal of both curves, which naturally takes the orientation and ordering of the vertices of both curves into account. For 1-dimensional curves, the difference is particularly jarring, as representing a *continuous* curve by the points lying on it essentially discards all information concerning the underlying dynamics when measuring the Hausdorff distance. Intuitively, the Fréchet distance between two curves can be thought of the shortest possible length of a rope that can connect two climbers that cooperatively travel along their respective routes from start to end. Another well-known analogy stems from the metaphor of a person walking a dog. In this setting, the connecting rope corresponds to a dog leash and we ask for the shortest leash that can be used for the walk.

The algorithmic complexity of the computation of the Fréchet distance has been thoroughly investigated and is well understood. For curves of complexity n, the Fréchet distance can be computed in time $\tilde{\mathcal{O}}(n^2)$ [1, 12, 16], where $\tilde{\mathcal{O}}$ hides polylogarithmic factors in n. Furthermore, this is hard in the sense that there cannot exist an $\mathcal{O}(n^{2-\epsilon})$ time algorithm in the plane for any $\epsilon > 0$, unless the Strong Exponential Time Hypothesis (SETH) fails even in one dimension [8, 15].

The Fréchet distance has been studied in many different contexts, leading to a plethora of variants, inspired both by applications as well as theoretical considerations, see [14, 19, 20, 24]. Each of the available variants fits into one of two classes, according to whether only the distances of vertices of the curves are considered (the discrete version), or whether the computed distance depends on all points along the straight line segments connecting them (the continuous variant).

While the continuous Fréchet distance naturally considers all points between two vertices and tends to give better practical results (e.g., no discretization artifacts), the discrete Fréchet distance is often easier to handle algorithmically as well as implementation-wise. One overarching goal of Fréchet related research is to match the algorithmic results that are attained in the discrete version with those in the continuous case.

Fréchet distance under translation or scaling. An important aspect of detecting movement patterns in different application areas is to consider the movement independent of its absolute location and scale, i.e., we want to know for which location and scale do the patterns look most similar. Consider, for example, a cardiogram of a patient with heart arrhythmia [5]. Intuitively, some of the shared characteristics of the observed heartbeats do not depend on their absolute location/scaling but instead on the relative movement of the wave. Similarly, identifying a trend in the stock market does not necessarily depend on the exact values of the stocks involved. Instead, a group of stocks may display similar relative behavior although their absolute values are far apart, in which case a natural approach is to allow arbitrary translation and rescaling of the curves to distill their concurrent behavior. These motivations directly lead to the idea of the Fréchet distance under translation or scaling. Concretely, the Fréchet distance under translation (resp. scaling) is the minimum Fréchet distance that we obtain by allowing an arbitrary translation (resp. scaling) of one curve.

Related work. As mentioned previously, due to the simpler setting, there are often more results in the discrete setting, as is also the case for the *discrete* Fréchet distance under translation. This problem was previously mainly considered in the Euclidean plane. The first algorithm due to Jiang, Xu, and Zhu [28] builds an arrangement of size $\mathcal{O}(n^4)$ over the translation space, and then queries an arbitrary representative of each cell of this arrangement with the quadratic-time Fréchet distance algorithm, leading to an $\mathcal{O}(n^6 \log n)$ running time (where the logarithmic factor stems from the usage of parametric search). Avraham, Kaplan, and Sharir [4] crucially observed that instead of re-computing the Fréchet distance for each cell of the arrangement, one can instead formulate the problem as an online dynamic reachability problem on a grid graph and provide a data structure with update time $\mathcal{O}(n)$, leading to an $\mathcal{O}(n^5 \log n)$ algorithm. The current best-known algorithm observes that these updates are offline, i.e., they can be known in advance, and design a tailored data structure for this problem reducing the update time to $\mathcal{O}(n^{2/3} \log^2 n)$, leading to a running time of $\mathcal{O}(n^{4+\frac{2}{3}} \log^3 n)$.[1] This result is complemented by a lower bound of $\mathcal{O}(n^{4-o(1)})$, conditional on the Strong Exponential Time Hypothesis (SETH), for the discrete Fréchet distance under translation in the plane [11].

The currently best algorithm for discrete time series that is explicitly described in the literature has running time $\mathcal{O}(n^3)$ [25], based on the solution to the decision version of the problem in [4]. We note that the approach of Bringmann, Künnemann, and Nusser [11] is also directly applicable to the 1-dimensional problem, which leads to an $\mathcal{O}(n^{8/3} \log^3 n)$ algorithm.[2]

The *continuous* Fréchet distance under translations was first studied in 2001 [2, 3, 23]. Shortly after, Wenk [30] considered the Fréchet distance under scaling and developed the currently best published algorithms for both variants (translation or scaling) in the continuous setting in d-dimensional Euclidean space. For time series, these algorithms achieve a running time of $\mathcal{O}(n^5 \log n)$. We note that for time series there is an unpublished $\tilde{\mathcal{O}}(n^4)$ algorithm for both problems that can be considered folklore. We briefly sketch the idea here. First, we build the arrangement of intervals separated by events at which the decision problem for the Fréchet distance under translation/scaling is subject to change. The crux is that in one dimension, there are only $\mathcal{O}(n^2)$ such events, as the edge-vertex-vertex events that appear in higher dimensions can be omitted as they are captured by the vertex-vertex events (see Corollary 23 and the full version for more details). Thus, computing the Fréchet distance for an arbitrary representative translation/scaling in each cell together with parametric search [18] yields an $\tilde{\mathcal{O}}(n^4)$ algorithm. We want to stress that, while indeed the events in one dimension only depend on vertex-vertex alignments, this does not directly enable the usage of the grid reachability data structures of [4] and [11], as we still have to compute the *continuous* Fréchet distance for each cell.

1.1 Our Contributions

We present the first new result on the continuous Fréchet distance under translation and the continuous Fréchet distance under scaling since the results by Wenk [30] in 2002. Concretely, we obtain the following two theorems:

[1] Meanwhile, this problem was also tackled from the algorithm engineering side, making use of Lipschitz optimization instead of dynamic graph algorithms [10].

[2] This is a result of the arrangement size in $\mathbb{R}$ being n^2, while in $\mathbb{R}^2$ it is n^4. Hence, the running time is reduced by a factor of n^2.

▶ **Theorem 1.** *There exists an algorithm to compute the continuous Fréchet distance under translation between two time series of complexity n in time $\mathcal{O}(n^{8/3}\log^3 n)$.*

▶ **Theorem 2.** *There exists an algorithm to compute the continuous Fréchet distance under scaling between two time series of complexity n in time $\mathcal{O}(n^{8/3}\log^3 n)$.*

These results are made possible by the introduction of a novel framework for studying (continuous) time series [6] and the offline dynamic grid reachability data structure of [11]. Our approach essentially reduces (in an algorithmic sense) the continuous problems to their discrete counterparts and hence surprisingly matches the results for the two distance measures in the discrete setting. We note that in the Euclidean plane, there still is a large gap between the discrete and continuous setting and, while there was significant progress on the discrete side, there was no progress for the continuous Fréchet distance under translation or scaling. We believe that our approach is also of independent interest and can potentially be applied to other continuous 1-dimensional Fréchet distance problems, to match the running times of the discrete setting.

The asymmetric case. We remark that the offline dynamic grid reachability data structure of [11] is only described for the symmetric case in which both curves have the same complexity. While we believe that this restriction can be eliminated, it would drastically complicate the exposition of our results, which is why we also make this assumption in the statements of our results. Otherwise this restriction would not be necessary.

1.2 Technical Overview

On a high level, our approach for the decision problem for a given $\delta > 0$ for both the translation and scaling invariant Fréchet distance can be summarized in the following three steps.

1. The curves are represented by their (slightly adapted) δ-signatures [22], which are simplifications at the given length-scale δ and encode the large scale behavior of the curve in terms of a subset of selected vertices that essentially form a discrete curve. Curves naturally decompose into three parts, the beginning, middle, and end, with the middle part given by the δ-signature. The task is to design and choose data structures for all parts in such a way that they can be efficiently updated and combined when the transformation changes.
2. To process the beginning and end of the curves, we introduce another simplification, and subsequently identify the first point in the beginning of one curve that matches the entire beginning of the other, and likewise for the end parts, where we instead identify the last point that allows a matching. The crux is that we need to be able to do this efficiently for different transformations. We achieve this by introducing the structural notion of deadlocks.
3. We identify and precompute a set of $\mathcal{O}(n^2)$ representative transformations at which the answer to the decision problem is subject to change, and for which the answer can be updated efficiently as we sweep over them. Since each part of the curves essentially behaves like a discrete curve, the decision problem ultimately reduces to a reachability question for an object very similar to the well-known free space matrix used in the decision problem for the discrete Fréchet distance. Similar to the best algorithm for the discrete Fréchet distance under translation, we then make use of the offline dynamic grid reachability data structure [11] to implement updates and queries efficiently.

A note on parametric search. As is common, in this work we mostly describe how we solve the decision version, to then subsequently apply parametric search [18]. We note that the algorithm for the discrete Fréchet distance under translation on time series of [25] cleverly avoids parametric search, and hence shaves a logarithmic factor that would otherwise appear when directly applying [4]. One reason why we cannot take a similar approach – ignoring the fact that this technique is used for the discrete setting – is that the avoidance of parametric search in [25] leads to updates that crucially depend on the results of the decider calls; the updates are therefore *online*. Hence, a combination of [25] with the *offline dynamic* data structure of [11] seems infeasible.

2 Preliminaries

We denote with $[n]$ the set $\{1, \dots, n\}$. For any two points $p_1, p_2 \in \mathbb{R}$, we denote with $\overline{p_1 p_2}$ the directed line segment from p_1 to p_2. A *time series* of complexity n is a 1-dimensional curve formed by n points $P(1), \dots, P(n) \in \mathbb{R}$ and the ordered line segments $\overline{P(i)P(i+1)}$ for $i = 1, \dots, n-1$. Such a time series can be viewed as a function $P : [1, n] \to \mathbb{R}$, where $P(i+\alpha) = (1-\alpha)P(i) + \alpha P(i+1)$ for $i = 1, \dots, n-1$ and $\alpha \in [0, 1]$. Sometimes, we denote P as $\langle P(1), P(2), \dots, P(n)\rangle$. The points $P(i)$ are called *vertices* of P and $\overline{P(i)P(i+1)}$ are called *edges* of P for $i = 1, \dots, n-1$. For $1 \le s \le t \le n$, we denote by $P[s, t]$ the subcurve of P obtained from restricting the domain to the interval $[s, t]$. Further, we denote with $B(P, \delta)$ the set of points having distance at most δ to a point of P, i.e., $B(P, \delta) \coloneqq \{x \mid \exists a \in [1, n] \text{ s.t. } |x - P(a)| \le \delta\}$. We define $\mathrm{im}(P)$ to be the image of the time series P, meaning that $\mathrm{im}(P) \coloneqq \{P(a) \mid a \in [1, n]\}$.

Degenerate point configurations. Our results do not depend on the assumption that the time series are in general position, as all such occurrences can be easily dealt with using arbitrary tie-breaks, or *symbolic perturbation*, where necessary. Every such instance is a result of degenerate vertex-vertex distances, and we discuss more concretely how they are dealt with when they arise.

To define the Fréchet distance, let P and Q be two time series of complexity n and m. Further, let $\mathcal{H}_n$ be the set of all continuous non-decreasing functions $h : [0, 1] \to [1, n]$ with $h(0) = 1$ and $h(1) = n$. The *continuous Fréchet distance* is defined as

$$d_F(P, Q) = \min_{h_P \in \mathcal{H}_n, h_Q \in \mathcal{H}_m} \max_{\alpha \in [0,1]} |P(h_P(\alpha)) - Q(h_Q(\alpha))|.$$

In this paper, we aim to determine the optimal translation or scaling of a time series that minimizes the Fréchet distance. For a time series $P = \langle P(1), \dots, P(n)\rangle$ and a value $t \in \mathbb{R}$, the *translated time series* P_t is $\langle P(1)+t, \dots, P(n)+t\rangle$ and the *Fréchet distance under translation* is defined as

$$d_F^T(P, Q) = \min_{t \in \mathbb{R}} d_F(P, Q_t).$$

For a value $s \in \mathbb{R}$, we define the *scaled time series* sP of P to be $sP = \langle sP(1), \dots, sP(n)\rangle$ and the *Fréchet distance under scaling* is defined as

$$d_F^S(P, Q) = \min_{s \in \mathbb{R}_{\ge 0}} d_F(P, sQ).$$

In contrast to the Fréchet distance under translation, the Fréchet distance under scaling is not symmetric. The above is the directed version, and one obtains the undirected version by minimizing over both directed variants. Whenever we just refer to the Fréchet distance, we mean the continuous Fréchet distance.

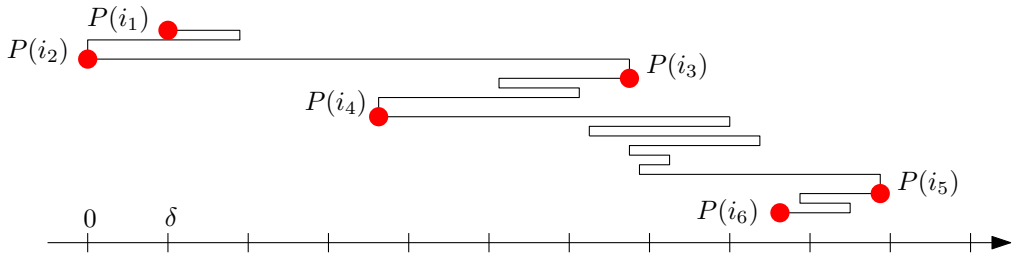

Figure 1 Throughout this paper, vertices of time series are drawn as vertical segments for clarity. The red vertices of the time series P are its δ-signature vertices. After linearly interpolating those red vertices, we get the extended δ-signature of P.

Figure 2 The left (resp. right) time series is δ-monotone increasing (resp. decreasing).

2.1 Signatures and Coupled Visiting Orders

A δ-signature of a time series P is a time series that consists of important maxima and minima of P. The concept of signatures was introduced by Driemel, Krivošija and Sohler [22]. Later, Blank and Driemel [6] extended the δ-signature by adding one vertex in the beginning and one in the end to obtain an extended δ-signature. In this paper, we only use extended δ-signatures. See Figure 1 for an example. Hence, whenever we say signature we mean extended signature. To define extended δ-signatures, we use the notion of δ-monotone time series. Examples of δ-monotone time series can be found in Figure 2.

▶ **Definition 3.** *A time series $P : [1, n] \to \mathbb{R}$ is* δ-monotone increasing (resp. decreasing) *if it holds that $P(s) \leq P(s') + \delta$ (resp. $P(s) \geq P(s') - \delta$) for all $s < s' \in [1, n]$.*

▶ **Definition 4** (extended δ-signature)**.** *Let $P = \langle P(1), \ldots, P(n)\rangle$ be a time series and $\delta \geq 0$. Then, an* extended δ-signature *$P' = \langle P(i_1), \ldots, P(i_t)\rangle$ with $1 = i_1 \leq i_2 < \ldots < i_{t-1} \leq i_t = n$ of P is a time series with the following properties:*

(a) (non-degenerate) *For $k = 2, \ldots, t-1$, it holds that $P(i_k) \notin \overline{P(i_{k-1})P(i_{k+1})}$.*

(b) (2δ-monotone) *For $k = 1, \ldots, t-1$, $P[i_k, i_{k+1}]$ is 2δ-monotone increasing or decreasing.*

(c) (minimum edge length) *If $t > 4$, then for $k = 2, \ldots, t-2$, $|P(i_k) - P(i_{k+1})| > 2\delta$.*

(d) (range)

- *For $k = 2, \ldots, t-2$, it holds that $\mathrm{im}(P[i_k, i_{k+1}]) = \overline{P(i_k)P(i_{k+1})}$, and*
- *$\mathrm{im}(P[1, i_2]) \subset [P(i_2), P(i_2) + 2\delta]$ or $\mathrm{im}(P[1, i_2]) \subset [P(i_2) - 2\delta, P(i_2)]$, and*
- *$\mathrm{im}(P[i_{t-1}, n]) \subset [P(i_{t-1}),\ P(i_{t-1}) + 2\delta]$ or $\mathrm{im}(P[i_{t-1}, n]) \subset [P(i_{t-1}) - 2\delta, P(i_{t-1})]$.*

The vertices of P' are called δ-signature vertices *of P.*

Driemel, Krivošija and Sohler [22] showed that there always exists a δ-signature and that it can be computed in $\mathcal{O}(n)$ time.[3] Bringmann, Driemel, Nusser and Psarros [9] defined δ-visiting orders and Blank and Driemel [6] used this concept to define coupled δ-visiting orders (see Figure 3), which can be used to decide whether the Fréchet distance between two time series is at most δ.

[3] They proved this statement for δ-signatures, but it can easily be shown for extended δ-signatures as well.

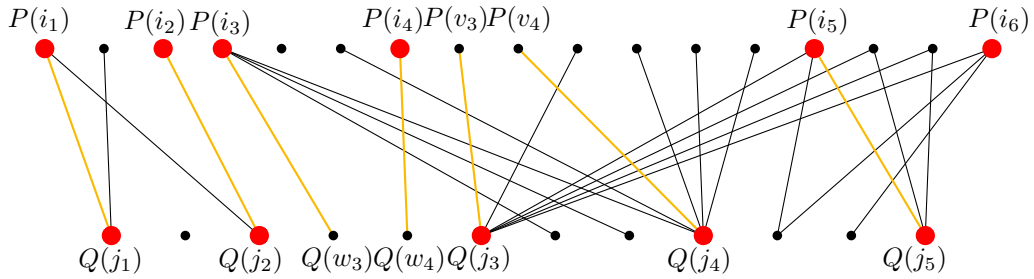

Figure 3 Visualization of a coupled δ-visiting order. Edges are drawn between vertices $P(i)$ and $Q(j)$, when one is a δ-signature vertex and $|P(i) - Q(j)| \leq \delta$. Then, a coupled δ-visiting order consists of a subset of the drawn edges, shown as an orange bipartite graph, where no two edges cross and it contains one incident edge for every δ-signature vertex.

▶ **Definition 5** (coupled δ-visiting order). *Consider two time series $P = \langle P(1), \dots, P(n)\rangle$ and $Q = \langle Q(1), \dots, Q(m)\rangle$. Then, a δ-visiting order of Q on P for the δ-signature vertices $Q(j_1), \dots, Q(j_{s_Q})$ is a sequence of indices $x_1 \leq \cdots \leq x_{s_Q}$ such that $|P(x_k) - Q(j_k)| \leq \delta$ for all k. We similarly define a δ-visiting order $y_1 \leq \cdots \leq y_{s_P}$ of P on Q for the δ-signature vertices $P(i_1), \dots, P(i_{s_P})$ of P. These two δ-visiting orders are said to be crossing-free if there exists no k, l such that $i_k < x_l$ and $j_l < y_k$, or $x_k < i_l$ and $y_l < j_k$. In this case, the ordered sequence containing all tuples (x_k, j_k) and (i_l, y_l), where $k = 1, \dots, s_Q$ and $l = 1, \dots, s_P$, is called* coupled δ-visiting order.

▶ **Lemma 6** (Lemma 9 of [6]). *Let P, Q be two time series and $\langle P(i_1), \dots, P(i_{s_P})\rangle$ and $\langle Q(j_1), \dots, Q(j_{s_Q})\rangle$ their δ-signatures. Then, $d_F(P, Q) \leq \delta$ if and only if there exist a coupled δ-visiting order $((v_1, w_1), (v_2, w_2), \dots, (v_t, w_t))$ of P and Q such that*

- **(i)** *if $v_2 = i_2$ (resp. $w_2 = j_2$), then $\exists w^* \in [w_2, \min\{w_2 + 1, j_2\}]$ (resp. $v^* \in [v_2, \min\{v_2 + 1, i_2\}]$) such that $d_F(P[1, v_2], Q[1, w^*]) \leq \delta$ (resp. $d_F(P[1, v^*], Q[1, w_2]) \leq \delta$), and*
- **(ii)** *if $v_{t-1} = i_{s_P-1}$ (resp. $w_{t-1} = j_{s_Q-1}$), then $\exists w^{**} \in [\max\{j_{s_Q-1}, w_{t-1} - 1\}, w_{t-1}]$ (resp. $v^{**} \in [\max\{i_{s_P-1}, v_{t-1} - 1\}, v_{t-1}]$) such that $d_F(P[v_{t-1}, v_t], Q[w^{**}, w_t]) \leq \delta$ (resp. $d_F(P[v^{**}, v_t], Q[w_{t-1}, w_t]) \leq \delta$).*

There is a small difference to the cited lemma, which we discuss in the full version.

2.2 Grid Reachability

▶ **Definition 7** (Offline Dynamic Grid Reachability). *Let G be the directed $n \times n$-grid graph in which every node is either activated or deactivated. We are given updates $u_1, \dots, u_U$, which are of the form "activate node (i, j)" or "deactivate node (i, j)" in an offline manner. The task of* offline dynamic grid reachibility *is to compute for all $1 \leq \ell \leq U$ if (n, n) can be reached by $(1, 1)$ after updates $u_1, \dots, u_\ell$ are performed.*

Our main results depend on the following theorem.

▶ **Theorem 8** (Theorem 3.1 of [11]). *Offline Dynamic Grid Reachability can be solved in time $\mathcal{O}(n^2 + Un^{2/3} \log^2 n)$.*

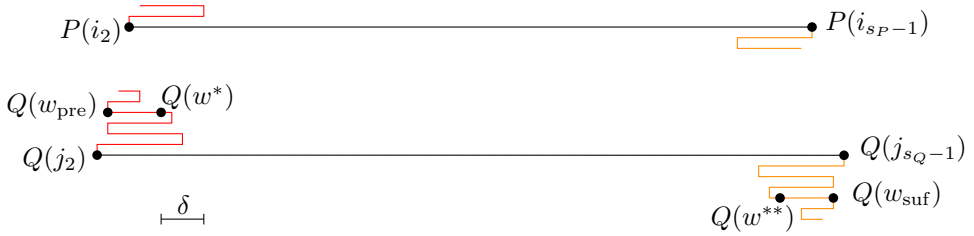

Figure 4 Minimal $\text{pre}(P)$-matcher on $\text{pre}(Q)$, w_{pre}, and minimal $\text{suf}(P)$-matcher on $\text{suf}(Q)$, w_{suf}.

3 The Static Algorithm

First, we discuss how the *modified free-space matrix* can be used to decide whether the Fréchet distance between two time series is at most a given threshold δ. Lemma 6 implies that, except for the beginning and the end, it is enough to look at pairs $(P(i), Q(j))$ of vertices, where one of the two vertices is a δ-signature vertex. Missing proofs for this section can be found in the full version.

▶ **Definition 9** (prefix and suffix). *Let P be a time series of complexity n and let $P(i_2)$ denote the second δ-signature vertex of P, and $P(i_{s_P-1})$ denote the penultimate δ-signature vertex of P. Then $P[1, i_2]$ is the prefix $\text{pre}(P)$ and $P[i_{s_P-1}, n]$ in reverse order defines the suffix $\text{suf}(P)$ of P. That is, the time series $P[i_{s_P-1}, n]$ is $\widehat{\text{suf}(P)}$, where $\widehat{P}$ denotes the time series defined by the vertices of P in reverse order.*

Observe that by the definition of the δ-signature vertices the time series $\text{pre}(P)$ and $\text{suf}(P)$ are each contained in some ball of radius δ.

▶ **Definition 10** (minimal matcher). *Let P and Q be two time series of complexity n and m respectively. The* minimal P-matcher on Q *is the smallest $w \in [m]$ such that*
1. $|P(n) - Q(w)| \leq \delta$, *and*
2. *there is a $w^* \in [w, \min(w+1, m)]$ such that $\text{d}_F(P, Q[1, w^*]) \leq \delta$.*

If no such value exists, we set it to ∞.

We denote by w_{pre} the minimal $\text{pre}(P)$-matcher on $\text{pre}(Q)$ and by v_{pre} the minimal $\text{pre}(Q)$-matcher on $\text{pre}(P)$. For the suffix, we denote by w_{suf} the index of the vertex in Q corresponding to the minimal $\text{suf}(P)$-matcher on $\text{suf}(Q)$ (and similarly v_{suf} when the roles of P and Q are swapped). See Figure 4 for an example.

Due to the next observation, we will only discuss how to process the prefix in Section 3.1, Section 4.2 and Section 5.

▶ **Observation 11.** *Let $\widehat{w_{\text{pre}}}$ be the minimal $\text{pre}(\widehat{P})$-matcher on $\text{pre}(\widehat{Q})$. If m is the complexity of Q, then $w_{\text{suf}} = m - (\widehat{w_{\text{pre}}} - 1)$.*

With these notions, we define the modified free-space matrix. See Figure 5 for an example.

▶ **Definition 12** (Modified Free-Space Matrix). *Let P and Q be two time series of complexity n and m. Further, let $\langle P(i_1), \ldots, P(i_{s_P})\rangle$ and $\langle Q(j_1), \ldots, Q(j_{s_Q})\rangle$ be their δ-signatures. We construct a matrix $M_\delta \in \{0,1\}^{n \times m}$, where the entry $M_\delta(i,j) = 1$ if*
a) *$P(i)$ and $Q(j)$ are both not δ-signature vertices, or*
b) *$|P(i) - Q(j)| \leq \delta$ and $(i,j) \notin [1, i_2] \times [1, j_2] \cup [i_{s_P-1}, n] \times [j_{s_Q-1}, m]$, or*
c) *$|P(i) - Q(j)| \leq \delta$ and $(i,j) \in \{(1,1), (n,m)\}$, or*
d) *$|P(i) - Q(j)| \leq \delta$ and $(i,j) = (i_2, j_2)$ and $d_F(\text{pre}(P), \text{pre}(Q)) \leq \delta$, or*

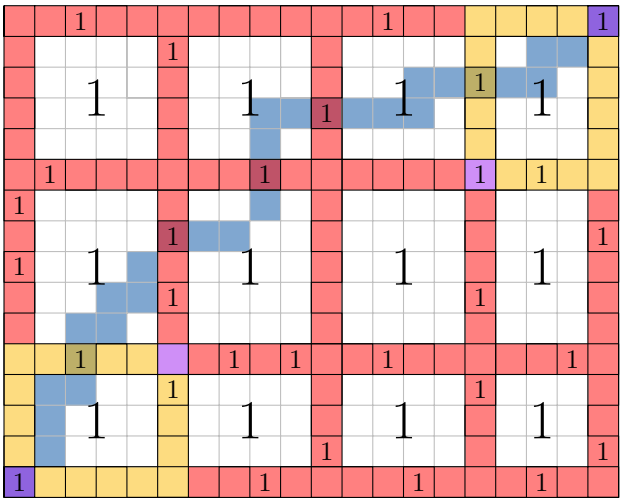

Figure 5 Example of a Modified Free-Space Matrix M_δ. The colored columns (resp. rows) correspond to the δ-signature vertices of P (resp. Q). The white entries are all 1 by Definition 12 a), the red entries are defined by b), the purple entries by c) and d) and e), and the yellow entries by f). The traversal drawn in blue uses only 1-entries of M_δ. Hence, $M_\delta(n, m)$ is reachable.

e) $|P(i) - Q(j)| \leq \delta$ *and* $(i, j) = (i_{s_P-1}, j_{s_Q-1})$ *and* $d_F(\mathrm{suf}(P), \mathrm{suf}(Q)) \leq \delta$, *or*
f) $(i, j) \in \{(i_2, w_{\mathrm{pre}}), (v_{\mathrm{pre}}, j_2), (i_{s_P-1}, w_{\mathrm{suf}}), (v_{\mathrm{suf}}, j_{s_Q-1})\}$.
Otherwise, the entry $M_\delta(i, j) = 0$. *Further, we say that an entry* $M_\delta(i, j)$ *is reachable if there exists a traversal* $(1, 1) = (a_1, b_1), (a_2, b_2), \ldots, (a_k, b_k) = (i, j)$ *such that* $M_\delta(a_l, b_l) = 1$ *and* $(a_l, b_l) \in \{(a_{l-1} + 1, b_{l-1}), (a_{l-1}, b_{l-1} + 1), (a_{l-1} + 1, b_{l-1} + 1)\}$ *for all* $l = 2, \ldots, k$.

The importance of the modified free-space matrix is that it can be used to answer the decision problem of whether or not $d_F(P, Q) \leq \delta$ essentially in the same way as it is done for the discrete Fréchet distance using the free-space matrix. The next lemma follows mainly from a result of [6]. For completeness, a proof is contained in the full version.

▶ **Lemma 13.** *It holds that* $d_F(P, Q) \leq \delta$ *if and only if* $M_\delta(n, m)$ *is reachable. This can be checked in* $\mathcal{O}(nm)$ *time.*

3.1 Prefix and Suffix

This section is dedicated to identifying the minimal $\mathrm{pre}(P)$-matcher on $\mathrm{pre}(Q)$. We often use the fact that $\mathrm{pre}(P)$ and $\mathrm{pre}(Q)$ are each contained in some δ-ball. We will show that the vital behavior of such constricted time series can be captured by their extreme points.

▶ **Definition 14** (extreme point sequence). *Let* P *be a time series of complexity* n, *such that* $P(n)$ *is a global extremum of* P *and* P *is contained in some* δ*-ball. We define the extreme point sequence* $1 = a_1 < a_2 < \cdots < a_p = n$ *to be a sequence of indices, such that*
- *(range-preserving)* $\mathrm{im}(P[1, a_{k+1}]) = \overline{P(a_k)P(a_{k+1})}$ *for all* k, *and*
- *(extreme point)* $P(a_k) = \min(P[1, a_k])$ *or* $P(a_k) = \max(P[1, a_k])$.

See Figure 6 and 7 for an example of both an extreme point sequence and their associated preliminary assignments, defined next.

▶ **Definition 15** (preliminary assignment). *Let* P *and* Q *be two time series such that the image of each time series is contained in some ball of radius* δ. *Let* $a_1 < \ldots < a_p$ *and* $b_1 < \ldots < b_q$ *be extreme point sequences of time series* P *and* Q *respectively. Define the*

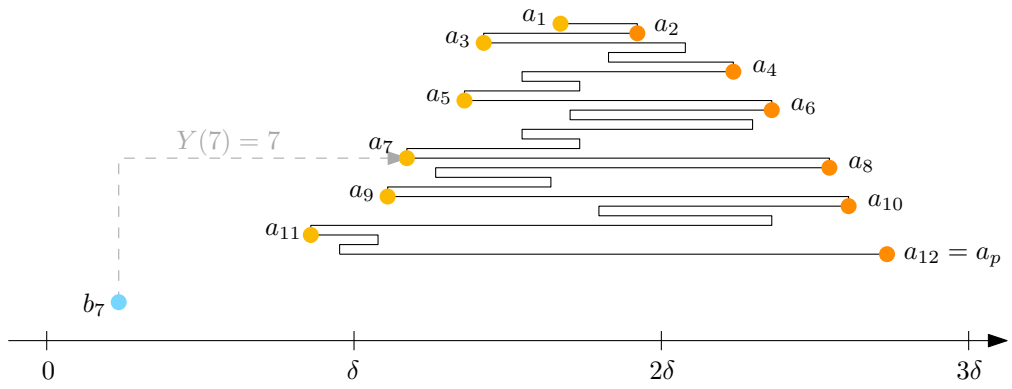

Figure 6 An extreme point sequence of the depicted time series P is $1 = a_1 < a_2 < \cdots < a_p$ and the preliminary assignment $Y(7)$ of Q on P is 7, since $Q(a_7)$ is the first vertex on P in $B(Q(b_7), \delta)$.

preliminary assignment $X(k)$ *of* P *on* Q *for every* $k \leq p$ *to be the smallest index such that* $|P(a_k) - Q(b_{X(k)})| \leq \delta$. *If no such index exists, we set* $X(k) = \infty$. *Let similarly* $Y(l)$ *be the preliminary assignment of* Q *on* P. *We say that* $X(k)$ *and* $Y(l)$ *form a* deadlock, *if* $l < X(k)$ *and* $k < Y(l)$.

Before we show how the preliminary assignment can be used to find the minimal pre(P)-matcher on pre(Q), we state some of its structural properties.

▶ **Lemma 16.** *Let* P *and* Q *be two time series such that the image of each time series is contained in some ball of radius* δ. *Let* $a_1 < \ldots < a_p$ *and* $b_1 < \ldots < b_q$ *be extreme point sequences of time series* P *and* Q. *If* $X(1) = 1$, *then the following holds.*

- **i)** *For any* $3 \leq k \leq p$ *it holds that* $X(k) \geq X(k-2)$.
- **ii)** *It holds that* $X(2k) = 1$ *for all* k *or* $X(2k-1) = 1$ *for all* k.
- **iii)** *If* $k < p$ *and* $X(k) \neq 1$, *then for any index* $l \geq X(k)$ *there is a* $t \in [b_{l-1}, b_l]$ *such that* $\mathrm{im}(P[1, a_{k+1}]) \subset B(Q(t), \delta)$.
- **iv)** *If* $X(k) > 1$ *and* $Y(l)$ *form a deadlock, then* $X(k)$ *and* $Y(X(k)-1)$ *form a deadlock.*

The importance of deadlocks is summarized in the following pivotal lemma.

▶ **Lemma 17.** *Let* P *and* Q *be time series such that the image of each time series is contained in some ball of radius* δ. *Let* $a_1 < \ldots < a_p$ *and* $b_1 < \ldots < b_q$ *be extreme point sequences of* P *and* Q. *For any* $w^* \leq b_q$, *it holds that* $d_F(P[1, a_p], Q[1, w^*]) \leq \delta$ *if and only if*

- **(i)** $|P(1) - Q(1)| \leq \delta$ *and* $|P(a_p) - Q(w^*)| \leq \delta$,
- **(ii)** $\mathrm{im}(P[1, a_p]) \subset B(Q[1, w^*], \delta)$,
- **(iii)** $\mathrm{im}(Q[1, w^*]) \subset B(P[1, a_p], \delta)$, *and*
- **(iv)** $X(k)$ *and* $Y(l)$ *do not form a deadlock for all* $k = 1, \ldots, p$ *and* $l = 1, \ldots, q$.

Observe that if $X(1)$ and $Y(1)$ do not form a deadlock then already $|P(1) - Q(1)| \leq \delta$.

Proof Sketch. First assume that $d_F(P[1, a_p], Q[1, w^*]) \leq \delta$. Then Condition (i)-(iii) hold by definition. Observe that if $X(k)$ and $Y(l)$ form a deadlock, then $|P(a_k) - Q(t)| > \delta$ for all $t \leq b_l$. However, in this case any traversal of P and Q would have to match $Q(b_l)$ with some $P(s)$ with $s < a_k$, since the part of Q before $Q(b_l)$ has to be traversed before reaching $P(a_k)$ as $d_F(P[1, a_p], Q[1, w^*]) \leq \delta$. As $X(k)$ and $Y(l)$ form a deadlock, also $|Q(b_l) - P(s)| > \delta$ for all $s \leq a_k$. Therefore, any traversal induces a cost greater than δ. Thus $X(k)$ and $Y(l)$ cannot form a deadlock, implying Condition (iv).

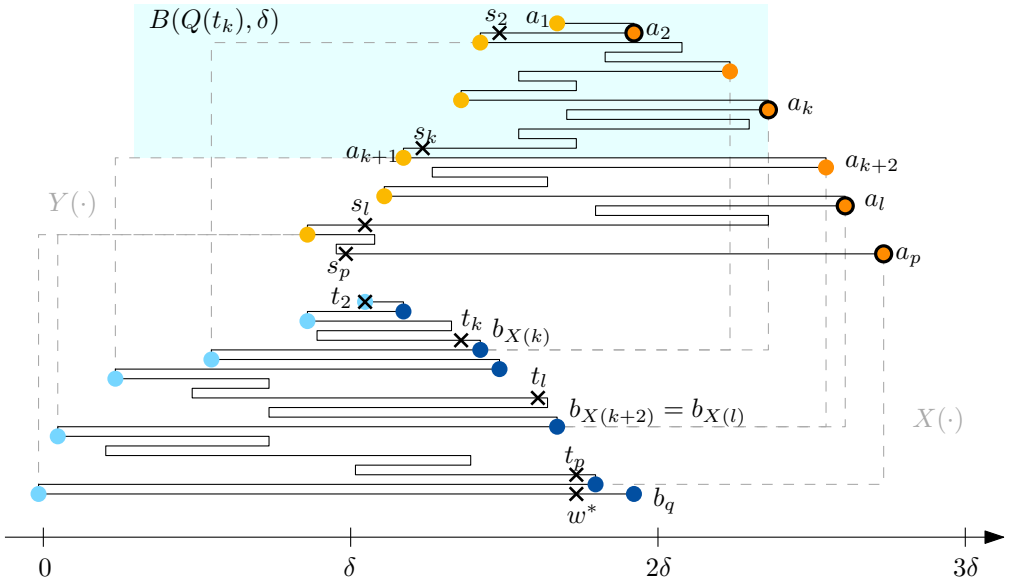

Figure 7 The gray dashed lines mark the preliminary assignments $X(\cdot)$ and $Y(\cdot)$. The points defined in the proof of Lemma 17 are marked. The circled points are the transition indices.

Now assume that Condition (i)-(iv) hold. Then, we explicitly construct a traversal of the two time series P and Q with cost $\leq \delta$. If $X \equiv 1$, then by Condition (iii) and (iv) there exists a point $s \in [a_{p-1}, a_p]$, such that $\mathrm{im}(Q[1, w^*]) \subset B(P(s), \delta)$ and $\mathrm{im}(P[s, a_p]) \subset B(Q(w^*), \delta)$. Then, matching $P[1, s]$ to $Q(1)$, and $Q[1, w^*]$ to $P(s)$, and $P[s, a_p]$ to $Q(w^*)$ results in a matching with cost $\leq \delta$. Otherwise, $X \not\equiv 1$. Let $\mathcal{K} = \{k \leq p-2 \mid X(k) \neq X(k+2)\} \cup \{p-1 \leq k \mid X(k) \neq 1\}$ be the set of *transition indices*, at which $X(k)$ is about to change when ignoring all 1-entries. To construct a matching between $P[1, a_p]$ and $Q[1, w^*]$, we define values $s_k \in [1, a_p]$ and $t_k \in [1, w^*]$ for all transition indices $k \in \mathcal{K}$ with the following properties. See Figure 7 and 8. The existence of those values is shown in the full version.

a) There is a $t_k \in [b_{X(k)-1}, \min\{w^*, b_{X(k)}\}]$ such that $\mathrm{im}(P[1, a_{k+1}]) \subset B(Q(t_k), \delta)$, with $a_{p+1} = a_p$.

b) If $k < p-1$, then there is an $s_k \in [a_k, a_{k+1}]$ such that $\mathrm{im}(Q[t_k, t_l]) \subset B(P(s_k), \delta)$, where l is the transition index after k.

c) If $k \geq p-1$, then there is an $s_k \in [a_{p-1}, a_p]$ such that $\mathrm{im}(Q[t_k, w^*]) \subset B(P(s_k), \delta)$ and $\mathrm{im}(P[s_k, a_p]) \subset B(Q(w^*), \delta)$.

Utilizing a)-d), we construct a traversal of P and Q as follows: Let k be the smallest transition index. Match $P[1, s_k]$ to $Q(t_k)$ with $t_k = 1$ via a). Now let k be the last handled transition index and let l be the next transition index after k. First match $Q[t_k, t_l]$ to $P(s_k)$ via b) (lightblue in Figure 8) and then match $P[s_k, s_l]$ to $Q(t_l)$ via a) (yellow in Figure 8). Lastly, let k be the last transition index. So far, the constructed traversal matches $Q[1, t_k]$ to $P[1, s_k]$. We now match $Q(t_k, w^*)$ to $P(s_k)$ and lastly $P[s_k, a_p]$ to $Q(w^*)$ via d) (darkblue and orange in Figure 8). This yields a traversal with cost $\leq \delta$, which concludes the proof. ◀

We use the next lemma to decide whether a minimal $\mathrm{pre}(P)$-matcher on $\mathrm{pre}(Q)$ exists.

▶ **Lemma 18.** *Let P and Q be two time series and $P(i_2)$ be the second δ-signature vertex of P and $Q(j_2)$ of Q. There exists a minimal $\mathrm{pre}(P)$-matcher on $\mathrm{pre}(Q)$ if and only if $X(k) < \infty$, and $X(k)$ and $Y(l)$ do not form a deadlock for all $k \in [p]$ and $l \in [q]$. If it exists, it is*

$$\min\{w = 1, \ldots, j_2 \mid |P(i_2) - Q(w)| \leq \delta,\ \mathrm{im}(\mathrm{pre}(P)) \subset B(Q([1, w+1]), \delta)\}.$$

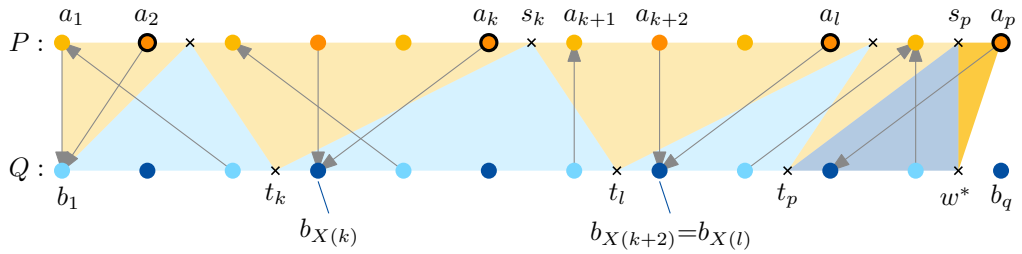

Figure 8 The transition indices are circled in black. The arrows link a_k and $X(k)$ as well as b_k and $Y(k)$ and for all a_k (resp. b_k) without an outgoing arrow it holds $X(k) = 1$ (resp. $Y(k) = 1$). The traversal described in the proof of Lemma 17 is visualized by the triangles.

Finally, we are ready to show how the minimal pre(P)-matcher on pre(Q) can be computed.

▶ **Lemma 19.** *Let P and Q be time series and let* im($Q[1, j]$) *be given for every $j = 1, \dots, q$. Further, assume the preliminary assignments X and Y of* pre(P) *and* pre(Q) *do not form a deadlock. Then we can compute the minimal* pre(P)*-matcher on* pre(Q) *in $\mathcal{O}(\log n)$ time.*

▶ **Lemma 20.** *Let P and Q be two time series and let extreme point sequences of* pre(P) *and* pre(Q) *be given. If the preliminary assignments of* pre(P) *and* pre(Q) *do not form a deadlock, then we can decide whether $d_F(\text{pre}(P), \text{pre}(Q)) \leq \delta$ in $\mathcal{O}(1)$ time. Otherwise, it holds that $d_F(\text{pre}(P), \text{pre}(Q)) > \delta$.*

The results of this section show how, using deadlocks, we can fill in the modified free-space matrix. In the following, we show that deadlocks allow efficient processing of updates of the transformations, which we crucially exploit for our algorithms.

4 1D Continuous Fréchet Distance Under Translation

Missing proofs for the statements in this section can be found in the full version.We first describe the reduction of the 1D continuous Fréchet distance under translation to an offline dynamic grid graph reachability problem. Subsequently we describe how we solve this problem for two time series P and Q both of complexity n in time $\mathcal{O}(n^{8/3} \log^3 n)$.

4.1 The $\mathcal{O}(n^2)$ Events

In this section, we show how to compute a set of $\mathcal{O}(n^2)$ translation values such that the Fréchet distance under translation between P and Q is at most δ if and only if there exists a translation value t in this set such that the Fréchet distance between P and Q_t is at most δ. We start by observing that it is sufficient to consider vertex-vertex events.

▶ **Lemma 21.** *Let $M(P, Q) = (m_{i,j})_{(i,j)\in[n]\times[n]}$ be the matrix where $m_{i,j} = \mathbb{1}_{|P(i)-Q(j)|\leq\delta}$. Let $t, t' \in \mathbb{R}$ be given. If $M(P, Q_t) = M(P, Q_{t'})$, then $d_F(P, Q_t) \leq \delta \iff d_F(P, Q_{t'}) \leq \delta$.*

▶ **Observation 22.** *Let P and Q be two time series of complexity n. There are at most $\mathcal{O}(n^2)$ many values t such that there are values $i, j \in [n]$ such that $|P(i)-Q_t(j)| = \delta$. These values are precisely the interval boundaries of intervals of the form $[P(i) - Q(j) - \delta, P(i) - Q(j) + \delta]$.*

We briefly discuss how to deal with degenerate cases, that is, cases where it is not true that for every $t \in \mathbb{R}$ exactly two values $i \neq j \in [n]$ exist such that $|P(i) - Q_t(j)| = \delta$, in the full version.

▶ **Corollary 23** (translation representatives). *There exist a sorted set $\mathfrak{T} \subset \mathbb{R}$ containing $\mathcal{O}(n^2)$ points and computable in $\mathcal{O}(n^2 \log n)$ time with the following properties.*

- *It holds that $d_F^T(P,Q) \leq \delta$ if and only if $\exists t \in \mathfrak{T}$ such that $d_F(P,Q_t) \leq \delta$.*
- *For two consecutive t, t' in $\mathfrak{T}$, there exist only one pair of indices $k, l \in [n]$ such that $|P(k) - Q_t(l)| \leq \delta$ and $|P(k) - Q_{t'}(l)| > \delta$, or the other way round. Further, for the set of all pairs of consecutive $t, t' \in \mathfrak{T}$, those indices can be computed in $\mathcal{O}(n^2 \log n)$ time.*

We call the set $\mathfrak{T}$ of Corollary 23 $\mathcal{O}(n^2)$ points the *translation representatives*.

4.2 Prefix and Suffix under Translation

In Section 3.1, we showed that the preliminary assignment can be used to determine the minimal $\mathrm{pre}(P)$-matcher on $\mathrm{pre}(Q)$. In particular, the minimal $\mathrm{pre}(P)$-matcher on $\mathrm{pre}(Q)$ can be computed in $\mathcal{O}(\log n)$ time, if we know whether there exists a deadlock or not. Therefore, we define the translated preliminary assignment and show how to keep track of whether a deadlock exists while translating the time series Q with the values in $\mathfrak{T}$.

▶ **Definition 24** (translated preliminary assignment). *Let P and Q be time series and let $t \in \mathbb{R}$. Define the* translated preliminary assignment *X_t to be the preliminary assignment of $\mathrm{pre}(P)$ on $\mathrm{pre}(Q_t)$. Let similarly Y_t be the preliminary assignment of $\mathrm{pre}(Q_t)$ on $\mathrm{pre}(P)$. We say that $X_t(k)$ and $Y_t(l)$ form a* deadlock*, if $l < X_t(k)$ and $k < Y_t(l)$.*

Given two time series P and Q together with extreme point sequences $a_1, \ldots, a_p$ and $b_1, \ldots, b_q$ of $\mathrm{pre}(P)$ and $\mathrm{pre}(Q)$, we show that we can compute the set $\mathcal{T} \subset \mathfrak{T}$ of translations for which X_t and Y_t do not form a deadlock in total time $\mathcal{O}(n^2 \log n)$.

▶ **Observation 25.** *For every $t \in \mathbb{R}$, the extreme point sequences of Q_t and Q coincide.*

▶ **Observation 26.** $\mathcal{T} \subset \{t \in \mathbb{R} | X_t(1) = 1\} = \{t \in \mathbb{R} | Y_t(1) = 1\}$.

The next observation and next lemma show that the preliminary assignments of two consecutive translations of the translation representatives differ only slightly.

▶ **Observation 27.** *Let two consecutive translation representatives t, t' be given. Then, X_t and $X_{t'}$ (resp. Y_t and $Y_{t'}$) agree everywhere except at the index that participates in the point-point distance inducing the arrangement boundary separating t and t'.*

▶ **Lemma 28.** *Let two consecutive translation representatives t, t' be given. Let k be the index of P and l the index of Q participating in the point-point distance inducing the arrangement boundary separating t and t'. Then, it holds that*

1. $|Y_t(l) - Y_{t'}(l)| \leq 2$,
2. $Y_t(l) = \infty$ *and* $Y_{t'}(l) \in \{p-1, p\}$, *or*
3. $Y_{t'}(l) = \infty$ *and* $Y_t(l) \in \{p-1, p\}$.

Similarly, it holds that

1. $|X_t(k) - X_{t'}(k)| \leq 2$,
2. $X_t(k) = \infty$ *and* $X_{t'}(k) \in \{q-1, q\}$, *or*
3. $X_{t'}(k) = \infty$ *and* $X_t(k) \in \{q-1, q\}$.

▶ **Lemma 29.** *There is an algorithm that correctly computes the set $\mathcal{T}$ of translations $t \in \mathfrak{T}$ for which X_t and Y_t do not form a deadlock in $\mathcal{O}(n^2 \log n)$. This is the set of translations in $\mathfrak{T}$ for which the preliminary assignments of $\mathrm{pre}(P)$ and $\mathrm{pre}(Q_t)$ do not form a deadlock. Similarly, we can compute the set of translations in $\mathfrak{T}$ for which $\mathrm{suf}(P)$ and $\mathrm{suf}(Q_t)$ do not form a deadlock in $\mathcal{O}(n^2 \log n)$ time.*

4.3 Computing the Fréchet Distance under Translation

We are now ready to prove our result for the decision problem of the Fréchet distance under translation of time series.

▶ **Lemma 30.** *We can decide the Fréchet distance under translation between two time series in time* $\mathcal{O}(n^{8/3}\log^2 n)$.

Proof. The goal is to apply Theorem 8 to maintain reachability in the modified free-space matrix defined in Definition 12 for all translations in $\mathfrak{T}$ from Corollary 23.

In a pre-processing step, we first compute the signatures of both input time series and extreme point sequences of $\text{pre}(P), \text{pre}(Q), \text{suf}(P), \text{suf}(Q)$, all in time $\mathcal{O}(n)$. We use Corollary 23 to compute the set $\mathfrak{T}$ of candidate translations that we have to check reachability for, and fix the order in which we check them (e.g., from left to right). Additionally, we invoke Lemma 29 to compute the set $\mathcal{T} \subset \mathfrak{T}$ for which there are no deadlocks of the prefixes and suffixes. The above steps take time $\mathcal{O}(n^2 \log n)$ each. It now suffices to show that if we consider the translations $\mathfrak{T}$ in order, there are only $\mathcal{O}(1)$ many updates per translation to the modified free-space matrix of Definition 12, for each type of entry (a) to (f). Furthermore, we need to determine all of these updates in time $\mathcal{O}(n^2 \log n)$.

Combining Corollary 23 and the information from the pre-computed signatures, we can pre-compute the $\mathcal{O}(1)$ many updates per translation in $\mathfrak{T}$ of type (a),(b), and (c) in time $\mathcal{O}(n^2 \log n)$. For entries of type (d) and (e), we first check whether the translation at hand incurs a deadlock or not (i.e., we check for containment in the pre-computed set $\mathcal{T}$). If it does not incur a deadlock, then we use Lemma 20 to determine in constant time whether $d_F(\text{pre}(P), \text{pre}(Q)) \leq \delta$ and $d_F(\text{suf}(P), \text{suf}(Q)) \leq \delta$. For type (f), we use the pre-computed signatures and Lemma 19 to compute $w_{\text{pre}}, v_{\text{pre}}, w_{\text{suf}}, v_{\text{suf}}$ in $\mathcal{O}(\log n)$ time.

Note that by the above, each entry type incurs at most $\mathcal{O}(1)$ updates per translation, and we therefore have $\mathcal{O}(n^2)$ updates in total. All of these updates can be pre-determined, i.e., they are offline. Consequently, we can apply Theorem 8 and obtain a running time of $\mathcal{O}(n^2 \cdot n^{2/3} \log^2 n) = \mathcal{O}(n^{8/3} \log^2 n)$. ◀

Using parametric search, the standard technique for solving the optimization problem of computing the Fréchet distance from the solution to the decision problem, we obtain the following theorem, proved in more detail in the full version.

▶ **Theorem 1.** *There exists an algorithm to compute the continuous Fréchet distance under translation between two time series of complexity* n *in time* $\mathcal{O}(n^{8/3}\log^3 n)$.

5 1D Continuous Fréchet Distance Under Scaling

Our algorithm for the Fréchet distance under scaling works in a similar way as our algorithm for translations. An additional obstacle to overcome is that scaling a time series can change the δ-signature. The next lemma shows that the inclusion of δ-signature vertices is monotonously increasing in the scaling. We can prove it using the observation that, if Q' is the δ-signature of Q, then sQ' is the δ-signature of sQ and previous results about signatures in [22].

▶ **Lemma 31.** *We can compute in* $\mathcal{O}(n \log n)$ *time all values* s_j *with* $j = 1, \ldots, n$ *such that the following holds. The vertex* $sQ(j)$ *is a* δ*-signature vertex of* sQ *if and only if* $s > s_j$.

As a result, by adding the events where the δ-signature changes to the arrangement for the scaling parameters, the decision problem can be solved similarly to the translation case, yielding the following theorem. See the full version for details.

▶ **Theorem 2.** *There exists an algorithm to compute the continuous Fréchet distance under scaling between two time series of complexity* n *in time* $\mathcal{O}(n^{8/3}\log^3 n)$.

On the Twin-Width of Smooth Manifolds

Kristóf Huszár
Institute of Geometry, Graz University of Technology, Austria

Abstract

Building on Whitney's classical method of triangulating smooth manifolds, we show that every compact d-dimensional smooth manifold admits a triangulation with dual graph of twin-width at most $d^{O(d)}$. In particular, it follows that every compact 3-manifold has a triangulation with dual graph of bounded twin-width. This is in sharp contrast to the case of treewidth, where for any natural number n there exists a closed 3-manifold such that every triangulation thereof has dual graph with treewidth at least n. To establish this result, we bound the twin-width of the dual graph of the d-skeleton of the second barycentric subdivision of the $2d$-dimensional hypercubic honeycomb. We also show that every compact, piecewise-linear (hence smooth) d-dimensional manifold has triangulations where the dual graph has an arbitrarily large twin-width.

1 Introduction

Structural graph parameters have become increasingly important in computational topology in the past two decades. This is mainly due to the emergence of fixed-parameter tractable (FPT) algorithms for problems on knots, links [13, 36, 37, 39] and 3-manifolds [15, 17, 18, 19, 20],[1] most of which are known to be NP-hard in general. Although these FPT algorithms may have exponential worst-case running time, on inputs with bounded *treewidth* they are guaranteed to terminate in polynomial (or even in linear) time.[2] In addition, some of these algorithms have been implemented in software packages such as `Regina`, providing practical tools for researchers in topology [12, 14].[3]

[1] Also see [2] for an FPT algorithm checking tightness of (weak) pseudomanifolds in arbitrary dimensions.
[2] Here the term *input* refers either to a link diagram $\mathcal{D}$, or to a 3-manifold triangulation $\mathcal{T}$. In the first case the treewidth means the treewidth of $\mathcal{D}$ considered as a 4-regular graph, in the second case it means the treewidth of the dual graph $\Gamma(\mathcal{T})$ of $\mathcal{T}$. The running times are measured in terms of the *size* of the input. The size of a link diagram is defined as the number of its crossings, and the size of a 3-manifold triangulation is the number of its tetrahedra. More definitions are given in Section 2.
[3] See [3] for an implemented algorithm to effectively compute certain Khovanov homology groups of knots. This algorithm is conjectured to be FPT in the *cutwidth* of the input knot diagram, cf. [3, Section 6].

The success of the above algorithms naturally leads to the following question. Given a 3-manifold $\mathcal{M}$ (resp. knot $\mathcal{K}$), what is the smallest treewidth that the dual graph of a triangulation of $\mathcal{M}$ (resp. a diagram of $\mathcal{K}$) may have?[4] Motivated by this challenge, in recent years several results have been obtained that reveal quantitative connections between *topological invariants* of knots and 3-manifolds, and *width parameters* associated with their diagrams [22, 35] and triangulations [26, 27, 28, 29, 30, 40], respectively. It turns out that topological properties of 3-manifolds may prohibit the existence of "thin" triangulations.[5,6] At the same time, geometric or topological descriptions of 3-manifolds can also give strong hints on how to triangulate them so that their dual graphs have constant pathwidth or treewidth, or at least bounded in terms of a topological invariant of these 3-manifolds.[7]

In this work we establish similar results for another graph parameter called *twin-width*. Introduced in [11], this notion has been subject of growing interest and found many algorithmic applications in recent years.[8] Namely, on classes of effectively[9] bounded twin-width, first-order properties can be decided efficiently[10] [11] (also see [8] for improved running times on specific problems definable in first-order logic), first-order queries can be enumerated fast [24], and enhanced approximation algorithms can be designed for several graph optimization problems [4]. Besides, classes of bounded twin-width are fairly general and broad. They for instance include classes of bounded tree-width, and even its dense analogue, clique-width, classes excluding a minor, proper permutation classes, d-dimensional grid graphs [11], some classes of cubic expanders [9], segment intersection graphs without biclique subgraphs of a fixed size [7], and modifications definable in first-order logic (called first-order *transductions*) of all these classes [11]. We observe that the definition of twin-width can readily be lifted to binary structures (i.e., edge-colored multigraphs).

Our first result shows that a compact d-dimensional smooth manifold always has a triangulation with dual graph of twin-width bounded in terms of d.

▶ **Theorem 1.** *Any compact d-dimensional smooth manifold $\mathcal{M}$ admits a triangulation (more specifically, a* Whitney triangulation[11]*) with dual graph of twin-width at most $d^{O(d)}$.*

Let us emphasize that, in an appropriate computational model, Whitney triangulations of smooth manifolds can be constructed algorithmically [5]. As every 3-manifold is smooth [41] (see also [38]), the next corollary follows immediately from Theorem 1. We recall that $\mathrm{tww}(G)$ denotes the twin-width of a graph G, and $\Gamma(\mathcal{T})$ denotes the dual graph of a triangulation $\mathcal{T}$.

▶ **Corollary 2.** *There exists a universal constant $C > 0$ such that every compact 3-dimensional manifold $\mathcal{M}$ admits a triangulation $\mathcal{T}$ with $\mathrm{tww}(\Gamma(\mathcal{T})) \leqslant C$.*

---

[4] For links and knots, this question was respectively asked in [37, Section 4] and [16, p. 2694].

[5] For non-Haken 3-manifolds of large Heegaard genus [30] or Haken 3-manifolds with a "complicated" JSJ decomposition [29], the dual graph of *any* triangulation must also have large treewidth.

[6] For results where the treewidth of a knot diagram is bounded below by topological properties of the underlying knot, see [22, 35].

[7] This is case with Seifert fibered spaces [28] or hyperbolic 3-manifolds [27, 40].

[8] For an introduction to twin-width and an overview of its applications, see [6] and the references therein.

[9] A class has *effectively bounded twin-width* if it has bounded twin-width, and contraction sequences of width $O(1)$ (objects witnessing the twin-width upper bound) can be found in polynomial time; see Section 2.1 for the definitions of *contraction sequences* and *twin-width*.

[10] More precisely, there is a *fixed-parameter tractable* algorithm that, given a first-order sentence φ and an n-vertex graph G with a contraction sequence of width d, decides if G satisfies φ in time $f(\varphi, d) \cdot n$, for some computable function f.

[11] We call a triangulation $\mathcal{T}$ of a compact smooth manifold $\mathcal{M}$ a *Whitney triangulation* of $\mathcal{M}$, if $\mathcal{T}$ is obtained via Whitney's method discussed in Section 3.

This is in sharp contrast to the case of treewidth, for which it is known that for every $n \in \mathbb{N}$ there are infinitely many 3-manifolds where the smallest treewidth of the dual graph of *every* triangulation is at least n [29, 30]. Complementing Theorem 1, we also show that for any fixed $d \geqslant 3$, the d-dimensional triangulations of large twin-width are abundant (Theorem 19). Moreover we show that any piecewise-linear (hence smooth) manifold of dimension at least three admits triangulations with dual graph of arbitrarily large twin-width.

▶ **Theorem 3.** *Let $d \geqslant 3$ be an integer. For every compact d-dimensional piecewise-linear manifold $\mathcal{M}$ and natural number $n \in \mathbb{N}$, there is a triangulation $\mathcal{T}$ of $\mathcal{M}$ with* $\mathrm{tww}(\Gamma(\mathcal{T})) \geqslant n$.

▶ Remark 4. The assumption of $d \geqslant 3$ in Theorem 3 is essential. Indeed, the dual graph of any triangulation of the genus-g surface S_g is, in particular, a graph that embeds into S_g and such graphs are known to have twin-width bounded above by $c(\sqrt{g}+1)$ for some universal constant $c > 0$ [32].[12]

Outline of the paper. In Section 2 we review the relevant notions from graph theory and topology. In Section 3 we recall Whitney's seminal work on triangulating smooth manifolds. This is followed by a detailed proof of Theorem 1 in Section 4. Finally, in Section 5 we prove the complementary results about triangulations with dual graph of large twin-width.

2 Preliminaries

Basic notation. For a finite set S we let $|S|$ denote its cardinality, while for a real number x we let $|x|$ denote its absolute value. For a positive integer $k \leqslant |S|$, we let $\binom{S}{k}$ denote the set of k-element subsets of S. For a positive integer n, we let $[n]$ denote the set of all positive integers up to n, and for two real numbers $a \leqslant b$, we use $[a, b]$ to denote the closed interval $\{x \in \mathbb{R} : a \leqslant x \leqslant b\}$. For a vector $y = (y_1, \ldots, y_d) \in \mathbb{R}^d$ we use $\|y\|$ to denote its Euclidean norm, i.e, $\|y\|^2 = \sum_{i=1}^{d} y_i^2$. However, if $\mathcal{X}$ is a (cubical or simplicial) complex, then $\|\mathcal{X}\|$ refers to its geometric realization.

2.1 Trigraphs, contraction sequences and twin-width

Following [11, Sections 3 and 4], in this section we review the graph-theoretic notions central to our work and collect some basic, yet important facts about twin-width.

Trigraphs. A *trigraph* G is a triple $G = (V, E, R)$, where V is a finite set of *vertices*, and $E, R \subseteq \binom{V}{2}$ are two disjoint subsets of pairs of vertices called *black edges* and *red edges*, respectively. We also refer to the sets of vertices, black edges and red edges of a given trigraph G as $V(G)$, $E(G)$ and $R(G)$, respectively. Any simple graph $G = (V, E)$ may be regarded as a trigraph (V, E, R) with $R = \emptyset$. For a vertex $v \in V(G)$ the *degree* $\deg(v)$ *of* v is the number of edges incident to it, i.e., $\deg(v) = |\{e \in E \cup R : v \in e\}|$. Additionally, the *red degree* $\deg_R(v)$ *of* v is the number of red edges incident to it, i.e., $\deg_R(v) = |\{e \in R : v \in e\}|$. A trigraph G for which $\deg_R(G) = \max_{v \in V(G)} \deg_R(v) \leqslant b$ is called a *b-trigraph*. Given two trigraphs $G = (V, E, R)$ and $G' = (V', E', R')$, we say that G' is a *subtrigraph* of G, if $V' \subseteq V$, $E' \subseteq E \cap \binom{V'}{2}$ and $R' \subseteq R \cap \binom{V'}{2}$.[13] In addition, if $E' = E \cap \binom{V'}{2}$ and $R' = R \cap \binom{V'}{2}$, then we say that G' is an *induced subtrigraph* of G. For a trigraph G and a subset $S \subseteq V(G)$ of its vertices, $G - S$ denotes the induced subtrigraph of G with vertex set $V(G) \setminus S$.

[12] This bound is sharp up to a constant multiplicative factor [32]. For $g = 0$, we know that planar graphs have twin-width at most eight [25], and there are planar graphs with twin-width equal to seven [31].
[13] As usual, subtrigraphs of graphs (those without any red edges) will also be called subgraphs.

Contraction sequences and twin-width. Let $G = (V, E, R)$ be a trigraph and $u, v \in V$ be two arbitrary distinct vertices of G. We say that the trigraph $G/u, v = (V', E', R')$ is obtained from G by *contracting* u and v into a new vertex w if **1.** $V' = (V \setminus \{u, v\}) \cup \{w\}$, **2.** $G - \{u, v\} = (G/u, v) - \{w\}$ and **3.** for any $x \in V' \setminus \{w\} = V \setminus \{u, v\}$ we have

- $\{w, x\} \in E'$ if and only if $\{u, x\} \in E$ and $\{v, x\} \in E$,
- $\{w, x\} \notin E' \cup R'$ if and only if $\{u, x\} \notin E \cup R$ and $\{v, x\} \notin E \cup R$, and
- $\{w, x\} \in R'$ otherwise.

We call the trigraph $G/u, v$ a *contraction* of G. A sequence $\mathfrak{S} = (G_1, \ldots, G_m)$ of trigraphs is a *contraction sequence* if G_{i+1} is a contraction of G_i for every $1 \leqslant i \leqslant m - 1$. Note that $|V(G_{i+1})| = |V(G_i)| - 1$. We use the notation "$\mathfrak{S} \colon G_1 \rightsquigarrow G_m$" to indicate that the trigraphs G_1 and G_m are initial and terminal entries of the contraction sequence $\mathfrak{S}$. The *width* $\mathrm{w}(\mathfrak{S})$ of a contraction sequence $\mathfrak{S} = (G_1, \ldots, G_m)$ is defined as $\mathrm{w}(\mathfrak{S}) = \max_{1 \leqslant i \leqslant m} \deg_R(G_i)$, i.e., the largest red degree of any vertex of any trigraph in $\mathfrak{S}$. Now, the *twin-width* $\mathrm{tww}(G)$ of a trigraph G is defined as the smallest width of any contraction sequence $(G_1, \ldots, G_{|V(G)|})$ with $G_1 = G$ and $G_{|V(G)|} = \bullet$, where $\bullet$ denotes the trigraph consisting of a single vertex.

Some properties of twin-width; grid graphs

We conclude this section by collecting some properties of twin-width that we will rely on later. The first one states that twin-width is monotonic under taking induced subtrigraphs and is a simple consequence of the definitions (cf. [11, Section 4.1]).

▶ **Proposition 5.** *If H is an induced subtrigraph of a trigraph G, then* $\mathrm{tww}(H) \leqslant \mathrm{tww}(G)$.

Smallness. An infinite class $\mathcal{G}$ of graphs is *small* if there exists a constant $c > 1$ such that for every $n \in \mathbb{N}$ the class $\mathcal{G}$ contains at most $n! c^n$ labeled graphs on n vertices. The next theorem says that every graph class of bounded twin-width – i.e., for which there exists a constant $C > 0$, such that $\mathrm{tww}(G) \leqslant C$ for every graph G in the class – is small.

▶ **Theorem 6** ([9, Theorem 2.5])**.** *Every graph class with bounded twin-width is small.*

Now let s be a non-negative integer. The *s-subdivision* of G is the graph $\mathrm{subd}_s(G)$ obtained from G by subdividing each edge in $E(G)$ exactly s times. A simple counting argument together with Theorem 6 yields the following:

▶ **Proposition 7.** *For any fixed integers $k \geqslant 4$ and $s \geqslant 0$, the class* $\mathrm{subd}_s(\mathcal{G}_k)$ *of s-subdivisions of k-regular*[14] *simple graphs is not small, hence has unbounded twin-width.*

This proposition follows from the adaptation of an argument given in the first paragraph of [23, Section 3]. For completeness, we spell out this proof below.

Proof of Proposition 7. Let $N_k(m)$ be the number of labeled k-regular simple graphs on m vertices. Note that if $N_k(m) > 0$, then km is even; which we now assume. It is known (cf. [42, Section 6.4.1]) that, asymptotically

$$N_k(m) \sim \exp\left(\frac{1 - k^2}{4}\right) \frac{(km)!}{(km/2)! \cdot 2^{km/2} \cdot (k!)^m} = \Omega\left(\frac{(km/2)!}{(k!)^m}\right), \tag{1}$$

which readily implies that k-regular graphs (for $k \geqslant 3$) do not form a small class.

[14] A simple graph $G = (V, E)$ is *k-regular* if every vertex $v \in V$ has degree $\deg(v) = k$.

Now, let $N_k^{(s)}(n)$ be the number of n-vertex graphs in the class $\mathrm{subd}_s(\mathcal{G}_k)$ of s-subdivisions of k-regular simple graphs. If a graph $G \in \mathrm{subd}_s(\mathcal{G}_k)$ has n vertices, then $n = m + \frac{km}{2}s$, where m is the number of vertices of G of degree k. Note that such a graph G can be obtained by first choosing a k-regular labeled graph H on m vertices, then ordering the remaining $n-m = kms/2$ vertices arbitrarily and evenly distributing them to the edges of H according to some fixed ordering of $E(H)$. It follows that

$$N_k^{(s)}(n) \geqslant \binom{n}{m} \cdot N_k(m) \cdot (n-m)! = n! \frac{N_k(m)}{m!} \overset{(1)}{=} n! \cdot \Omega\left(\frac{(km/2)!}{m! \cdot (k!)^m}\right). \tag{2}$$

Since $k \geqslant 4$, we have $km/2 \geqslant 2m$. This, together with $(2m)! \geqslant 2^m (m!)^2$ and (2) implies

$$N_k^{(s)}(n) \geqslant n! \cdot \Omega\left(\frac{m!}{(2 \cdot k!)^m}\right). \tag{3}$$

Recall that $m = 2n/(2+ks)$. In particular, m is proportional to n. Hence $m!/(2 \cdot k!)^m$ grows faster than c^n for any fixed constant $c > 1$. Thus the graph class $\mathrm{subd}_s(\mathcal{G}_k)$ is not small. ◀

Grid graphs. The *d-dimensional n-grid* P_n^d is the graph with vertex set $V(P_n^d) = [n]^d$, and $\{u, v\} \in E(P_n^d)$ for two vertices $u = (u_1, \ldots, u_d)$ and $v = (v_1, \ldots, v_d)$ if and only if $\sum_{i=1}^d |u_i - v_i| = 1$. The next result states that $\mathrm{tww}(P_n^d) \leqslant 3d$ irrespective of the value of n.

▶ **Theorem 8** (Theorem 4 in [11]). *For every positive d and n, the d-dimensional n-grid P_n^d has twin-width at most $3d$.*

The *d-dimensional n-grid with diagonals* $D_{n,d}$ is the graph with $V(D_{n,d}) = [n]^d$, and $\{u, v\} \in E(D_{n,d})$ for two vertices $u = (u_1, \ldots, u_d)$ and $v = (v_1, \ldots, v_d)$ if and only if $\max_{i=1}^d |u_i - v_i| \leqslant 1$. Now, for a given trigraph $G = (V, E, R)$ we set $\mathrm{red}(G) = (V, \emptyset, E \cup R)$. In words, $\mathrm{red}(G)$ is the trigraph obtained from G by replacing every black edge of G by a red edge between the same vertices. With this notation $\mathrm{red}(D_{n,d})$ is the *d-dimensional* ***red*** *n-grid with diagonals*, i.e., $\mathrm{red}(D_{n,d}) = ([n]^d, \emptyset, E(D_{n,d}))$. Clearly, $\mathrm{tww}(D_{n,d}) \leqslant \mathrm{tww}(\mathrm{red}(D_{n,d}))$.

▶ **Theorem 9** (Lemma 4.4 in [11]). *For every positive d and n, every subtrigraph of the d-dimensional red n-grid with diagonals $\mathrm{red}(D_{n,d})$ has twin-width at most $2(3^d - 1)$.*

2.2 Background in topology

For general background in (combinatorial and differential) topology we refer to [43].

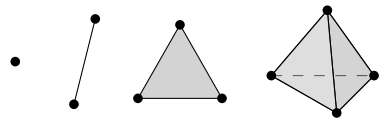
2.2.1 Simplicial and cubical complexes

Abstract simplicial complexes. Given a finite ground set $\mathcal{S}$, an *abstract simplicial complex* (or *simplicial complex*, for short) $\mathcal{X}$ over $\mathcal{S}$ is a downward closed subset of the power set $2^{\mathcal{S}}$, i.e., $\mathcal{F} \in \mathcal{X}$ and $\mathcal{F}' \subset \mathcal{F}$ imply $\mathcal{F}' \in \mathcal{X}$. Any element of $\mathcal{X}$ is called a *face* or *simplex* of $\mathcal{X}$, and for $\sigma \in \mathcal{X}$ the *dimension of* σ is defined as $\dim \sigma = |\sigma| - 1$. The *dimension of* $\mathcal{X}$, denoted by $\dim \mathcal{X}$, is then the maximum dimension of a face of $\mathcal{X}$. If $\dim \mathcal{X} = d$, we also say that $\mathcal{X}$ is a *simplicial d-complex*. For $0 \leqslant i \leqslant \dim \mathcal{X}$, we let $\mathcal{X}(i) = \{\sigma \in \mathcal{X} : \dim \sigma = i\}$ denote the set of i-dimensional faces (or i-faces, or i-simplices) of $\mathcal{X}$. The *i-skeleton* $\mathcal{X}_i = \bigcup_{j=0}^i \mathcal{X}(j)$ of $\mathcal{X}$ is the union of all faces of $\mathcal{X}$ up to dimension i. Note that any simple graph $G = (V, E)$ can be regarded as a 1-dimensional simplicial complex $\mathcal{X}_G$ with $\mathcal{X}_G(0) = \{\{v\} : v \in V\}$ and $\mathcal{X}_G(1) = E$. For $0 \leqslant i \leqslant 3$ the i-simplices of a simplicial complex $\mathcal{X}$ are respectively called the *vertices*, *edges*, *triangles*, and *tetrahedra* of $\mathcal{X}$.

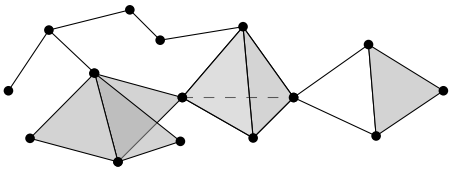
Geometric realization of simplicial complexes. Every abstract simplicial complex $\mathcal{X}$ may be realized geometrically as follows. To each abstract i-simplex $\sigma = \{v_0, v_1, \ldots, v_i\} \in \mathcal{X}$ we associate a *geometric i-simplex* $\|\sigma\| = [v_0, v_1, \ldots, v_i] \subset \mathbb{R}^i$ defined as the convex hull of $i+1$ affinely independent points in $\mathbb{R}^i$. We equip $\|\sigma\|$ with the subspace topology inherited from $\mathbb{R}^i$. Next, we consider the disjoint union $\bigsqcup_{\sigma\in\mathcal{X}} \|\sigma\|$ of these geometric simplices, and perform identifications along their faces that reflect their relationship in $\mathcal{X}$. The resulting space $\|\mathcal{X}\|$, equipped with the quotient topology, is called the *geometric realization of* $\mathcal{X}$, see Figure 1. The geometric realization of a simplicial complex is unique up to homeomorphism.

Cubical complexes. Analogous to simplicial complexes, a *cubical complex* $\mathcal{X}$ over a ground set $\mathcal{S}$ is a set system $\mathcal{X} \subset 2^{\mathcal{S}}$ that consists of "cubes" instead of simplices. The terminology is the same as in the simplicial case. The only difference is that a *geometric i-cube* is a topological space homeomorphic to $[0,1]^i$, where $[0,1]$ denotes the closed unit interval.

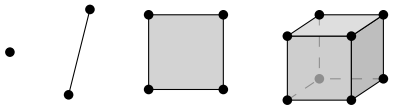
Cubical or simplicial complexes in this paper will typically be defined geometrically, and as such they will naturally come with a geometric realization.



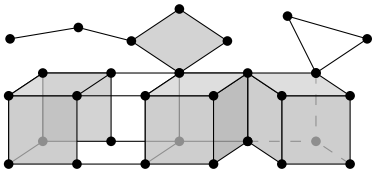
(a) Geometric i-simplices ($i = 0, 1, 2, 3$).



(b) Geometric realization of a simplicial 3-complex.



(c) Geometric i-cubes ($i = 0, 1, 2, 3$).



(d) Geometric realization of a cubical 3-complex.

Figure 1 The geometric perspective on simplicial and cubical complexes.

The hypercubic honeycomb. Let n and d be positive integers and consider the d-dimensional cube $[1,n]^d \subset \mathbb{R}^d$. The *$d$-dimensional hypercubic honeycomb* $\mathbf{H}^{d,n}$ is a cubical d-complex that decomposes $[1,n]^d$ into $(n-1)^d$ geometric cubes. The properties of this familiar object play an important role in this work, so we describe it for completeness. We define $\mathbf{H}^{d,n}$ geometrically, in a bottom-up fashion. First, the vertex set $\mathbf{H}^{d,n}(0)$ consists of precisely those points in $[1,n]^d$, which have only integral coordinates. Next, a 1-cube (i.e., an edge) is attached along its endpoints to vertices $u = (u_1, \ldots, u_d)$ and $v = (v_1, \ldots, v_d)$ in $\mathbf{H}^{d,n}(0)$ if and only if $\sum_{i=1}^{d} |u_i - v_i| = 1$. Thus the 1-skeleton $\mathbf{H}_1^{d,n}$ is just the d-dimensional grid graph P_n^d encountered in the end of Section 2.1. Finally, the higher dimensional skeleta of $\mathbf{H}^{d,n}$ are *induced* by its 1-skeleton: for each subcomplex $\mathcal{Y} \subset \mathbf{H}_i^{d,n}$ isomorphic to the boundary of a $(i+1)$-cube, we attach an $(i+1)$-cube to $\mathbf{H}_i^{d,n}$ along $\mathcal{Y}$. In words, starting from the 1-skeleton $\mathbf{H}_1^{d,n}$, whenever we have the possibility to attach a cube of dimension at least two (because its boundary is already present), we attach it. See, e.g., Figure 2.

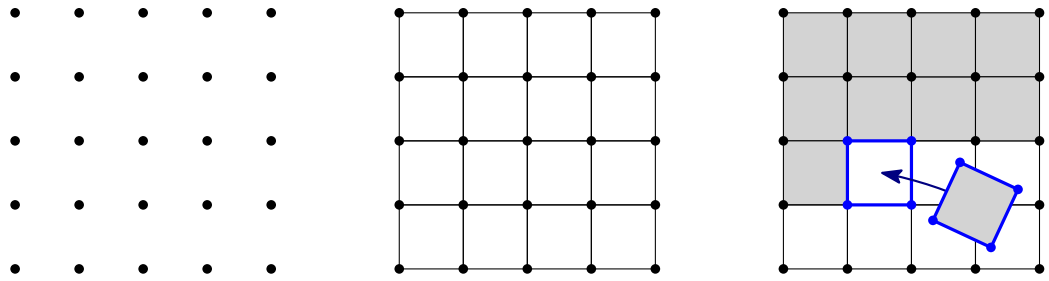


Figure 2 Constructing the complex $\mathbf{H}^{2,5}$. Its 1-skeleton $\mathbf{H}^{2,5}_1$ is isomorphic to the grid P^2_5.

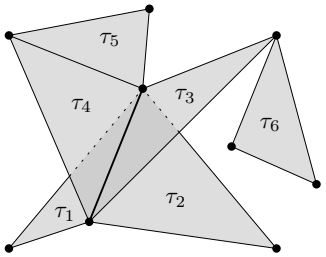
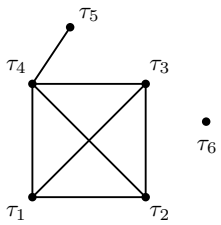
Pure complexes and their dual graphs. A (cubical or simplicial) complex $\mathcal{X}$ is *pure* if every face of $\mathcal{X}$ is contained in a face of dimension $\dim \mathcal{X}$. It follows that, for every i with $0 \leqslant i \leqslant \dim \mathcal{X}$, the i-skeleton $\mathcal{X}_i$ of a pure complex $\mathcal{X}$ is also pure. Examples of pure complexes include nonempty graphs without isolated vertices, or triangulations of manifolds (see Section 2.2.3). Given a pure complex $\mathcal{X}$, the *dual graph* $\Gamma(\mathcal{X}_i) = (V, E)$ of its i-skeleton is defined as the graph, where the vertex set V corresponds to the set $\mathcal{X}(i)$ of i-faces, and $\{\sigma, \tau\} \in E$ if and only if σ and τ share an $(i-1)$-dimensional face in $\mathcal{X}$, see Figure 3.



(a) A pure simplicial 2-complex $\mathcal{X}$ formed by six triangles τ_1, τ_2, τ_3, τ_4, τ_5, and τ_6, four of which meet along a single edge.



(b) The dual graph $\Gamma(\mathcal{X}_2)$ of $\mathcal{X}_2$. As τ_6 shares no edge with any other triangle in $\mathcal{X}$, its corresponding vertex is isolated.

Figure 3 Example of a pure simplicial 2-complex and its dual graph.

2.2.2 Barycentric subdivisions

Given a (cubical or simplicial) complex $\mathcal{X}$, its *barycentric subdivision* is a **simplicial** complex $\mathcal{X}'$ defined abstractly as follows. For the ground set $\mathcal{S}'$ of $\mathcal{X}'$ we have $\mathcal{S}' = \mathcal{X}$. A $(k+1)$-tuple $\{\sigma_0, \ldots, \sigma_k\} \subset \mathcal{S}'$ forms a k-simplex of $\mathcal{X}'$ if and only if $\sigma_i \subset \sigma_j$ for every $0 \leqslant i < j \leqslant k$. We denote the 2^{nd} (resp. ℓ^{th}) iterated barycentric subdivision of a complex $\mathcal{X}$ by $\mathcal{X}''$ (resp. $\mathcal{X}^{(\ell)}$). See [10, Appendix A] for examples. The following are simple consequences of the definitions.

▶ **Observation 10.** *For any $0 \leqslant l \leqslant k$, a k-simplex has $\binom{k}{l}$ l-faces.*

▶ **Observation 11.** *The barycentric subdivision of a k-simplex contains $(k+1)!$ k-simplices.*

▶ **Observation 12.** *The barycentric subdivision of a k-cube contains $2^k k!$ k-simplices.*

See [10, Appendix A] for a proof of Observation 12.

2.2.3 Manifolds and their triangulations

Manifolds can be regarded as higher dimensional analogs of surfaces. A *d-dimensional topological manifold with boundary* (or *d-manifold*, for short) is a topological space[15] $\mathcal{M}$, where every point has an open neighborhood homeomorphic to $\mathbb{R}^d$, or to the closed upper half-space $\{(x_1, \ldots, x_d) \in \mathbb{R}^d : x_1 \geqslant 0\}$. The points of $\mathcal{M}$ that do **not** have a neighborhood homeomorphic to $\mathbb{R}^d$ constitute the *boundary* $\partial\mathcal{M}$ of $\mathcal{M}$. If a manifold $\mathcal{M}$ satisfies $\partial\mathcal{M} = \emptyset$, then $\mathcal{M}$ is called a *closed* manifold. In this paper $\mathcal{M}$ always denotes a compact manifold.

Smooth manifolds. The main result of this paper (Theorem 1) applies for manifolds that have an additional property, namely *smoothness*. As we will not need to work with the actual definition of smoothness, but merely rely on it, we only give a brief definition here. For more background on smooth manifolds, we refer to [43, Chapter 5] and [33].

Given a connected and open subset $U \subset \mathcal{M}$ and a homeomorphism $\varphi\colon U \to \varphi(U)$ onto an open subset of $\mathbb{R}^d$, the pair (U, φ) is called a *chart*. Given two charts $(U_\alpha, \varphi_\alpha)$ and (U_β, φ_β) with $U_\alpha \cap U_\beta \neq \emptyset$, the map $\tau_{\alpha,\beta}\colon \varphi_\alpha(U_\alpha \cap U_\beta) \to \varphi_\beta(U_\alpha \cap U_\beta)$ defined via $\tau_{\alpha,\beta} = \varphi_\beta \circ \varphi_\alpha^{-1}$ is called a *transition map*. A *smooth structure* on a topological manifold $\mathcal{M}$ with $\partial\mathcal{M} = \emptyset$ is a collection $\mathcal{A} = \{(U_\alpha, \varphi_\alpha) : \alpha \in A\}$ of charts that satisfies the following three properties.

1. The sets U_α cover $\mathcal{M}$, that is $\bigcup_{\alpha\in A} U_\alpha = \mathcal{M}$.
2. For any $\alpha, \beta \in A$ with $U_\alpha \cap U_\beta \neq \emptyset$, the transition map $\tau_{\alpha,\beta}$ is smooth.[16]
3. The collection $\mathcal{A}$ is maximal in the sense that if (U, φ) is a chart and for every $\alpha \in A$ with $U \cap U_\alpha \neq \emptyset$ the transition maps $\varphi \circ \varphi_\alpha^{-1}$ and $\varphi_\alpha \circ \varphi^{-1}$ are smooth, then $(U, \varphi) \in \mathcal{A}$.

A topological manifold together with a smooth structure is called a *smooth manifold*. By an appropriate modification of property **2** above, the definition extends to manifolds with non-empty boundary as well. We refer to [43, Section 5.1.1] for details.

Triangulations. Let $\mathcal{M}$ be a compact topological d-manifold. A simplicial complex $\mathcal{T}$ whose geometric realization $\|\mathcal{T}\|$ is homeomorphic to $\mathcal{M}$ is called a *triangulation* of $\mathcal{M}$. It follows that $\mathcal{T}$ is a pure simplicial complex of dimension d (see Section 2.2.1). For $d \leqslant 3$, every topological d-manifold admits a triangulation [41, 44], however, for $d > 3$ this is generally not true (see [38] for an overview). Smooth manifolds can nevertheless always be triangulated, irrespective of their dimension, e.g., by work of Whitney [48, Chapter IV.B] (cf. Section 3).

Given a d-dimensional triangulation $\mathcal{T}$, recall that its *dual graph* $\Gamma(\mathcal{T})$ is the graph with vertices corresponding to the d-simplices of $\mathcal{T}$, and edges to the face gluings, i.e, those $(d-1)$-simplices of $\mathcal{T}$ that are contained in precisely two d-simplices. Note that $\deg(v) \leqslant d+1$ for any vertex v of $\Gamma(\mathcal{T})$. The following proposition is a consequence of the definitions.

▶ **Proposition 13.** *Let $\mathcal{T}$ be a triangulation of a d-manifold $\mathcal{M}$ and $\mathcal{U}$ be a collection of d-simplices of $\mathcal{T}$ that define a submanifold of $\mathcal{M}$. Then $\Gamma(\mathcal{U})$ is an induced subgraph of $\Gamma(\mathcal{T})$.*

3 Whitney's method

A seminal result of Whitney states that a smooth d-dimensional manifold $\mathcal{M}$ always admits a smooth embedding into a $2d$-dimensional Euclidean space.

[15] As a topological space a manifold is required to be *second countable* [43, p. 2] and *Hausdorff* [43, p. 87].
[16] See [43, p. 185] for a discussion of (smooth) maps of manifolds.

▶ **Theorem 14** (strong Whitney embedding theorem [47, Theorem 5], cf. [33, Theorem 6.19]). *For $d > 0$, every smooth d-manifold admits a smooth embedding into $\mathbb{R}^{2d}$.*

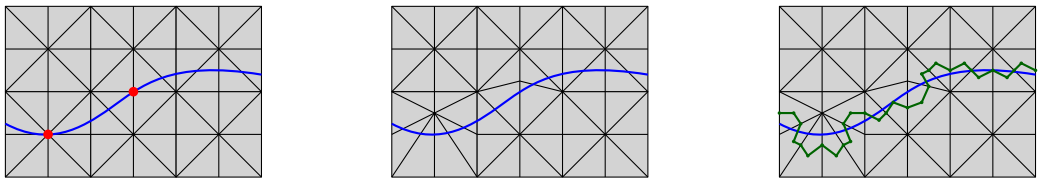
An important consequence of Theorem 14 is that smooth manifolds can be triangulated.

▶ **Theorem 15** (triangulation theorem [48, Chapter IV.B], cf. [5, Theorem 1.1]). *Every compact, smooth d-manifold $\mathcal{M}$ embedded in some Euclidean space $\mathbb{R}^m$ admits a triangulation.*

Next, we give a very brief and high-level overview of Whitney's method of triangulating smooth manifolds based on [48, Chapter IV.B] sufficient for our purposes. To the interested reader we also recommend [5], where Whitney's method is recast in a computational setting.

Triangulating smooth manifolds. Let $\mathcal{M}$ be a compact smooth d-manifold. By Theorem 14 there exists a smooth embedding $\iota\colon \mathcal{M} \to \mathbb{R}^{2d}$. Given such an embedding, we choose a sufficiently fine (with respect to ι) hypercubic honeycomb decomposition of $\mathbb{R}^{2d}$, denoted by L_0. Next, we pass to the first barycentric subdivision L of L_0. (Geometrically, L is obtained from L_0 by subdividing each k-dimensional hypercube of L_0 into $(2k)!!$ simplices.) By slightly perturbing the vertices of L we obtain a triangulation L^* of $\mathbb{R}^{2d}$, which is combinatorially isomorphic to L, but is in *general position* with respect to $\iota(\mathcal{M}) \subset \mathbb{R}^{2d}$. Now, by the work of Whitney, L^* induces a triangulation $\mathcal{T}$ of $\mathcal{M}$, where, importantly, $\mathcal{T}$ is a subcomplex of the d-skeleton of the barycentric subdivision $(L^*)'$ of L^*.

See Figure 4 for an illustration of this procedure for $d = 1$.



(a) The triangulation L and the image $\iota(\mathcal{M})$ (blue). The red points indicate the vertices of L contained by $\iota(\mathcal{M})$.

(b) The perturbed triangulation L^*, which in general position with respect to $\iota(\mathcal{M})$.

(c) The resulting triangulation $\mathcal{T}$ of $\mathcal{M}$ (dark green). $\mathcal{T}$ is a subcomplex of $(L^*)'$.

Figure 4 Illustration of Whitney's method of triangulating ambient submanifolds ($d = 1$).

Similar to Proposition 13, the next proposition is a direct consequence of the definitions.

▶ **Proposition 16.** *For any Whitney triangulation $\mathcal{T}$ of a compact smooth d-manifold $\mathcal{M}$, we have that the dual graph $\Gamma(\mathcal{T})$ is an induced subgraph of $\Gamma(((\mathbf{H}^{2d,n})'')_d)$.*

4 The proof of Theorem 1

In this section we prove our main result, i.e., every compact smooth d-manifold $\mathcal{M}$ has twin-width $\operatorname{tww}(\mathcal{M}) \leqslant d^{O(d)}$. To streamline the notation, we let $G_{d,n} = \Gamma(((\mathbf{H}^{2d,n})'')_d)$, i.e., $G_{d,n}$ denotes the dual graph of the d-skeleton[17] of the second barycentric subdivision of the hybercubic honeycomb $\mathbf{H}^{2d,n}$. The result is based on the following property of $G_{d,n}$.

[17] Recall that the dual graph $\Gamma(\mathcal{X})$ of a pure k-dimensional complex $\mathcal{X}$ has vertices corresponding to the k-faces of $\mathcal{X}$ and two vertices are connected if and only if their corresponding k-faces share a $(k-1)$-face.

▶ **Theorem 17.** *For the twin-width of the dual graph $G_{d,n} = \Gamma(((\mathbf{H}^{2d,n})'')_d)$ of the d-skeleton of the second barycentric subdivision of the hypercubic honeycomb $\mathbf{H}^{2d,n}$ we have*

$$\operatorname{tww}(G_{d,n}) \leqslant d^{O(d)}.$$

Before proving Theorem 17, we show how it implies Theorem 1.

Proof of Theorem 1. Let $\mathcal{M}$ be a compact, smooth d-dimensional manifold. Consider a Whitney triangulation $\mathcal{T}$ of $\mathcal{M}$. By Proposition 16, $\Gamma(\mathcal{T})$ is an induced subgraph of $G_{d,n}$ and by Theorem 17, $\operatorname{tww}(G_{d,n}) \leqslant d^{O(d)}$. Hence, since twin-width is monotone under taking induced subtrigraphs (Proposition 5), we obtain $\operatorname{tww}(\Gamma(\mathcal{T}))) \leqslant \operatorname{tww}(G_{d,n}) \leqslant d^{O(d)}$. ◀

To complete the proof of Theorem 1, it remains to show Theorem 17.

Proof of Theorem 17. We establish the theorem by exhibiting a $d^{O(d)}$-contraction sequence $\mathfrak{S}\colon G_{d,n} \rightsquigarrow \bullet$. We will obtain $\mathfrak{S}$ by concatenating two contraction sequences $\mathfrak{S}_1\colon G_{d,n} \rightsquigarrow G^*_{d,n}$ and $\mathfrak{S}_2\colon G^*_{d,n} \rightsquigarrow \bullet$, referred to as the *first* and the *second epoch*, where $G^*_{d,n}$ is an appropriate subtrigraph of $\operatorname{red}(D_{n,2d})$, the $2d$-dimensional red n-grid with diagonals. In the following we regard $\mathbf{H}^{2d,n}$ and its subdivisions mainly as abstract complexes, but we will also take advantage of their geometric nature.

Preparations. Consider the $(2d+1)$-coloring $\mathcal{C}\colon \mathbf{H}^{2d,n} \to \{0,\dots,2d\}$, where we color the cubes of $\mathbf{H}^{2d,n}$ by their dimension, that is, for $c \in \mathbf{H}^{2d,n}$ we set $\mathcal{C}(c) = \dim(c)$ (Figure 5a).

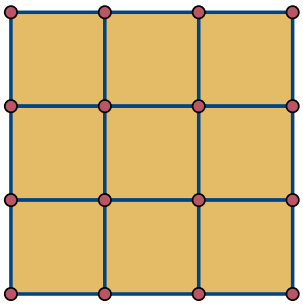
The coloring $\mathcal{C}$ induces a $(2d+1)$-coloring $\mathcal{C}''\colon (\mathbf{H}^{2d,n})'' \to \{0,\dots,2d\}$ of the simplices of the second barycentric subdivision $(\mathbf{H}^{2d,n})''$ as follows. The vertices of the first barycentric subdivision $(\mathbf{H}^{2d,n})'$ are in one-to-one correspondence with the cubes in $\mathbf{H}^{2d,n}$, hence $\mathcal{C}$ induces a coloring $\mathcal{C}'_0\colon (\mathbf{H}^{2d,n})'(0) \to \{0,\dots,2d\}$ via $\mathcal{C}'_0(v_c) = \mathcal{C}(c)$, where v_c denotes the vertex of $(\mathbf{H}^{2d,n})'$ corresponding to the cube $c \in \mathbf{H}^{2d,n}$ (Figure 5b). Geometrically, v_c is in the barycenter of the cube c. When we pass to the second barycentric subdivision, the vertices of $(\mathbf{H}^{2d,n})'$ become vertices of $(\mathbf{H}^{2d,n})''$, thus there is a natural inclusion $\iota\colon (\mathbf{H}^{2d,n})'(0) \to (\mathbf{H}^{2d,n})''(0)$. Let $\mathcal{V} = \operatorname{im}(\iota) \subset (\mathbf{H}^{2d,n})''(0)$ be the image of $(\mathbf{H}^{2d,n})'(0)$ under this inclusion ι. We color the elements of $\mathcal{V}$ identically to $\mathcal{C}'_0$, that is, we consider the coloring $\mathcal{C}''_{\mathcal{V}}\colon \mathcal{V} \to \{0,\dots,2d\}$ defined as $\mathcal{C}''_{\mathcal{V}}(v) = \mathcal{C}'_0(\iota^{-1}(v))$, see Figure 5c. Now, pick a simplex $\sigma \in (\mathbf{H}^{2d,n})''$ and note that $\bigcup_{v\in\mathcal{V}} \overline{\operatorname{st}}(v) = (\mathbf{H}^{2d,n})''$, i.e., the closed stars of the vertices $v \in \mathcal{V}$ cover $(\mathbf{H}^{2d,n})''$. Let $\mathcal{V}_\sigma = \{v \in \mathcal{V} : \sigma \in \overline{\operatorname{st}}(v)\}$. We now define $\mathcal{C}''(\sigma)$ as

$$\mathcal{C}''(\sigma) = \min\{\mathcal{C}''_{\mathcal{V}}(v) : v \in \mathcal{V}_\sigma\}. \tag{4}$$

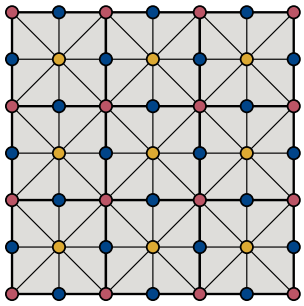
In words, $\mathcal{C}''(\sigma)$ is defined as the smallest dimension of any cube $c \in \mathbf{H}^{2d,n}$ such that σ belongs to the closed star of the vertex $\iota(v_c)$ in $(\mathbf{H}^{2d,n})''$, where v_c is the vertex of $(\mathbf{H}^{2d,n})'$ corresponding to c. We refer to Figure 5d for an example.

The first epoch. We start the description of the *first epoch* $\mathfrak{S}_1\colon G_{d,n} \rightsquigarrow G^*_{d,n}$ by considering the restriction $\mathcal{C}''_d\colon (\mathbf{H}^{2d,n})''(d) \to \{0,\dots,2d\}$ of the coloring $\mathcal{C}''$ to the d-simplices of $(\mathbf{H}^{2d,n})''$, see Figure 5e. Note that for each $i \in \{0,\dots,2d\}$, the i-colored d-simplices of $(\mathbf{H}^{2d,n})''$ form a family $\mathcal{F}_i = \{F_{i,c} : c \in \mathbf{H}^{2d,n}(i)\}$ of pairwise-disjoint connected subcomplexes of the d-skeleton of $(\mathbf{H}^{2d,n})''$, where $F_{i,c}$ denotes the subcomplex induced by the i-colored d-simplices of $(\mathbf{H}^{2d,n})''$ belonging to the closed star of the vertex $\iota(v_c)$, where v_c is the vertex of $(\mathbf{H}^{2d,n})'$ corresponding to the i-cube c in $\mathbf{H}^{2d,n}$ (Figure 5e). We also let $\mathcal{F} = \bigcup_{i=0}^{2d} \mathcal{F}_i$.

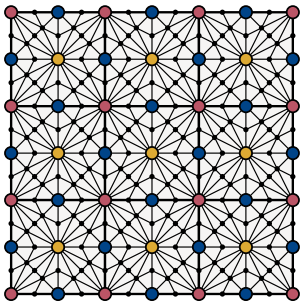
Since $G_{d,n}$ is defined as the dual graph of the d-skeleton of $(\mathbf{H}^{2d,n})''$, the nodes of $G_{d,n}$ are in one-to-one correspondence with the d-simplices of $(\mathbf{H}^{2d,n})''$. Let $\gamma\colon (\mathbf{H}^{2d,n})''(d) \to V(G_{d,n})$ denote the bijection realizing this correspondence. Henceforth, by a slight abuse of notation,



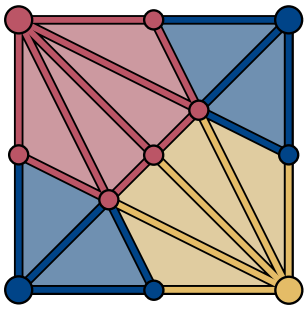
(a) The coloring $\mathcal{C}$ of the cubes of $\mathbf{H}^{2d,n}$ by their dimension.



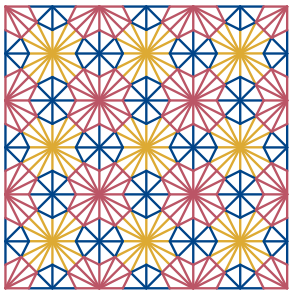
(b) The complex $(\mathbf{H}^{2d,n})'$ with its vertices colored by $\mathcal{C}'_0$.



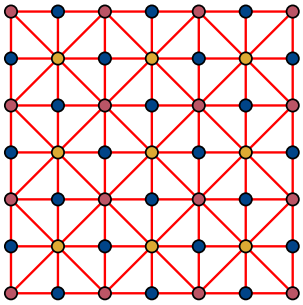
(c) The complex $(\mathbf{H}^{2d,n})''$ with its vertices in $\mathcal{V}$ colored by $\mathcal{C}''_{\mathcal{V}}$.



(d) The coloring $\mathcal{C}''$ near the upper left corner of $(\mathbf{H}^{2d,n})''$. The four larger disks represent vertices that belong to $\mathcal{V}$.



(e) The coloring $\mathcal{C}''$ restricted to the d-simplices of $(\mathbf{H}^{2d,n})''$. The color classes correspond to the families $\mathcal{F}_0$, $\mathcal{F}_1$ and $\mathcal{F}_2$.



(f) The trigraph $G^*_{d,n}$ obtained from $G_{d,n}$ by contracting each subtrigraph $C_{i,c}$ to a single node. All edges in $G^*_{d,n}$ are red.

Figure 5 (a)–(c) Illustrations of the cubical complex $\mathbf{H}^{2d,n}$ for $d = 1$ and $n = 4$, and of its first and second barycentric subdivisions (which are simplicial complexes) displaying the colorings described in the proof of Theorem 17. **(d)–(f)** Three essential steps in the proof of Theorem 17.

we also consider $\mathcal{C}''_d$ to be a $(2d+1)$-coloring of $V(G_{d,n})$ via $\mathcal{C}''_d(v) = \mathcal{C}''_d(\gamma^{-1}(v))$. Let $C_{i,c}$ denote the subtrigraph of $G_{d,n}$ induced by the nodes $\{\gamma(\sigma) : \sigma \in F_{i,c}\}$. Note that $\mathcal{C}''_d$ assigns the color i to all nodes of $C_{i,c}$. The first epoch $\mathfrak{S}_1 \colon G_{d,n} \rightsquigarrow G^*_{d,n}$ is merely the contraction sequence, where we contract each $C_{i,c}$ (where $0 \leqslant i \leqslant 2d$ and c is running over $\mathbf{H}^{2d,n}$) to a single node, in any order, obtaining a trigraph $G^*_{d,n}$ (Figure 5f).

The second epoch. $\mathfrak{S}_2 \colon G^*_{d,n} \rightsquigarrow \bullet$ is defined as an optimal contraction sequence of the trigraph $G^*_{d,n}$ to a single vertex. Since $G^*_{d,n}$ is a subtrigraph of $\mathrm{red}(D_{n,2d})$, the *$2d$-dimensional red n-grid with diagonals*, by Theorem 9 the width of $\mathfrak{S}_2$ is at most $2(3^{2d} - 1)$.

Bounding the width of the first epoch. We now give a rough estimate to show that the first epoch $\mathfrak{S}_1 \colon G_{d,n} \rightsquigarrow G^*_{d,n}$ is a $d^{O(d)}$-contraction sequence. The estimate is based on Claim 18 below, which follows from elementary properties of the hypercubic honeycomb and barycentric subdivisions.

▷ Claim 18. For any color $i \in \{0, \dots, 2d\}$ and cube $c \in \mathbf{H}^{2d,n}$, the subcomplex $F_{i,c}$ of $\mathbf{H}^{2d,n}$ (resp. the subtrigraph $C_{i,c}$ of $G_{d,n}$) defined above

1. has less than $h_1(d) = 4^d((2d)!)^2\binom{2d}{d}$ d-simplices (resp. nodes), and
2. less than $h_2(d) = 9^d$ incident subcomplexes $F_{i',c'} \in \mathcal{F}$ (resp. adjacent subtrigraphs $C_{i',c'}$).

Indeed, these two facts imply that by sequentially contracting each $C_{i,c}$ into a single node, the maximum red degree remains bounded by $O(h_1(d)^3 h_2(d))$ throughout the first epoch.

Proof of Claim 18. To bound the number of d-simplices in $F_{i,c}$, note that
- $F_{i,c}$ is covered by an appropriate translate of a $2d$-dimensional cube of $\mathbf{H}^{2d}$,
- the barycentric subdivision of a $2d$-cube contains $2^{2d}(2d)!$ $2d$-simplices (Observation 12),
- the barycentric subdivision of a $2d$-simplex contains $(2d)!$ $2d$-simplices (Observation 11),
- a $2d$-simplex has $\binom{2d}{d}$ faces of dimension d (Observation 10).

Multiplying these numbers, we obtain the first part of the claim.

To bound the number of subcomplexes $F_{i',c'} \in \mathcal{F}$ incident to $F_{i,c}$, note that the incidences between these subcomplexes reflect those between the handles in the canonical handle decomposition of $\mathbf{H}^{2d,n}$ obtained by "thickening up" its cubical cells. Thus, the number of subcomplexes in $\mathcal{F}$ incident to $F_{i,c}$ equals $3^{2d} - 1$ if $i \in \{0, 2d\}$ and $3^i + 3^{2d-i} - 2$ otherwise. Both of these numbers are less than 9^d, so the second part of the claim also holds. ◁

The width of $\mathfrak{S}$ is the maximum of the widths of $\mathfrak{S}_1$ and $\mathfrak{S}_2$, hence $\operatorname{tww}(G_{d,n}) \leqslant d^{O(d)}$. ◀

5 Triangulations with dual graph of arbitrary large twin-width

In Section 4 we showed that every compact, smooth d-manifold admits a triangulation with dual graph of twin-width at most $d^{O(d)}$. In this section we prove complementary results, showing that triangulations with dual graphs of large twin-width are abundant. We shed light on this fact in two ways. First, we show that for any fixed dimension $d \geqslant 3$, the class of $(d+1)$-regular graphs that can be dual graphs of triangulated d-manifolds is *not* small. Second, we show that the d-dimensional ball admits triangulations with a dual graph of arbitrarily large twin-width, which extends to every piecewise-linear (hence smooth) d-manifold. Both of these results rely on counting arguments, and thus are not constructive.

5.1 The class of dual graphs of triangulations is not small

Let us fix an integer $d \geqslant 3$. Following [21], we let $M_d(n)$ denote the number of colored[18] triangulations of closed orientable d-dimensional manifolds consisting of n d-simplices labeled from 1 to n. We assume n to be even. By [21, Theorem 1.1] we have[19]

$$n! \cdot n^{n/(2d)} \preceq M_d(n). \tag{5}$$

Ignoring the colors gives an uncolored triangulation, but any such d-dimensional triangulation can be obtained from $(d+1)!$ colored triangulations, since the $d+1$ colors can always be permuted. Now, any $(d+1)$-regular graph G with n vertices can be the dual graph of at most $d!^{n(d+1)/2}$ different d-dimensional triangulations. Indeed, if G is the dual graph of some d-dimensional triangulation, then each of the $n(d+1)/2$ edges of G corresponds to a face gluing, i.e., an identification of two $(d-1)$-dimensional simplices via a simplicial isomorphism, of which there are $d!$ many.[20] Hence by (5), for the number $\Gamma_d(n)$ of $(d+1)$-regular graphs on n labeled vertices that are dual graphs of some d-dimensional triangulations, we have

$$\frac{n! \cdot n^{n/(2d)}}{(d+1)! \cdot d!^{n(d+1)/2}} \preceq \Gamma_d(n). \tag{6}$$

As the left-hand side of (6) grows super-exponentially in n, the next theorem directly follows.

[18] We refer to [21, Section 2.1] for the precise definitions.

[19] Here "$\preceq$" denotes a comparison where exponential factors are ignored: more precisely, $f(n) \preceq g(n)$ means that there exists some constant $K > 0$, such that for n large enough, we have $f(n) \leqslant K^n g(n)$.

[20] This is because a simplicial isomorphism between two $(d-1)$-simplices σ and τ is determined by a perfect matching between the d vertices of σ and the d vertices of τ.

▶ **Theorem 19.** *For every $d \geqslant 3$, the class of $(d+1)$-regular graphs that are dual graphs of triangulations of d-manifolds is not small. In particular, there are graphs with arbitrarily large twin-width in this class.*

5.2 Complicated triangulations of the d-dimensional ball

In this section we show Theorem 3, according to which every piecewise-linear (PL) d-manifold ($d \geqslant 3$) admits triangulations with a dual graph of arbitrary large twin-width. To show the existence of such triangulations for every PL-manifold, we rely on the monotonicity of twin-width with respect to taking induced subtrigraphs (Proposition 5), the fact that the class of d-subdivisions of $(d+1)$-regular graphs is *not* small (Proposition 7) together with the following classical result from the theory of PL-manifolds. See [45] for an introduction.

▶ **Theorem 20** ([1, Corollary 1])**.** *Any triangulation of the boundary of a compact piecewise-linear (PL) manifold can be extended to a triangulation of the whole manifold.*

We first show that already the d-dimensional ball $\mathcal{B}^d = \{x \in \mathbb{R}^d : \|x\| \leqslant 1\}$ admits triangulations with dual graph of arbitrary large twin-width. More precisely, we prove:

▶ **Theorem 21.** *For every $m \in \mathbb{N}$ there is a triangulation $\mathcal{T}_m$ of the d-dimensional ball $\mathcal{B}^d$, such that $\operatorname{tww}(\Gamma(\mathcal{T}_m)) \geqslant m$ and $\partial\mathcal{T}_m = \partial\Delta^d$, the boundary of the standard d-simplex Δ^d.*

Proof. Let G_m be a d-subdivision of a $(d+1)$-regular graph G such that $\operatorname{tww}(G_m) \geqslant m$. The existence of such a graph is guaranteed by Proposition 7. Let $\mathcal{N}$ be a d-manifold homeomorphic to a closed regular neighborhood of a straight-line embedding of G in $\mathbb{R}^d$. Informally, $\mathcal{N}$ can be seen as a d-dimensional thickening of the graph G.

Construct an abstract triangulation of $\mathcal{N}$ as follows. Take a d-simplex σ_v for each node v of G, and fix a one-to-one correspondence between the $d+1$ facets of σ_v and the $d+1$ arcs incident to v in G. For every arc $\{u,v\} \in E(G)$, take a simplicial d-prism $P_{\{u,v\}} = \sigma_{\{u,v\}} \times [0,1]$, where $\sigma_{\{u,v\}}$ is a $(d-1)$-simplex, and attach $P_{\{u,v\}}$ to the simplices σ_u and σ_v by identifying $\sigma_{\{u,v\}} \times \{0\}$ (resp. $\sigma_{\{u,v\}} \times \{1\}$) with the facet of σ_u (resp. σ_v) that corresponds to the arc $\{u,v\}$. Now triangulate each prism $P_{\{u,v\}}$ with a minimal triangulation consisting of d d-simplices stacked onto each other, see [10, Appendix B].

Let $\mathcal{T}_{\mathcal{N}}$ denote the resulting triangulation of $\mathcal{N}$.

▷ Claim 22. For the dual graph of the triangulation $\mathcal{T}_{\mathcal{N}}$ we have $\Gamma(\mathcal{T}_{\mathcal{N}}) = G_m$.

Proof. The claim follows immediately from the facts that the dual graph of the constructed triangulation of the simplicial d-prism is merely a path of length d, and G_m is the d-subdivision of the $(d+1)$-regular graph G on which the triangulation $\mathcal{T}_{\mathcal{N}}$ is modeled. ◁

Pick a sufficiently large $\ell \in \mathbb{N}$ such that the ℓ^{th} iterated barycentric subdivision $\mathcal{T}_{\mathcal{N}}^{(\ell)}$ of $\mathcal{T}_{\mathcal{N}}$ embeds linearly in $\mathbb{R}^d$ and fix a simplex-wise linear embedding $\mathcal{E}\colon \|\mathcal{T}_{\mathcal{N}}^{(\ell)}\| \to \mathbb{R}^d$. Consider a large geometric d-simplex $\Sigma \subset \mathbb{R}^d$ that contains the image $\operatorname{im}(\mathcal{E})$ of $\mathcal{E}$ in its interior. Now $\Sigma_\circ = \Sigma \setminus \operatorname{int}(\operatorname{im}(\mathcal{E}))$ is a PL manifold[21] with triangulated boundary, so by Theorem 20 this boundary triangulation can be extended to a triangulation $\mathcal{T}_{\Sigma_\circ}$ of the entire manifold $\Sigma_\circ$. The boundary of $\mathcal{T}_{\Sigma_\circ}$ has two connected components: $\partial_1\mathcal{T}_{\Sigma_\circ} \cong \partial(\mathcal{T}_{\mathcal{N}}^{(\ell)})$ and $\partial_2\mathcal{T}_{\Sigma_\circ} \cong \partial\Delta^d$.

Let $\mathcal{Q}$ be a d-manifold homeomorphic to $\partial\mathcal{T}_{\mathcal{N}} \times [0,1]$. Take a triangulation $\mathcal{T}_{\mathcal{Q}}$ of $\mathcal{Q}$, such that for the two boundary components we have $\partial_1\mathcal{T}_{\mathcal{Q}} \cong \partial\mathcal{T}_{\mathcal{N}}$ and $\partial_2\mathcal{T}_{\mathcal{Q}} \cong \partial(\mathcal{T}_{\mathcal{N}}^{(\ell)})$. One way to construct such a triangulation is as follows. First, consider the decomposition $\mathcal{P}_{\mathcal{Q}}$ of $\mathcal{Q}$

[21] It is folklore that every codimension zero submanifold of a Euclidean space is a PL manifold, see, e.g., [34, p. 118] or [46, Remark 1.1.10].

into simplicial d-prisms induced by the product structure $\partial\mathcal{T}_\mathcal{N} \times [0,1]$. That is, $\mathcal{P}_\mathcal{Q}$ consists of d-prisms $P_\sigma \cong \sigma \times [0,1]$, one for each $(d-1)$-simplex σ of $\partial\mathcal{T}_\mathcal{N}$, glued together along their vertical boundary prisms the same way as the simplices of $\partial\mathcal{T}_\mathcal{N}$. The boundary $\partial\mathcal{P}_\mathcal{Q}$ of $\mathcal{P}_\mathcal{Q}$ has two connected components: $\partial_1\mathcal{P}_\mathcal{Q}$ and $\partial_2\mathcal{P}_\mathcal{Q}$, each combinatorially isomorphic to $\partial\mathcal{T}_\mathcal{N}$. Next, pass to the ℓ^{th} iterated barycentric subdivision of $\partial_2\mathcal{P}_\mathcal{Q}$. This operation turns each prism P_σ of $\mathcal{P}_\mathcal{Q}$ into a polyhedral cell R_σ. These cells form a polyhedral decomposition $\mathcal{R}_\mathcal{Q}$ of $\mathcal{Q}$, where $\partial_1\mathcal{R}_\mathcal{Q} \cong \partial\mathcal{T}_\mathcal{N}$ and $\partial_2\mathcal{R}_\mathcal{Q} \cong (\partial\mathcal{T}_\mathcal{N})^{(\ell)} = \partial(\mathcal{T}_\mathcal{N}^{(\ell)})$. Triangulate R_σ as follows. Consider an order $c_1 \prec c_2 \prec \cdots$ of the vertical cells[22] of R_σ, where $c_i \prec c_j$ implies $\dim(c_i) \leqslant \dim(c_j)$. Place a new vertex v_i in the barycenter of c_i and, iterating over the vertical cells in the above order, triangulate c_i by coning from v_i over its (already triangulated) boundary ∂c_i. It is clear that the resulting triangulation of R_σ is symmetric with respect to the symmetries of its base simplex σ. Applying this procedure for each polyhedral cell R_σ of $\mathcal{R}_\mathcal{Q}$ yields a triangulation $\mathcal{T}_\mathcal{Q}$ of $\mathcal{Q}$ with the desired properties.

Now the triangulation $\mathcal{T}_m$ of $\mathcal{B}^d$ is obtained by gluing together $\mathcal{T}_\mathcal{N}$, $\mathcal{T}_\mathcal{Q}$ and $\mathcal{T}_{\Sigma_\circ}$ via the identity maps along the isomorphic boundary-pairs $\partial\mathcal{T}_\mathcal{N} \cong \partial_1\mathcal{T}_\mathcal{Q}$ and $\partial_2\mathcal{T}_\mathcal{Q} \cong \partial_1\mathcal{T}_{\Sigma_\circ}$.

To conclude, note that the d-simplicies of $\mathcal{T}_\mathcal{N}$ triangulate a submanifold of $\|\mathcal{T}_m\|$, hence by Proposition 13 the graph $\Gamma(\mathcal{T}_\mathcal{N})$ is an induced subgraph of $\Gamma(\mathcal{T}_m)$. By Claim 22, $\Gamma(\mathcal{T}_\mathcal{N}) = G_m$ and by the initial assumption $\operatorname{tww}(G_m) \geqslant m$, hence by Proposition 5, $\Gamma(\mathcal{T}_m) \geqslant m$ as well. ◀

Proof of Theorem 3. Let $\mathcal{M}$ be an arbitrary PL-manifold possibly with non-empty boundary and $\mathcal{T}_\circ$ be a simplicial triangulation of $\mathcal{M}$. Consider a triangulation $\mathcal{T}_m$ of the d-ball with $\operatorname{tww}(\Gamma(\mathcal{T}_m)) \geqslant m$ as in Theorem 21. Let Δ be a d-simplex of $\mathcal{T}_\circ$ that is disjoint from $\partial\mathcal{M}$ (if $\mathcal{T}_\circ$ does not contain such a simplex, just replace $\mathcal{T}_\circ$ with its second barycentric subdivision). Since $\mathcal{T}_\circ$ is simplicial, Δ is embedded in $\mathcal{T}_\circ$ and is topologically a d-ball. Now replace Δ with $\mathcal{T}_m$ by first removing Δ from $\mathcal{T}_\circ$, thereby creating a boundary component isomorphic to $\partial\Delta$, then gluing $\partial\mathcal{T}_m$ to this new boundary component via a simplicial isomorphism. (Note that this is possible since $\partial\mathcal{T}_m \cong \partial\Delta$.) Let $\mathcal{T}$ denote the resulting triangulation of $\mathcal{M}$. By Propositions 5 and 13, it follows that $\operatorname{tww}(\Gamma(\mathcal{T})) \geqslant \operatorname{tww}(\Gamma(\mathcal{T}_m)) \geqslant m$. ◀

Abstract

We present a 1.8334-approximation algorithm for Vertex Cover on string graphs given with a representation, which takes polynomial time in the size of the representation; the exact approximation factor is $\frac{11}{6}$. Recently, the barrier of 2 was broken by Lokshtanov, Panolan, Saurabh, Xue, and Zehavi [SoGC '24] with a 1.9999-approximation algorithm. Thus we increase by three orders of magnitude the distance of the approximation ratio to the trivial bound of 2. Our algorithm is very simple. The intricacies reside in its analysis, where we mainly establish that string graphs without odd cycles of length at most 11 are 8-colorable. Previously, Chudnovsky, Scott, and Seymour [JCTB '21] showed that string graphs without odd cycles of length at most 7 are 80-colorable, and string graphs without odd cycles of length at most 5 have bounded chromatic number.

1 Introduction

The Vertex Cover problem[1] is one of Karp's 21 NP-complete problems [12]. While it admits several easy polynomial-time 2-approximation algorithms, it is an open question if an approximation factor of $2-\varepsilon$ can be achieved for some $\varepsilon > 0$. If the unique games conjecture (UGC) holds, then the answer to the latter question is negative [15]. Under the sole $\mathsf{P} \neq \mathsf{NP}$ assumption, it is currently only known that Vertex Cover cannot be approximated within ratio less than $\sqrt{2}$ [13, 9, 14].

On several graphs classes, better approximation algorithms of Vertex Cover exist. For instance, this problem can be exactly solved in polynomial time on bipartite graphs, as it reduces to a maximum flow problem [16]. It also admits a polynomial-time approximation scheme (PTAS) on planar graphs by Baker's technique [2]. On the contrary, a $(2-\varepsilon)$-approximation algorithm for Vertex Cover with $\varepsilon \in (0, 1/2]$ on triangle-free graphs would

[1] As an optimization problem, given a graph G, find a smallest possible vertex subset S such that $G - S$ (i.e., the subgraph of G induced by all the vertices *not* in S) is edgeless.

imply the same holding for general graphs. Indeed, one can observe that any vertex cover intersects each triangle on at least two vertices. One can thus repeatedly include all three vertices of a triangle in the approximate solution. Once the input graph has no triangle left, one calls the $(2-\varepsilon)$-approximation algorithm. This strategy can be seen to achieve approximation factor $\max(3/2, 2-\varepsilon)$ on general graphs. In particular, the former algorithm on triangle-free graphs would refute the UGC. Thus we say that $(2-\varepsilon)$-approximating Vertex Cover on triangle-free graphs is UGC-hard. It would be interesting to establish a dichotomy splitting the hereditary (i.e., closed under vertex removals) graph classes on which we know a $(2-\varepsilon)$-approximation algorithm from those on which this task is UGC-hard.

The class of *string graphs* consists of every intersection graph of connected sets in a planar graph. Alternatively string graphs are the intersection graphs of curves in the planes, called *strings*. The set of strings is called a *geometric representation* or *string representation*. The geometric representation may be convenient for drawing and in the proofs, but it is not so easy to handle as input. For that, we will also adopt a more combinatorial approach, based on the first definition of string graphs. A *representation* of a string graph G is a planar graph P and as many connected vertex subsets of P as G has vertices; two vertices are joined by an edge if and only if their corresponding subsets intersect. A caveat is that finding a (geometric) representation is NP-hard [19]. Furthermore, some string graphs G require representations whose size (i.e., the number of vertices of P or the number of crossings in a geometric representation) is exponential in $|V(G)|$ [20].

Recently Lokshtanov, Panolan, Saurabh, Xue, and Zehavi [23] presented a $(2-\varepsilon)$-approximation algorithm for Vertex Cover on string graphs, for some small positive $\varepsilon \approx 10^{-4}$. In this paper, we give a simpler algorithm with improved approximation factor $11/6 = 1.8333\ldots$

▶ **Theorem 1.** *Vertex Cover admits an $\frac{11}{6}$-approximation algorithm in string graphs given with a representation, whose running time is polynomial in the size of a representation.*

Our algorithm works as follows. We first get rid of all the odd cycles of length at most 11. This is done as in the abovementioned reduction to triangle-free graphs. While there is an odd cycle C with $|V(C)| \leqslant 11$, any vertex cover contains at least 6 vertices of C. We thus include all vertices of C in our approximate solution, and remove them from the graph. This ensures an 11/6 approximation factor, if such a factor can be achieved in the resulting graph. We can thus assume that our input graph has *odd girth*[2] more than 11. As the standard linear-programming (LP) formulation of Vertex Cover is half-integral [26], we can further assume that the vertex cover contains at least half of the vertices (see Theorem 14). Note that these opening steps are also present in [23].

We now deviate from the previous algorithm, and simply bound the chromatic number of string graphs of odd girth larger than 11.

▶ **Theorem 2.** *Every string graph of odd girth larger than 11 is 8-colorable, and given a representation, an 8-coloring can be found in time polynomial in the representation.*

A largest color class in a proper 8-coloring has size at least $n/8$ in an n-vertex graph. Thus, its complement is a vertex cover of size at most $7n/8$. As the optimum solution has size at least $n/2$, this yields a $7/4 = 1.75$ factor, and we conclude. Therefore, the main technical content of the paper is the proof of Theorem 2.

[2] The (odd) girth of a graph G is the length of a shortest (odd) cycle of G.

Outline of the proof of Theorem 2. Our strategy goes as follows. We make a breadth-first search (BFS) from some arbitrary vertex u_0 in each connected component of the graph G. We reserve colors $1, 2, 3, 4$ for the even-indexed BFS layer, and $5, 6, 7, 8$ for the odd-indexed BFS layer. We thus need to 4-color each connected component X of each subgraph induced by a single layer. Let R be a string representation of the entire graph, and $R[X]$ its restriction to X. As any face in the arrangement $R[X]$ can be made the infinite face, we can assume that the string of u_0 lies on the infinite face of $R[X]$. Now $R[X]$ has a nice property: The minimal topological disk D that contains it is such that each string of $R[X]$ intersects at least one string (in $R \setminus R[X]$) that itself crosses ∂D, the boundary of D. Indeed, such a string is given by a neighbor in the previous layer.

We now consider the string representation R_H made by X and at least one neighbor of the previous layer for each vertex of X, and intersect it by D. Each string of X remains in one piece, whereas the strings of the previous layer are possibly split into several strings in D. Let H be the intersection graph of R_H. We further layer X with the distance in H to a fixed vertex $w \in V(H) \setminus V(X)$. Let X_k be the vertices of H at distance exactly k from w in H.

We are left with proving that $H[X_k]$ is bipartite. For the sake of contradiction, we assume that there is an odd cycle C in $H[X_k]$. Our goal is to show that this odd cycle is contained in a ball of small radius around some vertex, yielding a contradiction in the form of a short odd cycle. For that, we establish that there is another odd cycle C' (built from C) such that the string of w is contained in a face F made by few strings of $N_H[C']$, with most of the rest of C' not intersecting F. A string defining F is then at a small distance of *every* string of C' since a (shortest) path from w to a vertex of the rest of C' has to cross the boundary of F. After which, the path has only a constant number of steps to reach its target since vertices of $N_H[C']$ are at distance $k-1$, k, or $k+1$ from w. The short odd cycle in H implies the existence of a short odd cycle in G, a contradiction.

Chromatic number of intersection graphs without short (odd) cycles. The chromatic number of intersection graphs of a given girth has a long history. Erdős and Gyárfás asked if girth-4 (i.e., triangle-free) segment intersection graphs have bounded chromatic number [10]. Kostochka and Nešetřil [17] raised the same question for 1-string graphs.[3] Both questions were answered in the negative in [27]. It was further shown by Walczak [28] that there are triangle-free segment intersection graphs without independent sets of size linear in the number of vertices. Nevertheless, Kostochka and Nešetřil [18] proved that 1-string graphs of girth at least 8 are 3-colorable, and asked [18, Problem 3] whether 8 could be replaced by 5. This has been confirmed for *outer* 1-strings by Das, Mukherjee, and Sahoo [7].

More relevant to our Vertex Cover application, the chromatic number of (1-)string graphs of a given odd girth has also been considered. (Note indeed that, in the design of a $(2-\varepsilon)$-approximation algorithm for Vertex Cover, whereas one can remove odd cycles up to any fixed size, the same trick does not apply to 4-vertex cycles.) McGuinness established that 1-string graphs of odd girth at least 7 have bounded chromatic number [24, 25]. Chudnovsky, Scott, and Seymour [6, Corollary from 12.4 and 12.5] further showed that string graphs of odd girth at least 9 are 80-colorable, and string graphs of odd girth at least 7 have bounded chromatic number. With proper adjustments, the former result can be turned into an algorithm that inputs a representation of any string graph G of odd girth at least 9, and outputs an 80-coloring of G in time polynomial in the representation. However, this would yield a significantly worse approximation factor for Vertex Cover.

[3] The 1-strings are strings every pair of which intersects at most once; note that it is not a property of particular objects but rather their arrangement.

The reason intersection graphs of 1-strings with girth at least 8 are 3-chromatic [18] is that they are 2-degenerate, i.e., (all their induced subgraphs) have a vertex of degree at most 2, which gives a recursive 3-coloring strategy. While string graphs of large odd girth are not d-degenerate for any d (they contain arbitrarily large bipartite complete graphs), we conjecture that they are nevertheless 3-colorable.

▶ **Conjecture 3.** *There is an integer k such that the class of string graphs of odd girth at least k is 3-chromatic.*

A stronger form of Conjecture 3 is that it holds for $k = 7$.

Limits of the method. The following observation summarizes the trade-off between required odd girth and bound on the chromatic number, in how they impact the approximation ratio.

▶ **Observation 4.** *Let $\mathcal{C}$ be a class such that there is a polynomial-time algorithm to c-color the graphs of $\mathcal{C}$ of odd girth at least an odd positive integer g. Then* Vertex Cover *admits a polynomial-time $2\max(\frac{g-2}{g-1}, \frac{c-1}{c})$-approximation algorithm in $\mathcal{C}$.*

We apply Observation 4 on represented string graphs with $g = 13$ and $c = 8$. Showing a counterpart of Theorem 2 with $g = 11$ and $c \leqslant 10$ would improve the ratio to $9/5 = 1.8$, and with $g = 9$ and $c \leqslant 8$, to $7/4 = 1.75$. Past this point, our 8-coloring starts being the bottleneck. The last possible step of this method would be to get parameters $g = 7$ and $c \leqslant 6$, for a ratio of $5/3 = 1.666\ldots$ Indeed we recall that string graphs of odd girth at least 5 have unbounded chromatic number [27], and do not necessarily have linear-size independent sets [28]. On the complexity side, we do not expect that Vertex Cover is APX-hard (i.e., NP-hard to approximate within some constant ratio $r > 1$) on represented string graphs as a quasipolynomial-time approximation scheme (QPTAS) exists [1, 11]. However, if a PTAS also exists, it will have to be found with a different approach than ours.

Let us emphasize that Theorem 2 is the only place where our algorithm actually requires a representation of the input to be given. Thus, an algorithm coloring string graphs with no short odd cycles, that works directly on the input graph G (not its representation), would yield an approximation algorithm for Vertex Cover in string graphs whose complexity is polynomial in the number of vertices of G. However, if we are only interested in the decision variant of the problem, the existential statement in Theorem 2 is sufficient to get the following result.

▶ **Theorem 5.** *Given a graph G and an integer k, in time polynomial in $|V(G)|$ we can distinguish the following cases:*
1. *G is a string graph and Vertex Cover$(G) \leqslant k$, and*
2. *G is a string graph and Vertex Cover$(G) > 11k/6$.*

If none of the cases applies, the algorithm terminates but its output is unspecified.

Let us remark that the authors of [23] claim that their algorithm can actually return a 1.9999-approximate solution in time polynomial in the number of vertices of the input graph but this is, unfortunately, not true. Indeed, one of the crucial steps in their argument is the application of a result of Lee [22, Theorem 4.2], whose proof has recently been realized to be flawed[4] [21, 3]. Seemingly the result [22, Theorem 4.2] can be reproven in a different way but only for *region intersection graphs* (a generalization of string graphs) [8], and the

[4] The inequality at the sixth line of the proof of Lemma 4.14 need not hold.

new approach requires that the representation is given (and still the final approximation ratio is much closer to 2 than the one given by Theorem 1). Similarly, it is claimed that the approach in [23] applies for all proper *induced-minor-closed* classes, but the problem lies in the same place: we are not aware of any way to fix the proof of Lee [22, Theorem 4.2] in such a general setting.

We leave as open questions if Vertex Cover admits, for some constant $\varepsilon > 0$, a $(2-\varepsilon)$-approximation algorithm on string graphs given without representation (which is very likely to be the case), and on classes excluding a fixed graph H as an induced minor.[5]

2 Definitions and preparatory lemmas

If $i \leqslant j$ are two non-negative integers, we denote by $[i,j]$ the set $\{i, i+1, \ldots, j-1, j\}$, and $[i]$ is a short-hand for $[1,i]$.

Graphs and odd cycles. We denote by $V(G)$ and $E(G)$ the set of vertices and edges of a graph G, respectively. A graph H is an *induced subgraph* (resp. *subgraph*) of a graph G if H can be obtained from G by vertex deletions (resp. by vertex and edge deletions). For $S \subseteq V(G)$, the *subgraph of G induced by S*, denoted $G[S]$, is obtained by removing from G all the vertices that are not in S. Then $G - S$ is a short-hand for $G[V(G) \setminus S]$. A set $X \subseteq V(G)$ is connected (in G) if $G[X]$ has a single connected component.

If C is a cycle, once a direction along the cycle is fixed, we may denote by $C[x \to y]$ the subpath of C from $x \in V(C)$ to $y \in V(C)$, turning in this direction.

▶ **Lemma 6.** *Let G be a graph that has an induced odd cycle C, and let $v \in V(G) \setminus V(C)$ have at least two neighbors in $V(C)$. Then there is a subpath of C that forms with v an induced odd cycle of G.*

Proof. Let $v_1, \ldots, v_h$ list the neighbors of v on C, starting at an arbitrary vertex and turning in a fixed (arbitrary) direction. The cycles $C_1, \ldots, C_h$, each with vertex set $\{v\} \cup C[v_i \to v_{i \pmod h + 1}]$ for $i \in [h]$, respectively, have a combined number of edges of $|V(C)| + 2h$; an odd number since $|V(C)|$ is odd. Hence at least one of $C_1, \ldots, C_h$ has odd length. ◀

Let G be a graph and $v \in V(G)$. We denote by $N_G(v)$ and $N_G[v]$, the open, respectively closed, neighborhood of v in G. For a non-negative integer r, we denote by $N_G^{\leqslant r}(v)$ (resp. $N_G^{=r}(v)$) the set of vertices of G at distance at most r (resp. exactly r) from v. We may call $N_G^{\leqslant r}(v)$ the ball of radius r around v (in G). We will rely on the observation that if a possibly long odd cycle is contained in a ball of small radius, then there is also a short odd cycle (in this ball).

▶ **Lemma 7.** *Let G be a graph, $v \in V(G)$, and r be a positive integer. Suppose $G[N_G^{\leqslant r}(v)]$ contains an odd cycle C. Then G (even $G[N_G^{\leqslant r}(v)]$) has an odd cycle of length at most $2r+1$. Furthermore, if $N_G^{=r}(v) \cap V(C)$ is an independent set of G, then G (even $G[N_G^{\leqslant r-1}(v)]$) has an odd cycle of length at most $2r-1$.*

Proof. Perform a breadth-first search (BFS) starting at v in $G[N_G^{\leqslant r}(v)]$. By definition, this breadth-first search has exactly $r+1$ layers $L_0, L_1, \ldots, L_r$, with $L_i := N_G^{=i}(v)$ for each $i \in [0,r]$. At least one L_i is *not* an independent set, otherwise $G[N_G^{\leqslant r}(v)]$ would be bipartite, and would not contain any odd cycle. Say $x, y \in L_i$ are adjacent, and let $z \in L_{i'}$ be their lowest common ancestor in the BFS tree (possibly $z = v$ and $i' = 0$). Then, there is a cycle

[5] i.e, H cannot be obtained from graphs of the class by removing vertices and contracting edges

of length $2(i-i')+1 \leqslant 2r+1$ in $G[N_G^{\leqslant r}(v)]$, consisting of the edge xy and the paths from z to x and from z to y in the BFS tree. Furthermore, if $N_G^{=r}(v) \cap V(C)$ is an independent set of G, then the odd cycle C has at least one of its edges with both endpoints in some $L_i \neq L_r$, which makes an odd cycle of length at most $2r-1$. ◀

String representations, and some useful notions and properties. A *string* is a subset of $\mathbb{R}^2$ homeomorphic to a closed segment. We may call a path-connected subset of a string s a *substring* of s. If R is a collection of strings in the plane, we denote their intersection graph by G_R, with one vertex per string, and an edge between every pair of intersecting strings. For any vertex $v \in V(G_R)$, we denote by $s_R(v)$ the string *representing* v in R. Conversely, we may denote by $v_R(s)$ the vertex represented by the string s. We typically drop the subscript when R is clear from the context. If X is an induced subgraph of G_R, we may denote by $R[X]$ the subset of strings of R corresponding to vertices of X.

A *face* of a geometric arrangement made by a collection $\mathcal{S}$ of strings, or more specifically of curves, in $\mathbb{R}^2$ is a connected component of $\mathbb{R}^2 \setminus \bigcup_{s\in\mathcal{S}} s$. A *closed face* is the topological closure of a face. If D is a topological disk, and more generally a face, we denote by ∂D its boundary. For instance, the curve ∂D defines two faces, one of which is finite ($D \setminus \partial D$), and admits D as a closed face. We may denote by $\overline{F}$ the closure of an (open) face F.

If P is an induced path represented by strings $s_1, \ldots, s_h$ (i.e., s_i and s_j intersect whenever $|i-j| = 1$), $a \in s_1$ and $b \in s_h$, we denote by $s[a, P, b]$ a minimal path-connected subset of $\bigcup_{i\in[h]} s_i$ containing a and b. In particular $s[a, P, b]$ is a string with endpoints a and b, coinciding with each s_i on a substring of positive length. Although $s[a, P, b]$ is not necessarily uniquely defined, every further claim will hold regardless of the actual choice for $s[a, P, b]$. It can thus be thought as a short-hand for: *fix any minimal path-connected subset of* $\bigcup_{i\in[h]} s_i$ *containing* a *and* b*, and denote it* $s[a, P, b]$.

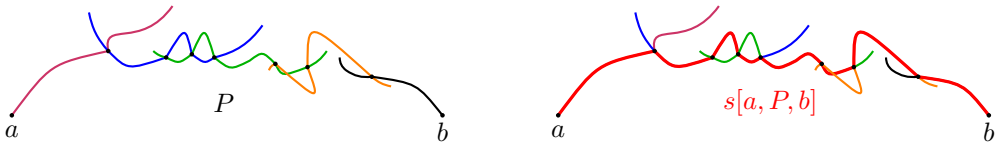

Figure 1 Left: 5-vertex path as the intersection graph of strings, where the first string of the path contains point a, and the last string of the path contains point b. Right: illustration of $s[a, P, b]$.

It will be convenient to extend the latter notation to induced cycles, that is, to allow s_1 and s_h to be adjacent. If P may be a cycle, then $s[a, P, b]$ is defined more specifically in the case when s_1 and s_h indeed intersect. If there is a point $c \in s_1 \cap s_h$ and two substrings $s'_1 \subseteq s_1, s'_h \subseteq s_h$ with endpoints a, c and b, c, respectively, such that $(s'_1 \cup s'_h) \cap \bigcup_{2\leqslant i\leqslant h-1} s_i = \emptyset$, then $s[a, P, b] := s'_1 \cup s'_h$. If not, then there is a (*non-self-intersecting*) string that starts at a, follows non-empty substrings of $s_1, \ldots, s_h$ in this order, and ends at b. We fix, as before, $s[a, P, b]$ to be any such string.

We will need the following lemma.

▶ **Lemma 8.** *Let D be a topological disk in the plane. Let $V \uplus W$ be a set of strings all contained in D, whose intersection graph is a cycle C, such that*

- *$|W| \geqslant 2$,*
- *every string of W has one or both endpoints in ∂D,*
- *no other point of a string of $V \cup W$ intersects ∂D, and*
- *no two strings of W (hence of $V \cup W$) intersect at a point of ∂D.*

Let s_p be a string contained in D with at least one endpoint p in ∂D, such that s_p does not intersect any string of $V \cup W$.

Then there are two strings $s \neq s' \in W$, and h strings $s_1, \ldots, s_h \in V$ with $v(s), v(s_1), \ldots, v(s_h), v(s')$ a subpath of C (or C itself), and s_p is contained in a closed face $\overline{F}$ of the arrangement $\{\partial D, s, s_1, \ldots, s_h, s'\}$ such that $\overline{F}$ does not intersect any string of $V \cup W$ outside of $s, s_1, \ldots, s_h, s'$, the two strings of $V \cup W$ intersecting s (including s_1), and the two string of $V \cup W$ intersecting s' (including s_h).

Proof. Let t, t' be two distinct strings of W, with $q \in t \cap \partial D$ and $q' \in t' \cap \partial D$. Let P_1, P_2 be the two paths from $v(t)$ to $v(t')$ in C. We define the strings $t_1 := s[q, P_1, q']$ and $t_2 := s[q, P_2, q']$. We denote by $\langle q, q' \rangle$ and $\langle q', q \rangle$ the two minimal path-connected subsets of ∂D containing q and q'. Let F_1, F_1' be the two finite (open) faces with boundary $\langle q, q' \rangle \cup t_1$ and $\langle q', q \rangle \cup t_1$, respectively. Similarly let F_2, F_2' be the two finite faces with boundary $\langle q, q' \rangle \cup t_2$ and $\langle q', q \rangle \cup t_2$, respectively.

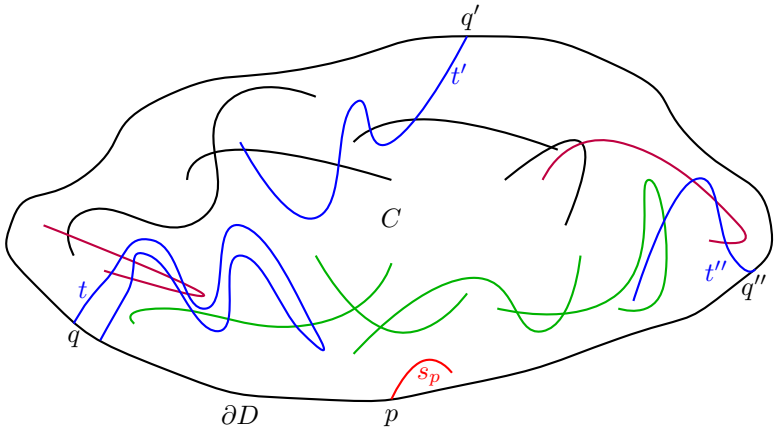

Figure 2 Illustration of the proof of Lemma 8. The strings of W are in blue. Say, we initially pick $t \neq t' \in W$ as depicted. The $v(t)$–$v(t')$ subpath of C enclosing s_p contains a string in W, namely t''. As qpq'' turns as qpq' along ∂D, t' will be set to t'', and the new P (green strings) is entirely in V, so the process stops. The strings $s := t, s' := t''$, the green strings, and ∂D form a closed face containing s_p that, among the strings of the rest of C, only the two purple strings (may) intersect.

As C is an induced cycle, at most one of $\overline{F_1}, \overline{F_1'}$ intersects the string of some vertex in $V(C) \setminus N_C[P_1]$. Without loss of generality, suppose that $\overline{F_1}$ does not intersect any string of $V(C) \setminus N_C[P_1]$. As s_p does not intersect t_1, it is contained in the closed face $\overline{F_1}$ or in the closed face $\overline{F_1'}$. If s_p is contained in $\overline{F_1}$, we set $P := P_1 - \{v(t), v(t')\}$ and $F := F_1$, and proceed to the next paragraph. Otherwise, we observe that s_p is contained in $\overline{F_2'}$, and $\overline{F_2'}$ does not intersect any string of $V(C) \setminus N_C[P_2]$. In which case we set $P := P_2 - \{v(t), v(t')\}$ and $F := F_2'$.

At this point, we have all the requirements of the lemma except that some strings of P may be in W. Let P be $v_1, \ldots, v_\ell$ with v_1 a neighbor of $v(t)$, and v_ℓ a neighbor of $v(t')$. While there is some string $t'' \in W$ with $v(t'') = v_i \in V(P)$, we let $q'' \in t'' \cap \partial D$ and distinguish two cases. If q, p, q'' turn along ∂D in the same direction as q, p, q', we set $t' := t''$ and $P := v_1, \ldots, v_{i-1}$. Otherwise we set $t := t''$ and $P := v_{i+1}, \ldots, v_\ell$. (Note that $|V(P)|$ decreases by at least one in each case.) When we exit the while loop, $s := t, s' := t' \in W$, and the subpath P of C (now only made of strings of V) satisfy the lemma statement. A visual recap is provided by Figure 2. ◀

3 String graphs of odd girth larger than 11 are 8-colorable

This section is devoted to the proof of Theorem 2. Let G be a string graph of odd girth strictly greater than 11, and R be a string representation of G. We may color each connected component of G independently, thus assume that G is connected. Let $u_0 \in V(G)$ be an arbitrary vertex. For each $i \geqslant 0$, let $L_i := N_G^{=i}(u_0) \subseteq V(G)$ be the set of vertices at distance exactly i from u_0. Note that $\{u_0\} = L_0, L_1, L_2, \ldots$ partition $V(G)$, and that there may be an edge between $x \in L_i$ and $y \in L_j$ only if $|i - j| \leqslant 1$.

Our goal is to 4-color $G[L_i]$ for each non-negative integer i. We are then done, since we can use two disjoint 4-color palettes for $G[\bigcup_{i \text{ is odd}} L_i]$ and $G[\bigcup_{i \text{ is even}} L_i]$. We fix i, and assume that $i \geqslant 2$ since L_0 is a singleton, and L_1 is an independent set, due to the condition on the odd girth. Note that it is sufficient to 4-color each connected component of $G[L_i]$. Let X be the vertex set of any connected component of $G[L_i]$.

Definition of the topological disk D. Let $R[X]$ be the string representation of $G[X]$ obtained by keeping the strings of R corresponding to vertices of X. Let D_0 be the topological disk whose boundary is the boundary of the infinite face in the arrangement $R[X]$. If $s(u_0)$ is contained in D_0, we draw R on a sphere, place any arbitrary free point (i.e., not occupied by a string of R) of the face containing $s(u_0)$ in $R[X]$ at its North pole, and consider the stereographic projection of this string representation. The latter is such that $s(u_0)$ is on the infinite face of the string arrangement $R[X]$. Thus we can in fact assume that $s(u_0)$ is not contained in D_0.

Note that every string of $R[X]$ is contained in D_0, and apart from those of $L_{i-1} \cup L_{i+1} \cup X$ no string of R intersects ∂D_0. Let $D \supset D_0$ be a very slightly augmented topological disk such that $\partial D_0 \subset D \setminus \partial D$, the property that no string outside $L_{i-1} \cup L_{i+1} \cup X$ intersects ∂D is preserved, no intersection of two strings of R lies on ∂D, and, for any point $q \in \partial D$, no string of R intersects ∂D at q without crossing it at q. We observe that every string of L_{i-1} with a neighbor in $V(X)$ intersects ∂D, and that every vertex of X has a neighbor in L_{i-1}.

Definition of the auxiliary graph H. Let R_H be the set of strings formed by $D \cap R[(L_{i-1} \cap N_G(V(X))) \cup V(X)]$, and H its intersection graph. Every vertex of X corresponds to a single vertex in H, whereas each vertex of $L_{i-1} \cap N_G(V(X))$ may split in several strings in H as the corresponding string in R may enter and exit D several times. However, the strings of R_H that correspond to the same vertex in $L_{i-1} \cap N_G(V(X))$ are pairwise non-intersecting and thus they form an independent set in H. Fix an arbitrary vertex $w \in L_{i-1} \cap N_G(V(X))$. Let X_j be the subset of vertices of X at distance exactly j from w in H. Again, $X_1, X_2, \ldots$ partition X. By the previous remarks, it is sufficient to show that that for any positive integer k, the graph $G[X_k] = H[X_k]$ is bipartite. We fix k, and show this fact in the next section.

3.1 $G[X_k]$ is bipartite

For the sake of contradiction assume that there is an induced odd cycle C in $G[X_k]$. We denote by $v_1, \ldots, v_h$ the vertices of C. For every $\ell \in [h]$, we fix some $w_\ell \in N_H(v_\ell) \setminus X$. Such a vertex exists since every vertex of L_i has at least one neighbor in L_{i-1} (possibly split into several strings in R_H, at least one of which intersects $s(v_\ell)$). Observe that $w_1, \ldots, w_h$ are not necessarily pairwise distinct. We set $W := \{w_1, \ldots, w_h\}$, with $1 \leqslant |W| \leqslant h$. We say that string $s(v_i)$ (and, by extension, vertex v_i) is *simply attached* in a cycle C' containing v_i if w_i has only one neighbor in $V(C')$, namely v_i. We denote by $r(w_i)$ one (arbitrary, if both endpoints are in ∂D) endpoint of w_i that is in ∂D.

Our plan is to show that there is an odd cycle C' contained in the ball of radius 6 around some vertex z in H such that $N_H^{=6}(z) \cap V(C')$ is an independent set. This implies, by Lemma 7, the existence of an odd cycle of length at most 11 in H, which in turn implies, as we will see, that the same happens in G. To do this, we exhibit a path $\widehat{P}$ in $H[V(C) \cup W]$ on at most four vertices, whose strings define with ∂D a (finite) closed face F containing $s(w)$ (recall that w is the arbitrary BFS root in H), and an odd cycle C' in $H[V(C) \cup W]$ "mostly" contained in $D \setminus F$. We then show that z can be chosen among the vertices of $\widehat{P}$.

Let us first establish the following lemma.

▶ **Lemma 9.** *There is an induced odd cycle C' in H such that $V(C') \subseteq V(C) \cup W$ and one of the following items holds*

- *$C' = C$ and every string of $V(C')$ is simply attached in C', or*
- *$V(C') \cap W = \{w_i\}$, for some $w_i \in W$, and $V(C') \setminus \{w_i\}$ induces a subpath of C whose internal vertices are all simply attached in C', or*
- *$|V(C') \cap W| \geqslant 2$, and there is a subpath $x, v_i, \ldots, v_j, y$ of C' (or C' itself) such that $x \neq y$, $\{x, y\} \subset W$, $\{v_i, \ldots, v_j\} \subset V(C)$ may be empty, $s(v_{i+1}), \ldots, s(v_{j-1})$ are all simply attached in C', and $s(w)$ is contained in a closed face of $\{\partial D, s(x), s(v_i), s(v_{i+1}), \ldots, s(v_{j-1}), s(v_j), s(y)\}$ that does not intersect any string of C' but $s(x), s(v_i), s(v_{i+1}), \ldots, s(v_{j-1}), s(v_j), s(y)$ and the other neighbor in C' of x and of y.*

Proof. If all the strings of C are simply attached, we are done as the first item holds. Otherwise there is some $w_i \in W$ with at least two neighbors in $V(C)$. By Lemma 6, there is an induced odd cycle C_1 such that $V(C_1)$ comprises w_i and a subpath of C.

Let $p \geqslant 1$, and suppose we have defined C_p. If C_p satisfies the second or the third item of the lemma, we are done; so we assume otherwise. We will show that we can find an induced cycle C_{p+1} in $H[V(C) \cup W]$ with fewer vertices in $V(C)$ than C_p has.

First, suppose that $V(C_p) \cap W$ is a singleton $\{x\}$. As C_p does not satisfy the second outcome, there is a vertex $v_i \in V(C_p) \setminus \{x\} \subseteq V(C)$ that is *not* simply attached nor adjacent to x in C_p. We then obtain C_{p+1} by applying Lemma 6 to the pair C_p, w_i.

Suppose instead that C_p has at least two vertices in W. By Lemma 8, $s(w)$ is contained in a closed face F of the arrangement $\{\partial D, s(x), s(v_i), s(v_{i+1}), \ldots, s(v_{j-1}), s(v_j), s(y)\}$ with $x \neq y$ and $\{x, y\} \subset W$ such that F does not intersect any string of C' outside $s(x'), s(x), s(v_i), s(v_{i+1}), \ldots, s(v_{j-1}), s(v_j), s(y), s(y')$ where x', y' are the unique vertices in $N_{C'}(x) \setminus \{v_i\}, N_{C'}(y) \setminus \{v_j\}$, respectively. As C_p does not satisfy the third item, $|j - i| \geqslant 2$ and there is some $v_{i'}$ with $i + 1 \leqslant i' \leqslant j - 1$ such that $s(v_{i'})$ is *not* simply attached in C_p. We then obtain C_{p+1} by applying Lemma 6 to the pair $C_p, w_{i'}$; see Figure 3.

In both cases, the number of vertices of $V(C)$ present in the current odd cycle drops by at least one when going from C_p to C_{p+1}. Thus, after at most $h = |V(C)|$ iterations, the procedure will return an odd cycle C_q in $H[V(C) \cup W]$ that satisfies the second or the third statement of the lemma. ◀

We can then obtain the announced milestone.

▶ **Lemma 10.** *There is an induced odd cycle C' in $H[V(C) \cup W]$, two distinct vertices x, y in W, possibly part of C', and a subpath P of C' on 0, 1, or 2 vertices, all in $V(C)$, such that*

- *if $V(P) \neq \emptyset$, then x is adjacent to one endpoint of P, and y, to the other (possibly equal) endpoint of P, and if $V(P) = \emptyset$, then x and y are adjacent,*
- *one finite closed face F_1 of the arrangement $\{\partial D, s[r(x), xPy, r(y)]\}$ contains $s(w)$, and*
- *the other finite closed face F_2 contains every string of $V(C') \setminus N_{C'}[V(P) \cup \{x, y\}]$.*

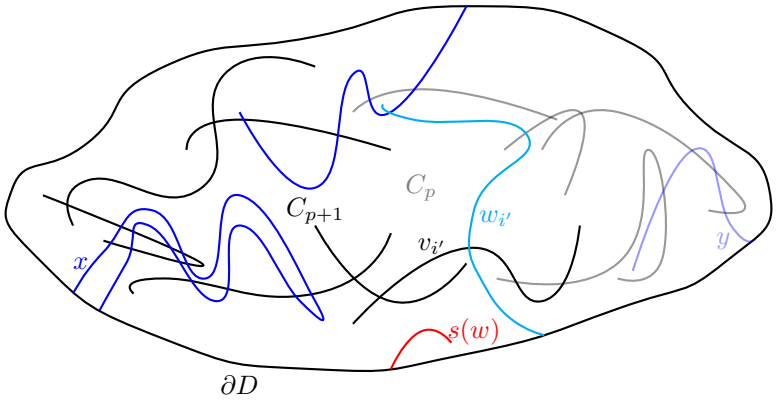

Figure 3 The string $w_{i'} \in W$ with several neighbors in $V(C_p)$, and the new odd induced cycle C_{p+1} obtained by Lemma 6. Lemma 8 will then locate $s(w)$ as enclosed by $x, w_{i'}$ and some (here, three) strings of V. For legibility, a string may be labeled by its corresponding vertex.

Proof. By Lemma 9, there is an induced odd cycle C' in $H[V(C) \cup W]$, two vertices $x' \neq y' \in W$, possibly part of C', and a possibly-empty subpath P of C' such that

- $V(P) \subset V(C)$ and each internal vertex of P is simply attached in C',
- $x'Py'$ is a path or a cycle (we allow x' and y' to be adjacent, even when $V(P) \neq \emptyset$),
- $\{\partial D, s[r(x'), x'Py', r(y')]\}$ has two finite closed faces $F_1 \supset s(w)$, and
- F_2 containing every string of $V(C') \setminus N_{C'}[V(P) \cup \{x', y'\}]$.

Indeed, we directly get this outcome if the third item of Lemma 9 holds. If instead the first item of Lemma 9 holds, we set $x' := w_i$ and $y' := w_j$ for any $v_i \neq v_j \in V(C) = V(C')$ such that $w_iw_j \notin E(H)$. This is possible to ensure since H is triangle-free and $|V(C)| \geqslant 3$. The path P is then chosen as the subpath of C from v_i to v_j such that $\partial D \cup s(x') \cup \bigcup_{u \in V(P)} s(u) \cup s(y')$ separates $s(w)$ from $V(C) \setminus N_C[P]$. If finally the second item of Lemma 9 holds, we set $x' := w_i$ for any $v_i \in V(C')$ such that $w_i \notin V(C')$, and y' is defined as the only vertex of $W \cap V(C')$. We then set P as previously.

Now, while the path P has at least three vertices and $s[r(x'), x'Py', r(y')]$ passes through the strings of P, let v_i be an internal vertex of P. By construction, $s(v_i)$ is simply attached in C'. Let P' be the subpath of P going from the endpoint of P neighboring x' to v_i, and P'' be the subpath of P going from v_i to its other endpoint (neighboring y'). Then, either P' and the pair $x' \neq w_i \in W$ or P'' and the pair $w_i \neq y'$ satisfy the four items of the previous paragraph. In the former case, we set $P := P'$ and $y' := w_i$, whereas in the latter, we set $P := P''$ and $x' := w_i$; see Figure 4.

We are done when $|V(P)| \leqslant 2$ or when $s[r(x'), x'Py', r(y')]$ is contained in $s(x') \cup s(y')$. In both cases, we set $x := x'$ and $y := y'$, and in the latter case, we set P to be empty. ◀

Following the notations of Lemma 10, we define z as the neighbor of x in P if $V(P) \neq \emptyset$, and as x otherwise.

▶ **Lemma 11.** $V(C') \subseteq N_H^{\leqslant 6}(z)$.

Proof. We keep the notations of Lemma 10. First we observe that any vertex in $N_{C'}[V(P) \cup \{x, y\}]$ is at distance at most 3 of z in H. It remains to see that every vertex z' of C' such that $s(z')$ is contained in F_2 is at distance at most 6 from z in H.

Note that every vertex of W is at distance $k-1$, k, or $k+1$ from w in H, since every vertex of C is at distance exactly k from w in H, and every vertex of W has a neighbor in $V(C)$. As $s(w)$ is in F_1, a (shortest) path from w to z' has to contain a vertex y' such

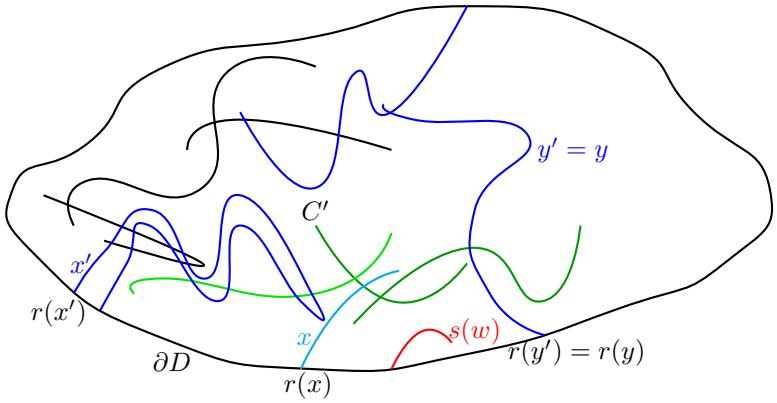

Figure 4 Example of strings $x' \neq y' \in W$ and the subpath P (three green strings) of C'. The internal node of P is simply attached to C'. This is the case when x' should be updated (to the vertex of the cyan string). The new path P (darker green) has two vertices, thus the process stops.

that $s(y')$ intersects $s[r(x), xPy, r(y)]$. Since vertices of $V(P) \cup \{x, y\}$ are at distance at least $k-1$ from w, vertex y' is at distance at least $k-2$ from w. Now, as vertices of C' are at distance at most $k+1$ from w, vertex y' is at distance at most 3 from z'. In turn, z is at distance at most 3 from y', and we conclude. ◀

We further show that no edge of C' can lie within $N_H^{=6}(z)$.

▶ **Lemma 12.** *$N_H^{=6}(z) \cap V(C')$ is an independent set of H or H admits an odd cycle of length at most 9.*

Proof. The proof of Lemma 11 shows that for some vertex $z' \in V(C')$ to be at distance 6 from z in H, there should be a 4-edge path from y to z'. Thus two vertices z', z'' adjacent in C' and at distance 6 from z in H entail an odd cycle of length *at most* 9 in H, built from y, the corresponding two (non-necessarily edge-disjoint) 4-edge paths, z', and z''. ◀

Lemmas 7, 11, and 12 imply the existence of an odd cycle C_o of length at most 11 in H. To reach the final contradiction, we build an odd cycle of at most the same length in G.

▶ **Lemma 13.** *Let C_o be an odd cycle in H. Then G has an odd cycle of length at most $|V(C_o)|$.*

Proof. We initialize a represented odd cycle $\widehat{C}$ to C_o realized by the corresponding strings of R_H. We make an induction on the number of strings of $\widehat{C}$ not part of the representation R of G. When this number is 0, we conclude since G contains the cycle $\widehat{C}$ as a subgraph. Let $y_1, \ldots, y_q \in V(\widehat{C})$ be all the vertices of $\widehat{C}$ whose strings are substrings of $s(y)$ for some $y \in L_{i-1} \cap N_G(V(X))$.

We further assume that starting at $y_1 \in V(\widehat{C})$, and turning in some fixed (arbitrary) direction along $\widehat{C}$, one encounters $y_1, y_2, \ldots, y_q$ in this order. Let, for every $a \in [q]$, ℓ_a be the number of edges of $\widehat{C}[y_a \to y_{a \pmod q+1}]$. As, $|V(\widehat{C})| = \sum_{a \in [q]} \ell_a$, at least one ℓ_a is odd. Recall that $\{y_1, \ldots, y_q\}$ is an independent set in H, hence every ℓ_a is strictly greater than 1. Then the string $s(y)$ and those of the internal vertices in the path between y_a and $y_{a \pmod q+1}$ form an odd cycle of length at least 3 and at most $|V(\widehat{C})|$. This defines the new represented odd cycle $\widehat{C}$, and concludes the proof. ◀

3.2 8-coloring algorithm

To claim Theorem 2, we finally need to check that, given a representation $P, \mathcal{S}$ of a string graph G of odd girth larger than 11, one can compute an 8-coloring of G in time polynomial in $|V(P)|$. Recall that P is a planar graph and $\mathcal{S}$ is a set of non-empty connected sets in P in one-to-one correspondence with $V(G)$ such that two distinct connected sets of $\mathcal{S}$ intersect if and only if the corresponding vertices of G are adjacent. Note that, as G is in particular triangle-free, $|V(G)| \leqslant 2|V(P)|$.

We remind the reader that we compute one BFS in G, and fewer than $|V(G)|$ BFSes in auxiliary graphs H of size at most $(|V(P)|+1)|V(G)|$. After this we simply 2-color bipartite graphs whose combined number of vertices is at most $|V(G)|$. Thus, we shall just detail how to compute each auxiliary graph H.

Let X be the component of $G[L_i]$ giving rise to H. We start by adding every vertex of X to $V(H)$. We compute the set $Y \subseteq V(P)$ of all the vertices contained in an element of $\mathcal{S}$ corresponding to a vertex of X. Let $u' \in V(P)$ be a vertex in the connected set of u_0. Let $Y' \subseteq Y$ be the vertices $v \in Y$ for which there is a path in P from u' to v whose internal vertices are all in $V(P) \setminus Y$. Note that Y' can be computed in polynomial time in $|V(P)|$ by checking if u' and y are in the same connected component of $P - (Y \setminus \{v\})$. The set Y' is the combinatorial counterpart of ∂D. In particular, we do not need to change the representation if u' is in a finite face "made by Y." This was merely helpful in the correctness proof.

For each vertex $v \in L_{i-1} \cap N_G(V(X))$ (alternatively we can only keep at least one neighbor per vertex of X), we add to $V(H)$ one vertex for each connected component of $S \cap Y$ in P, where S is the connected set of v. Note that $S' \cap Y' \neq \emptyset$ for every vertex set S' of such a connected component. This step adds to H fewer than $|V(G)| \cdot |V(P)|$ vertices. Graph H is finally defined as the intersection graph of all the connected sets of vertices in $V(H)$, which can be computed in time polynomial in $|V(P)|$.

4 Approximation algorithm for Vertex Cover

For a graph G, let $\mathsf{vc}(G)$ denote the size of a minimum vertex cover in G. We will use the following result of Chlebík and Chlebíková [5], which is a slight strengthening of the well-known Nemhauser–Trotter theorem [26].

▶ **Theorem 14** (Chlebík and Chlebíková [5], Nemhauser and Trotter [26]). *Given a graph G, one can compute in polynomial time a partition of $V(G)$ into $V_0, V_{1/2}, V_1$, such that*

1. *there are no edges between V_0 and $V_{1/2}$ or within V_0,*
2. $\mathsf{vc}(G[V_{1/2}]) \geqslant \frac{1}{2}|V_{1/2}|$, *and*
3. *every minimum vertex cover S of G satisfies $V_1 \subseteq S \subseteq V_1 \cup V_{1/2}$.*

Finally, we are ready to prove Theorem 1, which we restate for convenience.

▶ **Theorem 1.** *Vertex Cover admits an $\frac{11}{6}$-approximation algorithm in string graphs given with a representation, whose running time is polynomial in the size of a representation.*

Proof. Let G be the input graph, given along with a representation. The algorithm has three phases.

Phase one. We initialize $X = \emptyset$. If G contains an odd cycle of length at most 11, we include all its vertices into X and remove them from the graph. We repeat this step exhaustively; clearly this can be done in polynomial time. Let G' be the graph obtained after the last iteration of the process.

Phase two. We call the algorithm from Theorem 14 on the graph G' in order to obtain three sets $V_0, V_{1/2}$, and V_1. We denote $Y = V_1$ and $G'' = G'[V_{1/2}]$. Note that G'' is a string graph with odd girth larger than 11 and the representation of G'' can be easily obtained from the representation of G by removing objects corresponding to vertices in $V(G) \setminus V(G'')$.

Phase three. We apply the algorithm from Theorem 2 to find a proper coloring of G'' with at most 8 colors. Let c be the color that appears most frequently, and let Z be set of vertices of G'' *not* colored c. Clearly $|Z| \leqslant \frac{7}{8}|V(G'')|$, so $|V(G'')| \geqslant \frac{8}{7}|Z|$. The algorithm returns $Q = X \cup Y \cup Z$.

Analysis. First, let us argue that Q is indeed a vertex cover. Since $X \subseteq Q$, it is enough to show that $Q \cap V(G') = Y \cup Z$ is a vertex cover of G'. Note that by the first property in Theorem 14 and since $V_1 = Y$, all edges of G' not contained in G'' are covered by Q. So we are left with showing that $Q \cap V(G'') = Z$ is a vertex cover of G''. This is clearly true, as the complement of Z in G'' is an independent set (of color c).

Now let us analyze the approximation factor. Let S be an optimum solution, i.e., a vertex cover of G of size $\mathsf{vc}(G)$. Note that for each odd cycle C removed in the first phase, $S \cap C$ must contain at least $\frac{|C|}{2}$ vertices in order to cover all the edges of C. As each removed cycle has at most 11 vertices, we conclude that $|S \cap X| \geqslant \frac{6}{11}|X|$.

Note that $S' \setminus X$ is a vertex cover of G'. By the third property in Theorem 14 we observe that $Y = V_1 \subseteq S$, and so $S \setminus (X \cup Y)$ is a vertex cover of G''. By the second property in Theorem 14 we obtain that $|S \setminus (X \cup Y)| \geqslant \frac{1}{2}|V(G'')|$.

Summing up, we obtain

$$\begin{aligned}|S| &= |S \cap X| + |S \cap Y| + |S \setminus (X \cup Y)| \geqslant \frac{6}{11}|X| + |Y| + \frac{1}{2}|V(G'')| \\ &\geqslant \frac{6}{11}|X| + |Y| + \frac{4}{7}|Z| \geqslant \frac{6}{11}|X \cup Y \cup Z| = \frac{6}{11}|Q|,\end{aligned}$$

which means that $|Q| \leqslant \frac{11}{6}|S| = \frac{11}{6}\mathsf{vc}(G)$. This completes the proof. ◀

The proof above is easily adapted to show Theorem 5. The first two phases remain unchanged. Let $\mathcal{C}$ be the family of odd cycles found in phase one and let Y be the set found in phase two. Once we reach phase three, we do not call the coloring algorithm on G'', as its running time might not be polynomial in $|V(G)|$. Instead, we check if $\sum_{C \in \mathcal{C}} \lceil |V(C)|/2 \rceil + |Y| + |V(G'')|/2 > k$ and, if so, we reject the instance. Note that the sum in the expression above is a lower bound on $\mathsf{vc}(G)$, so this step is correct. Otherwise, we accept the instance. The approximation guarantee is estimated as in the proof of Theorem 1.

Abstract

Union volume estimation is a classical algorithmic problem. Given a family of objects $O_1, \dots, O_n \subset \mathbb{R}^d$, we want to approximate the volume of their union. In the special case where all objects are boxes (also called hyperrectangles) this is known as Klee's measure problem. The state-of-the-art $(1+\varepsilon)$-approximation algorithm [Karp, Luby, Madras '89] for union volume estimation as well as Klee's measure problem in constant dimension d uses a total of $O(n/\varepsilon^2)$ queries of three types: (i) determine the volume of O_i; (ii) sample a point uniformly at random from O_i; and (iii) ask whether a given point is contained in O_i.

First, we show that if an algorithm learns about the objects only through these types of queries, then $\Omega(n/\varepsilon^2)$ queries are necessary. In this sense, the complexity of [Karp, Luby, Madras '89] is optimal. Our lower bound holds even if the objects are equiponderous axis-aligned polygons in $\mathbb{R}^2$, if the containment query allows arbitrary (not necessarily sampled) points, and if the algorithm can spend arbitrary time and space examining the query responses.

Second, we provide a more efficient approximation algorithm for Klee's measure problem, which improves the running time from $O(n/\varepsilon^2)$ to $O((n+\frac{1}{\varepsilon^2}) \cdot \log^{O(d)}(n))$. We circumvent our lower bound by exploiting the geometry of boxes in various ways: (1) We sort the boxes into classes of similar shapes after inspecting their corner coordinates. (2) With orthogonal range searching, we show how to sample points from the union of boxes in each class, and how to merge samples from different classes. (3) We bound the amount of wasted work by arguing that most pairs of classes have a small intersection.

1 Introduction

We revisit the classical problem of *union volume estimation*: given objects $O_1, \ldots, O_n \subset \mathbb{R}^d$, we want to estimate the volume of $O_1 \cup \ldots \cup O_n$.[1] This problem has several important applications such as DNF counting and network reliability; see the discussion in Section 1.2.

The state-of-the-art solution [19] works in a model where one has access to each input object O_i by three types of queries: (i) determine the volume of the object, (ii) sample a point uniformly at random from the object, and (iii) ask whether a point is contained in the object. Apart from these types of queries, the model allows arbitrary computations. The complexity of algorithms is thus measured by the number of queries.

After Karp and Luby [18] introduced this model, Karp, Luby and Madras [19] gave an algorithm that $(1+\varepsilon)$-approximates the volume of n objects in this model with constant success probability.[2] It uses $O(n/\varepsilon^2)$ queries plus $O(n/\varepsilon^2)$ additional time, which improves earlier algorithms [18, 22], and only asks containment queries of previously sampled points. The last 35 years have seen no algorithmic improvement. Is this classical upper bound best possible? We resolve the question in this work by providing a matching lower bound.

The union volume estimation problem was also studied recently in the streaming setting [25, 23], where a stream of objects $O_1, \ldots, O_n \subset \Omega$ arrive in order. When we are at position i in the stream, we can only query object O_i. This line of work yields algorithms with constant success probability that use $O(\text{polylog}(|\Omega|)/\varepsilon^2)$ queries and additional time per object (and the same bound also holds for space complexity). Summed over all n objects, the bounds match the classical algorithm up to the $\text{polylog}(|\Omega|)$ factor. So, interestingly, even in the streaming setting the same upper bound can be achieved.[3]

The perhaps most famous application of the algorithm by Karp, Luby, and Madras [19] is *Klee's measure problem* [21]. This is a fundamental problem in computational geometry in which we are given n axis-aligned boxes in $\mathbb{R}^d$ and want to compute the volume of their union. An axis-aligned box is a set in the form $[a_1, b_1] \times \ldots \times [a_d, b_d] \subset \mathbb{R}^d$, and the input consists of the corner coordinates $a_1, b_1, \ldots, a_d, b_d$ of each box. A long line of research on this problem and various special cases (e.g., for fixed dimensions or for cubes) [31, 26, 11, 2, 1, 12, 32, 3] lead to an exact algorithm running in time $O(n^{d/2} + n \log n)$ for constant d [13]. A conditional lower bound suggests that any faster algorithm would require fast matrix multiplication techniques [12], but it is unclear how to apply fast matrix multiplication to this problem. On the approximation side, note that the three queries can be implemented in time $O(d)$ for any d-dimensional axis-aligned box. Thus the union volume estimation algorithm can be applied, and it computes a $(1+\varepsilon)$-approximation to Klee's measure problem in time $O(nd/\varepsilon^2)$, as

[1] Technically, the objects need to be measurable. In the most general form, $O_1, \ldots, O_n$ can be any measurable sets in a measure space, and we want to estimate the measure of their union. However, this work only deals with boxes in $\mathbb{R}^d$ (in our algorithm) and polygons in the plane (in our lower bound).
[2] The success probability can be boosted to $1-\delta$, adding a $\log(1/\delta)$ factor in time and query complexity.
[3] See also [30] for earlier work studying Klee's measure problem in the streaming setting.

has been observed in [4]. This direct application of union volume estimation was the state of the art for approximate solutions for Klee's measure problem until our work. See Section 1.2 for interesting applications of Klee's measure problem.

1.1 Our contribution

Lower bound for union volume estimation

Given the state of the art, a natural question is to ask *whether the query complexity of the general union volume estimation algorithm of [19] can be further improved.* Any such improvement would speed up several important applications, cf. Section 1.2. On the other hand, any lower bound showing that the algorithm of [19] is optimal also implies tightness of the known streaming algorithms (up to logarithmic factors), as the streaming algorithms match the static running time bound.

Previously, a folklore lower bound of $\Omega(n + 1/\varepsilon^2)$ was known. But between this and the upper bound $O(n/\varepsilon^2)$ there is still a large gap; consider for example the regime $\varepsilon = 1/\sqrt{n}$ where the bounds are $\Omega(n)$ and $O(n^2)$, respectively. We close this gap by strengthening the lower bound to $\Omega(n/\varepsilon^2)$, thereby also showing optimality of [19]. Note that the lower bound is about query complexity in the model; it does not make any computational assumption. In particular, it holds even if the algorithm spends arbitrary time and space in computation.

▶ **Theorem 1.** *Any algorithm that computes a $(1+\varepsilon)$-approximation to the volume of the union of n objects via volume, sampling and containment queries with success probability at least $2/3$ must make $\Omega(n/\varepsilon^2)$ queries.*

We highlight that our lower bound holds even for equiponderous, axis-aligned polygons in the plane.

Upper bound for Klee's measure problem

Our lower bound for union volume estimation implies that any improved algorithm for Klee's measure problem must exploit the geometric structure of boxes. To this end, we exploit our knowledge of the corner coordinates and classify the boxes by shapes. In addition, we apply the geometric tool of orthogonal range searching. They allow us to approximate Klee's measure problem faster than the previous $O(n/\varepsilon^2)$ algorithm. Here and throughout, we assume that the dimension d is a constant; in particular, we suppress factors of $2^{O(d)}$ in the time complexity.

▶ **Theorem 2.** *There is an algorithm that runs in time $O\left((n + \frac{1}{\varepsilon^2}) \cdot \log^{2d+1}(n)\right)$ and with probability at least 0.9 computes a $(1+\varepsilon)$-approximation for Klee's measure problem.*

This is a strict improvement when $\varepsilon \leq 1/\log^{d+1}(n)$ is small. Consider for example the regime $\varepsilon = 1/\sqrt{n}$: Our algorithm runs in near-linear time, whereas the previous algorithm runs in quadratic time. We remark that the success probability can be boosted to any $1 - \delta$ by standard techniques which incurs an extra $\log(1/\delta)$ factor in the running time. Finally, we highlight that the core of our algorithm is an efficient method to sample uniformly and independently with a given density from the union of the input boxes. This can be of independent interest outside the context of volume estimation.

1.2 Related work

A major application of union volume estimation is *DNF counting*, in which we are given a Boolean formula in disjunctive normal form and want to count the number of satisfying assignments. Computing the exact number of satisfying assignments is #P-complete, so it likely requires superpolynomial time. Approximating the number of satisfying assignments can be achieved by a direct application of union volume estimation, as described in [19]. Their algorithm remains the state of the art for approximate DNF counting, see e.g. [24]. This has been extended to more general model counting [27, 9, 24], probabilistic databases [20, 15, 28], and probabilistic queries on databases [7].

We also mention *network reliability* as another application for union volume estimation, which was already discussed in [19]. Additionally, Karger's famous paper on the problem [17] uses the algorithm of [19] as a subroutine. However, the current state-of-the-art algorithms no longer use union volume estimation as a tool [8].

Finally, we want to draw a connection to the following well-known query sampling bound. Canetti, Even, and Goldreich [6] showed that approximating the mean of a random variable whose codomain is the unit interval requires $\Omega(1/\varepsilon^2)$ queries, thus obtaining tight bounds for the sampling complexity of the mean estimation problem. Their bound generalize to $\Omega(1/(\mu\varepsilon^2))$ on the number of queries needed to estimate the mean μ of a random variable in general. Before our work it was thus natural to expect that the $1/\varepsilon^2$ dependence in the number of queries for union volume estimation is optimal. However, whether the factor n is necessary, or the number of queries could be improved to, say, $O(n + 1/\varepsilon^2)$, was open to the best of our knowledge.

Klee's measure problem is an important problem in computational geometry. One reason for its significance is that techniques developed for it can often be adapted to solve various related problems, such as the depth problem (given a set of boxes, what is the largest number of boxes that can be stabbed by a single point?) [13] or Hausdorff distance under translation in L_∞ [14]. Moreover, various other problems can be reduced to Klee's measure problem or to its related problems. For example, deciding whether a set of boxes covers its boundary box can be reduced to Klee's measure problem [13]. The continuous k-center problem on graphs (i.e., finding centers that can lie on the edges of a graph that cover the vertices of a graph) is reducible to Klee's measure problem as well [29]. Finding the smallest hypercube containing at least k points among n given points can be reduced to the depth problem [16, 10, 13]. In light of this, it would be interesting to see if our approximation techniques generalize to any of these related problems.

2 Technical overview

We now sketch our upper and lower bounds at an intuitive level. The formal arguments will be presented in Section 3 and Section 4, respectively. In this paper we denote $[n] := \{1, 2 \dots, n\}$.

2.1 Upper bound for Klee's measure problem

Due to our lower bound, we have to exploit the structure of the input boxes to obtain a running time of the form $O\left((n + \frac{1}{\varepsilon^2}) \cdot \text{polylog}(n)\right)$. We follow the common algorithmic approach of sampling. Specifically, we aim to sample a set S from the union of boxes such that each point is selected with probability density p. For appropriately defined p, the value $|S|/p$ is a good estimate of the volume of the union. In the overview we assume that a proper p is given and focus on the main difficulty: creating a sample set S for the given p.

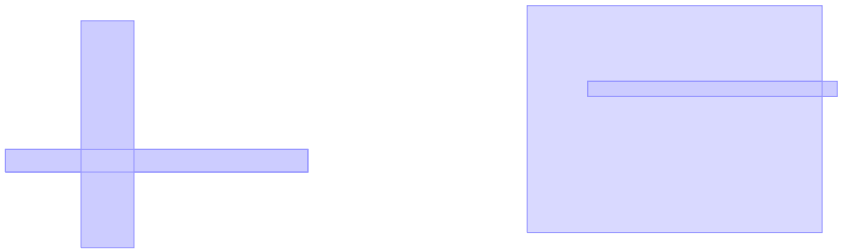

Figure 1 When the side lengths of two boxes differ a lot in at least one of their dimensions (in our examples, the y-axis), their intersection is small compared to their union.

We start by sorting the input boxes into *classes* by shape. Two boxes are in the same class if, in each dimension $k \in [d]$, their side lengths are both in $[2^{L_k}, 2^{L_k+1})$ for some $L_k \in \mathbb{Z}$. We call two classes *similar* if the corresponding side lengths are polynomially related (e.g., within a factor of n^4) in each dimension. We make two crucial observations:

1. Each class is similar to only polylogarithmically many classes (Observation 11).
2. Dissimilar classes have a small intersection compared to their union (Observation 12, Figure 1).

Our algorithm continues as follows. We scan through the classes in an arbitrary order. For each class, we sample with density p from the union of the boxes in this class, but we only keep a point if it is not contained in any class that comes later in the order. To efficiently test containment in a later class, we use an orthogonal range searching data structure (with an additional dimension for the index of the class). When the scan finishes, we obtain a desired sample set S.

Let us elaborate why the algorithm is efficient.

Sampling from a single class. Our approach is simple yet powerful: (i) grid the space into cells of side lengths comparable to the boxes in this class; (ii) sample points from the relevant cells uniformly at random; (iii) discard points outside the union by querying an orthogonal range searching data structure. See Figure 2. All these steps exploit the geometry of boxes. Since the grid cells and boxes have roughly the same shape, a significant fraction of the points sampled in (ii) are contained in the union, i.e., not discarded in (iii). The orthogonal range searching data structure allows us to quickly decide which points to discard. These explain the efficiency of sampling from a class.

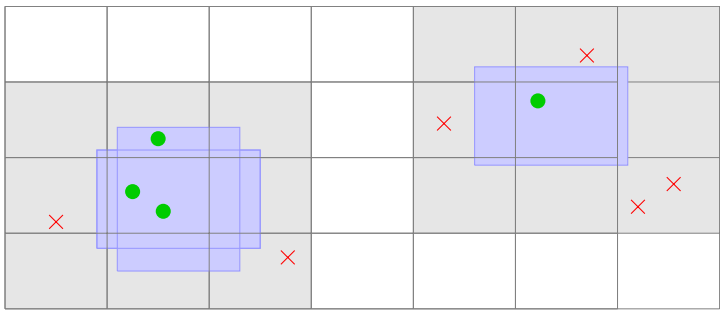

Figure 2 We sample points in the grid cells $\mathcal{G}$ that are intersected by a box $\mathcal{O}_i$ from a fixed class. We then use orthogonal range searching to determine whether a sampled point is in a box from the class and should be kept (•), or is not and should be discarded (×).

Bounding the amount of wasted work. Sampled points that appear in later classes also need to be discarded, and this is a potential (and only) source of inefficiency. So we need to bound the number of them. Such a point shows up later either (i) in a similar class, or (ii) in a dissimilar class. Our first observation stated that a class is similar to at most polylogarithmically many classes. So (i) can happen up to polylogarithmically many times from the perspective of a fixed point in the union. On the other hand, our second observation stated that the intersection of dissimilar classes is small. So on average (ii) rarely happens and does not affect the expected running time significantly.

2.2 Lower bound for union volume estimation

Our lower bound is shown by a reduction from the Query-Gap-Hamming problem: Given two vectors $x, y \in \{-1, +1\}^\ell$, distinguish whether their inner product is greater than $\sqrt{\ell}$ or less than $-\sqrt{\ell}$. It is known that any algorithm distinguishing these two cases with success probability at least $2/3$ must access $\Omega(\ell)$ bits of x and y.

We first sketch why $\Omega(1/\varepsilon^2)$ queries are necessary to $(1+\varepsilon)$-approximate the volume of the union of two objects in the query model. Given a Query-Gap-Hamming instance x, y, we construct two objects $X = \{(j, x_j) : j \in [\ell]\}$ and $Y = \{(j, y_j) : j \in [\ell]\}$. These are discrete point sets, but they can be inflated to polygons such that cardinality corresponds to volume. See Figure 3 for an example. Note that for all $k \in \{0, \dots, \ell\}$, we have

$$|X \cup Y| = \ell + k \iff \langle x, y\rangle = \ell - 2k.$$

If an algorithm $\mathcal{A}$ can $(1+\varepsilon)$-approximate $|X \cup Y|$, then it can approximate k within additive error $2\varepsilon\ell$, thus it can also approximate $\langle x, y\rangle$ within additive error $4\varepsilon\ell$. Setting $\ell = 1/(16\varepsilon^2)$, the additive error is at most $4\varepsilon\ell = 4 \cdot \frac{1}{4\sqrt{\ell}} \cdot \ell = \sqrt{\ell}$, which suffices to distinguish $\langle x, y\rangle = \sqrt{\ell}$ from $\langle x, y\rangle = -\sqrt{\ell}$ and thereby solves the Query-Gap-Hamming instance.

Note that $|X| = |Y| = \ell$, so a volume query does not disclose any information about x and y. Each sample or containment query accesses at most one bit of x or y. Therefore, algorithm $\mathcal{A}$ has to make $\Omega(\ell) = \Omega(1/\varepsilon^2)$ queries to X, Y.

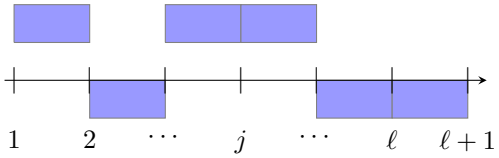

Figure 3 The vector $x = (+1, -1, +1, +1, -1, -1)$ represented as the set $\{(j, x_j) : j \in [6]\}$, where each point is drawn as a rectangle.

In order to generalize this lower bound for the union of two objects to an $\Omega(n/\varepsilon^2)$ lower bound for the union of n objects, we need to ensure that each query gives away only $O(1/n)$ bits of information about x and y. We apply two obfuscations that jointly slow down the exposure of bits; see Figure 4. Firstly, we introduce objects $X_1, \dots, X_n$ whose union is X and objects $Y_1, \dots, Y_n$ whose union is Y. Imagine cutting each X-induced rectangle in Figure 3 into n side-by-side pieces and distributing them randomly among $X_1, \dots, X_n$. Do the same for Y. The idea is that one needs to make $\Omega(n)$ containment queries on the rectangular region in order to hit the correct piece; only then is the corresponding bit revealed. Secondly, we introduce a large band shared by all X_i and Y_i for $i \in [n]$. In Figure 4, this is the long dark-blue rectangle that spans from left to right. Intuitively it enforces $\Omega(n)$ sample queries to obtain a single point that contains any information about x and y.

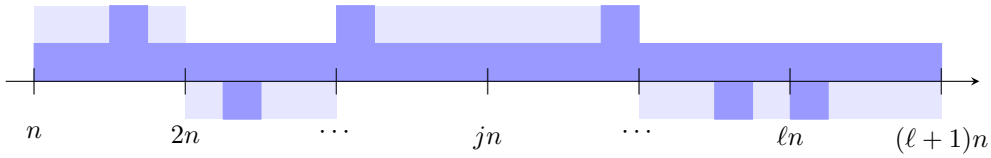

Figure 4 The vector y or $x = (+1, -1, +1, +1, -1, -1)$ gives rise to n polygons; one of these polygons is illustrated in dark blue. The light blue area indicates the union of all these n polygons.

3 Approximation algorithm for Klee's measure problem

In this section, we present our approximation algorithm for Klee's measure problem in constant dimension d:

▶ **Theorem 2.** *There is an algorithm that runs in time* $O\left((n + \frac{1}{\varepsilon^2}) \cdot \log^{2d+1}(n)\right)$ *and with probability at least* 0.9 *computes a* $(1+\varepsilon)$*-approximation for Klee's measure problem.*

Lemmas marked with $\star$ are folklore or straightforward. Their proofs can be found in the full version of this paper [5].

3.1 Preliminaries

In Klee's measure problem we are given *boxes* $O_1, \ldots, O_n \subset \mathbb{R}^d$. Here, a box is an object of the form $O_i = [a_1, b_1] \times \ldots \times [a_d, b_d]$, and as input we are given the coordinates $a_1, b_1, \ldots, a_d, b_d$ of each box. Based on these, it is easy to compute the side lengths and volume of each box.

Throughout we write $V := \text{Volume}(\bigcup_{i=1}^n O_i)$ for the volume of the union of boxes. The goal is to approximate V up to a factor of $1+\varepsilon$. Our approach is based on sampling, so now let us introduce the relevant notions.

Recall the Poisson distribution $\text{Pois}(\lambda)$ with mean and variance λ: It captures the number of active points in a universe, under the assumption that active points occur uniformly and independently at random across the universe, and that λ points are active on average. The following definition is usually referred to as a homogeneous *Poisson point process* at rate p. Intuitively, we activate each point in some universe $U \subset \mathbb{R}^d$ independently with "probability density" p, thus the number of activated points follows the Poisson distribution with mean $p \cdot \text{Volume}(U)$.

▶ **Definition 3** (p-sample)**.** *Let* $U \subset \mathbb{R}^d$ *be a measurable set, and let* $p \in [0,1]$*. We say that a random subset* $S \subseteq U$ *is a* p-sample of U *if for any measurable* $U' \subseteq U$ *we have that* $|S \cap U'| \sim \text{Pois}(p \cdot \text{Volume}(U'))$.

In particular, if S is a p-sample of U, then $|S| \sim \text{Pois}(p \cdot \text{Volume}(U))$. Two more useful properties follow from the definition:

(i) For any measurable subset $U' \subseteq U$, the restriction $S \cap U'$ is a p-sample of U'.

(ii) The union of p-samples of two disjoint sets U, U' is a p-sample of $U \cup U'$.

Besides sampling, we will apply orthogonal range searching to handle the so-called APPEARS(x, i) query: Given $x \in \mathbb{R}^d$ and $i \in \mathbb{N}$, is $x \in O_i \cup \cdots \cup O_n$?

▶ **Lemma 4** ($\star$)**.** *We can build a data structure in* $O(n \log^{d+1}(n))$ *time that answers* APPEARS(x, i) *queries in* $O(\log^{d+1}(n))$ *time.*

For our algorithm to work, we also need a constant-factor approximation of the volume V. It is known that this can be computed in $O(n)$ time [19]. In order to stay simple and self-contained, we state a weaker result by implementing the Karp-Luby algorithm [18] with the help of APPEARS queries.

▶ **Lemma 5** (⋆, adapted from [18]). *Given the data structure from Lemma 4, there exists an algorithm that computes in $O(n \log^{d+1}(n))$ time a 2-approximation to V with probability at least 0.9.*

3.2 Classifying boxes by shapes

As our first step in the algorithm, we classify boxes by their shapes.

▶ **Definition 6.** *Let $L_1, \ldots, L_d \in \mathbb{Z}$. We say that a box $O \subset \mathbb{R}^d$ is of type $(L_1, \ldots, L_d)$ if its side length in dimension k is contained in $[2^{L_k}, 2^{L_k+1})$, for all $k \in [d]$.*

Using this definition, we partition the input boxes $O_1, \ldots, O_n$ into *classes* $C_1, \ldots, C_m$ such that each class corresponds to one type of boxes. The notation is fixed from now on. For each $t \in [m]$, we denote $U_t := \bigcup_{O \in C_t} O \subset \mathbb{R}^d$, namely the union of boxes in class C_t.

Similar to APPEARS, we may use orthogonal range searching to handle the so-called INCLASS(x, t) query: Is a given point $x \in \mathbb{R}^d$ contained in U_t?

▶ **Lemma 7** (⋆). *We can build a data structure in $O(n \log^{d+1}(n))$ time that answers INCLASS(x, t) queries in $O(\log^{d+1}(n))$ time.*

Sampling from a class

The next lemma shows that we can p-sample from any U_t efficiently by rejection sampling.

▶ **Lemma 8.** *Given $t \in [m]$, $p \in [0, 1]$ and the data structure from Lemma 7, one can generate a p-sample of U_t in expected time $O(|C_t| \log |C_t| + p \cdot \text{Volume}(U_t) \cdot \log^{d+1}(n))$.*

Proof. Let $(L_1, \ldots, L_d)$ be the type of class C_t. We subdivide $\mathbb{R}^d$ into the grid

$$\mathcal{G}_\infty := \{[i_1\, 2^{L_1}, (i_1 + 1)\, 2^{L_1}) \times \cdots \times [i_d\, 2^{L_d}, (i_d + 1)\, 2^{L_d}) \mid i_1, \ldots, i_d \in \mathbb{Z}\}.$$

We call each element of $\mathcal{G}_\infty$ a *cell*. Let $\mathcal{G} := \{G \in \mathcal{G}_\infty \mid G \cap U_t \neq \emptyset\}$ be the set of cells that intersect with U_t. Let $U := \bigcup_{G \in \mathcal{G}} G$.

First we create a p-sample S of U as follows. Generate $K \sim \text{Pois}(p \cdot \text{Volume}(U))$, the number of points we are going to include. Then sample K points uniformly at random from U by repeating the following step K times: Select a cell $G \in \mathcal{G}$ uniformly at random and then sample a point from G uniformly at random. The sampled points constitute our set S.

Next we compute $S \cap U_t$: For each $x \in S$, we query INCLASS(x, t); if the answer is true then we keep x, otherwise we discard it. The resulting set $S \cap U_t$ is a p-sample of U_t, since restricting to a fixed subset preserves the p-sample property.

Before we analyze the running time, we show that U_t makes up a decent proportion of U. Recall that every box in class C_t is of type $(L_1, \ldots, L_d)$. Consider the projection to any dimension $k \in [d]$. Each projected box from C_t can intersect at most three projected cells from $\mathcal{G}$. So each box from C_t intersects at most 3^d cells from $\mathcal{G}$, implying that $|\mathcal{G}| \leq 3^d\, |C_t|$. Moreover, since the volume of any cell is at most the volume of a box in C_t, we have $\text{Volume}(U) \leq 3^d\ \text{Volume}(U_t)$.

Recall that we assume d to be constant and hence $3^d = O(1)$. The computation of $\mathcal{G}$ takes $O(|\mathcal{G}| \log |\mathcal{G}|) \subseteq O(|C_t| \log |C_t|)$ time. The remaining time is dominated by the inClass queries. The expected size of S is $p \cdot \text{Volume}(U) \leq 3^d\, p\, \text{Volume}(U_t)$. As we query inClass once for each point of S, the total expected time is $O(p \cdot \text{Volume}(U_t) \cdot \log^{d+1}(n))$ by Lemma 7. ◀

Classes do not overlap much

We show the following interesting property of classes, that the sum of their volumes is within a polylogarithmic factor of the total volume V.

▶ **Lemma 9.** *We have* $\sum_{t=1}^{m} \text{Volume}(U_t) \leq 2^{3d+1} \log^d(n) \cdot V$.

We later exploit it to draw p-samples from $\bigcup_{i=1}^{n} O_i = \bigcup_{t=1}^{m} U_t$ efficiently. Towards proving the lemma, let us collect some simple observations.

▶ **Definition 10.** *We say that a class of type* $(L_1, \ldots, L_d)$ *is* similar *to a class of type* $(L'_1, \ldots, L'_d)$ *if* $2^{|L_k - L'_k|} < n^4$ *for all* $k \in [d]$. *Otherwise they are said to be* dissimilar.

▶ **Observation 11.** *Every class is similar to at most* $8^d \log^d(n)$ *classes.*

Proof. Fix a type $(L_1, \ldots, L_d)$. For each $k \in [d]$, there are at most $8 \log n$ many integers L'_k such that $2^{|L_k - L'_k|} < n^4$. ◀

▶ **Observation 12.** *If two boxes* O, O' *are in dissimilar classes, then* $\text{Volume}(O \cap O') \leq 2V/n^4$.

Proof. Let $(L_1, \ldots, L_d)$ be the type of O, and $(L'_1, \ldots, L'_d)$ be the type of O'. Since the boxes belong to dissimilar classes, there is a dimension $k \in [d]$ such that $2^{|L_k - L'_k|} \geq n^4$. Without loss of generality, assume $2^{L_k - L'_k} \geq n^4$; the other case is symmetric. Let $[a_k, b_k]$ and $[a'_k, b'_k]$ be the projections of O and O' onto dimension k, respectively. Note that $b_k - a_k \in [2^{L_k}, 2^{L_k+1})$ and $b'_k - a'_k \in [2^{L'_k}, 2^{L'_k+1})$. So we have $\frac{b_k - a_k}{b'_k - a'_k} \geq 2^{L_k - (L'_k+1)} \geq n^4/2$. In other words, at most a $2/n^4$ fraction of the interval $[a_k, b_k]$ intersects the interval $[a'_k, b'_k]$. Hence, $\text{Volume}(O \cap O') \leq \text{Volume}(O) \cdot 2/n^4 \leq 2V/n^4$. ◀

Proof of Lemma 9. Without loss of generality assume $\text{Volume}(U_1) \geq \cdots \geq \text{Volume}(U_m)$. We construct a set of indices $T \subseteq [m]$ by the following procedure:

- Initialize $T = \emptyset$.
- For $t = 1, \ldots, m$, if C_t and C_s are dissimilar for all $s \in T$, then add t to T.

For $t \in [m]$, we have $t \notin T$ only if there exists an $s \in T$ such that C_s, C_t are similar and $\text{Volume}(U_s) \geq \text{Volume}(U_t)$; we call s a *witness* of t. If multiple witnesses exist, then we pick an arbitrary one. Conversely, every $s \in T$ can be a witness at most $8^d \log^d(n)$ times by Observation 11. Hence,

$$\sum_{t=1}^{m} \text{Volume}(U_t) \leq 8^d \log^d(n) \cdot \sum_{t \in T} \text{Volume}(U_t). \tag{1}$$

It remains to bound $\sum_{t \in T} \text{Volume}(U_t)$. Consider any distinct $s, t \in T$. By construction, C_s and C_t are dissimilar; and each class contains at most n boxes. So $\text{Volume}(U_s \cap U_t) \leq n^2 \cdot (2V/n^4) = 2V/n^2$ by Observation 12. Using this and inclusion-exclusion, we bound

$$\begin{aligned} \sum_{t \in T} \text{Volume}(U_t) \;&\leq\; \text{Volume}\left(\bigcup_{t \in T} U_t\right) + \sum_{\{s,t\} \subseteq T} \text{Volume}(U_s \cap U_t) \\ &\leq\; V + \binom{m}{2} \frac{2V}{n^2} \;\leq\; 2V. \end{aligned}$$

Plugging this into the right-hand side of Expression (1), we obtain the lemma statement. ◀

3.3 Joining the classes

Recall that $C_1, \ldots, C_m$ are the classes of the input boxes and $U_1, \ldots, U_m$ their respective unions. Assume without loss of generality that the boxes are ordered in accordance with the class ordering, that is, $C_1 = \{O_1, \cdots, O_{i_1}\}$ form the first class, $C_2 = \{O_{i_1+1}, \cdots, O_{i_2}\}$ form the second class, and so on. In general, we assume that $C_t = \{O_{i_{t-1}+1}, \ldots, O_{i_t}\}$ for all $t \in [m]$, where $0 = i_0 < i_1 < \ldots < i_m = n$.

Let $D_t := U_t \setminus (\bigcup_{s=t+1}^{m} U_s)$ be the points in U_t that are not contained in later classes. Note that $D_1, \ldots, D_m$ is a partition of $\bigcup_{t=1}^{m} U_t = \bigcup_{i=1}^{n} O_i$. Hence, to generate a p-sample of $\bigcup_{i=1}^{n} O_i$, it suffices to draw p-samples from each D_t and then take their union.[4] To this end, we draw a p-sample S_t from U_t via Lemma 8. Then we remove all $x \in S_t$ for which $\textsc{appears}(x, i_t + 1) = \text{true}$; these are exactly the points that appear in a later class. What remains is a p-sample of D_t. The union of these sets thus is a p-sample of $\bigcup_{i=1}^{n} O_i$, and we can use the size of this p-sample to estimate the volume V of $\bigcup_{i=1}^{n} O_i$. The complete algorithm is summarized in Algorithm 1.

Algorithm 1 Approximation of Klee's measure.

1. Partition the boxes into classes $C_1, \ldots, C_m$. Relabel the boxes so that their indices are in accordance with the class ordering, i.e., $C_t = \{O_{i_{t-1}+1}, \ldots, O_{i_t}\}$ for all $t \in [m]$.
2. Build the data structures from Lemmas 4 and 7.
3. Obtain a crude estimate $\widetilde{V}$ by Lemma 5. Set $p := 8/(\varepsilon^2 \widetilde{V})$.
4. For $t = 1, \ldots, m$ do:
   - Draw a p-sample S_t from the union $U_t = \bigcup_{O \in C_t} O$ via Lemma 8.
   - Compute $|S'_t|$ where $S'_t := \{x \in S_t : \textsc{appears}(x, i_t + 1) = \text{false}\}$.
5. Output $\sum_{t=1}^{m} |S'_t|/p$.

▶ **Lemma 13.** *Conditioned on $\widetilde{V} \le 2V$, Algorithm 1 outputs a $(1+\varepsilon)$-approximation to V with probability at least $3/4$.*

Proof. Note that for all $t \in [m]$, the set S'_t is a p-sample of D_t. Since $D_1, \ldots, D_m$ partition $\bigcup_{t=1}^{m} U_t = \bigcup_{i=1}^{n} O_i$, their union $\bigcup_{t=1}^{m} S'_t$ is a p-sample of $\bigcup_{i=1}^{n} O_i$. It follows that $N := \sum_{t=1}^{m} |S'_t| \sim \text{Pois}(pV)$. The expectation and variance of N are $pV = 8V/(\varepsilon^2 \widetilde{V}) \ge 4/\varepsilon^2$. So by Chebyshev,

$$\Pr(|N - pV| > \varepsilon pV) \le \frac{\text{Var}[N]}{(\varepsilon pV)^2} \le \frac{1}{4}.$$

Hence, with probability at least $3/4$, the output N/p is a $(1+\varepsilon)$-approximation to V. ◀

▶ **Lemma 14.** *Conditioned on $\widetilde{V} \ge \frac{V}{2}$, Algorithm 1 runs in time $O\left((n + \frac{1}{\varepsilon^2}) \cdot \log^{2d+1}(n)\right)$ in expectation.*

Proof. Step 1 takes $O(n \log n)$ time: we can compute the side lengths of each box, determine its class, then sort the boxes by class index. Step 2 takes $O(n \log^{d+1}(n))$ time by Lemmas 4 and 7. Step 3 takes $O(n \log^{d+1}(n))$ time by Lemma 5.

[4] This idea has previously been used on objects, by considering the difference $D'_i := O_i \setminus (\bigcup_{j=i+1}^{n} O_j)$ [18, 25], while we use this idea on classes.

In step 4, iteration t, sampling S_t costs expected time $O((i_t - i_{t-1})\log(i_t - i_{t-1}) + p\,\text{Volume}(U_t)\cdot\log^{d+1}(n))$ by Lemma 8, and computing S'_t costs expected time $O((1 + p\,\text{Volume}(U_t))\cdot\log^{d+1}(n))$ by Lemma 4. Over all iterations, the expected running time is

$$O\left(\log^{d+1}(n)\cdot\left(n + p\sum_{t=1}^{m}\text{Volume}(U_t)\right)\right).$$

Substituting $p = 8/(\varepsilon^2\tilde{V}) \le 16/(\varepsilon^2 V)$ and applying Lemma 9, we can bound

$$p\sum_{t=1}^{m}\text{Volume}(U_t) \le \frac{16}{\varepsilon^2 V}\sum_{t=1}^{m}\text{Volume}(U_t) \le \frac{2^{3d+5}\log^d(n)}{\varepsilon^2}.$$

Hence the expected running time of step 4 is $O\left(\log^{2d+1}(n)\cdot(n + \frac{1}{\varepsilon^2})\right)$.

Finally, step 5 takes $O(n)$ time. ◀

Proof of Theorem 2. Run Algorithm 1 with a time budget tenfold the bound in Lemma 14; abort the algorithm as soon as it spends more time than the budget allows. So the stated time bound is clearly satisfied. Now consider three bad events:

- $\widetilde{V} \notin [\frac{V}{2}, 2V]$.
- $\widetilde{V} \in [\frac{V}{2}, 2V]$, but the algorithm is aborted.
- $\widetilde{V} \in [\frac{V}{2}, 2V]$ and the algorithm is not aborted, but it does not output a $(1+\varepsilon)$-approximation to V.

By Lemma 5, the first event happens with probability at most 0.1. By Lemma 14 and Markov's inequality, the second event happens with probability at most 0.1. Lastly, by Lemma 13, the third event happens with probability at most 1/4. So the total error probability is at most $0.1 + 0.1 + \frac{1}{4} = \frac{9}{20}$. If none of the bad events happen, then the algorithm correctly outputs a $(1+\varepsilon)$-approximation to V. The success probability of $\frac{11}{20}$ can be boosted to, say, 0.9 by returning the median of a sufficiently large constant number of repetitions. ◀

4 Lower bound for union volume estimation

In this section, any randomized algorithm or protocol is assumed to have success probability at least 2/3. We consider the discrete version of union volume estimation in two dimensions, where each object O_i is a finite subset of the integer lattice $\mathbb{Z}^2$. The goal is to $(1+\varepsilon)$-approximate the cardinality $|O_1 \cup \ldots \cup O_n|$ of their union. The algorithm does not have direct access to the objects, but it can ask three forms of queries:

- Volume(O_i): Return the cardinality $|O_i|$.
- Sample(O_i): Draw a uniform random point from O_i.
- Contains($(a,b), O_i$): Given a point $(a,b) \in \mathbb{Z}^2$, return whether $(a,b) \in O_i$ or not.

We aim to prove that $\Omega(n/\varepsilon^2)$ queries are necessary. Later in Section 5 we translate this to a lower bound in the continuous space $\mathbb{R}^2$, thereby proving Theorem 1.

Our starting point is the Query-Gap-Hamming problem: The inputs are two (hidden) vectors $x, y \in \{-1,1\}^\ell$ and we can access one bit of x or y of our choice at a time. The goal is to distinguish the cases $\langle x, y\rangle \ge \sqrt{\ell}$ and $\langle x, y\rangle \le -\sqrt{\ell}$ using as few accesses as possible. The following lemma is folklore; its proof can be found in the full version of this paper [5].

▶ **Lemma 15 (⋆).** *There exists a constant $\delta \in (0,1)$ with the following property. For every $\ell \in \mathbb{N}$, any randomized algorithm for Query-Gap-Hamming on vectors of length ℓ needs at least $\delta\ell$ accesses in expectation.*

From now on, let us fix the constant $\delta \in (0,1)$ guaranteed by Lemma 15. Let $n \in \mathbb{N}$, $\varepsilon \in (0,1)$ be arbitrary and define $\ell := \frac{1}{36\varepsilon^2}$. We reduce Query-Gap-Hamming on vectors of length ℓ to estimating the cardinality of the union of $2n$ objects in $\mathbb{Z}^2$.

The reduction

From the hidden vectors $x, y \in \{-1,1\}^\ell$ we construct $2n$ objects $X_1, \ldots, X_n, Y_1, \ldots, Y_n \subset \mathbb{Z}^2$. Let $R := \{(n+1, 0), \ldots, (n\ell + n, 0)\}$. Take independent random permutations $\pi_1, \ldots, \pi_\ell$ of $[n]$ and define

$$X_i := R \cup \{(jn + \pi_j(i), x_j) : j \in [\ell]\}$$

for $i \in [n]$. Then take another set of independent random permutations $\tau_1, \ldots, \tau_\ell$ and define

$$Y_i := R \cup \{(jn + \tau_j(i), y_j) : j \in [\ell]\}$$

for $i \in [n]$. Note that R is a subset of all X_i and Y_i.

How is $\langle x, y\rangle$ related to the cardinality of the union $|X_1 \cup \cdots \cup X_n \cup Y_1 \cup \cdots \cup Y_n|$? Consider an arbitrary index $j \in [\ell]$. If $x_j = y_j$ then the point sets $\{(jn + \pi_j(i), x_j) : i \in [n]\}$ and $\{(jn + \tau_j(i), y_j) : i \in [n]\}$ are equal (regardless of the concrete permutations), so they together contribute n to the cardinality of the union. On the other hand, if $x_j \neq y_j$ then they are disjoint and thus contribute $2n$. Furthermore, the point set R is contained in all objects and contributes $n\ell$. Hence, the cardinality of the union is equal to

$$n\ell + \sum_{j : x_j = y_j} n + \sum_{j : x_j \neq y_j} 2n = \frac{5}{2} n\ell - \frac{1}{2} n \cdot \left(\sum_{j : x_j = y_j} 1 + \sum_{j : x_j \neq y_j} (-1) \right) = \frac{5}{2} n\ell - \frac{1}{2} n \langle x, y \rangle.$$

Suppose we get a $(1+\varepsilon)$-approximation ρ to the cardinality of the union, then

$$\rho \in \left[(1-\varepsilon)(\tfrac{5}{2} n\ell - \tfrac{1}{2} n\langle x, y\rangle),\ (1+\varepsilon)(\tfrac{5}{2} n\ell - \tfrac{1}{2} n\langle x, y\rangle) \right].$$

Since $|\langle x, y\rangle| \leq \ell$, by computing $(\frac{5}{2} n\ell - \rho) \cdot \frac{2}{n}$ we obtain a value in $\langle x, y\rangle \pm 6\varepsilon\ell$, that is, an additive $6\varepsilon\ell$ approximation to $\langle x, y\rangle$. Our choice of $\varepsilon = \frac{1}{6\sqrt{\ell}}$ allows to distinguish $\langle x, y\rangle \geq \sqrt{\ell}$ from $\langle x, y\rangle \leq -\sqrt{\ell}$.

The reduction is not yet complete. The catch is that an algorithm for union volume estimation can only learn about the objects via queries. It is left to *us* to answer those queries. In Algorithm 2 we describe how to answer queries on object X_i. Queries on object Y_i can be handled similarly by replacing π_j with τ_j and x_j with y_j. The correctness is easy to verify, and this completes the reduction. So far, the argument works for arbitrary permutations; randomness becomes relevant when we bound the number of bit accesses.

Algorithm 2 Answering queries.

- For query Volume(X_i): Return $(n+1)\ell$.
- For query Sample(X_i): Draw a random block $j \in [\ell]$ and a random shift $s \in [n]$. With probability $1 - \frac{1}{n+1}$ return $(jn + s, 0)$. Otherwise return $(jn + \pi_j(i), x_j)$.
- For query Contains($(a,b), X_i$): If $(a,b) \in R$ then return true. Else, compute $j := \lfloor a/n \rfloor$ and $s := a - jn$. If $j \notin [\ell]$ or $\pi_j(i) \neq s$ then return false. Otherwise, if $x_i = b$ then return true; else return false.

Bounding the number of accesses

Now for the sake of contradiction, suppose there exists a randomized algorithm $\mathcal{A}$ that $(1+\varepsilon)$-approximates the cardinality of the union of any $2n$ objects in $\mathbb{Z}^2$, using less than $\frac{\delta}{360\cdot 2^{9/\delta}} \cdot \frac{n}{\varepsilon^2}$ queries. We run $\mathcal{A}$ on the objects defined earlier (using Algorithm 2 to handle its queries). From the output, we can distinguish $\langle x, y\rangle \geq \sqrt{\ell}$ and $\langle x, y\rangle \leq -\sqrt{\ell}$. We claim that less than $\delta\ell$ bits of x, y are accessed from the side of Algorithm 2.

To this end, note that accesses to x, y only happen in the "otherwise" clauses of Sample() and Contains() in Algorithm 2. For analysis we isolate the following mini game:

▶ **Lemma 16.** *Consider a game of $m := \lfloor 2^{-9/\delta} n \rfloor$ rounds. At the start, Merlin generates a secret random permutation π of $[n]$. In each round, Arthur adaptively sends one of the following two requests to Merlin:*

- Random()*: Answer "yes" with probability $\frac{1}{n+1}$ and "no" with the remaining probability.*
- Probe(i, s)*: Answer "yes" if $\pi(i) = s$ and "no" otherwise.*

No matter what strategy Arthur employs, the probability that Merlin ever answers "yes" in the game is at most $2\delta/5$.

Proof. Let E be the event that Merlin ever answers "yes" *and* the first one was due to a Random() request. Let F be the event that Merlin ever answers "yes" *and* the first one was due to a Probe() request. We will bound $\Pr(E)$ and $\Pr(F)$ separately.

To bound $\Pr(E)$, define events $E_1, \ldots, E_m$ where E_t indicates that Arthur's t-th request is Random() and the answer is "yes". Clearly $\Pr(E_t) \leq \frac{1}{n+1}$, thus $\Pr(E) \leq \sum_{t=1}^{m} \Pr(E_t) \leq \frac{m}{n+1} < 2^{-9/\delta} < \delta/15$.

To bound $\Pr(F)$ we use an entropy argument. In particular, we will describe and analyze an encoding scheme for a random permutation π of $[n]$.

The encoder receives π and acts as Merlin in the game, using π as the secret permutation. It interacts with Arthur till the end of the game. If F does not happen then the encoding is simply a bit `0` followed by π. On the other hand, if F happens, then consider the first round $T \in [m]$ when "yes" appeared; denote that request by Probe(i, s). The encoding starts with a bit `1`, then the number T, and finishes with the ordering π' of $[n] \setminus \{i\}$ induced by π.

The decoder receives the encoding and tries to reconstruct π. First it reads the leading bit of the encoding. If the bit is `0` then π immediately follows. If the bit is `1` then the decoder recovers the number T. It pretends to be Merlin and starts a game with Arthur, using the same random tape as the encoder but without knowledge of π. For the first $T-1$ requests it just answers "no" to Arthur. Now comes the T-th request from Arthur, which must be a Probe(i, s) request with answer "yes". This allows the decoder to deduce $\pi(i) = s$. The remaining entries in π can be fully restored from π'.

Writing $p := \Pr(F)$, the encoding length is at most

$$\begin{aligned}
&(1-p)\Big(1 + \lceil \log(n!) \rceil\Big) + p\Big(1 + \lceil \log(m) \rceil + \lceil \log((n-1)!) \rceil\Big) \\
<&(1-p)\big(\log(n!) + 3\big) + p\big(\log(n) - 9/\delta + \log((n-1)!) + 3\big) \\
=&\log(n!) + 3 - 9p/\delta.
\end{aligned}$$

where we used $m := \lfloor 2^{-9/\delta} n \rfloor$ in the second line. Since the encoding length must be at least the Shannon entropy $\log(n!)$ of the encoded permutation π, we conclude that $\Pr(F) = p \leq \delta/3$.

Putting the two bounds together, we have $\Pr(E \cup F) \leq \Pr(E) + \Pr(F) \leq 2\delta/5$. ◀

Where does the game come into play? The reader might find it useful to recall Figure 4. The space $\mathbb{Z}^2$ is split into ℓ blocks horizontally, where each block $j \in [\ell]$ holds information about the j-th bit of the input vector. Let us focus on a particular block j. As $\mathcal{A}$ runs, some of

its queries "hit" this block while others don't. Precisely, we say that a Sample(X_i) query *hits* j if the random block chosen in Algorithm 2 is j. Likewise, we say that a Contains($(a,b), X_i$) query *hits* j if $\lfloor a/n \rfloor = j$. Now we restrict ourselves to the queries hitting j and ignore all the others. Then, over time, $\mathcal{A}$ (as Arthur) is exactly playing the game with us (as Merlin) on the secret permutation π_j: Sample() queries correspond to Random() requests; Contains() queries correspond to Probe() requests; Algorithm 2 branches to the "otherwise" clauses if and only if the answer is "yes". Whatever information $\mathcal{A}$ collects in the queries hitting other blocks j', it has no effect on the decision in this game, as all other permutations are independent of π_j, and as x, y do not play a role in this game.

With this in mind, let random variable N_j count the number of queries hitting j. Define

$$J := \{j \in [\ell] : x_j \text{ is accessed and } N_j \le m\} \quad \text{and} \quad J' := \{j \in [\ell] : N_j > m\}.$$

where $m := \lfloor 2^{-9/\delta} n \rfloor$. By Lemma 16, $\Pr(j \in J) \le 2\delta/5$ for every $j \in [\ell]$, so $\mathbb{E}[|J|] \le 2\delta\ell/5$. On the other hand, by definition of J' and our assumption that the number of queries is at most $\frac{\delta}{360 \cdot 2^{9/\delta}} \cdot \frac{n}{\varepsilon^2}$, we can bound

$$|J'| < \frac{1}{m+1} \cdot \frac{\delta}{360 \cdot 2^{9/\delta}} \cdot \frac{n}{\varepsilon^2} \le \frac{\delta\ell}{10}.$$

So Algorithm 2 accesses less than $\frac{2\delta\ell}{5} + \frac{\delta\ell}{10} = \frac{\delta\ell}{2}$ bits of x in expectation. Symmetrically, the same bound holds for y. Altogether it accesses less than $\delta\ell$ bits of x, y. But as we argued, the output can be used to distinguish $\langle x, y\rangle \ge \sqrt{\ell}$ and $\langle x, y\rangle \le -\sqrt{\ell}$. This contradicts Lemma 15.

5 Reduction from discrete to continuous space

Union volume estimation and Klee's measure problem were formulated in the continuous space $\mathbb{R}^d$. Their analogs in discrete space $\mathbb{Z}^d$ are only simpler due to the following reduction. Consider the natural embedding φ that blows up each point $x = (x_1, \ldots, x_d) \in \mathbb{Z}^d$ into a continuous cube $\varphi(x) = [x_1, x_1 + 1] \times \cdots \times [x_d, x_d + 1] \subset \mathbb{R}^d$. For any finite subset $X \subset \mathbb{Z}^d$, denote its image by $\varphi(X) \subset \mathbb{R}^d$. We have:

- Volume($\varphi(X)$) $= |X|$.
- To sample from $\varphi(X)$ uniformly, we can first sample $x \in X$ uniformly and then sample from $\varphi(x)$ uniformly.
- If X is a discrete box then $\varphi(X)$ is a continuous box, and vice versa.

Given this correspondence, our algorithm for Klee's measure problem can be made to handle discrete boxes in $\mathbb{Z}^d$. On the other hand, the discrete objects in our lower bound construction can be realized as axis-aligned polygons in $\mathbb{R}^2$.

Abstract

Given a point set P in the Euclidean space, a geometric t-spanner G is a graph on P such that for every pair of points, the shortest path in G between those points is at most a factor t longer than the Euclidean distance between those points. The value $t \geq 1$ is called the dilation of G. Commonly, the aim is to construct a t-spanner with additional desirable properties. In graph theory, a powerful tool to admit efficient algorithms is bounded tree-width. We therefore investigate the problem of computing geometric spanners with bounded tree-width and small dilation t.

Let d be a fixed integer and $P \subset \mathbb{R}^d$ be a point set with n points. We give a first algorithm to compute an $\mathcal{O}(n/k^{d/(d-1)})$-spanner on P with tree-width at most k. The dilation obtained by the algorithm is asymptotically worst-case optimal for graphs with tree-width k: We show that there is a set of n points such that every spanner of tree-width k has dilation $\mathcal{O}(n/k^{d/(d-1)})$. We further prove a tight dependency between tree-width and the number of edges in sparse connected planar graphs, which admits, for point sets in $\mathbb{R}^2$, a plane spanner with tree-width at most k and small maximum vertex degree.

Finally, we show an almost tight bound on the minimum dilation of a spanning tree of n equally spaced points on a circle.

1 Introduction

Geometric spanners are an extensively studied area in computational geometry, see [7, 23] for surveys. A geometric spanner for a point set $P \in \mathbb{R}^d$ is a weighted graph on P, where the weight of an edge is the Euclidean distance between its endpoints, aiming for sparsity while avoiding long paths between two points in P. This is formalised by the dilation $t = \max\left\{\frac{d(p,p')}{|pp'|} \mid p, p' \in P\right\}$, where $d(p, p')$ is the distance between two points in G and $|pp'|$ is the Euclidean distance between p and p'. A geometric spanner with dilation at most t is also called a *t-spanner*.

When geometric spanners were introduced in 1986 [12], sparsity was obtained by requiring planarity. Since then, plane geometric spanners have been widely studied [7]. But also other measures are of interest: Especially spanners with a linearly bounded number of edges or a bounded vertex degree have been widely researched [20, 23, 30, 18, 6, 14, 19, 5].

In graph theory, an important tool to design efficient algorithms for in general NP-hard problems is to restrict these problems to graphs which are bounded in certain parameters. Especially graphs with bounded *tree-width* [25, 26] allow polynomial-time algorithms for many in general NP-hard problems using a dynamic programming algorithm on the tree decomposition. By Courcelle's Theorem, every problem that is describable in monadic second

order logic with vertex and edge quantification is solvable in polynomial time for graphs with bounded tree-width [13]. Thus, geometric spanners with bounded tree-width would allow polynomial time solutions for many in general NP-hard problems and thus be a strong tool for many geometric applications. For instance, Cabello and Knauer [9] recently gave some examples for efficient algorithms for geometric problems on graphs with bounded tree-width. They show that via orthogonal range searching, for graphs of n vertices and tree-width k with $k \geq 3$, the sum of the distances between all pairs of vertices can be computed in $\mathcal{O}(n \log^{k-1} n)$ time. Further, they show that the dilation of a geometric graph of bounded tree-width can be computed in $\mathcal{O}(n \log^{k+1} n)$ time. That makes it possible to compute the dilation of every tree-width bounded graph, but does not lead to tree-width bounded spanners with low dilation. In [8], Cabello shows how to compute the inverse geodesic length in graphs of bounded tree-width. Further, Cabello and Rote [10] show how to compute obnoxious centers in graphs with bounded tree-width in $\mathcal{O}(n \log n)$ time.

Therefore, we aim to construct spanners with bounded tree-width. There are spanners with sublinear tree-width. More specifically, since planar graphs have tree-width $\mathcal{O}(\sqrt{n})$ [22] (where n is the number of vertices), for point sets in the Euclidean plane, constant dilation spanners with tree-width $\mathcal{O}(\sqrt{n})$ can be obtained by plane spanner approaches such as the Delaunay triangulation or the greedy triangulation. For point sets in $\mathbb{R}^d$, we point out that the greedy spanner has tree-width $\mathcal{O}(n^{1-1/d})$, using separator results from [21].

While this gives some first results, constructing spanners with tree-width $k \in o(n^{1-1/d})$ will require other constructions. The only known construction for small tree-width and a guarantee on the dilation is the Euclidean minimum spanning tree: it has tree-width $k = 1$ and worst-case dilation $n - 1$.

We present a first algorithm that provides a trade-off between tree-width and the dilation:

▶ **Theorem 1.** *Given a set $P \subset \mathbb{R}^d$ of n points for some fixed d and a positive integer $k \leq n^{1-1/d}$. There is a geometric spanner of tree-width k on P with a dilation of $\mathcal{O}\left(n/k^{d/(d-1)}\right)$ and bounded degree that can be computed in time $\mathcal{O}(n^2 \log n)$.*

We complement our result with a matching lower bound.

▶ **Theorem 2.** *Let $d \geq 2$ be a fixed integer. For positive integers n and $k \leq n^{(d-1)/d} \cdot (5d)^{1/d-2}$ there is a set of n points in $\mathbb{R}^d$, so that every geometric spanner of tree-width k on this set has dilation $\Omega\left(n/k^{d/(d-1)}\right)$.*

This proves that our algorithm for Theorem 1 has a worst-case optimal trade off between tree-width and dilation. We therefore now turn our attention to bounded tree-width spanners with an additional property. The most commonly studied property of geometric spanners is planarity.

For point sets in the Euclidean plane, we can adapt the construction of the spanner for Theorem 1 to obtain a planar spanner with bounded tree-width (and bounded degree), that is not necessarily plane. As a general tool to obtain bounded tree-width plane spanners, we provide the following strong dependency between tree-width and the number of edges in sparse connected planar graphs:

▶ **Theorem 3.** *Let G be a planar connected graph with n vertices and $n + \lfloor (k-1)^2/72 \rfloor$ edges, where $k \geq 2$ is an integer. The tree-width of G is at most k.*

This result is quite surprising, since for non-planar graphs, arbitrarily placed edges increase the tree-width linearly in the number of added edges, as there are graphs with m edges and tree-width at least $m \cdot \varepsilon$ for a constant ε [17].

It further yields an alternative proof for Theorem 1 for $d = 2$, creating a bounded tree-width spanner with additional properties:

▶ **Corollary 4.** *Given a set $P \subset \mathbb{R}^2$ of n points and some positive integer $k \leq 12\sqrt{n-3}$, a plane spanner with tree-width k, maximum vertex degree 4 and dilation $\mathcal{O}(n/k^2)$ can be constructed in $\mathcal{O}(n \log n)$ time.*

This follows immediately using an adapted version of the algorithm provided in [3]: Instead of the Delaunay triangulation, use a plane constant dilation spanner with maximum vertex degree 4, as provided in [19] and the MST of this spanner instead of the EMST.

In the last section, we answer an open question stated in [3] by giving some smaller results for spanners of bounded tree-width on points in convex position. In particular, we show that, for point sets P which are equally spaced on a circle, there is a tree spanner with dilation $\leq \frac{2n}{\pi} + \frac{\pi}{2n}$. This complements a lower bound given in [3]. Further, since plane spanners on points in convex position are outerplanar, there is a 1.88-spanner of tree-width 2 for P. Further, we give a (straight-forward) lower bound: There are sets of points in convex position on which every spanner of tree-width 2 has dilation at least 1.43.

2 Preliminaries

We start giving some preliminary definitions to clarify the notations we use later on.

In this paper, all graphs G are simple and undirected. We refer to the vertex set of G by $V(G)$ and to the edge set of G by $E(G)$. Euclidean graphs are complete and weighted and the edge weight is given by the Euclidean distance of the incident vertices. We denote the *degree* of a vertex $v \in V(G)$ by $\Delta_G(v)$ and the *maximum vertex degree* of a graph by $\Delta(G)$. By K_n we denote the complete graph on n vertices.

A *Euclidean 2-dimensional $n \times n$-grid* is defined as a graph on the point set $\{0, \dots, n-1\} \times \{0, \dots, n-1\}$ in $\mathbb{R}^2$. We call two vertices (x, y) and (x', y') *neighbouring*, if $|x-x'|+|y-y'| = 1$. The edge set of the $n \times n$ grid is then $\{\{(x, y), (x', y')\} \mid (x, y)$ and (x', y') are neighbouring$\}$.

A *Euclidean d-dimensional n^d-grid* is defined as a graph on the point set $\{0, \dots, n-1\}^d$. Here, two vertices $(x_1, \dots, x_d)$ and $(x'_1, \dots, x'_d)$ are called *neighbouring* if $|x_1 - x'_1| + \dots + |x_d - x'_d| = 1$. The edge set of the n^d grid is then $\{\{(x_1, \dots x_d), (x'_1, \dots, x'_d)\} \mid (x_1, \dots x_d)$ and $(x'_1, \dots x'_d)$ are neighbouring$\}$.

We use a standard definition of tree-width [26] in the following notation: A *tree decomposition* (T, X) is a tree T over a set of nodes I and a mapping $X : I \to 2^V$, where $X(i)$ is called the *bag* of i, so that the following conditions hold:

1. $\bigcup_{i \in I} X(i) = V$
2. $\bigcup_{i \in I} E(i) = E$ where $E(i) = \{\{u, v\} \in E \mid u, v \in X(i)\}$
3. If $v \in X(i)$ and $v \in X(k)$ for some $i, k \in I$ then $v \in X(j)$ holds for every j on the path in T between i and k.

The *width* of a tree decomposition is defined as $\max_{i \in I} |X(i)| - 1$. The *tree-width* $\mathrm{tw}(G)$ of G is the minimum width over all tree decompositions of G.

A minor of a graph can be obtained by subgraph operations and edge contractions. As, however, edge contractions in general do not maintain any properties of the embedding, which is essential for geometric graphs, we give the definition of contracting one vertex to another: For a graph G, *contracting vertex u* to v or equivalently *contracting vertex u* along e, we create a minor $G' = (V', E')$ of G with $V' = V \setminus \{u\}$ and $E' = \{\{u', v'\} \mid u', v' \in V', \{u', v'\} \in E\} \cup \{\{u', v\} \mid u' \neq v, \{u', u\} \in E\}$. Note that this is just another way of defining an edge contraction. Given a graph $G = (V, E)$, some vertex $v \in V$ and a path

$\gamma = v, v_2, ..., v_\ell$ inside G, we define the *path contraction* of γ to v to be the series of vertex contractions starting with the contraction of v_2 to v up to the contraction of v_ℓ to v. A graph H is a *minor* of G if it can be obtained by vertex contractions and subgraph operations. A class of graphs $\mathcal{G}$ is considered *minor closed* if every minor H of a graph $G \in \mathcal{G}$ is also in $\mathcal{G}$.

A *t-balanced separator* of size s of a graph G is an edge set $S \subseteq V(G)$, $|S| = s$ such that $V - S$ can be partitioned into two sets A and B with no edges between the vertices of A and B and $|A| \leq t \cdot |V|$ as well as $|B| \leq t \cdot |V|$. If $t = \frac{2}{3}$, we call S a *separator* of G.

3 Bounded tree-width spanners in higher dimensions

In this section, we present an algorithm for constructing bounded tree-width spanners for points in $\mathbb{R}^d$ for constant dimension d. As we will see later on, the trade-off between tree-width and dilation of this spanner is worst-case optimal.

The algorithm makes use of two ingredients: a Euclidean minimum spanning tree ($\mathcal{EMST}$) and a class of spanners with sublinear tree-width. For $d = 2$ a class of planar spanners can be used (and will be used in Section 5). For general d we can use the greedy spanner [2] instead.

▶ **Lemma*** **5.** *Let $P \subset \mathbb{R}^d$ be a set of n points and G the greedy 3/2-spanner of P. G has tree-width at most $15\eta_d c_d 8^d \cdot n^{1-1/d}$, where η_d is the packing constant in d-dimensional Euclidean space and $c_d \leq 2^{\mathcal{O}(d)}$ is a constant.*

The following algorithm computes a bounded tree-width spanner. The constant C is defined as $C = 30\eta_d c_d 8^d$.

Algorithm 1 d-`DimensionalBoundedTreeWidthSpanner`(P, k).

Require: a set of n points $P \subset \mathbb{R}^d$ and a natural number $k \leq n^{1-1/d}$
Ensure: an $\mathcal{O}(n \cdot k^{d/(1-d)})$-spanner $G = (P, E)$ of tree-width k

1: $\mathcal{EMST} \leftarrow$ Euclidean minimum spanning tree of P
2: **if** $k = 1$ **then**
3: **return** $\mathcal{EMST}$
4: $m \leftarrow \left\lceil (k/C)^{d/(d-1)} + 1 \right\rceil$
5: Compute a set $\mathcal{T}$ of m disjoint subtrees of $\mathcal{EMST}$, each containing $\mathcal{O}(n/m)$ points, as explained in the proof of Lemma 9.
6: For $T \in \mathcal{T}$ let $R(T)$ be the vertices in T incident to edges removed by the previous step.
7: For each $T \in \mathcal{T}$ iterate through its edges e from long to short. If e lies on a path between two vertices in $R(T)$, remove the edge. Let $E'(T)$ be the set of remaining edges.
8: $E' \leftarrow \bigcup_{T \in \mathcal{T}} E'(T)$
9: $(R, E'') \leftarrow$ greedy 3/2-spanner for $R = \bigcup_{T \in \mathcal{T}} R(T)$
10: **return** $G = (P, E' \cup E'')$

We now start with a detailed description on how the subtrees (line 5) are constructed. The following is a folklore result and is for instance mentioned in [22].

▶ **Fact*** **6.** *For any tree T on n vertices there is a separator vertex that splits T into subtrees each at most of size $n/2$ and can be found in time $\mathcal{O}(n)$.*

* The proofs of the results marked with $*$ can only be found in the full version due to space restrictions.

Considering the separator vertex v and its edges, we observe that one of the by removal of v induced subtrees must have size at least $n \cdot 1/\Delta(v)$. Let e be the edge that connects v to this subtree. Then, e separates the tree into one subtree of size at least $n \cdot 1/\Delta(v)$, this being the aforementioned subtree, and one of size at most $n \cdot (\Delta(v) - 1)/\Delta(v)$.

▶ **Lemma 7.** *For any tree T of degree Δ with n vertices there is a separator edge, that separates T into two subtrees, one of size at least $n \cdot 1/(\Delta + 1)$ and one of size at most $n \cdot \Delta/(\Delta + 1)$. This edge can be found in time $\mathcal{O}(n)$.*

This result can be extended as follows:

▶ **Lemma 8.** *Given a tree T of degree Δ, that has n vertices and some integer $m \geq 1$, there is a set of $m - 1$ edges of T, whose removal lead to m disjoint subtrees of size $\mathcal{O}(n/m)$. This set of edges can be found in time $\mathcal{O}(n(\Delta + 1)(\log m + \log(\Delta + 1)))$.*

Proof sketch. By Lemma 7 for any tree of size n there is always an edge, whose removal splits the tree into one subtree of size at most $n \cdot \Delta/(\Delta+1)$ and one of size at least $n \cdot 1/(\Delta+1)$. The idea now is to split subtrees until their sizes are sufficiently small. So given a tree on n vertices and some $m \in \mathbb{N}$, we keep splitting the largest subtrees until there is no subtree of size more than $(\Delta + 1) \cdot n/m$ left. Note that this procedure can only lead to subtrees as small as n/m and therefore only to at most m subtrees. To obtain exactly m subtrees we can simply continue splitting the largest remaining subtrees until the number of subtrees is exactly m. The subtrees are now at least of size $n/((\Delta + 1) \cdot m)$ and at most of size $(\Delta + 1) \cdot n/m$ and therefore of size $\mathcal{O}(n/m)$. For the running time, we refer to the full version of the paper. ◀

Since the $\mathcal{EMST}$ is of constant degree, we obtain the following corollary:

▶ **Lemma 9.** *Given the $\mathcal{EMST}$ of n points in $\mathbb{R}^d$ and some integer $m \geq 1$, there is a set of $m - 1$ edges of T, whose removal lead to m disjoint subtrees of size $\mathcal{O}(n/m)$. This set of edges can be found in time $\mathcal{O}(n \log m)$.*

We call a vertex a *representative* of a subtree $T \in \mathcal{T}$ if it was incident to an edge of the $\mathcal{EMST}$ that was removed in the construction of Lemma 8. While bounding the dilation of the spanner requires more work, we can already derive the running time and tree-width.

▶ **Lemma 10.** *Algorithm 1 constructs in $\mathcal{O}(n^2 \log n)$ time a graph with tree-width $\leq k$ and bounded degree.*

Proof. The greedy spanners in line 9 of the algorithm can be computed in $\mathcal{O}(n^2 \log n)$ time [6]. The $\mathcal{EMST}$ can be computed in subquadratic time [1], and all remaining steps take $\mathcal{O}(n \log n)$ time. The greedy t-spanner and the $\mathcal{EMST}$ both have bounded degree for fixed dimension (and t) [27, 23].

The set of representatives of all subtrees has size at most $2m - 2$, since each representative is incident to at least one of the $m - 1$ edges removed. Thus, $\mathcal{GS}$ is the greedy spanner of at most $2m - 2$ points. By Lemma 5 and the choice of the constant C the tree-width of $\mathcal{GS}$ is at most k. After line 7 of the algorithm each of the subtrees of the subtrees $T \in \mathcal{T}$ contains only one representative. Thus, the graph G consists of $\mathcal{GS}$ with a tree attached to each of its vertices. These trees do not increase the tree-width, since every tree contains only one vertex from $\mathcal{GS}$. Thus the tree-width of G is k. ◀

Next we bound the dilation of the computed spanner.

▶ **Lemma*** **11.** *Given a set $P \subset \mathbb{R}^d$ of n points for some fixed d and a positive integer $k \leq n^{1-1/d}$, Algorithm 1 computes an $\mathcal{O}(n/k^{d/(d-1)})$-spanner for P.*

Proof idea. First ignore that we removed edges in line 7. For two points p, q in the same subtree the dilation is small, since the edges of the path between p and q in the $\mathcal{EMST}$ are short, and since the path contains only few edges. For points in different subtrees the path in the $\mathcal{EMST}$ contains a representative of each of the two subtrees. We can take the paths to these representatives and between the representatives the greedy spanner.

Removing edges in line 7 complicates the argument, but we can use the lengths of the edges removed to bound the distances to the representatives. ◀

From the previous lemmas we now directly obtain the main result of this section.

▶ **Theorem 1.** *Given a set $P \subset \mathbb{R}^d$ of n points for some fixed d and a positive integer $k \leq n^{1-1/d}$. There is a geometric spanner of tree-width k on P with a dilation of $\mathcal{O}\left(n/k^{d/(d-1)}\right)$ and bounded degree that can be computed in time $\mathcal{O}(n^2 \log n)$.*

4 Lower bound

In the previous section it was shown that Algorithm 1 gives an upper bound for the dilation of tree-width bounded spanners. In this section, we investigate corresponding lower bounds. We show that the bound given in Theorem 1 for the dilation of a tree-width bounded spanner on Euclidean point sets is asymptotically tight:

▶ **Theorem 2.** *Let $d \geq 2$ be a fixed integer. For positive integers n and $k \leq n^{(d-1)/d} \cdot (5d)^{1/d-2}$ there is a set of n points in $\mathbb{R}^d$, so that every geometric spanner of tree-width k on this set has dilation $\Omega\left(n/k^{d/(d-1)}\right)$.*

To obtain this result, we construct a set of points resembling a grid. While it is commonly known that a two-dimensional grid has high tree-width, the $\left(k^{1/(d-1)}\right)^d$-grid does not necessarily have tree-width k. We thus construct a set of points resembling the $(h+1)^d$-grid, where $h = \left\lceil (9d/2 \cdot (k+2))^{1/(d-1)} - 1 \right\rceil$. To lower bound the tree-width of this grid, we generalise a basic idea for the 3-dimensional grid given by Korhonen in an online forum[1]:

▶ **Lemma*** **12.** *The n^d-grid has tree-width $\geq \frac{2}{9d} \cdot n^{d-1} - 1$.*

Thus, the tree-width of our grid is at least

$$\begin{aligned}
\frac{2}{9d} \cdot (h+1)^{d-1} - 1 &= \frac{2}{9d} \cdot \left(\left\lceil (9d/2 \cdot (k+2))^{1/(d-1)} - 1 \right\rceil + 1 \right)^{d-1} - 1 \\
&\geq \frac{2}{9d} \cdot \left((9d/2 \cdot (k+2))^{1/(d-1)} \right)^{d-1} - 1 \\
&= k+1.
\end{aligned}$$

Using an inductive construction for the $(h+1)^d$-grid, by taking d copies of the $(h+1)^{d-1}$-grid and connecting them using $(d-1) \cdot (h+1)^{d-1}$ edges, we can prove that the $(h+1)^d$-grid has a total of $d \cdot (h+1)^d + d \cdot (h+1)^{d-1}$ edges.

[1] https://cstheory.stackexchange.com/questions/53029/what-is-the-treewidth-of-the-3d-grid-mesh-or-lattice-with-sidelength-n

The constructing of the grid-like set $P_{d,n,k}$ is as follows: Let $m = \lfloor n/(d \cdot (h+1)^d + d \cdot (h+1)^{d-1}) \rfloor$, be the number of points representing an edge of the grid in $P_{d,n,k}$. For every dimension $i \in \{1, \dots, d\}$, we define the set

$$P_i = \bigcup_{j_1=0}^{h} \cdots \bigcup_{j_d=0}^{h} \{(j_1 \cdot m, \dots, j_{i-1} \cdot m, x_i, j_{i+1} \cdot m, \dots, j_d \cdot m) \mid x_i \in \{0, \dots, h \cdot m\}\},$$

which consists of $(h+1)^{d-1}$ sets of collinear points representing the grid edges parallel to the axis of the i-th dimension. Each of these collinear sets of points consists of $h \cdot m + 1$ points and represents h edges of the grid. Hence $|P_i| = (h \cdot m + 1) \cdot (h+1)^{d-1}$ for every i. We can now define the set $P_{d,n,k} = \bigcup_{i=1}^{d} P_i$ which represents the whole $(h+1)^d$-grid. (In Figure 1 an example is shown for a 2-dimensional point set.) Notice that the $(h+1)^d$ points $P_{\boxplus} = \{(j_1 \cdot m, \dots, j_d \cdot m) \mid j_1, \dots, j_d \in \{0, \dots, h\}\}$ are contained in every P_i. We call these points the *grid points* of the set $P_{d,n,k}$ and two grid points are called *neighbouring* if the Euclidean distance between them is m, which corresponds to them being connected through an edge in the $(h+1)^d$-grid.

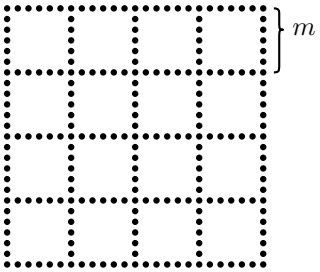

Figure 1 The set of points resembling the $(4+1)^2$-grid where $n = 240$ and $m = 6$.

▶ **Lemma*** **13.** *Let $d \geq 2$ be a fixed integer. The grid-like set $P_{d,n,k}$ is well-defined for every integer $n \geq d \cdot 64^{d \log d}$ and positive integer $k \leq n^{(d-1)/d} \cdot (5d)^{1/d-2}$ and is of size at most n.*

▶ **Lemma 14.** *If G is a geometric $o\left(n/k^{d/(d-1)}\right)$-spanner on $P_{d,n,k}$, then it must be of tree-width at least $k+1$.*

Proof. Let G be a $o(n/k^{d/(d-1)})$-spanner on $P_{d,n,k}$. Let $\mathcal{R}_x := x + [-m/4, m/4]^d$ denote the hypercube of side-length $m/2$ centered at x. For any pair $p, q \in P_{\boxplus}$ of neighbouring grid points, we consider the three hypercubes $\mathcal{R}_p, \mathcal{R}_q$, and $\mathcal{R}_s := s + [-m/4, m/4]^d$, where $s = \frac{p+q}{2}$ is the midpoint between p and q. We argue that there is a path in G from p to q such that: *(i)* the path only visits vertices in $\mathcal{R}_{p,q} := \mathcal{R}_p \cup \mathcal{R}_q \cup \mathcal{R}_s$ and *(ii)* for any $p' \in \mathcal{R}_p$ and $q' \in \mathcal{R}_q$, if the path visits p' and q' then it visits p' before it visits q'.

Let $p_0 = p, p_1, p_2, \dots p_m = q$ the ordered sequence of points representing the edge of the grid between p and q, and further let $s_i := \frac{p_i + p_{i+1}}{2}$. Since G is a $o(n/k^{d/(d-1)})$-spanner, we can assume that there is for every pair p_i, p_{i+1} a shortest path γ_i in G of length at most $m/4 = \Theta(n/k^{d/(d-1)})$. Such a path necessarily will remain with in $\mathcal{R}_{p_i} \cap \mathcal{R}_{p_{i+1}} \subset \mathcal{R}_{s_i}$. For $0 \leq i < m/2$ we have $\mathcal{R}_{s_i} \subset \mathcal{R}_p \cup \mathcal{R}_s$, and for $m/2 \leq i < m$ we have $\mathcal{R}_{s_i} \subset \mathcal{R}_q \cup \mathcal{R}_s$.

Consider the walk from p to q obtained by concatenating the paths $\gamma_0, \gamma_1, \dots \gamma_{m-1}$. It first only visits vertices in $\mathcal{R}_p \cup \mathcal{R}_s$ and then only vertices in $\mathcal{R}_q \cup \mathcal{R}_s$. By removing cycles we obtain a path $\gamma_{p,q}$ from p to q with this property. Thus, we have a path with the properties *(i)*+*(ii)* stated above.

We have such a path $\gamma_{p,q}$ for any pair $p, q \in P_{\boxplus}$. We claim that this implies that G must have a minor isomorphic to the $(h+1)^d$-grid and is therefore of tree-width $> k$. To show this, we perform a series of path contractions on G, obtaining a graph G'. More specifically, we first contract the edges of $\gamma_{p,q}$ starting from p, until we encounter as endpoint the last vertex in $\mathcal{R}_p$, identifying the merged vertices with p. After skipping an edge, we contract the remaining edges of $\gamma_{p,q}$, identifying the merged vertices with q. This is illustrated in Figure 2. After these contractions, the remaining edge of $\gamma_{p,q}$ is an edge from p to q.

Further we observe that *(i)* any vertex p' of $\gamma_{p,q}$ in $\mathcal{R}_p$ has been identified with p, *(ii)* any vertex q' of $\gamma_{p,q}$ in $\mathcal{R}_q$ has been identified with q, and *(iii)* any other vertex p'' of $\gamma_{p,q}$ does not also lie on another path $\gamma_{r,s}$ with $\{p,q\} \neq \{r,s\}$. The latter holds, since p'' cannot lie in $\mathcal{R}_{r,s}$. This means, that the paths $\gamma_{p,q}$ and $\gamma_{r,s}$ are contracted consistently. Thus, regardless of the order in which we contract the paths, we obtain a graph G' which has a minor isomorphic to the $(h+1)^d$-grid. In G', there is an edge between every neighbouring pair of grid points. Therefore the subgraph $G'[P_{\boxplus}]$ containing only the grid points is, if we remove edges between non-neighbouring grid points, isomorphic to the $(h+1)^d$-grid. We conclude that the spanner G has a minor isomorphic to the $(h+1)^d$-grid and by Lemma 12 therefore must be of tree-width at least $\frac{2}{9d}(h+1)^{d-1} - 1 \geq k+1$. ◀

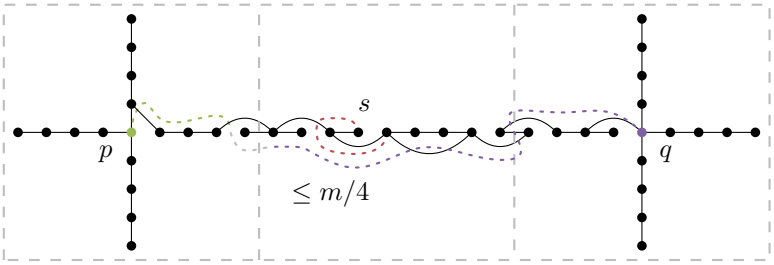

Figure 2 Grid points p and q as well as the three hypercubes centered at p, q and s. The subpath of $\gamma_{p,q}$ that is contracted to p is shown in green and the subpath that is contracted to q in purple. The red path is a detour of length $\leq m/4$ for points p_i and p_{i+1}.

5 Minor-3-cores and the tree-width of planar spanners

We now have given an asymptotically tight algorithm to obtain small bounded tree-width, with a dilation dependent on the chosen tree-width. We now focus on bounded tree-width spanners with the additional property of being plane.

In general, there are graphs with m edges and tree-width at least $m \cdot \varepsilon$ for a constant ε [17]. We show that this is not true for connected planar graphs, yielding a tight dependency between tree-width and the number of edges:

▶ **Theorem 3.** *Let G be a planar connected graph with n vertices and $n + \lfloor (k-1)^2/72 \rfloor$ edges, where $k \geq 2$ is an integer. The tree-width of G is at most k.*

5.1 Minor-3-cores

To obtain this Theorem, we first introduce the concept of *minor-3-cores*, in reference to the k-core which was established by Seidman [29] for the study of social networks. We then use this concept to obtain the tree-width of planar graphs with a certain fixed number of edges.

▶ **Definition 15** (Minor-3-Core). *Let G be a graph and H a minor of G with minimum degree 3. If there is no minor of minimum degree 3 that has more edges than H i.e., H is an edge maximal minor with this property, we call it a minor-3-core of G.*

This definition gives a very clear idea of what a minor-3-core should be, but unfortunately it does not lead to any structural insight concerning the concept. It especially leaves open whether minor-3-cores are unique or if there are multiple non-isomorphic minor-3-cores. We therefore need to further characterise minor-3-cores with regard to algorithmic properties and uniqueness. In order to answer these questions, we first define the disjoint-paths property.

▶ **Definition 16** (Disjoint-Paths Property). *Let G be a graph and let C be a minor-3-core of G as well as v be a vertex of the minor-3-core (and therefore a vertex of G that has not been contracted). We say that v fulfils the disjoint-paths property for C, if for every neighbour $u_1, ..., u_{\Delta_C(v)}$ of v in C, there is a path γ_i in G which leads from v to u_i and $\left(\bigcup_{u \text{ in } \gamma_i} u\right) \cap \left(\bigcup_{w \text{ in } \gamma_j} w\right) = \{v\}$ for every path γ_j for $j \neq i$.*

We now show that we can assume having the disjoint paths property in a minor-3-core:

▶ **Lemma*** **17.** *For every graph G and minor-3-core C of G, there is a minor-3-core isomorphic to C in which every vertex has the disjoint paths property.*

By Lemma 17 we now know that there is a minor-3-core, in which every vertex has the disjoint-paths property. We call a minor with this property a *canonical minor-3-core*:

▶ **Definition 18** (Canonical Minor-3-Core). *Let C be a minor-3-core of a graph G. We call C the canonical minor-3-core, if every vertex of C has the disjoint-paths property. The vertices of C are called the canonical vertices.*

We now show that the canonical minor-3-core is, as the name implies, unique:

▶ **Lemma*** **19.** *Let G be a graph, the canonical minor-3-core of G is unique.*

Combining Lemma 17 and Lemma 19, we can state that every minor-3-core C of G is isomorphic to the canonical minor-3-core of G. Thus we obtain uniqueness and can refer to *the minor-3-core*, instead of a minor-3-core, meaning the canonical minor-3-core.

We will now give an algorithmic characterisation for the minor-3-core. Similarly to k-cores [29] we can compute the minor-3-core by an iterative pruning process:

▶ **Theorem 20.** *Let G be a graph. The minor-3-core of G can be obtained by performing the following operations to exhaustion:*

- *Let e be an edge incident to a vertex v with degree ≤ 2. Contract v along e.*
- *If v is an isolated vertex, delete v.*

Proof. The graph H resulting from the iterative pruning process described above is clearly a minor of G, in which every vertex has degree at least 3. Let C be the canonical minor-3-core of G. Suppose that there is some edge in C that is not in H. For an edge to not be an edge of H one of the vertices of this edge needs to be contracted to one of its neighbours in the construction of H. Let u be the first vertex of C that is contracted in the construction of H. By definition of the pruning process u needs to be of degree ≤ 2 to be contracted. Since u by the definition of the disjoint-paths property starts off as a vertex of degree ≥ 3, there needs to be a contraction that reduces the degree of u to ≤ 2. For this to be possible, there needs to be a contraction of two neighbouring vertices of u, where both of these vertices are canonical vertices. This must be the case, since in G there are at least three disjoint

paths starting in u that lead to at least three different canonical vertices and there cannot be an edge between the vertices of the disjoint paths, since otherwise these vertices would be canonical vertices themselves. The vertices of this edge would need to be canonical as they are both connected to u, to one other canonical vertex each, as well as to each other by disjoint paths. But since we assumed u to be the first canonical vertex that gets contracted in the construction of H, we reach a contradiction. Hence every edge of C is also an edge of H and since C is edge maximal, H must be equal to the canonical minor-3-core C. ◀

In the following we use the minor-3-core in order to bound the tree-width of planar spanners. To begin the exploration of the relationship of minor-3-cores and tree-width we first make a couple of observations.

1. The minor-3-core of a tree is the empty graph.
2. The minor-3-core of a graph with at most one circle is the empty graph.
3. The K_4 is its own minor-3-core.

Even more, every graph without a K_4 minor has an empty minor-3-core.*

Considering a graph and then connecting a tree to some vertex of our graph, like a branch growing out of our graph, does not increase the tree-width of the graph. The same holds for edges that we replace with paths. So we can see that it is possible to increase the size of our graph without affecting the tree-width of the graph. This is a problem if we want to bound the tree-width of our graph through common separator arguments, for example using [24], since the bound on the tree-width there depends on the size of the graph. Hence it would be nice to have a tool that prunes our graph by removing "tree-like" structures from our graph. For that, we use the definition of minor-3-cores:

▶ **Theorem 21.** *Given a graph of tree-width $k \geq 3$, the tree-width of the minor-3-core of G is k as well.*

Proof. Let G be a graph of tree-width $k \geq 3$ and H its minor-3-core. Since H is a minor of G, the tree-width of H can be at most k. To prove that H must be of tree-width at least k, we prove that contracting a vertex of degree at most 2 does not decrease the tree-width. So let G be a graph of tree-width $k \geq 3$. Suppose that there is a vertex v of degree 2 and let u_1 and u_2 be the two vertices adjacent to v. Let G' be the graph resulting from the contraction of v to u_1. We now argue that G' must have tree-width k as well. Assume that G' has tree-width $k' < k$ and let (T', X') be a tree-decomposition of width k' for G'. We now construct a tree-decomposition (T, X) for G of width k' from (T', X'). In (T', X') there must be some bag $X(i)$ which contains both u_1 and u_2, since they are connected by an edge. We now create a new node, whose bag contains v, u_1 and u_2 and connect it to i by an edge. The tree-decomposition (T, X) is now a valid tree-decomposition for G with tree-width $k' < k$, which is a contradiction to G being of tree-width k. If v is of degree 1, the same argument holds, but we only consider u_1, which has to appear in at least one bag of (T', X'). ◀

As mentioned before we want to bound the tree-width of graphs (especially spanners) through the size of their minor-3-core. Therefore it would be useful to have a bound on the size of the minor-3-core of a graph. If a graph is very "tree-like", i.e. the graph can be decomposed into a set of trees by removing only a few edges, we expect it to have a small minor-3-core. We formalise this statement as follows:

▶ **Lemma*** **22.** *Let G be a connected graph with n vertices and $n-1+m$ edges, where $m \geq 1$ is some integer. The minor-3-core of G has at most $2 \cdot (m-1)$ vertices.*

This lemma is the last part we need to prove an upper bound for the tree-width of connected planar graphs. Intuitively the statement of the lemma could just as well be stated as a bound on the size of minor-3-cores of trees with an additional m edges. If we place these additional edges in a planar fashion, we can combine our bound on the size of minor-3-cores and the bound on the tree-width of planar graphs derived from Theorem 6.2 in [24] to obtain a bound on the tree-width of trees with additional edges that were placed without creating edge crossings. Using this, we can finally proof our second main result:

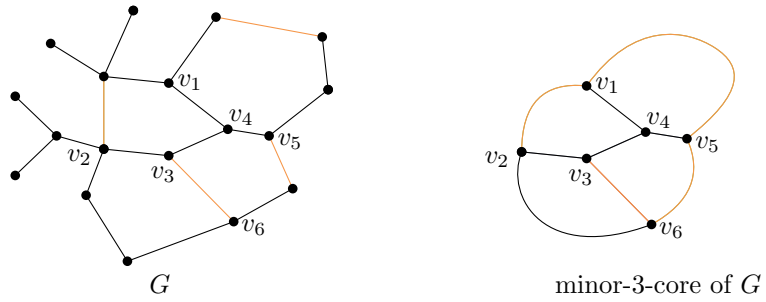

Figure 3 Minor-3-core of a graph G that consists of a tree with 4 additional edges (orange).

Proof of Theorem 3. Since G is a connected graph with $n + \lfloor (k-1)^2/72 \rfloor$ edges, its minor-3-core must by Lemma 22 have at most $\lfloor (k-1)^2/36 \rfloor$ vertices. Also, since the minor-3-core is a minor of G and G is planar, the minor-3-core must be planar as well. The tree-width of a planar graph with n vertices by [24] is at most $6\sqrt{n}+1$. The tree-width of the minor-3-core of G therefore is

$$6\sqrt{\lfloor (k-1)^2/36 \rfloor} + 1 \leq 6\sqrt{(k-1)^2/36} + 1 \leq k.$$

By Lemma 21 we can now conclude that the tree-width of G is either ≤ 2 or exactly k, so in both cases at most k. ◀

5.2 Tree-width of planar spanners

Theorem 3 allows us a stronger result than Theorem 1 in the Euclidean plane: Adjusting the algorithm given in [3], we obtain a plane bounded-degree spanner with bounded tree-width:

▶ **Corollary 4.** *Given a set $P \subset \mathbb{R}^2$ of n points and some positive integer $k \leq 12\sqrt{n-3}$, a plane spanner with tree-width k, maximum vertex degree 4 and dilation $\mathcal{O}(n/k^2)$ can be constructed in $\mathcal{O}(n \log n)$ time.*

Our main adjustment to the algorithm is to chose a plane constant-dilation spanner $\mathcal{S}$ of P with maximum degree 4, as provided in [19], instead of the Delaunay triangulation and to utilise a minimum spanning tree of $\mathcal{S}$ instead of the Euclidean MST. The full version of the algorithm can be found in the full version of the paper. Since the constructed spanner then is a subgraph of $\mathcal{S}$, it is plane and has maximum vertex degree 4. By Theorem 3, its tree-width can then be bounded by the given k. Further, the dilation is not affected, which follows directly by Lemma 4 in [3].

6 Bounded tree-width spanners on convex point sets

We have seen that for unrestricted sets of points in the plane the Delaunay triangulation is an 1.998-spanner of tree-width $6\sqrt{n}+1$. To obtain spanners with smaller tree-widths, we now look at sets of points in the plane that are convex or even lie on a circle.

6.1 Tree spanners

The Euclidean minimum spanning tree is an $(n-1)$-spanner for any set of n points in $\mathbb{R}^d$ of tree-width 1. Aronov et. al. [3] proved that there are sets of points, on which the dilation bound of the minimum spanning tree is almost optimal. To be more precise they showed that there is a set of points, on which any tree-spanner has dilation at least $\frac{2n}{\pi} - 1$. The set they used in their proof was a set of $n \geq 3$ points equally spaced on the unit circle. So, even for tree-spanners on convex sets and sets of points on a circle a dilation of $\Omega(n)$ may be unavoidable. The most obvious tree-spanner on a set of points equally spaced on the unit circle would probably be the spanner that consists of all the edges between points next to each other except for one edge. It is not hard to see that this spanner has dilation $n-1$. But we can show that for points equally spaced on the unit circle, there are tree-spanners with dilation almost $\frac{2n}{\pi} - 1$.

▶ **Lemma*** **23.** *Let P be a set of n points equally spaced on a circle. There is a tree-spanner on P with dilation $\leq \frac{2n}{\pi} + \frac{\pi}{2n}$.*

Proof Idea. Given some $n \geq 2$, let $p_i = \left(\sin\left(\frac{2\pi i}{n}\right), \cos\left(\frac{2\pi i}{n}\right)\right)$. We define $P = \{p_i \mid i \in \{0, \ldots, n-1\}\}$ which is the set of n points equally spaced on the unit circle, where one point is $(0, 1)$. Notice that for any i we have $p_i = p_{i+n}$.

We now construct a tree-spanner G for P with dilation $\leq \frac{2n}{\pi} + \frac{\pi}{2n}$. The spanner G is a path visiting each point on the unit circle in a sawtooth pattern. We define G as the path $p_0, p_{n-1}, p_1, \ldots, p_{\lfloor n/2 \rfloor}$ or more formally as the graph with edges

$$E = \{\{p_i, p_{n-1-i}\} \mid i \in \{0, \ldots, \lfloor n/2 \rfloor - 1\}\} \cup \{\{p_{i+1}, p_{n-i}\} \mid i \in \{0, \ldots, \lfloor (n-1)/2 \rfloor - 1\}\}.$$

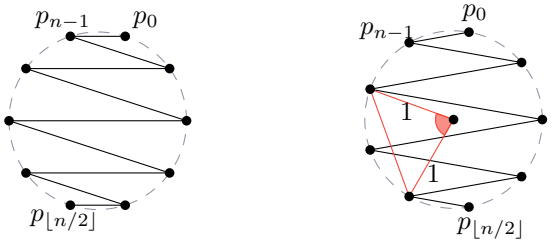

Figure 4 The spanner G on n points equally spaced on the unit circle for $n = 10$ (left) and for $n = 9$ (right).

The Euclidean distance between points p_i and p_j can be derived from the law of cosines:

$$|p_i p_j| = \sqrt{2 - 2\cos\left(\frac{2\pi}{n}(j-i)\right)} = \left|2\sin\left((j-i)\cdot\frac{\pi}{n}\right)\right|.$$

For the distance in G between two points we can add up the Euclidean distances between the points on the path connecting them. Since the spanner G is a path from p_0 to $p_{\lfloor n/2 \rfloor}$, we now let $q_1, ..., q_n$ be the vertices along the path G, where $q_1 = p_0$ and $q_n = p_{\lfloor n/2 \rfloor}$. The distance in G from some q_i to q_j for $i \leq j$ then is

$$d(q_i, q_j) = \sum_{k=i}^{j-1} 2\sin\left(\frac{\pi}{n}\cdot k\right).$$

To complete the proof, we still need to calculate $|q_iq_j|$ and then bound $\frac{d(q_i,q_j)}{|q_iq_j|}$. We can show that

$$|q_iq_j| = \left|2\sin\left(\left\lfloor\frac{j-i+1}{2}\right\rfloor\cdot\frac{\pi}{n}\right)\right|.$$

We then use trigonometric identities to bound $d(q_i,q_j)$ and $|q_iq_j|$ by simpler expressions, from which the lemma then follows. ◀

6.2 Spanners of tree-width 2

While for geometric spanners of tree-width 1, there are sets of points in convex position on which a dilation of $\Omega(n)$ is unavoidable, we can obtain some results for geometric spanners of tree-width 2 on sets of points in convex position.

As every plane graph on a set of points in convex position is outerplanar, and outerplanar graphs have tree-width ≤ 2 [15], every plane spanner on a set of points in convex position has tree-width ≤ 2. Let P be a point set with points in convex position. Since by [4], there is a plane 1.88-spanner for P, there is a 1.88-spanner of tree-width 2 for P. If the points are equally spaced on a circle, by [28] there is even a 1.4482-spanner with tree-width 2.

To show a lower bound, we build on the idea of [16]:

▶ **Lemma*** **24.** *Let P be the set of $n \geq 3$ points equally spaced on the unit circle. Every spanner on P with dilation < 2 must contain the convex hull of P.*

▶ **Lemma 25.** *Let P be the set of $n \geq 3$ points equally spaced on the unit circle. Every t-spanner for $t < 2$ of tree-width 2 on P is plane.*

Proof. Let G be a t-spanner for $t < 2$ of tree-width 2 on P. By Lemma 24, G contains the convex hull of P. For $n = 3$ the statement holds, since the K_3 is plane and has tree-width 2. So let $n \geq 4$ and suppose in the straight-line drawing of G there is an edge-crossing. Let these edges be $\{p,q\}$ and $\{p,q'\}$. On the convex hull of P there must be a path from p to p', not containing q and q', a path from p' to q, not containing p and q', a path from q to q' not containing p and p', and finally a path from q' to p, not containing p' and q. If we perform path-contractions along these paths, leaving only p, q, p' and p', the resulting graph is the K_4, which is of tree-width 3. We reach a contradiction and can conclude that G must be plane. ◀

The desired lower bound for spanners of tree-width 2 now follows from [16] combined with Lemma 25.

▶ **Proposition 26.** *Let P be a set of 23 points equally spaced on a circle. Every spanner of tree-width 2 on P has dilation at least 1.430814.*

7 Conclusion and open questions

In this paper, we give the first algorithm for computing geometric spanners with bounded tree-width for points in Euclidean space of constant dimension. Further, we show a strong dependency between the tree-width and the number of edges in connected planar graphs with few edges.

Our lower bound proves that the dilation of our spanner is worst-case optimal for tree-width k. This naturally leads to the question of optimisation: Given a set of points and a parameter k, can we compute the minimum-dilation spanner of tree-width k? Already for

$k = 1$, that is for minimum-dilation trees, the problem is NP-hard [20, 11]. This raises the question of approximation: Can we efficiently approximate the minimum-dilation spanner of tree-width k in terms of its dilation within a factor better than $\mathcal{O}(n/k^{d/d-1})$? As a bicriteria problem, the tree-width of the approximation may also be $f(k)$ for a suitable function f.

Abstract

Given a point set P in a metric space and a real number $t \geq 1$, an *oriented t-spanner* is an oriented graph $\overrightarrow{G} = (P, \overrightarrow{E})$, where for every pair of distinct points p and q in P, the shortest oriented closed walk in $\overrightarrow{G}$ that contains p and q is at most a factor t longer than the perimeter of the smallest triangle in P containing p and q. The *oriented dilation* of a graph $\overrightarrow{G}$ is the minimum t for which $\overrightarrow{G}$ is an oriented t-spanner.

For arbitrary point sets of size n in $\mathbb{R}^d$, where $d \geq 2$ is a constant, the only known oriented spanner construction is an oriented 2-spanner with $\binom{n}{2}$ edges. Moreover, there exists a set P of four points in the plane, for which the oriented dilation is larger than 1.46, for any oriented graph on P.

We present the first algorithm that computes, in Euclidean space, a sparse oriented spanner whose oriented dilation is bounded by a constant. More specifically, for any set of n points in $\mathbb{R}^d$, where d is a constant, we construct an oriented $(2+\varepsilon)$-spanner with $\mathcal{O}(n)$ edges in $\mathcal{O}(n \log n)$ time and $\mathcal{O}(n)$ space. Our construction uses the well-separated pair decomposition and an algorithm that computes a $(1+\varepsilon)$-approximation of the minimum-perimeter triangle in P containing two given query points in $\mathcal{O}(\log n)$ time.

While our algorithm is based on first computing a suitable undirected graph and then orienting it, we show that, in general, computing the orientation of an undirected graph that minimises its oriented dilation is NP-hard, even for point sets in the Euclidean plane.

We further prove that even if the oriented graph is already given, computing its oriented dilation is APSP-hard for points in a general metric space. We complement this result with an algorithm that approximates the oriented dilation of a given graph in subcubic time for point sets in $\mathbb{R}^d$, where d is a constant.

1 Introduction

While geometric spanners have been researched for decades (see [4, 19] for a survey), directed versions have only been considered more recently. This is surprising since, in many applications, edges may be directed or even oriented if two-way connections are not permitted. Oriented spanners were first proposed in ESA'23 [5] and have since been studied in [6] and [7].

Formally, let P be a point set in a metric space and let $\overrightarrow{G}$ be an oriented graph with vertex set P. For a real number $t \geq 1$, we say that $\overrightarrow{G}$ is an *oriented t-spanner*, if for every pair p, q of distinct points in P, the shortest oriented closed walk in $\overrightarrow{G}$ that contains p and q is at most a factor t longer than the shortest simple cycle that contains p and q in the complete undirected graph on P. Since we consider point sets in a metric space, we observe that the latter is the minimum-perimeter triangle in P containing p and q.

Recall that a *t-spanner* is an undirected graph G with vertex set P, in which for any two points p and q in P, there exists a path between p and q in G whose length is at most t times the distance $|pq|$. Several algorithms are known that compute $(1+\varepsilon)$-spanners with $\mathcal{O}(n)$ edges for any set of n points in $\mathbb{R}^d$. Examples are the greedy spanner [19], Θ-graphs [16] and spanners based on the well-separated pair decomposition (WSPD) [22]. Moreover, it is NP-hard to compute an undirected t-spanner with at most m edges [12].

In the oriented case, while it is NP-hard to compute an oriented t-spanner with at most m edges [5], the problem of constructing sparse oriented spanners has remained open until now. For arbitrary point sets of size n in $\mathbb{R}^d$, where $d \geq 2$ is a constant, the only known oriented spanner construction is a simple greedy algorithm that computes, in $\mathcal{O}(n^3)$ time, an oriented 2-spanner with $\binom{n}{2}$ edges [5]. If P consists of three vertices of an equilateral triangle in $\mathbb{R}^2$ and a fourth point in its centre, then the smallest oriented dilation for P is $2\sqrt{3} - 2 \approx 1.46$ [5]. Thus, prior to our work, no algorithms were known that compute an oriented t-spanner with a subquadratic number of edges for any constant t.

In this paper, we introduce the first algorithm to construct sparse oriented spanners for general point sets. For any set P of n points in $\mathbb{R}^d$, where d is a constant, the algorithm computes an oriented $(2+\varepsilon)$-spanner with $\mathcal{O}(n)$ edges in $\mathcal{O}(n \log n)$ time and $\mathcal{O}(n)$ space.

While our approach uses the WSPD [8, 22], this does not immediately yield an oriented spanner. An undirected spanner can be obtained from a WSPD by adding one edge per well-separated pair. This does not work for constructing an oriented spanner because a path in both directions needs to be considered for every well-separated pair. To construct such paths, we present a data structure that, given a pair of points, returns a point with an approximate minimum summed distance to the pair of the points, i.e. the smallest triangle in the complete undirected graph on P. Our algorithm first constructs an adequate undirected sparse graph and subsequently orients it using a greedy approach.

We also show in this paper that, in general, it is NP-hard to decide whether the edges of an arbitrary graph can be oriented in such a way that the oriented dilation of the resulting graph is below a given threshold. This holds even for Euclidean graphs.

For the problem of computing the oriented dilation of a given graph, there is a straightforward cubic time algorithm. We show a subcubic approximation algorithm.

The hardness of computing the dilation of a given graph, especially in the undirected case, is a long-standing open question, and only cubic time algorithms are known [15]. It is conjectured that computing the dilation is as hard as the all-pairs shortest paths problem (APSP). In this paper, we demonstrate that computing the oriented dilation is APSP-hard.

2 Preliminaries

Let $(P, |\cdot|)$ be a finite metric space, where the distance between any two points p and q in P is denoted by $|pq|$. When the choice between Euclidean and general metric distances is relevant for our results, we use the adjective *Euclidean* or respectively *metric graph*.

If p and q are distinct points in P, then $\Delta^*(p, q)$ denotes the shortest simple cycle containing p and q in the complete undirected graph on P; this is the triangle Δ_{pqx}, where

$$x = \arg\min\{(|px| + |qx|) \mid x \in P \setminus \{p, q\}\}.$$

We use $|\Delta^*(p, q)|$ to denote the perimeter of this triangle.

An *oriented graph* $\overrightarrow{G} = (P, \overrightarrow{E})$ is a directed graph such that for any two distinct points p and q in P, at most one of the two directed edges (p, q) and (q, p) is in $\overrightarrow{E}$. In other words, if (p, q) is in $\overrightarrow{E}$, then (q, p) is not in $\overrightarrow{E}$.

For two distinct points p and q in P, we denote by $C_{\overrightarrow{G}}(p, q)$ the *shortest closed walk* containing p and q in the oriented graph $\overrightarrow{G}$. The length of this walk is denoted by $|C_{\overrightarrow{G}}(p, q)|$; if such a walk does not exist, then $|C_{\overrightarrow{G}}(p, q)| = \infty$.

▶ **Definition 1** (oriented dilation). *Let $(P, |\cdot|)$ be a finite metric space and let $\overrightarrow{G}$ be an oriented graph with vertex set P. For two points $p, q \in P$, their* oriented dilation *is defined as*

$$\mathrm{odil}_{\overrightarrow{G}}(p, q) = \frac{|C_{\overrightarrow{G}}(p, q)|}{|\Delta^*(p, q)|}.$$

The oriented dilation of $\overrightarrow{G}$ is defined as $\mathrm{odil}(\overrightarrow{G}) = \max\{\mathrm{odil}_{\overrightarrow{G}}(p, q) \mid p, q \in P\}$.

An oriented graph with oriented dilation at most t is called an *oriented t-spanner*. Note thatthere is no oriented 1-spanner for sets of at least 4 points.

Let $G = (P, E)$ be an undirected graph. We call $\overrightarrow{G} = (P, \overrightarrow{E})$ an *orientation* of G, if for each undirected edge $\{p, q\} \in E$ it holds either $(p, q) \in \overrightarrow{E}$ or $(q, p) \in \overrightarrow{E}$.

2.1 Well-separated pair decomposition

In 1995, Callahan and Kosaraju [8] introduced the *well-separated pair decomposition* (WSPD) as a tool to solve various distance problems on multidimensional point sets.

For a real number $s > 0$, two point sets A and B form an *s-well-separated pair*, if A and B can each be covered by balls of the same radius, say ρ, such that the distance between the balls is at least $s \cdot \rho$. An *s-well-separated pair decomposition* for a set P of points is a sequence of s-well-separated pairs $\{A_i, B_i\}$, such that $A_i \cap B_i = \emptyset$ and for any two points $p, q \in P$, there is a unique index i such that $p \in A_i$ and $q \in B_i$, or $p \in B_i$ and $q \in A_i$.

The following properties are used repeatedly in this paper.

▶ **WSPD-Property 1** (Smid [22]). *Let $s > 0$ be a real number and let $\{A, B\}$ be an s-well-separated pair. For points $a, a' \in A$ and $b, b' \in B$, it holds that*

(i) $|aa'| \leq 2/s \cdot |ab|$, *and*

(ii) $|a'b'| \leq (1 + 4/s)|ab|$.

Callahan and Kosaraju [8] showed a fast WSPD-construction based on a split tree.

▶ **WSPD-Property 2** (Callahan and Kosaraju [8]). *Let P be a set of n points in $\mathbb{R}^d$, where d is a constant, and let $s > 0$ be a real number. An s-well-separated pair decomposition for P consisting of $\mathcal{O}(s^d n)$ pairs, can be computed in $\mathcal{O}(n \log n + s^d n)$ time.*

2.2 Approximate nearest neighbour queries

For approximate nearest neighbour queries, we want to preprocess a given point set P in a metric space, such that for any query point q in the metric space, we can report quickly its *approximate nearest neighbour* in P. That is, if q^* is the exact nearest neighbour of q in P, then the query algorithm returns a point q' in P such that $|qq'| \leq (1 + \varepsilon) \cdot |qq^*|$. Such a data structure is offered in [3] for the case when P is a point set in the Euclidean space $\mathbb{R}^d$:

▶ **Lemma 2** (Arya, Mount, Netanyahu, Silverman and Wu [3]). *Let P be a set of n points in $\mathbb{R}^d$, where d is a constant. In $\mathcal{O}(n \log n)$ time, a data structure of size $\mathcal{O}(n)$ can be constructed that supports the following operations:*

- *Given a real number $\varepsilon > 0$ and a query point q in $\mathbb{R}^d$, return a $(1+\varepsilon)$-approximate nearest neighbour of q in P in $\mathcal{O}(\log n)$ time.*
- *Inserting a point into P and deleting a point from P in $\mathcal{O}(\log n)$ time.*

3 Sparse oriented constant dilation spanner

This section presents the first construction for a sparse oriented $(2+\varepsilon)$-spanner for general point sets in $\mathbb{R}^d$. Our algorithm consists of the following four steps:

1. Compute the WSPD on the given point set.
2. For two points of each well-separated pair, approximate their minimum-perimeter triangle by our algorithm using approximate nearest neighbour queries presented in Section 3.1.
3. Construct an undirected graph whose edge set consists of edges of approximated triangles.
4. Orient the undirected graph using a greedy algorithm (see Lemma 3).

In Step 4, we modify a greedy algorithm from [5], which originally works as follows. Sort the $\binom{n}{3}$ triangles of the complete graph in ascending order by their perimeter. In this order, orient each triangle clockwise or anti-clockwise if possible; otherwise, we skip this triangle. At the end of the algorithm, all remaining edges are oriented arbitrarily. In [5], they show that this greedy algorithm yields an oriented 2-spanner. Note that this graph has $\binom{n}{2}$ edges.

Our modification of the greedy algorithm is to only consider the approximate minimum-perimeter triangles, rather than all $\binom{n}{3}$ triangles. Lemma 3 states that, for any two points whose triangles are $(1+\varepsilon)$-approximated in Step 2, the dilation between those points is at most $(2+2\varepsilon)$ in the resulting orientation.

▶ **Lemma 3.*** *Let P be a set of n points in $\mathbb{R}^d$, let $\varepsilon_1 > 0$ be a real number, and let L be a list of m point triples $(p,q;r)$, with p, q, and r being pairwise distinct points in P. Assume that for each $(p,q;r)$ in L,*

$$|\Delta_{pqr}| \leq (1+\varepsilon_1) \cdot |\Delta^*(p,q)|.$$

Let $G = (P,E)$ be the undirected graph whose edge set consists of all edges of the m triangles Δ_{pqr} defined by the triples $(p,q;r)$ in L. In $\mathcal{O}(m \log n)$ time, we can compute an orientation $\overrightarrow{G}$ of G, such that $\mathrm{odil}_{\overrightarrow{G}}(p,q) \leq 2+2\varepsilon_1$ for each $(p,q;r)$ in L.

▶ Remark. The above lemma only guarantees an upper bound on $\mathrm{odil}_{\overrightarrow{G}}(p,q)$ for $(p,q;r)$ in L. For such a triple, $\mathrm{odil}_{\overrightarrow{G}}(p,r)$ and $\mathrm{odil}_{\overrightarrow{G}}(q,r)$ can be arbitrarily large.

In Algorithm 1, we pick up to two points of A and up to two points of B for each well-separated pair $\{A,B\}$ and approximate the minimum-perimeter triangle for every combination of picked points, including pairs of points from the same set. The latter is necessary, to bound the size of the minimum triangle of two points in the same set (see Proof of Theorem 4). Considering all such combinations introduces a minor computational overhead, but improves the readability of the proof. Now, we show that Algorithm 1 constructs a sparse oriented $(2+\varepsilon)$-spanner for point sets in the Euclidean space $\mathbb{R}^d$:

▶ **Theorem 4.** *Given a set P of n points in $\mathbb{R}^d$ and a real number $0 < \varepsilon < 2$, an oriented $(2+\varepsilon)$-spanner for P with $\mathcal{O}(n)$ edges can be constructed in $\mathcal{O}(n \log n)$ time and $\mathcal{O}(n)$ space.*

* Due to space restrictions, proofs of results marked by $*$ are given in the full version of this paper.

Algorithm 1 Sparse $(2+\varepsilon)$-Spanner.

Require: Set P of n points in $\mathbb{R}^d$, positive reals $\varepsilon < 2$, ε_1, s
Ensure: $(2+\varepsilon)$-spanner for P with $\mathcal{O}(n)$ edges
  Compute an s-WSPD $\{A_i, B_i\}$ for $1 \le i \le m = \mathcal{O}(n)$
  Compute the data structure M on P to approximate nearest neighbours (see Lemma 2 [3])
  $L = \emptyset$
  for $i = 1$ **to** m **do**
    Pick $\min\{|A_i|, 2\}$ points of A_i
    Pick $\min\{|B_i|, 2\}$ points of B_i
    K = set of all picked points
    for each $\{p, q\} \in K \times K$ with $p \neq q$ **do**
      $\Delta_{pqr} = (1+\varepsilon_1)$-approximation of $\Delta^*(p, q)$ computed by Algorithm 2 given M, p, q, ε_1
      Add the point triple $(p, q; r)$ to L
  return oriented graph generated by the algorithm in Lemma 3, given P, ε_1, L

Proof. Let the constants in Algorithm 1 be equal to $\varepsilon_1 = \varepsilon/4$ and $s = 96/\varepsilon$. Let $\overrightarrow{G}$ be the graph returned by Algorithm 1.

For any two points $p, q \in P$, we prove that $|C_{\overrightarrow{G}}(p, q)| \le (2+\varepsilon) \cdot |\Delta^*(p, q)|$. The proof is by induction on the rank of $|pq|$ in the sorted sequence of all $\binom{n}{2}$ pairwise distances.

If p, q is a closest pair (for the definition see [22]), then the pair $\{\{p\}, \{q\}\}$ is in the WSPD. Therefore, a $(1+\varepsilon_1)$-approximation of $\Delta^*(p, q)$ is added to the list L of triangles, that define the edge set of $\overrightarrow{G}$, and, due to Lemma 3 and $\varepsilon_1 = \varepsilon/4$, we have $\mathrm{odil}_{\overrightarrow{G}}(p, q) \le 2 + 2\varepsilon_1 \le 2 + \varepsilon$.

Assume that p, q is not a closest pair. Let $\{A, B\}$ be the well-separated pair with $p \in A$ and $q \in B$. We distinguish cases based on whether p and/or q are picked by Algorithm 1 while processing the pair $\{A, B\}$.

Case 1. Neither p nor q are picked by Algorithm 1.

This implies $|A| \ge 3$ and $|B| \ge 3$. Let $a \in A$ and $b \in B$ be picked points. We prove

$$|C_{\overrightarrow{G}}(p, q)| \le |C_{\overrightarrow{G}}(p, a)| + |C_{\overrightarrow{G}}(a, b)| + |C_{\overrightarrow{G}}(b, q)| \le (2+\varepsilon) \cdot |\Delta^*(p, q)|.$$

A sketch of this proof is visualized in Figure 1.

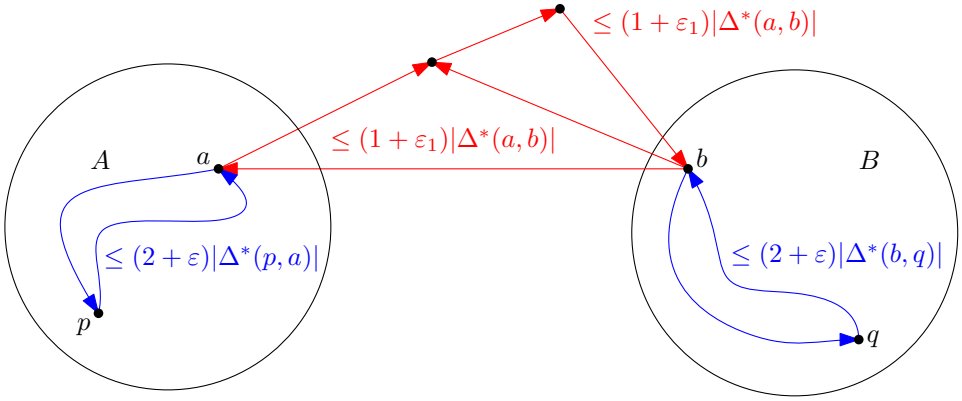

Figure 1 Visualization of Case 1: $|C_{\overrightarrow{G}}(p, q)| \le |C_{\overrightarrow{G}}(p, a)| + |C_{\overrightarrow{G}}(a, b)| + |C_{\overrightarrow{G}}(b, q)|$ in the proof of Theorem 4. $C_{\overrightarrow{G}}(a, b)$ is either a $(1+\varepsilon_1)$-approximation of $\Delta^*(a, b)$ or a union of two triangles (red), each of at most $(1+\varepsilon_1)|\Delta^*(a, b)|$. $|C_{\overrightarrow{G}}(p, a)|$ and $|C_{\overrightarrow{G}}(b, q)|$ (blue) are bounded inductively.

Since $|pa| < |pq|$ and $|bq| < |pq|$, we apply induction to bound $|C_{\overrightarrow{G}}(p,a)|$ and $|C_{\overrightarrow{G}}(b,q)|$. Since a and b are picked points, Lemma 3 applies, which gives us

$$|C_{\overrightarrow{G}}(p,q)| \leq (2+\varepsilon)|\Delta^*(p,a)| + (2+2\varepsilon_1)|\Delta^*(a,b)| + (2+\varepsilon)|\Delta^*(b,q)|.$$

Since $|A| \geq 3$, $|\Delta^*(p,a)|$ is at most the perimeter of any triangle with vertices p, a, and one other point in A. Each of the three edges of such a triangle can be bounded using WSPD-Property 1. It holds that

$$|\Delta^*(p,a)| \leq 3 \cdot 2/s \cdot |pq| \leq 3/s \cdot |\Delta^*(p,q)|, \tag{1}$$

where the last inequality $|\Delta^*(p,q)| \geq 2|pq|$ follows from the triangle inequality. Analogously, we bound $|\Delta^*(b,q)|$ by $3/s|\Delta^*(p,q)|$. By Lemma 5, we bound $|\Delta^*(a,b)|$ and achieve in total

$$|C_{\overrightarrow{G}}(p,q)| \leq 2(2+\varepsilon) \cdot 3/s|\Delta^*(p,q)| + (2+2\varepsilon_1)\,(1+8/s)\,|\Delta^*(p,q)|.$$

Since $\varepsilon_1 = \varepsilon/4$, $\varepsilon < 2$ and $s = 96/\varepsilon$, we conclude that

$$|C_{\overrightarrow{G}}(p,q)| \leq \left(2 + \frac{\varepsilon}{2} + \frac{28+10\varepsilon}{s}\right)|\Delta^*(p,q)| \leq \left(2 + \frac{\varepsilon}{2} + \frac{48}{s}\right)|\Delta^*(p,q)| = (2+\varepsilon)|\Delta^*(p,q)|.$$

Case 2. Either p or q is picked by Algorithm 1.

W.l.o.g., let p be picked for A and a distinct point b be picked for B.

Analogously to Case 1, we show that

$$|C_{\overrightarrow{G}}(p,q)| \leq |C_{\overrightarrow{G}}(p,b)| + |C_{\overrightarrow{G}}(b,q)| \leq (2+\varepsilon)|\Delta^*(p,q)|.$$

Case 3. Both p and q are picked by Algorithm 1.

An approximation of $\Delta^*(p,q)$ is added to L and then, due to Lemma 3 and $\varepsilon_1 = \frac{\varepsilon}{4}$, we have $\mathrm{odil}_{\overrightarrow{G}}(p,q) \leq 2 + 2\varepsilon_1 \leq 2 + \varepsilon$.

The initialisation is dominated by computing a WSPD in $\mathcal{O}(n \log n)$ time [8]. For each of the $\mathcal{O}(n)$ pairs, we pick at most four points and approximate the minimum triangle $\Delta^*(p,q)$ for at most six pairs $\{p,q\}$ of picked points. Therefore, computing the list L of $\mathcal{O}(n)$ triples costs $\mathcal{O}(n \log n)$ time (see Lemma 6) and orienting those costs $\mathcal{O}(n \log n)$ time (Lemma 3). Therefore, a $(2+\varepsilon)$-spanner can be computed in $\mathcal{O}(n \log n)$ time and $\mathcal{O}(n)$ space. ◀

3.1 The minimum-perimeter triangle

Let P be a set of n points in $\mathbb{R}^d$, and let p and q be two distinct points in P. The minimum triangle $\Delta^*(p,q)$ containing p and q can be computed naively in $O(n)$ time.

The following approach can be used to answer such a query in $O(n^{1-c})$ time, for some small constant $c > 0$ that depends on the dimension d. Note that computing $\Delta^*(p,q)$ is equivalent to computing the smallest real number $\rho > 0$, such that the ellipsoid

$$\sqrt{\sum_{i=1}^{d}(p_i - x_i)^2} + \sqrt{\sum_{i=1}^{d}(q_i - x_i)^2} \leq \rho$$

contains at least three points of P.

For a fixed real number ρ, we can count the number of points of P in the above ellipsoid: Using *linearization*, see Agarwal and Matousek [1], we convert P to a point set P' in a Euclidean space whose dimension depends on d. The problem then becomes that of counting

the number of points of P' in a query simplex. Chan [9] has shown that such queries can be answered in $O(n^{1-c})$ time, for some small constant $c > 0$. This result, combined with *parametric search*, see Megiddo [18], allows us to compute $\Delta^*(p, q)$ in $O(n^{1-c})$ time.

For many applications, including our $(2 + \varepsilon)$-spanner construction, an approximation of the minimum triangle is sufficient. The following lemma shows that a WSPD with respect to $s = 2/\varepsilon$ provides a $(1 + \varepsilon)$-approximation.

▶ **Lemma 5.*** *Let A and B be subsets of a point set P such that $\{A, B\}$ is an s-well-separated pair, and assume that $|B| \geq 2$.*

1. *For any point $a \in A$ and any two points $b, c \in B$, we have $|\Delta_{abc}| \leq (1 + 2/s)|\Delta^*(a, b)|$.*
2. *Assume that $|A| \geq 2$. For any two points $a, a' \in A$ and any two points $b, b' \in B$, it holds $|\Delta^*(a, b)| \leq (1 + 8/s)|\Delta^*(a', b')|$.*

Note that this works only if at least one subset of the well-separated pair contains at least two points. If both subsets have size one, we can use the following lemma to approximate the minimum triangle using approximate nearest neighbour queries.

▶ **Lemma 6.** *Let P be a set of n points in $\mathbb{R}^d$ and let $0 < \varepsilon_1 < 2$ be a real number. In $\mathcal{O}(n \log n)$ time, the set P can be preprocessed into a data structure of size $\mathcal{O}(n)$, such that, given any two distinct query points p and q in P, a $(1 + \varepsilon_1)$-approximation of the minimum triangle $\Delta^*(p, q)$ can be computed in $\mathcal{O}(\log n)$ time.*

Proof. The data structure is the approximate nearest neighbour structure of Lemma 2 [3]. The query algorithm is presented in Algorithm 2. Let the constants in this algorithm be equal to $\varepsilon_2 = \varepsilon_1/2$, $\alpha = 4/\varepsilon_1$, and $\varepsilon_3 = \frac{2}{3\sqrt{d}} \cdot \varepsilon_1$.

Let p and q be two distinct points in P. We prove that Algorithm 2 returns a $(1 + \varepsilon_1)$-approximation of $\Delta^*(p, q)$.

Algorithm 2 $(1 + \varepsilon_1)$-Approximation of the Minimum-Perimeter Triangle.

Require: Query points $p, q \in P$, positive reals $\varepsilon_1 < 2$, ε_2, ε_3, $\alpha > 2$, data structure M to approximate nearest neighbours
Ensure: Triangle Δ such that $|\Delta| \leq (1 + \varepsilon_1)|\Delta^*(p, q)|$
  $r = (1 + \varepsilon_2)$-approximate nearest neighbour of p (which is neither p nor q)
  if $|pr| > \alpha|pq|$, **then return** Δ_{pqr}
  else
    Let B be the hypercube with sides of length $3\alpha|pq|$ that is centred at p and divided into cells with sides of length of $\frac{2}{3\sqrt{d}} \cdot \varepsilon_1|pq|$
    for each cell in B **do**
      $x_c = (1 + \varepsilon_2)$-approximate nearest neighbour of the cell centre (with $x_c \neq p$, $x_c \neq q$)
    return the triangle Δ_{pqx_c} with the smallest perimeter across all cells

Throughout this proof, we denote the third point of $\Delta^*(p, q)$ by x. Let r be the $(1 + \varepsilon_2)$-approximate nearest neighbour of p in $P \setminus \{p, q\}$ that is computed by the algorithm. By the triangle inequality, it holds

$$|\Delta_{pqr}| = |pq| + |qr| + |pr| \leq 2|pq| + 2|pr|. \tag{2}$$

Case 1. $|pr| > \alpha|pq|$.

Let p^* be the exact nearest neighbour of p in the set $P \setminus \{p, q\}$. Since r is a $(1+\varepsilon_2)$-approximate nearest neighbour of p in $P \setminus \{p, q\}$, and since $|\Delta^*(p, q)| \geq 2|px|$, we have

$$|pr| \leq (1+\varepsilon_2)|pp^*| \leq (1+\varepsilon_2)|px| \leq (1+\varepsilon_2)|\Delta^*(p, q)|/2.$$

Combining this inequality with Equation (2) and the assumption that $|pr| > \alpha|pq|$, we have

$$|\Delta_{pqr}| \leq (2 + 2/\alpha)|pr| \leq (1 + 1/\alpha)(1+\varepsilon_2)|\Delta^*(p, q)|.$$

Since $\varepsilon_2 = \varepsilon_1/2$, $\alpha = 4/\varepsilon_1$ and $\varepsilon_1 < 2$, we have

$$|\Delta_{pqr}| \leq (1+\varepsilon_1/4)(1+\varepsilon_1/2)|\Delta^*(p, q)| = (1+3\varepsilon_1/4+\varepsilon_1^2/8)|\Delta^*(p, q)| \leq (1+\varepsilon_1)|\Delta^*(p, q)|.$$

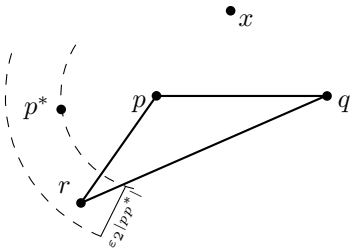

Figure 2 Visualization of Case 1 in the proof of Lemma 6. Since r is a $(1+\varepsilon_2)$-approximated nearest neighbour of p, the returned triangle Δ_{pqr} is a $(1+\varepsilon_1)$-approximation of $\Delta^*(p, q) = \Delta_{pqx}$.

Case 2. $|pr| \leq \alpha|pq|$.

Consider the hypercube B with sides of length $3\alpha|pq|$ that is centred at p.

We first prove that the third point x of $\Delta^*(p, q)$ is in B. Using Equation (2), the assumption that $|pr| \leq \alpha|pq|$, and the fact that $\alpha \geq 2$, we have

$$|\Delta^*(p, q)| \leq |\Delta_{pqr}| \leq (2 + 2\alpha)|pq| \leq 3\alpha|pq|.$$

Since $|\Delta^*(p, q)| \geq 2|px|$, it follows that $|px| \leq (3\alpha/2)|pq|$ and, therefore, $x \in B$.

Let C be the cell of B that contains x, let c be the centre of C, let c^* be the exact nearest neighbour of c in $P \setminus \{p, q\}$, and let x_c be the $(1+\varepsilon_2)$-approximate nearest neighbour of c that is computed by the algorithm. We first prove an upper bound on the distance $|xx_c|$:

$$|xx_c| \leq |xc| + |cx_c| \leq |xc| + (1+\varepsilon_2)|cc^*| \leq |xc| + (1+\varepsilon_2)|cx| = (2+\varepsilon_2)|cx| \leq 3|cx|.$$

Since x and c are in the same $\varepsilon_3|pq|$-sized cube and $\varepsilon_3 = \frac{2}{3\sqrt{d}} \cdot \varepsilon_1$, it follows that

$$|xx_c| \leq 3 \cdot \sqrt{d}/2\varepsilon_3|pq| = \varepsilon_1|pq| \leq (\varepsilon_1/2)|\Delta^*(p, q)|.$$

where the last inequality $|\Delta^*(p, q)| \geq 2|pq|$ follows from the triangle inequality.

Let $\Delta_{pqx_{c'}}$ be the triangle that is returned by the algorithm. Then

$$|\Delta_{pqx_{c'}}| \leq |\Delta_{pqx_c}| \leq |pq|+|qx|+|xx_c|+|x_cx|+|xp| = |\Delta^*(p, q)|+2|xx_c| \leq (1+\varepsilon_1)|\Delta^*(p, q)|.$$

The query algorithm performs two deletions, two insertions, and $1 + (3\alpha/\varepsilon_3)^d = \mathcal{O}(1)$ approximate nearest neighbour queries in the data structure of Lemma 2 [3]. Each such operation takes $\mathcal{O}(\log n)$ time. Therefore, the entire query algorithm takes $\mathcal{O}(\log n)$ time. ◀

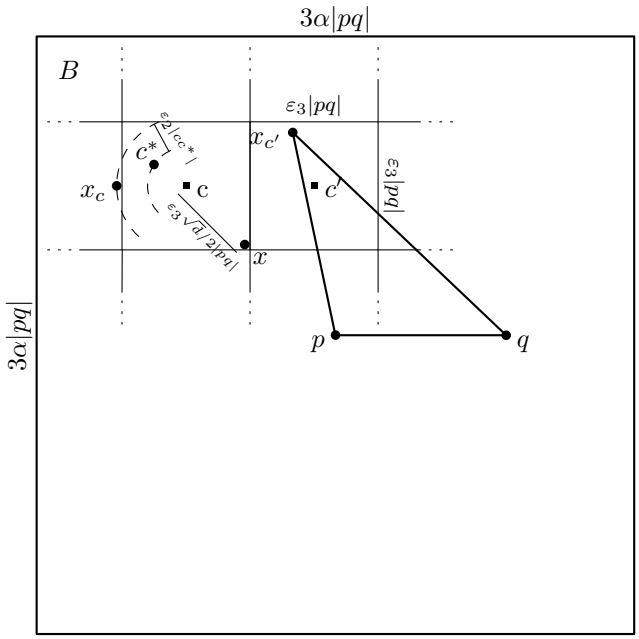

Figure 3 Visualization of Case 2 in the proof of Lemma 6. The third point x of $\Delta^*(p,q)$ lies in the cell centred at c. Since $\Delta_{pqx_{c'}}$ is returned, it holds $|\Delta_{pqx_{c'}}| \leq |\Delta_{pqx_c}|$, where $x_{c'}$ and x_c are $(1+\varepsilon_2)$-approximated nearest neighbours of c' and c.

3.2 NP-hardness

Our $(2+\varepsilon)$-spanner construction involves computing undirected $(1+\varepsilon)$-approximations of minimum-perimeter triangles, which are subsequently oriented. A similar approach is used in [5] where they prove, for convex point sets, orienting a greedy triangulation yields a plane oriented $O(1)$-spanner. Both results could be improved by optimally orienting the underlying undirected graph. The authors in [5] pose, as an open question, whether it is possible to compute, in polynomial time, an orientation of any given undirected geometric graph, that minimises the oriented dilation. We answer this question by showing NP-hardness.

▶ **Theorem 7.*** *Let P be a finite set of points in a metric space and let G be an undirected graph with vertex P. Given a real number t', it is NP-hard to decide if there exists an orientation $\overrightarrow{G}$ of G with oriented dilation $\operatorname{odil}(\overrightarrow{G}) \leq t'$. This is even true for point sets in the Euclidean plane.*

We give a proof idea, which is mainly described graphically, for details check the full version of this paper.

Proof sketch. We reduce from the NP-complete problem planar 3-SAT [17]. We start with a planar Boolean formula φ in conjunctive normal form with an incidence graph G_φ as illustrated in Figure 4. This graph can be embedded on a polynomial-size grid whose cells have side length one [13, 17]. Let $t' = 1.043$. We construct a graph G based on G_φ such that there is an orientation $\overrightarrow{G}$ of G with dilation $\operatorname{odil}(\overrightarrow{G}) \leq t'$ if and only if φ is satisfiable.

In the following, every point $p = (x, y)$ on the grid is replaced by a so-called *oriented point*, which is a pair of points $P = \{t(p), b(p)\}$ with *top* $t(p) = (x, y + \frac{\varepsilon}{2})$ and *bottom* $b(p) = (x, y - \frac{\varepsilon}{2})$, where $\varepsilon \geq 0$ is a small constant.

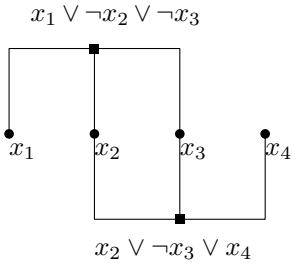

Figure 4 Example: Incidence graph of a planar 3-SAT formula embedded on a square grid.

We add an edge between $t(p)$ and $b(p)$, and its orientation encodes whether this points represent "true" or "false". W.l.o.g. we assume that an oriented edge from $b(p)$ to $t(p)$, in other words an *upwards* edge, represents "true", whereas an oriented edge from $t(p)$ to $b(p)$, in other words a *downwards* edge, represents "false".

First, we add (a polynomial number of) grid points on the edges such that all edges have length 1. Then, we replace all edges in the embedding of our formula graph G_φ by *wire* gadgets as shown in Figure 5. Note that wires propagate the orientation of oriented points – if two points next to each other on a wire have different orientations, their dilation is significantly larger than $t' = 1.043$, since the shortest oriented cycle needs to go through an additional oriented point. If they have the same orientation, their dilation is (almost) 1. To switch a signal (for a negated variable in a formula), we start the wire as in Figure 6.

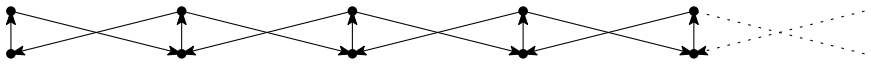

Figure 5 A wire where oriented points are oriented upwards.

Figure 6 A wire where the orientation is switched to negate the signal.

To ensure that all clause gadgets encode the same orientation of oriented points as "true", we add a *tree of knowledge*. This is a tree with vertices on the grid shifted by $(0.5, 0.5)$ relative to the grid of G_φ and with wires as edges. The tree has two leaves per clause (see Figure 7). W.l.o.g., we assume that all oriented points of the tree of knowledge are oriented upwards (thus "true").

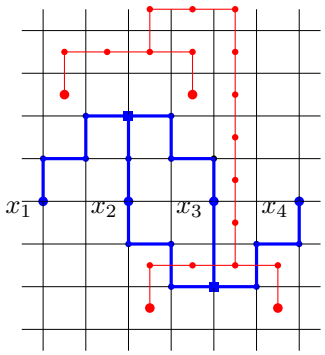

Figure 7 G_φ (blue) and its underlying grid together with a tree of knowledge (red).

All oriented points, which are not direct neighbours of a wire, are linked by a $K_{2,2}$ (compare to Figure 8). This ensures that the dilation of those points is (almost) 1. Note that the dilation of $t(p)$ and $b(p)$ is 1, regardless of whether p and p' are direct neighbours or not.

Figure 8 $K_{2,2}$ for oriented points with same orientation (left) and different orientation (right).

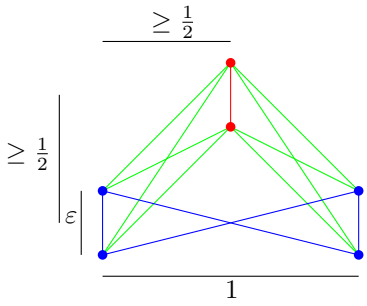

Figure 9 A wire (blue) can not be shortcut by $K_{2,2}$ gadgets (green).

Adding these $K_{2,2}$ gadgets does not affect the functionality of a wire gadget: Since any other point has at least distance $(0.5, 0.5)$ to two direct neighbours, a wire can not be shortcut by $K_{2,2}$ gadgets (compare to Figure 9).

For every clause, its two leaves in the tree of knowledge are not linked by a $K_{2,2,}$, but rather by a *clause gadget*. Figure 10 shows the two leaves and G_φ at the clause. We can assume that G_φ is embedded as shown, in particular, leaving the area directly above the clause empty. We illustrate a clause gadget in Figure 11, and in Figure 12 with more detail.

The oriented points L (left), R (right) and B (bottom) are the ends of the variable wires of a clause. They are placed such that they lie just inside an ellipse with the leaves l_1 and l_2 as foci, and without any other points in the ellipse (compare to Figures 10 and 11). As proven later, the gadget as shown in Figure 12 guarantees that, in order to obtain $\mathrm{odil}(L_1, L_2) \leq t'$, one of $\{L, R, B\}$ must lie on a shortest closed walk containing L_1, and L_2 and the orientation of that point must be the same as of L_1 and L_2 (thus, the literal is "true").

For each of $\{L, R, B\}$, we ensure there exists a *satellite* point, which is an oriented point on the variable wire, which is close but outside the ellipse. Its purpose is to ensure that the oriented dilation of L_1 (and likewise L_2) with L, B and R is below t', even if the orientation of that point is different as of L_1 and L_2, in other words, if the corresponding literal does not satisfy the clause.

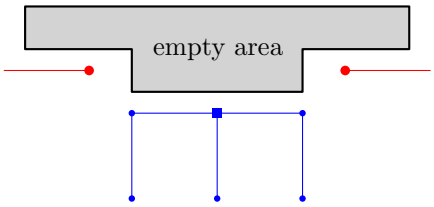

Figure 10 Embedded clause.

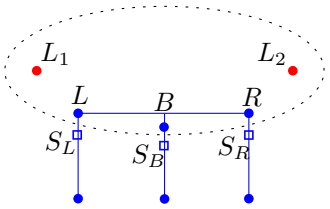

Figure 11 Clause gadget.

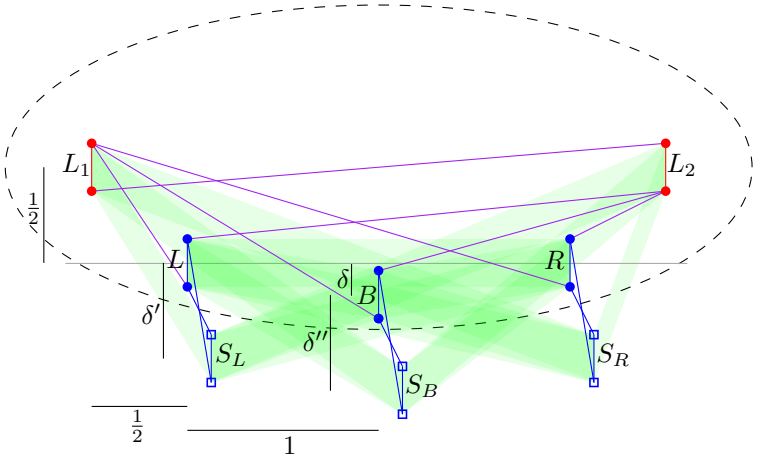

Figure 12 Detailed clause gadget. $K_{2,2}$ gadgets are indicated by green parallelograms.

By setting $\delta := 0.1335$, $\delta' := 0.0152$ and $\delta'' := 0.0304$, we obtain the following properties:

- The dilation of L_1 (and likewise L_2) with L, B and R is below t', even if the orientation of that point is different as of L_1 and L_2.
- If one of $\{L, B, R\}$ is oriented upwards, the dilation of L_1 and L_2 is smaller than $t' := 1.043$.
- If none of $\{L, B, R\}$ is oriented upwards, the dilation of L_1 and L_2 is greater than t'.

Thus, formula φ is satisfiable if and only if there exists an orientation of our constructed graph with dilation at most 1.043. ◀

Following the construction in the proof of Theorem 7, Figure 13 illustrates the graph for the formula $\varphi = (x_1 \vee \neg x_2 \vee \neq x_3) \wedge (x_2 \vee \neg x_3 \vee x_4)$ (see also Figures 4 and 7).

4 Oriented dilation

Computing the dilation of a given graph is related to the all-pairs shortest paths problem. There is a well-known cubic-time algorithm for APSP by Floyd and Warshall [11, 23]. By using their algorithm (and computing the minimum triangles naively), the oriented dilation of a given graph with n points can be computed in $\mathcal{O}(n^3)$ time.

We prove APSP-hardness for computing the oriented dilation. Since the APSP-problem is believed to need truly cubic time [20], it is unlikely that computing the oriented dilation for a given graph is possible in subcubic time.

Our hardness proof is a subcubic reduction to MinimumTriangle, which is the problem of finding a minimum weight cycle in an undirected graph with weights in $[7M, 9M]$, where the minimum weight cycle is a triangle. For two computational problems A and B, a *subcubic reduction* is a reduction from A to B where any subcubic time algorithm for B would imply a subcubic time algorithm for A (for a more thorough definition see [24]). We use the notation $A \leq_3 B$ to denote the existence of a subcubic reduction from A to B.

Vassilevska Williams and Williams [24] proved APSP-hardness for detecting if a weighted graph has a triangle of negative edge weight. Following thier proof, we prove APSP-hardness of the more specific problem MinimumTriangle:

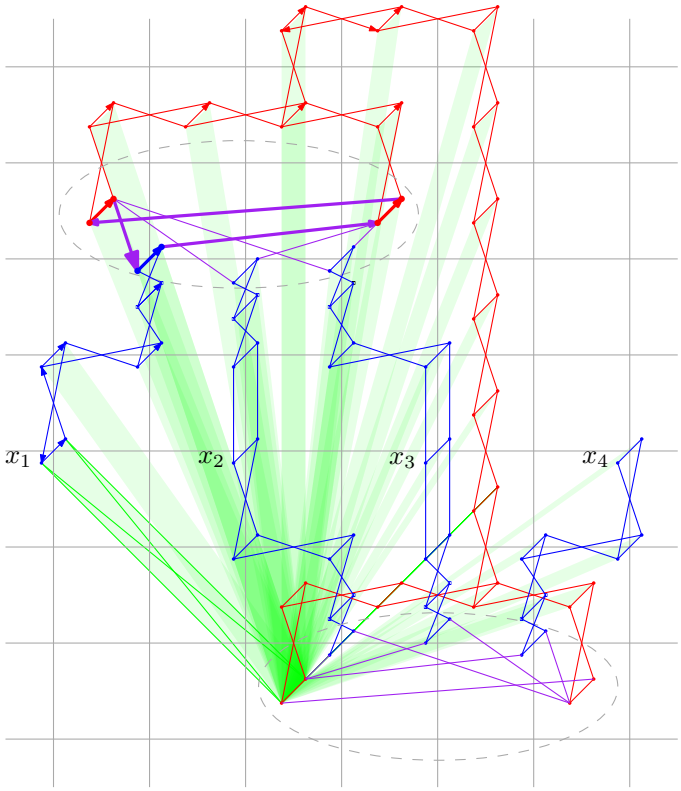

Figure 13 Graph constructed for $\varphi = (x_1 \vee \neg x_2 \vee \neg x_3) \wedge (x_2 \vee \neg x_3 \vee x_4)$. For visibility, oriented points are placed diagonally instead of vertically. Only for one point, all $K_{2,2}$-gadgets are indicated by green parallelograms. If the oriented point at the end of the wire from x_1 (blue) is – as indicated – oriented the same way as the tree of knowledge (red), this corresponds to setting it to true, resulting in an oriented closed walk in the clause gadget (purple) that gives a dilation smaller than 1.043.

▶ **Theorem 8.*** (APSP $\leq_3$ MinimumTriangle). *Let G be an undirected graph with weights in $[7M, 9M]$ whose minimum weight cycle is a triangle. Then, it is APSP-hard to find a minimum weight triangle in G.*

By reduction to MinimumTriangle, we prove APSP-hardness for ODIL, which is the problem of computing the oriented dilation of a given oriented graph in a metric space.

▶ **Theorem 9** (APSP $\leq_3$ Odil)**.** *Let $\overrightarrow{G}$ be an oriented metric graph. It is APSP-hard to compute the oriented dilation of $\overrightarrow{G}$.*

Proof. Due to Theorem 8, it is sufficient to prove MinimumTriangle $\leq_3$ Odil.

Let $G = (P, E)$ be an undirected graph with $|P| = n$ and weights $w : E \to [7M, 9M]$ in which the minimum weight cycle C of G is a triangle. Note that the weights of G fulfil the triangle inequality.

We define a metric space $(P', |\cdot|)$ with $P' = P \cup \{u, v\}$ by the following distances:

- $|pq| = w(p, q) + 15M$, for $\{p, q\} \in E$,
- $|pq| = 14M + 15M = 29M$, for $\{p, q\} \notin E$, and
- $|up| = |vp| = |vu| = 15M + 15M = 30M$ for $p \in P$.

So, for each missing edge of a complete graph on P, we assign its weight to be $14M$. Therefore, we obtain a metric with distances in $[7M, 14M]$. Then, we add the points u and v with distance $15M$ to each point in $p \in P$. To preserve the metric, we increase the distance of every tuple by $15M$. This construction is visualised in Figure 14.

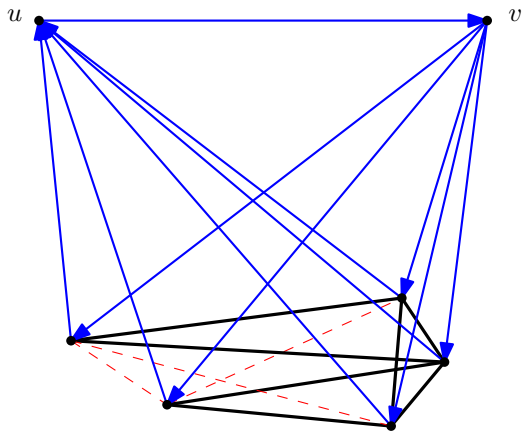

Figure 14 Graph construction in the proof of Theorem 8. Given an undirected graph on P (black), we add two points u, v with a large distance to all other points and augment it to a complete graph (red, dashed). The oriented graph $\overrightarrow{G}$ (blue) ensures that every shortest closed walk containing p and q in P visits u and v.

Let $\overrightarrow{G} = (P', \overrightarrow{E})$ be an oriented graph with $\overrightarrow{E} = \{(p,u),(v,p) \mid p \in P\} \cup \{(u,v)\}$.

We prove that the weight $w(C)$ of the minimum triangle can be computed by computing $\operatorname{odil}(\overrightarrow{G})$. In particular, we show that $w(C) = \frac{180M}{\operatorname{odil}(\overrightarrow{G})} - 45M$.

We proceed by computing the oriented dilation of $\overrightarrow{G}$. We first note that all edges of $\overrightarrow{G}$ have weight $30M$.

For every tuple of u or v and a point $p \in P$, the shortest closed walk is a triangle of length $|C_{\overrightarrow{G}}(u,p)| = |C_{\overrightarrow{G}}(v,p)| = |C_{\overrightarrow{G}}(u,v)| = 3 \cdot 30M = 90M$. Their minimum triangle contains two edges of length $30M$. Therefore, their dilation is

$$\operatorname{odil}(u,p) = \frac{|C_{\overrightarrow{G}}(u,p)|}{|\Delta^*(u,p)|} \leq \frac{90M}{2 \cdot 30M} = 1.5.$$

Analogously, it holds that $\operatorname{odil}(v,p) \leq 1.5$ for $p \in P$.

For u and v, it holds that $\operatorname{odil}(u,v) = 1$, because every triangle in P' containing u and v is an oriented closed walk in $\overrightarrow{G}$.

For two distinct points $p, q \in P$, the shortest closed walk containing p and q visits u and v and has length $|C_{\overrightarrow{G}}(p,q)| = 6 \cdot 30M = 180M$. For their minimum triangle holds $|\Delta^*(p,q)| \leq 3 \cdot 29M = 87M$. Since their dilation is larger than 2, a worst-case pair of $\overrightarrow{G}$ must be a pair in P. Therefore, the oriented dilation of the constructed graph $\overrightarrow{G}$ is

$$\operatorname{odil}(\overrightarrow{G}) = \max_{p,q \in P} \frac{|C_{\overrightarrow{G}}(p,q)|}{|\Delta^*(p,q)|} = \frac{180M}{\min\limits_{p,q,p^* \in P} w'(p,q) + w'(q,p^*) + w'(p,p^*)} > 2.$$

Since C is a triangle and $w(C) \leq 27M$, it holds that

$$\min_{p,q,p^* \in P} |pq| + |qp^*| + |p,p^*| = \min_{p,q,p^* \in P} w(p,q) + w(q,p^*) + w(p,p^*) + 3 \cdot 15M = w(C) + 45M.$$

Therefore, the oriented dilation of $\overrightarrow{G}$ is achieved by the minimum-length triangle C. Consequently, given the oriented dilation of $\overrightarrow{G}$, the length of C is $w(C) = \frac{180M}{\operatorname{odil}(\overrightarrow{G})} - 45M$.

The most expensive operation in our reduction is defining the metric on $\mathcal{O}(n^2)$ points with distances in $[22M, 30M]$. Following the definitions in [24], all instances have size $\mathcal{O}(n^2 \operatorname{polylog}(M))$ and all operations take subcubic time.

Thus, computing the oriented dilation of an oriented metric graph is at least as hard as finding a minimum weight triangle in an undirected graph. ◀

To compute the oriented dilation, testing all $\binom{n}{2}$ point tuples seems to be unavoidable. However, to approximate the oriented dilation, we show that, a linear set of tuples suffices.

▶ **Theorem 10.*** *Let P be a set of n points in $\mathbb{R}^d$, let $\overrightarrow{G}$ be an oriented graph on P, and let $\varepsilon > 0$ be a real number. Assume that, in $T(n)$ time, we can construct a data structure such that, for any two query points p and q in P, we can return, in $f(n)$ time, a k-approximation to the length of a shortest path in G between p and q. Then we can compute a value $\overline{\operatorname{odil}}$ in $\mathcal{O}(T(n) + n(\log n + f(n)))$ time, such that $(1-\varepsilon) \cdot \operatorname{odil}(\overrightarrow{G}) \leq \overline{\operatorname{odil}} \leq k \cdot \operatorname{odil}(\overrightarrow{G})$.*

Our approximation algorithm (Algorithm 3) uses the WSPD to achieve a suitable selection of $\mathcal{O}(n)$ point tuple that needs to be considered. The algorithm and its analysis work similar to our $(2+\varepsilon)$-spanner construction (compare to Algorithm 1). For each selected tuple, the algorithm approximates their oriented dilation by approximating their minimum triangle and shortest closed walk.

The precision and runtime of this approximation depend on approximating the length of a shortest path between two query points. The point-to-point shortest path problem in directed graphs is an extensively studied problem (see [14] for a survey). Alternatively, shortest path queries can be preprocessed via approximate APSP (see [10, 21, 25]). For planar directed graphs, the authors in [2] present a data structure build in $\mathcal{O}(n^2/r)$ time, such that the exact length of a shortest path between two query points can be returned in $\mathcal{O}(\sqrt{r})$ time. Setting $r = n^{2/3}$ minimizes the runtime of our Algorithm 3 to $\mathcal{O}(n^{4/3})$. It should be noted that even with an exact shortest path queries ($k = 1$) the oriented dilation remains an approximation due to the minimum-perimeter triangle approximation.

Algorithm 3 Approximate Oriented Dilation.

Require: Oriented graph $\overrightarrow{G} = (P, \overrightarrow{E})$, positive reals ε, ε_1, s, parameter k
Ensure: Value $\overline{\operatorname{odil}}$, such that $(1-\varepsilon)\operatorname{odil}(\overrightarrow{G}) \leq \overline{\operatorname{odil}} \leq k \operatorname{odil}(\overrightarrow{G})$
  Compute s-WSPD with the pairs $\{A_i, B_i\}$ for $1 \leq i \leq m$
  Compute the data structure M on P to approximate nearest neighbours (see Lemma 2 [3])
  $\overline{\operatorname{odil}} = 1$
  for $i = 1$ **to** m **do**
    $A =$ Pick $\min\{|A_i|, 2\}$ points of A_i
    $B =$ Pick $\min\{|B_i|, 2\}$ points of B_i
    for each $\{a, b\} \in A \times B$ **do**
      $\overline{d}(a,b) = k$-approximation of the length of a shortest path from a to b in $\overrightarrow{G}$
      $\overline{d}(b,a) = k$-approximation of the length of a shortest path from b to a in $\overrightarrow{G}$
      $\Delta_{abc} = (1+\varepsilon_1)$-approximation of $\Delta^*(a,b)$ by Algorithm 2 given M, a, b, ε_1
      $\overline{\operatorname{odil}} = \max\left\{\frac{\overline{d}(a,b)+\overline{d}(b,a)}{|\Delta_{abc}|}, \overline{\operatorname{odil}}\right\}$
  return $\overline{\operatorname{odil}}$

5 Conclusion and outlook

We present an algorithm for constructing a sparse oriented $(2+\varepsilon)$-spanners for multidimensional point sets. Our algorithm computes such a spanner efficiently in $O(n \log n)$ time for point sets of size n. In contrast, [5] presents a plane oriented $\mathcal{O}(1)$-spanner, but only for points in convex position. Developing algorithms for constructing plane oriented $\mathcal{O}(1)$-spanners for general two-dimensional point sets remains an open problem. Another natural open problem is to improve upon $t = 2 + \varepsilon$. For this, the question arises: Does every point set admit an oriented t-spanner with $t < 2$? Even for complete oriented graphs this is open.

Both algorithms could be improved by optimally orienting the underlying undirected graph, which is constructed first. We discard this idea by proving that, given an undirected graph, it is NP-hard to find its minimum dilation orientation. In particular, is the problem NP-hard for plane graphs or for complete graphs?

In the second part of this paper, we study the problem of computing the oriented dilation of a given graph. We prove APSP-hardness of this problem for metric graphs. We complement this by a subcubic approximation algorithm. This algorithm depends on approximating the length of a shortest path between two given points. Therefore, improving the approximation of a shortest path between two given points in directed/oriented graphs is an interesting problem. The APSP-hardness of computing the oriented dilation of metric graphs seems to be dominated by the computation of a minimum-perimeter triangle. However, for Euclidean graphs, the minimum-perimeter triangle containing two given points can be computed in $o(n)$ time. This raises the question: is computing the oriented dilation of a Euclidean graph easier than for general metric graphs?

Finally, as noted in [5], in many applications some bi-directed edges might be allowed. This opens up a whole new set of questions on the trade-off between dilation and the number of bi-directed edges. Since this is a generalisation of the oriented case, both of our hardness results also apply to such models.

Abstract

We present a framework to classify PL-types of large censuses of triangulated 4-manifolds, which we use to classify the PL-types of all triangulated 4-manifolds with up to 6 pentachora. This is successful except for triangulations homeomorphic to the 4-sphere, $\mathbb{C}P^2$, and the rational homology sphere $QS^4(2)$, where we find at most four, three, and two PL-types respectively. We conjecture that they are all standard. In addition, we look at the cases resisting classification and discuss the combinatorial structure of these triangulations – which we deem interesting in their own rights.

1 Introduction

In the context of computational topology it is desirable to have a data set of examples on which to perform experiments and test hypotheses. As such, an exhaustive list of all 4-manifold triangulations of a certain size and type, called a *census*, serves as such a useful reference. In dimension three we currently have censuses available with up to 11 tetrahedra (containing 13 400 closed, orientable, prime, minimal triangulations). In dimension 4, where a closed 4-manifold requires an even number of pentachora, censuses are currently limited to triangulations with 2, 4, and 6 pentachora. However, despite this relative scarcity of data, even with just three tiers of the census, there are a total of 441 287 triangulations to consider.

Given a smooth manifold X, another smooth manifold X' is called *exotic (with respect to X)*, if X' is homeomorphic, but not diffeomorphic to X. In other words, X and X' represent the same topological manifold but are distinct as smooth manifolds. Dimension four is the first dimension in which exotic smooth structures appear. It is a fundamental problem in 4-manifold topology to determine the number of smooth structures a particular 4-manifold admits. The simplest and most famous instance of this problem is the *smooth 4-dimensional Poincaré conjecture* (S4PC for short):

▶ **Conjecture 1** (S4PC). *There do not exist exotic 4-spheres.*

It is typical to discuss exotic structures in relation to a "standard" or canonical smooth structure. For example, the standard structure on $\mathbb{R}^n$ is the one given by a single chart with the identity map; on $\mathbb{S}^n$ it is the one with two charts given by stereographic projection.

▶ Remark 2. The concept of a standard smooth structure is not well-defined in isolation. For instance, let $K3$ be the $K3$ *surface* with the standard smooth structure coming from being the zero-set of $w^4+x^4+y^4+x^4=0$ in $\mathbb{C}P^3$, and let $\mathbb{C}P^2$ be the standard complex projective plane. Then each of the connected sums[1] $X_1 = \#_3\mathbb{C}P^2\#_{20}\overline{\mathbb{C}P^2}$ and $X_2 = K3\#\overline{\mathbb{C}P^2}$ inherits a standard smooth structure from their summands. It is known that $X_1 \cong_{\text{TOP}} X_2$ but $X_1 \ncong_{\text{DIFF}} X_2$ [28], meaning X_1 is exotic with respect to X_2 and vice versa. The smallest triangulations of two 4-manifolds that are known to be homeomorphic, but not diffeomorphic, are *ideal triangulations* (i.e., triangulations of manifolds with non-empty boundary where the boundary is given by a neighbourhood of a vertex) with 10 pentachora [7]. The authors are not aware of any triangulations of closed 4-manifolds which are homeomorphic, but not diffeomorphic, and which are not simply formed from a connected sum of 'standard' well-known manifolds (such as X_1 and X_2 above).

Cairns [15, 16] and Whitehead [37] show that every smooth n-manifold can be triangulated, that is, admits a piecewise-linear (PL) structure. Moreover, every PL n-manifold for $n \leq 6$ admits a compatible smooth structure which is unique up to diffeomorphism [26, 32]. Hence, there is a bijective correspondence between isotopy classes of smooth and PL structures on 4-manifolds, and so we speak of smooth and PL structures on a 4-manifold interchangeably.

Related Work

The past decade has seen significant interest in the problem of enumerating and classifying triangulations, including several other attempts at classifying and simplifying triangulations of 4-manifolds, particularly 4-spheres. Most recently, Pérez [20], building on the work of Joswig et al. [27], analysed the same census we investigate in this paper.

More broadly, there has been a growing body of utilising Pachner moves to either simplify triangulations or establish PL-homeomorphisms. For example, the work Björner and Lutz [3], Lutz and Tsuruga [36], the second author [11], Altmann and the third author [2], the second and third author [14], and more recently the first author [7]. We note that whilst Björner, Lutz, Joswig et al., and Tsuruga, and (to some extent) Pérez use *simplicial complexes*, the work of the authors and Altmann instead use *generalised triangulations* (see Section 2.1). These are more "flexible" than simplicial complexes since, for example we allow two facets of the same simplex to be identified.

[1] Given two d-manifolds X and Y, their *connected sum*, written $X\#Y$ is formed by removing an open d-ball from each of X and Y and gluing them together along their resulting boundaries. We use $\#_k X$ to denote the k-fold connected sum of X with copies of itself. The operation is independent of the d-ball removed from their summands.

Our Contributions

We study the census of triangulations of closed, orientable, 4-manifolds with up to 6 pentachora. This data set contains 8 triangulations with 2, 784 triangulations with 4, and 440 495 triangulations with 6 pentachora, respectively. It includes a variety of triangulations with interesting combinatorial and topological features (see Tables 1–3 for a breakdown of numbers of triangulations by (PL-)topological types). The dataset was first generated by Budney and the second author [4] using `tricensus`, a utility of [12].

In addition, we present a new algorithm for finding PL-homeomorphisms between large numbers of 4-manifold triangulations by combining original heuristics and computational tools. This algorithm yields a near complete classification of the PL-types in the census. We note that, due to the undecidability of the 4-manifold homeomorphism problem [30], we do not expect there to be an efficient deterministic algorithm to complete this task. We also investigate the combinatorial structure of the triangulations resisting classification.

Specifically, we improve on the results of Pérez, reducing the upper bounds on the number of potential PL classes for $\mathbb{C}P^2$ and $\mathbb{S}^4$: within the set of 6-pentachoron triangulations homeomorphic to $\mathbb{C}P^2$, we reduce the number of potential PL classes from 5 down to 3; within the set of 4-pentachoron triangulations homeomorphic to $\mathbb{S}^4$, we reduce from 3 to 2; and finally for the set of 6-pentachoron triangulations homeomorphic to $\mathbb{S}^4$, we obtain at most 4 potential classes, down from 36 in [20].

2 Preliminaries

2.1 Triangulations

We refer to a 4-simplex as a *pentachoron* (plural: *pentachora*). The tetrahedral cells of a pentachoron are referred to as *facets*. We label the vertices of a pentachoron by elements of $\{0, 1, 2, 3, 4\}$, and use the convention that facet i refers to the facet opposite to the vertex labelled by i. A *(generalised, 4-dimensional) triangulation* $\mathcal{T}$ is a finite collection of n abstract pentachora, some or all of whose $5n$ facets are affinely identified ("glued") in pairs. These generalised triangulations are typically far more efficient than simplicial complexes, since we allow two facets of the same pentachoron to become identified.

The *boundary* of $\mathcal{T}$ consists of all the facets that are not identified with any other facets. We allow facets of the same pentachoron to be identified. The gluings defining $\mathcal{T}$ also have the effect of merging vertices, edges, triangles, and tetrahedra of the pentachora into equivalence classes, which we refer to as the *vertices*, *edges*, *triangles*, and *tetrahedra* of $\mathcal{T}$.

The *link* $\mathrm{lk}(v)$ of a vertex v of $\mathcal{T}$, is the "frontier" of a small regular neighbourhood of v. We treat vertex links as triangulated 3-dimensional spaces, formed by inserting a small tetrahedron into each corner of each pentachoron, and then joining together the tetrahedra from adjacent pentachora along their triangular faces. This mirrors the traditional concept of a link in a simplicial complex, but is modified to support generalised triangulations.

If v lies in the boundary of $\mathcal{T}$, its link is a space with boundary. If the link is homeomorphic to B^3, then we refer to v as a *boundary vertex*. If the link is any other space with boundary then we say v is an *invalid vertex*. On the other hand, if v does not lie in the boundary of $\mathcal{T}$, its link is a closed space. If the link is (PL-)homeomorphic to $\mathbb{S}^3$, then v is an *internal vertex*, and if it is any other closed space then it is referred to as an *ideal vertex*.

We insist that no edge of $\mathcal{T}$ is identified with itself in reverse, and that no triangle is identified with itself via a non-identity permutation. This, together with the condition that the link of every vertex is either B^3 or $\mathbb{S}^3$, guarantees that $\mathcal{T}$ triangulates a 4-manifold.

Given a triangulation $\mathcal{T}$ of a 4-manifold, the vector $f(\mathcal{T}) = (f_0, f_1, f_2, f_3, f_4)$, where f_i denotes the number of i-dimensional faces in $\mathcal{T}$, is called its *face vector*, or *f-vector* for short. Since $\mathcal{T}$ triangulates a 4-manifold, it satisfies the following equations

$$-2f_3 + 5f_4 = 0 \quad (1)$$
$$2f_1 - 3f_2 + 4f_3 - 5f_4 = 0 \quad (2)$$
$$f_0 - f_1 + f_2 - f_3 + f_4 = \chi(\mathcal{T}) \quad (3)$$

known as *generalised Dehn-Sommerville equations* [35]. Here, $\chi(\mathcal{T})$ denotes the *Euler characteristic* of $\mathcal{T}$, a topological invariant. Observe that Equation (1) implies that a triangulation of a closed 4-manifold must have an even number of pentachora.

To encode a triangulation, we give each pentachoron a label and an ordering of its five vertices. Two triangulations are *(combinatorially) isomorphic* if they are identical up to relabelling of pentachora and/or reordering of the pentachoron vertices. We can uniquely identify any isomorphism class of triangulations using an efficiently-computable string called an *isomorphism signature* [11]. Every triangulation has a unique isomorphism signature, and two triangulations have the same signature if and only if they are isomorphic.

An important tool in the study of triangulations is the *dual graph* (also known as the *face pairing graph*). Given a triangulation $\mathcal{T}$, its dual graph $\Gamma(\mathcal{T})) = (V, E)$ is the multigraph whose nodes are the pentachora in $\mathcal{T}$, and for each gluing that identifies two tetrahedral facets of p_i and p_j we add an arc between the corresponding nodes in V. By construction, $\Gamma(\mathcal{T})$ has maximum degree ≤ 5, and is 5-regular when $\mathcal{T}$ triangulates a closed 4-manifold $\Gamma(\mathcal{T})$.

The dual graph as defined above does not retain any information about the permutations used in the face identifications, and so $\mathcal{T}$ cannot be reconstructed from $\Gamma(\mathcal{T})$ alone. Nevertheless, some information about the underlying topology of the 4-manifold can still be extracted from $\Gamma(\mathcal{T})$. It also proves to be useful as a visual tool when discussing triangulations.

▶ Housekeeping 1. In order to avoid confusion, we use the terms *vertices* and *edges* exclusively when referring to triangulations, and *nodes* and *arcs* when referring to graphs.

2.2 Local Moves and the Pachner Graph

We modify our triangulations using *Pachner moves* (or *bistellar flips*), which are local moves that change a triangulation but not its underlying PL-type [33]. Informally, an (i, j) Pachner move can be thought of as taking a subcomplex of i pentachora in the boundary comlpex of the 5-simplex $\partial\Delta^5$, and replacing them with its complement in $\partial\Delta^5$ of $6 - i = j$ pentachora. This necessarily means that *(a)* the i pentachora share a common $(5 - i)$-dimensional face – which is removed from the triangulation; and *(b)* the j pentachora share a common $(i-1)$-face – which is newly inserted into the triangulation. See Figure 1 for an illustration of Pachner moves in dimension four, and see [33] for more details.

The use of Pachner moves has several key benefits: Firstly, two PL manifolds X, and X' are PL-homeomorphic if and only if there exists a sequence of Pachner moves between X and X'. This statement is known as *Pachner's theorem* and was first proven in [33]. We can therefore certify that two triangulations are PL-homeomorphic by finding a connecting sequence of Pachner moves. Even without a guarantee that this algorithm will terminate, it is effective in practice. Secondly, Pachner moves can be used to reduce the size of a triangulation (without changing the underlying PL-type). Finally, Pachner moves are already implemented and ready-to-use in several software packages. Here, we use *Regina* [12].

The *Pachner graph* of a PL manifold X, denoted by $\mathcal{P}(X)$, is used to describe and track how distinct triangulations of a 4-manifold can be related via Pachner moves. It is the (infinite) graph with nodes corresponding to isomorphism classes of triangulations of X; and two nodes of $\mathcal{P}(X)$ are joined by an arc if and only if there is a single Pachner move that takes one triangulation to the other. We refer the reader to [11] for further details.

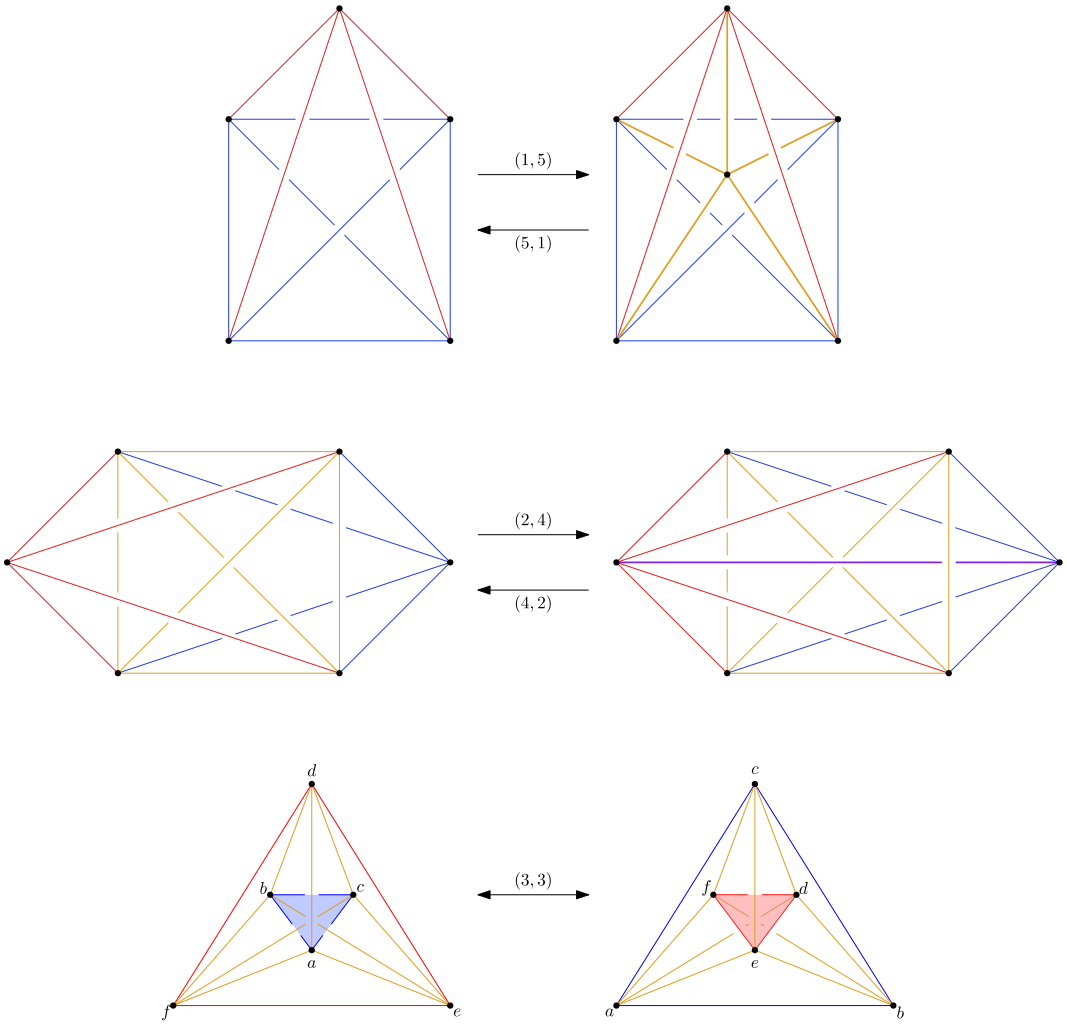

Figure 1 Pachner moves and their inverses in dimension 4.

There are many other local modifications which can be expressed by sequences of Pachner moves. When moving through the Pachner graph, using these additional modifications can be powerful, since they allow the use of "short-cuts" into different areas of the graph. In this article, we make extensive use of two of these additional moves, the 2-0-*edge move* and the 2-0-*triangle move*. The 2-0-edge move takes two pentachora, identified along three tetrahedra to form a "pillow" around a common edge, and flattens them to form two tetrahedra. The 2-0-triangle move is similar. Here, two pentachora, are identified along two tetrahedra to form a pillow around a common triangle, and flattens them to form three tetrahedra.

2.3 4-Manifolds

Let $\mathcal{T}$ be a 4-manifold triangulation. For the *ring of coefficients* $\mathbb{Z}$, the *group of p-chains*, $0 \leq p \leq 4$, denoted $C_p(\mathcal{T}, \mathbb{Z})$, of $\mathcal{T}$ is the group of formal sums of p-dimensional faces with $\mathbb{Z}$ coefficients. The *boundary operator* is a linear operator $\partial_p : C_p(\mathcal{T}, \mathbb{Z}) \to C_{p-1}(\mathcal{T}, \mathbb{Z})$ such that $\partial_p \sigma = \partial_p\{v_0, \cdots, v_p\} = \sum_{j=0}^{p}\{v_0, \cdots, \widehat{v_j}, \cdots, v_p\}$, where σ is a face of $\mathcal{T}$, $\{v_0, \ldots, v_p\}$ represents σ as a face of a pentachoron of $\mathcal{T}$ in local vertices $v_0, \ldots, v_p$, and $\widehat{v_j}$ means v_j is deleted from the list. Denote by $Z_p(\mathcal{T}, \mathbb{Z})$ and $B_{p-1}(\mathcal{T}, \mathbb{Z})$ the kernel and the image of ∂_p respectively. Observing $\partial_p \circ \partial_{p+1} = 0$, we define the *p-th homology group* $H_p(\mathcal{T}, \mathbb{Z})$ of $\mathcal{T}$ by the quotient $H_p(\mathcal{T}, \mathbb{Z}) = Z_p(\mathcal{T}, \mathbb{Z})/B_p(\mathcal{T}, \mathbb{Z})$. Each homology group H_p is a finitely generated $\mathbb{Z}$-module, and is a topological invariant of the manifold triangulated by $\mathcal{T}$. We write $\beta_p = \dim(H_p(\mathcal{T}, \mathbb{Z}))$ for the dimension of (the free part of) H_p. Informally, $H_p(\mathcal{T}, \mathbb{Z})$, $0 \leq p \leq 4$, of a triangulation $\mathcal{T}$ counts the number of "p-dimensional holes" in $\mathcal{T}$. For a more thorough introduction to homology theory see [25].

Let X be a closed, oriented 4-manifold. Representatives of classes in $H_2(X; \mathbb{Z})$ generically intersect in a finite number of points (possibly after isotoping them into transverse position). The *intersection form* Q_X of X, is the symmetric, unimodular, bilinear form defined by

$$Q_X : H_2(X; \mathbb{Z}) \times H_2(X; \mathbb{Z}) \to \mathbb{Z}, \quad Q_X(\alpha, \beta) = S_\alpha \cdot S_\beta := \sum_{S_\alpha \cap S_\beta} \pm 1,$$

where S_α, and S_β are 2-chains representing the classes $\alpha, \beta \in H_2(X; \mathbb{Z})$. If X is smooth, S_α, and S_β can be chosen to be oriented surfaces embedded in X [23, Proposition 1.2.3].

A landmark result of 4-manifold topology is the following classification result for simply connected (i.e. having trivial fundamental group[2]) topological 4-manifolds due to Freedman.

▶ **Theorem 3** (Freedman [21]). *For every symmetric, unimodular, bilinear form Q, there exists a closed simply connected topological 4-manifold X such that $Q_X = Q$. If Q is even, this manifold is unique up to homeomorphism. If Q is odd then are exactly two different homeomorphism types of manifolds with the given intersection form, however only at most one of these admits a PL structure.*

Shortly after Freedman's result, Donaldson showed the following equally important result.

▶ **Theorem 4** (Donaldson [19]). *The symmetric unimodular bilinear form $\oplus_m[+1]$ is the only positive definite form that can be realised as the intersection form of a PL 4-manifold.*

The results by Freedman and Donaldson (together with Serre's algebraic classification of indefinite forms) imply the following key result.

▶ **Theorem 5.** *Two simply connected PL 4-manifolds are homeomorphic if and only if their intersection forms have the same rank, signature, and parity.*

▶ Housekeeping 2. All manifolds are assumed to be PL/smooth, closed, connected, and orientable, unless explicitly stated otherwise.

▶ **Example 6.** The 4-sphere $\mathbb{S}^4$ has no 2-homology and so $Q_{\mathbb{S}^4} = \varnothing$. The complex projective plane, $\mathbb{C}P^2$, has $Q_{\mathbb{C}P^2} = [+1]$, and the oppositely oriented manifold $\overline{\mathbb{C}P^2}$ has $Q_{\overline{\mathbb{C}P^2}} = [-1]$. $S^2 \times S^2$ has intersection form $Q_{S^2 \times S^2} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$.

[2] The *fundamental group* of a manifold X, denoted $\pi_1(X)$, describes closed paths in X up to homotopy, with the group operation of path concatenation.

2.4 Handle Decompositions and Kirby Diagrams

In the smooth setting, we primarily work with 4-manifolds via *handle decompositions*. Let X, X' be two smooth 4-manifolds. We say X is obtained from X' by attaching a (4-dimensional) k-handle, denoted $X = X' \cup_\varphi h^k$, if there is an embedding $\varphi : S^{k-1} \times D^{4-k} \to \partial X'$ such that X is of the form $X = \left[X' \sqcup D^k \times D^{4-k}\right] / \varphi(x) \sim x$, where D^k denotes the closed k-disk ($k \in \{1, 2, 3, 4\}$). There always exists a Morse function $f : X \to \mathbb{R}$ inducing a handle decomposition $X = \bigcup_{i=0}^{n} X_i$ with $\varnothing = X_{-1} \subset X_0 \subset \cdots \subset X_n = X$ in which X_i is obtained from X_{i-1} by attaching i-handles [31]. Since X is closed and connected, it can be assumed that there is a single 0- and 4-handle. Hence a closed 4-manifold X is obtained from B^4 by attaching 1-, 2-, and 3-handles and finally capping off with another B^4. Given such a handle decomposition, we depict X by drawing the attaching regions of the handles in the boundary of the 0-handle ($\partial B^4 \cong \mathbb{S}^3 \cong \mathbb{R}^3 \cup \{*\}$). By a result of Laudenbach and Poenaru [29], 3- and 4-handles attach uniquely up to diffeomorphism, and so it suffices to understand how the 1- and 2-handles attach. We depict 1-handles by "dotted" unknots (see Section 5.4 of [23] for details of this notation). 2-handles are attached via a map of the form $S^1 \times D^2 \to S^3$. These maps are determined up to isotopy by (i) an embedding $S^1 \times \{0\} \to S^3$ (i.e. a *knot*) and (ii) a choice of normal vector field on the knot. Classes of such vector fields are in bijection with the integers [23]. As such, we draw a 2-handle as a knot decorated with an integer. A decorated link diagram of this form – dotted unknots and integer decorated links – is called a *Kirby diagram* and gives a combinatorial encoding of a closed 4-manifold up to diffeomorphism. Figure 2 is an example of a typical Kirby diagram.

3 Topological Classification

We describe a classification of the triangulations in the census up to topological homeomorphism. This serves as a stepping board to then carry out the PL classification. We start by grouping the triangulations of the census by their homology groups. Since all manifolds under consideration are closed and orientable, we omit $H_0(X; \mathbb{Z}) \cong H_4(X; \mathbb{Z}) \cong \mathbb{Z}$ from the homology vector, i.e. we simply write $(H_1(X; \mathbb{Z}), H_2(X; \mathbb{Z}), H_3(X; \mathbb{Z}))$. In a second step, and in the case of simply connected triangulations, we use *Regina*'s built-in intersection form routine and Theorem 5 to split these groups further.

For the remaining triangulations, we simply guess their topological types, build triangulations of these manifolds (using *Katie*, see Section 4.4, and built-in functionality of *Regina*), and compare them to the census manifolds using Pachner moves (that is, we establish a PL homeomorphism). Altogether, this leads to the following classification, summarised in Tables 1, 2, and 3 (note that the content of the fourth column refers to work done in Section 4). In Table 2, we begin to see the appearance of S^1-bundles over *lens spaces*, denoted $L(p, q)$, which are important class of 3-manifold obtained by gluing two solid tori together (see [34] for more).

Rational Homology 4-Spheres with Finite Fundamental Group

Before giving the table for 6-pentachora, we first define a particular family of 4-manifolds. Let $R(n)$ denote the 4-manifold given by the Kirby diagram in Figure 2, in which there are n strands wrapping around the 1-handle.

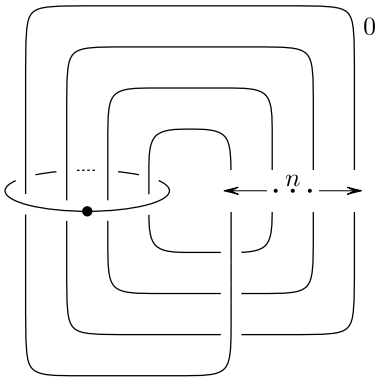

Figure 2 Kirby diagram of the rational ball $R(n)$.

$R(n)$ is a *rational homology ball*. Let $QS^4(n)$ denote the double of $R(n)$, that is $QS^4(n) := DR(n) = R(n) \cup_{\mathrm{id}} R(n)$. $QS^4(n)$ is then a *rational homology 4-sphere* with $\pi_1(QS^4(n)) \cong \mathbb{Z}_n$ and homology vector $(\mathbb{Z}_n, \mathbb{Z}_n, 0)$. By using a combination of *Katie*, Up-Side-Down-Simplify (see Section 4), and *Regina*, we obtain representative triangulations of $QS^4(n)$ for $n \in \{2, 3\}$, each with six pentachora respectively.

▶ Remark 7. We note that the topological type of $QS^4(n)$ was not identified in [20].

4 The PL classification algorithm

In this section we present our search heuristic to establish piecewise linear homeomorphisms between large quantities of triangulated manifolds conjectured to be in the same PL class. We first start by going over some subroutines before sketching the algorithm as a whole.

4.1 Important subroutines

Up-Side-Down-Simplify (USDS): This subroutine is the heart of our algorithm. It is relatively easy to describe, but details are very important. We point out that it is difficult to design a method which is efficient for both triangulations that can trivially be merged

Table 3 Topological classification of the closed orientable 6-pentachoron census.

# Pentachora	4-Manifold	# Triangulations	# PL Classes
6	$\mathbb{S}^4$	405 188	≤ 4
	$S^3 \times S^1$	29 124	1
	$\mathbb{C}P^2$	4 423	≤ 3

	$L(5,2) \tilde{\times} S^1$	1	1
	$QS^4(2)$	84	≤ 2
	$QS^4(3)$	4	1

with a different class, as well as pathological cases needing millions, if not billions of moves to escape a local area of the Pachner graph (apart from the triangulation presented in Section 5 resisting classification altogether, there are four more 4-pentachoron triangulations requiring a large number of moves before being classified as standard). Extensive research has been done to find effective strategies to compare PL homeomorphism types for triangulated 4-manifolds, see Section 1 for a detailed discussion. At least in the case of the census of small 4-manifold triangulations, the below strategy yields the best results on a consistent basis.

Our heuristic is a slight variation of a standard biased Markov chain-style random walk through the Pachner graph of a triangulation. We bias the sizes of the triangulations visited by the random walk around a fixed target size of $\hat{n}$ pentachora (in our calculations, we used $8 \leq \hat{n} \leq 12$). If the current state of the random walk has more than $\hat{n}$ pentachora, an exponential penalty is imposed on choosing a Pachner move further increasing the size of the state. The same is true for a current state of smaller size than $\hat{n}$ and moves further reducing its size.

The core idea of our approach lies in the type of moves we choose to increase and decrease the sizes of our triangulations: we use 2-4-Pachner moves to increase the size of a triangulation, but 2-0- edge- and triangle-moves to reduce the size of a triangulation. Moreover, we use standard 3-3-Pachner moves to change triangulations while keeping their f-vector constant.

Empirical evidence suggest, that this approach mixes triangulations much faster than by just using standard Pachner moves. This approach has already been used very successfully by the first author [7] in the search of minimal triangulations. The method used there is even simpler in structure than the one presented below.

Our base method has four input parameters that stay fixed for the duration the method is run: *(a)* A set probability $x \in [0,1]$ to decide whether a 3-3-move or some other move is performed, *(b)* a target size $\hat{n}$ for triangulations to be visited in the random walk, *(c)* a parameter $\alpha \in \mathbb{R}$ determining the severity of the penalty for sampling a triangulation of size away from $\hat{n}$, and *(d)* a number of steps $s \in \mathbb{Z}$.

Heuristic 1

Setup:

- $x \in [0,1]$, $\alpha \in \mathbb{R}$, $\hat{n} \in \mathbb{Z}$, $s \in \mathbb{Z}$

Main Loop:

- Set $\mathcal{T} = \mathcal{T}_0$
- For each step $1 \leq i \leq s$ and while $|\mathcal{T}| \neq n$:
  1. Update $\mathcal{T} = \mathcal{T}'$
  2. Update $\beta = \frac{e^{\alpha(\hat{n}-|\mathcal{T}|)}}{1+e^{\alpha(\hat{n}-|\mathcal{T}|)}} \in [0,1]$
  3. Sample $u \in \mathcal{U}([0,1])$
  4. Case $u > x$: if available, perform 3-3-move on $\mathcal{T}$ to return triangulation $\mathcal{T}'$
  5. Sample $v \in \mathcal{U}([0,1])$
  6. If $v > \beta$: if available, perform 2-0-edge- or triangle-move on $\mathcal{T}$ to return triangulation $\mathcal{T}'$
  7. Perform 2-4-move on $\mathcal{T}$ to return triangulation $\mathcal{T}'$
- If $\mathcal{T}$ and $\mathcal{T}_0$ are in different classes, merge classes

Adjust-Vertex-Number: This subroutine takes a triangulated 4-manifold $\mathcal{T}_0$ as input, and outputs a PL homeomorphic triangulation with v vertices.

If $\mathcal{T}_0$ has fewer than v vertices, perform 1-5-moves $v - f_0(\mathcal{T}_0)$ times to obtain a v-vertex triangulation. If, on the other hand, the input triangulation has more than v vertices, we randomly perform edge collapses. If not enough edge collapses are available, we run USDS in between until they become available. It is worthwhile noting that the latter case has no guarantee to terminate in general, but does very quickly in practice.

4.2 The algorithm

Our implementation is based on establishing PL-homeomorphisms using Pachner's theorem [33], i.e. by describing sequences of Pachner moves transforming one triangulation into another. Our computations are organised in a Union-Find structure: at any step of our calculations, every triangulation is associated to a class of triangulations for which pairwise PL homeomorphisms have already been established. Each class has a unique representative triangulation. If a sequence of Pachner moves is found turning a triangulation from one class into a triangulation from another class, both classes are merged with the representative of the latter class, and we continue. This way, if the task is to classify N triangulations, we only need to establish $O(N)$, rather than $O(N^2)$ PL homeomorphisms.

We start with a large number of triangulations $\mathcal{T}_1, \ldots, \mathcal{T}_N$. Here, we assume that all triangulations have the same number of n pentachora, but this is not necessary for the algorithm to work. We furthermore assume that we have already established that all triangulations $\mathcal{T}_i$, $1 \leq i \leq N$, are homeomorphic. Again, this is not a necessary requirement for the algorithm to work, but we require, however, that all triangulations have already been tested to have the same Euler characteristic m.

For n-pentachora triangulations of Euler characteristic m, it is a consequence of Equations (1)–(3) that their f-vector is determined by their number of vertices. We have the following algorithm.

Main Algorithm

1. Initialise the UNION-FIND structure with N classes $\{\mathcal{T}_i\}$, $1 \leq i \leq N$ of size 1.
2. Fix $v = \min\{f_0(\mathcal{T}_i) | 1 \leq i \leq N\}$, the smallest number of vertices found in our list.
3. For all $1 \leq i \leq N$:
   a. Use ADJUST-VERTEX-NUMBER to produce a v-vertex triangulation $\mathcal{T}'$
   b. Use USDS to connect $\mathcal{T}'$ to $\mathcal{T}_j$, $f_0(\mathcal{T}_j) = v$, $f_4(\mathcal{T}_j) = n$, from the list
   Once this step is complete, every PL class has a v-vertex representative.
4. For all classes, run USDS to connect its representative to a new class. Use a moderate time-out threshold to skip hard cases.
5. As long as there are still more than K classes, goto **6.**
6. For remaining classes, run USDS with relaxed parameters.

4.3 Implementation, timings, and remarks

Our implementation of the algorithm described in this section is available at `https://github.com/raburke/Dim4Census`.

Our guiding principle for the implementation is to minimise human intervention. We point out that we can modify arbitrarily many triangulations in parallel until they can be merged with an existing component of the UNION-FIND structure. This parallelises the bottleneck of the computation for large censuses of largely easy-to-handle triangulations. When dealing with pathologically difficult combinatorial structures, running different random walks on the same triangulation may lead to similar speed-ups. However, for the 6-pentachoron census with its $\approx 400,000$ triangulations, parallelisation is not crucial and we hence defer its implementation to future work.

For some indications of running times, we ran our algorithm on a laptop with an 11th Gen Intel i7 processor and 32GB of RAM, with input the 405 188 6-pentachoron triangulations homeomorphic to S^4. We obtained the following timings for first running ADJUST-VERTEX-NUMBER (referred to as *Step 1*), then running USDS until only 10 connected components are left over (*Step 2*), and then the times to merge any additional component until we reduce to 6 connected components, which is when we stopped our calculations.

Table 4 Sample running times of the Main Algorithm with input 405 188 6-pentachoron 4-spheres.

Step 1 (s)	Step 2 (s)	9 comp (s)	8 comp (s)	7 comp (s)	6 comp (s)	Total time (s)
13 686	10 752	88	4 787	11 008	4 987	45 308
14 061	10 306	373	1 097	335	1 143	27 315
14 170	9 264	365	451	464	3 754	28 468
14 182	9 359	1 116	1 772	99	3 772	30 300
14 142	9 791	405	811	1 598	7 961	34 708
13 212	9 342	302	48	3 100	3 155	29 159

Achieving 5 connected components usually does not take much longer (with 1 611 and 18 929 additional seconds in two of the six runs summarised above). Achieving four connected components takes around a week, as we were able to observe on multiple occasions. The algorithm never achieved 3 connected components. Running the complete algorithm in parallel on 100+ cores may produce additional results. Alternatively, exhaustive enumeration on a larger machine with more memory may lead to additional merges of connected components.

Table 5 Sample running times of PL classification for selected manifolds.

Manifold	Step 1 (s)	Step 2 (s)	1 comp. (s)	Total time (s)
$S^3 \times S^1$	2480	119	51	2650
$S^2 \tilde{\times} S^2$	115	0	4 514	4 629
$\#_2\mathbb{C}P^2$	27	0	1 531	1 558
$S^3 \times S^1 \# \mathbb{C}P^2$	1 060	140	42	1 242
$S^3 \times S^1 \#_2 \mathbb{C}P^2$	0	0	62 022	62 022

PL classification of other topological types was achieved through a combination of exhaustive enumeration and our main algorithm. Relevant timings are summarised below.

4.4 *Katie* and PL classification results

As discussed in Section 4, our PL classification algorithm determines whether two given triangulations are PL homeomorphic. What is missing from this algorithm is a reference triangulation for which its PL homeomorphism type is known.

For this we use the software tool *Katie* [6, 7], developed by the first author. *Katie* is based on an algorithm due to Casali and Cristofori [18]. It takes as input a Kirby diagram and produces a triangulation of the associated PL 4-manifold. For each of the topological types in Tables 1–3, we start with the Kirby diagram representing its canonical PL-type, and compare the resulting triangulation to the triangulations in the census.

For all but three topological types, all triangulations homeomorphic to a given 4-manifold, are pairwise PL-homeomorphic. The three exceptions are $\mathbb{S}^4$, $\mathbb{C}P^2$, and the $\mathbb{Q}$-homology sphere $QS^4(2)$, cf. Table 3 for which we find 4, 3, and 2 components respectively.

As already documented in Section 4.3, our algorithm reliably takes all 405 188 triangulations homeomorphic to $\mathbb{S}^4$ from the 6-pentachoron census and classifies them into around 5 PL classes within a day of computation time. Some of the remaining classes have remarkable combinatorial properties, which are discussed in more detail in Section 5. These remaining classes are certified to be impossible to connect to other classes using an exhaustive enumeration and traversal of the Pachner graph with an excess height of 6 (that is, only triangulations with number of pentachora up to $6 + 6 = 12$ are considered).

In some contrast to the triangulations homeomorphic to $\mathbb{S}^4$, we can connect all but four of the 29 124 triangulations homeomorphic to $S^3 \times S^1$ using exhaustive simplification and traversal of the Pachner graph, with an excess height of at most four. The remaining four can be confirmed to be standard $S^3 \times S^1$s by (i) retriangulating to show they were all PL-homeomorphic to each other, and then (ii) traversing the Pachner graph with an excess height of at most 6. Alternatively, using our algorithm, all 29 124 triangulations homeomorphic to $S^3 \times S^1$ can be connected within an hour of computation time, see Section 4.3.

This difference in behaviour is noteworthy since $\mathbb{S}^4$ and $S^3 \times S^1$ are the only two 4-manifolds which can be triangulated using only 2 pentachora.

5 Pathological triangulations and future work

5.1 Combinatorial obstructions

Many of the triangulations resisting classification contain a particular 2-pentachoron subcomplex which we discuss briefly in this section. The complex in question, denoted C, has isomorphism signature `cHIbbb0bRbpb`, f-vector $(1, 1, 5, 6, 2)$, and has boundary a 2-tetrahedron solid torus. Considered in isolation, C is not a triangulation of a manifold (its

vertex link is a pinched genus-4 handlebody, and the link of its edge is a thrice-punctured sphere). However, C can be uniquely closed into an ideal triangulation of a 4-manifold: the unique[3] 2-pentachoron triangulation of a Cappell–Shaneson 2-knot complement [5]. This is a triangulation of the complement of a "knotted" 2-sphere in the 4-sphere, $S^4 - \nu S^2$.

The "cut-open" Cappell–Shaneson complex C embeds in a topological 4-ball B^4_C, where B^4_C is obtained from the unique 4-pentachoron 4-sphere still resisting classification (`eAMPcaabcddd+aoa+aAa8aQara`) by ungluing a single facet identification. We denote this 4-sphere by S^4_C. The isomorphism signature of B^4_C is `eGzMkabcdddcaGa8aAa0awa`. Its fundamental group presentation, as simplified by *Regina* [12] or GAP's `SimplifiedFpGroup` [24], is $\langle a, b \mid a^3b^3a^{-2}b^{-2}, a^{-3}b^{-1}a^5b^2\rangle$; moreover, GAP certifies that this is a presentation of the trivial group. It seems natural to assume that S^4_C relates – in some way – to the Cappell–Shaneson spheres, formerly conjectured to be exotic [17], and shown to be standard in [1, 22].

It is worthwhile to note that, when B^4_C is attached to a larger triangulation, the B^4_C subcomplex remains intact through very large flip sequences. In this sense, C, or B^4_C, is a potential combinatorial obstruction to simplify triangulations it appears within (similar to the Dunce hat being a combinatorial obstruction to collapsing a contractible space). Additionally, the presentation of the fundamental group of B^4_C is also challenging to simplify, but possible using the simplification heuristic for finitely presented groups implemented in GAP [24].

We have the following results and conjectures concerning B^4_C and S^4_C.

▶ **Conjecture 8.** *B^4_C is PL-homeomorphic to the standard 4-ball.*

We conjecture that B^4_C supports the standard PL structure because of its small size. Another reason is its relation to a Cappell-Shaneson sphere that is known to be standard [1, 22], see above.

▶ **Proposition 9.** *If there exists a sequence of Pachner moves connecting S^4_C to a triangulation of the standard PL 4-sphere, then this sequence must contain at least one triangulation with at least 12 pentachora.*

Proof. Running an exhaustive enumeration of all local move sequences starting from S^4_C and visiting triangulations up to 10 pentachora (i.e., an excess height of 6) does not connect S^4_C to any other 4-pentachoron triangulation of the 4-sphere. ◀

To conclude this article, we detail how to extend the observations made in this section and, more broadly, in this article to two research directions for future work.

5.2 The 8-Pentachoron Census

Generating a census (of any type) with n simplicies consists of two stages: First, enumerate all possible dual graphs with n nodes; then, for each graph, test all possible $5n/2$ facet gluings and retain those that yield valid triangulations. For 2, 4, and 6 pentachora there are 3, 26, and 638 such graphs, leading to 8, 784, and 440 495 valid 4-manifold triangulations, respectively.

We can deduce from this that only a very small fraction of possible gluings give rise to a triangulation of a 4-manifold, implying that various optimisations are possible (and needed) to build the census even only up to 6 pentachora (cf. [9, 10, 13] for an overview

[3] Verifiable via a very short exhaustive search of the ideal 2-pentachoron census.

of such optimisations in the 3-dimensional setting). In the case of 8 pentachora however, existing optimisations are no longer sufficient. Consequently, entirely new algorithms are in development to complete this next step of the 4-dimensional census. A completed 8-pentachoron census will come with new challenges for classifying their PL-types. Undoubtedly, more interesting pathological triangulations will emerge and in greater numbers. This is work in progress.

5.3 2-Knot Complements

The Cappell – Shaneson subcomplex C, discussed at the beginning of this section is only one of many such topological objects that can be described using only a small number of pentachora. In theory, each of them can lead to difficult triangulations of 4-balls and 4-spheres, related to B^4_C and S^4_C. Such examples are very useful for constructions in low-dimensional topology, or to benchmark future iterations of search methods. Given such a collection of examples, the major challenge is to either rigorously quantify how difficult they are to simplify, or to relate them to former or present potential counterexamples to S4PC.

Abstract

The generalized persistence diagram (GPD) is a natural extension of the classical persistence barcode to the setting of multi-parameter persistence and beyond. The GPD is defined as an integer-valued function whose domain is the set of intervals in the indexing poset of a persistence module, and is known to be able to capture richer topological information than its single-parameter counterpart. However, computing the GPD is computationally prohibitive due to the sheer size of the interval set. Restricting the GPD to a subset of intervals provides a way to manage this complexity, compromising discriminating power to some extent. However, identifying and computing an effective restriction of the domain that minimizes the loss of discriminating power remains an open challenge.

In this work, we introduce a novel method for optimizing the domain of the GPD through gradient descent optimization. To achieve this, we introduce a loss function tailored to optimize the selection of intervals, balancing computational efficiency and discriminative accuracy. The design of the loss function is based on the known erosion stability property of the GPD. We showcase the efficiency of our sparsification method for dataset classification in supervised machine learning. Experimental results demonstrate that our sparsification method significantly reduces the time required for computing the GPDs associated to several datasets, while maintaining classification accuracies comparable to those achieved using full GPDs. Our method thus opens the way for the use of GPD-based methods to applications at an unprecedented scale.

1 Introduction

Persistent homology, a central tool in topological data analysis (TDA), enables the study of topological features in datasets through algebraic invariants. In the classical one-parameter setting, the persistence barcode (or equivalently, the persistence diagram) serves as a complete, discrete, and computationally tractable invariant of a persistence module. Persistent homology can be extended to multi-parameter persistent homology, which provides tools for capturing the topological features of datasets using multiple filtrations instead of just one. However, the transition to multi-parameter persistent homology introduces significant complexity into the algebraic structure of the associated persistence modules [3, 6, 9].

Nevertheless, the generalized persistence diagram (GPD) extends the notion of persistence diagram from the one-parameter to the multi-parameter setting in a natural way [20, 33]. Although the GPD has been extensively studied in terms of stability, discriminating power, computation, and generalizations (see, e.g., [1, 13, 16, 17, 20, 22, 23, 24]), the computational complexity of GPDs remains a major obstacle [19]. The primary challenge arises from the size of their domain: the domain of the complete GPD is either $\mathrm{Int}(\mathbb{R}^d)$, the set of all intervals in $\mathbb{R}^d$, or any appropriately chosen, finite subset of $\mathrm{Int}(\mathbb{R}^d)$ – however, in this case, domains still tend to be enormous to avoid sacrificing the GPD discriminating power [13]. Nevertheless, GPDs are flexible, in the sense that they are still well-defined on *any finite* subdomain $\mathcal{I} \subset \mathrm{Int}(\mathbb{R}^d)$. Even if the subdomain has small size, as the GPD over $\mathcal{I}$ is simply defined as the Möbius inversion of the generalized rank invariant (GRI) over $\mathcal{I}$ (see Definition 1). This allows to control the aforementioned complexity of GPD computation by picking a small, or *sparse*, subdomain $\mathcal{I}$. Moreover, the topological information loss due to using such sparse subdomains can be mitigated by looking for *relevant* intervals, i.e., intervals that are rich in topological content; indeed, even with a substantially small subdomain $\mathcal{I} \subset \mathrm{Int}(\mathbb{R}^d)$, the GPD over $\mathcal{I}$ can still be finer than other traditional invariants of multi-parameter persistence modules, such as the rank invariant (RI) [9]; see [13] for details. However, how to design these subdomains in the "best" way so as to reduce computational cost while maintaining the discriminating power of the GPD is a question that has not been much explored so far.

Sparsification of the GPD via gradient descent. Motivated by the computational challenges of the GPD and the flexibility of this invariant upon selecting subsets of intervals as its domain, we propose a method for *automatically sparsifying GPDs* computed from $\mathbb{R}^2$-persistence modules based on gradient descent. Namely, we consider the following scenario.

Suppose we aim at classifying instances of a given dataset based on their topological features, and we have already computed a set of corresponding persistence modules $\{M_i : \mathbb{R}^2 \to \mathrm{vect}_k\}_{1\leq i\leq t}$ from the dataset, where each persistence module corresponds to an individual data point. We consider the set $\{\mathrm{dgm}^{\mathcal{I}}_{M_i}\}_{1\leq i\leq t}$ of GPDs of M_i over a large set $\mathcal{I}$ of intervals in $\mathbb{R}^2$ (cf. Definition 1). We refer to these as the *full GPDs*.

Let $n \gg 1$ be the cardinality of $\mathcal{I}$, and let m be a sparsification parameter $m \in \mathbb{N}^* = \{1, 2, \ldots\}$, which is typically significantly smaller than n. Let $\binom{\mathrm{Int}(\mathbb{R}^2)}{m}$ denote the set of m-subsets of $\mathrm{Int}(\mathbb{R}^2)$, i.e., $\{\mathcal{J} \subset \mathrm{Int}(\mathbb{R}^2) : |\mathcal{J}| = m\}$. In order to identify an m-subset of intervals in $\mathbb{R}^2$ over which the new GPDs are computed (and subsequently used to classify the persistence modules $\{M_i\}_{1\leq i\leq t}$), we proceed as follows. **Firstly,** we identify a loss function *defined on* $\binom{\mathrm{Int}(\mathbb{R}^2)}{m}$:

$$\begin{array}{rccl} \mathcal{L}_{d_\ell, m, \{M_i\}_{1\leq i\leq t}} : & \binom{\mathrm{Int}(\mathbb{R}^2)}{m} & \to & \mathbb{R} \\ & \mathcal{J} & \mapsto & \sum_{i=1}^{t} d_\ell(\mathrm{dgm}^{\mathcal{J}}_{M_i}, \mathrm{dgm}^{\mathcal{I}}_{M_i}), \end{array} \tag{1}$$

where d_ℓ is an appropriate dissimilarity function. **Secondly,** we search for a minimizer of the loss function. The goal of this search is to identify a subset $\mathcal{J}^*$ of m intervals such that the GPDs of the $\{M_i\}_i$ over this sparse subset $\{\mathrm{dgm}_{M_i}^{\mathcal{J}^*}\}_{1\leq i\leq t}$, the *sparse GPDs*, best approximate their corresponding full counterparts overall. One natural way of searching for a (local) minimizer is through **gradient descent**, starting from a randomly chosen m-subset $\mathcal{J}_{\mathrm{init}}$ of $\mathcal{I}$. To achieve this, the following requirements either must be met or highly desirable:

- **(I)** (Distance) A suitable distance or dissimilarity function d_ℓ, utilized in constructing the loss function above, ideally satisfying certain stability guarantees w.r.t. the *interleaving distance* between persistence modules [12, 25],
- **(II)** (Vectorization) A certain representation of the loss function $\mathcal{L}_{d_\ell,m,\{M_i\}_{1\leq i\leq t}}$ as a map defined on some subset $\mathcal{D}$ of Euclidean space,
- **(III)** (Convexity) Convexity of the subset $\mathcal{D}$,
- **(IV)** (Loss regularity) Lipschitz stability and differentiability of $\mathcal{L}_{d_\ell,m,\{M_i\}_{1\leq i\leq t}}$, and
- **(V)** (Feasibility) Computational feasibility of $\mathcal{L}_{d_\ell,m,\{M_i\}_{1\leq i\leq t}}$ for practical implementation.

Our contributions can be listed according to Items (I)-(V) mentioned above.

Summary of contributions.

- A natural choice for d_ℓ in Item (I) would be to use the *erosion distance* d_{E} [13, 33], a standard metric between GPDs,[1] that is known to be stable under perturbations of input persistence modules w.r.t. the interleaving distance. However, the use of the erosion distance requires GPDs to be defined on the *same* set of intervals (Definition 3) that is *closed under thickening*, which implies the domain must be *infinite*. All these make it difficult to directly utilize d_{E}. Hence, **we introduce the sparse erosion distance $\hat{d}_{\mathbf{E}}$ between GPDs relative to (possibly) *different* interval sets, as an adaptation of $d_{\mathbf{E}}$ (Definition 4, Proposition 6 (ii), and Corollary 7)**.[2]
- Regarding Item (V), we restrict our focus to intervals in $\mathbb{R}^2$ with a small number of minimal and maximal points (Remark 10). Then, if the sparse erosion distance $\hat{d}_{\mathrm{E}}$ is computed between GPDs of the *same* persistence module M, **we prove that $\hat{d}_{\mathbf{E}}$ depends solely on the domains $\mathcal{I},\mathcal{J}$, and *not* on the input persistence module, i.e. $\hat{d}_{\mathbf{E}}((\mathbf{dgm}_M,\mathcal{I}),(\mathbf{dgm}_M,\mathcal{J})) = \hat{d}(\mathcal{I},\mathcal{J})$ (Proposition 6 (iii))**. This fact significantly enhances the tractability of gradient descent as it allows to avoid recomputing the GPDs at every iteration. Moreover, **we derive a closed-form formula for the computation of $\hat{d}(\mathcal{I},\mathcal{J})$ (Theorem 9 (i)).**
- For achieving Items (II)–(IV), we only consider intervals with at most two minimal points and one maximal point. This ensures the existence of natural embeddings of these intervals into Euclidean space $\mathbb{R}^6$, which can be obtained by stacking up the coordinates of the interval middle points (x,y) together with the lengths $a,b,c,d\geq 0$ needed to define the interval lower boundaries (Figure 1). The main advantages of this vectorization method (w.r.t. the other natural ones) are that (1) it allows for **a simple formulation of the loss function (Theorem 9 (ii))**, and (2) its variables are all independent from each other, which makes the implementation of gradient descent easier (Remarks 10

[1] Note that d_{E} is also referred to as a metric between generalized rank invariants (GRIs), e.g., in [13, 21]. Since the GPD and the GRI determine one another (cf. Remark 2 (i) and (iii)), d_{E} can thus also be viewed as a metric between GPDs, as in [33, 36].

[2] Another possibility would be to use bottleneck and Wasserstein distances, however we show in Remark 17 in the full version [11] that they fail to ensure continuity of the loss function.

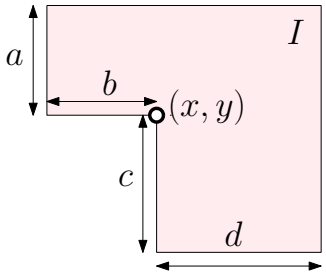

Figure 1 Any $(2,1)$-interval I of $\mathbb{R}^2$, as depicted above, is represented by $\mathbf{v}_I = (x, y, a, b, c, d) \in \mathbb{R}^6$. Any $(1,1)$-interval can also be represented by $(x, y, a, b, c, d) \in \mathbb{R}^6$ with $b = c = 0$.

and 11).[3] Using this vectorization method, **we also prove that $\mathcal{D}$ not only forms a convex subset of Euclidean space $\mathbb{R}^{6m}$ (Proposition 13), but also ensures the Lipschitz stability and almost everywhere differentiability of the loss function $\mathcal{L}_{d_\ell, m, \{M_i\}_{1\leq i\leq t}}$ (Theorem 14 and Proposition 16)**. In fact, we prove that the loss function can actually be realized as

$$\begin{array}{rccl} \mathcal{L}_{\hat{d_{\mathrm{E}}},m}: & \mathcal{D}(\subset \mathbb{R}^{6m}) & \to & \mathbb{R} \\ & \mathbb{v}_{\mathcal{J}} & \mapsto & t \cdot \hat{d}(\mathcal{I}, \mathcal{J}), \end{array} \tag{2}$$

where $\mathbb{v}_{\mathcal{J}}$ is our $6m$-dimensional embedding of $\mathcal{J}$. Since t (the size of the dataset) is a constant, the (local) minimizers of $\mathcal{L}_{\hat{d_{\mathrm{E}}},m}$ coincide with those of the map $t^{-1} \cdot \mathcal{L}_{\hat{d_{\mathrm{E}}},m} : \mathbb{v}_{\mathcal{J}} \mapsto \hat{d}(\mathcal{I}, \mathcal{J})$. Hence, searching for a (local) minimizer of $\mathcal{L}_{\hat{d_{\mathrm{E}}},m}$ is essentially searching for the (locally) best m intervals that represent the domain $\mathcal{I}$ of the full GPDs.

Finally, regarding Item (V) again, and in order to showcase the efficiency of our proposed sparsification method, **we provide numerical experiments on topology-based time series classification with supervised machine learning (Section 5 and Figure 2)**, in which we show that the sparse GPDs $\{\mathrm{dgm}_{M_i}^{\mathcal{J}^*}\}_{1\leq i\leq t}$ can be computed in much faster time than the full GPDs, while maintaining similar or better classification performances from random forests models. Our code is fully available at sparse GPDs.

Comparison with other works. While there exist many existing works that utilize multi-parameter persistent homology to enhance the performance of machine learning models [10, 14, 27, 29, 32, 34, 35, 37], our work takes a different approach as it focuses on methods to mitigate the computational overhead associated with multi-parameter persistence descriptors.

The works most closely related to ours are [29] and [37], which use the RI or GRI for multi-parameter persistence modules in a machine learning context. Firstly, [29] is based on an equivalent representation of the GPDs (computed from rectangle intervals[4]) as *signed measures* [7], which allows to compare GPDs with optimal transport distances, as well as to deploy known vectorization techniques intended for general measures. Secondly, the approach proposed in [37] involves vectorizing the GRIs of 2-parameter persistence modules by evaluating them on intervals with specific shapes called *worms*. Our goal is different: we rather aim at vectorizing and sparsifying the *domains* of the GPDs in order to achieve good

[3] Alternatively, we can consider intervals with one minimal points and at most two maximal points. Either choice ensures that our restricted GPDs are not a weaker invariant than the rank invariant or the signed barcode [7]; see [13, Section 4].

[4] This types of GPDs are often called signed barcodes.

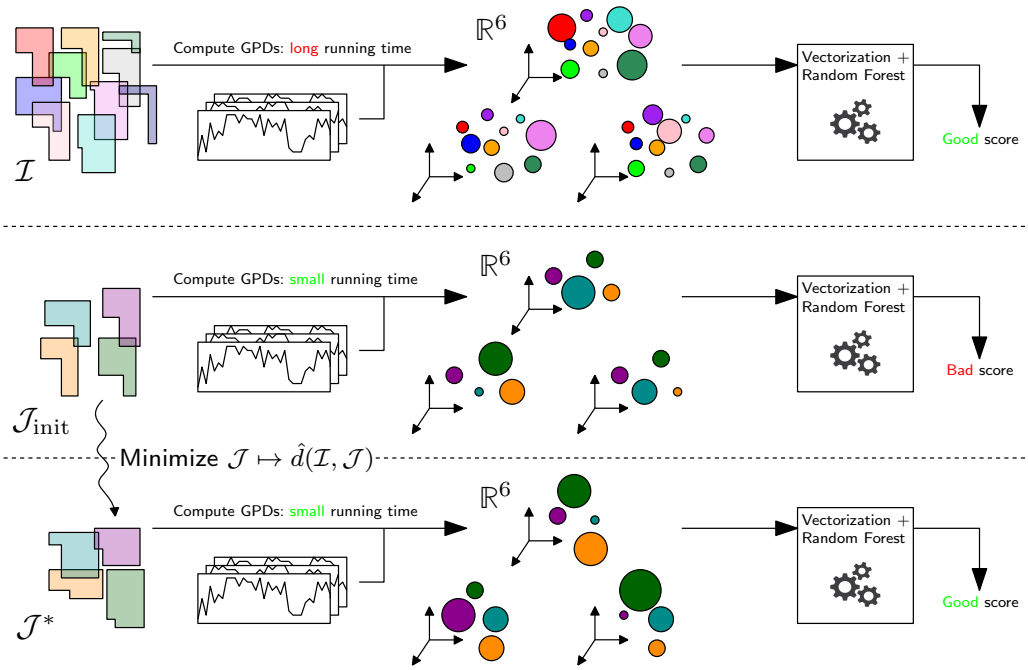

Figure 2 Our pipeline for sparsifying GPDs in the context of time series classification. The sizes of the GPD points in $\mathbb{R}^6$ are proportional to their multiplicities.

performance scores. In fact, the sparsification process that we propose can actually be used complementarily to both [29] and [37] by first sparsifying the set of rectangles or worms before applying their vectorization methods. Note that differentiability properties of both of these approaches *w.r.t. the multi-parameter filtrations* were recently established [32, 34]; in contrast, our work deals with the differentiability of a GPD-based loss function *w.r.t. the interval domains* (while keeping the multi-parameter filtrations fixed).

Organization. Section 2 reviews basic properties of the GPD and GRI. Section 3 introduces the *sparse* erosion distance, clarify its relation to the erosion distance given in [13], and presents its closed-form formula, which is specialized and useful in our setting. Section 4 establishes the Lipschitz stability and differentiability of our loss function. Section 5 presents our numerical experiments. Finally, Section 6 discusses future research directions.

2 Preliminaries

In this article, $P = (P, \leq)$ stands for a poset, regarded as the category whose objects are the elements of P, and for any pair $p, q \in P$, there exists a unique morphism $p \to q$ if and only if $p \leq q$. All vector spaces in this article are over a fixed field k. Let vect_k denote the category of finite-dimensional vector spaces and linear maps over k. A functor $P \to \text{vect}_k$ will be referred to as a **(P-)persistence module**. The **direct sum** of any two P-persistence modules is defined pointwise. Any $M : P \to \text{vect}_k$ is **trivial** if $M(x) = 0$ for all $x \in P$. If a

nontrivial M is not isomorphic to a direct sum of any two nontrivial persistence modules, M is **indecomposable**. Every persistence module is decomposed into a direct sum of indecomposable modules, uniquely determined up to isomorphism [2, 4].

An **interval** I of P is a subset $I \subseteq P$ such that: (i) I is nonempty. (ii) If $p, q \in I$ and $p \leq r \leq q$, then $r \in I$. (iii) I is **connected**, i.e. for any $p, q \in I$, there is a sequence $p = p_0, p_1, \cdots, p_\ell = q$ of elements of I with p_i and p_{i+1} comparable for $0 \leq i \leq \ell - 1$. By $\mathrm{Int}(P)$ we denote the set of all intervals of P.

Given any $I \in \mathrm{Int}(P)$, the **interval module** k_I is the P-persistence module, with

$$(k_I)(p) := \begin{cases} k & \text{if } p \in I \\ 0 & \text{otherwise.} \end{cases}, \qquad k_I(p \leq q) := \begin{cases} \mathrm{id}_k & \text{if } p \leq q \in I \\ 0 & \text{otherwise.} \end{cases}$$

Every interval module is indecomposable [5, Proposition 2.2]. A P-persistence module M is **interval-decomposable** if it is isomorphic to a direct sum $\bigoplus_{j \in J} k_{I_j}$ of interval modules. In this case, the **barcode** of M is defined as the multiset $\mathrm{barc}(M) := \{k_{I_j} : j \in J\}$.

For $p \in P$, let $p^\uparrow$ denote the set of points $q \in P$ such that $p \leq q$. Clearly, $p^\uparrow$ belongs to $\mathrm{Int}(P)$. A P-persistence module is **finitely presentable** if it is isomorphic to the cokernel of a morphism $\bigoplus_{a \in A} k_{a^\uparrow} \to \bigoplus_{b \in B} k_{b^\uparrow}$, where A and B are finite multisets of elements of P.

When P is a connected poset, the **(generalized) rank** of M, denoted by $\mathrm{rank}(M)$, is defined as the rank of the canonical linear map from the limit of M to the colimit of M, which is a nonnegative integer [20]. This isomorphism invariant of P-persistence modules, which takes a single integer value, can be refined into an integer-valued function as follows. Let $\mathcal{I}$ be any nonempty subset of $\mathrm{Int}(P)$. The **generalized rank invariant (GRI) of M over $\mathcal{I}$** is the map $\mathrm{rk}_M^{\mathcal{I}} : \mathcal{I} \to \mathbb{Z}_{\geq 0}$ given by $I \mapsto \mathrm{rank}(M|_I)$, where $M|_I$ is the restriction of M to I [20]. When $\mathcal{I} = \mathrm{Int}(P)$, we denote $\mathrm{rk}_M^{\mathcal{I}}$ simply as rk_M.

The generalized persistence diagram (GPD) of M over $\mathcal{I}$ captures the changes of the GRI values when $I \in \mathcal{I}$ varies. Its formal definition follows.

▶ **Definition 1** ([13]). *The **generalized persistence diagram (GPD) of M over $\mathcal{I}$** is defined as the function $\mathrm{dgm}_M^{\mathcal{I}} : \mathcal{I} \to \mathbb{Z}$ that satisfies:*[5]

$$\text{for all } I \in \mathcal{I}, \quad \mathrm{rk}_M^{\mathcal{I}}(I) = \sum_{\substack{J \in \mathcal{I} \\ J \supseteq I}} \mathrm{dgm}_M^{\mathcal{I}}(J). \tag{3}$$

▶ Remark 2 ([13, Sections 2 and 3] and [7]).

(i) If $\mathcal{I}$ is finite, then $\mathrm{dgm}_M^{\mathcal{I}}$ exists.

(ii) If $\mathrm{dgm}_M^{\mathcal{I}}$ exists, then it is unique.

(iii) If $\mathrm{dgm}_M^{\mathcal{I}}$ exists, then $\mathrm{dgm}_M^{\mathcal{I}}$ and $\mathrm{rk}_M^{\mathcal{I}}$ determine one another.

(iv) (Monotonicity) $\mathrm{rk}_M^{\mathcal{I}}(I) \leq \mathrm{rk}_M^{\mathcal{I}}(J)$ for any pair $I \supseteq J$ in $\mathcal{I}$.

(v) (The GPD generalizes the barcode) Let $\mathcal{I} = \mathrm{Int}(P)$. If M is interval decomposable, then $\mathrm{dgm}_M^{\mathcal{I}}$ exists. In this case, for any $I \in \mathrm{Int}(P)$, $\mathrm{dgm}_M^{\mathcal{I}}(I)$ coincides the multiplicity of I in $\mathrm{barc}(M)$. Also, $\mathrm{dgm}_M^{\mathcal{I}}$ often exists even when M is not interval decomposable.

(vi) If M is a *finitely presentable* $\mathbb{R}^d$-persistence module, then the GPD over $\mathrm{Int}(\mathbb{R}^d)$ exists [13, Theorem C(iii)].

In the rest of the article, every $\mathbb{R}^d$-persistence module M is assumed to be finitely presentable, thus its GPD over $\mathrm{Int}(\mathbb{R}^d)$ exists, and is denoted by dgm_M.

[5] The condition in Equation (3) is a generalization of *the fundamental lemma of persistent homology* [18].

3 Sparse erosion distance between GPDs relative to sampled intervals

We adapt the notion of erosion distance to define a distance between *GPDs relative to (possibly different) sampled intervals*. When comparing the same GPD *with two different sampled intervals*, this distance simplifies to a distance between sampled intervals. This is relevant in our case, as we compare the full and sparse GPDs of the *same* persistence module.

3.1 Sparse erosion distance

In this section, we review the definition of the erosion distance and adapt it to define the sparse erosion distance between *GPDs relative to sampled intervals*.

For $\epsilon \in \mathbb{R}$, the vector $\epsilon(1, \dots, 1) \in \mathbb{R}^d$ will be simply denoted by ϵ whenever there is no risk of confusion. For $I \in \mathrm{Int}(\mathbb{R}^d)$ and $\epsilon \in \mathbb{R}_{\geq 0}$, we consider the *$\epsilon$-thickening* $I^\epsilon := \bigcup_{p \in I} B_\epsilon^\square(p)$ of I, where $B_\epsilon^\square(p)$ stands for the closed ϵ-ball around p w.r.t. the supremum distance, i.e. $B_\epsilon^\square(p) = \{q \in \mathbb{R}^d \mid p - \epsilon \leq q \leq p + \epsilon\}$. See Figure 3. A subset $\mathcal{I} \subset \mathrm{Int}(\mathbb{R}^d)$ is said to be **closed under thickening** if for all $I \in \mathcal{I}$ and for all $\epsilon \in \mathbb{R}_{\geq 0}$, the interval I^ϵ belongs to $\mathcal{I}$.

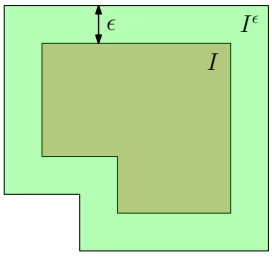

Figure 3 ϵ-thickening I^ϵ.

▶ **Definition 3** ([13, Definition 5.2]). *Let M and N be $\mathbb{R}^d$-persistence modules. Let $\mathcal{I}$ be any subset of* $\mathrm{Int}(\mathbb{R}^d)$ that is closed under thickening. *The* ***erosion distance*** *between* $\mathrm{dgm}_M^{\mathcal{I}}$ *and* $\mathrm{dgm}_N^{\mathcal{I}}$ *(and equivalently between* $\mathrm{rk}_M^{\mathcal{I}}$ *and* $\mathrm{rk}_N^{\mathcal{I}}$ *by Remark 2 (ii)) is*

$$d_{\mathrm{E}}(\mathrm{dgm}_M^{\mathcal{I}}, \mathrm{dgm}_N^{\mathcal{I}}) := \inf(\epsilon > 0 : \textit{for all } I \in \mathcal{I},\ \mathrm{rk}_N(I^\epsilon) \leq \mathrm{rk}_M(I) \textit{ and } \mathrm{rk}_M(I^\epsilon) \leq \mathrm{rk}_N(I)).$$

A **correspondence** between nonempty sets A and B is a subset $\mathcal{R} \subset A \times B$ satisfying the following: (1) for each $a \in A$, there exists $b \in B$ such that $(a, b) \in \mathcal{R}$, and (2) for each $b \in B$, there exists $a \in A$ such that $(a, b) \in \mathcal{R}$. For $\epsilon \in \mathbb{R}_{\geq 0}$, an ***$\epsilon$*-correspondence** $\mathcal{R}$ between nonempty $\mathcal{I}, \mathcal{J} \subset \mathrm{Int}(\mathbb{R}^d)$ is a correspondence $\mathcal{R} \subset \mathcal{I} \times \mathcal{J}$ such that for all $(I, J) \in \mathcal{R}$, $J \subset I^\epsilon$ and $I \subset J^\epsilon$. Blending the ideas of the Hausdorff and erosion distances, we obtain our new distance between *GPDs relative to sampled intervals*:

▶ **Definition 4** (Sparse erosion distance between GPDs relative to sampled intervals). *For any $M, N : \mathbb{R}^d \to \mathrm{vect}_k$ and any nonempty $\mathcal{I}, \mathcal{J} \subset \mathrm{Int}(\mathbb{R}^d)$, the* ***sparse erosion distance*** *between pairs* $(\mathrm{dgm}_M, \mathcal{I})$ *and* $(\mathrm{dgm}_N, \mathcal{J})$ *is*

$$\hat{d}_{\mathrm{E}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{J})) := \inf(\epsilon > 0 :\ \textit{there exists an } \epsilon\text{-correspondence } \mathcal{R} \subset \mathcal{I} \times \mathcal{J}$$
$$\textit{s.t.} \forall (I, J) \in \mathcal{R},\ \forall \delta \in \mathbb{R}_{\geq 0},\ \mathrm{rk}_N(J^{\epsilon+\delta}) \leq \mathrm{rk}_M(I^\delta) \textit{ and } \mathrm{rk}_M(I^{\epsilon+\delta}) \leq \mathrm{rk}_N(J^\delta)).$$

We remark that $\hat{d}_{\mathrm{E}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{J}))$ captures not only (1) the algebraic difference between $[M$ with respect to $\mathcal{I}]$ and $[N$ with respect to $\mathcal{J}]$, but also (2) the geometric difference between the domains $\mathcal{I}$ and $\mathcal{J}$. To see (1), consider, for example, the $\mathbb{R}$-persistence modules

$M = k_{[0,1]}$ and $N = k_{[0,2]}$, and let both $\mathcal{I}$ and $\mathcal{J}$ be the singleton set $\{[3,4]\}$. Then, one can see that $\hat{d_{\mathrm{E}}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{J})) = 0$ from the fact that $\mathrm{rk}_M^{\mathcal{I}} = \mathrm{rk}_N^{\mathcal{J}} = 0$ and the monotonicity of rk_M and rk_N. To see (2), let M and N be any isomorphic $\mathbb{R}$-persistence modules, and set $\mathcal{I} := \{[0, \frac{1}{2}]\}$ and $\mathcal{J} := \{[0,1]\}$. Then, we obtain $\hat{d_{\mathrm{E}}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{J})) \geq 1/2$, solely due to the difference between $\mathcal{I}$ and $\mathcal{J}$.

▶ **Proposition 5.** *$\hat{d_{\mathrm{E}}}$ is an extended pseudometric. (See the full version [11] for the proof.)*

For any nonempty $\mathcal{I}, \mathcal{J} \subset \mathrm{Int}(\mathbb{R}^d)$, let

$$\hat{d}(\mathcal{I}, \mathcal{J}) := \inf(\epsilon > 0 : \text{ there exists an } \epsilon\text{-correspondence between } \mathcal{I} \text{ and } \mathcal{J}). \tag{4}$$

We clarify the relationship among d_{E}, $\hat{d_{\mathrm{E}}}$, and $\hat{d}$:

▶ **Proposition 6.** *Let $M, N : \mathbb{R}^d \to \mathrm{vect}_k$ and let $\mathcal{I}, \mathcal{J} \subset \mathrm{Int}(\mathbb{R}^d)$ be nonempty. We have:*

(i) $\hat{d}(\mathcal{I}, \mathcal{J}) \leq \hat{d_{\mathrm{E}}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{J}))$.

(ii) *If $\mathcal{I} = \mathcal{J}$ are closed under thickening, then*

$$\hat{d_{\mathrm{E}}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{J})) \leq d_{\mathrm{E}}(\mathrm{dgm}_M^{\mathcal{I}}, \mathrm{dgm}_N^{\mathcal{I}}). \tag{5}$$

(iii) *If $M \cong N$ or $\mathrm{dgm}_M = \mathrm{dgm}_N$, then*

$$\hat{d_{\mathrm{E}}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{J})) = \hat{d}(\mathcal{I}, \mathcal{J}). \tag{6}$$

(See the full version [11] for the proof.)

We remark that the inequality given in Item (i) can be strict. For instance, let $d = 1$, $\mathcal{I} = \mathcal{J} = \mathrm{Int}(\mathbb{R}^d)$, $M = 0$, and $N = k_{[0,1)}$. Then, $0 = \hat{d}(\mathcal{I}, \mathcal{J}) < \hat{d_{\mathrm{E}}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{J}))$.

By Proposition 6 (ii) and the prior stability result of d_{E} [13, Theorem H], we have:

▶ **Corollary 7.** *For any $M, N : \mathbb{R}^d \to \mathrm{vect}_k$ and for any $\mathcal{I} \subset \mathrm{Int}(\mathbb{R}^d)$, we have*

$$\hat{d_{\mathrm{E}}}((\mathrm{dgm}_M, \mathcal{I}), (\mathrm{dgm}_N, \mathcal{I})) \leq d_{\mathrm{I}}(M, N),$$

where the right-hand side is the interleaving distance between M and N.

3.2 Closed-form formula for the sparse erosion distance

In this section, we find a closed-form formula for the right-hand side of Equation (6), when each interval in $\mathcal{I}$ and $\mathcal{J}$ has only finitely many minimal and maximal points (Theorem 9). This result is essential when studying our loss function in Section 4 and optimizing the domains of the GPDs in Section 5.

For $p, q \in \mathbb{N}^*$, an interval $I \in \mathrm{Int}(\mathbb{R}^2)$ is a (p,q)-interval if I has exactly p minimal points and exactly q maximal points. For any interval $I \in \mathrm{Int}(\mathbb{R}^2)$, let $\min(I)$ (resp. $\max(I)$) be the set of all minimal (resp. maximal) elements of I. For $(x,y) \in \mathbb{R}^2$, define

$$\delta(x,y) := \begin{cases} 1 & \text{if} \quad x \leq y \\ 0 & \text{if} \quad x > y. \end{cases} \tag{7}$$

▶ **Lemma 8.** *For $p_r, q_r, p'_s, q'_s \in \mathbb{N}^*$, let $I_r, J_s \in \mathrm{Int}(\mathbb{R}^2)$ be (p_r, q_r)- and (p'_s, q'_s)-intervals, respectively. Then, for any $\epsilon \in \mathbb{R}_{\geq 0}$, $J_s \subset I_r^{\epsilon}$ and $I_r \subset J_s^{\epsilon}$ if and only if*

$$\epsilon \geq \max\left(\max_k a_k, \max_l b_l, \max_i a'_i, \max_j b'_j\right), \quad \textit{where}$$

- *i, j, k, l range from 1 to p_r, q_r, p'_s, q'_s respectively; a_k and b_l are defined as (8) and (9) respectively; a'_i and b'_j are obtained by interchanging the roles of i and k in (8), and those of j and l in (9), respectively;*
- $\min(I_r) =: \{(x_i^r, y_i^r) : 1 \le i \le p_r\}$, $\min(J_s) =: \{(x_k^s, y_k^s) : 1 \le k \le p'_s\}$,
  $\max(I_r) =: \{(X_j^r, Y_j^r) : 1 \le j \le q_r\}$, $\max(J_s) =: \{(X_l^s, Y_l^s) : 1 \le l \le q'_s\}$.

$$\min_i \Big(\max\Big((1 - \delta(x_i^r, x_k^s))|x_k^s - x_i^r|, (1 - \delta(y_i^r, y_k^s))|y_k^s - y_i^r| \Big) \Big) \tag{8}$$

$$\min_j \Big(\max\Big(\delta(X_j^r, X_l^s)|X_l^s - X_j^r|, \delta(Y_j^r, Y_l^s)|Y_l^s - Y_j^r| \Big) \Big) \tag{9}$$

(See the full version [11] for the proof.) Let $\mathcal{I} := \{I_r\}_{r=1}^n$ and $\mathcal{J} := \{J_s\}_{s=1}^m$ be sets of intervals of $\mathbb{R}^2$ with only finitely many minimal and maximal points. Let $\mathcal{E}$ the $(n \times m)$-matrix (ϵ_{rs}) where ϵ_{rs} is the RHS of the inequality given in Lemma 8, i.e.

$$\epsilon_{rs} = \max(\max_k a_k, \max_l b_l, \max_i a'_i, \max_j b'_j) \tag{10}$$

and $i, j, k, l, a_k, b_l, a'_i, b'_j$ as defined in Lemma 8. Next, we show that $\hat{d}(\mathcal{I}, \mathcal{J})$, as defined in Equation (4), equals the largest of the smallest elements across all rows and columns of $\mathcal{E}$. In particular, the following variables and functions are useful for describing the closed form formula for $\hat{d}(\mathcal{I}, \mathcal{J})$, when each of $\mathcal{I}$ and $\mathcal{J}$ consists solely of $(1,1)$- or $(2,1)$-intervals.

When I_r and J_s are $(2,1)$-intervals, as depicted in Figure 4, let

$$\begin{aligned}
x_1 &:= x_2^r, & y_1 &:= y_1^r, & a &:= Y_1^r - y_1^r, & b &:= x_2^r - x_1^r,\\
c &:= y_1^r - y_2^r, & d &:= X_1^r - x_2^r, & x_2 &:= x_2^s, & y_2 &:= y_1^s,\\
e &:= Y_1^s - y_1^s, & f &:= x_2^s - x_1^s, & g &:= y_1^s - y_2^s, & h &:= X_1^s - x_2^s.
\end{aligned}$$

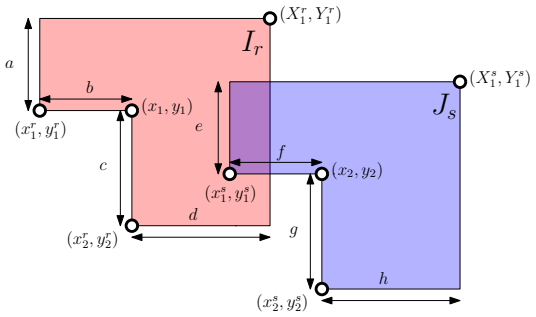

Figure 4 The parametrization of I_r and J_s.

When I_r (resp. J_s) is a $(1,1)$-interval, set $x_1^r = x_2^r$, $y_1^r = y_2^r$ and thus $b = c = 0$ (resp. $x_1^s = x_2^s$, $y_1^s = y_2^s$ and thus $f = g = 0$). Also, let

$$\begin{aligned}
F(w_1, w_2, w_3, w_4) &:= \max\big(\delta(w_1, w_2)|w_2 - w_1|, \delta(w_3, w_4)|w_4 - w_3|\big),\\
G(m_1, m_2, m_3, m_4, m_5) &:= \min(F(m_1, m_2, m_3, m_4), m_5),\\
H(o_1, o_2, o_3, o_4) &:= \max\big(\min(o_1, o_2), \min(o_3, o_4)\big),
\end{aligned}$$

where all input variables of F, G and H are real numbers.

▶ **Theorem 9.** *Let $\mathcal{I} := \{I_r\}_{r=1}^n$ and $\mathcal{J} := \{J_s\}_{s=1}^m$ be sets of intervals of $\mathbb{R}^2$ with only finitely many minimal and maximal points.*

(i) *We have $\hat{d}(\mathcal{I}, \mathcal{J}) = \max\Big(\max_r(\min_s \epsilon_{rs}), \max_s(\min_r \epsilon_{rs})\Big)$ where ϵ_{rs} is as defined in Equation (10) and I_r (resp. J_s) is a (p_r, q_r)-interval (resp. (p'_s, q'_s)-interval).*

(ii) *If $\mathcal{I}$ and $\mathcal{J}$ consist solely of $(1,1)$- or $(2,1)$-intervals, then ϵ_{rs} is the maximum of (11)-(14).*

$$H\Big(F(x_2 - f, x_1 - b, y_2, y_1), F(x_2 - f, x_1, y_2, y_1 - c), \\ F(x_2, x_1 - b, y_2 - g, y_1), F(x_2, x_1, y_2 - g, y_1 - c)\Big) \tag{11}$$

$$F(x_1 + d, x_2 + h, y_1 + a, y_2 + e) \tag{12}$$

$$H\Big(F(x_1 - b, x_2 - f, y_1, y_2), F(x_1 - b, x_2, y_1, y_2 - g), \\ F(x_1, x_2 - f, y_1 - c, y_2), F(x_1, x_2, y_1 - c, y_2 - g)\Big) \tag{13}$$

$$F(x_2 + h, x_1 + d, y_2 + e, y_1 + a) \tag{14}$$

(See the full version [11] for the proof.)

▶ Remark 10. In Theorem 9 (i), as p_r, q_r, p'_s, and q'_s increase, the complexity of computing ϵ_{rs} increases. This is because, the ranges over which the maxima on the RHS of Equation (10) increase, thereby increasing the computational complexity of $\hat{d}(\mathcal{I}, \mathcal{J})$ as well.

4 Lipschitz stability and differentiability of the loss function

The goal of this section is to establish Lipchitz continuity/stability and (almost everywhere) differentiability of our loss function (cf. Equation (2)). From Figure 1, recall that we denote the embedding of a $(1,1)$-or $(2,1)$-interval I of $\mathbb{R}^2$ into $\mathbb{R}^6$ by $\mathbf{v}_I$.

▶ Remark 11 (Independence of variables). Although there are multiple ways to embed (p,q)-intervals of $\mathbb{R}^2$ into Euclidean space, for any $p, q \in \mathbb{N}$, some vectorization methods are more efficient than others in our context. For instance, suppose that we represent the $(2,1)$-interval I in Figure 1 by simply concatenating the coordinates of its minimal and maximal points. Namely, we represent I with the vector $(x_1, y_1, x_2, y_2, X, Y) \in \mathbb{R}^6$, where $x_1 = x - b$, $y_1 = y$, $x_2 = x$, $y_2 = y - c$, $X = x + d$, $Y = y + a$. A difficulty with this embedding in the context of gradient descent is that the variables are *not* independent: one must have $(x_1, y_1) \leq (X, Y)$, $(x_2, y_2) \leq (X, Y)$, and $(x_2, y_2) \not\leq (x_1, y_1)$. Ensuring such relations between variables is not trivial in non-convex optimization (without using refined techniques such as projected gradient descent). On the other hand, using our proposed embedding is more practical, as all variables are independent, and our only requirements are that a, b, c, d must be nonnegative, which can easily be imposed using, e.g., exponential or ReLU functions.

Let $\mathcal{I} := \{I_r\}_{r=1}^n$ and $\mathcal{J} := \{J_s\}_{s=1}^m$ consist solely of $(1,1)$- or $(2,1)$-intervals of $\mathbb{R}^2$.

▶ **Lemma 12.** *For $I_r \in \mathcal{I}$ and $J_s \in \mathcal{J}$, consider $\mathbf{v}_{I_r} = (x_1, y_1, a, b, c, d)$ and $\mathbf{v}_{J_s} = (x_2, y_2, e, f, g, h)$ defined as in Figure 1. If $||\mathbf{v}_{I_r} - \mathbf{v}_{J_s}||_\infty \leq \epsilon$, then $\epsilon_{rs} \leq 2\epsilon$ where ϵ_{rs} is described as in Theorem 9 (ii). (See the full version [11] for the proof.)*

We define $\mathbb{v}_{\mathcal{I}}$ as the concatenation of $\mathbf{v}_{I_r}$ for all $I_r \in \mathcal{I}$, i.e., $\mathbb{v}_{\mathcal{I}} := (\mathbf{v}_{I_1} | \dots | \mathbf{v}_{I_n}) \in \mathbb{R}^{6n}$. Let $\mathfrak{I}$ be the collection of all ordered n-sets $\mathcal{I}$ of $(1,1)$-or $(2,1)$-intervals of $\mathbb{R}^2$. Then, define the function $V : \mathfrak{I} \to \mathbb{R}^{6n}$ by $\mathcal{I} \mapsto \mathbb{v}_{\mathcal{I}}$.

▶ **Proposition 13.** *The image of $\mathfrak{I}$ via the function V is a convex subset of $\mathbb{R}^{6n}$.*

Proof. Let S be the collection of all $(1,1)$- and all $(2,1)$-intervals of $\mathbb{R}^2$. Consider the map from S to $\mathbb{R}\times\mathbb{R}\times\mathbb{R}_{>0}\times\mathbb{R}_{\geq 0}\times\mathbb{R}_{\geq 0}\times\mathbb{R}_{>0}$ depicted in Figure 1. Clearly, this map is a surjection. It follows that the image of S via the map $I\mapsto(x,y,a,b,c,d)$ depicted in Figure 1 is a convex subset of $\mathbb{R}^6$. Now, observe that the image of $\mathfrak{I}$ via the map V is equal to the n-fold Cartesian product of the image of S, which is a subset of $\mathbb{R}^{6n}$. The fact that any Cartesian product of convex sets is convex implies our claim. ◀

▶ **Theorem 14** (Lipschitz stability of loss function)**.** *Let $\mathcal{K}$ be any finite set of $(1,1)$- or $(2,1)$-intervals, and let $\mathcal{J}_1,\mathcal{J}_2$ be any two n-sets of $(1,1)$- or $(2,1)$-intervals for some $n\in\mathbb{N}^*$. Then, we have $|\hat{d}(\mathcal{K},\mathcal{J}_1)-\hat{d}(\mathcal{K},\mathcal{J}_2)|\leq 2\cdot\min_\pi||\mathbb{v}_{\pi(\mathcal{J}_1)}-\mathbb{v}_{\mathcal{J}_2}||_\infty$, where the minimum is taken over all permutations on $\mathcal{J}_1$.*

Proof. By the triangle inequality, we have $|\hat{d}(\mathcal{K},\mathcal{J}_1)-\hat{d}(\mathcal{K},\mathcal{J}_2)|\leq\hat{d}(\mathcal{J}_1,\mathcal{J}_2)$ and thus it suffices to show that $\hat{d}(\mathcal{J}_1,\mathcal{J}_2)\leq 2\cdot\min_\pi||\mathbb{v}_{\pi(\mathcal{J}_1)}-\mathbb{v}_{\mathcal{J}_2}||_\infty$. Let π_0 be a permutation on $\mathcal{J}_1$ that attains the minimum. Let $\mathcal{I}:=\pi_0(\mathcal{J}_1)$ and $\mathcal{J}:=\mathcal{J}_2$. By Lemma 12, ϵ_{rr} (resp. ϵ_{ss}) $\leq 2\epsilon$ for all $r,s\in\{1,\dots,n\}$ and hence $\min_s\epsilon_{rs}$ (resp. $\min_r\epsilon_{rs}$) $\leq 2\epsilon$ for each r (resp. s). Thus, we have $\max_r(\min_s\epsilon_{rs})\leq 2\epsilon$ and $\max_s(\min_r\epsilon_{rs})\leq 2\epsilon$. By Theorem 9 (i), we are done. ◀

▶ Remark 15. The opposite direction of Theorem 14 does not hold, i.e. there does not exist $c>0$ such that $|\hat{d}(\mathcal{K},\mathcal{J}_1)-\hat{d}(\mathcal{K},\mathcal{J}_2)|\geq c\cdot\min_\pi||\mathbb{v}_{\pi(\mathcal{J}_1)}-\mathbb{v}_{\mathcal{J}_2}||_\infty$. However, the non-existence of such $c>0$ is *not* an issue in our work as what we require is the Lipschitz stability and almost everywhere differentiability of the loss function (which we establish in the next proposition), in order to prevent erratic and oscillating gradient descent iterations.

▶ **Proposition 16.** *The loss function given in Equation (2) is differentiable almost everywhere.*

Proof. The three maps $\mathbb{R}^2\to\mathbb{R}$ given by $(x,y)\mapsto\delta(x,y)|y-x|$ (cf. Equation (7)), $(x,y)\mapsto\max\{x,y\}$, and $(x,y)\mapsto\min\{x,y\}$ are finitely segmented piecewise linear. Therefore, the functions given in Equations (11)–(14) are all finitely segmented piecewise linear on Euclidean spaces, and thus so are ϵ_{rs} given in Theorem 9 (ii). Hence, trivially, these functions are differentiable almost everywhere. Now, Proposition 6 (iii) implies our claim. ◀

5 Numerical Experiments on Sparsification

In this section, we make use of the results proved above to provide a method for *sparsifying* GPDs. Indeed, computing a single GPD $\mathrm{dgm}_M^{\mathcal{I}}$ on a persistence module M coming from a simplicial complex S requires computing zigzag persistence modules on all intervals of $\mathcal{I}$, as described in [16], and then computing the corresponding Möbius inversion, yielding a time complexity of $O(n^3)$, where n is the number of intervals in $\mathcal{I}$, due to the need to compute the Möbius function value for all possible pairs of intervals, each requiring $O(n)$ operations to iterate over each interval. Thus, the complexity of computing a single GPD is $O(n\times N_s^{2.376}+n^3)$, where N_s is the number of simplices [30]. Hence, computing all GPDs from a dataset of persistence modules becomes intractable when n is large.

Therefore, as described in the introduction, our goal in this section is to design a *sparse* subset of $(2,1)$-intervals $\mathcal{J}^*$ of size $m\ll n$ that minimizes the loss function in Equation (2) with gradient descent by treating every interval in $\mathcal{J}$ as a parameter to optimize.

Time-series datasets. The datasets we consider are taken from the UCR repository [15], and correspond to classification tasks that have already been studied with persistent homology before [29, Section 4.2]. More precisely, instances in these datasets take the form of labelled time series, that we pre-process with time-delay embedding in order to turn them into point clouds. Specifically, each labelled time series $T = \{f(t_1), \dots, f(t_n)\}$ of length n is transformed into a point cloud $X_T \subset \mathbb{R}^3$ of cardinality $n-2$ with

$$X_T := \{(f(t_1), f(t_2), f(t_3))^T, \dots, (f(t_{n-2}), f(t_{n-1}), f(t_n))^T\}.$$

Then, we compute both the Vietoris-Rips filtration and the sublevel set filtration induced by a Gaussian kernel density estimator (with bandwidth $\sigma = 0.1 \cdot \mathrm{diam}(X_T)$, where $\mathrm{diam}(X_T) := \max_{x,y \in X_T} \|x - y\|_2$ is the diameter of the point cloud) using the `PointCloud2FilteredComplex` function of the `multipers` library [28] (a tutorial is available in [26]). Both filtrations are then normalized so that their ranges become equal to the unit interval $[0, 1]$.

Loss function. In order to compute GPDs out of these 2-parameter filtrations and modules, one needs a subset of intervals. As explained in the introduction, we then minimize

$$\mathcal{L}_{\hat{d_{\mathrm{E}}},m} : \mathbb{V}_{\mathcal{J}} \mapsto \hat{d}(\mathcal{I}, \mathcal{J}),$$

where the full domain $\mathcal{I}$ (resp. the sparse domain $\mathcal{J}$) is comprised of $n = 1,600$ (resp. $m = 400$) $(2,1)$-intervals obtained from a grid in $\mathbb{R}^6$ computed by evenly sampling 10 (resp. 5) values for x and y and 2 values for a, b, c, d within their corresponding filtration ranges.[6] Note that while the $(2,1)$-intervals in $\mathcal{J}$ are treated as parameters to optimize, the $(2,1)$-intervals in $\mathcal{I}$ are fixed throughout the optimization process. Moreover, the formula that we provided in Theorem 9 (ii) can be readily implemented in any library that uses auto-differentiation, such as `pytorch`. In particular, we run stochastic gradient descent with momentum 0.9 on $\mathcal{L}$ for 750 epochs using learning rate $\eta = 0.001$ with exponential decay of factor 0.99 to achieve convergence, and obtain our sparse subset $\mathcal{J}^*$. See Figure 5 for a visualization of the loss decrease. Note how the Lipschitz stability proved in Theorem 14 translates into a smooth decrease with small oscillations.

Accuracy scores. In order to quantify the running time improvements as well as the information loss (if any) when switching from the full domain $\mathcal{I}$ to the optimized sparse one $\mathcal{J}^*$, we computed the full and sparse GPDs in homology dimensions 0 and 1 with the zigzag persistence diagram implementation in `dionysus` [31], and then we trained random forest classifiers on these GPDs to predict the time series labels.[7] In order to achieve this, we first turned both the full and optimized GPDs into Euclidean vectors by first binning every GPD (seen as a point cloud in $\mathbb{R}^6$) with a fixed 6-dimensional histogram, and then convolving this histogram with a 6-dimensional Gaussian kernel in order to smooth its values, with a procedure similar to the one described in [29, Section 3.2.1]. Both the histogram bins and the kernel bandwidths were found with 3-fold cross-validation on the training set (see the provided code for hyperparameter values). Then, random forest classifiers were trained on these smoothed histograms to predict labels; in Table 1 we report the accuracy scores

[6] We also tried random uniform sampling for the initial distributions of x, y, a, b, c, d, but this resulted in slower convergence and lower performances.

[7] Recall that optimizing the sparse domain can be performed without computing GPDs, so the optimization process described in the previous paragraph is done once and for all, before computing the GPDs.

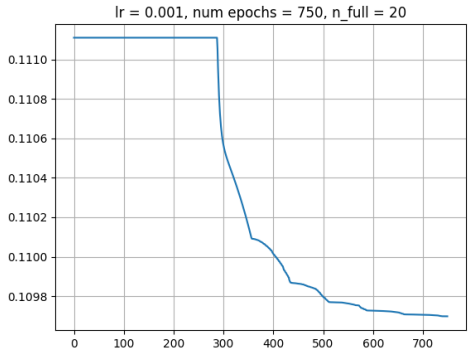

Figure 5 Loss decrease across gradient descent iterations. Note that the loss value stays on a plateau for the first ∼300 iterations; this is due to the fact that during these first iterations, the parameters in $\mathcal{J}$ that are updated with gradient descent are not yet the ones achieving the maxima and minima in the closed-form formula provided in Theorem 9 (ii). Moreover, in this example, gradient descent converges to a local minimum of the loss that is only ∼0.01 lower than the initial value, partially because we are using the small learning rate 0.001.

of these classifiers for the initial (before optimization) sparse domain $\mathcal{J}_{\text{init}}$, the optimized sparse domain $\mathcal{J}^*$, and the full domain $\mathcal{I}$. Moreover, in Table 2, we report the running time needed to compute all GPDs using either $\mathcal{J}_{\text{init}}$, $\mathcal{J}^*$, or $\mathcal{I}$, as well as the improvement when switching from $\mathcal{J}^*$ to $\mathcal{I}$. Note that our goal is not to improve on the state-of-the-art for time series classification, but rather to assess whether optimizing the loss $\mathcal{L}_{\hat{d_{\text{E}}},m}$ based on our upper bound is indeed beneficial for improving topology-based models. See Figure 2 for a schematic overview of our full pipeline.

Discussion on results. As one can see from Table 1, there is either a clear improvement or a comparable performance in accuracy scores after optimizing $\mathcal{J}$. Indeed, by minimizing $\mathcal{L}_{\hat{d_{\text{E}}},m}$, one forces the sparse domain $\mathcal{J}$ to be as close as possible to the full domain $\mathcal{I}$, and thus to retain as much topological information as possible. Hence, either the full GPDs are more efficient than the initial sparse GPDs, in which case the optimized GPDs perform much better than the initial sparse ones, or the full GPDs are less efficient than the initial sparse GPDs,[8] in which case the optimized GPDs have comparable or slightly worse performances than the initial sparse ones thanks to the small sizes of their domains (except for the PC and IPD datasets, for which the optimized GPDs still perform interestingly better). In all cases, we emphasize that optimized GPDs provide the best solution: *they maintain scores at levels that are either comparable or better than the best solution between the initial sparse and full GPDs, while avoiding to force users to choose interval domains* (as their domains are obtained automatically with gradient descent). Note in particular that whenever optimized GPDs do not achieve the best scores, their performances remain of the same order as those of their competitors (see, e.g., DPC or SC), whereas when optimized GPDs are the best, the performances of the other two competitors are sometimes far behind (see, e.g., GPA).

[8] Recall that the accuracy score is only an *indirect* measure: While the full GPDs are *always* richer in topological information, we hypothesize that their scores might still be lower due to a large number of intervals on which the full GPDs vanish – a question that we leave for further study.

As for running times, we observe a slight increase from the running times associated to the initial sparse GPDs (except for the IPD dataset), which we hypothesize is due to the use of optimized intervals that intersect more with each other, and thus induce more poset relations when computing Möbius inversions, and a strong improvement over the running times associated to the full GPDs, with ratios ranging between 5 and 15 times faster. *Our optimized GPDs thus achieve the best of both worlds: they are strinkingly fast to compute while keeping high accuracy scores.* Our code was run on a `2x Xeon SP Gold 5115 @ 2.40GHz`, and is fully available at sparse GPDs.

Table 1 Accuracy scores (%) of random forest classifiers trained on several UCR datasets. Underline indicates best score between the initial and optimized sparse domains, while bold font indicates best score overall. See the full version [11] for the dataset full names.

6 Conclusion

Our sparsification method demonstrates the practicality of approximating full GPDs with sparse ones: while significantly reducing computational costs, our appropriate loss function also ensures that their discriminative power is not too compromised. We thus believe that our work paves the way for efficiently deploying multi-parameter topological data analysis to large-scale applications, that are currently out of reach for most multi-parameter topological invariants from the literature. In what follows, we outline several potential future directions.

Optimization for finer GPDs. In our experiments, we optimized the GPDs over intervals with at most two minimal points and exactly one maximal point. Allowing more complex intervals, as well as dataset-dependent terms in the loss function, could improve performance,

but finding suitable embeddings of such intervals into Euclidean space remains a challenge (cf. Remark 11) and would increase the computational cost (cf. Remark 10). It would also be interesting to quantify the discriminating power of GPDs with measures that are more direct than the score of a machine learning classifier (or at least to further study the dependencies between GPD sparsification and classifier scores), and to investigate on heuristics (based on drops in the loss values) for deciding whether sparse GPDs are sufficiently good so that optimization can be stopped.

Experimental validation for other GRI-based descriptors. While we only focused on sparsifying GPDs in this work, it would be interesting to measure the extent to which our interval domain optimization adapts to other descriptors based on the GRI from the TDA literature; of particular interest are the GPDs/signed barcodes coming from *rank exact decompositions*, which have recently proved to be stable [8] (see also Section 8.2 in [7] which discusses the influence of the choice of the interval domains on the resulting invariants), as well as GRIL, which focuses on specific intervals called *worms* [37].

Abstract

We consider the problem of computing Schnyder woods for graphs embedded on the torus. We design simple linear-time algorithms based on canonical orderings that compute toroidal Schnyder woods for simple toroidal triangulations. The Schnyder woods computed by one of our algorithm are crossing and satisfy an additional structural property: at least two of the mono-chromatic components of the Schnyder wood are connected. We also exhibit experimental results empirically confirming three conjectures involving the structure of toroidal and higher genus Schnyder woods.

1 Introduction

Graphs embedded on surfaces exhibit many significant structural properties. In the planar case, one of the most elegant characterizations is provided by Schnyder woods, a profound combinatorial structure introduced by W. Schnyder to define a new planarity criterion [31] and to design an efficient and elegant straight-line grid drawing algorithm [32]. Schnyder woods lead to a global characterization of planar graphs in terms of spanning trees and have inspired numerous generalizations and applications in various fields, including graph drawing [17, 18, 19], graph encoding [10, 11], enumerative combinatorics [2, 20], random sampling [29] and plane spanners [4].

The first generalizations [5, 14, 15] of Schnyder woods to non planar graphs were motivated by applications involving graph encoding problems, aiming to preserve their global spanning properties. Since then the study of Schnyder woods and related structures for graphs embedded on toroidal [3, 6, 12, 16, 21, 22, 27] and higher genus [1, 14, 15, 25, 33] surfaces have attracted a lot of attention. This is particularly true in the toroidal case, for which some elegant generalizations lead to applications ranging from graph drawing [22] to bijective encodings [3, 16, 21].

Toroidal Schnyder woods

A key property of *toroidal triangulations* is that the number of edges is exactly three times the number of vertices, by Euler's formula. Gonçalves and Lévêque [22] show how to endow a simple toroidal triangulation with an edge orientation and coloring with three colors [1] $\{0, 1, 2\}$ where every vertex has outgoing degree 3 and satisfies a local Schnyder rule (as in the plane). It turns out that the i-cycles [2] are directed, non-contractible and homotopic, and they do not intersect each other. Moreover, any toroidal triangulation admits a *crossing Schnyder wood* for which every pair of i-cycles and j-cycles (for $i \neq j$) are crossing, which is particularly relevant for graph drawing applications. Indeed, the crossing condition is crucial for obtaining a periodic straight-line drawing [22] of toroidal maps on a grid of polynomial resolution, which extends the face-counting approach of planar Schnyder drawings [32, 18, 19].

1.1 Contribution

Addressing two questions left open in [22, 27], we design and implement a simple algorithm for computing (crossing) toroidal Schnyder woods: our approach is based on the vertex shelling paradigm involving canonical orderings [3] and allows us to get mono-chromatic components which are connected, for at least two of the three colors. Our main result is stated below:

▶ **Theorem 1.** *Given a simple toroidal triangulation $\mathcal{T}$ it is possible to compute in linear time a crossing Schnyder wood of $\mathcal{T}$ such that the mono-chromatic components of color* 0 *and of color* 1 *are connected.*

As far as we know, our approach leads to the first implementation for computing toroidal Schnyder woods: previous solutions [22, 27] rely on a very involved case analysis or on unpublished results (requiring more than linear time) and, to our knowledge, they have not been implemented, even in the triangulated case (see Section 1.2 for a more detailed discussion), nor do they provide a guarantee on connectness of any mono-chromatic component.

We also conduct experiments providing an empirical answer to conjectures stated in [1, 22] regarding the existence of Schnyder woods for higher genus surfaces.

1.2 Related works: computing crossing toroidal Schnyder woods

Via edge contractions. One can compute crossing Schnyder woods for essentially 3-connected toroidal maps making use of the approach based on edge contractions [22]. The main idea is to perform a sequence of edge contractions until we are left with few vertices: the Schnyder wood can be recovered by assigning colors after the edge expansions (in reverse order). The validity of this approach relies on a very involved case analysis [22, 27]: this results in a polynomial time algorithm, but it is not known how to get linear time while preserving the crossing condition, which is a non-local property.

Via three paths meeting at a vertex. For simple triangulations another way [22] to compute toroidal Schnyder consists in cutting a toroidal triangulation $\mathcal{T}$ along three non-contractible (and non-homotopic) cycles $\Gamma_0, \Gamma_1, \Gamma_2$ whose intersection is a common single vertex v. As

[1] In our pictures we use red for color 0, blue for color 1 and black for color 2.
[2] An i-cycle, for $i \in \{0, 1, 2\}$, is a mono-chromatic cycle whose edges are of color i.
[3] In the planar case there exists a linear time algorithm for computing Schnyder woods via canonical orderings [8, 26] performing vertex shellings: the fact that such an algorithm also exists in the toroidal case has been left as an open question in [27].

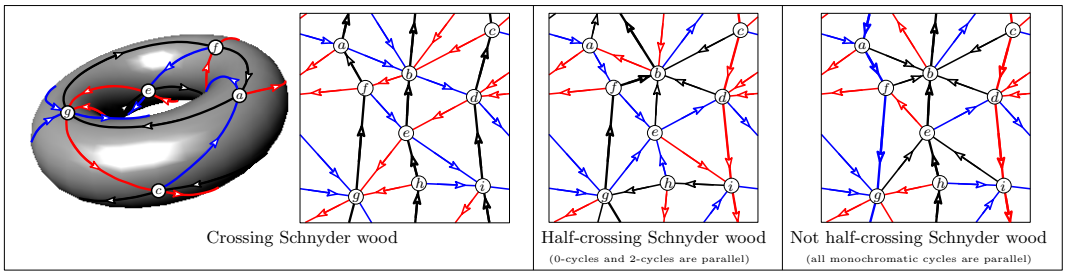

Figure 1 A toroidal simple triangulation of size 9, endowed with three different Schnyder woods.

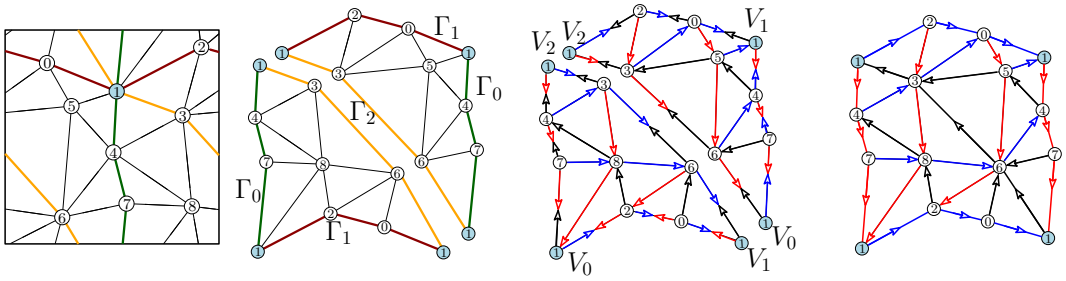

Figure 2 Computing a toroidal Schnyder wood via 3 non-contractible cycles crossing at v_1.

result one obtains a partition of $\mathcal{T}$ into two quasi-triangulations G_1 and G_2, which are internally 3-connected and can be endowed with a planar Schnyder wood (refer to [18, 19]). Then computing Schnyder woods for G_1 and G_2 and gluing them yields a crossing Schnyder wood for $\mathcal{T}$ (see Fig. 2). The Schnyder wood satisfies the following 3-*cycles property*: there are (at least) three mono-chromatic cycles, one for each color, crossing at a single vertex and which are disjoint elsewhere. It is worth noting that the construction described in [22] does not guarantee that the mono-chromatic components are connected (the Schnyder wood could have several disjoint mono-chromatic i-cycles). Unfortunately, as pointed out in [27], it is not clear how to get a linear-time algorithm: the pre-processing phase relies on an unpublished result by Fijavz (the computation of three non-homotopic and non-contractible cycles whose intersection is a common vertex) which involves a result on disjoint paths in [30].

Via reversal of oriented cycles. In the triangulated case, the basic approach using edge contraction (without maintaining crossing property) leads to an algorithm for computing balanced toroidal Schnyder woods in linear time (Thm 10 in [27]). As shown in [27] (Thm 11) it is possible to turn a balanced Schnyder wood into a half-crossing one by performing the reversal of oriented cycles. Then one can perform another cycle reversal phase in order to make the Schnyder wood crossing (Thm 13 in [27]). All these phases can be executed in linear time, but we are not aware of any existing implementation. [4]

[4] For a fast implementation one needs to efficiently process contractible edges and to maintain the map data structure under local updates: this is not trivial in practice, even in the (planar) triangulated case.

2 Preliminaries

Toroidal and cylindric triangulations

In this work we deal with *toroidal triangulations* which are maps on the torus with only triangular faces (such maps are *simple* if they have no loops nor multiple edges). We will denote by n the total number of vertices. In our drawings we will represent such maps in the planar model of the flat torus. We also consider (simple) *cylindric triangulations*, which are planar maps with a marked inner face of simple contour denoted C_{in} (the outer face contour being denoted C_{ext}) such that all other inner faces have degree 3. G is *non-degenerate* if C_{in} and C_{ext} are disjoint (not sharing any vertex). We will denote by n the number of vertices of $G \setminus C_{in}$, and will also use notation $\partial^i G$ for C_{in} and $\partial^e G$ for C_{ext}. We will draw cylindric triangulations either in the annular representation or in the flat model of the cylinder.

Toroidal Schnyder woods (for triangulations)

▶ **Definition 2** ([22, 27]). *Let $\mathcal{T}$ be a toroidal triangulation. A* Schnyder wood *of $\mathcal{T}$ is an orientation and labeling, with colors in $\{0, 1, 2\}$ of the edges of $\mathcal{T}$ so as to satisfy the following* ***local Schnyder condition (for all vertices):*** *for each vertex v, the edges incident to v in counterclockwise (*ccw*) order are: one outgoing edge colored 2, zero or more incoming edges colored 1, one outgoing edge colored 0, zero or more incoming edges colored 2, one outgoing edge colored 1, and zero or more incoming edges colored 0.*

A Schnyder wood is half-crossing *if there are two distinct colors $i, j \in \{0, 1, 2\}$ such that there is an i-cycle crossing a j-cycle (in which case all i-cycles cross all j-cycles). A Schnyder wood is* crossing *if for each pair of distinct colors $i, j \in \{0, 1, 2\}$ there is an i-cycle crossing a j-cycle).*

The pictures in Fig. 1 show a toroidal triangulation endowed with three Schnyder woods. Definition 2 is particularly elegant since it preserves the symmetry of the three colors, but in general the global spanning property of Schnyder woods is lost: the graph induced by any given color could consist of several disjoint connected components, each component being made of a cycle with trees attached to it (as every vertex has outdegree 1 in a given color).

Canonical orderings for cylindric triangulations

As shown in [12], it is possible to extend the notion of canonical orderings [23] to the cylindric case as follows. A *cylindric canonical ordering* is an ordering $\pi = \{v_1, \dots v_n\}$ of the vertices of $G \setminus C_{in}$ such that, for every $k \geq 0$, the map G_k induced by $C_{in} \cup \{v_1, \dots, v_k\}$ is a cylindric (possibly degenerate) triangulation, and such that, for every $k \geq 1$, the vertex v_k belongs to the outer boundary cycle of G_k, denoted $\partial^e G_k$, and its neighbors in G_{k-1} are consecutive boundary vertices on $\partial^e G_{k-1}$. Such an ordering can be computed in linear time via an incremental vertex shelling procedure, where vertices together with their incident edges and faces are removed in reverse order from the boundary $\partial^e G_k$ ($n \geq k \geq 1$). In order to be removed, a vertex $v \in \partial^e G_k \setminus C_{in}$ must be *free*: v cannot be incident to a chord of $\partial^e G_k$. The existence of free vertices on $\partial^e G_k$ relies on an inductive argument similar to the planar case (we refer to [12] for more details).

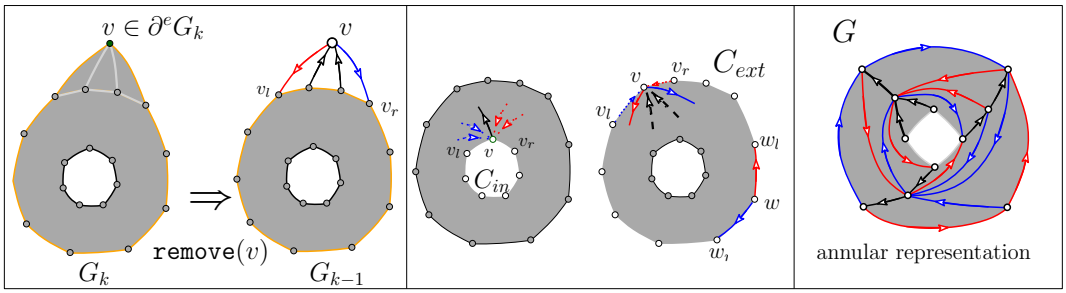

Figure 3 Left: coloring rule associated to the `remove` operator. Center: local conditions for vertices on C_{in} and C_{ext}. Right: a cylindric Schnyder wood of a cylindric triangulation.

3 From cylindric Schnyder woods to toroidal Schnyder woods

For the simple triangulated case, we show how to derive toroidal Schnyder woods from the notion of cylindric canonical orderings [12]. We first planarize the input triangulation $\mathcal{T}$ cutting along a chordless non-contractible cycle Γ, getting a non-degenerate cylindric triangulation G (a non-contractible cycle can be computed in linear time [9]).

Algorithm 1 Computation of a toroidal Schnyder wood via a cylindric canonical ordering.

Data: a simple toroidal triangulation $\mathcal{T}$, a non-contractible chordless cycle Γ
Result: a toroidal Schnyder wood $S(\mathcal{T})$
cut $\mathcal{T}$ along Γ: the result is a cylindric triangulation G with boundaries C_{in}, C_{ext};
$k \leftarrow n$;
$G_k \leftarrow G$, $\partial^e G_k \leftarrow C_{ext}$;
while $\partial^e G_k \neq C_{in}$ **do**
  $v \leftarrow$ any free vertex on $\partial^e G_k$;
  `remove`(v) from $\partial^e G_k$; `/* Orient the edges incident to` v `in` G_k `*/`
  $k \leftarrow k - 1$;
end
identify edges of C_{in} and C_{ext} ;

Then we compute a cylindric canonical ordering of G and we proceed as in the planar case by defining a vertex removal operation: at a given shelling step k, `remove`(v) updates the outer boundary of G_k by removing vertex v while assigning colors and orientations to edges incident to v in G_k, as illustrated in the left picture of Fig. 3: the left and right edges (v, v_{left}) and (v, v_{right}) become outgoing from v (of color 0 and 1), and all remaining edges get oriented toward v (of color 2). This shelling procedure is described in detail in [12], the pseudocode is provided in Algorithm 1. As a result we get a *cylindric Schnyder wood* $S(G)$, i.e., a coloring (in 0, 1 or 2) and an orientation for all edges in $G \setminus C_{in}$ satisfying the three conditions below (depicted in Fig. 3):

- **inner vertices** satisfy the local Schnyder condition as in Definition 2.
- **local condition for** C_{ext}: each vertex $v \in C_{ext}$ has exactly two outgoing edges (of color 0 and 1). When traversing the neighbors of $v \in C_{ext}$ in ccw order around v we encounter: a (possibly empty) set of incoming edges (of color 1), an outgoing edge of color 0, a (possibly empty) set of incoming edges (of color 2), an outgoing edge of color 1, and the remaining edges (if any) are incoming of color 0.

- **local condition for** C_{in}: each vertex $v \in C_{in}$ has one outgoing incident edge e of color 2; all remaining incident edges are incoming at v, being of color 1 if they are at the left of e, and of color 0 otherwise.

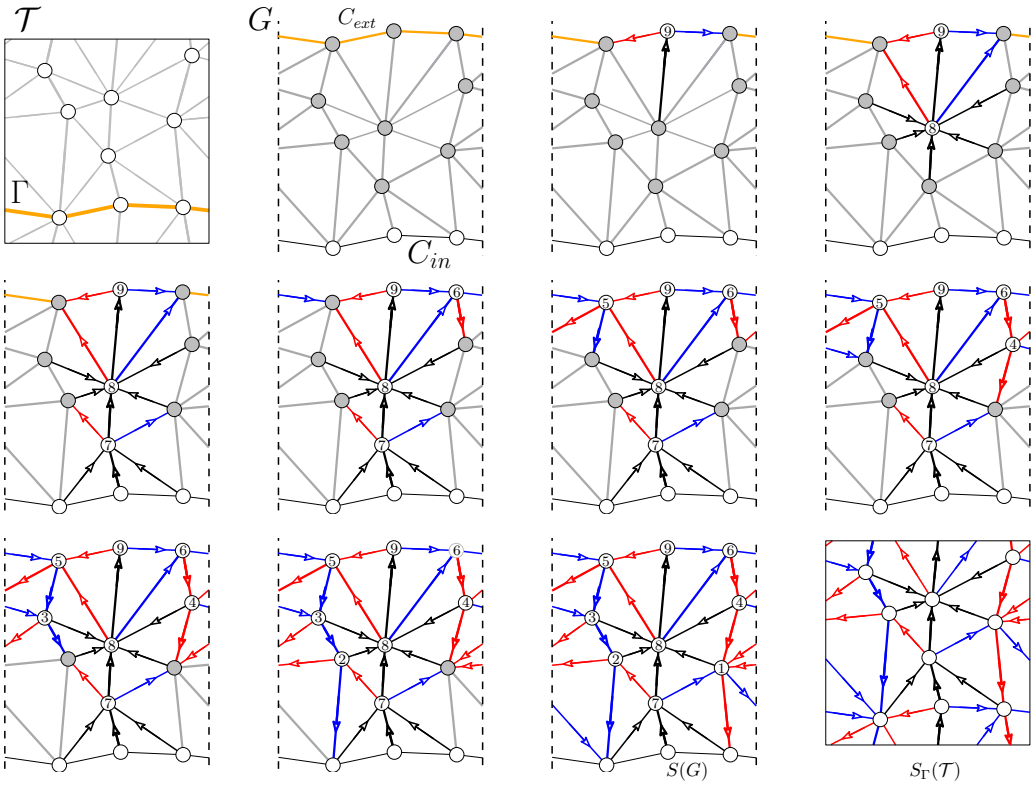

Figure 4 Illustration of Algorithm 1. The toroidal triangulation $\mathcal{T}$ is cut along a non-contractible and chordless cycle Γ. The resulting cylindric triangulation G is endowed with a cylindric canonical ordering (vertices are labeled accordingly), yielding a cylindric Schnyder wood $S(G)$: after gluing C_{in} and C_{ext} we get a toroidal Schnyder wood $S_\Gamma(\mathcal{T})$.

After identification of the cycles C_{ext} and C_{in} we get back the toroidal triangulation $\mathcal{T}$ endowed with a toroidal Schnyder wood $S_\Gamma(\mathcal{T})$ satisfying the additional properties expressed in the Lemma below (the proof is provided in [13]).

▶ **Lemma 3.** *Let $\mathcal{T}$ be a simple toroidal triangulation and Γ a chordless non-contractible cycle. The Schnyder woods $S(G)$ and $S_\Gamma(\mathcal{T})$ computed as above satisfy (see Fig. 4):*

1. *in $S(G)$ the edges of color 2 define a spanning forest of $G \setminus C_{ext}$, whose (directed) trees are rooted on a vertex of C_{ext}; Similarly, the edges of color 0 (resp. 1) define a spanning forest of $G \setminus C_{in}$, whose (directed) trees are rooted on a vertex of C_{in};*
2. *in $S_\Gamma(\mathcal{T})$ all i-cycles cross the cycle Γ and are not homotopic to Γ (for $i \in \{0, 1, 2\}$);*
3. *if $S_\Gamma(\mathcal{T})$ is half-crossing then the 0-cycles and 1-cycles are pairwise crossing.*

Balanced Schnyder woods

As illustrated in Fig. 4 the Schnyder woods computed by Algoritm 1 may fail to be crossing or half-crossing (we will remedy this in the next sections), but as we show here they satisfy the important property of being balanced. A Schnyder wood is called *balanced* if every

non-contractible (undirected) cycle C has the same number of outgoing edges on each side. It is actually sufficient (Lemma 34 in [27]) to have the condition satisfied by two non-contractible cycles that are not homotopic (see [13] for the proof of the statement below).

▶ **Corollary 4.** *The Schnyder woods computed by Algorithm 1 are balanced.*

Balanced Schnyder woods are very instrumental in the bijective encoding [16, 21] of simple toroidal triangulations by decorated unicellular maps (which yields an asymptotically optimal encoding procedure). Indeed the first step of the construction is to compute the so-called *minimal* balanced Schnyder wood of the simple toroidal triangulation $\mathcal{T}$ to be encoded. It turns out that this can easily be done in linear time (by an adaptation of the planar-case arguments given in [7], see also [24, Lemma 3.2]) starting from an arbitrary balanced Schnyder wood of $\mathcal{T}$, as provided by Algorithm 1.

3.1 Constrained cylindric Schnyder woods

Assume we are given a cylindric triangulation G with two boundary cycles C_{in} and C_{ext} (with no chord at C_{in}) and a chordless path $P = \{u_0, u_1, \dots u_{t-1}\}$ originating from vertex $u_0 \in C_{in}$ and ending at $u_{t-1} \in C_{ext}$, such that P intersects the boundary cycles of G only at u_0 and u_{t-1}. We explain here how to adapt the shelling procedure so as to obtain a cylindric Schnyder wood of G such that P is a directed path in color 2.

▶ **Definition 5.** *Let $P = \{u_0, u_1, \dots u_{t-1}\}$ be a path satisfying the conditions above. A cylindric Schnyder wood of G is called* P-constrained *if every edge $(u_i, u_{i+1}) \in P$ is oriented toward u_{i+1} and has color 2.*

We say that a boundary vertex $v \in \partial^e G_k \setminus P$ (for $k \geq 1$) is *strongly free (with respect to P)* if v is free and not adjacent to any vertex of P_k, where $P_k = P \cap (G_k \setminus \partial^e G_k)$ is the restriction of P to the interior of G_k. The vertex $u \in P \cap \partial^e G_k$ is strongly free if it does not have any incident chord at $\partial^e G_k$. We modify the shelling procedure described in the previous section by removing at each shelling step only vertices on $\partial^e G_k$ which are strongly free, as illustrated in Fig. 5 (see [13] for the proof of the Lemma below).

▶ **Lemma 6.** *Given a cylindric triangulation G and a path P defined as above, the adapted shelling procedure outputs a P-constrained Schnyder wood of G, and runs in linear time.*

4 Rivers

We consider here a particular type of "thin" cylindric triangulations called *rivers*, for which we compute a so-called *rigthmost* (resp. *leftmost*) P-constrained Schnyder wood. Rivers, and properties of their rightmost (resp. leftmost) Schnyder wood, are key to obtain the half-crossing (resp. crossing) property, as presented in Section 5 (resp. Section 6).

4.1 Definition of a river

Let us define a *river* R as a non-degenerate simple cylindric triangulation whose outer and inner boundary cycles, denoted $\partial^i R = \{x_0, x_1, \dots, x_{r-1}\}$ and $\partial^e R = \{z_0, z_1, z_2, \dots, z_{s-1}\}$, satisfy the following conditions: $\partial^i R$ and $\partial^e R$ are chordless cycles such that every vertex $z \in \partial^e R$ has an incident edge $(z, \bar{x})$, where $\bar{x} \in \partial^i R$, and every vertex $x \in \partial^i R$ has an incident edge $(x, \bar{z})$, where $\bar{z} \in \partial^e R$ (such edges are called *non-trivial chords* of R).

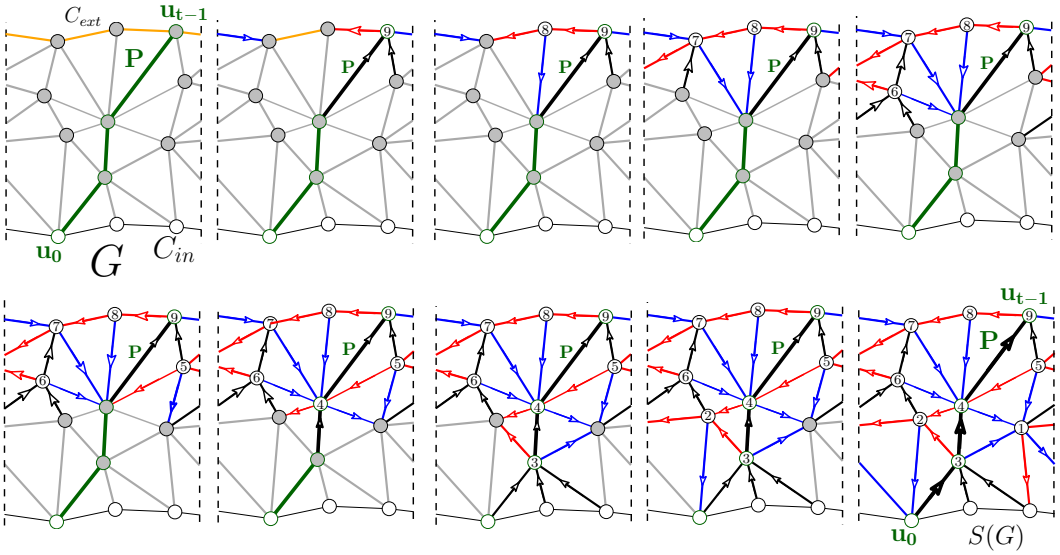

Figure 5 Computation of a P-constrained Schnyder wood (Lemma 6): only vertices which are strongly free (with respect to the path $P = \{u_0, \ldots, u_{t-1}\}$) can be removed at each step.

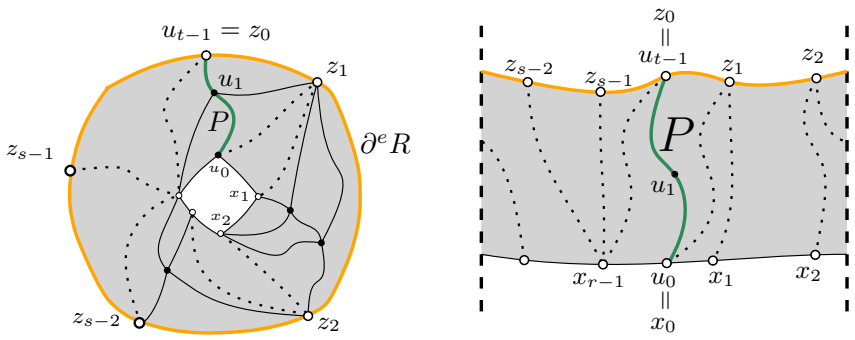

Figure 6 (Left) annular representation of a river R with a chordless path P crossing only once its boundary cycles. Right: only non-trivial chords are drawn, as dotted arcs.

4.2 Right-most (left-most) cylindric canonical ordering of a river

Let us assume that R is provided with a chordless path $P = \{u_0, \ldots, u_{t-1}\}$ intersecting its boundaries only once, at $u_0 = x_0$ and $u_{t-1} = z_0$ (refer to Fig. 6). Observe that the non-trivial chords (u, y), where u is either u_0 or u_{t-1} and $y \in (\partial^i R \cup \partial^e R) \setminus P$, can be partitioned into two (possibly empty) sets, depending on whether (u, y) is at the right or at the left of the path P. We classify the vertex u_{t-1} according to four types (see Fig. 7):

(A): u_{t-1} has chords both at the left and at the right of P;

(B): u_{t-1} has no chords at the left nor at the right of P, so that (u_0, u_{t-1}) is the only chord at u_{t-1};

(C1): u_{t-1} has chords at the right of P, but not at the left of P;

(C2): u_{t-1} has chords at the left of P, but not at the right of P.

Let us now define the *right-most traversal* of R with respect to P (yielding a P-constrained cylindric Schnyder wood) as given by Algorithm 2 below (refer also to Fig. 7 for an illustration):

Algorithm 2 Right-most traversal of a river.

Data: a river R, a path $P = \{u_0, u_1, \ldots, u_{t-1} = z_0\}$
Result: a P-constrained cylindric Schnyder wood of R
if u_{t-1} *is of* ***type (A)*** **then**
  $v \leftarrow z_1$;
else
  $v \leftarrow z_0$;
end
$x_c \leftarrow$ extremity of the left-most chord of v ;
remove v from the outer boundary $\partial^e R$;
while $\partial^e R \neq \partial^i R$ **do**
  $v \leftarrow$ the strongly free vertex on $\partial^e R$ which is closest to x_c at its right;
  remove v from the outer boundary $\partial^e R$;
end

One crucial property is that, after computing a P-constrained Schnyder wood $S_P(R)$ according to a right-most traversal, if u_{t-1} is of type (A), (B) or (C1) then every vertex z on $\partial^e R$ lies on a path of color 1 ending at P. If u_{t-1} is of type (C2) this property may fail, but the right-most traversal leads to the existence of a ccw-oriented contractible cycle enclosed in R. These properties are a consequence of the statement below (see [13] for the proof).

▶ **Lemma 7.** *Let us consider a river R and a chordless path P as defined above. Let $S_P(R)$ be the P-constrained cylindric Schnyder wood computed by Algorithm 2. Then we have:*

1. *if u_{t-1} is of type (A), then for every vertex $z_i \in \partial^e R$ with $1 < i < s$, the path of color 1 starting from z_i passes by u_{t-1};*
2. *if u_{t-1} is of type (B) or (C1), then for every vertex $z \in \partial^e R$, the path of color 1 starting from z ends at u_0;*
3. *if u_{t-1} is of type (C2): then all vertices z_i are lying on a path of color 1 ending either at P or at x_c. Moreover, there exists at least one vertex z_i lying on a ccw-oriented cycle (enclosed in R) defined by $(x_c, u_{t-1}, z_{s-1}, \ldots, z_i)$.*

Left-most traversal. One can define left-most traversals proceeding in a symmetric way with respect to Algorithm 2: at the beginning we set $v = z_{s-1}$ if u_{t-1} is of type (A) and $v = z_0$ otherwise; x_c is set to be the extremity of the right-most chord of v; finally, at each shelling step one removes the strongly free vertex which is closest at the left of x_c.

Similarly to the properties stated in Lemma 7 one can show that if u_{t-1} is of type (A), (B) or (C2) then each vertex z on $\partial^e R$ lies on a path of color 0 ending at P.

5 Algorithm for half-crossing toroidal Schnyder woods

We describe in this section an algorithm to compute a half-crossing toroidal Schnyder wood for any simple toroidal triangulation, with the further property that the mono-chromatic component in color 0 or in color 1 is connected.

5.1 Existence of a river in cylindric triangulations

A key ingredient of the algorithm is the computation of a river in the cylindric triangulation that is obtained by cutting along a chordless non-contractible cycle.

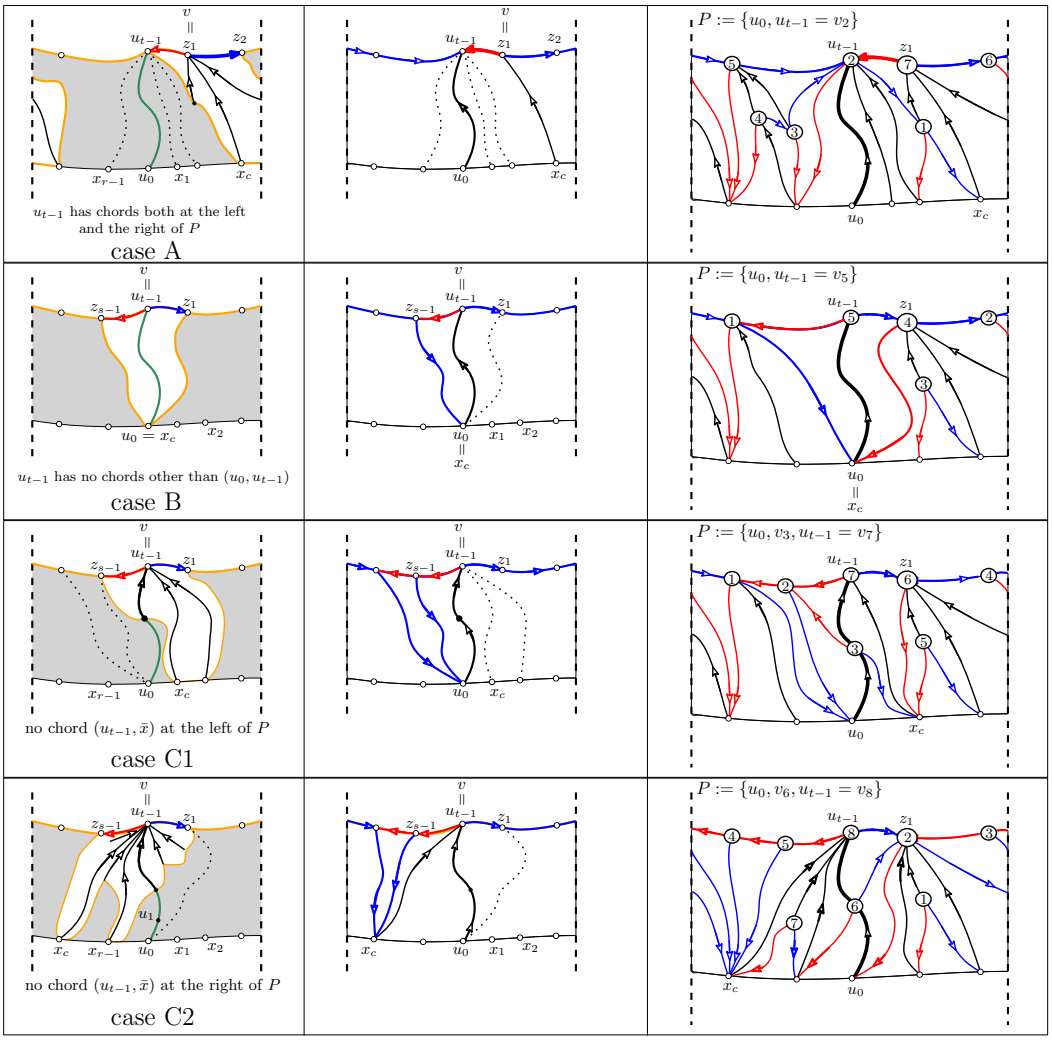

Figure 7 Illustration of Algorithm 2 and Lemma 7: we distinguish four cases for the right-most traversal of a river R. Left pictures: removal of the first vertex on $\partial^e R$. Center pictures: paths of color 1 obtained via a right-most traversal of R. Right pictures: complete execution of Algorithm 2 on four examples (vertex labels are assigned according to the cylindric canonical ordering).

▶ **Lemma 8.** *Given a non-degenerate cylindric triangulation G with no chord at C_{in} or C_{ext}, it is possible to compute in linear time a river R contained in G, whose inner and outer boundaries are homotopic to $\partial^i G$ (the proof is provided in [13]).*

5.2 Algorithm

Let $\mathcal{T}$ be a simple toroidal triangulation. We now describe the algorithm computing a half-crossing Schnyder woods of $\mathcal{T}$; the complete pseudo-code is provided in Algorithm 3, see also Figure 8 for an illustration on an example. After cutting $\mathcal{T}$ along a non-contractible and chordless cycle Γ (as in Section 3), we obtain a non-degenerate cylindric triangulation G, and compute a river R in G (Lemma 8). As a result, the faces of G are partitioned into three regions: G_{top} (a possibly degenerate cylindric triangulation), the river R, and G_{bottom} (a possibly degenerate cylindric triangulation).

Algorithm 3 Half-crossing Schnyder woods (with a connected mono-chromatic component).

Data: a simple toroidal triangulation $\mathcal{T}$, a non-contractible chordless cycle Γ
Result: a half-crossing Schnyder wood
// Pre-processing step
cut $\mathcal{T}$along Γ: let G be the resulting cylindric triangulation ;
compute a river R and the partition $G = G_{top} \cup R \cup G_{bottom}$;
// First pass
compute a Schnyder wood $S(G_{top})$ of G_{top} ;
choose an arbitrary non trivial chord $e = (x, z)$ of R ;
$P \leftarrow \{x, z\}$;
if z *has* ***type (A), (B) or (C1)*** **then**
  run the right-most P-constrained traversal of (R, P);
  $r \leftarrow 1$;
else
  run the left-most P-constrained traversal of (R, P) ;
  $r \leftarrow 0$;
end
compute a Schnyder wood $S(G_{bottom})$ of G_{bottom} ;
glue boundary cycles together and let $S(\mathcal{T}) = S(G_{bottom}) \cup S(R) \cup S(G_{top})$;
if *the r-cycle and 2-cycles are crossing in* $S(\mathcal{T})$ **then**
  return $S(\mathcal{T})$;
end
// Run a second pass on R
$\gamma_2 \leftarrow$ any 2-cycle of $S(\mathcal{T})$; // Remark: the r-cycle and 2-cycles are parallel
$P_2 \leftarrow \gamma_2 \cap R$; // restriction of γ_2 to the river R
$u \leftarrow \partial^e R \cap P_2$;
if u *has* ***type (A), (B) or (C1)*** **then**
  run the right-most P-constrained traversal of (R, P_2);
  $r \leftarrow 1$;
else
  run the left-most P-constrained traversal of (R, P_2) ;
  $r \leftarrow 0$;
end
// Remark: $S(G_{bottom})$ and $S(G_{top})$ are P_2-constrained
glue boundary cycles together and let $S(\mathcal{T}) = S(G_{bottom}) \cup S(R) \cup S(G_{top})$;
return $S(\mathcal{T})$;

The algorithm relies on two passes (the second one not always necessary). In the first pass, we let P be an arbitrary non-trivial chordal edge $\{x, z\}$ for the river R. If z is not of type C2, we perform a rightmost traversal of R, otherwise a leftmost traversal. We also compute in an independent way two (arbitrary) Schnyder woods of G_{top} and G_{bottom}: after boundary identifications we obtain a Schnyder wood $S(T)$ of $\mathcal{T}$. It follows from Lemma 7 (see the proof of Proposition 9) that if z is not (resp. is) of type C2, then there is a single monochromatic cycle C of color 1 (resp. color 0), and moreover it winds only once around Γ (it may share edges with Γ but reaches it only once from the left). If C crosses any cycle of color 2, then we output $S(\mathcal{T})$. Otherwise we need a second pass. Let γ_2 be an arbitrary

2-cycle. Note that γ_2 winds once around Γ since it is homotopic to C. Due to edge colors and local Schnyder conditions, it intersects γ_2 at a single vertex (as opposed to C it can not share edges with Γ). Hence, if we cut γ_2 along Γ, we obtain a path $P_2 \subset G$ which is chordless and meets the boundary cycles only at its extremities. We can then adjust the Schnyder wood in R as follows: if the upper end of P_2 is not of type C2, we perform a rightmost traversal of R with respect to P_2, otherwise a leftmost traversal. This updates $S(\mathcal{T})$ into a half-crossing Schnyder wood, such that in the first (resp. second) case there is a single cycle of color 1 (resp. 0) and it the cycle γ_2 of color 2 (as expressed by Proposition 9).

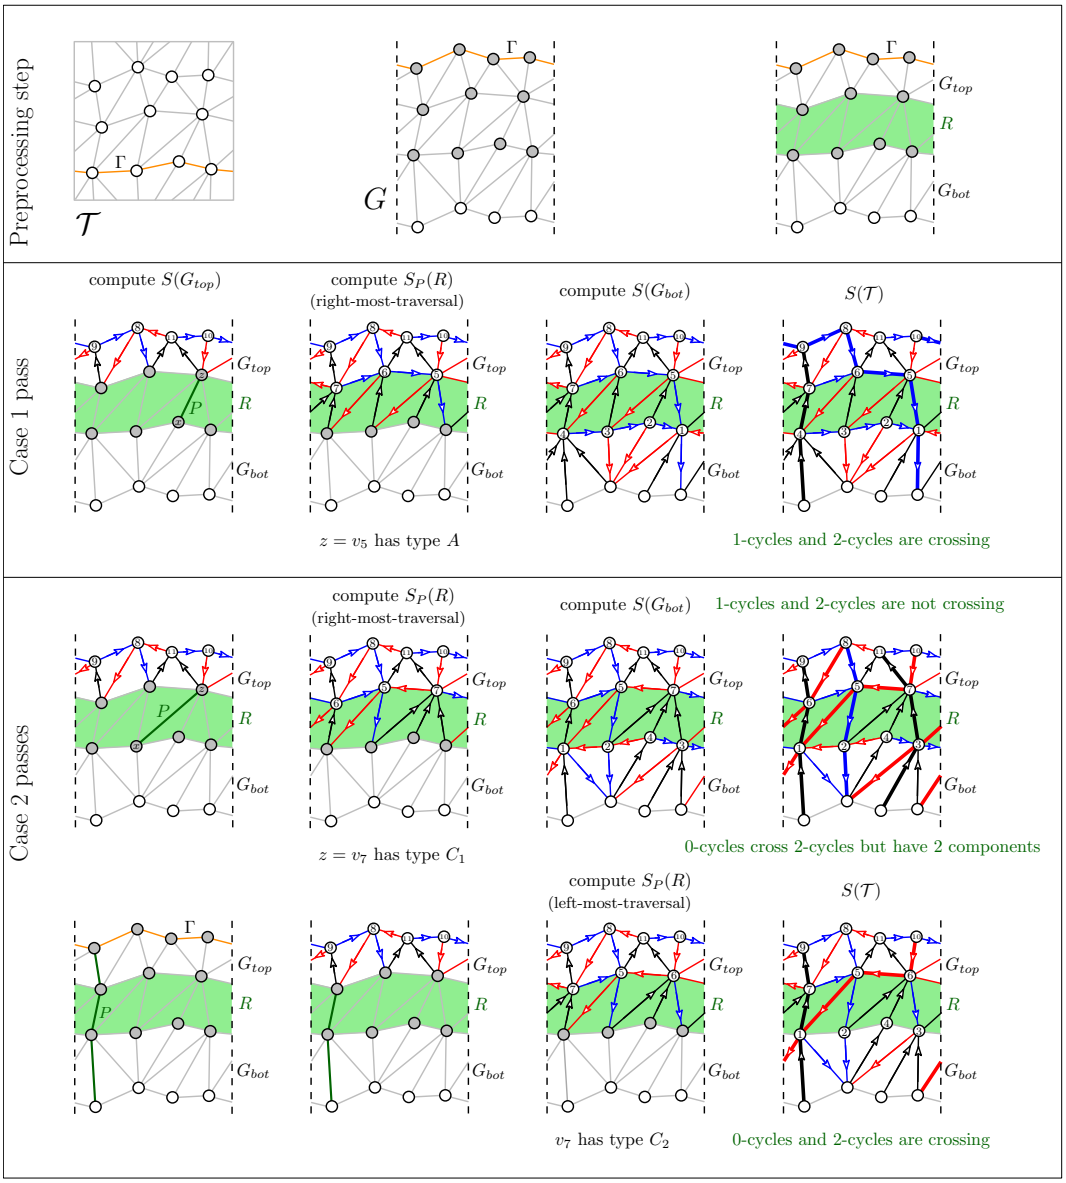

Figure 8 Execution of Algorithm 3 on a small example.

▶ **Proposition 9.** *Given a simple toroidal triangulation $\mathcal{T}$, Algorithm 3 computes in linear time a half-crossing Schnyder wood of $\mathcal{T}$ via vertex shellings. More precisely, there is $r \in \{0, 1\}$ such that the edges of color r define a single connected component, and the unique r-cycle crosses the 2-cycles (see [13] for the proof).*

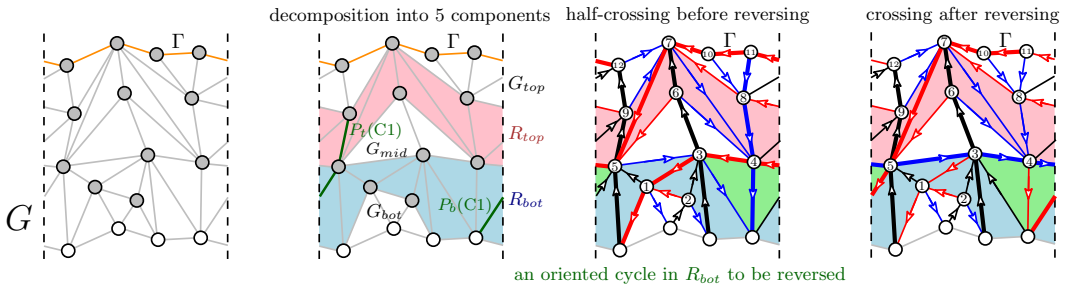

Figure 9 Illustration of the algorithm of Section 6.2 for computing crossing Schnyder woods. At the end of the first phase the Schnyder wood is half-crossing but not crossing (the 1-cycle is parallel to the 2-cycles). But the bottom river contains a ccw-oriented contractible cycle C (enclosing the shaded green region): the reversal of C leads to a 1-cycle parallel to Γ and thus crossing the 2-cycles, making the Schnyder wood crossing. The edges of color 0 and 1 define a connected component.

6 Algorithm for crossing toroidal Schnyder woods

Building on the ideas of Section 5, we give in this section a linear-time algorithm for computing a crossing toroidal Schnyder wood, with the additional property that the mono-chromatic components in color 0 and in color 1 are connected, as stated in Theorem 1.

6.1 Existence of two non-overlapping rivers in cylindric triangulations

Compared to the procedure for half-crossing Schnyder woods, the algorithm for crossing Schnyder woods now requires the computation of two parallel and non-overlapping rivers R_t and R_b in the cylindric triangulation obtained after cutting along a non-contractible and chordless cycle. The existence of such a pair of rivers is guaranteed by the next statement.

▶ **Lemma 10.** *Given a non-degenerate cylindric triangulation G with no chord at C_{in} or C_{ext}, nor between C_{in} and C_{ext}, it is possible in linear time to compute a pair of non-overlapping rivers R_t (top river) and R_b (bottom river) contained in G, whose inner and outer boundaries are homotopic to $\partial^i G$ (see [13] for the proof).*

6.2 Algorithm

Given a toroidal simple triangulation $\mathcal{T}$, as before the first step consists in cutting $\mathcal{T}$ along a chordless non-contractible cycle Γ, yielding a cylindric triangulation G. Since Γ is chordless, the triangulation G has no chord at C_{in} or at C_{ext}, nor chords from C_{in} to C_{ext} (such an edge would correspond to a chord of Γ starting at one side and ending at the other side). Hence we can apply Lemma 10, which yields a decomposition of G into five components (from top to bottom): a top cylindric triangulation G_{top}, the river R_t, a middle cylindric triangulation G_{middle}, the river R_b, and a bottom cylindric triangulation G_{bottom}. Note that G_{top}, G_{middle} and G_{bottom} are possibly degenerate. We then follow the pipeline used in Algorithm 3: one river (resp. the other river) is used to guarantee that color 0 (resp. color 1) is crossing color 2, and that the mono-chromatic component is connected.

Precisely, in a first pass, we choose a chord e_t in R_t that is the leftmost chord at its top vertex, and let $P_t = e_t$ be the path according to which we perform a rightmost traversal of R_t (note that (R_t, P_t) is of type B or C_1). Similarly, we choose a chord e_b in R_b that is the rightmost chord at its top vertex, and we let $P_b = e_b$ be the path according to which we

perform a leftmost traversal of R_b (note that (R_b, P_b) is of type B or C_2). We also compute an arbitrary cylindric Schnyder wood for each of the three components G_{top}, G_{middle}, and G_{bottom}. Then we glue together the Schnyder woods for the five components. Identifying C_{in} with C_{ext} we obtain a toroidal Schnyder wood of $\mathcal{T}$. From Lemma 7 and arguments already used in Section 5, the mono-chromatic component of color 1 (resp. color 0) is connected, thanks to the top-river (resp. bottom river). If the Schnyder wood is crossing we return it as the output.

If it is not crossing we need a second pass, similarly to Section 5. By the 3rd item in Lemma 3 we must have either color 1 parallel to color 2, or color 0 parallel to color 2. In both cases, due to the rivers, the non-contractible cycles of color 2 must wind only once (they cross Γ at a single vertex), so in G such a cycle γ_2 gives a path P_2 from C_{in} to C_{ext}. Keeping the Schnyder woods for G_{top}, G_{middle}, and G_{bottom} unchanged, we need a second pass to adjust those for R_t and R_b in order to obtain the crossing property. Precisely, let P_t (resp. P_b) be the restriction of P_2 to R_t (resp. R_b). If (R_t, P_t) and (R_b, P_b) are not both of type C2 or are not both of type C1, then we can choose one of them, denote it by (R', P'), not to be of type C2, and the other one, denote it by (R'', P''), not to be of type C1. Then we perform a right-most traversal for (R', P'), and a left-most traversal for (R'', P''). After these updates on the Schnyder woods for the two rivers, and by the arguments of Section 5, the toroidal Schnyder wood of $\mathcal{T}$ now has the property that cycles of color 1 (resp. 0) cross cycles of color 2 thanks to R' (resp. R''), and that the monochromatic component of color 1 (resp. 0) are still connected.

It remains to treat the case where at the second pass we have (R_t, P_t) and (R_b, P_b) both of type C1 or both of type C2. Let us assume they are both of type C2. Then we adjust the Schnyder woods in R_t and R_b by performing the leftmost P_t-constrained traversal of R_t, and the rightmost P_b-constrained traversal of R_b. At this point we have the crossing of color 0 with color 2, thanks to the top river and the 2nd item in Lemma 3. In color 1 the crossing property may however fail. But we can take advantage of the 3rd item in Lemma 7, which guarantees the existence of a specific directed cycle C in R_b. Reversing this cycle makes $\partial^e R_b$ a cycle in color 1 that is parallel to Γ.

▷ Claim 11. If in the second phase the rivers (R_t, P_t) and (R_b, P_b) are of type C2, then after reversing the cycle C, the toroidal Schnyder wood of $\mathcal{T}$ is crossing, and the mono-chromatic components of color 0 and of color 1 are connected (see [13] for the proof).

The case where (R_t, P_t) and (R_b, P_b) are both of type C1 can be handled very similarly, by performing the rightmost P_t-constrained traversal of R_t, the leftmost P_b-constrained traversal of R_b, and reversing the specific directed cycle in R_b that is guaranteed by the mirror-statement of the 3rd item in Lemma 3.

This concludes the proof of our main result, as stated in Theorem 1.

▶ Remark 12. An alternative to our algorithm is given by Theorem 13 in [27], which allows to obtain a crossing Schnyder wood from a half-crossing one (such as computed by Proposition 9), however without guarantee of connectedness for the mono-chromatic components. It relies on the repeated reversal of carefully chosen directed cycles. As a comparison, our algorithm needs to reverse at most one directed cycle, and it is easy to implement in linear time (even though the overall proof of correctness is a bit involved).

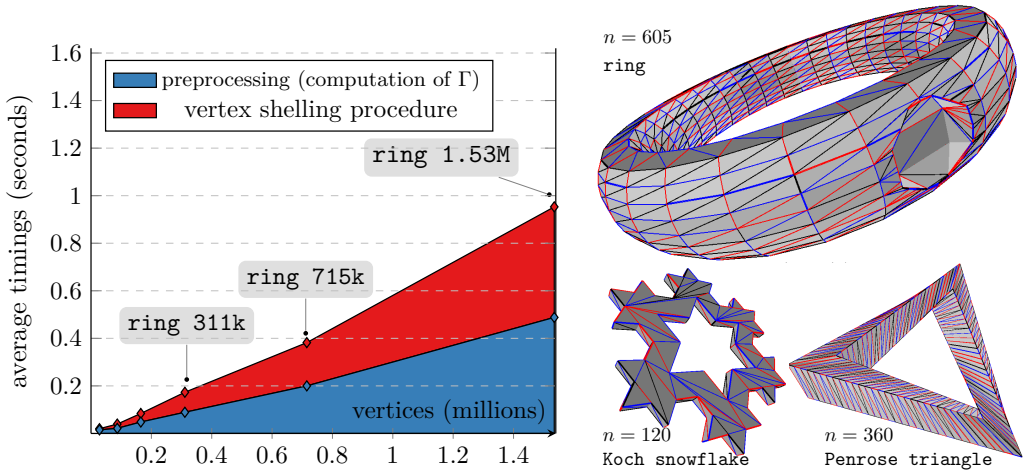

Figure 10 (Left) runtime performances of Algorithm 1: average timings (computed over several runs) are expressed in seconds as a function of the size (millions of vertices). (Right) examples of genus 1 triangle meshes endowed with a toroidal Schnyder wood.

7 Experimental results

7.1 Implementation and experiments

We have written `Java` implementations [5] of our algorithms and performed tests on genus 1 triangle meshes of various sizes (mostly taken from *Thingi10K* repository). Our algorithms for computing toroidal Schnyder woods are significantly simpler to analyze (in particular regarding the linear time complexity) and implement than previous solutions [22]. As confirmed by the runtime plots of Fig. 10, the approach based on vertex shelling leads to a very fast implementation: we can process more than $1M$ vertices per second (our experiments are run on a single core of a `core i7-9700` cpu, allocating $8GB$ memory for the JVM, running `Java 1.8` under Ubuntu Linux).

7.2 Conjectures on higher genus Schnyder woods: empirical results

We have conducted experiments providing an empirical confirmation of three conjectures involving Schnyder woods for triangulations in genus 1 and genus 2. We wrote a `Java` program that exhaustively generates all possible 3-orientations (see definition below in genus more than 1) and Schnyder woods for triangulations of genus $g \leq 2$. Our generator is fast enough to process all tiny triangulations (generated using `surftri` [34], see Table 1) in a reasonable amount of time, allowing us to compute some statistics and test some conjectures.

Connectedness of the three mono-chromatic graphs in genus 1

We have checked that all toroidal simple triangulations of size at most 11 admit a Schnyder wood for which the edges of the same color define a connected graph (having thus 3 mono-chromatic cycles, one for each color), providing an empirical answer to an open question stated in [22] (our algorithm of Section 6 guarantees a positive answer in two of the three colors). We also consider a second open question asked in [22] concerning the existence of

[5] Datasets, runnable programs and source code (pure Java) are made available at: `www.lix.polytechnique.fr/~amturing/software.html`.

Table 1 Simple triangulations of genus 1 and 2 (enumerated using `surftri` [34]).

g=1	irreducible triang.	all triangulations
n=7	1	1
n=8	4	7
n=9	15	112
n=10	1	2109
n=11	-	37867

g=2	irreducible triang.	all triangulations
n=7	-	-
n=8	-	-
n=9	-	-
n=10	865	865
n=11	26276	113506

crossing Schnyder woods satisfying a stronger requirement (referred to as *connected* 3*-cycles property*): the Schnyder wood is crossing, the three mono-chomatic components consist of a single connected component and the intersection of the three non trivial cycles is a single vertex [6]. Our experiments provide an empirical positive answer to this question (for $n \leq 11$): we report in Figure 11 some statistics and the list of irreducible [7] triangulations of genus 1, each endowed with a crossing Schnyder wood satisfying this stronger condition.

Existence of Schnyder woods in genus 2

For a simple triangulation of genus $g \geq 1$, a *3-orientation* is an orientation such that for every vertex v the out-degree is divisible by 3 and at least 3 (no sinks). In genus $g \geq 2$ some vertices must have degree more than 3, since $\sum_v(\deg(v) - 3) = 6g - 6$ according to the Euler relation. It is shown in [1] that any simple triangulation of genus $g \geq 2$ admits a 3-orientation. The following natural open question (asked in [27]) then arises: for every simple triangulation of genus $g \geq 2$, is it always possible to find a 3-orientation for which the edges can be colored so as to satisfy a *multiple* local Schnyder condition at every vertex (as depicted in Fig. 12)? In his PhD dissertation J. Suagee [33] shows that the answer is positive for every simple triangulation of genus $g \geq 2$ having edge-width at least $40(2^g - 1)$. We have checked that the answer is actually positive for every simple triangulations of genus 2 and $n \leq 11$, suggesting that the assumption on the large edge-width is maybe unnecessary.

8 Concluding remarks

We expect that the construction of Section 3 can be extended to 3-connected toroidal maps using the notion of cylindric toroidal canonical ordering defined for the 3-connected case in [12], leading to a fast linear-time algorithm. As in the triangulated case, the obtained Schnyder woods should have the property of being balanced, which is instrumental in the bijective encoding of 3-connected toroidal maps [3] (indeed it relies on the computation of the *minimal* balanced Schnyder wood of the map, which can easily be obtained in linear time starting from an arbitrary balanced Schnyder wood).

[6] Observe that Thm. 9 in [22] guarantees the existence of three edge-disjoint mono-chromatic cycles crossing at a single vertex, but each mono-chromatic graph may consist of several disjoint components.
[7] A triangulation is irreducible if no edge can be contracted without producing multiple edges.

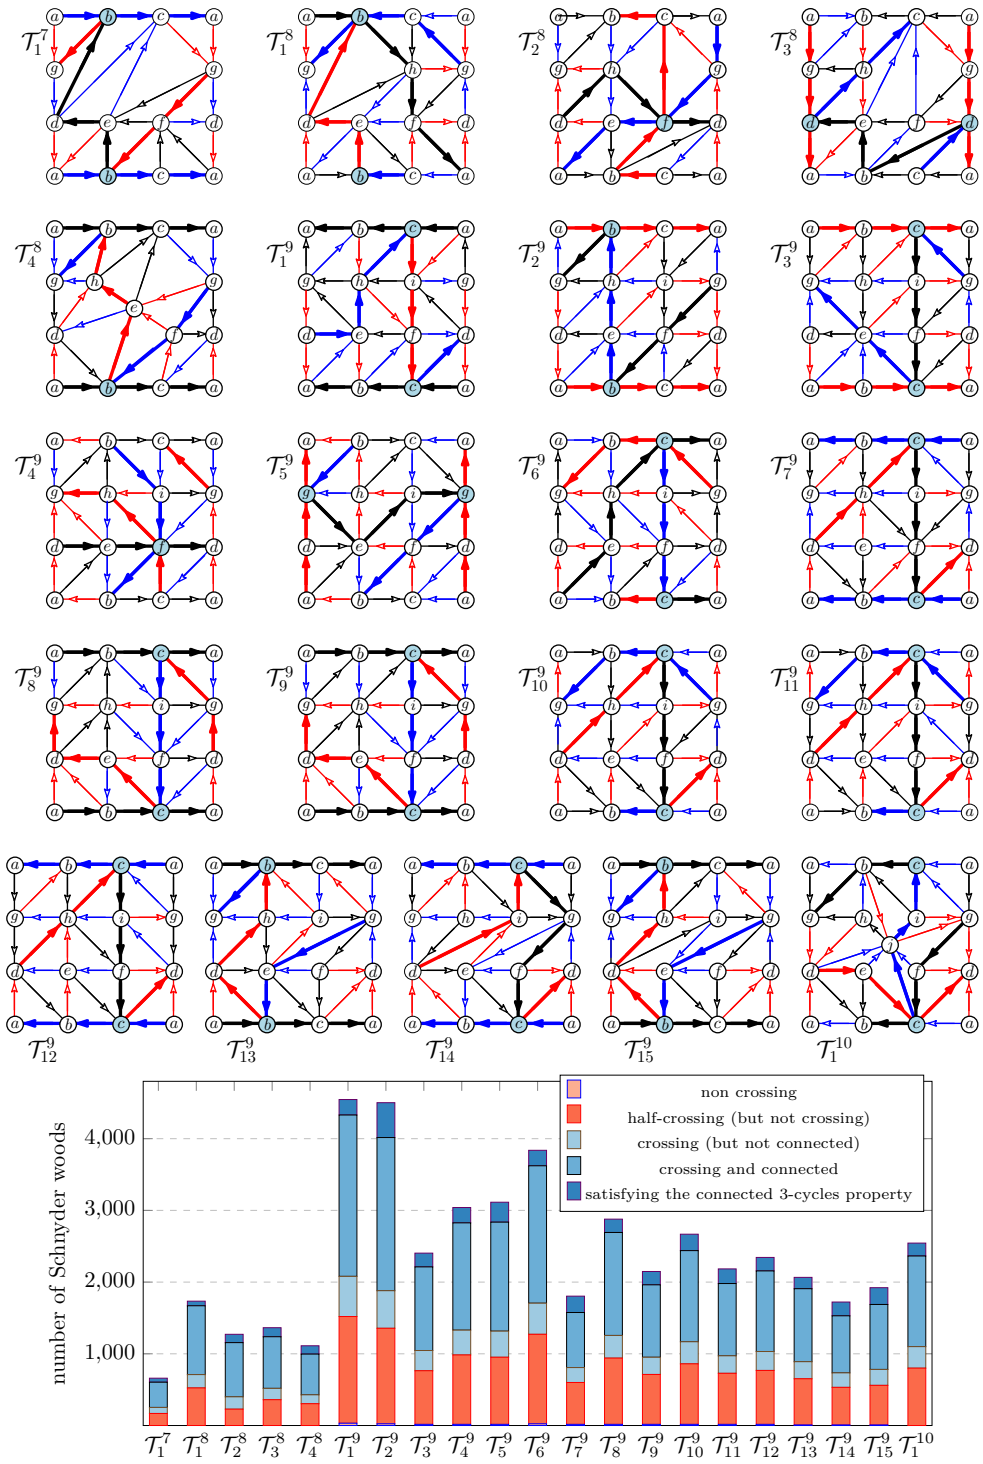

Figure 11 List of genus 1 irreducible triangulations (the embeddings are provided in [28]). Each triangulation is endowed with a Schnyder wood satisfying the connected 3-cycles property computed by our generator. The bottom plots report some statistics computed by our generator.

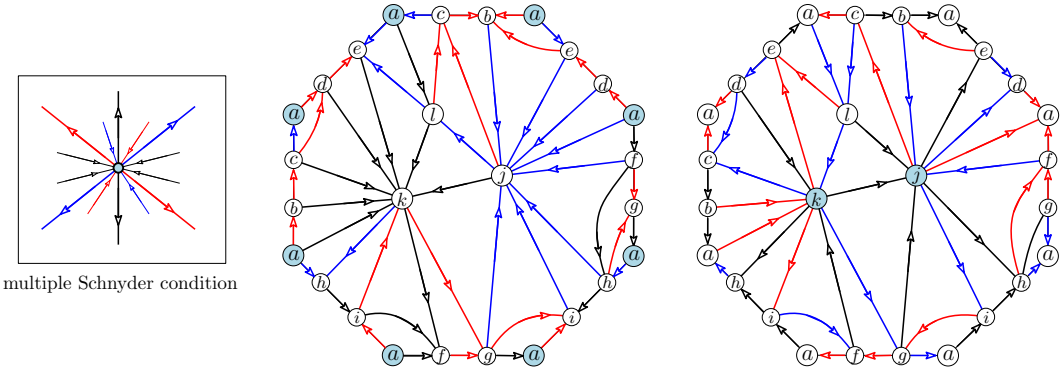

Figure 12 Planar layout of a genus 2 triangulation: it is endowed with two Schnyder woods satisfying the multiple Schnyder condition computed by our generator. In the left case vertex a has outgoing degree 9, while in the right one vertices j and k have outgoing degree 6. This triangulation admits 16.421.904 3-orientations and 509844 valid Schnyder woods.

A Linear Time Algorithm for the Maximum Overlap of Two Convex Polygons Under Translation

Timothy M. Chan

Abstract

Given two convex polygons P and Q with n and m edges, the *maximum overlap* problem is to find a translation of P that maximizes the area of its intersection with Q. We give the first randomized algorithm for this problem with linear running time. Our result improves the previous two-and-a-half-decades-old algorithm by de Berg, Cheong, Devillers, van Kreveld, and Teillaud (1998), which ran in $O((n+m)\log(n+m))$ time, as well as multiple recent algorithms given for special cases of the problem.

1 Introduction

Problems related to convex polygons are widely studied in computational geometry, as they are fundamental and give insights to more complex problems. We consider one of the most basic problems in this class:

▶ **Problem 1.** *Given two convex polygons P and Q in the plane, with n and m edges respectively, find a vector $t \in \mathbb{R}^2$ that maximizes the area of $(P+t) \cap Q$, where $P+t$ denotes P translated by t.*

This problem for convex polygons was first explicitly posed as an open question by Mount, Silverman, and Wu [34]. In 1998, de Berg, Cheong, Devillers, van Kreveld, and Teillaud [21] presented the first efficient algorithm which solves the problem in $O((n+m)\log(n+m))$ time. As many problems have $n \log n$ complexity, this would appear to be the end of the story for the above problem – or is it?

Motivation and Background. The computational geometry literature is replete with various types of problems about polygons [36], e.g., polygon containment [14] (which has seen exciting development even in the convex polygon case, with translations and rotations, as recently as last year's SoCG [13]). The maximum overlap problem may be viewed as an outgrowth of polygon containment problems.

The maximum overlap problem may also be viewed as a formulation of *shape matching* [7], which has numerous applications and has long been a popular topic in computational geometry. Many notions of distance between shapes have been used in the past (e.g., Hausdorff distance, Fréchet distance, etc.), and the overlap area is another very natural measure (the larger it is, the closer the two shapes are) and has been considered in numerous papers for different classes of objects (e.g., two convex polytopes in higher dimensions [3, 5, 4], two arbitrary polygons in the plane [18, 25], two unions of balls [10], one convex polygon vs. a discrete

point set[1] [9, 1], etc.) as well as different types of motions allowed (translations, rotations, and scaling – with translations-only being the most often studied). Problem 1 is perhaps the simplest and most basic version, but is already quite fascinating from the theoretical or technical perspective, as we will see.

A Superlinear Barrier? Due to the concavity of (the square root of) the objective function [21], it is not difficult to obtain an $O((n+m)\,\mathrm{polylog}(n+m))$-time algorithm for the problem by applying the well-known *parametric search* technique [30, 2] (or more precisely, a multidimensional version of parametric search [38]). De Berg, Cheong, Deviller, van Kreveld, and Teillaud [21] took more care in eliminating extra logarithmic factors to obtain their $O((n+m)\log(n+m))$-time algorithm, by avoiding parametric search and instead using more elementary binary search and matrix search techniques [24]. But any form of binary search would seem to generate at least one logarithmic factor, and so it is tempting to believe that their time bound might be the best possible.

On the other hand, in the geometric optimization literature, there is another well-known technique that can give rise to *linear*-time algorithms for various problems: namely, *prune-and-search* (pioneered by Megiddo and Dyer [31, 22, 32]). For prune-and-search to be applicable, one needs a way to prune a fraction of the input elements at each iteration, but our problem is sufficiently complex that it is unclear how one could throw away any vertex from the input polygons and preserve the answer.

Perhaps because of these reasons, no improved algorithms have been reported since de Berg et al.'s 1998 work. This is not because of lack of interest in finding faster algorithms. For example, a (lesser known) paper by Kim, Choi, and Ahn [28] considered an unbalanced case of Problem 1 and gave an algorithm with $O(n+m^2\log^3 n)$ running time, which is linear when $m \ll \sqrt{n/\log^3 n}$. Ahn et al. [6] investigated *approximation* algorithms for the problem and obtain logarithmic running time for approximation factor arbitrarily close to 1, while Har-Peled and Roy [25] more generally gave a linear-time algorithm to approximate the entire objective function, which was then used to obtain a linear-time approximation algorithm for an extension of the problem to polygons that are decomposable into $O(1)$ convex pieces.

Our Result. We obtain a randomized (exact) algorithm for Problem 1, running in *linear* (i.e., $O(n+m)$) expected time! This is the first improvement to de Berg et al.'s result [21] in 26 years, and is clearly optimal, and so fully settles the complexity of Problem 1.

A New Kind of Prune-and-Search? Besides our result itself, the way we obtain linear time is also interesting. As mentioned, if one does not care about extra $\log(n+m)$ factors, one can use (multidimensional) parametric search to solve the problem. Specifically, parametric search allows us to reduce the optimization problem to the implementation of a *line oracle* (determining which side of a given line the optimal point t^* lies in), which in turn can be reduced to a *point oracle* (evaluating the area of $(P+t)\cap Q$ for a given point t). A point oracle can be implemented in linear time by computing the intersection $(P+t)\cap Q$ explicitly. (In de Berg et al.'s work [21], they directly implemented the line oracle in linear time.)

Various linear-time prune-and-search algorithms (e.g., for low-dimensional linear programming [31, 22, 32], ham-sandwich cuts [33], centerpoints [26], Euclidean 1-center [23], rectilinear 1-median [39, 35], etc.) also exploit line or point oracles; using (in modern parlance)

[1] In the discrete case, we are maximizing the number of points inside the translated polygon.

cuttings [16], such oracle calls let them refine the search space and eliminate a fraction of the input at each iteration. Unfortunately, for our problem, we can't technically eliminate any part of the input polygons P and Q. Instead, our new idea is to reduce the *cost* of the oracles iteratively as the search space is refined, which effectively is as good as reducing the input complexity itself. As the algorithm progresses, oracles get cheaper and cheaper, and we will bound the total running time by a geometric series.

To execute this strategy, one should think of oracles as data structures with sublinear query time (i.e., sublinear in the original input size $n + m$). Our key idea to designing such data structures is to divide the input polygons into *blocks* of a certain size based on angles/slopes. This idea is inspired by the recent work of Chan and Hair [13] (they studied the convex polygon containment problem with both translations and rotations, and although our problem without rotations might seem different, their divide-and-conquer algorithms also crucially relied on division of the input convex polygons by angles/slopes). We show that at each iteration, as we refine the search space, we can use the current "block data structure" to obtain a better "block data structure" with a larger block size. (The refinement process from one block structure to another block structure shares some general similarities with the idea of *fractional cascading* [17].)

We are not aware of any prior algorithms in the computational geometry literature that work in the same way (which makes our techniques interesting). A linear-time algorithm by Chan [12] for a matrix searching problem (reporting all elements in a Monge matrix less than given value) has a recurrence similar to the one we obtain here, but this appears to be a coincidence. An algorithm for computing so-called "ε-approximations" in range spaces by Matoušek [29] also achieved linear time (for constant ε) by iteratively increasing block sizes, but the algorithm still operates in the realm of traditional prune-and-search (reducing actual input size). Chazelle's infamous linear-time algorithm for triangulating simple polygons [15] also iteratively refines a "granularity" parameter analogous to our block size, and as one of many steps, also requires the implementation of oracles (for ray shooting, in his case) whose cost similarly varies as a function of the granularity (at least from a superficial reading of his paper) – fortunately, our algorithm here will not be as complicated!

Remarks. Recently, Jung, Kang, and Ahn [27] have announced a *linear*-time algorithm for a related problem: given two convex polygons P and Q in the plane, find a vector $t \in \mathbb{R}^2$ that minimizes the area of the convex hull $(P + t) \cup Q$. Although the problem may look similar to our problem on the surface, it is in many ways different: in the minimum convex hull problem, the optimal point t^* is known to lie on one of $O(n + m)$ candidate lines (formed by an edge of one polygon and a corresponding extreme vertex of the other polygon), whereas in the maximum overlap problem (Problem 1), t^* lies on one of $O((n + m)^2)$ candidate lines (defined by pairs of edges of the two polygons). Thus a more traditional prune-and-search approach can be used to solve the minimum convex hull problem, but not the maximum overlap problem. Indeed, Jung et al.'s paper [27] considered the maximum overlap problem, but they do not give an improvement over de Berg et al.'s $O((n + m) \log(n + m))$ time algorithm for the two-dimensional case. Instead, they give some new results for the problem in higher dimensions d, but their time bound is $O(n^{2\lfloor d/2 \rfloor})$, which is much larger than linear.

We observe that, in the specific case of maximum overlap for convex polytopes in dimension $d = 3$, one can obtain a significantly faster $O((n + m) \operatorname{polylog}(n + m))$-time algorithm by directly using multi-dimensional parametric search [38], since a point oracle (computing the area of the intersection of two convex polytopes in $\mathbb{R}^3$) can be done in $O(n+m)$ time by explicitly computing the intersection [15, 11], and this is parallelizable with

$O((n+m)\operatorname{polylog}(n+m))$ work and $O(\operatorname{polylog}(n+m))$ steps by known parallel algorithms for intersection of halfspaces in $\mathbb{R}^3$, i.e., convex hull in $\mathbb{R}^3$ in the dual (e.g., see [8]). This observation seems to have not appeared in literature before (including [40, 27]).

2 Preliminaries

We may assume that P and Q have no (adjacent) parallel edges, as these can be merged. Without loss of generality, P and Q both contain the origin as an interior point. Throughout, we assume that the edges of P and Q are given in counterclockwise order. We define $N := n + m$, and we use $[x]$ to denote the set $\{1, \ldots, x\}$. If x is not an interger, then we use $[x]$ to denote the set $\{1, \ldots, \lceil x \rceil\}$, i.e., x is implicitly rounded up to the nearest integer. "*With high probability*" means "with probability at least $1 - n^{-\Omega(1)}$." The *interior* of a triangle refers to all points strictly inside of its bounding edges, and the *interior* of a line segment refers to all points strictly between its bounding points.

The Objective Function. We want to find a translation maximizing

$$\operatorname{Area}((P + t) \cap Q).$$

De Berg, Cheong, Devillers, van Kreveld, and Teillaud showed several interesting properties of the area as a function of t [21]. For our purposes, we only need to import the following.

▶ **Lemma 1.** *$\sqrt{\operatorname{Area}((P + t) \cap Q)}$ is downward concave over all values of t that yield nonzero overlap of $P + t$ with Q.*

The restriction on t is important, as $A(t)$ suddenly transitions from a convex function to a constant function $A(t) = 0$ when t is outside of the specified region. For our algorithm, however, this technicality will have little impact.

Cuttings. First, we give a definition of the type of cuttings we use.

▶ **Definition 2** (ε-Cuttings). *A cutting for a set X of n hyperplanes in $\mathbb{R}^d$, for any $d \geq 1$, is a partition of $\mathbb{R}^d$ into simplices such that the interior of every simplex intersects at most $\varepsilon \cdot n$ hyperplanes of X.*

Endowed with the ability to sample random hyperplanes, we can actually produce such a cutting with very high probability in sublinear time, as per Clarkson and Shor [19, 20] (roughly, we can take logarithmically many random hyperplanes, and return a canonical triangulation of their arrangement).

▶ **Lemma 3.** *Let X be a set of n hyperplanes in $\mathbb{R}^d$, for any $d \geq 1$. Assume we can sample a uniformly random member of X in expected time $O(n^{0.1})$. Let ε be any constant. Then in $O(n^{0.1+o(1)})$ expected time, we can find a set of $O(1)$ simplices that constitutes an ε-cutting of X with high probability.*

Area Prefix Sums. Let $v_1, \ldots, v_n$ be the vertices of P listed in counterclockwise order, and let $v'_1, \ldots, v'_m$ be the vertices of Q listed in counterclockwise order. Let $P[v_x : v_y]$ denote the convex hull of the set of points containing: (i) the origin, (ii) the vertices v_x and v_y, and (iii) all vertices encountered when traversing the boundary of P in counterclockwise order from v_x to v_y. We define $Q[v'_x : v'_y]$ analogously.

By a standard application of prefix sums, we can produce a data structure to report $\text{Area}(P[v_x : v_y])$ and $\text{Area}(Q[v'_x : v'_y])$ with $O(N)$ preprocessing time and $O(1)$ query time. This is since (taking $\text{Area}(P[v_x : v_y])$ as an example):

$$\text{Area}(P[v_x : v_y]) = \text{Area}(P[v_1 : v_y]) - \text{Area}(P[v_1 : v_x]) \text{ when } y > x, \text{ and}$$
$$\text{Area}(P[v_x : v_y]) = \text{Area}(P) - (\text{Area}(P[v_1 : v_x]) - \text{Area}(P[v_1 : v_y])) \text{ when } y < x.$$

Throughout, we refer to the above data structure as the *area prefix sums for P and Q*.

The Configuration Space. Consider two convex polygons A and B, or more generally, two polygonal chains A and B. Let e be an edge of A and let e' be an edge of B. These two edges define a parallelogram $\pi(e, e')$ in configuration space such that, for any vector $t \in \mathbb{R}^2$, we have that $e + t$ intersects e' iff $t \in \pi(e, e')$. Let $\partial\pi(e, e')$ denote the set of four line segments defining $\pi(e, e')$. We define the set of all such line segments as

$$\Pi(A, B) := \bigcup_{\text{edge } e \text{ of } A, \text{ edge } e' \text{ of } B} \partial\pi(e, e'). \tag{1}$$

We define $\overleftrightarrow{\Pi}(A, B)$ to be $\Pi(A, B)$ where each line segment is extended to a line.

Angles and Angle Ranges. The *angle* of an edge e on the boundary of an arbitrary convex polygon A, denoted $\theta_A(e)$, is the angle (measured counterclockwise) starting from a horizontal rightward ray and ending with a ray coincident with e that has A on its left side. We always have that $\theta_A(e) \in [0, 2\pi)$. For any subset X of the edges of A, let $\Lambda_A(X)$ denote the minimal interval in $[0, 2\pi)$ such that $\theta_A(e) \in \Lambda_A(X)$ for all $e \in X$. We call $\Lambda_A(X)$ the *angle range* for the subset X with respect to A.

3 Blocking Scheme

Given a parameter $b \in \mathbb{N}$, referred to as the *block size*, we define a partition[2] of P and Q into *blocks* $P_1, \ldots, P_{\lceil N/b \rceil}$ and $Q_1, \ldots, Q_{\lceil N/b \rceil}$ as follows. First (implicitly) sort the set[3]

$$\{\theta_P(e) : e \text{ is an edge of } P\} \cup \{\theta_Q(e) : e \text{ is an edge of } Q\}$$

in increasing order and then partition the resulting sequence into consecutive subsequences $S_1, \ldots S_{\lceil N/b \rceil}$ of length b each (except possibly the last one). We then define P_i as the convex hull of the origin and the set of edges[4] $\{e : e \text{ is an edge of } P, \text{ and } \theta_P(e) \in S_i\}$. We define Q_j similarly. See Figure 1 for an example.

Now, b uniquely defines the partition, so we refer to $P_1, \ldots, P_{\lceil N/b \rceil}$ and $Q_1, \ldots, Q_{\lceil N/b \rceil}$ as the *blocks determined by parameter b*. This scheme is useful because the angle ranges $\Lambda_P(E_P(P_i))$ and $\Lambda_Q(E_Q(Q_j))$ are strictly disjoint whenever $i \neq j$, where $E_P(P_i)$ is the set of edges that P_i shares with P, and $E_Q(Q_j)$ is the set of edges that Q_j shares with Q. We call $E_P(P_i)$ the *restriction of P_i's edges to P*, and similarly for $E_Q(Q_j)$.

[2] Actually, it isn't quite a partition because the boundaries may overlap, but these have zero area.
[3] We assume that no angles are shared between the edges of P and Q, as this case can be handled easily but requires a clumsier definition.
[4] The set of edges may be empty, in which case the block is just a single point (the origin).

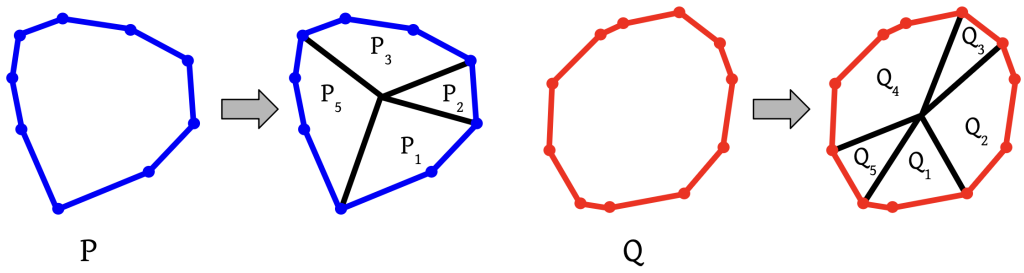

Figure 1 A partition of example polygons P and Q into blocks, with $b = 4$. Note that the spatial *sizes* of blocks may vary greatly, and the number of edges in each P_i and Q_j may differ. In fact, for some indices i, one of P_i or Q_j may contain just the origin.

3.1 A Data Structure Using Blocks

Towards producing a prune-and-search style algorithm, we want some way to reduce the time required to compute the vector t^* which maximizes $\text{Area}((P + t^*) \cap Q)$. Instead of reducing the complexity of P or Q directly, we maintain and refine a specific data structure that contains information about P and Q and allows us to rapidly search for optimal placements.

▶ **Definition 4** ($(\mu, b, \mathcal{T})$-Block Structure). *A $(\mu, b, \mathcal{T})$-block structure is a data structure containing the following:*

1. *Access to the vertices of P and Q in counterclockwise order with $O(1)$ query time, and access to the area prefix sums for P and Q with $O(1)$ query time.*
2. *A block size parameter b, which implies blocks $P_1, \ldots, P_{\lceil N/b \rceil}$ and $Q_1, \ldots, Q_{\lceil N/b \rceil}$.*
3. *A region $\mathcal{T} \subset \mathbb{R}^2$ that is either (i) a triangle, (ii) a line segment, or (iii) a point.*
4. *A partition of $S := [N/b]$ into subsets S_{Good} and S_{Bad}, with the requirement $|S_{\text{Bad}}| \leq \mu$.*
5. *For every $i \in S_{\text{Good}}$, access in time $O(1)$ to a constant-complexity quadratic function f_i such that $f_i(t) = \text{Area}((P_i + t) \cap Q_i)$ for all $t \in \mathcal{T}$.*

Throughout, we assume that S_{Good} and S_{Bad} are sorted, since we can apply radix sort in time $O(|S_{\text{Good}}| + |S_{\text{Bad}}|)$. When using the block structure, we aim to *decrease* the size of $\mathcal{T}$ while *increasing* the block size b. If this is done carefully enough, we get a surprising result: a sublinear time oracle to report $\text{Area}((P + t) \cap Q)$ for any translation $t \in \mathcal{T}$.

4 The Linear Time Algorithm

We will reduce Problem 1 to a few different subroutines/oracles. Roughly speaking, these allow us to produce a highly refined block structure in linear time, which can be used along with multidimensional parametric search [38] to find the translation of P maximizing its area of intersection with Q in time $O(N/\log N)$.

▶ **Problem 2** (MaxRegion). *Given a $(\mu, b, \mathcal{T})$-block structure for P and Q, find*

$$\max_{t \in \mathcal{T}} \text{Area}((P + t) \cap Q)$$

along with the translation $t^* \in \mathbb{R}^2$ realizing this maximum.[5]

[5] During some calls to MaxRegion, $\mathcal{T}$ may *not* contain the global optimum.

▶ **Problem 3** (CASCADE). *Given a $(\mu, b, \mathcal{T})$-block structure, parameters μ' and b' such that b divides b', and a triangle or line segment $\mathcal{T}' \subseteq \mathcal{T}$, either produce a $(\mu', b', \mathcal{T}')$-block structure, or report failure. Failure may be reported only if the interior of $\mathcal{T}'$ intersects more than $\mu'/2$ lines from the set*

$$\mathcal{S} := \bigcup_{k \in \{0,\ldots,\lceil N/b' \rceil - 1\}} \left(\bigcup_{(i,j) \in [\frac{b'}{b}] \times [\frac{b'}{b}]} \overleftrightarrow{\Pi}(P_{k \cdot \frac{b'}{b}+i}, Q_{k \cdot \frac{b'}{b}+j}) \right), \tag{2}$$

where $P_1, \ldots, P_{\lceil N/b \rceil}$ and $Q_1, \ldots, Q_{\lceil N/b \rceil}$ are the blocks of P and Q determined by b.

The set $\mathcal{S}$ may appear mysterious, but it simply corresponds to the line extensions for the edges that could "cause trouble" for the cascading procedure. The only observation necessary right now is that $|\mathcal{S}| = O(Nb')$, i.e., $\mathcal{S}$ is near-linear in size for all $b' = N^{o(1)}$.

We write the expected time complexity of the fastest algorithm for MAXREGION as $T_{d\text{-MAX}}(N, b, \mu)$, where d is the dimension of the region $\mathcal{T}$. We write the expected time complexity of the fastest algorithm for CASCADE as $T_{\text{CASCADE}}(N, b, b', \mu)$. The latter will not depend on μ' or the dimensions of $\mathcal{T}$ and $\mathcal{T}'$.

The next lemmas will be proved in Sections 5 and 6. The main idea behind proving each is to group most of the blocks of P and Q into larger convex polygons that intersect in at most a constant number of locations, and then to process the rest via brute force.

▶ **Lemma 5** (Point Oracle). *For all $2 \le b \le N$, for all μ,*

$$T_{0\text{-MAX}}(N, b, \mu) = O\left(N \cdot \frac{\log^2 b}{b} + \mu b\right).$$

▶ **Lemma 6** (Cascading Subroutine). *For all $2 \le b, b' \le N$ such that b divides b', for all μ,*

$$T_{\text{CASCADE}}(N, b, b', \mu) = O\left(N \cdot \frac{\log b' \log b}{b} + \mu b^2\right).$$

4.1 Reducing to the Point Oracle and Cascading Subroutine

We now give an algorithm for MAXREGION when the input $(\mu, b, \mathcal{T})$-block structure has $\mathcal{T}$ being a triangle or line segment. The algorithm works by invoking MAXREGION on regions with lower dimension to iteratively shrink $\mathcal{T}$.

▶ **Lemma 7.** *For all $2 \le b, b' \le N^{o(1)}$ such that b divides b', for all μ, μ' such that $\mu' = N^{1-o(1)}$,*

$$\begin{aligned} T_{2\text{-MAX}}(N, b, \mu) &= O(\log(Nb'/\mu')) \cdot T_{1\text{-MAX}}(N, b, \mu) + O(N^{0.1+o(1)}) + \\ &\quad O(1) \cdot T_{\text{CASCADE}}(N, b, b', \mu) + T_{2\text{-MAX}}(N, b', \mu') \\ T_{1\text{-MAX}}(N, b, \mu) &= O(\log(Nb'/\mu')) \cdot T_{0\text{-MAX}}(N, b, \mu) + O(N^{0.1+o(1)}) + \\ &\quad O(1) \cdot T_{\text{CASCADE}}(N, b, b', \mu) + T_{1\text{-MAX}}(N, b', \mu'). \end{aligned}$$

Proof. The algorithm for when $\mathcal{T}$ is a line segment is nearly identical to the algorithm for when $\mathcal{T}$ is a triangle, so for brevity we only focus on the triangle case. Let $P_1, \ldots, P_{\lceil N/b \rceil}$ and $Q_1, \ldots, Q_{\lceil N/b \rceil}$ be the blocks of P and Q determined by block size parameter b.

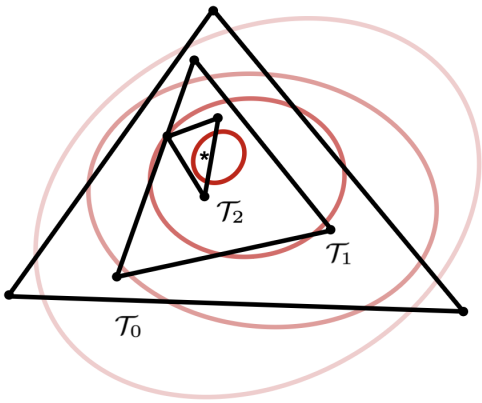

Figure 2 A series of triangles $\mathcal{T}_0$, $\mathcal{T}_1$, and $\mathcal{T}_2$ as produced by the algorithm. The (unknown) optimal placement t^* is denoted by an asterisk. The red curves indicate contour lines of the objective function, with darker circles indicating larger values of $\text{Area}((P+t) \cap Q)$.

Define $\mathcal{T}_0 := \mathcal{T}$. We will produce a series of triangles $\mathcal{T}_0 \supset \mathcal{T}_1 \supset \mathcal{T}_2 \supset \ldots$ such that each triangle is guaranteed to contain the optimal translation t^* for the original region $\mathcal{T}$, and then take the final triangle in this sequence as $\mathcal{T}'$. Once we have $\mathcal{T}'$, we invoke Cascade to produce a $(\mu', b', \mathcal{T}')$-block structure, and then find the optimal translation within $\mathcal{T}'$ (along with the area for this translation) by invoking MaxRegion on this new block structure.

In the subsequent analysis, we show that, with high probability, the interior of $\mathcal{T}'$ produced as per our sequence will intersect at most $\mu'/2$ lines of the set $\mathcal{S}$. If this event occurs, then Cascade will be *forced* to produce a $(\mu', b', \mathcal{T}')$-block structure. If this event does not occur, and Cascade returns failure, we can re-run the randomized algorithm to produce a new $\mathcal{T}'$ and try again. The expected number of attempts is $O(1)$, and so all of the steps (except for producing $\mathcal{T}'$) have a time overhead of $O(1) \cdot T_{\text{Cascade}}(N, b, b', \mu) + T_{2\text{-Max}}(N, b', \mu')$.

Producing $\mathcal{T}'$. As per the above, the expected number of times we need to make $\mathcal{T}'$ is $O(1)$, so we only focus on the time complexity to make $\mathcal{T}'$ once. Consider producing a triangle $\mathcal{T}_{x+1}$ from a triangle $\mathcal{T}_x$ in the sequence. As a first step, we use Lemma 3 to make, with high probability, a $\frac{1}{2}$-cutting for the lines of $\mathcal{S}$ that intersect the interior of $\mathcal{T}_x$.

To apply this lemma, we need an efficient sampler. We argue that naive rejection sampling will suffice. Observe that if rejection sampling fails to find a random line of $\mathcal{S}$ that intersects the interior of $\mathcal{T}_x$ within time $O(N^{0.1})$, then with high probability only $N^{1-\Omega(1)}$ lines of $\mathcal{S}$ intersect $\mathcal{T}_x$. By assumption $\mu'/2 = N^{1-o(1)}$, so we can directly take $\mathcal{T}' = \mathcal{T}_x$. If rejection sampling is fast enough, then we can produce the required $\frac{1}{2}$-cutting with high probability in time $O(|\mathcal{S}|^{0.1+o(1)}) = O(N^{0.1+o(1)})$. Then, we intersect this cutting with $\mathcal{T}_x$ and re-triangulate the resulting cells, which takes $O(1)$ time in total.

The final step is to locate the cell of this triangulation that contains t^*. This cell will be $\mathcal{T}_{x+1}$. To do this, we check all $O(1)$ triangles by recursing in the dimension. We assume that t^* is strictly contained within some cell, as the case that it is on the boundary can be detected similarly. Consider a single triangle $\mathcal{X}$. Let $\mathcal{X}^-$ be an infinitesimally smaller copy of $\mathcal{X}$ that is strictly inscribed within $\mathcal{X}$.[6] All $O(1)$ bounding line segments for $\mathcal{X}$ and $\mathcal{X}^-$

[6] Infinitesimal shifts are a standard trick, and all of the algorithms in this paper can handle them without modification as long as they are implemented carefully enough.

are contained within $\mathcal{T}$. Therefore, we can use the input $(\mu, b, \mathcal{T})$-block structure as a block structure for these line segments, and find the optimal translation (along with the area of intersection) restricted to each line segment in time $O(1) \cdot T_{\text{1-MAX}}(N, b, \mu)$. If one of the line segments for $\mathcal{X}^-$ has a translation realizing a larger area than all of the line segments for $\mathcal{X}$, then by Lemma 1 we know that $t^* \in \mathcal{X}$. Otherwise, $\mathcal{X}$ does not contain t^*.[7]

With high probability, the interior of $\mathcal{T}_{x+1}$ will intersect at most half as many lines of $\mathcal{S}$ as $\mathcal{T}_x$. By construction and the fact that b divides b' (and hence $b \leq b'$), we have $|\mathcal{S}| = O(Nb')$. Thus there are at most $O(\log \frac{|\mathcal{S}|}{\mu'}) = O(\log(Nb'/\mu'))$ iterations before we produce a triangle that intersects at most $\mu'/2$ lines of $\mathcal{S}$ with high probability and hence can be taken as $\mathcal{T}'$. The time for all iterations is $O(\log(Nb'/\mu')) \cdot (T_{\text{1-MAX}}(N, b, \mu) + O(N^{0.1+o(1)})) = O(\log(Nb'/\mu')) \cdot T_{\text{1-MAX}}(N, b, \mu) + O(N^{0.1+o(1)})$. ◀

4.2 Putting it all Together

We now present our linear time algorithm. This amounts to solving a curious recurrence, and we actually have significant freedom in choosing the values for b and b'.

▶ **Theorem 8.** *There is an algorithm for Problem 1 running in expected time $O(n + m)$.*

Proof. We will always take $\mu := 20 \cdot N/b^3$ and $\mu' := 20 \cdot N/(b')^3$, so we can drop the μ and μ' arguments from the time complexity of each subroutine/oracle. We begin by reducing from Problem 1 to an instance of MaxRegion over a $(20 \cdot N/2^3, 2, \mathcal{T})$-block structure, which requires no work beyond computing the area prefix sums because we can take $S_{\text{Bad}} = [\lceil N/2 \rceil]$ and $S_{\text{Good}} = \emptyset$. Thus the total expected running time for Problem 1 will be $O(N) + T_{\text{2-MAX}}(N, 2)$.

Before analyzing $T_{\text{2-MAX}}(N, 2)$, we find a closed-form expression for $T_{\text{1-MAX}}(N, b)$ when $2 \leq b \leq N^{o(1)}$. As per Lemmas 5, 6, and 7, we have the following for any $2 \leq b, b' \leq N^{o(1)}$ such that b divides b':

$$T_{\text{1-MAX}}(N, b) = O\left(N \cdot \frac{\log b' \log^2 b}{b}\right) + T_{\text{1-MAX}}(N, b').$$

We can efficiently parallelize the algorithm for zero-dimensional MaxRegion given in the proof of Lemma 5. So via a standard application of multidimensional parametric search (see Theorem 4.4 in the full version of [38]) that uses zero-dimensional MaxRegion for the decision problem, $T_{\text{1-MAX}}(N, b) = O(N/\log N)$ when $b \geq (\log N)^{C_1}$ for some constant C_1. If we take $b' = 2b$ (for example) and solve the recurrence, we get

$$T_{\text{1-MAX}}(N, b) = O\left(\frac{N}{\log N} + \sum_{a=\log b}^{O(\log \log N)} N \cdot \frac{\log^3(2^a)}{2^a}\right) = O\left(N \cdot \frac{\log^3 b}{b} + \frac{N}{\log N}\right).$$

Using the above along with Lemmas 5, 6, and 7, we have the following for any $2 \leq b, b' \leq N^{o(1)}$ such that b divides b':

$$T_{\text{2-MAX}}(N, b) = O\left(N \cdot \frac{\log b' \log^3 b}{b} + N \cdot \frac{\log b'}{\log N}\right) + T_{\text{2-MAX}}(N, b').$$

[7] All invocations might return a maximum area of zero, but we can handle this in $O(1)$ time by checking whether an arbitrary translation that causes P and Q to overlap is located within $\mathcal{X}$.

If we again take $b' = 2b$ and stop to apply multidimensional parametric search when $b' = (\log N)^{C_2}$ for some constant C_2, we have $O(\log\log N)$ recursion depth, and $\log b'$ never exceeds $O(\log\log N)$. Solving the recurrence in the same way as for $T_{1\text{-MAX}}(N, b)$ gives:

$$T_{2\text{-MAX}}(N, b) = O\left(N \cdot \frac{\log^4 b}{b} + N \cdot \frac{\log^2 \log N}{\log N}\right).$$

Clearly $T_2(N, 2) = O(N)$, and the theorem follows. ◀

5 Constructing the Point Oracle

In this section, we prove the Point Oracle Lemma, restated below:

▶ **Lemma 5** (Point Oracle). *For all $2 \le b \le N$, for all μ,*

$$T_{0\text{-MAX}}(N, b, \mu) = O\left(N \cdot \frac{\log^2 b}{b} + \mu b\right).$$

In other words, we need to use a given $(\mu, b, \mathcal{T})$-block structure (where $\mathcal{T}$ is just a single point t^*) to calculate $\text{Area}((P + t^*) \cap Q)$. We can decompose the area function as

$$\text{Area}((P + t^*) \cap Q) = \sum_i \text{Area}((P_i + t^*) \cap Q_i) + \sum_{i \neq j} \text{Area}((P_i + t^*) \cap Q_j)$$

and then solve for each individual summation rapidly. The first summation is quite easy to compute by simply reading through the lists S_{Good} and S_{Bad} that are provided.

▶ **Lemma 9.** *There is an algorithm running in time $O(N/b + \mu b)$ such that, given a $(\mu, b, \mathcal{T})$-block structure, where $2 \le b \le N^{o(1)}$ and $\mathcal{T}$ consists of just a single point t^*, it will compute*

$$\sum_i \text{Area}((P_i + t^*) \cap Q_i),$$

where $P_1, \ldots, P_{\lceil N/b \rceil}$ and $Q_1, \ldots, Q_{\lceil N/b \rceil}$ are the blocks of P and Q determined by parameter b.

Proof. By definition of the block structure, we have a partition of $S = [N/b]$ into two subsets S_{Good} and S_{Bad} such that $|S_{\text{Bad}}| \le \mu$, and for each $i \in S_{\text{Good}}$ we have a constant complexity quadratic function $f_i(t) = \text{Area}((P_i + t) \cap Q_i)$ for all $t \in \mathcal{T}$.

We can thus compute

$$\sum_{i \in S_{\text{Good}}} \text{Area}((P_i + t^*) \cap Q_i)$$

in time $O(N/b)$ by simply evaluating each $f_i(t^*)$. Since $|S_{\text{Bad}}| \le \mu$, we can compute

$$\sum_{i \in S_{\text{Bad}}} \text{Area}((P_i + t^*) \cap Q_i)$$

by evaluating the area for each $(P_i + t^*) \cap Q_i$ directly. The time required is $O(\mu b)$ using known algorithms for intersecting two convex polygons whose edges are in sorted order. ◀

We now turn our attention to the summation $\sum_{i \neq j} \text{Area}((P_i + t^*) \cap Q_j)$. Because every term amounts to computing the intersection for two blocks with *different* angle ranges, we could use binary searches to evaluate each term in $O(\text{polylog}(b))$ time. However, this is too slow for our purposes, as there are a near quadratic number of terms. Instead, we take advantage of additional structure to decompose the summation into $O(N/b)$ intersections of *unions of blocks*, such that each intersection can still be computed via binary search.

As a tool, we need a way to efficiently intersect convex chains that meet certain conditions.

▶ **Lemma 10.** *Let A and B be any two convex polygons, and let X and Y be any two polygonal chains whose edges are a subset of the edges of A and B, respectively. If $\Lambda_A(X) \cap \Lambda_B(Y) = \emptyset$, then X and Y intersect at most twice, and we can find the intersection point(s) in time $O(\log|X| \log|Y|)$.*

Proof. Because the angle ranges for X and Y are disjoint, they act as pseudo-disks, and hence can intersect at most twice. We can find the intersection point(s), if they exist, using a standard nested binary search in $O(\log|X| \log|Y|)$ time (or a more clever binary search [37] in $O(\log|X| + \log|Y|)$ time, though we don't need this improvement). ◀

Now we can show how to compute $\sum_{i \neq j} \text{Area}((P_i + t^*) \cap Q_j)$.

▶ **Lemma 11.** *There is an algorithm running in time $O(N \cdot \frac{\log^2 b}{b})$ such that, given a $(\mu, b, \mathcal{T})$-block structure, where $\mathcal{T}$ consists of just a single point t^*, it will compute*

$$\sum_{i \neq j} \text{Area}((P_i + t^*) \cap Q_j),$$

where $P_1, \ldots, P_{\lceil N/b \rceil}$ and $Q_1, \ldots, Q_{\lceil N/b \rceil}$ are the blocks of P and Q determined by parameter b.

Proof. We give a recursive algorithm for the problem. As a subroutine, we consider the problem of computing, given two integers $x, y \in [N/b]$ with $x > y$,

$$\sum_{(i,j) \in W(x,y)} \text{Area}((P_i + t^*) \cap Q_j), \text{ with } W(x,y) := \{(i,j) \in [N/b] \times [N/b] : i \neq j, x \leq i, j \leq y\}.$$

Let $T(y - x, b)$ be the time complexity of this subroutine. Since the original summation $\sum_{i \neq j} \text{Area}((P_i + t^*) \cap Q_j)$ is equivalent to $\sum_{(i,j) \in W(1, \lceil N/b \rceil)} \text{Area}((P_i + t) \cap Q_j)$, the lemma amounts to showing that $T(\lceil N/b \rceil - 1, b) = O(N \cdot \frac{\log^2 b}{b})$, or more generally, $T(z, b) = O(z \log^2 b)$.

Consider an instance of this subroutine with any parameters $y > x$. Let $m := \lceil \frac{x+y}{2} \rceil$ and $z := y - x$. We can decompose the target summation as follows:

$$\begin{aligned}\sum_{(i,j) \in W(x,y)} \text{Area}((P_i + t^*) \cap Q_j) \;=\; & \\ \sum_{(i,j) \in W(x,m-1)} \text{Area}((P_i + t^*) \cap Q_j) \;+\; & \sum_{(i,j) \in W(m,y)} \text{Area}((P_i + t^*) \cap Q_j) \;+ \\ \sum_{x \leq i < m \leq j \leq y} \text{Area}((P_i + t^*) \cap Q_j) \;+\; & \sum_{x \leq j < m \leq i \leq y} \text{Area}((P_i + t^*) \cap Q_j).\end{aligned}$$

The first two summations can be evaluated in time at most $2T(\lceil \frac{y-x}{2} \rceil, b)$ via recursion (unless $x - y = 1$, in which case they are automatically zero). The last two summations can actually be evaluated directly. We consider the case of the very last summation; the remaining one can be evaluated via a symmetric process. First note that

$$\sum_{x \leq j < m \leq i \leq y} \text{Area}((P_i + t^*) \cap Q_j) \;=\; \text{Area}\left(\left(\bigcup_{m \leq i \leq y} P_i + t^*\right) \cap \left(\bigcup_{x \leq j < m} Q_j\right)\right).$$

Let $A = \bigcup_{x \leq i < m} P_i$ and $B = \bigcup_{m \leq j \leq y} Q_j$. Observe that A and B are both convex polygons, since each is the union of consecutive blocks. By construction, the edges that A shares with P and the edges that B shares with Q form two convex polygonal chains that

have disjoint angle ranges, i.e., $\Lambda_P(E_P(A)) \cap \Lambda_Q(E_Q(B)) = \emptyset$. These chains account for all but two edges of A and two edges of B. Thus we can decompose A and B into $O(1)$ convex polygonal chains satisfying the preconditions of Lemma 10. This implies that A and B intersect in at most a constant number of locations, and furthermore we can find the intersection points in time $O(\log^2(bz))$.

By decomposing A and B into $O(1)$ pieces based on the intersection locations, we can use the area prefix sums[8], along with a direct computation on the $O(1)$ intersecting pairs of edges, to find the area of intersection in $O(1)$ additional time. So the recurrence is $T(z, b) = 2T(\lceil z/2 \rceil, b) + O(\log^2(bz))$ when $z > 1$ and $T(1, b) = O(\log^2 b)$. This solves to $T(z, b) = O(z \log^2 b)$. ◀

6 Constructing the Cascading Subroutine

The last step is to prove the Cascading Subroutine Lemma, restated below:

▶ **Lemma 6** (Cascading Subroutine). *For all $2 \le b, b' \le N$ such that b divides b', for all μ,*

$$T_{\textsc{Cascade}}(N, b, b', \mu) = O\left(N \cdot \frac{\log b' \log b}{b} + \mu b^2\right).$$

In other words, given a $(\mu, b, \mathcal{T})$-block structure, parameters μ' and b', and a triangle or line segment $\mathcal{T}'$, we want to either produce a valid $(\mu', b', \mathcal{T}')$-block structure, or report that more than $\mu'/2$ lines of the set $\mathcal{S}$ intersect $\mathcal{T}'$. Throughout, let $P_1, \ldots, P_{\lceil N/b \rceil}$ and $Q_1, \ldots, Q_{\lceil N/b \rceil}$ be the blocks of P and Q determined by block size parameter b, and let $P'_1, \ldots, P'_{\lceil N/b' \rceil}$ and $Q'_1, \ldots, Q'_{\lceil N/b' \rceil}$ be the blocks of P and Q determined by block size parameter b'.

First, we show that constant-complexity quadratic functions may actually be used to summarize the area function for certain block pairs.

▶ **Lemma 12.** *Let A and B be any convex polygons, and let $\mathcal{T}'$ be any triangle or line segment contained in one cell of $\Pi(A, B)$.*[9] *Then there exists a constant-complexity quadratic function f such that $f(t) = \text{Area}((A + t) \cap B)$ for all $t \in \mathcal{T}'$.*

Proof. This follows from known observations by de Berg et al. [21]. ◀

Before describing how to perform cascading, we need a tool to help classify the new blocks based on their relationship with $\mathcal{T}'$.

▶ **Lemma 13.** *Let A and B be any two convex polygons, and let X and Y be any two polygonal chains whose edges are a subset of the edges of A and B, respectively. Let $\mathcal{T}'$ be any triangle or line segment. If $\Lambda_A(X) \cap \Lambda_B(Y) = \emptyset$, then we can determine if some line segment in $\Pi(X, Y)$ intersects the interior of $\mathcal{T}'$ in time $O(\log |X| \log |Y|)$.*

Proof. Let the set of vertices for $\mathcal{T}'$ be $V(\mathcal{T}')$. For each $t \in V(\mathcal{T}')$, we know that, by Lemma 10, $X + t$ and Y can intersect in at most two points, and we can find the two pairs of edges that contain these intersection(s) in time $O(\log |X| \log |Y|)$.[10] Let the set of all $O(1)$ edge pairs (e_X, e_Y) for all vertices in $V(\mathcal{T}')$ be L. We can determine if $\mathcal{T}' \subseteq \pi(e_X, e_Y)$ for

[8] The area prefix sums for P and Q also act as ares prefix sums for A and B.

[9] It is permissible for $\mathcal{T}'$ to touch the boundary of one cell, as long as it doesn't strictly intersect.

[10] There is an edge case where at least one of the intersections occurs at a vertex of X or a vertex of Y, but this can be handled with slightly more work without increasing the asymptotic running time.

all $(e_X, e_Y) \in L$ via brute force in time $O(1)$. If this is *not* the case, then some line segment of $\Pi(X, Y)$ intersects the interior of $\mathcal{T}'$, and we are done. If this *is* the case, then because $\mathcal{T}'$ is convex and each $\pi(e_X, e_Y)$ is convex, we have that each translation $t \in \mathcal{T}'$ realizes a set of intersecting pairs that is a (possibly strict) superset of L.

It remains to determine if any translations $t \in \mathcal{T}'$ realize an intersecting pair not in L, because this case (and only this case) would mean that a line segment in $\Pi(X, Y)$ intersects the interior of $\mathcal{T}'$. Let X^- be X with its edges participating in L deleted, and let Y^- be Y with its edges participating in L deleted. In time $O(\log|X|\log|Y|)$ we can use techniques similar to the ones given above to determine if the interior of the (implicitly generated) Minkowski sum of $\mathcal{T}'$ and X^- has any intersection with Y, and then if the interior of the (implicitly generated) Minkowski sum of $\mathcal{T}'$ and X has any intersection with Y^-. ◀

We are now ready to prove Lemma 6. The main observation is that the new quadratic functions stored in this data structure only need to apply when $t \in \mathcal{T}'$, not the more general case that $t \in \mathcal{T}$, so many of the previously difficult blocks can now be handled. We will find a quadratic function for almost all indices $k \in [N/b']$ in two steps:

1. Scan through the information provided in the input $(\mu, b, \mathcal{T})$-block structure, and use this to recover part of the function $\text{Area}((P'_k + t) \cap Q'_k)$.
2. Recover the missing information for $\text{Area}((P'_k + t) \cap Q'_k)$ by intersecting $O(\frac{b'}{b})$ pairs of convex polygons with disjoint angle ranges. We evaluate these using nested binary searches (Lemma 10 or 13) and area prefix sums.

Proof. For all $k \in [N/b']$, note that because b divides b', we have a set of indices $C_k = \{(k-1)\cdot\frac{b'}{b}+1, \ldots, k\cdot\frac{b'}{b}\}$ such that $P'_k = \bigcup_{i\in C_k} P_i$ and $Q'_k = \bigcup_{j\in C_k} Q_j$.[11] If for all $(i,j) \in C_k \times C_k$ and for all $t \in \mathcal{T}'$ we can summarize $\text{Area}((P_i+t)\cap Q_j)$ with a constant-complexity quadratic function, then we can simply add these to get a new function $f_k(t) = \text{Area}((P'_k + t) \cap Q'_k)$.

We first argue that each quadratic function $f_k(t)$ can be found efficiently, if it exists. Consider just a single value of k. We use the decomposition

$$f_k(t) = \sum_{(i,j)\in C_k\times C_k} \text{Area}((P_i+t)\cap Q_j) = \sum_{i\in C_k} \text{Area}((P_i+t)\cap Q_i) + \sum_{\substack{(i,j)\in C_k\times C_k:\\ i\neq j}} \text{Area}((P_i+t)\cap Q_j).$$

For the first summation on the right hand side, we scan through the list S_{Good} from the original $(\mu, b, \mathcal{T})$-block structure. Each function $\text{Area}((P_i + t) \cap Q_i)$ with $i \in S_{\text{Good}}$ already has a quadratic function, and reading these takes time $O(\frac{b'}{b})$ for each k, or $O(N/b)$ time for all k. Globally, there are at most μ indices i not in S_{Good}. For each of these, we can check whether $\mathcal{T}'$ lies in a single cell of $\Pi(P_i, Q_i)$ via directly examining each line segment in $\Pi(P_i, Q_i)$ in time $O(b^2)$. If this is the case, then by Lemma 12, $\text{Area}((P_i + t) \cap Q_i)$ can be summarized by a quadratic function for all $t \in \mathcal{T}'$, and we find the function via directly examining each parallelogram in $\Pi(P_i, Q_i)$ in time $O(b^2)$; the total additional time is $O(\mu b^2)$. (If this fails for some $i \in C_k$, we will add the index k to S'_{Bad}.)

Now consider the second summation on the right hand side. We can rewrite this as

$$\sum_{\substack{(i,j)\in C_k\times C_k:\\ i\neq j}} \text{Area}((P_i + t) \cap Q_j) = \sum_{i\in C_k} \left(\text{Area}((P_i + t) \cap Q^-_{i,k}) + \text{Area}((P_i + t) \cap Q^+_{i,k})\right),$$

where $Q^-_{i,k}$ is the union of all Q_j's in the original sum with $j < i$, and $Q^+_{i,k}$ is the union of all Q_j's in the original sum with $j > i$. We evaluate each of the terms individually.

[11] The set may be smaller for the very last value of k, but this does not impact the proof.

Consider the case of $\text{Area}((P_i+t)\cap Q^-_{i,k})$, as the case of $\text{Area}((P_i+t)\cap Q^+_{i,k})$ is symmetric. Now, $Q^-_{i,k}$ is a convex polygon, because it is the union of consecutive blocks. By construction, $\Lambda_P(E_P(P_i)) \cap \Lambda_Q(E_Q(Q^-_{i,k})) = \emptyset$. Therefore, we can break $P_i + t$ and $Q^-_{i,k}$ into $O(1)$ pieces that satisfy the preconditions of Lemma 10, showing that $P_i + t$ and $Q^-_{i,k}$ can only intersect at a constant number of locations for any translation $t \in \mathbb{R}^2$. These same pieces allow us to apply Lemma 13 to determine if $\mathcal{T}'$ lies in a single cell of $\Pi(P_i, Q^-_{i,k})$, which takes time $O(\log|P_i|\log|Q^-_{i,k}|) = O(\log b \log b')$. If this is the case, then by Lemma 12 there exists a quadratic function equal to $\text{Area}((P_i+t)\cap Q^-_{i,k})$ for all $t \in \mathcal{T}'$. The nonconstant components of this quadratic function only depend on the $O(1)$ intersecting pairs of edges, and we have already found these via Lemma 13. Thus we can break P_i and $Q^-_{i,k}$ into $O(1)$ pieces based on the intersection points, and use the area prefix sums from the $(\mu, b, \mathcal{T})$-block structure (which also serve as area prefix sums for P_i and $Q^-_{i,k}$), to find the quadratic function equal to $\text{Area}((P_i + t) \cap Q^-_{i,k})$ in $O(1)$ additional time. (If this fails for some $i \in C_k$, we will add the index k to S'_{Bad}.)

Adding the time across all terms for all $k \in [N/b']$ gives an overall time of $O(N \cdot \frac{\log b \log b'}{b})$.

Each index k for which we found a function $f_k(t)$ is added to S'_{Good}, and we store its function. The remaining indices are added to S'_{Bad}. The last step is to argue that $|S'_{\text{Bad}}| \le \mu'$, meaning we have constructed a valid $(\mu', b', \mathcal{T}')$-block structure.

By construction, note that every $k \in S'_{\text{Bad}}$ corresponds to an intersection between $\bigcup_{(i,j)\in C_k\times C_k} \Pi(P_i, Q_j)$ and the interior of $\mathcal{T}'$. Also by construction (see Equation 2), each line $\overleftrightarrow{\mathcal{L}}$ in $\mathcal{S}$ has at most two indices k such $\overleftrightarrow{\mathcal{L}}$ is the line extension of some line segment in $\bigcup_{(i,j)\in C_k\times C_k} \Pi(P_i, Q_j)$. Therefore we can charge each $k \in S'_{\text{Bad}}$ to different lines of $\mathcal{S}$ in such a way that each line of $\mathcal{S}$ will be charged at most twice. Thus if $|S'_{\text{Bad}}| > \mu'$, this implies that more than $\mu'/2$ lines of $\mathcal{S}$ intersect the interior of $\mathcal{T}'$, so the algorithm can just return failure in this case. ◀

Abstract

In a series of papers, Avraham, Filtser, Kaplan, Katz, and Sharir (SoCG'14), Kaplan, Katz, Saban, and Sharir (ESA'23), and Katz, Saban, and Sharir (ESA'24) studied a class of geometric optimization problems – including reverse shortest path in unweighted and weighted unit-disk graphs, discrete Fréchet distance with one-sided shortcuts, and reverse shortest path in visibility graphs on 1.5-dimensional terrains – for which standard parametric search does not work well due to a lack of efficient parallel algorithms for the corresponding decision problems. The best currently known algorithms for all the above problems run in $O^*(n^{6/5}) = O^*(n^{1.2})$ time (ignoring subpolynomial factors), and they were obtained using a technique called *shrink-and-bifurcate*. We improve the running time to $\tilde{O}(n^{8/7}) \approx O(n^{1.143})$ for these problems. Furthermore, specifically for reverse shortest path in unweighted unit-disk graphs, we improve the running time further to $\tilde{O}(n^{9/8}) = \tilde{O}(n^{1.125})$.

1 Introduction

Parametric search is one of the most well-known and powerful techniques for solving geometric optimization problems [5]. First introduced by Megiddo [26] in the 80s, the technique has since found countless applications in computational geometry and beyond. To search for the optimal value r^* of an optimization problem, we first solve the decision problem: given an input value r, decide whether $r^* \leq r$. The idea is to simulate an algorithm $\mathcal{A}$ for the decision problem[1] with the input value being the unknown r^* itself; whenever $\mathcal{A}$ makes a comparison with the unknown r^*, we resolve the comparison by calling the decision algorithm. Megiddo showed that if $\mathcal{A}$ is parallelizable with polylogarithmic number of rounds, then the simulation can be done efficiently with only a polylogarithmic factor increase in the total running time.

Over the years, a number of refinements and alternatives to parametric search have been proposed (e.g., Cole's trick [14], matrix searching [18, 19], expander-based approaches [24], Chan's randomized optimization technique [8] and implicit linear programming technique [10, 11]), but these alternatives are more specialized and are mainly about lowering the extra polylogarithmic factors in the running time.

[1] The algorithm $\mathcal{A}$ that we are simulating need not solve the decision problem, although it often is the case, so long as the optimal value r^* is one of its "critical values".

In the last couple of years, Avraham, Filtser, Kaplan, Katz, and Sharir [6], Wang and Zhao [29], Kaplan, Katz, Saban, and Sharir [21], Katz, Saban, and Sharir [23], and Agarwal, Kaplan, Katz, and Sharir [3] have identified and explored a natural class of geometric optimization problems (listed below) where parametric search does not do too well. For these problems, efficient near-linear-time decision algorithms exist, but they do not seem efficiently parallelizable (the decision version of these problems are related to single-source shortest paths, but breadth-first search (BFS) and Dijkstra's algorithm are inherently sequential). For many of the problems in this class, the search spaces are actually Euclidean distances defined by pairs of input points, and so parametric search could be replaced by binary search using an oracle for *distance selection*, but unfortunately, known distance selection algorithms requires near $O(n^{4/3})$ time in the plane [1, 24, 28, 13].

To overcome these issues, Avraham *et al.* [6] introduced a new clever variant of the parametric search technique they termed *shrink-and-bifurcate*, which was subsequently adopted by Kaplan *et al.* [21], Katz *et al.* [23], and Agarwal *et al.* [3]. The technique is able to solve most of these problems with an unusual running time between near-linear and $n^{4/3}$: namely, $O^*(n^{6/5})$.[2]

Although Avraham *et al.*'s improvement may seem incremental, this $O^*(n^{6/5})$ bound has remained stagnant (Avraham *et al.*'s paper appeared over 10 years ago), despite more applications and more appearances of this bound in recent papers [21, 23, 3]; the ideal goal of obtaining near-linear time at the moment seems far out of reach. In this work, we want to understand this class of problems better, and to see if this mysterious exponent 6/5 can be improved.

In the following, we state the specific problems considered in this class and review their background.

Reverse shortest path in (unweighted) unit-disk graphs. We start with the simplest of these problems: *reverse shortest path* for unit-disk graphs. For every set of points P in the plane and positive real number r, let $G_r(P)$ denote the graph with vertex set P, where we put an edge between two points iff their Euclidean distance is at most r; equivalently, $G_r(P)$ is the intersection graph of the disks with centers P and radius $r/2$. Note that $G_r(P)$ is a *unit-disk graph* (since we can rescale the radius to 1). In the reverse shortest path problem, one is given a set of points P in the plane, two vertices $s, t \in P$, and a positive integer λ, and is asked to compute the minimum real number r^* such that $G_{r^*}(P)$ contains an s-to-t path with at most λ edges.

This problem is quite natural and can be viewed equivalently as finding the minimum bottleneck path from s to t that uses at most λ links (or "hops"), where minimizing *bottleneck* refers to minimizing the longest edge in the path. (As is well known, computing minimum bottleneck paths without constraints on the number of links reduces to minimum spanning trees; *e.g.*, see [20]. It is reasonable to add restrictions on the number of links.)

The decision version of this problem takes an extra parameter r, and asks one to determine whether $G_r(P)$ contains an s-to-t-path with at most λ edges. The decision problem (or computing the minimum-link s-to-t path in a unit disk graph) can be solved in $O(n \log n)$ time, as shown by Cabello and Jejčič [7] using the Delaunay triangulation, or alternatively by Chan and Skrepetos [12] using a grid-based approach, or even earlier by Efrat, Itai, and Katz [17] (who solved a very similar problem as a subroutine for computing bichromatic maximum matchings). Now, since r^* is always the Euclidean distance between two input

[2] In this paper, we use the O^* and $\tilde{O}$ notation to hide $n^{o(1)}$ and $(\log n)^{O(1)}$ factors respectively.

points, it was immediately noted by Cabello and Jejčič that reverse shortest path can be solved in $\tilde{O}(n^{4/3})$ time by binary search, using an $\tilde{O}(n^{4/3})$-time distance selection algorithm (as we have mentioned earlier) to guide the search.

The first algorithm to beat $n^{4/3}$ for reverse shortest path was discovered by Wang and Zhao [29], using a grid-based approach. Their algorithm runs in $\tilde{O}(n^{5/4})$ time. Subsequently, Kaplan *et al.* [21] presented a different, faster randomized algorithm running in $O^*(n^{6/5})$ time, by applying the aforementioned shrink-and-bifurcate technique.

Reverse shortest path in weighted unit-disk graphs. In a *weighted* unit-disk graph, each edge is weighted by the Euclidean distance between the centers of the two disks. The reverse shortest path problem can be defined in a similar way, except that λ is now a cap on the sum of the weights along the s-to-t path.

Wang and Xue [27] gave an $O(n \log^2 n)$-time algorithm for the decision problem in the weighted case. Wang and Zhao [29] extended their $\tilde{O}(n^{5/4})$-time algorithm for reverse shortest path to weighted unit-disk graphs (with a slightly larger polylogarithmic factor). Kaplan *et al.* [21] similarly extended their $O^*(n^{6/5})$-time randomized algorithm to the weighted case, again via shrink-and-bifurcate.

Reverse shortest path in unweighted and weighted disk graphs. The reverse shortest path problem can be generalized to intersection graphs of disks with arbitrary radii. The input is a set S of disks in the plane, and $G_r(S)$ is defined as the graph with S as vertices, where we put an edge between two disks iff their distance is at most r (this is sometimes referred to as a *proximity graph*); equivalently, $G_r(S)$ is the intersection graph of the disks with the same centers as S but radii increased additively by $r/2$. In the weighted case, each edge is weighted by the Euclidean distance between the centers of the two disks (or alternatively, the Euclidean distance of the centers minus the sum of the two radii).

As shown by Kaplan *et al.* [21], the decision problem can be solved in $\tilde{O}(n)$ time by a careful implementation of BFS (in the unweighted case) or Dijkstra's algorithm (in the weighted case), using known dynamic geometric data structures [22] (which have large hidden polylogarithmic factors).

Wang and Zhao's grid-based approach to reverse shortest path does not extend to arbitrary disk graphs. However, the shrink-and-bifurcate approach is still applicable, and yields an $O^*(n^{5/4})$-time randomized algorithm as shown by Kaplan *et al.* [21].

Reverse shortest path in segment proximity graphs. Another generalization is to the case of line segments. Given a set S of *disjoint* line segments in the plane, define the segment proximity graph $G_r(S)$ to be the graph with S as vertices, where we put an edge between two segments iff their distance is at most r. The reverse shortest path problem for (unweighted) line segments can then be defined in the same way.

This problem was first considered by Agarwal *et al.* [4], who gave a randomized $O^*(n^{4/3})$-time algorithm. Later, Agarwal *et al.* [3] solved the corresponding decision problem in $O(n \log^2 n)$-time. They then applied the shrink-and-bifurcate technique to obtain an improved randomized algorithm for the optimization problem running in $O^*(n^{6/5})$ time, assuming that the spread (the maximum-to-minimum distance ratio) is polynomially bounded.

Discrete Fréchet distance with one-sided shortcuts. The *discrete Fréchet distance* is a popular measure of closeness between two polygonal chains. Given polygonal chains $P = \langle p_1, \ldots, p_{|P|} \rangle$ and $Q = \langle q_1, \ldots, q_{|Q|} \rangle$ with $|P| + |Q| = n$, consider two frogs, a P-frog

and a Q-frog, starting at points p_1 and q_1 respectively. In each move, one frog leap from its current vertex to the next vertex on their respective polygonal chain, while the other frog stays at its current vertex. The discrete Fréchet distance between P and Q is defined as the minimum distance r^* for which the two frogs can arrive at $p_{|P|}$ and $q_{|Q|}$, such that the Euclidean distance between the two frogs is always at most r^* before and after every leap.

The discrete Fréchet distance with *one-sided shortcuts* is defined similarly, except that we allow one frog, say the P-frog, to leap to any vertex ahead during each move. In other words, the one-sided discrete Fréchet distance between P and Q is the minimum discrete Fréchet distance between P' and Q, over all subsequences P' of P that start at p_1 and end at $p_{|P|}$. The problem of computing the discrete Fréchet distance with one-sided shortcuts is what first prompted Avraham *et al.* [6] to introduce their shrink-and-bifurcate technique. They noted a linear-time algorithm for the decision problem and obtained an $O^*(n^{6/5})$-time randomized algorithm for the optimization problem.

Reverse shortest path in visibility graphs over 1.5-dimensional terrains. A *terrain* T in 1.5 dimensions refers to an x-monotone polygonal chain in the plane. Two points p, q on or above the terrain are said to *see* each other if the line segment $\overline{pq}$ does not intersect T. Given a 1.5-dimensional terrain T and a set of points P on or above T with $|P| + |T| = n$, the visibility graph $G(P, T)$ is a graph with vertices P and edges indicating which pairs of points see each other.

In the reverse shortest path problem over a terrain T, we are given a set P of points on T, and we want to erect a tower at each point in P. In particular, given a terrain T, a set of points P on T, a pair of points $s, t \in P$, and a positive integer λ, we are asked to find the minimum real number h^* such that the visibility graph $G(P(h^*), T)$ contains an s-t path with at most λ edges, where $P(h^*)$ is the tips of the towers of height h^* erected at the points of P.

This problem was first introduced by Agarwal *et al.* [4], who gave a randomized $O^*(n^{4/3})$-time algorithm. Katz *et al.* [23] solved the decision problem in $\tilde{O}(n)$ time by a careful implementation of BFS on the visibility graph, with clever uses of range searching data structures. Katz *et al.* then applied the shrink-and-bifurcate technique to obtain a randomized $O^*(n^{6/5})$-time algorithm for the optimization problem.

1.1 The Shrink-and-Bifurcate Technique

As noted, the current fastest algorithms for all of the above problems are obtained via the shrink-and-bifurcate technique introduced by Avraham *et al.* [6]. The setting requires that critical values (values that the decision algorithm may compare the input value against) are distances defined by pairs of input objects for some distance function. The strategy consists of two stages, *interval shrinking* and *bifurcation*.

1. The interval shrinking stage is a relaxed version of binary search – instead of insisting on finding the answer r^* immediately, we seek an interval $(r^-, r^+]$ that contains r^* and that contains at most L critical values for a given parameter L. In the case of Euclidean distances of points in the plane, Avraham *et al.* showed that this stage can be done in $O^*(n^{4/3}/L^{1/3} + D(n))$ time (using randomization), where $D(n)$ is the running time of the decision algorithm. This is potentially better than the $\tilde{O}(n^{4/3})$ time bound for distance selection.

2. The bifurcation stage then uses this interval $(r^-, r^+]$ to simulate the decision algorithm at the unknown r^* more efficiently than standard parametric search when the decision algorithm is not parallelizable. Avraham et al. showed that this simulation can be done in $\tilde{O}(L^{1/2}D(n))$ time.

When $D(n) = \tilde{O}(n)$, choosing $L = n^{2/5}$ to balance the costs of the two stages gives an overall running time of $O^*(n^{6/5})$.

Some of the applications use distance functions other than Euclidean distances of points in the plane, but the $O^*(n^{4/3}/L^{1/3} + D(n))$ bound for interval shrinking is still applicable. An exception is the reverse shortest path problem for general disk graphs. Here, the corresponding distance selection problem requires $O^*(n^{3/2})$ time, and the interval shrinking subproblem is solved in $O^*(n^{3/2}/L^{1/2} + D(n))$ time instead. When $D(n) = \tilde{O}(n)$, choosing $L = n^{1/2}$ to balance the costs of the two stages gives an overall running time of $O^*(n^{5/4})$ instead.

1.2 New Results

The new contributions in this paper are twofold:

1. We improve all the previous $O^*(n^{6/5})$ time bounds – for reverse shortest path in unit-disk graphs, weighted unit-disk graphs, segment proximity graphs, visibility graphs over 1.5-dimensional terrains, and discrete Fréchet distance with one-sided shortcuts – to $\tilde{O}(n^{8/7})$. (In particular, for discrete Fréchet distance with one-sided shortcuts, this is the first improvement on the exponent in 10 years.)

   For reverse shortest path in arbitrary disk graphs (unweighted or weighted), we improve the previous $O^*(n^{5/4})$ time bound to $O^*(n^{6/5})$.

   Although the improvements are incremental, they are all obtained from one simple idea for improving interval shrinking (we keep the bifurcation part unchanged) – the simplicity and generality of our idea make it easy to apply to existing (and potentially future) applications of the shrink-and-bifurcate approach, and are the main takeaways of the paper. More precisely, we show how to lower the $O^*(n^{4/3}/L^{1/3} + D(n))$ time bound for interval shrinking subproblem to $\tilde{O}(n^{4/3}/L^{2/3} + D(n))$ (or in the arbitrary disk graph case, lower $O^*(n^{3/2}/L^{1/2} + D(n))$ to $O^*(n^{3/2}/L^{3/4} + D(n))$). The original interval shrinking method by Avraham *et al.* needs to modify range searching techniques for distance selection, constructing "partial biclique covers" and then applying random sampling. Our new method, in contrast, can be described in just a few lines, and simply uses a known distance selection algorithm *as a black box* on random subsets (see Section 2).

2. Next, we focus more closely on the simplest of this class of problems, namely, reverse shortest path in (unweighted) unit-disk graphs. For this specific problem, we are able to further improve the running time to $\tilde{O}(n^{9/8})$. The improvement of the exponent from $6/5 = 1.2$ to $9/8 = 1.125$ is a bigger increment (for example, comparable in magnitude to Wang and Zhao's original improvement [29] from $4/3 \approx 1.333$ to $5/4 = 1.25$, or Kaplan *et al.*'s improvement [21] from $5/4 = 1.25$ to $6/5 = 1.2$).

   Interestingly, we obtain our result by combining the shrink-and-bifurcate technique with Wang and Zhao's original grid-based approach! Although it may be natural to consider combining the two approaches, how to do so is not obvious at all. We need to put together several nontrivial technical ideas – this is the most intricate part of the paper (see Section 3).

2 Interval Shrinking

In this section, we formally define the *interval shrinking* subproblem in an abstract, self-contained setting, and then describe our new randomized method for this subproblem.

▶ **Subproblem 1** (Interval shrinking). *Suppose we have an unknown value r^*. Suppose there is a* decision oracle *that can decide whether $r^* \le r$ for an input value r in $D(n)$ time where $D(n) \ge n$.*

Let $\delta(\cdot,\cdot)$ be a function over pairs of objects. Suppose there is a selection oracle *that, given two sets P and Q of objects and a number k, can compute the k-th smallest value in $\delta(P,Q) := \{\delta(p,q) \mid (p,q) \in P \times Q\}$ in $K(|P|,|Q|) = \tilde{O}(|P|^\alpha |Q|^\alpha + |P| + |Q|)$ time for some constant $\alpha < 1$.*

Given two sets P and Q of objects with $|P|+|Q| = n$ and a number L, we want to compute an interval $(r^-, r^+]$ that contains r^* and that contains at most $\tilde{O}(L)$ values in $\delta(P,Q)$.

If δ is the Euclidean distance function for points in the plane (which is the case for the applications to reverse shortest path in unit-disk graphs or discrete Fréchet distance with one-sided shortcuts), known distance selection algorithms [1, 24, 28, 13] between an m-point set and an n-point set run in $K(m,n) = \tilde{O}(m^{2/3}n^{2/3} + m + n)$ time, and thus we have $\alpha = 2/3$. In this planar Euclidean case, Avraham *et al.* [6] solved the above interval shrinking problem in $O^*(n^{4/3}/L^{1/3} + D(n))$ time with high probability. We will describe an improved method.

It suffices to describe how to find an $r^+ > r^*$ such that $[r^*, r^+]$ contains at most $\tilde{O}(L)$ values in $\delta(P,Q)$, since finding r^- is analogous. Also, it suffices to design an algorithm which is correct with probability $\Omega(1)$, since we can get an algorithm which is correct w.h.p.[3] by repeating for logarithmically many trials and returning the minimum r^+ found.

2.1 First Version

Our first interval shrinking algorithm is simple, as presented in Algorithm 1.

Algorithm 1 Basic interval shrinking.

1. Take random subsets $\widehat{P} \subseteq P$ and $\widehat{Q} \subseteq Q$ where each element is chosen independently with probability $\frac{1}{\sqrt{L}}$
2. **return** the successor r^+ of r^* in $\delta(\widehat{P},Q) \cup \delta(P,\widehat{Q})$, which can be computed by binary searches in $\delta(\widehat{P},Q)$ and $\delta(P,\widehat{Q})$ using the selection and decision oracles

Correctness. Let $E \subseteq P \times Q$ be the set of L pairs that have the L smallest $\delta(\cdot,\cdot)$ values after r^*. Think of E as a bipartite graph between P and Q. Then E has at least $\sqrt{L}$ non-isolated vertices in P or at least $\sqrt{L}$ non-isolated vertices in Q (because otherwise, E would have fewer than L edges). W.l.o.g., assume the former. Then $\widehat{P} \times Q$ hits E with probability at least $1 - (1 - \frac{1}{\sqrt{L}})^{\sqrt{L}} = \Omega(1)$. This implies that there are at most L values in $\delta(\widehat{P},Q)$ between r^* and r^+ with probability $\Omega(1)$.

[3] With high probability, i.e., probability $1 - O(1/n^c)$ for an arbitrarily large constant c.

Running time. Note that $|\widehat{P}|, |\widehat{Q}| = \tilde{O}(\frac{n}{\sqrt{L}})$ w.h.p. Using the selection and decision oracles, w.h.p., the binary searches can be done in time

$$\tilde{O}\left(\left(\frac{n}{\sqrt{L}}\right)^{\alpha} n^{\alpha} + n^{\alpha}\left(\frac{n}{\sqrt{L}}\right)^{\alpha} + D(n)\right) = \tilde{O}(n^{2\alpha}/L^{\alpha/2} + D(n)).$$

For planar Euclidean distances with $\alpha = 2/3$, we have thus recovered the $O^*(n^{4/3}/L^{1/3} + D(n))$ result of Avraham *et al.* [6]. However, our algorithm is arguably simpler, because, unlike Avraham *et al.*, we invoke distance selection as a black box, without needing to modify the internal mechanisms of distance selection.

We remark that the idea of randomly sampling *pairs* of input objects is more common and has been used before in the context of slope selection or distance selection [25, 16, 9] (and in Avraham *et al.*'s previous method [6]). But here we are sampling the input objects themselves (which in some sense is even simpler, though the analysis is slightly trickier).

2.2 Improved Version

Upon closer examination, one may notice that the basic algorithm has room for improvement. In particular, if E has $\Theta(\sqrt{L})$ non-isolated vertices in P and $\Theta(\sqrt{L})$ non-isolated vertices in Q, then clearly our samples $\widehat{P} \times Q$ and $P \times \widehat{Q}$ are wasteful. Indeed, we can eliminate such redundancy by sampling in P and Q simultaneously with different rates. We present the details in Algorithm 2.

Algorithm 2 Improved interval shrinking.

for $i = 1, \ldots, \log n$ **do**
  Take a random subset $\widehat{P}_i \subseteq P$ where each element is chosen independently with probability $\frac{1}{\lceil L/2^i \rceil}$
  Take a random subset $\widehat{Q}_i \subseteq Q$ where each element is chosen independently with probability $\frac{1}{2^i}$
end
return the successor r^+ of r^* in $\bigcup_{i=1}^{\log n} \delta(\widehat{P}_i, \widehat{Q}_i)$, which can be computed by binary search in each $\delta(\widehat{P}_i, \widehat{Q}_i)$ using the selection and decision oracles

Correctness. Let $E \subseteq P \times Q$ be the set of $L \log n$ pairs that have the $L \log n$ smallest $\delta(\cdot, \cdot)$ values after r^*. Consider the bipartite graph $H = (P \sqcup Q, E)$. Let $M_i \subseteq P$ be the vertices with degree in the range $[2^{i-1}, 2^i)$ in H. Since $\sum_{i=1}^{\log n} 2^i |M_i| \geq L \log n$, there must exist an index i_0 for which $|M_{i_0}| \geq \lceil L/2^{i_0} \rceil$. Observe that $\widehat{P}_{i_0} \times \widehat{Q}_{i_0}$ hits E if

(i) $\widehat{P}_{i_0}$ hits M_{i_0}, and

(ii) for some $p \in \widehat{P}_{i_0} \cap M_{i_0}$, $\widehat{Q}_{i_0}$ hits the neighborhood of p in E.

Now, (i) holds with probability at least $1 - (1 - \frac{1}{\lceil L/2^{i_0} \rceil})^{\lceil L/2^{i_0} \rceil} = \Omega(1)$. For a fixed $p \in \widehat{P}_{i_0} \cap M_{i_0}$, the probability that $\widehat{Q}_{i_0}$ contains at least one neighbor of p is at least $1 - (1 - \frac{1}{2^{i_0}})^{2^{i_0 - 1}} = \Omega(1)$. Thus, conditioned on (i), the probability of (ii) is $\Omega(1)$. Hence, $\widehat{P}_{i_0} \times \widehat{Q}_{i_0}$ hits E with probability $\Omega(1)$. This implies that there are at most $L \log n$ values in $\delta(P, Q)$ between r^* and r^+ with probability $\Omega(1)$.

Running time. Note that $|\widehat{P}_i| = \tilde{O}(\frac{n}{\lceil L/2^i \rceil})$ and $|\widehat{Q}_i| = \tilde{O}(\frac{n}{2^i})$ w.h.p. Using the selection and decision oracles, w.h.p. the binary searches can be done in time

$$\tilde{O}\left(\sum_{i=1}^{\log n}\left(\left(\frac{n}{\lceil L/2^i \rceil}\right)^{\alpha}\left(\frac{n}{2^i}\right)^{\alpha} + D(n)\right)\right) = \tilde{O}(n^{2\alpha}/L^{\alpha} + D(n)).$$

▶ **Theorem 2.** *Subproblem 1 (interval shrinking) can be solved in $\tilde{O}(n^{2\alpha}/L^{\alpha} + D(n))$ time w.h.p.*

For example, for planar Euclidean distances, the bound is $\tilde{O}(n^{4/3}/L^{2/3} + D(n))$, which is noticeably better than $\tilde{O}(n^{4/3}/L^{1/3} + D(n))$.

2.3 Combining with Bifurcation

After interval shrinking, Avraham *et al.* [6] devised a clever variant of parametric search via an idea called *bifurcation* (also redescribed in more generality in Kaplan *et al.*'s subsequent paper [21]) which accomplishes the following:

▶ **Lemma 3** (Bifurcation [6])**.** *Suppose we have an unknown value r^*. Suppose there is a* decision oracle *that can decide whether $r^* \le r$ for an input value r in $D(n)$ time.*

Suppose we have an algorithm $\mathcal{A}$ that has one input parameter and runs in no more than $O(D(n))$ time, and during the execution of the algorithm, it can only access its input parameter via binary comparisons. The values that $\mathcal{A}$ can compare its input parameter with are called the critical values*.*

Lastly, suppose that we are also given an interval $(r^-, r^+]$ that is guaranteed to contain r^* and that contains at most $\tilde{O}(L)$ critical values.

Then we can simulate $\mathcal{A}$ on input r^* in $\tilde{O}(L^{1/2}D(n))$ time.

Typically, in applications of the technique, the algorithm $\mathcal{A}$ we want to simulate is the decision algorithm itself; here, the simulation produces an interval containing r^* such that all input values lying in the interval have the same computation path and thus the same answer as r^* (namely, "yes"), and so the left endpoint of this interval gives us precisely the value of r^*.

We will not redescribe the proof of the above lemma, as we will only use it as a black box. (The rough idea in bifurcation is to simulate multiple branches of $\mathcal{A}$ at the same time, until we have accumulated sufficiently many comparisons and will then resolve all of them as a batch using the decision oracle; comparisons with values outside the interval $(r^-, r^+]$ are free.) Combining our improved interval shrinking method with bifurcation, we immediately obtain better results for all optimization problems stated in the introduction:

▶ **Theorem 4.**

(a) *The reverse shortest path problem in unweighted and weighted unit-disk graphs, segment proximity graphs (assuming polynomial spread), and visibility graphs over 1.5-dimensional terrains, and the discrete Fréchet distance problem with one-sided shortcuts, as defined in the introduction, can all be solved in $\tilde{O}(n^{8/7})$ time w.h.p. by (Las Vegas) randomized algorithms.*

(b) *The reverse shortest path problem in unweighted and weighted disk graphs can be solved in $O^*(n^{6/5})$ time w.h.p. by (Las Vegas) randomized algorithms.*

Proof. As mentioned in the introduction, all these problems have known decision algorithms running in $D(n) = \tilde{O}(n)$ time [6, 21, 23, 3]. In all these decision algorithms, critical values are indeed obtained from some function δ over pairs of input objects.

For all the applications in (a), the function δ satisfies $\alpha = 2/3$. (Some care is needed for reverse shortest path in visibility graphs in 1.5-dimensional terrains; see the full version.)

Combining Theorem 2 with Lemma 3, we get total running time

$$\tilde{O}\left(\frac{n^{4/3}}{L^{1/3}} + L^{1/2}n\right).$$

Choosing $L = n^{2/7}$ yields $\tilde{O}(n^{8/7})$.

For the applications in (b), we have $\alpha = 3/4 + o(1)$ [21]. The total running time becomes

$$O^*\left(\frac{n^{3/2}}{L^{3/4}} + L^{1/2}n\right).$$

Choosing $L = n^{2/5}$ yields $O^*(n^{6/5})$. ◀

3 Reverse Shortest Path in Unweighted Unit-Disk Graphs

For reverse shortest path in unweighted unit-disk graphs, we show how to improve the running time even further.

In this section, $\delta(p, q)$ denotes the Euclidean distance between points p and q, and $\delta(P, Q) := \{\delta(p, q) \mid (p, q) \in P \times Q\}$ for two point sets P and Q. Let $d_G(s, t)$ denote the shortest-path distance between s and t in a graph G.

We are given an input set P of n points in the plane, $s, t \in P$, and a number λ. Let $G_r(P)$ be the (unweighted) graph with vertex set P, where we put an edge between p and q iff $\delta(p, q) \leq r$. We want to compute the smallest r^* for which $d_{r^*}(s, t) \leq \lambda$, where we use $d_r(s, t)$ as a shorthand for $d_{G_r(P)}(s, t)$.

3.1 Recap of Chan and Skrepetos' Decision Algorithm

Our algorithms rely on the details of the known $\tilde{O}(n)$-time decision algorithm by Chan and Skrepetos [12], so we will first give a quick recap of their algorithm.

Given an input value r, we want to compute $d_r(s, t)$. We first create a uniform grid Ψ_r of side length $r/\sqrt{2}$. Chan and Skrepetos' algorithm is a careful implementation of BFS using the grid. We start from s and generate each level of the BFS tree (the "frontier") one at a time. The key observation is that each grid cell only needs to be visited a constant number of times during the BFS, because (i) points in the same cell have the roughly same shortest-path distance ± 1 from s in $G_r(P)$ and so each cell "appears" in only $O(1)$ levels of the BFS tree, and (ii) each cell has only $O(1)$ neighboring cells – we say that two cells are *neighboring* if the minimum Euclidean distance between the two cells is at most r. Given one level of the BFS tree, we can generate the next level (i.e., "expand" the frontier) by solving the following subproblems between cells in the current level and their neighboring cells:

▶ **Subproblem 5.** *Given an input value r, a subset of n_r red points in one grid cell σ and a subset of n_b blue points in a neighboring grid cell σ', determine for each blue point whether there is a red point at distance at most r from it.*

Chan and Skrepetos solved the above subproblem in $O(n_r + n_b)$ time, assuming that the input points are pre-sorted, by using envelopes of pseudo-lines. As a result, the total running time of their algorithm is linear after pre-sorting.

The above algorithm is not efficiently parallelizable (since the number of levels in the BFS may be large). Instead, we can apply the bifurcation technique to simulate the algorithm on r^*. However, one issue arises: the envelope computations requires critical values defined

by triples of input elements, not pairs. As noted in other papers [21, 29], this can be fixed by switching to a different solution to Subproblem 5 which is slightly slower by a logarithmic factor but is simpler: namely, we compute the nearest red neighbor to each blue point by point location in the Voronoi diagram of the red points in $O((n_r + n_b)\log(n_r + n_b))$ time [15]; then for each blue point, we just compare r with its nearest neighbor distance. This way, the critical values are all Euclidean distances of pairs of input points.

Another issue is the construction of the grid Ψ_r, i.e., the assignment of input points to grid cells in Ψ_r. This part is easily parallelizable, and so we can apply standard parametric search to construct the grid Ψ_{r^*} in $\tilde{O}(n)$ time, all done as preprocessing. (In fact, the time bound for constructing Ψ_{r^*} is $O(n \log n)$, as shown by Wang and Zhao [29].)

3.2 Heavy vs. Light Cells

Applying the shrink-and-bifurcate technique to the preceding decision algorithm using our improved interval shrinking method yields an overall time bound of $\tilde{O}(n^{8/7})$, as we have already shown in Theorem 4(a). To obtain our best result, we will combine with another idea that was used in Wang and Zhao's original paper [29]: heavy vs. light cells.

Recall that we have already constructed the grid Ψ_{r^*}. Let Δ be a parameter to be chosen later. Call a grid cell σ *heavy* if $|P \cap \sigma| \geq \Delta$, or *light* otherwise. The number of heavy cells is clearly at most $O(n/\Delta)$. Furthermore, a pair of neighboring cells (σ, σ') is called a *light pair* if one of σ and σ' is a light cell (the other may be light or heavy).

Our new strategy is as follows. First, we perform interval shrinking, but only with respect to distances of points from light pairs. Intuitively, there are fewer such distances and so interval shrinking should be doable faster. This allows us to simulate Chan and Skrepetos' algorithm at r^* on a modified graph where heavy cells are eliminated – or more precisely, points in a common heavy cell are contracted into a single vertex. When we "uncontract" the heavy cells, this causes an $O(n/\Delta)$ additive error to all the shortest-path distances in $G_{r^*}(P)$. As a final step, we show how to use a dynamic program to recover the value r^*. In the next three subsections, we provide the details of all these steps.

3.3 Faster Interval Shrinking for Light Pairs

In the following, we show how to solve the interval shrinking problem faster for distances from light pairs. More precisely, define $\delta_{\text{light}}(p, q) = \delta(p, q)$ if $p \in \sigma$ and $q \in \sigma'$ for some light pair (σ, σ'), and $\delta_{\text{light}}(p, q) = \infty$ otherwise. We apply Algorithm 2 to do interval shrinking with respect to δ_{light}.

To analyze the running time, we need an efficient implementation of the selection oracle for

$$\delta_{\text{light}}(\widehat{P}_i, \widehat{Q}_i) \;=\; \bigcup_{\text{light pair } (\sigma,\sigma')} \delta(\widehat{P}_i \cap \sigma, \widehat{Q}_i \cap \sigma') \;\cup\; \{\infty\}.$$

Let $n_\sigma := |P \cap \sigma|$ for each cell σ. Note that $|\widehat{P}_i \cap \sigma| = \tilde{O}(\frac{n_\sigma}{\lceil L/2^i \rceil})$ and $|\widehat{Q}_i \cap \sigma'| = \tilde{O}(\frac{n_{\sigma'}}{2^i})$ for every (σ, σ') w.h.p. We already have a selection oracle for each $\delta(\widehat{P}_i \cap \sigma, \widehat{Q}_i \cap \sigma')$ that w.h.p. runs in time

$$\tilde{O}\left(\left(\frac{n_\sigma}{\lceil L/2^i \rceil}\right)^{2/3}\left(\frac{n_{\sigma'}}{2^i}\right)^{2/3} + n_\sigma + n_{\sigma'}\right) \;=\; \tilde{O}\left(\frac{n_\sigma^{2/3} n_{\sigma'}^{2/3}}{L^{2/3}} + n_\sigma + n_{\sigma'}\right).$$

To obtain a selection oracle for $\delta_{\text{light}}(\widehat{P}_i, \widehat{Q}_i)$, we face a problem analogous to selection in a union of multiple sorted arrays, except that the arrays are implicitly given. Frederickson and Johnson [18] gave an algorithm for selection in k sorted arrays of size n running in $O(k \log n)$ time; the algorithm proceeds in $O(\log n)$ rounds, and in each round, it looks up only $O(1)$ elements in each array. In our scenario, each array lookup corresponds to a call to the selection oracle for $\delta(\widehat{P}_i \cap \sigma, \widehat{Q}_i \cap \sigma')$ for a light pair (σ, σ'). Thus, by Frederickson and Johnson's algorithm, selection in the union $\delta_{\text{light}}(\widehat{P}_i, \widehat{Q}_i)$ can be done in total time

$$\tilde{O}\left(\sum_{\text{light pair } (\sigma,\sigma')} \left(\frac{n_\sigma^{2/3} n_{\sigma'}^{2/3}}{L^{2/3}} + n_\sigma + n_{\sigma'}\right)\right)$$
$$\leq \tilde{O}\left(\sum_{\text{light pair } (\sigma,\sigma')} \frac{\Delta^{1/3}(n_\sigma + n_{\sigma'})}{L^{2/3}} + n_\sigma + n_{\sigma'}\right) = \tilde{O}\left(\frac{\Delta^{1/3} n}{L^{2/3}} + n\right),$$

since $\min\{n_\sigma, n_{\sigma'}\} \leq \Delta$ for each light pair (σ, σ'), and $\sum_{\text{neighboring pair } (\sigma,\sigma')}(n_\sigma + n_{\sigma'}) = O(n)$. Therefore, the total time for interval shrinking with respect to δ_{light} is $\tilde{O}(\Delta^{1/3} n / L^{2/3} + D(n))$ w.h.p.

3.4 Computing Distances with $O(n/\Delta)$ Additive Error

Let H_r be the graph obtained from $G_r(P)$ by contracting the points inside each heavy cell of Ψ_r into a single vertex. Since there are $O(n/\Delta)$ contracted vertices in H_r, we have $d_r(s,p) - k \leq d_{H_r}(s,p) \leq d_r(s,p)$ with $k = O(n/\Delta)$, for every $p \in P$.

It is straightforward to modify Chan and Skrepetos' decision algorithm to do BFS on this modified graph H_r. Expanding the frontier again reduces to solving Subproblem 5 for pairs of neighboring cells. Note that for two neighboring cells that are both heavy, we can determine whether there is an edge between them by pre-computing the bichromatic closest pair between the points in the neighboring cells (via Voronoi diagrams) and testing r against this closest pair distance – call this a *special* distance. This pre-computation takes $O(n \log n)$ total time.

After performing interval shrinking as described in previous subsection, we apply the bifurcation technique (Lemma 3) to simulate BFS on H_{r^*}. The critical values indeed are all Euclidean distances from light pairs only, except for the $O(n)$ special distances above, but initially before the simulation starts, we can resolve the comparisons with all $O(n)$ special distances by binary search using $O(\log n)$ calls to the decision algorithm in $\tilde{O}(n)$ time.

At the end of the simulation, we will then have computed $d_{H_{r^*}}(s,p)$ for all $p \in P$, which yield estimates to $d_{r^*}(s,p)$ with additive error $O(n/\Delta)$. To summarize:

▶ **Lemma 6.** *In time $\tilde{O}(\Delta^{1/3} n / L^{2/3} + L^{1/2} n)$, one can compute for every $p \in P$ an estimate $\tilde{d}_p$ with $d_{r^*}(s,p) - k \leq \tilde{d}_p \leq d_{r^*}(s,p)$, where $k = O(n/\Delta)$.*

3.5 Recovering r^*

Finally, we will compute r^* using the estimates obtained in Lemma 6. This final step is done via a dynamic program, and does not require any knowledge of the details of the earlier steps.

▶ **Lemma 7.** *Given a number k and estimates $\tilde{d}_p$ with $d_{r^*}(s,p) - k \leq \tilde{d}_p \leq d_{r^*}(s,p)$ for all $p \in P$, one can compute r^* in $\tilde{O}(kn)$ time.*

To prove Lemma 7, it is helpful to view the problem as computing a *minimum bottleneck path* from s to t with at most λ links (as mentioned in the introduction), i.e., a path from s to t with at most λ links that minimizes the maximum Euclidean length of the edges along the path.

There is a straightforward dynamic programming solution to this problem: Let $D_i(p)$ denote the minimum bottleneck value over all paths from s to p with i links. We want $r^* = \min_{i \le \lambda} D_i(t)$. We have the following recursive formula: for each $p \in P$,

$$D_i(p) = \min_{q \in P} \max\{D_{i-1}(q), \delta(p,q)\}, \tag{1}$$

with $D_0(s) = 0$ and $D_0(p) = \infty$ for all $p \in P - \{s\}$ as base cases. Unfortunately, in this dynamic program, the number of table entries is $O(n\lambda)$, which is $O(n^2)$ in the worst case.

We use the given estimates $\tilde{d}_p$ to speed up the dynamic program. The main observation is that it suffices to generate $D_i(p)$ when $i - k \le \tilde{d}_p \le i$. The number of such table entries is thus reduced to $O(kn)$.

More precisely, define a subset $P_i = \{p \in P : i - k \le \tilde{d}_p \le i\}$ for each i. Since a point belongs to $O(k)$ of these subsets, $\sum_i |P_i| = O(kn)$. For each $p \in P_i$, define

$$\widehat{D}_i(p) = \min_{q \in P_{i-1}} \max\{\widehat{D}_{i-1}(q), \delta(p,q)\}, \tag{2}$$

with $\widehat{D}_0(s) = 0$. (All unspecified $\widehat{D}_i(p)$ values are implicitly set to ∞.)

We claim that $r^* = \min_{i \le \lambda} \widehat{D}_i(t)$.

Correctness. It is obvious that $\widehat{D}_i(p) \ge D_i(p)$ for all p and i. Thus, $\min_{i \le \lambda} \widehat{D}_i(t) \ge \min_{i \le \lambda} D_i(t) = r^*$.

For the reverse direction, take a shortest path $\langle u_0, u_1, \ldots, u_i \rangle$ from s to t in $G_{r^*}(P)$, with $u_0 = s$, $u_i = t$, and $i \le \lambda$. Note that $d_{r^*}(s, u_j) = j$ for every $j = 0, \ldots, i$. So, $j - k \le \tilde{d}_{u_j} \le j$, i.e., $u_j \in P_j$ for every $j = 0, \ldots, i$. It follow from (2) that $\widehat{D}_0(u_0) = 0$, $\widehat{D}_1(u_1) \le r^*$, $\widehat{D}_2(u_2) \le r^*$, $\ldots$, $\widehat{D}_i(u_i) \le r^*$ (since $\delta(u_0, u_1), \ldots, \delta(u_{i-1}, u_i) \le r^*$). Thus, $\min_{i \le \lambda} \widehat{D}_i(t) \le r^*$.

Running time. For an efficient implementation of the dynamic program, we need a data structure for the following variant of nearest neighbor queries:

▶ **Lemma 8.** *Given a set Q of n points in the plane where each point q has a weight w_q, we can preprocess Q in $O(n \log^2 n)$ time so that given any query point p, we can find $q \in Q$ minimizing $\max\{\delta(p,q), w_q\}$ in $O(\log^2 n)$ time, where $\delta(\cdot,\cdot)$ denotes Euclidean distance.*

Proof. We apply standard multi-level geometric data structuring techniques [2]: Order Q by increasing weights. Split Q into the left half Q_L and the right half Q_R. Store a point location structure for the Voronoi diagram of Q_L [15]. Recursively build data structures for Q_L and for Q_R. The preprocessing time satisfies the recurrence $P(n) = 2P(n/2) + O(n \log n)$.

Given a query point p, we first find its nearest neighbor q_L in Q_L in $O(\log n)$ time.

- Case 1: $\delta(p, q_L) \le w_{q_L}$. Then $\min_{q \in Q_R} \max\{\delta(p,q), w_q\} \ge w_{q_L} = \max\{\delta(p, q_L), w_{q_L}\}$, and so it suffices to recurse in Q_L.
- Case 2: $\delta(p, q_L) > w_{q_L}$. Then $\min_{q \in Q_L} \max\{\delta(p,q), w_q\} = \delta(p, q_L)$, and so it suffices to recurse in Q_R.

The query time satisfies the recurrence $Q(n) = Q(n/2) + O(\log n)$, and thus we have $Q(n) = O(\log^2 n)$. ◀

Having computed $\widehat{D}_{i-1}(\cdot)$, we can evaluate $\widehat{D}_i(\cdot)$ according to (2) by preprocessing P_{i-1} in the data structure from Lemma 8 (with weights $w_q := \widehat{D}_{i-1}(q)$) and answering $|P_i|$ queries. The running time is $\tilde{O}(|P_{i-1}| + |P_i|)$. Summing over all i yields total running time $\tilde{O}(kn)$. This completes the proof of Lemma 7.

▶ **Theorem 9.** *The reverse shortest path problem in (unweighted) unit-disk graphs can be solved in $\tilde{O}(n^{9/8})$ time w.h.p. by a (Las Vegas) randomized algorithm.*

Proof. By combining Lemma 6 and Lemma 7, we obtain an algorithm that runs in time

$$\tilde{O}\left(\frac{\Delta^{1/3}n}{L^{2/3}} + L^{1/2}n + \frac{n^2}{\Delta}\right).$$

Choosing $L = n^{1/4}$ and $\Delta = n^{7/8}$ yields the desired result. ◀

Abstract

In this paper we study the hypergraph Zarankiewicz's problem in a geometric setting – for r-partite intersection hypergraphs of families of geometric objects. Our main results are essentially sharp bounds for families of axis-parallel boxes in $\mathbb{R}^d$ and families of pseudo-discs. For axis-parallel boxes, we obtain the sharp bound $O_{d,t}(n^{r-1}(\frac{\log n}{\log\log n})^{d-1})$. The best previous bound was larger by a factor of about $(\log n)^{d(2^{r-1}-2)}$. For pseudo-discs, we obtain the bound $O_t(n^{r-1}(\log n)^{r-2})$, which is sharp up to logarithmic factors. As this hypergraph has no algebraic structure, no improvement of Erdős' 60-year-old $O(n^{r-(1/t^{r-1})})$ bound was known for this setting. Futhermore, even in the special case of discs for which the semialgebraic structure can be used, our result improves the best known result by a factor of $\tilde{\Omega}(n^{\frac{2r-2}{3r-2}})$.

To obtain our results, we use the recently improved results for the graph Zarankiewicz's problem in the corresponding settings, along with a variety of combinatorial and geometric techniques, including shallow cuttings, biclique covers, transversals, and planarity.

1 Introduction

1.1 Background

Zarankiewicz's problem for graphs. A central research area in extremal combinatorics is *Turán-type questions*, which ask for the maximum number of edges in a graph on n vertices that does not contain a copy of a fixed graph H. This research direction was initiated in 1941 by Turán, who showed that the maximum number of edges in a K_r-free graph on n vertices is $(1-\frac{1}{r-1}+o(1))\frac{n^2}{2}$. Soon after, Erdős, Stone and Simonovits solved the problem for all non-bipartite graphs H. They showed that the maximum number is $(1-\frac{1}{\chi(H)-1}+o(1))\frac{n^2}{2}$, where $\chi(H)$ is the chromatic number of H.

The bipartite case turned out to be significantly harder. In 1951, Zarankiewicz raised the following Turán-type question for complete bipartite graphs: Given $n, t \in \mathbb{N}$, what is the maximum number of edges in a *bipartite*[1] graph G on n vertices that does not contain a copy of the complete bipartite graph $K_{t,t}$? This question, known as "Zarankiewicz's problem", has become one of the central open problems in extremal graph theory (see [18]). In one of the cornerstone results of extremal graph theory, Kővári, Sós and Turán [15] proved an upper bound of $O(n^{2-\frac{1}{t}})$. This bound is sharp for $t = 2, 3$ and known matching lower bound constructions use geometric bipartite intersection graphs [3]. The question whether this bound is tight for $t \geq 4$ is widely open.

In recent years, numerous works obtained improved bounds on the number of edges in various algebraic and geometric settings (e.g., [2, 5, 9, 11, 12, 13, 14, 17, 20, 21]). Several of these works studied Zarankiewicz's problem for *intersection graphs* of two families of geometric objects. In such a graph $G(A_1, A_2)$, the vertices are two families A_1, A_2 of geometric objects, and for $a_1 \in A_1$ and $a_2 \in A_2$, (a_1, a_2) is an edge of G if $a_1 \cap a_2 \neq \emptyset$. In particular, Chan and Har-Peled [5] obtained an $O(tn(\frac{\log n}{\log \log n})^{d-1})$ bound for intersection graphs of points vs. axis-parallel boxes in $\mathbb{R}^d$, improving upon results of [2, 21], and observed that a matching lower bound construction appears in a classical paper of Chazelle [6]. They also obtained an $O(tn \log \log n)$ bound for intersection graphs of points vs. pseudo-discs in the plane, and bounds for points vs. halfspaces, balls, shapes with "low union complexity", and more. Keller and Smorodinsky [14] proved a bound of $O_t(n\frac{\log n}{\log \log n})$ for intersection graphs of two families of axis-parallel rectangles in the plane and a bound of $O_t(n)$ for intersection graphs of two families of pseudo-discs. Both bounds are sharp, up to the dependence on t.

Zarankiewicz's problem for hypergraphs. The "hypergraph analogue" of Zarankiewicz's problem asks for the maximum number of hyperedges in an r-uniform hypergraph on n vertices that does not contain $K^r_{t,t,\ldots,t}$ (i.e., the complete r-partite r-uniform hypergraph with all parts having size t) as a subhypergraph.[2] This question was raised in 1964 by Erdős [10], who obtained an upper bound of $O(n^{r-\frac{1}{t^{r-1}}})$ and an almost matching lower bound of $\Omega(n^{r-\frac{c}{t^{r-1}}})$ for general hypergraphs. Note that $\Omega(n^{r-1})$ is a trivial lower bound for this problem, as the complete r-partite graph $K^r_{n,n,\ldots,n,t-1}$ has $(t-1)n^{r-1}$ edges and is clearly $K^r_{t,t,\ldots,t}$-free.

In recent years, a number of works obtained improvements of the bound of Erdős under various algebraic assumptions on the hypergraph. Do [8] obtained a bound of the form $O_{D,d,t,r}(n^{r-\alpha})$ for semialgebraic hypergraphs in $\mathbb{R}^d$, where $\alpha = \alpha(r, d) < 1$ and D is the description complexity. (Here and in the sequel, the asymptotic notation $g = O_x(f)$ means that the dependence on the parameter x, which is assumed to be constant, is not specified). Improved bounds in the same setting were later obtained by Do [9] and by Tidor and Yu [19]. In particular, the results of [19] yield a bound of the form $O_{t,r}(n^{r-\frac{r}{3r-2}})$ for r-partite intersection hypergraphs of r families of discs in the plane. Tong [22] generalized the results of [8] to classes of hypergraphs that satisfy the distal regularity lemma. Basit, Chernikov, Starchenko, Tao, and Tran [2] obtained an improved bound for semilinear hypergraphs. In particular, their technique yields the bound $O_{d,t,r}(n^{r-1}(\log n)^{d(2^{r-1}-1)})$, for r-partite intersection hypergraphs of r families of axis-parallel boxes in $\mathbb{R}^d$ (see definition below).

---

[1] Note that asking the question for bipartite graphs G like Zarankiewicz did, leads to the same order of magnitude of the size of the extremal graph like in Turán's original question which considers general graphs G, as any graph G with e edges contains a bipartite subgraph with at least $e/2$ edges.

[2] Like in the case of graphs, asking the question for r-partite r-uniform hypergraphs leads to the same order of magnitude of the size of the extremal hypergraph, as any r-uniform hypergraph H with e hyperedges contains an r-partite sub-hypergraph with at least $e \cdot \frac{r!}{r^r}$ hyperedges.

All these improved bounds use in a crucial way the algebraic structure of the hypergraph. No improvements of the bound of Erdős in non-algebraic settings are known.

1.2 Our results

In this paper we study Zarankiewicz's problem in intersection hypergraphs of families of geometric objects. In such an r-uniform r-partite hypergraph $H(A_1, A_2, \ldots, A_r)$, the vertices are r families $A_1, A_2, \ldots, A_r$ of geometric objects, and for $a_1 \in A_1, \ldots, a_r \in A_r$, $(a_1, a_2, \ldots, a_r)$ is a hyperedge of H if $a_1 \cap \ldots \cap a_r \neq \emptyset$. The number of hyperedges in H is denoted by $\mathcal{E}(H)$.

Intersection hypergraphs of axis-parallel boxes. Our first main result is the following upper bound for Zarankiewicz's problem for r-uniform intersection hypergraphs of axis-parallel boxes in $\mathbb{R}^d$. For convenience, we assume that all boxes involved are in a general position, meaning that no two ℓ-dimensional faces in the same directions lie on the same ℓ-flat.

▶ **Theorem 1.** *Let $r, t, d \geq 2$, and let H be the intersection hypergraph of families $A_1, \ldots, A_r$ of n axis-parallel boxes in $\mathbb{R}^d$, such that $A_1 \cup \ldots \cup A_r$ is in a general position. If H is $K^r_{t,\ldots,t}$-free, then*

$$|\mathcal{E}(H)| = O_{r,d}\left(t^2 n^{r-1} \left(\frac{\log n}{\log\log n}\right)^{d-1}\right).$$

This result, which improves the aforementioned result of Basit et al. [2] by a factor of about $(\log n)^{d(2^{r-1}-2)}$, is sharp, up to a factor of $O_{r,d}(t)$. Indeed, as was mentioned above, Chan and Har-Peled [5, Appendix B] showed that for $r = 2$, a lower bound of $\Omega_d(tn(\frac{\log n}{\log\log n})^{d-1})$ for the intersection graph of n points and n axis-parallel boxes in $\mathbb{R}^d$ follows from an old result of Chazelle [6]. This bound clearly holds also for the intersection graph of two families of n axis-parallel boxes in $\mathbb{R}^d$, and thus, it trivially yields an $\Omega_d(tn^{r-1}(\frac{\log n}{\log\log n})^{d-1})$ lower bound for r families, by adding $r-2$ families of n large boxes that contain all the boxes of the two first families.

Our proof exploits geometric properties of axis-parallel boxes and builds upon the upper bounds for Zarankiewicz's problem for intersection graphs of two families of axis-parallel boxes, obtained in [5] for intersections of points and boxes in $\mathbb{R}^d$, and in [14] for intersections of two families of rectangles in $\mathbb{R}^2$. In fact, a direct application of the result of [14] yields a weaker bound with t^6 instead of t^2. We improve the bound to t^2, and show that this is the best bound that can be obtained with the general strategy of [14]. However, we believe that the right dependence on t is linear.

It is somewhat surprising that the power of $\log n$ in the bound does not depend on r. Showing this is the most complex part of our proof, which uses biclique covers [7] and a non-standard inductive argument.

Intersection hypergraphs of pseudo-discs. Our second main result concerns intersection hypergraphs of pseudo-discs. A family of simple Jordan regions in the plane is called *a family of pseudo-discs* if the boundaries of every two regions intersect at most twice. For technical reasons, it is convenient to assume that the pseudo-discs are y-monotone, namely, that the intersection of any vertical line with a region from the family is either empty or an interval. In addition, we assume that the pseudo-discs are in general position, namely, no three boundaries intersect in a point.

▶ **Theorem 2.** *Let $r, t \geq 2$, and let H be the intersection hypergraph of families $A_1, \ldots, A_r$ of n y-monotone pseudo-discs in general position in the plane. If H is $K^r_{t,\ldots,t}$-free, then $|\mathcal{E}(H)| = O_r(t^6 n^{r-1} (\log n)^{r-2})$.*

This result is obviously sharp up to a factor of $O(t^5 (\log n)^{r-2})$. Our proof builds upon the upper bound for Zarankiewicz's problem for intersection graphs of two families of pseudo-discs obtained in [14], and uses geometric properties of pseudo-discs and shallow cuttings [16]. As general intersection hypergraphs of pseudo-discs have no algebraic structure, no improvement of the 60-year-old $O(n^{r-\frac{1}{t^{r-1}}})$ bound of Erdős [10] was known in this setting. Furthermore, in the special case of discs whose semialgebraic structure allows applying the previous algebraic works, our result improves over the best known previous result of Tidor and Yu [19] by a factor of $\tilde{\Omega}(n^{\frac{2r-2}{3r-2}})$.

Organization of the paper. In Section 2 we present the proof of Theorem 1. In Section 3 we present the proof of Theorem 2. In the appendices we prove several lemmas that are used in the proofs of the theorems.

2 Intersection Hypergraphs of Axis-Parallel Boxes

In this section we prove our new bound for Zarankiewicz's problem for intersection hypergraphs of axis-parallel boxes in $\mathbb{R}^d$ – namely, Theorem 1. First, in Section 2.1 we present a bound for the *lopsided* Zarankiewicz problem for intersection *graphs* of two families of boxes. Then, in Section 2.2 we use the lopsided version to handle r-partite intersection hypergraphs of boxes.

2.1 Lopsided version of Zarankiewicz's problem for two families of boxes

In this subsection we bound the number of edges in a $K_{t,gt}$-free intersection graph of two families of axis-parallel boxes in $\mathbb{R}^d$. We prove the following:

▶ **Theorem 3.** *Let A, B be two multisets of boxes in $\mathbb{R}^d$ where $|A| = n, |B| = m$ and $m = \text{poly}(n)$. If their intersection graph $G_{A,B}$ is $K_{t,gt}$-free (t on the side of A), then*

$$|E(G_{A,B})| \leq O_d(gtnf_{d,t}(n) + mf_{d,t}(m)),$$

where $f_{d,t}(n) = t(\frac{\log n}{\log \log n})^{d-1}$.

Theorem 3 is a generalization and an improvement of the bound on intersections between two families of axis-parallel rectangles in $\mathbb{R}^2$ proved in [14, Theorem 1.7]. Compared to the result of [14], Theorem 3 applies in $\mathbb{R}^d$ for all $d \geq 2$, is not restricted to the symmetric case of $K_{t,t}$, and has a better dependence on t.

▶ Remark 4. We state the theorem in terms of the auxiliary function $f_{d,t}(n)$, as in the sequel it will be used in a blackbox manner. We conjecture that $f_{d,t}(n)$ can be replaced with $(\frac{\log n}{\log \log n})^{d-1}$, which would lead to a bound of $O_{d,r}(tn^{r-1}(\frac{\log n}{\log \log n})^{d-1})$ for Zarankiewicz's problem for r-partite intersection hypergraphs of axis-parallel boxes in $\mathbb{R}^d$, which is sharp in terms of both n and t.

The proof of Theorem 3 is divided into two main cases, based on the following observation. Any intersection between two axis-parallel boxes belongs to one of two types:

1. *Vertex containment intersections*, in which a vertex of one box is contained in the other box;

2. *Facet intersections*, in which a facet of one box intersects a facet of the other box.

We bound each type of intersections with a different divide-and-conquer argument, as presented below.

2.1.1 Bounding vertex containment intersections

Due to the lack of symmetry between the two sides, we have to consider separately two types of intersections:

- Intersections in which a vertex of a box in A is contained in a box in B;
- Intersections in which a vertex of a box in B is contained in a box in A.

For each type, the problem reduces to bounding the number of edges in $K_{t,gt}$-free intersection graphs of points and axis-parallel boxes. Indeed, for the first case we can bound the number of intersections by $|E(G_{A',B})|$, where A' is the set of vertices of the boxes in A. The second case can be handled similarly. We prove the following proposition, which is a lopsided version of the bound of [5, Theorem 4.5] on the number of edges in $K_{t,t}$-free bipartite intersection graphs of points and axis-parallel boxes in $\mathbb{R}^d$ (though, with a weaker dependence on t).

▶ **Proposition 5.** *Let A be a multiset of points in $\mathbb{R}^d$ and let B be a multiset of axis-parallel boxes, where $|A| = n$ and $|B| = m$. Then for any $\epsilon > 0$,*

1. *If the bipartite intersection graph $G_{A,B}$ is $K_{t,gt}$-free (t on the side of A) then it has $O_\epsilon\left(gt^2 n(\frac{\log n}{\log\log n})^{d-1} + tm(\frac{\log n}{\log\log n})^{d-2+\epsilon}\right)$ edges.*
2. *If the bipartite intersection graph of $G_{A,B}$ is $K_{gt,t}$-free (t on the side of B) then it has $O_\epsilon\left(tn(\frac{\log n}{\log\log n})^{d-1} + gt^2 m(\frac{\log n}{\log\log n})^{d-2+\epsilon}\right)$ edges.*

As we show below, this provides a sufficiently strong bound on the vertex containment intersections, for the needs of Theorem 3.

Due to space constraints, the proof of Proposition 5 is presented in the full version of the paper [4].

2.1.2 Bounding facet intersections

We claim that for a large n, the number of facet intersections is significantly smaller than the number of vertex containment intersections.

▶ **Proposition 6.** *Let A, B be multisets of axis-parallel boxes in $\mathbb{R}^d$, where $|A| = n$ and $|B| = m$. If the bipartite intersection graph $G_{A,B}$ is $K_{t,gt}$-free (t on the side of A) then the number of facet intersections between a box in A and a box in B is*

$$O_d\left(gt^2 n(\log n)^{d-2} + tm(\log n)^{d-2}\right).$$

We use the following lemma.

▶ **Proposition 7.** *Let A be a multiset of horizontal segments in $\mathbb{R}^2$ and let B be a multiset of vertical segments in $\mathbb{R}^2$, where $|A| = n$ and $|B| = m$. Let $g > 0$. If the bipartite intersection graph $G_{A,B}$ is $K_{t,gt}$-free (where the t is on the side of A) then it has $O(gt^2 n + tm)$ edges.*

Due to space constraints, the proof of Proposition 7 is presented in the full version of the paper [4].

Proof of Proposition 6. The proof is by induction on d. The base case $d = 2$ amounts to bounding the number of edges in a $K_{2t,2gt}$-free bipartite intersection graph of a multiset A of horizontal segments in $\mathbb{R}^2$ and a multiset B of vertical segments in $\mathbb{R}^2$. Indeed, each "facet

intersection" in the plane is either an intersection between a horizontal edge of a rectangle in A with a vertical edge of a rectangle in B, or vice versa. We can bound the number of facet intersections of the first type by $|E(G_{A',B'})|$, where A' is the multiset of horizontal edges of rectangles in A and B' is the multiset of vertical edges of rectangles in B. Note that this intersection graph is $K_{2t,2gt}$-free, as otherwise, $G_{A,B}$ would contain $K_{t,gt}$. The second type can be handled similarly. Hence, Proposition 7 yields a bound of $O(gt^2n + tm)$ in this setting, which proves the induction basis.

In the induction step, we assume that for $(d-1)$-dimensional boxes, the number of facet intersections is bounded by

$$O_d(gt^2n(\log n)^{d-3} + tm(\log n)^{d-3}).$$

We bound the number of facet intersections between $x \in A$ and $y \in B$, such that the intersecting facets are othogonal to the $(d-1)$'th and the d'th axis, respectively. A bound on the total number of facet intersections clearly follows by multiplying with d^2. In the rest of the proof, we call such special intersections "good facet intersections", or just "intersections" for brevity. We make sure that in the dimension reductions in the induction process presented below, every time the first coordinate is the one that is removed, and thus, the good facet intersections are not affected.

We use the following auxiliary notion. Let $I_d(n, m)$ be the maximum number of good facet intersections between multisets A, B of axis-parallel boxes inside a "vertical strip" $\mathcal{U} = \{x \in \mathbb{R}^d : u_L < x_1 < u_R\}$ of $\mathbb{R}^d$, where:

1. Each box in A, B has either half of its vertices or all of its vertices in $\mathcal{U}$;
2. The total number of vertices of boxes in A (resp., boxes in B) inside $\mathcal{U}$ is $n \cdot 2^{d-1}$ (resp., $m \cdot 2^{d-1}$);
3. The bipartite intersection graph of A, B is $K_{t,gt}$-free.

We shall prove that

$$I_d(n, m) \leq O_d(gt^2n(\log n)^{d-2} + tm(\log n)^{d-2}).$$

This clearly implies the assertion of the proposition, as by considering a vertical strip $\mathcal{U}$ that fully contains all boxes in A and B (where $|A| = n$ and $|B| = m$), we get that the number of good facet intersections between A and B is at most $I_d(2n, 2m)$. (Note that we neglect factors of $O_d(1)$).

Let A, B be multisets of boxes that satisfy assumptions (1)–(3) with respect to a strip $\mathcal{U} \subset \mathbb{R}^d$. We divide $\mathcal{U}$ into two vertical sub-strips $\sigma_1 = \{x \in \mathbb{R}^d : u_L < x_1 < u'\}$ and $\sigma_2 = \{x \in \mathbb{R}^d : u' < x_1 < u_R\}$, such that each sub-strip contains $n \cdot 2^{d-2}$ vertices of boxes in A. For $i = 1, 2$, we denote by A_i (resp., B_i) the boxes in A (resp., B) that have at least one vertex in σ_i, and by A'_i (resp., B'_i) the boxes in A (resp., B) that intersect σ_i but do not have vertices in it. Note that $A'_1 \subset A_2, A'_2 \subset A_1$, and similarly for B. We also denote the number of vertices of boxes in B contained in σ_i by $2^{d-1} \cdot m_i$.

The number of good facet intersections in $\mathcal{U}$ between boxes in A and boxes in B is at most

$$I(A_1, B_1) + I(A_2, B_2) + I(A_1, B'_1) + I(A'_2, B_2) + I(A_2, B'_2) + I(A'_1, B_1), \tag{1}$$

where $I(X, Y)$ denotes the number of good facet intersections between an element of X and an element of Y.

Indeed, $I(A_1, B_1)$ (resp., $I(A_2, B_2)$) counts intersections between pairs of boxes that have at least one vertex in σ_1 (resp., σ_2). $I(A_1, B_1') + I(A_2', B_2)$ upper bounds the number of intersections between a box in A that has a vertex in σ_1 and a box in B that has a vertex in σ_2. $I(A_2, B_2') + I(A_1', B_1)$ upper bounds the number of intersections between a box in A that has a vertex in σ_2 and a box in B that has a vertex in σ_1.

By the definitions, we have $I(A_1, B_1) \leq I_d(\frac{n}{2}, m_1)$ (where σ_1 is taken as the vertical strip instead of $\mathcal{U}$). Similarly, $I(A_2, B_2) \leq I_d(\frac{n}{2}, m_2)$.

To handle the other types of intersections, we observe that a box in A_1 intersects a box in B_1' if and only if their projections on the hyperplane $\mathcal{H} = \{x \in \mathbb{R}^d : x_1 = u'\}$ (which are $(d-1)$-dimenstional boxes) intersect. Let $\bar{A}_1$ and $\bar{B}_1'$ denote the corresponding families of projections. We have $|\bar{A}_1| = |A_1| = \frac{n}{2}$ and $|\bar{B}_1'| = |B_1'| \leq m_2$. The multisets $\bar{A}_1$ and $\bar{B}_1'$ are multisets of axis-parallel boxes in $\mathbb{R}^{d-1}$ whose bipartite intersection graph is $K_{t,gt}$-free. Hence, by the induction hypothesis we have

$$\begin{aligned} I(A_1, B_1') = I(\bar{A}_1, \bar{B}_1') &\leq O_d\left(gt^2 \tfrac{n}{2} \left(\log \tfrac{n}{2}\right)^{d-3} + tm_2 \left(\log \tfrac{n}{2}\right)^{d-3}\right) \\ &\leq O_d\left(gt^2 \tfrac{n}{2} (\log n)^{d-3} + tm_2 (\log n)^{d-3}\right), \end{aligned}$$

Applying the same argument to $I(A_2', B_2), I(A_1', B_1)$ and $I(A_2, B_2')$, we get

$$\begin{aligned} &I(A_1, B_1') + I(A_2', B_2) + I(A_2, B_2') + I(A_1', B_1) \\ &\quad \leq O_d(4gt^2 \tfrac{n}{2} (\log n)^{d-3} + 2tm_2 (\log n)^{d-3} + 2tm_1 (\log n)^{d-3}) \\ &\quad = O_d(2gt^2 n (\log n)^{d-3} + 2tm (\log n)^{d-3}). \end{aligned}$$

Combining this with the bounds on $I(A_1, B_1)$ and $I(A_2, B_2)$ and substituting to (1), we obtain the recursive formula

$$I_d(n, m) \leq \max_{m_1 + m_2 = m} \left(I_d(\tfrac{n}{2}, m_1) + I_d(\tfrac{n}{2}, m_2) + O_d(2gt^2 n (\log n)^{d-3} + 2tm (\log n)^{d-3})\right),$$

which solves to

$$I_d(n, m) \leq \log n \cdot O_d(gt^2 n (\log n)^{d-3} + tm (\log n)^{d-3}) \leq O_d(gt^2 n (\log n)^{d-2} + tm (\log n)^{d-2}).$$

This completes the proof. ◀

2.1.3 Completing the proof of Theorem 3

Now we are ready to wrap up the proof of Theorem 3.

Proof of Theorem 3. Let A, B be multisets of axis-parallel boxes in $\mathbb{R}^d$ that satisfy the assumptions of the theorem. As written above, the intersections between A and B can be divided into *vertex containment intersections* and *facet intersections*.

To bound the number of vertex containment intersections, we apply Proposition 5, with $\epsilon = \frac{1}{2}$. Specifically, we use Proposition 5(1) to bound the number of intersections in which a vertex of $a \in A$ is contained in a box $b \in B$. Furthermore, we use Proposition 5(2) *with the roles of n and m reversed* to bound the number of intersections in which a vertex of $b \in B$ is contained in a box $a \in A$. We get that the number of vertex containment intersections is at most

$$O_d\left(gt^2 n (\tfrac{\log n}{\log \log n})^{d-1} + tm (\tfrac{\log n}{\log \log n})^{d-1.5} + tm (\tfrac{\log m}{\log \log m})^{d-1} + gt^2 n (\tfrac{\log m}{\log \log m})^{d-1.5}\right).$$

By Proposition 6, the number of facet intersections is at most

$$O_d(gt^2n(\log n)^{d-2} + tm(\log n)^{d-2}).$$

Note that for a large n, we have $(\log n)^{d-2} = o((\frac{\log n}{\log\log n})^{d-1.5})$, and hence, the number of facet intersections is dominated by the number of vertex containment intersections.

Finally, since $m = \text{poly(n)}$, the terms $tm(\frac{\log n}{\log\log n})^{d-1.5}$ and $gt^2n(\frac{\log m}{\log\log m})^{d-1.5}$ are dominated by the two other terms. Therefore, we have

$$|E(G_{A,B})| \leq O_d\left(gt^2n(\tfrac{\log n}{\log\log n})^{d-1} + tm(\tfrac{\log m}{\log\log m})^{d-1}\right) = O_d(gtnf_{d,t}(n) + mf_{d,t}(m)),$$

as asserted. This completes the proof. ◀

2.2 Zarankiewicz problem for r-partite intersection hypergraph of boxes

Using Theorem 3, we can relatively easily obtain Proposition 8 below, which is a weaker version of Theorem 1. Since the proof of the weaker result may serve as a good introduction to the proof of Theorem 1, we present it in Section 2.2.1, and then we pass to the proof of Theorem 1 in Section 2.2.2.

2.2.1 Proof of a weaker variant of Theorem 1

We prove the following.

▶ **Proposition 8.** *Let $A_1, A_2, \ldots, A_r$ be families of n axis-parallel boxes in $\mathbb{R}^d$, and let H be their r-partite intersection hypergraph. If H is $K^r_{t,t,\ldots,t}$-free, then $|\mathcal{E}(H)| = O_r\left(t\left(nf_{d,t}(n)\right)^{r-1}\right)$.*

The proof of Proposition 8 is by induction on r. For the sake of simplicity, we present here the proof for $r = 3$, and complete the argument for a general r in the full version of the paper [4].

Proof of Proposition 8 for $r = 3$. Let $A_1 = A, A_2 = B, A_3 = C$. Let AB be the following multiset of axis-parallel boxes: $AB = \{a \cap b : a \in A, b \in B, a \cap b \neq \emptyset\}$. (Note that the intersection of two axis-parallel boxes is indeed an axis-parallel box). Let G be the bipartite intersection graph of the families C and AB. It is clear that $|E(G)| = |\mathcal{E}(H)|$, since there is a clear one-to-one correspondence between edges of G and hyperedges of H.

We claim that for a sufficiently large constant M, the graph G is $K_{t,Mtnf_{d,t}(n)}$-free. Indeed, assume to the contrary that G contains a copy of $K_{t,Mtnf_{d,t}(n)}$, for a "large" M. This means that there exist t boxes $c_1, c_2, \ldots, c_t \in C$ which all have a non-empty intersection with certain $Mtnf_{d,t}(n)$ axis-parallel boxes of the form $a_i \cap b_i$, with $a_i \in A$, $b_i \in B$. Denote by A' the set of all $a_i \in A$ that participate in such intersections, and by B' the set of all $b_i \in B$ that participate in such intersections. Let G' be the bipartite intersection graph of A', B'. We have $|E(G')| \geq Mtnf_{d,t}(n)$, and hence, by Theorem 3 (applied with $m = n$ and $g = 1$), it contains a $K_{t,t}$ (using the assumption that M is sufficiently large). This means that there exist $a_1, a_2, \ldots, a_t \in A$ and $b_1, b_2, \ldots, b_t \in B$ such that for all $1 \leq i, j \leq t$, we have $a_i \cap b_j \neq \emptyset$, and both a_i and b_j have a non-empty intersection with each of $c_1, \ldots, c_t$ (since they participate in pairs whose intersection with each of $c_1, \ldots, c_t$ is non-empty). As any three pairwise intersecting axis-parallel boxes have a non-empty intersection, this implies that $a_i \cap b_j \cap c_k \neq \emptyset$ for all $1 \leq i, j, k \leq t$, and consequently, H contains a $K_{t,t,t}$, a contradiction.

We have thus concluded that G is $K_{t,Mtnf_{d,t}(n)}$ free, for a sufficiently large constant M. By Theorem 3, applied with n, $m = n^2$, and $g = Mnf_{d,t}(n)$, this implies that

$$|\mathcal{E}(H)| = |E(G)| \leq O\left(t\left(nf_{d,t}(n)\right)^2\right).$$

This completes the proof. ◀

Note that in this proof, we used the fact that axis-parallel boxes in $\mathbb{R}^d$ have *Helly number 2*, namely, that any pairwise intersecting family of axis-parallel boxes has a non-empty intersection. Without this property, the existence of $K_{t,t}$ in G' does not necessarily imply the existence of $K_{t,t,t}$ in H.

The proof for a general r is an inductive process, in which at the ℓ'th step, one considers an auxiliary bipartite intersection graph of boxes, whose vertex sets are the multiset $A_1A_2 \dots A_{\ell+1} = \{(a_1 \cap \dots \cap a_{\ell+1}) : \forall i, a_i \in A_i, \cap_{i=1}^{\ell+1} a_i \neq \emptyset\}$, where the multiplicity of each element is the number of $(a_1, \dots, a_{\ell+1})$ tuples that lead to it, and $A_{\ell+2}$. At each step, Theorem 3 is applied once again, and the fact that axis-parallel boxes have Helly number 2 is deployed once again. As this part of the proof is a bit more cumbersome and is not needed for the proof of Theorem 1 presented below, we provide it in the full version of the paper [4].

2.2.2 Proof of Theorem 1

In Proposition 8, the polylogarithmic factor in the upper bound increases with r, since at each step of the inductive process we apply Theorem 3 and "pay" another $f_{d,t}(n)$-factor. In this subsection, we show how to avoid this dependency on r. Let us restate Theorem 1.

▶ **Theorem 9** (Theorem 1 restated). *Let $r, d, t \geq 2$ and let H be the intersection hypergraph of r families $A_1, \dots, A_r$ of n axis-parallel boxes in general position in $\mathbb{R}^d$. If H is $K^r_{t,\dots,t}$-free, then $|\mathcal{E}(H)| = O_{r,d}(tn^{r-1}f_{d,t}(n))$, where $f_{d,t}(n) = t(\frac{\log n}{\log\log n})^{d-1}$.*

In the proof, we use the following modification of the *biclique cover theorem* (see [7]) for axis-parallel boxes, that may be of independent interest. We note that the relation between Zarankiewicz's problem and biclique covers was already observed in [5, 9].

▶ **Definition 10.** *A biclique cover of a graph $G = (V, E)$ is a collection of pairs of vertex subsets $\{(A_1, B_1), \dots, (A_l, B_l)\}$ such that $E = \bigcup_{i=1}^{l}(A_i \times B_i)$.*

▶ **Lemma 11.** *Let $n, m, b \in \mathbb{N}$ be such that $b \leq \min(n, m)$, and let A, B be families of axis-parallel boxes in $\mathbb{R}^d$, with $|A| = n$ and $|B| = m$. Then the bipartite intersection graph of A, B can be partitioned into a union of $O(b\log^{d-1} b)$ bicliques (with no restriction on their size) and $O(b\log^{d-1} b)$ "partial bicliques" (namely, subgraphs of bicliques), each of size at most $\frac{n}{b} \cdot \frac{m}{b}$.*

Due to space constraints, the proof of the lemma is presented in the full version of the paper [4].

The motivation behind our proof of Theorem 1 is as follows: Assume that we add an additional assumption that the $(r-1)$-partite intersection graph of the families $A_1, \dots, A_{r-1}$ is complete. Namely, that for all $1 \leq i < j \leq r-1$, any box in A_i intersects any box in A_j. Furthermore, assume that by applying (only once!) Theorem 3, we show that the bipartite intersection graph of the multiset $A_1A_2 \dots A_{r-1} = \{a_1 \cap \dots \cap a_{r-1} : \forall i, a_i \in A_i, \cap_{i=1}^{r-1} a_i \neq \emptyset\}$ and the family A_r contains $K_{gt,t}$, for $g = n^{r-2}$. This means that some t boxes from A_r intersect $gt = tn^{r-2}$ boxes of the type $\{a_1 \cap \dots \cap a_{r-1} : a_i \in A_i\}$. These gt boxes involve at

least t boxes from each A_i ($1 \leq i \leq r-1$). Thus, by our additional assumption and by the fact that axis-parallel boxes admit Helly number 2, the existence of $K_{gt,t}$ in the bipartite intersection graph, implies the existence of $K^r_{t,\ldots,t}$ in the original r-partite intersection hypergraph. Therefore, the suggested additional assumption enables avoiding repeated applications of Theorem 3, and hence obtaining a bound with a logarithmic factor that does not increase with r.

In order to show that we can indeed make the additional assumption described above without affecting the final bound, we define a constraints graph G, not to be confused with the auxiliary graph G from Section 2.2.1.

▶ **Definition 12.** *For an r-tuple of set families $A_1, \ldots, A_r$, the* constraints graph $G = G_{A_1,\ldots,A_r}$ *is defined as follows. The vertex set of G is $V(G) = \{1, 2, \ldots, r\}$, and $(i, j) \in G$ if $\exists a_i \in A_i, a_j \in A_j$ such that $a_i \cap a_j = \emptyset$.*

This graph G represents the "distance" of the r-tuple of families $A_1, \ldots, A_r$ from the desired setting in which there exists i such that any box from A_j intersects any box from A_k, for all $j, k \neq i$. Our goal in the proof below is to remove all the edges from G, except for those emanating from a single vertex i. This will show that one can indeed make the additional assumption described above without affecting the final bound.

Proof of Theorem 9. Let $T_G(n_1, \ldots, n_r)$ be the maximum number of hyperedges in a $K^r_{t,\ldots,t}$-free r-partite intersection hypergraph H of r families $A_1, \ldots, A_r$ of axis-parallel boxes in $\mathbb{R}^d$, where $|A_i| = n_i$, and the constraints graph of r-tuple $A_1, \ldots, A_r$ is G. Denote $T_G(n) = T_G(n, \ldots, n)$. In order to prove the theorem, it is clearly sufficient to prove that for any constraint graph G, we have $T_G(n) \leq O(tn^{r-1} f_{d,t}(n))$. We prove this claim by induction on $|E(G)|$.

If $E(G) = \emptyset$, then for all $i \neq j$, any $a_i \in A_i$ intersects any $a_j \in A_j$. Since H is $K^r_{t,\ldots,t}$-free, this implies $n < t$ and we are done.

In the induction step, we assume that we have already proved the claim for any constraints graph with a smaller number of edges, and we now consider a constraints graph G. We consider three cases:

- Case A: G contains two non-adjacent edges;
- Case B: G is a triangle;
- Case C: G is a star.

Clearly, any graph G belongs to one of the three cases.

Case A: G contains two non-adjacent edges. Say these two non-adjacent edges are $(1, 2)$ and $(3, 4)$. Our goal now is to "remove" the edge $(1, 2)$ (and later, also the edge $(3, 4)$) from G, by partitioning the intersection graph of A_1 and A_2 into bicliques. To this end, we use Lemma 11 with a large constant b to partition the entire hypergraph into smaller hypergraphs, induced by a partition of the bipartite intersection of A_1 and A_2 to "full" bicliques and "partial" bicliques. We obtain the recursion:

$$T_G(n) \leq O(b \log^{d-1} b) T_G(\tfrac{n}{b}, \tfrac{n}{b}, n, \ldots, n) + O(b \log^{d-1} b) O(tn^{r-1} f_{d,t}(n)), \tag{2}$$

where the right term comes from applying the induction hypothesis on the hypergraphs induced by full bicliques, whose constraints graph is $G \setminus \{(1, 2)\}$, and the left term comes from the partial bicliques.

Now, to bound $T_G(\frac{n}{b}, \frac{n}{b}, n, \ldots, n)$, we do the same with the sets A_3, A_4 and obtain

$$T_G(\tfrac{n}{b}, \tfrac{n}{b}, n, \ldots, n) \leq O(b \log^{d-1} b) T_G(\tfrac{n}{b}, \tfrac{n}{b}, \tfrac{n}{b}, \tfrac{n}{b}, n, \ldots, n) + O(b \log^{d-1} b) O(tn^{r-1} f_{d,t}(n)). \tag{3}$$

Combining (2) and (3) together, we get

$$T_G(n) \leq O(b^2 \log^{2d-2} b) \left(T_G(\tfrac{n}{b}, \tfrac{n}{b}, \tfrac{n}{b}, \tfrac{n}{b}, n, \ldots, n) + O(tn^{r-1} f_{d,t}(n))\right). \tag{4}$$

To bound the left term in the right hand side, we partition the hypergraph into b^{r-4} hypergraphs which r sides of size $\frac{n}{b}$ by partitioning each of the sets $A_5, \ldots, A_r$ arbitrarily into b parts, each of size $\frac{n}{b}$. We obtain

$$T_G(n) \leq O(b^2 \log^{2d-2} b) \left(b^{r-4} T_G(\tfrac{n}{b}) + O(tn^{r-1} f_{d,t}(n))\right). \tag{5}$$

The recursion (5) solves to $T_G(n) = O(tn^{r-1} f_{d,t}(n))$, and we are done.

Case B: G is a triangle. Say $E(G) = \{(1,2), (2,3), (1,3)\}$. In this case, we first split A_1 and A_2 by Lemma 11, then we split A_2 and A_3 and then we split A_1 and A_3.

Using the induction hypothesis, by splitting A_1, A_2 we obtain

$$T_G(n) \leq O(b \log^{d-1} b) \left(T_G(\tfrac{n}{b}, \tfrac{n}{b}, n, \ldots, n) + O(tn^{r-1} f_{d,t}(n))\right). \tag{6}$$

By splitting A_2, A_3, we get

$$T_G(\tfrac{n}{b}, \tfrac{n}{b}, n, \ldots, n) \leq O(b \log^{d-1} b) \left(T_G(\tfrac{n}{b}, \tfrac{n}{b^2}, \tfrac{n}{b}, n, \ldots, n) + O(tn^{r-1} f_{d,t}(n))\right), \tag{7}$$

and by splitting A_1, A_3 we have

$$T_G(\tfrac{n}{b}, \tfrac{n}{b^2}, \tfrac{n}{b}, n, \ldots, n) \leq O(b \log^{d-1} b) \left(T_G(\frac{n}{b^2}, \frac{n}{b^2}, \frac{n}{b^2}, n, \ldots, n) + O(tn^{r-1} f_{d,t}(n))\right). \tag{8}$$

Combining (6)-(8), we obtain

$$T_G(n) \leq O(b^3 \log^{3d-3} b) \left(T_G(\tfrac{n}{b^2}, \tfrac{n}{b^2}, \tfrac{n}{b^2}, n, \ldots, n) + O(tn^{r-1} f_{d,t}(n))\right), \tag{9}$$

and by partitioning each of $A_4, \ldots, A_r$ arbitrarily into b^2 equal parts, we get

$$T_G(n) \leq O(b^{2r-3} \log^{3d-3} b) T_G(\tfrac{n}{b^2}) + O(b^3 \log^{3d-3} b) O(tn^{r-1} f_{d,t}(n)). \tag{10}$$

As above, this recursion solves to $T_G(n) = O(tn^{r-1} f_{d,t}(n))$.

Case C: G is a star. Say G is a star centered at A_r. In this case we don't apply the induction hypothesis. Instead, we apply Theorem 3 (only once, in contrast to the argument in Section 2.2.1).

Assume on the contrary that $T_G(n) > Ctn^{r-1} f_{d,t}(n)$ for some large constant C. Consider the intersection graph between the multiset $A_1 A_2 \ldots A_{r-1} = \{a_1 \cap \ldots \cap a_{r-1} : \forall i, a_i \in A_i, \cap_{i=1}^{r-1} a_i \neq \emptyset\}$ and the family A_r. Since the number of edges in this graph is at least $\Omega(tn^{r-1} f_{d,t}(n))$, by Theorem 3 (with the parameters $n, m = n^{r-1}$ and $g = n^{r-2}$), this intersection graph contains $K_{gt,t}$.

This means that some t specific boxes from A_r intersect $gt = n^{r-2}t$ boxes of the type $a_1 \cap \ldots \cap a_{r-1}$ ($a_i \in A_i$). These gt boxes involve at least t boxes from each A_i ($1 \leq i \leq r-1$). Hence, there exist $A'_1 \subset A_1, \ldots, A'_r \subset A_r$, each of size t, such that any $a_1, \ldots, a_r$, where $a_1 \in A'_1, \ldots, a_r \in A'_r$, are pairwise intersecting. (Here we use the setting of case C in which for all $1 \leq i < j \leq r-1$, any two boxes $a_i \in A_i$ and $a_j \in A_j$ intersect.) Since axis-parallel boxes have Helly number 2, this implies that for all $a_1 \in A'_1, \ldots, a_r \in A'_r$ we have $a_1 \cap \ldots \cap a_r \neq \emptyset$, and hence, the restriction of H to $A'_1 \cup \ldots \cup A'_r$ is a copy of $K^r_{t,t,\ldots,t}$, a contradiction. This completes the proof of Theorem 9, and thus of Theorem 1. ◀

3 Intersection Hypergraphs of Pseudo-discs

In this section we prove Theorem 2. Let us recall the statement of the theorem.

▶ **Theorem 2.** Let $r, t \geq 2$ and let H be the r-partite intersection hypergraph of families $A_1, \ldots, A_r$ of n y-monotone pseudo-discs in general position in the plane. If H is $K^r_{t,\ldots,t}$-free, then $|\mathcal{E}(H)| = O(t^6 n^{r-1} (\log n)^{r-2})$.

A tool crucially used in the proof is a lopsided version of the following result from [5].

▶ **Theorem 13** ([5, Corollary 5.1])**.** *Let P be a set of n points in the plane, and let $\mathcal{F}$ be a family of m y-monotone pseudo-discs in general position in the plane. If the bipartite intersection graph $G(P, \mathcal{F})$ is $K_{t,t}$-free ($t \geq 2$), then*

$$|E(G(P, \mathcal{F}))| = O(tn + tm \log\log m + \log t).$$

The lopsided variant of Theorem 13 reads as follows.

▶ **Theorem 14** (Lopsided variant of Theorem 13)**.** *Let P be a multiset of n points in the plane, and let $\mathcal{F}$ be a multiset of m y-monotone pseudo-discs in general position in the plane. If the bipartite intersection graph $G(P, \mathcal{F})$ is $K_{gt,t}$-free ($t, g \geq 2$, gt on the side of the points), then*

$$|E(G(P, \mathcal{F}))| = O(tn + gtm \log m).$$

Due to space constraints, the proof of Theorem 14, which uses the geometric technique of *shallow cuttings* [16], is presented in the full version of the paper [4]. Note that for $g = 1$, the bound we obtain is weaker than the bound of Theorem 13. The reason for this is explained in the full version of the paper [4].

The proof of Theorem 2 uses induction on r, where the induction basis ($r = 2$) is the following theorem from [14]:

▶ **Theorem 15** ([14, Theorem 1.6])**.** *Let $t \geq 2$ and let G be the bipartite intersection graph of two families of pseudo-discs, each of size n. If G is $K_{t,t}$-free then $|E(G)| = O(t^6 n)$.*

Proof of Theorem 2. The proof is by induction on r, the base case being Theorem 15 above. In the induction step, we use the following observation: If r simple Jordan regions in $\mathbb{R}^2$ intersect, then either

- There is a pair of regions a_1, a_2 such that an intersection point of their boundaries is contained in all other $r - 2$ regions, or
- There is a region a_1 which is fully contained in all other $r - 1$ regions.

(To see why this holds, take a point in the intersection and look at all points on the boundaries of the regions which can be reached from it without crossing a boundary of one of the regions. If all these points belong to the same region, the second case holds. If not, by the assumptions one of these points is an intersection point of two regions and the first case holds).

We call an intersection of the first type a *type A* - intersection, and an intersection of the second type a *type B* - intersection.

For each intersecting pair $\{a_1, a_2\}$ of pseudo-discs we define a special point $p(a_1, a_2)$ as follows: If the intersection of a_1 and a_2 is of type A, then $p(a_1, a_2)$ is the left intersection point of the boundaries of a_1 and a_2. If this intersection is of type B, where $a_1 \subset a_2$, then $p(a_1, a_2)$ is the leftmost point of a_1.

Without loss of generality, both for Type A and for Type B, we count intersections of the type $a_1 \cap \ldots \cap a_r \neq \emptyset$ ($a_i \in A_i$), where $p(a_1, a_2)$ is contained in $a_3 \cap \ldots \cap a_r$. This affects the final bound by a multiplicative factor of $O_r(1)$.

Let P be the multiset $P = \{p(a_1, \ldots, a_{r-1}) : a_i \in A_i\}$, where $p(a_1, \ldots, a_{r-1})$ is $p(a_1, a_2)$ with multiplicity which is determined by the number of other tuples of a_i's whose intersection contains it. Clearly, $|P| \leq n^{r-1}$. Let G be the bipartite intersection graph of the multiset of points P and the family of pseudo-discs A_r. If $|\mathcal{E}(H)| > C_r t^6 n^{r-1} (\log n)^{r-2}$ (for a sufficiently large constant C_r), then by Theorem 14, G contains $K_{gt,t}$ for $g = C_{r-1} t^5 n^{r-2} (\log n)^{r-3}$ (where C_{r-1} will be specified below, and C_r is taken to be sufficiently large for the statement to hold by Theorem 14). This $K_{gt,t}$ comes from a set S of $gt = C_{r-1} t^6 n^{r-2} (\log n)^{r-3}$ distinct tuples of the form $(a_1, \ldots, a_{r-1})$ where $a_i \in A_i$, and a set T of t pseudo-discs from A_r. Let $Z = \bigcap\{a_r : a_r \in T\}$ be the intersection of all the pseudo-discs in T. Since all the elements of T contain a common point (e.g., each point in P), Z is non-empty, and it follows from properties of pseudo-discs families that Z is connected. (For a proof of this geometric fact, see [1, Theorem 4.4]).

Now, we clip each pseudo-disc $s \in A_1 \cup \ldots \cup A_{r-1}$ to $s' = s \cap Z$, and slightly perturb the boundaries such that the family $\{s' : s \in A_1 \cup \ldots \cup A_{r-1}\}$ is still a family of pseudo-discs. This perturbation can be performed as follows: Define a partial ordering on $A_1 \cup \ldots \cup A_{r-1}$, by considering the intersection of each pseudo-disc with the boundary of Z and ordering by inclusion. Extend the ordering into a linear ordering arbitrarily. Clip the pseudo-discs close to the boundary of Z from the inside, in such a way that a "smaller" pseudo-disc (according to the linear ordering) is clipped closer to the boundary. In this way, an intersection is added only to pairs of pseudo-discs whose boundaries have only one intersection point inside Z, and therefore, any two boundaries of $\{s' : s \in A_1 \cup \ldots \cup A_{r-1}\}$ intersect at most twice.

Consider the $(r-1)$-partite intersection hypergraph H' of the families $A'_1, \ldots, A'_{r-1}$, where $A'_i = \{s' : s \in A_i\}$. H' has at least $|S|$ hyperedges, since for each $(a_1, \ldots, a_{r-1}) \in S$, the point $p(a_1, \ldots, a_{r-1})$ is contained in Z, and hence, $a'_1 \cap a'_2 \cap \ldots \cap a'_{r-1} \neq \emptyset$. Since $|S| > C_{r-1} t^6 n^{r-2} (\log n)^{r-3}$, by the induction hypothesis H' contains a $K^{r-1}_{t,\ldots,t}$ all of whose elements are fully contained in $Z = \bigcap\{a : a \in T\}$. (Here, C_3 is chosen to be sufficiently large for applying the inductive hypothesis.) Together with the set $T \subset A_r$, we obtain $K^r_{t,\ldots,t}$ in H. This completes the proof. ◀

Abstract

While there are software systems that simplify trajectory streams on the fly, few curve simplification algorithms with quality guarantees fit the streaming requirements. We present streaming algorithms for two such problems under the Fréchet distance d_F in $\mathbb{R}^d$ for some constant $d \geq 2$.

Consider a polygonal curve τ in $\mathbb{R}^d$ in a stream. We present a streaming algorithm that, for any $\varepsilon \in (0,1)$ and $\delta > 0$, produces a curve σ such that $d_F(\sigma, \tau[v_1, v_i]) \leq (1+\varepsilon)\delta$ and $|\sigma| \leq 2\,\mathrm{opt} - 2$, where $\tau[v_1, v_i]$ is the prefix in the stream so far, and $\mathrm{opt} = \min\{|\sigma'| : d_F(\sigma', \tau[v_1, v_i]) \leq \delta\}$. Let $\alpha = 2(d-1)\lfloor d/2 \rfloor^2 + d$. The working storage is $O(\varepsilon^{-\alpha})$. Each vertex is processed in $O(\varepsilon^{-\alpha} \log \frac{1}{\varepsilon})$ time for $d \in \{2,3\}$ and $O(\varepsilon^{-\alpha})$ time for $d \geq 4$. Thus, the whole τ can be simplified in $O(\varepsilon^{-\alpha}|\tau| \log \frac{1}{\varepsilon})$ time. Ignoring polynomial factors in $1/\varepsilon$, this running time is a factor $|\tau|$ faster than the best static algorithm that offers the same guarantees.

We present another streaming algorithm that, for any integer $k \geq 2$ and any $\varepsilon \in (0, \frac{1}{17})$, maintains a curve σ such that $|\sigma| \leq 2k-2$ and $d_F(\sigma, \tau[v_1, v_i]) \leq (1+\varepsilon) \cdot \min\{d_F(\sigma', \tau[v_1, v_i]) : |\sigma'| \leq k\}$, where $\tau[v_1, v_i]$ is the prefix in the stream so far. The working storage is $O((k\varepsilon^{-1} + \varepsilon^{-(\alpha+1)}) \log \frac{1}{\varepsilon})$. Each vertex is processed in $O(k\varepsilon^{-(\alpha+1)} \log^2 \frac{1}{\varepsilon})$ time for $d \in \{2,3\}$ and $O(k\varepsilon^{-(\alpha+1)} \log \frac{1}{\varepsilon})$ time for $d \geq 4$.

1 Introduction

The pervasive use of GPS sensors has enabled tracking of moving objects. For example, a car fleet can use real-time information about its vehicles to deploy them in response to dynamic demands. The sensor periodically samples the location of the moving object and sends it as a vertex to the remote cloud server for storage and processing. The remote server interprets the sequence of vertices received as a polygonal curve (trajectory).

For a massive stream, it has been reported [6, 7, 18, 19] that sending all vertices uses too much network bandwidth and storage at the server, and it may aggravate issues like out-of-order and duplicate data points. Software systems have been built for the sensor side to simplify trajectory streams on the fly (e.g. [16, 17, 18, 27, 28]). A local buffer is used. Every incoming vertex in the stream triggers a new round of computation that uses only the incoming vertex and the data in the local buffer. At the end of a round, these systems may determine the next vertex and send it to the cloud server, but they may also send nothing.

It is important to keep the local buffer small [16, 17, 18, 27, 28]. It means a small working storage and less computation in processing the next vertex in the stream, which enables real-time response and requires less computing power. In theoretical computer science,

streaming algorithms have three goals [22]. Let n be the number of items in the stream so far. First, the working storage should be $o(n)$ if not polylog(n). Second, an item in the stream should be processed in polylog(n) time or at worst $o(n)$ time because items are arriving continuously. Third, although the best solution is unattainable as the entire input is not processed as a whole, the solution should be provably satisfactory. Let τ be the curve in the stream. The abovementioned software systems only deal with some local error measures between the simplified curve σ and τ. We want to provide guarantees on the size of σ and the global similarity between σ and τ.

A popular similarity measure is the *Fréchet distance* [14]. Let $\rho_\tau : [0,1] \to \mathbb{R}^d$ be a *parameterization* of τ such that, as t increases from 0 to 1, $\rho_\tau(t)$ moves from the beginning of τ to its end without backtracking. It is possible that $\rho_\tau(t) = \rho_\tau(t')$ for two distinct $t, t' \in [0,1]$. We can similarly define a parameterization ρ_σ for σ. These parameterizations induce a *matching* $\mathcal{M}$ between $\rho_\sigma(t)$ and $\rho_\tau(t)$ for all $t \in [0,1]$. A point may have multiple matching partners. The Fréchet distance is $d_F(\sigma,\tau) = \inf_{\mathcal{M}} \max_{t\in[0,1]} d(\rho_\sigma(t), \rho_\tau(t))$. We call a matching that realizes the Fréchet distance a *Fréchet matching*.

We study two problems. The *δ-simplification problem* is to compute, for a given $\delta > 0$, a curve σ of the minimum size (number of vertices) such that $d_F(\sigma,\tau) \le \delta$. The *$k$-simplification problem* is to compute, for a given integer $k \ge 2$, a curve σ of size k that minimizes $d_F(\sigma,\tau)$.

Given a polygonal curve $\tau = (v_1, v_2, \ldots)$, $|\tau|$ denotes its number of vertices, and for any $i < j$, $\tau[v_i, v_j]$ denotes the subcurve $(v_i, v_{i+1}, \ldots, v_j)$. For a subset $P \subset \mathbb{R}^d$, $d(x,P) = \inf_{p\in P} d(x,p)$. Given two points $x, y \in \mathbb{R}^d$, xy denotes the oriented line segment from x to y.

1.1 Related works

Static δ-simplification. Let $n = |\tau|$. In $\mathbb{R}$, if the vertices of σ are restricted to lie on τ (anywhere), then $|\sigma|$ can be minimized in $O(n)$ time [24]; if the vertices of σ must be a subset of those of τ, it takes $O(n)$ time to compute σ such that $|\sigma|$ is at most two more than the minimum [10]. In $\mathbb{R}$, there is a data structure [25] that, for any given δ, reports a curve σ with the minimum $|\sigma|$ such that the vertices of σ lie on τ (anywhere) and $d_F(\sigma,\tau) \le \delta$. The query time is $O(|\sigma|)$, and the preprocessing time is $O(n)$.

In $\mathbb{R}^2$, a curve σ with minimum $|\sigma|$ such that $d_F(\sigma,\tau) \le \delta$ can be computed in $O(n^2 \log^2 n)$ time [15]. In $\mathbb{R}^d$ for $d \ge 3$, if the vertices of σ must be a subset of those of τ, then $|\sigma|$ can be minimized in $O(n^3)$ time [5, 24, 26]. If there is no restriction on the vertices of σ, it has been recently shown that $|\sigma|$ can be minimized in $O\big((|\sigma|n)^{O(d|\sigma|)}\big)$ time [9].

Faster algorithms have been developed by allowing inexact output. Let $\kappa(\tau, r)$ be the minimum simplified curve size for an error r. In $\mathbb{R}^2$, it was shown [3] that for any $\delta > 0$, a curve σ can computed in $O(n \log n)$ time such that $d_F(\sigma,\tau) \le \delta$ and $|\sigma| \le \kappa(\tau, \delta/2)$. It is possible that $\kappa(\tau,\delta/2) \gg \kappa(\tau,\delta)$. A better control of the curve size has been obtained later. In $\mathbb{R}^d$, it was shown [24] that for any $\varepsilon \in (0,1)$ and $\delta > 0$, a curve σ can be constructed in $O(\varepsilon^{2-2d} n^2 \log n \log\log n)$ time such that $d_F(\sigma,\tau) \le (1+\varepsilon)\delta$ and $|\sigma| \le 2\kappa(\tau,\delta) - 2$.[1] Later, it was shown [8] that for any $\alpha, \varepsilon \in (0,1)$ and $\delta > 0$, a curve σ can be computed in $\tilde{O}\big(n^{O(1/\alpha)} \cdot (d/(\alpha\varepsilon))^{O(d/\alpha)}\big)$ time such that $d_F(\sigma,\tau) \le (1+\varepsilon)\delta$ and $|\sigma| \le (1+\alpha)\cdot\kappa(\tau,\delta)$.

The algorithms above for $d \ge 2$ do not fit the streaming setting [3, 5, 8, 9, 15, 24, 26]. In [3], the simplified curve σ is a subsequence of the vertices in τ, and the vertices of σ are picked from τ in a traversal of τ. Given the last pick v_i, for any $j > i$, whether v_j should

[1] In [24], the first and last vertices of σ are restricted to be the same as those of τ.

be included in σ is determined by examining the subcurve $\tau[v_i, v_j]$. This requires an $O(n)$ working storage which is too large. If the algorithms in [5, 8, 9, 15, 24, 26] are used in the streaming setting, the processing time per vertex would be $O(n)$ or more which is too high.

Static k-simplification. In $\mathbb{R}$, for any given k, the data structure for δ-simplification in [25] can be queried in $O(k)$ time to report a curve σ such that $|\sigma| = k$, the vertices of σ lie on τ (anywhere), and $d_F(\sigma, \tau)$ is minimized. In $\mathbb{R}^d$, if the vertices of σ must be a subset of those of τ, it was shown [14] that a solution σ can be computed in $O(n^4 \log n)$ time such that $d_F(\sigma, \tau) \leq 7 \cdot \min\{d_F(\sigma', \tau) : |\sigma'| \leq k$, no restriction on the vertices of $\sigma'\}$. The factor 7 can be reduced to 4 by a better analysis [3]. Nevertheless, if this algorithm is used in the streaming setting, the vertex processing time would be $O(n^3 \log n)$ or more, which is way too high.

Streaming line simplification. A *line simplification* σ of a stream τ is a subsequence of the vertices such that the first and last vertices of σ are the first and last vertices in the stream so far. In $\mathbb{R}^2$, for any integer $k \geq 2$ and any $\varepsilon \in (0, 1)$, it was shown [1, 2] how to maintain σ such that $|\sigma| \leq 2k$ and $d_F(\sigma, \tau) \leq (4\sqrt{2} + \varepsilon) \cdot \text{opt}_k$, where $\text{opt}_k = \min\{d_F(\sigma', \tau) :$ line simplification σ' of τ, $|\sigma'| \leq k\}$. The working storage is $O(k^2 + k\varepsilon^{-1/2})$. Each vertex is processed in $O(k \log \frac{1}{\varepsilon})$ amortized time. There are also streaming software systems for this problem that minimize some local error measures (e.g. [13, 20, 21, 23]); however, they do not provide any guarantee on the global similarity between τ and the output curve.

Discrete Fréchet distance. The *discrete* Fréchet distance $d_{\text{dF}}(\sigma, \tau)$ is obtained with the restriction that the parameterizations ρ_σ and ρ_τ must match the vertices of σ to those of τ and vice versa. Note that $d_{\text{dF}}(\sigma, \tau) \geq d_F(\sigma, \tau)$ and $d_{\text{dF}}(\sigma, \tau) \gg d_F(\sigma, \tau)$ in the worst case.

There are several results in $\mathbb{R}^3$ [4]. A curve σ with the minimum $|\sigma|$ such that $d_{\text{dF}}(\sigma, \tau) \leq \delta$ can be computed in $O(n \log n)$ time; if the vertices of σ must be a subset of those of τ, the computation time increases to $O(n^2)$. On the other hand, if k is given instead of δ, a curve σ such that $|\sigma| = k$ and $d_{\text{dF}}(\sigma, \tau)$ is minimized can be computed in $O(kn \log n \log(n/k))$ time; if the vertices of σ must a subset of those of τ, the computation time increases to $O(n^3)$.

In $\mathbb{R}^d$, a streaming k-simplification algorithm was proposed in [11] with guarantees on $d_{\text{dF}}(\sigma, \tau)$, where τ is the curve seen in the stream so far. It was shown that for any integer $k \geq 2$ and any $\varepsilon \in (0, 1)$, a curve σ can be computed such that $|\sigma| \leq k$ and $d_{\text{dF}}(\sigma, \tau) \leq 8 \cdot \min\{d_{\text{dF}}(\sigma', \tau) : |\sigma'| \leq k\}$. The working storage is $O(kd)$.

Improved results have been obtained subsequently [12]. For the streaming δ-simplification problem, there is a streaming algorithm in $\mathbb{R}^d$ that, for any $\gamma > 1$, computes a curve σ such that $d_{\text{dF}}(\sigma, \tau) \leq \delta$ and $|\sigma| \leq \kappa(\tau, \delta/\gamma)$. This algorithm relies on a streaming algorithm for maintaining a γ-approximate minimum closing ball (MEB) of points in $\mathbb{R}^d$; the processing time per vertex is asymptotically the same as the γ-approximate MEB streaming algorithm. There are two streaming k-simplification algorithms in [12]. The first one uses $O(\frac{1}{\varepsilon} kd \log \frac{1}{\varepsilon}) + O(\varepsilon)^{-(d+1)/2} \log^2 \frac{1}{\varepsilon}$ working storage and maintains a curve σ such that $|\sigma| \leq k$ and $d_{\text{dF}}(\sigma, \tau) \leq (1 + \varepsilon) \cdot \min\{d_{\text{dF}}(\sigma', \tau) : |\sigma'| \leq k\}$. The second algorithm uses $O(\frac{1}{\varepsilon} kd \log \frac{1}{\varepsilon})$ working storage and maintains a curve σ such that $|\sigma| \leq k$ and $d_{\text{dF}}(\sigma, \tau) \leq (1.22 + \varepsilon) \cdot \min\{d_{\text{dF}}(\sigma', \tau) : |\sigma'| \leq k\}$.

1.2 Our results

We present streaming algorithms for the δ-simplification and k-simplification problems in $\mathbb{R}^d$ for $d \geq 2$ under the Fréchet distance. Let $\tau = (v_1, v_2, \ldots)$ be the input stream.

Streaming δ-simplification. Our algorithm outputs vertices occasionally and maintains some vertices in the working storage. The simplified curve σ for the prefix $\tau[v_1, v_i]$ in the stream so far consists of vertices that have been output and vertices in the working storage. Vertices that have been output cannot be modified, so they form a prefix of all simplified curves to be produced in the future for the rest of the stream.

For any $\varepsilon \in (0, 1)$ and any $\delta > 0$, our algorithm produces a curve σ for the prefix $\tau[v_1, v_i]$ in the stream so far such that $d_F(\sigma, \tau[v_1, v_i]) \leq (1 + \varepsilon)\delta$ and $|\sigma| \leq 2\kappa(\tau[v_1, v_i], \delta) - 2$. Let $\alpha = 2(d-1)\lfloor d/2 \rfloor^2 + d$. The working storage is $O(\varepsilon^{-\alpha})$. Each vertex in the stream is processed in $O(\varepsilon^{-\alpha} \log \frac{1}{\varepsilon})$ time for $d \in \{2, 3\}$ and $O(\varepsilon^{-\alpha})$ time for $d \geq 4$. If our algorithm is used in the static case, the running time on a curve of size n is $O(\varepsilon^{-\alpha} n \log \frac{1}{\varepsilon})$. Ignoring polynomial factors in $1/\varepsilon$, our time bound is a factor n smaller than the $O(\varepsilon^{2-2d} n^2 \log n \log \log n)$ running time of the best static algorithm that achieves the same error and size bounds [24].

Intuitively, our streaming algorithm finds a line segment that stabs as many balls as possible that are centered at consecutive vertices of τ with radii $(1 + O(\varepsilon))\delta$. If such a line segment ceases to exist upon the arrival of a new vertex, we start a new line segment. Concatenating these segments forms the simplified curve. For efficiency, we approximate each ball by covering it with grid cells of $O(\varepsilon\delta)$ width. In [24], vertex balls and their covers by grid cells of $O(\varepsilon\delta)$ width are also used. Connections between all pairs of balls are computed to create a graph such that the simplified curve corresponds to a shortest path in the graph. In contrast, we maintain some geometric structures so that we can read off the next line segment from them. We prove an $O(\varepsilon^{-\alpha})$ bound on the total size of these structures, which yields the desired working storage and processing time per vertex.

Streaming k-simplification. A memory budget may cap the size of the simplified curve, motivating the streaming k-simplification problem. For example, in some wildlife tracking applications, the location-acquisition device is not readily accessible after deployment, and data is only offloaded from it after an extended period [19].

Our algorithm maintains the simplified curve σ in the working storage for the prefix $\tau[v_1, v_i]$ in the stream so far. For any $k \geq 2$ and any $\varepsilon \in (0, \frac{1}{17})$, our algorithm guarantees that $|\sigma| \leq 2k - 2$ and $d_F(\sigma, \tau[v_1, v_i]) \leq (1 + \varepsilon) \cdot \min\{d_F(\sigma', \tau[v_1, v_i]) : |\sigma'| \leq k\}$. Recall that $\alpha = 2(d-1)\lfloor d/2 \rfloor^2 + d$. The working storage is $O((k\varepsilon^{-1} + \varepsilon^{-(\alpha+1)}) \log \frac{1}{\varepsilon})$. Each vertex in the stream is processed in $O(k\varepsilon^{-(\alpha+1)} \log^2 \frac{1}{\varepsilon})$ time for $d \in \{2, 3\}$ and $O(k\varepsilon^{-(\alpha+1)} \log \frac{1}{\varepsilon})$ time for $d \geq 4$. We first simplify as in the case of δ-simplification. When the simplified curve reaches a size of $2k - 1$, the key idea is to run our δ-simplification algorithm with a suitable error tolerance to bring its size down to $2k - 2$.

There is only one prior streaming k-simplification algorithm [1, 2]. It works in $\mathbb{R}^2$. It restricts the vertices of the simplified curve σ to be a subset of those of τ, whereas our algorithm does not. It uses $O(k^2 + k\varepsilon^{-1/2})$ working storage, processes each vertex in $O(k \log \frac{1}{\varepsilon})$ amortized time, and guarantees that $|\sigma| \leq 2k$ and $d_F(\sigma, \tau) \leq (4\sqrt{2} + \varepsilon) \cdot \text{optimum}$ under the requirement that the vertices of σ must be a subset of those of τ. For $d = 2$, our algorithm uses $O((k\varepsilon^{-1} + \varepsilon^{-5}) \log \frac{1}{\varepsilon})$ working storage, processes each vertex in $O(k\varepsilon^{-5} \log^2 \frac{1}{\varepsilon})$ worst-case time, and guarantees that $|\sigma| \leq 2k - 2$ and $d_F(\sigma, \tau) \leq (1 + \varepsilon) \cdot \text{optimum}$. Ignoring the restriction on the vertices of σ, we offer a better approximation ratio for $d_F(\sigma, \tau)$. Although our vertex processing time bound is larger, it is worst-case instead of amortized. The comparison between working storage depends on the relative magnitudes of k and $1/\varepsilon$.

2 Streaming δ-simplification

Given a subset $X \subseteq \mathbb{R}^d$, we use $\text{conv}(X)$ to denote the convex hull of X. For any point $x \in \mathbb{R}^d$, let B_x denote the d-ball centered at x with radius δ. Consider the infinite d-dimenisonal grid with x as a grid vertex and side length $\varepsilon\delta/(2\sqrt{d})$. Let G_x be the subset of grid cells that intersect the ball centered at x with radius $(1+\varepsilon/2)\delta$. We say that an oriented line segment s *stabs the objects* $O_1, \ldots, O_m$ *in order* if there exist points $x_i \in s \cap O_i$ for $i \in [m]$ such that $x_1, \ldots, x_m$ appear in this order along s [15].

2.1 Algorithm

The high-level idea is to find the longest sequence $v_1, v_2, \ldots, v_i$ of vertices such that there is a segment s_1 that stabs B_{v_a} for $a \in [i]$ in order. Then, restart to find the longest sequence $v_{i+1}, \ldots, v_j$ such that there is a segment s_2 that stabs B_{v_a} for $a \in [i+1, j]$ in order. Repeating this way gives a sequence of segments $s_1, s_2, \ldots$. Concatenating these segments gives the simplified curve. The problem is the large working storage: a long vertex sequence may be needed to determine a line segment. We use several ideas to overcome this problem.

First, we approximate B_{v_a} by $\text{conv}(G_{v_a})$ and find a line segment that stabs the longest sequence $\text{conv}(G_{v_1}), \ldots, \text{conv}(G_{v_i})$ in order. We will show that it suffices for this line segment to start from the set P of grid points in G_{v_1}. So $|P| = O(\varepsilon^{-d})$.

Second, as the vertices arrive in the stream, for each point $p \in P$, we construct a structure $S_a[p]$ inductively as follows:

- Set $S_1[p] = \{p\}$ for all $p \in P$. We write $S_1[p] = p$ for convenience.
- For all $a \geq 1$, set $S_{a+1}[p] = \text{conv}(G_{v_{a+1}}) \cap F(S_a[p], p)$ for all $p \in P$, where $F(S_a[p], p) = \{y \in \mathbb{R}^d : py \cap S_a[p] \neq \emptyset\}$.

If $p \in S_a[p]$, then $F(S_a[p], p) = \mathbb{R}^d$ and hence $S_{a+1}[p] = \text{conv}(G_{v_{a+1}})$. If $S_a[p] = \emptyset$, then $F(S_a[p], p) = \emptyset$ and hence $S_{a+1}[p] = \emptyset$. Otherwise, by viewing p as a light source, $F(S_a[p], p)$ is the unbounded convex polytope consisting of $S_a[p]$ and the non-illuminated subset of $\mathbb{R}^d$.

We will show that for $a \geq 2$, $S_a[p]$ is equal to $\{x \in \text{conv}(G_{v_a}) : px$ stabs $\text{conv}(G_{v_1}), \ldots, \text{conv}(G_{v_a})$ in order$\}$. We will also show that for each $p \in P$, $S_a[p]$ and $F(S_a[p], p)$ have $\text{poly}(1/\varepsilon)$ complexities, and they can be constructed in $\text{poly}(1/\varepsilon)$ time. The array S_a is deleted after computing S_{a+1}, which keeps the working storage small.

We pause when we encounter a vertex v_{i+1} such that $S_{i+1}[p] = \emptyset$ for all $p \in P$. We choose any vertex q of any non-empty $S_i[p]$ (which must exist) and output the segment pq. Since pq stabs $\text{conv}(G_{v_1}), \ldots, \text{conv}(G_{v_i})$ in order, we can show that $d_F(pq, \tau[v_1, v_i]) \leq (1+\varepsilon)\delta$. All is well except that S_i has been deleted after computing S_{i+1}. A fix is that after processing a vertex v_a, we store a segment pq in a buffer $\tilde{\sigma}$ for an arbitrary vertex q of an arbitrary non-empty $S_a[p]$. We output the content of $\tilde{\sigma}$ after discovering that $S_{i+1}[p] = \emptyset$ for all $p \in P$.

Afterward, we reset P as the set of grid points in $G_{v_{i+1}}$ and restart the above processing from v_{i+1}. That is, reset $S_{i+1}[p] = p$ for all $p \in P$. One of the points in P will be the start of the next segment that will be output in the future. The start of this next segment may be far from $\text{conv}(G_{v_i})$, which contains the end of $\tilde{\sigma}$ that was just output. For $a = i+1, i+2, \ldots$, we set $S_{a+1}[p] = \text{conv}(G_{v_{a+1}}) \cap F(S_a[p], p)$ for all $p \in P$ until $S_a[p]$ becomes empty for all $p \in P$ again. In summary, the simplified curve σ is the concatenation of the output segments $s_1, s_2, \ldots$, i.e., the end of s_j is connected to the start of s_{j+1}. Figure 1 illustrates a few steps of this algorithm. The procedure Simplify(ε, δ) in Algorithm 1 gives the details.

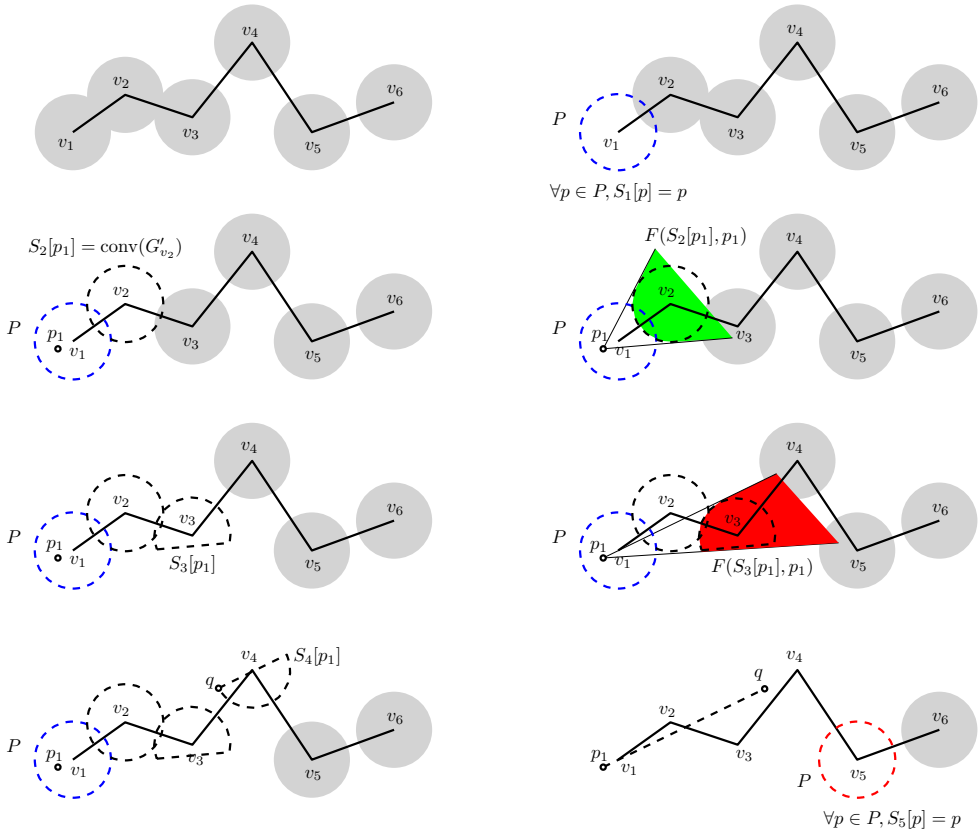

Figure 1 The shaded balls denote the $\mathrm{conv}(G_{v_a})$'s. The vertices arrive in order (from left to right and top to bottom). The first P consists of the grid points inside the blue dashed ball. Let p_1 be a grid point in P. $F(S_2[p_1], p_1)$ is the green unbounded convex region that is bounded by the tangents from p_1 to $S_2[p_1]$. $S_3[p_1] = \mathrm{conv}(G_{v_3}) \cap F(S_2[p_1], p_1)$ is denoted by the dashed clipped ball around v_3. Similarly, $F(S_3[p_1], p_1)$ is the red unbounded convex region that is bounded by the tangents from p_1 to $S_3[p_1]$. $S_4[p_1]$ is denoted by the dashed clipped ball around v_4. In this example, $S_5[p] = \emptyset$ for all $p \in P$, so we output $\tilde{\sigma}$ which may be equal to (p_1, q) for a vertex q of $S_4[p_1]$. We reset P as the set of grid points in G_{v_5} (inside the red dashed ball) and reset $S_5[p] = p$ for all $p \in P$.

2.2 Analysis

Given a polytope $Q \subset \mathbb{R}^d$, let $|Q|$ denote its complexity, i.e., the total number of its faces of all dimensions.

▶ **Lemma 1.** *Let P be the set of grid points in G_{v_i}. Assume that $S_i[p] = p$ for all $p \in P$. Take any $p \in P$ and any index $j \geq i+1$ such that $S_a[p] \neq \emptyset$ for all $a \in [i, j-1]$.*

(i) *$S_j[p] = \{x \in \mathrm{conv}(G_{v_j}) : px$ stabs $\mathrm{conv}(G_{v_i}), \ldots, \mathrm{conv}(G_{v_j})$ in order$\}$.*

(ii) *$S_j[p]$ is a convex polytope that can be computed in $O\big(|S_{j-1}[p]| + N \log N + N^{\lfloor d/2 \rfloor}\big)$ time, where N is any upper bound on the number of support hyperplanes of $F(S_{j-1}[p], p)$ such that $N = \Omega(\varepsilon^{(1-d)\lfloor d/2 \rfloor})$.*

▶ **Lemma 2.** *Let $\tau[v_1, v_i]$ be the prefix in the stream so far. The simplified curve σ satisfies the properties that $d_F(\sigma, \tau[v_1, v_i]) \leq (1+\varepsilon)\delta$ and $|\sigma| \leq 2\kappa(\tau[v_1, v_i], \delta) - 2$.*

▶ **Theorem 3.** *Let τ be a polygonal curve in $\mathbb{R}^d$ that arrives in a data stream. Let $\alpha = 2(d-1)\lfloor d/2 \rfloor^2 + d$. For every $\delta > 0$ and every $\varepsilon \in (0,1)$, the output curve σ of* Simplify(ε, δ) *satisfies $d_F(\sigma, \tau) \leq (1+\varepsilon)\delta$ and $|\sigma| \leq 2\kappa(\tau, \delta) - 2$. The working storage is $O(\varepsilon^{-\alpha})$. Each vertex is processed in $O(\varepsilon^{-\alpha} \log \frac{1}{\varepsilon})$ time for $d \in \{2, 3\}$ and $O(\varepsilon^{-\alpha})$ time for $d \geq 4$.*

Algorithm 1 SIMPLIFY.

Input: A stream $\tau = (v_1, v_2, \ldots)$, ε, and δ.

Output: The output curve σ consists of the sequence of vertices output so far and the vertices in the buffer $\tilde{\sigma}$. After processing the last vertex v_i at the end of the stream, SIMPIFY returns (P, S_i), which will be useful for the k-simplification problem.

function SIMPLIFY(ε, δ)
  read v_1 from the data stream; $i \leftarrow 1$; *init* $\leftarrow$ true; $\tilde{\sigma} \leftarrow \emptyset$
  while true do
    if *init* = true **then**
      init $\leftarrow$ false
      output the vertices in $\tilde{\sigma}$ ▷ output the line segment in $\tilde{\sigma}$
      $\tilde{\sigma} \leftarrow (v_i)$ ▷ view v_i as a degenerate line segment
      $P \leftarrow$ the grid points of G_{v_i}
      $S_i[p] \leftarrow p$ for all $p \in P$
    else
      choose a vertex q of some non-empty $S_i[p]$
      $\tilde{\sigma} \leftarrow (p, q)$ ▷ update the last edge of the simplified curve
    end if
    if end of data stream **then**
      output $\tilde{\sigma}$
      return (P, S_i) ▷ will be useful for k-simplification
    else
      read v_{i+1} from the data stream
    end if
    $S_{i+1}[p] \leftarrow \mathrm{conv}(G_{v_{i+1}}) \cap F(S_i[p], p)$ for all $p \in P$
    delete S_i
    init $\leftarrow$ true if $S_{i+1}[p] = \emptyset$ for all $p \in P$
    $i \leftarrow i + 1$
  end while
end function

Proof. The guarantees on σ follow from Lemma 2. We will bound the number of support hyperplanes and complexities of $S_j[p]$ and $F(S_{j-1}[p], p)$. The working storage and processing time then follow from Lemma 1(ii) and the fact that $|P| = O(\varepsilon^{-d})$.

A *bounding halfspace* of a convex polytope O is a halfspace that contains O and is bounded by the support hyperplane of a facet of O. We count the bounding halfspaces of $S_j[p]$. Some are bounding halfspaces of $F(S_{j-1}[p], p)$ whose boundaries pass through p and are tangent to $S_{j-1}[p]$. We call them the *pivot* bounding halfspaces. The remaining ones are bounding halfspaces of $\mathrm{conv}(G_{v_a})$ for some $a \le j$. We call these *non-pivot* bounding halfspaces.

Since $\mathrm{conv}(G_{v_a})$'s are translates of each other, their facets share a set V of unit outward normals. We have $|V| \le |\mathrm{conv}(G_{v_a})| = O(\varepsilon^{(1-d)\lfloor d/2 \rfloor})$. No two facets of $S_j[p]$ have the same vector in V because the two corresponding bounding halfspaces would be identical or nested – neither is possible. This feature helps us to prevent a cascading growth in the complexities of $S_j[p]$ in the inductive construction.

Take a pivot bounding halfspace h of $S_j[p]$. Suppose that h was introduced for the first time as a bounding halfspace of $S_i[p]$ for some $i \le j$. The boundary of h, denoted by ∂h, passes through p and is tangent to $S_{i-1}[p]$ at a $(d-2)$-dimensional face f of $S_{i-1}[p]$. Let

g_1 and g_2 be the bounding halfspaces of $S_{i-1}[p]$ whose boundaries contain the two facets of $S_{i-1}[p]$ incident to f. We make three observations. First, $F(S_{i-1}[p], p)$ lies inside the cone C_i of rays that shoot from p towards $S_{i-1}[p]$. Second, h is a bounding halfspace of C_i. Third, $S_a[p] \subseteq C_i$ for all $a \in [i, j]$.

We claim that neither ∂g_1 nor ∂g_2 passes through p. Neither g_1 nor g_2 is equal to h because h was not introduced before $S_i[p]$. If both ∂g_1 and ∂g_2 pass through p, then f spans a $(d-2)$-dimensional affine subspace ℓ that passes through p. But then ∂h meets C_i at ℓ only, which is a contradiction because ∂h should support a facet of $S_j[p]$. If either ∂g_1 or ∂g_2 passes through p, say ∂g_2, then the affine subspace spanned by f does not pass through p. But then p and f span a unique hyperplane, giving the contradiction that $g_2 = h$.

By our claim, g_1 and g_2 are non-pivot bounding halfspaces of $S_{i-1}[p]$. We charge h to (ϕ_1, ϕ_2) or (ϕ_2, ϕ_1), where ϕ_1 and ϕ_2 are the outward unit normals of g_1 and g_2, respectively. The pair (ϕ_1, ϕ_2) is charged if a ray that shoots from p to an interior point of $g_1 \cap g_2$ arbitrarily near $\partial g_1 \cap \partial g_2$ hits ∂g_1 before ∂g_2. Otherwise, the pair (ϕ_2, ϕ_1) is charged. Suppose that h is charged to (ϕ_1, ϕ_2). We argue that (ϕ_1, ϕ_2) is not charged again at some $(d-2)$-dimensional face of $S_a[p]$ for all $a \in [i, j-1]$ due to another pivot bounding halfspace of $S_j[p]$.

Assume to the contrary that (ϕ_1, ϕ_2) is charged again at some $(d-2)$-dimensional face of $S_b[p]$ for some $b \in [i, j-1]$ due to a pivot bounding halfspace h' of $S_j[p]$. Either the dimension of $\partial h' \cap C_i$ is zero or one, or the dimension of $\partial h' \cap C_i$ is two. In the first case, $\partial h'$ cannot support any facet of $S_j[p]$, a contradiction. In the second case, since h' is charged to the same ordered pair (ϕ_1, ϕ_2), $\partial h'$ must separate $S_b[p]$ from ∂h. Therefore, the cone of rays C_b that shoot from p towards $S_b[p]$ meets ∂h only at p. However, $S_j[p] \subseteq C_b$, which means that ∂h cannot support any facet of $S_j[p]$, a contradiction.

In all, $S_j[p]$ has $O(\varepsilon^{(1-d)\lfloor d/2 \rfloor})$ non-pivot bounding halfspaces and at most $|V|(|V|-1) = O(\varepsilon^{2(1-d)\lfloor d/2 \rfloor})$ pivot bounding halfspaces. The same bounds hold for $S_{j-1}[p]$. If a support hyperplane L of $F(S_{j-1}[p], p)$ is not a support hyperplane of $S_{j-1}[p]$, then L passes through p and is tangent to $S_{j-1}[p]$ at some $(d-2)$-dimensional face f. Since L is different from the support hyperplanes of the two facets of $S_{j-1}[p]$ incident to f, these two hyperplanes do not pass through p. So the two facets incident to f induce some non-pivot bounding halfspaces of $S_{j-1}[p]$, implying that $F(S_{j-1}[p], p)$ has $O(\varepsilon^{2(1-d)\lfloor d/2 \rfloor})$ bounding halfspaces. It follows that $\left|S_j[p]\right|$ and $\left|F(S_{j-1}[p], p)\right|$ are $O(\varepsilon^{2(1-d)\lfloor d/2 \rfloor^2})$. ◀

3 Streaming algorithm for the k-simplification problem

3.1 Algorithm

Let σ_i^* be the optimal solution for the k-simplification problem for $\tau[v_1, v_i]$. If we knew $\delta_i^* = d_F(\sigma_i^*, \tau[v_1, v_i])$, we could call Simplify$(\varepsilon, \delta_i^*)$ to obtain an approximate solution for the k-simplification problem. Therefore, we try to estimate δ_i^* on the fly.

We maintain an output simplified curve σ_i in the working storage after processing every vertex v_i in the stream. The first simplified curve σ_{2k-1} is obtained by calling Simplify, via an invocation of a new procedure Compress, on $\tau[v_1, v_{2k-1}]$ with δ equal to some value δ_{2k-1}. Given a curve of size $2k-1$, Compress simplifies it to a curve of size at most $2k-2$.

For $i \geq 2k$, when a vertex v_i arrives in the stream, we either update the last edge of σ_{i-1} to produce σ_i as in Simplify, or start a new segment (initially just the vertex v_i) as in Simplify. Suppose that we start new segment. If $|\sigma_{i-1}| < 2k-2$, we can append v_i to σ_{i-1} to form σ_i. Otherwise, σ_i is obtained by calling Simplify, via an invocation of Compress, on $\sigma_{i-1} \circ (v_i)$ with δ equal to some value δ_i to be specified later. We will prove in Lemmas 4–8 that $\delta_i \leq (1 + O(\varepsilon))\delta_i^*$. Afterward, we repeat the above to process the next vertex in the stream. The above processing is elaborated in Reduce in Algorithm 2.

We define a curve τ_i for every $i \geq 2k-1$ in the comments in lines 6, 11, and 22. These curves facilitate the analysis, but they are not maintained by the algorithm as variables. For each i, τ_i is the curve from which the simplification σ_i is computed. Therefore, $\tau_{2k-1} = \tau[v_1, v_{2k-1}]$ (line 6). Consider any $i \geq 2k$. If we call Compress to simplify $\sigma_{i-1} \circ (v_i)$ to a curve σ_i of size at most $2k-2$, we set $\tau_i = \sigma_{i-1} \circ (v_i)$ (line 22). Otherwise, σ_i is obtained by simplifying $\tau_{i-1} \circ (v_i)$ whether we start a new segment at v_i or not, so $\tau_i = \tau_{i-1} \circ (v_i)$ (line 11).

The input parameter r of Reduce needs an explanation. We will show how to compute a lower bound $\delta_{\min} > 0$ for $d_F(\sigma^*_{2k-1}, \tau[v_1, v_{2k-1}])$. For $i \geq 2k-1$, let $r_i \geq 1$ and $s_i \geq 0$ be integers such that

$$\frac{1}{\varepsilon^{s_i}}\delta_{\min} \leq \frac{(1+\varepsilon)^{r_i-1}}{\varepsilon^{s_i}}\delta_{\min} \leq \delta^*_i \leq \frac{(1+\varepsilon)^{r_i}}{\varepsilon^{s_i}}\delta_{\min} \leq \frac{1}{\varepsilon^{s_i+1}}\delta_{\min}.$$

We will show that if we can start the processing of the data stream with an initial error tolerance of $\delta_{2k-2} = \varepsilon(1+\varepsilon)^{r_i+1}(1-4\varepsilon)^{-1}\delta_{\min}$, then the output curve σ_i will be within a Fréchet distance of $\varepsilon^{-s_i}(1+\varepsilon)^{r_i+1}(1-4\varepsilon)^{-1}\delta_{\min}$ from $\tau[v_1, v_i]$. By the definitions of r_i and s_i, the error is at most $(1+O(\varepsilon))\delta^*_i$. The correct values of r_i and s_i are unknown to us. Nevertheless, no matter what s_i is, we have $1 \leq r_i \leq \lfloor \log_{1+\varepsilon} \frac{1}{\varepsilon} \rfloor$. We launch $\lfloor \log_{1+\varepsilon} \frac{1}{\varepsilon} \rfloor = O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ independent runs of Reduce for each r between 1 and $\lfloor \log_{1+\varepsilon} \frac{1}{\varepsilon} \rfloor$. After processing the arriving vertex v_i, the run with the minimum δ_i gives the right answer. This idea of using multiple independent runs to capture the right δ was proposed in [12] for streaming k-simplification under the discrete Fréchet distance. We still have to obtain s_i. This is achieved by establishing a lower bound for δ^*_i (Lemma 5) and computing a particular upper bound for δ^*_i in line 2 of Compress.

We assume that no three consecutive vertices in the stream are collinear. We enforce it using $O(1)$ more working storage as follows. Remember the last two vertices (x, y) in the stream, but do not feed y to Reduce yet. Wait until the next vertex z arrives. If x, y and z are not colinear, feed y to Reduce and remember (y, z) as the last two vertices. If x, y and z are collinear, then drop y, make (x, z) the last two vertices, and wait for the next vertex.

Algorithm 3 shows the procedure Compress. If Compress is called when processing v_i, its task is to simplify $\tau_i = \sigma_{i-1} \circ (v_i)$ to a curve σ_i of size at most $2k-2$ with error estimate $\delta_i = \varepsilon^{-t}\delta_{i-1}$, where t is some judiciously chosen positive integer.

3.2 Analysis

Lemma 4 below gives a lower bound for the Fréchet distance between a curve of size m and another curve of size n such that $m \geq 2n-1$. An application of this result shows that $\delta_{\min}$ computed in line 4 of Reduce is a lower bound for $d_F(\sigma^*_{2k-1}, \tau[v_1, v_{2k-1}])$ as $|\sigma^*_{2k-1}| = k$.

▶ **Lemma 4.** *Let $\xi = (p_1, \ldots, p_m)$ and $\zeta = (q_1, \ldots, q_n)$ be any two curves such that $m \geq 2n-1$. Then, $d_F(\xi, \zeta) \geq \frac{1}{2}\min\{d(p_i, p_{i-1}p_{i+1}) : i \in [2, m-1]\}$.*

Lemma 5 below shows that a curve $(p_1, \ldots, p_{2k-1})$ can be simplified to a curve of size at most $2k-2$ using an error tolerance of $\frac{1}{2}\min\{d(p_j, p_{j-1}p_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\}$. By Lemma 5, Compress always returns a curve of size at most $2k-2$.

▶ **Lemma 5.** *Let $\xi = (p_1, \ldots, p_{2k-1})$. Assume no three consecutive vertices are collinear. Let $\hat{\delta}$ be the minimum value such that calling* Simplify$(\varepsilon, \hat{\delta})$ *on ξ produces a curve of size at most $2k-2$. Then,*

$$\hat{\delta} \leq \frac{1}{2}\min\{d(p_j, p_{j-1}p_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\} \leq (1+\varepsilon)\hat{\delta}.$$

Algorithm 2 REDUCE.

Input: A data stream $\tau = (v_1, v_2, \ldots)$ and three parameters r, ε, and k.
Output: Let $\tau[v_1, v_i]$ be the prefix in the stream so far. A curve σ_i is maintained such that $|\sigma_i| \leq 2k-2$ and $d_F(\sigma_i, \tau[v_1, v_i]) \leq (1+\varepsilon)\delta_i$.

procedure REDUCE(r, ε, k)
  read the first $2k-1$ vertices $v_1, \ldots, v_{2k-1}$ of τ
  ▷ no three consecutive vertices are collinear
  $\delta_{\min} \leftarrow \frac{1}{2}\min\{d(v_i, v_{i-1}v_{i+1}) : i \in [2, 2k-2]\}$
  $\delta_{2k-2} \leftarrow \varepsilon(1+\varepsilon)^{r+1}(1-4\varepsilon)^{-1}\delta_{\min}$
  $\sigma_{2k-2} \leftarrow \tau[v_1, v_{2k-2}]$ ▷ $\tau_{2k-1} \leftarrow \tau[v_1, v_{2k-1}]$
  $(\sigma_{2k-1}, \delta_{2k-1}, P, S_{2k-1}) \leftarrow$ COMPRESS$(\tau[v_1, v_{2k-1}], \varepsilon, k, \delta_{2k-2})$
  $i \leftarrow 2k$
  while true do
    read v_i from the data stream
    $\delta_i \leftarrow \delta_{i-1}$ ▷ $\tau_i \leftarrow \tau_{i-1} \circ (v_i)$
    $S_i[p] \leftarrow \mathrm{conv}(G_{v_i}) \cap F(S_{i-1}[p], p)$ for all $p \in P$, where G_{v_i} is defined with $\delta = \delta_i$
    if $S_i[p] \neq$ null for some $p \in P$ **then**
      ▷ update the last possibly degenerate segment as in SIMPLIFY
      $q \leftarrow$ any vertex of $S_i[p]$
      $\sigma_i \leftarrow \sigma_{i-1}$ with the last segment replaced by pq
    else if $|\sigma_{i-1}| < 2k-2$ **then** ▷ start a new segment as in SIMPLIFY
      $P \leftarrow$ the grid points of G_{v_i} ▷ G_{v_i} is defined with $\delta = \delta_i$
      $S_i[p] \leftarrow p$ for all $p \in P$
      $\sigma_i \leftarrow \sigma_{i-1} \circ (v_i)$ ▷ treat v_i as a degenerate segment
    else ▷ simplify $\sigma_{i-1} \circ (v_i)$ to produce σ_i
      $(\sigma_i, \delta_i, P, S_i) \leftarrow$ COMPRESS$(\sigma_{i-1} \circ (v_i), \varepsilon, k, \delta_{i-1})$ ▷ $\tau_i = \sigma_{i-1} \circ (v_i)$
    end if
    delete σ_{i-1}, δ_{i-1}, and S_{i-1}
    $i \leftarrow i+1$
  end while
end procedure

Algorithm 3 COMPRESS.

Input: A polygonal curve $(x_1, \ldots, x_{2k-1})$ and three parameters ε, k, and δ.
Output: $(\zeta, \varepsilon^{-t}\delta, P, S)$, where ζ is the output curve of calling SIMPLIFY$(\varepsilon, \varepsilon^{-t}\delta)$ on $(x_1, \ldots, x_{2k-1})$ for some $t \in \mathbb{N}$, and (P, S) are the output returned by SIMPLIFY after processing x_{2k-1}.

function COMPRESS$((x_1, \ldots, x_{2k-1}), \varepsilon, k, \delta)$
  $t \leftarrow \min\left\{i \in \mathbb{N} : i \geq 1, \varepsilon^{-i}\delta \geq \frac{1}{2}\min\{d(x_j, x_{j-1}x_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\}\right\}$
  $\zeta \leftarrow$ output curve produced by calling SIMPLIFY$(\varepsilon, \varepsilon^{-t}\delta)$ on $(x_1, \ldots, x_{2k-1})$
  $(P, S) \leftarrow$ output returned by the above call of SIMPLIFY after processing x_{2k-1}
  return $(\zeta, \varepsilon^{-t}\delta, P, S)$
end function

Proof. Consider the run of SIMPLIFY$(\varepsilon, \hat{\delta})$ on ξ. Let $p_{i_1}, p_{i_2} \ldots$ be the vertices in order along ξ at which SIMPLIFY starts a new segment. Note that $i_1 = 1$ and $i_{j+1} \geq i_j + 2$ for all j.

SIMPLIFY replaces each subcurve $\xi[p_{i_j}, p_{i_{j+1}-1}]$ by a segment. The simplified curve is a concatenation of these segments. Since $|\xi| = 2k-1$, there must be an index j such that $i_{j+1} > i_j + 2$ so that SIMPLIFY$(\varepsilon, \hat{\delta})$ simplifies ξ to a curve of size at most $2k-2$. Let $b = \min\{j : i_{j+1} > i_j + 2\}$. Because $i_1 = 1$ and $i_{j+1} = i_j + 2$ for all $j \in [b-1]$, we know that i_j is odd for every $j \in [b]$ and $i_b + 1$ is even. It follows from the choice of b that SIMPLIFY does not start a new segment at p_{i_b+2}. By the working of SIMPLIFY$(\varepsilon, \hat{\delta})$, there is a grid point p in $G_{p_{i_b}}$ (defined with $\delta = \hat{\delta}$) such that $S_{i_b+2}[p] \neq \emptyset$. By the reasoning in the proof of Lemma 2, for any point $x \in S_{i_b+2}[p]$, $d_F(px, \xi[p_{i_b}, p_{i_b+2}]) \leq (1+\varepsilon)\hat{\delta}$. On the other hand, by Lemma 4, $d_F(px, \xi[p_{i_b}, p_{i_b+2}]) \geq \frac{1}{2} d(p_{i_b+1}, p_{i_b} p_{i_b+2})$. Hence, $(1+\varepsilon)\hat{\delta} \geq \frac{1}{2} d(p_{i_b+1}, p_{i_b} p_{i_b+2}) \geq \frac{1}{2} \min\{d(p_j, p_{j-1}p_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\}$.

It remains to argue that $\hat{\delta} \leq \frac{1}{2} \min\{d(p_j, p_{j-1}p_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\}$. Let $\delta = \frac{1}{2} \min\{d(p_j, p_{j-1}p_{j+1}) : j \in [2, 2k-2], j \text{ is even}\}$. It suffices to show that calling SIMPLIFY(ε, δ) on ξ returns a curve of size at most $2k-2$. Let $p_{a_1}, p_{a_2}, \ldots$ be the vertices in order along ξ at which SIMPLIFY(ε, δ) starts a new segment. Let c be the even number in $[2, 2k-2]$ such that $d(p_c, p_{c-1}p_{c+1}) = \min\{d(p_j, p_{j-1}p_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\}$.

Suppose that there is an index j that satisfies $a_j \leq c-1$ and $a_{j+1} > a_j + 2$. Since $\xi[p_{a_j}, p_{a_{j+1}-1}]$ is simplified to a line segment, the prefix $\xi[p_1, p_{a_{j+1}-1}]$ is simplified to a curve of size at most $a_{j+1} - 2$, i.e., at least one vertex less. We are done because the size of the whole simplified curve must be at most $2k-2$.

The remaining possibility is that $a_{j+1} = a_j + 2$ for all $a_j \in [c-1]$. Since $a_1 = 1$ and c is even, we have $a_1 = 1, a_2 = 3, a_3 = 5, \ldots, a_j = c-1$. It follows that SIMPLIFY starts a new segment at p_{c-1}. Let $r = d(p_c, p_{c-1}p_{c+1})$.

We claim that there is a line segment xy such that $d_F(xy, \xi[p_{c-1}, p_{c+1}]) \leq r/2$. Let z be the nearest point in $p_{c-1}p_{c+1}$ to p_c. So zp_c has length r. Let z' be the midpoint of zp_c. Translate $p_{c-1}p_{c+1}$ by the vector $z' - z$ to obtain a segment xy. Observe that $z' \in xy$ and $d(x, p_{c-1}) = d(y, p_{c+1}) = d_F(z', p_c) = r/2$. By linear interpolations between xz' and $p_{c-1}p_c$ and between $z'y$ and $p_c p_{c+1}$, we have $d_F(xy, \xi[p_{c-1}, p_{c+1}]) \leq r/2$, establishing our claim.

By the choice of c, $\frac{1}{2}r = \frac{1}{2} d(p_c, p_{c-1}c_{c+1}) = \delta$. Then, our claim implies that xy stabs balls of radii δ centered at p_{c-1}, p_c, p_{c+1} in order. There is a grid point p' in $G_{p_{c-1}}$ (defined using δ) within a distance $\varepsilon\delta/2$ from x. By a linear interpolation between $p'y$ and xy, we know that $p'y$ stabs $\text{conv}(G_{p_{c-1}}), \text{conv}(G_{p_c}), \text{conv}(G_{p_{c+1}})$ in order. Therefore, $S_{c+1}[p'] \neq \emptyset$ by Lemma 1(i), implying that SIMPLIFY does not start a new segment at p_{c+1}. Hence, SIMPLIFY replaces a subcurve $\xi[p_{c-1}, p_e]$ for some $e \geq c+1$ by a segment and produces a curve of size at most $2k-2$. This proves that $\delta \geq \hat{\delta}$. ◀

Recall the curves τ_i for $i \geq 2k-1$ defined in the comments in lines 6, 11, and 22. The next result follows immediately from the working of REDUCE.

▶ **Lemma 6.** *For $i \geq 2k-1$, σ_i computed by* REDUCE *can also be produced by calling* SIMPLIFY(ε, δ_i) *on τ_i.*

▶ **Lemma 7.** *Assume that $\varepsilon \in (0, 1/3]$. For $i \geq 2k-1$, $d_F(\tau_i, \tau[v_1, v_i]) \leq 2\varepsilon\delta_i$.*

Recall that σ_i^* is the curve of size k at minimum Fréchet distance from $\tau[v_1, v_i]$ and that $\delta_i^* = d_F(\sigma_i^*, \tau[v_1, v_i])$. Also, recall that for $i \geq 2k-1$, $r_i \geq 1$ and $s_i \geq 0$ are integers that satisfy the following inequalities:

$$\frac{1}{\varepsilon^{s_i}}\delta_{\min} \leq \frac{(1+\varepsilon)^{r_i-1}}{\varepsilon^{s_i}}\delta_{\min} \leq \delta_i^* \leq \frac{(1+\varepsilon)^{r_i}}{\varepsilon^{s_i}}\delta_{\min} \leq \frac{1}{\varepsilon^{s_i+1}}\delta_{\min}. \tag{1}$$

By Lemma 4, $\delta_{\min} \le \delta^*_{2k-1}$. Also, $\delta^*_a \le \delta^*_b$ for all $a < b$ because a Fréchet matching between σ^*_b and $\tau[v_1, v_b]$ also matches $\tau[v_1, v_a]$ to a curve of size at most k. Therefore, $\delta_{\min} \le \delta^*_i$ for $i \ge 2k-1$, which implies that r_i and s_i are well defined for $i \ge 2k-1$. Note that r_i is an integer between 1 and $\lfloor \log_{1+\varepsilon}(1/\varepsilon) \rfloor$.

▶ **Lemma 8.** *For all $i \ge 2k-1$ and $\varepsilon \in \big(0, \frac{1}{17}\big)$, $\textsc{Reduce}(r_i, \varepsilon, k)$ computes $\delta_i \le (1+8\varepsilon)\delta^*_i$.*

Proof. We prove that $\textsc{Reduce}(r_i, \varepsilon, k)$ computes $\delta_i \le \varepsilon^{-s_i}1+\varepsilon)^{r_i+1}(1-4\varepsilon)^{-1}\delta_{\min}$. By (1), this is at most $(1+\varepsilon)^2(1-4\varepsilon)^{-1}\delta^*_i \le (1+8\varepsilon)\delta^*_i$ for $\varepsilon \le 1/17$.

Consider the case of $i = 2k-1$. We examine the call $\textsc{Reduce}(r_{2k-1}, \varepsilon, k)$. By (1), $\varepsilon^{-s_{2k-1}}(1+\varepsilon)^{r_{2k-1}-1}\delta_{\min} \le \delta^*_{2k-1} \le \varepsilon^{-s_{2k-1}}(1+\varepsilon)^{r_{2k-1}}\delta_{\min}$. Theorem 3 and Lemma 5 imply that $\varepsilon^{-s_{2k-1}}(1+\varepsilon)^{r_{2k-1}-1}\delta_{\min} \le \delta^*_{2k-1} \le \frac{1}{2}\min\big\{d(v_j, v_{j-1}v_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\big\} \le (1+\varepsilon)\delta^*_{2k-1} \le \varepsilon^{-s_{2k-1}}(1+\varepsilon)^{r_{2k-1}+1}\delta_{\min}$. Since the input parameter r of Reduce is equal to r_{2k-1}, line 5 of Reduce sets $\delta_{2k-2} = \varepsilon(1+\varepsilon)^{r_{2k-1}+1}(1-4\varepsilon)^{-1}\delta_{\min}$. For $\varepsilon \le 1/17$, we have $\varepsilon^{-1} > (1+\varepsilon)^2(1-4\varepsilon)^{-1}$, and so $\varepsilon^{1-s_{2k-1}}(1+\varepsilon)^{r_{2k-1}+1}(1-4\varepsilon)^{-1}\delta_{\min} < \varepsilon^{-s_{2k-1}}(1+\varepsilon)^{r_{2k-1}-1}\delta_{\min} \le \frac{1}{2}\min\big\{d(v_j, v_{j-1}v_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\big\}$. As a result, line 2 of Compress ensures that $\delta_{2k-1} = \varepsilon^{-s_{2k-1}}(1+\varepsilon)^{r_{2k-1}+1}(1-4\varepsilon)^{-1}\delta_{\min}$.

Consider an index $i > 2k-1$. We examine the call $\textsc{Reduce}(r_i, \varepsilon, k)$. Define:

$$\Delta = \varepsilon^{-s_i}(1+\varepsilon)^{r_i+1}\delta_{\min}. \tag{2}$$

Our goal is to prove that $\delta_i \le (1-4\varepsilon)^{-1}\Delta$. We rewrite the middle inequalities in (1) as

$$(1+\varepsilon)^{-2}\Delta \le \delta^*_i \le (1+\varepsilon)^{-1}\Delta. \tag{3}$$

Define:

$$a = \max\big\{j \in [2k-2, i] : \delta_j \le \varepsilon(1-4\varepsilon)^{-1}\Delta\big\}. \tag{4}$$

The index a is well defined because one can verify that $\delta_{2k-2} = \varepsilon(1+\varepsilon)^{r_i+1}(1-4\varepsilon)^{-1}\delta_{\min} \le \varepsilon(1-4\varepsilon)^{-1}\Delta$.

By (4), (2), line 5 of Reduce, and line 2 of Compress, $\delta_a = \varepsilon^h(1-4\varepsilon)^{-1}\Delta$ for some integer $h \ge 1$. If $a = i$, then $\delta_i = \delta_a \le \varepsilon(1-4\varepsilon)^{-1}\Delta$, so we are done. Suppose that $a < i$. Note that $\delta_{a+1} \ne \delta_a$ by (4), which implies that $\delta_{a+1} > \delta_a$. So $\tau_{a+1} = \sigma_a \circ (v_{a+1})$, and $\textsc{Compress}(\tau_{a+1}, \varepsilon, k, \delta_a)$ is called to produce σ_{a+1} and δ_{a+1}. We have

$$\begin{aligned} d_F(\sigma^*_{a+1}, \tau_{a+1}) &\le d_F(\sigma^*_{a+1}, \tau[v_1, v_{a+1}]) + d_F(\tau_{a+1}, \tau[v_1, v_{a+1}]) \\ &= \delta^*_{a+1} + d_F(\tau_{a+1}, \tau[v_1, v_{a+1}]) \ \le\ \delta^*_i + d_F(\tau_{a+1}, \tau[v_1, v_{a+1}]). \end{aligned} \tag{5}$$

If $a+1 = 2k-1$, then $\tau_{a+1} = \tau_{2k-1} = \tau[v_1, v_{2k-1}]$, so $d_F(\tau_{a+1}, \tau[v_1, v_{a+1}]) = 0$. Suppose that $a+1 > 2k-1$. By Lemma 6 and Theorem 3, $d_F(\sigma_a, \tau_a) \le (1+\varepsilon)\delta_a$. By Lemma 7, $d_F(\tau_a, \tau[v_1, v_a]) \le 2\varepsilon\delta_a$. So $d_F(\tau_{a+1}, \tau[v_1, v_{a+1}]) \le d_F(\sigma_a, \tau[v_1, v_a]) \le d_F(\sigma_a, \tau_a) + d_F(\tau_a, \tau[v_1, v_a]) \le (1+3\varepsilon)\delta_a$. Since $\delta_a \le \varepsilon(1-4\varepsilon)^{-1}\Delta$, we conclude that

$$d_F(\tau_{a+1}, \tau[v_1, v_{a+1}]) \le \varepsilon(1+3\varepsilon)(1-4\varepsilon)^{-1}\Delta. \tag{6}$$

Plugging (6) into (5) and using (3), we obtain the following inequality for $\varepsilon < 1/17$:

$$d_F(\sigma^*_{a+1}, \tau_{a+1}) \le \left(\frac{1}{1+\varepsilon} + \frac{\varepsilon+3\varepsilon^2}{1-4\varepsilon}\right)\Delta \le \frac{\Delta}{(1+\varepsilon)(1-4\varepsilon)}. \tag{7}$$

Consider the call of Simplify in $\textsc{Compress}(\tau_{a+1}, \varepsilon, k, \delta_a)$. By (7) and Theorem 3, calling Simplify on τ_{a+1} with an error tolerance of $\frac{1}{(1+\varepsilon)(1-4\varepsilon)}\Delta$ will produce a curve of size at most $2k-2$. Then, by Lemma 5, $\frac{1}{2}\min\big\{d(v_j, v_{j-1}v_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\big\} \le$

$(1+\varepsilon)\cdot\frac{1}{(1+\varepsilon)(1-4\varepsilon)}\Delta = (1-4\varepsilon)^{-1}\Delta$. Line 2 of Compress ensures that $\delta_{a+1} = \varepsilon^{-t}\delta_a = \varepsilon^{h-t}(1-4\varepsilon)^{-1}\Delta$ for the smallest integer $t \geq 1$ such that $\delta_{a+1} \geq \frac{1}{2}\min\{d(v_j, v_{j-1}v_{j+1}) : j \in [2, 2k-2],\ j \text{ is even}\}$. Hence, t cannot be greater than h. But t cannot be less than h because $\delta_{a+1} > \varepsilon(1-4\varepsilon)^{-1}\Delta$ by (4). So $\delta_{a+1} = (1-4\varepsilon)^{-1}\Delta$. For every $b \in [a+2, i]$,

$$\begin{aligned} d_F(\sigma_b^*, \tau_{a+1}\circ\tau[v_{a+2}, v_b]) &\leq d_F(\sigma_b^*, \tau[v_1, v_b]) + d_F(\tau_{a+1}\circ\tau[v_{a+2}, v_b], \tau[v_1, v_b]) \\ &\leq \delta_b^* + d_F(\tau_{a+1}, \tau[v_1, v_{a+1}]) \\ &\leq \delta_i^* + \varepsilon(1+3\varepsilon)(1-4\varepsilon)^{-1}\Delta \qquad (\because (6)) \\ &< (1-4\varepsilon)^{-1}\Delta = \delta_{a+1}. \qquad (\because (3)) \end{aligned}$$

Then, when processing v_{a+2}, Lemma 6 and Theorem 3 imply that Reduce executes lines 10–20 with $\delta_{a+2} = \delta_{a+1} = (1-4\varepsilon)^{-1}\Delta$ to produce σ_{a+2} of size at most $2k-2$. Applying this reasoning inductively gives $\delta_i = (1-4\varepsilon)^{-1}\Delta$. ◀

▶ **Theorem 9.** *Let τ be a polygonal curve in $\mathbb{R}^d$ that arrives in a data stream. Let $\alpha = 2(d-1)\lfloor d/2\rfloor^2 + d$. There is a streaming algorithm that, for any integer $k \geq 2$ and any $\varepsilon \in (0, \frac{1}{17})$, maintains a curve σ such that $|\sigma| \leq 2k-2$ and $d_F(\tau,\sigma) \leq (1+\varepsilon)\cdot\min\{d_F(\tau,\sigma') : |\sigma'| \leq k\}$. It uses $O\big((k\varepsilon^{-1} + \varepsilon^{-(\alpha+1)})\log\frac{1}{\varepsilon}\big)$ working storage and processes each vertex of τ in $O(k\varepsilon^{-(\alpha+1)}\log^2\frac{1}{\varepsilon})$ time for $d \in \{2,3\}$ and $O(k\varepsilon^{-(\alpha+1)}\log\frac{1}{\varepsilon})$ time for $d \geq 4$.*

Proof. Let $\delta^* = \min\{d_F(\tau,\sigma') : |\sigma'| \leq k\}$. By Lemma 8, if we launch $\lfloor\log_{1+\varepsilon/10}(10/\varepsilon)\rfloor = O(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon})$ runs of Reduce using $\varepsilon/10$ instead of ε, there is a run that outputs a curve σ such that $d_F(\tau,\sigma) \leq (1+\varepsilon/10)(1+8\varepsilon/10)\delta^* \leq (1+\varepsilon)\delta^*$. Then, the working storage and processing time per vertex follow from Theorem 3. ◀

Abstract

The primary tool in topological data analysis (TDA) is persistent homology, which involves computing a *barcode* – often from point-cloud or scalar field data – that serves as a topological signature for the underlying function. In this work, we introduce *sub-barcodes* and show how they arise naturally from *factorizations* of persistence module homomorphisms. We show that, as a partial order induced by factorizations, the relation of being a sub-barcode is strictly stronger than the rank invariant, and we apply sub-barcode theory to the problem of inferring information about the barcode of an unknown Lipschitz function from samples. The advantage of this approach is that it permits strong guarantees – with no noise – while requiring no sampling assumptions, and the resulting barcode is guaranteed to be a sub-barcode of every Lipschitz function that agrees with the data. We also present an algorithmic theory that allows for the efficient approximation of sub-barcodes using filtered Delaunay triangulations for Euclidean inputs.

1 Introduction

Topological data analysis (TDA) seeks to compute topological properties of unknown functions from finite samples. The most widely-used tool for TDA is persistent homology (PH), and the most widely-studied functions are distance functions. Thus, the algorithmic problems arising in this field tend to be either algebraic (PH computation), geometric (distance function representation), or both.

A PH pipeline starts with a real-valued function as input, and then considers the sublevel sets of this function. The homology of the sublevels at each threshold value are tracked and aggregated into a *barcode* (see Figure 1). The goal is to compute or approximate this barcode, which often requires substantial assumptions on the quality of the sample.

In this paper, we relax this goal to instead compute whatever *sub-barcode* is supported by the data we have. We form a sub-barcode by taking a sub-interval of each bar in the barcode. The formal definition of a sub-barcode and how it arises naturally in PH is covered in Section 3. The main idea is that, given *some* of the data, we compute *some* of the underlying structure.

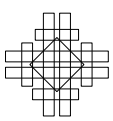

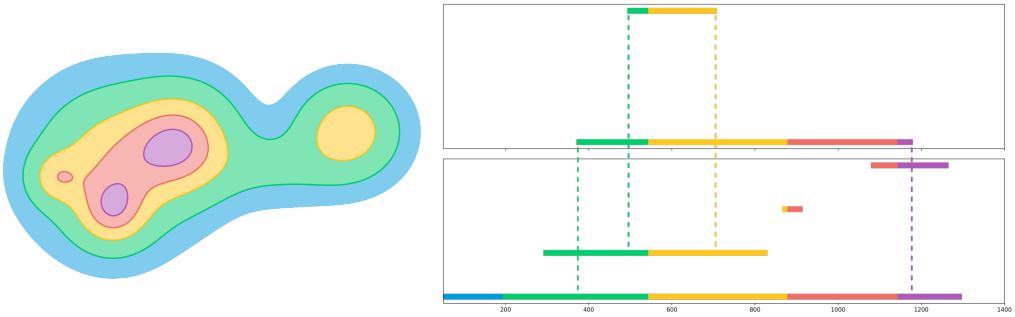

Figure 1 (Left) A contour plot of a Lipschitz function $f : X \to \mathbb{R}$. (Right) The barcode $\mathsf{Bar}(f)$ of f (bottom) and a sub-barcode (top). All colors correspond to the function values indicated on the axis (bottom-right).

In practice, analyzing the topology of a finite sample entails two main challenges:

- **Extension:** If S is a finite sample of the underlying space X, then we need to extrapolate the values for a function f from the known values at S to the unknown values at the rest of X. We won't get the exact answer, but we would like some guarantees on the extension.
- **Discretization:** Having a good approximation to the function is insufficient: we also need a reliable discrete representation of the underlying space. In practice, these representations usually arise in the form of a simplicial complex or a simplicial set.

In the classic setting of distance functions in Euclidean space, strong sampling assumptions guarantee that the distance to a sample approximates the distance to the underlying set. The Delaunay triangulation provides a perfect discretization, capturing the exact homology of the distance sublevels. This was the original setting for PH [13].

Lipschitz functions generalize distance functions and allow us to represent a much wider class of inputs. Several previous papers have shown that, given a sufficiently dense sample, a good approximation to the barcode of a Lipschitz function can be computed [6, 8, 11]. The guarantees from such work is that the output barcode is close to the true barcode in a standard metric called the bottleneck distance. Our approach eliminates all sampling assumptions, but gives guarantees in terms of a partial order on barcodes; that is, it is guaranteed to produce no noise or spurious bars, but finds only those topological features (bars) that are sufficiently supported by the sample.

Contributions and Outline

The background and definitions appear in sections 2 and 3. The *algebraic theory* of sub-barcodes is presented in Section 4. First, we show how sub-barcodes are related to the widely-studied rank invariant. Surprisingly, despite being a complete invariant for persistence, the natural extension of the rank invariant to a partial order is strictly less discriminating than sub-barcodes. This would be useless if it were not the case that sub-barcodes can be computed, a fact we show in the main sub-barcode theorem (Theorem 4), which states that sub-barcodes arise whenever we have one persistence module homomorphism factoring through another.

In Section 5, we lay out the *extension theory*. According to the algebraic theory of the previous section, the key to producing sub-barcodes is to find suitable upper and lower bounds on the unknown function. We show that maximum and minimum Lipschitz extensions serve

this purpose (Figure 2), as well as how to give good guarantees with only an approximation to the upper and lower bounds (Corollary 9). This section also contains a much more general result to encompass other classes of functions beyond Lipschitz functions (Theorem 11).

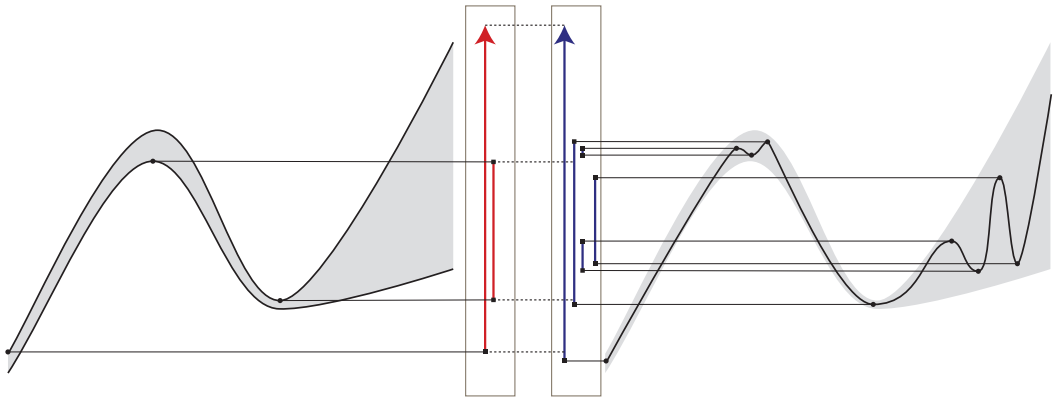

Figure 2 On the left, two functions are depicted, one is an upper bound and the other is a lower bound on an unknown function $f : \mathbb{R} \to \mathbb{R}$. There is a corresponding barcode associated with the pair that matches minima in the upper bound to maxima in the lower bound. On the right is a candidate function f that lies between the upper and lower bounds and its barcode $\mathsf{Bar}(f)$. The barcode of the inclusion of the upper and lower bounds is a sub-barcode of $\mathsf{Bar}(f)$.

The *discretization theory* is presented in Section 6. Here, we show how to approximate the Lipschitz extension sub-barcode of the previous section using Delaunay triangulations. This leads to a theory of semi-supervised TDA in which only a subset of function values are known (Theorem 13). We also give a tighter approximation using the barycentric decomposition of the Delaunay triangulation (Theorem 14), and show that this method also applies to a wider class of functions (Example 15).

The *categorical theory* of sub-barcodes is presented in Section 7. The TDA and PH pipeline depend on category theory to express the way relationships between inputs impact relationships between outputs, i.e., barcodes. We relate sub-barcodes to the classic approach of smoothing barcodes and show how this arises naturally from categorical considerations. We also give a new perspective on barcodes in general for which sub-barcodes are shown to be true subobjects in the categorical sense, and discuss how this construction is related to the theory of fuzzy sets [15, 1, 21].

2 Background

Functions and Filtrations

Let (X, d) be a metric space. When the metric is Euclidean, we denote the distance as a norm, i.e., $\mathrm{d}(x, y) := \|x - y\|$. The distance from a point x to a (finite) set U is denoted $\mathrm{d}(x, U) := \min_{u \in U} \mathrm{d}(x, u)$.

The real-valued functions $f : X \to \mathbb{R}$ form a vector space where $(f + \alpha\, g)(x) := f(x) + \alpha\, g(x)$, for all $\alpha \in \mathbb{R}$. We also have a poset of functions, where $f \geq g$ iff $f(x) \geq g(x)$ for all $x \in X$. A function $f : X \to \mathbb{R}$ is λ-*Lipschitz* if, for all $x, y \in X$, we have

$$f(y) - \lambda\, \mathrm{d}(x, y) \leq f(x) \leq f(y) + \lambda\, \mathrm{d}(x, y).$$

If λ is not specified, then it is assumed that $\lambda = 1$. This is perhaps not the most common way to express the Lipschitz condition, but it is closest to how it is used in this work.

The *t-sublevel set* $\mathrm{Sub}_f(t)$ of f is the set of points $x \in X$ with $f(x) \leq t$:

$$\mathrm{Sub}_f(t) := f^{-1}((-\infty, t]) = \{x \in X \mid f(x) \leq t\}.$$

This notation is designed to indicate that Sub_f is a *filtration*: for $s \leq t$ we have $\mathrm{Sub}_f(s) \subseteq \mathrm{Sub}_f(t)$. There is a partial order on sublevel filtrations where $\mathrm{Sub}_f \subseteq \mathrm{Sub}_g$ iff $\mathrm{Sub}_f(t) \subseteq \mathrm{Sub}_g(t)$ for all $t \in \mathbb{R}$. It is a simple exercise to check that, if $f \geq g$, then $\mathrm{Sub}_f \subseteq \mathrm{Sub}_g$; i.e., larger functions have smaller sublevel sets.

▶ Remark 1. The mapping from a function to its sublevel filtration is a contravariant functor from the poset of functions to the poset of filtrations. The filtrations themselves are functors $\mathbb{R} \to \mathbf{Top}$ from the totally ordered set $\mathbb{R}$ of real numbers to **Top**, the category of topological spaces. Throughout, we use remarks like this one to highlight the categorical interpretations. The reader who is unfamiliar with these terms may still follow all definitions and algorithms.

Persistence Modules

A *pointwise finite dimensional (p.f.d.) persistence module* $M : \mathbb{R} \to \mathbf{vec}$ assigns a (finite-dimensional) vector space $M(t)$ to all $t \in \mathbb{R}$ and a linear map $M_{s \leq t} : M(s) \to M(t)$ for all $s \leq t$. The map $M_{s \leq s}$ is the identity on $M(s)$, and for all $s \leq t \leq u$, $M_{s \leq u} = M_{t \leq u} \circ M_{s \leq t}$. For persistence modules M and N, a homomorphism $\phi : M \to N$ assigns linear maps $\phi_t : M(t) \to N(t)$ for all $t \in \mathbb{R}$ so that for all $s \leq t$, we have $\phi_t \circ M_{s \leq t} = N_{s \leq t} \circ \phi_s$.

▶ Remark 2. A persistence module M is a functor $M : \mathbb{R} \to \mathbf{vec}$, and a persistence module homomorphism $M \to N$ is a natural transformation $\phi : M \Rightarrow N$ between functors $\mathbb{R} \to \mathbf{vec}$, so that the category of persistence modules is precisely the category $\mathbf{vec}^{\mathbb{R}} = [\mathbb{R}, \mathbf{vec}]$ of functors $\mathbb{R} \to \mathbf{vec}$.

A *factorization* of homomorphisms $F : M \to N$ to $G : M' \to N'$ is given by a pair of homomorphisms $\varphi = \big(\varphi_1 : M' \to M,\ \varphi_2 : N \to N'\big)$ such that $G = \varphi_2 \circ F \circ \varphi_1$ (Diagram 1).

$$\begin{array}{ccc} M & \xleftarrow{\varphi_1} & M' \\ \downarrow{\scriptstyle F} & & \downarrow{\scriptstyle G} \\ N & \xrightarrow{\varphi_2} & N'. \end{array} \tag{1}$$

Let $\mathbf{Fac}(\mathbf{vec}^{\mathbb{R}})$ denote the category with homomorphisms of persistence modules as objects, and arrows $\varphi : F \to G$. Then $\varphi : F \to G$ is a factorization of G through F.

▶ **Example 3.** Letting $M(\epsilon)$ denote a persistence module M shifted by a constant $\epsilon \in \mathbb{R}$, a 2ϵ-interleaving is traditionally given by a pair of commuting diagrams

$$\begin{array}{ccc} M(-\epsilon) & \xrightarrow{M\varepsilon} & M(\epsilon) \\ & {\scriptstyle \Phi(-\epsilon)} \searrow \quad \nearrow {\scriptstyle \Psi} & \\ & N & \end{array} \tag{2}$$

$$\begin{array}{ccc} & M & \\ & {\scriptstyle \Psi(-\epsilon)} \nearrow \quad \searrow {\scriptstyle \Phi} & \\ N(-\epsilon) & \xrightarrow[N\varepsilon]{} & N(\epsilon) \end{array} \tag{3}$$

depicting factorizations of homomorphisms $M\varepsilon : M(-\epsilon) \to M(\epsilon)$ and $N\varepsilon : N(-\epsilon) \to N(\epsilon)$ by a pair $\big(\Phi : M \to N(\epsilon),\ \Psi : N \to M(\epsilon)\big)$. In this section, we show that the commutativity of Diagrams (2) and (3) imply sub-barcode relations $\mathsf{Bar}(M\varepsilon) \sqsubseteq \mathsf{Bar}(N)$ and $\mathsf{Bar}(M) \sqsupseteq \mathsf{Bar}(N\varepsilon)$.

Homology

Homology is a topological invariant that is particularly useful because it is both informative and efficiently computable for triangulable topological spaces. A homology functor $\mathrm{H} : \mathbf{Top} \to \mathbf{vec}$ associates a vector space $\mathrm{H}(X)$ to a topological space X, and takes continuous maps between topological spaces to linear maps between the corresponding vector spaces.

Persistence modules naturally arise in TDA by taking the homology of a sublevel filtration of a function. This assembles the functorial TDA pipeline from functions to filtrations to persistence modules. It is useful to see these as functors and not just functions because the additional structure of functoriality tells us that, if $f \geq g$, then there is a persistence module homomorphism $\mathrm{H}\,\mathrm{Sub}_f \to \mathrm{H}\,\mathrm{Sub}_g$. As we will see, these homomorphisms can be combined into factorizations (leading to sub-barcodes) and interleavings (leading to approximations).

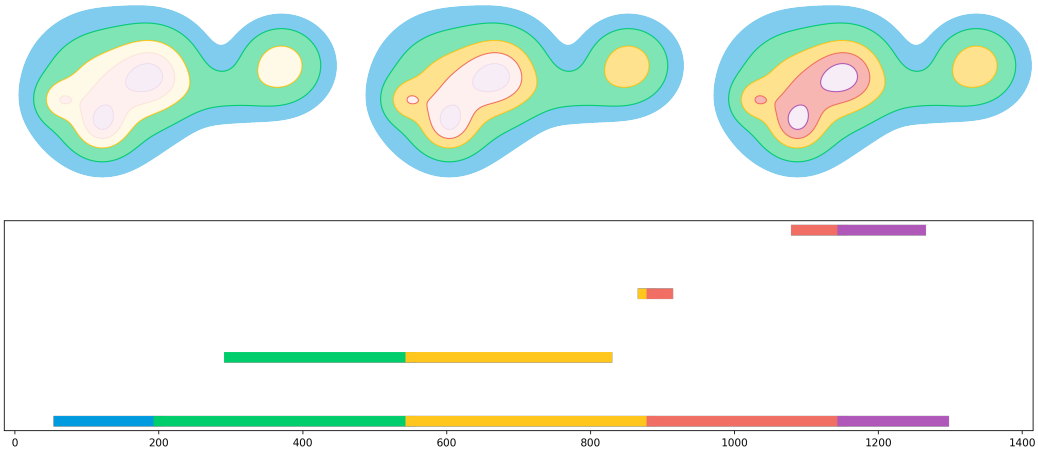

Figure 3 Sublevels of a 3-Lipschitz function $f : X \to \mathbb{R}$ on a subset of $\mathbb{R}^2$ (top) and its barcode $\mathsf{Bar}(f) = \mathsf{Bar}(\mathrm{H}_1\mathrm{Sub}_f)$ in dimension 1 (bottom). Colors correspond to the function values indicated on the bottom-axis.

3 Barcodes and Sub-Barcodes

Let $\mathcal{I}$ denote the poset of intervals on $\mathbb{R}$ ordered by inclusion. A *barcode* B is a function $B : \underline{B} \to \mathcal{I}$ where $\underline{B}$ is a set whose elements $\beta \in \underline{B}$ are called *bars*. The barcode assigns an interval to each bar. Note that B is not necessarily injective. When there is no confusion, we identify the bars in a barcode with their corresponding intervals. A *sub-barcode mapping* between barcodes A and B is a function $\phi : \underline{A} \to \underline{B}$ such that, for all $\alpha \in \underline{A}$, we have $A(\alpha) \subseteq B(\phi(\alpha))$. If ϕ is injective, then we call it a *sub-barcode matching* and say A is a *sub-barcode* of B, denoted $A \sqsubseteq B$. That is, A is a sub-barcode of B if A can be formed from B by taking a subinterval of each bar in a subset of $\underline{B}$ (Figure 4).

There is a barcode $\mathsf{Bar}(M)$ corresponding to any persistence module M. Note, the image of a persistence module homomorphism $\phi : M \to N$ is also persistence module. We overload notation and write $\mathsf{Bar}(\phi)$ to indicate $\mathsf{Bar}(\operatorname{im}\phi)$.

From the PH pipeline, we have persistence modules $\mathrm{H}\,\mathrm{Sub}_f$ associated with each continuous function $f : X \to \mathbb{R}$. We again simplify our notation and write $\mathsf{Bar}(f)$ to denote $\mathsf{Bar}(\mathrm{H}\,\mathrm{Sub}_f)$ and $\mathsf{Bar}(f \geq g)$ to denote $\mathsf{Bar}(\operatorname{im}\mathrm{H}(\mathrm{Sub}_f \subseteq \mathrm{Sub}_g))$. The object giving us a barcode is always clear from context.

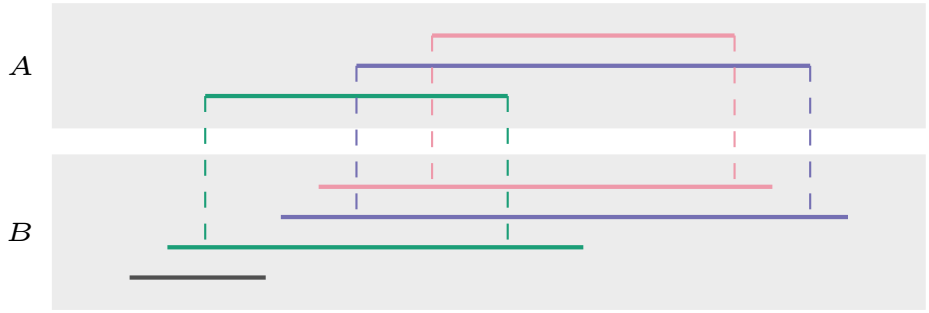

Figure 4 Two barcodes A and B and a sub-barcode matching $M : A \to B$.

We now have enough definitions to state the main theorem of sub-barcodes. The proof is postponed until Section 4 when we will have developed some necessary tools.

▶ **Theorem 4** (The Sub-Barcode Theorem)**.** *If there exists a factorization $\varphi : F \to G$ of persistence module homomorphisms (i.e., $G = \varphi_2 F \varphi_1$), then* $\mathsf{Bar}(G) \sqsubseteq \mathsf{Bar}(F)$.

4 The Algebraic Theory

4.1 Sub-barcodes vs. Ranks

Let $\mathrm{rk}\ m$ denote the *rank* of a linear map m defined as the dimension of its image, $\mathrm{im}\, m$. The *rank invariant* rank_M of a persistence module $M : \mathbb{R} \to \mathbf{vec}$ is a function from ordered pairs in $\mathbb{R}$ to the natural numbers defined as $\mathrm{rank}_M(s \leq t) := \mathrm{rk}\, M_{s \leq t}$. It is straightforward to extend this invariant to homomorphisms $F : M \to N$ by letting $\mathrm{rank}_F(s \leq t) := \mathrm{rk}\,(F_t \circ M_{s \leq t})$. In the following, we consider the rank invariant for a persistence module M to be the rank invariant of its identity homomorphism, i.e., $\mathrm{rank}_M := \mathrm{rank}_{1_M}$.

A basic fact from linear algebra is that, if a linear map g factors through a second linear map f, then $\mathrm{rk}\,(g) \leq \mathrm{rk}\,(f)$. It follows immediately that, if there is a factorization $F \to G$ of persistence module homomorphisms, then for all $s \leq t$,

$$\mathrm{rank}_G(s \leq t) \leq \mathrm{rank}_F(s \leq t).$$

This puts a partial order on rank invariants that we call the *sub-rank relation* and denote by $\mathrm{rank}_G \leq \mathrm{rank}_F$.

▶ Remark 5. rk is a contravariant functor $\mathbf{Fac}(\mathbf{vec}) \to \mathbb{N}$ and rank is a contravariant functor $\mathbf{Fac}(\mathbf{vec}^{\mathbb{R}}) \to \mathbb{N}$, i.e., from factorizations of vector spaces (resp. persistence modules) to the poset of natural numbers. An ordering of two rank invariants is a natural transformation between these functors.

In light of the sub-barcode theorem, the rank invariant is the same *type* of invariant as sub-barcodes. It puts a partial order on morphisms induced by factorizations. However, although the barcode can be constructed from the rank invariant, the natural ordering of rank invariants is a weaker invariant than sub-barcodes as expressed in the following.

▶ **Theorem 6.** *The sub-barcode order is a more discriminating invariant than the sub-rank order in the sense that, for all persistence module homomorphisms F and G,* $\mathsf{Bar}(G) \sqsubseteq \mathsf{Bar}(F)$ *implies that* $\mathrm{rank}_G \leq \mathrm{rank}_F$*, but not vice-versa.*

Proof. The rank invariant is easily extracted from a barcode: $\operatorname{rank}_F(s \leq t)$ is the number of bars in $\mathsf{Bar}(F)$ that contain the closed interval $s \leq t$. It follows immediately from the injectivity of the sub-barcode matching (and the pigeonhole principle) that $\mathsf{Bar}(G) \sqsubseteq \mathsf{Bar}(F)$ implies that $\operatorname{rank}_G \leq \operatorname{rank}_F$.

For the other side of the proof, it suffices to give an example of persistence modules M and N such that $\operatorname{rank}_M \leq \operatorname{rank}_N$ while $\mathsf{Bar}(M) \not\sqsubseteq \mathsf{Bar}(N)$.[1] Let M be a persistence module where $\mathsf{Bar}(M)$ has two bars corresponding to intervals $[0, 1)$ and $[2, 3)$, and let N be a persistence module such that $\mathsf{Bar}(N)$ has only one bar corresponding to the interval $[0, 3)$. Clearly, $\operatorname{rank}_M \leq \operatorname{rank}_N$, but it is not possible for a barcode with two bars to be a sub-barcode of one with only one bar. Thus $\mathsf{Bar}(M) \not\sqsubseteq \mathsf{Bar}(N)$. ◀

4.2 Induced Matching Theory Proof of the Sub-Barcode Theorem

Although not expressed in these terms, Bauer and Lesnick's theory of induced matchings [3] shows that sub-barcode matchings arise from certain homomorphisms. The induced matchings in that work are matchings between the bars that do not (necessarily) satisfy the inclusion requirement of a sub-barcode matching. They showed that for any homomorphism $F : M \to N$, there is a partial bijective function (a *matching*) between the bars with the property that every bar of $\mathsf{Bar}(F)$ is the intersection of the intervals of the matched bars from $\mathsf{Bar}(M)$ to $\mathsf{Bar}(N)$. These are constructed from the pair of canonical (functorial) matchings $\mathsf{Bar}(M) \to \mathsf{Bar}(F) \to \mathsf{Bar}(N)$ induced by the epi-mono factorization of F through its image. Translated into the vocabulary of sub-barcodes, this result implies that $\mathsf{Bar}(F) \sqsubseteq \mathsf{Bar}(M)$ and $\mathsf{Bar}(F) \sqsubseteq \mathsf{Bar}(N)$.

More generally, if F is a monomorphism (all maps F_t are injective), then $\mathsf{Bar}(M) \sqsubseteq \mathsf{Bar}(N)$. This is because the induced matching of a monomorphism matches every bar, in addition to the property that, if $[a, b]$ is matched to $[c, d]$, then $a \geq c$ and $b = d$; thus, a submodule relation between persistence modules implies a sub-barcode relation between the barcodes.

If F is an epimorphism (all maps F_t are surjective), then the induced matching is surjective, and if $[a, b]$ is matched to $[c, d]$, then $a = c$ and $d \leq b$. So, reversing this induced matching, we get $\mathsf{Bar}(N) \sqsubseteq \mathsf{Bar}(M)$. We use these matchings in the proof of the Sub-Barcode Theorem below.

Proof of The Sub-Barcode Theorem (Theorem 4). The factorization $\varphi = (\varphi_1, \varphi_2) : F \to G$ entails $G = \varphi_2 F \varphi_1$. Let $m : \operatorname{im} G \hookrightarrow \operatorname{im} \varphi_2 F$ be the unique monomorphism given by the universal property of images, and let $e : \operatorname{im} F \twoheadrightarrow \operatorname{im} \varphi_2 F$ be the epimorphism given by resticting φ_2 to $\operatorname{im} F$. Using the induced matching theory, m gives a sub-barcode matching $\mathsf{Bar}(\varphi_2 F) \sqsubseteq \mathsf{Bar}(F)$. Then, the reverse of the matching induced by e gives a sub-barcode matching $\mathsf{Bar}(G) \sqsubseteq \mathsf{Bar}(\varphi_2 F)$. Putting these together, we get

$$\mathsf{Bar}(G) \sqsubseteq \mathsf{Bar}(\varphi_2 F) \sqsubseteq \mathsf{Bar}(F).$$ ◀

The following corollary for ordered sequences of functions forms the basis for all of our applications of sub-barcodes in TDA.

▶ **Corollary 7.** *If $h \geq g \geq f \geq e$ are functions $X \to \mathbb{R}$, then $\mathsf{Bar}(h \geq e) \sqsubseteq \mathsf{Bar}(g \geq f)$.*

Proof. It suffices to observe that the ordering on the functions gives a factorization $(g \geq f) \to (h \geq e)$ of $h \geq e$ through $g \geq f$. By the functoriality of the sublevel functor and homology, we get the corresponding factorization of persistence modules. The claim then follows from Theorem 4. ◀

[1] As before, rank_M is shorthand for $\operatorname{rank} 1_M$.

5 The Extension Theory

Given an unknown Lipschitz function $f : X \to \mathbb{R}$ and a sample $S \subset X$, let f_S denote the function f restricted to the points of S. The pair (S, f_S) denotes input to a TDA problem where the goal is to infer as much as possible about f. Any function $g : X \to \mathbb{R}$ that agrees with f_S at the points of S is called an *extension* of f_S. If g is also Lipschitz, then it is called a *Lipschitz extension*. By the definition of Lipschitz continuity, each point $s \in S$ puts an upper bound and a lower bound on the unknown f so that

$$f(s) - \mathrm{d}(x, s) \leq f(x) \leq f(s) + \mathrm{d}(x, s).$$

The combination of these upper and lower bounds gives the *maximum and minimum Lipschitz extensions*, defined respectively for each $x \in X$ as

$$\check{f}_S(x) := \min_{s \in S} f(s) + \mathrm{d}(x, s) \quad \text{and} \quad \hat{f}_S(x) := \max_{s \in S} f(s) - \mathrm{d}(x, s).$$

Note that the max extension is the minimum of the upper bounds and vice versa (see also [17]).

The following theorem states that, for every Lipschitz function f that agrees with the data, the max and min Lipschitz extensions yield a barcode that is contained in $\mathsf{Bar}(f)$.

▶ **Theorem 8.** *Given $S \subseteq X$ and $f_S : S \to \mathbb{R}$, for all Lipschitz extensions f of f_S, we have $\mathsf{Bar}(\check{f}_S \geq \hat{f}_S) \sqsubseteq \mathsf{Bar}(f)$.*

Proof. It suffices to observe that for all Lipschitz extensions of f, we have $\check{f}_S \geq f \geq \hat{f}_S$. Because $\mathsf{Bar}(f) = \mathsf{Bar}(f \geq f)$, the result follows from Corollary 7. ◀

The Choice of Lipschitz Constants

It is natural to ask whether (and how) the choice of the Lipschitz constant affects this result. The previous statements have all assumed 1-Lipschitz functions. More generally, tuning the Lipschitz constant naturally leads to a filtration of the barcode itself as shown in the following.

▶ **Corollary 9.** *For any $t \in \mathbb{R}$, let $\check{f}_S^{(t)}$ and $\hat{f}_S^{(t)}$ denote the (resp.) max and min t-Lipschitz extensions. If f_S is t_0-Lipschitz and $t_0 \leq t_1 \leq t_2$, then $\mathsf{Bar}(\check{f}_S^{(t_1)} \geq \hat{f}_S^{(t_1)}) \sqsubseteq \mathsf{Bar}(\check{f}_S^{(t_2)} \geq \hat{f}_S^{(t_2)})$.*

A Sub-Barcode that is Close in Bottleneck Distance

A fundamental challenge in computing sub-barcodes from Lipschitz extensions is that it is not clear how to construct a simplicial complex that can represent the sublevel sets of both the max and min extension at the same time. So, in order to still derive guarantees, it will suffice to have approximations to these extensions. The following theorem shows that a bottleneck-close sub-barcode is possible if we have close approximations to the upper and lower bounds.

▶ **Theorem 10.** *Let $u' \geq u \geq f \geq \ell \geq \ell'$ be an ordered sequence of functions $X \to \mathbb{R}$ such that $\|\ell - \ell'\|_\infty \leq \varepsilon$ and $\|u - u'\| \leq \varepsilon$. Then, $\mathrm{d}_B\big(\mathsf{Bar}(u \geq \ell), \mathsf{Bar}(u' \geq \ell')\big) \leq \varepsilon$.*

Proof. The proof is a straightforward application of the general stability theorem for image persistence. The bounds $\|\ell - \ell'\|_\infty \leq \varepsilon$ and $\|u - u'\| \leq \varepsilon$ imply that $\ell' + \varepsilon \geq \ell \geq \ell'$ and $u' \geq u \geq u' - \varepsilon$. As all maps from ordered functions induce inclusions of sublevel sets, all required maps commute to form an interleaving in the arrow category of filtrations. This gives an interleaving in the arrow category of persistence modules which leads to an ε-interleaving of the image persistence modules. ◀

Beyond Lipschitz Functions

The careful reader may note that there is nothing particularly special about Lipschitz functions in the treatment above. One could consider other classes of functions as well. More generally, it suffices to have an upper and lower bound on the unknown function. In the Lipschitz case, the Lipschitz extensions form a lattice of hypotheses that we are considering. Recall that a poset is a lattice if every subset has a join (least upper bound) and a meet (greatest lower bound). The symbol $\vee$ is used for joins and $\wedge$ is used for meets. This is the origin of our notation $\check{f}_S$ and $\hat{f}_S$.

For a set $\mathcal{F}$ of functions, let $\bigvee \mathcal{F} := \bigvee_{f\in\mathcal{F}} f$ and $\bigwedge \mathcal{F} := \bigwedge_{f\in\mathcal{F}} f$. In particular, if $\mathcal{F}$ denotes the set of Lipschitz extensions of f_S, then $\check{f}_S = \bigvee \mathcal{F}$ and $\hat{f}_S = \bigwedge \mathcal{F}$. For other lattices of hypotheses, the same proof as for the Lipschitz case (Theorem 8) implies the following theorem.

▶ **Theorem 11.** *Given a lattice $\mathcal{F}$ of functions $X \to \mathbb{R}$, for all $f \in \mathcal{F}$, we have*

$$\mathsf{Bar}\big(\bigvee \mathcal{F} \geq \bigwedge \mathcal{F}\big) \sqsubseteq \mathsf{Bar}(f).$$

6 The Discretization Theory

The preceding sections laid out the theory of sub-barcodes for persistence modules, as well a the useful setting of Lipschitz functions. The following section shows how to approximate these barcodes.

The fundamental challenge is to provide a single discretization of space that approximates (or at least bounds) both Lipschitz extensions at the same time. We assume throughout this section that X is a convex polytope in $\mathbb{R}^d$.[2] For a finite set $S \subset X$, the *Voronoi diagram* assigns a convex polytope called the *Voronoi cell* to each point $s \in S$ defined as

$$\mathrm{Vor}_S(s) := \{x \in X \mid \mathrm{d}(x,s) = \mathrm{d}(x,S)\}.$$

The *radius* of $\mathrm{Vor}_S(s)$ is the maximum distance from s to any point in the cell: $r_s := \max_{x\in\mathrm{Vor}_S(s)} \mathrm{d}(x,s)$. More generally, for $\sigma \subseteq S$, we have a Voronoi cell

$$\mathrm{Vor}_S(\sigma) := \bigcap_{s\in\sigma} \mathrm{Vor}_S(s).$$

Dually, the *Delaunay triangulation* Del_S associated with S is the simplicial complex with vertex set S and simplices $\mathrm{Del}_S = \{\sigma \subseteq S \mid \mathrm{Vor}_S(\sigma) \neq \emptyset\}$. The Delaunay triangulation is widely used for persistent homology on Euclidean inputs.

6.1 Simple Voronoi Extensions and a Delaunay Filtration

The most direct way to use a Delaunay triangulation to estimate the persistence diagram of a set of points is to extend the function from the vertex set to the simplices, setting the value at the simplex be the maximum value at its vertices. This corresponds to the piecewise linear extension of the function to the geometric realization of the complex (see Section 2.5, Morozov [20]). Unfortunately, this can fail badly in the absence of strong sampling

[2] The convexity of X can be relaxed in many settings. Assuming X is convex simplifies our use of the Nerve theorem.

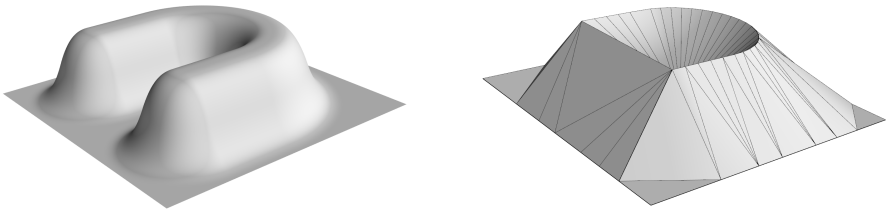

Figure 5 A function and its linear extension onto the Delaunay triangulation of a sample. The discretization introduces a spurious feature because it does not register the opening.

guarantees; Figure 5 shows an example where the piecewise linear extension introduces spurious features. Thus, the problem with some samples is not only that we can miss features, but that we may hallucinate them as well.

The key to using a discretization is to use an image filtration (see Cohen-Steiner et al. [12], Bauer [4]) capturing both an upper and lower bound. The following theorem states that we can compute a sub-barcode for any Lipschitz function by filtering the Delaunay triangulation by upper and lower bounds given on the input values and the radius of the Voronoi cells.

▶ **Theorem 12.** *Let S be a finite subset of a polytope $X \subset \mathbb{R}^d$. Let $f_S : S \to \mathbb{R}$ be a sample of an unknown Lipschitz function $f : X \to \mathbb{R}$. For each $s \in S$, let r_s denote the radius of the Voronoi cell $\mathrm{Vor}_S(s)$. Let u and ℓ be functions $\mathrm{Del}_S \to \mathbb{R}$ defined on Delaunay simplices $\sigma \in \mathrm{Del}_S$ as*

$$u(\sigma) := \max_{s\in\sigma} f_S(s) + r_s \quad \textit{and} \quad \ell(\sigma) := \max_{s\in\sigma} f_S(s) - r_s.$$

Then, $\mathsf{Bar}(u \geq l) \sqsubseteq \mathsf{Bar}(f)$.

Proof. To relate the barcodes, we will first construct functions on X that have the same barcode as the simplicial functions u and ℓ. Second, we will relate these functions to the Lipschitz extensions $\check{f}_S$ and $\hat{f}_S$.

We define piecewise constant functions on X using the Voronoi cells and f_S as

$$u^*(x) := \max_{s|x\in\mathrm{Vor}_S(s)} f_S(s) + r_s \quad \text{and} \quad \ell^*(x) := \max_{s|x\in\mathrm{Vor}_S(s)} f_S(s) - r_s.$$

By the Persistent Nerve Lemma (Chazal et al. [9], Lemma 3.4), there is a homotopy equivalence between the sublevels of u and u^* that commutes with inclusions (see also [2]). The same holds for ℓ and ℓ^*. It follows that $\mathsf{Bar}(u \geq \ell) \cong \mathsf{Bar}(u^* \geq \ell^*)$.

For any $x \in X$, there is an $s \in S$ such that $x \in \mathrm{Vor}_S(s)$ and $u^*(x) = f_S(s) + r_s$, so

$$u^*(x) = f_S(s) + r_s \geq f_S(s) + \mathrm{d}(x, s) \geq \min_{s_0\in S} f_S(s_0) + \mathrm{d}(x, s_0) = \check{f}_S(x).$$

Similarly, there is an $s \in S$ such that $x \in \mathrm{Vor}_S(s)$ and $\ell^*(x) = f_S(s) - r_s$, so

$$\ell^*(x) = f_S(s) - r_s \leq f_S(s) - \mathrm{d}(x, s) \leq \max_{s_0\in S} f_S(s_0) - \mathrm{d}(x, s_0) = \hat{f}_S(x),$$

thus $u^* \geq \check{f}_S \geq \hat{f}_S \geq \ell^*$, and Corollary 7 therefore implies

$$\mathsf{Bar}(u \geq \ell) \cong \mathsf{Bar}(u^* \geq \ell^*) \sqsubseteq \mathsf{Bar}(\check{f}_S \geq \hat{f}_S) \sqsubseteq \mathsf{Bar}(f).$$ ◀

6.2 Semi-Supervised TDA

We have assumed thus far that we have access to function values at all points in the sample. This resembles a supervised learning problem. If instead we only have function values at a subset $P \subset S$, we can still use the points of S to improve our approximation. We call this *semi-supervised TDA*.

The most common guarantees in PH are derived from interleavings, and thus yield bottleneck distance bounds on the resulting barcodes. In this section, we combine those results with the Lipschitz extension sub-barcode and the Delaunay filtration above to get a guaranteed approximation. Throughout, we assume that S is a sample of X, and that we only have function values $f_P : P \to \mathbb{R}$ for $P \subset S$. The algorithm extends $\check{f}_P$ and $\hat{f}_P$ to the points of S and then use the Delaunay filtration from the previous subsection.

In the following, we say that S is an *ε-sample* of X if every point of X is within ε of a point in S. Equivalently, the radius of every Voronoi cell $\mathrm{Vor}_S(s)$ is at most ε.

▶ **Theorem 13.** *Let $X \subset \mathbb{R}^d$ be a convex polytope, and suppose $S \subset X$ is an ε-sample. Let $f_P : P \to \mathbb{R}$ be a sample of an unknown Lipschitz function $f : X \to \mathbb{R}$ defined on a subset $P \subset S$, and let u and ℓ be functions $\mathrm{Del}_S \to \mathbb{R}$ defined on each Delaunay simplex $\sigma \subseteq S$ as*

$$u(\sigma) = \max_{s \in \sigma} \check{f}_P(s) + \varepsilon \quad \text{and} \quad \ell(\sigma) = \max_{s \in \sigma} \hat{f}_P(s) - \varepsilon.$$

Then, $\mathsf{Bar}(u \geq \ell) \sqsubseteq \mathsf{Bar}(f)$, and $\mathrm{d}_B\big(\mathsf{Bar}(u \geq \ell), \mathsf{Bar}(\check{f}_P \geq \hat{f}_P)\big) \leq \varepsilon$.

Proof. The sub-barcode relation follows from Theorem 12 and the observation that the radius $r_s \leq \varepsilon$ for all s in an ε-sample. The bottleneck bound follows from a more general theory of interleaving of image persitence modules. It depends only on the fact that the extensions u^* and ℓ^* of u and ℓ to piecewise constant functions on Voronoi cells (as in the proof of Theorem 12) satisfy $\|u^* - \check{f}_P\|_\infty \leq \varepsilon$ and $\|\ell^* - \hat{f}_P\|_\infty \leq \varepsilon$, respectively. These bounds yeild an ε-interleaving of the sublevels, and thus give an interleaving of the images.[3] ◀

6.3 Finer Approximation with Barycentric Subdivision

In general, we would like to have tight approximations to the sub-barcode of Lipschitz extensions without requiring any sampling assumptions. One way to get a better bound is to manually add points to reduce the radii of the cells. Another approach would be to consider the barycentric subdivision. This makes sense because it can be understood as assigning function values to Delaunay simplices individually rather than inducing the values from the function on the vertices. In this section, we show how to define such constructions in a way that applies to a much more general class of functions.

For each sample $s \in S$, knowing the value of $f(s)$ implies an upper bound and a lower bound on f. Thus far, these bounds came from the assumption that f is Lipschitz. Similar upper and lower bounds can be defined for other classes of functions. We only assume that these bounds are *distance monotone*. That is, the upper bound $\check{f}_s$ for a point s satisfies the condition that if $\mathrm{d}(x, s) \leq \mathrm{d}(y, s)$, then $\check{f}_s(x) \leq \check{f}_s(y)$. For the lower bound $\hat{f}_s$ at s values decrease with distance, i.e., if $\mathrm{d}(x, s) \leq \mathrm{d}(y, s)$, then $\hat{f}_s(x) \geq \hat{f}_s(y)$. We call $\{\check{f}_s\}$ and $\{\hat{f}_s\}$ a family of *pointwise distance monotone bounds*. As before, we let $\check{f}_S(x) := \min_{s \in S} \check{f}_s(x)$ and $\hat{f}_S(x) := \max_{s \in S} \hat{f}_s(x)$.

[3] A more general theorem for stabilty of image persistence can be found in the full version of this paper [10].

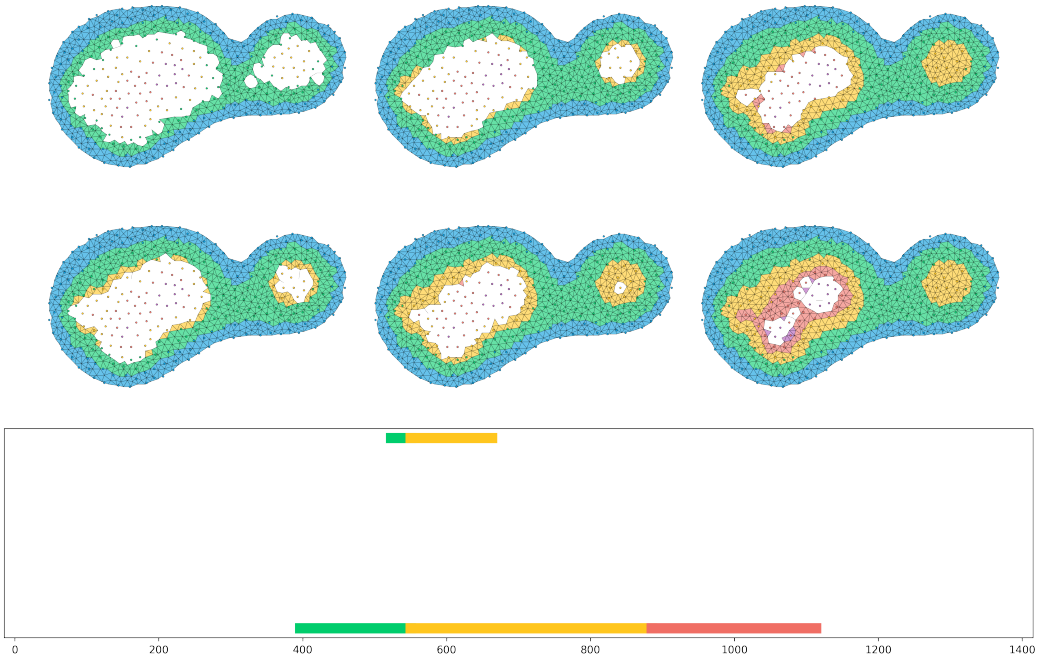

Figure 6 The top row shows the Delaunay filtration of the max Lipschitz extension. The next row shows the min extension. The barcode of the image suppresses the small spurious features and captures the two main features.

Although the term baryentric subdivision implies that subdivision happen at the barycenters of the cells, we define this operation instead as a combinatorial operation on simplicial complexes. For any simplicial complex K, we define $\mathsf{bary}K$ to be the simplicial complex with a vertex for each simplex in K and a simplex for each ordered subset of simplices (the ordering is by inclusion). For any function $g : K \to \mathbb{R}$, we can extend it to a filtration G on $\mathsf{bary}K$, as $\sigma_0 \hookrightarrow \cdots \hookrightarrow \sigma_k$ is in $G(t)$ if and only if $g(\sigma_i) \leq t$ for all $i \in \{0, \ldots, k\}$. Proof of the following theorem may be found in the full version [10].

▶ **Theorem 14.** *Let S be a finite sample of a convex polytope X, and let $\{\check{f}_s : \mathrm{Vor}_S(s) \to \mathbb{R} \mid s \in S\}$ and $\{\hat{f}_s : \mathrm{Vor}_S(s) \to \mathbb{R} \mid s \in S\}$ be families of pointwise distance-monotone bounds on some unknown function $f : X \to \mathbb{R}$. Aggregate these bounds as $\check{f}_S := \bigwedge_{s\in S} \check{f}_s$ and $\hat{f}_S := \bigvee_{s\in S} \hat{f}_s$. For $\sigma \in \mathrm{Del}_S$, let*

$$u(\sigma) := \min_{x \in \mathrm{Vor}_S(\sigma)} \check{f}_S(x) \quad \text{and} \quad \ell(\sigma) := \min_{x \in \mathrm{Vor}_S(\sigma)} \hat{f}_S(x).$$

Extend u and ℓ to $\mathsf{bary}\mathrm{Del}_S$. Then, $\mathsf{Bar}(u \geq \ell) = \mathsf{Bar}(\check{f}_S \geq \hat{f}_S) \sqsubseteq \mathsf{Bar}(f)$.

▶ **Example 15.** To apply this theorem to the special case of Lipschitz functions, the resulting filtration captures the usual Lipschitz upper and lower bounds restricted to the Voronoi cells. That is,

$$\check{f}_s : \mathrm{Vor}_S(s) \to \mathbb{R} : x \mapsto f_S(s) + \mathrm{d}(x, s) \quad \text{and} \quad \hat{f}_s : \mathrm{Vor}_S(s) \to \mathbb{R} : x \mapsto f_S(s) - \mathrm{d}(x, s).$$

Letting $\alpha(\sigma) := \min_{x\in \mathrm{Vor}_S(\sigma)} \mathrm{d}(x, \sigma)$ be the birth time of the simplex σ in the standard Delaunay filtration (also known as the α-complex filtration). Then, the corresponding filtration on $\mathsf{bary}\mathrm{Del}_S$ is induced by

$$u(\sigma) := \max_{s\in\sigma} f_S(s) + \alpha(\sigma), \quad \text{and} \quad \ell(\sigma) := \min_{s\in\sigma} f_S(s) - \alpha(\sigma).$$

7 Categorical Constructions

The following section describes how the concepts presented above fit neatly into a category-theoretic framework. It contains some technical concepts that may unfamiliar to computational geometers.

7.1 Smoothing Persistence Modules

Given a barcode B, an ε-smoothing is a new barcode defined by eliminating bars of length at most 2ε, and replacing all other bars $[b, d]$ with a $[b + \varepsilon, d - \varepsilon]$; that is, we trim ε from the beginning and the end of each bar. The idea of a smoothed barcode naturally arises in the literature on the stability of persistence modules [7, 5, 18]. It is clear from the definition that the smoothed barcode is a sub-barcode of the original. This relationship can be expressed clearly as arising from a factorization as follows.

Let δ_- and δ_+ be order-preserving maps $\mathbb{R} \to \mathbb{R}$ with the property that, for all $t \in \mathbb{R}$, we have $\delta_-(t) \leq t \leq \delta_+(t)$. Order preserving maps between posets are functors, so the pointwise order relations on δ_- and δ_+ correspond to natural transformations

$$\varepsilon_0 : \delta_- \Rightarrow 1_{\mathbb{R}} \quad \text{and} \quad \varepsilon_1 : 1_{\mathbb{R}} \Rightarrow \delta_+.$$

So, for any persistence module $M : \mathbb{R} \to \mathbf{vec}$, composition with M yields the following factorization.

$$\begin{array}{ccc} M\varepsilon_0 & \longrightarrow & M\varepsilon_1 \\ & \searrow \quad \nearrow & \\ & 1_M & \end{array} \tag{4}$$

Letting $\varepsilon = \varepsilon_1 \circ \varepsilon_0$, we can view $M\varepsilon$ (or equivalently, its image) as the smoothed persistence module. The factorization induces the sub-barcode matching in the obvious way:

$$\mathsf{Bar}(M\varepsilon) \sqsubseteq \mathsf{Bar}(M).$$

From this perspective, an interleaving of persistence modules may be viewed as a pair of compatible factorizations rather than a pair of compatible (shifted) homomorphisms. In fact, the pair (δ_-, δ_+) corresponds to an *adjunction* with counit ε_0 and unit ε_1 (see [14]).

7.2 Sub-Barcodes are Subobjects

Within the literature, there are several different categorifications of persistence barcodes (or equivalently persistence diagrams). Here, we identify a natural way to define a category of barcodes that plays nicely with our treatment of sub-barcodes.

First, recall that unlike much of the prior work, we do not regard barcodes as multisets. Instead, we define a barcode to be a function from a set to the intervals. In computer programming terms, we have an "is a" versus "has a" distinction; in the multiset view, each bar *is an* interval. In our view, each bar *has an* interval.

A standard categorical approach to construct a category $\int_{\mathbf{C}} F$ from a (pseudo)functor $\mathbf{C} \to \mathbf{Cat}$ is the Grothendieck construction. Let $F : \mathbf{C}^{\mathsf{op}} \to \mathbf{Cat}$ be a functor from a category $\mathbf{C}$ to the category $\mathbf{Cat}$ of (small) categories. For the purposes of this work, the *(covariant) Grothendieck construction* yields a category $\int_{\mathbf{C}} F$ with objects given by pairs (C, x) for each $C \in \mathbf{C}$ and $x \in F(C)$, and arrows $(f, h) : (C, x) \to (C', x')$ for each pair of arrows $f : C \to C'$ in $\mathbf{C}$ and $h : x \to F[f](x')$ in $F(C)$.

Let $[-,\mathcal{I}] : \mathbf{Set} \to \mathbf{Cat}$ be the (pseudo)functor that takes a set X and returns the category $\mathcal{I}^X = [X,\mathcal{I}]$ of functors $X \to \mathcal{I}$. Then the category $\mathbf{Bar}$ of barcodes described in Section 3 is a contravariant Grothendieck construction

$$\mathbf{Bar} = \int_{\mathbf{Set}} [-,\mathcal{I}].$$

The objects of $\mathbf{Bar}$ are pairs $(\underline{B}, B : \underline{B} \to \mathcal{I})$ – i.e. barcodes – and a morphism of $\mathbf{Bar}$ $(\underline{A}, A) \to (\underline{B}, B)$ is a function $\phi : \underline{A} \to \underline{B}$ such that for all $\alpha \in \underline{A}$, we have that $A(\alpha) \subseteq B(\phi(\alpha))$. To see this as a Grothendieck construction, it suffices to observe that the barwise inclusion ordering is a natural transformation $A \Rightarrow B\phi$ in $[\underline{A},\mathcal{I}]$.

The condition on morphisms ensures that a bar α can only map to a bar β when $A(\alpha) \subseteq B(\beta)$. Thus, a injective morphism is exactly a sub-barcode matching. These injective morphisms are the monomorphsisms in this category and thus sub-barcodes are subobjects in this category.

▶ Remark 16. The category $\mathbf{Bar}$ defined above is also known as the category of $\mathcal{I}$-fuzzy sets [15], and the construction of a category of fuzzy sets using the Grothendieck construction also noted by Jardine [16]. It is also possible to replace $\mathbf{Set}$ with $\mathbf{Mch}$, the category of sets with partial injective maps (i.e., matchings), to construct barcodes as $\int_{\mathbf{Mch}}[-,\mathcal{I}]$, or more generally, to replace $\mathbf{Set}$ with the category $\mathbf{Set}_+ \supset \mathbf{Mch}$ of sets and *partial functions*. In both cases, the monomorphisms are injective sub-barcode matchings that yield sub-barcode relations.

7.3 Ranks via Presheaves

The rank functor was previously constructed directly from a persistence module, or more generally, a factorization of persistence module homomorphisms. In this section, we show how the rank functor can also be constructed from a barcode. This is already well-known; the novelty here is that we show how the rank functor can be factored through the category of barcodes. This gives the more abstract proof that sub-barcodes are more discriminating than ranks.

For any category $\mathbf{C}$, there is a functor $L : \int_{\mathbf{Set}}[-,\mathbf{C}] \to [\mathbf{C}^{\mathsf{op}},\mathbf{Set}]$ given for $A : \underline{A} \to \mathbf{C}$ by

$$LA(c) = \{a \in \underline{A} \mid \exists c \to A(a)\}.$$

The morphisms $L(A)(c \to c')$ are inclusions $L(A)(c') \subseteq L(A)(c)$. For $(f,\varepsilon) : A \to B$ in $\int_{\mathbf{Set}}[-,\mathbf{C}]$, it is easy to check that f gives a natural transformation $LA \Rightarrow LB$.

For the special case where $\mathbf{C} = \mathcal{I}$, this is a functor from barcodes to presheaves of intervals. The intuitive meaning is that, for a barcode B, the presheaf LB maps an interval J to the set of bars in B that contain all of J. All morphisms in the image of L are inclusions, and so, for $J \supseteq I$, we have $LB(J) \subseteq LB(I)$ and thus $|LB(J)| \leq |LB(I)|$. Here the vertical bars indicate set cardinality which is a functor card from the poset of finite sets with inclusions to the poset $\mathbb{N}$. Thus, we have a functor $\mathsf{card} \circ L : \mathbf{Bar} \to \mathbf{Set}^{\mathcal{I}^{\mathsf{op}}}$.

It is now an easy exercise to show that $\mathrm{rank} = \mathsf{card} \circ L \circ \mathsf{Bar}$. All morphisms in the functor category $[\mathcal{I}^{op},\mathbb{N}] = \mathbb{N}^{\mathcal{I}^{\mathsf{op}}}$ are monomorphisms, so clearly a sub-barcode relation (a monomorphism of barcodes) yields a subrank relation (a monomorphism of rank invariants). The other direction doesn't hold. The most natural way to define a barcode from the rank invariant does not give a functor to barcodes. The example is given in the proof of Theorem 6.

▶ Remark 17. Barr [1] showed that, when the indexing poset L is a Heyting algebra, the category of L-fuzzy sets is equivalent to a category of sheaves of monomorphisms. Following this result, many of the recent applications of fuzzy sets [21, 19] have defined fuzzy sets

directly as functors $L \to \mathbf{Set}$. Unfortunately, because the poset of intervals $\mathcal{I}$ is not a Heyting algebra, this equivalence cannot be applied directly to the category $\mathbf{Bar}$. On the other hand, the category of intervals with the product or Egli-Milner ordering is a Heyting algebra. Extending Barr's equivalence to a category of barcodes and partial functions is the subject of future work.
